In the present work, several unstabilized cotton and wood cellulose nitrates containing 100% sulphate acid ester were prepared. Slurry titrations were performed on these samples. Using 98 for the equivalent weight of the sulphate acid ester, RSO_4H, the slurry titer was converted to sulphate and expressed as % H_2SO_4. The latter value represented the sulphate due to ester and was expressed as a percentage of the standard gravimetric sulphate. The per cent sulphate acid ester content thus obtained was compared to 100% (the ester content determined by the hydrolysis method, which was taken as a standard). It was found that sulphate acid ester contents determined in this way for cotton cellulose nitrates were too low. However, in the case of wood cellulose nitrates, there was better agreement; the mean difference was -7.3%, the standard deviation 5.2, and the 95% confidence limits were $-7.3\% \pm 4.6$.

The slurry titration cannot be used as a direct method for determining sulphate acid ester in cellulose nitrates which contain less than 100% ester.

THE DECOMPOSITION OF NITROUS OXIDE AT LOW PRESSURES ON NICKEL OXIDE CATALYSTS[1]

J. DEWING[2] AND R. J. CVETANOVIĆ

ABSTRACT

Heterogeneous decomposition of nitrous oxide at pressures between 10^{-5} and 10^{-4} mm. on nickel oxide and doped nickel oxide catalysts has been studied in the temperature range 350° to 500° C. Under most experimental conditions the reaction is first order in nitrous oxide. The observed activation energies are considerably smaller than those observed in previous work and are decreased on doping with Li_2O and increased on adding Cr_2O_3. The results are explained by assuming that changes in the steady-state surface coverage with chemisorbed oxygen affect strongly the heats of chemisorption and, therefore, also the activation energies of the primary reactions.

INTRODUCTION

The heterogeneous decomposition of nitrous oxide has received considerable attention in the past. Studies on metallic catalysts (1, 2, 3, 4) have led to the conclusion that the decomposition is first order with respect to nitrous oxide and that the rate is reduced by the presence of oxygen. The work on metallic oxide catalysts has produced a less clear picture of the reaction kinetics (5, 6, 7, 8). In general the reaction appears to be retarded by the presence of oxygen. Some workers find a first-order dependence on nitrous oxide although a variable order and dependence on catalyst composition have also been observed (6).

In recent years the reaction has assumed considerable importance in the study of the catalytic properties of semiconductor systems with the object of correlating the electrical and catalytic properties.

In view of the apparent complexity of this decomposition we decided that it would be profitable to study the reaction at very low pressures under conditions of small percentage decomposition in an attempt to eliminate to a very large extent the effect of the products of the reaction and any diffusion effects which might interfere with the reaction.

EXPERIMENTAL

The reaction was carried out in a flow system in which nitrous oxide was streamed over the flat surface of a disk of the catalyst material at pressures between 10^{-4} and 10^{-5} mm. Hg. The rate of flow of gas over the catalyst was sufficiently fast for the transfer of gas to the internal pore structure of the catalyst to be negligibly small compared with the total flow. The undecomposed nitrous oxide was condensed in liquid nitrogen and the pressure of the noncondensable products measured continuously with a thermionic ionization gauge.

Nitrous oxide was allowed to stream through a capillary from a 5-liter reservoir filled initially to about 10^{-1} mm. The gas emerging from the capillary impinged on the surface of the catalyst and was rapidly removed by condensation in a liquid nitrogen trap placed as close to the reacting system as possible. The products nitrogen and oxygen were removed by a mercury diffusion pump with a pumping speed of 20 l./sec. They were pumped to the ionization gauge which was in turn evacuated through a narrow

[1]*Manuscript received December 4, 1957.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 4655.
[2]*National Research Council Postdoctorate Fellow 1955–57. Present address: Imperial Chemical Industries Ltd., Billingham, Co. Durham, England.*

glass tubing by a second mercury diffusion pump at a rate of 0.1 l./sec. Thus the pressure of the products was increased in the region of the ionization gauge by the ratio of the pumping speeds at the catalyst and at the ionization gauge. The pumping speed at the catalyst was about 2 l./sec.

The reactor was constructed from Pyrex glass with the exception of the vacuum envelope which was of silica. The general design of the reactor was similar to the one used by Crocker (9) in the study of decomposition reactions on single crystal planes. The inlet capillary was jacketed so that the incoming gas could be held at a different temperature from that of the catalyst. It was hoped that by doing this the effect of the temperature of the incoming gas could be studied, but this was found to be impossible because of the relatively large number of secondary collisions made by the molecules before they were removed from the reaction zone. Only about 10% of the collisions with the catalyst were the initial collisions of the incoming gas. The reactor was heated by an external furnace and the catalyst temperature was measured by a Pt–Pt–Rh thermocouple pressed against the back surface of the catalyst disk. Diagrams of the reaction system and the reactor are given in Figs. 1 and 2.

The nitrous oxide was purified by the usual triple distillation procedure and was stored in a 2-liter glass bulb. Periodic repurifications were carried out to guard against possible contamination during storage over long periods of time. Pressure measurements before and after freezing out in liquid nitrogen showed a noncondensable impurity content of less than 1 p.p.m.

The catalysts were prepared from "Baker Analysed" nickel oxide. The pure nickel oxide catalysts were made by mixing a portion of the nickel oxide with distilled water, drying, and heating to 1000° C. The cake of nickel oxide was then ground in an agate mortar until it would all pass a 30-mesh screen. This powder was then pressed into a flat disk at a pressure of 700 kg./cm.^{2}, which was then sintered at 1000° C. for 3 hours. In the case of catalysts containing lithia the water was replaced by a measured amount of lithium hydroxide solution and during drying the mixture was stirred at frequent intervals to prevent concentration of the lithium at the drying surface. The rest of the

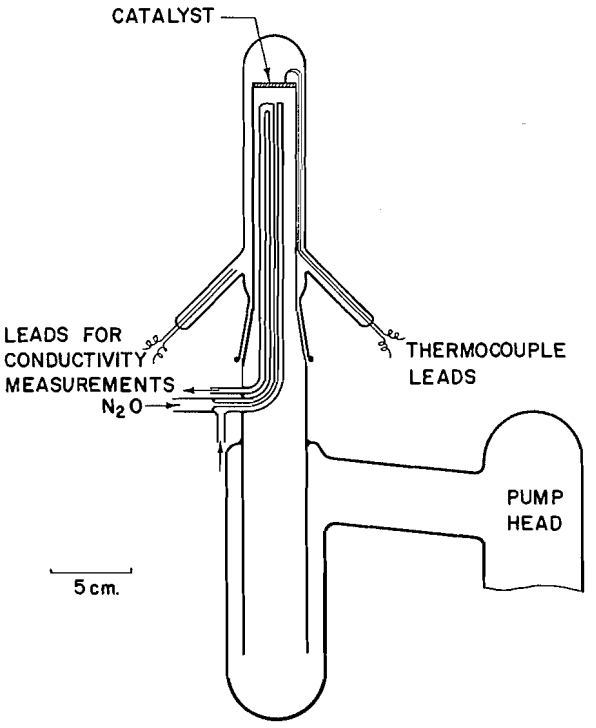

FIG. 2. Reactor. (The leads for conductivity measurements extend to the upper surface of the catalyst—this is not shown in the figure to avoid cluttering. No cooling of the capillary jacket—as indicated by the arrows—was employed in the present work, for reasons given in the text.)

preparative procedure was the same. Chromia was introduced by using a solution of ammonium dichromate.

Platinum wires were embedded in some of the catalysts before sintering to allow measurements to be made of the electrical conductivity under the reaction conditions.

RESULTS

Runs were made by filling the reservoir to a known pressure between 10^{-2} and 10^{-1} mm. with N_2O and allowing this to stream through the reactor. The pressure over the catalyst was proportional to the reservoir pressure and in a steady-state flow system the pressure of products can be taken as a measure of the rate of reaction at any instant. The reading of the ionization gauge was followed as the reservoir pressure dropped and was a measure of the variation of the rate with reactor pressure. Thus the kinetics of the reaction were easily studied even though no runs were carried out in which more than 1% decomposition occurred.

In the later runs the output of the ionization gauge was connected to a recording potentiometer. This increased the accuracy of the measurements, as it was possible to smooth the trace to reduce the effect of random fluctuations of the gauge reading.

In all experiments the apparatus was pumped down so that a reading of the order of 2×10^{-6} mm. was obtained on the ionization gauge with the catalyst at 500° C. This usually required about 16 hours when a new catalyst was used.

A typical run is shown in Fig. 3. The intercept on the axis at zero reservoir pressure represents the background pressure in the apparatus. It is clear that the reaction is first order with respect to the nitrous oxide. This first-order reaction was observed under

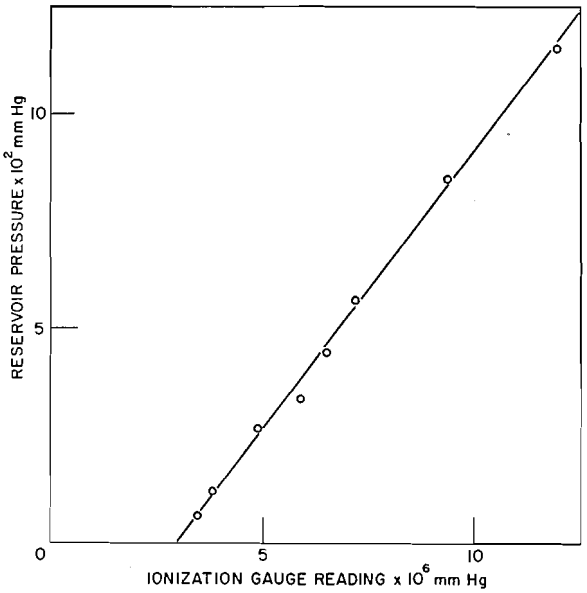

FIG. 3. Change of ionization gauge reading with reservoir pressure in a typical run (pure NiO catalyst), 442° C.

most experimental conditions. All the catalysts showed this behavior at temperatures above 400° C., but below this temperature pure NiO and NiO catalysts with up to 0.5 mole per cent lithia added showed a more complex behavior with an apparent order of reaction between 1.0 and 1.1. In cases where this complex order was observed the extrapolated rate for zero N_2O pressure was taken. This rate was found to fit well with the results taken at higher temperatures when the Arrhenius activation energy was determined.

All the results are reported in terms of the concentration of foreign ions added initially, since this appears to be the usual method of reporting such data and in terms of the surface concentrations is probably as meaningful as the analysis figures. Analysis showed, however, that about half of the added lithia distilled out of the samples during sintering.

Electrical-conductivity measurements were made on some of the catalysts during the course of the reaction using an a-c. bridge at 500 c./s. Additions of lithia had a marked effect on conductivity. One mole per cent of lithia, for example, increased the conductivity of the NiO by a factor of 10^4 at 400° C. and the apparent activation energy for conduction was lowered from 18.5 kcal. to 4.1 kcal. No attempt was made to measure the small conductivities of NiO with chromia added. There was a measurable increase in conductivity of pure NiO on admission of N_2O but this was small and tended to increase with time so that it could not be studied systematically.

The effects of the additions of foreign ions to the nickel oxide on the apparent activation energies for conduction and for the reaction are compared in Fig. 4. In the case of lithia additions the activation energy was lowered by 2 to $2\frac{1}{2}$ kcal. and the activity at 400° C. was reduced to about half that for pure NiO. Comparisons of activity are, however, of necessity very approximate since the variation is of the same order as the reproducibility of activity between different samples of catalysts of the same composition.

Additions of chromia increased the activation energy for the reaction to such an extent that a great loss of activity occurred in the temperature range used.

An attempt was made to obtain more information regarding the complex-order reaction

Broken line represents the activation energies for electrical conductivity.

occurring at lower temperatures. The results were not very reproducible but they suggested that a time-dependent loss of activity of the catalyst might be responsible for the deviation from a first-order reaction. The curvature of the plots of reaction rate against N_2O pressure was more marked after the catalyst had been evacuated at a high temperature just prior to the run. If two low-temperature runs were done consecutively, without raising the temperature in between, the first run showed a higher apparent order than the second.

DISCUSSION

Heterogeneous decomposition of nitrous oxide on a *p*-type semiconducting oxide catalyst and in the temperature region of interest in the present investigation may in general be considered in terms of the following reactions:

$$N_2O_{(g)} + S \rightleftharpoons N_2O_{(s)} \quad [1]$$

$$N_2O_{(s)} \rightarrow N_{2(g)} + O^-_{(s)} + \oplus \quad [2]$$

$$O^-_{(s)} + O^-_{(s)} + 2\oplus \rightleftharpoons O_{2(g)} \quad [3]$$

$$O^-_{(s)} + N_2O_{(g)} + \oplus \rightarrow N_{2(g)} + O_{2(g)} \quad [4]$$

$$O^-_{(s)} \rightleftarrows O^=_{(s)} + \oplus \quad [5]$$

where S represents an adsorption site on the catalyst surface, $\oplus$ a "positive hole", and subscripts (g) and (s) indicate gas phase and chemisorbed particles, respectively. All

these reactions have been considered by different authors before. The experimental conditions were, in some instances, widely different, and varying emphasis was placed on the relative importance of the individual steps in the reaction scheme.

Amphlett (8) used a great excess of oxygen, containing only 10–1000 p.p.m. of N_2O. At a constant oxygen pressure the rate expression reduces under these conditions to

$$-d(N_2O)/dt = K(N_2O)$$

and is in agreement with the observed first order in N_2O. Under conditions employed in these experiments it is likely that reaction [4] is responsible for the decomposition of N_2O. The effect of controlled impurities was not investigated. The over-all activation energy was found to be dependent on the temperature range in which the measurements were made.

Hauffe, Glang, and Engell (6) have studied the decomposition of N_2O in the presence of comparable amounts of oxygen on nickel oxide and doped nickel oxide catalysts. Percentage conversions were measured as a function of temperature and the apparent order of the reaction and the activation energy were deduced by assuming constant values of these quantities throughout the temperature ranges covered. There was a marked dependence of both the order of the reaction and the activation energy on catalyst composition. It would be difficult to explain by a detailed mechanism the wide variation of the apparent order of the reaction, although it is possible that the apparent complexity may be due to the particular method employed in evaluating this quantity. There was, however, a distinct effect of the doping on the percentage conversion, and this was interpreted by Hauffe (10) in terms of an increase in the rates of reactions [3] and [4] with increasing concentration of positive holes. These two reactions are assumed to be slow and, therefore, the rate-determining ones under most conditions.

Under most of the experimental conditions in the present work a reaction rate of first order in nitrous oxide was observed. The decomposition of N_2O amounted to less than 1%. From the observed pressure in the ionization gauge and in view of the ratio of pumping speed of the mercury diffusion pumps it is estimated that the steady-state partial pressure of gaseous oxygen over the catalyst was of the order of 10^{-6} mm. or smaller. It is, therefore, likely that under these conditions interference by secondary chemisorption of oxygen, the reverse of reaction [3], was negligibly small. Inasmuch as this assumption is correct, primary chemisorption and splitting of N_2O must play the main role in the decomposition, and the measured rates and the observed activation energies are those of the chemisorption reactions [1] and [2] and not of the desorption reactions [3] and [4]. Reactions [1] and [2] cannot be expected to be affected directly by the concentration of positive holes in the catalyst unless $N_2O_{(s)}$ is a negative ion, in which case an increase in positive-hole concentration would only tend to accelerate the reverse of reaction [1]. The dependence on doping observed in the present work is, therefore, not explainable by a direct effect of positive-hole concentration on the rates of these reactions. The indirect effect of the concentration of positive holes on the surface coverage and therefore also on the heat of adsorption, on the other hand, appears to provide a satisfactory explanation of the doping effect.

An increase in the concentration of positive holes will speed up the desorption reactions, which are dependent on electron transfer to the catalyst, and decrease the surface coverage under the steady-state reaction conditions. In our experiments the surface coverages were very small and their variations due to doping could not have significant effect on the number of available surface sites. On the other hand, these variations should affect strongly the heats of adsorption. The heat of adsorption of oxygen on NiO has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

been shown to be very strongly dependent on surface coverage. Dell and Stone (11) have made calorimetric measurements of the heat of adsorption on NiO films on the surface of metallic nickel and have found values falling from 54 kcal./mole for a surface largely depleted of oxygen to 20 kcal./mole for a surface with 10% of the B.E.T. surface area covered with oxygen. The theoretical work of Takaishi (12) suggests, subject to certain assumptions, that in the case of *p*-type semiconducting oxides the decline in the heat of adsorption with increasing surface coverage should be particularly large at very low coverages. Therefore, any increase in the rate of the desorption reactions (as, for example, due to doping with Li_2O) which results in a decrease in the steady-state concentration of chemisorbed oxygen will lead to an increase in its binding energy. It is reasonable to suppose that this will result in a reduction of the potential energy of the activated complex leading to the adsorbed oxygen and thus in a lowering of the activation energy for the reaction. These views are in agreement with the observed results. Doping with Li_2O to increase the concentration of positive holes results in a decrease in the observed activation energy in the predicted manner, while additions of Cr_2O_3 have the expected opposite effect. Furthermore, the activation energies observed in the present work are much lower than have been observed by other workers. In agreement with the expressed views this provides indirect evidence for very low surface coverages under the experimental conditions employed.

The apparent complex order observed at lower temperatures is qualitatively explainable by assuming some occurrence of reaction [5] under certain conditions. Gray and Darby (13) have made a thorough study of the different processes involved in the chemisorption of oxygen on nickel oxide. They find that the rate of desorption of oxygen is extremely slow at temperatures below about 300° and requires an apparent activation energy of the order of 60 kcal./mole. At lower reaction temperatures the reverse of [5] can therefore be relatively slow and thus lead to a build-up of surface oxygen which is removed slowly on evacuation. At higher reaction temperatures deviations from the first order were not observed. Also, with NiO doped with more than about 0.5 mole per cent of Li_2O no deviations from the first order were apparent. This is in agreement with the suggested explanation since doping with Li_2O would be expected to increase the rate of the reverse reaction [5].

The trend in activation energies of conductivity shown in Fig. 4 appears to be roughly comparable with the one established by Verwey *et al.* (14). The values of the activation energies are considerably lower than those of Keier, Roginski, and Sasonov (15) at comparable atomic concentrations of lithium. The somewhat different method of catalyst preparation and the different ambient atmosphere in the present work are probably responsible for the discrepancy. At the present state of knowledge of the physical and chemical phenomena involved it would be difficult to attempt a quantitative correlation between the observed activation energies for electrical conductivity and for the decomposition reaction in terms of the mechanism proposed for the latter.

THE NON-ENZYMATIC HYDROLYSIS OF *p*-NITROPHENYL PHOSPHATE[1]

K. A. HOLBROOK[2] AND LUDOVIC OUELLET

ABSTRACT

The kinetics of the non-enzymatic hydrolysis of *p*-nitrophenyl phosphate have been studied in aqueous solution in the pH range 2.6 to 9.0 and at temperatures from 68.0° to 82.0° C. The reaction has been followed by colorimetric measurement of the nitrophenol produced by the reaction

$$O_2NC_6H_4OPO_3H^- + H_2O \rightarrow O_2NC_6H_4OH + H_2PO_4^-.$$

The reaction is first order with respect to *p*-nitrophenyl phosphate and has an activation energy of 26.0 kcal./mole at pH 2.6. An explanation has been proposed in terms of the different rates of hydrolysis of the various ionic species of the ester present in solution.

INTRODUCTION

Studies have been made of enzymatic hydrolyses of *p*-nitrophenyl phosphate by Morton (1) using alkaline phosphatases of cow's milk and calf intestinal mucosa and by Axelrod (2) using enzymes present in citrus juices. In both cases the hydrolysis produces inorganic phosphate and *p*-nitrophenol by the simple reaction

$$O_2NC_6H_4OPO_3H^- + H_2O \rightarrow O_2NC_6H_4OH + H_2PO_4^-.$$

In view of current theories (3, 4) of organic phosphate hydrolyses it seemed desirable to make a more complete study of this reaction over a wide range of pH in the absence of enzymes.

EXPERIMENTAL

Materials

p-Nitrophenyl phosphate (disodium salt) was supplied by Mann Research Laboratories Inc. and was used without further purification. A stock solution (about 8×10^{-2} *M*) was kept in cold storage. Analysis indicated the presence of about 0.5% *p*-nitrophenol in the original phosphate.

p-Nitrophenol used for calibration purposes was purified by boiling with dilute hydrochloric acid and activated charcoal. The recrystallized material had a melting point of 114.0° C.

Buffer solutions.—The following buffer solutions were used and their pH values at 76.9° C. (given in parentheses) were measured using Beckman high-temperature electrodes: acid potassium phthalate/hydrochloric acid (2.6), acid potassium phthalate (3.8), acetic acid/sodium acetate (4.7), acid potassium phthalate/potassium hydroxide (5.8), trishydroxymethylaminomethane/hydrochloric acid (7.4), boric acid/sodium hydroxide (9.0). The concentrations of these buffers were adjusted and potassium chloride was added to make the ionic strength of the reaction mixtures 0.1.

Procedure

Kinetic runs were done using the apparatus described in a previous paper (5). The rate of reaction was measured by following colorimetrically the concentration of *p*-nitrophenol produced, the method being similar to that of Axelrod (2). One-milliliter aliquots were extracted from the reaction mixture at convenient time intervals and diluted by adding to 10 ml. *M*/6 sodium hydroxide at room temperature. This effectively stops all

reaction (see Fig. 2) and produces the yellow color characteristic of the *p*-nitrophenylate ion. The absorbance of the solution was measured in a Beckman model DU spectrophotometer at 400 mμ at which wavelength there is strong absorption due to the salt form (6). The addition of 1 ml. of reaction mixture did not alter the pH of the sodium hydroxide sufficiently to affect the calibration. A standard calibration graph of absorbance versus *p*-nitrophenol concentration was prepared using the purified *p*-nitrophenol described above.

RESULTS

Order of the Reaction

The reaction at 76.9° C. was found to be first order with respect to *p*-nitrophenyl

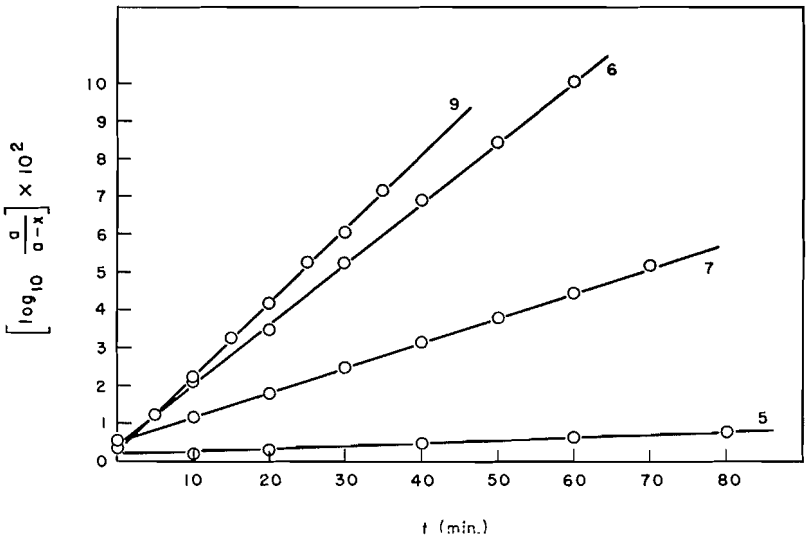

FIG. 1. Temperature = 76.9° C.

Run	5	7	6	9
Initial concn. phosphate $\times 10^3$ *M*	0.834	0.834	0.834	1.657

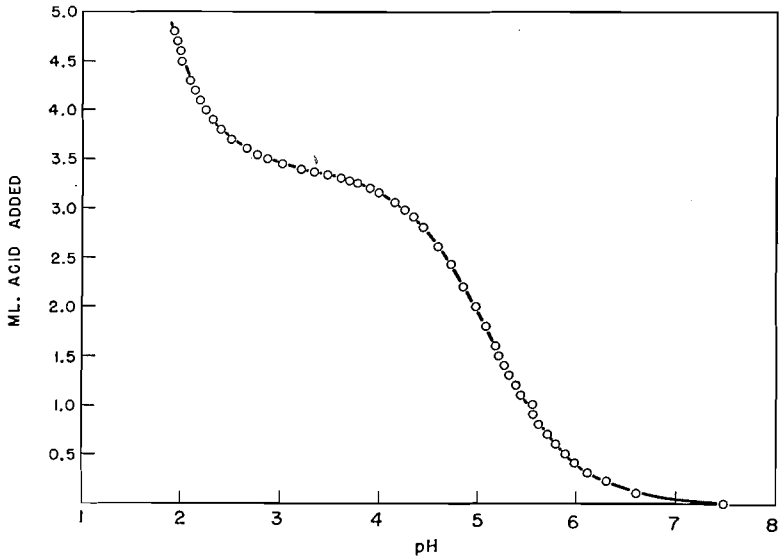

FIG. 3. Temperature = 25° C.

phosphate and first order with respect to time, over the first 10–20% hydrolysis. This is illustrated by plots of the first-order log function against time for different initial conditions of pH and phosphate concentration shown in Fig. 1.

The Effect of pH

Runs were done at different pH values from 2.6 to 9.0 at 76.9° C. and Fig. 2 shows a plot of the first-order rate constant against pH. For comparison, Fig. 3 shows a microtitration curve of *p*-nitrophenyl phosphate obtained (at 25° C.) using the standard procedure. It can be seen that the increase in rate obtained at lower pH values parallels the change in ionic form of the phosphate ester.

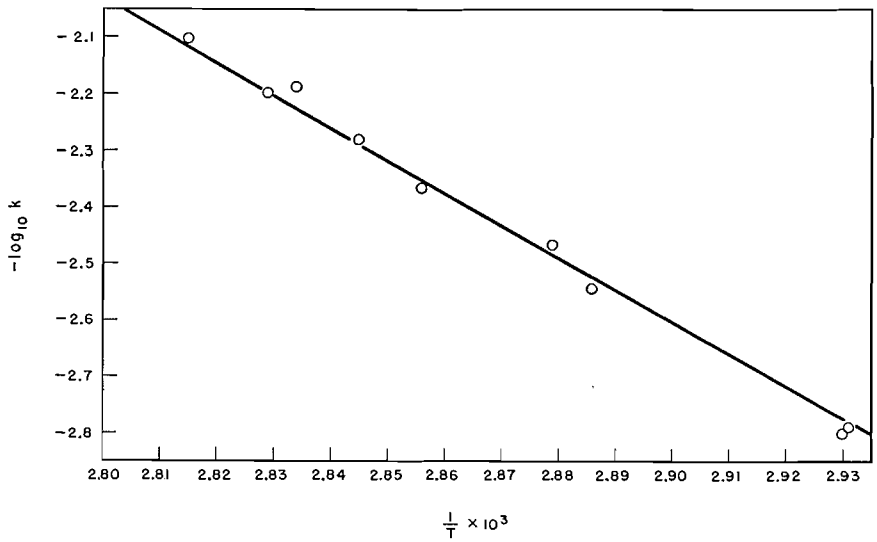

FIG. 4. pH = 2.6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The Activation Energy

The activation energy corresponding to the first-order rate constant at pH 2.6 was obtained by measuring the rate as a function of temperature from 68.0° to 82.0° C. Fig. 4 shows a plot of $\log_{10}k$ versus $1/T°$ K.

DISCUSSION

Although the enzymatic hydrolyses of a number of organic phosphates have been studied at physiologically important pH values, relatively few attempts have been made to study these hydrolyses over a wide range of pH values in the absence of enzyme.

We have previously studied the non-enzymatic hydrolyses of ATP (7) and ADP (5) and have found that the effect of pH upon these hydrolyses could be explained in terms of the differing rates of hydrolysis of different ionic species present in solution.

The hydrolysis of *p*-nitrophenyl phosphate, which follows the simple over-all equation

$$NO_2.C_6H_4OPO_3H^- + H_2O \rightarrow NO_2.C_6H_4OH + H_2PO_4^-, \quad [1]$$

shows a similar relationship between the effect of pH (Fig. 2) and the titration curve of the ester (Fig. 3).

The inflection point in the latter at about pH 5.0 presumably corresponds to the equilibrium

$$NO_2C_6H_4OPO_3^= + H^+ \rightleftarrows NO_2C_6H_4OPO_3H^-.$$

At pH 9.0 it has been observed that the rate of hydrolysis is practically zero, when the ester is largely present as the completely ionized form $NO_2C_6H_4OPO_3^=$, whereas at pH 2.6–2.7, when the predominant ionic species present is the singly charged $NO_2C_6H_4OPO_3H^-$ (assuming no large variation in the equilibrium constant from 25° to 70° C.), the rate of hydrolysis is appreciable.

The general expression for the rate of hydrolysis between pH 2.6 and 9.0 can be written

$$\text{rate} = [H_2O]\{k_1[NO_2C_6H_4OPO_3H^-]+k_2[NO_2C_6H_4OPO_3^=]\},$$

where [*p*-nitrophenyl phosphate]$_0$ = $[NO_2C_6H_4OPO_3H^-] + [NO_2C_6H_4OPO_3^=]$. Hence under the conditions at pH 2.6, an approximation is

$$\text{rate} = k_1[H_2O]\,[p\text{-nitrophenyl phosphate}]_0.$$

At this pH, the first order of the reaction with respect to the phosphate ester has been demonstrated (Fig. 1) and the activation energy has been found to be 26.0 kcal. An entropy of activation $\Delta S_1 = -14.0$ e.u. (taking $[H_2O] = 55.5$ moles/liter) was calculated.

Whether the rate-determining hydrolysis of the singly charged species occurs by a C—O or O—P bond splitting is uncertain and could only be decided by H_2O^{18} experiments. The mechanism by which this step occurs may well involve a proton transfer as suggested by Westheimer and Kumamoto (8) for the hydrolysis of the mono anions of mono- and di-benzyl phosphates.

The entropy of activation of −14.0 e.u. is more negative than those found for the O—P splitting of the adenosine phosphates at alkaline pH values (5) although larger negative values have been reported by Friess (9) for ATP, pyrophosphoric acid, and triphosphoric acid under mildly acidic conditions. In a recent study of the hydrolyses of substituted phenyl phosphates, Chanley and Feageson (10) have noted that singly charged species tend to hydrolyze more rapidly than either the completely ionized or the uncharged species. This was explained in terms of Koshland's nucleophilic displacement mechanism (4) for such reactions.

Table I gives a comparison of the rates of hydrolysis of substituted aromatic phosphates observed by Chanley and Feageson (10) with our observed rate of hydrolysis of *p*-nitrophenyl phosphate under identical conditions. The rates are shown to increase in accordance with the increase in electrophilic character of the group attached to the phosphorus atom, as would be predicted from a nucleophilic displacement mechanism.

TABLE I

RATES OF HYDROLYSIS OF SOME AROMATIC PHOSPHATES

Compound	Dissociation constants		pH of reaction	Rate, $hr.^{-1} \times 10$, at 80° C.
	pk_1	pk_2		
Phenyl phosphate	1.00	5.88	3.83	1.16
m-Carboxyphenyl phosphate	0.85	3.91	2.36	1.61
p-Carboxyphenyl phosphate	0.88	4.20	2.31	3.07
p-Nitrophenyl phosphate	<2	~5	2.70	3.62

RÉSUMÉ

La cinétique de l'hydrolyse non-enzymatique du *p*-nitrophényl phosphate en solution aqueuse a été étudiée à des pH allant de 2.6 à 9.0 et à des températures allant de 68.0° C. à 82.0° C. La réaction a été suivie par la mesure colorimétrique du *p*-nitrophénol libéré selon la réaction

$$O_2NC_6H_4OPO_3H^- + H_2O \rightarrow O_2NC_6H_4OH + H_2PO_4^-.$$

La réaction est du premier ordre par rapport au *p*-nitrophényl phosphate et elle a une énergie d'activation de 26.0 kcal./mole à pH 2.6. On propose une explication en termes du taux d'hydrolyse des différentes espèces ioniques en solution.

PHOTOLYSIS OF *n*- AND *i*-PROPYL PROPIONATE[1]

M. H. J. WIJNEN

ABSTRACT

The photolysis of *n*- and *i*-propyl propionate has been studied in the temperature range of 30° to 170° C. The results strongly indicate that the following three primary processes may occur:

$$C_2H_5COOC_3H_7 + h\nu \rightarrow C_2H_5CO + C_3H_7O, \quad [1a]$$

$$C_2H_5COOC_3H_7 + h\nu \rightarrow C_2H_5 + CO_2 + C_3H_7, \quad [1b]$$

$$C_2H_5COOC_3H_7 + h\nu \rightarrow C_2H_5COOH + C_3H_6. \quad [1c]$$

Based on these primary steps a qualitative explanation may be given for the formation of all reaction products.

INTRODUCTION

In previous investigations of methyl acetate (1), methyl d_3-acetate (2), and ethyl propionate (3) it could be shown that the main primary step in the photolysis of these esters consisted in the break of the ester into RCO and RO radicals. It was possible to obtain information on the reactivity and thermal stability of the RO radicals thus produced.

It seemed interesting to extend these investigations to higher-boiling esters. The photolysis of *n*- and *i*-propyl propionate has therefore been studied.

EXPERIMENTAL

The experimental technique is essentially the same as described elsewhere (1). A Hanovia S-500 medium pressure arc was used as the light source. The light of the S-500 arc was not filtered, and its intensity was varied by inserting wire gauze screens between reaction cell and arc. The amount of decomposition did not exceed 5% of the compound under investigation.

As reaction products of the photolysis of *n*-propyl propionate were observed: CO, CO_2, CH_2O, C_2H_4, C_2H_6, C_3H_6, C_3H_8, *n*-C_4H_{10}, *n*-C_5H_{12}, *n*-C_3H_7OH, and CH_3CH_2CHO. *n*-Propyl alcohol was determined by mass spectrometer analysis of the residue after all other products had been removed by Toepler pump at −120° C. The total volume of these products was measured, after which analysis was carried out by mass spectrometer.

The following reaction products were observed in the photolysis of *i*-propyl propionate: CO, CO_2, CH_4, C_2H_4, C_2H_6, C_3H_6, C_3H_8, *n*-C_4H_{10}, *i*-C_4H_{10}, *i*-C_5H_{12}, $\{CH(CH_3)_2\}_2$, CH_3CHO, CH_3COCH_3, $C_2H_5COCH_3$, $C_2H_5COC_2H_5$, and *i*-C_3H_7OH. The C_1 to C_5 hydrocarbons and the carbon oxides were pumped over at −130° C., measured, and analyzed by mass spectrometer. The other products such as ketones, isopropyl alcohol, and 2,3-dimethylbutane were determined by mass spectrometer analysis of the residue.

Typical results obtained at various temperatures by photolysis of *n*-propyl propionate are given in Table I, those obtained by photolysis of *i*-propyl propionate in Table II.

DISCUSSION OF RESULTS

n-Propyl Propionate

To explain the formation of products in the photolysis of *n*-propyl propionate the following primary steps are suggested:

$$n\text{-}C_2H_5COOC_3H_7 + h\nu \rightarrow C_2H_5CO + n\text{-}C_3H_7O, \quad [1a]$$

$$\rightarrow C_2H_5 + CO_2 + n\text{-}C_3H_7, \quad [1b]$$

$$\rightarrow C_2H_5COOH + C_3H_6. \quad [1c]$$

Steps [1*a*] and [1*b*] have been shown to occur in the photolysis of methyl acetate and ethyl propionate. Step [1*a*] produces *n*-propoxy and propionyl radicals. Propionyl radicals are known (4) to be quite unstable and decompose readily into ethyl radicals and carbon monoxide. The possibility that at 40° C. some C_2H_5CO radicals survive long enough to form diethyl ketone and possibly propyl ethyl ketone as has been observed in the case of isopropyl propionate may, however, not be excluded. Carbon monoxide is observed at all temperatures as the main reaction product. The presence of *n*-propoxy radicals is confirmed by the formation of *n*-propyl alcohol and of propionaldehyde at 40° C. Step [1*b*] produces ethyl and propyl radicals in addition to carbon dioxide. Accepting that practically all C_2H_5CO radicals decompose into C_2H_5 and CO, it would be expected that at any given temperature the ratio CO/CO_2 would be constant. This is confirmed by the results, as shown in Table I, which indicate that step [1*a*] occurs about four times as frequently as step [1*b*]. The presence of propyl radicals during the photolysis of *n*-propyl propionate is confirmed by reaction products such as propane, propylene, and pentane. The formation of butane, ethane, and ethylene confirms the presence of ethyl radicals, suggested to be formed by step [1*b*] and by step [1*a*] via the C_2H_5CO radical.

If reactions [1*a*] and [1*b*] were the only primary steps, then it would be expected that $R_{CO_2} = R_{C_3}$, where R_{C_3} is the rate of production of all compounds containing *n*-propyl radicals so that $R_{C_3} = R_{C_5H_{12}} + R_{C_3H_8} + R_{C_3H_6}$. Table I shows $R_{C_3} \gg R_{CO_2}$. This indicates that more products, containing propyl radicals, are formed than can be accounted for by step [1*b*]. To explain this, step [1*c*] has been suggested. Propionic acid in trace amounts is not detected by mass spectrometer analysis, as could be shown by adding small amounts of propionic acid to the *n*-propyl propionate residue of the photolysis before analysis. Confirmation for step [1*c*] may, however, be found (1) in the rather large amounts of propylene produced, especially if compared to the amounts of propane formed, and (2) in the fact that chemical analysis indicated the presence of an acid among the reaction products.

This investigation was mainly undertaken to obtain information regarding the *n*-propoxy radical. However, neither propyl alcohol nor propionaldehyde could be detected at 130° C. and higher temperatures. This seems to indicate that the *n*-propoxy radical is not very stable thermally. Since no hydrogen was observed among the reaction products, the results indicate that the *n*-propoxy radical decomposes into ethyl radicals and formaldehyde according to the reaction

$$n\text{-}C_3H_7O \rightarrow C_2H_5 + CH_2O. \qquad [2]$$

This type of decomposition reaction for the alkoxy radical has been suggested previously by other authors (5, 6). It is important to point out that relatively large amounts of formaldehyde were produced. In the extreme case where all *n*-propoxy radicals would decompose according to reaction [2], it would be expected that $R_{CO} = R_{CH_2O}$. This has not been observed. Since formaldehyde polymerizes easily it is probable that part of the formaldehyde was left behind in the apparatus as polymer and thus was not available for analysis.

The fact that no ethers were formed even at 40° C., which could conceivably be produced by recombination between alkyl and propoxy radicals, indicates that the concentration of propoxy radicals must be small. This is also confirmed by the fact that propionaldehyde, possibly a product of disproportionation reactions involving the propoxy radical, has only been observed in trace amounts at low temperatures.

i-Propyl Propionate

Primary steps similar to those suggested in the photolysis of *n*-propyl propionate will produce ethyl, *i*-propoxy, *i*-propyl, and propionyl radicals in addition to carbon oxides and propionic acid.

The isopropoxy radical has been suggested (6) to decompose according to the following reactions:

$$(CH_3)_2CHO \rightarrow CH_3 + CH_3CHO \quad [3]$$

and

$$(CH_3)_2CHO \rightarrow CH_3COCH_3 + H. \quad [4]$$

Reaction [3] is confirmed by the fact that large amounts of acetaldehyde were observed among the reaction products. The presence of methyl radicals is shown by the formation of methane and isobutane. Since it is not possible to decide to what extent methyl radicals are involved in the production of ethane and propane, it is difficult to draw a comparison between the amounts of acetaldehyde and methyl radicals produced by reaction [3]. No reliable data were obtained for the production of acetone although it could be established that some acetone was produced, especially at low temperatures. Since no hydrogen was observed, it is unlikely that acetone was formed by reaction [4]. More probable is the formation of acetone via disproportionation reactions involving the isopropoxy radical. Accepting primary steps [1*a*], [1*b*], [1*c*], and reaction [3], all other reaction products may be explained by abstraction, recombination, and disproportionation reactions of the radicals thus produced.

The fact that methyl ethyl ketone and diethyl ketone are found at 33° C. indicates some stability for the C_2H_5CO radical. This is in agreement with previous results for the photolysis of diethyl ketone, where a quantum yield of 0.6 (7) was observed for the production of CO at 25° C. The ratio R_{CO}/R_{CO_2} indicates that step [1*a*] occurs about 2.4 times as frequently as step [1*b*]. Comparison with the similar ratio for *n*-propyl propionate indicates that step [1*a*] is relatively more important for normal propyl propionate than it is for isopropyl propionate.

The sharp decrease of isopropyl alcohol formation with increasing temperature seems to indicate that the isopropoxy radical is not very stable thermally. In all respects our results indicate that both *n*- and *i*-propoxy radicals react very similarly and decompose readily by breakage of the carbon–carbon bond rather than by splitting off of hydrogen atoms.

ACKNOWLEDGMENTS

The author wishes to thank Dr. H. D. Medley for his constant interest in the fundamental research program of this laboratory. Special thanks are due to Mr. R. W. Jarrett and Mr. R. M. Guedin for calculation and interpretation of the mass spectrometer data.

INFLUENCE OF WATER CONCENTRATION ON THE HYDROLYSIS OF UNSTABILIZED CELLULOSE NITRATE IN ACETONE/WATER SOLUTION[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] BRIAN T. NEWBOLD, AND J. THOMAS

ABSTRACT

The influence of water concentration upon the hydrolysis of the sulphate acid ester in unstabilized cotton and wood cellulose nitrates in acetone/water solution at 25°±0.1° C. has been determined. When the water content of these systems was increased, the rate of hydrolysis of the sulphate acid ester in cotton or wood cellulose nitrates decreased. This effect was greatest in the first hour of hydrolysis. The presence of more than about 2% water in the acetone/water solution prevented the completion of hydrolysis after 24 hours.

INTRODUCTION

The hydrolysis of the sulphate ester in unstabilized cellulose acetate sulphate in acetone is rapid compared to that of the acetate ester (1). Recently, it was found that hydrolysis of the sulphate acid ester, RSO_4H, in unstabilized cotton and wood cellulose nitrate in acetone was rapid compared to that of the nitrate ester (2).

The hydrolysis of the sulphate ester in cellulose acetate sulphate in acetone is greatly affected by temperature and is complete after 24 hours at 25° C. (1). There is much evidence that the rate of solvolysis of the sulphate ester in a cellulose-mixed ester depends to a great extent upon the liquid medium employed (3, 4). It was shown previously that hydrolysis of the sulphate acid ester in unstabilized cellulose nitrate proceeded rapidly in 99% acetone/water, but was stopped in 90% acetone/water solution (2).

The object of the present work was to determine the influence of water concentration upon the hydrolysis of the sulphate acid ester in unstabilized cotton and wood cellulose nitrates.

EXPERIMENTAL

Cellulose Nitrate

The unstabilized cotton and wood cellulose nitrates were prepared by the method previously mentioned (5).

Hydrolysis of Unstabilized Cellulose Nitrate

The cellulose nitrates were washed and dried. Moist samples of different weights (2–5 g. for cotton and 3–7 g. for wood) were dissolved in acetone (700 ml.) containing 0.63% water, and hydrolysis experiments were carried out at 25°±0.1° C., using the method recently given (2). The initial acidity of the cellulose nitrates before hydrolysis started was determined by titration in 90% acetone (2).

In other experiments, moist samples of equal weight (2 g. for cotton and 5 g. for wood) of cellulose nitrates were dissolved in different acetone/water solutions (700 ml.) containing 0.63 to 4.20% water.

RESULTS AND DISCUSSION

Effect of Water Content of Cellulose Nitrate upon Hydrolysis of the Sulphate Acid Ester

The rates of hydrolysis of the sulphate acid esters in unstabilized cotton and wood

[1]*Manuscript received December 20, 1957.*

cellulose nitrates could not be strictly compared because the samples, although having the same ester content, had different water contents.

In view of the above observation it was of interest to determine the effect of water content upon the rate of hydrolysis of the sulphate acid ester in unstabilized cellulose nitrates. Accordingly, many experiments were performed using moist cotton cellulose nitrate samples of variable water content. For example, in two experiments, the rates of hydrolysis of the sulphate acid esters in 11.4% N cellulose nitrates having different water contents, 0.16 and 0.28%, were compared.

It was seen that the release of sulphuric acid was most rapid in the case of the cellulose nitrate containing least water. For instance, in the first experiment, after 5 minutes, the per cent sulphuric acid released was 1.58 whereas for the same time, in the second experiment, it was only 1.25. The difference between the water contents of the two cellulose nitrates concerned was only 0.12%. The effect of the water content was greatest upon the initial hydrolysis, that taking place in the first 15 minutes. Later, the hydrolysis proceeded normally. For instance, in the above experiments, the percentages of sulphuric acid released after 30 minutes were about the same, 2.07 and 2.13 respectively. Similar results were obtained with unstabilized wood cellulose nitrates.

It is evident that small differences in the water content had a significant effect upon the rate of hydrolysis of the sulphate acid ester, RSO_4H, as shown in Fig. 1 for two cotton cellulose nitrates containing 100% sulphate acid ester and 11.4 and 9.7% nitrogen respectively.

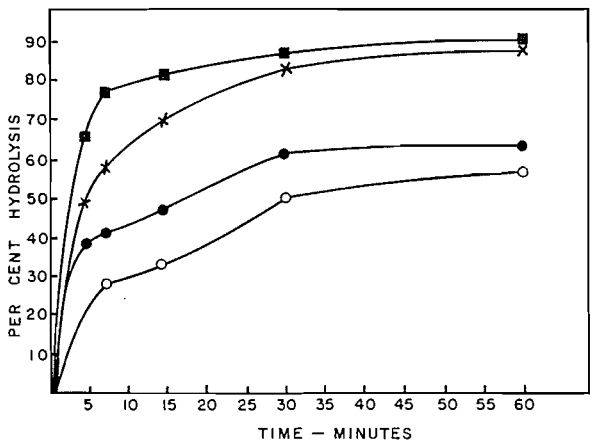

FIG. 1. Effect of water content of cellulose nitrate upon hydrolysis of sulphate acid ester.

When the water content was increased, the rate of hydrolysis of the sulphate acid ester in unstabilized cotton cellulose nitrate decreased. Similar results were obtained with wood cellulose nitrate.

Effect of Water Content of Acetone upon Hydrolysis of Sulphate Acid Ester

The hydrolysis of the sulphate acid ester in both unstabilized cotton and wood cellulose nitrates was stopped in the presence of acetone containing 10% water (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

In the present work, the effect of the water content of the acetone hydrolysis medium upon the rate of hydrolysis of the sulphate acid ester in unstabilized cellulose nitrates was carefully investigated. Hydrolysis experiments were carried out using cotton cellulose nitrate samples containing about the same amount of water, dissolved in various acetone/water solutions. For example, cellulose nitrates containing about 11.4% nitrogen, 100% sulphate acid ester, and 0.13% water, expressed as % vol. in the acetone medium, were used for hydrolysis experiments.

It was seen that the rate of hydrolysis decreased as the water content of the acetone increased. For instance, 0.54% sulphuric acid was released in the first 5 minutes of hydrolysis when the acetone contained 0.63% water, in one experiment, whereas in another none was released with 4.20% water present in the acetone. In some experiments, there was 100% hydrolysis of the sulphate acid ester, but in others the hydrolysis was not complete after 24 hours because of the presence of too much water in the acetone.

The effect of the water content of the acetone upon the rate of hydrolysis of the sulphate acid ester in an unstabilized cotton cellulose nitrate is shown in Fig. 2. It is seen that increase of water content greatly reduced the rate of hydrolysis in the first hour. For example, with only 0.63% water in the acetone medium there was about 78% hydrolysis after 1 hour, whereas with a water content of 4.20%, the corresponding value was only 6%.

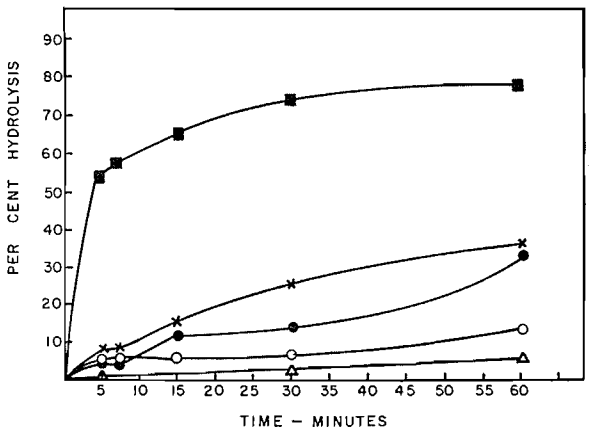

FIG. 2. Effect of water content of acetone upon hydrolysis of sulphate acid ester in cotton cellulose nitrates.

	■	×	●	○	△

Water concn., in acetone, % vol.	0.63	1.34	2.06	3.49	4.20
Sulphate acid ester, %	100	100	100	83	79

Furthermore, hydrolysis experiments were performed on unstabilized wood cellulose nitrates, and the results obtained for a sample containing about 10.7% nitrogen, 100% sulphate acid ester, and 0.35% water, expressed as % vol. in the acetone medium, were similar to those given by cotton cellulose nitrates.

The effect of the water content of the acetone medium upon the rate of hydrolysis of the sulphate acid ester in a wood cellulose nitrate is shown in Fig. 3. The results were very similar to those obtained with cotton cellulose nitrate (Fig. 2).

In the present work, cotton and wood cellulose nitrates containing 100% sulphate

acid ester were used. In some experiments, in the case of both cotton and wood cellulose nitrates, the sulphate acid ester content determined by the hydrolysis method (6) was too low in comparison to the true value, 100%. For instance, the ester contents for two cotton cellulose nitrates were 83 and 79%, and for wood cellulose nitrates, they were 67 and 62%, respectively. These low results were due to the fact that the sulphate acid ester was not completely hydrolyzed after 24 hours.

The effect of the increase in water content upon the degree of hydrolysis of the sulphate acid ester in both cotton and wood cellulose nitrates after 24 hours is shown in Fig. 4.

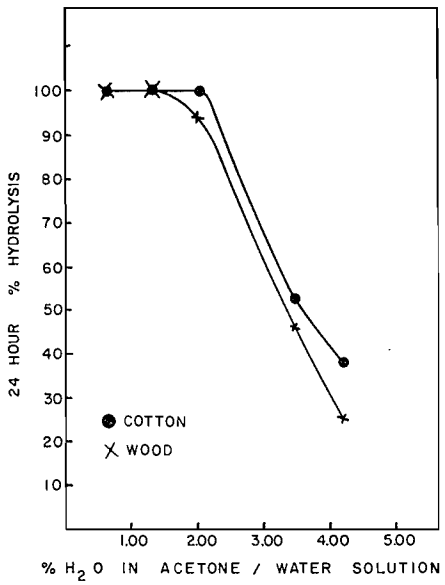

FIG. 4. Effect of water content of acetone upon the 24-hour hydrolysis of sulphate acid ester in cellulose nitrates.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

It is evident that with less than 2% water in the acetone the sulphate acid ester is completely hydrolyzed after 24 hours; but with higher water contents, the degree of hydrolysis decreases rapidly.

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

I. SUR LA SYNTHÈSE DES MONOARYL-*p*-BENZOQUINONES[1]

P. BRASSARD[2] ET P. L'ÉCUYER

RÉSUMÉ

Une étude de la réaction des sels de diazonium avec la *p*-benzoquinone a été faite. Exécutée selon des conditions bien déterminées quant à la nature du solvant, la concentration de la solution tampon et la température du milieu, cette réaction constitue une excellente méthode générale de synthèse des monoaryl-*p*-benzoquinones.

INTRODUCTION

Borsche (1, 2) réussit, en 1899, la première synthèse d'une monoaryl-*p*-benzoquinone. Par l'action d'un grand excès de chlorure de benzène-diazonium sur le *p*-nitrosophénol en milieu alcalin, il parvint à isoler le 2-phényl-4-nitrosophénol et le 2,6-diphényl-4-nitrosophénol dont la réduction en aminophénols et l'oxydation de ces derniers ont fourni, avec un rendement insignifiant, les 2-phényl- et 2,6-diphényl-*p*-benzoquinones. La très sérieuse difficulté de cette préparation réside dans l'isolement et la purification du phénylnitrosophénol.

En 1924, Günther (3) rapporta la première préparation de quelques monoaryl-*p*-benzoquinones par l'action de sels de diazonium sur la *p*-benzoquinone en solution alcoolique diluée et en présence d'acétate de sodium. Enfin, en 1934, Kvalnes (4) modifia la méthode de Günther pour préparer quelques autres monoaryl-*p*-benzoquinones dont le résidu phényle est porteur d'un substituant en position 4. Il ne fait aucune mention du rendement des quinones pures.

Cette modification comporte à peu près les mêmes inconvénients que la méthode originale de Günther. En effet, l'une et l'autre ne sont réalisables qu'avec les sels de diazonium porteurs d'un substituant en position 4 ou en 3, à la condition dans ce dernier cas qu'il soit fortement électronégatif. Autrement la réaction ne marche pas, comme Kvalnes l'admet lui-même à la suite de son insuccès à préparer les *o*-nitrophényl-, 2,6-xylényl- et α-naphtyl-*p*-benzoquinones.

D'ailleurs, quelques-unes des préparations décrites par Kvalnes, lorsque reprises par Asano et Kameda (5), se sont avérées beaucoup moins efficaces tant au point de vue des rendements que de l'homogénéité du produit. Celui-ci est toujours contaminé par une certaine quantité de substances polysubstituées dont il est souvent difficile de se débarrasser.

Enfin, en 1950, Schimmelschmidt (6), en utilisant le bicarbonate de sodium en milieu aqueux, a synthétisé l'*o*-chloro-, l'*o*-nitro- et d'autres phénylquinones ayant dans le résidu aromatique plusieurs substituants dont un halogène en position 2.

Cette dernière modification constitue sous certains aspects une amélioration appréciable à la méthode de Günther. Cependant le bicarbonate de sodium donne une solution tampon alcaline dans les conditions suivies par Schimmelschmidt. Or une étude de l'influence du pH du mélange sur la réaction nous a permis de constater que le pH idéal est 5. Un pH plus élevé entraîne invariablement la formation de résines.

Il est vrai que Schimmelschmidt a obtenu un excellent rendement dans la préparation

TABLEAU I

INFLUENCE DU SOLVANT

Solvant organique, ml.	Eau, ml.	NaOAc.3H_2O en moles	Rdt. d'*o*-tolylquinone	
			Produit brut, %	Produit pur, %
—	1000	0.225	78	58
Ethanol (200)	50	0.300	—	0
Ethanol (200)	800	0.300	64	41
Acétone (200)	800	0.300	—	—
Formamide (150)	100	0.300	—	0

Influence de la nature et de la concentration de la solution tampon

La nature et la concentration de la solution tampon, tout comme dans la réaction de Meerwein, s'avère d'une importance primordiale. De toutes les substances déjà utilisées par Meerwein (10), Schimmelschmidt (6) et surtout Rondestvedt et Vogl (11), c'est l'acétate de sodium qu'il est préférable d'employer dans la proportion de 2 moles par mole de réactif. Le pH du mélange réactionnel est alors 5.

En faisant varier la quantité d'acétate de sodium de 2 à 5 équivalents, la vitesse de la réaction s'accélère et le rendement du produit brut s'accroît, mais sa qualité se détériore graduellement avec l'augmentation de la concentration de l'acétate. Il s'ensuit en définitive une diminution du rendement de la substance pure; car il se forme une quantité proportionnelle de produits de décomposition et on éprouve une difficulté croissante à purifier la substance recherchée (Tableau II).

TABLEAU II

INFLUENCE DE LA CONCENTRATION D'ACÉTATE DE SODIUM HYDRATÉ

Température		Poids de NaOAc. 3H_2O en grammes	Rdt. d'*o*-tolylquinone	
Initiale	Finale		Produit brut, %	Produit pur, %
10°	25°	27.2 (0.200 m.)	77	65
10°	25°	30.6 (0.225 m.)	78	62
10°	25°	34.0 (0.250 m.)	83	53
10°	25°	40.8 (0.300 m.)	89	—
20°	30°	68.0 (0.500 m.)	95	30

Influence de la température

La température initiale optimum de la réaction se situe entre 10° et 15° pour tous les sels de diazonium. A cette température le dégagement gazeux se fait à une vitesse convenable et l'aryl-*p*-benzoquinone qui précipite est relativement pure. A moins de 10°, en l'absence d'un excès d'acétate, le produit formé prend généralement une teinte verdâtre indiquant la formation de quinhydrone. Par contre, il y a avantage à laisser le mélange se réchauffer lentement et atteindre la température ambiante vers la fin de la réaction, pour que se complète heureusement la transformation du composé intermédiaire. Une baisse de température à ce moment favorise la formation de sous-produits phénoliques, tandis qu'une température initiale supérieure à 15° ou une élévation trop rapide de celle-ci entraîne invariablement la formation de goudrons (Tableau III).

Influence de la nature de l'anion du sel de diazonium

Contrairement à ce qui se produit dans la réaction de Meerwein où seul l'emploi du chlorure et, dans une plus faible mesure, du bromure est possible, le chlorure, le bromure,

TABLEAU III

INFLUENCE DE LA TEMPÉRATURE

Température		$NaOAc.3H_2O$ en moles	Rdt. d'*o*-tolylquinone	
Initiale	Finale		Produit brut, %	Produit pur, %
4°	20°	0.225	78	60
10°	25°	0.225	78	62
15°	25°	0.225	78	58
20°	30°	0.250	71	43

le phosphate et le sulfate de diazonium réagissent indifféremment avec la *p*-benzoquinone (le sulfate requiert une plus grande quantité d'acétate pour neutraliser l'ion bisulfate) sans que le rendement ne soit affecté d'une façon appréciable. Seul le nitrate s'avère insatisfaisant, en donnant lieu à la formation de produits de décomposition (Tableau IV).

TABLEAU IV

INFLUENCE DE L'ANION DU SEL DE DIAZONIUM

Température		$NaOAc.3H_2O$ en moles	Acide en mole	Rdt. d'*o*-tolylquinone	
Initiale	Finale			Produit brut, %	Produit pur, %
10°	25°	0.225	HCl (0.3)	78	62
10°	25°	0.225	HBr (0.3)	77	60
10°	25°	0.425	H_2SO_4 (0.25)	78	61
10°	25°	0.225	H_3PO_4 (0.3)	76	—
10°	25°	0.225	HNO_3 (0.3)	71	—

Influence du chlorure cuivrique comme catalyseur

Ce catalyseur, employé dans la réaction de Meerwein, nuit à la réaction. Toutefois, en opérant dans l'acétone aqueux à 20% et à pH = 3, il a été possible d'isoler de l'*o*-chlorophényl-*p*-benzoquinone à peu près exempte de goudrons. Malgré tout, la substance était encore contaminée par une certaine quantité de produits huileux provenant sans doute d'une réaction secondaire du type de celle de Sandmeyer. D'ailleurs, l'addition fréquente de quantités appréciables du catalyseur devenait essentielle au maintien d'une vitesse convenable du dégagement gazeux.

Influence de la nature et de la position de substituant

Le rendement semble peu affecté par la nature du substituant dans le sel de diazonium. L'allusion maintes fois répétée (12, 13, 14, 15, 16) à l'effet que la présence d'un groupe méthoxyle diminue le rendement dans la réaction de Meerwein ne s'applique pas ici ni dans le travail de Rondestvedt et Vogl (17).

L'arylation par les sels de diazonium substitués en position 2 s'effectue avec d'excellents rendements à la condition que le substituant ne soit ni fortement électropositif ni trop électronégatif, mais il importe d'opérer dans des conditions nettement déterminées, car autrement les rendements peuvent diminuer considérablement et la pureté du produit se déteriorer à un point où il est difficile d'en isoler une substance pure.

Lorsque le substituant en 2 est très électronégatif ou très électropositif, on obtient malgré toutes les précautions une certaine proportion de polymères, d'hydrocarbures, de phénols et même de diazoiques résultant de la copulation du sel de diazonium avec les phénols.

La plupart des phényl-*p*-benzoquinones substituées en position 2 du résidu hydrocarbonné sont très solubles dans les solvants organiques et ont un point de fusion assez bas, de sorte que leur purification présente des inconvénients et des difficultés. Il est alors préférable d'extraire le produit brut à l'éther de pétrole bouillant, d'évaporer à sec l'extrait éthéré, de traiter le résidu au noir animal et ensuite de le cristalliser ou distiller sous vide. Toutefois, même en opérant dans les conditions les plus favorables, les rendements des monoaryl-*p*-benzoquinones obtenues à partir de sels de diazonium *o*-substituées sont inférieurs de 10% à 30% à ceux qui proviennent des isomères para.

Enfin, il semble que l'encombrement stérique en 2 joue un rôle très négligeable dans la réaction. Ainsi le sel de diazonium de l'*o*-aminodiphényle donne, malgré la grosseur du substituant, un rendement de 88% d'*o*-diphényl-*p*-benzoquinone pure. De plus, il est vrai que la 2,6-diméthylaniline ne donne qu'un faible rendement même du produit brut; mais, lorsque la réactivité de cette amine est rehaussée par la bromuration en 4, la réaction procède avec facilité pour fournir un excellent rendement de 2,6-diméthyl-4-bromophényl-*p*-benzoquinone.

Quelques-unes des synthèse décrites par Kvalnes ont été répétées en tenant compte des conditions les plus favorables telles qu'établies antérieurement. Dans tous les cas, les rendements de la substance brute approchaient 100% et, après purification, le pourcentage de récupération a toujours été supérieur à 90%. Plusieurs autres monoaryl-*p*-benzoquinones, même celles qu'il serait impossible d'obtenir par la méthode de Kvalnes, ont été synthétisées avec d'excellents rendements (Tableau V).

TABLEAU V

MONOARYL-*p*-BENZOQUINONES

Groupe substituant	Rdt., %	P.f., °C.	Formule	C		H

PARTIE EXPÉRIMENTALE*

La synthèse des monoaryl-*p*-benzoquinones décrites dans ce mémoire a été réalisée en tenant compte des conditions optimum d'opération telles qu'établies dans la partie théorique. Comme la façon de préparer les sels de diazonium et d'effectuer leur réaction avec la *p*-benzoquinone est à peu près constamment la même pour toutes les synthèses,

**Les points de fusion ont été pris à l'aide de l'appareil de Johns. Les combustions ont été faites par les auteurs.*

nous ne la donnons en détail que pour la première, nous contentant d'en mentionner, le cas échéant, les modalités.

Un excès de 20% de quinone facilite la purification du produit de la réaction. L'excès de quinone reste en solution dans les eaux-mères. Au contraire, l'emploi de quantités équivalentes de sels de diazonium et de quinone occasionne la formation de résines.

Phényl-p-benzoquinone (*10*)

Une solution d'aniline (9.3 g., 0.1 mole) dans 25 ml. d'acide chlorhydrique concentré étendu de 100 ml. d'eau est refroidie à une température inférieure à 5° et diazotée, en agitant régulièrement, par l'addition goutte à goutte d'une solution de 7.0 g. de nitrite de sodium dans 25 ml. d'eau. On vérifie la fin de la réaction à l'aide de papier iodo-amidonné. La solution ainsi obtenue est ensuite versée d'un seul trait dans une suspension de *p*-benzoquinone (13.0 g., 0.12 mole) dans 850 ml. d'eau à 15° qui contient en solution 30.6 g. (0.225 mole) d'acétate de sodium hydraté comme tampon. On agite énergiquement au moyen d'un agitateur mécanique.

Le dégagement gazeux qui caractérise la réaction commence immédiatement et le mélange se réchauffe lentement pour atteindre finalement la température ambiante. Après une heure d'agitation la réaction est terminée. On filtre la solution et on recueille 16.9 g. de produit brut sous forme d'une poudre jaune qu'on cristallise dans l'éther de pétrole (p.é. 65°–110°). Après avoir laissé séjourner la solution pendant quelque temps au réfrigérateur à −10°, on la filtre et on recueille 15.4 g. de phényl-*p*-benzoquinone pure cristallisée en paillettes jaune doré.

p-Hydroxyphényl-p-benzoquinone

On diazote comme précédemment 10.9 g. de *p*-aminophénol dissous dans 50 ml. d'eau et 14 g. d'acide sulfurique concentré et on verse cette solution dans un mélange de 13.0 g. de *p*-benzoquinone, de 54.4 g. d'acétate de sodium hydraté et 200 ml. d'alcool éthylique, tout en agitant mécaniquement. La réaction commence immédiatement à 15° et elle est terminée à la température ordinaire après 2 heures d'agitation. Après dilution avec un assez grand volume d'eau (environ 1 litre) la majeure partie du liquide surnageant le précipité est décantée et la *p*-hydroxyphényl-*p*-benzoquinone, qui s'est séparée sous forme de cristaux rouges, est filtrée. Elle cristallise dans l'alcool dilué en fines aiguilles rouges.

p-Anisyl-p-benzoquinone (*10*)

La réaction entre le chlorure de diazonium de la *p*-anisidine (12.3 g.) et la *p*-benzoquinone (13.0 g.) se fait en 30 minutes. On cristallise dans l'acétone aqueux (2:1) et on récupère 19.9 g. de *p*-anisyl-*p*-benzoquinone sous forme de lamelles rouges.

p-Chlorophényl-p-benzoquinone

On diazote de la façon habituelle, entre 5° et 10°, de la *p*-chloraniline (12.8 g.) et on fait réagir la solution du sel de diazonium avec la *p*-benzoquinone (13.0 g.) dans 1000 ml. d'eau à la température ambiante. La réaction dure 3 heures. On obtient 21.4 g. de produit pulvérulent jaune pâle. Après cristallisation dans un mélange d'alcool éthylique et d'acétone (2:1), on recueille 19.2 g. de *p*-chlorophényl-*p*-benzoquinone pure cristallisée en aiguilles jaunes.

p-Nitrophényl-p-benzoquinone (*10*)

La *p*-benzoquinone (13.0 g.) dans 1350 ml. d'eau à 20° réagit pendant 2 heures avec le sel de diazonium de la *p*-nitraniline (13.8 g.). La réaction terminée, on filtre le précipité jaune-orangé. On cristallise dans un mélange d'éthanol et d'acétone (2:1) pour obtenir 20.3 g. de *p*-nitrophényl-*p*-benzoquinone pure sous la forme d'aiguilles jaune-orangé.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

3,4-Diméthoxyphényl-p-benzoquinone (*1*)

La réaction du chlorure de diazonium de la 3,4-diméthoxy-aniline (15.3 g.) avec la *p*-benzoquinone (13.0 g.) commencée à 12°, en présence de 34.0 g. d'acétate de sodium hydraté, se termine en moins d'une heure à la température ambiante. Après refroidissement du mélange on filtre le précipité rouge et on le cristallise dans un mélange éthanol–acétone (2:1). On obtient la 3,4-diméthoxy-*p*-benzoquinone pure (20.3 g.) sous la forme de lamelles rouges.

m-Tolyl-p-benzoquinone

On fait réagir le chlorure de diazonium de la *m*-toluidine (10.7 g.) avec la *p*-benzoquinone (13.0 g.). La réaction met plusieurs heures à se compléter. On obtient, par filtration, 18.4 g. de produit jaune brunâtre. On extrait celui-ci plusieurs fois à l'éther de pétrole (p.é. 65°–110°) bouillant. On évapore à sec sous pression réduite les extraits réunis, on dissout le résidu dans un mélange d'acétone, de méthanol et d'eau (1:1:1) et on bout cette solution pendant 15 minutes avec du noir animal. Après filtration à chaud et refroidissement à $-10°$ pendant quelques jours, la *m*-tolyl-*p*-benzoquinone pure cristallise en paillettes jaune pâle.

m-Chlorophényl-p-benzoquinone

La réaction entre le chlorure de diazonium de la *m*-chloraniline (12.8 g.) et la *p*-benzoquinone (13.0 g.) se fait dans 1000 ml. d'eau. Commencée à 15° elle dure 3 heures. On recueille par filtration 21.2 g. de produit pulvérulent jaune. Cristallisée à $-10°$ dans un mélange d'éthanol et d'acétone (2:1), la *m*-chlorophényl-*p*-benzoquinone pure (19.7 g.) est obtenue sous la forme de lamelles jaune pâle.

m-Acétophényl-p-benzoquinone

La réaction du chlorure de diazonium de la *m*-acétophénone (13.5 g.) avec la *p*-benzoquinone (13.0 g.) est commencée à 10° et dure 2 heures. Le produit (21.0 g.) cristallise, après traitement à l'ébullition avec du noir animal dans un mélange d'acétone, de méthanol et d'eau (1:2:1), en aiguilles jaune-orangé.

Méthane sulfonate de la 2-hydroxyphényl-p-benzoquinone

Le méthane sulfonate d'*o*-aminophénol (9.4 g., 0.05 mole) dissous dans un mélange d'acide chlorhydrique concentré (12.5 ml.) et de 50 ml. d'eau est diazoté par une solution de 3.5 g. de nitrite de sodium dans 15 ml. d'eau et versé dans une suspension de 6.5 g. de *p*-benzoquinone dans 425 ml. d'eau à 10° et 15.3 g. d'acétate de sodium hydraté. Après cristallisation du produit de la réaction dans l'éthanol, on récupère 10.7 g. de méthane sulfonate de la 2-hydroxyphényl-*p*-benzoquinone sous la forme d'aiguilles jaune pâle.

o-Tolyl-p-benzoquinone

Un mélange de *o*-toluidine (10.7 g.) diazotée et de *p*-benzoquinone (13.0 g.) réagit pendant plusieurs heures. On isole ensuite le produit cristallin brunâtre (15.4 g.) et on l'extrait à l'éther de pétrole (p.é. 65°–110°) bouillant. Après l'évaporation à sec des extraits éthérés sous pression réduite, on dissout le résidu à chaud dans un mélange de méthanol, d'acétone et d'eau (1:1:1), on bout en présence de noir animal et on obtient, après filtration et refroidissement de la solution à $-10°$, 12.3 g. d'*o*-tolyl-*p*-benzoquinone cristallisée sous la forme de paillettes jaunes.

o-Anisyl-p-benzoquinone

Le chlorure de diazonium de l'*o*-anisidine (12.3 g.) met 3 heures à réagir avec la *p*-benzoquinone (13.0 g.). Le produit visqueux, que l'on obtient, est extrait à l'éther de pétrole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(p.é. 65°–110°) bouillant. Les extraits réunis sont évaporés à sec sous vide et le résidu est repris à l'ébullition avec du noir animal dans un mélange d'acétone, de méthanol et d'eau (1:1:1). Après cristallisation à -10°, on récupère 17.4 g. d'*o*-méthoxyphényl-*p*-benzoquinone pure sous forme d'un mélange polymorphe d'aiguilles jaune-orangé, p.f. 58°–59°, et de lamelles rouges, p.f. 64°–65°.

o-Diphényl-p-benzoquinone

Le produit brut (25 g., 96%) résultant de l'action du chlorure de diazonium de l'*o*-aminodiphényle (16.9 g.) sur la *p*-benzoquinone (13.0 g.) est isolé après 3 heures de réaction sous la forme d'une poudre jaune amorphe. On le purifie en bouillant à reflux sa solution dans l'acide acétique à 80% avec du noir animal. L'*o*-diphényl-*p*-benzoquinone pure (22.8 g.) cristallise en lamelles jaunes.

o-Chlorophényl-p-benzoquinone

Il faut agiter mécaniquement pendant 5 heures pour que la réaction entre le chlorure de diazonium de l'*o*-chloraniline (12.8 g.) et la *p*-benzoquinone (13.0 g.) se complète. Le dégagement gazeux terminé, on isole 21.1 g. de produit cristallin légèrement brunâtre. On peut le purifier selon l'une ou l'autre des façons suivantes:

Méthode A.—On extrait le produit brut jusqu'à épuisement avec plusieurs portions d'éther de pétrole (p.é. 65°–110°) bouillant et on évapore à siccité sous pression réduite les extraits réunis. On fait bouillir à reflux le résidu avec du noir animal dans un mélange de méthanol, d'acétone et d'eau (1:1:1). Après avoir éliminé le noir animal, la substance pure cristallise dans le mélange de solvants refroidi. On en récupère ainsi 18.1 g.

Méthode B.—On peut également cristalliser le résidu deux fois dans le même mélange de solvants en bouillant chaque fois la solution à reflux avec du noir animal. Le rendement de l'*o*-chlorophényl-*p*-benzoquinone pure cristallisée en paillettes jaunes est alors de 17.2 g.

o-Bromophényl-p-benzoquinone

La réaction du chlorure de diazonium de l'*o*-bromaniline (17.2 g.) avec la *p*-benzoquinone (13.0 g.) dure 6 heures. Le précipité jaune-orangé obtenu pèse 25.6 g. On le cristallise deux fois dans un mélange de méthanol, d'acétone et d'eau (1:1:1) en ayant soin chaque fois de faire bouillir la solution à reflux avec du noir animal. L'*o*-bromophényl-*p*-benzoquinone cristallise en lamelles jaunes.

o-Carbométhoxyphényl-p-benzoquinone

On fait réagir pendant 3 heures le chlorure de diazonium de l'anthranilate de méthyle (15.1 g.) et la *p*-benzoquinone (13.0 g.). Le produit brut filtré et séché pèse 22.2 g. On le cristallise à −10° dans un mélange de méthanol, d'acétone et d'eau (1:1:1) (noir animal). L'*o*-carbométhoxyphényl-*p*-benzoquinone pure (19.5 g.) s'obtient sous forme d'aiguilles jaunes.

o-Nitrophényl-p-benzoquinone

On triture 13.8 g. d'*o*-nitraniline dans 25 ml. d'acide chlorhydrique concentré jusqu'à l'obtention d'une pâte homogène; on étend alors de 100 ml. d'eau et on diazote de la façon habituelle. On fait réagir avec 13.0 g. de *p*-benzophénone. On essore 21.6 g. de produit cristallin. La quinone est isolée en faisant plusieurs extractions successives à l'éther de pétrole (p.é. 90°–110°) bouillant. Les extraits réunis sont évaporés à sec et le résidu cristallisé dans un mélange d'acétone, de méthanol et d'eau (1:2:1) (noir animal). L'*o*-nitrophényl-*p*-benzoquinone pure (17.3 g.) s'obtient en lamelles jaunes.

For personal use only.

2,6-Diméthyl-4-bromophényl-p-benzoquinone (16)

On essore 26.8 g. du produit brut de la réaction du chlorure de diazonium de la 2,6-diméthyl-4-bromaniline (20.0 g.) et de la *p*-benzoquinone (13.0 g.) On l'extrait à l'éther de pétrole (p.é. 65°–110°) bouillant. Après l'évaporation à sec des extraits sous pression réduite, le résidu est cristallisé dans un mélange d'acétone, de méthanol et d'eau (1:2:1), après traitement au noir animal. On obtient ainsi 24.1 g. de 2,6-diméthyl-4-bromophényl-*p*-benzoquinone pure sous la forme de paillettes jaunes.

2,6-Dichlorophényl-p-benzoquinone

On obtient de la réaction du chlorure de diazonium de la 2,6-dichloraniline (16.2 g.) et de la *p*-benzoquinone (13.0 g.) 22.7 g. de produit que l'on purifie en extrayant à plusieurs reprises à l'éther de pétrole (p.é. 65°–110°) bouillant, en chassant le solvant des extraits et en cristallisant le résidu dans un mélange d'acétone, de méthanol et d'eau (1:1:1) (noir animal). La 2,6-dichlorophényl-*p*-benzoquinone pure (18.5 g.) cristallise à $-10°$ en lamelles jaunes.

α-Naphtyl-p-benzoquinone

Une suspension d'α-naphtylamine (14.3 g.) dans 300 ml. d'eau est traitée par 16.7 ml. d'acide sulfurique concentré et diazotée de la façon habituelle par 7.0 g. de nitrite de sodium dans 50 ml. d'eau. On verse ensuite cette solution dans une suspension de 13.0 g. de *p*-benzoquinone et de 30.6 g. d'acétate de sodium hydraté dans 650 ml. d'eau à 10°. On agite mécaniquement et on maintient le pH à 5 pendant toute la durée de l'expérience en ajoutant régulièrement de l'acétate de sodium en petites portions. La température s'élève lentement et l'on prend soin de la maintenir inférieure à 20° par l'addition de glace. Après plusieurs heures, on obtient une substance visqueuse qui, après la décantation de la liqueur, est séchée et extraite à la ligroine (p.é. 90°–120°) bouillante. Les extraits refroidis sont de nouveau portés à l'ébullition et décantés. On répète ce procédé jusqu'à ce qu'il ne précipite plus, à la température ordinaire, de goudrons qui restent insolubles à chaud. Les extraits sont alors évaporés à sec sous pression réduite et le résidu est cristallisé dans le méthanol. L'α-naphtyl-*p*-benzoquinone pure (12.3 g.) est obtenue en aiguilles rouges.

REMERCIEMENTS

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

II. SUR LA SYNTHÈSE DES 2,5-BISARYL-*p*-BENZOQUINONES[1]

P. BRASSARD[2] ET P. L'ÉCUYER

RÉSUMÉ

Nous avons réussi la synthèse des 2,5-bisaryl-*p*-benzoquinones en faisant réagir des sels de diazonium avec des monoaryl-*p*-benzoquinones. Cette réaction donne des rendements fort convenables et elle constitue une méthode générale pour la préparation de cette classe de composés, quand elle est exécutée dans des conditions bien déterminées.

INTRODUCTION

Il n'existe à date aucune méthode générale de synthèse (1, 2, 3, 4, 5, 6, 7, 8, 9, 10) des 2,5-bisphénylquinones substituées dans les groupements phényles. Quoique Kvalnes (11) ait constaté qu'il n'est possible de les obtenir qu'avec de très faibles rendements et contaminées par de fortes proportions de dérivé tétrasubstitué par l'action des sels de diazonium sur la benzoquinone, il nous a semblé que la réaction de ces sels avec les monophénylquinones dans des conditions appropriées devrait pouvoir servir de méthode générale pour leur synthèse.

C'est le cas, si on opère dans un milieu qui favorise la précipitation de la 2,5-bisphénylquinone aussitôt formée et l'empêche ainsi de réagir à son tour avec le sel de diazonium. La benzoquinone réagit facilement avec les sels de diazonium en milieux aqueux (12, 13) pour donner des monophénylquinones. Celles-ci sont cependant, en général, trop insolubles dans l'eau pour réagir dans les mêmes conditions, mais elles le font dans un mélange d'un solvant organique et d'eau. L'acide acétique dilué ou l'acétone aqueux s'est révélé, selon le cas, le milieu le plus propice à l'introduction d'un deuxième résidu phényle dans la quinone.

Lorsque la phénylquinone de départ est très soluble dans les solvants organiques, il est préférable d'employer le mélange eau – acide acétique pour éviter la formation du dérivé tétrasubstitué. Par contre, avec une phénylquinone moins soluble le mélange eau–acétone donne de meilleurs résultats. Il faut toutefois dans cette dernière alternative opérer à une température inférieure à 0°.

Nous n'avons constaté aucun avantage à employer des sels cuivriques (chlorure ou acétate) comme catalyseur de la réaction. Ceci est d'autant plus surprenant que d'après Marini-Bettòlo et Rossi (14) l'addition de poudre de bronze améliore le rendement de l'arylation de la 1,4-naphtoquinone en milieu acétique.

Nous avons vérifié la généralité de cette méthode de synthèse des 2,5-bisphénylbenzoquinones en en préparant plusieurs à partir de sels de diazonium représentant toute la gamme de réactivité (Tableau I).

PARTIE EXPÉRIMENTALE

On diazote entre 0° et 5° l'amine (0.05 mole) dissoute dans un mélange de 25 ml. d'eau et de 12.5 ml. d'acide chlorhydrique concentré en ajoutant lentement une solution de 3.5 g. de nitrite de sodium dans 15 ml. d'eau. La solution du sel de diazonium est ensuite versée dans un mélange de la phénylquinone (0.045 mole), de 20.4 g. (0.15 mole)

**Les points de fusion ont été pris à l'aide de l'appareil de Johns.*

d'acétate de sodium trihydraté et de 200 à 250 ml. d'acide acétique agité mécaniquement. On ajoute alors suffisamment d'eau (environ 75 à 100 ml.) pour produire une légère précipitation de la quinone de départ. Tout en maintenant l'agitation du milieu, on peut laisser réagir à la température ambiante ou, s'il le faut, on chauffe très légèrement le mélange jusqu'à l'obtention d'un dégagement modéré d'azote sans toutefois dépasser une température de 40° à 45°.

Une fois le dégagement gazeux terminé, on étend d'eau, on isole le précipité et on le dissout dans un mélange d'acétone et de méthanol (1:4) bouillant. On laisse cristalliser la quinone en abandonnant la solution pendant quelques jours au réfrigérateur à −10°. En diluant les eaux-mères de cristallisation avec un peu de méthanol et en les laissant séjourner au réfrigérateur on augmente le rendement d'une façon appréciable. La 2,5-bisphénylquinone est obtenue presque pure. Si nécessaire, on peut la purifier davantage en la recristallisant dans les solvants appropriés.

Quand la phénylquinone de départ n'est pas assez soluble dans l'acide acétique ou lorsque le sel de diazonium l'exige, ce qui est le cas, par exemple, pour la *m*-chlorophénylquinone et le sel de diazonium de la β-naphtylamine, on dissout la phénylquinone dans l'acétone (300 ml. pour 0.045 mole), on refroidit la solution à −5° et on y verse la solution du sel de diazonium. Tout en agitant mécaniquement et en maintenant la température à −5°, on introduit l'acétate de sodium trihydraté (20.4 g. en tout) en petites portions durant une période de 20 minutes. On laisse ensuite le mélange se réchauffer à la température ambiante. L'isolement de la quinone se fait comme précédemment.

REACTIVITY STUDIES ON NATURAL PRODUCTS

IV. DISSOCIATION CONSTANTS OF THE CYANOHYDRINS OF SOME STEROID KETONES[1]

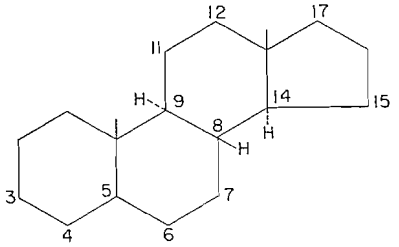
OWEN H. WHEELER[2] AND JOSÉ L. MATEOS[3]

ABSTRACT

The dissociation constants of the cyanohydrins of 3-, 6-, and 7-ketocholestane, 3-keto-coprostane, Δ^4- and Δ^5-cholestenone, and Δ^7-, $\Delta^{8(9)}$-, $\Delta^{8(14)}$-, and Δ^{14}-ergosten-3-one have been measured in 80% dioxane at 25.0°. Cholestan-3-one and coprostan-3-one have essentially the same reactivity. 6- and 7-Ketocholestane show "eclipsing" effects of neighboring hydrogen atoms. Δ^4- and Δ^5-Cholestenone are less reactive than cholestanone owing to the electronic effect of the double bond, but Δ^7-, $\Delta^{8(9)}$-, $\Delta^{8(14)}$-, and Δ^{14}-ergostenone are more reactive, the effect decreasing with the distance of the double bond from the 3-keto group.

INTRODUCTION

While quantitative studies have been made on the reactivity of steroid esters and alcohols (1, 2), few quantitative data have been published on the relative reactivity towards addition reactions of a keto group in various positions of the steroid molecule, the only work of this nature being studies of the rates of oxime formation of 3-, 4-, 6-, and 7-ketocholestane (3), and of the borohydride reduction of 3- and 20-ketopregnanone (4). It is known that certain postions, e.g., 11 and 12, are unreactive with respect to a 3-keto group, but no systematic study has been made of the reactivity of groups in rings A and B, where reactivity differences would be expected to be small. The determination of ketone–cyanohydrin equilibria provides a convenient method of studying ketone reactivity towards addition reactions (5), and the dissociation constants of the cyanohydrins of 3-keto-cholestane and -coprostane (rings A/B *trans* and *cis*, respectively), 6- and 7-keto-cholestane, and 3-keto steroids with double bonds in positions 4,5,7,8(9),8(14), and 14 have been measured in 80% dioxane–water at 25.0° (see Table I), to investigate the influence of substitution in various positions, of *cis-trans* ring A/B fusion, and the effect of double bonds.



Cholestan-3-one and coprostan-3-one differ only in the nature of the ring A/B fusion. The *trans* fusion in the former case gives the molecule a continuous zigzag form, whereas the *cis* fusion, in the latter, leads to an L-shaped structure (6, 7). In cholestane the methyl group at C-10 and the 9—10 bond are *axial and equatorial* respectively (with respect to ring A), and in the second case are reversed, but in both cases the hydrogen atom at

[b]*Ratio of dissociation constant to cyclohexanone = 1.0.*

C-5, one carbon atom nearer, is axial and the 5—6 bond equatorial and thus no large steric effect to cyanohydrin formation due to "axial crowding" (5) would be expected, and both these ketones have essentially the same cyanohydrin dissociation constant as cyclohexanone. The small increased reactivity of cholestanone with respect to cyclohexanone may be due to an "equatorial crowding" effect (5) similar to that observed in alkyl cyclohexanones, whereby the large internal carbonyl angle of the ketone distorts both rings A and B. The distortion is relieved in forming an addition product and addition is, therefore, facilitated.

6- and 7-Ketocholestane both have an extra alkyl substituent in the α-position, and this will exert an inductive effect which will increase the dissociation constant (5). However, the 6-ketone shows only a small increase while the 7-ketone actually shows a large decrease in dissociation constant and another effect must be operating. Construction of models shows that in the case of the 7-ketone the steric geometry of the steroid molecule is such that an α-hydrogen atom at C-15 is brought very close to the carbonyl group. Addition to the keto group gives a staggered structure and reduces the unfavorable oxygen–hydrogen interactions and is thus favored (8). This shielding or "eclipsing" effect has previously been observed to affect the stabilities of α-decalone and the 1,4-ketoperhydrophenanthrenes (9). In the case of the 6-ketone the small "eclipsing" effect of the hydrogen atoms on C-4 will tend to increase the extent of cyanohydrin formation, but there will be an "axial crowding" effect (5) in the cyanohydrin, between the methyl group at C-10 (2) and the cyanide (or hydroxyl) group. The net result of these opposing effects is a small decrease in reactivity, with respect to cholestan-3-one.

Δ^4- and Δ^5-Cholestan-3-one are both less reactive towards cyanohydrin formation than 3-cholestanone. In the former case, addition to the ketone grouping will destroy the resonance conjugation of the α,β-unsaturated ketone system and hence cyanohydrin formation will be difficult. (Whether addition was 1,4 as well as 1,2 was not determined. However, the reaction was unimolecular in ketone and cyanide.) The decreased reactivity of Δ^4-3-keto steriods, as compared to 3-keto steroids, towards dioxalan formation (10), ketal formation (11), and borohydride reduction (12) has previously been noted. In the Δ^5-compound there will be an inductive (or hyperconjugative) donation of electrons by the double bond to the ketone group (analogous to double-bond participation in the solvolysis of cholesteryl-*p*-toluene sulphonate (13)) and this will decrease the polarity of the ketone grouping and reduce nucleophilic attack of cyanide ion.

For personal use only.

In contrast to the behavior of the Δ^4- and Δ^5-compounds, the four ergosten-3-ones (Δ^7, $\Delta^{8(9)}$, $\Delta^{8(14)}$, and $\Delta^{(14)}$) show increased reactivity but in an order decreasing with distance of the double bond from the ketone grouping, until no effect is apparent in the Δ^{14}-compound. This effect is probably not electronic, since the double bonds are too far removed from the keto group, and though the Δ^4- and Δ^5-ketones show displacements of ketone absorption in both the ultraviolet and the infrared (see Table II) due to electronic effects, the ergostenones are no different from cholestanone.

TABLE II

[c] *As ethanolic solutions. Present work, unless otherwise stated.*

[d] *Ref. 40.*

Cyclohexene exists in a preferred "half-chair" conformation (14, 15), in which all the angles are slightly distorted (16), and introduction of a double bond into the steroid nucleus will lead to an over-all flattening of the rings. This will slightly distort ring A and introduce small non-bonded interactions. Cyclohexanone, itself, is a slightly distorted structure and its reactivity is due partly to the tendency to form an undistorted addition product (8). The presence of a keto group in ring A will introduce non-bonded interactions in this ring, and these will be increased by the conformational distortions produced by a double bond in a neighboring ring. Thus addition to the keto group, which will partially relieve the unfavorable interactions, will take place more readily than in the case of the saturated ketones. The effect of Δ^7 and $\Delta^{8(9)}$ double bonds, which are on either side of the C-3 to C-8 axis of rings A and B, is the same. A $\Delta^{8(14)}$ double bond, which is exocyclic to these two rings, has less effect and a Δ^{14} double bond, one more carbon atom remote and in another ring, has no measurable effect. Barton and co-workers (17, 18) have recently shown the operation of long-range effects in the mutarotation of steroid 5,6-dibromides and in the condensation of 3-keto triterpenes with benzaldehyde and has introduced the term "conformational transmission" for the transmission of distortions through a molecule by flexing of valency angles and alteration of atomic co-ordinates. Since no electronic interactions are involved and the effect is purely a steric one, it will manifest itself in an entropy term, and Barton and Head observed no difference in the energy of activation for the dibromides studied, but found small differences in the frequency factor. In the present work the maximum difference, between $\Delta^{8(9)}$-ergosten-3-one and cholestan-3-one, corresponds to a free-energy difference of only 0.18 kcal.

The ketones were generally prepared by standard methods (see Experimental), but in the course of the work some interesting observations were made. Ergosteryl acetate is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

hydrogenated in ethyl acetate under ordinary conditions to Δ^7-ergostenyl acetate, but with Raney nickel at high temperature and pressure the product formed was $\Delta^{8(14)}$-ergostenyl acetate. This isomerization has previously been noted with platinum oxide in acetic acid (19). As an alternative to oxidation with chromium trioxide in acetic acid and benzene (20), or Oppenauer oxidation (21), the oxidation of some of the unsaturated alcohols with chromium trioxide in pyridine (the Sarett reagent (22)) was investigated. Cholesterol itself gave a mixture consisting largely of Δ^4-cholestenone but oxidation of Δ^7-ergostenol proceeded without rearrangement. This reagent has been recently used for the oxidation of ursa-9(11),12-dien-3-ol (23) without rearrangement of the double bond. However, it was found that use of only a small excess of chromium trioxide in acetic acid and benzene gave better yields, and this method was generally employed. The isomerization of $\Delta^{8(14)}$-ergostenone to Δ^{14}-ergostenone with hydrogen chloride in chloroform (24, 25) proved to be incomplete (26, 27). Various conditions of time and temperature were tried but the best yield obtained was only a 20% conversion. The isomerization of the corresponding acetate or alcohol gave poorer yields.

EXPERIMENTAL

Ketones

Cyclopentanone and cyclohexanone were specimens which had been previously prepared in this laboratory (5).

Cholestanone, m.p. 129°–130°, was prepared by oxidation of cholestanol (28), and coprostanone, m.p. 61°–63°, $(\alpha)_D$ +36°, by reduction of cholestenone (21) over a palladium charcoal catalyst in ethyl acetate, with the addition of two drops of piperidine. Δ^5-Cholestenone was prepared by the oxidation and subsequent zinc-dust reduction of cholesterol dibromide (29).

Cholestan-6-one

Cholesterol was converted to cholesteryl bromide, m.p. 97°–98°, $(\alpha)_D$ −20° (lit. m.p. 97°–99°, $(\alpha)_D$ −21.6° (30)), with phosphorus tribromide in benzene (31) and the bromide nitrated with fuming nitric acid and sodium nitrite to 3-bromo-6-nitrocholest-5-ene, m.p. 153°–155°, λ_{max} 262 mμ, ϵ 2200. Zinc-dust reduction (32) gave the required ketone.

Cholestan-7-one

Cholesteryl acetate was oxidized with *t*-butyl chromate (33) to 7-ketocholesteryl acetate, m.p. 157°–160°, $(\alpha)_D$ −86°, which was converted by refluxing with concentrated hydrochloric acid to $\Delta^{3,5}$-cholestadien-7-one, m.p. 112°–113° (lit. m.p. 112° (34)). Reduction of this compound with platinum oxide in ethyl acetate gave the required ketone, m.p. 116°–118°, $(\alpha)_D$ −28°, λ_{max} 292 mμ, ϵ 70 (lit. m.p. 116°–118° (35)).

Δ^7-*Ergosten-3-one*

Hydrogenation of ergosterol in ethyl acetate and ether at 30 lb. pressure with a platinum oxide catalyst gave Δ^7-ergosten-3-ol. Oxidation by the method of Oppenauer, with chromium trioxide (1.2 equiv.) in acetic acid and benzene, or by the method of Sarett, gave the ketone, m.p. 159°–160°, $(\alpha)_D$ +22° (lit. m.p. 159°, $(\alpha)_D$ +22° (36)), in about 50% yield in each case. Hydrogenation of ergosteryl acetate in ethyl acetate and acetic acid at 30 lb. pressure with a 5% palladium–charcoal catalyst, or in ethyl acetate at 1000 lb. pressure and 100° using a Raney nickel catalyst, gave $\Delta^{8(14)}$-ergostenyl acetate.

$\Delta^{8(14)}$-*Ergosten-3-one*

Oxidation of $\Delta^{8(14)}$-ergostenol with chromium trioxide in acetic acid and benzene gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

the ketone, m.p. 128°–129°, $(\alpha)_D$ +31.5° (lit. m.p. 129°–130°, $(\alpha)_D$ +30° (36)), in 70% yield. Oppenauer oxidation gave a 50% yield.

$\Delta^{8(9)}$-Ergosten-3-one

This was prepared by oxidation of $\Delta^{8(9)}$-ergostenol (37) with chromium trioxide in benzene and acetic acid, and had m.p. 118°–120°, $(\alpha)_D$ +70°.

Δ^{14}-Ergosten-3-one

This was prepared by isomerization of $\Delta^{8(14)}$-ergosten-3-one with hydrogen chloride in chloroform. The method gave only partial conversion, but the two isomers could be separated by careful chromatography on neutral alumina using hexane as eluent. The highest conversion (20%) was obtained by saturating with hydrogen chloride at 0° and allowing to stand 3–4 days in a refrigerator at *ca.* 5°. Poorer conversions were obtained with the alcohol or acetate. The pure ketone had m.p. 149°–150°, $(\alpha)_D$ +40° (lit. m.p. 149°–151°, $(\alpha)_D^{20}$ +36.4° (26)).

Solvents

Dioxane (Matheson, Coleman, and Bell) was refluxed with potassium hydroxide and fractionated from a fresh quantity. This dioxane (80 vol.) was mixed with distilled water (20 vol.), and the resulting solvent had d_4^{25} 1.0345.

Cyanohydrin Formation

Some preliminary experiments were carried out to find a suitable solvent. The steroids were not sufficiently soluble in ethanol. The dissociation constants of the cyanohydrin of cyclopentanone in anhydrous dioxane and 95% dioxane at 25° were *ca.* 700×10^{-2} and 200×10^{-2} respectively. Accordingly 80% dioxane was chosen as a solvent in which the steroids were reasonably soluble and which gave convenient dissociation constants. The procedure adopted was to dissolve the ketone (0.2–0.4 g.) in 80% dioxane in a 100 ml. graduated flask and then to add a solution of hydrogen cyanide (10 ml. of *ca.* 0.15 *N*), prepared from sodium cyanide and sulphuric acid and dissolved in 80% dioxane. A catalyst solution (1 ml.) of 2% tri-*n*-propylamine in 80% dioxane was added and the flask made up to the mark and allowed to equilibrate in a bath at 25.0°±0.1° for 6 hours. Aliquots (10 ml.) of the solution were withdrawn, added to excess silver nitrate (*ca.* 0.1 *N*) containing 0.5% nitric acid, and the excess silver nitrate titrated with potassium thiocyanate (0.05 *N*), using ferric ammonium sulphate as indicator (38, 39). Each experiment was repeated three or more times and the results, together with their mean standard deviations, are given in Table I.

NOTES

THE DETERMINATION IN SITU OF THE CARBON CONTENT OF SOLID PRODUCTS IN REACTION VESSELS[1]

A. W. TICKNER

During an investigation of the reactions of methane in an electric discharge it was found that part of the methane was converted to a solid product which appeared as a thin film on the electrodes and, to a lesser extent, on the walls of the discharge tube. Enough of the solid was obtained by running for a long period at relatively high discharge currents to show that the composition was, very approximately, $(C_2H_3)_n$. Since the total weight of the deposit was usually of the order of 0.1 mg. and it was distributed over an area of between 10 and 100 cm.^{2} on surfaces which were not readily accessible, it was difficult to determine the total amount of carbon in the deposit by any of the standard procedures. The procedure described in this note was worked out in an effort to estimate the total carbon content of the solid product and thus to complete the material balance for the discharge reaction.

The discharge tube used was made of Pyrex tubing 4.0 cm. in diameter and was so designed that it could be surrounded by liquid nitrogen during an experiment. The electrodes were stainless steel disks 3.5 cm. in diameter mounted 3.0 cm. apart. Since direct current was used, this arrangement had the effect, at the pressures employed, of restricting the discharge to the negative glow. The total volume of the discharge system was approximately 500 cm.^{3}

After a discharge experiment with methane, the volatile products were removed, leaving the solid deposit on the electrodes and walls of the discharge tube. The discharge tube was then immersed in liquid nitrogen, and oxygen was introduced to a pressure of about 1 mm. of mercury. The discharge was turned on and run at a current of about 10 ma. until the oxygen pressure had fallen to a constant value. This constant value, which was usually about 0.3 or 0.4 mm. below the initial pressure, was attained in a few minutes and coincided with the disappearance of the last visible traces of the deposit from the cathode, where it had been deposited most heavily. The discharge was then turned off and the remaining oxygen pumped away.

Following the removal of the oxygen the discharge tube was warmed to the temperature of dry ice. This temperature was chosen in order to retain any water formed. The gas evolved was removed with a Toepler pump and its volume measured. Analysis on a mass spectrometer showed that the gas consisted of carbon dioxide and a small amount of oxygen. On the assumption that all of the carbon in the deposit had been converted into carbon dioxide, it was then possible to calculate the carbon content of the solid product obtained in the discharge reaction.

In order to test the method, a number of determinations were made using deposits consisting of measured amounts of materials of known carbon content. Each substance was made into a solution (in the case of graphite, a suspension) of known concentration, and a measured volume was evaporated on the surface of the cathode. It was estimated that the weight of a deposit produced in this way was known to within $\pm 2\%$. The

[1]*Issued as N.R.C. No. 4652.*

cathode was inserted into the discharge tube, which was evacuated and surrounded with liquid nitrogen. The deposit was then oxidized with the oxygen discharge and the products were measured and analyzed as described in the preceding paragraph.

The substances used were chosen to represent different types of compounds. All of them were required to have low volatility since the discharge tube had to be thoroughly evacuated before each experiment. The graphite used was Acheson Colloids Co. "Aquadag". Its graphite content was determined by drying a sample at 180° C. for 24 hours. It was used in the form of a suspension in distilled water. A sample of polyethylene polymer having a molecular weight of about 2500 was obtained and applied to the electrode as a toluene solution. Reagent grade *o*-terphenyl was used in benzene solution and Reagent grade sucrose in water. In addition, a luminous burner flame was used to deposit a thin but clearly visible deposit of carbon black on the cathode. The oxygen used was from a standard cylinder supply having a stated purity of 99.9%. It was passed through a trap cooled by liquid nitrogen and was used without any further purification.

The results of these determinations have been summarized in Table I. In each case the recovery of carbon as carbon dioxide was sufficiently quantitative to meet the present requirements.

TABLE I

RECOVERY OF CARBON AS CARBON DIOXIDE

Sample	Gram atoms of carbon deposited ($\times 10^6$)	Moles of carbon dioxide recovered ($\times 10^6$)	% Theoretical
Graphite	16.9	16.7	99
Polyethylene	12.4	12.0	97
o-Terphenyl	11.7	11.8	101
Sucrose	15.0	14.3	95

In addition, the experimental results showed another, and rather unexpected, correlation. As reported above, the gas recovered after the oxidation of each deposit contained some oxygen in addition to the carbon dioxide. This amount of oxygen could not be decreased even by prolonged pumping with the products of the discharge oxidation frozen out at the temperature of liquid nitrogen. A relationship appeared to exist between the percentage of oxygen in the carbon dioxide recovered and the amount of hydrogen present in the compound which had been oxidized. The values obtained for the various substances used are shown graphically in Fig. 1. On this basis the composition of the solid product formed in the discharge reaction of methane is given approximately by the formula $(CH)_n$.

No detailed explanation is offered to account for the oxygen retained in the discharge product. The 8 or 9% of oxygen found in the products of the discharge oxidation of pure carbon may represent oxygen retained in some way by the solid carbon dioxide or as an unstable carbon–oxygen compound which decomposes on being warmed to −78° C. The remainder of the oxygen, the part which appears to be related to the hydrogen content of the solid being oxidized, may be due to the formation of hydrogen–oxygen compounds which decompose on being warmed above the temperature of liquid nitrogen. Such compounds have been reported by Jones and Winkler (1) and by Giguère, Secco, and Eaton (2) as products of the decomposition of water vapor in the electric discharge.

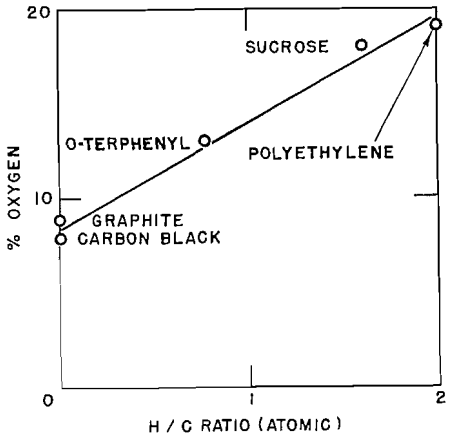

FIG. 1.

The method described above would seem to be capable of fairly wide application to situations in which it is desired to determine the carbon content of small amounts of organic solids deposited in inaccessible locations. While the work reported here has made use of a direct-current discharge in a tube with internal electrodes, it seems likely that an electrodeless discharge using radio-frequency power would also be effective. Furthermore, although the present discharge tube was arranged to allow it to be immersed in liquid nitrogen, it should be possible to carry out the oxidation successfully in a system in which the oxygen is circulated through the discharge and subsequently passed through a cold trap before being returned to the discharge chamber. With these variations it should be possible to apply the method to the determination of carbon in organic deposits in a variety of reaction vessels, including, for example, the reaction cells used in photochemical experiments. In addition, it may be possible to use the method to estimate the hydrogen content of such deposits.

THE THERMODYNAMIC PROPERTIES OF BENZOIC ACID[1]

R. GOTON AND E. WHALLEY

Dr. R. S. Jessup has pointed out to us in a private communication that in a previous note (1) of the same title we have used the wrong value for the standard heat of combustion of benzoic acid to calculate its thermodynamic properties. The value that we used, 26,428.4±2.6 int. j. g.$^{-1}$, should be replaced by 26,420.4±2.6 int. j. g.$^{-1}$. This value has been corrected for the changed atomic weight of carbon (2) by Dr. Jessup to give 3226.99±.31 kj. mole^{-1}. In addition there are numerical errors in our table of entropies,

For personal use only.

and consequently also in the free energies. The entropy relative to that at 0° K. had been calculated by Furukawa, McCoskey, and King (3), in a paper which we had overlooked; our revised values agree with theirs.

Solid benzoic acid at room temperature is composed of molecules of dimer (4) and no thermal transition has been observed between 15° K. and room temperature (3). If the hydrogen bonds in the dimer are completely disordered the zero-point entropy is $\frac{1}{2}R\ln 2$ (5). There is no experimental information on the zero-point entropies of carboxylic acids, but the disordered structure of ice and heavy water is well verified. If the maximum disorder is present in benzoic acid, and this seems likely, 0.347 should be added to $(S-S_0°)/R$ to give the entropy. The entropies thus obtained are given in the revised Table I,

TABLE I

410	27.40	32.80	14.54	56.98

herewith. The free energy and the free energy of formation have also been recalculated. The free energy of graphite was obtained by graphical interpolation of the data in Reference 6 below 300° K., and of those in Reference 7 above 300° K.

The revised heat of formation at 0° K. is $-367.75\pm.45$ kj. mole^{-1} and at 25° C. is $-385.16\pm.40$ kj. mole^{-1}. The physical constants used are from References 2 and 8, and 1 mole of benzoic acid refers to the formula $C_7H_6O_2$.

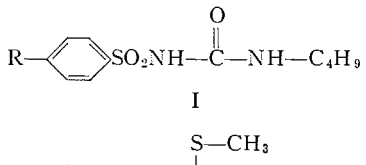
1-ARYLSULPHONYL-3-*n*-BUTYL-2-METHYL-2-THIOPSEUDOUREAS

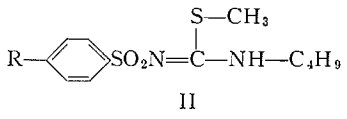
STANLEY O. WINTHROP AND GREGORY GAVIN

Compounds containing the thiopseudourea grouping have recently come under investigation in our laboratories (1). Since certain 1-arylsulphonyl-3-*n*-butylureas (I) have been shown to possess useful hypoglycemic activity, it was of interest to prepare some 1-arylsulphonyl-3-*n*-butyl-2-methyl-2-thiopseudoureas (II) for pharmacological screening. Cox (2) has reported the preparation of a series of 1-arylsulphonyl-2-methyl-2-thiopseudoureas which have shown some value as bacteriostatic agents.



I

(*a*) R = CH_3
(*b*) R = $NHCOCH_3$
(*c*) R = NH_2



II

The sulphonylthiopseudoureas were prepared by the condensation of the appropriate sulphonyl chlorides with 1-*n*-butyl-2-methyl-2-thiopseudourea. Acid hydrolysis of 1-(*p*-acetaminobenzenesulphonyl)-3-*n*-butyl-2-methyl-2-thiopseudourea (II*b*) gave the 1-(*p*-aminobenzenesulphonyl)-3-*n*-butyl-2-methyl-2-thiopseudourea (II*c*).

The sulphonylthiopseudoureas were administered orally to rabbits which had been fasted for 24 hours. None of the compounds tested showed a significant hypoglycemic action.

EXPERIMENTAL*

1-(p-Toluenesulphonyl)-3-n-butyl-2-methyl-2-thiopseudourea

Potassium carbonate (33 g., 0.24 mole) was suspended in 90 ml. of a 3:1 acetone–water solution cooled in an ice-water bath. A well-ground mixture of *p*-toluenesulphonylchloride (12.4 g., 0.065 mole) and 1-*n*-butyl-2-methyl-2-thiopseudourea hydroiodide† (19.9 g., 0.0725 mole) was slowly added with vigorous stirring. The addition was completed after 30 minutes and the stirring was continued at room temperature for another 3 hours. The reaction contents were then added to 250 ml. of water, causing the product to separate out, 17.8 g. (91% yield), m.p. 72°–77° C. Two recrystallizations from isopropanol gave 11.5 g., m.p. 85°–86° C. Calculated for $C_{13}H_{20}N_2S_2O_2$: C, 51.97; H, 6.71; N, 9.32; S, 21.35. Found: C, 52.25; H, 6.92; N, 9.19; S, 20.93.

1-(p-Acetaminobenzenesulphonyl)-3-n-butyl-2-methyl-2-thiopseudourea

This compound was prepared in the same manner as the preceding example. Potassium carbonate (66 g., 0.48 mole), *p*-acetaminobenzenesulphonyl chloride (30.3 g., 0.13 mole), and 1-*n*-butyl-2-methyl-2-thiopseudourea hydroiodide† (39.2 g., 0.143 mole) gave 44 g. of product with m.p. 129°–135° C. Two recrystallizations from isopropanol gave 21.8 g., m.p. 141°–142° C. Calculated for $C_{14}H_{21}N_3S_2O_2$: C, 48.96; H, 6.17; N, 12.24; S, 18.67. Found: C, 49.15; H, 6.02; N, 12.11; S, 18.51.

**All melting points are uncorrected.*
†The preparation of this compound is described by Kirsten and Smith (3).

THE MOLECULAR WEIGHT OF POLYETHYLENE AND OF OTHER HIGH-MOLECULAR-WEIGHT ORGANIC COMPOUNDS[1]

R. TREMBLAY,[2] A. F. SIRIANNI, AND I. E. PUDDINGTON

ABSTRACT

The temperature range of the measurement of vapor-pressure depression using a sensitive differential mercury micromanometer has been extended, and the behavior of a series of polyethylene samples having a molecular-weight range of 2500 to 24,000 was examined in toluene solutions at 75° C. Good agreement was obtained between vapor-pressure lowering and other means of determining number-average molecular weights of several special compounds.

INTRODUCTION

Number-average molecular weights lower than about 40,000 have been determined satisfactorily for a number of compounds of known constitution and for a series of vinyl-acetate polymers, by measuring the differences in vapor pressure between solutions of these substances and the pure solvent (1, 2, 3). The present communication describes similar measurements on a series of polymers of ethylene prepared by a high-pressure process and obtained through the courtesy of Canadian Industries Limited. The individual samples designated as melt index 200,000, 20,000, 7000, 700, 2, and 0.2 cover an approximate molecular-weight range of 2500 to 24,000.

It has been shown that individual samples of polyethylene can have weight-average–number-average molecular weight ratios as high as 70 with very broad distributions of the molecular sizes (4, 5, 6, 7). Differences of 25% in number-average molecular weight, attributed to membrane permeability, have been found when the same samples were examined osmometrically and cryoscopically (8). Increases in $\bar{M}_n$ as large as 100% have been effected with no change in the melt index by mild extractive fractionation (8). It has also been suggested that the result obtained may be influenced by the solvent used in ebulliometric measurements (9). It therefore seemed worth while to test the usefulness of an additional method for measuring $\bar{M}_n$, which is not too restricted in temperature of operation and not subject to membrane permeability, in the characterization of these interesting polymers.

Since polyethylene has limited solubility in most solvents below about 70° C. (10, 11), it was necessary to raise the temperature at which the vapor-pressure measurements were made from 55° C., which was used for most of the previous work, to 75° C. A number of comparative determinations were made on polymers of ethylene oxide and an esterified

sucrose* that had molecular weights in the vicinity of 3000 and 1800 respectively and which had been examined by other methods.

APPARATUS AND EXPERIMENTAL

The apparatus and experimental technique have already been described (1, 2). Molecular-weight determinations on carbowax and sucrose myristate were carried out both in benzene at 42.5° C. and in toluene at 75° C. All determinations on polyethylene were made in toluene at 75° C. Solutions in all cases were optically clear and no evidence of insolubility, which would lead to fictitiously high values, was noted.

The dried polymers were stored *in vacuo* and 0.7 to 4 mg. quantities were used in preparing the solution. A drop of redistilled solvent was used to stick the newly weighed samples to their containers to reduce the danger of mechanical loss during subsequent operations. Care was taken to avoid overheating the polymers, especially when in contact with air, to minimize the possibility of molecular degradation. Solutions of the polymer were prepared in the usual way by condensing a known amount of solvent on the solid polymer after the sample holder had been sealed to the apparatus and the assembly evacuated.

RESULTS

The variation of apparent molecular weight with solution concentration for the series of polyethylenes is shown in Fig. 1. These values were calculated from Raoult's law. In estimating solution concentrations, corrections for the nonideality of the solvent vapor have been applied using Berthelot's equation of state and the critical data. However, without this correction, only a very small error is introduced in the molecular weight at infinite dilution. While it is evident that the apparent molecular weight of polyethylene samples having melt indexes of 0.2 and 2 is not a linear function of concentration over the whole range studied, a straight line fits the experimental points reasonably well at the lower concentrations. There is little evidence of curvature for all other samples and a straight line fits the experimental points over the whole concentration range covered. Similar behavior was observed for polyvinyl acetate in benzene at 55° C. (2).

The solute–solvent interaction coefficient, μ_1, of the system polyethylene–toluene was calculated from the well-known theoretical equation due to Huggins (12, 13) and Flory (14, 15)

$$\phi = (\ln a_1 - \ln V_1)/V_2 - 1 = \bar{V}_1/\bar{V}_2 + \mu_1 V_2,$$

where the symbols have their usual meaning.

The linear plots of ϕ vs. V_2 for the various polyethylene samples are shown in Fig. 2.

In calculating the solution concentration, it was assumed that the volumes of solute and solvent are additive (16) and the value for the density of ethylene polymer was taken as 0.92. The density of polyethylene in the molecular-weight range of 10,000 to 26,000 varies from 0.91 to 0.93 (17).

The molecular weights obtained from Raoult's law and those calculated from the

The results of the molecular-weight determinations for some other organic substances are shown in Fig. 3. Curves 1 and 2 were obtained for a sample of commercial carbowax.

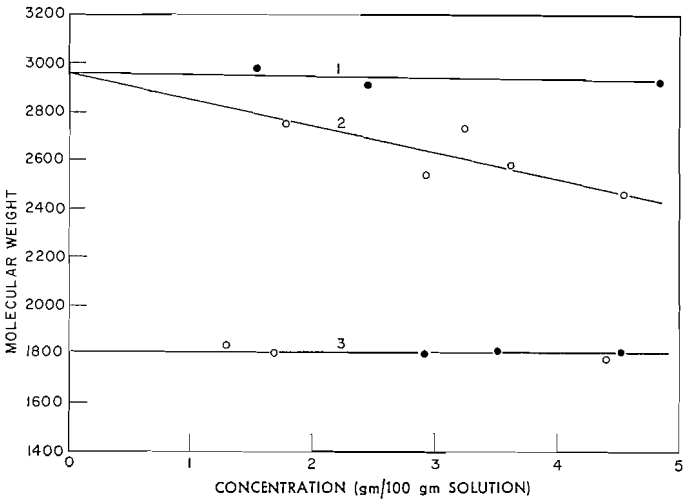

FIG. 3. Apparent molecular weight vs. solute concentration for a sample of carbowax and sucrose myristate. Curve 1, first measurements on carbowax; Curve 2, normal measurements; Curve 3, sucrose myristate (open circle, in toluene at 75° C.; closed circle, in benzene at 42.5° C.).

The first determinations were found to be independent of concentration; subsequent determinations were characterized by Curve 2. While the reason for this behavior is not too clear, the phenomenon has been observed previously with some samples of polyvinyl acetate and may be due to a slight amount of residual moisture trapped in the polymer and slightly reducing its solubility, causing the initial solutions to behave like an "ideal"

system. The molecular weight at infinite dilution was virtually identical for both curves, however. Curve 3 was obtained for a sample of sucrose myristate in benzene at 42.5° C. and in toluene at 75° C. A summary of the results for carbowax and sucrose myristate using the vapor-pressure lowering technique compared to other methods is given in Table II.

TABLE II

MOLECULAR WEIGHT OF CARBOWAX AND SUCROSE MYRISTATE OBTAINED BY DIFFERENTIAL MANOMETRY AND BY OTHER METHODS

Solute	Solvent	Mol. wt.	Method
Carbowax	Benzene	2960	Vapor pressure
Carbowax		2975	End-group analysis
Sucrose myristate	Benzene	1813	Vapor pressure
Sucrose myristate	Toluene	1813	Vapor pressure
Sucrose myristate	Benzene	1820	Cryoscopic

DISCUSSION

The similarity in the $\bar{M}_n$ values obtained when the results of cryoscopic and end-group analysis are compared to the vapor-pressure procedure lends support to the confidence that may be placed in that method. Unfortunately molecular weights of about 3000 are approaching the maximum values with which the available facilities for the former two methods are useful and it was not possible to extend the comparison.

Table I indicates satisfactory agreement between the two methods of treating the vapor-pressure data. The value of μ_1 found in this work is close to the value of 0.42 previously reported for polyethylene of melt index 200,000 in benzene at 80° C. (18). Values of 0.29 and 0.31 found for polyethylene samples having melt indexes of 20,000 and 7000 respectively in toluene at 110° C. (18) differ from the values obtained here in the expected direction when the temperature difference at which the measurements were made is considered. In contrast to the behavior of other polymers (2, 3, 13) there was virtually no dependence of the numerical value of μ_1 on molecular weight. This observation agrees with the findings of Muthana and Mark (17) and of Harris (18).

Differences between $\bar{M}_n$ values found here and those reported in the literature for polyethylene of similar melt index are not excessive in view of the variations noted recently in results obtained when the same sample of polymer is examined by different methods, and the large increase in $\bar{M}_n$ caused by the selective removal of about 1% of the sample (8).

No particular difficulty was found in the operation of the vapor-pressure apparatus at 75° C. Vapor-pressure differences normally become constant sufficiently quickly to allow check readings on the manometer at 60–90-minute intervals. It might be anticipated that volatility of mercury could become troublesome, however, if the operating temperature were raised too much higher. High-temperature operation might necessitate substitution of the mercury manometer with some form of diaphragm gauge and the cutoffs with valves. Under the present system of operation the limit on the precision of the measurement appeared to be controlled by variation in ΔP rather than by the ability of the manometer to measure these differences accurately.

The agreement between the results of the vapor-pressure and the ebulliometric procedures is excellent for the lower-molecular-weight polymers. Since several unrecorded measurements at 85° C. indicated the same molecular weight as shown for the sample of melt index 2 at 75° C., the discrepancy in the results of the two methods for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

higher-molecular-weight polymers does not appear to be due to incomplete solubility of the polymer at 75°. It may, however, be related to possible surface activity of these samples in the solvents used.

With the exception of the Huggins treatment shown in Fig. 2, the more conventional methods of presenting the experimental data offered little improvement in linearity of the curves obtained, over the plot of apparent molecular weight vs. concentration, and the simpler procedure was therefore used. It seems probable, however, that the molecular weights shown at infinite dilution may be slightly low because the linear extrapolation actually employed may not be entirely justified.

ACKNOWLEDGMENT

We are deeply indebted to Dr. W. R. Blackmore, Canadian Industries Limited, for the ebulliometric results included in Table I.

REACTOR NEUTRON-CAPTURE CROSS SECTION OF 18-MINUTE Rb^{88} [1]

J. C. Roy, P. J. Berry,[2] and L. P. Roy

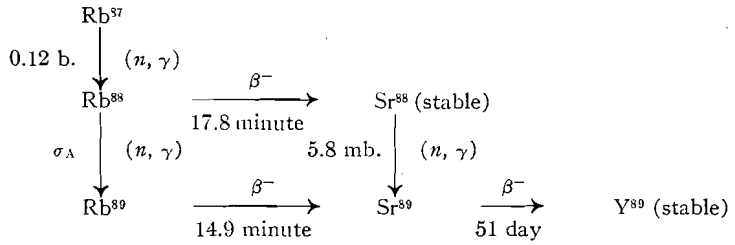
ABSTRACT

The reactor neutron-capture cross section of 18-minute Rb^{88} has been determined by an activation method. The yield of Rb^{89} formed by successive neutron capture in Rb^{87} was determined by counting the beta rays emitted by its daughter, 51-day Sr^{89}. In these experiments Sr^{89} is also produced by the $Sr^{88}(n, \gamma)Sr^{89}$ reaction from the Sr^{88} contamination in the rubidium target and from Sr^{88} formed by the beta decay of Rb^{88}. Corrections for the contributions from these sources to the yield of Sr^{89} have been measured experimentally. The reactor neutron-capture cross section of Sr^{88} has been measured to be 5.8 mb. for the conditions of the experiment. Taking 0.12 ± 0.3 barn for the thermal cross section of Rb^{87}, the cross section of Rb^{88} was found to be 1.0 ± 0.3 barn for reactor neutrons.

INTRODUCTION

A measurement of the capture cross section of 18-minute Rb^{88} for reactor neutrons has been made using an activation method depending on successive neutron capture in Rb^{87}. Using the same technique Katcoff (1) set an upper limit of 200 barns for the thermal-neutron capture of Rb^{88}. With the advantage of much higher neutron flux than the one available to Katcoff, it has been possible to improve upon his measurement.

The following nuclear reactions occur when Rb^{87} is irradiated with neutrons:



The cross section of Rb^{88} was determined by measuring the Sr^{89}, daughter of Rb^{89}, which is formed by successive neutron capture in Rb^{87}.

According to the reactions listed above three processes lead to the formation of Sr^{89}. First, Sr^{89} can be formed from strontium impurity by neutron capture in Sr^{88}. The contribution of this first-order reaction to the observed yield of Sr^{89} can be determined experimentally by irradiating a sample at a low neutron flux so that the successive neutron capture in Rb^{87} is negligible. Then the formation of Sr^{89} from Sr^{88} in the higher flux irradiations is calculated from the measured cross section of Sr^{88} using the following equation:

$$[1] \qquad N_1 = (N_K \sigma_K \phi / \lambda)(1 - e^{-\lambda t}),$$

where N_1 is the number of atoms of Sr^{89} at the end of the irradiation formed from strontium impurity,

[1]*Manuscript received January 7, 1958.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 564.
[2]*Present address: St. Augustine's Seminary, Toronto, Ontario.*

N_K is the number of atoms of Sr^{88} in the rubidium samples as determined by measurement at low neutron flux,
σ_K is the cross section of Sr^{88},
ϕ is the neutron flux,
t is the time of irradiation,
λ is the decay constant of Sr^{89}.

Secondly, Sr^{89} is formed by neutron capture in Sr^{88} formed by beta decay of Rb^{88} during the irradiation. The contribution of this process can be calculated using the following equation derived by Katcoff (2):

$$[2] \qquad N_2 = N_S\sigma_S\sigma_K\phi^2/\lambda^2\left[\lambda t-(1+T_A/T)(1-e^{-\lambda t})+\frac{T_A\lambda(e^{-\lambda_A t}-e^{-\lambda t})}{T(\lambda-\lambda_A)}\right],$$

where N_2 is the number of atoms of Sr^{89} at the end of the irradiation from Sr^{88} formed by beta decay of Rb^{88},
N_S is the number of atoms of Rb^{87} initially present,
σ_S is the neutron-capture cross section of Rb^{87}, taken to be 0.12 b. (3),
T_A is the half-life of Rb^{88}, taken to be 17.8 minutes (4),
T is the half-life of Sr^{89}, taken to be 51 days (5),
λ_A is the decay constant of Rb^{88}.
The other symbols have been defined under Eq. [1].

Thirdly, Sr^{89} is formed by the reaction under study: decay of Rb^{89} produced by successive neutron capture in Rb^{87}. The equation which describes this process is derived as follows: the time rate of change of Sr^{89}, dN_3/dt, is equal to its rate of production by beta decay from Rb^{89}, $\lambda_B N_B$, minus its natural disintegration rate, i.e.,

$$[3] \qquad dN_3/dt = \lambda_B N_B - \lambda N_3.$$

According to Ref. 2 N_B is given by:

$$[4] \qquad N_B = \frac{N_S\sigma_S\sigma_A\phi^2}{\lambda_A\lambda_B(\lambda_B-\lambda_A)}[\lambda_B(1-e^{-\lambda_A t})-\lambda_A(1-e^{-\lambda_B t})].$$

Substituting Eq. [4] in Eq. [3] and solving with $N_3 = 0$ at $t = 0$ gives:

$$[5] \qquad N_3 = \frac{N_S\sigma_S\sigma_A\phi^2}{\lambda_A(\lambda_B-\lambda_A)}\left[\frac{T(T_A-T_B)(1-e^{-\lambda t})}{T_AT_B}+\frac{T_AT(e^{-\lambda t}-e^{-\lambda_A t})}{T_B(T_A-T)}+\frac{T_BT(e^{-\lambda_B t}-e^{-\lambda t})}{T_A(T_B-T)}\right],$$

where N_3 is the number of atoms of Sr^{89} at the end of the irradiation, produced by decay of Rb^{89},
σ_A is the cross section to be measured,
T_B is the half-life of Rb^{89}, taken to be 14.9 minutes (6),
λ_B is the decay constant of Rb^{89}.
The other symbols have been defined under Eq. [1] and Eq. [2].

Equation [5] gives only the Sr^{89} present at the end of the irradiation. Another term should be added to take into account the formation of Sr^{89} from Rb^{89} by beta decay after the irradiation. This term is equal to N_B, the number of atoms of Rb^{89} present at the end of the irradiation, and is given by Eq. [4]. Therefore the Sr^{89} from beta decay of Rb^{89} is equal to N_3+N_B.

A re-evaluation of the neutron-capture cross section of Sr^{88} was made. A value of 5 ± 1 mb. has been reported by Seren *et al.* (7) for the thermal-neutron-capture cross

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

section of Sr^{88}, but considering the potential importance of the (n, γ) reaction on Sr^{88} in these experiments, this cross section was measured under conditions similar to those used in the measurement of the cross section of Rb^{88}.

A spectrographic analysis of the rubidium chloride showed that there was less than 0.02 p.p.m. of yttrium and zirconium. Therefore the formation of Sr^{89} by $Y^{89}(n, p)$ and $Zr^{92}(n, \alpha)$ processes on these two elements is ruled out.

EXPERIMENTAL

Samples of rubidium chloride were irradiated in the NRX reactor at Chalk River. The experimental conditions are given in Table I.

TABLE I

EXPERIMENTAL CONDITIONS USED FOR THE IRRADIATIONS

Experiment No.	RbCl irradiated (g.)	Irradiation time (hr.)	Neutron flux (n./cm.²/sec.)	Chemical yield (%)	Self-scattering* and self-absorption (%)
1	0.6375	16.5	6.57×10^{13}	77.0	+ 8.0
2	0.5922	16.3	6.37×10^{13}	84.2	+ 8.0
3	0.6366	16.5	6.64×10^{13}	40.2	+10.0
4	0.5528	108.8	7.83×10^{12}	53.6	+10.0
5	0.5298	109.8	3.25×10^{12}	67.9	+ 9.0

**The plus sign indicates that the net effect of self-scattering and self-absorption was an increase in the counting rate.*

The chemical purification was started about one month after the end of the irradiation. The rubidium samples were dissolved in 2–3 ml. of distilled water in the presence of 20 mg. of strontium carrier. Strontium nitrate was precipitated by addition of fuming nitric acid, centrifuged, washed with fuming nitric acid, and finally dissolved in a minimum amount of water in the presence of rubidium carrier. After this purification cycle was repeated four or five times, the strontium nitrate was dissolved in 6–8 ml. of water and several ferric hydroxide scavengings were made by addition of gaseous ammonia; the precipitates were discarded. The solution was then prepared for ion-exchange purification by precipitating strontium as carbonate. The precipitate was centrifuged and dissolved in the minimum amount of HCl, to which solution calcium and barium carriers and an equal volume of 1.5 *M* ammonium lactate were added. The solution was passed through Dowex-50 ion-exchange column using conditions similar to those described by Milton and Grummitt (8) for the separation of alkaline-earths using 1.5 *M* ammonium lactate as an eluant at pH 7. The strontium fraction was reduced in volume from 40 to 15 ml. and 2 ml. of 3 *N* sulphuric acid plus 2 ml. ethyl alcohol was added. This solution was allowed to stand overnight to let the strontium sulphate form and digest. The precipitate was centrifuged and washed with 1 ml. of water and ethyl alcohol. Finally it was transferred to a weighed aluminum counting tray, dried, weighed, and counted.

The disintegration rate of the strontium fraction was determined with an anthracene beta-counter having a window thickness of 2.16 mg./cm.² The counter was shielded with 4 inches of lead. The background was 9.7 c.p.m. and the variation during the interval over which the samples were counted was ±0.3 c.p.m. The counter efficiency was determined with a weightless source of P^{32}, mounted on an aluminum tray and prepared from a N.B.S. Standard. The efficiency found in this way was 32%. The

combined effects of self-scattering within the sources and self-absorption were determined in a separate experiment by the following method (9): To a thin layer of Sr^{89} activity, prepared by the $Sr^{88}(n, \gamma)Sr^{89}$ reaction, successive layers of inert strontium sulphate were added and the observed intensity was plotted against the weight of the inert material. The correction for self-scattering and self-absorption for a particular source thickness was then obtained from this curve after the amount of strontium sulphate present in each source was divided by two to take into account the homogeneous distribution of activity throughout the sources. The net effect was an increase in counting rates of about $9\pm3\%$.

RESULTS

Strontium-89 was identified by its maximum beta-ray energy and its decay period measured over two half-lives. The absorption curves in aluminum of the beta radiations of the activity found in experiments 1, 2, 3, and of Sr^{89}, prepared by (n, γ) reactions on strontium, were the same. A typical curve and the Sr^{89} standard curve are shown in Fig. 1. Fig. 2 shows the decay curves for the activities produced in two irradiations

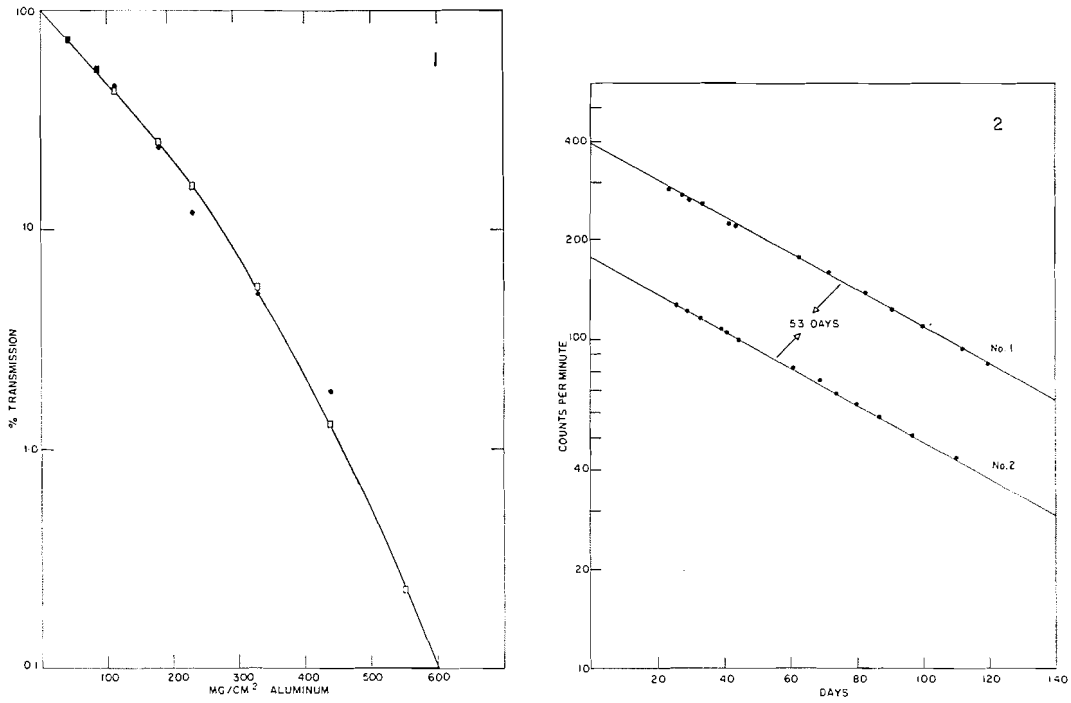

FIG. 1. Absorption curve of Sr^{89}; the circles are from the activity in the separated strontium, the squares are from a Sr^{89} standard prepared by a (n, γ) reaction in strontium.

FIG. 2. Decay curves of activities in experiments 1 and 2. The counting rates in experiment 1 have been multiplied by two.

done in a high neutron flux (expts. 1 and 2); the third one (expt. 3) is not included, because its decay has been measured for only 20 days. The measured value of the half-life in both experiments was 53 days, which, within the errors of the measurements, is in agreement with the value of 51 days for Sr^{89} (5). In experiments 4 and 5 done at low neutron flux a long-lived radioactive impurity amounting to 4 c.p.m. was found. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

this has been subtracted the remaining activity showed a 51-day half-life. This Sr^{89} activity arises mainly from neutron capture in Sr^{88} impurity present in the samples as described in the introduction.

The results are summarized in Table II. The observed counting rates were extrapolated to the end of the irradiation and absolute disintegration rates were obtained by making corrections for chemical yield, counting efficiency of the beta detector, and the combined effects of self-scattering and self-absorption within the sample.

TABLE II

NEUTRON-CAPTURE CROSS SECTION OF Rb^{88}

Experiment No.	Sr^{89} measured experimentally (dis./min.)	Sr^{89} due to Sr impurity λN_1 (dis./min.)	Sr^{89} calculated from Eq. 2 λN_2 (dis./min.)	Sr^{89} due to β decay of Rb^{89} $\lambda(N_3+N_B)$ (dis./min.)	σ_A Rb^{88} (barn)
4	209	156	23	30	
5	113	105	3	5	
1	724	320	40	364	0.96
2	608	286	34	288	0.88
3	787	323	41	423	1.1
				Average	0.98

The average value for the Sr^{88} present as an impurity in the irradiated rubidium was determined from experiments 4 and 5 to be $1.7\pm0.4\times10^{-6}$ part per atom of Rb^{87}. Its contribution to the formation of Sr^{89} was calculated using Eq. [1]. Likewise the contribution from neutron capture in Sr^{88}, formed by beta decay of Rb^{88} during the irradiation, was calculated using Eq. [2]. The contribution of these two processes, subtracted from the total activity measured in experiments 1, 2, and 3, gives the Sr^{89} formed by successive neutron capture in Rb^{87}.

The neutron flux in each experiment was determined by measuring the activity in a weighed piece of pure cobalt wire, 0.005 inch in diameter and 0.4 inch long, with an ionization chamber calibrated with standardized Co^{60} sources. A correction of 2.1% was applied to take into account the self-shielding of the cobalt wire (10). The reactor cross section of Co^{60} was calculated to be 36.6 barns, taking 36.0 ± 1.5 barns (3) for its thermal-neutron-capture cross section and 48.6 for its resonance integral (11). A value of 5.20 years (12) was taken for the half-life of Co^{60}.

By solving Eqs. [4] and [5] the cross section of Rb^{88} was obtained for each experiment and the results are given in Table II. The mean is 1.0 ± 0.25 barn. The limits of error of the measurements which contributed most to the quoted error are: $\pm20\%$ from the precision with which the amount of strontium impurity is known; $\pm7\%$ from the value of the neutron-capture cross section of Sr^{88}; $\pm8\%$ from the counting; and $\pm2\%$ for the neutron-flux determination. Combining these errors by the method of the square root of sum of squares type of addition, the resulting error in the mean value is ±0.25 barn. The assigned error of $\pm25\%$ in the value of the thermal-neutron cross section of Rb^{87} is not included in the error of the present measurement. The cross section refers to reactor spectrum neutrons, since no experiments were done to determine the epicadium contribution.

For the measurement of the neutron-capture cross section of Sr^{88} two weighed strontium carbonate samples were irradiated in two different neutron fluxes in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

NRX reactor. A few days after the end of the irradiation, the samples were dissolved in a minimum amount of dilute HCl and the volume made up to 10 ml. Weightless Sr^{89} sources were prepared for beta-counting by pipetting 50λ aliquots onto aluminum trays.

Counting and determination of the neutron flux were done by the technique described above. An absorption curve in aluminum showed the presence of a gamma component, due to 65-day Sr^{85}. This contribution amounted to 2.5% of the observed activity and was subtracted from it. Errors of 5% in the counting and of 2% in the neutron-flux determination were estimated.

The cross section was thus measured to be 5.8 ± 0.4 mb. for reactor neutrons; this is the average of the two, which agreed within 1%. Within the limits of errors quoted by Seren *et al.* (7), this value is in agreement with theirs.

ALKYLGUANIDINE NITRATES AND ALKYLNITROGUANIDINES[1]

PAUL E. GAGNON, JEAN L. BOIVIN,[2] PAUL A. BOIVIN,[3] AND JOHN H. DICKSON[4]

ABSTRACT

The fusion of mixtures of alkylamine nitrates, $RR'NH.HNO_3$ ($R' = H$ when R = methyl, isopropyl, isobutyl, *n*-amyl, and phenyl, and $R' = C_2H_5$ when R = ethyl), and dicyandiamide, or calcium cyanamide, or calcium cyanamide and urea, yielded alkylguanidine nitrates. The latter were also obtained by heating solutions of alkylamine nitrates and calcium cyanamide. By treatment of the alkylguanidine nitrates with sulphuric acid, alkylnitroguanidines were prepared in good yields. A study of the effect of temperature on the yield of *n*-amyl and of time and temperature on the yields of methyl, isopropyl, and isobutyl nitroguanidine was made. The solubility of methyl, isopropyl, isobutyl, and *n*-amyl nitroguanidine in water and 10% and 20% sulphuric acid solutions at 0° C. was determined.

INTRODUCTION

Calculations based on the heat of combustion and on the empirical formula indicated that 1-methyl-3-nitroguanidine would be a more effective coolant than nitroguanidine in double base propellants. Since its density was satisfactory and it was relatively insoluble in the solvents and plasticizers used in propellant manufacture, further work was undertaken.

Davis (3) prepared alkylnitroguanidines by direct nitration of alkylguanidine sulphates in sulphuric acid and also by reacting nitroguanidine with alkylamines (2, 4). Yields were satisfactory but the preparation required nitroguanidine. McKay and Wright (6) improved this method by reacting alkylamine hydrochlorides with the potassium salt of nitroguanidine. The yield, however, did not exceed 70% based on nitroguanidine. When we consider that picrite is made in 55% yield from calcium cyanamide or 70% from dicyandiamide, the yield of alkylnitroguanidine could not be greater than 40–50%. Therefore other methods of producing this material should be considered. Methods described herein are based on calcium cyanamide, dicyandiamide, and alkylamine nitrates.

Werner and Bell (9) have stated that the fusion of dicyandiamide with alkylamine hydrochlorides gives a nearly quantitative yield of alkylguanidine hydrochlorides. This statement has been challenged by other investigators (7), who reported a yield in the order of 80%. Moreover, alkylguanidine hydrochlorides would not be of much value for the preparation of alkylnitroguanidine, since they would have to be converted into either the sulphate or the nitrate.

It was believed that methods employed to produce alkylguanidine nitrates from calcium cyanamide or dicyandiamide would give better yields if alkylamine nitrates were used in place of ammonium nitrate.

In the present work, alkylguanidine nitrates were synthesized from alkylamine nitrates and then converted into alkylnitroguanidines.

Alkylguanidine Nitrates

The alkylguanidine nitrates were synthesized by the fusion of alkylamine nitrates with

(*a*) dicyandiamide, (*b*) calcium cyanamide, and (*c*) calcium cyanamide and urea. They were also obtained by heating aqueous solutions of alkylamine nitrates and calcium cyanamide.

Alkylamine Nitrates and Dicyandiamide

The fusion of dicyandiamide with ammonium nitrate yielded guanidine nitrate. The reaction was mildly exothermic at 170° C. Similarly, when dicyandiamide and methylamine nitrate were fused together, an exothermic reaction took place at 170° C. but was less pronounced than in the previous case and was more easily controlled. Since alkylguanidine nitrates seemed stable in the fused state up to 190° C., when decomposition occurred, the reaction mixture, which became fluid at temperatures as low as 140° C., was maintained at a temperature of 170°–180° C. throughout the reaction.

By the reaction of 1 mole of dicyanamide (I) and 2 moles of alkylamine nitrate (II), 2 moles of alkylguanidine nitrate (III) were produced according to the following equation:

$$\underset{\text{I}}{\begin{matrix}\text{NH—CN}\\ |\\ \text{C=NH}\\ |\\ \text{NH}_2\end{matrix}} + \underset{\text{II}}{2\text{RR'NH.HNO}_3} = \underset{\text{III}}{\begin{matrix}\text{NR'R}\\ |\\ 2\text{C=NH}\\ |\\ \text{NH}_2\text{.HNO}_3\end{matrix}}$$

R′ = H when R = methyl, isopropyl, isobutyl, *n*-amyl, phenyl, and R′ = C_2H_5 when R = ethyl.

Alkylamine Nitrates and Calcium Cyanamide

The fusion of calcium cyanamide with ammonium nitrate has always been considered a hazardous process because of the high melting point of ammonium nitrate (170° C.) and its oxidizing properties when molten. However, when using alkylamine nitrates, which decomposed slightly at temperatures above 170° C., direct fusion of calcium cyanamide with alkylamine nitrates was considered practical.

By heating calcium cyanamide (55% pure) and alkylamine in a molar ratio of 1:3, alkylamines were evolved according to the following equation:

$$CaCN_2 + 3RR'NH.HNO_3 = RR'NC(NH)NH_2.HNO_3 + 2RR'NH + Ca(NO_3)_2.$$

Since calcium cyanamide contains approximately 20% of calcium oxide, more alkylamine was evolved:

$$CaO + 2RR'NH.HNO_3 = 2RR'NH + Ca(NO_3)_2 + H_2O.$$

An efficient recovery of the alkylamine evolved and of the unreacted alkylamine nitrate was necessary. Two methods were investigated in which calcium was discarded either as the carbonate or as the sulphate.

Calcium carbonate method.—By passing the alkylamine and carbon dioxide simultaneously into a solution of calcium nitrate at 60° C., precipitation of calcium carbonate commenced at pH 8.0. It was believed that calcium hydroxide was initially precipitated by alkylamine when pH 8.0 was reached:

$$Ca(NO_3)_2 + RR'NH = Ca(OH)_2 + RR'NH.HNO_3.$$

The carbon dioxide then reacted with calcium hydroxide:

$$CO_2 + Ca(OH)_2 = CaCO_3 + H_2O.$$

After the calcium carbonate was removed, the filtrate was evaporated to dryness, leaving alkylamine nitrate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Calcium sulphate method.—This method consisted in the absorption of alkylamine in dilute sulphuric acid to form alkylamine sulphate. The solution was then added to the filtrate containing calcium nitrate. Calcium sulphate was precipitated and the filtrate evaporated to dryness to yield alkylamine nitrate according to the equation:

$$(RR'NH_2)_2SO_4 + Ca(NO_3)_2 = 2RR'NH.HNO_3 + CaSO_4.$$

Alkylamine Nitrates, Calcium Cyanamide, and Urea

Urea was used successfully in the Wright (fusion) process (5, 10), where it acted as a melting-point depressant for ammonium nitrate. When urea was added to alkylamine nitrates, fusion could be carried out effectively with calcium cyanamide at 90° C.

Alkylamine Nitrates, Calcium Cyanamide, and Water

The process patented by Burns, Gay, and I.C.I. (1) makes use of an aqueous solution of ammonium nitrate and calcium cyanamide to produce guanidine nitrate. It was considered of interest to react alkylamine nitrates and calcium cyanamide in a similar manner. By heating aqueous solutions of alkylamine nitrates and calcium cyanamide, alkylamines were evolved as before but the yields of alkylguanidine nitrates, with the exception of phenylguanidine nitrate, were lower.

Alkylnitroguanidines

Alkylnitroguanidines, $RR'NC(NH)NHNO_2$, were prepared by treatment of alkylguanidine nitrates, $RR'NC(NH)NH_2.HNO_3$, with sulphuric acid. This reaction was believed to be a dehydration process in which 1 mole of water was removed from the alkylguanidine nitrate by sulphuric acid to form a hydrate or 85% sulphuric acid. However, in the case of nitroguanidine, it was found that the guanidine nitrate – sulphuric acid mixture is a nitrating mixture in which NO_2^+ ions are present (8). A similar mechanism is probably responsible for the formation of alkylnitroguanidine from alkylguanidine nitrate.

Of the six alkylguanidine nitrates studied, the phenyl- and diethyl-nitroguanidines could not be isolated. In the case of the phenylguanidine nitrate, nitroguanidine itself was isolated.

Since these alkylnitroguanidines were crystallized from dilute sulphuric acid solutions, the solubilities of these compounds in water and 10% and 20% sulphuric acid solutions at 0° C. were determined and were found to decrease with the increasing molecular weight.

A number of experiments were performed in order to show the effects of time and temperature on the yields of methyl, isopropyl, and isobutyl nitroguanidine. When the reaction time was arbitrarily set at 21 minutes, the most efficient temperature was found to be between 0° and 5° C. as indicated in Table II. The nitration of methylguanidine nitrate was found to be almost instantaneous at 40° C. when the time was limited to 5 minutes. However, this was not true in the cases of isopropyl and isobutyl guanidine nitrate where the best yields were obtained at 0° C. with a reaction time of 5 to 15 minutes as shown in Table III.

The degrading effect of the temperature over a reaction period of 1 hour is shown in Fig. 1 where the maximum yield of 91% of *n*-amylnitroguanidine at 0° C. decreases to a yield of 15% at 30° C.

EXPERIMENTAL

Alkylamine Nitrates

Dilute nitric acid was treated with an excess of the alkylamine. The solution was

For personal use only.

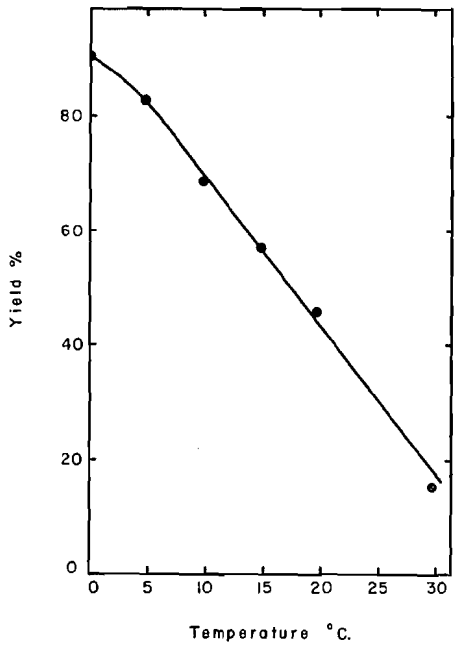

FIG. 1. Effect of temperature on the yield of *n*-amylnitroguanidine.

filtered and allowed to evaporate on a steam bath. In most cases the cooled product solidified.

Alkylguanidine Nitrates

The alkylguanidine nitrates were obtained by four different methods. The results in each case are given in Table I.

Alkylamine nitrates and dicyandiamide.—The alkylamine nitrate and dicyandiamide in a molar ratio of 2.1:1 were mixed together and heated on an oil bath. The fusion commenced at about 70° C. and the reaction mixture became clear at 135°–140° C. A temperature of 170°–180° C. was maintained for 3 hours. During this time a small amount of the alkylamine was evolved possibly owing to the decomposition of the slight excess of alkylamine nitrate employed. The reaction product, which solidified at about 35° C., was recrystallized from water.

Alkylamine nitrates and calcium cyanamide.—The alkylamine nitrate and calcium cyanamide in a molar ratio of 4:1 were mixed together and heated at 110° C. on an oil bath for 1 hour. Most of the alkylamine produced in the reaction was evolved during this time. About 40–50 ml. of hot distilled water was added to the flask and the mixture filtered while hot. In some cases more hot water was required. This necessitated the evaporation of the excess under vacuum. Finally when the solution was cooled to room temperature, the alkylguanidine crystallized, and it was recrystallized several times from water.

Alkylamine nitrates, calcium cyanamide, and urea.—The alkylamine nitrate, urea, and calcium cyanamide in a molar ratio of 4:3:1 were mixed together and heated at 90° C. for 1 hour. The alkylamine was evolved as before. The reaction products were treated with hot distilled water as described in the previous method.

with stirring and cooling. After all the solid material had been added, the mixture was stirred at this temperature for 21 minutes and then poured over cracked ice. A white solid precipitated out of the diluted acid solution and was recrystallized from water. The crude yields and the yields corrected for solubility are given in Table II in grams and per cent respectively for methyl, isopropyl, and isobutyl nitroguanidine. When *n*-amylguanidine nitrate was used, the reaction time was arbitrarily set at 1 hour. The results obtained are shown in Fig. 1.

Studies were also made of the effect of the reaction time on the yields of methyl, isopropyl, and isobutyl nitroguanidines at various temperatures. The reaction time was taken as half of the addition time plus the stirring time. The results are given in Table III.

Solubility Determinations

An accurately weighed quantity of the alkylnitroguanidine was added to 50 ml. of distilled water. The solution was cooled to 0° C. and maintained at this temperature for 24 hours. After it had been filtered on a sintered glass crucible, the residue was dried over calcium chloride in a vacuum disiccator for 8 days. The weight of the insoluble material remaining as residue was subtracted from the original weight and the solubility was calculated.

The same procedure was used to determine the solubility of the alkylnitroguanidine in 10% and 20% sulphuric acid solutions. In these cases the residue was washed with a saturated solution of the alkylnitroguanidine after filtration.

The solubilities in grams at 0° C. in 100 g. of water and 10% and 20% sulphuric acid solutions for the different nitroguanidines were, respectively:

methyl —0.704, 0.977, and 1.29; isopropyl—0.502, 0.528, and 1.70;
isobutyl—0.483, 0.528, and 1.70; *n*-amyl—0.128, 0.110, and 0.13.

ELECTROLYTIC CONDUCTANCE IN HYDROGEN PEROXIDE – WATER MIXTURES

PART II. SOME MONOBASIC AND DIBASIC ACIDS[1]

D. K. THOMAS[2] AND O. MAASS

ABSTRACT

Measurements of the equivalent conductance of sulphuric, nitric, and hydrofluoric acids were made in water – hydrogen peroxide mixtures by means of a direct-current method. It was found that in solvents containing a high percentage of hydrogen peroxide the conductivities of these acids were extremely low, and it is proposed that this results from a marked decrease in their degrees of dissociation. This proposal is supported by similar measurements made on the system water – strong acid – weak acid.

INTRODUCTION

As stated in a previous communication (1), measurements of the conductance of acids such as sulphuric and nitric in hydrogen peroxide – water mixtures (2) show that their values are considerably lower than those in aqueous solution. When the composition of the solvent is of the order of 90% to 100% hydrogen peroxide, Shanley *et al.* (2) found that when the composition of the solvent is of the order of 99% to 100% H_2O_2, sulphuric acid possesses a lower conductance than its potassium salt. They regarded the reduced conductance of the acid as being due partly to a decrease in the second dissociation step of HSO_4^- to H^+ and $SO_4^=$. The further suggestion was made that the solvated proton $H^+.H_2O_2$ showed a chain conductance in anhydrous hydrogen peroxide which was greatly reduced in the presence of water.

In the present work three acids, namely sulphuric, nitric, and hydrofluoric, have been studied at a few temperatures in solvents of composition ranging from 0 to 98 weight % of hydrogen peroxide.

EXPERIMENTAL PROCEDURE

The conductance measurements were carried out in exactly the same way as those in Part I; for the measurements on solutions of hydrofluoric acid a specially constructed Teflon cell was employed. The tin probe electrodes and current-carrying electrodes were found to be suitable for use in solutions of the concentration encountered in this work. As before, all solutions were made up by weight from the pure constituents and measurements were made with the cell immersed in a thermostat controlled to $\pm 0.01°$ C.

MATERIALS

(*i*) *Hydrogen peroxide.*—Becco chemicals 98% hydrogen peroxide was used throughout, and dilution was carried out with water of specific conductance 1.5×10^{-6}.

(*ii*) *Acids.*—The sulphuric, nitric, and hydrofluoric acids employed were all of analytical grade, the amount of metallic and other impurity being less than 0.0001%.

RESULTS

The results for the three systems studied are shown in Table I A (sulphuric acid), B (nitric acid), and C (hydrofluoric acid). The extrapolated values of Λ_0 are also given. In Fig. 1 the data of Shanley *et al.* (2) (called Becco a-c. results on the figure) for the

system H_2SO_4–H_2O–H_2O_2 are plotted together with the results of the present work on the same system, and this serves to demonstrate the measure of agreement attainable between the two experimental techniques.

DISCUSSION

It is of interest to record the variation in conductivity with temperature in H_2O_2–H_2O–electrolyte systems. In Table II are given such data using the relationship $\Lambda T_0 = \Lambda_{25}[1+x(T-25)]$.

TABLE II

VARIATION IN Λ WITH TEMPERATURE OVER THE RANGE 10° C. TO 25° C.

0	0.0145	0.0150
31	0.0161	0.0169
78	0.0134	0.0144
98	0.0086	0.0063

In Table I A, B, and C the solute concentration (C) is expressed in g-equiv. per liter, and the values quoted are equivalent conductances corrected for the solvent conductance.

The results presented in Table I A, B, and C possess one feature in common, namely that an increase in the weight % of hydrogen peroxide greatly reduces the equivalent conductance of the system H_2O–acid–H_2O_2, and in the case of almost anhydrous hydrogen peroxide the conductance has a value which is an order of magnitude less than that in aqueous solution.

Now the exceptional mobility of the proton in aqueous solution is attributed to a special mechanism of transport known as 'chain conductance'. This is made possible by the nature of the solvent itself, and requires that (*a*) the solvent molecules should possess an affinity for protons and (*b*) they should form a three-dimensional hydrogen-bonded network in the liquid state. In general, therefore, we should expect hydroxylic solvents such as the alcohols, glycols, and hydrogen peroxide to be able to sustain this 'chain conductance' process.

In the liquid state it is certain that hydrogen peroxide and water have very similar structures, both being highly associated through intermolecular hydrogen-bonding. The magnitude of the frequency shifts (3) observed in the infrared absorption spectra of the two compounds suggests that the hydrogen bond formed in hydrogen peroxide is somewhat stronger than that formed in water. Furthermore, evidence from a number of properties such as heat of mixing (4), vapor pressure (5), density (6, 7), viscosity (8, 9), and dielectric constant (10) indicates that the number, or force, of attractions increases upon the addition of the former to the latter. In other words, hydrogen bonds between water and hydrogen peroxide molecules are more stable than those between molecules of the pure substances. Thus hydrogen peroxide, which is capable of participating in twice as many intermolecular hydrogen bonds as is water, would have the effect of 'tightening' the structure of the latter, and one might anticipate that the proton mobility in H_2O–H_2O_2 mixtures would be as great as that in pure water. The fact that this supposition is so greatly at variance with the experimental results may be due to two things:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(*a*) the chain-conductance process is no longer occurring in anhydrous hydrogen peroxide and addition of peroxide to the water–acid system brings about a gradual breakdown in this process, and/or

(*b*) the number of ions present in the solution is greatly decreased as the result of a reduction in the degree of dissociation of the acid.

In view of the similarity which has been established between the liquid structures of pure water, pure hydrogen peroxide, and mixtures of the two, suggestion (*a*) above is hardly likely to be true, and an explanation of the experimental results must be sought principally in terms of effect (*b*).

The extent to which an acid will dissociate in solution is determined by the basic nature of the solvent and its dielectric properties. Referring again to pure water and almost anhydrous hydrogen peroxide, we find that the difference in dielectric constant is small but that there is an appreciable difference in their relative acidities. Measurements of the pH of mixtures of H_2O–H_2O_2 have been made and, although data from different sources (11, 12) do not agree well (see Fig. 2), they all show that the acidity increases considerably with percentage H_2O_2.

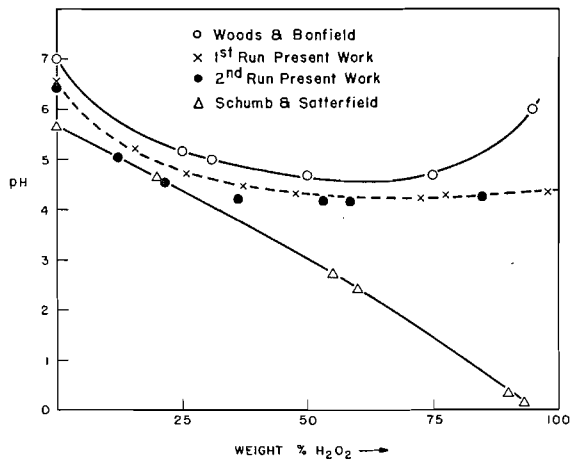

FIG. 2.

In the system H_2O–acid–H_2O_2 the following equilibria are possible:

(i) $HA + H_2O \rightleftharpoons H_3O^+ + A^-$,

(ii) $HA + H_2O_2 \rightleftharpoons H_3O_2^+ + A^-$,

(iii) $H_3O_2^+ + H_2O \rightleftharpoons H_3O^+ + H_2O_2$.

In case (i) when HA is a strong acid, the equilibrium will lie far to the right owing to the affinity of the water molecule for protons. As the basicity of the solvent molecule decreases, so too will the stability of the corresponding oxonium ion, and it is for this reason that the equilibrium position in (ii) lies well to the left. An independent measure of the relative stabilities of H_3O^+ and $H_3O_2^+$ has been given by Uri and Evans (13), who estimated a ΔH value of 4.2 kcal. per mol. for process (iii); thus assuming the entropy change to be small they find $\Delta G^\circ \simeq \Delta H^\circ = -4.2$ kcal., which gives an equilibrium constant of $K \simeq 10^3$.

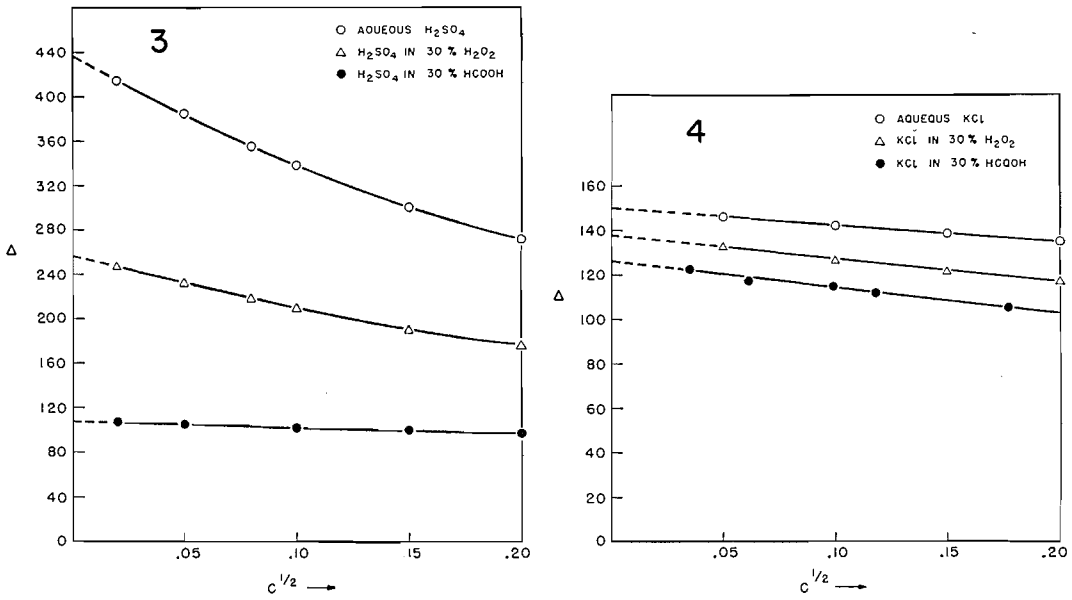
As the concentration of H_2O_2 increases with respect to that of H_2O the number of ions produced by process (i) will decrease and become a minimum in almost anhydrous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

hydrogen peroxide. This addition of H_2O_2 will bring about a gradual reduction in the equivalent conductance of the system, and the form of the pH curve suggests that the decrease will be most rapid for additions up to 30 weight %. Furthermore, although the degree of dissociation decreases, the mechanism of conductance remains the same as in aqueous solution, and so the temperature coefficients of conductances should also remain unchanged (except for a small change due to the effect on the dissociation constant).

These suppositions are in good agreement with the experimental results for the acids studied, and the very different behavior displayed by the alkali chlorides (1) in identical solvents adds strength to these opinions. If this is indeed a true picture of what is occurring, then similar effects should be observed in mixtures of water and any other weakly acidic substance. Conductivity measurements were therefore made in aqueous formic acid. Formic acid possesses both weakly acidic properties and a reasonably high dielectric constant (14). (It was because of its low dielectric constant that acetic acid was not used.) The effect of the reduced dielectric constant of H_2O–HCOOH mixtures as compared with that of H_2O–H_2O_2 mixtures can be assessed by measuring the conductance of KCl in a solvent of the same composition.

The results obtained are shown graphically in Figs. 3 and 4, and do indeed show that H_2SO_4 gives an over 100% lower conductance in H_2O–HCOOH than in H_2O–H_2O_2 mixtures. This would be expected from the greater acidity of HCOOH compared with H_2O_2. The results for KCl show that it behaves very much as it did in H_2O–H_2O_2 mixtures, the 7% lower values probably being due to the lower dielectric constant of the solvent.



FIGS. 3 and 4.

CONCLUSION

Abnormally low values are observed for the conductance of strong acids in water – hydrogen peroxide mixtures, the value being a minimum in almost anhydrous hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

peroxide. An explanation is given in terms of a decrease in the degree of dissociation of these acids with increase in concentration of hydrogen peroxide in the solvent.

The proposals made were verified by conductance measurements on sulphuric acids and potassium chloride in water – formic acid mixtures.

ACKNOWLEDGMENTS

SEVEN- AND EIGHT-MEMBERED RINGS CONTAINING CARBON AND TWO SULPHUR ATOMS[1]

MARSHALL KULKA

ABSTRACT

7-Chloro-2,3-dihydrobenzo(*f*)-1,4-dithiepin (IV) has been synthesized from 2-(2-chloroethylmercapto)-5-chlorobenzyl chloride (I). Attempts to synthesize the higher homologues of IV by this method failed because the required intermediates cleaved at the alkyl–sulphur bond. A reaction product of *p*-chlorothiophenol, formaldehyde, and hydrogen chloride has been identified as 2,8-dichloro-6H,12H-dibenzo(*b*,*f*)-1,5-dithiocin (VI), a tricyclic system with the eight-membered ring containing two sulphur atoms.

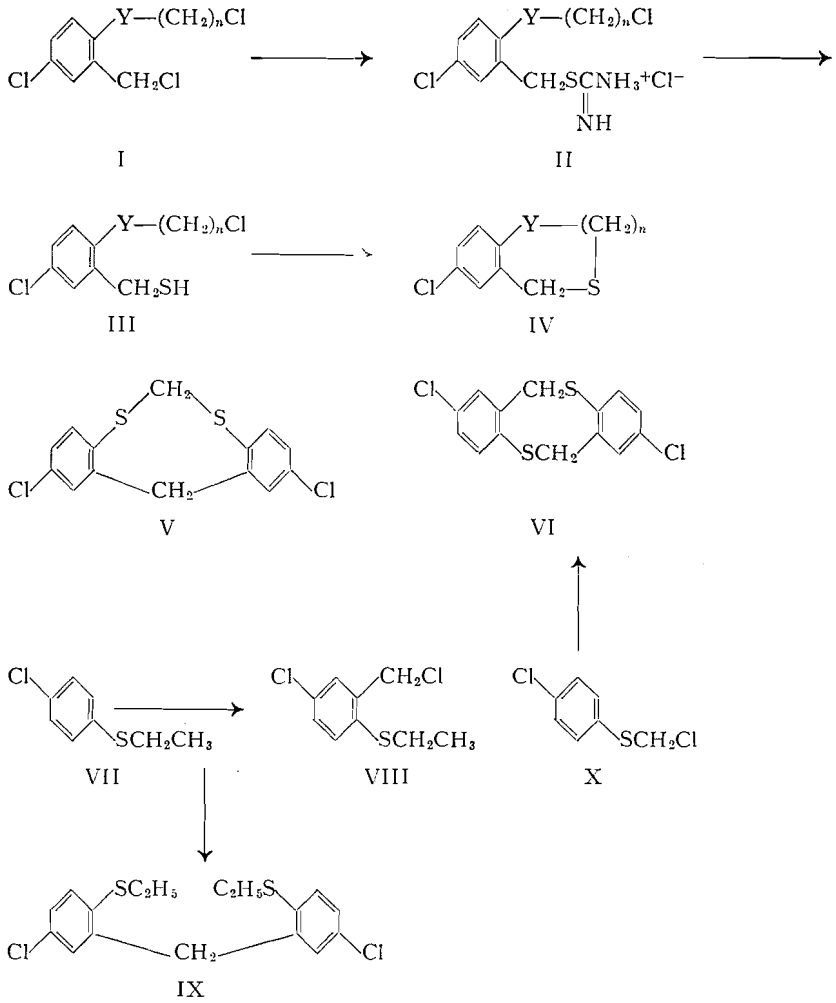
It has been previously shown (1, 2) that *o*-ω-chloroalkoxybenzyl isothiuronium chlorides (II, Y = O) undergo simultaneous degradation and cyclization in the presence of dilute alkali to form macrorings IV (Y = O) containing carbon, oxygen, and sulphur. It was also indicated that this reaction involves the intermediate III (Y = O). The ease with which these macrorings formed was attributed to the presence of the two heteroatoms which provided favorable bond angles.

In the present investigation it was decided to examine the preparation of rings containing two sulphur atoms. Accordingly *p*-chlorophenyl 2-chloroethyl sulphide was chloromethylated and the resulting 2-(2-chloroethylmercapto)-5-chlorobenzyl chloride (I, Y = S, $n = 2$) was treated with thiourea. This produced the required isothiuronium salt II (Y = S, $n = 2$) which when added to a large volume of hot dilute alkali yielded 7-chloro-2,3-dihydrobenzo(*f*)-1,4-dithiepin (IV, Y = S, $n = 2$). Attempts to synthesize the higher homologues of IV (Y = S, $n > 2$) failed because the required intermediates I (Y = S, $n > 2$) could not be obtained.

It was found that the sulphur–alkyl linkage of *p*-$ClC_6H_4S(CH_2)_nCl$ (where $n > 2$), unlike the ether linkage of *p*-$ClC_6H_4O(CH_2)_nCl$, was susceptible to cleavage under the acidic conditions of chloromethylation. Thus when *p*-chlorophenyl 4-chlorobutyl sulphide was subjected to the same chloromethylation conditions as were used in the preparation of 2-(2-chloroethylmercapto)-5-chlorobenzyl chloride (I, Y = S, $n = 2$) from *p*-chlorophenyl 2-chloroethyl sulphide, no reaction occurred. However, when the amount of condensing agent (zinc chloride) was increased, reaction did occur but I (Y = S, $n = 4$) was not the product. Instead, a high-melting, difficultly soluble compound was isolated. This compound was also formed when *p*-chlorothiophenol, bis(*p*-chlorophenylmercapto)-methane (3, 4), 1,2-bis(*p*-chlorophenylmercapto)ethane, and 1,4-bis(*p*-chlorophenylmercapto)butane but not 1,3-bis(*p*-chlorophenylmercapto)-2-chloropropane (5) were subjected to the more drastic chloromethylation. It became evident that *p*-chlorothiophenol was the intermediate in the formation of the high-melting compound and that the sulphides produced this intermediate by cleavage at the sulphur–alkyl bond. That 1,3-bis(*p*-chlorophenylmercapto)-2-chloropropane did not undergo cleavage under the acidic conditions of chloromethylation may be attributed to the steric hindrance offered by the alkyl chlorine atom. It is remarkable that bis(*p*-chlorophenyl) disulphide also remained unaltered under these conditions.

The structure of the unknown high-melting compound obtained from *p*-chlorothiophenol was determined in the following manner. Analyses revealed the empirical

[1]*Manuscript received January 15, 1958.*
Contribution from the Dominion Rubber Company Limited Research Laboratories, Guelph, Ontario.



formula $C_{14}H_{10}Cl_2S_2$. A low molecular weight was indicated from the fact that the compound could be sublimed *in vacuo*, and a determination according to the method of Rast gave a figure of 315. On the basis of the properties and the origin of the compound, two possible structures, V and VI, were proposed. Further examination of the unknown compound showed that it was stable under a variety of acidic conditions and this finding eliminated the structure V, which is a mercaptal and therefore susceptible to acid hydrolysis. An attempt to synthesize V by preparing 2,2′-bis(ethylmercapto)-5,5′-dichlorodiphenylmethane (IX) from VII and VIII and subjecting it to chloromethylation resulted only in resinous material.

There are two possible routes by which the compound of structure VI could form from *p*-chlorothiophenol, formaldehyde, and hydrogen chloride in the presence of zinc chloride. Firstly, C-chloromethylation could occur to form 2-mercapto-5-chlorobenzyl chloride, two molecules of which could then react with each other in the presence of zinc chloride to form VI. Secondly, S-chloromethylation could occur to form *p*-chlorophenyl chloromethyl sulphide (X), two molecules of which could then undergo a Friedel–Crafts reaction with each other to form VI. That VI was formed via the second route was shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

by synthesis. *p*-Chlorothiophenol was treated with formaldehyde and hydrogen chloride according to the method of Scherer and Fink (6) to form *p*-chlorophenyl chloromethyl sulphide (X). Then when X was heated with zinc chloride in acetic acid 2,8-dichloro-6H,12H-dibenzo(*b*,*f*)-1,5-dithiocin (VI) was formed in high yield. On the other hand 2-ethylmercapto-5-chlorobenzyl chloride (VIII) when heated with zinc chloride in acetic acid saturated with hydrogen chloride did not produce VI.

The reaction of *p*-chlorothiophenol with formaldehyde and hydrogen chloride follows a course unlike that of its oxygen analogue. Thus when *p*-chlorophenol was treated with formaldehyde and hydrogen chloride under the conditions used in the preparation of VI, there was formed 6-chloro-8-chloromethyl-1,3-benzodioxane (7). This is obviously a reaction product of only one molecule of *p*-chlorophenol. *p*-Thiocresol did not produce a dithiocin of the type VI when subjected to chloromethylation. The product was a resin.

The chloromethylation of *p*-chlorothiophenol now provides an easy access to the ring system VI, which up to the present time was available only in the form of dibenzo(*b*,*f*)-1,5-dithiocin-6,12-dione, a dehydration product of thiosalicylic acid (8).

EXPERIMENTAL

2-(2-Chloroethylmercapto)-5-chlorobenzyl Chloride (*I*, *Y* = *S*, *n* = *2*)

A reaction mixture of acetic acid (300 ml.), paraformaldehyde (10 g.), zinc chloride (15 g.), and 2-chloroethyl *p*-chlorophenyl sulphide (60 g.) (5) was saturated with hydrogen chloride and then heated at 85°–90° for 3 days. The reaction mixture was concentrated *in vacuo* to about half its original volume and then diluted with dilute hydrochloric acid. The precipitated oil was extracted with benzene, the benzene solution washed with water, with aqueous sodium bicarbonate, and with water. The solvent was removed and the residue fractionally distilled. Fraction 1, b.p. (12 mm.) = 150°–170°, 20 g.; fraction 2, b.p. (12 mm.) = 170°–185°, 13 g.; and fraction 3, b.p. (12 mm.) = 185°–190°, 25 g. Fraction 3, which was the required product, was not purified but was used directly in the formation of the isothiuronium salt (see below).

2-(2-Chloroethylmercapto)-5-chlorobenzyl Isothiuronium Chloride (*II*, *Y* = *S*, *n* = *2*)

A solution of crude 2-(2-chloroethylmercapto)-5-chlorobenzyl chloride (fraction 3 above) (20 g.), thiourea (10 g.), and ethanol (120 ml.) was heated under reflux for 3 hours. The solvent was removed *in vacuo*, the residue dissolved in hot water (50 ml.), and the solution was allowed to cool. The white precipitate (15 g.) was filtered, washed with cold water and with benzene, and crystallized from water, yielding white prisms melting at 143°–145°. Anal. Calc. for $C_{10}H_{13}N_2Cl_3S_2$: C, 36.20; H, 3.92. Found: C, 36.01; H, 4.04.

7-Chloro-2,3-dihydrobenzo(f)-1,4-dithiepin (*IV*, *Y* = *S*, *n* = *2*)

A solution of 2-(2-chloroethylmercapto)-5-chlorobenzyl isothiuronium chloride (8 g.) in methanol (50 ml.) and water (50 ml.) was added dropwise to a stirred hot solution of sodium hydroxide (5 g.) in water (500 ml.) heated on the steam bath. The addition time was approximately $\frac{1}{2}$ hour and the reaction mixture was heated for an additional $\frac{1}{2}$ hour. The precipitated yellow oil was extracted with benzene, the solution washed with water, and the solvent removed. The residue distilled at 180°–182° (12 mm.) and the distillate when crystallized from methanol yielded golden prisms (1.9 g. or 35%) melting at 91°–92°. Anal. Calc. for $C_9H_9ClS_2$: C, 49.87; H, 4.14. Found: C, 50.23, 49.96; H, 4.15, 3.94.

p-Chlorophenyl 4-Chlorobutyl Sulphide

To a solution of potassium hydroxide (30 g.) in methanol (100 ml.) was added *p*-chlorothiophenol (73 g.) and 1,4-dichlorobutane (300 ml.), and the resulting reaction mixture

was heated on the steam bath for ½ hour. There was a slight exothermic reaction at the beginning. Water was added to dissolve the precipitated salt and the organic layer was washed with aqueous alkali and with water. The excess 1,4-dichlorobutane was removed *in vacuo* and the residue was distilled, yielding a colorless liquid (92 g.) boiling at 180° (12 mm.), n_D^{20} = 1.5793. Anal. Calc. for $C_{10}H_{12}Cl_2S$: C, 51.07; H, 5.11. Found: C, 51.58; H, 5.27.

The residue from the distillation when crystallized from methanol gave white prisms of *1,4-bis(p-chlorophenylmercapto)butane* (6 g.) melting at 73°–74°. Anal. Calc. for $C_{16}H_{16}Cl_2S_2$: C, 55.98; H, 4.67. Found: C, 55.74; H, 4.48.

2,8-Dichloro-6H,12H-dibenzo(b,f)-1,5-dithiocin (VI)

(*a*) *From p-chlorothiophenol.*—A reaction mixture of *p*-chlorothiophenol (50 g.), zinc chloride (40 g.), paraformaldehyde (20 g.), and acetic acid (350 ml.) was saturated with hydrogen chloride and then heated on the steam bath for 16 hours. The resulting white precipitate was filtered from the cooled reaction mixture, washed with acetic acid, with concentrated hydrochloric acid, and with water, and dried. The crude product (35 g.) melted at 244°–246° and was insoluble in most organic solvents. When crystallized from benzene or N,N-dimethylformamide it melted at 254°–255°. Its melting point was not depressed by the products obtained in (*b*) or (*c*) (see below). Anal. Calc. for $C_{14}H_{10}Cl_2S_2$: C, 53.68; H, 3.19; Cl, 22.70; S, 20.45. Found: C, 53.87, 53.41; H, 2.92, 3.12; Cl, 23.37; S, 20.66, 20.85.

(*b*) *From sulphides.*—When bis(*p*-chlorophenylmercapto)methane (3, 4), 1,2-bis(*p*-chlorophenylmercapto)ethane (5), and 1,4-bis(*p*-chlorophenylmercapto)butane were subjected to chloromethylation as in (*a*) in each case a product was obtained melting at 254°–255° alone or in admixture with the 2,8-dichloro-6H,12H-dibenzo(*b,f*)-1,5-dithiocin (VI) obtained in (*a*).

(*c*) *From p-chlorophenyl chloromethyl sulphide (X).*—A solution of *p*-chlorophenyl chloromethyl sulphide (X) (6) (5 g.) in acetic acid (50 ml.) and zinc chloride (20 g.) was heated on the steam bath for 2 days. The white precipitate was filtered, washed with acetic acid and with methanol, and crystallized from N,N-dimethylformamide. The white needles (3.5 g. or 86%) melted at 251°–254° alone or in admixture with the compound obtained from *p*-chlorothiophenol (see Section (*a*)).

p-Chlorophenyl Ethyl Sulphide (VII)

This was prepared in quantitative yield by treating a hot alkaline solution of *p*-chlorothiophenol with diethyl sulphate in the usual manner. It boiled at 123° (18 mm.), n_D^{20} = 1.5800. Anal. Calc. for C_8H_9ClS: C, 55.67; H, 5.22. Found: C, 56.35; H, 5.72.

2-Ethylmercapto-5-chlorobenzyl Chloride (VIII)

A mixture of *p*-chlorophenyl ethyl sulphide (45 g.), acetic acid (200 ml.), paraformaldehyde (10 g.), and zinc chloride (10 g.) was saturated with hydrogen chloride and the resulting solution was heated on the steam bath for 20 hours. The reaction mixture was concentrated *in vacuo* to about one-half of its original volume and the residue treated with water and then extracted with benzene. The benzene extract was washed with water, with aqueous sodium bicarbonate, and with water, and the solvent removed. The residue was distilled yielding three fractions: fraction 1, b.p. (11 mm.) = 110°–135°, 4 g.; fraction 2, b.p. (11 mm.) = 135°–170°, 30 g.; and fraction 3, b.p. (11 mm.) = 200°–250°, 8 g. Fraction 2 was redistilled yielding a colorless liquid (20 g.) of VIII boiling at 150°–152° (11 mm.), n_D^{20} = 1.5933. Anal. Calc. for $C_9H_{10}Cl_2S$: C, 48.87; H, 4.52. Found: C, 49.23, 49.61; H, 4.41, 4.73.

Fraction 3 was crystallized from benzene yielding white prisms (0.7 g.) melting at 250°–252° alone or in admixture with *2,8-dichloro-6H,12H-dibenzo(b,f)-1,5-dithiocin* (*VI*) prepared from *p*-chlorothiophenol.

The mother liquors from the crystallization of fraction 3 were taken to dryness and the residue crystallized from methanol yielding white prisms (1 g.) melting at 96°–98° alone or in admixture with *2,2′-bis(ethylmercapto)-5,5′-dichlorodiphenylmethane* prepared from VII and VIII (see below).

2-Ethylmercapto-5-chlorobenzyl Isothiuronium Chloride

2-Ethylmercapto-5-chlorobenzyl chloride (16 g.), thiourea (5 g.), and ethanol (100 ml.) were heated together under reflux for 3 hours. The solvent was removed *in vacuo*, the residue was dissolved in warm water (300 ml.), the solution washed with benzene and then concentrated *in vacuo* to about 25 ml. The white needles (12 g.), which precipitated when the solution was cooled, were filtered, washed, and dried, m.p. 204°–206°. Anal. Calc. for $C_{10}H_{14}N_2Cl_2S_2$: C, 40.40; H, 4.71; N, 9.42. Found: C, 40.73, 40.73; H, 4.88, 4.85; N, 9.91, 9.99.

2,2′-Bis(ethylmercapto)-5,5′-dichlorodiphenylmethane (*IX*)

A reaction mixture of 2-ethylmercapto-5-chlorobenzyl chloride (VIII) (5 g.), *p*-chlorophenyl ethyl sulphide (VII) (5 g.), zinc chloride (12 g.), and acetic acid (25 ml.) was heated under reflux for 1 hour and then poured into dilute hydrochloric acid. The precipitated oil was extracted with benzene, the benzene solution was washed with water, and the solvent removed. The residue was distilled and the fraction boiling at 175°–190° (0.5 mm.) collected. When this distillate was crystallized twice from methanol it yielded white prisms (3.5 g.) melting at 95°–97°. Anal. Calc. for $C_{10}H_{14}N_2Cl_2S_2$: C, 57.13; H, 5.04. Found: C, 57.06, 57.31; H, 5.27, 5.17.

STRUCTURE OF AN ARABOGALACTAN FROM WHITE SPRUCE (PICEA GLAUCA (MOENCH) VOSS)[1]

G. A. ADAMS

ABSTRACT

A water-soluble polysaccharide isolated from white spruce wood contained D-galactose, L-arabinose, and D-xylose in a molar ratio of 21:3:1. Hydrolysis of the fully methylated polysaccharide yielded 2,3,5-tri-*O*-methyl-L-arabinose (12 moles); 2,3,4,6-tetra-*O*-methyl-D-galactose (29 moles); 2,3,4-tri-*O*-methyl-D-galactose (34 moles); 2,6-di-*O*-methyl-D-galactose (0.5 moles); 2,4-di-*O*-methyl-D-galactose (45 moles); 2,3-di-*O*-methyl-D-xylose (5 moles); and monomethyl xylose (1 mole). When oxidized by periodate the polysaccharide consumed 1.18 moles of oxidant, and yielded 0.56 moles of formic acid per mole of anhydro-D-galactose. The D-xylose was attributed to the presence of a xylan mixed with the arabogalactan in the original polysaccharide preparation. The methylation and periodate oxidation data showed that the arabogalactan possessed a highly branched structure with the anhydro-D-galactose units being joined by 1→3 and 1→6 glycosidic bonds. All of the L-arabinose was present in the furanoside form as non-reducing terminal units.

Water-soluble polysaccharides of the arabogalactan type occur predominantly in the larches (1, 2, 3, 4, 5), although lesser amounts have been found in black spruce (*Picea mariana*) (6), southern yellow pine (*Pinus palustris*) (7), Jeffrey pine (*Pinus jeffreyi*) (8), and jack pine (*Pinus banksiana*) (9). The polysaccharides isolated from southern yellow pine and black spruce contained uronic acid residues in addition to arabinose and galactose. Fractionation of the water-soluble polysaccharides from the various sources has shown that some are heterogeneous. The heterogeneous nature of the polysaccharides from *Larix occidentalis* was demonstrated by Peterson *et al.* (10) and the arabogalactan from the European larch (*Larix decidua*) similarly was shown to be heterogeneous by Campbell *et al.* (11). On the other hand, the arabogalactans from Jeffrey pine (8) and jack pine (9) have been regarded as homogeneous. In an extensive investigation on the structure of the arabogalactan of western larch (*L. occidentalis*) (4, 12, 13, 14) White regarded the polysaccharide as homogeneous, a view which has been disputed by Campbell *et al.* (11).

A previous paper from this laboratory reported the isolation and composition of a

water-soluble polysaccharide from white spruce (*Picea glauca*) (15). It contained galactose, arabinose, xylose (molar ratio, 21:3:1), and a small amount of uronic acid (3.0%), and had a specific rotation $[\alpha]_D^{25} = -7°$. Results of several fractionation procedures indicated that the polysaccharide was essentially homogeneous and this conclusion was further confirmed by electrophoretic examination.

The present investigation was concerned with the structure of the polysaccharide as shown by methylation and periodate oxidation studies. The polysaccharide was methylated and the methyl ether subjected to methanolysis and hydrolysis. The methylated sugars were separated chromatographically on a Celite column (16) into 10 fractions as shown in Table I.

Further separations of mixtures were made and the main methylated sugars were characterized by isolation of appropriate crystalline derivatives. The amounts and molar ratios of the various sugar components are shown in the following table.

TABLE II

YIELD OF METHYLATED SUGARS

Methylated sugar	Wt. (mg.)	Millimoles	Molar ratio
2,3,5-Tri-*O*-methyl-L-arabinose	236	1.23	12
2,3,4,6-Tetra-*O*-methyl-D-galactose	695	2.94	29
2,3,4-Tri-*O*-methyl-D-galactose	758	3.43	34
2,6-Di-*O*-methyl-D-galactose	10	0.05	0.5
2,4-Di-*O*-methyl-D-galactose	942	4.55	45
2,3-Di-*O*-methyl-D-xylose	89	0.50	5
Monomethyl xylose	18	0.10	1

The polysaccharide was considered to be an arabogalactan and the small amount of xylose present after hydrolysis was attributed to an admixed xylan. The methylation data showed that the xylan had the usual 1→4 linked structure with some branching present at $C_{(2)}$ and/or $C_{(3)}$. No tri-*O*-methyl-D-xylose, representative of the non-reducing end of the xylan, could be found, undoubtedly because the amount present was too small to be detected. The presence of xylan of the usual type which has a characteristically high negative rotation could account for the present polysaccharide having a slightly negative specific rotation (−7°) compared with the small positive rotation previously reported for arabogalactans (10, 8, 9).

Results of the methylation studies showed that the arabogalactan must contain the following units, in the relative amounts shown:

The high proportion of terminal units of arabinose (I) and galactose (II) showed that the polysaccharide molecule was highly branched, the branches occurring at positions as shown by III, IV, and V. Although the present data do not permit the assignment of a unique structure to the molecule, certain structural features are evident. The main chain or "backbone" of the molecule can be visualized as D-galactopyranose units linked 1→6. The relatively high proportion of IV showed that considerable branching occurred at $C_{(3)}$ and subsidiary chains of 1→6 linked D-galactopyranose units could be attached at this point. This arrangement provides for a branch-on-branch type of structure terminated at the non-reducing ends by unsubstituted D-galactopyranose and L-arabofuranose residues. The small amount of 2,6-di-*O*-methyl-D-galactose (0.5 moles) found in the hydrolysis products showed that a small amount of branching also occurred at $C_{(3)}$ and $C_{(4)}$ of some anhydro-D-galactose units. The number of sugar units (45.5) forming branch points (IV and V) was slightly more than the number (41) of non-reducing terminal units (I and II). The ratio of methylated arabinose to methylated galactose (12:108) found on hydrolysis was less than that in the original polysaccharide molecule (arabinose: galactose 1:7). Both of these discrepancies were probably caused by some loss of the volatile methyl glycoside of 2,3,5-tri-*O*-methyl-L-arabinose. No partially methylated arabinose units were present after hydrolysis and hence the likelihood was remote that the 2,3,5-tri-*O*-methyl-L-arabinose had its origin in an admixed araban. The absence of unoxidized arabinose units after treatment with periodate further confirmed these conclusions. The change in specific rotation on hydrolysis of the methylated polysaccharide ($[\alpha]_D^{25}$ −55 to +75°) indicated that the glycosidic bonds were mainly in the β-configuration. An arabogalactan having structural features as described should consume 1.15 moles of periodate per mole of anhydro-D-galactose and produce 0.55 moles of formic acid; the actual values of 1.18 moles of periodate and 0.56 moles of formic acid provided excellent agreement.

The structural features of the white spruce arabogalactan conform in general to those found in other arabogalactans of wood (12, 13, 14, 8, 9, 11). These structural characteristics include a high degree of branching through positions 6 and 3 of the anhydro-D-galactose units with the arabinose units attached as end groups on some of the branches. The white spruce arabogalactan resembled rather closely the arabogalactan of jack pine (9) although the latter contained proportionately less arabinose. It differed from the arabogalactan of Jeffrey pine (8) by having its arabinose units exclusively in terminal positions and also a greater proportion of the galactose units as non-reducing end groups. The arabogalactan of larch (14) differed by having more branching at position 3 of the galactose units.

The problem of heterogeneity makes positive interpretation of the methylation and periodate oxidation data difficult; the existence of a galactan admixed with the arabogalactan is a possibility that cannot be excluded.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated and melting points are corrected.

Paper Chromatography

Chromatographic separations were carried out using the following solvent systems (v/v ratios): (A) pyridine:ethyl acetate:water (2:1:2); (B) methyl ethyl ketone:water (2:1); (C) ethanol:benzene:water (47:200:15); (D) *n*-butanol: ethanol:water (40:11:19); and (E) ethyl acetate:acetic acid:formic acid:water (18:3:1:4). Separations were per-

formed by the descending technique on Whatman No. 1 filter paper. Methylated sugars were located on the papers by *p*-anisidine hydrochloride spray reagent (17).

Composition of the Polysaccharide

The polysaccharide was prepared from a water-soluble extract of white spruce (*Picea glauca* (Moench) Voss) as described previously (15). The material was soluble in water and had the following analysis: D-galactose, L-arabinose, and D-xylose (molar ratio 21:3:1); Klason lignin, 3.0%; ash (sulphated), 2.5%; uronic acid 3.3% and $[\alpha]_D^{25} = -7° \pm 2.5°$ (*c*, 0.7% in 10% sodium hydroxide).

Methylation

Hemicellulose (6.40 g.) was dissolved in water (25 ml.) and methylated by the dropwise addition of dimethyl sulphate (60 ml.) and 45% sodium hydroxide solution (100 ml.) with stirring. The reagent additions required a period of 4 hours and the solution was kept alkaline at all times. After stirring for 1 hour, the foregoing methylation was repeated and the solution was stirred overnight. Complete methyl glycoside formation was indicated by a negative reduction test with Fehling's solution. A 100-ml. quantity of 45% sodium hydroxide was added at one time and further methylation carried out by the addition of dimethyl sulphate (60 ml.) over 3 hours. This treatment was repeated once more, the reaction mixture being stirred overnight and then heated at 85° C. for $1\frac{1}{2}$ hours. The solution was cooled in an ice bath and brought to pH 7.0 with acetic acid. The salts were dissolved by the addition of water and the partially methylated polysaccharide was extracted by shaking with chloroform. The extracts were dried by anhydrous sodium sulphate and evaporated to yield a glassy solid (4.10 g.). Dialysis of the extracted water phase, followed by freeze-drying of the salt-free solution, yielded a further quantity of partially methylated polysaccharide (1.74 g.). Three additional methylations of this fraction, as described above, followed by chloroform extraction, yielded a more highly methylated polysaccharide (1.04 g.). Both fractions showed a definite hydroxyl band at 3500–3600 $cm.^{-1}$ in their infrared spectra. The fractions were combined (wt. = 5.14 g.) and dissolved in tetrahydrofurane (100 ml.). Powdered sodium hydroxide (35 g.) and dimethyl sulphate (35 ml.) were added, the latter over a period of 4 hours. Recovery of the methylated polysaccharide by chloroform extraction as described before yielded a glassy solid (3.69 g.) which still showed a distinct hydroxyl band in its infrared spectrum. The partially methylated product was dissolved in methyl iodide:methanol (100:5) and methylated by addition of silver oxide (10 g.) in portions of 2 g. every hour. The solution was refluxed overnight and the methylated product was recovered by extraction with chloroform. Three additional methylations by this method were necessary to yield a product which had no hydroxyl band at 3500–3600 $cm.^{-1}$ in its infrared spectrum. The methylated polysaccharide was a yellowish solid (3.96 g.) having $[\alpha]_D^{25} = -55° \pm 1°$ (*c*, 1.0% in chloroform) and OMe 42.8% (theoretical value for $(C_9H_{16}O_5)_n$, 45.3%).

Hydrolysis of Methylated Polysaccharide

The methylated polysaccharide (3.96 g.) was heated with 8% methanolic hydrogen chloride (150 ml.) in a boiling water bath for 12 hours. Methanol was evaporated by a stream of air from a fan at room temperature, *N* hydrochloric acid (60 ml.) was added, and the methyl glycosides were hydrolyzed on a boiling water bath for 10 hours. A small insoluble precipitate was filtered off and the acidic solution was neutralized by Amberlite 1R-45 resin. The neutral solution was concentrated to a thin sirup, taken up in aqueous ethanol, clarified with charcoal, and concentrated to a thick sirup. After

further drying over calcium chloride in a desiccator *in vacuo* the product weighed 3.18 g. and had $[\alpha]_D^{25} = +75° \pm 1°$ (*c*, 1.56 in water). Chromatographic examination of the sirup on paper strips (solvent D) indicated the presence of the following methylated sugars: 2,3,5-tri-*O*-methyl-L-arabinose (R_g 0.96); 2,3,4,6-tetra-*O*-methyl-D-galactose (R_g 0.92); 2,3,4-tri-*O*-methyl-D-galactose (R_g 0.76); 2,4-di-*O*-methyl-D-galactose (R_g 0.54); 2,6-di-*O*-methyl-D-galactose (R_g 0.58); 2,3-di-*O*-methyl-D-xylose (R_f 0.50–0.52, solvent B); and a methylated uronic acid.

Separation of Methylated Sugars

The mixture of methylated sugars (3.1 g.) was separated on a Celite column using *n*-butanol saturated with water as the developing phase (16). The eluate was collected by an automatic fraction collector in 15 ml. quantities at $2\frac{1}{2}$-minute intervals. Chromatographic examination of every fifth tube on paper strips (solvent D) permitted the grouping of fractions of similar composition. The fractions were taken to dryness and weighed; Table I gives yields and the rotations of the various fractions without further purification. A small amount of uronic acid was removed from the column with water. As the amount was small and the acid was mixed with partially methylated sugars it was not examined further.

Identification of the Methylated Sugars

Fraction 1.—The sugar was dissolved in water, charcoal was added, the solution filtered and taken to dryness (236 mg.). Chromatographic examination in solvents B, C, and D showed that this sugar moved at the same rate as 2,3,5-tri-*O*-methyl-L-arabinose. Specific rotation $[\alpha]_D^{25} = -35° \pm 1°$ and OMe, 47.6% (calculated for $C_8H_{16}O_5$: OMe, 48.4%) further identified it as 2,3,5-tri-*O*-methyl-L-arabinose. The amide of the corresponding arabonic acid was prepared as follows: a portion of the sirup (140 mg.) was dissolved in water (3 ml.) and oxidized by bromine (0.5 ml.) for 50 hours at room temperature. After removal of the bromine by aeration, the solution was neutralized with silver carbonate; excess silver ions were removed by hydrogen sulphide. The solution was evaporated to dryness and 2,3,5-tri-*O*-methyl-L-arabonic acid recovered as a sirup. The acid was lactonized by distillation (bath temperature 120°–145° C. at 0.025 mm.). Addition of methanol saturated with ammonia to the lactone for 24 hours at 5° C. yielded the amide which was recovered by removal of the solvent in a desiccator. The amide crystallized on nucleation and on recrystallization from methanol–ether solution yielded pure 2,3,5-tri-*O*-methyl-L-arabonamide, m.p. 136° (undepressed with an authentic sample) and $[\alpha]_D^{25} = -18° \pm 3°$ (*c*, 1% in water); these values agree with those reported for this compound (18).

Fraction 2.—This sugar (636 mg.) was identical with 2,3,4,6-tetra-*O*-methyl-D-galactose when compared chromatographically in solvents B, C, and D. A portion of the sirup (96.4 mg.) was refluxed with aniline (50 mg.) in ethanol (5 ml.) for $2\frac{1}{2}$ hours. The aniline derivative crystallized during the heating period and after recrystallization from ethanol had a m.p. and mixed m.p. 196°–197° C. and $[\alpha]_D^{25} = -137° \pm 1°$ (*c*, 0.92 in pyridine) and thus was identified as 2,3,4,6-tetra-*O*-methyl-N-phenyl-D-galactosylamine (19).

Fraction 3.—Chromatographic evidence indicated that this sirup (181 mg.) was a mixture of 2,3,4,6-tetra-*O*-methyl-D-galactose and a dimethyl xylose. Separation was achieved on an alumina column (15 × 80 mm.) using the solvents listed below and the eluates were collected on an automatic fraction collector. The presence of the various sugars was indicated by spotting 10 drops of the eluate on paper and spraying with *p*-anisidine reagent. The results are as follows:

Fraction	Solvent	Compound	Yield (mg.)
3A (Tube 9–47)	Chloroform	2,3,4,6-Tetra-*O*-methyl-D-galactose	59
3B (Tube 48–78)	Ethanol	Dimethyl xylose	57
3C (Tube 79–100)	Water	Dimethyl xylose	32

Subfraction 3A.—This sirup was chromatographically identical in solvents B, C, and D with 2,3,4,6-tetra-*O*-methyl-D-galactose. The sirup (52 mg.) was converted as described above into its aniline derivative which had a m.p. of 196° C. and $[\alpha]_D^{25} = -137° \pm 1°$ (c, 1.0% in pyridine).

Subfraction 3B.—This sirup (57 mg.) travelled at the same rate on a paper chromatogram as 2,3-di-*O*-methyl-D-xylose in solvents B, C, and D. These solvents served to distinguish it from 2,4-di-*O*-methyl-D-xylose and also 3,4-di-*O*-methyl-D-xylose (20). A portion of the sugar (46 mg.) was heated with aniline (28.6 mg.) in ethanol (5 ml.) for 3 hours. Slow removal of the solvent in a desiccator containing calcium chloride under reduced pressure yielded crystals of 2,3-di-*O*-methyl-N-phenyl-D-xylosylamine, which on recrystallization from ethyl acetate solution had a m.p. and mixed m.p. of 126° C., reported value 126° C. (21).

Subfraction 3C.—This fraction (32 mg.) was found to be 2,3-di-*O*-methyl-D-xylose by the chromatographic separations applied to subfraction 3B.

Fraction 4.—The sirup (735 mg.) was chromatographically identical in solvents B and D with 2,3,4-tri-*O*-methyl-D-galactose. The identity of the sugar was established by formation of the amide of the corresponding galactonic acid as follows: a portion of the sirup (133.2 mg.) was dissolved in water (2 ml.) and bromine (0.5 ml.) was added and the oxidation was allowed to proceed for 50 hours. Bromine was removed by aeration and the acidity was neutralized with silver carbonate. The 2,3,4-tri-*O*-methyl-D-galactonic acid was lactonized by distillation (bath temperature 150°–170° C./0.02 mm.). Addition of methanolic ammonia yielded 2,3,4-tri-*O*-methyl-D-galactonamide, m.p. and mixed m.p. 166°–167° C. and $[\alpha]_D^{25} = 32.5° \pm 2°$ (c, 1% in water) in good agreement with the reported value (22). Further confirmation of identity was provided by preparation of the corresponding anilide by refluxing the sugar (86.4 mg.) with aniline (44.6 mg.) in ethanol (5 ml.) for 3 hours. Removal of solvent yielded crystals which on recrystallization from ethyl acetate proved to be 2,3,4-tri-*O*-methyl-N-phenyl-D-galactosylamine, m.p. and mixed m.p. 165°–166° C. and $[\alpha]_D^{25} = 40° \pm 2°$ (c, 1.2% in methanol); melting points of 164° C. and 167° C. have been reported (19, 22).

Fraction 5.—Chromatographic examination in solvents B and D showed that this sirup (28 mg.) was a mixture of a trimethyl galactose, dimethyl galactose, and a monomethyl xylose. The rate of movement in solvent D showed that the trimethyl galactose (R_g 0.73–0.75) was identical with 2,3,4-tri-*O*-methyl-D-galactose, the dimethyl-D-galactose (R_g 0.59–0.60) was identical with 2,6-di-*O*-methyl-D-galactose and different from 2,4-di-*O*-methyl-D-galactose (R_g 0.51–0.52). The monomethyl xylose was chromatographically indistinguishable in solvents B and D from 2-*O*-methyl-D-xylose and 3-*O*-methyl-D-xylose. The ratio of the three sugars in the mixture was determined, after spraying with *p*-anisidine reagent, by modifying a densitometer method described for unsubstituted sugars (23); the ratio found for the three methylated sugars was 4:1:1.

Fraction 6.—This sirup (22 mg.) was also a mixture as shown by chromatographic examination in solvents B and D and contained the same sugars as Fraction 5. The component sugars 2,3,4-tri-*O*-methyl-D-galactose, 2,6-di-*O*-methyl-D-galactose, and monomethyl xylose were present in a ratio of approximately 1:1:2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Fraction 7.—The sirup (16 mg.) was chromatographically identical in solvents B and D with 2,4-di-*O*-methyl-D-galactose and had $[\alpha]_D^{25} = +83° \pm 1°$ constant value in 24 hours (*c*, 1% in water). This material was identical with the main Fraction 8 and no further identifications were made.

Fraction 8.—The sirup (893 mg.) crystallized when it was left standing and it corresponded chromatographically in solvents B and D to 2,4-di-*O*-methyl-D-galactose. On recrystallization from ether, 2,4-di-*O*-methyl-D-galactose monohydrate (22) was obtained, m.p. 100°–101° C. with sintering at 73°–76° C., $[\alpha]_D^{25} = +125°$ (5 minutes) $\rightarrow +84° \pm 1°$ in 24 hours (*c*, 1% in water). Anhydrous 2,4-di-*O*-methyl-D-galactose was obtained by drying the monohydrate at 55° C. at 0.1 mm. over phosphorus pentoxide for 20 hours. The anhydrous product had a m.p. and mixed m.p. 103°–104° C. (no sintering) and $[\alpha]_D^{25} = 125°$ (5 minutes) $\rightarrow +87° \pm 1°$ in 24 hours (*c*, 1% in water) in good agreement with the reported values (9). A portion of the sugar (77.0 mg.) was refluxed with aniline (40.2 mg.) in ethanol (5 ml.) for 3 hours. The aniline derivative was obtained in crystalline form on evaporation of the reaction mixture and on recrystallization from ethyl acetate yielded 2,4-di-*O*-methyl-N-phenyl-D-galactosylamine (22) having a m.p. and mixed m.p. 218°–220° C. and $[\alpha]_D^{25} = -181° \pm 4°$ (*c*, 0.92 in pyridine).

Fraction 9.—The sirup (83 mg.) partially crystallized when it was left standing and was chromatographically identical in solvents B and D with 2,4-di-*O*-methyl-D-galactose. Recrystallization from ether yielded 2,4-di-*O*-methyl-D-galactose monohydrate (40 mg.), m.p. and mixed m.p. 100°–101° C. with sintering at 73°–76° C. and $[\alpha]_D^{25} = +125°$ (5 minutes) $\rightarrow +84° \pm 1°$ in 24 hours (*c*, 1.2% in water).

Fraction 10.—The sirup (9 mg.) on chromatographic examination in solvents B and C appeared to be a monomethyl galactose. The material was not investigated further.

The amounts of the main methylated sugar components and their molar ratios are given in Table II.

Periodate Oxidation

Spruce polysaccharide (100 mg. duplicate samples) was dissolved in water (50 ml.) and oxidized by 0.1 *M* sodium periodate (50 ml.) in the dark at 16° C. Analysis for periodate consumption and formic acid production (24) gave the following results:

Time, hours	12	22	72	120	144
Formic acid, moles per $C_5H_8O_4$	0.51	0.55	0.65	0.71	0.73
Periodate consumption, moles per $C_5H_8O_4$	1.03	1.12	1.29	1.37	1.40

The time at which the oxidation was completed was found by extrapolating the flat portion of the time curve to zero time. The values of 1.15 moles of periodate per mole of anhydrogalactose residue and 0.55 moles of formic acid were obtained. In a separate experiment, 50 mg. of the polysaccharide was oxidized for 48 hours, the excess periodate was destroyed by the addition of 2,3-butanediol and the solution dialyzed. The nondialyzable solids were recovered by freeze-drying and then hydrolyzed with *N* sulphuric acid. Chromatographic examination of the neutralized solution showed galactose to be the only sugar present.

ACKNOWLEDGMENTS

The author wishes to thank A. E. Castagne for valuable technical assistance throughout the course of this investigation. Thanks are also tendered to Dr. H. Schwartz, Superintendent, Forest Product Laboratories, Ottawa, Canada, who kindly supplied an authenticated specimen of white spruce wood.

STUDIES IN THE WAGNER–MEERWEIN REARRANGEMENT. PART III[1]

F. A. L. Anet and P. M. G. Bavin[2]

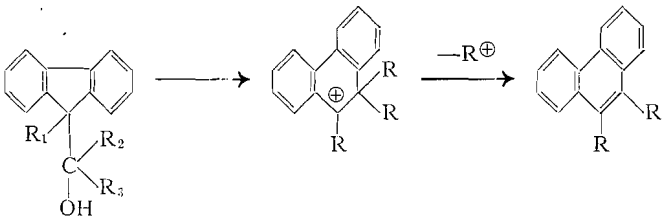
ABSTRACT

2-(9-Methyl-9-fluorenyl)-propan-2-ol and 3-(9-ethyl-9-fluorenyl)-pentan-3-ol have been prepared and shown to give 9,10-dimethyl- and 9-10-diethylphenanthrene, respectively, when heated with polyphosphoric acid.

In Part I of this series (1), we reported that dehydration-rearrangement of 9-*t*-butyl-9-fluorenylmethanol (I, R_1 = *t*-butyl; R_2 = R_3 = hydrogen) by the action of polyphosphoric acid gave rise to a considerable amount of phenanthrene. Since 9-*t*-butylphenanthrene was stable under these conditions, loss of the alkyl group appeared to take place during the rearrangement process. Accordingly, we tried to prepare 2-(9-*t*-butyl-9-fluorenyl)-propan-2-ol (I, R_1 = *t*-butyl; R_2 = R_3 = methyl), which was expected to lead to 9,10-dimethylphenanthrene by expulsion of the *t*-butyl group and a double Wagner–Meerwein rearrangement. Our attempts to prepare this carbinol from methyl 9-*t*-butylfluorene-9-carboxylate have failed (see below), but we have made some related carbinols in which rearrangement and aromatization involved expulsion of an alkyl group.

Methyl magnesium iodide reacted with methyl 9-methylfluorene-9-carboxylate to give 2-(9-methyl-9-fluorenyl)-propan-2-ol (I, R = methyl) in 70–80% yield. Heating of this alcohol with polyphosphoric acid gave 9,10-dimethylphenanthrene. Similarly, ethyl magnesium iodide reacted with methyl 9-ethylfluorene-9-carboxylate to give 3-(9-ethyl-9-fluorenyl)-pentan-3-ol (I, R = ethyl), which gave by heating with polyphosphoric acid 9,10-diethylphenanthrene. In both reactions with polyphosphoric acid the yield of crude hydrocarbon was about 30–50%, but only about 4–10% was obtained completely pure.

These rearrangements may be represented as shown below. It is possible that a shuffling of the alkyl groups in II takes place, and this point could be examined by using suitably labelled alkyl groups.



I II

The increase in resonance energy on passing from II to the 9,10-dialkylphenanthrene probably supplies the driving force for the expulsion of the alkyl group (R).

It was shown previously (1) that methyl 9-*t*-butylfluorene-9-carboxylate was saponified much more slowly than the 9-methyl compound, the difference being attributed to steric hindrance in the former compound. In agreement with this we have found that the 9-*t*-

[1]*Manuscript received January 10, 1958.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1954–1956. Present address: the Ohio State University, Columbus 10, Ohio.*

butyl derivative was recovered unchanged after boiling for 1 hour with ethereal methyl magnesium iodide. Prolonged reaction with lithium methyl or the Grignard reagent gave a mixture which we were unable to resolve.

EXPERIMENTAL

Preparation of the Tertiary Carbinols

Methyl 9-methylfluorene-9-carboxylate (1) (3 g.) was boiled under reflux for 2 hours with ethereal methyl magnesium iodide (6 equivalents). The complex was decomposed with ice and ammonium chloride. Evaporation of chloroform extracts gave an oil which crystallized when left overnight in the ice chest under a little hexane. Recrystallization from hexane gave *2-(9-methyl-9-fluorenyl)-propan-2-ol* as long, colorless prismatic needles (2.1 g., 70%), m.p. 68°–69°. Found: C, 85.75; H, 7.52%. Calc. for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

Reaction of methyl 9-ethylfluorene-9-carboxylate (1) with ethyl magnesium iodide gave, in the same way, *3-(9-ethyl-9-fluorenyl)-pentan-3-ol* in 79% yield. It crystallized from hexane as short stout prisms, m.p. 103°–105°. Found: C, 85.55; H, 8.40%. Calc. for $C_{20}H_{24}O$: C, 85.66; H, 8.63%.

The infrared spectra of carbon disulphide solutions of the carbinols showed strong O–H stretching bands at 3615 $cm.^{-1}$. Solutions of the carbinols in cold concentrated sulphuric acid were carmine.

The crude carbinols melted over a wide range and 20°–30° below the pure compounds, although the infrared spectra did not show carbonyl absorption. It is likely that the carbinols have high molar depression constants, as have been found for other highly branched compounds (2).

Reaction of the Carbinols with Polyphosphoric Acid

The methyl carbinol (1 g.) and polyphosphoric acid (150 ml.) were heated together with stirring at 160° for 1 hour and then at 180° for 15 minutes. The cooled mixture was poured onto ice and extracted with chloroform. Evaporation left an oil which was dissolved in hexane and purified by passage through a column of alumina. Further elution and subsequent evaporation gave a colorless oil. Crystallization from methanol–acetone gave white needles, m.p. 134°–137°, raised to 142°–144° by three more crystallizations. The melting point was not depressed when the compound was mixed with authentic 9,10-dimethylphenanthrene (3), m.p. 143°–144°. Alternatively the hydrocarbon was purified through its picrate or trinitrobenzene complex.

In a similar way the ethyl carbinol gave 9,10-diethylphenanthrene, which formed glistening plates, m.p. 103°–105°, after four crystallizations from methanol–acetone. The melting point was not depressed when the compound was mixed with authentic 9,10-diethylphenanthrene (4), m.p. 106°–107°. The identities were confirmed by comparison of infrared spectra.

Attempted Preparation of 2-(9-t-Butyl-9-fluorenyl)-propan-2-ol

Methyl 9-*t*-butylfluorene-9-carboxylate (1) (12 g.) and ethereal methyl magnesium iodide (12 equivalents) were boiled under reflux for 24 hours. The product was isolated in the usual way, dissolved in hexane, and passed through a short column of activated alumina. When the product was concentrated to 15 ml. and left standing in the ice chest for 3 weeks it gave colorless prisms (7.4 g.). These were collected, washed with a little ice-cold pentane, and recrystallized from hexane (10 ml.) as before to give 4.2 g. of prisms, m.p. 70°–71°. The infrared spectrum of a chloroform solution did not show

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

hydroxyl or carbonyl absorption. The yield of this compound was erratic. A solution of the crude product in carbon bisulphide showed an O–H stretching band at 3618 cm.$^{-1}$.

ACKNOWLEDGMENT

The authors are grateful to Dr. D. McNeil and Dr. C. K. Bradsher for authentic samples of 9,10-dimethyl- and 9,10-diethylphenanthrene, respectively.

SOME STRUCTURAL FEATURES OF DELCOSINE[1]

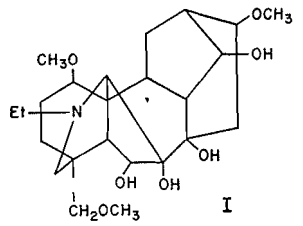
RAGINI ANET[2] AND LÉO MARION

ABSTRACT

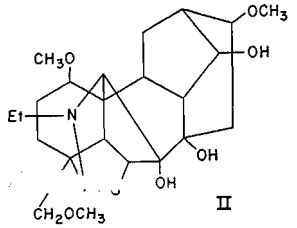
The alkaloid delcosine has previously been assigned tentatively the same carbon–nitrogen skeleton as lycoctonine to which it appears to be closely related in properties. Oxidation experiments now reported provide supporting evidence of the presence of two vicinal tertiary hydroxyl groups attached to a five- and a six-membered ring that are directly linked together at the two carbons carrying the hydroxyls. There is a methoxyl in a position β to the tertiary hydroxyl of the six-membered ring. Evidence is also provided as to the size of the heterocyclic ring and the presence of a methylene group next to the nitrogen.

The tentative structure I previously advanced for delcosine ($C_{24}H_{39}O_7N$) was based on an assumed relationship with the alkaloid lycoctonine, and on the possibility on this assumption[3] of explaining the nature of the oxidation products that had been described (1). We now wish to report further oxidation studies carried out with anhydrohydroxydelcosine II ($C_{24}H_{37}O_7N$), which lend support to some of the features of structure I.

Whereas lycoctonine (2) and demethylenedelpheline (3) yield oxo-derivatives that can be cleaved smoothly with periodic acid or lead tetraacetate, the corresponding bases are not oxidized in a satisfactory manner under the same conditions. Similarly, treatment of delcosine with periodic acid or sodium periodate at room temperature resulted in 4.5 moles of the reagent being consumed in 120 hours, the oxidation continuing until 21 moles had been consumed. The behavior with lead tetraacetate was equally indefinite.[4]



I



II

Anhydrohydroxydelcosine, an oxidation product which has been formulated as II, is much less basic than delcosine (1) and thus was expected to lend itself to cleavage with periodic acid more satisfactorily than the alkaloid. Indeed, it has now been found that on treatment with periodic acid at room temperature, anhydrohydroxydelcosine consumes 1 mole of the reagent in 24 hours. It has not been possible to obtain the oxidation product crystalline even after purification by chromatography on alumina, but its infrared absorption spectrum (in chloroform) contained two carbonyl bands at 1750 and 1710 cm.$^{-1}$ (no aldehyde stretching band at 2600–2800 cm.$^{-1}$) characteristic of a five- and a six-membered ketone respectively, as well as a band at 1000 cm.$^{-1}$ shown also by the spectrum of anhydrohydroxydelcosine in the same solvent. Clearly the oxidation product

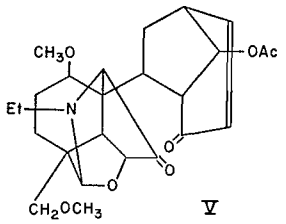
is anhydrohydroxydelcosine-*seco*diketone III formed by cleavage of a vicinal glycol system in which one of the hydroxyls is a substituent on a five-membered ring, and the other on a six-membered ring.

Although the *seco*diketone III could not be induced to crystallize, it formed a crystalline acetyl derivative IV ($C_{26}H_{37}O_8N$). In the infrared this derivative showed bands at 1763 and 1705 cm.$^{-1}$ characteristic of the carbonyls of a five-membered and a six-membered cyclic ketone, and at 1738 and 1233 cm.$^{-1}$ due to the acetate grouping. There was no absorption in the hydroxyl region. On treatment with acid under carefully controlled conditions, the acetyl derivative IV lost the elements of methanol and gave rise to desmethanol-anhydrohydroxydelcosine-*seco*diketone acetate, $C_{25}H_{33}O_7N$ (V), which in the infrared showed absorption bands at 1760, 1740, 1680, and 1615 cm.$^{-1}$. The shift in the frequency of the carbonyl band of the six-membered cyclic ketone from 1705 to 1680 cm.$^{-1}$ corresponds to the change to be expected in going from a saturated to an α,β-unsaturated ketone (4). In the ultraviolet spectrum of V the absorption at λ_{max} 232 mμ, logϵ 3.89, was somewhat higher than expected for an α,β-unsaturated-β-monosubstituted ketone (5) although the same as that occurring in the spectrum of desmethanol-hydroxylycoctonam-*seco*diketone (λ_{max} 230–233 mμ, logϵ 3.74) (6). Hence it is very probable that the double bond in V is α,β- to the carbonyl of the six-membered cyclic ketone. This parallels the chemistry of lycoctonine, and provides evidence concerning the vicinal glycol in delcosine and its environment. Consequently, on the basis of the proposed structure I, the desmethanol-derivative V can be represented as follows:



V

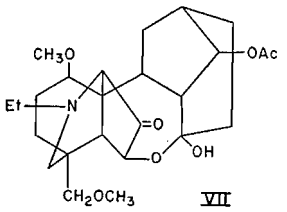
The amorphous anhydrohydroxydelcosine-*seco*diketone III was reduced with sodium borohydride to a compound VI ($C_{23}H_{37}O_6N$) which had lost the elements of methanol. Under the alkaline conditions of the reduction, the β-methoxyl group had been eliminated, and the carbonyls of both the six-membered and five-membered cyclic ketones had been reduced to secondary alcoholic groups. The infrared spectrum of VI showed no absorption in the carbonyl region. The presence of a double bond was confirmed by catalytic hydrogenation in the course of which 1 mole of hydrogen was absorbed smoothly. The behavior of the derivative III, on reduction, was markedly different from that of lycoctonam-*seco*diketone in which only the five-membered, but not the six-membered, ketone was reduced (2). A plausible explanation for this difference is that the internal ether present in compound V orients the carbonyls away from each other so that neither is hindered.

Hydrogenation of the *seco*diketone acetate IV, or its desmethanol-derivative V, in the presence of Adams' catalyst gave erratic results, but in the presence of palladium–charcoal in 50% acetic acid the compound V absorbed 2 moles of hydrogen in 30 minutes. No further absorption took place in the next 2 hours. The product was a crystalline compound VII ($C_{25}H_{37}O_7N$) obtained in 90% yield. Since under similar conditions anhydrohydroxydelcosine was rapidly reduced to delcosine (1), it was assumed that in the product VII the internal ether as well as the double bond had been hydrogenated. The

infrared absorption spectrum of VII contained bands at 3475 cm.$^{-1}$ indicative of a hydroxyl group; and at 1743, 1728, and 1255 cm.$^{-1}$, the first attributable to a five-membered ketone and the last two to an acetate group. The fact that no absorption occurred at 1700–1720 cm.$^{-1}$ whereas a well-resolved band in that region was present in the spectrum of the *seco*diketone acetate IV seemed to indicate that the six-membered ketone was no longer present in VII. Of the two moles of hydrogen absorbed, one was taken up by the double bond, the other must have reduced the internal ether, and therefore, the disappearance of the carbonyl of the six-membered ketone must be attributed to a rearrangement.

The reduction product VII, when oxidized with potassium permanganate in acetone containing acetic acid, gave rise to a neutral product VIII ($C_{25}H_{35}O_8N$). This neutral product had an infrared absorption spectrum containing bands in the hydroxyl region at 3470 cm.$^{-1}$ and in the carbonyl region at 1762 cm.$^{-1}$ characteristic of a five-membered cyclic ketone, at 1728 and 1255 cm.$^{-1}$ due to an acetate group, and at 1665 cm.$^{-1}$ indicative of an amide carbonyl. On vigorous alkaline hydrolysis, compound VIII produced a gum that could not be crystallized, but still showed in the infrared an absorption band at 1640 cm.$^{-1}$ (in chloroform). It has been shown previously that N-acetyl-N-desethyldelcosine is deacetylated readily under milder conditions, and hence it can be concluded that compound VIII does not contain an aliphatic amide but a lactam which from the frequency of its absorption in the infrared must be at least six-membered. This is the first evidence of the size of the heterocyclic ring in delcosine and of the presence next to the nitrogen of a methylene group consistent with the tentative structure I.

Delcosine is readily oxidized to a carbinolamine internal ether, anhydrohydroxydelcosine II, formed by elimination of water between the carbinolamine hydroxyl and one of the hydroxyls originally present in the base (1). Hence, to account for the facile oxidation of the compound VII to a lactam, it seems necessary to assume that in the course of the hydrogenation in which compound VII was produced, the hydroxyl liberated from the internal ether by reduction must have become masked. A possible explanation is that in the conversion of V to VII, this hydroxyl, set free by the hydrogenation, forms a hemiketal with the carbonyl of the six-membered ketone so that VII could be represented as follows:



VII

The oxidation product VIII would therefore be the corresponding lactam. The infrared spectra of both VII and VIII seem to be in agreement with the presence of a hemiketal, since they contain absorption bands in the regions 1158–1190, 1124–1143, and 1063–1098 cm.$^{-1}$ (cf. 7).

EXPERIMENTAL

Ultraviolet absorption spectra were recorded with a Beckman DU spectrophotometer. The infrared absorption spectra were recorded with a Perkin-Elmer double-beam model

For personal use only.

21 instrument with a rock salt prism. Unless otherwise mentioned the samples were suspended in nujol. All melting points were determined on a microscope hot stage and are uncorrected.

Cleavage of Anhydrohydroxydelcosine with Periodic Acid

To anhydrohydroxydelcosine (146 mg.) in water (5 ml.) 0.12 *M* periodic acid (1.5 ml.) was added and the mixture kept at room temperature in the dark for 25 hours. The aqueous solution was neutralized with sodium bicarbonate and extracted with chloroform. On evaporation, the extract yielded a gum which was dissolved in benzene and chromatographed on neutral alumina (activity III). Anhydrohydroxydelcosine-*seco*diketone was eluted from the column with benzene–ether (1:1). It consisted of a gum that could not be crystallized but was converted to an amorphous white solid in contact with petroleum ether. Its infrared absorption spectrum contained carbonyl bands at 1755 and 1710 $cm.^{-1}$.

O-Acetyl-anhydrohydroxydelcosine-secodiketone

Anhydrohydroxydelcosine (164 mg.) in periodic acid (3 ml.) was allowed to stand for 27 hours. The crude product, obtained as described above, was added to acetic anhydride (5 ml.) containing a few drops of pyridine, and left at room temperature for 18 hours. The acetic anhydride and pyridine were distilled off under reduced pressure at a temperature not exceeding 60°. The residue was dissolved in chloroform and the solution washed with dilute sodium bicarbonate and with water. The combined aqueous washings were extracted with a fresh quantity of chloroform and the combined chloroform extract dried over sodium sulphate and evaporated to dryness under reduced pressure. The residue thus obtained was an oil (90 mg.) that crystallized in contact with a little anhydrous ether. Recrystallized from acetone–ether it consisted of colorless needles, m.p. 189°–190°. Found: C, 63.64; H, 7.44; N, 2.76. Calc. for $C_{26}H_{37}O_8N$: C, 63.52; H, 7.59; N, 2.85%. $[\alpha]_D^{25}$ +131.6° (*c*, 0.38 in chloroform). The compound was very sensitive to alkali and acid and was best purified in neutral solvents. In the ultraviolet it has a maximum, λ_{max} 311 mμ, log ϵ 2.46.

Desmethanol-O-acetyl-anhydrohydroxydelcosine-secodiketone

To a solution of O-acetyl-anhydrohydroxydelcosine-*seco*diketone (200 mg.) in acetic acid (5 ml.), concentrated sulphuric acid (0.5 ml.) was added and the solution heated on the steam bath for 30 minutes. The solution turned pale yellow after 10 minutes and the color deepened slightly towards the end of the heating period. The solution was cooled, neutralized with sodium carbonate, and extracted with chloroform. The residual gum left after evaporation of the chloroform extract was dissolved in benzene and chromatographed on alumina (activity IV). Elution with benzene gave 123 mg. of a base that crystallized from acetone–ether in plates, m.p. 178.5°–179°. Further elution of the column with polar solvents did not yield any crystalline products. For analysis the product was recrystallized three times from the same solvent and dried *in vacuo* at 100°. Found: C, 65.23; H, 7.25; N, 3.11; OCH_3, 13.76. Calc. for $C_{25}H_{33}O_7N$: C, 65.34; H, 7.24; N, 3.05; $2OCH_3$, 13.51%. $[\alpha]_D^{25}$ +76.25° (*c*, 0.8 in chloroform). Ultraviolet: λ_{max} 231–232 mμ, log ϵ 3.89; λ_{max} 312 mμ, log ϵ 2.46. The crystalline desmethanol compound was sensitive to acids and alkalies and with the latter gave a soluble yellow substance which was rapidly oxidized to a tar.

Reduction of Anhydrohydroxydelcosine-secodiketone

A small quantity of the chromatographed amorphous *seco*diketone dissolved in 50%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

methanol was treated with sodium borohydride at room temperature for 3 hours. Water was then added and the solution extracted with chloroform. Evaporation of the extract left an oil that crystallized from acetone in plates, m.p. 253°–254°. Found: C, 65.08; H, 8.98; N, 3.34; OCH_3, 16.42. Calc. for $C_{23}H_{37}O_6N$: C, 65.22; H, 8.81; N, 3.31; $2OCH_3$, 14.64%. $[\alpha]_D^{25}$ +34° (*c*, 0.4 in chloroform).

Hydrogenation of Desmethanol-O-acetyl-anhydrohydroxydelcosine-secodiketone

The desmethanol compound (V) (253 mg.) dissolved in 50% acetic acid (8 ml.) was hydrogenated at room temperature and atmospheric pressure in the presence of palladium–charcoal (175 mg.). Two moles of hydrogen were absorbed in 30 minutes and no further uptake was observed during the next 2 hours. The catalyst was filtered out and washed thoroughly with dilute acetic acid. The combined filtrate and washings were neutralized with sodium bicarbonate and extracted with chloroform. The extract on evaporation left a gum (240 mg.) that crystallized when triturated with ether, m.p. 178°–181° (compound VII). Chromatography and further crystallization did not raise the melting point. Found: C, 64.79; H, 7.98; N, 3.19. Calc. for $C_{25}H_{37}O_7N$: C, 64.77; H, 8.05; N, 3.02%. $[\alpha]_D^{25}$ −14° (*c*, 0.75 in chloroform).

Oxidation of Compound VII

The product VII of the catalytic hydrogenation (220 mg.) was dissolved in acetone (20 ml.) containing 50% acetic acid (1 ml.). Powdered potassium permanganate (153 mg.) was added portionwise to the solution over a period of 2 hours. The reaction mixture was allowed to stand at room temperature for 20 hours, excess permanganate destroyed by the careful addition of a saturated solution of sodium bisulphite, and the manganese dioxide filtered off and washed with acetone. The combined filtrate and washings were evaporated under diminished pressure and the residue dissolved in chloroform. The chloroform solution was washed with dilute sulphuric acid and the acid washings extracted once with chloroform. The combined chloroform solutions were dried and evaporated to dryness. There was left a froth which was dissolved in benzene and chromatographed on alumina (activity IV). The fraction eluted with chloroform yielded 130 mg. of the lactam VIII which crystallized from ether – petroleum ether as colorless prisms, m.p. 183°–184°. Found: C, 62.70; H, 7.33; N, 3.08. Calc. for $C_{25}H_{35}O_8N$: C, 62.87; H, 7.39; N, 3.08%. $[\alpha]_D^{25}$ −17° (*c*, 1.1 in chloroform).

ACKNOWLEDGMENTS

The authors wish to express their indebtedness to Dr. R. N. Jones and Mr. R. Lauzon of these laboratories for the determination of the infrared absorption spectra.

REACTION OF TRICHLOROACETONITRILE WITH PRIMARY AND SECONDARY AMINES

PART I. PREPARATION OF SOME TRICHLOROACETAMIDINES[1]

JOHN C. GRIVAS[2] AND ALFRED TAURINS

ABSTRACT

Trichloroacetonitrile reacts with primary and secondary aliphatic and primary aromatic amines to give N-substituted trichloroacetamidines. A series of N-mono- and N-di-substituted trichloroacetamidines, $CCl_3—C(=NH)—NHR$ and $CCl_3—C(—NR_1R_2)=NH$, was prepared by carrying out the reaction in water, in water–methanol solutions, or in the absence of solvents.

INTRODUCTION

Although acetonitrile forms N-substituted acetamidines by the addition of amines only in the presence of anhydrous aluminum chloride (1), trichloroacetonitrile reacts with amines more easily. The German Patent No. 671,785 (2) reported the preparation of some trichloroacetamidines by the direct interaction of trichloroacetonitrile with aliphatic primary amines at low temperature, without giving any details. Oxley (3) prepared trichloroacetamidine and N,N-ethylene-bis-trichloroacetamidine in benzene solution. Backer and Wanmaker (4) isolated N-methyl- and N-piperidyl-trichloroacetamidine only in the form of picrates. They found that the addition of aromatic amines to trichloroacetonitrile proceeded only in the presence of methanol or acetone. The role of methanol in the reaction was explained by assuming that methanol first adds to trichloroacetonitrile to form an iminoether as an intermediate which subsequently reacts with aniline to give the amidine.

The objective of the present work was the investigation of the preparation of trichloroacetamidines by the direct addition of amines to trichloroacetonitrile without using any catalysts. In the next part, a kinetic study of the reaction will be presented, followed by the investigation of the correlation between the infrared spectra and the structure of amidines.

DISCUSSION

The preparation of the N-substituted trichloroacetamidines involved three general procedures: (*a*) the lower primary and secondary aliphatic amines were treated with trichloroacetonitrile in water solutions; (*b*) the reactions of the higher aliphatic and cyclic amines were carried out in the absence of solvents; and (*c*) the aromatic primary amines were allowed to react with trichloroacetonitrile in water–methanol solution. The results are summarized in Table I. The three procedures are characterized by their simplicity, the absence of catalysts, and the high yields of the reaction products.

The lower aliphatic N-substituted trichloroacetamidines are colorless liquids possessing an unpleasant smell. They can be distilled at low pressure in a dry nitrogen atmosphere, whereas they decompose vigorously on being heated at normal pressure. It was found

that the salts of the primary and secondary amines do not react with trichloroacetonitrile in water solution.

The additon of the primary and secondary amines to the carbon–nitrogen triple bond seems to be an ionic reaction, which is facilitated by polar solvents, such as water and methanol. In the absence of kinetic data no proof of the mechanism is possible; however, the information obtained in this work may suggest the following scheme:

$$Cl_3C{\leftarrow}C{\equiv}\ddot{N}: + R{-}\ddot{N}H_2 \rightarrow Cl_3C{-}C{=}\ddot{N}:^- \rightarrow Cl_3C{-}C{=}\ddot{N}H$$

$$\qquad\qquad\qquad\qquad\quad H{-}N^+{-}H \qquad\qquad H{-}\ddot{N}:$$

$$\qquad\qquad\qquad\qquad\quad\ \ R \qquad\qquad\quad\ R$$

The chlorine atoms in the position α to the nitrile group increase the positive charge of the carbon atom of the nitrile group by the inductive ($-$Is) effect. The attack of the unshared electron pair of the amine nitrogen on the positive carbon is followed by the formation of a bond between these atoms, the liberation of a proton, and the subsequent addition of the proton to the negatively charged nitrogen atom. This scheme may explain the failure of the reaction between the amine salts and trichloroacetonitrile, and also the lower reactivity of the aromatic amines in which the mobility of the unshared electron pair of the nitrogen atom is decreased by the resonance effect. The ionic intermediate also explains the activating influence of water and methanol in the reaction of trichloroacetonitrile with amines.

As has been mentioned above, it has been suggested (4) that methanol is essential in the reaction of trichloroacetonitrile with aniline by forming the intermediate amidine methyl ether. Our experiments indicated that this view cannot stand, for the following reasons: (*a*) aniline reacts with trichloroacetonitrile even in the absence of methanol or other solvents; (*b*) the reaction occurs also in ethanol, which, contrary to methanol, does not react with trichloroacetonitrile.

EXPERIMENTAL

The following procedures were applied for the synthesis of N-substituted trichloroacetamidines.

Procedure A—In Water Solutions

This procedure is useful for commercial aqueous solutions of primary and secondary aliphatic amines.

N-Methyl-2,2,2-trichloroacetamidine.—Trichloroacetonitrile (8 ml.) was added dropwise with stirring over a period of 10 minutes to 15 ml. of 25% aqueous solution of methylamine. The reaction was exothermic and the flask containing the reaction mixture was cooled in an ice-water bath. The lower layer was separated, dried, and distilled. B.p. 129° at 60 mm. pressure. Yield 11.5 g., 86% of the theoretical.

N,N-Dimethyl-2,2,2-trichloroacetamidine.—Trichloroacetonitrile (7.2 g., 0.05 M.) was added to 4 ml. of an aqueous solution of dimethylamine containing 2.25 g. of the pure amine. The mixture was shaken for half an hour. The lower layer was separated, dried, and distilled. B.p. 51°–52° at 2 mm. pressure. Yield 6.45 g., 68% of the theoretical.

Procedure B—In the Absence of Solvents

This procedure can be applied successfully to the reactions of higher aliphatic primary and secondary amines, and also to piperidine and morpholine. The reaction time was 3 hours at least, and the reactions were carried out at room temperature.

N-n-Butyl-2,2,2-trichloroacetamidine.—Trichloroacetonitrile (7.2 g.) was added dropwise to 3.65 g. (0.05 M.) of pure *n*-butylamine. The temperature rose considerably and the mixture turned yellow. The distillation of the reaction product gave a colorless liquid. B.p. 71°–72° at 2 mm. pressure. Yield 9.92 g., 92% of the theoretical.

Procedure C—In Water–Methanol or Methanol Solutions at Room Temperature

This method was applied to the reactions of primary aromatic amines with trichloroacetonitrile. After a period of 3 days the reaction products were precipitated by the addition of water in almost quantitative yields. They were recrystallized from petroleum ether or water–methanol mixtures.

Reaction of Aniline and Trichloroacetonitrile

(*a*) *In the absence of solvents.*—Trichloroacetonitrile (1.44 g., 0.01 M.) was mixed with 0.93 g. of aniline (0.01 M.) and left at room temperature for 5 days. The mixture turned red, brown, and finally black, and after 48 hours crystals started to precipitate in small quantity. The mixture was diluted with 7 ml. of methanol. The reaction product was precipitated by addition of water, filtered, and crystallized from a methanol–water mixture, m.p. 101°–102°. The yield was 1.27 g. (54% of the theoretical).

(*b*) *In ethanol solution.*—Equimolar quantities of the reactants mentioned in (*a*) were dissolved in 5 ml. of ethanol and left at room temperature for 5 days. Addition of water, at the end of this period, caused the precipitation of N-phenyltrichloroacetamidine which melted at 101°–102° after crystallization from water–methanol. Yield 1.8 g. (76%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Preparation of Picrates and Hydrochlorides

The picrates of trichloroacetamidines were obtained by the addition of equimolar quantities of the amidines and picric acid in benzene solution. The precipitated picrates were crystallized from water. Hydrochlorides of amidines were prepared by passing of a hydrogen chloride gas through solutions of amidines in dry ether.

SOME NEW SULPHONAMIDES AND DERIVATIVES OF BICYCLIC GUANIDINES[1]

M.-E. Kreling and A. F. McKay

ABSTRACT

The preparations and bacteriostatic activities of some sulphonamide derivatives of the bicyclic guanidines are described. Some 1-(2-hydroxy-3-(aryloxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazoles have also been prepared.

DISCUSSION

A series of arylsulphonyl derivatives of 2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole (1, 2), Δ^8-hexahydro-1,4,8-pyrimidazole (3), and Δ^9-1,4,9-triazabicyclo(5.3.0)decene (3) have been prepared for evaluation as bacteriostats. Their properties are listed in Table II. An examination of Table I shows that these compounds display bacteriostatic activity against a number of organisms. Moreover, the activity of the 1-*p*-aminobenzenesulphonyl-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole is of the same order as 1-*p*-acetylaminobenzenesulphonyl-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole. Both the *p*-aminobenzenesulphonyl-derivatives are fairly toxic compounds. The LD_{50} values for mice by intraperitoneal injection lie within the range of 100–150 mg./kg.

**Picrate.*

zole. 1,2-Epoxy-3-(*o*- or *p*-chlorophenoxy)propane gave the expected derivative I (Ar = *o*- or *p*-chlorophenyl) and a small amount (3.8%) of a by-product. The by-product was identified as a di-(2-hydroxy-3-(*o*- or *p*-chlorophenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazolium chloride by analysis. It gave a test for chloride ion and it formed a picrate whose analysis also agreed with this structure. This indicates that the 1,2-epoxy-3-(*o*- or *p*-chlorophenoxy)propane was contaminated with at least 3.8% of the corresponding chlorohydrin derivative, which was most likely used in the preparation of the epoxy compound.

1-(2-Hydroxy-3-(*m*-methylphenoxy)propyl)- and 1-(2-hydroxy-3-(*o*- or *p*-chlorophenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazoles gave LD_{50} values of 125–150 mg./kg. and 150–200 mg./kg. respectively on intraperitoneal injection in mice. These compounds produced convulsions at the toxic level.

EXPERIMENTAL[2]

Preparation of the Arylsulphonyl Derivatives of the Bicyclic Guanidines

Since all of the arylsulphonyl derivatives of the bicyclic guanidines were prepared in the same manner, only the preparation of 1-*p*-toluenesulphonyl-Δ^8-hexahydro-1,4,8-pyrimidazole is described in detail. The properties of the arylsulphonyl derivatives are described in Table II.

To a stirred solution of Δ^8-hexahydro-1,4,8-pyrimidazole (5.0 g., 0.04 mole) and *p*-toluenesulphonyl chloride (7.60 g., 0.04 mole) in water (25 ml.) covered with ether (20 ml.) was added a solution of sodium hydroxide (11 ml. of 3.65 *N* sodium hydroxide solution). After the dropwise addition of the sodium hydroxide solution, which required 20 minutes, the reaction mixture was stirred for an additional 40 minutes at room temperature. The product (11.06 g.) was recovered by filtration and then crystallized from ethyl acetate.

1-p-Aminobenzenesulphonyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

A mixture of 1-(*p*-acetylaminobenzenesulphonyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)-imidazole (9 g., 0.03 mole), ethanol (200 ml.), and 5 *N* sodium hydroxide solution (50 ml.) was heated under reflux for 15 minutes. The solution on cooling and dilution with water deposited crystals, yield 6.7 g. (85.5%). The crude product (m.p. 181°–184°C.) was purified by crystallizing from an acetone–hexane (4:1) solution. 1-*p*-Aminobenzenesulphonyl-Δ^9-1,4,9-triazabicyclo(5.3.0.)decene (Table II) was prepared in a similar manner from 1-*p*-acetylaminobenzenesulphonyl-Δ^9-1,4,9-triazabicyclo(5.3.0)decene.

1-(2-Hydroxy-3-(m-methylphenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

2,3,5,6-Tetrahydro-1-imidaz(1,2-*a*)imidazole (4.44 g., 0.04 mole) and 1,2-epoxy-3-(*m*-methylphenoxy)propane (6.57 g., 0.04 mole) in absolute methanol (30 ml.) were refluxed for $3\frac{1}{2}$ hours. After the solvent was removed *in vacuo* under nitrogen, a yellow oil was obtained, yield 11.05 g. (99.7%). This oil slowly crystallized over a period of several days. Recrystallization from acetone–hexane gave a 57% yield of pure product (m.p. 102.5°–104° C.). Anal. Calc. for $C_{15}H_{21}N_3O_2$: C, 65.43; H, 7.69; N, 15.27. Found: C, 65.09; H, 7.70; N, 15.42%.

A paper chromatogram of the product on No. 1 Whatman paper developed with butanol – acetic acid – water (40:10:50) gave an R_f value of 0.72 ± 0.01.

Its picrate formed in the usual manner from water melted at 127°–132° C., yield

[2]*All melting points are uncorrected. The microanalyses were determined by Micro-Tech Laboratories, Skokie, Illinois.*

85.8%. One crystallization from absolute ethanol raised the melting point to 143.5°–144° C. Anal. Calc. for $C_{21}H_{24}N_6O_9$: C, 50.00; H, 4.79; N, 16.66. Found: C, 50.10; H, 4.67; N, 16.92%.

1-(2-Hydroxy-3-(o- or p-chlorophenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

To a solution of 2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole (4.44 g., 0.04 mole) in absolute methanol (35 ml.) was added 1,2-epoxy-3-(*o*- or *p*-chlorophenoxy)propane (7.35 g., 0.04 mole) and the mixture was refluxed for 3 hours. Evaporation of the solution *in vacuo* gave 11.7 g. (99%) of semicrystalline solid. A paper chromatogram on No. 1 Whatman paper, which was developed with butanol–acetic acid–water (40:10:50) solvent, gave two spots on spraying with bromcresol green solution with R_f values of 0.77±0.01 and 0.88. The two components were separated by crystallization from acetone. An acetone-insoluble fraction was obtained with an R_f value of 0.88, yield 0.78 g. (3.8%). Two crystallizations from methanol – ethyl acetate (1:5) solution raised the melting point from 183°–189° C. to a constant value of 190°–191° C. These crystals gave a positive test for chloride ion with silver nitrate solution. The analytical values agreed with those calculated for a di-(2-hydroxy-3-(*o*- or *p*-chlorophenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz-(1,2,-*a*)imidazolium chloride. Anal. Calc. for $C_{23}H_{28}Cl_3N_3O_4$: C, 53.46; H, 5.46; Cl, 20.58; N, 8.13. Found: C, 53.53; H, 5.53; Cl, 20.83; N, 8.01%.

A picrate (m.p. 162.5°–164° C.) was formed in 80% yield in the usual manner from water. The melting point was not changed by further crystallization. Anal. Calc. for $C_{29}H_{30}Cl_2N_6O_{11}$: C, 49.09; H, 4.26; Cl, 9.99; N, 11.85. Found: C, 49.01; H, 4.32; Cl, 10.06; N, 11.89%.

The acetone filtrate from above on cooling deposited 8.37 g. (71.2%) of crystals melting at 149°–153° C. Three crystallizations from acetone raised the melting point to 153.5°–154° C. (R_f, 0.77±0.01). Anal. Calc. for $C_{14}H_{18}ClN_3O_2$: C, 56.86; H, 6.13; Cl, 11.99; N, 14.21. Found: C, 57.32; H, 6.02; Cl, 12.12; N, 14.52%.

A picrate (m.p. 127°–128° C.) was formed in the usual manner from water, yield 86.2%. Two crystallizations from methanol–ether (1:1) solution raised the melting point to 129°–130° C. Anal. Calc. for $C_{20}H_{21}ClN_6O_9$: C, 45.77; H, 4.03; Cl, 6.76; N, 16.02. Found: C, 46.12; H, 4.19; Cl, 6.95; N, 16.14%.

1-(2-Hydroxy-3-(2,4-dichlorophenoxy)propyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

A solution of 2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole (4.44 g., 0.04 mole) and 1,2-epoxy-3-(2,4-dichlorophenoxy)propane (8.79 g., 0.04 mole) in absolute methanol (35 ml.) was refluxed for 3 hours. Evaporation of the solution gave 13.04 g. (98.7%) of dark viscous oil. A paper chromatogram prepared as described above gave two basic spots with R_f values of 0.77 and 0.46. The latter value indicated the presence of unchanged 2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole.

The crude oil (11.04 g.) was refluxed with water (25 ml.) and the aqueous phase was removed by decantation. This process was repeated twice to remove the unchanged starting material from the product. After the sticky residue was triturated with acetone (50 ml.), crystallization occurred, yield 2.36 g. (17.9%). The melting point of these crystals was raised from 154°–156.5° C. to 155°–156.5° C. (R_f, 0.77) by crystallizing from ethanol–water (2:3) solution. Anal. Calc. for $C_{14}H_{17}Cl_2N_3O_2$: C, 50.92; H, 5.19; Cl, 21.48; N, 12.73. Found: C, 50.96; H, 5.23; Cl, 21.83; N, 12.34%.

The picrate was prepared by dissolving a sample of the crystals in the minimum amount of methanol and adding saturated aqueous picric acid solution. The picrate (m.p. 144°–146° C.) was obtained in 66% yield. It was purified to a constant melting point

VOLTAIC CELLS IN FUSED SALTS

PART III. THE SYSTEM SILVER - SILVER CHLORIDE, CADMIUM - CADMIUM CHLORIDE[1]

S. N. FLENGAS[2] AND T. R. INGRAHAM

ABSTRACT

Using a silver – silver chloride reference electrode, the standard electrode potential has been established for the equilibrium $Cd|Cd^{++}$ in melts containing equimolar quantities of KCl and NaCl. The experimentally obtained standard potential was greater than that calculated from theoretical thermodynamic data. This difference was attributed to the formation of a cadmium complex in the melt. A dissociation constant for the complex was calculated.

The effect of temperature on the electromotive force of the silver–cadmium voltaic cell was also measured, and the heat of the cell reaction was calculated from the data. To extend the temperature range of the cadmium data, a cadmium–lead alloy was used in the higher temperature experiments. To correlate these data with those for the pure cadmium system, the activity coefficients of cadmium in the alloy were determined electrometrically using the silver – silver chloride electrode as a reference. It was found that the activity coefficients were in agreement with previously published data obtained at lower temperatures using a pure cadmium reference electrode. The activity coefficients were virtually independent of temperature but showed large positive deviations from unity when the mole fraction of cadmium was decreased below about 0.8.

INTRODUCTION

Parts I and II of this series (1, 2) described the development and use of a reversible silver – silver chloride reference electrode for determining the electromotive forces of voltaic cells in chloride melts at high temperatures.

In this paper, experiments will be described in which the silver – silver chloride reference electrode was used to study the cadmium – cadmium chloride equilibria. An equimolar mixture of molten potassium and sodium chlorides was used as the common solvent.

These results are an additional contribution to the current program of establishing electromotive series for metals in molten salts at different temperatures.

EXPERIMENTAL

The technique used to study the Cd–Ag system was essentially the same as that previously described (1). During the preliminary experimental work it became apparent that because of the relatively high vapor pressure of molten cadmium and the inflammability of cadmium vapor in air, a closed cell operating with an inert atmosphere would be required. The complete cell design is shown in Fig. 1. The cell was constructed from silica tubing of 2 in. diameter and consisted of two sections connected by a ground silica joint. The upper section of the cell was closed with a cork stopper, into which were fitted the silver – silver chloride reference electrode, the thermocouple well, the feeding pipe with stirrer, and the gas inlet tube. The cork stopper was covered externally with Pyseal cement and then water-cooled to prevent the melting of the cement from the heat of the furnace. The inner surface of the cork stopper was covered with a close-fitting layer of asbestos. The lower section of the cell was used as a container for the molten metal indicator electrode and the molten salts. Electrical contact with the indicator electrode was made by means of a tungsten wire sealed into silica tubing and dipped into the metal pool.

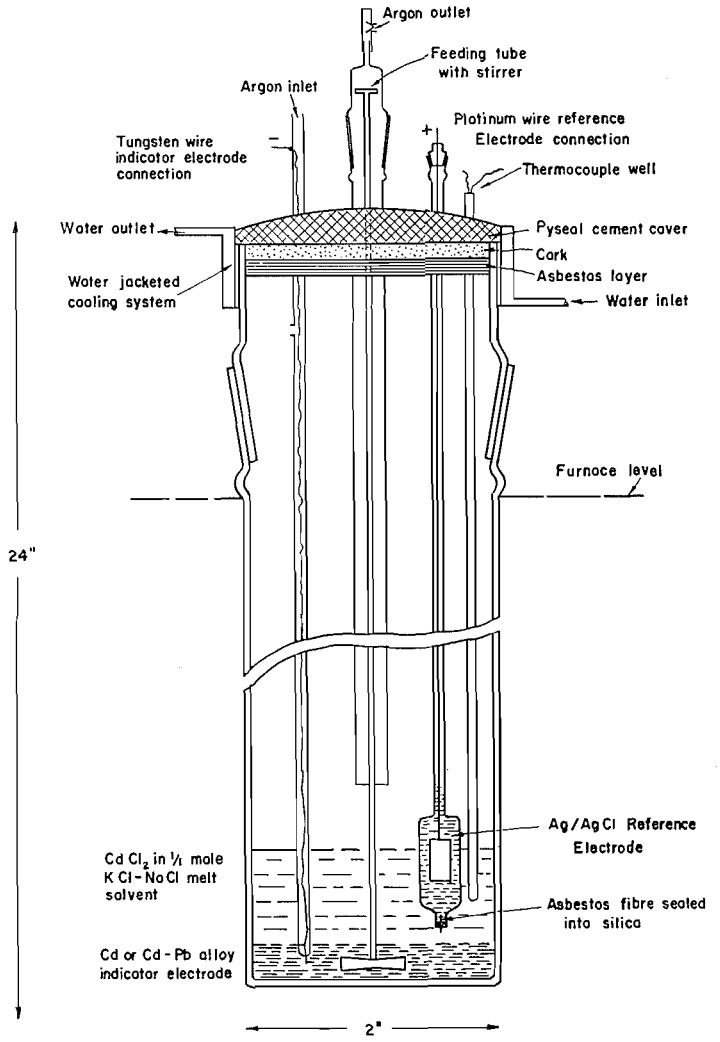

FIG. 1. All silica cell.

For potential measurements at temperatures below the boiling point of cadmium (767° C.), the indicator electrode was either pure molten cadmium metal or cadmium–lead alloy. At temperatures above 767° C., a high boiling point cadmium–lead alloy was used to determine the electromotive forces over a range of temperature in excess of 100 Centigrade degrees and thus clearly establish the linearity of the data.

To protect the contents of the cell from the atmosphere, purified argon was introduced continuously into the cell and released through a small Bunsen valve. The slight positive pressure of argon in the cell protected the contents completely over the full course of runs lasting up to 2 days.

The voltaic cell used during the experiments may be represented as follows:

$$\underset{(-)}{M} \mid \underset{\text{(indicator electrode)}}{\begin{matrix}CdCl_2\ (x_2)\\ KCl\text{–}NaCl\ (1/1\ \text{mole})\end{matrix}} \parallel \text{Asbestos fiber} \parallel \underset{\text{(reference electrode)}}{\begin{matrix}AgCl\ (x_1)\\ KCl\text{–}NaCl\ (1/1\ \text{mole})\end{matrix}} \mid \underset{(+)}{Ag}$$

where M is cadmium or a cadmium-lead alloy, and x_1 and x_2 are, respectively, the mole fractions of AgCl and $CdCl_2$ in the alkali chloride melt solvent. The cell reaction in an ideal solution should be:

$$Cd + 2Ag^+ = Cd^{++} + 2Ag.$$

The relationship between the electromotive force and the metal-ion concentration in the experimental cell is given by the Nernst equation in the form:

$$E_{cell} = (E^\circ_M - E^\circ_{Ag}) - (2.303RT/2\mathcal{F}) \log(x_2/x_1^2 a_m) \quad [1]$$

where E°_M and E°_{Ag} are, respectively, the standard electrode potentials of the half-cells $M/CdCl_2$ and $Ag/AgCl$ under the conditions of the experiment, and a_m represents the activity of cadmium in the metallic electrode. For pure cadmium, $a_m = 1$.

Determination of Metal Activities in Alloys

The use of equation [1] for the calculation of standard electrode potentials requires a knowledge of the activity (a_m) of cadmium in the cadmium–lead alloy. Since the activities of cadmium in this alloy were known only for temperatures up to 570° C. (3), it was necessary to determine these values experimentally at higher temperatures. This was done by calculating the electromotive force, ΔE, of the following hypothetical metal-alloy concentration cell:

$$Cd \left| \begin{matrix} CdCl_2\ (x) \\ KCl\text{–}NaCl\ (1/1\ mole) \end{matrix} \right| Cd(a_m)\text{–}Pb.$$

This electromotive force was derived from the difference between the potential of the experimental cell using the cadmium–lead alloy as an indicator electrode, and that of the same cell when using pure cadmium metal. The alloy was prepared *in situ* by adding small pieces of 99.9% lead to the molten cadmium electrode, or, when the equilibrium was to be approached from the pure lead side, by adding small pellets of 99.99% cadmium to the molten lead electrode. The alloy electrodes were homogenized by a small stirrer inserted through the feeding tube of the cell. The activity of cadmium in the alloy was then calculated by the equation:

$$\Delta E = 2.303RT/2\mathcal{F} \log(1/a_m). \quad [2]$$

RESULTS AND DISCUSSION

The electromotive force of the cadmium cell was measured first as a function of the metal-ion concentration and then as a function of temperature. The results of the experiments in which the concentration of the metal ion was varied at constant temperature are shown in Table I.

From equation [1] it follows that the relationship between E_{cell} and $\log(x_2/x_1^2)$ should be linear; and that when x_1 and x_2 are chosen so that the log term of this equation becomes zero, then

$$E_{cell} = E^\circ_M - E^\circ_{Ag}.$$

When the electromotive forces of the cells were plotted against $\log(x_2/x_1^2)$, as calculated from the experimental data given in Table I, the results were well represented by a straight line in agreement with the theory, as shown in Fig. 2. The slope of the experimental line agrees well with the theoretical values calculated from equation [1] for a two-electron electrode reaction. The results of these calculations are given in Table II.

It is of theoretical interest to compare the experimentally obtained standard potential of the voltaic cell with the theoretical value calculated from the thermodynamic data. If the difference is entirely attributed to the presence of a cadmium complex in the alkali chloride melt solvent, the dissociation constant, K_d, of the complex can be calculated, using the method previously described (1):

$$K_d \text{ (Cd complex)} = 1.17 \times 10^{-2}.$$

The magnitude of this value indicates the presence of a fairly stable cadmium complex in the melt.

The effects of temperature change on the electromotive forces of the cadmium–lead alloy – silver and the cadmium–silver voltaic cells were investigated next. The results are shown in Table III and Fig. 3. (The procedure by which the activity a_m and the standard electrode potentials included in Table III were obtained will be described later in the text.)

It is of interest to note, in Fig. 3, that the two straight lines which express the relationship between the electromotive force of the foregoing cells and temperature are essentially parallel. This shows that the activity of cadmium in a cadmium–lead alloy is almost independent of temperature. The results of experiments to determine the activities a_m of cadmium in a cadmium–lead alloy at one temperature (680° C.) are shown in Table IV. The activity coefficients were calculated using the well-known equation:

$$a_m = x_m \gamma_m \qquad [3]$$

0.6	1.48	1.48	1.44	1.44	1.50

* *Values obtained in the present investigation.*

It will be observed that temperature change has a very small effect on the values of the activity coefficients. This is in agreement with the previous observations on temperature effects in Fig. 3. The two lines are essentially parallel and the difference between the values of the respective electromotive forces corresponds to a $(2.303RT/2\mathcal{F})\log a_m$ term, where a_m is the activity of the cadmium in the alloy at the lower temperature of 680° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Having established the activities of cadmium in a cadmium–lead alloy, it was possible to use equation [1] to calculate the standard electrode potential of cadmium ($E°_{Cd} - E°_{Ag}$) at different temperatures from the data in columns 1 and 2 of Table III(b). From these standard potentials, using the well-known equations

$$\Delta F° = -nE°\mathcal{F}, \qquad [4]$$

$$\Delta F° = -2.303RT \log K,$$

the equilibrium constant for the cell reaction given in Table II was calculated for various temperatures. The results of these calculations are shown in Fig. 5, where log K was plotted against the reciprocal of the absolute temperature. The curve is linear over the

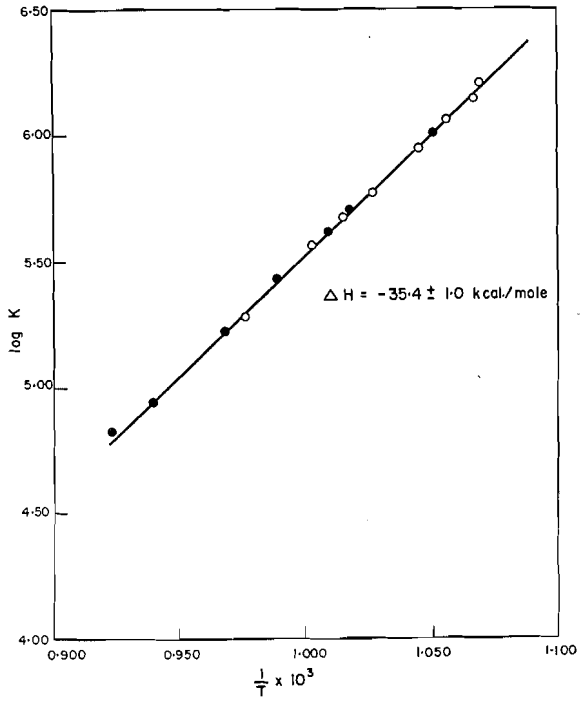

FIG. 5. The variation of log K with the reciprocal of temperature for the system:
Cd(a_m = 0.7654)–Pb | $CdCl_2$ ($x_2 = 3.785\times10^{-2}$) || AgCl ($x_1 = 6.103\times10^{-2}$) | Ag

THE EFFECT OF THE AMBIENT GASES ON THE SURFACE PHOTOCURRENT IN ANTHRACENE[1]

T. C. WADDINGTON[2] AND W. G. SCHNEIDER

ABSTRACT

Following the observation that the photocurrent in anthracene is markedly affected by an atmosphere of oxygen over the system, the behavior of anthracene in the presence of atmospheres of other gases has been investigated. The effect has been shown to be confined to the surface photocurrent, and the active gases have been shown to fall into two classes: (1) gases which are electron acceptors, e.g. BF_3, HCl, O_2, and NO, which all *increase* the photocurrent markedly; (2) gases and vapors which are electron donors, e.g. NH_3, $(CH_3)_2O$, and $(CH_3)_3N$, which all *decrease* the photocurrent markedly. The effect of the pressure of the ambient gas and of the temperature of the system on the photocurrent has also been investigated.

INTRODUCTION

Though the photoconductivity of anthracene was observed as early as 1913 by Volmer (1) it was not until the last decade that systematic investigations of its behavior were undertaken. It was recognized by Vartanyan (2) that the photoconductivity of a polycrystalline layer of anthracene was markedly affected by oxygen in contact with it, the photoconductivity being decreased on hard pumping. These observations were confirmed in this laboratory by Chynoweth (3), who transferred his attention to single crystals, because of the difficulty of outgassing multicrystalline layers and therefore of obtaining meaningful and reproducible results. The effect of oxygen on the photoconductivity of crystalline anthracene was also investigated by Bree, Carswell, and Lyons (4), working with sublimation flakes.

In view of the effect of oxygen it was decided to study the effect of other gases and vapors on the photocurrent in anthracene single crystals. A brief, preliminary account (5) of this work, which is reported here in greater detail, has already appeared. About the same time a note was published by Bree and Lyons (6) on the effect of oxygen, nitric oxide, and sulphur dioxide on the photoconductivity of anthracene. Subsequently a note (7) has appeared reporting the effects of temperature on the photoconductivity in the presence of oxygen.

EXPERIMENTAL

The photoconductivity cell was similar to that described by Chynoweth and Schneider (8). The gases used were obtained commercially and were of high purity. The nitrogen and argon were spectroscopically pure. The anthracene used in growing the crystals employed in the above experiments was purified by continuous chromatography in the manner described by Sangster and Irvine (9). Two types of crystals were employed. Large crystals were cut from long single crystals kindly grown for us by Dr. Lipsett in a Bridgeman-type furnace. Sublimation flakes were grown in an atmosphere of argon. Electrodes were painted onto the crystals with aquadag.

RESULTS

(*a*) *Effects of Gases on the Photocurrent in the Sandwich Cell*

Using a sandwich cell of polycrystalline anthracene Chynoweth (3) observed a large effect, with oxygen, on the photocurrent. Working with single crystals he found only a 20% to 30% increase over the hard-vacuum level of the photocurrent. In order to see if the presence of oxygen or other gases at the illuminated face of the crystal had any effect on the true bulk photocurrent in anthracene, an earthed guard ring was placed on the edge of the sandwich cell and the photocurrent measured *in vacuo* and in the presence of oxygen and of other gases. In no case could any change in the level of the photocurrent be detected. It was concluded that the gases only affected the current flowing in the surface layers of the crystal and all subsequent observations were made using the surface-cell arrangement.

(*b*) *Surface Cell—Equilibrium Behavior*

(1) *Qualitative account of the effects of various gases.*—The gases BF_3, HCl, SO_2, NO, and O_2 on admission to the photocell were all found to increase the photocurrent in the surface arrangement to a steady value well above the hard-vacuum value. Typical increases were by a factor of 20. The gases and vapors NH_3, $(CH_3)_3N$, $(CH_3)_2O$, $(C_2H_5)_2O$, C_2H_5OH, H_2O, and $(CH_3)_2CO$ were all found to decrease the photocurrent to a steady value below that of the high-vacuum value. Typical decreases were by a factor of 5 to 10. The gases and vapors CO_2, N_2, A, CH_4, and $(CH_3)_4C$ were found to have no effect on the level of the vacuum photocurrent.

(2) *The effect of the pressure of ambient gas on the level of the surface photocurrent.*—The dependence of the photocurrent on the pressure of oxygen gas has already been reported by Bree and Lyons (6). Our results are in agreement with theirs. The pressure dependence has the shape of a Langmuir adsorption isotherm, and a plot of the photocurrent minus its hard-vacuum value, i.e., $i_p - i_{vac}$, against the pressure, p, is initially linear. A plot of $p/(i_p - i_{vac})$ against p gives a good straight line. This was also found to be the case for BF_3 and HCl.

The dependence of the photocurrent on gas pressure was also studied in the presence of ammonia, of trimethylamine, and of acetone vapor. A plot of the hard-vacuum value minus the value found in the presence of ammonia, i.e., $i_p - i_{vac}$, against the pressure, p, resembled a Langmuir adsorption isotherm, being initially linear and saturating in the usual manner. A plot of $p/(i_p - i_{vac})$ against p gave a good straight line. Similar results were obtained for trimethylamine. A plot of $i_p - i_{vac}$ for acetone does not give a Langmuir isotherm, the shape of the curve resembling more nearly that for multilayer adsorption. The plots of $i_p - i_{vac}$ against p and $p/(i_p - i_{vac})$ against p are shown in Figs. 1 and 2, respectively, for BF_3 and NH_3.

(3) *The effect of temperature on the level of the surface photocurrent in the presence of an ambient gas.*—The effect of temperature (in the range $-130°$ to 55° C.) on the value of the photocurrent in the surface and sandwich cell in a hard vacuum has been reported in a previous communication (10). It takes the form of an exponential relation $i = i_0 \exp(-E/RT)$. In the presence of an ambient gas such as O_2 or BF_3 the behavior falls into two classes:

(*a*) In the case where the pressure is above the saturation value for the Langmuir isotherm, e.g., $p > p_{sat}$, the behavior is exactly the same as in the case of the hard vacuum.

(*b*) In the case where the pressure is below the saturation value for the Langmuir isotherm, e.g., $p < p_{sat}$, the behavior is different to the hard-vacuum case and the

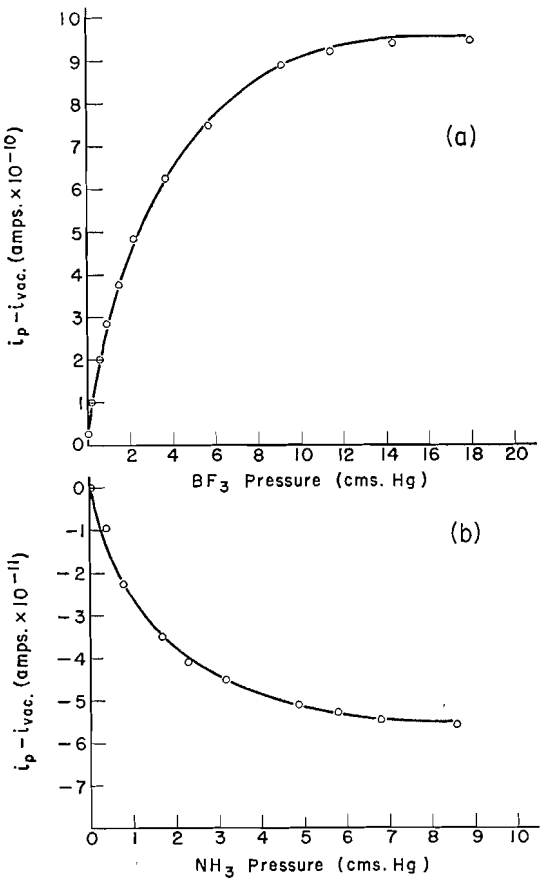

FIG. 1. (*a*) Increase of photocurrent of anthracene as a function of BF_3 gas pressure. (*b*) Decrease of photocurrent of anthracene as a function of NH_3 gas pressure.

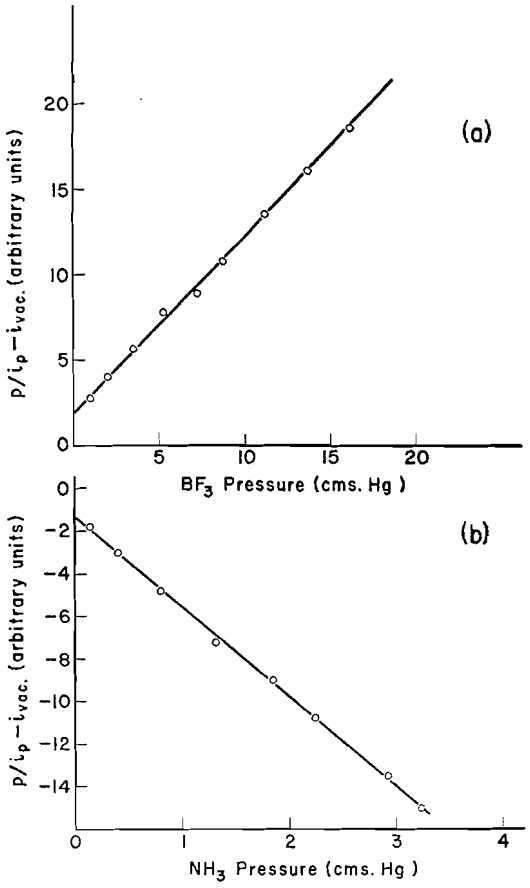

FIG. 2. Plot of $p/(i_p - i_{vac})$ vs. p for (*a*) BF_3 and (*b*) NH_3 on anthracene single crystals.

photocurrent temperature relation cannot be fitted to a simple $i = i_0 \exp(-E/RT)$ relationship.

(4) *Effect of wavelength on the photocurrent in the presence of an ambient gas.*—Some experiments were carried out on the effect of oxygen on the wavelength dependence of the photocurrent. No significant change could be found, the wavelength dependence in the surface cell showing the same type of behavior in each case.

(*c*) *Surface Cell—Non-equilibrium Behavior*

Though the effect of the ambient gases on the photocurrent is generally very rapid, there are one or two cases where the photocurrent takes an appreciable while to reach its equilibrium value. This is particularly noticeable in the case of SO_2, where several hours are required in the dark for the photocurrent to rise to a steady value after the admission of the gas to the cell. The rise is much more rapid when the crystal is illuminated than when it is in the dark. Over the somewhat limited range with which it was possible to work with SO_2 the effect was markedly dependent on temperature, the rise time being shortened by a rise in temperature.

DISCUSSION

Though at the moment sufficient information, theoretical or experimental, is not available for a detailed mechanism of the effects of ambient gases on the photoconductivity of anthracene to be given, certain definite generalizations can be made and some tentative suggestions advanced. The most important first point is that though anthracene possesses both a surface and a bulk photocurrent only the surface photocurrent is affected by the adsorbed gases. Secondly, since the wavelength dependence of the surface photocurrent is not altered by the adsorbed gases, they probably do not affect the process of carrier formation but only the movement of charge carriers.

The gases in class two, water vapor, ammonia, dimethyl ether, trimethylamine, etc., appear to be only weakly adsorbed. This is shown by the ease with which the photocurrent can be restored to its vacuum level by pumping. All these gases are electron donors of varying power, all possessing lone pairs, and they all reduce the photoconductivity. The gases in class one, oxygen, nitric oxide, boron trifluoride, etc., are all strongly adsorbed, probably chemisorbed. This is indicated by the difficulty of pumping them off the crystal as indicated by a return of the photocurrent to its hard-vacuum value. The photocurrent–pressure behavior can be fitted to a Langmuir adsorption isotherm. These gases must be interacting strongly with the π-electrons of the surface anthracene molecules, either because they possess acidic protons, e.g. HCl, or because they have a vacant orbital of low energy, e.g. boron trifluoride.

Other evidence, presented elsewhere (10), suggests that the majority charge carriers in anthracene are positive holes. Many other photoconductors show an effect due to ambient gases on the surface photocurrent and this behavior is usually explained in terms of the effect on the surface energy levels of the crystal by the gas (11, 12, 13). However, none of these materials, such as germanium, zinc sulphide, and cadmium sulphide, are as sensitive as anthracene is to the effect of adsorbed gases. If it is assumed that on the surface of an anthracene crystal *in vacuo* the energy levels of the positive-hole band are lower than in the bulk of the crystal and that the effect of the ambient gas is to raise or lower the energy levels at the surface depending on whether the gas is an electron donor or an electron acceptor relative to anthracene, then a simple phenomenological explanation is given of the behavior outlined in this paper. It is also interesting to note that if the above explanation is the correct one then the surface semiconductivity of anthracene and similar crystals might very well be expected to be affected by the presence of adsorbed gases. Pick and Wissman (14) have studied the semiconductivity of napthalene crystals and report that the pre-exponential factor and the energy of activation are altered by the presence of oxygen, the conductivity being increased.

NUCLEAR MAGNETIC RESONANCE MEASUREMENTS OF PROTON TRANSFERS IN ACETYLACETONE IN DIETHYLAMINE AND TRIETHYLAMINE[1]

L. W. REEVES[2] AND W. G. SCHNEIDER

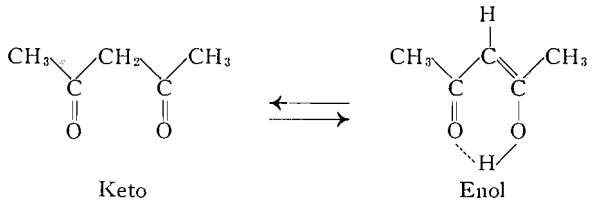
ABSTRACT

Solutions of acetylacetone in triethylamine are completely enolic at all dilutions studied (0.1 to 0.85 mole fraction). The nature of the proton resonance signals in the NMR spectrum indicates a proton exchange between the OH and =CH— groups of the enol tautomer. Addition of diethylamine to acetylacetone results in the formation of a white crystalline 1:1 molecular complex which melts at 41.5° C. The NMR spectrum of the complex reveals a simultaneous proton exchange between the amine NH group and the OH and =CH— groups of the enol tautomer. The mechanism of this exchange is discussed. In effect the addition of amines to acetylacetone not only alters the keto–enol equilibrium very markedly, but also increases the keto–enol conversion rate. With diethylamine the conversion rate becomes sufficiently high to "average out" the individual NMR spectra of the two tautomers.

INTRODUCTION

The proton magnetic resonance technique provides a fruitful method for investigating systems capable of undergoing keto–enol conversion. Typical of such systems is acetylacetone, for which the keto–enol equilibrium may be represented as follows:

[1]



Keto ⟷ Enol

The conversion rate between the two tautomers is sufficiently slow so that the NMR spectrum of acetylacetone, under ordinary conditions, shows separate and distinct proton signals of both the keto and enol tautomers. Hence from the relative intensities of the signals the equilibrium concentrations of each of the two tautomers can be determined (1, 2). The proton resonance spectrum of acetylacetone together with the assignment of the individual proton signals is reproduced in Fig. 1.

In the sense that the keto–enol conversion involves a transfer of a proton from a carbon atom to an oxygen atom, the process may be regarded as a proton exchange phenomenon. Depending on the rate of proton exchange, the shape of the proton resonance signals may be modified in a characteristic way. If we consider a simple example of a proton capable of exchanging between two sites, A and B, we may define lifetimes, τ_A and τ_B, which are a measure of the mean time that the proton spends at each site. When the exchange is slow two separate proton signals appear in the NMR spectrum corresponding to the different environment of the proton at each of the two sites. If the rate of exchange is increased, as for example by raising the temperature, then the two proton signals may be observed to broaden, and eventually at even higher rates of exchange, to coalesce to a single averaged signal at an intermediate position.

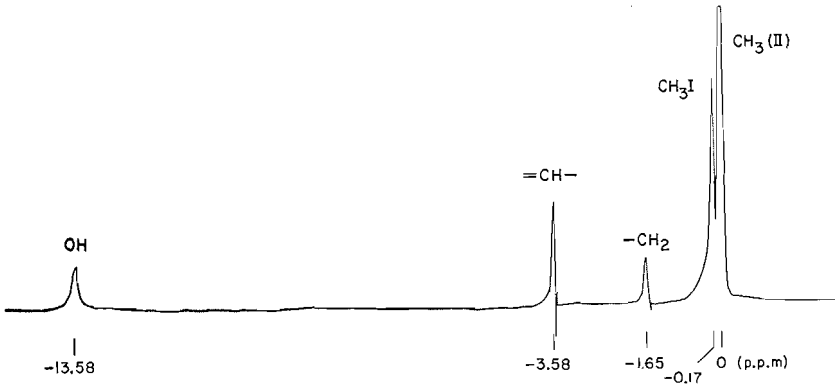

FIG. 1. Proton resonance spectrum of pure acetylacetone at 40 Mc./s. Chemical shifts are shown in p.p.m. Reading from left to right (low field to high field) the signal assignment is respectively: enol OH group, enol =CH— group, keto —CH_2— group, keto CH_3 groups, and enol CH_3 groups.

The general problem of proton exchange between two sites has been treated by Gutowsky and co-workers (3, 4, 5). If the separation of the two signals when the exchange is slow is $2\pi(\nu_A - \nu_B)$, where ν_A and ν_B are the resonance frequencies of the proton at each of the two sites, then under certain simplifying assumptions the condition for coalescence of the two signals is

$$\tau \leqslant \sqrt{2}/[2\pi(\nu_A - \nu_B)], \quad [2]$$

where $\tau = \frac{1}{2}\tau_A = \frac{1}{2}\tau_B$. This type of behavior can be observed, for example, in a 2:1 alcohol–water mixture. At room temperature two proton signals corresponding to the two different OH groups are observed, which when the temperature is raised gradually broaden and coalesce to a single signal at 72° C. (6).

Returning to the acetylacetone system, it may be noted that the separation* of the OH signal of the enol form and the —CH_2— signal of the keto form in frequency units is ~480 c./s. Thus to obtain a coalescence or averaging of these signals would require τ to be of the order of 5×10^{-4} seconds. The lifetime of the keto and enol tautomers is evidently much greater than this. Attempts to increase the conversion (exchange) rate sufficiently by heating and thus to produce a single averaged spectrum for the two tautomers were unsuccessful. When the temperature was raised to 150° C. no indication of signal coalescence, or even a noticeable signal broadening, was apparent. However, as described in the present paper, addition of triethylamine or diethylamine to acetylacetone not only disturbs the keto–enol equilibrium in a profound way, but also substantially alters the keto–enol conversion rate such that under certain conditions an "averaged" proton spectrum is observed.

EXPERIMENTAL

The method of purification of the acetylacetone used in the present work has been described previously (2). Diethylamine and triethylamine were redistilled once from C.P. material.

The proton resonance measurements were made with a V-4300 Varian high resolution spectrometer operating at a fixed frequency of 40 Mc./s. A device which was used for simultaneously spinning and heating the samples, contained in 5-mm. o.d. glass tubes, has been described elsewhere (7).

For a measuring frequency of 40 Mc./s.

RESULTS

In a previous paper (2) it was reported that acetylacetone in solution in triethylamine is completely converted to the enol tautomer. Solutions of acetylacetone in triethylamine, studied in the range 0.1 to 0.85 mole fraction acetylacetone, gave rise to proton resonance spectra which, in addition to the signals of the amine, showed only the three signals characteristic of the enol tautomer (cf. Fig. 1). It was observed, however, that the signals arising from the OH group and the =CH— group *both* showed pronounced broadening, suggesting an exchange behavior involving these protons. If this were so, heating the solution should cause further broadening and ultimate coalescence of the two signals when the exchange rate is sufficiently high. Fig. 2 shows NMR traces of the

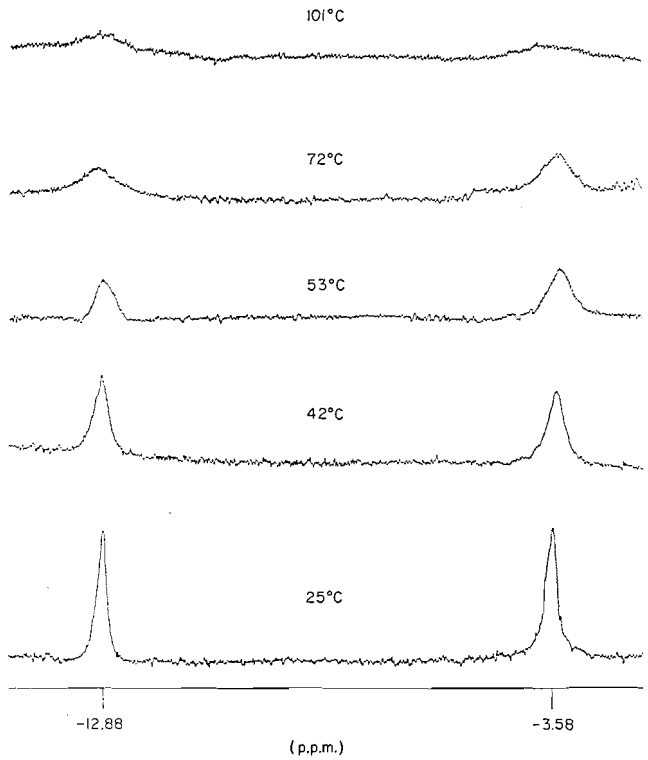

FIG. 2. NMR traces of the enol OH and =CH— group signals of acetylacetone (mole fraction 0.316) in triethylamine at various temperatures.

OH and =CH— signals of a solution of acetylacetone (mole fraction 0.316) in triethylamine at various temperatures. The increased signal broadening is evident. The solution was heated to 165° C. At this temperature the signals became so broad as to be lost in the background noise, and of course under these conditions it is difficult to avoid signal saturation. The coalesced signal, which requires still higher rates of proton exchange, must therefore appear at a much higher temperature. A further solution containing 0.703 mole fraction acetylacetone was also investigated. Apart from some chemical shift displacements in the spectrum, the same features were observed.

From the relative broadening of the signals as a function of temperature, shown in

Fig. 2, rate constants can be determined, permitting an evaluation of the activation energy for the proton exchange process. For this purpose we may employ the simple relation*

$$1/T_2' = 1/T_2 + 1/2\tau,$$

where $1/T_2'$ is related to the half-width of the broadened signal, $1/T_2$, to the corresponding half-width in the absence of exchange, and 2τ is the mean lifetime of the proton at either site. Thus, assuming negligible exchange at 25° C., values of τ at each temperature can be derived from the broadened signals. The results yield an activation energy of approximately 8 kcal./mole for the exchange process. This value is rather inaccurate, however, because of partial signal saturation broadening at the higher temperatures.

Diethylamine affects the keto–enol conversion to a much greater extent than triethylamine. In solutions of acetylacetone in diethylamine, as with triethylamine, no signals which could be assigned to the keto tautomer appear in the NMR spectrum. A specific molecular interaction between diethylamine and acetylacetone is indicated by the formation of a 1:1 molecular compound, with evolution of heat, when the two substances are mixed in equimolar quantities. The molecular complex is a white crystalline solid melting at 41.5° C. Both the amine and acetylacetone can be recovered from the complex. The complete binary freezing-point diagram of the diethylamine–acetylacetone system is shown in Fig. 3.

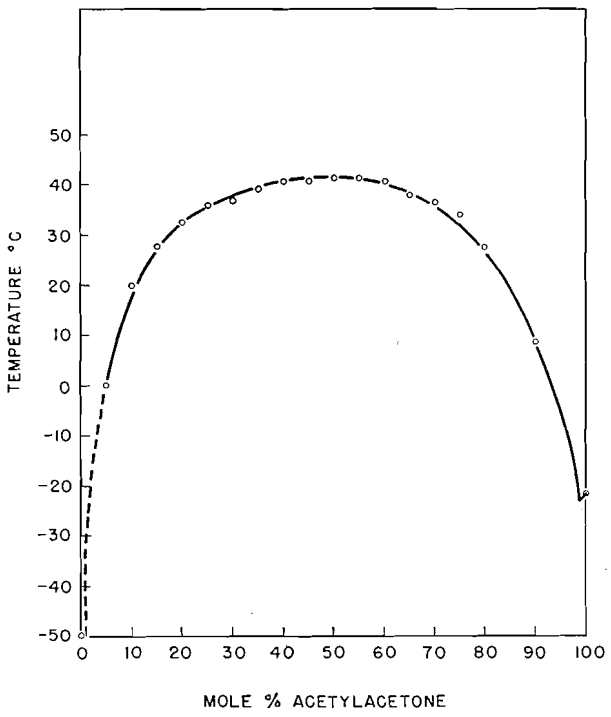

FIG. 3. The binary freezing-point diagram of acetylacetone and diethylamine.

*As pointed out by Professor H. S. Gutowsky (private communication), this relation follows from Eq. (3) of Ref. (5) with the assumption of slow exchange and no overlap of the two component signals. The derivation and application of this relation has been discussed by Grunwald, Lowenstein, and Meiboom, J. Chem. Phys. **27**, 630 (1957).*

The NMR spectrum of the 1:1 complex at a temperature just above the melting point (where a partial dissociation may be expected) is reproduced in Fig. 4. The chemical

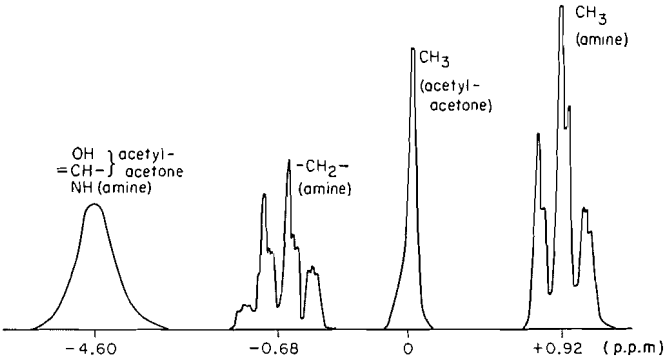

FIG. 4. NMR spectrum of 1:1 acetylacetone–diethylamine mixture (~43° C.). Chemical shifts are shown in p.p.m. The individual resonance signals were recorded at different receiver gain. The relative intensities are therefore not comparable.

shift and assignment of the individual signals are given. Thus after the two signals arising from the ethyl group of the amine are allowed for, the spectrum of the acetylacetone contains but two signals. The sharp signal on the high-field side, which was used as the reference signal in measuring the chemical shifts, must be assigned to the methyl groups of the acetylacetone. This leaves the rather broad signal at low field to account for the signals arising from the OH and =CH— groups of the enol tautomer,* as well as the NH group of the amine. The broad, structureless nature of this signal suggests that all three of these groups are simultaneously exchanging protons. This expectation was indeed confirmed by observing the proton resonance spectrum of the complex dissolved in CCl_4 at a concentration of about 15 mole per cent of complex. The spectrum was similar to that of Fig. 4 except that the low-field signal was now split into two signals having relative intensities 2:1. These two signals, shown in Fig. 5, confirm the assignment of the low-field signal in Fig. 4 as arising from *three* protons, since a 2:1 intensity ratio of the decomposed signal must involve at least three protons. Of the two signals (Fig. 5) the one at higher field, with intensity 1, can be assigned to the

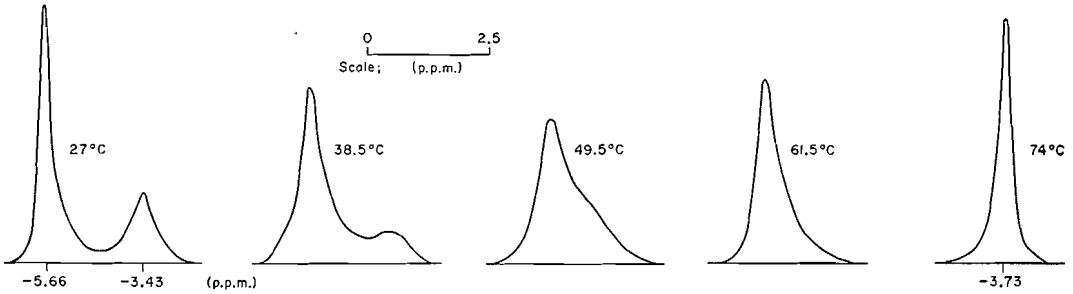

FIG. 5. NMR traces at various temperatures of the enol OH and diethylamine NH groups (low-field signal) and of the enol =CH— group (high-field signal) from 15 mole per cent solution of the 1:1 acetylacetone–diethylamine complex in CCl_4.

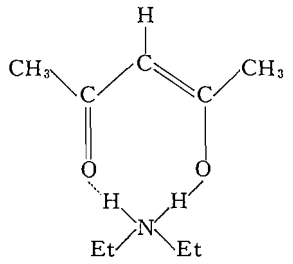
**This assumes, by analogy with the behavior in triethylamine, the acetylacetone spends most of its time as the enol tautomer.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

enol =CH— group, since it appears at very nearly the same position as the corresponding signal in the spectrum of acetylacetone in triethylamine. The lower field signal with intensity 2 must then be assigned to the OH group and the NH group of the amine. This observed pattern of signals suggests that these two groups are rapidly exchanging protons, but the exchange of these protons with the =CH— group is much slower when the system is diluted in CCl_4 than in the pure molecular complex of acetylacetone and diethylamine. However, as shown in Fig. 5, heating the CCl_4 solution causes an increase in the exchange rate and a coalescence of the separate signals, at which point all three protons are again undergoing rapid exchange with each other.

INTERPRETATION OF RESULTS

The most striking and perhaps surprising feature of the results is the involvement of the =CH— group of the enol tautomer in a rapid proton exchange with the OH group and also with the NH group of the diethylamine. In triethylamine, which lacks the latter group but does possess a basic N atom, this exchange is evidently considerably slower. In the presence of either amine the enol tautomer of acetylacetone predominates, suggesting a preferred interaction between the amine and this tautomer. This interaction is undoubtedly through hydrogen bonds. The internal hydrogen bond in the enol tautomer may be expected to become disrupted in the presence of the strong donor N atom of the amine, the OH group then tending to form a bond with the N atom. In general, proton exchange is greatly favored in strong hydrogen bonds, the hydrogen bond providing the exchange path (6). On this basis a fast exchange between the enol OH group and the NH group of the diethylamine can be understood in terms of hydrogen-bonded structures such as the following:



which permits a rapid transfer of protons between oxygen and nitrogen.

A simultaneous rapid exchange of the =CH— group proton under certain conditions, as indicated by the NMR results, is rather more difficult to interpret. It does in fact appear that such an exchange must take place via the keto tautomer as a short-lived intermediate state. A plausible mechanism, which can be illustrated with the aid of a molecular model shown in Fig. 6, is the following. The model of the enol tautomer in the figure shows a configuration in which the internal hydrogen bond has been broken and the OH group is rotated out of the molecular plane. In this configuration the OH proton finds itself adjacent to two electron donor sites. One electron donor site is represented by the electron lone pair of the carbonyl oxygen atom, the other by the olefinic π-bond. There is now ample evidence that the π-electrons in such bonds can act as electron donor sites for molecular interactions with H—X acceptor groups (8, 9, 10). Accordingly in the above configuration of the enol form, conditions are favorable for the NH group of a neighboring amine molecule to orient itself such that the OH group can form a hydrogen

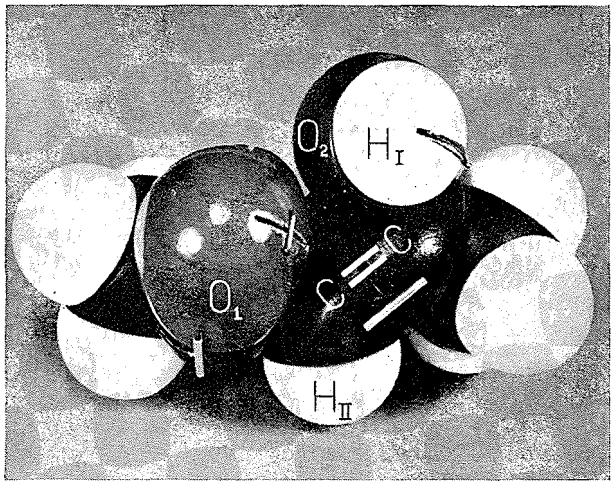

FIG. 6. Molecular model of the enol tautomer of acetylacetone.

bond to the donor lone pair electrons of the N atom, and the H atom of the NH group can bond to either of two donor sites, the carbonyl oxygen atom or the π-bond. This then permits rapid proton exchange among all sites. The individual proton exchanges taking place may be represented by:

(1) $OH\cdots N \longleftrightarrow O\cdots H{-}N$

(2) $H_{II}{-}C(=C)\cdots H{-}N \longleftrightarrow H_{II}{-}C(-C){-}H_I\cdots N$

Enol Keto

(3) $H_{II}{-}C(=C)\cdots H{-}O \longleftrightarrow H_{II}{-}C(-C){-}H_I\cdots O$

Enol Keto

Process (1) may be expected to be rapid under all conditions. Process (3) is simply the ordinary keto–enol conversion and both (2) and (3) involve the keto tautomer as an intermediate "exchange" state. However the lifetime of this state must be small, since no separate signals corresponding to the keto form are observed in the NMR spectra of the amine solutions. This together with the relatively weak donor property of the π-bond of the enol form would account for the observed lower probability of processes (2) and (3) relative to that of (1). These processes are nevertheless sufficiently rapid to average out the separate spectra of the two tautomers. The spectrum of acetylacetone in diethylamine shown in Fig. 4 can in fact be regarded as an averaged spectrum of the two tautomers. It will be noted, however, that formation of the keto tautomer as a short-lived intermediate state permits the protons H_I and H_{II} to become equivalent, and accordingly both can take part in the exchange process. In this way the exchange of the enolic =CH— group (proton$_{II}$) can be accounted for.

The conclusion indicated by the present study is that amines, by virtue of strong hydrogen bonding interactions with acetylacetone, not only alter the keto–enol equilibrium very extensively, but also greatly increase the keto–enol conversion rate. The conversion rate is more rapid in diethylamine than in triethylamine, presumably because the latter lacks an exchangeable proton of its own.

THE INFRARED SPECTRA OF 4-SUBSTITUTED-THIOSEMICARBAZIDES AND DIAZOTIZATION PRODUCTS[1]

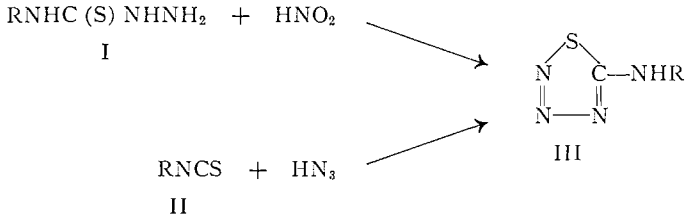
EUGENE LIEBER,[2] C. N. R. RAO,[3] C. N. PILLAI,[3] J. RAMACHANDRAN,[3] AND RALPH D. HITES[4]

ABSTRACT

The infrared absorption spectra of 4-substituted-thiosemicarbazides, 5-(substituted)amino-1,2,3,4-thiatriazoles, and the corresponding isomeric tetrazolinethiones have been studied and structural assignments of importance to these systems made or suggested. Important conclusions drawn from the spectral data are: there is no suggestion of any thiol–thione tautomerism for the solid 4-substituted-thiosemicarbazides and that the thione structure predominates for these substances; that the so-called 5-thiol-tetrazoles also exist as thiones; and that the diazotization products of the 4-substituted-thiosemicarbazides yield 1,2,3,4,-thiatriazoles rather than the isomeric open chain thiocarbamyl azides. The C═S, —N—C═S, and cyclic —N—N═N— configurational assignments, which are of importance to the classes of compounds studied, are discussed.

INTRODUCTION

In a previous communication, Lieber, Pillai, and Hites (1) reported that the reaction of 4-alkyl- or 4-aryl-thiosemicarbazides, I, with nitrous acid, as well as the reaction of alkyl- or aryl-isothiocyanates, II, leads to the identical 5-(substituted)amino-1,2,3,4-thiatriazoles, III:



The 5-(substituted)amino-1,2,3,4-thiatriazoles (III) on treatment with base undergo two competitive reactions (1):

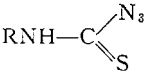
the extent of mode (*a*) or (*b*) depending on the electronegativity of the substituent R.* One of the invaluable aids in treading through the pathways of these reactions involved the application of infrared absorption spectroscopy (1). Thus the chemistry of the 5-(substituted)amino-1,2,3,4-thiatriazoles, III, could be explained in terms of the isomeric thiocarbamyl azide structure, VI:



VI

except for the fact that III shows a complete absence of the azido-group frequencies in the infrared region (1). This communication reports the infrared absorption data obtained on structures I, III, and IV obtained in the course of the investigation summarized above.

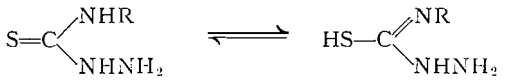
EXPERIMENTAL

The spectra were recorded on a Perkin-Elmer single-beam spectrometer (Model 12C) with sodium chloride prism. The positions of the absorption maxima are listed in Tables I, II, and III with the intensities being indicated by the following symbols: s, strong; m, medium; w, weak; vw, very weak; and v, variable. The compounds studied were those reported upon in the previous communication (1). The spectra were taken in Nujol mulls.

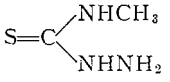
DISCUSSION

4-Substituted-thiosemicarbazides

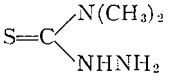
All of the important absorption bands of the 4-substituted-thiosemicarbazides in the region 1640–780 cm.$^{-1}$ are summarized in Table I. No SH band was found in these compounds in the region 2600–2500 cm.$^{-1}$, the range in which the SH stretching vibrations are most likely to appear (2). This clearly shows that there is no thiol–thione tautomerism in these compounds in the solid state:



A similar conclusion has been drawn by Bogomolov and co-workers (3). All of the compounds studied showed N—H stretching modes of vibration. In general, the important infrared absorption frequencies of the 4-substituted-thiosemicarbazides can be summarized as in Table IV. The bands due to the hydrazino-, —$NHNH_2$, portion of the structure have been assigned on the basis of studies presented by Randall (4) and Lieber (5). Both the 4-methyl- (VII) and 4,4-dimethyl- (VIII) thiosemicarbazides:



VII



VIII

show weak absorption at 1439 cm.$^{-1}$ and 1447 cm.$^{-1}$, respectively. In agreement with Bellamy (2) these bands can be assigned to the C—H deformation mode in N—CH_3 but do not seem to be too closely defined to afford any useful correlation. The medium or

**More recently it has been found that for III (R = alkyl) a third mode of decomposition can also take place in alkaline media involving an internal oxidation–reduction leading to the formation of nitrogen, sulphur, and further degradation products. This work will be reported in a separate communication.*

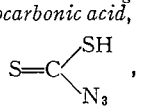
weak intensity bands observed in the region 1232–1155 cm.$^{-1}$ may be ascribed to the C—N stretching vibration (2, 4). Ueno (6) has recently assigned the region 1300–1273 cm.$^{-1}$ to the C—N stretching vibration of the para-amino group of azobenzenes. In addition to the absorption bands discussed above, bands due to other functional groups and substituted aromatic rings were also observed.

5-(Substituted)amino-1,2,3,4-thiatriazoles

The most significant observation arising out of this study of the infrared absorption spectra of a series of fourteen 5-(substituted)amino-1,2,3,4-thiatriazoles, summarized in Table II, is the absence of an absorption band in the region 2170–2080 cm.$^{-1}$. This rules out (1, 7) the presence of an azido group, supporting structure III and eliminating from consideration structure VI as proposed by Olivari-Mandala (8). Recent studies (9) have confirmed the strong absorbance for the azido group which occurs with great consistency close to 2130 cm.$^{-1}$. This intense N≡N asymmetric stretching absorption is so strong and so little altered by environmental groups as to make its absence in an infrared spectrum a guarantee that the compounds under scrutiny are free of this structural entity.* As

Lieber, Pillai, Ramachandran, and Hites (J. Org. Chem. **22, 1750 (1957)) have recently shown that the reaction products of azide ion and carbon disulphide, which have long been regarded in the literature (Audrieth, Chem. Revs. **15**, 169 (1934)) as derivatives of azidodithiocarbonic acid,*



show no azido group frequency in the infrared and in reality are derivatives of the 1,2,3,4-thiatriazole ring system.

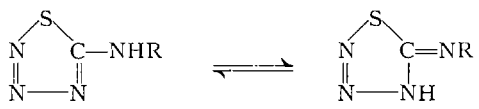
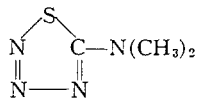
additional confirmation of the assigned structure the characteristic absorptions for C=S and —N—C=S are also absent (Table II).

A number of the 5-(substituted)amino-1,2,3,4-thiatriazoles exhibit a band of weak or medium intensity in the region 1724–1695 cm.$^{-1}$. Randall (4) found a strong absorption band in the region 1695–1664 cm.$^{-1}$ for guanidine. Lieber (5) reported a strong absorption band in the region 1681–1661 cm.$^{-1}$ for a series of guanidine derivatives. In a few cases a band was observed a few hundredths of a micron on either side of this region. Kumler (11) repeated the infrared spectral studies of Lieber (5) on a more limited number of nitroguanidine derivatives and reported bands in the region 1663–1618 cm.$^{-1}$. All investigators (2, 4, 5, 10, 11, 12) are in agreement in assigning these bands to the C=N stretching frequency, the unit occurring in imine-type structures, >C=N—, i.e. in an open chain. Randall (4) assigned a strong 1697 cm.$^{-1}$ band to open-chain C=N linkage in N-carbethoxybenzalhydrazone and a strong band at 1694 cm.$^{-1}$ to C=N$^+$ type of linkage in phenaceturiminomethyl ether hydrochloride. It is therefore possible that the moderate to weak band in the region 1724–1695 cm.$^{-1}$ in 1,2,3,4-thiatriazole derivatives is due to an external C=N linkage. This could arise by a tautomeric shift of a proton as in structures III to IX:



III IX

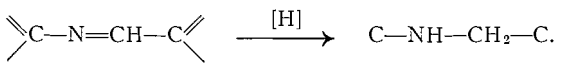
the intensity of the band depending upon the ratio of IX to III. In dimethylamino-1,2,3,4-thiatriazole, X:



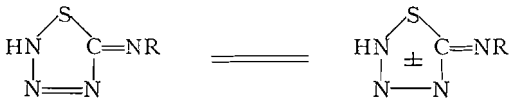
X

this tautomeric shift is not possible and the band at 1724–1695 cm.$^{-1}$ is missing, although no firm conclusion can be drawn from this since the band is also missing in those thiatriazole derivatives in which tautomeric shifts are possible.

All of the compounds listed in Table II exhibit a strong intensity band between 1618 and 1525 cm.$^{-1}$. Bellamy (2) assigns a band of variable intensity in the region 1660–1480 cm.$^{-1}$ for the C=N stretching vibration in conjugated cyclic compounds. Since the —N=N— absorption is generally weak and variable it is unlikely that the band in the 1618–1525 cm.$^{-1}$ region is due to —N=N— stretching. Ueno (6) examined a series of 17 azobenzenes and assigned the —N=N— stretching frequency to two bands of variable intensity in the 1455–1400 cm.$^{-1}$ region. On the other hand, when the nitrogen atom of the C=N bond is so substituted that it is able to take on a polar character, the characteristic frequency alters considerably. Goulden (13) quotes the region of 1659–1510 cm.$^{-1}$ for situations of this type. More recently, Clougherty (14) examined the infrared spectra of aromatic Schiff bases and ascribed the band of medium intensity in the 1631–1613 cm.$^{-1}$ region to the conjugated C=N stretching frequency. Of considerable interest is the fact that this band disappeared on reduction of the Schiff base to a secondary amine:



On the basis of chemical and ultraviolet spectral evidence Lieber (1) suggested that 5-(substituted)amino-1,2,3,4-thiatriazoles may possibly exist in the so-called mesoionic form, XI:



XI

Accordingly, it is possible that the two bands observed in the region 1724–1695 cm.$^{-1}$ (weak or medium intensity) and 1618–1525 cm.$^{-1}$ are due to the mesoionic structure, XI, although not enough information exists in the literature (15, 16) to firmly support this viewpoint.

The dimethylamino derivative (structure X) exhibits two weak bands at 1441 and 1404 cm.$^{-1}$ (Table II) which when combined result in a medium-intensity band at 1425 cm.$^{-1}$. The methylamino derivative (structure III, R = CH_3) exhibits a prominent shoulder at 1395 cm.$^{-1}$. These bands probably can be ascribed (2, 12) to the N—CH_3 absorption. It is also possible that the band observed in the 1217–1148 cm.$^{-1}$ region (Table II) in all of the derivatives is due to C—N vibration. All of the derivatives exhibit a medium-intensity absorption band between 1297 and 1280 cm.$^{-1}$. The significance of this region will be discussed below. From Table II it can be seen that there are a few characteristic skeletal vibration bands due to the thiatriazole ring itself in the regions 911–889 cm.$^{-1}$, 962–930 cm.$^{-1}$, 1060–1030 cm.$^{-1}$, and 1122–1090 cm.$^{-1}$.

1-Substituted-tetrazolinethiones

It has recently been found (1) that 5-(substituted)amino-1,2,3,4-thiatriazoles can be partially converted to a tetrazole derivative when the substituent was an aryl group (structure III, R = aryl). The tetrazole derivative produced could be represented in the *thione* (structure IV) or *thiol* (structure V) forms. It was found that structures of the types IV and V could easily be differentiated by a study of their infrared spectra. The results of the present study establish the *thione* (IV) structure for these compounds. Table III summarizes the important bands observed for these derivatives.

In all of the compounds studied, the —N—C=S and C=S bands are strong and are found in the regions 1500–1474 cm.$^{-1}$ and 1359–1338 cm.$^{-1}$, respectively. The more important observation for these series of compounds was the fact that the presence of the SH band in the region 2600–2550 cm.$^{-1}$ (2) was not apparent. This supports the *thione* (IV) structure rather than the *thiol* (V) structure for these compounds.

A few absorption bands are observed in the 1650–1500 cm.$^{-1}$ region. However, no differentiation of the —N=N— linkage is possible. As Ueno (6) and Bellamy (2) point out, the main difficulty is that the —N=N— absorptions are expected to appear in the double-bond region, so that they may well be merged with the conjugated and stronger aromatic ring absorptions. All of the tetrazole derivatives studied (Table III) exhibit two bands of medium intensity around 1210 cm.$^{-1}$ and 1170 cm.$^{-1}$, the former band being very weak in some cases. It is possible that these bands may be due to the C—N linkage. All of the derivatives, including 1-benzyl-tetrazoline-5-thione (IV, R =

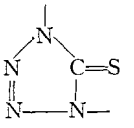
$C_6H_5CH_2$—), show a strong or medium intensity band around 1280 cm.$^{-1}$. The interpretation of this band is discussed below.

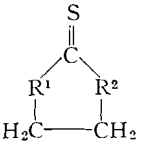
All of the observed frequencies in the region 1115–980 cm.$^{-1}$ have been tabulated. Although a few of the weak bands could be due to the substituted aromatic ring, it is also possible that some of the bands are characteristic skeletal vibration bands of the tetrazolinethione system:



In a few cases, only two strong and/or medium-intensity bands at about 1040 and 990 cm.$^{-1}$ are found. If the small peaks in the other compounds are combined into a broad band, two maxima are invariably found at about 1085 and 1040 cm.$^{-1}$, which in addition to the 990 cm.$^{-1}$ band appear to be common to all these compounds. The results are in general agreement with the earlier observations by Lieber (5) for tetrazole derivatives.

The C=S *Frequency*

Bellamy (2) states that no adequate correlation has yet been worked out for this linkage. Colthup (17) and Thompson (18) have suggested the range 1400–1300 cm.$^{-1}$ for the C=S absorption but there is no indication of the classes of compounds on which the assignment is based. Mecke (19) in a recent study ascribed a band of strong intensity in the region 1200–1050 cm.$^{-1}$ for a series of compounds of the type:



where R^1 and R^2 represented the groups CH_2, NH, O, and S, the spectral maps for ethylenethiourea ($R^1 = R^2 = NH$), oxazolthione ($R^1 = NH$, $R^2 = O$), thiopyrrolidone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(R^1 = NH, R^2 = CH_2), thiothiazolidone (R^1 = NH, R^2 = S), and ethylenetrithiocarbonate (R^1 = R^2 = S) being presented in their paper. An examination of these maps reveals bands of strong intensity in the much less variable region of 1350–1300 cm.$^{-1}$. It is more likely that this latter region corresponds to the C=S frequency and that the more variable region of 1200–1050 cm.$^{-1}$ could be assigned to either C—N, C—S, or C—O skeletal vibrations. From the data (Tables I, II, and IV) of the present investigation a frequency assignment of 1395–1338 cm.$^{-1}$ for the C=S linkage can be made.

TABLE IV

IMPORTANT INFRARED FREQUENCY ASSIGNMENTS FOR 4-SUBSTITUTED-THIOSEMICARBAZIDES

$R_1R_2NC(S)NHNH_2$

Frequency, cm.$^{-1}$	Assignment
1555–1488(s)	—N—C=S
1395–1346	C=S
Ref. (4), (5)	—$NHNH_2$ structural
1639–1610(s)	NH_2 deformation, asym.
1280–1259(v)	NH_2 deformation, sym.
1094–1058(v)	NH rocking
996–956(m/s)	NH rocking
815–774(w/m)	NH bending

The —N—C=S *Frequency*

Randall (4) has assigned a strong band to the structure R—N—C=S or R—NH—C=S in the region 1613–1471 cm.$^{-1}$. Mann (20) assigns a band at 1495 cm.$^{-1}$ for this group. Bellamy (2) feels that there is justification for a tentative assignment to the 1500–1470 cm.$^{-1}$ region. From the data of the present investigation on 4-substituted-thiosemicarbazides (Tables I and IV) and on the tetrazolinethiones (Table III) an assignment to the region 1555–1474 cm.$^{-1}$ can be made.

The 1300–1270 cm.$^{-1}$ Frequency Region

From Tables II and III it can be seen that the thiatriazole and tetrazolinethione rings exhibit a band in the 1300–1270 cm.$^{-1}$ region* of variable intensity. Since no other assignment seems possible, a tentative assignment of this frequency to the cyclic —N—N=N— linkage is suggested. It is interesting to note that the variable symmetric vibration band of the azido group, N_3, has been assigned the region of 1343–1177 cm.$^{-1}$ by Sheinker and Syrkin (21). Lieber (9) has recently assigned the 1297–1256 cm.$^{-1}$ region to this symmetric vibration band. From the results of Lieber, Levering, and Patterson (5) it can be seen that quite a large number of tetrazole derivatives show this absorption in the 1300–1270 cm.$^{-1}$ region, lending support to a cyclic —N—N=N— assignment.

RADIOCHEMICAL EVIDENCE FOR HETEROGENEITY IN WHEAT STARCH[1]

A. S. PERLIN

ABSTRACT

Wheat starches labeled with carbon-14 have been fractionated by a novel leaching procedure to give amylose, amylopectin, and a highly-branched minor fraction designated "amylopectin C". Marked differences in the specific activity of the fractions are found. Subfractionation of amylopectin also gives products of varying specific activity. These findings provide radiochemical evidence for heterogeneity in wheat starch.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Starch is composed of D-glucopyranose units joined together, chiefly by 1,4-α-glycosidic linkages, in two distinct macromolecular patterns, one linear and the other highly branched. It is generally accepted that these structural forms are represented in the starch granule by two components, amylose and amylopectin, respectively, which can be isolated and readily differentiated by chemical and physical means (1, 2). In turn, amylose and amylopectin may be subfractionated into products having characteristics substantially different from each other (1, 2, 3, 4, 5, 6), the electrophoretic examination of starch by Lewis and Smith (6) affording particularly striking evidence for such heterogeneity. However, a minority opinion (e.g. 7, 8) holds that starch is homogeneous and that amylose, amylopectin, and subfractions of these are artifacts generated by scission of unstable linkages in an indefinitely large starch molecule. These diverse views on the structure of starch are evaluated critically by Greenwood (2), who concludes that the concept of heterogeneity is favored, a conclusion reached also by Schoch (9), but underlines the difficulty in experimentally proving or disproving such postulates. The current paper provides new evidence for heterogeneity in starch based on differences in the carbon-14 content of amylose, amylopectin, and subfractions of amylopectin, which have been isolated from C^{14}-labeled wheat starches (10).

Amylose and amylopectin are most satisfactorily separated by complete dispersion of the starch in water following which the amylose is preferentially precipitated with a suitable complexing agent (1, 2). The C^{14}-labeled wheat starches were dispersed in water by autoclaving according to the procedure of Schoch (1). It was found, however, that material corresponding to amylopectin (referred to as "amylopectin B") contaminated with very little amylose ("blue values" (11) of 0.1 or less) could be separated out as a gel in a preparative-type ultracentrifuge. Addition of *n*-amyl alcohol to the supernatant solution then precipitated the amylose, which was also of relatively high purity ("blue values" of 1.0 or more). This modification of Schoch's procedure in effect constitutes a leaching process (1, 9) and in its end result resembles the method of Baum, Gilbert, and Wood (12), which employs mild heating in an oxygen-free atmosphere. After removal of the amylose a third starch fraction, referred to as "amylopectin C", was obtained from the solution by flocculation with excess ethanol.

Amylopectin C appears not to have been described by earlier workers. Its yield varied, but averaged about 5% of the total starch. On treatment with iodine the material gave a red color resembling the usual amylopectin–iodine color and, like the major amylopectin fraction ("amylopectin B"), had a "blue value" of 0.1 or less. A comparison of periodate end-group values indicated that the average unit chain lengths of amylopectins B and C

are of approximately the same order, but an accurate measure was not obtained because the polysaccharides were overoxidized. The apparent degree of hydrolysis of amylopectin C to maltose by β-amylase was 48–53%, somewhat less than the value of 55–60% found for amylopectin B. These properties, together with the fact that the material did not form an insoluble complex with *n*-amyl alcohol, served to characterize the minor starch component as a polymer closely related to amylopectin.

Two samples of amylopectin B were subfractionated, in turn, to give three products each. The first of these was obtained as a flocculus by acidifying an alkaline solution of amylopectin B. High-speed centrifugation of the opaque dispersion remaining yielded a second subfraction as a gel, and a third was precipitated from solution with ethanol. Each of these subfractions was degraded to approximately the same extent (55–60%) by β-amylase.

Marked differences in specific activity were found among the starch fractions and subfractions (Table I), the variations being dependent on the stage of plant growth at which tracer was administered. Amylose thus possessed a lower specific activity than amylopectin B if glucose-1-C^{14} or acetate-C^{14} was fed early, or higher, if a late injection was made. These observed fluctuations are thought to reflect the mode of biosynthesis of the amylose and amylopectin components of wheat starch (13). The specific activity–time pattern of labeling of the amylopectin C fractions was distinct from that of amylopectin B but closely resembled the pattern shown by amylose. Differences were found also among the subfractions of amylopectin B, subfractions 2 and 3 having similar specific activities but subfraction 1 having much higher (early injection) or lower (late injection) specific activity.

TABLE I

SPECIFIC ACTIVITY* OF STARCH FRACTIONS AND SUBFRACTIONS

†*Days after seeding.*

These variations in the quantity of carbon-14 incorporated strongly suggest that amylose and amylopectin are deposited in the kernel at far from parallel rates and that the various branched components also are not synthesized simultaneously. Accordingly, wheat starch may be considered heterogeneous in a biosynthetic sense. If starch is a giant homogeneous molecule, and the various materials isolated from it were to represent products of random degradation, differences in the specific activity of these fragments would not be expected. However, the current data do not disagree with the view that starch is an indefinitely large molecule, but require that it be built up in a stepwise manner, the stages being distinguishable by differing chemical characteristics and susceptibilities to degradation. In these terms the concept of heterogeneity in starch is meaningful even if linear and branched components are joined together at certain points within the granule by unstable linkages (7). Alternatively, if amylose and amylopectin

are to be regarded as distinct entities, the present radiochemical evidence indicates that amylopectin is itself heterogeneous and may be fractionated into components which differ in physical properties and, possibly to a lesser extent, in chemical structure.

EXPERIMENTAL

C^{14}-labeled wheat starches were isolated as described earlier (10) from the kernels of mature plants grown under field conditions, a given tracer being administered to the plants at various periods of the growing season (14).

Fractionation of Wheat Starch

The starch (0.2–1.0 g.) was extracted exhaustively with hot methanol (1) and air-dried. It was suspended in water at a concentration of 2% and gelatinized on the steam bath and then autoclaved at 18 lb./sq. in. for 4 hours (1). After cooling, the dispersion was centrifuged in a Spinco preparative ultracentrifuge at 40,000 r.p.m. for 25 minutes, giving a gelatinous sediment. The latter was washed in the centrifuge with water and recovered after dehydration with ethanol and ether (amylopectin B). The combined aqueous supernatant solutions were heated on the steam bath, amyl alcohol (1/10 volume) was added, and the suspension stirred gently and allowed to cool slowly (1). After 18 hours at 3° C., the suspension was centrifuged at 25,000 r.p.m. for 20 minutes, the precipitate was washed in the centrifuge with amyl alcohol-saturated water, then several times with ethanol and ether, and dried (amylose). Methanol (4 volumes) was added to the clear supernatant remaining after separation of amylose, and material which precipitated was recovered and dried after ethanol and ether washes (amylopectin C).

Amylose accounted for 28–33% and amylopectin B for 58–65% of the weight of the starches. The yield of amylopectin C varied widely, ranging in amount from 1 to 15% and averaging about 5% of the starches. Iodine absorption values at 610 mμ ("blue values" (11)), measured for the fractions of four starches by the procedure of McCready and Hassid (15), were as follows: amylose—1.0, 1.1, 1.2, 1.2; amylopectin B—0.08, 0.10, 0.12, 0.16; amylopectin C—0.06, 0.08, 0.10, 0.14. All amylose samples gave the typical intense blue color with iodine, and all amylopectin B and C samples a red-purple color of low intensity.

Subfractionation of Amylopectin B

Amylopectin B (0.5 g.), moistened with ethanol, was pasted in *N* sodium hydroxide (6 ml.). Boiling water (50 ml.) was added, the dispersion cooled, acidified with acetic acid, and centrifuged at 5000 r.p.m. affording a precipitate (subfraction 1). Centrifugation at 40,000 r.p.m. gave a second product as a clear gel (subfraction 2), and addition of methanol (30 ml., 1/2 volume) then yielded a bulky precipitate (subfraction 3). All three materials were recovered by washing with methanol and drying. Two samples of amylopectin B fractionated in this way gave the following percentage yields of subfractions 1, 2, and 3, respectively: 16 and 19, 23 and 21, 51 and 47.

Measurement of β-Amylase Degradation

The amylopectin sample (10 mg.) was pasted in *N* sodium hydroxide (0.2 ml.), then taken up in hot water (1 ml.), and the hydrogen-ion concentration of the cooled solution adjusted to pH 5.0 with acetic acid. An excess of a β-amylase preparation was added and the reaction allowed to proceed at room temperature. Aliquots of the solution were withdrawn at intervals and analyzed for reducing power with the Somogyi reagent (16). Hydrolysis was virtually terminated in 2–3 hours, reducing values being increased by less than 5% during a further 20 hours' reaction time. Chromatographic examination of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

the hydrolyzate, after precipitation of limit dextrin with ethanol and removal of sodium ions with Amberlite IR-120, showed maltose as the single sugar produced by β-amylase degradation. The degree of hydrolysis (maltose produced in 5 hours from measure of total reducing power) of four samples of amylopectin B was 55, 58, 59, and 60%, and of four samples of amylopectin C 48, 48, 50, and 53%. Under the same reaction conditions samples of amylose were 90–95% hydrolyzed in 20 hours.

Periodate Oxidation

The starch fraction (15 mg.) was suspended in ethanol (1 ml.), 0.04 *M* sodium metaperiodate (9 ml.) was added, and the mixture stored in the dark at 19.5° C. Aliquots were withdrawn at intervals, excess periodate was destroyed with ethylene glycol, and acid formed was titrated with dilute sodium hydroxide using methyl red indicator. Acid produced (moles/mole) at 75 and 120 hours, respectively, by two samples of amylopectin B: 0.036, 0.041 and 0.052, 0.047; by two samples of amylopectin C: 0.041, 0.039 and 0.053, 0.047.

Measurement of Specific Activity

Specific activity was estimated by the method of Buchanan and Nakao (17). Samples were combusted, and the carbon dioxide liberated was estimated manometrically and its specific activity measured in a gas counter. Reproducibility of the method is ±3%.

ACKNOWLEDGMENTS

The author gratefully expresses thanks to Mr. J. W. L. C. Christ for technical assistance, Dr. W. B. McConnell for samples of starch-C^{14}, Dr. A. C. Neish and Mr. J. Dyck for specific activity measurements, and Dr. L. R. Wetter for assistance in assaying β-amylase degradation.

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

III. SUR LA SYNTHÈSE DES ARYL-CHLORO-*p*-BENZOQUINONES[1]

P. BRASSARD[2] ET P. L'ÉCUYER

RÉSUMÉ

La chloroquinone réagit avec les sels de benzène- et de *p*-chlorobenzène-diazonium pour donner un mélange de deux isomères monoarylés. La majeure partie du produit de la réaction est l'isomère 2,6 et le reste l'isomère 2,3.

INTRODUCTION

Les phénylbenzoquinones réagissent en solution tampon avec les sels de diazonium (1) pour donner les 2,5-bisphénylquinones correspondantes. Günther (2) a constaté que la chloroquinone réagit aussi avec les sels de diazonium et a même isolé un composé qu'il n'a pas identifié. Était-ce l'isomère 2,5? Il y avait lieu d'en douter; car la chloroquinone et la phénylquinone constituent deux systèmes dans lesquels les effets électromères devraient affecter différemment l'orientation de l'entrée du groupement phényle.

Dans le but d'établir la position du groupe phényle, nous avons effectué la réaction de la chloroquinone avec les chlorures de benzène- et de *p*-chlorobenzène-diazonium dans les mêmes conditions que nous avons établies pour la réaction de la benzoquinone avec ces sels (3), soit en milieu aqueux tamponné par l'acétate de sodium. La purification du produit de la réaction a révélé qu'il se forme dans chaque cas deux isomères au lieu d'une seule substance. Une première cristallisation a permis de les séparer grossièrement. Nous avons ensuite procédé à la purification de chacun d'eux en le cristallisant dans un solvant approprié. Dans les deux cas la purification de l'isomère le moins soluble a été facile, mais celle de l'isomère le plus soluble s'est révélée plus difficile et même impossible dans le cas particulier de l'isomère dans lequel le résidu hydrocarboné est le groupe phényle. Ce dernier composé reste toujours contaminé par une certaine quantité de l'isomère le moins soluble. Pour cette raison nous avons choisi d'identifier d'abord les deux isomères dans lesquels le résidu aryle est le groupe *p*-chlorophényle avant de caractériser l'isomère où le reste aryle est le groupement phényle.

Les analyses indiquaient que nous avions réellement affaire à deux 2-chloro-*x*-(*p*-chlorophényl)-benzoquinones isomères. Or théoriquement, il était possible d'obtenir deux des trois isomères inconnus I, II et III. En l'absence de méthode pour préparer ces derniers de façon non équivoque, la preuve de structure que nous avons établie repose essentiellement sur l'identité des *x*,*x'*-dichloro-*x''*-(*p*-chlorophényl)-benzoquinones obtenues de deux façons différentes. Selon la première, nous avons additionné de l'acide chlorhydrique aux deux 2-chloro-*x*-(*p*-chlorophényl)-benzoquinones isomères, la substance II (Ar = groupe *p*-chlorophényle), p.f. 150°, et la substance I (Ar = groupe *p*-chlorophényle), p.f. 103°, et oxydé ensuite en quinones les hydroquinones que nous avions ainsi obtenues. Selon la deuxième, nous avons fait réagir le chlorure de *p*-chlorobenzène-diazonium avec la 2,3- et la 2,6-dichlorobenzoquinone (V et IV).

La substance II (Ar = groupe *p*-chlorophényle), p.f. 150°, après l'addition de l'acide chlorhydrique et l'oxydation du produit de la réaction au chlorure ferrique, donne un mélange constitué, en majeure partie, de 2,3-dichloro-5-(*p*-chlorophényl)-benzoquinone

[1]*Manuscrit reçu le 3 février 1958.*

Ar = groupe phényle ou *p*-chlorophényle

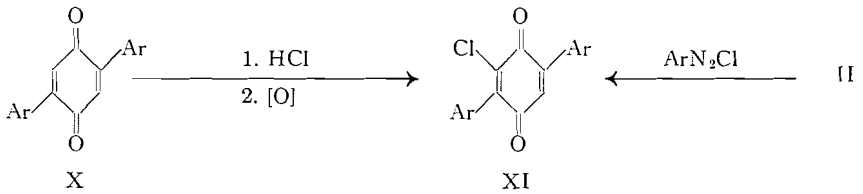
(VIII), p.f. 166°–167°, composé que nous avons aussi obtenu par la condensation du chlorure de *p*-chlorobenzène-diazonium avec la 2,3-dichlorobenzoquinone (V), et d'une autre substance, p.f. 144°–145°, différente de l'isomère dichloré en 2,6 (VI), p.f. 116°–117°, et obtenue de IV (Ar = groupe *p*-chlorophényle) par réaction avec le chlorure de *p*-chlorobenzène-diazonium. Cette dernière substance ne peut être que la 2,5-dichloro-3-(*p*-chlorophényl)-benzoquinone (VII), car il ne reste pas d'autre alternative.

L'isomère I (Ar = groupe *p*-chlorophényle), p.f. 103°, soumis à la même série de réactions donne exclusivement une seule substance identique à la 2,5-dichloro-3-(*p*-chlorophényl)-benzoquinone (VII), p.f. 144°–145°, aussi obtenue de l'isomère II, tel que mentionné précédemment. Leur identité a été vérifiée par leur point de fusion mixte. Le fait que celui-ci n'est pas déprimé constitue une preuve rigide que l'isomère II est bien la 2-chloro-6-(*p*-chlorophényl)-benzoquinone et l'isomère I la 2-chloro-3-(*p*-chlorophényl)-benzoquinone.

D'ailleurs, nous avons aussi confirmé ces résultats de la façon suivante. La produit de la réaction de l'isomère II (Ar = groupe phényle), p.f. 128°–129°, avec le chlorure de benzène-diazonium et celui que l'on obtient par l'oxydation de l'hydroquinone résultant de l'addition de l'acide chlorhydrique à la 2,5-bisphénylquinone (X, Ar = groupe

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

phényle) ne sont qu'une seule et même substance, soit la 3-chloro-2,5-bisphénylbenzoquinone (XI, Ar = groupe phényle). Leur point de fusion est identique et n'est pas déprimé lorsque les deux produits sont mélangés. Donc l'isomère II (Ar = groupe phényle) est bien la 2-chloro-6-phénylbenzoquinone.



X XI

Ar = groupe phényle ou *p*-chlorophényle

L'isomère II (Ar = groupe *p*-chlorophényle), p.f. 150°, et la 2,5-bis-*p*-chlorophénylbenzoquinone (X, Ar = groupe *p*-chlorophényle) sont beaucoup plus inertes, mais donnent néanmoins par les mêmes réactions une seule et même substance, la 3-chloro-2,5-bis-*p*-chlorophénylquinone (XI, Ar = groupe *p*-chlorophényle), comme le montre le point de fusion mixte. Donc, c'est là une autre preuve que l'isomère II (Ar = groupe *p*-chlorophényle) est bien la 2-chloro-6-*p*-chlorophénylbenzoquinone.

PARTIE EXPÉRIMENTALE*

2-Chloro-6-phénylbenzoquinone (*II*, Ar = *groupe phényle*)

Une solution de chlorure de benzène-diazonium, préparée par la diazotation de 9.3 g. (0.1 mole) d'aniline dissoute dans 25 ml. d'acide chlorhydrique concentré et 100 ml. d'eau, est versée dans un mélange de 15.7 g. (0.11 mole) de chloroquinone et de 30.6 g. (0.225 mole) d'acétate de sodium trihydraté dans 1300 ml. d'eau. On agite vigoureusement à la température ambiante jusqu'à ce qu'il ne se dégage plus d'azote. On essore le précipité (18.5 g., 84% de la théorie) et on l'extrait à l'éther de pétrole bouillant. Après l'évaporation du solvant on cristallise le résidu dans l'éthanol. Une deuxième cristallisation dans le même solvant donne 11.9 g. (54%) de 2-chloro-6-phénylbenzoquinone pure sous forme de paillettes jaunes, p.f. 127°–129°. Calculé pour $C_{12}H_7O_2Cl$: C, 65.92%; H, 3.21%. Trouvé: C, 85.8%; H, 3.8%. Les eaux-mères de cristallisation contiennent un autre isomère; mais il a été impossible de le débarrasser complètement de l'isomère 2,6 qui est beaucoup moins soluble que lui dans les solvants organiques.

Pour fin d'identification l'isomère 2,6 a été préparé de la façon suivante. On fait barboter de l'acide chlorhydrique gazeux anhydre dans une suspension de 10.0 g. de phénylquinone dans 100 ml. d'acide acétique glacial; la quinone passe lentement en solution au fur et à mesure que celle-ci se sature d'acide chlorhydrique. On refroidit à la température ambiante et on ajoute d'un seul trait 100 ml. d'une solution de chlorure ferrique à 30%. On agite durant quelques secondes et on verse dans un grand volume d'eau. On essore le précipité et on le cristallise dans l'éthanol à 90%. On obtient ainsi 9.7 g. (81%) de 2-chloro-6-phénylbenzoquinone, p.f. 129°–130°. Un mélange en proportions égales de deux échantillons de la quinone obtenue par les deux méthodes différentes fond aussi à 129°–130°.

2,3-Dichloro-5-phénylbenzoquinone (*VIII*, Ar = *groupe phényle*)

En opérant comme précédemment, on additionne à la 2-chloro-6-phénylbenzoquinone (5.0 g.) dans l'acide acétique glacial (75 ml.) de l'acide chlorhydrique anhydre, on oxyde

**Les points de fusion ont été pris à l'aide de l'appareil de Johns.*

à l'aide de 50 ml. d'une solution de chlorure ferrique à 30% et on verse dans 300 ml. d'eau froide. On essore 4.4 g. (76%) de 2,3-dichloro-5-phénylbenzoquinone presque pure. Elle cristallise dans l'acool éthylique en lamelles jaunes, p.f. 166°–167°. Calculé pour $C_{12}H_6O_2Cl_2$: C, 56.95%; H, 2.39%. Trouvé: C, 56.9%; H, 2.5%.

Une solution de chlorure de benzène-diazonium, obtenue par la diazotation de 4.7 g. (0.05 mole) d'aniline dans un mélange de 12.5 ml. d'acide chlorhydrique et de 50 ml. d'eau, est versée dans une solution de 9.7 g. (0.055 mole) de 2,3-dichlorobenzoquinone dans 200 ml. d'acide acétique glacial à la température ambiante. On munit le récipient d'un agitateur mécanique et on y ajoute 15.3 g. d'acétate de sodium trihydraté dissous dans 100 ml. d'eau. Une fois la réaction terminée (environ 12 heures), le produit brut est filtré et bouilli en présence de noir animal dans un mélange de méthanol, d'acétone et d'eau (1:1:1). La solution est filtrée à chaud, refroidie et mise au réfrigérateur. On essore 8.7 g. (69% de la théorie) de 2,3-dichloro-5-phénylbenzoquinone, p.f. 166°–167°. Calculé pour $C_{12}H_6O_2Cl_2$: C, 56.95%; H, 2.39%. Trouvé: C, 57.3%; H, 2.4%. Le mélange d'un échantillon de cette quinone avec un autre de la 2,3-dichloro-5-phénylbenzoquinone obtenue de la façon décrite précédemment fond aussi à 166°–167°.

2-Chloro-6-(p-chlorophényl)-benzoquinone (*II*, Ar = *groupe p-chlorophényle*) *et 2-chloro-3-(p-chlorophényl)-benzoquinone* (*I*, Ar = *groupe p-chlorophényle*)

En condensant, dans les mêmes conditions que pour la synthèse de la 2-chloro-6-phénylquinone, le chlorure de *p*-chlorobenzène-diazonium (0.1 mole) avec la chloroquinone (0.1 mole), on recueille, la réaction terminée, 25.9 g. d'un mélange de deux isomères. On extrait le matériel brut à l'éther de pétrole (p.é. 65°–110°) bouillant et on laisse refroidir les extraits à la température ambiante. Il se sépare d'abord une huile rouge foncé, puis il se dépose des cristaux rouges. Lorsque des aiguilles jaunes commencent à apparaître, on décante la solution (qu'on conserve pour isoler l'autre isomère) et on cristallise le résidu dans l'éthanol. Après quelques cristallisations on obtient 16.0 g. (66% de la théorie) de 2-chloro-6-(*p*-chlorophényl)-benzoquinone pure sous forme d'aiguilles rouges, p.f. 150°. Calculé pour $C_{12}H_6O_2Cl_2$: C, 56.95%; H, 2.39% .Trouvé: C, 56.8%; H, 2.5%.

On évapore à sec la solution dans l'éther de pétrole qu'on a décantée dans la préparation précédente. On dissout ensuite le résidu dans un mélange bouillant de méthanol, d'acétone et d'eau (1:1:1), on traite la solution au noir animal et, après cristallisation, on essore 4.5 g. (18% de la théorie) de 2-chloro-3-(*p*-chlorophenyl)-benzoquinone pure cristallisée en paillettes jaunes, p.f. 103°. Calculé pour $C_{12}H_6O_2Cl_2$: C, 56.95%; H, 2.39%. Trouvé: C, 56.5%; H, 2.5%.

2,3-Dichloro-5-(p-chlorophényl)-benzoquinone (*VIII*, Ar = *groupe p-chlorophényle*) *et 2,5-dichloro-3-(p-chlorophényl)-benzoquinone* (*VII*, Ar = *groupe p-chlorophényle*)

On fait barboter de l'acide chlorhydrique gazeux anhydre dans une suspension de 2-chloro-6-(*p*-chlorophényl)-benzoquinone (2.0 g.) dans l'acide acétique glacial (50 ml.) jusqu'à saturation et, après avoir chassé la majeure partie du gaz chlorhydrique, on oxyde à la température ambiante à l'aide de 50 ml. d'une solution de chlorure ferrique à 30% et on verse dans 300 ml. d'eau froide. Après filtration et cristallisation du précipité dans l'éthanol, on essore 1.4 g. (61%) de 2,3-dichloro-5-(*p*-chlorophényl)-benzoquinone pure sous forme de longues aiguilles rouges, p.f. 166°–167°. Calculé pour $C_{12}H_5O_2Cl_3$: C, 50.12%; H, 1.75%. Trouvé: C, 50.3%; H, 1.9%.

En étendant d'eau les eaux-mères de cristallisation de la 2,3-dichloro-5-(*p*-chlorophényl)-benzoquinone on obtient l'isomère 2,5-dichloro-3-(*p*-chlorophényl)-benzoquinone

qui, après cristallisation dans le méthanol, donne 0.3 g. (14% de la théorie) de la substance pure sous forme d'aiguilles jaunes, p.f. 144°–145°. Calculé pour $C_{12}H_5O_2Cl_3$: C, 50.12%; H, 1.75%. Trouvé: C, 49.9%; H, 1.8%.

Dans le but d'identifier ces deux isomères, le rouge p.f. 166°–167°, et le jaune p.f. 144°–145°, nous avons préparé la 2,3-dichloro-5-(*p*-chlorophényl)-benzoquinone de la façon suivante: la *p*-choraniline (6.4 g., 0.05 mole) dissoute dans un mélange de 12.5 ml. d'acide chlorhydrique concentré et 50 ml. d'eau est diazotée et la solution du sel de diazonium est versée dans un mélange de 9.7 g. (0.055 mole) de 2,3-dichlorobenzoquinone (V) et de 20.4 g. de trihydrate d'acétate de sodium dans 200 ml. d'acide acétique à la température ambiante. Tout en agitant mécaniquement le mélange, on y verse suffisamment d'eau pour produire une légère précipitation de la quinone de départ. Une fois le dégagement gazeux terminé, on filtre et cristallise dans l'éthanol. On essore 11.6 g. (81% de la théorie) de 2,3-dichloro-5-(*p*-chorophényl)-benzoquinone pure sous la forme d'aiguilles rouges, p.f. 166°–167°. Calculé pour $C_{12}H_5O_2Cl_3$: C, 50.12%; H, 1.75%. Trouvé: C, 50.1%; H, 2.0%. Elle est identique à l'isomère rouge obtenu précédemment comme le montre le p.f. 166°–167° de leur mélange.

Une suspension de 2-chloro-3-(*p*-chlorophényl)-benzoquinone (I, Ar = groupe *p*-chlorophényle) (1.5 g.) dans l'acide acétique glacial (20 ml.) est saturée par un courant d'acide chlorhydrique sec et la solution d'hydroquinone obtenue est oxydée par l'addition de 50 ml. d'une solution de chlorure ferrique à 30%. On isole par cristallisation dans l'éthanol 1.2 g. (67% de la théorie) de 2,5-dichloro-3-(*p*-chlorophényl)-benzoquinone pure, p.f. 144°–145°. On ne décèle aucune dépression du point de fusion du mélange de cette substance avec l'isomère jaune, p.f. 144°–145°, obtenu par l'addition d'acide chlorhydrique à la 2-chloro-6-(*p*-chlorophényl)-quinone.

2,6-Dichloro-3-(p-chlorophényl)-benzoquinone (*VI*, Ar = *groupe p-chlorophényle*)

La condensation du chlorure de *p*-chlorobenzène-diazonium (0.1 mole) avec une suspension de 2,6-dichloroquinone (0.1 mole) à la température ambiante dans 300 ml. d'acide acétique en présence du trihydrate d'acétate de sodium (0.225 mole) dure 12 heures. On dilue à l'eau, on décante la liqueur et on extrait le résidu à plusieurs reprises à l'éthanol (80%) bouillant. Les extraits réunis, bouillis avec du noir animal, filtrés à chaud et refroidis donnent 18.1 g. (72% de la théorie) de 2,6-dichloro-3-(*p*-chlorophényl)-benzoquinone pure sous forme de paillettes orangées, p.f. 116°–117°. Calculé pour $C_{12}H_5O_2Cl_3$: C, 50.12%; H, 1.75%. Trouvé: C, 50.3%; H, 2.0%.

3-Chloro-2,5-bisphénylbenzoquinone (*XI*, Ar = *groupe phényle*)

En suivant la technique déjà décrite précédemment, on additionne de l'acide chlorhydrique gazeux à 2.8 g. de 2,5-bisphénylquinone (IX, Ar = groupe phényle) et on oxyde ensuite au chlorure ferrique à 30%. On obtient 2.9 g. (91%) de 3-chloro-2,5-bisphénylbenzoquinone qui cristallise dans l'acide acétique en aiguilles orangées, p.f. 188°–189°. Calculé pour $C_{18}H_{11}O_2Cl$: C, 73.35%; H, 3.76%. Trouvé: C, 73.6%; H, 3.9%.

Cette quinone s'obtient également en faisant réagir une solution de chlorure de benzènediazonium (0.05 mole) avec la 2-chloro-6-phénylbenzoquinone (0.045 mole) dans 300 ml. d'acétone à −5°. Tout en s'assurant d'une forte agitation et du maintien de la température du milieu à moins 0° on ajoute en petites portions de l'acétate de sodium trihydraté (20.4 g. en tout) durant une période de 30 minutes. On laisse ensuite le mélange prendre lentement la température ambiante. La réaction terminée, on étend d'eau, on isole le précipité et on le cristallise dans l'acide acétique. On essore la 3-chloro-2,5-bisphénylbenzoquinone (2.7 g., 20%), p.f. 188°–190°. La technique des points de fusion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

mixtes montre que cette substance est identique à celle qui a été obtenue par la méthode précédente.

3-Chloro-2,5-(p-chlorophényl)-benzoquinone (*XI*, Ar = *groupe p-chlorophényle*)

On l'obtient en opérant comme pour la synthèse de la 3-chloro-2,5-bisphénylbenzoquinone par l'addition d'acide chlorhydrique à la 2,5-bis-(*p*-chlorophényl)-benzoquinone suivie de l'oxydation au chlorure ferrique et l'arylation de la 2-chloro-6-(*p*-chlorophényl)-benzoquinone par le chlorure de *p*-chlorobenzène-diazonium. La 3-chloro-2,5-bis-(*p*-chlorophényl)-benzoquinone cristallise dans l'acide acétique en aiguilles orangées de p.f. 205°–207°. Calculé pour $C_{18}H_9O_2Cl_3$: Cl, 32.16%. Trouvé: Cl, 31.9%.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada et la Shell Oil Company of Canada pour des bourses d'études accordées à l'un de nous (P.B.).

THE INFRARED SPECTRA OF ORGANO-PHOSPHORUS COMPOUNDS

II. THE 1–2.6 μ REGION[1,2]

R. A. McIvor, C. E. Hubley, G. A. Grant, and A. A. Grey

ABSTRACT

The application of near infrared spectra to the study of phosphorus compounds has been investigated. It has been found that each type of radical gives a characteristic set of bands, which are not appreciably affected by changes in the molecule more than two atoms distant. Characteristic group frequencies are given for MeO, EtO, *n*-PrO, *i*-PrO, *n*-BuO, Me, Et, Me_2N, Et_2N, and *i*-Pr_2N groups attached to phosphorus. Only the MeP bands are noticeably altered by the nature of the substitution on the phosphorus atom. Qualitative predictions of the spectra of compounds containing more than one type of C—H group may be made by summing the contributions of the components.

INTRODUCTION

In a previous paper (1) certain features of the infrared spectra of organo-phosphorus compounds were discussed and some new assignments proposed in the 2–26 μ region. In some cases useful information about the environment of the phosphorus atom was obtained by a study of the C—H bending vibrations associated with the ester groups attached to phosphorus. With the advent of commercial spectrophotometers designed to give high resolution in the 0.7–2.5 μ overtone-combination region, it was decided to examine the spectra of organo-phosphorus compounds in this region to determine whether the improved resolution would lead to more information about the environment of hydrogen-containing groups.

EXPERIMENTAL

The preparation of most of the compounds examined has been described elsewhere (2, 3).

A Cary Model 14PM double-beam recording spectrophotometer was used for all spectra. Most spectra were run as approximately 1% w/v solutions in Spectrograde carbon tetrachloride. The path lengths used were 10 cm. and 5 cm. in the 1.0–2.1 μ and 2.1–2.5 μ regions respectively. For the remaining spectra, approximately 0.5% w/v carbon tetrachloride was used in 10-cm. cells over the entire 1.0–2.5 μ region. Bands are cited to the nearest 0.001 μ, and the limits given indicate the maximum variation occurring in the compounds examined. The quoted intensities are 100 times the molar extinction coefficients. The instrumental calibration was checked by comparing the benzene spectrum with that reported by Kaye (4).

RESULTS AND DISCUSSION

Bands in the 1–2.5 μ region arise chiefly from overtones and combination bands involving hydrogen vibrations. Most of the compounds examined show two principal sets of bands at the concentration used: set A, near 1.7 μ, is attributed to the first overtone of the C—H stretching vibrations, with the 4 ν C—H bending vibrations superimposed; set B, located in the 2.2–2.5 μ region, is more intense and is attributed to binary C—H stretching and bending combinations, with lesser contributions from ternary bending

Contribution from the Defence Research Chemical Laboratories, Ottawa, Canada. Issued as D.R.C.L. Report No. 234A. Presented in part at the 16th International Conference of the International Union of Pure and Applied Chemistry, Paris, France, July, 1957.
[2]*Reference 1 is considered to be Paper No. I in this series.*

combinations and overtones. In addition, there are corresponding band groups when OH is present which exhibit marked changes as the concentration is altered.

Assignments for various types of hydrogen bands are presented in an excellent review of this field published by Kaye (4). The present work, however, is concerned with the contour of the band envelope associated with larger structural groups in the molecule (e.g. EtO, BuO, —NMe_2, etc.). We have found that the bands associated with any one of these groups are remarkably constant, being virtually insensitive to structural changes more than two atoms away, although these changes may affect the C—H fundamentals (1). Despite the variations in the slit widths and the degree of overlapping of bands, useful quantitative data can be obtained from the extinction coefficients associated with various bands in any one type of band envelope.

The various groups examined will be discussed separately. The generalized group frequencies are presented in the text, and most of the detailed examples in the Appendix.

(*a*) MeO *and* MeS *Bands*

Phosphorus compounds containing MeO (Appendix—Table XI) have, in general, two principal bands and several lesser bands in region A. The former occur at $1.680 \pm 0.002\ \mu$ (5952 $cm.^{-1}$) and $1.720 \pm 0.001\ \mu$ (5814 $cm.^{-1}$) with average intensities of 13 and 12 respectively. Similar bands occur in dimethyl carbonate and MeS compounds although MeS bands are more intense. In certain cases the concentration was too low to permit accurate readings for these weak bands, and for the additional weaker bands, one of which occurs at $1.666 \pm 0.017\ \mu$ (6002 $cm.^{-1}$).

The B region contains four principal bands up to $2.5\ \mu$. There appear to be other bands beyond $2.5\ \mu$, in particular one near $2.52\ \mu$, but not all of the compounds were investigated in that region, because of instrumental difficulties. The bands occur at $2.254 \pm 0.002\ \mu$ (4437 $cm.^{-1}$), $2.334 \pm 0.004\ \mu$ (4285 $cm.^{-1}$), $2.387 \pm 0.005\ \mu$ (4189 $cm.^{-1}$), and $2.471 \pm 0.005\ \mu$ (4047 $cm.^{-1}$) with average intensities of 174, 41, 70, and 63 per MeO group respectively. On the basis of intensities MeS seems to have all but the $2.387\ \mu$ band and both MeS-containing compounds have an additional band at $2.319\ \mu$ (4312 $cm.^{-1}$) with an intensity of 164. Dimethyl carbonate has similar bands but methanol has only two.

TABLE I

EtO bands			EtS bands		
Band position		$\epsilon \times 10^2$ per EtO group	Band position		$\epsilon \times 10^2$ per EtO group

(*b*) EtO *and* EtS *Bands*

Organo-phosphorus compounds whose only C—H bands are contained in ethoxy groups have four bands in the A region and six bands in the B region listed in Table I.

The ethylthio group frequencies, also given in Table I, are based on SSS-triethyl phosphorotrithioate only.

The bands of the compounds on which these characteristic frequencies are based are listed in the Appendix (Table XII), along with the bands for ethanol, ethanethiol, diethyl carbonate, and diethyl oxalate. The EtO compounds without phosphorus have spectra generally similar to the EtO—P compounds. Diethyl oxalate, in particular, has a spectrum almost indistinguishable from those of EtO—P containing compounds.

(*c*) *n*-PrO *Bands*

n-PrO—P compounds have three bands in the A region and nine bands in the B region, the frequencies for which are listed in Table II.

TABLE II

			2.551±0.007	3920	51			
			2.587±0.007	3865	49			

(*d*) *i*-PrO *Bands*

i-PrO bands have five bands in the A region and eleven bands in the B region as shown in Table II.

Isopropyl alcohol has similar bands in the A region, shifted slightly to lower frequencies, but the B region is quite different, as there are only four main bands, with numerous shoulders not recorded in the table. Isopropyl frequencies and intensities are not as constant as those due to *n*-propyl.

(*e*) *n*-BuO *Bands*

The characteristic frequencies are also listed in Table II. It is noted from the examples in the Appendix that the intensities of the bands in the B region are in general greater for compounds containing P→S than for those with P→O.

(*f*) MeP *and* MeI *Bands*

Three compounds were examined which contained only Me—P groups. These are listed in Table III along with methyl iodide. Because of the differences among MeI,

Me—P(O), and Me—P(S) type compounds, separate values are given for each class. It is interesting to note that MeI and Me—P compounds show greater dissimilarity in the 1–2.6 μ region than in the 3–16 μ region.

(*j*) *i*-Pr_2N *Compounds*

Four compounds were examined which contained *i*-Pr_2N in conjunction with other alkoxy groups. A pure sample of a compound containing C—H in *i*-Pr_2N groups only has

not yet been obtained. An attempt was made to predict the spectrum of such a compound by subtracting the contributions of the alkoxy groups. The results are indicated in Table VII. The bands for these compounds are given in Appendix Table XV. Because of the similarity of *i*-PrO and *i*-Pr_2N bands the values in column 3 are probably most reliable.

(*k*) *Miscellaneous*

Although the P—H group does not give rise to any sharp bands in this region, a weak diffuse band appears at about 1.892 ± 0.001 (5258 $cm.^{-1}$), with an intensity of 24 as indicated in Table VIII.

TABLE VIII

P—H VIBRATIONS

Compound	μ	$cm.^{-1}$	$\epsilon \times 10^2$
Dimethyl hydrogen phosphonate	1.892	5285	26
Diethyl hydrogen phosphonate	1.891	5288	20
Diethyl hydrogen phosphonothioate	1.893	5283	25
Dibutyl hydrogen phosphonate	1.891	5288	23

The P—SH grouping is mainly unbonded at the concentrations used and gives rise to a weak doublet at 1.970 μ (5076 $cm.^{-1}$) and 1.999 μ (5002 $cm.^{-1}$) with intensities of 19 and 19 as indicated in Table X. In contrast, diethylaminoethanethiol and ethanethiol have a band near 1.740 μ (5747 $cm.^{-1}$) in the C—H A region which might be attributed to the S—H group. Phosphorothioic acids, which appear from the 3–15 μ region to have the P(S)OH structure, have a band at 1.908 μ (5241 $cm.^{-1}$) which may arise from the P—OH grouping.

Diethyl phosphoroamidate had NH overtones at 1.481 μ (6739 $cm.^{-1}$) and 1.488 μ (6720 $cm.^{-1}$) and a combination band at 1.992 μ (5020 $cm.^{-1}$) with intensities of 50, 56, and 197 respectively whereas C—NH bands absorb at 1.531 μ (6532 $cm.^{-1}$) and 1.548 μ (6460 $cm.^{-1}$) with intensities of 72 and 73 in isopropylamine and diisopropylamine respectively. There are numerous weak combination bands in these aliphatic amines, none with intensities over 55.

Ethanethiol	1.741	5744	65			
Ethyl methylphosphonothioic acid	1.906	5247	26			
Diethyl phosphorothioic acid	1.909	5238	49			

APPLICATION

A larger number of compounds have been examined which have C—H present in more than one type of group. Spectra have been predicted for these compounds and in Table IX the observed spectra are compared with the predicted spectra. For example, the spectrum of diethyl methylphosphonate is predicted by summing the band positions and intensities for one Me—P(O) and two EtO—P groups. Where bands occur within 0.005 μ in both types of group, or at greater separations in the case of broad bands, one band is predicted at intermediate values with intensity equal to the sum of both contributing groups.

It will be apparent that spectra of compounds with more than one type of C—H containing group cannot be predicted as accurately as those with only one such group. In particular, it is difficult to know when to average positions for bands of neighboring frequencies. Sometimes an average frequency band appears with intensities close to the summed value, and sometimes shoulders appear on the main band with intensities greater than would be predicted owing to the intensity contribution of the larger band. Bands which are weak in the parent compound may be absent or may appear as weak shoulders on the side of a larger band with consequently greater than predicted intensity. It is surprising that the agreement is as good as it is considering that the original intensity assignments are based on peak heights on a band contour, without analysis of the curves. Agreement in the B region is not so good, probably because of the greater complexity, and therefore greater interference from neighboring groups.

The same type of prediction can be made instrumentally. If it is desired to know the spectrum of a compound R′R″R‴P(X), where R′, R″, and R‴ are hydrogen-containing groups, equimolar quantities of R′P(X)Y_2, R″P(X)Y_2, and R‴P(X)Y_2, where Y is any group not containing hydrogen, are placed in series in the spectrophotometer and the addition spectrum is recorded. Three examples of this type of prediction are shown in Fig. 1. The intensities on the graphs are not directly comparable as different concentrations were used in the two cases. The extinction coefficients calculated from the curves show agreement of the same order with those calculated by addition of the extinction coefficients of the component curves.

ACKNOWLEDGMENT

Diethylaminoethanethiol was kindly supplied by Dr. K. F. Jennings, formerly of these Laboratories.

RÉSUMÉ

On a étudié les spectres infrarouges de quelques composés phosphorés dans la région 1.0–2.6 μ. Chaque radical donne plusieurs bandes charactéristiques qui sont presque indépendants des altérations de la molécule à des distances supérieures à deux atomes. On propose des fréquences charactéristiques pour les groupements MeO, EtO, *n*-PrO, *i*-PrO, *n*-BuO, Me, Et, Me_2N, Et_2N, et *i*-Pr_2N reliés directement au phosphore. Les autres substituants de l'atome de phosphore n'affectent que les bandes attribuées au groupement Me—P. D'ailleurs, on peut prédire qualitativement l'allure des spectres des composés contenant plus qu'un type de groupement C—H, en additionnant les fréquences et les intensités des groupes composants.

SEPARATIONS OF THE PLATINUM METALS BY ION EXCHANGE[1]

S. S. Berman and W. A. E. McBryde

ABSTRACT

Distribution coefficients for the chlorides of ruthenium, rhodium, palladium, iridium(III and IV), and platinum have been determined between the anion exchanger Amberlite IRA-400 and hydrochloric acid solutions of various molarities. Separations of various combinations of rhodium, iridium, palladium, and platinum in amounts of 0.5 mg. or less are described. When, in the course of these separations, the four metals are present together, special procedures are required to ensure complete recovery of platinum.

There have been several attempts to employ ion exchange in the separation of the platinum metals, but only a limited degree of success has been achieved. MacNevin and Crummett (1) suggested that a separation of rhodium, iridium, palladium, and platinum might be possible owing to the graded stabilities of the chloride and ammine complexes of these metals, but presented no experimental data. Another report by the same authors (2) elaborated on a separation of iridium from palladium achieved by converting the palladium to a cationic diammine, leaving the iridium as an anion, and separating the two on this basis. Stevenson *et al.* (3) submitted a note on the separation of the four metals on the cation exchanger Dowex-50, based on the formation of perchlorates of these metals by fuming their solutions with perchloric acid. No data were given, but this separation is of questionable value because of the inability to keep even milligram quantities of platinum and iridium from precipitating in this medium. Blasius and Wachtel (4) achieved separations of platinum from the other three metals by adsorbing the platinum complex on the anion exchanger Permutit-ES in the hydroxide form. The other three metals were eluted by a solution of sodium hydroxide, and the platinum recovered by elution with nitric acid. MacNevin and McKay (5) have prepared spectrographically pure rhodium through the formation of a cationic rhodium species, the other metals being left as anions. This separation is not quantitative. The separations of rhodium and iridium have been discussed in a previous paper (6).

The only equilibrium data recorded concerning the behavior of platinum metal complexes toward ion exchangers are those of Kraus *et al.* (7). These workers measured the distribution coefficients of chloroplatinate (IV) and chloropalladate (II) relative to the anion exchanger Dowex-1 in hydrochloric acid solutions.

In the following report the measurement of the distribution coefficients of ruthenium, rhodium, iridium, palladium, and platinum in hydrochloric acid solutions relative to the anion exchanger Amberlite IRA-400 is described, as well as a series of separations of these metals.

EXPERIMENTAL

Standard Solutions

Palladium.—A stock solution was prepared by dissolving pure palladium sponge in aqua regia, evaporating several times to dryness with hydrochloric acid, and then dissolving the residue and diluting with 0.1 *M* hydrochloric acid. This solution was standardized gravimetrically by precipitation with salicylaldoxime (8). Analyses for palladium were generally made colorimetrically by the potassium iodide method (9),

[1]*Manuscript received December 3, 1957.*
Contribution from the Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada.

but very small amounts (less than 10 μg.) were determined by the *p*-nitrosodimethylaniline procedure (10).

Platinum.—The stock solution was prepared by the dissolution of pure platinum sponge in aqua regia and treatment similar to that described for palladium. The solution was standardized by precipitation with 4-phenylthiosemicarbazide (11). Colorimetric analyses were made by the tin(II) chloride method (12).

Ruthenium.—A stock solution was prepared in 0.5 *M* hydrochloric acid from ammonium chlororuthenate crystallized from a solution of sodium chlororuthenate in hydrochloric acid. The solution was standardized by the evaporation of a measured quantity, followed by reduction of the salt to metallic ruthenium with hydrogen. Analyses were made colorimetrically by the thiourea procedure (13).

Rhodium and Iridium.—The preparation of standard solutions of these metals is described in a previous paper (6).

The Resin and Columns

The resin used in this research was Amberlite IRA-400 in an analytical grade. The dried resin was ground to yield fractions of various degrees of fineness. The portion of mesh size 70 to 100 was used for the measurement of distribution coefficients. It was found to be hygroscopic, and was dried at 100° C. prior to weighing, and was stored over anhydrous magnesium perchlorate. The exchange capacity was found to be 3.78 meq. per gram of dry resin. This was determined for 5.00-g. samples by the procedure of Fisher and Kunin (14).

For column work the resin of <100 mesh was used. The manner of preparing the resin to rid it of fine particles has been described in a previous paper (6). The columns were of conventional design in two sizes, having internal diameters of 10 mm. and 5 mm. respectively. The depth of resin in the bed varied among the different experiments, and is stated in the description of each. The flow of liquid through the beds was maintained at about 50 ml. per hour.

Measurement of Distribution Coefficients

The distribution coefficients of chloropalladate(II), chloroplatinate(IV), chloroiridate (IV), chloroiridate(III), chlororhodate, and chlororuthenate were measured in hydrochloric acid solutions. This was done by shaking a weighed amount, approximately 0.3 g., of resin with measured quantities of platinum metal solutions in 25.0 ml. of hydrochloric acid of various molarities for 40 hours. The mixtures were filtered, and 20.0-ml. aliquots of the filtrates analyzed. The amounts of metal adsorbed on the exchanger were thus found, and the distribution coefficients (amount of metal per kilogram of resin/amount per liter of solution) were calculated. In regions of very high adsorption 300 ml. of acid solution was used, and 250-ml. aliquots taken for analysis.

TABLE I

DISTRIBUTION COEFFICIENTS

	D

The amounts of resin and solution were selected to limit loading of the resin to no more than 2% of capacity.

The results are summarized in Table I and in Fig. 1.

A comparison of these values with those obtained by Kraus *et al.* (7) for Pd(II) and Pt(IV) shows good agreement in the low-adsorption range where these workers had low degrees of loading. In the high-adsorption range where these workers allowed the loading to become large there is a marked divergence, their distribution coefficients being much lower than those given here.

It is readily seen that Pt(IV) and Ir(IV) are very strongly adsorbed throughout the whole hydrochloric acid range, and Pd(II) at low hydrochloric acid concentrations.

According to Walton (15) practically all ion-exchange distribution data can be expressed by the Rothmund–Kornfeld equation

$$M_x/M_y = K\,((x)/(y))^p,$$

where M_x and M_y are the moles of x and y per gram of exchanger and (x) and (y) are their molar concentrations in solution; K and p are constants. Then by plotting $\log(M_x/M_y)$ against $\log((x)/(y))$ one should obtain a straight line.

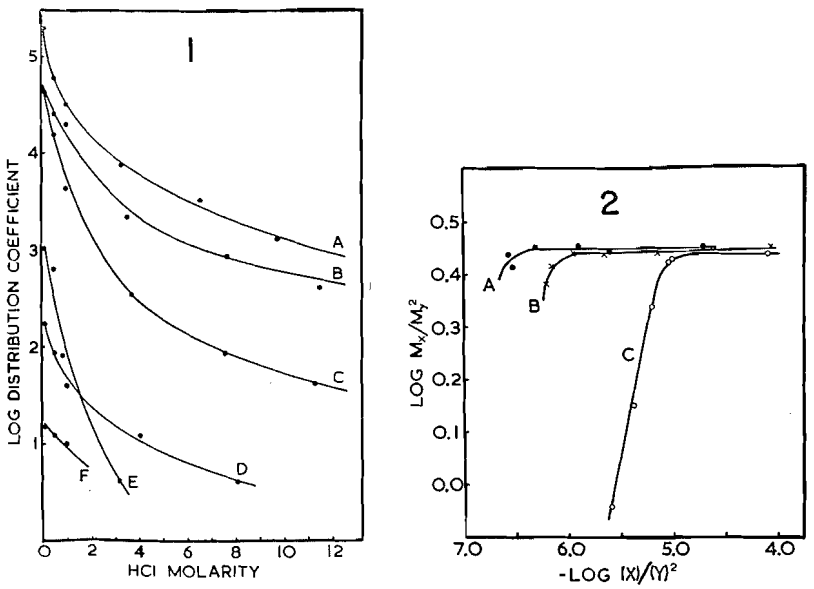

FIG. 1. The distribution coefficients of rhodium, iridium, platinum, palladium, and ruthenium in hydrochloric acid solutions. A: chloroiridate(IV), B: chloroplatinate(IV), C: chloropalladate(II), D: chlororuthenate(III), E: chloroiridate(III), F: chlororhodate.

FIG. 2. The distribution data plotted according to the Rothmund–Kornfeld equation. A: chloroiridate (IV), B: chloroplatinate(IV), C: chloropalladate(II).

This is, more or less, what happened when the data for Rh, Ru, and Ir(III) were plotted. However, the three other complexes produced interesting curves (Fig. 2). In regions of very high adsorption M_x/M_y^2 (the squared term arises since these complexes are doubly charged) is seen to be almost independent of the concentration ratio of complex to chloride in solution; i.e., $p \simeq 0$.

This might indicate that in these instances simple exchange equilibria are not taking place and that some mechanism other than ion exchange is the predominant factor.

An analogy may be seen here between this strong adsorption and the solubility of quaternary amine platinum metal chlorides. It is well known that Pt(IV) and Ir(IV) form relatively insoluble salts with quaternary amines of the type $(R_4N)_2PtCl_6$. Since the anion exchanger is in effect a polystyrenedivinylbenzene quaternary amine, it may be that the same forces that produce the insoluble salts contribute to the strong adsorption of these complexes on the resin. Palladium(II) is known to form a number of insoluble diammine dichloride complexes, the solubility of which is greater in concentrated hydrochloric acid than in neutral solution. The behavior of palladium toward the resins may be, in the same fashion, compared with the formation of ammine precipitates of this sort.

To further illustrate this analogy 5 ml. of 0.2 *M* tetrabutylammonium chloride was added to 10 mg. of each of the six complexes in 5 ml. of 0.5 *M* hydrochloric acid. Precipitates formed in the tubes containing Pd(II), Pt(IV), and Ir(IV). When 1 ml. of concentrated hydrochloric acid was added to each of these, the palladium precipitate dissolved instantly and the iridium precipitate partially dissolved. Further addition of hydrochloric acid resulted in the complete dissolution of the iridium precipitate, but the platinum precipitate could only be partially dissolved by this means.

While the above experiment does not prove that stable resin–platinum metal compounds are formed analogous to insoluble precipitates, the parallel between these observations and subsequent column experiments was striking. For example, it was possible to remove Pd(II) from the resin by elution with concentrated hydrochloric acid. Pt(IV) and Ir(IV) cannot be completely recovered by this means. The iridium complex may be removed by a hot extraction with hydrochloric acid, but even this rather violent treatment will only partially remove the platinum complex.

The Separation of Palladium and Platinum

The purpose of this research was to develop an ion-exchange procedure for this separation which could be integrated with the rhodium–iridium separation previously reported (6). Also, the recovery of Pd(II) and Pt(IV) from anion exchangers by a wet method has long been a problem and an obstacle in the application of anion exchange in the separation of platinum from base metals.

It was confirmed that Pd(II) and Pt(IV) can be quantitatively adsorbed from dilute hydrochloric acid solutions on an anion exchanger, Amberlite IRA-400.

The Recovery of Palladium

Five milliliters of 1 *M* hydrochloric acid containing approximately 500 γ of palladium were fed onto 2.5-cm. resin beds in the larger columns which had been previously washed with 25 ml. of the acid solution. Complete recovery of the palladium was achieved by 100 ml. of 12 *M* hydrochloric acid.

Number of experiments	5
Palladium taken	478 γ
Palladium recovered (range)	476–480 γ (see Fig. 3)

It was found that no platinum was eluted provided these beds were at least 2.3 cm. deep.

The work was repeated with 3-cm. beds in the smaller columns. Complete recovery was achieved by 40 ml. of 12 *M* hydrochloric acid or by 60 ml. of 9 *M* acid (see Fig. 3). The use of 6 *M* acid resulted in too much tailing to be of value. However, it was found that 40 ml. of 12 *M* hydrochloric acid eluted much platinum, whereas 60 ml. of 9 *M* acid eluted none.

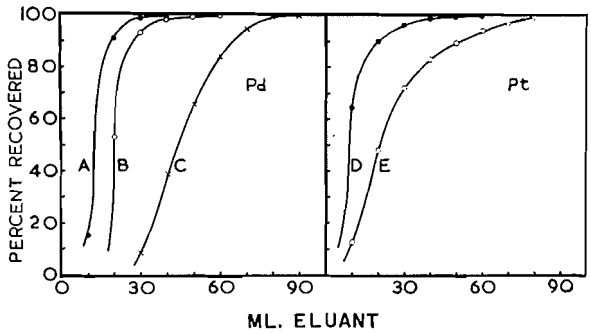

FIG. 3. Some typical elution curves for chloropalladate(II) and chloroplatinate(IV). A: chloropalladate(II) eluted with 12 *M* hydrochloric acid solution (small column), B: chloropalladate(II) eluted with 9 *M* hydrochloric acid solution (small column), C: chloropalladate(II) eluted with 12 *M* hydrochloric acid solution (large column), D: chloroplatinate(IV) eluted with 2.4 *M* perchloric acid solution (small column), E: chloroplatinate(IV) eluted with 15% (w/v) zinc chloride in 9 *M* hydrochloric acid solution at 96° C. (large column).

It was also shown that Pd(II) could be easily recovered by elution with dilute perchloric acid solutions. The recoveries observed for elution with 40 ml. of 0.5 *M* perchloric acid were as follows:

Number of experiments	3
Palladium taken	478 γ
Palladium recovered	478–481 γ

Since perchloric acid was later shown to be a good eluant for Pt(IV) this reagent cannot be used to separate the two metals.

Recovery of Platinum

Platinum was fed onto 2.5-cm. resin beds in the larger columns in a manner similar to the palladium.

It was verified that solutions of hydrochloric, nitric, or sulphuric acids, either dilute or concentrated, elute only part of the Pt(IV). The same is true for ammoniacal eluants. Working at elevated temperatures produced only minor improvements in the recoveries.

Kraus and his co-workers (7, 16) noted the high affinities of zinc and cadmium chloride in hydrochloric acid solutions toward anion exchangers. Preliminary experiments with 2.5 *M* solutions of both these salts in 9 *M* hydrochloric acid showed better recoveries of platinum than had been previously achieved. It was found that 93% of the Pt(IV) could be recovered by the zinc chloride solution, and that quantitative recoveries could be achieved if the column were surrounded with a hot-water jacket at 96° C. The following recoveries were made by elution with 90 ml. of a 15% (w/v) solution of zinc chloride in 9 *M* hydrochloric acid at 96° C. (see also Fig. 3).

Number of experiments	3
Platinum taken	490 γ
Platinum recovered	488–494 γ

Experiments showed that the Pt(IV) could also be quantitatively recovered by 90 ml. of 2.4 *M* perchloric acid. The same observation was made with 3-cm. resin beds in the smaller columns; in these cases the platinum was recovered by 60 ml. of the 2.4 *M* perchloric acid (see Fig. 3).

Number of experiments	7
Platinum taken	490 γ
Platinum recovered (4 cases)	488–492 γ (l)*
(3 cases)	488–490 γ (s)*

*l means larger column, s smaller.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Attempts to recover the Pt(IV) by a Soxhlet extraction were unsuccessful. Extraction with 6 *M* hydrochloric acid produced recoveries of only about 30%. Recoveries of about 90% were achieved with 8 *M* nitric acid.

The recovery of platinum by ashing the exchanger was also investigated. This method had previously been reported as successful by Sussman *et al.* (17) but no data were given. The resin containing the adsorbed Pt(IV) and the glass wool plug were transferred to a small crucible and dried under a heat lamp. The crucible was placed in a furnace at 300° C. and the temperature raised to 900° over the course of an hour. The crucible was removed, cooled, and set over a boiling-water bath for 1 hour after the addition of 3 or 4 ml. of aqua regia. There was no residue evident in the crucible after this treatment save for the bit of fused glass wool. Results of the analysis of this solution after filtration are given below, and indicate that this procedure is a simple and satisfactory one for the recovery of the metal.

Number of experiments	3
Platinum taken	490 γ
Platinum recovered	491–492 γ

Separation of Palladium and Platinum

Separations were carried out in both large and small columns. Mixtures of the metals containing 6 mg. of sodium chloride (to prevent baking of the metal on the bottom of the beaker) were evaporated to dryness and the residue dissolved in one or two milliliters of water. This solution was fed onto the resin bed with a dropper. The larger beds were 2.5 cm. deep and were eluted with 100 ml. of 12 *M* hydrochloric acid followed by 90 ml. of 2.4 *M* perchloric acid. The smaller columns contained resin beds 3 cm. deep, and were eluted with 60 ml. of 9 *M* hydrochloric acid followed by 75 ml. of 2.4 *M* perchloric acid. The results are summarized below:

Number of experiments	7	2
Platinum taken	490 γ	98 γ
Platinum recovered (4 cases)	487–496 γ (l)	
(3 cases)	490–491 γ (s)	97–102 γ
Palladium taken	478 γ	96 γ
Palladium recovered (4 cases)	468–480 γ (l)	
(3 cases)	476–478 γ (s)	95–96 γ

Separations of Various Mixtures of Platinum Metals in Solution

From the satisfactory results obtained in the rhodium–iridium and palladium–platinum separations it was felt that separations of all combinations of the four metals could be achieved, although separations of mixtures containing both rhodium and iridium would obviously have to be carried out in two stages. This turned out to be an overly optimistic assumption when iridium, palladium, and platinum are all present, but, generally, some very satisfactory separations were made.

Rhodium and Palladium

This separation was first done on 2.3-cm. beds in the larger columns. The beds were washed prior to use with 10 ml. of 2 *M* hydrochloric acid. A solution containing the two metals in 5 ml. of 2 *M* hydrochloric acid was fed onto the bed, and the latter eluted with 90 ml. of the acid solution to remove the rhodium. Elution was continued with 100 ml. of 12 *M* hydrochloric acid to recover the palladium. A previous experiment showed that no palladium was eluted by 90 ml. of the 2 *M* hydrochloric acid. The results of this separation are tabulated below.

Further separations were carried out in the smaller columns with 3-cm. resin beds which were previously washed with 10 ml. of 2 *M* hydrochloric acid. In this case the solutions

were evaporated to dryness with 6 mg. of sodium chloride, redissolved in one or two milliliters of water, and fed onto the bed with a dropper. Elutions were made with 50 ml. of 2 *M* hydrochloric acid followed by 50 ml. of 9 *M* hydrochloric acid. The results are included in the following table.

Number of experiments	6
Rhodium taken	499 γ
Rhodium recovered (3 cases)	499–500 γ (l)
(3 cases)	500–501 γ (s)
Palladium taken	478 γ
Palladium recovered (3 cases)	478–479 γ (l)
(3 cases)	476–478 γ (s)

It was noticed in this separation that as the rhodium was being eluted with the 2 *M* hydrochloric acid the palladium band slowly moved and diffused part way down the bed. This is the only instance in this work where a platinum metal band was seen to move. Owing to this partial migration it was possible to recover the palladium with 40 ml. of 9 *M* hydrochloric acid (Fig. 4) in contrast to the 60 ml. needed in the palladium–platinum separation.

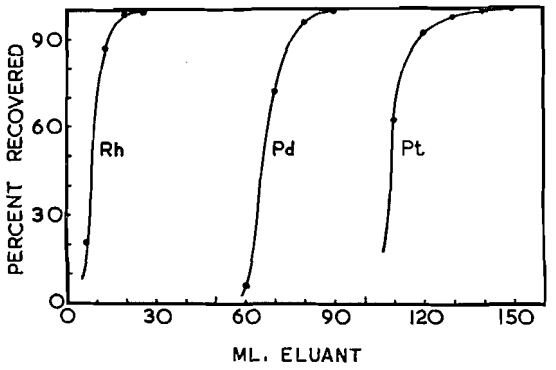

FIG. 4. Elution curves for the separation of rhodium, palladium, and platinum (small column). Rh: eluted with 50 ml. 2 *M* hydrochloric acid solution, Pd: eluted with 50 ml. 9 *M* hydrochloric acid solution, Pt: eluted with 75 ml. of 2.4 *M* perchloric acid solution.

Rhodium and Platinum

This separation was not attempted, but since the separation of rhodium, palladium, and platinum is feasible (see below) there is no reason why it should not be easily accomplished.

Iridium and Palladium

This separation was done in the larger columns in a manner similar to the separation of rhodium and palladium. The iridium was reduced to the tervalent state by hydroxylamine prior to feeding onto the column. The bed was eluted with 90 ml. of 2 *M* hydrochloric acid to recover the iridium, and then 100 ml. of 12 *M* hydrochloric acid for the palladium. The results are summarized as follows:

Number of experiments	3
Iridium taken	454 γ
Iridium recovered	452–454 γ
Palladium taken	478 γ
Palladium recovered	474–478 γ

Iridium and Platinum

This separation was not tried, but experiments described below indicate that it is quite feasible.

Rhodium, Palladium, and Platinum

One separation of these three metals was made to gather data for Fig. 4. This is the only three-metal separation that can be made with only one column. A solution containing the three metals was evaporated to dryness with 6 mg. of sodium chloride. The residue was redissolved in 2 ml. of 2 *M* hydrochloric acid solution and fed with a dropper onto a small 3-cm. resin bed which had been previously washed with 10 ml. of the acid solution. The bed was eluted with 50 ml. of 2 *M* hydrochloric acid, followed by 50 ml. of 9 *M* hydrochloric acid, and then 70 ml. of 2.4 *M* perchloric acid.

Rhodium, Iridium, and Palladium

Solutions of these three metals were evaporated to dryness with 6 mg. of sodium chloride and the residues redissolved in 1 ml. of water. The iridium was reduced with a few drops of 1% hydroxylammonium chloride solution, and the solutions fed onto 3-cm. beds in small columns. These beds had been previously washed with 10 ml. of 2 *M* hydrochloric acid. The beds were eluted with 80 ml. of the acid solution to recover the rhodium and iridium, followed by 50 ml. of 9 *M* hydrochloric acid for the palladium. The first effluents were evaporated to dryness and the residues redissolved in 2 ml. of 0.8 *M* hydrochloric acid (also containing cerium(IV) sulphate at a concentration of 0.001 *M*). These solutions were fed with a dropper onto small columns containing 3-cm. beds of resin which had been prepared with quadrivalent cerium, and the rhodium–iridium separation was carried out as described in the previous communication (6).

The procedure was repeated but the palladium was eluted with 50 ml. of 0.5 *M* perchloric acid. The rhodium and iridium were not determined in these experiments. The various results are summarized below.

Number of experiments	3
Iridium taken	454 γ
Iridium recovered	451–456 γ
Rhodium taken	499 γ
Rhodium recovered	495–500 γ
Palladium taken	478 γ
Palladium recovered	476–479 γ (eluted with HCl) 476–479 γ (3 eluted with $HClO_4$)

Rhodium, Iridium, and Platinum

The procedure was exactly as described above except that the beds were eluted with 80 ml. of 2 *M* hydrochloric acid followed by 75 ml. of 2.4 *M* perchloric acid for the platinum.

Number of experiments	3
Iridium taken	454 γ
Iridium recovered	451–456 γ
Rhodium taken	499 γ
Rhodium recovered	498–501 γ
Platinum taken	490 γ
Platinum recovered	490–492 γ

Rhodium, Iridium, Palladium, and Platinum

Solutions containing these four metals were evaporated to dryness with 6 mg. of sodium chloride, and the residues redissolved in 1 ml. of water. A few drops of hydroxylamine solution were added to reduce the iridium, and the solutions were then fed onto 3-cm. beds in small columns. The beds were eluted with 80 ml. of 2 *M* hydrochloric acid followed by 50 ml. of 9 *M* hydrochloric acid, and then with 75 ml. of 2.4 *M* perchloric acid. The first effluents were treated for a separation of rhodium and iridium as described above. Good results were obtained for the recovery of rhodium, iridium, and palladium, but the platinum recoveries were all low by about 25%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Further examination showed that some platinum was being eluted along with the palladium but had not been noticed since this small quantity produced a negligible interference in the palladium determinations. It is believed that this early elution of the platinum was due to a partial reduction of the quadrivalent metal to the bivalent state by the hydroxylamine used to reduce the iridium. The bivalent platinum evidently has much the same affinity for the resin as the bivalent palladium.

An unsuccessful search was made for a reducing agent which would reduce the quadrivalent iridium but not any of the quadrivalent platinum. Best results (94% recovery of the platinum in the "platinum fraction") were obtained by the slow reduction of the iridium in neutral solution by sodium oxalate.

An attempt to reoxidize the platinum on the exchanger with cerium(IV) after the removal of the tervalent iridium was also unsuccessful.

One separation of the four metals was carried out in which the "palladium fraction" was evaporated to a few milliliters, boiled with nitric acid to oxidize the platinum, and evaporated twice to dryness with hydrochloric acid. The residue was dissolved in a few milliliters of 2 *M* hydrochloric acid, and this solution treated as described above for the separation of palladium and platinum. In this way platinum was completely recovered in two fractions.

	Taken	Found
Rhodium	499 γ	501 γ
Iridium	454 γ	451 γ
Palladium	478 γ	479 γ
Platinum	490 γ	363 plus 127 = 490 γ

Hydrolytic Separation of Rhodium, Iridium, and Palladium from Platinum on a Microgram Scale

The generally accepted procedure of precipitating rhodium, iridium, and palladium as hydrated oxides as a method of separating these metals from platinum has never been applied on a microgram scale. In view of the relative difficulty encountered in the four-metal separation described above it was decided to investigate the possibility of removing the platinum by this method prior to applying an ion-exchange separation for the remaining three metals.

The procedure followed was generally that described in *Applied inorganic analysis* (18), pp. 376–377, except that a carrier was employed to aid in the precipitation of the small quantities of the metals present. Both titanium(IV) sulphate and cerium(IV) sulphate were used for this purpose. The cerium salt was finally chosen because its precipitate was easier to handle.

A solution of platinum was evaporated to dryness with 6 mg. of sodium chloride in a 30-ml. beaker. The residue was dissolved in 1 ml. of 2 *M* hydrochloric acid and diluted to about 5 ml. with water. The solution was then heated to boiling and about 5 mg. of cerium(IV) sulphate was added followed by 5 ml. of a filtered solution of sodium bromate. A filtered 10% solution of sodium bicarbonate was added slowly until the first trace of a permanent precipitate formed. Then 5 ml. more of the sodium bromate solution was added. Addition of bicarbonate was continued until no further precipitation was evident. Another 5 ml. of bromate solution was added, and the mixture was boiled for 10 minutes. The mixture was allowed to cool, the precipitate to settle, and the whole was then filtered through a porcelain filter crucible of medium porosity. The precipitate was washed with 0.1 *M* sodium chloride solution. The filtrate was boiled with hydrochloric acid to destroy the bromate, and analyzed for platinum. Complete recovery of the platinum was obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Solutions of the four metals were treated as above, and again all the platinum was found in the filtrates, indicating its separation from the other three metals.

The oxide precipitate from one of these experiments was dissolved in concentrated hydrochloric acid, evaporated to dryness, and the three metals separated as described above. A quantitative separation of the four metals was accomplished by this means.

	Taken	Found
Rhodium	499 γ	502 γ
Iridium	454 γ	451 γ
Palladium	478 γ	481 γ
Platinum	490 γ	492 γ

These experiments indicate that the ion-exchange separations may be integrated with a Gilchrist–Wichers type of scheme (18) for the analysis of the platinum metals on a microgram scale.

Separation of Rhodium and Ruthenium

It has been noted that this separation is of interest to radiochemists since rhodium is a daughter of ruthenium by beta decay. Some qualitative experiments were made to determine the feasibility of making the separation by ion exchange.

Ruthenium behaves toward the exchanger much like iridium. The quadrivalent complex is strongly adsorbed but appears to be partially reduced by the resin so that relatively large losses occur in the feed effluent. This can be remedied by the addition of an oxidant such as cerium(IV) to the feed solution. Attempts to elute the quadrivalent ruthenium with hydrochloric acid were unsuccessful, as was an attempt to reduce it on the resin with a 1% solution of hydroxylammonium chloride. The tervalent complex has a very low affinity for the resin, and a separation of it from tervalent rhodium does not seem to be possible.

It is possible that a procedure similar to that evolved for the separation of rhodium and iridium could be developed to separate the two metals in solution, but the problem of the quantitative removal of the quadrivalent ruthenium from the resin requires further study.

ACKNOWLEDGMENTS

This investigation was assisted by a grant from the University of Toronto's Advisory Committee on Scientific Research, for which grateful acknowledgment is made. One author (S.S.B.) was holder in 1955–56 and 1956–57 of a fellowship given to the university by Canadian Industries Ltd., for which our thanks are here recorded.

THE SEPARATION OF RHODIUM AND IRIDIUM BY ION EXCHANGE[1]

S. S. Berman and W. A. E. McBryde

ABSTRACT

Separations of rhodium and iridium as chlorides by means of columns of the anion exchanger Amberlite IRA-400 are described. Iridium is maintained in the quadripositive state by the addition of cerium(IV), the presence of which is necessary to counteract the reducing action of the resin. The marked difference in affinity toward the resin of Ir(IV) and Rh(III) makes the separation possible. Rhodium can easily be eluted from the resin by 2 *M* hydrochloric acid. Removal of all the iridium from the resin is accomplished in a Soxhlet extractor with 6 *M* hydrochloric acid. A number of less successful procedures for this separation are discussed.

In recent years there have appeared several procedures employing ion-exchange resins for the separation of rhodium and iridium, an operation which may be regarded as the most difficult step in the analysis of the elements of the platinum metal group. Cluett *et al.* (1) proposed a method applicable to mixtures containing 10 mg. or more of each of the metals. This method can be criticized on two accounts. Removal of iridium from the exchanger required the use of large quantities of salts and acids which must be destroyed prior to the determination of the iridium. Also, losses of iridium in the feed solution indicated that attempts to use the procedure for smaller quantities of the metals would lead to relatively appreciable quantities of iridium remaining with the rhodium. The method of Berg and Senn (2) which separates the metals on the basis of oppositely-charged thiourea complexes suffers from the time-consuming necessity of destroying the thiourea prior to the analysis of the rhodium and iridium. MacNevin and McKay (3) claim to produce spectrographically pure rhodium from a rhodium–iridium mixture, but the separation is not quantitative.

The purpose of this work was to develop a relatively simple quantitative separation of the two metals which would lend itself to their subsequent analysis without difficulty. This separation is necessary, since, to date, no satisfactory specific reagent for either of these elements has been found.

The procedure described below is based, like that of Cluett *et al.*, on the strong affinity of chloroiridate(IV) toward the anion exchanger in contrast with the relatively weak affinity of the chlororhodate complex. Losses of iridium in the feed solution have been eliminated by the choice of a suitable oxidant, and a simple method of extraction of the iridium complex from the resin has been developed.

EXPERIMENTAL

Apparatus and Solutions

Stock solutions of rhodium and iridium were prepared by dissolving highly refined chloro salts, which had been obtained from the International Nickel Company of Canada, respectively in 0.05 *M* and 0.1 *M* hydrochloric acid. The rhodium solution was standardized gravimetrically (4) and the iridium solution volumetrically (5). These solutions contained approximately two milligrams of metal per milliliter of solution. They were diluted 20-fold with 0.1 *M* hydrochloric acid in the following work.

Two sizes of columns, of conventional design, were used. The larger were 10 mm. in internal diameter and about 20 cm. in height; the smaller were 5 mm. in internal diameter and about 12 cm. in height. A flow rate of about 50 ml. per hour was used.

The resin used was Amberlite IRA-400 of an analytical grade. Conversion to the chloride form was ensured by stirring the resin for several hours with a large excess of 2 *M* hydrochloric acid. At the same time the resin was freed of small bits of foreign matter which usually floated on the surface of the supernatant liquid. The resin was dried at 110° C. and ground to yield two fractions, one of which was of mesh size 70 to 100 and the second of mesh size less than 100. The latter fraction was freed of very fine particles by shaking with the acid solution, allowing the bulk of the resin to settle, and pouring off the fines. This was repeated until the resin settled completely within a few minutes. The resin was stored in a solution of 2 *M* hydrochloric acid.

In some experiments the iridium was removed from the resin by a Soxhlet extraction. For this purpose a microextractor was used, Corning No. 3860.

Methods of Analysis

Determinations of rhodium were made with the colorimetric procedure employing tin(II) chloride described by Sandell (6). Dilutions were made with 2 *M* hydrochloric acid. Optical densities were measured with a Beckman Model DU spectrophotometer at 470 mμ.

Iridium was determined by the tin(II) chloride–hydrobromic acid procedure of Berman and McBryde (7).

The Adsorption of Iridium on the Exchanger

The development of a sensitive colorimetric procedure for the determination of iridium enabled the authors to carry out a more extensive study of the adsorption of quadrivalent iridium on the resin than was previously possible.

It had been previously demonstrated by Cluett *et al.* (1) that maximum adsorption of chloroiridate(IV) by the exchanger necessitated the presence of an oxidizing agent. That the resin is indeed a mild reducing agent was demonstrated by the following experiments.

A solution containing approximately 500 γ of iridium in 5 ml. of 1 *M* hydrochloric acid was fed onto a 3-cm. bed of 70–100-mesh resin, which had been previously washed with a solution of 1 *M* hydrochloric acid. A dark brown band, characteristic of chloroiridate(IV), formed at the top of the bed. After 16 hours of standing the color of the band had appreciably lightened. After 40 hours the band was no longer visible. This seemed to indicate that the quadrivalent iridium had been slowly reduced to the almost colorless tervalent complex. Elution of the resin bed with 100 ml. of 6 *M* hydrochloric acid yielded about 350 γ of iridium in the effluent, indicating that the reduction was not complete.

Ten milliliters of a 0.1 *N* solution of potassium dichromate was fed onto a resin bed, resulting in an orange-red adsorption band at the top of the bed. After a day a green solution, presumably containing tervalent chromium, was seen diffusing down through the bed.

A solution of 0.8 *M* hydrochloric acid containing about 5 mg. of cerium as cerium (IV) sulphate was passed very slowly through a resin bed. The effluent was colorless, characteristic of a solution of cerium(III).

Bromine as the Oxidant

Choice of a suitable oxidant to counteract the effect of the resin is limited by the fact that chloroiridate(IV) is itself a strong oxidant (E^0 = 1.02 v. (8)). The first choice for this purpose was bromine (E^0 = 1.09 v.). Resin beds 2.5 cm. deep were prepared by transferring the 70–100-mesh resin to the larger columns, and shaking with one or two columnfuls of 0.1 *M* hydrochloric acid containing 10% saturated bromine water by

volume. (The resin had been previously extracted with 6 *M* hydrochloric acid in a Soxhlet extractor to minimize color throwing.) Then 454 γ of iridium in 5 ml. of 0.1 *M* hydrochloric acid was fed onto the column. In most of the experiments the bed was washed with a quantity of the bromine water – hydrochloric acid solution prior to the feeding of the iridium solution. After feeding, the resin bed was washed with 20 ml. of this same solution, and was then eluted with more of the solution to simulate the removal of rhodium. The feed and wash effluents and the simulated "rhodium fraction" were collected separately and evaporated to about one milliliter in volume. A few milliliters of 30% hydrogen peroxide solution was added to each to destroy a yellow-colored material in solution which was usually present and presumably came from the resin. The solutions were boiled to expel bromine and excess hydrogen peroxide, evaporated to near dryness, and analyzed for iridium. To check whether the colored species in the iridium analysis was due to iridium and not to some interfering foreign matter, the spectral curve of each sample was examined in the vicinity of 402 mμ and compared with a known iridium spectrum.

In the following account the bromine water – hydrochloric acid solution will be referred to as the feed solution. It is evident from Table I that the losses of iridium may be considerably reduced by substantial pretreatment of the resin bed. Losses in the last three experiments amount to less than 0.25% of the iridium fed onto the bed.

TABLE I

EFFECT OF PRETREATMENT OF RESIN ON ADSORPTION OF 454 γ OF CHLOROIRIDATE(IV)

Columns of feed soln. shaken with resin	Volume of preliminary wash, ml.	Volume of eluant, ml.	Ir in feed and rinse, μg.	Ir in "Rh fraction", μg.
1	0	100	22	4
1	5	100	2.7	7.6
1	80	100	1.5	3.0
2	100	100	1.0	1.8
2	200	70	Combined — 0.0	
2	200	75	Combined — 1.1	
2	200	75	Combined — 1.1	

However, further work showed that 75 ml. of the feed solution would elute only about 90% of a 499-γ rhodium sample treated in a manner similar to the last three experiments described in Table I, and that any procedure which would quantitatively recover the rhodium resulted in a loss of 4 to 5 γ, or approximately 1% of the iridium taken.

It was also shown, by taking a 45.4-γ sample of iridium, that the loss is more or less an absolute one, and not strictly proportional to the quantity of iridium fed. This may be a serious drawback if such a procedure were to be adapted to micro separations, as the relative loss of iridium would be significant.

An explanation of why losses occur in the presence of this oxidant may be based on the following observation. It was noticed that when the bed was washed with a quantity of the feed solution prior to the feeding of the iridium, the bromine was adsorbed from the solution in a red band at the top of the resin bed. When the quadrivalent iridium was fed, the dark brown band due to this complex did not form at the top of the bed but rather directly below the bromine band, indicating that the bromine had occupied sites on the resin and had made them unavailable to the chloroiridate(IV). Since chloroiridate(IV) has an exceptionally high affinity for the resin, the bromine must indeed be very strongly bound, with a resultant decrease in its activity and in its ability to act as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

a mobile oxidant toward any iridium that may have been reduced by the resin. The strong affinity of bromine for the resin was further demonstrated by the inability of a sample of resin which had been saturated with bromine to adsorb any chloroiridate(IV).

Substantially the same results were obtained when chlorine was used as the oxidant in place of bromine.

Cerium(IV) as the Oxidant

In view of the above experience with bromine it was decided that a truly effective oxidant would have to be one which would not itself be adsorbed by the exchanger, nor would oxidize chloride at the concentrations of hydrochloric acid used. The only oxidant found which met these conditions was quadrivalent cerium. The use of cerium(IV) limits the acid concentration permissible to the range of 0.5 *M* to 1 *M*. In acid solutions below this range the cerium salts hydrolyze. In solutions more concentrated than this range chloride is oxidized to chlorine.

The oxidizing solution was prepared by adding 1 ml. of 0.1 *M* cerium(IV) sulphate to 100 ml. of 0.8 *M* hydrochloric acid.

Resin beds 2.5 cm. deep were washed with 10 ml. of water and then rinsed with 10 ml. of the cerium solution. The washing with water was found to be essential for the elimination of iridium losses, although the authors can find no plausible explanation for this. Five milliliters of 0.1 *M* hydrochloric acid solution containing 454 γ of iridium was fed onto the beds, which were then eluted with a further 90 ml. of the cerium solution to simulate the removal of rhodium. The feed effluents and the "rhodium fractions" were passed through large cation-exchange beds to remove the cerium, evaporated to near dryness, and analyzed for iridium. A yellow residue was always present which was found to contain iron (presumably from the resin). Examination of the spectra in the vicinity of 402 mμ showed that no iridium was present.

Similar experiments with 499 γ of rhodium showed that this element is quantitatively recovered in the combined feed and eluate solutions. It was also established that cerium interferes but little in the colorimetric determination of rhodium, and need not be removed if a set of appropriate standards is prepared for comparison. If desired, the cerium can easily be removed by passage of the solution through a bed of Dowex-50.

The Recovery of Iridium

The recovery of iridium adsorbed on an anion exchanger has long been a problem. The metal cannot be conveniently recovered by ashing the resin as Sussman *et al.* (9) did for platinum and palladium because of the difficulty in redissolving it for the purpose of analysis. The only successful wet procedure reported is that of Cluett *et al.* (1) which is very time-consuming and extravagant of reagents.

Elution of Iridium by a Reducing Agent

Since the affinity of chloroiridate(III) for the exchanger is small in hydrochloric acid solutions more concentrated than 1 *M* it was thought that it might be possible to reduce the quadrivalent iridium complex on the resin and elute the tervalent species with hydrochloric acid. The choice of reductants is limited by three factors. Iridium is a noble metal; the determination of iridium is impossible in the presence of most metals; and, also, the reductant should not be adsorbed on the exchanger or the same type of situation may result as was experienced with bromine.

Several experiments were conducted using 1% and 4% solutions of hydroxylammonium chloride and hydrazine hydrochloride as the reductants. The iridium solutions were fed in the presence of cerium(IV) as described in the adsorption experiments. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

bed was rinsed with 20 ml. of 0.8 *M* hydrochloric acid to remove the cerium, and then 25 ml. of the reducing solution was passed through, followed by a dilute solution of hydrochloric acid. The two effluents were collected together and several milliliters of 30% hydrogen peroxide solution was added to destroy the reductant. The solutions were evaporated to near dryness to destroy most of the acid, and then were analyzed for iridium.

Results for the two reductants were much the same. Immediately they came in contact with the adsorption band, it disappeared, indicating that reduction had taken place. Recoveries of iridium ranged from 88% to 96%, and did not seem to depend on the concentration of the reducing agent or on the concentration of the hydrochloric acid eluant. It appears that some of the adsorbed iridium is not readily available for reduction. These results compare closely with those obtained with an ammoniacal elution (1) which also involves a reduction process.

Perchloric Acid as an Eluant

It was hoped that the affinity of the perchlorate anion, which is by far the strongest of all common anions for the exchanger (10), would be great enough to displace the chloroiridate(IV) complex.

The resin beds were fed with iridium as described above and then eluted with 100 ml. of a 10% (v/v) solution of perchloric acid. The bands slowly faded and the effluents were the color of chloroiridate(IV). However, recoveries of only about 80% were achieved, and they were not improved by increasing the concentration of the acid or the volume of the eluting solution.

Recovery by Soxhlet Extraction

Iridium was fed onto resin beds 2 cm. deep in small columns as described above, and the beds were washed free of cerium with 20 ml. of 0.8 *M* hydrochloric acid. The upright part of the column was removed and the beds allowed to drain. The columns were then inverted and the resin bed was shoved out, along with the glass-wool supporting pad, with a stirring rod into a specially prepared glass thimble. This thimble was made by blowing a small hole in the bottom of a soft-glass test tube, cutting the tube to the appropriate length, and pulling some glass wool through the hole so that liquids would pass through but not resin particles. (The resin used in these experiments had previously been extracted to reduce color-throwing.) The thimble was placed in the small extractor and 15 ml. of 6 *M* hydrochloric acid in the pot, and the resin extracted for ½ hour.

The solutions in the pot after the extractions were pale brown in color, not as dark as chloroiridate(IV) but far from the almost colorless chloroiridate(III). These were transferred to 30-ml. beakers, evaporated to almost dryness, and analyzed for iridium with results as follows:

Number of experiments	3
Iridium taken	454 γ
Iridium recovered (range)	452–455 γ

The recovery of iridium is quantitative by this procedure. A possible explanation for the success of this operation is that the increase in temperature enhanced the reducing properties of the resin, causing reduction of the iridium most intimately bound in the resin matrix, and making it available for leaching with the hot acid solution. It is probably this iridium that cannot be reached by conventional eluants. That partial reduction had taken place was demonstrated by the restoration of the intense chloroiridate(IV) color on the addition of a few drops of 30% hydrogen peroxide solution.

Although this operation may seem rather complicated it is in reality quite simple and quick. The recovery and analysis of the iridium can easily be done in $1\frac{1}{2}$ hours.

Separation and Analysis of Rhodium–Iridium Mixtures in Solution

The following procedure was successfully used to separate and analyze mixtures of rhodium and iridium in hydrochloric acid solution.

The samples were evaporated to dryness with a few milliliters of concentrated hydrochloric acid and 6 mg. of sodium chloride in 30-ml. beakers. The residues were dissolved in about 2 ml. of 0.8 *M* hydrochloric acid, and fed with a dropper onto 1.5-cm. beds of 70–100-mesh resin in small columns (which had been previously washed with 10 ml. of water and 10 ml. of the cerium(IV) solution as described above). The beakers were twice rinsed with 2 ml. of the acid solution, and the beds then eluted with 90 ml. of the cerium solution. The effluents were collected together, evaporated to a few milliliters, and analyzed for rhodium. The resin bed was extracted as described above and the recovered iridium determined.

Number of experiments	4	2
Iridium taken	454 γ	45.4 γ
Iridium recovered (range)	453–457 γ	45.0–45.2 γ
Rhodium taken	499 γ	49.9 γ
Rhodium recovered	500 γ	50.1–50.3 γ

Batch Separations of Rhodium and Iridium

An attempt to separate these two metals by stirring a solution containing them with a quantity of resin in the presence of an oxidant was not successful. Although conditions were found where no rhodium was adsorbed by the exchanger the rhodium always contained at least 10% of the iridium originally present.

The Separation of Chlororhodate and Chloroiridate(III)

Examination of the distribution coefficients (11) for the chlororhodate and chloroiridate(III) complexes indicates that a separation of these two species should be feasible on an anion exchanger with dilute hydrochloric acid solutions as eluants. A procedure of this nature would have the advantage of having the iridium on the resin in an easily eluted state.

Solutions containing approximately 500 γ of rhodium and iridium and 6 mg. of sodium chloride were evaporated to dryness. The residues were dissolved in 1 ml. of water, a few drops of a 1% solution of hydroxylammonium chloride added to reduce the quadrivalent iridium, and the solutions fed onto 3-cm. beds of $<$100-mesh resin in the small columns.

The rhodium complex formed a red band at the top of the bed. This band is not visible when the rhodium is fed in hydrochloric acid medium more concentrated than 0.5 *M*. The tervalent iridium band was not visible.

It was found that the rhodium could be quantitatively eluted by 80 ml. of 0.5 *M* hydrochloric acid, but that this quantity of eluant also removed significant amounts of iridium from the resin.

Elution of a bed fed with 454 γ of tervalent iridium by 100 ml. of 0.1 *M* hydrochloric acid yielded about 50 γ of iridium in the effluent. Examination of successive 10-ml. quantities of this effluent taken by a fraction collector showed that the iridium appeared shortly after the start of the elution, and that the quantity of the metal in each fraction remained almost constant at about 5 to 6 γ. This leakage of iridium could be lessened by elution with more dilute acid, but this retarded the elution of the rhodium.

It would appear that the rhodium is more strongly adsorbed than is indicated by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

distribution coefficients. Such behavior of the rhodium complex is not surprising and is in agreement with the observations of Cluett *et al.* (1), who noted that it was more difficult to remove rhodium that had been fed from a freshly prepared chlororhodate solution (which we have in this case) than from a solution that had been standing for a while.

Attempts to produce a partially hydrolyzed rhodium solution, which would have a lower affinity for the resin, by boiling, and also by adding a small quantity of urea to the solution and heating, were successful in that the ease of elution of the rhodium by 0.01 *M* hydrochloric acid was improved. However, the recoveries were still incomplete, ranging from 90% to 98% for elution with 30 ml. of the acid solution. Continued elution produced no more rhodium in the effluent. Removal of the remaining metal required an acid solution of at least 0.5 *M*. This appears to indicate that the conversion to a hydrolyzed form is not complete.

No iridium was found in the effluent on elution with 30 ml. of 0.01 *M* hydrochloric acid, but subsequent treatment with 0.5 *M* acid solution eluted small quantities of iridium.

In the face of the apparent inability to remove the rhodium without small quantities of iridium, work on this procedure was not continued.

The Separation of Partially Hydrolyzed Chlororhodate and Chloroiridate(IV)

When 5 ml. of the stock iridium solution is diluted to 100 ml. with water the resulting solution is 0.005 *M* in hydrochloric acid. It was noted that if 5 ml. of this dilute solution is fed onto a resin bed the adsorption band, while still brown in color, is not as dark as a band that is formed when the iridium is fed from a solution that has previously been boiled with hydrochloric acid or evaporated with a few milligrams of sodium chloride. Elution of the iridium adsorbed from this diluted solution with 100 ml. of 0.01 *M* hydrochloric acid produced no iridium in the effluent, but elution with 50 ml. of 6 *M* hydrochloric acid quantitatively removed the iridium.

Obviously this iridium was not in the form of chloroiridate(IV). Since the stock solution from which the diluted solution was prepared was nearly two years old, it may be assumed that the chloroiridate(IV) had undergone partial hydrolysis. Such behavior would parallel that of a chlororhodate solution (see above) except that in this case the rate of hydrolysis is probably much slower.

Repetition of this procedure with the rhodium solution showed that 25 ml. of the 0.01 *M* acid solution removed 86% to 92% of the rhodium from the resin with no more metal being removed by further elution with this solution. Removal of the rest of the rhodium could not be accomplished except under conditions which would also remove some iridium.

It was felt that if the degree of hydrolysis of the rhodium could be increased it would be possible to recover the rhodium without eluting any iridium. This was accomplished by the addition of 7 *M* ammonium hydroxide solution until a precipitate formed, and the subsequent dissolution of the precipitate with a minimum of 2 *M* hydrochloric acid. When a dilute rhodium solution was treated in this manner and fed onto a resin bed the rhodium could be completely recovered with 25 ml. of water.

Evidently this treatment produces one or more rhodium species which have no affinity for an anion exchanger. Passage of a similar solution through a cation-exchanging resin bed resulted in only partial adsorption of the rhodium, indicating that both cationic and neutral species are probably present.

Separations were carried out from the dilute, partially hydrolyzed solutions. To 5-ml. samples, each containing about 500 γ of each of the metals, were added three drops of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

7 *M* ammonium hydroxide solution. The addition of the third drop produced a yellow precipitate which was redissolved by five drops of 2 *M* hydrochloric acid. The resulting solution was fed onto a 2.5-cm. resin bed of 70 to 100 mesh in a larger column, and the bed washed with 25 ml. of water followed by 50 ml. of 6 *M* hydrochloric acid. The feed and water-wash effluents were analyzed for rhodium, and the acid effluent for iridium. Quantitative separations were achieved by these means.

Unfortunately, the above separation could not be repeated when fresh rhodium and iridium solutions were used. Attempts to hydrolyze these solutions by dilution and boiling prior to the ammonia treatment resulted in maximum recoveries of 98% for rhodium and 95% for iridium. The rhodium could be completely recovered by passing the iridium fraction, after evaporation and re-treatment, through the column again. From a sample containing four times as much rhodium the same percentage loss occurred as for the smaller samples.

Although it is possible to recover all the rhodium in two stages, and presumably all the iridium by a Soxhlet extraction, the authors cannot recommend this procedure in place of the simpler and shorter method utilizing cerium(IV) described above. The one advantage of this procedure is that rhodium is produced free of other metallic elements.

By coincidence, some of this work was paralleled in the recent report by MacNevin and McKay (3), who used sodium hydroxide to precipitate the rhodium. Dissolution of this precipitate gave a solution containing almost entirely cationic rhodium, which they adsorbed on a cation exchanger to separate it from the iridium which remained in an anionic form. This reaction, like that described above, was not quantitative, and a complete separation was not achieved.

The above work demonstrates the extreme complexity of the chemistry of the platinum metals in solution, and the importance of taking into account the history of a solution sample cannot be overemphasized.

ACKNOWLEDGMENTS

This investigation was assisted by a grant from the University of Toronto's Advisory Committee on Scientific Research, for which grateful acknowledgment is made. One author (S.S.B.) was holder in 1955–56 and 1956–57 of a fellowship given to the university by Canadian Industries Ltd., for which thanks are here recorded.

THE CHEMISTRY OF THE "AMINOCHROMES"*

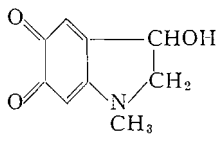
PART I. THE PREPARATION AND PAPER CHROMATOGRAPHY OF PURE ADRENOCHROME[1]

R. A. Heacock, C. Nerenberg, and A. N. Payza

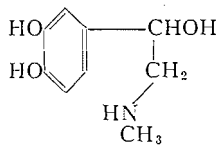
ABSTRACT

The preparation of adrenochrome in a pure stable crystalline form has been carried out by the silver oxide oxidation of adrenaline in methanol with the use of an anion-exchange resin (Dowex-1(Cl^-)) to remove heavy metal ions from the reaction mixture prior to the isolation of the product. Its paper chromatographic behavior together with that of three derivatives (adrenolutin, adrenochrome monosemicarbazone, and adrenochrome monoisonicotinic acid hydrazide) in six different solvent systems has been examined. Water was found to be the best paper chromatographic solvent so far examined for this series of compounds.

Adrenochrome (I), the substance mainly responsible for the red colors produced during the mild oxidation of adrenaline (II), was first isolated from the products of an enzymatic oxidation by Green and Richter (1). Subsequently, inorganic oxidizing agents, particularly



I



II

silver oxide, were successfully employed and it was observed that adrenochrome could be crystallized from methanol (containing a little formic acid) at −80° (cf. Veer (2); MacCarthy (3); Harley-Mason (4); Sobotka and Austin (5)). Green and Richter reported that adrenochrome was unstable both in the solid state and in solution (1); however, Sobotka and Austin claim that the dry crystalline material can be kept indefinitely at 0° (5). The stability of aqueous solutions of adrenochrome has been shown to be markedly affected by pH (cf. Zambotti and Moret (7)); under alkaline conditions and in the presence of certain metallic cations, particularly zinc, adrenochrome readily rearranges into adrenolutin (*N*-methyl-3,5,6-indoletriol, III) (cf. Lund (8); Fischer, Derouaux, Lambot, and Lecomte (9); Harley-Mason and Bu'Lock (10); Fischer and Lecomte (11)).

**The term "aminochromes" was suggested by Sobotka and Austin (5) for the highly colored cyclic oxidation products of β-(3,4-dihydroxyphenyl)-ethylamines and related compounds. These substances are often formulated as substituted 2,3-dihydroindole-5,6-quinones, although there is some uncertainty as to the existence of a true o-quinonoid structure (4, 6).*

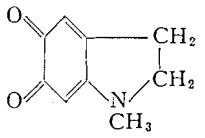
Many samples of adrenochrome, prepared by existing methods, that were available to the authors appeared to contain varying amounts of adrenolutin (shown paper chromatographically by a method to be discussed later) and black water-insoluble melanin-like compounds. It appeared not improbable that contamination of the products by metal in a colloidal form or metallic ions, derived from the oxidizing agent, might be responsible for the deterioration of the samples and for the apparent instability of their aqueous solutions. In order to eliminate or drastically reduce the contamination by silver ions, the adrenaline – silver oxide reaction mixture in methanol was filtered through an anion-exchange resin bed in the chloride form prior to crystallization (at $-20°$) in order to remove ionic silver from solution as silver chloride. In this manner a highly crystalline product containing only traces of silver was obtained ($\gtrsim 0.01\%$).

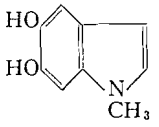
The paper chromatographic behavior of adrenochrome and related compounds has recently been studied by Fischer using *n*-butanol: acetic acid: water (8:2:2) and *i*-propanol: 0.880 ammonia: water (8:1:1) solvent systems (12). The results reported were unsatisfactory, since some of the substances apparently decomposed in these solvents. This is not altogether surprising in view of the known sensitivity of these compounds toward acids and alkalies (7, 8, 9), and furthermore Pavolini, Gambarin, and Godenigo in a study on the action of ammonia on some 5,6-indolequinones, including adrenochrome, reported a definite reaction in this case with the formation of an unstable substance, exhibiting a yellow-green fluorescence, which rapidly turns brown (13). We have repeated Fischer's work and observed with the *i*-propanol–ammonia system that the bright red non-fluorescent adrenochrome spot rapidly turned brownish-yellow in color and exhibited a yellow-green fluorescence, even on exposure to ammonia fumes, and in contact with the solvent the spot soon became dark brown indicating that marked decomposition had occurred. In the acid solvent system, a slower but definite decomposition of the adrenochrome spot was observed during the chromatography. We have found that dilute aqueous solutions of adrenochrome prepared by our method are relatively stable and that distilled water and 2% acetic acid in water are the most suitable solvents for paper chromatography. Pure adrenochrome gave a single spot $R_f 0.8 \pm 0.02$ in water on previously washed Whatman No. 1 paper. Adrenolutin had an R_f of *ca.* 0.4 under these conditions. Contamination of adrenochrome samples with adrenolutin can easily be observed paper chromatographically, since the characteristic yellow adrenolutin spot showing a strong yellow-green fluorescence is soon visible behind the red adrenochrome spot; this can be observed very quickly as it is only necessary to allow the chromatogram to run a few inches in order to see the two spots. The adrenolutin spot is quite distinct and not a diffuse "tail" to the adrenochrome spot, indicating that the impurity was present initially and not formed by continuous isomerization of the starting material. Polymeric melanin-type impurities stay in the position of the original spot. An interesting phenomenon was observed on drying of the paper chromatograms; as the paper was allowed to dry at room temperature, the color of the adrenochrome spot gradually changed from red to yellow-brown and the spot began to exhibit the characteristic adrenolutin fluorescence. The partial formation of adrenolutin was confirmed by two-dimensional chromatography, using water as running solvent in both directions, although only one spot $R_f 0.8$ was observed in the initial run; after drying and rerunning at 90° to the original direction two distinct spots with the characteristic R_f's for adrenochrome and adrenolutin appeared.

Euler, in describing the paper chromatography of adrenaline, states that after the chromatograms have been dried adrenaline spots show an apple-green fluorescence (14, p. 16). A possible explanation of this observation would be the air-oxidation of the

spot to adrenochrome followed by isomerization to adrenolutin on the paper. Therefore it would appear that a thin film of adrenochrome on paper will spontaneously rearrange into adrenolutin. This type of behavior has also been observed by Austin, Chanley, and Sobotka with the related compound epinochrome (IV), which even in the crystalline form undergoes a slow spontaneous rearrangement to 5,6-dihydroxy-*N*-methylindole (V) (15, 16). The paper chromatography of adrenochrome, adrenolutin, adrenoxyl (adrenochrome monosemicarbazone) (VI), and adrenochrome monoisonicotinic acid hydrazide



IV



V

(VII) has been studied in six different solvent systems: (*a*) water, (*b*) 2% acetic acid in water, (*c*) 75% methanol in water, (*d*) 75% ethanol in water, (*e*) *n*-butanol: acetic acid: water (8:2:2), and (*f*) *i*-propanol: 0.880 ammonia: water (8:1:1). Although all solvents proved satisfactory for either of the two derivatives, VI and VII, only (*a*) and (*b*) were suitable for adrenochrome and possibly only (*a*) for adrenolutin, since even in (*b*), (*c*), and (*d*) the fluorescence characteristics of the compound seem to be irreversibly altered.

An attempt to purify impure preparations of adrenochrome on cellulose columns using water as solvent was disappointing, since, although pure aqueous solutions of adrenochrome were probably obtained, it was not possible to crystallize the adrenochrome from water, and all samples prepared by freeze-drying under high vacuum (a technique which gave a very finely divided product) were shown chromatographically to be contaminated to some extent with adrenolutin (fortuitously formed during the drying process).

In view of the very considerable interest that has developed, in the physiological activity of adrenochrome and related compounds, in recent years (see Bacq (17) and Hoffer (18) for lists of references) the necessity for working with the compounds in a pure and stable form has become of paramount importance.

EXPERIMENTAL

Preparation of Adrenochrome

L-Adrenaline (9.15 g.) was suspended in methanol (360 ml.) and 90% formic acid added dropwise with stirring until a clear solution was obtained (*ca.* 3.5 ml.). Freshly prepared silver oxide (36.3 g.) was added portionwise during a period of 3 minutes, the reaction temperature being maintained between 18° and 23° during the addition of the oxidant. The reaction mixture was filtered (with suction) through a Dowex-1(Cl^-) (200/400 mesh) resin bed (diam. = 6.5 cm., height = 3.7 cm.)* and the deep red filtrate was allowed to crystallize slowly at −20°. Pure adrenochrome (1.6 g.) was obtained in deep-violet needles, m.p. 112° with decomposition. Found: C, 60.30; H, 4.69; N, 7.76. Calc. for $C_9H_9O_3N$: C, 60.33; H, 5.02; N, 7.81%. The ultraviolet and visible absorption spectra were measured in aqueous solution (λ_{max}: 301, 487 mμ; λ_{mln}: 262, 361 mμ).

Samples of adrenochrome which we have prepared by repeating existing procedures contain, in our view, less well defined crystals than the product obtained as described above (rapid cooling to −80° tends to produce an amorphous product) and the products are

**The resin was prepared by extensive washing: (1) with 3N hydrochloric acid, (2) with water until neutral to litmus, and (3) finally with methanol until the washings were transparent to ultraviolet light.*

invariably more or less contaminated with adrenolutin and melanin. This has been demonstrated paper chromatographically (using Whatman No. 1 paper with water as running solvent). No particular advantage either in yield, purity, or crystalline form, appeared to attend the use of absolutely dry methanol. The silver contents of adrenochrome samples prepared in this manner and by the method of Sobotka and Austin (5) were determined by the dithizone method after complete oxidation of the organic material in the sample with a mixture of nitric and perchloric acids (cf. 19, p. 544) and were observed to be very low (not greater than *ca.* 100 parts per million) whereas preparations obtained by other routes had considerably higher silver contents (of the order of 1000 p.p.m.). Sobotka and Austin filtered the methanol reaction mixture through a sodium sulphate bed prior to crystallization. This may have fortuitously acted as an anion-exchange resin and removed silver ions from solution as the sulphate. It is conceivable that both the resin and the sodium sulphate beds would help to hold back colloidal as well as ionic silver. One possible advantage of the resin over sodium sulphate would be that it would enable the reaction to be carried out in aqueous solution if required.

The mother liquors were examined chromatographically on paper using water as solvent and there was evidence that they contained adrenochrome R_f 0.82, a little adrenolutin R_f 0.4–0.45, a non-fluorescent dark-violet unidentified compound R_f 0.92, and a non-fluorescent colorless zone R_f 0.0–0.4. All these zones gave blue colors (i.e. reduced) with the ferric chloride – potassium ferricyanide reagent (see next section). The low R_f area probably contained some unchanged adrenaline, since it gave a red color when sprayed with potassium ferricyanide or ammonium persulphate solution.

Paper Chromatography of Adrenochrome and Related Compounds

Whatman No. 1 paper was washed with distilled water for 12 hours and dried prior to use. It was observed that unwashed paper caused some decomposition of the adrenochrome. The ascending method for paper chromatography was invariably employed, and 10–20 μg. of sample were applied to the paper in each case. The results obtained are given in Table I.

In all cases, the solvent was allowed to ascend a distance of *ca.* 9 to 12 inches. There was a considerable variability in the time required for this to occur; water and 2% acetic acid having the advantage of giving considerably quicker results than the other solvent systems. The approximate times taken by the various solvents are given in Table II.

Detection of Spots

All four compounds are colored and therefore are self-indicating. Adrenolutin (III) also exhibits a marked yellow-green fluorescence in ultraviolet light. It has been previously stated that, on drying, the spots of I undergo a slow change to III; this substance, being a catechol derivative, has reducing properties and the chromatogram can be developed in the following manner (if a permanent record is required). The developing solution was prepared immediately before use, and consisted of 3% ferric chloride solution (5 ml.), 3% potassium ferricyanide solution (5 ml.), and water (90 ml.). The papers were dipped in the reagent and the reducing compounds formed permanent blue spots. The excess reagent was washed off; the papers were dipped in 2 *N* hydrochloric acid and finally excess acid was washed off. Other chromogenic reagents for adrenochrome include: (*a*) Ehrlich's reagent (violet spot), (*b*) 3% ferric chloride solution (gray-brown spot), (*c*) diazotized *p*-nitroaniline (red-brown spot), and (*d*) zinc chloride solution (yellow-green fluorescent spot in ultraviolet light).

TABLE I

R_f IN STATED SOLVENT SYSTEMS

Compound	A	B	C	D	E	F
Adrenochrome (I)	0.8 ±0.02	0.82±0.02	S. dec. (0.7–0.8)	S. dec. (0.7–0.8)	R. dec.¶	R. dec.
Adrenolutin (III)*	0.45±0.05	0.47±0.03§	S. dec. (0.7–0.8)	S. dec. (0.7–0.8)	R. dec.	R. dec.

A STUDY OF GRAFT COPOLYMERS

I. PREPARATION AND VISCOSITY BEHAVIOR[1]

J. A. MANSON[2] AND L. H. CRAGG

ABSTRACT

Graft polymers were prepared by the redox polymerization of styrene in the presence of oxidized polystyrene or copolymers of styrene and 4-vinylcyclohexene-1; the maximum number of hydroperoxide groups per thousand monomeric units in the oxidized polymers was 18. Evidence that grafting had indeed occurred was obtained from measurements of monomer disappearance, of the decrease in hydroperoxide content of the backbone polymer during reaction, and of the infrared absorption by the polymer before and after the grafting procedure.

Although the experimental results clearly support the conclusion that branching occurred, values of Huggins' k' for both unfractionated and fractionated graft polymers were no higher than for linear polystyrene ($0.39 < k' < 0.41$ in butanone). It was concluded that, though k' is sensitive to bushy branching, Huggins' k' is not measurably affected by the presence in a polymer of a few linear branches per molecule.

INTRODUCTION

The study of branching in high polymers is important to the understanding of the relationships between molecular structure and physical properties. It is all the more important because most polymers, even ones usually assumed to be linear, are branched to some extent.

Unfortunately, the determination of the extent, or degree, of branching (that is, the average number of branches per molecule) is seldom easy. The most rigorous method is based on the fact that the size, and hence intrinsic viscosity, is less for a branched molecule than for a linear molecule of the same molecular weight (26, 29). The application of this method requires the making of viscosity and light-scattering measurements, which are tedious and which require expensive equipment. Another method for the detection of branching has been based upon the determination of Huggins' k' (14), the slope constant of the curve relating reduced viscosity to concentration; a great deal of empirical evidence has been found indicating a correlation between the presence of branching in a polymer and unusually large values of k' (10, 18, 25). Since accurate viscosity measurements can be made readily with fairly simple equipment, this method would, if generally applicable, be very useful.

Since, however, no suitable comparison of these two methods had been made, it was decided to undertake a study of the relationship between Huggins' k' and the degree of branching as determined from measurements of the intrinsic viscosity and molecular weight of branched and unbranched polymers.

In this study it was desirable to have samples of a high polymer, in some of which the molecules would all be essentially linear, while in others each of the molecules would have a known number of linear side chains attached to the main chain. However, most methods available at the time for the preparation of branched polymers with fairly high molecular weights had serious drawbacks.

If one uses polymerization methods involving chain transfer (1, 3, 13), or copolymerizes

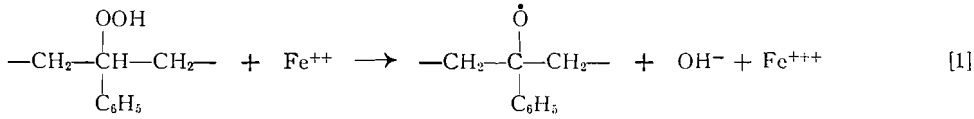
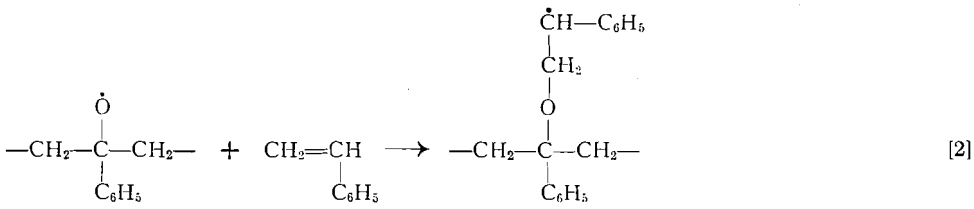
a monomer with a cross-linking agent, such as a divinyl compound (6, 28), or irradiates a partially halogenated polymer in the presence of its monomer (15, 16), one obtains a complex mixture of linear and branched polymers that is often difficult to resolve into its components. Moreover, these methods do not yield polymers with simple branches, but rather encourage the growth of branches on branches or the formation of gel.

The condensation of a monomer with a molecule having a known number of reactive functional groups was used by Schaefgen and Flory (24) to produce polymers having a known number of branches per molecule, but the average molecular weights obtained were rather low (less than 38,000) and the structure of the branched molecule was unusual (all branches radiating from a single "hub").

By contrast, the technique developed at the Polytechnic Institute of Brooklyn (21) for the grafting of side-chains onto a vinyl-type backbone seemed very attractive. In this method the hydroperoxide resulting from the oxidation of a vinyl polymer is used to initiate the polymerization of a vinyl monomer under redox conditions (see equations 1 and 2). As well as making possible the control of the degree of branching (by varying the degree of oxidation of the backbone polymer), this method should, in principle, yield a product free of linear material.



[1]



[2]

Several such graft polymerizations were carried out. The backbone polymers used were polystyrene and copolymers of styrene and 4-vinylcyclohexene-1—the latter because they were expected to oxidize more readily than styrene alone. These polymers were oxidized to varying degrees, and the products were used as initiators in the redox emulsion polymerization of styrene. Since this work was first reported at St. Catharines, Metz and Mesrobian have published a report of similar experiments (22); they were, however, unable to achieve satisfactory oxidation of polystyrene itself. Similar studies have also been described by Hahn and Lechtenböhmer (9). In neither case were measurements of Huggins' k' reported.

In this paper the preparation of the graft polymers is described and evidence that grafting did, in fact, occur is presented and discussed. Finally, measurements of intrinsic viscosity and Huggins' k' are given for the graft polymers and for their fractions.

Other more direct evidence for grafting, based on viscosity and light-scattering measurements, will be given elsewhere (19).

EXPERIMENTAL

1. Materials

Monomers were provided by the Polymer Corporation, Limited, Sarnia. Before use they were freed of inhibitor by washing with dilute aqueous potassium hydroxide, rinsed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

with distilled water, and dried with Drierite. Cumene hydroperoxide (60%) was also provided by the Polymer Corporation. Phenyl-β-naphthylamine and benzoyl peroxide were both practical grade reagents supplied by the Eastman Kodak Company.

Polystyrene samples used for oxidation were prepared by a method described earlier (18); copolymers of styrene and 4-vinylcyclohexene-1 were prepared according to a similar recipe.

Tetralin, of Certified Chemical grade, was obtained from the British Drug Houses. Other solvents were of technical grade, and were used without further purification.

Inorganic reagents were of Analar grade, supplied by the British Drug Houses, or of equivalent quality. Nitrogen was purified by passing it first through Fieser's solution (8, p. 395) and then through a saturated solution of lead acetate.

2. Oxidations

Solutions of the backbone polymers in tetralin were oxidized at temperatures within the range 70° to 80° C.—usually at 75(±0.2)° C.— by passing oxygen through a sintered-glass bubbling tube in the solution at a rate sufficient to bring about rapid and thorough bubbling without excessive foaming. (No attempt was made to purify the oxygen or to regulate its flow precisely.)

Suitable concentrations ranged from 2 g./dl. for a high-molecular-weight polymer to 5 g./dl. for a low-molecular-weight one. In general, the oxidation was more successful with the lower-molecular-weight polymers.

After bubbling had been continued for a time estimated to correspond to the degree of oxidation desired the product was precipitated in methanol or ethanol. In order to remove tetralin (and its hydroperoxide), the gummy precipitate was reprecipitated several times from a solution in butanone before drying under reduced pressure at 45° C. to constant weight. The addition of Dry Ice to either the solution or the precipitant was found to help in obtaining a porous, easily dried material. Tests showed that with repeated precipitation the observed hydroperoxide content for the precipitated and reprecipitated polymers decreased rapidly at first, but then leveled off to an approximately constant value when a clear, porous product, free from the odor of tetralin, had been obtained.

3. Analysis for Hydroperoxide Content

Determination of the peroxide or hydroperoxide content of a high polymer is difficult (2, 27). Although iodometric methods should give values closer to absolute ones than do methods using ferrous ion, the most consistently reproducible results were obtained using the spectrophotometric procedure, based on the oxidation of ferrous ion, which was developed by Laitinen and Nelson (17). Provided that freshly prepared solutions were used, and that a calibration had been made recently, results for various samples of the same polymer were reproducible to within ±10% in most runs (or, at worst, to within ±20%).

In order to see whether or not the spectrophotometric method gave reliable absolute values for hydroperoxide content, the purity of a sample of 60% cumene hydroperoxide was determined. The average value, a mean of 13 determinations, was 108(±11)%, as compared to an average value of 62(±1)% obtained by means of a conventional iodometric titration (27, p. 53). Although cumene hydroperoxide is not necessarily a valid standard for the analysis of a high polymer, its structure is similar to that of the polymeric hydroperoxide. It is possible, then, that the values of hydroperoxide content found for the polymers studied are somewhat high.

In this paper hydroperoxide content is expressed as a "hydroperoxide number": the number of hydroperoxide groups per thousand monomeric styrene units.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

4. Graft Polymerizations

Graft polymers were prepared in emulsion at 35(±0.2)° C. A typical recipe follows:

Oxidized polymer (in this example, one with a hydroperoxide number of 10)	2.0 g.
Monomer	15.0 g.
Soap flakes	5.0 g.
Water	90.0 g.
Potassium pyrophosphate	2.2 g.
Ferrous ammonium sulphate (hexahydrate)	0.2 g.

Thus, with 2.0 g. of a polymer of hydroperoxide number 10, the amounts of pyrophosphate and ferrous salts listed above were used; with a polymer of higher hydroperoxide content, proportionately larger amounts of the salts were used. If more than 15 ml. of styrene was required to dissolve the backbone polymer, proportionately more soap and water were used.

First, the backbone polymer was allowed to stand with enough styrene to effect solution. Then the required amount of water was divided into two portions—one for a soap solution, and one for a ferrous pyrophosphate solution. Both solutions were prepared by heating to 60° C.

As soon as the polymer had dissolved, the two hot solutions were swept out with purified nitrogen, combined, and placed with the polymer solution in a 250 ml. bottle fitted with a self-sealing cap. After the contents had been swept out again with nitrogen, the bottles were capped and, by means of a syringe, charged with nitrogen at a pressure of 10 to 15 p.s.i. The bottles were shaken vigorously in order to ensure emulsification, placed in a rack held in a constant-temperature bath, and rotated end-over-end at 33 r.p.m.

When desired, aliquot samples were withdrawn by syringe, and the polymer in them precipitated in methanol containing 0.1% hydroquinone; the percentage conversion was determined from the dry weight of the precipitated polymer. When the polymerization was judged to have proceeded to the desired degree of conversion, the contents of the bottles were poured into methanol–hydroquinone solution. After it was aged overnight, the precipitated polymer was washed with hot distilled water, rinsed three times with methanol, and dried at 45° C. under reduced pressure to constant weight.

5. Infrared Spectra

Infrared spectra were determined with a Perkin-Elmer recording spectrophotometer, Model 21. Solutions in chloroform of two graft polymers, GC-211 and GC-220, and of two blanks, GC-320 and GC-321 (prepared just as the graft polymers were, except that unoxidized polystyrene was used in place of oxidized polystyrene), were examined in calcium fluoride cells throughout the range 1200–3800 cm.$^{-1}$. Spectra for films of samples GC-210, GC-220, GC-250, and GC-320 were obtained independently in the laboratories of the Polymer Corporation, Limited.

6. Fractionation

The primary fractionation of a graft polymer was achieved by fractional precipitation, at 45° C., from a solution in butanone or in a butanone–benzene mixture, by the progressive addition of methanol or a methanol–butanone mixture. The fractions taken weighed not more than one-fourth of the original weight of the polymer fractionated, and with each polymer the fractionation was continued until at least three-fourths of the polymer had been precipitated.

After each swollen precipitate had been separated, it was carefully washed with a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

small portion of solvent, and reprecipitated from a solution in butanone. The fibrous product was recovered by filtration, washed with methanol, and dried under reduced pressure at 45° C. to constant weight.

7. Viscosity Measurements

Values of intrinsic viscosity, $[\eta]$, were, unless otherwise noted, determined as described previously (18), by means of the equation of Mead and Fuoss (20):

$$(\ln \eta_r)/c = [\eta] - \beta[\eta]^2 c. \qquad [3]$$

Values of $(\ln t_r)/c$ (where t_r = flow time of solution/flow time of solvent) were determined and plotted against concentration; since Ubbelohde viscometers having negligible kinetic energy corrections were used (7), $(\ln t_r)/c$ is equivalent to $(\ln \eta_r)/c$. Values of k', the slope constant of the Huggins' equation,

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c, \qquad [4]$$

were computed from the relation $k' + \beta = 0.50$.

RESULTS AND DISCUSSION

1. Oxidations

In Fig. 1 are presented some typical results showing the effect of duration of the period of oxidation on the hydroperoxide content of low-molecular-weight polymers ($0.5 < [\eta]$ in butanone < 0.8). Lengths of the vertical lines represent approximately the error in the determination of hydroperoxide number. Although the points are rather scattered, partly because of variations in the rate of flow of oxygen, the data show that the maximum hydroperoxide content was usually reached after oxidation had proceeded for 8–12 hours.

In order to find out whether degradation had occurred during oxidation, the intrinsic

For personal use only.

viscosities of several polymers were determined before and after oxidation. No decrease in intrinsic viscosity was observed, and it was concluded that degradation had not occurred.

The data in Fig. 1 confirm the importance of the solvent to the oxidation (22). While relatively high hydroperoxide contents were obtained for polymers oxidized in tetralin (which is itself readily oxidized to its hydroperoxide under the conditions used here), hydroperoxide numbers for polymers oxidized in *m*-xylene were very close to those found for unoxidized polymers.[3]

It is also clear that pure polystyrene is not readily oxidized by molecular oxygen (9); the highest hydroperoxide number obtained was 9, corresponding to a hydroperoxide concentration of about one mole per cent.

In the hope of obtaining higher hydroperoxide numbers, several modifications of the procedure were tried:

1. The use of copolymers of styrene and 4-vinylcyclohexene-1, the oxidation of which should be unaffected by the steric effects encountered with pure polystyrene (22).
2. The use of partially isopropylated polystyrene.
3. The use of catalysts, such as benzoyl peroxide or cumene hydroperoxide.

However, none of these modified procedures gave values of hydroperoxide content greater than 18. Although this value, the highest observed, was obtained with a styrene-vinylcyclohexene copolymer, no correlation was found between hydroperoxide number and vinylcyclohexene content.

2. Evidence for Grafting

(a) Conversion Studies

Proof that the polymeric hydroperoxides initiated the rapid polymerization of styrene was obtained from measurements of the percentage conversion of styrene to polymer as a function of time. Conversion data for a typical graft polymerization, GC-140, are given in Fig. 2; for comparison, data are included for a blank polymerization, GC-141,

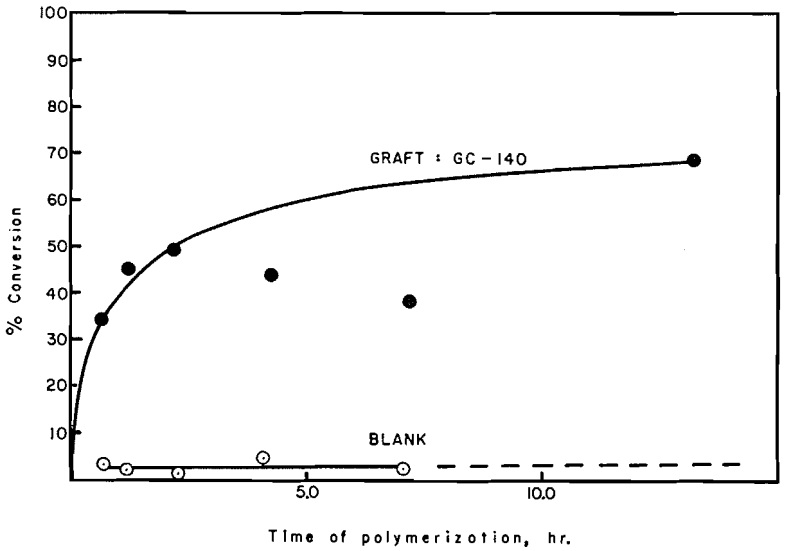

FIG. 2. Dependence of percentage conversion on time for a graft and a blank polymerization. ● Graft. ○ Blank.

[3]*As mentioned above, care was taken to remove residual tetralin from the oxidized polymers.*

a duplicate of GC-140, except for the omission of oxidized polymer from the polymerization recipe. After 1 hour of reaction, only a small amount (<3%) of the initial styrene had been polymerized in the blank, whereas in the same period more than half of the initial styrene in the graft polymerization had been polymerized.

As the polymerization proceeded, the conversion data tended to become scattered, probably because the emulsion had usually broken within the first three hours and it was consequently impossible to take truly representative samples. However, the value of percentage conversion for the total polymer (corresponding to the last point in the curve for GC-140) always fitted in well with values found for aliquot samples taken during the early stages of polymerization.

Further evidence for the initiation of polymerization by the polymeric hydroperoxides is given in Tables I and II, in which are summarized polymerization and conversion data for several series of graft polymers, and for a number of "blank" polymers prepared (with one exception, GC-141) by replacing oxidized polymer with ordinary polymer.

Without exception, a larger proportion—usually a much larger proportion—of the styrene was polymerized with oxidized than with ordinary polymer. (The relatively

low conversions in polymerizations GC-161 to GC-200 may be due to the low hydroperoxide content of the backbone polymers used in these runs, but, in general, no close relationship between percentage conversion and hydroperoxide content is evident.) These data also indicate no correlation between the vinylcyclohexene content of the backbone polymer and the percentage conversion.

(*b*) *Disappearance of Hydroperoxide Groups*

The evidence just cited indicates that, under the conditions of our grafting experiments, the formation of polymer is initiated by the hydroperoxide groups in the parent (or backbone) polymer. Other evidence of this was obtained from measurements of hydroperoxide content before and after polymerization. Results of such measurements are assembled in Table III. The formation of new polymer in the presence of the parent

**Calculated on the assumption that none of the polymeric hydroperoxide groups disappear during polymerization.*

†Appears to be anomalous.

polymer must yield a product whose hydroperoxide number (the number of hydroperoxide groups per thousand monomer units) is less than that of the parent polymer. This would be true regardless of whether or not the new polymer is attached to the old. If none of the hydroperoxide groups on the backbone chain were used up in initiating new polymer growth, the hydroperoxide number of the product would still be less because the number of monomer units in the polymer would be increased. In column 3 are listed the values of hydroperoxide number calculated on the assumption that the decrease is merely due to this "dilution" effect;[4] in column 4 are the values actually observed. Even after allowance is made for the rather imprecise results obtained in these analyses, it is clear that hydroperoxide groups do disappear in these graft polymerizations. The precautions taken to remove residual tetralin hydroperoxide were such that at worst the contribution of tetralin hydroperoxide to the hydroperoxide number of the backbone

[4]*The following expression was used for the calculation:*

$$\frac{\text{wt.}_{bb} \times \text{hydroperoxide no.}_{bb} + \text{wt.}_{ps} \times 0.50}{\text{wt. graft polymer}}$$

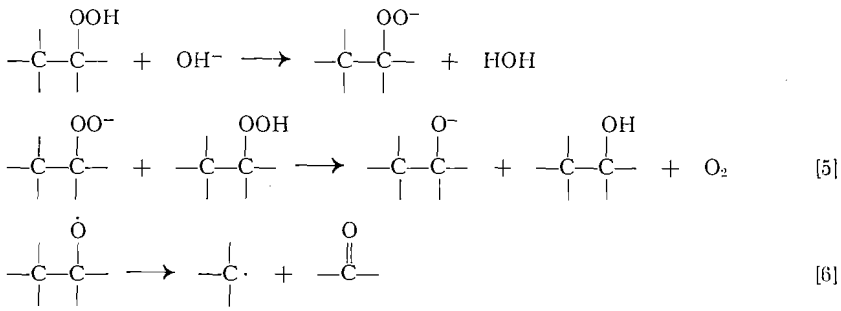
where the subscripts bb *and* ps *refer to backbone polymer and polymerized styrene, respectively. For convenience, it is assumed that the hydroperoxide number of the polymerized styrene is 0.50, a reasonable value slightly lower than the average of 0.55 found for the blanks GC-320, GC-321, GC-322, and GC-323; choice of an even lower value would not affect the conclusions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

polymer would be less than 1. The polymerization must, therefore, have occurred mainly at the polymeric hydroperoxide sites.

(*c*) *Absence of Side Reactions*

So far in this discussion it has been assumed that in the presence of an excess of monomer a polymeric hydroperoxide group disappears by the series of reactions outlined in equations [1] and [2], rather than by such polar or radical side reactions as the following:



[5]

[6]

The occurrence of reactions represented by equations [5] and [6] would result in the disappearance of hydroperoxide groups, and, in the case of the free-radical reaction, in the formation of free radicals that would initiate the formation of linear polymer. Experimental evidence for the occurrence of these side reactions was sought, but in vain.

That a polar decomposition induced by the alkaline nature of the emulsion did not occur was demonstrated in the following way. Emulsions of two different polymeric hydroperoxides were prepared, following the recipe for graft polymerizations in all respects except that the ferrous salt was omitted, and these emulsions were rotated in the constant-temperature bath for 1.5 hours and 1.0 hour, respectively—times sufficient in a graft polymerization for the conversion of most of the monomer to polymer. The resulting change in hydroperoxide number was negligible: from 4.9 to 4.6 and from 5.2 to 5.6, respectively. It was concluded that the polymeric hydroperoxides used in this study were stable at the pH existing in the emulsions.

The reaction represented by equation [6] would result in the formation of terminal carbonyl groups. The infrared spectra for graft polymers GC-211 and GC-220 and for blanks GC-320 and GC-321 were carefully examined for the presence of absorption peaks corresponding to the absorption frequency of the carbonyl group (in the range 1720–1730 $cm.^{-1}$). Although the carbonyl group is detectable at low concentrations (23), no such peaks were found. The spectra for the graft polymers were in fact identical in this range with those for the blanks. These findings were confirmed by examination of the spectra for films prepared from the graft polymers GC-210 and GC-220, and from blanks GC-250 and GC-320.

These findings, though negative, constitute additional justification for our assumption that, under the conditions of our grafting experiments, hydroperoxide radicals on the parent polymer molecules initiate the growth of polymer branches.

(*d*) *Fractionation Behavior*

Finally, it should be pointed out that the fractionation behavior of the graft polymers also indicates that grafting has occurred. In carrying out a primary fractionation of linear polystyrene, it is relatively easy to control the number and size of the fractions. With the graft polymers, however, this was very difficult; once precipitation began, a very slight excess of non-solvent tended to bring down all or most of the polymer. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

is the behavior to be expected if the polymer molecules are all large and branched (as they would be if the polymer chains formed were all attached to a pre-existing backbone chain). It is not the behavior to be expected if the new polymer chains were independent molecules, for then there would be the usual wide distribution of molecular weights, and the usual wide differences in solubility.

All of this evidence is consistent with only one conclusion: that in the polymerizations described in this paper grafting had occurred, that is, branched polystyrene molecules had been formed by the growth of polystyrene chains onto a polystyrene backbone chain.

3. Viscosity Results

If every, or almost every, hydroperoxide group in the backbone polymer became a point of attachment for a branch, the graft polymer molecules must have been fairly extensively branched. For example, molecules of the backbone polymer for the graft polymer GC-210 (Table I) contained, on the average, nine hydroperoxide groups per 1000 monomer units, and hence an average molecule of the graft polymer may have had as many as nine branches per 1000 monomeric units in the backbone chain (i.e., $9 \times DP/1000$ branches, where DP is the degree of polymerization of the parent polymer).

It was expected, therefore, that Huggins' k' would have higher values for the graft polymers than for linear polystyrene. The experimental values did not, however, show this difference. In the (unfractionated) graft polymers they fell within the range characteristic of linear polystyrene (0.39–0.44 in butanone, 0.37–0.39 in benzene), and the averages of the values obtained with fractions also fell within these ranges (see Reference 19, Table IV).

Evidently k' is not measurably affected by the branching present in these polymers. This was an unexpected finding. Even a very little (i.e., 0.01%) divinylbenzene copolymerized with styrene was found to produce sufficient non-linearity in the polymer to increase k' appreciably (6, 19). Indeed, a great deal of evidence has been accumulated for many different polymers showing that non-linearity in polymers leads to high values of k'.

A careful re-examination of this evidence discloses, however, that when these increases have been observed the non-linearity of the polymer was due either to a small degree of cross-linking or to branching resulting from reactions which could have led (and probably had led) to branches that were themselves branched. Schaefgen and Flory (24) have indeed reported a very slight increase in k' for a branched condensation polymer prepared in such a way as to preclude branched branches, but in view of the errors involved in the determination of k' it is questionable whether the increase observed (average value of k' for linear polymer, 0.36, for polymer with eight branches, 0.38) is significant.

On the basis of the evidence now available, it may be concluded that k' is affected more by bushy branching than by simple branching. Indeed, it may well be that measurements of k' could afford a means of distinguishing between different types of branching.

This conclusion seems to be reasonable, for k' is a function of the segment density in the molecular coil (4), and at the same temperature and in the same solvent, the segment density for a molecule consisting of a backbone carrying a few long branches should be significantly less than that for a bushy molecule, and probably little different from that for a linear molecule of the same weight.

It would seem, then, that what affects k' is not branching per se but branching of such a type and to such a degree that the segment density in the molecular coil is significantly altered. Multiple branching (either of the bushy type or of the loose network type) is the kind most likely to increase the segment density. But if the considerable degree

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

of linear branching characteristic of our graft polymers does not affect k', it is to be expected that a small degree of multiple branching will not affect it. It is probably for this reason that, to cite two examples, Cragg and Brown (5) found k' to be normal for low-conversion GR-S, and Hobbs *et al.* (11, 12) found that a high-molecular-weight sample of polyvinyl acetate known to be branched (and probably with bushy branches) gave normal k' values.[5]

ACKNOWLEDGMENTS

We wish to acknowledge with thanks assistance given at various times by Mrs. D. Coleman, Mr. J. Hunt, Mr. L. Murrell, and Mr. D. M. Wiles. We are indebted to Mr. G. Perry for infrared measurements, and to Dr. H. L. Williams of the Polymer Corporation, Limited, for helpful discussions; we are also grateful to the Polymer Corporation, Limited, which provided many materials and help with infrared measurements.

[5]*It has recently been reported (11) that branching may be detected, by a change in the slope of η_{sp}/c vs. c curves, when the change in k' is too small to be detected with certainty. When this method was applied to our graft polymers, an increase in slopes (over that obtained with linear polystyrene of the same intrinsic viscosity) was noted in the curves obtained with benzene solutions but not in those obtained with butanone solutions.*

LIGHT-ABSORPTION STUDIES

PART X. ULTRAVIOLET SPECTRA IN ACID AND BASIC MEDIA—SOME FURTHER OBSERVATIONS ON THE ORTHO EFFECT[1]

W. F. Forbes, Audrey S. Ralph, and
(in part) Rosemarie Gosine

ABSTRACT

The spectra of acetophenones and related compounds are obtained in acid and basic solution and are compared with previously reported spectra of substituted benzene derivatives. Evidence is adduced that the B-bands, not only in neutral solution, but also in acid or basic solution, are determined primarily by steric and mesomeric interactions.

Following previous work, the main cause of the ortho effect in the B-band of electronic spectra is ascribed to steric interactions between the vicinal substituents, and in this way, steric interactions explain the frequent similarity in the spectra of meta and ortho isomers. Other factors also play a part, and one of these, a short-range interaction between the substituent and the benzene ring, is discussed.

INTRODUCTION

In Part III (1) of this series it was stated that the B-band of orthodisubstituted benzene derivatives in neutral solution would be approximately the same as the B-band of para isomers, except for steric inhibition of resonance. This statement was based on the assumption that in the B-band the so-called mesomeric (resonance) interactions are of greater importance than inductive-type interactions. The effects of mesomeric interaction in spectra were also developed in previous papers (2, 3, 4).

The purpose of the present communication is to extend these hypotheses to spectra in acid and alkaline solution. The spectra under these conditions frequently exhibit pronounced similarity for the ortho and meta isomers. This has been noted by Doub and Vandenbelt (5), and has also received a quantum-mechanical interpretation by Förster (6). The latter interpretation, however, is inadequate for many of the compounds under investigation. It will be shown that an equally satisfactory explanation can be obtained by assuming approximate identity of the resonance interactions in ortho and para isomers in the absence of steric and other interfering interactions. The similarity of the spectra of ortho and meta isomers may then be related to the observation that frequently both spectra resemble that of one of the monosubstituted parent compounds. In this way, the frequently observed identity in monosubstituted parent compounds and ortho and meta isomers is explained, since in the meta isomer no interaction between the two substituents occurs because of the absence of suitable resonance forms; in the ortho isomer such resonance interaction is prevented because of steric interaction between the vicinal substituents.

ULTRAVIOLET ABSORPTION SPECTRA IN ACID AND BASIC MEDIA

Table I shows spectra of benzene derivatives in acid and basic media compared with the same spectra in neutral, aqueous solution. Both B- and C-bands are listed but the discussion will be limited to B-bands. This follows, because although B- and C-bands both provide a potential measure of interaction between two or more substituents in benzene derivatives, the C-band is dependent on the B-band (3) and hence less easily related

[1]*Manuscript received December 23, 1957.*

directly to electronic interactions. The limited data available in Table I listing both B- and C-bands confirm the suggestion made in Part VIII (3) that both bands are of similar character, since comparable wavelength displacements are again observed on changing the hydrogen-ion concentration of the solvent.

TABLE I

EFFECT OF ACIDITY AND BASICITY ON SPECTRA OF BENZENE DERIVATIVES
(Values in italics represent inflections in this and subsequent tables.)

Compound	Neutral solvent		Acid (0.1 *N* HCl) solvent		Base (*N* NaOH) solvent	
	λ_{max}, mμ	ϵ_{max}	λ_{max}, mμ	ϵ_{max}	λ_{max}, mμ	ϵ_{max}

**See Table III and Refs. 5 and 7.*

In discussing these spectra it should first be noted that numerous "exceptional" changes occur. These exceptions may be defined as effects where the acidity or basicity causes a fundamental change in the molecular entity. Thus, the removal from the conjugated system of the unshared electron pair in the amino group by the addition of acid, and the presence of base replacing either the OH group by an ONa group or the COOH by a COONa group, represent examples of this type of change.

Similarly, the effect of acid on benzoic acid spectra is to cause a change in the molecular species present, since the equilibrium

$$C_6H_5COOH \text{ hydrate} + H_2O \rightleftharpoons C_6H_5COO^- \text{ hydrate} + H_3O^+$$

will occur in aqueous solution (cf. 8), whereas in acid media the benzoate-ion concentration will be negligible. An analogous difficulty arises in the study of benzoic acid spectra in sulphuric acid, where again the molecular entities are altered to give rise to completely ionized acids $R.CO_2H_2^+$ (cf. 9). Likewise, the actual molecular species of carbonyl compounds in concentrated sulphuric acid will be predominantly $>C{=}OH^+$, again different

from the species present in neutral solution (cf. 10). Since, when the acidity of the solvent is changed, some changes in the molecular species occur almost invariably, it is difficult to determine the effect of acidity on a single molecular species.

On the other hand, it seems incorrect to neglect completely the effects of acid or base, *qua* acid or base (for instance, the effect of a changed dielectric constant), on absorption curves of a single molecular entity. That is, although the presence of a proton, for example, may lead to a complete change in the electronic structure of the molecule, sometimes this addition will merely cause a small change in the coulomb or resonance integral of the relevant atoms. This appears to be borne out by the observation of Nagakura *et al.* (10) that absorption curves of acetone in sulphuric acid media at higher acid concentrations do not cross at the isosbestic point.

This inherent effect of acid or base, apart from the frequent ability of acid or base to change the molecular species present, usually represents a *minor* effect in electronic absorption spectra. This is illustrated in Table I by a number of spectra. For instance, the addition of dilute acid or base to aqueous solutions of diphenyl, benzaldehyde, acetophenone, or nitrobenzene, or the addition of dilute acid to aqueous solutions of phenol, does not, apparently, alter the characteristic spectra to any appreciable extent. A slight change, which is evident in Table I for the above-mentioned compounds, is a small variation in the absorption intensity as measured by the molecular extinction coefficients (ϵ). These ϵ values may show either an increase or a decrease. This change, in turn, may be related to small changes in the force constants of the central linkages, a change which has previously been shown (11) to give rise mainly to intensity changes.

Further, there appears to be some evidence that this effect is transmitted preferentially across the ends of a conjugated system particularly if mesomeric or resonance interaction is appreciable. Then this interaction may cause appreciable spectral changes. For example, the spectra of *p*-aminoacetophenone, *p*-hydroxybenzoic acid, and *p*-nitrophenol, when the pH is changed, are altered to a greater extent and differently than the spectrum of either of the two monosubstituted parent compounds with similar pH changes. A similar enhanced effect is not always observed for the corresponding meta isomers (see Table I), and it may also be noted from Lemon's data (12) that spectral changes due to alkalinity in the B-band are much more pronounced in the para isomer of *p*-hydroxybenzaldehyde than in the ortho or meta isomers.

STERIC EFFECTS IN ACID AND BASIC MEDIA

A number of spectra in sulphuric acid media have already been determined (see Part VIII (3), Table II), and it was then noted that in this medium a bathochromic shift is generally observed in both B- and C-bands, compared with the spectra in neutral solution. Such a bathochromic shift would be anticipated on theoretical grounds, since generally the more ready formation of dipolar forms, because of the greater polarity of the solvent, would be more important in the electronic excited state than in the ground state.

The sulphuric acid data also indicate that the steric effect of ortho substituents in the B-band is apparently more pronounced in acidic than in neutral solution. For example, *o*-methylbenzaldehyde compared with *p*-methylbenzaldehyde in hexane solution does not show a wavelength shift in the B-band and the intensity ratio is 0.87, while in sulphuric acid solution for the same pairs of compounds a wavelength shift of 15 mμ is observed and the intensity ratio is 0.74 (3). For *o*-methyl- and *p*-methyl-acetophenone in ethanolic solution the wavelength shift for the B-band is 10 mμ, whereas in sulphuric acid solution the wavelength shift is 16 mμ. For *o*-chloro- and *p*-chloro-benzoic acid in ethanolic

solution the wavelength shift in the B-band is 5 mμ (3), whereas in dilute acid solution the wavelength shift is 12 mμ (7). These and other examples may be rationalized by supposing that the increased polarity of the solvent will often tend to keep the molecule planar, and incidentally will more effectively dislodge a less firmly held substituent in the ortho position. In this way a methyl substituent, for example in *o*-methylacetophenone, which is held in the plane of π–π conjugation by π–σ interaction, is more readily bent in sulphuric acid solution than in ethanolic solution, presumably because π–σ conjugation, compared with π–π interaction, is less effectively strengthened by the increased polarity.

This explanation shows why steric inhibition of resonance is frequently apparently more enhanced in acid media. An additional, not unrelated, effect may also be noted. If inhibition of resonance is often more at the expense of the weaker electronic interaction, the spectra of orthodisubstituted compounds in acid media would frequently be expected to resemble that of one of the monosubstituted parent compounds. In other words, steric interactions in acid solution are more likely to cause steric effects in which conjugation is sufficiently inhibited for the molecule to absorb as two distinct entities.

Further, it may be deduced from this hypothesis that ortho and meta isomers almost invariably afford similar spectra, particularly in acid or basic media. This important observation has already been noted, and has been extremely well documented by Doub and Vandenbelt (5). On the basis of simple resonance theory and our general theory of steric inhibition of resonance (1) this ortho–meta similarity may be rationalized. This follows because in meta isomers primary resonance (mesomeric) interaction is ruled out; in ortho isomers, this same mesomeric interaction is often also ruled out because of steric interaction between the two vicinal atoms or groups (see previous paragraph). Since the B- and C-bands are determined primarily by steric and mesomeric interactions, ortho and meta isomers would be expected to be similar and an enhanced similarity would be anticipated in acid and basic media. This is in fact observed. A corollary of this hypothesis would be that for such examples of ortho–meta similarity both spectra should also resemble the spectrum of one of the monosubstituted parent compounds, except that the second substituent may exert a secondary short-range effect of the type mentioned in a previous paper (11). Some relevant examples are collected in Table II, which lists spectra of ortho- and meta-disubstituted compounds together with suitable reference compounds, and also records the wavelength displacements due to the above-mentioned short-range interaction. This latter interaction will be discussed again in the next section.

The examples chosen in Table II represent groups of spectra determined under similar conditions whenever possible. Quite frequently, however, the values in a particular group represent data obtained by different workers using a variety of instruments. Even then, the data not only show a pronounced similarity in the ortho and meta isomers, but frequently also show a similarity for the above-mentioned short-range interaction. Thus, for example, in six different hydroxysubstituted compounds the wavelength shift due to the OH group is 7 ± 1.5 mμ. Likewise, for six different methylsubstituted compounds the shift due to the methyl group is 5.5 ± 1.5 mμ (see Table II). The value for the methyl group may also be compared with the well-known observation that a methyl group usually gives rise to a bathochromic shift of about 5 mμ in a variety of ethylenic systems (14). Similar sets of values may also be obtained for other substituents, for example the values for chlorine in Table II, but for many substituents the agreement is not good, particularly if the substituent is large. Some of these data will be discussed separately elsewhere (15).

In determining the wavelength shift, because of the additional effect of the secondary substituent, the meta isomer has been used, since in the ortho isomer intramolecular

hydrogen bonding, field or inductive effects, and steric effects on the primary substituent are likely to affect the absorption. An illustration of the effect of intramolecular hydrogen bonding may be provided by the spectrum of *o*-nitrophenol, which on the basis of infrared measurements (16) is believed to exist in the hydrogen-bonded form. Steric effects on the primary substituent may be assumed to occur when both ortho substituents are large. In this way, *two* steric interactions between the two vicinal substituents may occur. First, one of the two substituents may remain in the plane of the benzene ring whereas the other is twisted away from this plane. This represents a common type of steric effect as indicated both by the data recorded in the present communication and from infrared data (cf. 17). Secondly, as steric interaction further increases, the coplanarity of *both* substituents with the plane of the benzene ring may be affected. An example of this may be provided by the spectrum of *o*-chloronitrobenzene in Table II. It may be supposed that there the chloro substituent is sufficiently dislodged from the plane of the benzene ring to prevent appreciable resonance interaction between the chlorine atom and the nitro group. At the same time, the nitro group also twists in order to reduce interaction between the two vicinal substituents, and consequently the absorption of *o*-chloronitrobenzene is not that of nitrobenzene but rather that of nitrobenzene sterically hindered.

It should also be noted that the above interactions in ortho isomers may not be entirely steric in origin, since short-range inductive or field effect interactions, for example between the chloro and nitro substitutents, may contribute to the observed effect. The latter type of interaction has previously been briefly discussed for fluoro substituents (18), and may be assumed to play a part in determining spectra. Further, in this section the buttressing effect may be mentioned since it may partly account for some of the anomalous values, for example the hypsochromic shift observed in *m*-chloronitrobenzene compared with nitrobenzene (cf. 19).

THE NATURE OF THE SHORT-RANGE INTERACTION

It was shown in the previous section that sometimes the series, monosubstituted parent compound, ortho- and meta-disubstituted compound, exhibits very similar B-band maximal wavelengths (cf. for example the spectral data of acetophenone and *o*- and *m*-chloroacetophenone in Table II). In others an effect of the second substituent on the benzene ring must first be taken into account before the wavelength values are comparable. This effect has been described as a "short-range" interaction, to distinguish it from interaction which is associated with electron mobility acting along systems of conjugated bonds (mesomeric interaction). This nomenclature is based on the observation that the interaction, in the absence of other factors (see above), appears to be similar in both ortho and meta positions, and, further, the similarity of the spectra apparently still exists even if the ortho isomer is most probably non-planar (cf. for example the spectra of the toluic acids in concentrated sulphuric acid as shown in Table II).

The second point concerning the nature of this interaction is that we consider it to be of minor importance compared with the major interactions (steric and mesomeric effects) determining electronic absorption spectra. This may be deduced from the magnitude of the wavelengths shifts caused by the interactions. For example, whereas the average wavelength displacements, because of the short-range interaction, for the two substituents described in Table II are -Me 5.5 mμ, and -OH 7 mμ, the corresponding wavelength shifts caused by mesomeric interaction (as judged for shifts obtained in the parasubstituted acetophenones) are -Me 12 mμ, and -OH 14 mμ (2, 3). Even if the short-range interaction is large, as for NH_2 and O^- substituents, when wavelength shifts of up to

25 mμ are obtained, the corresponding wavelength shifts because of mesomeric interaction in the acetophenone series are 76 mμ (2) and 79 mμ (7) respectively, that is, very much larger. Further, since steric interaction can completely inhibit mesomeric interaction, both may be considered to be of similar importance in electronic spectra. Consequently, we conclude that if in substituted benzene derivatives mesomeric interaction is possible, this will normally determine predominantly the B-band of electronic absorption spectra, while the other, short-range interaction is only of secondary importance. We may also note in passing that this short-range interaction probably corresponds to the interaction deduced theoretically by Förster (6). Both these considerations point against a residual mesomeric interaction which still operates in the ortho isomer. This follows because the interaction is discernible in both ortho and meta positions to a similar extent, and is not generally more enhanced in the ortho position, as would be expected for a residual mesomeric interaction. Further, precisely such a residual mesomeric interaction may partly account for the occasional bathochromic wavelength displacement observed for the ortho isomer (see, for example, the spectra of chlorobenzaldehydes in Table II), and under these circumstances the expected bathochromic displacement relative to the meta isomer *is* obtained.

Next, it follows from theoretical considerations (cf. 20) that when both short-range and mesomeric interactions operate and when both are appreciable, the total effect will almost certainly not be simply additive but will follow a more complex pattern. This will be of importance for many paradisubstituted and, incidentally, monosubstituted benzene derivatives and may account for some of the anomalous mesomeric interactions. For example, Doub and Vandenbelt (5) found that nitro compounds frequently do not fit the normal displacement patterns; and this anomaly may be related to the relatively large short-range interaction for the nitro group (15, 21). A similar lack of additivity also prevails if more than one substituent contributes to the short-range interaction exerted on the benzene ring (cf. section on trisubstituted benzene derivatives). This again is more pronounced if the short-range interaction is large, as for example in *m*-diaminobenzene, which absorbs maximally at 240 mμ, the second amino substituent in this way causing a wavelength shift of only about 5 mμ (5).

Further, it may be noted that the order of magnitude for the short-range interaction may be related qualitatively both to the order observed for frequency displacements in some vibrational spectra and to the order of acidity constants for some aromatic acids. For example, the asymmetric stretching vibrations of nitrobenzenes are shifted to lower frequency (i.e. to longer wavelength) for meta substituents in the order $-NH_2 > -H > -NO_2$ (17), and this is qualitatively the same order as for the acidity-constant decreases in metasubstituted benzoic acids (22) and for the present short-range interactions. Generally—and this is by no means intended to rule out exceptions—all these effects will presumably be determined largely by the over-all electronegativity and hence these data may be expected to correlate also with the inductive effect. This is in fact indicated since the order for the halogens in their short-range interactions sometimes suggests the order of the inductive effects. For example, Ungnade (23) reports an order of $-F > -Cl > -Br > -I$ for the negative wave-length displacements relative to nitrobenzene. However, the inductive effect does not fully explain many of the wavelength displacements caused by the short-range interaction and hence it is preferable to consider the over-all electronegativity independently for each set of examples (15).

It also follows from the above considerations that it will normally be difficult to detect short-range interactions in the electronic absorption spectra of paradisubstituted benzene

derivatives. Exceptions may occur in compounds where the mesomeric interaction is relatively small compared with the short-range interaction. Examples of this may be provided by the various *p*-alkylsubstituted compounds which exhibit wavelength shifts in the order -*tert*-butyl > -methyl, i.e. in the order of their over-all inductive effects (cf. 24, 25).

THE B-BANDS OF TRISUBSTITUTED BENZENE DERIVATIVES

From a consideration of the previous sections it might be anticipated that the B-band spectra of trisubstituted benzene derivatives will normally be determined by the interaction of the two substituents, which when linked to the phenyl ring give rise to maximum resonance interaction and thus cause absorption at longest wavelength; the remaining substituent would be expected to exert only the short-range interaction. This expectation is supported by the observed spectra (see Table III). The data are largely those determined by Doub and Vandenbelt (13) who have already shown that the B-bands of trisubstituted benzene derivatives often closely resemble the most displaced B-band of one of the disubstituted parent compounds.

We can now relate this observation with our previous hypotheses by again postulating that one of the three substituents because of steric interactions no longer, or only partly, contributes to the observed B-band. Without introducing any additional hypotheses the data in this way correlate well with expectation. More precisely, the effects of the third substituent on the wavelength of the B-band can be classified into three types. The substituent may be almost completely dislodged, when the spectrum of the trisubstituted benzene derivative will closely resemble that of the disubstituted parent compound (see Table III, Section A). The latter is usually the para compound, but if the absorption of one of the meta or ortho isomers occurs at longer wavelength (i.e. is caused by an energetically more favorable transition) than that of the para compound, the absorption of the trisubstituted benzene derivative may resemble that of the meta or ortho isomer; the spectrum of the trisubstituted benzene derivative may also resemble that of the monosubstituted benzene derivative, if interaction between any two substituents is small. This is illustrated for a number of 2,5-disubstituted benzoic acids for which benzoic acid may be taken as the reference compound (see Table III, Section A). Sometimes also two B-bands occur for trisubstituted benzene derivatives, one corresponding to the ortho isomer and the other to the para isomer (15, cf. also 26).

Examples where some interaction with the third substituent occurs are illustrated in Section B of Table III which lists compounds where the ortho substituent makes some resonance contribution and in this way causes a bathochromic displacement of more than 5 mμ. In accordance with expectation this displacement only occurs if the vicinal ortho substituents are small, or if the interaction is essentially π–p bond interaction, which has been shown to be less direction-dependent than other interactions (3). This additional resonance interaction incidentally is assumed to include intramolecular hydrogen bonding and it should also be noted that the interaction may contribute to some of the lesser ortho effects shown in Section A of Table III. This follows because the anticipated bathochromic displacement may be cancelled out by steric effects as described in the succeeding paragraph.

Section C of Table III lists examples where the ortho substituent interferes appreciably with the resonance interaction of the reference compound and thereby gives rise to a hypsochromic wavelength displacement. This type of displacement has already been ascribed to steric effects on the primary substituent (see section on "Steric effects in acid

*Ref. 13.
†Ref. 7.
‡This series of papers.
§Ref. 5.
¶*Doub and Vandenbelt (13) refer to this band as the secondary primary band while designating the band at 275 mμ as the first primary band (B-band). Further in p-aminobenzoic acid the 270 mμ band is referred to (4) as the secondary band (C-band) and the band at 226.5 mμ as the first primary band. Our interpretation is to regard both the bands at 226.5 and 231 mμ as B-bands (first primary bands) and the bands at 270 and 275 mμ as C-bands (secondary bands). A similar reassignment has also been assumed for a number of other compounds in this table.*

and basic media"). The explanation now receives support since the shift is usually associated with decreased absorption intensity, and most frequently occurs if the third substituent is large or if the primary substituent is sensitive to steric interaction as for example in neutral solution (see Section C of Table III). Again steric effects of this type are also evident to a lesser extent in the other sections of Table III, particularly noticeable being the frequent loss of absorption intensity in the trisubstituted compound.

EXPERIMENTAL

All spectra were determined in duplicate on a Unicam SP. 500 spectrophotometer with 1 cm. quartz cells. Where applicable, the data obtained compared well with previous data reported in the literature.

Commercial samples, purified by crystallization or distillation, were used. Sodium hydroxide (1 *N*) was made up immediately before use from Fisher Certified pellets ($Na_2CO_3 < 0.5\%$), or when necessary from 5 *N* sodium hydroxide, volumetric solution, carbonate-free.

ACKNOWLEDGMENTS

The authors gratefully acknowledge a research grant from the National Research Council of Canada and a research fellowship (to A.S.R.) sponsored jointly by the following organizations: The Geological Survey of Newfoundland (Department of Mines and Resources), the Newfoundland and Labrador Corporation, and the British Newfoundland Corporation.

NOTES

2-BENZHYDRYLIMINO-4-THIAZOLIDONES AND RELATED COMPOUNDS

STANLEY O. WINTHROP AND GREGORY GAVIN

The synthesis of a series of 1-benzhydryl-2-alkyl-2-thiopseudoureas has recently been reported from this laboratory (1). These compounds exhibited a central stimulating action when administered to experimental animals. In the present investigation, certain cyclic thiopseudoureas with a structural relationship to the above compounds were prepared and screened for their pharmacological activity. The preparation of the 1-benzhydrylthioureas used in the present study was described in the previous paper (1).

The reaction of an unsymmetrically substituted thiourea with an α-haloester may produce one of two possible isomeric 4-thiazolidones depending on the manner in which the cyclization occurs (2). Thus 1-benzhydrylthiourea and ethyl α-bromoacetate yielded either 2-benzhydrylimino-4-thiazolidone or 3-benzhydryl-2-imino-4-thiazolidone. A proof of structure was carried out by the method of Davis and Dains (3). Condensation with benzaldehyde in the presence of piperidine gave 2-benzhydrylimino-5-benzal-4-thiazolidone which was then hydrolyzed by hydrochloric acid to yield 5-benzal-2,4-thiazolidinedione, a known compound. Other 1-benzhydrylthioureas and other α-haloesters gave 2-benzhydrylimino-4-thiazolidones substituted in the 3 and the 5 positions. They are listed in Table I.

2-Benzhydrylaminothiazole has been prepared by Kaye (4) from 1-benzhydrylthiourea and dimethyl chloroacetal. In a like manner 1-benzhydrylthiourea and α-chloroacetone gave 2-benzhydrylamino-4-methylthiazole. The reaction of 1-benzhydrylthiourea with β-iodopropionic acid gave 2-benzhydrylimino-4-keto-1,3-thiazane. The preparation of some 2-alkylimino-4-keto-1,3-thiazanes by a similar procedure has been reported (5). Bose and Nandi (6) have shown that the reaction between a 1-alkylthiosemicarbazide and ethyl α-chloroacetate yields a 2-alkylimino-5-keto-1,3,4-thiadiazane and not a 2-alkylamino-3-amino-4-thiazolidone. In the present investigation, 1-benzhydrylthiosemicarbazide and ethyl α-chloroacetate gave 2-benzhydrylimino-5-keto-1,3,4-thiadiazane.

Some of the cyclic thiopseudoureas were found to be central-nervous-system depressants. This is in contrast to the stimulant properties shown by the acyclic benzhydrylthiopseudoureas.

EXPERIMENTAL*

2-Benzhydrylimino-4-thiazolidone.—A solution of 1-benzhydrylthiourea (2.42 g., 0.01 mole) and ethyl α-bromoacetate (2.5 g., 0.015 mole) in 75 ml. of ethanol was allowed to stand for 16 hours at room temperature. Ether was then added to ensure complete precipitation of the product, which was filtered off and dried to yield 2.17 g., m.p. 252°–253° C. One recrystallization from 2-propanol did not change the melting point (see Table I).

2-Benzhydrylimino-5-methyl-4-thiazolidone.—1-Benzhydrylthiourea (4.8 g., 0.02 mole) and ethyl α-bromopropionate were dissolved in 50 ml. of glacial acetic acid and the solution refluxed for 16 hours. On cooling and addition of water, the product precipitated,

**All melting points are uncorrected.*

[c] *Chlorine: Calc., 9.77; found, 9.84.*

4.8 g., m.p. 195°–208° C. Two recrystallizations from ethanol raised the melting point to 245°–246° C. (see Table I).

2-Benzhydrylimino-3-hydroxyethyl-4-thiazolidone hydrochloride. — 1-Benzhydryl-3-hydroxyethylthiourea (5.7 g., 0.02 mole) and α-chloroacetic acid (1.9 g., 0.02 mole) in 25 ml. of 2-propanol containing sodium acetate (1.6 g., 0.02 mole) were refluxed for 1 hour. The sodium chloride was then removed and an excess of ethereal hydrogen chloride was added to the filtrate causing the product hydrochloride to separate, 3.7 g., m.p. 168°–169° C. Two recrystallizations from a methanol–ether mixture raised the melting point to 174°–175° C. (see Table I).

2-Benzhydrylimino-5-benzal-4-thiazolidone.—2-Benzhydrylimino-4-thiazolidone (2.6 g., 0.009 mole) and benzaldehyde (0.95 g., 0.009 mole) were dissolved in 10 ml. of absolute ethanol containing a few drops of piperidine. The reaction mixture was refluxed for 2 hours. On cooling, 2.6 g. of product precipitated, m.p. 252°–257° C. Two recrystallizations from a large amount of ethanol raised the melting point to 265°–268° C. Calc. for $C_{23}H_{18}N_2SO$: N, 7.54; S, 8.65. Found: N, 7.82; S, 8.71.

5-Benzal-2,4-thiazolidinedione.—2-Benzhydrylimino-5-benzal-4-thiazolidone (0.3 g.) was dissolved in a solution of 80 ml. ethanol and 40 ml. concentrated hydrochloric acid. The reaction mixture was refluxed for 24 hours. On cooling and removal of the ethanol *in vacuo*, the product precipitated, 0.08 g., m.p. 246°–247° C. (lit. m.p. 243° C.) (3). Calc. for $C_{10}H_7NSO_2$: S, 15.62. Found: S, 15.35.

2-Benzhydrylamino-4-methylthiazole hydrochloride.—1-Benzhydrylthiourea (4.8 g., 0.02 mole) and α-chloroacetone (2.03 g., 0.022 mole) were dissolved in 150 ml. of 1:1 ether–acetone solution. The reaction mixture was allowed to stand at room temperature for 16 hours during which time the product hydrochloride precipitated, 3.3 g., m.p. 188°–189° C. One recrystallization from ethanol did not change the melting point. Calc. for $C_{17}H_{17}N_2SCl$: C, 64.39; H, 5.36; N, 8.84; S, 10.03. Found: C, 64.48; H, 5.23; N, 9.01; S, 10.03.

2-Benzhydrylimino-4-keto-1,3-thiazane hydroiodide.—1-Benzhydrylthiourea (4.8 g., 0.02 mole) and β-iodopropionic acid (4.0 g., 0.02 mole) were dissolved in 50 ml. of absolute ethanol and the solution refluxed for 4 hours. The ethanol was then removed *in vacuo* and 25 ml. of acetic anhydride added. The reaction mixture was again heated for 4 hours on a steam bath. On cooling and addition of ether, 6.1 g. of product separated out, m.p. 191°–193° C. dec. One recrystallization from acetonitrile did not change the melting point. Calc. for $C_{17}H_{17}N_2SIO$: N, 6.62; S, 7.55; I, 29.95. Found: N, 6.98; S, 7.91; I, 30.00.

2-Benzhydrylimino-5-keto-1,3,4-thiadiazane.—1-Benzhydrylthiosemicarbazide (8.9 g., 0.032 mole), α-chloroacetic acid (3.0 g., 0.032 mole), and sodium acetate (2.6 g., 0.032 mole) were added to 75 ml. of 2-propanol and refluxed for 4 hours. Water was then added causing the product to separate out as an oil, which eventually solidified to yield 7.6 g., m.p. 114°–124° C. Two recrystallizations from ethanol gave an analytically pure material, m.p. 141°–142° C. Calc. for $C_{16}H_{15}N_3SO$: C, 64.62; H, 5.09; N, 14.13; S, 10.77. Found: C, 64.80; H, 4.94; N, 14.10; S, 10.68.

ACKNOWLEDGMENTS

The authors would like to thank Dr. C. I. Chappel for the pharmacological screening, Mr. W. J. Turnbull for the analyses, and Dr. Gilles Papineau-Couture and Mrs. J. Jachner for numerous infrared spectra.

HYDROGEN PEROXIDE AND ITS ANALOGUES

VIII. EXCESS FUNCTIONS FOR THE BINARY SYSTEMS H_2O–H_2O_2 AND D_2O–D_2O_2 [1]

PAUL A. GIGUÈRE, OSVALD KNOP,[2] AND MICHAEL FALK[3]

ABSTRACT

Recent volumetric and calorimetric data have been used to calculate the excess functions for mixtures of water and hydrogen peroxide over the entire concentration range. The results are compared with those for the corresponding deuterium compounds. The existing calorimetric and vapor-pressure measurements are not comprehensive nor accurate enough to support discussion of the finer details of the excess quantities. A maximum in the excess-volume curves, presumably related to the formation of the compound $H_2O_2.2H_2O$, persists in the liquid mixtures over an appreciable temperature range above the melting point of that compound. A possible crystal structure is proposed for the latter.

New density determinations were carried out on mixtures of heavy water and deuterium peroxide at 0° and 20° C. and the effect of deuterium peroxide on the temperature of maximum density of heavy water was measured and compared with that of deuterated alcohols. It is concluded that the structure of liquid water is easily penetrated by hydrogen peroxide molecules.

INTRODUCTION

Mixtures of hydrogen peroxide and water represent one of the simplest possible examples of a binary system of strongly polar liquids with extensive hydrogen bonding. So far the investigation of solutions on non-electrolytes for the purpose of testing the existing theories has been largely confined to non-polar systems. However, if the theory is to be extended to hydrogen-bonded systems, the gaps in the present experimental data on such systems will have to be lessened. With this aim in mind we are presenting here a comparative study of the associative properties, in the form of excess functions, of the binary system H_2O–H_2O_2 and its deuterated analogue D_2O–D_2O_2. The excess functions are based in part on our calorimetric measurements reported in paper VII of this series (1).*

SYMBOLS AND DEFINITIONS

T	temperature in ° K.
N_p	mole fraction of hydrogen (or deuterium) peroxide.
N_w	mole fraction of water (or heavy water).

**Shortly after our data were published a new diphenyl ether calorimeter was described by R. S. Jessup of the National Bureau of Standards, Washington, D.C. (2). The calibration factor of this instrument, 18.90, is slightly different from the one we used, 19.01 cal./g. Hg (3). There is little doubt that the factor found by Jessup is more accurate, as both his apparatus and calibration technique were much more elaborate than ours. Furthermore, most causes of error will give too high a factor, and Jessup's value is the lowest of all those reported so far. The resulting uncertainty in our published results (less than 0.5%) affects in no way the present discussion.*

V_p, V_w	molar volume of peroxide and water, respectively.
V	actual volume of one mole of solution.
$V^\circ = N_w V_w + N_p V_p$	ideal volume of one mole of solution.
$V^E = V - V^\circ$	excess volume of mixing.
$\theta = -100\,V^E/V^\circ$	per cent volume contraction.
C_p	actual heat capacity of solution (average value between 0° and 26.9° C.).
$C^E_p = C_p - C^\circ_p$	excess heat capacity of solution (called $\Delta_m C_p$ in paper VII).
$H^E = H^M$	excess heat of mixing (called $\Delta_m H_{mix}$ in paper VII).
$F^E = F^M - F^\circ$	excess free energy of mixing.
$S^E = S^M - S^\circ$	excess entropy of mixing.

MOLAR VOLUMES

Several sets of density determinations on aqueous solutions of hydrogen peroxide can be found in the literature. The most recent ones, showing good mutual consistency, have been combined into cubic polynomials in either weight fraction of peroxide or temperature (4). From these expressions we have calculated the molar volumes and the excess volumes of mixing over the entire composition range and from 0° to 96° C. The temperature range was extended, though with reduced accuracy, down to the liquidus curve of the system (Table I) by including the low-temperature measurements of Giguère and Geoffrion (5). The ideal volumes below 0° C. were estimated by graphical extrapolation since the density of supercooled hydrogen peroxide is not known and that of supercooled water is known only down to −20° C.

0.8964	0.8209	0.200	—	—	—	—

The excess volume of the mixtures is everywhere negative, as may be seen from the plots in Fig. 1. The variation of θ with temperature and composition is shown in Fig. 2. The pronounced maxima in the curves of Fig. 1 correspond to the maximum deviation from ideality, max θ. Fig. 3 illustrates the temperature dependence of the position of max θ. The equation of the best straight line fitting all the points of that curve up to 50° C. was found by least squares to be

$$\log \max \theta = -8.391\times10^{-3}T+2.512. \quad [1]$$

At higher temperatures the uncertainty in the density measurements was too great to yield reliable values of the maximum.

The position of max θ converges with decreasing temperature towards $N_p = 1/3$, that is

towards the composition of the only crystalline compound, $H_2O_2.2H_2O$, in the system. The near coincidence, though not the convergence, of the position of max θ in these mixtures at ordinary temperatures with the composition of the compound had already been pointed out in somewhat different terms in a paper which recently came to our attention (6).

The experimental data for the mixtures of deuterated compounds are naturally much fewer and less accurate than for the hydrogen compounds. To supplement the first

set of measurements made in this laboratory some years ago (7) we have repeated a number of determinations to define better the region of max θ. The results (Table II) show definite improvement over those of the first series owing to the larger quantity of deuterium peroxide available this time. As far as can be judged from Fig. 4, max θ occurs at the same composition in the two systems, but there is an increase in the absolute value for the deuterium system amounting to about 17% at 0° C. and about 5% at 20°.

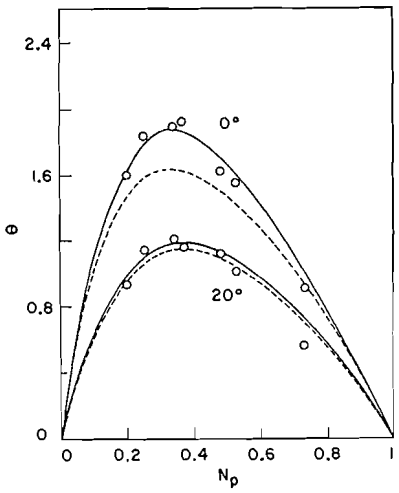

FIG. 4. Per cent volume contraction of mixtures of heavy water and deuterium peroxide at 0° and 20° C. Broken lines are the corresponding curves for the system H_2O–H_2O_2.

THERMODYNAMIC EXCESS FUNCTIONS

Another measure of the associative properties of solutions is given by the excess functions. These quantities are usually derived from vapor pressures and calorimetric data through the equations

$$F^E = RT \sum N_i \ln \gamma_i, \quad [2]$$

$$TS^E = H^E - F^E, \quad [3]$$

where the γ's are the activity coefficients. Unfortunately no complete set of data is available yet for both properties *at the same temperature.* The latest and most extensive determinations of vapor pressure and vapor composition by Scatchard *et al.* (8) were carried out at 60°, 75°, and 90° C. over a wide concentration range, and at 44.5° and 105° each for equimolar mixtures.* But the heat of mixing has been measured so far only at 0° and 26.9°, and the latter corrected to 25°. For correlation purposes one must either recalculate the H^E to 60°, 75°, and 90° or else extrapolate the vapor-pressure data down to 0° and 25°. The former procedure was deemed less reliable at this stage because it requires accurate knowledge of the heat capacity of the solutions, and the only existing set (1) consists of average values between 0° and 26.9°.

On the other hand extrapolation of the vapor pressures is not without risk. Indeed, in consolidating their results Scatchard *et al.* estimated that their vapor-composition

**However, in a paper presented at the Am. Chem. Soc. meeting in Dallas, April 1956, J. D. Floyd, J. W. Turner, and P. M. Gross, Jr. reported on measurements of vapor pressure and vapor composition of hydrogen peroxide – water mixtures at 25°, 40°, 50°, 60°, and 75° C. over the entire concentration range.*

For personal use only.

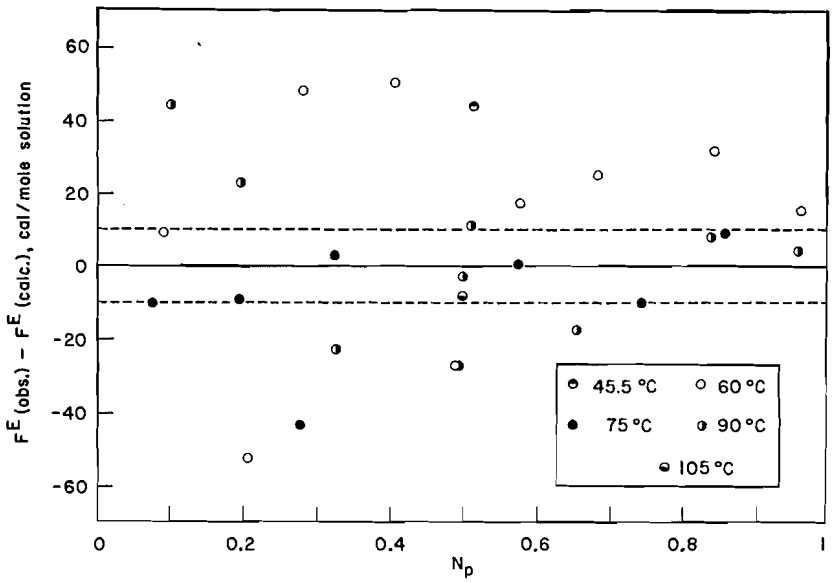

FIG. 5. Deviation of the F^E values based on individual vapor-pressure and vapor-composition measurements of Scatchard *et al.* (8) from their smoothed values obtained through equation [4].

measurements were not accurate enough for calculation of the activity coefficients.* Instead they assumed for the excess free energy an equation of the form

$$[4] \qquad F^E = N_w N_p [B_0(T) + B_1(N_p - N_w) + B_2(N_p - N_w)^2]$$

and obtained the numerical value of the B coefficients by successive graphical and analytical fitting of the experimental vapor pressures to an equation derived from [4] through the excess chemical potentials. Furthermore, in view of the rather narrow temperature range covered they used only one set of coefficients, smoothed with respect to temperature. Therefore, their calculated excess heat and entropy of mixing are temperature independent. The extent of deviation of the former quantity from our own calorimetric determinations at 0° and 26.9° has already been pointed out (Fig. 4 of paper VII). As regards the excess entropy given by their equation

$$[5] \qquad S^E = -0.97 N_p (1 - N_p)$$

it is necessarily symmetrical with respect to concentration about the middle value $N_p = 0.5$ as shown by the broken line in Fig. 6. This is to be compared with the excess-entropy curves based on our calorimetric data for 0° and 25°. Not only are they markedly unsymmetrical, but the entropy term becomes positive at 0° for dilute solutions ($N_p < 0.2$). One might be tempted to relate this feature to some property of the pure components, like the density anomaly of liquid water near the melting point. However, such inferences must be viewed with caution considering the present status of experimental evidence. Because the entropy term is obtained as the difference between two large quantities [3], even its sign in that concentration range remains uncertain pending more extensive and more accurate thermal and vapor-pressure measurements. Considerable effort will be

*In that connection it is interesting to note that although their equilibrium still was capable of greater accuracy than the static method used before by Giguère and Maass (9) their "experimental" points still show considerable spread (Fig. 5).

For personal use only.

needed to improve significantly over the present data owing to the tendency of hydrogen peroxide to decompose spontaneously.

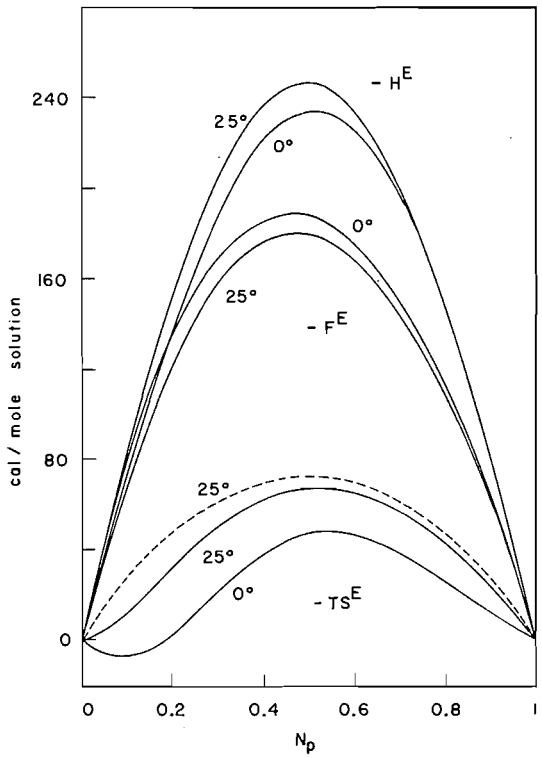

FIG. 6. Thermodynamic excess functions of aqueous solutions of hydrogen peroxide at 0° and 25° C. from calorimetric values of the heat of mixing and extrapolated vapor-pressure data.

CORRELATION OF VOLUME AND THERMODYNAMIC PROPERTIES

The excess volume of mixing is related to the other excess functions through equations

[6] $$V^E = \partial F^E/\partial p = RT \sum N_i(\partial \ln \gamma_i/\partial p)$$

and

[7] $$H^M = RT^2 \sum N_i(\partial \ln \gamma_i/\partial T).$$

Unfortunately certain information, such as the compressibility of peroxide solutions, is lacking for use in these equations, so that some sort of empirical relationship must be resorted to. A priori it seems reasonable to expect that both V^E and H^E are directly related to the number of hydrogen bonds formed on mixing. This is by no means the only factor responsible for the deviations from ideality, as proved by the fact that the curves for these two properties do not coincide. Moreover, instances are known of strongly associated binary mixtures for which the two excess quantities have opposite signs (10). However, in the present case the two are negative at all concentrations, suggesting that the assumption of proportionality to hydrogen-bond formation is tenable. Existence of such a relationship may be illustrated by plotting against composition the differences between the experimental values at 0° and at 26.9° for the three excess functions H^E, θ, and V^E, all normalized to C^E_p. Since all the points fall closely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

on the same curve (Fig. 7) whatever factors, besides the number of extra hydrogen bonds formed in that temperature interval, may be responsible for the non-ideal behavior, they must affect equally the thermal and the volume excess functions of the peroxide solutions. Whether the excess heat capacity corresponds to the same modes as in the pure components cannot be decided because of the complexity of this binary system.

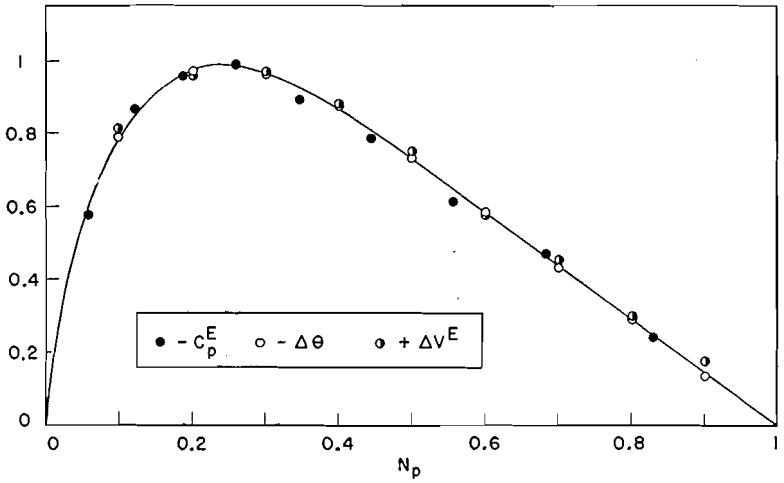

FIG. 7. Normalized values of the difference in $H^E = C_p{}^E\Delta T$, θ and V^E taken between 0° and 26.9° C.

The normalizing factor employed above in converting θ to $C^E{}_p$ may be used in turn to obtain a set of values for H^E from θ at various temperatures relative to its value at 26.9°. Obviously this procedure is open to criticism as it stands or falls with the relative

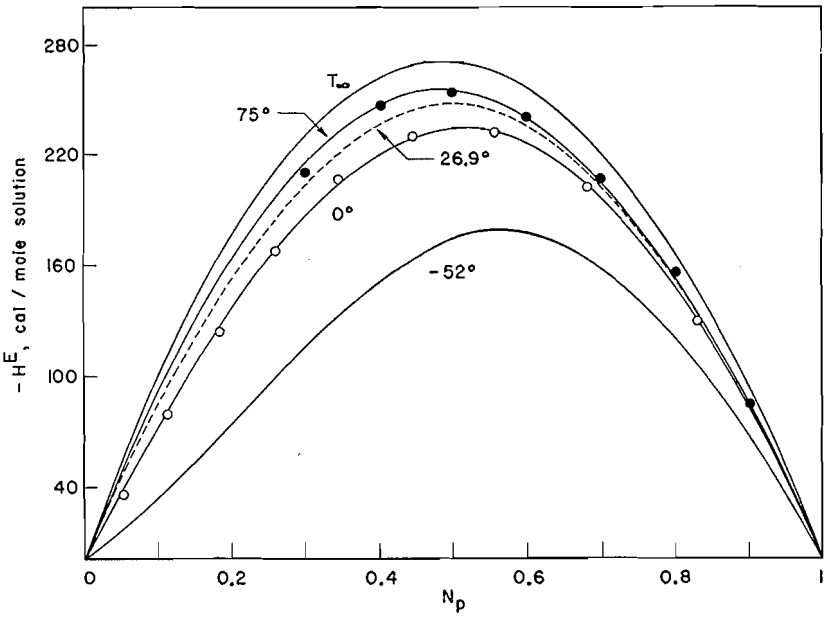

FIG. 8. Heats of mixing of water and hydrogen peroxide from the correlation of H^E and V^E. The experimental points for 75° are taken from Scatchard *et al.* (8), those at 0° from Ref. (1).

For personal use only.

constancy of the average C^{E}_{p} at higher temperatures. Nevertheless, a fair agreement is obtained (Fig. 8) with the calculated H^{E} of Scatchard *et al.*, for 75°, their most favorable temperature. Actually the agreement is not too surprising since the excess heat of mixing is not particularly sensitive to temperature. Extension of the calculation to the high-temperature (T_{∞}) and the low-temperature limits (−52°, the melting point of the solid hydrate) gives an idea of the extent of variation of H^{E}.

Next to the number of extra hydrogen bonds, the most important factor should be the relative strength of such bonds between unlike molecules. The two factors are by no means equivalent, the former being essentially of a configurational nature. Indeed, a peroxide molecule with one site engaged in hydrogen bonding still has five other sites available for potential bond formation: either three acceptors and two donors or four acceptors and one donor. A water molecule in similar circumstances has only three sites available. Thus addition of hydrogen peroxide to water may have a cementing effect on the open, fragmentary ice structure which persists in the liquid above its melting point. This is borne out by the large effect of hydrogen peroxide in lowering the temperature of maximum density of water, as already pointed out (11), in contrast with the behavior of alcohols (Fig. 9).

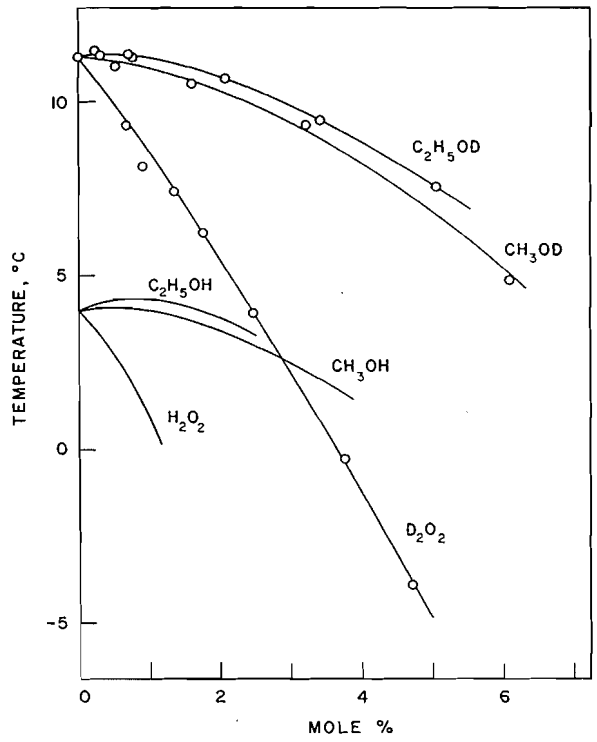

FIG. 9. Effect of different solutes on the temperatures of maximum density of water and heavy water. The curves for water are from Ref. (11).

As regards the strength of hydrogen bonds in the solutions relative to those in the pure components, the experimental evidence is meager and inconclusive. Bain (12) observed a slight shift of the O—H stretching fundamentals in the infrared spectra of peroxide solutions but he did not investigate its dependence on composition. In the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Raman spectra Taylor and Cross (13) detected a shoulder on the low-frequency side of the O—H stretching bands whose intensity increased with peroxide concentration up to a distinct maximum in the range $N_p = 0.2$ to 0.4 at $-40°$ C. At room temperature the intensity increased likewise but did not reach a maximum. The same authors also observed a concentration-dependent shift towards higher frequencies of the bending vibration ν_2 of both the water and hydrogen peroxide molecules. A systematic infrared study of these mixtures in the solid state at low temperatures (14) has confirmed these results and revealed, in addition, a number of extra bands in the low-frequency region with maximum intensity at about $N_p = 0.3$. It has been concluded (13) that an increase in the number of hydrogen bonds on mixing must be responsible for the above shifts of the bending modes towards higher frequencies, this being the experience also with other liquids. However, it is practically impossible with these methods to differentiate between varying hydrogen-bond strength and number of bonds. Refined X-ray diffraction techniques coupled with nuclear magnetic resonance investigations of the hydrate should provide useful structural data to supplement the thermodynamic arguments.

The maxima in the V^E of θ curves (Fig. 1) are obviously related in some way to the existence of the crystalline hydrate $H_2O_2.2H_2O$. In view of the presumably three-dimensional structural network and the low stability of the solid, the latter confirmed by the shape of the liquidus curve, it may not be appropriate to speak of persistence of the hydrate in the liquid above its melting point. It seems certain, however, that the packing and bonding factors are particularly favorable in liquid mixtures of water and hydrogen peroxide at N_p close to 1/3, so that optimum association ensues. The distinction between the two ways of stating the situation is mainly a matter of wording.

THE CRYSTALLINE HYDRATE

Knowledge of the structure of the solid hydrate would be valuable for interpreting the excess properties of the liquid mixtures. Unfortunately very little is known about it. Natta and Rigamonti (15) obtained an X-ray powder diffraction photograph of the solid and concluded that it had a lattice of low symmetry. The suggestion that the tetragonal symmetry of pure hydrogen peroxide degenerates progressively into monoclinic on addition of water (16) is unsubstantiated. The symmetry degeneration would entail formation of solid solutions contrary to definite experimental evidence (17). The same conclusion was already reached by Natta and Rigamonti, who failed to observe any shift in the positions of the peroxide lines in X-ray diffraction photographs of solid hydrogen peroxide containing 10 and 18% water. The extra features appearing on addition of water were assigned by them to the presence of the solid hydrate as a separate phase.

It is not difficult to visualize for that hydrate a highly organized structure which might be related to molecular aggregates of short lifetime existing in the liquid at low temperatures, and responsible for local density increases. The only requirement is the maximum engagement of the available donor and acceptor sites in hydrogen bonding. There is a total of six donor and eight acceptor sites per "molecule" of the compound, the water molecules contributing four of each kind and the peroxide molecule, two donors and four acceptors. With maximum possible engagement there will always remain two vacant acceptor sites.

The structure that we suggest here (Figs. 10 and 11) is based on the following assumptions: the unengaged acceptor sites are located on the peroxide oxygens; each peroxide molecule is surrounded by four water molecules; each water molecule is surrounded by

FIG. 10. Possible structure of the crystalline hydrate $H_2O_2.2H_2O$ viewed along the rows of peroxide molecules. (White balls, peroxide oxygens; black balls, water oxygens; hydrogen atoms not shown.)
FIG. 11. Same structure as in Fig. 10 viewed in a direction normal to the puckered water–peroxide sheets.

two water and two peroxide molecules; all hydrogen bonds are linear and of equal length; all bond angles are tetrahedral. The resulting structure is of orthorhombic symmetry with two $H_2O_2.2H_2O$ "molecules" per unit cell. Assuming 2.8 Å for the length of the hydrogen bond and 1.5 Å for the O–O distance in the peroxide molecule, the calculated density turns out to be close to the value 1.20 indicated in preliminary measurements at the melting point of the hydrate, −52° C. The structure can, in fact, be looked upon as an extreme case of the substitution process proposed by Abrahams, Collin, and Lipscomb (16). Alternate molecules in the infinite chains of pure peroxide are replaced by pairs of water molecules of appropriate orientations. The original helical peroxide chains are transformed into puckered sheets of water and peroxide molecules held in parallel stacks through hydrogen bonds normal to the sheets.

Although we assumed tetrahedral angles, this is not a necessary requirement. Even with bond angles close to their values in the free molecules the symmetry of the lattice could be preserved and the distortion would be slight. In fact, the distance between the unengaged acceptor sites of nearest peroxide oxygens would then become slightly larger than 2.8 Å, which is perhaps nearer the expected separation. Bond angle distortion in a peroxide molecule can easily take place through twisting about the O–O bond. Indeed, spectroscopic evidence indicates that the restoring force for that deformation is rather small (4); also, a recent infrared investigation of the crystalline dihydrate at low temperature leads to the conclusion that the peroxide molecule is somewhat distorted in that compound (14).

There are other ways in which the hydrogen bonds in solid $H_2O_2.2H_2O$ can be arranged into three-dimensional networks similar to the one just described. The oxygen atoms of some of such structures are roughly in the same relationship to each other as the silicon atoms in β-tridymite to those of β-cristobalite. They are all structures of equal or almost equal density, and probably also of very similar lattice energies. The similarity might account for the strong association in aqueous solutions of hydrogen peroxide, since aggregates of high local density may be formed in several, more or less equivalent ways.

COMPARISON OF THE HYDROGEN AND DEUTERIUM SYSTEMS

The pair of binary systems H_2O–H_2O_2 and D_2O–D_2O_2 offer a particularly favorable situation for investigating the effects of isotopic substitution on the thermodynamic properties of highly associated liquids. Obviously, one cannot expect any detailed information from mere determinations of bulk properties. Comparative studies of hydrogen-bonded crystals by Ubbelohde and his co-workers (18–20) have established that deuterium substitution leads to a measurable lengthening of the short bonds (shorter than about 2.65 Å) whereas for longer bonds, as in the present case, the effect is either a small contraction or is not observable at all. No such observations have been made on liquids, but the same situation may be presumed to obtain.

It is generally agreed that the zero-point energy is the main factor responsible for bond-energy difference in isotopic compounds, although the contribution of thermal energy should not be overlooked entirely. Since the extent of hydrogen bonding in associated liquids varies with temperature, comparison of the hydrogen and deuterium systems of compounds should be made at the appropriate "corresponding temperatures". We may illustrate this point by considering the effect of deuterium substitution on the temperature of maximum density of liquid water. In D_2O the temperature interval between the melting point and the maximum density (3.8° to 11.2° C.) is nearly double that for H_2O (0° to 4.1°). This anomaly in both liquids is due to persistence above the melting point of some of the residual "open structure" of ice, a structure resulting from the strongly directional character of the hydrogen bonds. Bending of these bonds is achieved mainly through rocking or "libration" of the individual water molecules about their center of gravity. Since the moments of inertia of D_2O are roughly double (1.90 times) those of H_2O, the thermal energy required for the process should therefore be double, as observed. The amount of residual ice structure must be approximately the same in water at 4.1° and in heavy water at 11.2°. This is in agreement with our observations on the effect of deuterium peroxide and deuterated alcohols on the temperature of maximum density of heavy water. As may be seen in Fig. 9 the curves for the various isotopic pairs are nearly parallel.

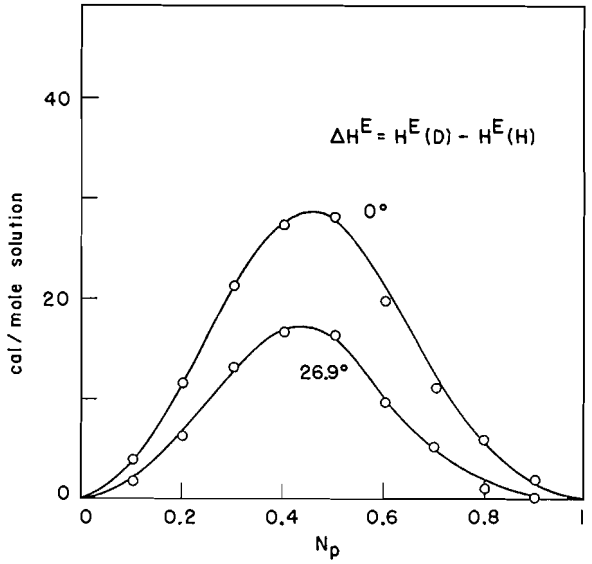

FIG. 12. Differences in the heats of mixing of the isotopic water–peroxide mixtures.

For the pure components comparison of the melting point (21), heat capacity, and heat of vaporization (1) denotes a slightly greater association of the deuterium compounds. By simple analogy we would expect correspondingly higher values of the excess functions of mixing for the deuterium system, and this is true of C^E_p and V^E. Quite unexpectedly, however, this trend is reversed in the case of H^E, the values for the deuterium compounds being significantly smaller (by nearly 10% at 25°) than for the hydrogen compounds (Fig. 12). If a temperature correction is applied to bring the two systems to the same "corresponding residual-structure states" as suggested above, namely by raising the temperature of the D_2O–D_2O_2 system by some 7°, then the two V^E curves (Fig. 4) are brought into near coincidence and the difference at the maximum in the two H^E curves is reduced by about one-third. The rest might be interpreted as an indication of weakening of the hydrogen bond on deuterium substitution. Before a more precise appraisal of the relative importance of the configurational and the other factors involved can be achieved more experimental data will be necessary, in particular on the temperature dependence of the heat capacity of the two isotopic systems. We are planning to complete such measurements at a variety of temperatures over the range 0° to 75° at all concentrations.

ACKNOWLEDGMENTS

We are indebted to the National Research Council for financial assistance, to the Shawinigan Chemical Co. for a fellowship, and to Dr. L. C. Leitch for the gift of samples of deuterated alcohols.

RÉSUMÉ

A partir de données récentes sur les propriétés volumiques et thermiques des solutions de peroxyde d'hydrogène et d'eau on a calculé les fonctions d'excès de ce système binaire. On a repris les mesures de densité des solutions de peroxyde de deutérium et d'eau lourde et on a étudié l'effet de divers composés deutérés sur la température de densité maximum de l'eau lourde. De cette étude il appert que les molécules de peroxyde d'hydrogène s'insèrent facilement dans la structure de l'eau et disloquent les traces de réseau cristallin qui y persistent encore au-dessus du point de fusion.

On propose une structure cristalline pour le composé $H_2O_2.2H_2O$.

INFLUENCE OF CALCIUM IONS ON THE MYOSIN-CATALYZED HYDROLYSIS OF ADENOSINE TRIPHOSPHATE[1]

G. E. Pelletier and Ludovic Ouellet

ABSTRACT

The activation of the myosin-catalyzed hydrolysis of adenosine triphosphate by calcium ions has been studied at pH 7.5 over a range of temperature extending from 3° to 25° C. There is evidence that the activation is due to the equilibrium formation of a complex between adenosine triphosphate and calcium ions.

From such a reaction mechanism, values of equilibrium constants are reported for the binding of adenosine triphosphate to the myosin in the presence and in the absence of calcium ions, together with stability constants for the calcium complexes of both the adenosine triphosphate and the myosin – adenosine triphosphate. The influence of hydrogen-ion concentrations on these constants is indicated.

INTRODUCTION

In the presence of myosin, a muscle protein, adenosine triphosphate (ATP) is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate. This reaction has already been studied and related to the process of muscular contraction by Szent-Gyorgyi (1) and Engelhardt and Liubimova (2).

Various aspects of the kinetics of this reaction have been reported by Mommaerts (3, 4) including the influence of pH, magnesium, and ADP on the rate of the reaction at 27° C.

The influence of temperature on both the over-all rate and the enzyme substrate interaction constant has been reported previously (5). Pressure and ionic strength effects were studied by Laidler and Beardell (6).

This paper reports on the activation of the reaction by calcium ions at pH 7.5 over a range of temperatures. The reaction is interesting from this particular point of view as it proceeds both in the presence and in the absence of calcium ions (4).

Treatment of the Data

In the formation of enzyme–substrate–modifier complexes, the modifier (activator or inhibitor) is usually treated as being bound to an enzyme active site. If instead the modifier were bound in the complex to the substrate only, a general reaction mechanism for such a system could be represented by the following equations:

$$[1] \qquad S + M \overset{K_1}{\rightleftharpoons} SM,$$

$$[2] \qquad E + S \overset{K_2}{\rightleftharpoons} ES \overset{k_0}{\rightarrow} E + \text{Products},$$

$$[3] \qquad E + SM \overset{K_3}{\rightleftharpoons} ESM,$$

$$[4] \qquad ES + M \overset{K_4}{\rightleftharpoons} ESM \overset{k_r}{\rightarrow} E + \text{Products}.$$

In this scheme S is a substrate molecule, E and M are enzyme and modifier molecules that form with S the binary complexes ES and SM, and the ternary complex ESM. Only the complexes ES and ESM dissociate into products. The rate constants k_0 and

[1]*Manuscript received January 29, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada. Grateful acknowledgment is made to the National Research Council of Canada for financial assistance.

k_r are first-order rate constants for the breakdown of ES and ESM into enzyme and products of the reaction. All other constants are considered to be equilibrium constants.

The rapid equilibrium hypothesis yields an expression which is adequate to describe the experimental results in the kinetic behavior of the myosin – ATP – calcium ions system. As pointed out by Schwert (7), this observation does not eliminate the possibility that steady-state conditions prevail. Evidence along these lines arises from other considerations (8).

Under equilibrium conditions the rate of formation of products v in the above system can be written as

$$[5] \qquad v = \frac{k_r[\mathrm{E}]_0}{1+(1/K_2K_4[\mathrm{M}][\mathrm{S}])+(1/K_4[\mathrm{M}])} + \frac{k_0[\mathrm{E}]_0}{1+(1/K_2[\mathrm{S}])+K_4[\mathrm{M}]},$$

The different equilibrium constants can be evaluated through a proper choice of experimental conditions.

If $[\mathrm{M}] = 0$ or $K_4[\mathrm{M}] \gg 1$, equation [5] reduces to well-known Michaelis–Menten equations (9). K_2 and K_3 can then be obtained from plots of $1/v$ against $1/[\mathrm{S}]$ (10).

If $K_2[\mathrm{S}] \gg 1$ the equation can be rearranged to

$$[6] \qquad v-v_0 = \frac{(k_r-k_0)[\mathrm{E}]_0}{1+(1/K_4[\mathrm{M}])}$$

where $v_0 = k_0[\mathrm{E}]_0$. In this case a plot of $1/(v-v_0)$ against $1/[\mathrm{M}]$ gives K_4.

K_1 can be obtained from the thermodynamic relation

$$[7] \qquad K_1K_3 = K_2K_4.$$

If specific binding of the modifier on the enzyme did occur, equation [1] would become

$$[8] \qquad \mathrm{E} + \mathrm{M} \overset{K_1'}{\rightleftharpoons} \mathrm{EM}$$

and equation [3],

$$[9] \qquad \mathrm{EM} + \mathrm{S} \overset{K_3'}{\rightleftharpoons} \mathrm{EMS}.$$

Assuming equilibrium conditions, a simple expression can be derived for a system involving equations [8], [9], [2], and [4] (11). Although the expression obtained is different from equation [5], it reduces to simple Michaelis–Menten relations for both $[\mathrm{M}] = 0$ and $K_4[\mathrm{M}] \gg 1$, and to equation [6] for the cases where $K_2[\mathrm{S}]$ or $K_3[\mathrm{S}] \gg 1$. The interpretation of the constants is of course different. Evidence for the first mechanism proposed will be presented later in this paper.

EXPERIMENTAL PART

Reagents

The dipotassium salt of adenosine triphosphate (Pabst Laboratories, Milwaukee, Wis.) was used throughout these experiments. Tris(hydroxymethyl)aminomethane (THAM) (Fisher purified grade) and potassium chloride (Fisher certified reagent) were recrystallized from glass-distilled water. Calcium chloride was a certified reagent (Fisher). Acetic acid was Merck reagent grade.

Rabbit back-muscle myosin of the Weber-Edsall type was prepared according to a procedure described by Botts and Morales (12). Myosin concentrations were determined by a micro-Kjeldahl nitrogen-determination method. The myosin had a specific activity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

of 5.1×10^{-6} moles of ATP hydrolyzed per second per gram of protein, at pH 7.5, in 0.6 M potassium chloride and 0.01 M calcium chloride, at 25° C.

Procedure

All reactions were carried out in buffered solutions containing 0.6 mole of potassium chloride and 0.1 mole of THAM per liter adjusted at the proper pH with acetic acid using a Beckman model G pH meter. These buffers were so adjusted at a series of temperatures, since the pH of THAM-buffered solutions varies considerably with temperature.

The solutions were kept in a constant-temperature bath (±0.1° C.) for 15 minutes, then mixed. At measured intervals of time, samples were pipetted into equal volumes of 20% trichloroacetic acid, thus precipitating the myosin which was removed by filtration through a dry filter paper. Phosphate concentrations in the filtrate were determined colorimetrically by the Fiske – Subba Row method (13), using a model DU Beckman spectrophotometer.

The rate of the reaction was measured as the number of moles of inorganic orthophosphate produced per liter per second.

RESULTS AND DISCUSSION

At constant concentration of myosin, in the presence of 5×10^{-4} moles per liter of ATP, the rate was found to increase with the concentration of calcium chloride according to equation [6]. At concentrations of calcium chloride higher than 0.01 M an already reported (4) lowering of the rate has been observed. Fig. 1 shows the results of a series of experiments at pH 7.5 and three temperatures. For the determination of the constants, the rates at zero concentration of calcium ion v_0 were subtracted from the rates obtained in the presence of calcium ions v, and the reciprocal of these values was plotted against the reciprocal of the calcium-ion concentrations. From these plots values for the constant K_4 for the binding of the calcium ions on the myosin–ATP complex were determined for each temperature. The apparent heat of reactions, $-\mathrm{R}\ d\ln K_4/d(1/T)$, was −3.5 kcal. per mole of calcium ions. The change in entropy was +3.0 e.u.

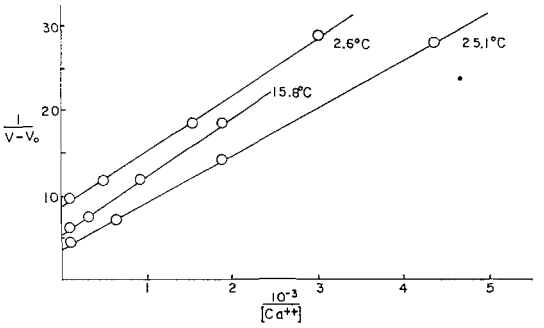

FIG. 1. Determination of K_4 in liters per mole by plotting $1/(v-v_0)$ against the reciprocal of the calcium-ion concentration in moles per liter at pH 7.5.

The pH of the solution had little effect on this constant. At 25° C. in the presence of 0.75 g. of myosin per liter K_4 was found to be 7.5×10^2 liters per mole at pH 7.5 and 8.0×10^2 liters per mole at pH 8.5. These values are consistent with data reported by Green and Mommaerts (4).

There is some evidence that the values of the experimentally determined constants

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

depend on the concentration of enzyme. Fig. 2 shows the effect of the enzyme concentration on the constant K_4 at 25° C. Assuming that the only effect of the enzyme is to decrease somewhat the concentration of the calcium ion in solution by non-specific binding, extrapolation to zero concentration of enzyme should give the constant K_4 independent of enzyme concentration. The extrapolated value of K_4 at 25° C. is approximately 1.5×10^3 liters per mole.

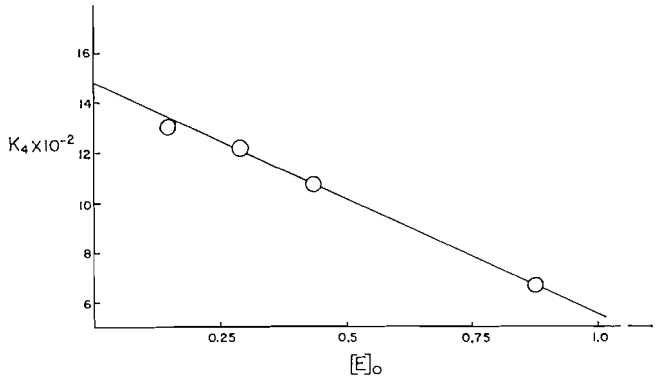

FIG. 2. Variation of the constant K_4 with enzyme concentration at 25° C. [ATP] = 5×10^{-4} M at pH 7.5.

It is interesting to note at this point that the stability constant of ATP Ca^{-2} is given by Smith and Alberty (14) as 1970 ± 280 at 25° C. and an ionic strength of 0.2. The agreement between this value and the above extrapolated value of K_4, although it could be a pure coincidence, supports the assumption made at the beginning of this paper that the activator calcium ion is bound to the ATP molecule in the ternary myosin–ATP–calcium complex. This would not of course exclude non-specific binding of calcium ions on the protein. The variation of K_4 with enzyme concentration would indeed suggest that calcium ions are bound to a considerable extent on the protein.

The constants K_2 and K_3 for the formation of the enzyme–substrate complex in the absence and in the presence of calcium ions were determined at pH 7.5 over a range of temperatures. Fig. 3 shows the results of these experiments as log K against $1/T$. The data from this figure suggest $\Delta H = +9$ kcal. per mole and $\Delta S° = 50$ e.u. The presence of calcium ions apparently does not affect to any great extent the binding of ATP on myosin. The interpretation of the above enthalpy and entropy values is complicated by contributions from hydrogen-ion concentration effects. Raising the pH from 7.0 to 9.3 lowers the value for the constant K_3 from 9.2×10^4 to 1.2×10^4 liters per mole at 25° C. (Fig. 4). A detailed description of K_3 as a function of hydrogen-ion concentration is made difficult by the fact that at high pH the enzyme is deactivated rapidly as shown by a sharp drop in the activity–pH curve around pH 9.5.

From equation [7] and the fact that $K_2 \cong K_3$, one finds that $K_1 \cong K_4$. This would imply that the calcium ion is bound just as readily to the substrate in the enzyme–substrate complex as it is to the substrate alone. As in the case of K_4 the value obtained for the constant K_1 is very close to that reported for the ATP calcium-ion stability constant (14). In an ATP – calcium ion system, there exists independently of any mechanism an equilibrium between the ATP–calcium complex and the ATP and calcium ions. The fact that this equilibrium constant has within experimental error the same value as the constant obtained in these experiments for K_1 supports the idea that K_1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

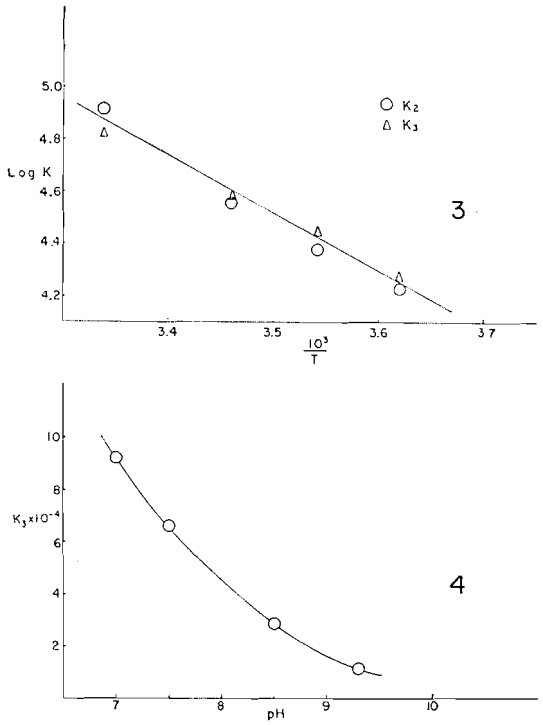

FIG. 3. Variation of the equilibrium constants for the formation of the myosin–ATP complex in the absence of calcium ions (○) and in 0.01 *M* calcium chloride solution (△).
FIG. 4. Influence of the pH on K_3 at 25° C.

actually is the equilibrium constant for the binding of calcium ions on ATP rather than the equilibrium constant for the binding of calcium ions on myosin. On the other hand, this might not be unequivocal evidence for the mechanism suggested here. As pointed out previously, the present treatment of data (equation [6]) would still describe the system if the calcium ions were bound to the active site of the enzyme.

As the variation of K_2 with temperature follows that of K_3, K_1 includes the same thermodynamic quantities as K_4, that is $\Delta H = -3.5$ kcal. per mole, $\Delta S° = +3$ e.u. These values are quite different from those reported by Smith and Alberty (14) for orthophosphate, where the formation of the calcium phosphate complex is mostly due to an increase of entropy. The behavior of ATP towards calcium ions however could be somewhat different from that of orthophosphate.

CONCLUSION

The data presented in this paper are consistent with the suggestion that the activation of the myosin-catalyzed hydrolysis of ATP by calcium ions is due to the formation of an ATP–calcium complex. The formation of such a complex would be slightly exothermic and accompanied by a small increase in entropy.

RÉSUMÉ

L'influence de la concentration des ions calcium sur le taux d'hydrolyse de l'adénosine triphosphate à été étudiée à des températures allant de 3° à 25° C. Il existe des indications que l'"activation" du système dépend de la formation d'un complexe ATP–calcium, en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

état d'équilibre. Utilisant ce mécanisme, on a déterminé des constantes d'équilibre se rapportant à la formation du complexe myosine–ATP en la présence et en l'absence d'ions calcium, de même que les constantes de formation à l'équilibre des complexes des ions calcium avec l'adénosine triphosphate et l'intermédiaire myosine – adénosine triphosphate. L'influence de la concentration des ions hydrogène est mentionnée.

LYCODINE, A NEW ALKALOID OF LYCOPODIUM ANNOTINUM[1]

F. A. L. Anet and C. R. Eves

ABSTRACT

A new alkaloid, lycodine, $C_{17}H_{24}N_2$, m.p. 118°, has been isolated from *Lycopodium annotinum*. Lycodine is a tetracyclic diacidic base containing a secondary nitrogen atom, a 2,3-disubstituted pyridine ring, and a C-methyl group. The 2,3-disubstitution is in the form of a saturated six-membered ring.

The alkaloids of *Lycopodium annotinum* L. have been studied by several groups of workers in Canada and in Europe (1, 2, 3, 4, 5). The structure of annotinine, $C_{16}H_{21}O_3N$, which is the main alkaloid of this species, is now known (6, 7) and is of a quite novel type. It therefore becomes of interest to study the chemical structure of the minor alkaloids of this plant.

During the process of developing suitable methods for the separation of the many minor alkaloids which have been reported to occur in this *Lycopodium* species, we noticed that certain fractions possessed ultraviolet absorption characteristic of a pyridine chromophore, more or less submerged behind general absorption. This paper describes the isolation, characterization, and partial determination of the structure of a new alkaloid, lycodine, which was responsible for this characteristic absorption.

Lycodine was concentrated by countercurrent distribution of the alkaloid mother liquors from the crystallization of annotinine. Two successive countercurrent distributions were carried out, first in six large separatory funnels with the system chloroform–buffer of pH 6 and then in a 60-tube Craig machine with the system chloroform–buffer of pH 5.2. From these countercurrent distributions an alkaloid fraction was obtained which had the correct ultraviolet absorption. By chromatography of this fraction on activated alumina pure crystalline lycodine was obtained.

Lycodine, m.p. 118°, $[\alpha]_D$ −10°, had the formula $C_{17}H_{24}N_2$ and gave a characteristic dipicrate, m.p. 229°–233° (decomp.), which was sparingly soluble in methanol. Titration of the base in 50% methanol showed that the pK_a's of the base were 3.97 and 8.08. One C-methyl group was found to be present by the Kuhn–Roth method. The ultraviolet spectra of the base in neutral and in acid solutions are shown in Fig. 1, and correspond to an unconjugated pyridine chromophore in the base and salt forms respectively. A fuller discussion of these spectra will be left till after consideration of other results (see below).

The infrared spectrum of the base (in Nujol) is shown in Fig. 2; the sharp band at 3270 cm.$^{-1}$ must be due to a N—H group (8). As often happens (8) this band is of very low intensity in the spectrum (Fig. 2) of the carbon tetrachloride solution of the compound. The presence of a pyridine ring is confirmed by the band (9) at 1580 cm.$^{-1}$ (in Nujol) and that of a C-methyl group by a band (10) at 1382 cm.$^{-1}$ (in CCl_4). Acetylation of lycodine with acetic anhydride gave a N-acetyl derivative, isolated as the monopicrate. Titration of the picrate showed that the acetylated base had only one basic center (pK_a 4.95). Hydrolysis of N-acetyl lycodine gave back lycodine, thus confirming the presence of a secondary nitrogen atom in the alkaloid.

In order to determine the substitution on the pyridine ring we examined the NMR spectrum (Fig. 3) of lycodine. Under moderately high resolution there are three peaks of

equal area at low field. These are probably due to protons on the pyridine ring (11). The sharp peak at highest field has three times the area of any of the peaks at lowest field and must correspond to the C-methyl group already found. It may be observed that the low value (61% of theoretical) found in the Kuhn–Roth estimation and the fact that the C-methyl peak in the NMR spectrum is unsplit both suggest that the methyl group is attached to a quaternary carbon atom. The other peaks in the spectrum correspond to the remaining protons in the molecule.

The spectrum of the low field part is shown at higher resolution above the main spectrum in Fig. 3. Each peak is split into four peaks, not always very well resolved.

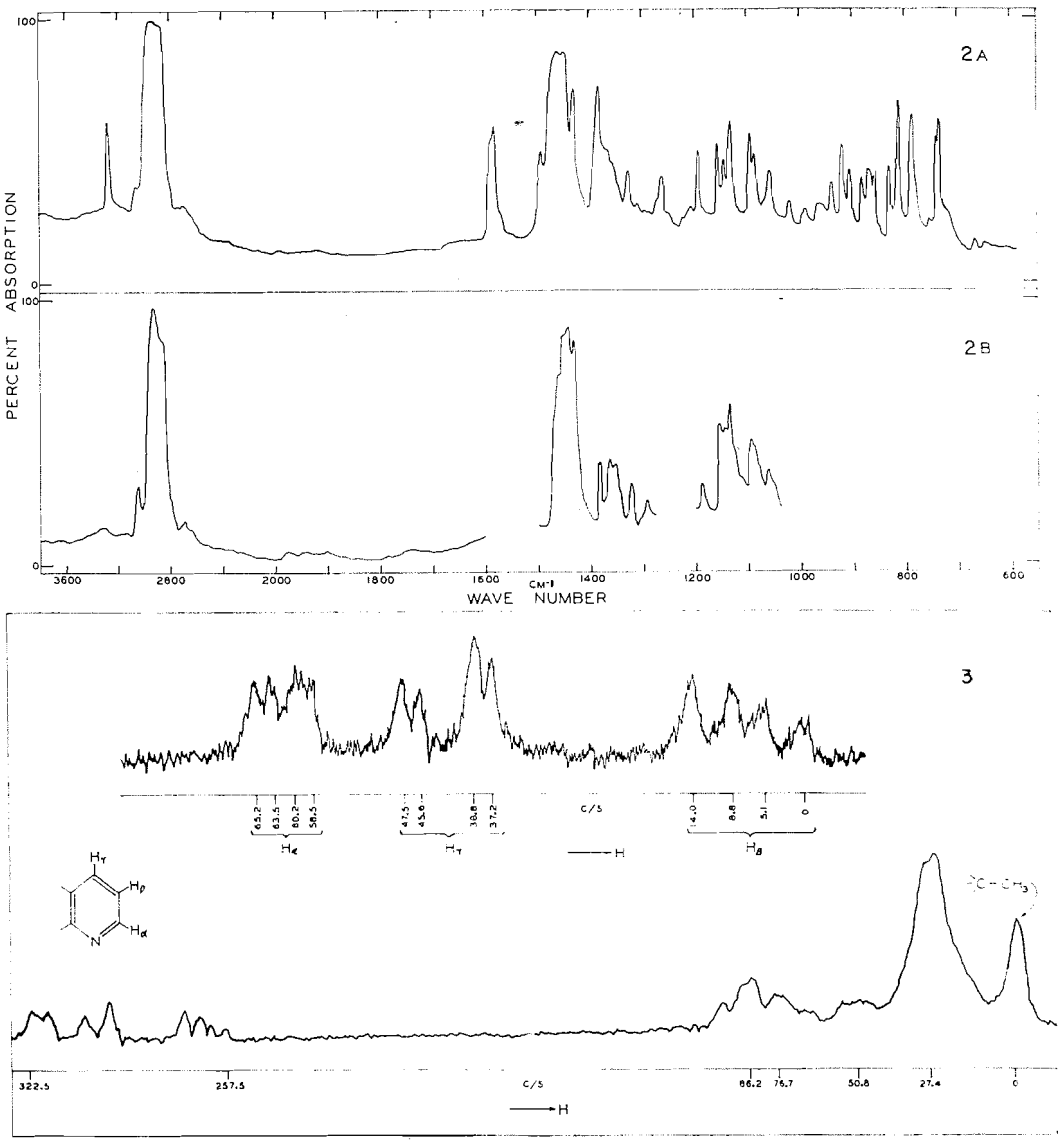

FIG. 2. Infrared absorption spectra of lycodine. A, Nujol mull; B, CCl_4 solution (1 mm. path length, 31 mg. per ml.).

FIG. 3. Nuclear magnetic resonance spectrum of lycodine. The upper curve represents the peaks at left of lower curve at higher resolution.

Bernstein, Pople, and Schneider (11, 12, 13) have recently examined the spectra of pyridine and various substituted pyridines and discussed the effect of chemical shifts and coupling constants on the spectra. From their analysis it can be seen that lycodine must be a 2,3-disubstituted pyridine, and in fact the spectrum of lycodine is very similar to that of 2,3-lutidine except for a difference in the relative chemical shift of the γ proton. The three peaks at low field may be assigned, from left to right, to the α, γ, and β protons of the pyridine ring.

The relative chemical shifts and coupling constants of the pyridine protons of lycodine

compared with those of 2,3-lutidine and pyridine are given in Table I. The observed intensities and energies of the signals from the pyridine protons of lycodine are in satisfactory agreement (Table II) with those calculated from the above parameters by the method of Bernstein, Schneider, and Pople (11). This confirms that the three peaks at low field indeed originate from the protons on the pyridine ring, and not from any other

protons. The reason for the abnormal chemical shift of the γ proton of lycodine may be due to the nearness of the secondary nitrogen atom. Although, as will be shown later (see below), the secondary nitrogen atom is most probably separated from the pyridine ring by more than one carbon atom, it may still be fairly close in space to the γ proton. The abnormal chemical shift is not due to the fact that in lycodine, as will also be shown below, the 2,3-substitution is in the form of a saturated six-membered ring, since 5,6,7,8-tetrahydroquinoline gave a NMR spectrum closely similar to that of 2,3-lutidine.

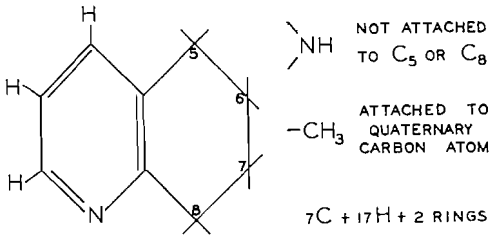
We may be certain, therefore, of the presence of a 2,3-disubstituted pyridine ring in lycodine. Recently Godar and Mariella (14) have recorded the ultraviolet absorption spectra of 2,3-lutidine, 2,3-trimethylene-, 2,3-tetramethylene-, and 2,3-pentamethylene-pyridine both as free bases and as salts. Their data have been replotted in Fig. 1 using a linear ϵ scale, instead of the original log scale, which facilitates the comparison of these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

curves with those of lycodine. It is clear that lycodine shows the greatest similarity to 2,3-tetramethylenepyridine (5,6,7,8-tetrahydroquinoline) and therefore that lycodine has in fact a saturated six-membered ring fused 2,3 to the pyridine ring.

The pK_a's (3.97 and 8.08) of lycodine are appreciably different from those of nicotine (3.35 and 7.70) determined under identical conditions. The difference in pK_a's of the non-pyridine nitrogen atoms may be due to the secondary nature of the nitrogen atom in one case and the tertiary nature in the other. The difference in the pK_a's of the pyridine nitrogen atoms, however, cannot be due to such an effect, but is readily understood if the saturated nitrogen atom is further (i.e. at least β) from the pyridine ring in the case of lycodine than in the case of nicotine.

Lycodine does not seem to contain unsaturation apart from the pyridine ring, as far as is shown by U.V., I.R., and NMR spectra. Therefore lycodine contains four rings, and the facts known about its constitution may be summarized by the following partial structure:



Finally, it may be mentioned that there appears to be a close similarity between lycodine and the *Lycopodium* alkaloid, β-obscurine, $C_{17}H_{24}ON_2$, which has been shown by Marion and Moore (15) to have an α-pyridone chromophore. Although the empirical formula of β-obscurine is correct for it to be the α-pyridone analogue of lycodine, the relationship between the two alkaloids cannot be so simple, for the basic nitrogen atom of β-obscurine appears to be tertiary, as the alkaloid could not be acetylated.

EXPERIMENTAL

Ultraviolet spectra were measured in methanol on a Beckman DK-2 spectrophotometer. Determinations of pK_a values were made by electrometric titrations in 50% aqueous methanol on 10–15-mg. samples. The infrared spectra of Fig. 2 (A) and (B) were measured on a Perkin-Elmer double-beam spectrometer, model 21B, with sodium chloride optics. Other infrared spectra were measured on a Perkin-Elmer single-beam double-pass instrument. The NMR spectra of compounds, as concentrated carbon tetrachloride solutions, were recorded (11) with a Varian V-4300 NMR spectrometer, equipped with field stabilizer, at a fixed frequency of 40 Mc./sec., with spinning sample tubes. Signal separations were measured by the side-band technique in the usual manner.

Isolation of Lycodine

From preliminary countercurrent distribution experiments with buffer of pH 6 and chloroform it was observed that most of the alkaloids have a high partition coefficient (conc. in buffer/conc. in $CHCl_3$) with this system, but that annotinine, lycopodine, acetyl acrifoline (alkaloid L.12), and lycodine have low partition coefficients. Alkaloids with a partition coefficient close to unity are present to only a minor extent in the batches of alkaloids used. Annotine (alkaloid L.11), which has such a partition coefficient (16), is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

not present to a significant extent (16) in the crude alkaloid mixture which was available to us. On the basis of the above results the lycodine was concentrated in several stages.

(*a*) *Countercurrent distribution* (*large scale*).—The mother liquors from the crystallization of annotinine (approx. 40 g. of crude alkaloid) were first partitioned by countercurrent distribution between chloroform and concentrated citrate–phosphate buffer, pH 6 (600 ml. in each phase), using six 2-liter separatory funnels. The extraction scheme used was that of Bush and Densen (17). At each transfer the pH of the buffer was checked and corrected to pH 6, if necessary. Of the six chloroform phases (C-1 to C-6) and the six buffer phases (B-1 to B-6) obtained, the four containing lycodine (C-1 to C-4) were mixed and concentrated for the next step. The remaining fractions were retained for the separation of other alkaloids.

(*b*) *Countercurrent distribution* (*Craig machine*).—The chloroform fractions, C-1 to C-4, concentrated to 120 ml., were placed in the initial three tubes (40 ml. each) of a 60-tube Craig countercurrent machine (18) and partitioned through 60 transfers between chloroform and citrate–phosphate buffer, pH 5.2 (40 ml. in each phase). Examination of the fractions by their ultraviolet absorption disclosed the presence of lycodine in tubes 30 to 40. The alkaloids contained in both phases of these 11 tubes were then isolated in the usual manner. Paper chromatography (19) of the material by the descending technique with Whatman No. 1 paper buffered to pH 2.5, with *n*-butanol saturated with water as solvent, showed the presence of alkaloids after spraying with Dragendorff's reagent.

(*c*) *Absorption chromatography on activated alumina.*—The alkaloid mixture (2.6 g.) from tubes 30 to 40 of the Craig machine was then chromatographed on activated alumina, using *n*-pentane–benzene (1:1). The first alkaloid eluted from the column was the known alkaloid, lycopodine, followed by lycodine. A third alkaloid component, as yet uncharacterized, followed lycodine from the column upon elution wth benzene. The fractions containing lycodine were again detected by their ultraviolet absorption and by paper chromatography.

Characterization of Lycodine

Initially, lycodine was isolated as the dipicrate, which crystallized easily from methanol solution in characteristic radiating clusters of prisms, m.p. 229°–233° (decomp.). Calc. for $C_{17}H_{24}N_2.2C_6H_3O_7N_3$: C, 48.74; H, 4.23; N, 15.68%. Found: C, 48.20, 48.47; H, 4.02, 4.03; N, 15.91, 15.64%.

Lycodine dipicrate was converted to the base which was distilled at 100°–110° (air bath) (0.18 mm. Hg) to give a colorless distillate which crystallized spontaneously. The lycodine so obtained has m.p. 118°, $[\alpha]_D$ −10°±2° (*c*, 1.01 in ethanol). Calc. for $C_{17}H_{24}N_2$: C, 79.64; H, 9.43; N, 10.93; C—Me, 5.85%; M.W., 256.4. Found: C, 79.50, 79.46; H, 9.44, 9.38; N, 11.16; C—Me, 3.56%; M.W. (Rast), 246. Titration of lycodine in 50% aqueous methanol gave an equivalent weight of 255.8 (based on the strongly basic nitrogen) and pK_a's, 3.97 and 8.08.

Later, it was found that lycodine could be crystallized from *n*-pentane when seeded. This method was used to crystallize the base from the alumina fractions above, purification of the alkaloid in a number of instances being effected by means of recrystallizations of lycodine dipicrate. In all, about 400 mg. of lycodine was obtained. Attempts to obtain the monopicrate, diperchlorate, dihydrochloride, dihydroiodide, di-*p*-tolulene sulphonate, or the distyphnate in a crystalline state were unsuccessful. From the position of lycodine in the countercurrent distribution mentioned above, the distribution coefficient of the alkaloid in the system chloroform–buffer of pH 5.2 was calculated to be 1.4 (conc. in buffer/conc. in $CHCl_3$).

Acetylation of Lycodine

Lycodine (39.5 mg.) was refluxed in an excess of acetic anhydride under nitrogen for 2 hours. The solution was cooled and methanol added to react with the remaining acetic anhydride. After removal of the methyl acetate by distillation the residue was acidified with 5% hydrochloric acid and washed with ether. The aqueous solution was then made basic with sodium hydroxide solution and extracted with ether to obtain the base. N-Acetyl lycodine was isolated as the monopicrate, which crystallized from water as yellow needles, m.p. 180°–182.5° (decomp.). Calc. for $C_{19}H_{26}ON_2.C_6H_3O_7N_3$: C, 56.92; H, 5.54; N, 13.28%. Found: C, 56.58; H, 5.39; N, 13.69%. The free base was not obtained crystalline. The infrared absorption spectrum (in Nujol) of N-acetyl lycodine contained a band at 1661 cm.$^{-1}$ characteristic of an amide carbonyl, which band was not present in the spectrum of lycodine. By means of descending paper chromatography using Whatman No. 1 paper buffered at pH 3, and *n*-butanol saturated with water as the moving phase, lycodine (R_f, 0.35) was easily distinguished from N-acetyl lycodine (R_f, 0.65).

Hydrolysis of N-Acetyl Lycodine

N-Acetyl lycodine obtained from the monopicrate was refluxed in conc. hydrochloric acid for 6 hours. After cooling, the solution was rendered basic with sodium hydroxide solution and extracted with ether. The ether extractions were each washed with water and dried over anhydrous sodium sulphate before being evaporated to dryness. The residue was distilled around 125° (air bath) (0.8 mm. Hg) and the clear distillate crystallized on standing. These crystals had m.p. 118° either alone or mixed with lycodine.

Attempted Acetylation of β-Obscurine

β-Obscurine (*ca.* 1 mg.) was subjected to the same reaction conditions as used for the acetylation of lycodine. After removal of the remaining acetic anhydride, the product gave only one spot which corresponded to that of β-obscurine when it was paper chromatographed. The same result was obtained when β-obscurine was acetylated with acetic anhydride, using anhydrous sodium acetate as catalyst, for double the length of time. The neutral fraction of the product did not contain any substance having an α-pyridone chromophore.

ACKNOWLEDGMENTS

We are greatly indebted to Dr. Léo Marion, of the National Research Council, for providing us with the mother liquors from the crystallization of annotinine, to Dr. H. J. Bernstein, of the National Research Council, for taking the NMR spectra and for discussion of the results, to Dr. E. M. Godar and Dr. R. P. Mariella, of Loyola University, Chicago, Illinois, for generously providing us with a sample of tetrahydroquinoline, to Dr. D. B. McLean, of McMaster University, for a gift of obscurine, and to Mr. R. Lauzon and Dr. R. N. Jones, of the National Research Council, for the infrared spectra taken on the double-beam instrument. We wish to thank the National Research Council for a grant in aid of this work. One of the authors (C. R. E.) wishes to thank the Commissioner, Royal Canadian Mounted Police, whose kind permission and support enabled him to take part in this work.

THE VAPOR PRESSURE OF LITHIUM IN THE REDUCTION OF LITHIUM OXIDE BY SILICON[1]

W. MORRIS[2] AND L. M. PIDGEON

ABSTRACT

The vapor pressure of lithium over the system lithium oxide – calcium oxide – silicon has been measured using the gas entrainment method at temperatures between 970° C. and 1025° C. The experimental results are summarized in the form $4 \log P = 43.1 - (6.69/T) \times 10^4$, where P is in atmospheres and T in ° A. The reaction, as usually written,

$$2Li_2O + 2CaO + Si = 4Li(g) + 2CaO.SiO_2,$$

does not describe the process completely.

INTRODUCTION

The classical method of producing alkali metals involves electrolysis of fused chlorides, preferably a mixture of chlorides in order to utilize a low-melting-point eutectic. Lithium is so produced using LiCl–KCl mixtures. In this case, however, certain inherent disadvantages of electrolytic processes are intensified. Lithium is at the head of the electromotive series; hence, any metallic impurities present in the bath would be deposited at the cathode and find their way into the final product. The purity of the metal is dependent on the purity of the charge material.

These characteristics, together with the low electrochemical equivalent of lithium (6.94 lb. of Li per 500 amp-days of power) and the reactivity of the metal, justify the search for alternative methods in the form of thermal reduction techniques. The relative volatility of lithium metal should permit its evolution in the gaseous state from a reaction mixture consisting of the oxide and a suitable reducing agent.

Such a method has been successfully applied to magnesium, where calcined dolomite is reacted with silicon (as ferrosilicon) in the solid state, the reaction occurring being described as

$$2CaO.MgO(s) + Si(s) = 2Mg(g) + 2CaO.SiO_2(s). \quad [1]$$

Kroll and Schlechten (1) examined a number of reducing agents and decided that a reaction similar to that for magnesium was feasible and, in fact, preferable to others. For this purpose, these authors calcined mixtures of Li_2CO_3–CaO, which were subsequently briquetted with FeSi to provide the charge for their experiments. In a manner analogous to the magnesium-forming reaction, lime was added so that a calcium silicate rather than a lithium silicate would form according to the postulated reaction

$$2Li_2O(s) + 2CaO(s) + Si(s) = 4Li(g) + 2CaO.SiO_2(s). \quad [2]$$

These authors described the general procedures adopted and were not concerned with the measurement of the pressures of lithium over the system.

This paper describes measurements of the equilibrium pressures of lithium over a mixture of calcined $Li_2CO_3.CaO$ and silicon. The magnitude of this pressure is the effective driving force of the reaction, and directly controls the feasibility of a practical reduction process of this type.

EXPERIMENTAL

From preliminary experiments, it was found that the reaction pressure of lithium in the reduction process was in the order of 5 mm. Hg at 1000° C. As a result, the entrainment method was adopted, similar to that used by Pidgeon and King (2) and later by Ellingsgaeter and Rosenqvist (3) in their examination of reaction [1].

Purified argon was employed as the carrier gas, which was saturated with lithium vapor. The metal vapors were carried downstream to a point where conditions were appropriate for condensation.

Owing to the reactivity of lithium metal, the reaction tube adopted was a clean 30-inch length of black iron pipe (1 inch diameter) enclosed by a heat-resisting nickel–chromium tube. Insert condensers were troublesome, and it was decided to utilize the downstream portion of the iron reaction tube itself as condenser. At the end of an experimental run the tube was cut in two, separating the condensing section from the charge zone. The condensed product could not be weighed directly because of the rapid formation of lithium nitride in the atmosphere. As a result, the deposit was dissolved in hot distilled water, and the amount of lithium collected determined by polarographic means (4).

Clean steel wool placed at the extreme downstream section of the charge prevented the contamination of the condensing section of the reaction tube by fine particles entrapped in the gas stream. Vapor-phase condensation of the lithium vapor similar to the formation of "blue powder" in the thermal reduction of ZnO was eliminated by inserting a second piece of clean steel wool slightly downstream from the point where the bulk of the condensation occurred. This vapor-phase condensation phenomenon is caused by the "cold blanket" of carrier gas on the walls of the condenser. Steel wool serves to eliminate this phenomenon and also acts as a dust trap.

The reaction zone was equipped with baffles which maintained a 3-inch zone constant to ±1° C.

CHARGE MATERIAL

Li_2O was produced by thermal dissociation of reagent grade Li_2CO_3–CaO mixtures in vacuum according to the procedures described by Kroll and Schlechten (1). The calcined product, originally containing 60% CaO and 40% Li_2CO_3, was mixed with a 20% addition of 100% −100 mesh ferrosilicon analyzing 79% Si, and subsequently briquetted to provide particles $\frac{1}{3}$ inch in average dimension. The mixture for reduction analyzed 7.0% Li and 16.9% Si.

PROCEDURE

Reduction briquettes were charged to the reaction tube and heated to the required temperature. After the passage of a given amount of argon, sufficient to bring about 5–10% reduction (i.e., approximately 0.3 g. Li collected), the reaction tube was removed from the furnace and cooled in argon. When the tube had cooled sufficiently, it was subsequently sectioned, and the product in the condensing section was dissolved and analyzed.

From the volume of argon used, corrected to N.T.P., and the amount of lithium collected, the reaction pressure of lithium over the system was calculated.

RESULTS

A series of experiments at a temperature of 993° C. and flow rates varying from 2.0 to 8.0 cc. per second was performed. The results are shown in Table I and plotted in Fig. 1.

From the graph (Fig. 1), it can be seen that the extrapolation to zero flow rate yields

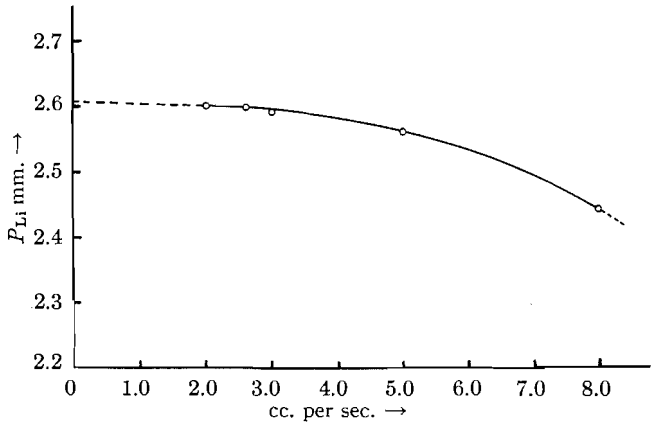

FIG. 1. Effect of flow rate on apparent vapor pressure.

TABLE I

Rate (cc./sec.)	P_{Li} mm. Hg)
2.0	2.60
2.6	2.60
3.0	2.59
5.0	2.56
8.0	2.44

a value of the vapor pressure essentially the same as the value at a flow rate of 2.6 cc. per second. At flow rates above 2.6 cc. per second saturation of the argon carrier gas was not established. This is shown by the lower values of the apparent vapor pressures at these higher rates.

The flow rate of 2.6 cc. per second is large enough to overcome thermal-diffusion effects, and small enough to establish saturation. At very low flow rates, it was observed that the iron reaction tube was bright-annealed by the lithium vapors upstream from the reaction zone, caused by the back-diffusion of lithium in the gas stream. At the saturation rates, this bright-annealing effect was not observed.

Saturation experiments were also performed at 972° C. and results similar to those at 993° C. were obtained.

EFFECT OF TEMPERATURE

At temperatures below 970° C., consistent results could not be obtained; at temperatures above 1025° C., the charge showed definite evidence of the formation of a liquid phase. Successful measurements were therefore restricted to this range of temperature.

DISCUSSION

The reaction [2] as proposed by Kroll and Schlechten (1) served as a basis for the calculations. Experiments were performed in which the reaction was completed *in vacuo*. X-Ray diffractometer investigations on the solid residue revealed the presence of dicalcium silicate, excess CaO, and excess FeSi. The diffractometer traces also showed the presence of other compounds which could not be identified, suggesting that equation [2] is not the only reaction occurring.

The presence of the diatomic species of lithium vapor (Li_2), at a total pressure $P_{(Li+Li_2)}$ equal to 40 or 50 mm. Hg, would account for approximately 7% of the vapor phase at these temperatures (5). However, at the pressures of lithium involved in this research (in the order of 2–6 mm. Hg), the diatomic species can be shown to play a negligible role.

Assuming that the major reaction is reaction [2], equilibrium constants were computed and plotted against $1/T°$ K., both from the experimental values and from the calculated values for the reaction. The experimental values are shown in Table II and

TABLE III

P_{Li} (mm.)	log K_p (atm.)	° K.
2.46	−9.956	1200
4.94	−8.744	1250
9.25	−7.656	1300

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

plotted in Fig. 2. The calculated values are shown in Table III and are also plotted in Fig. 2.

For these calculations, the solids as predicted by reaction [2] were assumed to be present as pure, distinct phases; thus, their activities were equated to unity and the lithium vapors present were assumed ideal; hence, the equilibrium constant was written in the form

$$K_p = (P_{Li})^4.$$

The thermodynamic data used for the calculated values of the equilibrium constant were taken from Kubaschewski and Evans (6), Coughlin (7), and Kelley (8).

A statistical analysis of the experimental points gives the equation of the straight line in Fig. 2 in the form

$$\log_{10}K_p = 43.1 - (6.69\times10^4/T) \qquad [3]$$

corresponding to a heat of reaction of 306,000 cal. The calculated value for the heat of reaction utilizing the values shown in Table III is 164,000 cal.

The discrepancy between the calculated and the observed values is greater than either the experimental error or the uncertainty of the thermodynamic data used. The discrepancy must lie, then, in the assumption of unit activities or be due to the fact that the reaction cited (equation [2]) is an oversimplification.

It is quite probable that the formation of a lithium silicate should be accounted for, since in a series of experiments above 1025° C. the charge showed distinct evidence of the formation of a liquid phase. The melting point of pure Li_2SiO_4 is approximately 1025° C. A further possibility is the formation of the double silicate of Ca and Li.

In general, it can be stated that, if any side reaction occurs that effectively ties up any lithium, an increase in the heat of reaction would be observed.

CONCLUSIONS

1. The values of the pressure of lithium encountered in the reduction reaction are of sufficient magnitude to warrant a commercial thermal reduction process.

2. The experimental values are summarized in the form $\log_{10}P = 43.1 - (6.69/T)\times10^4$, where P is in atmospheres and T in ° K.

3. The reaction occurring, written in the form

$$2Li_2O + 2CaO + Si = 4Li + 2CaO.SiO_2,$$

is an oversimplification.

SUR LES RÉACTIONS DES POLYESTERS AVEC LE TÉTRACHLORURE DE TITANE

I. LA RÉACTION DE L'OXALATE DE DIÉTHYLE AVEC LE TÉTRACHLORURE DE TITANE[1]

RÉAL AUBIN[2] ET ROLAND RIVEST

SOMMAIRE

On montre dans ce mémoire que l'oxalate de diéthyle réagit avec le tétrachlorure de titane pour donner un composé d'addition moléculaire: le diéthyl oxalate-1,2 tétrachlorure de titane IV. On examine quelques propriétés de ce complexe de coordination et on propose pour ce composé la structure d'un chélate monomérique de configuration *cis*.

INTRODUCTION

Les réactions des polyesters avec le tétrachlorure de titane ont été peu étudiées; Demarçay (1) paraît en avoir donné la première description et depuis, seulement deux autres réactions (2, 3) ont été signalées. Des travaux parallèles conduits par Hieber et Reindl (4) sur le tétrachlorure d'étain et l'analyse récente menée par Archambault (5) sur les réactions acide–base du titane avec certains composés électrodotiques nous ont incités à entreprendre une étude systématique et comparée des réactions des polyesters avec le tétrachlorure de titane.

L'atome tétravalent du titane possède dans plusieurs composés connus un nombre de coordination (6). Dans le tétrachlorure, il peut donc recevoir deux doublets additionnels d'électrons venant d'une substance électrodotique appropriée. Il adopte alors une configuration octaédrique très stable de type d^2sp^3. Les diesters sont des polydentates présentant plusieurs possibilités de réaction avec le tétrachlorure de titane. Ils peuvent donner des chélates où les liaisons chimiques diester–tétrachlorure peuvent être en position *cis* ou *trans* selon la stéréochimie du diester impliqué dans la formation du composé. Il est aussi possible qu'un empêchement stérique s'oppose à la cyclisation et dans ce cas, le produit obtenu pourrait être soit un polymère, soit un composé d'addition simple.

Dans le but de vérifier ces différentes possibilités nous avons entrepris l'étude des trois types de diesters suivants:

(*a*) Les diesters à constitution $R—O—\overset{\overset{O}{\|}}{C}—(CH_2)_n—\overset{\overset{O}{\|}}{C}—O—R$, où "R" et "*n*" peuvent varier. Exemple: l'oxalate de diéthyle.

(*b*) Les polyesters du type $R—\overset{\overset{O}{\|}}{C}—O—(CH_2)_n—O—\overset{\overset{O}{\|}}{C}—R$. Exemple: le diacétate d'éthylène.

(*c*) Les polyesters aromatiques $Ar(COOR)_2$, tels l'isophthalate de diméthyle.

Comme premier terme de notre investigation, la réaction de l'oxalate de diéthyle sur le tétrachlorure de titane semblait particulièrement bien adaptée à notre projet puisque la description de Demarçay (1) et les brefs commentaires de Wurtz (7) n'avaient guère précisé la structure et les propriétés générales du complexe issu de cette réaction.

PARTIE EXPÉRIMENTALE

Purification des produits chimiques

On utilise pour cette réaction le tétrachlorure "purifié" de la compagnie Fisher Scientific. On met en œuvre une méthode de purification achevée en appliquant le mode opératoire de Gilchrist et de ses collaborateurs (8). On obtient ainsi un produit de haute pureté sans traces de chlore ni de vanadium.

L'oxalate de diéthyle est également un produit "purifié" de Fisher Scientific. Le diester est desséché sur du sulfate de sodium anhydre et soumis à une distillation fractionnée sous pression réduite. La fraction médiane est conservée sur le sulfate de sodium anhydre.

Au cours de l'addition des deux substances concernées dans cette réaction, le tétrachlorure de carbone tient lieu de solvant usuel. Il reçoit un traitement identique à celui de l'oxalate de diéthyle sauf en ce qui a trait à la pression, lors de la distillation fractionnée.

Mode opératoire

Comme le tétrachlorure de titane réagit violemment avec certains polyesters, nous diluons les réactifs dans le tétrachlorure de carbone.

Le tétrachlorure de carbone (100 ml.) est placé dans un ballon de 250 ml. Un courant d'azote sec chasse l'air humide et prévient l'hydrolyse au cours des opérations subséquentes. Une quantité mesurée du réactif qui doit être en excès est alors ajoutée à l'aide d'une seringue graduée à aiguille de Téflon. L'agitation du mélange est provoquée par un agitateur magnétique. Une portion mesurée de l'autre réactif est alors ajoutée lentement à l'aide d'une autre seringue graduée à aiguille de Téflon. Une coloration jaune apparaît aussitôt. Bien que l'addition s'opère à température normale, la chaleur de réaction n'augmente pas trop la température du système, si l'addition est assez lente, l'agitation suffisante et les dilutions dans CCl_4 assez poussées. Bientôt le complexe précipite sous forme finement cristallisée.

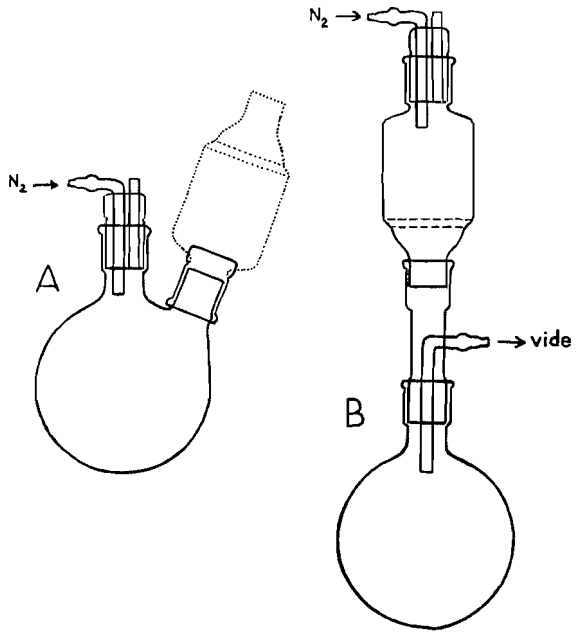

FIG. 1. Appareils utilisés: pour l'addition des réactifs (A); pour l'extraction, la purification et le séchage du complexe formé (B).

Le tout est transféré quantitativement sur un filtre de porosité moyenne. On maintient une atmosphère d'azote dans l'appareil et le précipité est lavé une dizaine de fois avec des portions de 20 ml. de CCl_4 pour le débarrasser de l'excès de réactif très soluble dans le tétrachlorure de carbone.

Le complexe cristallisé et lavé est séché durant quelques heures sous une pression inférieure à 1 mm. de mercure et à température ordinaire. Le produit est conservé dans un récipient scellé ou dans un dessiccateur renfermant du pentoxyde de phosphore.

Le schéma des appareils utilisés pour ces opérations est donné dans la figure 1.

Méthodes d'analyse

Le point de fusion (p.f.) est corrigé; il a été déterminé dans un appareil de Thiele.

Le poids moléculaire a été évalué par ébullioscopie dans le benzène anhydre chez Huffman Microanalytical Laboratories, Wheatridge, Colorado.

La détermination gravimétrique du chlore a été conduite selon le protocole analytique décrit par Vogel (9). Le titane a été déterminé gravimétriquement sous forme de TiO_2.

Les spectres infrarouges ont été déterminés à l'aide d'un spectromètre "Perkin-Elmer", modèle 112, à simple faisceau et parcours double.

RÉSULTATS ET DISCUSSION

Structure du produit de la réaction

Les travaux de Sisler et de ses collaborateurs (10) ont montré que le rapport de l'addition moléculaire dans ce genre de réaction se trouve parfois être 1:2 ou 1:1 selon qu'il y a, ou non, excès de réactif électrodotique. Nous avons voulu préciser la valeur de ce rapport dans la réaction d'addition de l'oxalate de diéthyle avec le tétrachlorure de titane; dans ce dessein, nous avons effectué plusieurs additions de l'oxalate de diéthyle dans des concentrations relatives variables par rapport au tétrachlorure de titane. C'est ainsi que nous avons utilisé l'oxalate de diéthyle en excès sur le tétrachlorure de titane, les deux réactifs en proportions équivalentes et finalement, l'oxalate de diéthyle avec un excès de tétrachlorure de titane. Le tableau I résume les résultats obtenus dans les dosages du titane et du chlore des différents composés d'addition réalisés. On voit clairement que le rapport de l'addition moléculaire demeure toujours et seulement 1:1, quelles que

TABLEAU I

TABLEAU COMPARATIF DES VALEURS (%) DE Ti ET DE Cl DANS LES COMPOSÉS THÉORIQUES 1:1 ET 1:2 ET DANS LES COMPOSÉS FORMÉS EXPÉRIMENTALEMENT

Valeurs calculées	% Ti	% Cl	Valeurs trouvées	% Ti	% Cl
$1TiCl_4.1(COOC_2H_5)_2$	14.26	42.22	Addition avec TiCl en excès	14.48	40.40
			Addition sans excès de réactif	14.40	41.27
$1TiCl_4.2(COOC_2H_5)_2$	9.93	29.41	Addition avec $(COOC_2H_5)_2$ en excès	14.48	41.38

soient les concentrations respectives de l'oxalate de diéthyle et du tétrachlorure de titane. En aucun cas, nous n'avons pu obtenir le rapport d'addition 1:2, soit $TiCl_4.2(COOC_2H_5)_2$.

Une détermination du poids moléculaire par ébullioscopie dans le benzène rigoureusement anhydre, non seulement justifie la formule brute $TiCl_4.(COOC_2H_5)_2$ pour le complexe formé, mais, également, met en évidence le caractère monomérique de la structure moléculaire recherchée; le poids moléculaire théorique 335.9 g. coïncide assez bien avec le poids moléculaire trouvé 364.

La structure cyclique ou chélatée du présent complexe de coordination est déduite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

des mesures dans l'infrarouge, des vibrations du groupe C=O de la molécule du diester. Des mesures effectuées sur l'oxalate de diéthyle pur montrent une bande C=O à 1770 cm^{-1} et à 1745 cm^{-1}. Il est vrai que Randall et ses collaborateurs (11) ne mentionnent pour l'oxalate de diéthyle qu'une seule bande C=O à 1757 cm^{-1} mais, d'autre part, nos résultats rejoignent bien les mesures plus récentes de Bender (12): 1771 cm^{-1} et 1747 cm^{-1}.

L'existence d'une structure cyclique exige ici des modifications de ces deux valeurs de bande C=O; en effet, si l'on retrouve dans le complexe l'une ou l'autre de ces valeurs inchangée, alors seulement on pourra penser que l'un des groupes C=O est demeuré libre. Mais, dans ces conditions, on se demande comment les exigences du nombre de coordination maximum du titane IV pourraient être sauvegardées, le caractère monomérique du complexe et la valeur 1:1 du rapport d'addition demeurant acquis. Si, par ailleurs, les deux valeurs de bande C=O sont modifiées en passant du diester pur au complexe, il faut attribuer cette modification à une variation de la distance C=O et, pour autant, à une liaison quelconque de l'atome d'oxygène de chaque groupe C=O avec un autre atome. Puisque les deux groupes C=O habitent déjà la même molécule et que le ou les atomes liants ne peuvent se trouver que sur une seule autre molécule, on doit nécessairement envisager une structure cyclique.

Or le spectre infrarouge du complexe (émulsion dans le nujol, prisme NaCl) révèle un déplacement marqué des deux bandes C=O vers une plus grande longueur d'onde; les valeurs obtenues pour le diester pur sont disparues et remplacées par deux nouvelles bandes à 1698 cm^{-1} et à 1675 cm^{-1}, soit un décalage moyen de 71 cm^{-1} par rapport aux valeurs des bandes C=O libres. Il est donc normal de déduire une liaison nouvelle dans chacun des groupes C=O et partant, une structure cyclique.

Gordy (13) a d'ailleurs montré que la chélation du groupe C=O se traduit possiblement par un effet dans le sens que nous avons observé et Bryant et ses collaborateurs (14) ont noté que l'importance du déplacement de la bande C=O est reliée à la nature des atomes du cycle résultant et dépend aussi des substituants greffés sur le cycle.

On peut donc raisonnablement proposer une structure chélatée pour le produit de l'addition de l'oxalate de diéthyle avec le tétrachlorure de titane.

La configuration *cis* ou 1,2 doit enfin être préférée à la forme *trans* ou 1,6. On considère avec Martell et Calvin (15) qu'il est stériquement impossible pour les oxygènes de l'oxalate d'occuper deux coins opposés 1,6 de l'octaèdre du titane IV. En effet, la distance entre les deux atomes d'oxygène concernés serait très voisine de 2.73 Å pour la forme *cis* de l'oxalate de diéthyle tandis que la distance entre deux coins opposés 1,6 de l'octaèdre du titane dépasse 4.3 Å. Par contre, la distance entre deux coins voisins 1,2 de l'octaèdre du titane est de l'ordre de 3.0 Å; ces dernières positions sont donc nettement favorisées du point de vue stérique.

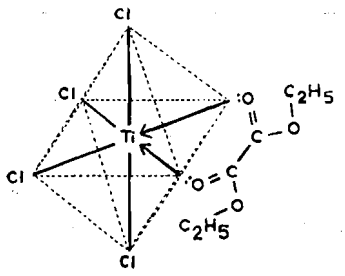

FIG. 2. Structure proposée pour $TiCl_4.(COOC_2H_5)_2$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Dans l'évaluation de la distance entre les deux atomes d'oxygène de l'oxalate de diéthyle, il n'y a pas d'objection à postuler la forme *cis* pour le diester pur à l'état liquide car les recherches de Jatkar et Phansalkar (16) justifient l'hypothèse d'une rotation libre des deux groupes estérifiés autour de la liaison CO—CO.

Nous proposons donc la structure représentée dans la figure 2 pour le diéthyl oxalate-1,2 tétrachlorure de titane IV.

Quelques propriétés du complexe $TiCl_4.(COOC_2H_5)_2$

Le point de fusion de ce composé (p.f.) est 104–105° C.; la fusion est probablement accompagnée de décomposition partielle du complexe.

L'analyse élémentaire donne pour $TiCl_4.(COOC_2H_5)_2$:

	% Ti	% Cl
Valeurs calculées	14.26	42.22
Valeurs trouvées	14.48	41.72

Le complexe d'addition est un solide jaune pâle finement cristallisé, à odeur d'acide chlorhydrique. Il est extrêmement hygroscopique et s'hydrolyse rapidement en présence d'humidité. Quand le composé est chauffé, il donne d'abord un liquide jaune clair, puis une pâte brun foncé et finalement un résidu blanc identifié comme TiO_2. Conservé dans un récipient scellé et sous atmosphère d'azote sec, le composé conserve son état initial pendant plusieurs mois.

Nous avons étudié avec une attention particulière la solubilité de $TiCl_4.(COOC_2H_5)_2$ dans une gamme de solvants organiques usuels. Chacun de ces solvants a été séché au préalable selon le procédé le plus approprié à chaque cas. Le tableau II résume les résultats quantitatifs obtenus.

TABLEAU II

SOLUBILITÉ DE $TiCl_4.(COOC_2H_5)_2$ À TEMPÉRATURE ORDINAIRE

Nom du solvant	Formule du solvant	Solubilité en g./100 ml.
Chlorure de *n*-butyle	$CH_3—(CH_2)_2—CH_2Cl$	26.4
Dichlorure d'éthylène	$ClCH=CHCl$	49.0
Chloroforme	$CHCl_3$	64.4
Tétrachlorure de carbone	CCl_4	0.3
n-Hexane	$CH_3—(CH_2)_4—CH_3$	Insoluble
Cyclohexane	C_6H_{12}	Insoluble
Sulfure de carbone	CS_2	1.1
Éther	$C_2H_5OC_2H_5$	5.9
Dioxane	$C_4H_8O_2$	1.8
Acétone	CH_3COCH_3	87.8
Oxalate de diéthyle	$(COOC_2H_5)_2$	50.3
Acétate d'éthyle	$CH_3COOC_2H_5$	97.3
Benzène	C_6H_6	61.6
Toluène	$C_6H_5CH_3$	32.6
Xylène	$C_6H_4(CH_3)_2$	5.5
Chlorobenzène	C_6H_5Cl	43.2

On voit que le complexe est tout à fait insoluble dans les hydrocarbures saturés. Les dérivés halogénés les plus polaires sont de meilleurs solvants; si la solubilité est peu élevée dans les éthers, elle est très convenable dans les esters. Enfin, une substitution sur le noyau benzénique semble diminuer l'efficacité du solvant.

$TiCl_4.(COOC_2H_5)_2$ s'hydrolyse instantanément dans l'eau. Ce composé est soluble dans les alcools mais il réagit avec ces derniers. Il réagit aussi avec les amines et les amides.

HYDROGENOLYSIS OF CARBOHYDRATES

V. ISOMERIZATION OF METHYL β-L-ARABOPYRANOSIDE[1]

A. S. PERLIN, E. VON RUDLOFF, AND A. P. TULLOCH[2]

ABSTRACT

Treatment of methyl β-L-arabopyranoside under hydrogenolytic conditions with copper chromium oxide catalyst induces extensive isomerization. Products formed include glycosides of D-ribose, D-xylose, D-lyxose, and L-lyxose which together represent about an 80–90% conversion of starting material. Isolation of these compounds shows that carbons 2, 3, and 4 undergo isomerization, but no evidence has been obtained of anomerization. These findings possibly explain the formation of an optically *inactive* mixture of *cis*- and *trans*-tetrahydropyran-3,4-diol under slightly more drastic reaction conditions.

INTRODUCTION

The hydrogenolysis of methyl β-L-arabopyranoside (I) at 250° C. using copper chromium oxide catalyst has yielded mainly a mixture of dihydro-arabinal and -xylal (*cis*- and *trans*-3,4-dihydroxytetrahydropyran) (1). These products appeared to have been formed by reductive cleavage of the glycosidic methoxyl group and of the 2- or 4-hydroxyl group giving, respectively, the *cis*-(*arabo*-) or *trans*-(*xylo*-)isomer. However, the mixture of compounds was optically inactive and hence not the expected L-diols II and III, and it was suggested that isomerization may have occurred (1). Reinvestigation of the reaction under conditions slightly milder than used earlier has now shown, in fact, that methyl β-L-arabopyranoside readily undergoes isomerization, yielding a mixture of pentosides.

At 200° C. very little tetrahydropyrandiol was formed from methyl arabinoside although about half of the pentoside had reacted. A portion of the crude product was hydrolyzed with dilute acid, and examination of the liberated sugars by paper chromatography and electrophoresis indicated the presence in the mixture of ribose, lyxose, and xylose, the latter two being clearly distinguishable only by paper electrophoresis. In addition, an unidentified reducing material (R_{rham} 0.9) and a non-reducing product (R_{rham} 0.4) were detected on the chromatograms as minor components. The mixture of methyl pentosides proved difficult to resolve by cellulose column chromatography (2). A series of fractions was obtained, some containing predominantly one or another sugar. From one of these fractions a small quantity of a crystalline glycoside was isolated and this was shown by specific rotation, mixed melting point, and X-ray powder diagram to be methyl α-D-lyxopyranoside (IV). Chromatographic separation of the mixture of sugars after hydrolysis afforded D-xylose (V), L-lyxose (VI), and D-ribose (VII). The first two were characterized as crystalline sugars and the latter as the *p*-toluenesulphonhydrazone (3) by specific rotations, mixed melting points, and X-ray diffraction diagrams or infrared absorption spectra. Visual examination of the mixture of free pentoses on paper chromatograms and electrophoretograms suggested that lyxose and ribose were formed in about equal amounts, that approximately twice as much xylose was produced, and that these pentoses together corresponded to perhaps 40% of the starting material, i.e., to about 90% conversion.

[1]*Manuscript received February 17, 1958.*
Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan.
Issued as N.R.C. No. 4702 and as Paper No. 253 on the Uses of Plant Products.
[2]*National Research Council of Canada Postdoctorate Fellow, 1956–57.*

Other instances of hydrogenolytic isomerization of carbohydrates have recently been found in this laboratory, i.e., the formation of dihydro-D-altral from methyl α-D-glucopyranoside (4) and of *O-iso*propylidene-L-idose from 1,2-*O-iso*propylidene-D-glucose (4a). These findings suggest, therefore, that isomerization may occur frequently and may constitute an important reaction quantitatively when carbohydrates are subjected to catalytic hydrogenation conditions. Isomerization of hexitol dianhydrides (5), cyclic alcohols (6), and inositol derivatives (7) under such conditions has been established, the reactions probably involving dehydrogenation to form intermediate ketones. It is reasonable to expect that the carbohydrate isomerizations take place by a similar mechanism.

The wide variety of products obtained from methyl arabinoside by isomerization shows that the reaction involves attack at carbons 2, 3, and 4, sometimes at one carbon individually, sometimes at more than one. Thus, the formation of methyl D-xyloside requires isomerization at carbon 4, and of methyl L-lyxoside at carbon 3. Carbons 3 and 4 are both attacked in the production of methyl D-riboside and carbons 2 and 4 in the production of methyl D-lyxoside. The 2-position is least affected by isomerization; little methyl D-lyxoside is produced as indicated by the isolation of virtually pure L-lyxose from the mixture of free sugars. Since each of the secondary hydroxyl groups is affected to some degree it is possible that D-arabinose, L-xylose, and L-ribose are also products of the reaction but have not been detected. However, there is as yet no evidence for isomerization at carbon 1; the configuration at carbon 1 is retained in methyl α-D-lyxoside, the one intact glycoside isolated. Also, it may be concluded that the L-lyxoside is present in the mixture as the β-glycoside, i.e., that anomerization has not occurred, for the α-D-isomer could not have been separated from methyl α-L-lyxoside by the isolation procedure used.

The finding that extensive isomerization can accompany the hydrogenolysis of methyl β-L-arabopyranoside points to a reaction mechanism somewhat more complex than had been indicated earlier (1). Reductive cleavage of carbon–oxygen bonds at the glycosidic center and at position 2 or 4 should yield dihydro-L-arabinal (II) and -L-xylal (III), respectively (*cis*- and *trans*-L-diol). However, with the isomeric pentosides formed as intermediates, this sequence of reactions should yield the *cis*- and *trans*-D-isomer (VIII and IX, respectively), also, as indicated in the following table:

	Product obtained when secondary position attacked	
Glycoside	2-Position	4-Position
L-Arabinoside	*cis*-L	*trans*-L
D-Xyloside	*trans*-D	*trans*-L
D-Riboside	*cis*-D	*cis*-L
L-Lyxoside	*trans*-L	*cis*-L
D-Lyxoside	*trans*-D	*cis*-D

It is seen that all four isomeric diols are obtainable by hydrogenolysis of the mixture of glycosides. Formed in the proper proportions these products could have accounted for the observation that the mixture of diols isolated was optically inactive (1). Such a possibility is increased by the fact that the rotatory power of the *cis*- and *trans*-diols is of approximately the same magnitude (dihydro-D-xylal and dihydro-D-arabinal show $[\alpha]_D$ −45° (8) and −48° (8), respectively). According to these findings, it is possible also that hydrogenolysis does not involve both positions 2 and 4. The fact that *cis*- and *trans*-diol were produced led to the early suggestion that each of these positions is attacked. A mixture of all four isomers may be obtained, however, by reductive cleavage only of the 2-hydroxyl group and the glycosidic methoxyl. By contrast, if hydrogenolysis were to occur at position 4 rather than at 2 the product would be almost exclusively a mixture of L-isomers and hence strongly dextrorotatory. The present results do not completely resolve these questions. They show, however, that isomerization can occur, which possibly leads to the formation of optically inactive hydrogenolysis products.

EXPERIMENTAL

Melting points are corrected. Infrared spectra were prepared by the potassium bromide window technique (9).

Chromatographic Methods

Paper chromatograms were developed on Whatman No. 1 paper using the following solvents: (A) phenol saturated with water (10), (B) ethyl acetate–acetic acid–water (9:2:2, v/v) (11, 12), and (C) *n*-butanol–pyridine–benzene–water (5:4:1:3 v/v) (13). None of these solvents satisfactorily resolved a sugar mixture consisting of D-ribose, D-xylose, L-arabinose, and D-lyxose. Solvent A gave a partial separation of xylose and lyxose, solvent C a good separation of ribose, xylose (or lyxose), and arabinose.

Paper electrophoresis (14) was carried out in borate buffers (pH 8–10) with a Spinco apparatus, Model R, and Whatman No. 1 paper; the current and voltage applied were 4.5 ma. and 900 volts, respectively. At pH 9.7 lyxose and xylose were completely separated (respective distances traveled in 5 hours, 3.2 cm. and 5.5 cm.) but these in turn were not as clearly separated from ribose (3.7 cm.) and arabinose (4.9 cm.). Lyxose and xylose were also separable at pH 8.0 (3.7 cm. and 4.9 cm., respectively, in 7.5 hours), but now the relative speeds of ribose and arabinose were reversed (5.4 cm. and 3.9 cm.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

respectively; compare (14)). Conditions were not found for complete resolution of the mixture.

Cellulose column chromatography was carried out using as solvents: (D) *n*-butanol one-eighth saturated with water, and (E) benzene–ethanol–water (10:1:trace).

Isomerization of Methyl β-L-Arabopyranoside

Methyl β-L-arabopyranoside (10 g.) in ethanol (100 ml.) was treated with hydrogen in the presence of copper chromium oxide catalyst (1 g.) at 200° C. and 2000 p.s.i. initial pressure for 4 hours. After removal of the catalyst a crystalline solid (2.1 g.) separated out; it was found to be slightly impure methyl arabinoside for it yielded mainly arabinose (detected chromatographically) on acid hydrolysis. A sirupy product (7.6 g.) was then obtained by evaporating the solvent. The sirup (5.4 g.) in 0.2 *N* sulphuric acid (100 ml.) was hydrolyzed on the steam bath for 4 hours, the solution was then neutralized with barium carbonate, and the filtered solution concentrated to dryness (weight 4.3 g.). Examined by paper chromatography, the residue was found to contain two minor products, one having R_{rham} 0.9 (yellow color with *p*-anisidine hydrochloride spray (12)), the other having R_{rham} 0.41 (non-reducing, detected with silver nitrate spray (10)), and major components corresponding to ribose, xylose and/or lyxose, and arabinose.

Identification of the Reaction Products

The mixture of sugars (3.5 g.) obtained on hydrolysis of the reaction product was chromatographed on a column (25 inches × $2\frac{1}{2}$ inches) of powdered cellulose using solvent D, 17 1-liter fractions were collected, and the sugars present in these were tentatively identified by paper chromatography and electrophoresis. Complete resolution of the sugar mixture was not obtained. Accordingly, those fractions found to consist chiefly of one or another sugar were selected and the products characterized as described below. The proportion of the pentoses present in each fraction was approximated visually from the intensity and area of the spots developed on the chromatograms and electrophoretograms with *p*-anisidine hydrochloride spray, a spray suited to the estimation of sugars (15). Related to the known weight of each fraction and the amount of arabinose separated earlier as the crystalline glycoside, these evaluations suggested that the ratio of arabinose–xylose–lyxose–ribose in the reaction mixture was about 5:2:1:1.

D-*Ribose.*—Fraction 8 contained only ribose. The sirup (124 mg.) obtained on removal of the solvent was treated with *p*-toluenesulphonhydrazide (120 mg.) in methanol (6 ml.) affording the corresponding hydrazone of D-ribose (93 mg.), m.p. 160°–162° C., after two recrystallizations from methanol; mixed melting point with D-ribose *p*-toluenesulphonhydrazone (m.p. 161°–163° C.) 160°–163° C., $[\alpha]_D$ 22.9° (45 minutes) → 12.5° (18 hours) (*c*, 1.0, moist pyridine). (Literature (3), $[\alpha]_D$ 42.0° (initial) → 14.0° (17 hours) (moist pyridine).) Calc. for $C_{12}H_{18}O_6N_2S$: C, 45.28%; H, 5.70%. Found: C, 45.46%; H, 5.71%. The identity of the compound was confirmed by comparison of its infrared absorption spectrum and X-ray powder diagram with those of an authentic specimen.

L-*Lyxose.*—Fraction 10 contained lyxose and a smaller proportion of xylose. On being seeded with L-lyxose the sirupy product (160 mg.) crystallized, and after recrystallization twice from ethanol – ethyl acetate and once from *n*-propanol had m.p. 104° – 106° C., undepressed on admixture with L-lyxose (m.p. 107°–108° C.), $[\alpha]_D$ 12.0° (equilibrium value) (*c*, 1.0, water). Calc. for $C_5H_{10}O_5$: C, 40.02%; H, 6.71%. Found: C, 39.89%; H, 6.71%. The X-ray powder diagram of the product and that of L-lyxose were indistinguishable.

D-*Xylose.*—Fraction 12 contained mainly xylose and a small percentage of lyxose. The sirup (170 mg.) was taken up in glacial acetic acid and crystallization promoted by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

seeding with D-xylose. One recrystallization from ethanol gave a product (70 mg.) having m.p. 138°–141° C., undepressed on admixture with D-xylose, $[\alpha]_D$ 18.6° (equilibrium value) (*c*, 1.0, water). Calc. for $C_5H_{10}O_5$: C, 40.02%; H, 6.71%. Found: C, 39.80%; H, 6.71%. The infrared absorption spectrum of the compound was indistinguishable from that of D-xylose.

Methyl α-D-lyxopyranoside.—The mixture of glycosides obtained by isomerization of methyl arabinoside was chromatographed on a cellulose powder column using solvent E, a series of fractions being collected and examined chromatographically. One of these fractions, which on hydrolysis was found to contain mainly lyxose, yielded a crystalline product, m.p. 106°–107° C. after recrystallization from acetone–ether, undepressed by admixture with methyl α-D-lyxopyranoside, $[\alpha]_D$ 59.0° (*c*, 1.0, water). Calc. for $C_6H_{12}O_5$: C, 43.90%; H, 7.37%. Found: C, 44.00%; H, 7.37%. The X-ray powder diagram of the compound and that of methyl α-D-lyxopyranoside were indistinguishable.

ACKNOWLEDGMENTS

The technical assistance of Mr. M. Granat is gratefully acknowledged. The authors also thank Mr. J. A. Baignée for microanalyses, Mr. T. M. Mallard for X-ray diffraction diagrams, and Mr. G. B. Rennie for infrared absorption analyses.

THE CHEMISTRY OF PEAT

II. THE TRITERPENES OF PEAT MOSS (SPHAGNUM)[1]

D. A. J. IVES[2] AND A. N. O'NEILL

ABSTRACT

By further chromatographic fractionation of the unsaponifiable matter from an extract of peat moss (*Sphagnum*) three crystalline triterpenes have been isolated. They have been identified as α-amyrin, taraxerone, and taraxerol by their physical and chemical properties.

In the preceding paper (5) the method of separating the crude unsaponifiable material present in peat moss was described. Two sterols were isolated and identified. This paper deals with some of the other compounds isolated during the chromatography of the crude extract. The fraction of unsaponifiable material eluted from the alumina column with benzene represented approximately five per cent of the total. This material consisted of a light yellow oil which crystallized on standing. Attempts to purify it by crystallization from methanol or ethanol failed. However, if the material was taken up in light petroleum, a yellow sirup was dissolved leaving a white crystalline mass, which after filtration could be readily recrystallized from chloroform–methanol solution. The crystals melted at 238°–239° and had a specific rotation of +12°. The material gave a crystalline derivative with 2,4-dinitrophenylhydrazine and showed a marked peak in the infrared at 1705 cm.$^{-1}$, indicative of a carbonyl group. The infrared spectrum of this ketone from peat moss also showed the presence of a double bond by a band at 816 cm.$^{-1}$ and the position of the band indicated a trisubstituted double bond in a six-membered ring. The high melting point and comparatively few functional groups, in addition to a positive Liebermann–Burchard reaction, indicated that the compound could be a triterpene, possibly of the allobetulin series. This hypothesis was reached since derivatives of allobetulin have been found in lignite (8), a decomposition product of peat. However, analysis showed the presence of only one oxygen function, the carbonyl group, whereas allobetulin itself has two, one being an ether function. A search of the literature showed that the ketone was possibly taraxerone (I), previously isolated from *Taraxacum officinale* (3) and *Alnus glutinosa* L. (1), and further chemical evidence confirmed this. The ketone was reduced with lithium aluminum hydride to give the alcohol (II, R = H), which had the physical constants of taraxerol. This was confirmed by the preparation of the acetate in the usual way (II, R = Ac). This acetate was treated with hydrochloric acid in acetic acid (1) and the resulting product crystallized from chloroform–methanol to give β-amyrin acetate (III, R = Ac), identified by melting point and rotation and the melting point and rotation of the derived alcohol (III, R = H) β-amyrin. This rearrangement has been shown to involve the migration of a methyl group from C_{13} to C_{14} with the concomitant movement of the double bond from the 14,15-position to the 12,13-position. The process is concerted and there are no intermediates. It is also irreversible and the yield of β-amyrin is virtually 100%. The rearrangement is typical of taraxerol and some of its derivatives, and treatment of taraxerone under the same conditions afforded β-amyrone (I). Reduction by the Wolff–Kishner procedure afforded the unsaturated hydrocarbon taraxerene (VI), recently

isolated from a lichen by Bruun (2). The amount of taraxerone present in the unsaponifiable extract was approximately two per cent.

The ether fraction of the crude chromatogram gave, in its earlier subfractions, a highly crystalline colorless solid. The amounts however were small, at 50–100 mg. per extraction. The material was only very slightly soluble in ethanol and ether, and could be readily recrystallized from benzene and chloroform. The same compound was also obtained from the fraction of the unsaponifiable material insoluble in light petroleum, extracted before chromatography of the crude unsaponifiable fraction. If this mixture was chromatographed roughly on alumina, elution with benzene afforded taraxerone and elution with chloroform–methanol (5:1) gave the insoluble compound. On recrystallization from chloroform–methanol this material had a melting point of 278°–279°, characterized by a change of crystalline form between 200° and 220°. The specific rotation was 0°. The infrared absorption spectrum showed the presence of a secondary hydroxyl group by bands at 3571 and 1035 cm.$^{-1}$ and the presence of a trisubstituted double bond from a band at 816 cm.$^{-1}$. The spectrum had many of the characteristics of taraxerone and the alcohol corresponded in physical constants and infrared spectrum to taraxerol (see Table I).

The material was shown to be identical with the reduced taraxerone by melting point

and mixed melting point. Oxidation of the alcohol with chromium trioxide in pyridine gave taraxerone, as proved by melting point, mixed melting point, and specific rotation. The amount of taraxerol present in the extract was difficult to estimate owing to its insolubility, but it was approximately 1.5% of the unsaponifiable material or 0.02% by weight of the dried moss. It is probable that some was lost on the chromatographic column. The final proof of the identity of the material was provided by a mixed melting point with a genuine specimen of taraxerol.

The third triterpene isolated from the unsaponifiable extract was α-amyrin (V, R = H). This was not found in the preliminary extractions of the moss, possibly owing to the fact that it requires fairly careful chromatography to separate it from the sterols. However, on working up the ether–methanol fraction from the chromatography of 450 g. of unsaponifiable material, approximately 3.5 g. of α-amyrin were obtained. Chromatography of the acetylated material after the low-melting lignoceryl alcohol had been removed as previously described afforded α-amyrin acetate in the petrol–benzene (4:1) fraction and the steroid acetates in the petrol–benzene (2:1) fraction. The identity of the material was proved by the melting point and rotation of the alcohol, the derived acetate, and the derived benzoate (V, R = Ac and R = Bz respectively). The compound also had an infrared spectrum identical with that published for α-amyrin by Cole (4). A mixed melting point with an authentic specimen of α-amyrin was undepressed.

EXPERIMENTAL

All rotations were measured in a 1 dm. tube with a Rudolph polarimeter. Melting points were observed on a Kofler micromelting-point apparatus and are corrected. The infrared spectra were determined in carbon disulphide solution with a Baird double-beam infrared spectrophotometer, model 4-55. Light petroleum refers to the fraction with boiling point 35°–36°. For the method of obtaining the unsaponifiable fraction of the peat moss, see Part I (5).

Isolation of Taraxerone

The benzene fraction (1 g.) from the chromatography of the crude unsaponifiable extract was extracted with light petroleum and the white crystalline residue filtered off. Recrystallized from chloroform–methanol, it gave taraxerone (500 mg.), m.p. 238°–239°, $[\alpha]_D^{24}$ +12° (c = 1.34 in chloroform). Anal. Calc. for $C_{30}H_{48}O$: C, 84.84; H, 11.39. Found: C, 84.92; H, 11.31. The material gave a purple color in the Liebermann–Burchard test. The yellow 2,4-dinitrophenylhydrazone had m.p. 260°–262°.

Reduction of Taraxerone

Taraxerone (300 mg.) was dissolved in ether (50 ml.) and lithium aluminum hydride (500 mg.) added. The mixture was refluxed for 3 hours. The excess lithium aluminum hydride was decomposed with ethyl acetate and the ether layer washed with dilute acid and water and evaporated to dryness. The resulting product was crystallized from chloroform–methanol to give taraxerol, m.p. 279°–280°, $[\alpha]_D^{24}$ 0° (c = 1.2 in chloroform). For the constants recorded in the literature see Table I.

Acetylation

Taraxerol (200 mg.) was dissolved in pyridine (10 ml.) and acetic anhydride (3 ml.) added. The mixture was heated on the steam bath for 1 hour, then diluted with benzene and washed with dilute alkali, dilute acid, and water, and evaporated to dryness. The crude product, dissolved in benzene, was filtered through alumina and, after removal of the solvent, the material was crystallized from chloroform–methanol to give the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

derived acetate with m.p. 300°–301°, $[\alpha]_D^{25}$ +9° (c = 1.56 in chloroform). Anal. Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Found: C, 81.99; H, 11.00.

Rearrangement of Taraxerol Acetate

Taraxerol acetate (300 mg.) was suspended in acetic acid (30 ml.) and heated to 90°. Concentrated hydrochloric acid (1 ml.) was added and the mixture heated for 15 minutes on the steam bath, in which time all the taraxerol acetate went into solution. The acetic acid was distilled off under reduced pressure and the resulting product crystallized from chloroform–methanol to give β-amyrin acetate (200 mg.), m.p. 239°–240°, $[\alpha]_D^{25}$ +79° (c = 1.15 in chloroform). The values recorded in the literature for the constants are m.p. 241°, $[\alpha]_D$ +82° (11).

The β-amyrin acetate was hydrolyzed in the usual manner to give β-amyrin. Crystallized from aqueous ethanol this had m.p. 195°–196°, $[\alpha]_D^{24}$ +88° (c = 1.34 in chloroform). The values recorded in the literature for the constants are m.p. 197°, $[\alpha]_D$ +89° (11).

The rearrangement when repeated on taraxerone gave β-amyrone, with m.p. 174°–176°, $[\alpha]_D^{24}$ +109° (c = 1.41 in chloroform). The values recorded in the literature for the constants are m.p. 178° $[\alpha]_D$ +107° (7).

Wolff–Kishner Reduction of Taraxerone

Taraxerone (200 mg.) was added to a solution of sodium (500 mg.) in ethanol (5 ml.). Hydrazine hydrate (100%, 1 ml.) was added and the mixture heated in a sealed tube at 180° overnight. The mixture was diluted with benzene, washed with dilute acid and water, and evaporated to dryness. The crude product, dissolved in benzene, was filtered through alumina. After evaporation of the solvent, the resulting product was crystallized from chloroform–methanol to give taraxerene, m.p. 236°–238°, $[\alpha]_D^{24}$ +1° (c = 1.42 in chloroform). The values for the constants reported in the literature are m.p. 237°–238°, $[\alpha]_D$ +1° (2). The infrared absorption spectrum of the material showed no absorption at 1705 cm.$^{-1}$, which would indicate a carbonyl function, and no absorption at 3600 cm.$^{-1}$, which would indicate a hydroxyl group. This proved that the reduction was complete.

Isolation of Taraxerol from Peat Moss

The petrol-insoluble portion of the unsaponifiable material was dissolved in benzene and chromatographed on alumina. Elution with benzene afforded taraxerone (300 mg.), identified by its infrared spectrum. Elution with chloroform–methanol (4:1) afforded taraxerol (400 mg.), recrystallized from chloroform–methanol to give m.p. 278°–279°, $[\alpha]_D^{24}$ 0° (c = 1.17 in chloroform). The melting point was undepressed on admixture with a specimen obtained from the lithium aluminum hydride reduction of taraxerone, and also undepressed on admixture with a genuine specimen of taraxerol of like melting point. Anal. Calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81. Found: C, 84.77; H, 11.53.

Oxidation of Taraxerol

Taraxerol (500 mg.) was dissolved in pyridine (10 ml.) and the solution added to a suspension of chromium trioxide (1 g.) in pyridine (10 ml.). The mixture was allowed to stand overnight at room temperature, then diluted with water, and sulphur dioxide passed through to destroy the excess chromium trioxide. The mixture was extracted with benzene, and the benzene extract washed free of acid and evaporated to dryness. The crude product was dissolved in benzene and the solution filtered through alumina. After evaporation of the solvent, the resulting material was crystallized from chloroform–methanol to give taraxerone, identical in m.p., specific rotation, and infrared spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

with that isolated directly from the unsaponifiable material. This method of oxidation had to be used, since oxidation with chromium trioxide in acetic acid solution led to an impure product, which probably contained β-amyrone, owing to the acid rearrangement of taraxerone.

Isolation of α-Amyrin

The unsaponifiable material (450 g.) from the benzene–ethanol extract of 22 kg. of *Sphagnum* was chromatographed on a 60×4 in. column of alumina using the same solvents as described previously. After the ether–methanol fraction had been treated with urea to remove the lignoceryl alcohol, the residue (50 g.) was acetylated and the mixed acetates chromatographed on alumina. Elution with petrol–benzene (7:3) gave a white crystalline solid (3.5 g.), which on recrystallization from aqueous ethanol had m.p. 224°–225°, $[\alpha]_D^{25}$ +78° (c = 1.26 in chloroform). Anal. Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Found: C, 82.69; H, 11.23. Vesterberg (11) reports m.p. 225°–226° and $[\alpha]_D$ +79° for α-amyrin acetate.

Hydrolysis

α-Amyrin acetate (500 mg.) was dissolved in dioxane (15 ml.) and methanol (20 ml.). Potassium hydroxide (1 g.) in water (3 ml.) was added and the solution heated under reflux for 1 hour. The solution was diluted with water and extracted with benzene, and the extract washed well with dilute acid and water and evaporated to dryness. The product was crystallized from methanol to give m.p. 183°–184°, undepressed on admixture with a genuine sample of α-amyrin, $[\alpha]_D^{25}$ +85° (c = 0.58 in chloroform). Anal. Calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81. Found: C, 84.56; H, 11.43. The values recorded in the literature for the constants are m.p. 186°, $[\alpha]_D$ +84° (11).

Benzoylation

α-Amyrin (250 mg.) was dissolved in pyridine (5 ml.) and benzoyl chloride (0.25 ml.) added. The mixture was heated on the steam bath for 50 minutes. The solution was diluted with benzene and washed well with dilute alkali, dilute acid, and water. It was then evaporated to dryness. The crude benzoate was dissolved in benzene and the solution filtered through alumina. After evaporation of the solvent the product was crystallized from chloroform–methanol to give α-amyrin benzoate m.p. 191°–193°, $[\alpha]_D^{25}$ +95° (c = 0.86 in chloroform). Anal. Calc. for $C_{37}H_{54}O_2$: C, 83.72; H, 10.25. Found: C, 83.81; H, 9.92. The values recorded in the literature for the constants are m.p. 193°–194°, $[\alpha]_D$ +95° (9).

ACKNOWLEDGMENT

The authors wish to thank Professor F. S. Spring, F.R.S., of the Royal Technical College, Glasgow, for his generous gifts of taraxerol and α-amyrin.

THE EFFECT OF WATER REMOVAL ON THE CRYSTALLINITY OF CELLULOSE[1]

M. KOURIS,[2] H. RUCK,[3] AND S. G. MASON

ABSTRACT

The effect of various modes of drying upon the crystallinity of cellulose has been determined by X-ray diffraction.

No change in the crystallinity index was observed when previously undried pure cellulose fibers from softwood were dried from water under a wide range of conditions, but a lower value was obtained when they were dried from benzene to which the fibers were accommodated by a series of solvent exchanges. Heat of wetting determinations on the same samples indicated changes in the accessibility with different drying methods. Qualitative variations in the degree of intrafiber bonding were also detected by a differential staining method. The X-ray measurements suggested that drying from water either produces no change in lateral order or that such changes are too small to be detectable by X-rays.

The crystallinity of cellulose prepared by dry-milling whole fibers was studied. The crystallinity was substantially reduced in a Wiley mill and obliterated in a ball mill. X-Ray diffraction showed that wetting with water and then drying restored the crystallinity, while similar treatment with other liquids yielded less definite results. However, by following the destruction of the lattice with progressive periods of milling, it was concluded that alcohols reform this lattice to a limited extent depending, among other factors, upon the swelling capacity.

INTRODUCTION

The formation of intermolecular bonds between adjacent cellulose chains by the removal of water is of considerable importance, particularly in connection with technical applications of cellulose, e.g. in textiles and in paper, and has been the subject of numerous investigations. It is now reasonably well established that most of the bonds, which can be either intra- or inter-fiber, depending upon whether or not the cellulose chains are in the same fiber, are due to hydrogen bridges (1) between hydroxyl groups of adjoining chains. As a consequence, the number of available hydroxyl groups, and therefore the accessibility of the fibers, would be reduced if additional hydrogen bridge bonds are formed.

The decrease in accessibility with evaporation-drying has been amply verified by Jayme (2, 3) and Purves *et al.* (4), the former by noting the decreased swelling capacity of dried fibers and the latter by applying the thallous-ethylation method.

Since the drying of cellulose is an irreversible process, any lateral order established by hydrogen-bonding may be expected to increase with repeated wetting and drying of the fibers, and cause a sharpening of the X-ray diffraction pattern of the crystalline portion. In this connection, it has been shown that the capacity of the fibers to reabsorb and retain the water decreases with the severity of drying conditions (3). Recently, it has been observed that freezing the wet fibers before air-drying the thawed material adversely affected the interfiber bonding of paper (5, 6). This effect was attributed to partial dehydration of the fibers as a result of freezing.

The mobility, and hence the alignment of the molecular chains in the amorphous regions of wet cellulose fibers, may be expected to be greatly reduced by freezing the water and removing it by sublimation- or freeze-drying, or by replacing the water by

[3]*Present address: Industrial Cellulose Research Limited, Hawkesbury, Ontario.*

a non-polar liquid before drying (6). Fibers dried by this means would be expected to have a higher accessibility than fibers dried by evaporation of liquid water. Although little work has been done on the accessibility of freeze-dried fibers, solvent-exchanged fibers show an increase in reactivity towards various reagents. Thus Siggia *et al.* (7) found an increased accessibility of cotton linters to HIO_4 solution, while Conrad and Scroggie (8) found the same effect towards HCl–$FeCl_3$ attack. A similar trend was observed by Brown and Purves (9) in their nitration experiments on cotton linters. In addition, several workers have shown that a reduction in interfiber bonding, during freeze-drying from water or evaporation-drying from a non-swelling liquid, may be responsible for adversely affecting paper strength. Van den Akker (5), Broughton and Wang (10), and Marchessault, Lodge, and Mason (6) demonstrated that the strength of paper handsheets dried by such methods was considerably less than the strength of normally air-dried sheets. From this it can be seen that the method of drying influences the physical properties of cellulose fibers. In turn these properties may be assumed to be closely related to the degree of hydrogen-bonding, and in turn to the lateral order introduced in the fibers by the drying operation.

In the investigation to be described the effect of different drying conditions on the crystallinity of cellulose fibers was determined by an X-ray diffraction method using the crystallinity index parameter introduced by Ant-Wuorinen (11). This parameter may be considered to be a relative (but not absolute) measure of the fraction of crystalline material. Heat of wetting determinations and a differential staining procedure were also applied to the fibers.

As the crystallinity index of whole fibers proved to be insensitive to drying, attempts were made to magnify the effects by first reducing the crystallinity by mechanical attrition and then wetting with various liquids and drying.

The almost complete destruction of crystallinity of dried cellulose I fibers by ball-milling has been shown by Hess (12) and by Hermans (13), using X-ray diffraction. These workers also showed that wetting the pulverized material resulted in partial recrystallization accompanied by a lattice modification to cellulose II. In the present investigation similar behavior was observed upon rewetting cellulose whose crystallinity had been drastically reduced by dry-grinding fibers in both a Wiley and a ball mill. However, no lattice modifications were observed on wetting. In the case of the Wiley-milled material, recrystallization was observed to occur upon exposure to water vapor of high relative humidity.

The recrystallization of mechanically degraded fibers by non-aqueous liquids has received little attention. Investigating the sorption of vapors by cellulose fibers, Kanamaru and Chao (14), Lauer (15), and Stamm and Tarkow (16) found that the sorptive capacity of cotton for the normal alcohols decreased regularly with increasing molecular weight of the homologous series. From the sparse data available, it is now generally accepted that the penetration and appreciable swelling of cellulosic material can occur only with polar liquids. Furthermore, to encourage rearrangement of the fibers and increase lateral order the swelling medium must be capable of promoting hydrogen-bonding. In this connection, it has been shown that the strength of paper handsheets made by drying from benzene was considerably less than that of handsheets dried from ethanol (10).

In the experiments described below, the variations in the crystallinity index of the mechanically degraded cellulose treated with various organic liquids appeared to parallel their sorption capacity by cellulose.

EXPERIMENTAL

1. Materials

Cellulose Fibers

Softwood dissolving-grade sulphite pulp which had never been previously dried was kindly supplied by Fraser Companies Ltd., Campbellton, N.B., together with the following analytical data:

Viscosity	25.4 cp.
Resin	0.37%
Pentosan	2.42%
Rayon yield	93.7%
10% Caustic insoluble	89.3%

Dried samples were prepared as follows:

Sample F-1.—Oven dried at 105° C.

Sample F-2.—Dried at room temperature. The drying was conducted in two stages. The pulp was first placed in a vacuum desiccator containing concentrated sulphuric acid. After about two days, when the moisture content was reduced to approximately 15%, the pulp was transferred to a desiccator containing phosphorus pentoxide and again evacuated for several days.

Sample F-3.—Cyclic wetting and oven drying. After oven drying at 105° C., the pulp was suspended in water at room temperature for 24 hours, the excess water removed under mild suction, and the pulp again dried at 105° C. This operation was repeated until the sample had been exposed to 10 complete drying cycles.

Sample F-4.—Cyclic wetting and room temperature drying. This sample was subjected to 10 wetting and drying cycles the same as for F-3, except that each drying stage was carried out at room temperature as for F-2.

Sample F-5.—Freeze-drying from water. The water-wet pulp was initially frozen at −78° C. by immersion in acetone/Dry Ice. The ice was then removed by sublimation under vacuum in a laboratory-model freeze-drier.

Sample F-6.—Freeze-drying from benzene. The water-wet pulp was suspended in 200 cc. of acetone which had previously been distilled over activated alumina to remove traces of water. The acetone was replaced several times by a fresh batch until titration of an aliquot with Karl Fischer reagent indicated the absence of water. The pulp was then suspended in 300 cc. of dry benzene, and allowed to stand for 24 hours in a stoppered flask. After a further immersion of 24 hours in a fresh batch of benzene, the latter was decanted and the pulp frozen at −78° C. The benzene (m.p. 5.3° C.) was removed by sublimation under vacuum as for F-5. It was noted that on rewetting the sample with water a strong odor of benzene was detectable. It has been shown that up to 1.5% benzene can be retained in this way (17).

Sample F-7.—Freezing in liquid nitrogen. The adverse effect of ice formation on the bonding properties of fibers has been attributed to a partial dehydration of the fibers at low temperature (6). To determine the effect of this partial dehydration on the crystallinity of cellulose, water-wet pulp was suspended in liquid nitrogen (−195.8° C.) until it had frozen solidly. It was then allowed to thaw at room temperature and finally dried as for F-2. The physical state of the dried pulp depended upon the method of drying. Evaporation of liquid water allowed the capillary forces of water to exert their influence in promoting interfiber bonding, and the fibers tended to be densely packed.

Cyclic wetting and drying produced a bulkier pulp in which the fibers were more easily separated. Pulp which had been dried either by freeze-drying, or from a non-swelling liquid such as benzene, was even less highly bonded than when cyclically dried by evaporation of water.

Wiley-Milled Cellulose

A portion of the same batch of virgin pulp used in the preceding preparation was dried at 105° C. and subsequently milled for 90 minutes in a laboratory attrition mill. An intermediate model Wiley mill was used for this purpose, with a clearance of 7.5×10^{-3} cm. between the stationary and revolving blades. Small quantities of the milled material, which was fine enough to pass a 60-mesh screen, were immersed in pure liquids, having various swelling capacities, for 24 hours at room temperature and then dried as listed in Table I.

TABLE I

TREATMENT OF WILEY-MILLED SAMPLES

Sample	
M-1	Original milled sample
M-2	M-1 immersed in water, 24 hours R.T., dried at 105° C.
M-3	Treatment for M-2 repeated 10 times
M-4	M-1 immersed in ethanol, 24 hours R.T., dried at 105° C.
M-5	Treatment for M-4 repeated 10 times
M-6	M-1 immersed in acetone, 24 hours R.T., dried at 105° C.
M-7	Treatment for M-6 repeated 10 times
M-8	M-1 exposed in a vacuum desiccator to water vapor at 93.3% R.H. for 48 hours, dried at 105° C.

Ball-Milled Cellulose

A series of ball-milled samples of dissolving grade "Rayaceta" wood pulp were kindly supplied by Dr. J. A. Howsmon of the American Viscose Corporation, Marcus Hook, Pa. The dry material had been milled for various times up to 153 hours under the following conditions:

Initial treatment of pulp	Wiley Mill, 20-mesh screen
Ball-mill charge	1200 g. steel balls, 40 g. pulp
Mill speed	47 r.p.m.

To follow the destructive action of ball-milling on the crystallinity of cellulose the samples milled for progressive periods were subjected to X-ray measurements. These samples are denoted by the letter H, followed by the number of hours milled.

In addition, small quantities of sample H-153, which was completely pulverized, were subjected to various wetting and drying treatments as outlined in Table II. Except for sample B-4, the wetting and drying procedures were as for the Wiley-milled material.

The differently treated samples prepared from both sets of milled materials remained powdery and to the eye were unchanged from the untreated material.

2. EXPERIMENTAL METHODS AND RESULTS

X-Ray Measurements

General

A transmission technique based on that of Hermans (18) was adopted for the X-ray measurements, except that air scattering was used as a reference for the incident X-ray

intensity instead of a Goppel (19) camera, and the samples were mounted in the form of compressed pellets which were supported in a holder during an exposure. In addition, a nickel foil was used for X-ray absorption measurements.

Fig. 1 shows the disposition of the various parts of the camera and collimating system. The nickel-filtered copper radiation was delivered by a Muller MC-50 tube. A 9×12 cm. flat film camera, manufactured commercially by R. Seifert & Co., Hamburg, Germany, was used. Its collimator was replaced by a four-pinhole system and a removable nickel foil was incorporated as shown in Fig. 1. Details of construction are to be published separately.

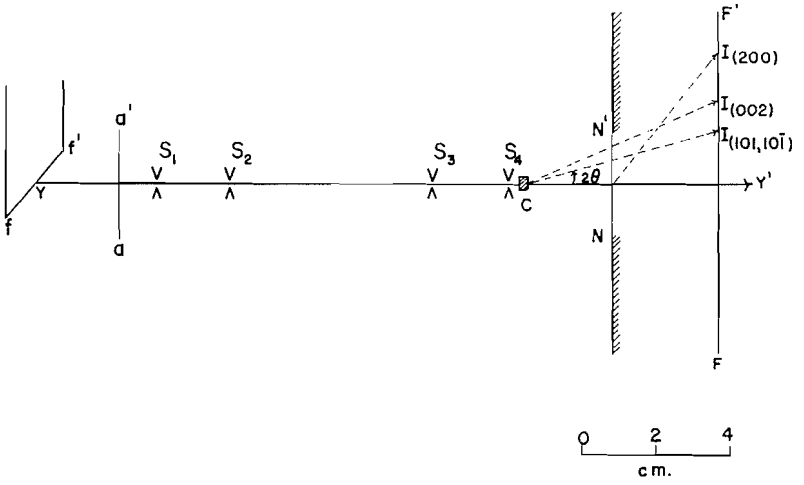

FIG. 1. Camera and collimating system. ff′ = Focal spot of tube. YY′ = Path of primary beam. aa′ = Nickel filter. S_1S_4 = Pinhole apertures, 1 mm. S_2S_3 = Pinhole apertures, 0.7 mm. C = Sample. NN′ = Nickel foil, 0.021 mm. thick, supported on metal frame. FF′ = Film. $I_{(200)}$ = Nickel interference. $I_{(101,10\bar{1})}$, I_{002} = Cellulose A_4 and A_1 interference respectively.

Mounted pellets were prepared from whole fibers by separating them with two dissecting needles until the resulting material was a mass of loosely tangled individual fibers. A weight of 3 mg. ±3% of the loose fibers was placed in a metal sample holder and compressed into a pellet by a specially-constructed press, care being taken to ensure isotropic packing in the plane of the holder. Pellets of the milled cellulose were formed in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

same manner but with no previous scraping. For an exposure to the X-ray beam, the loaded pellet holder was mounted on the collimator. The dimensions and densities of the pellets are given in Table III.

TABLE III

DIMENSIONS AND DENSITIES OF PELLETS

Pellets	Diameter, mm.	Thickness (t), mm.	Density (ρ), g./cm.^{3}
Cellulose fibers	3.0	1.7	0.25
Wiley-milled cellulose	3.0	0.5	0.85
Ball-milled cellulose	3.0	0.4	1.06

All exposures were made at room temperature and at the prevailing relative humidity, which was in the region of 50%. Ilford-B film was used throughout.

Measurements of Intensity

To determine the intensities of X-ray diffraction lines on a film, a continuous recording microdensitometer, manufactured by A. Krüss, Hamburg, Germany, was used. The sensitivity of the galvanometer was adjusted to give zero deflection in the unexposed region, and a full-scale deflection of 80 mm. when no light was transmitted through the film. Fig. 2 is a reproduction of a photometer trace of a diffraction pattern of wood

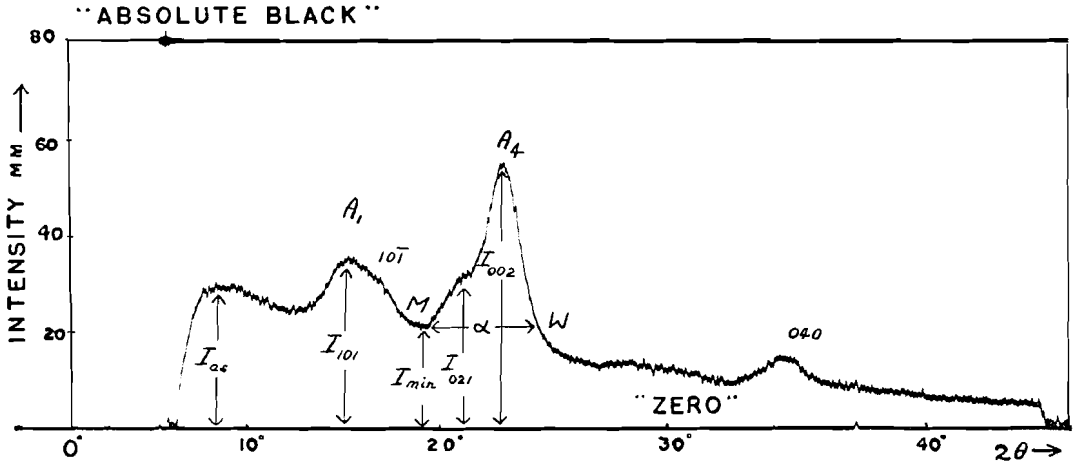

FIG. 2. Radial photometer trace of an X-ray diffraction pattern of wood pulp. I_{as} = Maximum intensity of air scattering. I_{101} = Intensity of (101) peak. I_{min} = Intensity of minimum point M. I_{021} = Intensity of (021) peak. I_{002} = Intensity of (002) peak. α = Width MW of peak (002) in radians. A_1, A_4 = Herzog designation of peaks (101) and (002), respectively.

pulp. The traces of the extreme positions of the galvanometer deflections are shown as the "zero" and "absolute black" lines. The height in mm., above the "zero" line, of any point on the trace is a measure of its intensity. The Herzog (20) designations and Miller (21) indices (hkl) of the principal planes of cellulose corresponding to the various peaks are included in Fig. 2. The maximum intensity of air scattering, I_{as}, occurs at an angle $2\theta = 7° 30'$.

Measurements of Absorption

Since sample F-6 contained entrapped benzene, measurements were made to determine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

any change in its X-ray absorption coefficient, using sample F-1 as a standard. In making absorption measurements the sample was alternately placed in position and removed, and two exposures at the same intensity were made of the nickel foil NN′ (Fig. 1). From the difference in intensity of the (200) nickel interference the absorption $\mu_m \rho t$ of the sample was calculated using (see Ref. 18):

$$\ln(I_{Ni})_{air} - \ln(I_{Ni})_{cell.} = \mu_m \rho t, \quad [1]$$

where

$(I_{Ni})_{cell.}$, $(I_{Ni})_{air}$ = intensity of (200) nickel interference with and without sample in position respectively,
μ_m = mass absorption coefficient of the sample (cm.^{2}/g.),
ρ = packing density in the sample (g./cm.^{3}),
t = thickness of the sample in cm.

The resulting values of $\mu_m \rho t$ for samples F-1 and F-6, 0.383 and 0.363 respectively, agreed within experimental error indicating equal absorption coefficients. Hence, no correction was applied to the observed peak height of sample F-6; in Hermans' experiments such corrections were necessary (22).

Determination of Crystallinity Index

(*i*) *Cellulose Fibers*

Following the method of calculation used by Ant-Wuorinen (11), the per cent crystallinity index, X, is given by the following equation, which is readily derived from Ant-Wuorinen's equations:

$$X = \{1 - [80\alpha/(I_{002} - I_{min})]\} \times 100, \quad [2]$$

where, as illustrated in Fig. 2,

I_{002} = height of A_4 peak in mm.,
I_{min} = height of minimum point M above "zero" line in mm.,
α = width (MW) of peak A_4 in radians.

TABLE IV

PROCEDURE FOR IRRADIATION OF SAMPLES

Series	Samples	Pellets per sample	Exposures per pellet	Anode voltage, kv.	Anode current, ma.	Time of each exposure, min.
1	F-1 to F-7	4	1	30	20	65
2	M-1 to M-8	1	3	30	≈20	45, 80, 100
3	B-1 to B-12	1	3	30	≈20	45, 80, 100
4	H-0 to H-153	1	1	30	≈20	80

The conditions of irradiation for Series I, Table IV, produced a maximum intensity of air scattering, I_{as}, of 30 mm. and α was found to be independent of the intensity of irradiation. The results of the X-ray measurements for cellulose fibers are shown in Table V. Sample M-1 has been included for comparison.

(*ii*) *Milled Cellulose Samples*

For every sample in Series 2 and 3, Table IV, I_{as} was plotted against the corresponding values of I_{101}, I_{002}, and I_{min} obtained from the photometer trace as in Fig. 2. Excellent

straight lines of the type shown in Fig. 3 were obtained. The lines passed through the origin and the linearity was maintained up to an optical density of film blackening of 0.9. The values at I_{as} = 30 mm. were obtained from the respective graphs and X determined from Equation [2]. The same procedure was applied to samples exhibiting no interferences associated with crystallinity, except that the maximum intensity of the "amorphous" halo, I_{AmH}, was measured. Furthermore, the absence of the peaks A_4 and A_1 eliminated the minimum point M between them, and α could not be measured.

The results of the X-ray measurements on the Wiley- and ball-milled cellulose are recorded in Tables VI and VII, respectively.

For Series 4, Table IV, the values of I_{101}, I_{021}, I_{002}, I_{min}, and I_{AmH}, measured at the I_{as} of the exposure, were reduced to an I_{as} = 30 mm. by multiplying by the factor 30/measured I_{as}. The results of the X-ray experiments on the samples milled for progressive periods are recorded in Table VIII. It is interesting to note that it took more than 100 hours of ball-milling to render the photometer tracing uniform. Ellefsen *et al.* (23) report that no change was observed after 6 hours of milling in their recent experiments.

Value of K_{hkl} and Crystallinity

The ratio of a cellulose interference, I_{hkl}, and the intensity of a reference line of the Goppel (19) camera used by Hermans (18) yields a value independent of the energy of irradiation. A similar result is obtained if the Goppel interference is replaced by the maximum intensity of air scattering, I_{as}, occurring at an angle $2\theta = 7° 30'$.

Thus

$$I_{hkl}/I_{as} = K_{hkl}. \qquad [3]$$

Any variation of I_{as} with atmospheric pressure was neglected.

The air scattering peak did not contain any appreciable contribution from the cellulose. This was established by means of diffraction patterns of cellulose obtained with a Kiessig small-angle vacuum camera, both with and without a vacuum. Under vacuum the scattered intensity at 7° 30′ was negligible, a circumstance which made it possible to use air scattering for standardization.

In Table VI it is seen that in certain cases, although the diffraction pattern showed the unmistakable presence of A_1 and A_4 peaks, X failed to represent the state of crystallinity of samples subjected to severe mechanical degradation. In addition, the difficulty in measuring α caused by the broadening of the minimum between A_1 and A_4 peaks introduces an error of (0.16 to 0.20) X, when X is in the range 20 to 30%. Since the A_4 peak is more sensitive to crystallinity changes than A_1, the value of K_{002} may provide a parameter which is less susceptible to error and which is capable of continuously representing the state of crystallinity of cellulose. Assuming approximately equal size distribution of crystallites, I_{002} for a given I_{as} will be greater for a more crystalline than for a less crystalline sample.

In Tables VI and VII, K_{002} was determined from the slope of the straight lines obtained by plotting I_{as} vs. I_{002}. Fig. 3 shows the plot of I_{002} vs. I_{as} of four cellulose samples of different degrees of crystallinity. Dewaxed cotton linters, a cellulose of high crystallinity which is estimated from various methods to amount to 70% (22), was included for comparison. I_{002}, X at $I_{as} = 30$, and K_{002} are given in Table IX. Fig. 3 and Table IX show that K_{002} decreases together with X, and in addition, gives a positive value in the case of sample M-1 where X indicates somewhat misleadingly the total destruction of crystallinity.

TABLE IX

VARIATION OF I_{002}, X, AND K_{002} WITH DEGREE OF CRYSTALLINITY

No.	Sample	A_4 I_{002}, mm.	X, %	K_{002}
1	Dewaxed cotton linters	58.5	79.8	1.950
2	F-7	44.3	67.0	1.535
3	M-2	37.0	50.5	1.230
4	M-1	28.0	0.0	0.934

Heats of Wetting

Heats of wetting by liquid water were measured for samples F-1 to F-7 and M-1 using a Bunsen isothermal calorimeter with diphenyl ether as the working substance (24). The apparatus was kept in a thermostat maintained at 26.90±0.003° C. The results of these experiments are given in Table V.

Differential Staining

Differential staining of fibers provides a visual and qualitative means of demonstrating variations in the density of amorphous cellulose and the degree of fibrillation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(25). Samples F-1 to F-7 were dyed with a solution of equal parts of Benzo-Fast Yellow A and Benzo Brilliant Blue 6BS. The dyes were obtained from Bayer, Farbenfabriken, Leverkusen, Germany. The technique used by Jayme (26) was followed in its entirety. The results of the differential staining experiments are shown in Table X.

TABLE X

DIFFERENTIAL STAINING

Sample No.	Sample preparation	Color after staining
1	Sample F-2 (at room temperature over P_2O_5)	Pale green
2	Sample F-4 (10 times as No. 1)	Pale green
3	Wet (virgin) pulp	Yellowish
4	Sample F-3 (10 times as No. 8)	Blue
5	Sample F-5 (freeze-dried)	Greenish yellow
6	Sample F-7 (wet sample in liquid N dried as No. 1)	Greenish yellow
7	Sample F-6 (solvent exchanged)	Yellowish
8	Sample F-1 (dried once at 105°)	Blue to blue-green

Viscosity

To follow the effect of mechanical degradation on the degree of polymerization (D.P.), viscosity measurements were made on samples F-1 and M-1 and H-0 to H-153. The viscosity pipette procedure described in Tappi, method T-230 sm-50, was followed in its entirety.

The intrinsic viscosities were calculated from Schulz and Blaschke's (27) equation:

$$\eta_{sp}/c = [\eta](1+k'\eta_{sp}), \qquad [4]$$

where

η_{sp} = specific viscosity,
c = concentration of cellulose in g./dl.,
k' = $2.303k$,
k = 0.13 (Martin's (28) constant),
$[\eta]$ = intrinsic viscosity in dl./g.

The degree of polymerization was calculated from the equation in Ref. (29):

$$\text{D.P.} = 156[\eta]. \qquad [5]$$

The intrinsic viscosities and D.P. values are recorded in Table XI.

TABLE XI

VARIATION OF D.P. OF CELLULOSE WITH MECHANICAL TREATMENT

Sample No.	$[\eta]$, dl./g.	D.P.
F-1	2.70	422
M-1	2.49	389
H-0	4.83	755

DISCUSSION

Cellulose Fibers

From Table V it is seen that drying cellulose fibers under different conditions produced little change in the crystallinity index, X. Although the diffraction pattern of fibers dried by evaporation of water and freeze-drying remained unaltered, the heats of wetting varied with the method of drying. Only in sample F-6 (the results of which were duplicated) could a change in X be detected. On immersing sample F-6 in water at room temperature for 24 hours and then drying for 24 hours, it was found that X increased to 67.6% so that the increase in X due to drying from water must be considered to be real.

The results obtained for samples F-1 to F-4 and F-7 suggest that any relative changes in crystallinity, arising from variations in intrafiber bonding with the method of drying, were small compared with other changes tending to decrease the accessibility, as indicated, by the heats of wetting. Since the quantity of heat evolved when cellulose is wetted with water is believed to be primarily due to an interaction of the water molecules with free hydroxyl groups of the cellulose, it may be taken as a measure of the accessibility of these hydroxyl groups (30). On this assumption, it may be inferred that in conformity with previous findings, the vitrified regions (2) and junction points (31) established with a first drying in samples F-1 and F-2 increase with repeated wetting–drying cycles (samples F-3 and F-4) as well as with the temperature of drying. The formation of impenetrable vitreous regions and junction points would then immobilize and prevent the interaction of any available hydroxyl groups with the water molecules without necessarily increasing lateral order.

Freezing the fibers as in sample F-7 may have reduced their hydrophilic (32) character and produced the same effect on the accessibility as drying at a temperature between 105° C. and room temperature. In freeze-drying cellulose fibers the plasticizing action of water is reduced and the mobility of the molecular chains curtailed. In addition, previous work has shown that freeze-drying decreases interfiber bonding especially in the absence of hemicellulosic material (5, 6). Since benzene is a poor swelling and a poor hydrogen-bonding medium, it may be reasonable to conclude that the degree of alignment of the molecular chains in the amorphous region during drying from benzene is less than with water. Hence, any additional crystallization produced in this manner in drying from water will be absent with benzene-dried fibers. Fibers dried in this manner would be expected to have a lower X (as was found for sample F-6) and a higher value of heat of wetting than fibers dried by evaporation of water. However, since sample F-6 contained trapped benzene, the heat of wetting of 11.98 cal./g. is of doubtful validity.

An attempt was made to determine X by taking a diffraction diagram of wet (virgin) fibers, but it proved unsuccessful because it was not possible to make a quantitative separation of the X-ray scattering due to water from that due to cellulose.

Table X shows the effect of different drying procedures on the staining of cellulose fibers. The color differences resulting from the staining procedure depend upon the dyeing properties of the different components of the dyes. The main component of the yellow dye has a greater affinity for cellulose than either component of the blue dye, but the blue dye is composed of smaller molecules than the yellow dye. Hence, the blue dye can enter a capillary network into which the yellow dye, in spite of its greater affinity for cellulose, is not admitted (26). A cellulose structure having fine capillaries will be dyed blue to blue-green, while a structure in which the molecular chains are less highly bonded would stain yellow.

For personal use only.

As could be seen under the microscope, in the virgin as well as the solvent-exchanged sample, intrafiber bonding was least and a yellow color resulted. In contrast, the highly bonded fibers resulting from the evaporation of water acquired a similar blue to blue-green color exhibited by the oven-dried sample. The color of the freeze-dried sample further indicated that drying by sublimation of water reduced intrafiber bonding to a smaller extent than drying by solvent exchange.

The variations in color became more distinct when the stained fibers were viewed in bulk. The most striking differences in color were again exhibited by the undried (virgin) and solvent-exchanged samples No. 3 and 7, respectively. Fibers dried by room-temperature evaporation of water stained pale green (No. 1) and the color did not intensify when the fibers were stained after having been wetted, and dried 10 times (No. 2). Fibers dried by evaporation of water at 105° C. stained pale blue (No. 8), while fibers which had been wetted at room temperature and dried at 105° C. exhibited a more intense blue color upon staining (No. 4). Freeze-drying (No. 5) or treatment with liquid nitrogen (No. 6) resulted in greenish-yellow fibers upon staining.

From these results it could be inferred that intrafiber bonding was least in the undried (virgin) pulp sample and greatest in sample F-3 (No. 4). Further work is in hand to measure the reflection spectra between 400 and 700 mμ of the differentially stained pulps. Preliminary measurements have indicated that a quantitative method of measuring the degree of vitrification can be worked out.

Milled Cellulose

From Tables V, VI, and VII it is seen that Wiley-milling increased the heat of wetting of cellulose fibers and reduced X to zero, while ball-milling completely destroyed the crystallinity. Figs. 4, 5, and 6 are reproductions of photometer traces of X-ray diffraction patterns of F-1, M-1 and M-2, B-1, B-2 and B-4, and B-1 (in the dry and wet state), respectively. By comparing Fig. 4(*b*) with 4(*a*), the following points may be noted:

(1) Wiley-milling reduced the intensity of the A_1 and A_4 peaks.

(2) The grinding action preferentially destroyed the $A_4(002)$ planes, reducing the A_4 peak intensity to 57% of its value in F-1, while the A_1 peak suffered a reduction of only 20%.

(3) The width α in M-1, a measure of the crystallite size, was also reduced.

In contrast, the X-ray diffraction pattern of B-1 showed only a diffuse halo, which

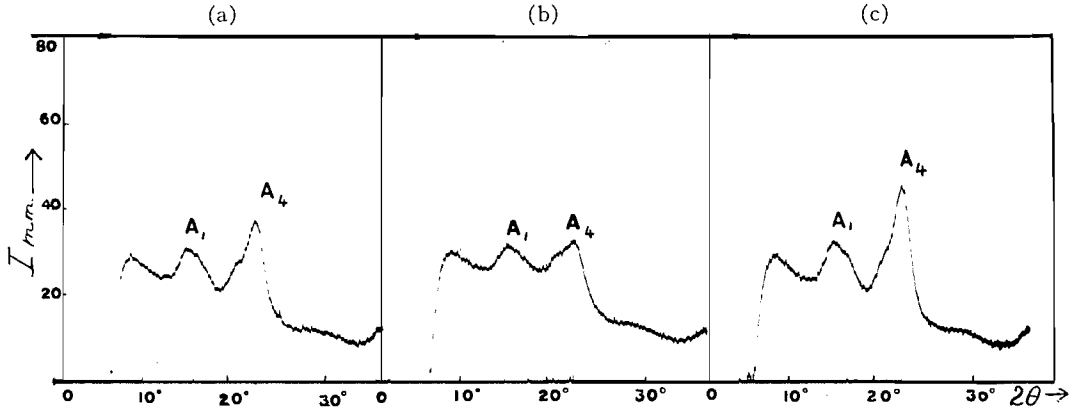

FIG. 4. Radial photometer traces of X-ray diffraction patterns of cellulose fibers and Wiley-milled cellulose. (*a*) Sample M-2. (*b*) Sample M-1. (*c*) Sample F-1.

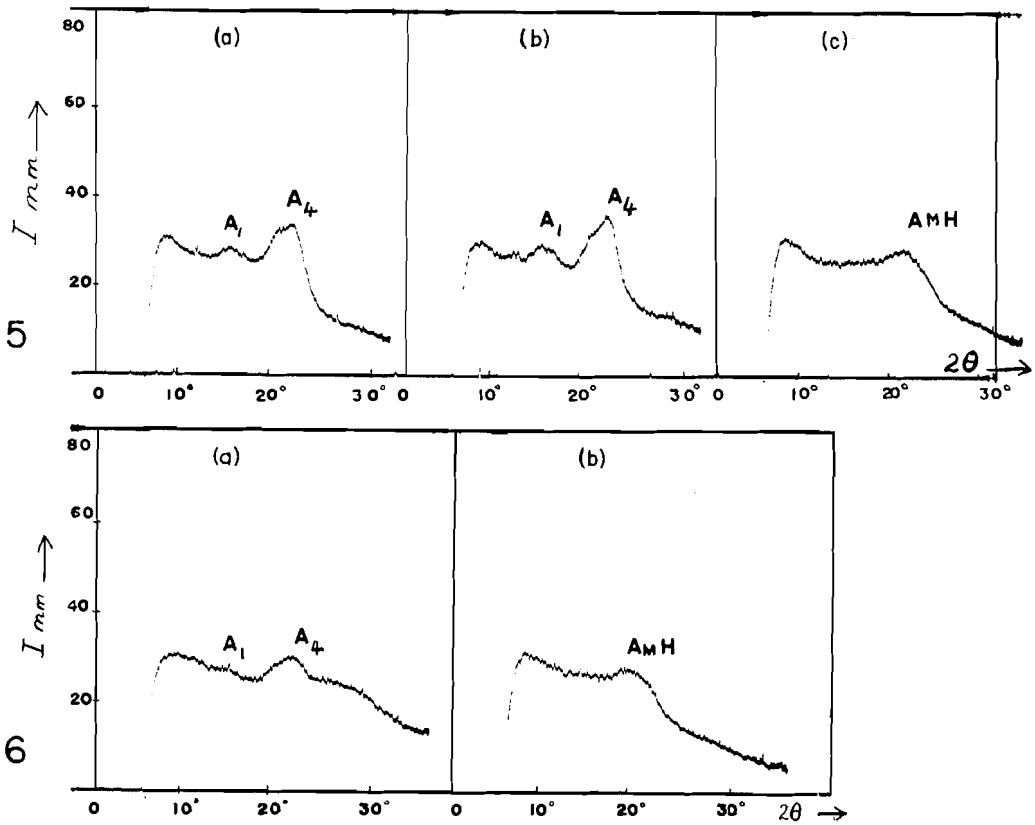

FIG. 5. Radial photometer traces of X-ray diffraction patterns of ball-milled cellulose. (*a*) Sample B-4. (*b*) Sample B-2. (*c*) Sample B-1.

FIG. 6. Radial photometer traces of X-ray diffraction patterns of dry and wet ball-milled cellulose. (*a*) Sample B-1—wet. (*b*) Sample B-1—dry.

can be seen in Fig. 5(*a*) as a broad maximum in the region previously occupied by the (021) peak.

Treatment of the milled material with water resulted in the following behavior:

(1) Partial restoration of crystallinity, Figs. 4(*c*) and 5(*b*).

(2) Exposure of the Wiley-milled product to water vapor at 93.3% R.H. resulted in the same degree of recrystallization as for M-2.

(3) Repeated wetting and drying (samples M-3 and B-3) further increased X.

(4) Recrystallization of B-1 occurred in the wet state, Figs. 6(*a*) and 6(*b*).

(5) Displacing the water from the wetted ball-milled sample with benzene and drying from the non-polar solvent resulted in a smaller degree of recrystallization than with B-2, Fig. 5(*c*).

(6) No modification to cellulose II occurred, but a slight shift was observed in the position of the A_4 peak of the treated ball-milled samples.

Treatment of the Wiley-milled samples with organic liquids gave smaller X values than with water. Because of the large error associated with such small values of X, the state of crystallinity can be better appreciated by referring to the K_{002} values. It is seen that a single wetting with ethanol gave, as expected from its greater swelling power, a larger K_{002} value than acetone. Anomalously, a lower K_{002} value was obtained

for repeated wetting and drying from ethanol than for a similar treatment using acetone, but this may have been due to contamination of the acetone with water. In contrast, treatment of the ball-milled samples with organic liquids produced no detectable X-ray interferences associated with crystallinity.

The increase in the heat of wetting of sample M-1 may be readily explained by an increase in the number of available hydroxyl groups. The disruption of the hydrogen-bonded crystalline lattice and the reduction in the degree of polymerization of the fibers with grinding (Table XI) exposed hitherto unavailable hydroxyl groups which could then react with the water molecules. Although a reduction in the size of the crystallites may be expected to produce an increase in the width α of the A_4 peak in sample M-1, the observed decrease may be attributed to a change in the distribution of the crystallite size with the larger crystallites surviving the destruction action better than the smaller ones. The progressive decrease in α with milling, observed in Table VIII, is at present inexplicable.

In order to explain the recrystallization of the milled material with water it may be assumed that mechanical degradation, in destroying the crystalline regions, also ruptures the junctions restraining normal swelling of the fibers. The plasticizing action of water, by conferring mobility on the chains, allows their realignment and the surface tension of water during drying promotes hydrogen-bonding, which increases the lateral order. Repeated wetting and drying may be expected to further extend the process of realignment and a higher degree of lateral order may be attained.

The identical results obtained for samples M-2 and M-8 may indicate that removal of the water in the earlier stages of drying contributes little to recrystallization. Upon addition of water beyond the range of "bound" water the rapid rise in the sorption isotherm in the high humidity regions cannot be explained by assuming formation of new sorption sites by swelling. In the opinion of various workers, water in the high relative humidity regions is adsorbed as multilayers (33), or by capillary condensation (34), or by solution of the non-crystalline cellulose (35).

Such water will condense within the structure with heat effects associated with normal condensation (36, 37). However, since only imbibed water can affect the intrinsic properties of the fibers and promote their rearrangement, it is reasonable to assume that recrystallization of M-8 had occurred in the range of 60–70% R.H.

Broughton and Wang (10), investigating the strength of handsheets dried from non-aqueous liquids, observed a similar behavior. Upon conditioning butanol-dried handsheets to water vapor of 85% R.H., the strength attained was found to be as great as that of a sheet initially formed from water. These authors did not discount the possibility of an increase in bonding occurring only at the onset of capillary condensation. According to Barkas (38), such condensation begins at a relative humidity of 65–70%.

By comparing values of α for the undegraded and milled material, it may be inferred that the mending action of water reproduced the same distribution of crystallite size existing before degradation. The low X and K_{002} values obtained for sample B-4 fall within expectation. Here, as in sample F-6, the mobility of the chains in benzene was greatly curtailed and there was little tendency for hydrogen-bonding, and hence on drying resulted in a low degree of lateral order. These results further confirm previous findings that drying from benzene is much less effective in bond formation in fibers than drying by sublimation of water (10).

The results obtained for samples M-4 to M-7 indicate that the amount of recrystallization occurring on drying increases with the swelling capacity of the liquid. As expected,

ethanol produced a higher lateral order than acetone, but less than for water. From the results of the ball-milled samples treated separately with benzene and acetone, it is concluded that no recrystallization is possible with these liquids. The almost complete absence of order in the ball-milled samples, and the smaller swelling capacities for cellulose of the alcohols with respect to water, may be responsible for the failure of these media to produce any detectable recrystallization. Here, it may be assumed that the relatively weaker swelling medium is unable to align the molecular chains without the initial presence of well-defined crystallites to act as anchoring points.

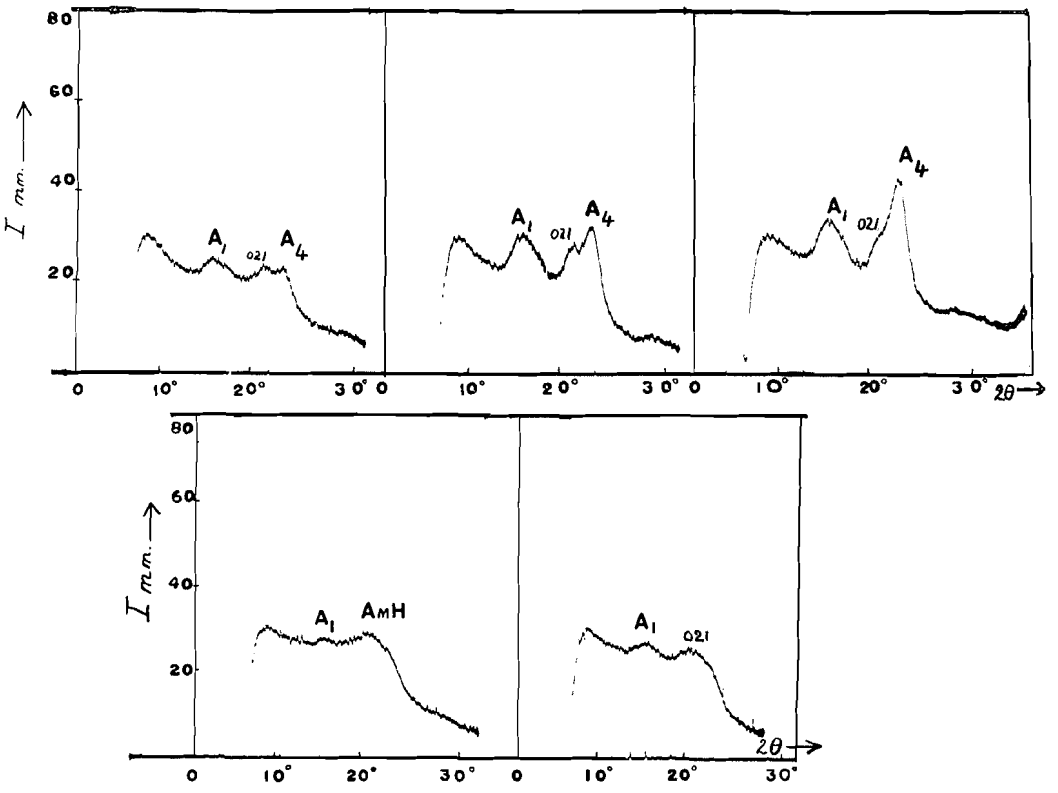

FIG. 7. Radial photometer traces of X-ray diffraction patterns of cellulose ball-milled for progressive periods. *Top*—Left: Sample H-68. Center: Sample H-32. Right: Sample H-0. *Bottom*—Left: Sample H-132. Right: Sample H-96.

Although in this case the presence of nuclei of ordered regions appears necessary for recrystallization, a further conclusion may be drawn from the variations in the intensity of the amorphous halo I_{AmH}, for the alcohol-treated samples. Fig. 7 is a reproduction of photometer traces of X-ray diffraction patterns of H-0, H-32, H-68, H-96, and H-132. From the traces and Table VIII, the following observations were made:

(1) The A_4 peak diminished steadily and disappeared after 80 hours of milling.

(2) The (021) peak also diminished and disappeared between 68 and 80 hours of milling, being replaced by an amorphous halo.

(3) The position of the maximum intensity of the amorphous halo coincided with the position of the (021) peak it replaced.

(4) The intensity of the amorphous halo increased and finally levelled out after 132 hours of milling.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(5) The A_1 peak resisted initial degradation and began to suffer only after 32 hours of milling.

(6) Table VIII shows that the intensity of I_{mln} increased with decreasing crystallinity and hence may be taken as a measure of the amorphous content.

(7) The increasing intensity of I_{mln} helped to maintain constant the intensity of the A_1 peak which merged with the background after 132 hours of milling.

Fig. 8 shows a plot of the intensity of the (021) peak against time of milling. The curve has a minimum region where the transition from the (021) peak to the amorphous halo takes place. The intensity of the (021) peak decreases gradually with milling until, after 70 hours, the intensity of the amorphous halo predominates, and increases with continued milling. After approximately 130 hours, it reaches its final value of 28.5 mm. This stage appears to mark the limiting effect of the grinding process, for although the sample probably is not completely amorphous, the intensity of the "amorphous" halo remains constant with further milling.

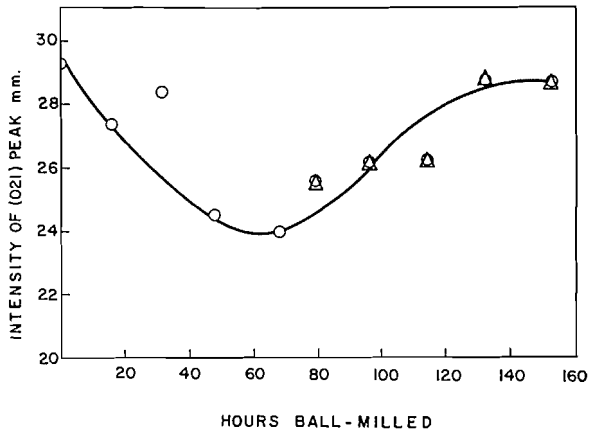

FIG. 8. Variation in intensity of (021) peak with time of ball-milling. Circles: I_{021}. Triangles: I_{AmH}.

The variations in I_{AmH} may be taken to herald the beginnings of the (021) lattice planes of cellulose I, and the I_{AmH} values for the ethanol- and methanol-treated samples may be considered to be I_{021} values on the left of the transition region in Fig. 8. It is evident that propanol and butanol are hindered (sterically or otherwise) from penetrating the degraded cellulosic structure; no (021) lattice planes are formed. Although the evidence is inconclusive, the formation of the (021) lattice planes under these conditions should not be discounted.

ACKNOWLEDGMENTS

The authors are indebted to Dr. R. M. Screaton for measuring the heats of wetting.

ÉTARD REACTION

II. POLYCYCLIC AROMATIC AND HETEROCYCLIC COMPOUNDS[1]

OWEN H. WHEELER

ABSTRACT

Polycyclic aromatic compounds can, in a number of cases, be oxidized with chromyl chloride, whereas heterocyclic compounds are unaffected.

The Étard oxidation of a number of substituted toluenes to substituted benzaldehydes with chromyl chloride was reported in a previous publication (1). The reaction should be extendable to methyl-substituted polycyclic aromatics and possibly to heterocyclic compounds. The only such reference in the literature is the statement, without experimental details, that some substituted polycyclic aromatics are oxidized to traces of quinones (2).

In the case of many of the polycyclic aromatic compounds studied (see Table I) products could be isolated by chromatography from the tarry residues formed in the reaction.

TABLE I

Reactant	Product	Yield, %
Anthracene	Anthraquinone	12
Naphthalene	—	—
2-Methylnaphthalene	—	—
9-Methylanthracene	Anthraquinone	70
2-Methylanthracene	2-Methylanthraquinone	42
	Anthraquinone-2-aldehyde	25
9-Methylphenanthrene	9-Phenanthraldehyde	30
	Phenanthraquinone	18
9,10-Dihydroanthracene	Anthraquinone	32, 62[a]
9,10-Dihydrophenanthrene	Phenanthraquinone	35
Fluorene	Fluorenone	35
2-Picoline	—	—
2-Picoline-N-oxide	—	—
3-Methylthiophene	—	—

[a]*Time of reaction reduced to 6 hours.*

Anthracene gave 12% anthraquinone as well as a small amount of uncrystallizable oil, but naphthalene gave only traces of a dark red oil. 2-Methylnaphthalene also gave only small quantities of a yellow oil. However, 9-methylanthracene gave anthraquinone in good yield (70%). The only previous observation of the removal of a methyl group by this reagent is the conversion of isopropylbenzene to acetophenone (2, 3). The oxidation of 2-methylanthracene took place at two positions giving 2-methylanthraquinone (42%) and anthraquinone-2-aldehyde (25%). No 2-anthraldehyde was isolated and it is to be expected that the 9,10 positions would be more reactive. 9-Methylphenanthrene also gave two products: 9-phenanthraldehyde (30%) and 9,10-phenanthraquinone (18%), again with displacement of a methyl group.

Considering the high reactivity of the 9,10 positions of anthracene and phenanthrene, it should be possible to oxidize their 9,10-dihydro derivatives, and 9,10-dihydroanthracene and 9,10-dihydrophenanthrene readily gave anthraquinone and phenanthraquinone,

[1]*Manuscript received February 17, 1958.*
Contribution from the Department of Chemistry, Dalhousie University, Halifax, N.S. For Part I of this series see Can. J. Chem. **36**, *667 (1958).*

respectively. In the latter case the yield was considerably improved by reducing the reaction time, suggesting that the yields in other cases might be improved by using shorter periods of reaction. Fluorene was also converted readily into fluorenone.

2-Picoline and 2-picoline-N-oxide both formed solid complexes with chromyl chloride, but on decomposition no aldehydic products could be isolated. Continuous ether extraction of the basified aqueous extracts gave some recovered starting material and the reaction complexes must have been salts between the base and the Lewis acid, chromyl chloride. Similarly, 3-methylthiophene gave no oxidized product and was recovered unchanged. This heterocyclic could also act as a Lewis base towards chromyl chloride and complexing on the heteroatom would prevent further reaction on the methyl group.

Details of only some typical oxidations are given in the experimental section but in the other cases the identity of the isolated products was checked by mixed melting-point determinations.

EXPERIMENTAL

Many of the compounds used were commercially available samples.

2-Methylanthracene.—2-Methylanthraquinone (10 g.) in xylene (100 ml.) was refluxed with aqueous ammonia (300 ml.) and zinc dust (100 g.) added in portions during 6 hours (4). The organic layer was evaporated and the residue in benzene chromatographed on alumina using benzene–hexane mixtures as eluent. 2-Methylanthracene (5.5 g.), m.p. 206° from ethanol (lit. m.p. 207° (5)), was eluted first, followed by 2-methylanthrone (3.5 g.), m.p. *ca.* 75°. Reduction with sodium hydroxide and zinc dust gave no reaction and phosphorus and hydriodic acid gave only 2-methyloxanthranol.

9-Methylphenanthrene.—9-Phenanthraldehyde (6) was converted to its hydrazone, m.p. 102°, from ethanol. The hydrazone (16 g.) was heated with sodium (3 g.) in ethylene glycol (100 ml.) to 200° for 18 hours (7). The reaction mixture was diluted with water and extracted with ether. The residue left when the ether was evaporated was chromatographed as above and gave 9-methylphenanthrene (1.9 g.), m.p. 93–94°, from ethanol (lit. m.p. 91–92.5° (8)).

9,10-Dihydrophenanthrene was prepared by catalytic hydrogenation of purified phenanthrene (9).

2-Picoline-N-oxide resulted from peracetic acid oxidation of 2-picoline (10).

Oxidation of 9-methylanthracene.—9-Methylanthracene (0.95 g.) in carbon tetrachloride (80 ml.) was treated dropwise with chromyl chloride (1.70 g., 10% excess) in carbon tetrachloride (20 ml.) with stirring at 20–25°. The reaction was stirred for a total of 2 hours and allowed to stand overnight. The mixture was worked up by pouring into excess ice-cold aqueous sodium sulphite. The residue left after evaporation of the solvent was taken up in benzene and chromatographed on alumina using hexane, hexane–benzene mixtures, and benzene as successive eluents. The product (720 mg.) had m.p. 286°, undepressed on admixture with anthraquinone.

Oxidation of 2-methylanthracene (300 mg.) gave on chromatography 2-methylanthraquinone (145 mg.), followed by anthraquinone-2-aldehyde (95 mg.), m.p. 182–184° (lit. m.p. 188–189° (11)).

Oxidation of 9-methylphenanthrene (810 mg.) gave 9-phenanthraldehyde (260 mg.), m.p. 95–97° (lit. m.p. 100–101° (6)), and 9,10-phenanthraquinone (155 mg.), m.p. 196° (lit. m.p. 198° (12)).

ACKNOWLEDGMENTS

Dr. H. Estrada and Dr. J. Romo kindly supplied samples of 9,10-dihydroanthracene and 9-methylanthracene.

MOLECULAR SIZE AND CONFIGURATION OF CELLULOSE TRINITRATE IN SOLUTION[1]

M. M. HUQUE,[2] D. A. I. GORING, AND S. G. MASON

ABSTRACT

Viscosity and light-scattering measurements were made on several fractions and two unfractionated samples of cellulose trinitrate. The samples were prepared from bleached ramie, unbleached ramie, and cotton linters. The solvents were acetone and ethyl acetate. Viscosity was measured in a multishear viscometer designed for the purpose. Light-scattering measurements were made in a Brice-Phoenix Light-scattering Photometer modified to accommodate a cell which could be ultracentrifuged.

The range of molecular weight investigated was from 6.5×10^5 to 25.0×10^5. The relationship between the z-average mean-square radius of gyration, $\overline{s_z^2}$, and the z-average molecular weight was approximately linear in both solvents. The ratio of $\overline{(s_0^2)_z}/\overline{M_z}$ (where $\overline{(s_0^2)_z}$ is the value of $\overline{s_z^2}$ in the unperturbed state) was found constant in acetone but to increase with $\overline{M_z}$ in ethyl acetate. This indicated that, whereas in acetone random coil configuration was attained, a configurational transition occurred in ethyl acetate in the molecular weight range investigated.

The value of the exponent a in the relationship between intrinsic viscosity and molecular weight was found to be lower than unity but approximately equal in both solvents.

The significance of the experimental data is discussed.

INTRODUCTION

Recent studies of the solution properties of cellulose trinitrate (designated CTN hereafter) have revealed certain unusual characteristics of the macromolecule. For example, Hunt *et al.* (1) and Holtzer *et al.* (2) showed that for CTN the ratio of the mean-square radius of gyration to the molecular weight increased with increasing molecular weight and reached a constant value at a M.W. of about 400,000. This is much higher than the value of 30,000 found for some vinyl polymers (3). This behavior was considered to arise from the unusual stiffness of the cellulose chain which attained a Gaussian configuration only at relatively high molecular weights. Holtzer *et al.* failed to observe an expected decrease in the exponent of the intrinsic viscosity – molecular weight relationship; but because of experimental difficulties these authors regarded their data for M.W.'s higher than 1.5×10^6 as unreliable. Such a decrease in the exponent has been reported by Badger and Blaker (4) and by Münster (5). There are, therefore, some anomalies and contradictions in the published data, particularly for high molecular weight material.

Apart from interest in the behavior of cellulose derivatives in solution, there is a more practical aspect of this work. Timell (6) has shown that with careful nitration the cellulose chain is made soluble without degradation. Trinitration, followed by fractionation and measurement of intrinsic viscosity, can be used to find the size distribution in any given sample of cellulose. Timell (7) has found that undegraded celluloses from a variety of sources all have rather high molecular weights ($>10^6$). In order to compute reliable values of molecular weight from intrinsic viscosities, the configurational behavior of the molecule should be understood.

The purpose of the present work was to study the configuration of high molecular weight CTN in a good (ethyl acetate) and a poor (acetone) solvent. Viscosity and light-

scattering methods were used and the results interpreted in the light of modern theories of the solution properties of polymers.

EXPERIMENTAL PART

Materials

Cellulose Nitrate

Cellulose trinitrates prepared from unbleached raw ramie, bleached ramie, and cotton linters (designated respectively by H, M, and T) were used in this investigation. The method of nitration has been described by Timell (6). The nitrogen contents are given in Table I.

TABLE I

ANALYTICAL DATA OF CELLULOSE NITRATES

Source	Nitrogen* content, % N	Degree of substitution	Base molecular weight
Unbleached raw ramie (H)	13.68	2.90	288
Bleached ramie (M)	13.80	2.93	290
Cotton linters (T)	13.57	2.88	285

**Complete nitration to cellulose trinitrate would correspond to 14.14% N with a base molecular weight of 297.*

Fractionation

The samples were fractionated by adding water to an acetone solution following the method of Mitchell (8). The exact quantities of water necessary for precipitation were ascertained from exploratory fractionations. Fractionation data for samples M and H are given in Tables II and III respectively.

TABLE II

FRACTIONATION DATA ON SAMPLE M

Fraction	Water added, cc.	Weight, g.	Yield, %
M-1	31.0	1.190	28.4
M-2A*	4.8	0.723	17.0
M-2B*	5.2	0.524	12.3
M-3	12.1	0.578	13.8
M-4		0.880	19.5
Undissolved material		0.320	7.1
Loss			1.9

**Fractions M-2A and M-2B had nearly identical intrinsic viscosities and were blended by dissolving in acetone and precipitating by addition of water. The blended sample is referred to as M-2 hereafter.*

For sample M, 4.5 g. was soaked in an acetone–water mixture (91: 9) for 24 hours and then stirred vigorously for 6 hours to yield a 0.1% solution; solutions of higher concentration were too viscous for convenient handling. The solution was then centrifuged at 500*g* for 20 minutes to remove any undissolved material. The decanted solution was placed in a 25° C. bath and distilled water added to it dropwise with vigorous stirring.

TABLE III

FRACTIONATION DATA ON SAMPLE H

Fraction	Water added, cc.	Weight, g.	Yield, %
H-1	34.0	0.369	18.5
H-2	10.3	0.548	27.4
H-3	40.0	0.397	19.8
H-4	—	0.265	13.3
H-5	—	0.340	17.0
Undissolved material		0.020	1.0
Loss			3.0

When the previously determined quantity of water had been added, the system was allowed to stand for 1 hour in the bath while the stirring was continued. The precipitate was separated by centrifuging for 20 minutes at 500*g*. The precipitate in the centrifuge cups was gel-like in appearance. It was found that addition of methanol facilitated removal of the precipitate from the cups. Excess liquid was squeezed out of the solid, which was then vacuum-dried at about 45° C. This procedure was repeated to yield four fractions (M-1, M-2A, M-2B, and M-3).

The solution remaining after separation of M-3 was evaporated to dryness to yield M-4.

Sample H was fractionated in essentially the same way from a 0.1% solution of 2 g. in acetone. The solution left after separation of the third fraction was evaporated to about one-quarter of its original volume by blowing air through it and stirring. The resulting suspension was centrifuged to take out the fourth fraction. The final fraction was obtained as before by evaporating the remaining liquid to dryness.

All fractions were stored over fused calcium chloride in a refrigerator.

Sample T, also, was fractionated after the method of Mitchell (8). Ten fractions were obtained, of which only T-6 and T-8 were used in this study. These fractions were chosen in order to extend the range to a somewhat lower molecular weight than values found for the fractions of M and H.

Finally a fraction, P, from an exploratory fractionation of bleached ramie nitrate was used to fill the gap of molecular weights between M-2 and M-3.

In the fractionation of samples M and H the solutions developed a cloudiness which increased as the fractionation proceeded. Repeated centrifugations did not remove the cloudiness. The effect seemed greater in sample H, possibly because of its lower nitrogen content. Evidently part of the precipitate remained suspended as colloidal material. It is possible that the non-sedimentable aggregates from one cycle were precipitated on the next addition of water.

Solvents

Reagent grade acetone was used for fractionation. For viscosity and light-scattering measurements reagent grade solvents were redistilled. Boiling ranges for acetone and ethyl acetate were 56.3–56.8° C. and 77–77.3° C. respectively.

Preparation of Solutions

Solutions were made up by shaking CTN in solvent for 24 hours in a wrist-action shaker. This was followed by centrifugation in stainless-steel tubes at 24,000*g* for 30 minutes to remove any undissolved material. Three-fourths of the liquid in the centrifuge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

tubes was decanted into a glass-stoppered flask. This served as stock solution from which solutions were made for viscosity and light-scattering measurements. A calibrated 10-cc. hypodermic syringe was used for transfer of liquids.

It was thought possible that CTN might form aggregates on repeated cycles of dissolution, recovery (by precipitation or evaporation), and re-solution, and thus yield erroneous results from the light-scattering measurements. Such cycles were inevitable in fractionation and recovery. A careful series of experiments on approximately 0.2% solution of bleached ramie nitrate in both acetone and ethyl acetate showed, however, that the light-scattering dissymmetry did not change when such cycles were repeated. This indicated absence of significant aggregate formation.

Viscosity Measurements

Since the viscosity of solutions of high DP cellulose nitrate is shear-dependent, a standard shear rate of 500 sec.$^{-1}$ was adopted following the convention of Newman *et al.* and others (9, 10). A modified form of the suspended-level dilution capillary viscometer of Schurz and Immergut (11) was used. The viscometer had four bulbs, which enabled measurements to be made at different rates of shear calculable from the expression (12)

$$G_i = 8V_i/3\pi r^3 t_i, \quad [1]$$

where G_i = mean rate of shear corresponding to bulb i,
V_i = volume of bulb i,
t_i = efflux time of V_i,
r = radius of viscometer capillary.

Efflux times were measured at 25.00±0.01° C. to 0.1 second for each of the four bulbs for pure solvent and over a range of concentrations of the solutions obtained by progressive dilution of the solution first introduced in the viscometer. Efflux times for five or six concentrations were measured on each sample. Kinetic energy corrections (amounting to 0.2 to 3 per cent) were applied in the usual way (13) and values of the specific viscosity, η_{sp}, at shear rates calculated from Eq. [1] were obtained.

The concentration, c, of the initial solution was determined in a duplicate measurement by evaporation and weighing. The solid from 10 cc. of the solution was dried in vacuum to constant weight in a weighed aluminum cup. In determining the concentration of ethyl acetate solutions, filtered ethyl alcohol was added during evaporation to aid in the complete removal of ethyl acetate (1).

From these data, plots of log (η_{sp}/c) against log G for different concentrations were obtained. Fig. 1 shows an example. From these plots the values of η_{sp}/c for G = 500 sec.$^{-1}$ were obtained by interpolation. A plot of η_{sp}/c vs. c was then made as shown in Fig. 2. Linear extrapolation to zero concentration gave the intrinsic viscosity, $[\eta]_{500}$. In a similar manner intrinsic viscosities were obtained for a range of G values between 300 and 700 sec.$^{-1}$.

The Huggins' interaction constant (14), k'_{500}, was calculated from the slope of the η_{sp}/c vs. c line at 500 sec.$^{-1}$ using the equation

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c. \quad [2]$$

For some solutions at very low concentrations the plot η_{sp}/c vs. c deviated from linearity and showed marked upward curvature. This effect has been observed by others (15, 16)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

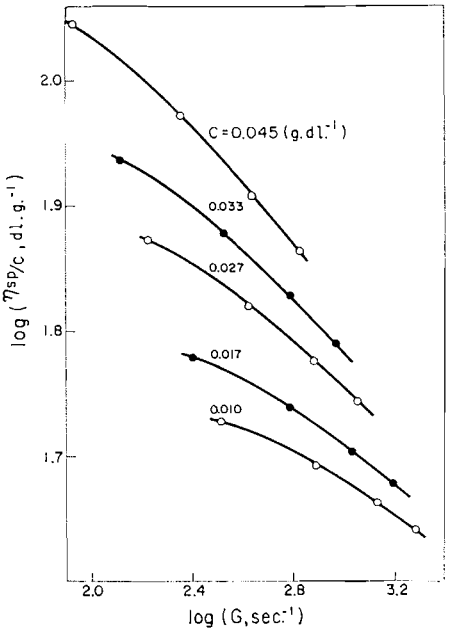

FIG. 1. Log of reduced viscosity vs. log of rate of shear at different concentrations for fraction H-2 in acetone.

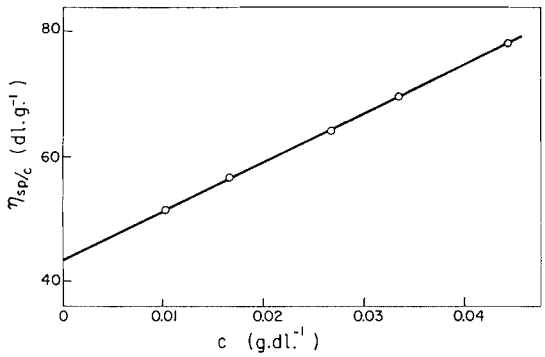

FIG. 2. Reduced viscosity vs. concentration for fraction H-2 in acetone at a shear rate of 500 sec.$^{-1}$.

and was shown by Öhrn (15) to be due to adsorption of polymer on the walls of the capillary. Extrapolation of the η_{sp}/c vs. c line to $c = 0$ was always carried out from concentrations at which the effect was negligible.

Light Scattering

Apparatus

Light-scattering measurements were made in a Brice-Phoenix photometer. The instrument was modified to accommodate cells of the type described by Dandliker and Kraut (17) in which the solution is clarified by ultracentrifugation *in situ*. This course was found necessary after attempts to remove stray dust from the solutions by conventional means such as centrifugation (outside the measuring cell) and filtration proved unsatisfactory. Despite elaborate care, the solution, clarified by centrifuging, became contaminated with dust in the transfer to the measuring cell; when ultrafine sintered-glass filters were used, the solute was retained by adsorption on the filter.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Details of the modification of the photometer are expected to be reported in a separate paper (18). After modification the intensity emitted by a dilute solution of fluorescein was constant to $\pm 1\%$ from angles of 30° to 135°. Negligible background scattering was found with toluene and acetone. Calibration with Ludox (19) was checked by measuring the excess turbidity of a 0.50% solution of Cornell standard polystyrene in toluene. The value found was 3.26×10^{-3} cm.$^{-1}$ and is in good agreement with the National Bureau of Standards' value (20) of 3.30×10^{-3} cm.$^{-1}$. The Rayleigh ratio of redistilled and filtered benzene was found to be 49.6×10^{-6} cm.$^{-1}$, also in good agreement with Maron and Lou's (21) value of 49.7×10^{-6} cm.$^{-1}$.

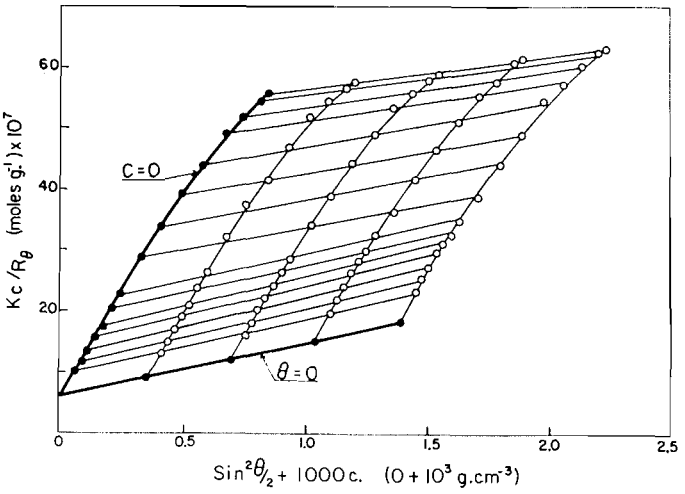

FIG. 3. Zimm plot of light-scattering data for fraction M-2 in acetone.

Zimm plots, an example of which is shown in Fig. 3, were obtained from the light-scattering data in the usual way by plotting Kc/R_θ vs. $\sin^2\theta/2+kc$, where

K = $2\pi^2 n_s^2 (dn/dc)^2/N\lambda^4$,
n_s = refractive index of solvent,
dn/dc = refractive index increment,
λ = wave length in vacuum,
θ = angle between scattered and transmitted beam,
R_θ = Rayleigh ratio at angle θ,
k = an assigned constant,
N = Avogadro's number,
c = concentration in grams per cc.

The weight-average molecular weight, $\overline{M_w}$, was obtained from the intercept from

[3] $$\overline{M_w} = 1/(Kc/R_\theta)_{c,\theta=0}$$

and the z-average radius of gyration, $\sqrt{\overline{s_z^2}}$, was computed from the initial slope of the $c = 0$ line by means of the expression

[4] $$\frac{\text{initial slope}}{\text{intercept}} = \frac{16\pi^2}{3} \cdot \overline{s_z^2} \cdot (n/\lambda)^2,$$

where n is the refractive index of the solution. The concentration dependence of the intensity can be written as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

[5] $$Kc/R_\theta = [1/MP(\theta)]+2A_2c$$

where $P(\theta) = (R_\theta^\circ/R_\theta)$. R_θ° is the Rayleigh ratio if there is no intraparticle interference. A_2 is the second virial coefficient and is computed from the slope of the $(Kc/R_\theta)_{\theta=0}$ vs. c line in the Zimm plot (22).

Refractive Index Measurements

The increment of refractive index dn/dc of the solution over that of the solvent was measured by means of a Brice-Phoenix differential refractometer for $\lambda = 4358$ Å at 25° C. The instrument was calibrated with sucrose solutions of different concentrations using sodium light ($\lambda = 5890$ Å). The calibration was checked by measurement of Δn for a 4% aqueous KCl solution. The measured value was within 0.4% of the value calculated from data obtained from the International Critical Tables.

RESULTS

Viscosity and Light Scattering

The experimental results from viscosity and light-scattering measurements are listed in two tables. Table IV contains the results in acetone solution while the contents of Table V are for ethyl acetate solutions. The quantities given for each sample are the weight-average molecular weight, $\overline{M_w}$, z-average root-mean-square radius of gyration, $\sqrt{\overline{s_z^2}}$, the second virial coefficient, A_2, the intrinsic viscosity, $[\eta]_{500}$, and the Huggins' interaction constant, k'_{500}.

In order to derive the configurational parameters from the light-scattering data, certain assumptions about the molecular weight distribution were necessary since polydispersity is inevitable even in carefully fractionated material (1, 2). A suitable distribution is one

in which the z-average, weight-average, and number-average molecular weights, represented respectively by $\overline{M}_z$, $\overline{M}_w$, and $\overline{M}_n$, are related in the proportion 3:2:1. Such a distribution has been used by others (2, 22) and was assumed by Hunt *et al.* (1) for their high molecular weight samples. This proportionality will be assumed in computing $\overline{M}_z$ and $\overline{M}_n$ from the values of $\overline{M}_w$ obtained from light scattering.

The initial concentrations of solutions employed for light-scattering measurements varied from 0.12 to 0.35 g./dl. depending on the molecular weight. At the lowest concentration the solvent scattering intensity was 50% of the scattering intensity from solution. The initial concentration range in viscometry was 0.035 to 0.085 g./dl. depending on the molecular weight. The lowest concentration in viscometric measurements was a fifth or sixth of the initial concentration.

The refractive index increments, dn/dc, at 25° C. used for the calculation of K were 0.104 cc. g.$^{-1}$ and 0.105 cc. g.$^{-1}$ for ethyl acetate and acetone solution respectively. These were the mean values from solutions of bleached and unbleached (raw) ramie nitrate. The corresponding K values were 1.85×10^7 and 1.84×10^7 respectively for ethyl acetate and acetone.

Shear Dependence of Viscosity

Shear dependence of intrinsic viscosity in the range of rate of shear between 300 and 700 sec.$^{-1}$ was estimated. For the complete range of molecular weight studied $[\eta]$ was found to be independent of G in acetone solution. A typical plot of η_{sp}/c vs. c for different G is shown in Fig. 4.

In ethyl acetate solution, on the other hand, $[\eta]$ showed slight dependence on the rate of shear for the higher molecular weight samples. An example is shown in Fig. 5, where the values for H-2 have been plotted. The magnitude of the dependence decreased with decreasing molecular weight and below $[\eta] = 30$ the dependence was no longer observed. Similar results for the shear dependence in ethyl acetate solution were obtained by Timell (10).

In those cases where such dependence was noticed, $[\eta]$ values at different G were linearly related to the rate of shear. Fig. 6 shows the variation of $[\eta]$ with G for samples M, M-2, M-1, and H-2. Extrapolation of these lines gave values of the intrinsic viscosity at zero rate of shear, $[\eta]_0$ which have been included in Table V.

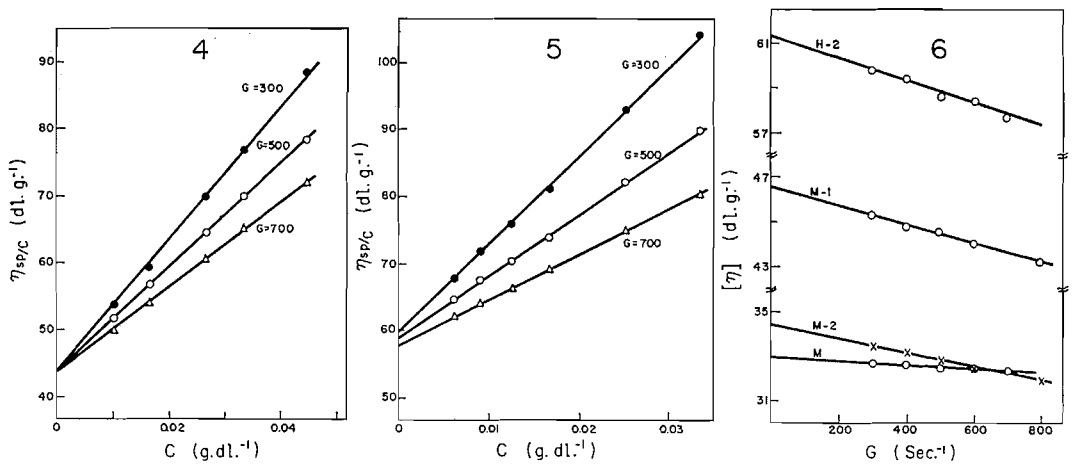

FIG. 4. Reduced viscosity vs. concentration for fraction H-2 in acetone at different rates of shear.
FIG. 5. Reduced viscosity vs. concentration for fraction H-2 in ethyl acetate at different rates of shear.
FIG. 6. Intrinsic viscosity vs. rate of shear for samples M, M-1, M-2, and H-2 in ethyl acetate.

For personal use only.

These results show a small or no dependence of $[\eta]$ on G in the range of shear studied. As clearly shown in Figs. 4 and 5 marked shear dependence of η_{sp}/c occurs at finite concentration. This shear dependence is probably due to molecular interaction, which will increase as concentration increases, rather than to deformation or orientation of isolated molecules. A similar result has been noted recently by Nawab and Mason (23) for suspensions of model filaments. In the present work the reservation must be made that the range of shear was small, and a more marked variation of $[\eta]$ with G may have been detected had measurements been made at much lower shear rates.

Anomalous Light Scattering

Early in the work certain persistent irregularities were noted in the light-scattering measurements. In all samples the graph of Kc/R_θ vs. $\sin^2\theta/2+kc$ at $\theta = 0$ curved downwards after a certain concentration was reached and in some cases passed through a maximum. Fig. 7 is a Zimm plot showing this effect. The concentration, c_c, at which the curvature became noticeable decreased approximately linearly with increasing molecular weight. The curvature started at such low concentration with the very high molecular weight fraction H-1 in acetone solution that determination of $\overline{M_w}$ by extrapolation was not possible. The effect was also observed in solutions which were centrifuged for 1 hour or more instead of the usual 30 minutes, so that the effect was not caused by the presence of debris.

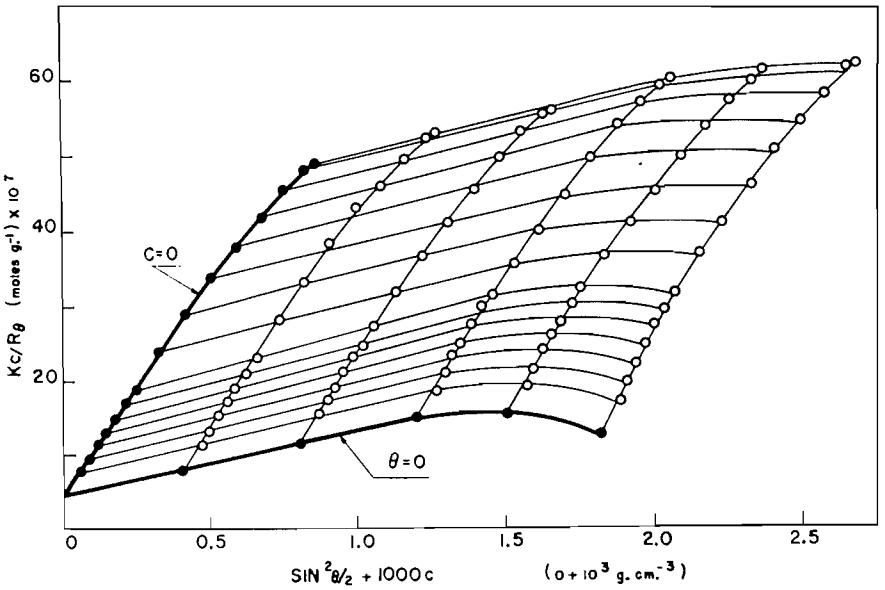

FIG. 7. Zimm plot of light-scattering data for fraction M-1 in acetone showing deviation from linearity of $(Kc/R_\theta)_{\theta=0}$ vs. c line at high concentration.

At about the same concentration at which the deviation from linearity of Zimm plots occurred, a curious optical phenomenon was noted. If the solution was centrifuged for 30 minutes at 55,000g, placed in the light-scattering apparatus and the scattered beam observed in a mirror held at low angles, quite clear vertical striations, i.e., vertical bands of scattering substance, could be seen. They were observed in nearly all samples provided that the concentration was sufficiently high.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Striations occurred only on high-speed centrifugation; none could be seen in a fresh, uncentrifuged solution. Thus the phenomenon was associated in some way with ultracentrifugation. If a centrifuged solution was allowed to stand, the striations gradually disappeared over a period of several hours, indicating that the process was reversible. In some solutions the discontinuities were not stationary but appeared to drift gradually.

The effect of striations on the scattering intensity was relatively small. A variation of intensity by about $\pm 5\%$ was found in successive measurements. No clear trend of increase or decrease in scattering intensity was noted on standing. Also the polarization of the transmitted or scattered light was unaffected.

Similar behavior for high molecular weight nitrocellulose has been reported by Holtzer *et al.* (2). These authors found that prolonged centrifugation at high speed caused the effect to disappear. However, in the present work striations were observed in a sample centrifuged at 55,000*g* for 5 hours. Also, a number of experiments were made which showed that their origin was not a trivial one, e.g. concentration or density gradients produced by sedimentation.

It is proposed to publish a separate account of deviations from linearity in Zimm-type plots and of striations.

DISCUSSION

Variation of Radius of Gyration with Molecular Weight

The radius of gyration is a characteristic dimension of the molecule in solution and, as expected, increased with increasing molecular weight (Tables IV and V). Also, for a given sample, $\sqrt{\overline{s^2}}$ was higher in ethyl acetate than in acetone, thus indicating greater extension in the former solvent.

In both solvents the relationship between $\overline{s_z^2}$ and $\overline{M_z}$ was approximately linear as shown in Figs. 8 and 9. In acetone the line passed through the origin and is expressed by the equation

$$\overline{s_z^2} = 0.80 \times \overline{M_z}. \qquad [6]$$

For ethyl acetate the relationship is

$$\overline{s_z^2} = 1.33\overline{M_z} - 3.55. \qquad [7]$$

If the data for CTN in ethyl acetate obtained by Hunt *et al.* (1) are included in Fig. 9, it is seen that below a molecular weight of about 800,000 the graph curves towards the origin. Similarly in Fig. 8 the data of Holtzer *et al.* (2) suggest a breakdown in the linearity at low molecular weight. Recently Notley and Debye (24) have noted a similar trend in the relationship between molecular dimensions and weights of polystyrene.

Configurational Change with Molecular Weight

The deviation from linearity in Figs. 8 and 9 could be expected if a transition to non-Gaussian behavior occurred at low molecular weight. Such configurational changes have been treated theoretically by Benoit and Doty (25) in terms of a stiffness parameter, the persistence length, q. The persistence length was defined originally by Porod and Kratky (26, 27) as the mean value of the projection of an infinitely long chain along the direction of the first element in the chain. The expression deduced by Benoit and Doty is

$$\overline{s_0^2} = q^2[(x/3) - 1 + (2/x) - 2(1 - e^{-x})/x^2] \qquad [8]$$

where $\sqrt{\overline{s_0^2}}$ is the unperturbed radius of gyration (described later) and x is the number of units of length q in the fully extended molecule. The value of x is given by

$$[9] \qquad x = r_{max}/q = [(DP)/q].L = (\overline{M}/M_0).(L/q),$$

r_{max} being the length of the fully extended chain and L being the length of one monomer unit which was taken as 5.15 Å. Here $\overline{M}$ is the average molecular weight and M_0 is the monomer molecular weight.

For large x (i.e., large $\overline{M}$) Eq. [8] reduces to

$$[10] \qquad \overline{s_0^2}/r_{max} = q/3,$$

which for a Gaussian coil corresponds to $(\overline{s_0^2}/\overline{M})$ being constant. For smaller x, the other terms decrease the value of $\overline{s_0^2}/\overline{M}$, indicating an approach to the rod-like configuration.

After the manner of Hunt *et al.* (1), the experimentally determined values of $(\overline{s_0^2})_z/\overline{M_z}$ may be plotted against $\overline{M_z}$ and compared with the theoretical curve deduced from Eq. [8]. The unperturbed radius of gyration was obtained from the relationship

$$[11] \qquad \sqrt{\overline{s_z^2}} = \alpha\sqrt{(\overline{s_0^2})_z},$$

where the expansion factor, α, was calculated from the second virial coefficient by the method of Orofino and Flory (28). As found by Hunt *et al.* for CTN in ethyl acetate, α was near unity for all samples in both solvents (1.03–1.09) and showed a very slight increase with increasing molecular weight. The persistence length, q, required in Eq. [8], was calculated by means of Eq. [10], from $(\overline{s_0^2})_z$ and $\overline{M}_z$ for the two highest molecular weight samples. Averages of the values of q were 115 Å and 200 Å in acetone and ethyl acetate, respectively. Hunt *et al.* (1) used a q value of 117 Å derived from the data on their three highest molecular weight samples.

In Figs. 10 and 11 $(\overline{s_0^2})_z/\overline{M}_z$ is plotted against $\overline{M}_z$ for acetone and ethyl acetate, respectively. Values of $(\overline{s_0^2})_z$ and $\overline{M}_z$ are given in Table VI. The data of Holtzer *et al.* (2) for CTN in acetone are included in Fig. 10 and the data of Hunt *et al.* (1) for CTN in ethyl acetate are included in Fig. 11.

TABLE VI

MOLECULAR AND HYDRODYNAMIC PARAMETERS

	In acetone			In ethyl acetate		
Sample	$\overline{M}_z\times10^{-6}$	$(\overline{s_0^2})_z\times10^{-6}$, Å²	$\Phi'\times10^{-22}$	$\overline{M}_z\times10^{-6}$	$(\overline{s_0^2})_z\times10^{-6}$, Å²	$\Phi'\times10^{-22}$
T-8	0.98	0.66	2.34	1.01	0.85	2.95
T-6	1.26	0.80	2.90	1.17	1.08	2.83

P	1.71	1.21	2.97	—	—	—
M	2.30	1.85	2.21	2.42	2.01	3.52
M-2	2.54	1.93	2.62	2.39	2.47	2.86
M-1	3.42	2.27	3.91	3.48	4.07	2.64
H	3.57	2.32	4.32	—	—	—
H-2	3.75	2.63	4.11	3.75	4.59	3.28

As predicted by theory, the combined data in both cases show increase of $(\overline{s_0^2})_z/\overline{M}_z$ with $\overline{M}_z$. In the case of acetone, the results from the present investigation lie in the region of constant $(\overline{s_0^2})_z/\overline{M}_z$ while at lower molecular weight the data of Holtzer *et al.* (2) show decrease in $(\overline{s_0^2})_z/\overline{M}_z$. Their results indicated that at $\overline{M}_z$ values above 10^6 the molecule behaves like a Gaussian coil. For ethyl acetate, except for one point, $(\overline{s_0^2})_z/\overline{M}_z$ increases with $\overline{M}_z$ over the complete range of molecular weights. This suggests that in the molecular weight range studied, CTN does not attain the random coil configuration in ethyl acetate. Curve *H* in Fig. 11 is the theoretical one given by Hunt *et al.*, which is based on a persistence length of 117 Å computed from the results for their three highest molecular weight samples. The points from the present investigation are well above their theoretical line. This discrepancy indicates that Hunt *et al.* (1) did not use a high enough value of $\overline{M}_z$ in computing q. It must also be noted that because of increasing trend of $(\overline{s_0^2})_z/\overline{M}_z$ with $\overline{M}_z$, the value of q computed for samples M-1 and H-2 may also be erroneously low.

The higher value of the persistence length in ethyl acetate was unexpected since, to a first approximation, q must depend only on orientation and steric factors in the chain itself. It is possible, however, that the greater solvation in ethyl acetate may cause an added inflexibility due to more extensive packing of solvent molecules around the polymer in the better solvent.

The values of x calculated from $\overline{M}_w$ by means of Eq. [9] ranged from 60 to 370. Peterlin (29) has shown that such values of x lead to perceptible downward curvature in the usual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

graph of the angular distribution of light scattering intensity at zero concentration. For example, in the case of samples M-2 and M-1 (Figs. 3 and 7) the theoretical envelope for the Porod chain was deduced from the data of Peterlin (29). The envelope was assumed to deviate from the linear graph (tangential at the origin), which is expected for a completely flexible polymer with $\overline{M_z}$: $\overline{M_w}$: $\overline{M_n}$ = 3:2:1. For both sample M-2 and M-1, the theoretical curve was found to coincide almost exactly with the experimentally determined points. However no systematic analysis of the light-scattering envelopes was attempted because measurements at high angles were not precise enough.

Variation of Intrinsic Viscosity with Molecular Weight

The intrinsic viscosity is a measure of the effective hydrodynamic volume of a solute and, as expected, $[\eta]_{500}$ increased with $\overline{M_w}$. The values of the constants $\boldsymbol{K}$ and a in the intrinsic viscosity – molecular weight relationship

$$[\eta] = \boldsymbol{K}\overline{M_w}^{a} \qquad [12]$$

were obtained from plots of log $[\eta]_{500}$ vs. log $\overline{M_w}$ shown in Figs. 12 and 13 respectively for acetone and ethyl acetate solution. The values are given in Table VII along with the more recent values obtained by other workers. If $[\eta]_0$ at $G = 0$ (obtained as described previously) is used, a increases from 0.83 to 0.86 in ethyl acetate. Similar adjustment leaves a unchanged for acetone solutions since $[\eta]$ was found to be independent of G.

Present†	Acetone	65–250	Light scattering	500	0.91	5.96×10^{-5}	
Newman *et al.*	Ethyl acetate	9.3–150	Ultracentrifuge	500	0.99	4.82×10^{-5}	(14)
Hunt *et al.*	Ethyl acetate	4.1–57.3	Light scattering	0	1.01	2.50×10^{-5}	(4)
Present	Ethyl acetate	68–250	Light scattering	500	0.83	2.60×10^{-4}	
Present	Ethyl acetate	68–250	Light scattering	0	0.86	1.66×10^{-4}	

**Values of a and K are derived from the six highest molecular weight samples.*
†The standard error in a was 0.08 in all cases.

The intrinsic viscosity of CTN has been shown to vary considerably with small changes in the nitrogen content of the sample (30, 31, 32). The intrinsic viscosity was corrected by the method of Lindsley and Frank (30) to a hypothetical value, $[\eta]^T$ corresponding to 14.14% nitrogen. The results are shown in Table VIII: $[\eta]^T$ is considerably higher than the corresponding $[\eta]$ value given in Tables IV and V. Plots of log $[\eta]^T_{500}$ vs. log $\overline{M}_w$ yield $a = 0.77$ in ethyl acetate and $a = 0.87$ in acetone. With $[\eta]^T_0$ (i.e. $[\eta]^T$ at zero rate of shear) the value of a becomes 0.82 in ethyl acetate.

TABLE VIII

VALUES OF INTRINSIC VISCOSITIES AFTER CORRECTION FOR NITROGEN CONTENT

Sample	In acetone	In ethyl acetate		% Nitrogen
	$[\eta]^T_{500}$, dl. g.$^{-1}$	$[\eta]^T_{500}$, dl. g.$^{-1}$	$[\eta]^T_0$, dl. g.$^{-1}$	
T-8	14.5	20.3	20.3	13.58
T-6	18.7	24.4	24.4	13.58
M-3	20.9	27.2	27.2	13.84
P	23.4	—	—	13.74
M	24.6	36.1	36.7	13.81
M-2	28.8	36.3	40.1	13.83
M-1	40.4	49.0	51.1	13.85
H	50.4	—	—	13.68
H-2	49.4	66.5	69.5	13.76

The value of a is influenced by two factors: (i) the configuration of the molecule and (ii) its permeability to solvent. Any increase in molecular extension would cause an increase in a whereas a change from the free-draining to the solvated (solvent immobilizing) state would cause a to decrease.

As shown in Table VII, a was lower than unity in both solvents in contrast to the results of Holtzer *et al.* (2), Hunt *et al.* (1), and Newman *et al.* (9). The lower value of a in the high molecular weight range is in conformity with the theory of Kirkwood and Riseman (32) and the data of Badger and Blaker (4) and Münster (5). Also, it is supported by the agreement between the present data and those for the six highest molecular weight samples of Holtzer *et al.* (2). Further, the low value of a is accentuated by the correction of the $[\eta]$ values for variation in nitrogen content. Thus the data support in a general way the assumption of a more coiled configuration at high molecular weights as demonstrated by the light-scattering results.

Within experimental error a was equal in both acetone and ethyl acetate in the molecular weight range studied. This applies to the work of others (2, 1, 9) as well, and is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

contrary to the behavior of other polymers (e.g., polystyrene (33)) in good and bad solvents. This seeming anomaly may be due to the increased solvation in the good solvent which will decrease a by contributing to the solvent immobilizing character and compensating for extension effects. The low a in ethyl acetate may also be related to the configurational behavior discussed above. The data in Figs. 10 and 11 show that, while the configuration in acetone was constant in the present range, it changed continuously in ethyl acetate. For ethyl acetate, therefore, it is unlikely that the value of the exponent can be assigned with certainty to any model and a should remain an empirical quantity determined for various ranges of M.

The Hydrodynamic Parameter Φ

It was of interest to compute the universal hydrodynamic parameter Φ introduced by Flory (34). Following the notations of Hunt *et al.* (1) the intrinsic viscosity may be related to the chain dimensions by the equation

$$[\eta] = \Phi'(\overline{s_0^2}/\overline{M})^{3/2}\overline{M}^{1/2}\alpha^3. \qquad [13]$$

The prime is appended to Φ to indicate use of the radius of gyration instead of the end-to-end distance as customarily used (34). Values of Φ' for CTN samples in both solvents calculated according to the procedure of Hunt *et al.* are given in Table VI.

As shown in Table VI, Φ' increases with molecular weight in acetone. This is contrary to the conclusion of Holtzer, Benoit, and Doty (2) whose results suggest that Φ' is constant and approximately equal to 2.8×10^{22} in agreement with the values for our lower molecular weights. In ethyl acetate, on the other hand, Φ' is seen to be virtually constant with a mean of $2.86(\pm0.33)\times10^{22}$, which is in good agreement with the values for the two highest molecular weight samples of Hunt *et al.* (1) and close to the constant experimental value of 3.2×10^{22} obtained for the synthetic polymers.

The data can be further analyzed if Eq. [13] is written as

$$\Phi' = k[\eta]\overline{M}_z/(\overline{s_z^2})^{3/2} \qquad [14]$$

or

$$\Phi' = k.[1/(\overline{s_z^2}/\overline{M}_z)].[\eta]/\sqrt{\overline{s_z^2}}, \qquad [15]$$

where k is a constant for each solvent derived after the manner of Hunt *et al.* (1) and depends on the polydispersity. For a random coil $\overline{s_z^2}/\overline{M}_z$ is constant (α is taken as unity) according to Benoit and Doty (25) and Hunt *et al.* (1). Also, Kunst (35) has shown that $[\eta]$ is directly proportional to $\sqrt{\overline{s_z^2}}$ for polyisobutylene in different solvents. Similar direct proportionality between $[\eta]$ and $\sqrt{\overline{s_z^2}}$ can be derived from results on polystyrene (36), polymethylmethacrylate (37), and polyvinyl acetate (38), all of which have been shown to obey random flight statistics. Therefore, Φ' is constant for these polymers. In the case of CTN, $[\eta]/\sqrt{\overline{s_z^2}}$ increases with intrinsic viscosity in ethyl acetate and acetone in the range investigated, as shown in Fig. 14. Since $\overline{s_z^2}/\overline{M}_z$ is constant in acetone, Φ' will increase with increasing $\overline{M}$; whereas the increase of $\overline{s_z^2}/\overline{M}_z$ with $\overline{M}$ in ethyl acetate apparently just compensates the increase in $[\eta]/\sqrt{\overline{s_z^2}}$, leaving Φ' constant. The change of $[\eta]/\sqrt{\overline{s_z^2}}$ might be expected in ethyl acetate for which a configurational transition occurs throughout the range studied. In acetone, however, the light-scattering data suggest that a random coil configuration was attained. The increase of $[\eta]/\sqrt{\overline{s_z^2}}$ may, therefore, be related to a decreasing degree of free-draining as the molecular weight increases.

Interaction Constants

The Huggins' interaction constant, k', is an empirical quantity, but its value has been used as an indication of molecular branching (39). It was, therefore, of interest to consider the variation of k' for change of solvent and shear rate. A typical set of results is shown in Table IX. The value of k' is higher in the poor solvent, acetone, which is in agreement with the findings of Alfrey *et al.* (40) for polymethylmethacrylate in different solvents. It may also be noted that k' decreases with increasing rate of shear, in agreement with the results of Masson and Goring (41) on carrageenin—a polygalactose sulphate—and Conrad *et al.* (42) on cellulose in cuprammonium and cupriethylenediamine. In consideration of the dependence of k' on such variables as solvent and rate of shear, one must be cautious in using k' as a criterion for detecting branching, especially in the case of solutions showing non-Newtonian viscosity behavior.

TABLE IX

HUGGINS' INTERACTION CONSTANT, k', FOR FRACTION H-2 IN TWO SOLVENTS AT DIFFERENT SHEAR RATES

G (sec.$^{-1}$)	In acetone	In ethyl acetate
300	0.514	0.366
400	0.450	0.310
500	0.407	0.274
600	0.364	0.232
700	0.330	0.206

The variation of k'_{500} and A_2, the second virial coefficient in light scattering, with molecular weight is shown in Fig. 15 for both solvents. The graphs are irregular, but there is a significant decrease in k'_{500} with increase in $\overline{M}$ for both solvents. This is contrary to Huggins' (14) suggestion that it should be independent of molecular weight. Similar dependence of k'_{500} on molecular weight was found by Timell (43) for CTN in ethyl acetate and Alfrey *et al.* (40) for polymethylmethacrylate in different solvents.

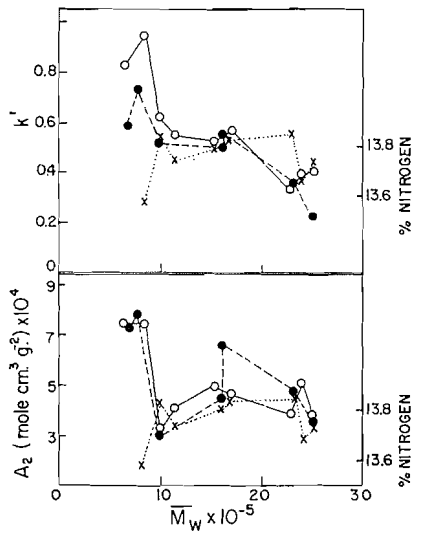

FIG. 15. The second virial coefficient, A_2, and the Huggins' interaction constant, k', vs. molecular weight of the samples in acetone and ethyl acetate. Nitrogen content of the samples have also been included in the graph. ●—Ethyl acetate. ○—Acetone. ×—Nitrogen content.

The second virial coefficient, A_2, for a polymer–solvent system should decrease slowly with increasing molecular weight. For the same polymer the value of A_2 is dependent on the nature of the solvent, being higher in a good solvent. These two general characteristics of A_2 which have been observed in the case of other polymers are not found for CTN solutions. Holtzer *et al.* (2) found negligible and irregular change of A_2 with molecular weight. In ethyl acetate, for low molecular weight fractions, Hunt *et al.* (1) obtained values of A_2 which were practically the same as found by Holtzer *et al.* except the lowest molecular weight sample for which the value was slightly higher. In the present investigation, values of A_2 were found to be the same, within experimental error, in both solvents; a slight decrease in A_2 with increase of $\overline{M_w}$ can, however, be detected.

An obvious feature of Fig. 15 is the irregularity of the data. Similar irregular results for the Huggins' constant have been reported by other workers (40, 42, 43). Irregularities in both k'_{500} and A_2 show the same trend in the two different solvents, indicating that this behavior is due to the samples rather than to experimental error. The nitrogen contents of the samples have been included in Fig. 15. Except for two points, it is seen that there is a rough correlation between the nitrogen content and the fluctuations in k'_{500} (44) and A_2. A more detailed study would be required to elucidate more clearly the source of these irregularities.

ACKNOWLEDGMENTS

The authors wish to thank Dr. T. E. Timell for kindly supplying the ramie and fractionated cotton nitrates, and Dr. R. F. Robertson for use of a Spinco preparative ultracentrifuge.

PHOTOÖXIDATION OF BUTENE-1 AND ISOBUTENE BY NITROGEN DIOXIDE[1]

S. SATO[2] AND R. J. CVETANOVIĆ

ABSTRACT

Reactions of oxygen atoms, produced by photolysis of nitrogen dioxide at 3660 Å, with butene-1 and isobutene have been studied at room temperature. In the case of butene-1, α-butene oxide and n-butanal have been identified as the major products, and methyl ethyl ketone, propanal, acetaldehyde, and ethyl nitrate as minor products. With isobutene, isobutanal was recovered as the major product and acetone, methyl ethyl ketone, methyl nitrate, and nitromethane as minor products. The absence of isobutene oxide in the recovered products from the isobutene reaction is due to its rapid reaction with nitrogen dioxide.

The following values were obtained for the relative reaction rates of oxygen atoms with nitrogen dioxide (k_2), butene-1 (k_{4a}), and isobutene (k_{4b}): $k_2/k_{4a} = 1.9$, $k_2/k_{4b} = 0.34$, $k_{4b}/k_{4a} = 5.5$.

INTRODUCTION

The photochemical reaction between nitrogen dioxide and olefins has been studied especially from the point of view of its relation to "smog" formation in polluted atmosphere (1), but little information has been obtained about the reaction mechanism and the type of products formed. In a previous communication (2) the authors have reported a long wave length threshold for the photochemical reaction between nitrogen dioxide and butene-1. The reaction occurs at 4047 Å and shorter wave lengths, with the formation of α-butene oxide and n-butanal as the main products, but does not occur at 4358 Å and longer wave lengths. It has, therefore, been assumed that even at 4047 Å nitrogen dioxide decomposes and forms free oxygen atoms in their ground electronic state,

$$NO_2 + h\nu = NO + O(^3P). \qquad (1)$$

The photolysis of nitrogen dioxide itself has been extensively investigated (3). In the absence of foreign gases reaction (1) is followed by

$$O + NO_2 = NO + O_2. \qquad (2)$$

When an olefin is added, nitrogen dioxide and the olefin compete for the oxygen atoms formed in reaction (1).

Reactions of oxygen atoms, produced by the mercury-photosensitized decomposition of nitrous oxide, have been studied in this laboratory for some time. In the case of olefins (4), studied at pressures between about 50 and 600 mm., oxygen atoms add to the olefinic double bond, and isomeric epoxides, aldehydes, and ketones are formed as the main products when the olefins consist of more than three carbon atoms. Propylene and ethylene require a collisional stabilization of the addition products formed.

In this paper, results of a study of the photochemical reaction of nitrogen dioxide with butene-1 and isobutene at 3660 Å are reported. At this wave length oxygen atoms produced in reaction (1) are in their ground state.

EXPERIMENTAL

Nitrogen dioxide was obtained from Matheson Co., Inc., and was further purified by repeated bulb-to-bulb distillation *in vacuo* at Dry Ice temperature. The middle third was

[1]*Manuscript received February 13, 1958.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4728.
[2]*National Research Council Postdoctorate Fellow 1956–58.*

retained and stored at liquid nitrogen temperature. The color of the solid was pure white. Butene-1 and isobutene were Phillips reagent grade products, and were purified by repeated bulb-to-bulb distillation *in vacuo*. Nitrogen gas was supplied by Linde Air Products Co., and was used without further purification.

Because of rapid reaction of nitrogen dioxide with mercury it was necessary to use a mercury-free apparatus. Stopcocks were lubricated with Myvacene-S (Dow Corning) which was not attacked by nitrogen dioxide. Pressures were measured by means of a Bourdon gauge and the compensating pressures were read on a mercury or a silicon oil manometer. The reaction cell consisted of a 300 ml. quartz cylindrical vessel with an all-glass circulating pump supported on teflon bearings and a trap for condensing the reactants attached to it. The light from a medium-pressure mercury arc (Hanovia S 500) was used with Corning glass filter 7-60 so that essentially only the monochromatic light of 3660 Å entered the reaction cell. The cell and the attachments were screened from the diffuse light in the room.

The products formed were fractionated on a LeRoy still (5). Unreacted butene was pumped off at −120° C. and the remainder was transferred into a sampling tube containing a few drops of mercury to remove the unreacted nitrogen dioxide. This tube had been previously evacuated on a second, mercury-containing, high-vacuum apparatus. After the completion of the reaction between nitrogen dioxide and mercury, the tube was evacuated again at liquid nitrogen temperature. Subsequently the products were analyzed by gas–liquid chromatography (GLC) using a 7 ft. dinonyl-phthalate-on-glass-beads column (6, 4) and helium as the carrier gas. To confirm the identity of the compounds separated by GLC, use was made of infrared and mass spectroscopy. The quantitative estimate of the products was based on GLC peak areas.

RESULTS AND DISCUSSION

Thermal Reaction

Nitrogen dioxide attacks olefins thermally and forms addition products (7). Under the conditions employed in this work, however, the thermal reaction was much slower than the photochemical reaction. Moreover, it was found that no products formed in the thermal reaction, with the exception of nitric oxide, were recorded by the GLC. The thermal reaction between nitrogen dioxide and butene was, therefore, ignored in the present work.

Photochemical Reaction

The amounts of the main products formed* at various irradiation times and constant light intensity in the reaction of 3 mm. nitrogen dioxide with 3 mm. and 30 mm. butene-1 are shown in Fig. 1(*a*), and with 3 mm. isobutene in Fig. 1(*b*). The products formed increase almost linearly with the irradiation time up to 30 minutes and the primary processes of these reactions were subsequently studied within this time interval.

The main products formed in the case of butene-1 are the same as found previously for this reaction with the use of O atoms produced by mercury-photosensitized decomposition of nitrous oxide (4). In the case of isobutene, however, isobutene oxide, one of the two main products of the reaction (4), was usually not observed (Fig. 1*b*). This was shown to be due to its rapid reaction with excess nitrogen dioxide. A sample of isobutene oxide was kindly supplied by Dr. A. M. Eastham of these laboratories and its removal

**In the presence of large excess of unreacted NO_2 no attempt could be made to analyze for NO, formed in reactions (1) and (2), and for O_2, formed in reaction (2). A knowledge of the amounts of these products, however, is not essential for the present study.*

in the presence of nitrogen dioxide and under conditions employed in the present experiments was demonstrated. The much greater reactivity of isobutene oxide relative to that of the 1,2-epoxides of *n*-olefins has been observed before (8).

Typical chromatograms of the reaction products are shown in Fig. 2. In the case of butene-1 (Fig. 2, A), the main products are α-butene oxide and *n*-butanal, and the minor products are methyl ethyl ketone, propanal, acetaldehyde, ethyl nitrate, and two unidentified compounds (compounds *a* and *b*). In the case of isobutene (Fig. 2, B) isobutanal appears as the only major product since isobutene oxide is removed by excess

nitrogen dioxide; acetone, methyl nitrate, methyl ethyl ketone, nitromethane, and two unknown compounds (compounds *c* and *d*) are minor products. It was shown that these minor products were not formed in the thermal reaction of isobutene oxide and nitrogen dioxide.

Fig. 2, C shows the chromatogram of the products of a simultaneous photoöxidation of butene-1 and isobutene. No new products are observed but only those obtained in the reactions of the two butenes separately. This is in agreement with the previous conclusion (4) that the principal reactions under consideration do not involve a free-radical mechanism.

Effect of Pressure

Figs. 3(*a*) and 3(*b*) show the effect of pressure on the photochemical reactions of nitrogen dioxide with butene-1 and isobutene, respectively, at a constant irradiation time of 30 minutes. In both cases 1 mm. each of nitrogen dioxide and the olefin and various amounts of nitrogen were used. There is a pressure effect of the type observed previously (4) for propylene but in the present case it is confined to the pressures below about 30 mm. The lifetimes of the "hot" addition products formed appear to be an order of magnitude longer

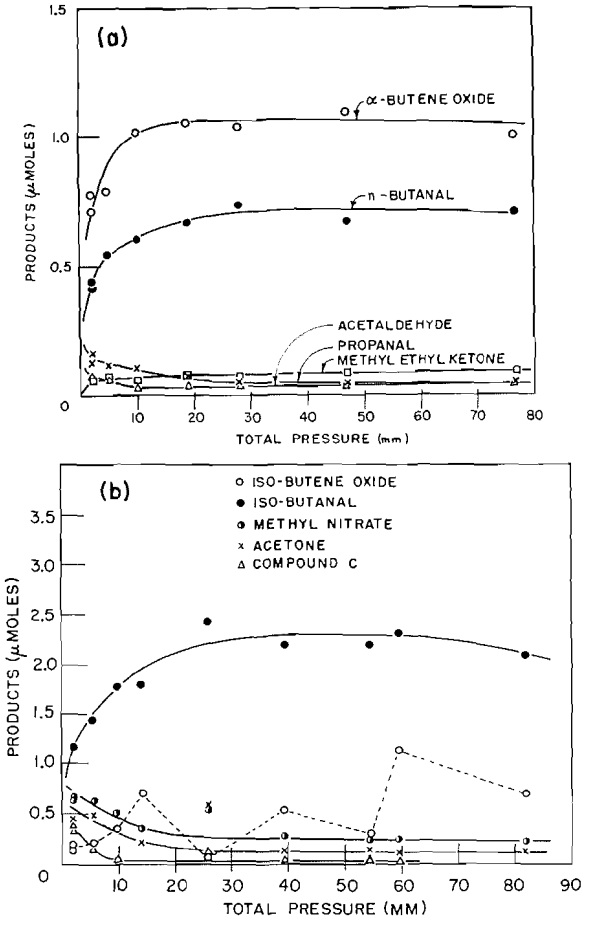

FIG. 3. Pressure effects in the photoöxidation of (*a*) butene-1 and (*b*) isobutene.

than in the case of propylene and the collisional stabilization, therefore, takes place at much smaller pressures. At pressures higher than about 70 mm. the rates of formation of the major products seem to show a tendency to decrease again. This is probably due to the additional consumption of oxygen atoms in the three-body reaction

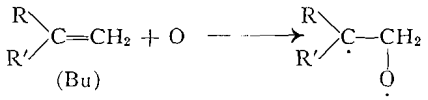
$$O + NO_2 + M = NO_3 + M. \qquad (3)$$

No analogous decline was observed when O atoms were generated by the mercury-photosensitized decomposition of nitrous oxide (4).

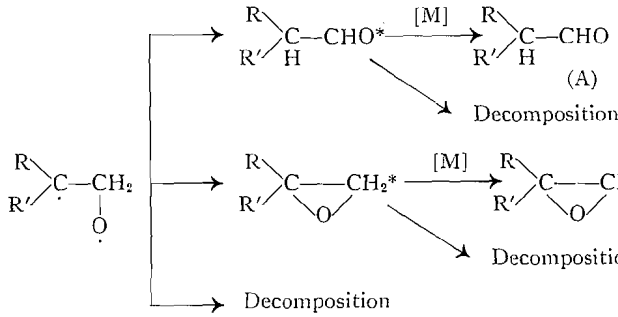
In the case of butene-1 throughout the investigated pressure range the ratio of *n*-butanal to α-butene oxide was 0.40 ± 0.02 to 0.60 ± 0.02. In the case of isobutene only small and irregular quantities of isobutene oxide were recovered, for reasons already discussed. In the nitrous oxide work (4) the respective ratios of the aldehyde to the epoxide formed for the case of butene-1 and isobutene were 0.43 to 0.57 and 0.42 to 0.58.

Relative Reaction Rates of Oxygen Atoms with Nitrogen Dioxide, Butene-1, and Isobutene

Oxygen atoms are believed (4) to react with terminal monoölefins according to the following scheme:



(4)



(5)
(6)
(7)
(8)
(9)

At a pressure of, for example, 40 to 50 mm. reactions (6) and (8) need not be considered. At small conversions and on applying the usual steady-state treatment to the remaining reactions and writing Bu for the butene and A for the aldehyde formed in reaction (5), the following relationship is obtained:

[1] $$\frac{\alpha\phi I[NO_2]}{R_A} = 1+\frac{k_2\,[NO_2]}{k_4\,[Bu]}\left(1+\frac{k_3}{k_2}[M]\right),$$

where $\phi I[NO_2]$ is the rate of light absorption by nitrogen dioxide (at small I and $[NO_2]$), R_A the rate of formation of the aldehyde A produced in reaction (5), and α the ratio of molecules of A formed to the number of oxygen atoms consumed in reaction (4). At constant $[NO_2]$, [M], irradiation time, and light intensity (I) a plot of reciprocal GLC peak areas of the compound A against $[NO_2]/[Bu]$ is linear. The slope-to-intercept ratio is

[2] $$m = \frac{k_2}{k_4}\left(1+\frac{k_3}{k_2}[M]\right).$$

Also

[3] $$k_{4a}/k_{4b} = m_b/m_a,$$

where the suffixes *a* and *b* refer to the butene-1 and the isobutene reaction, respectively.

The composition of the main products recovered after 15 minutes irradiation of NO_2–butene-1 mixtures at a total pressure of 50 mm. and at constant NO_2 but variable $[NO_2]/[Bu]$ ratios is shown in Table I, and for the NO_2–isobutene mixtures at a total pressure of 40 mm. in Table II.

0.75	3.1	39.6	4.2	7.7	2.1	1.9	0	0.2	0.5	0.2	0.7

i-Bu = *isobutene;* *i*-BuA = *isobutanal;* *i*-BuO = *isobutene oxide;* MEK = *methyl ethyl ketone; n.d. = not determined.*

The reciprocal peak areas of *n*-butanal and isobutanal, respectively, are plotted against $[NO_2]/[Bu]$ in Figs. 4(*a*) and 4(*b*). There is an appreciable scatter of experimental values and the least mean squares treatment gives $m_a = 2.1$ and $m_b = 0.38$. These quantities are approximately equal to k_2/k_{4a} and k_2/k_{4b}, respectively, since at pressures of 40 to 50 mm. the expression in the bracket in Eq. [2] does not differ much from unity. According to Ford and Endow (9), $k_3[M]/k_2 = 47.6$ [M] (where [M] is in mole/l.) so that the corrected values are

$$k_2/k_{4a} = 1.9, \text{ and } k_2/k_{4b} = 0.34.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

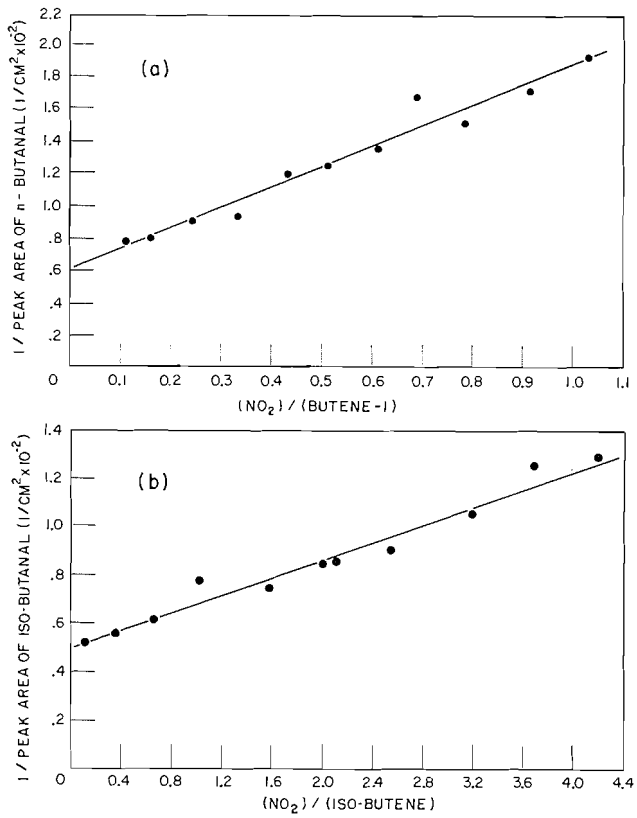

FIG. 4. (*a*) Reciprocal GLC peak areas of *n*-butanal as a function of the $[NO_2]/[\text{butene-1}]$ ratio (*b*) Reciprocal MLC peak areas of isobutanal as a function of the $[NO_2]/[\text{isobutene}]$ ratio.

The ratio of the rate constants of the reactions of oxygen atoms with butene-1 and isobutene is, therefore,

$$k_{4b}/k_{4a} = 5.5.$$

By photolyzing nitrogen dioxide in the presence of mixtures of butene-1 and isobutene, this ratio of the rate constants can be also evaluated from the relationship

$$[4] \qquad \frac{k_{4b}}{k_{4a}} = \frac{[R_A]_b}{[R_A]_a}\frac{\alpha_a}{\alpha_b}\frac{[\text{butene-1}]}{[\text{isobutene}]}.$$

Table III shows the amounts of *n*-butanal and isobutanal formed with various mixtures of butene-1 and isobutene. The two aldehydes have essentially the same molar GLC responses, as is shown in Fig. 5. Since it has also been found before (4) that $\alpha_a/\alpha_b \simeq 1$, the relative rate constant in Eq. [4] is obtained simply by multiplying the ratio of the GLC peak areas of the two aldehydes by the inverse ratio of the concentrations of the butenes. The values obtained are given in the last column of Table III. The mean value of about 5.8 agrees well with the above value of 5.5. There is, however, a considerable scatter from the mean value and perhaps also a systematic drift with the ratio of the two olefins: a decrease with decreasing isobutene to butene-1 ratio extrapolating to a limit of about 4.5 as the amount of isobutene tends to zero. In view of this and of the

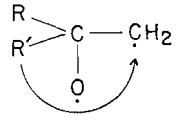
scatter of points in the plots in Figs. 4(*a*) and 4(*b*), it is felt that there is probably an experimental uncertainty of the order of 20 to 30 per cent in the relative rate constants determined in the present work. Previously (4) a value of 4.2 was obtained for k_{4b}/k_{4a}, which within the estimated experimental uncertainties agrees with the present value.

Formation of Minor Products

The complexity of the reactions and the incomplete analytical information preclude a detailed explanation of the method of formation of minor products.

Small amounts of methyl ethyl ketone were found in the case of both butene-1 and isobutene. The formation of this compound has been explained before (4) by addition of a small amount of oxygen atoms to the "more-substituted" carbon atom in the two butenes followed by migration of H or CH_3.



This migration is probably largely intramolecular, although the formation of nitromethane in the isobutene system suggests the presence of some free methyl radicals.

Most of the minor products increase at lower pressures, as is shown in Figs. 3(*a*) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

3(*b*). This is in agreement with an increasing importance of reactions (6) and (8) at lower pressures. However, even at higher pressures certain amounts of minor products are still formed, suggesting also the occurrence of some pressure-independent decomposition (reaction (9)).

Finally, it should be mentioned that under certain conditions in the presence of molecular oxygen propanal and acetone are formed as major products in the reactions of butene-1 and isobutene, respectively, besides the C_4 epoxides and aldehydes which are normally the only major products in these reactions. While these effects require further investigation, it is possible that oxygen produced in reaction (2) may contribute to some extent to the formation of propanal and acetone even when only nitrogen is used as diluent.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. C. Horswill for a sample of ethyl nitrate, Dr. A. W. Tickner for mass spectrometer analyses, and the Analytical Section of this Division for infrared analyses.

CHEMICAL EFFECTS OF THE $Br^{81}(\gamma, \alpha)As^{77}$ REACTION IN BROMIDES[1]

D. H. NELSON AND K. J. MCCALLUM

ABSTRACT

An investigation has been made of the chemical forms of the arsenic produced when solid bromides, following irradiation with high-energy gamma rays, are dissolved in aqueous solution. The As^{77} is found to appear in both the pentavalent and the trivalent forms, the ratio AsV/AsIII increasing with an increase in the number of moles of water present in the hydrated solid. For the monohydrate of lithium bromide, the ratio depends upon the pH of the solution in which the solid is dissolved.

INTRODUCTION

When bromine atoms are exposed to high-energy gamma rays, one of the nuclear reactions which occurs involves the ejection of alpha particles, with the formation of As^{77}, a beta-emitting nuclide with a half-life of 39 hours (1). The present work is concerned with the chemical forms assumed by the radioactive arsenic when bromides which have been irradiated with gamma rays from a betatron are dissolved in aqueous solutions.

The As^{77} nuclide decays with the emission of a beta particle with 0.68 Mev. maximum energy to form stable Se^{77}. From the known masses of Br^{81} and Se^{77} (2), and the energy of the beta particles, the threshold energy for the $Br^{81}(\gamma, \alpha)As^{77}$ reaction can be calculated to be about 7 Mev. When betatron gamma rays of 23 Mev. peak energy are used to bring about this nuclear reaction, the maximum recoil energy imparted to the As^{77} nucleus is about 0.9 Mev.

Taylor and Haslam (3) have determined the activation and cross section curves for this reaction. From their results it can be calculated that for an irradiation dose of 10,000 roentgens with betatron gamma rays of 23 Mev. peak energy, the As^{77} produced in a 30 g. sample of KBr should have an initial decay rate equivalent to 200 disintegrations per second. This is sufficiently high to make the separation and measurement of the chemical forms of the As^{77} feasible by the carrier technique.

EXPERIMENTAL AND RESULTS

All of the bromide salts used were of reagent grade and were dried before use. The hydrated salts were prepared by the evaporation of solutions of the bromides, and drying the residue over the corresponding anhydrous salt. The water content of the hydrates so prepared did not differ by more than 2% from the theoretical quantity.

Sixty-gram samples of the bromides were exposed to radiation from a betatron operating at a peak energy of 23 Mev. for a period of 10 minutes. The intensity at the position of irradiation varied from about 1000 to 2000 roentgens per minute in different experiments. A number of different radioactive species resulted from this treatment. To determine the total amount of As^{77} produced in an irradiation a chemical separation was necessary before counting. The following procedures were used.

A weighed amount of the irradiated sample, approximately 30 g., was mixed with 40 mg. of powdered arsenic metal and the mixture was dissolved in 200 ml. of cold 6 *M* nitric acid. When the initial evolution of free bromine had ceased, the solution was then made

basic with ammonia, and the arsenate precipitated as $MgNH_4AsO_4.6H_2O$. The precipitate was separated by filtration, dissolved and reprecipitated twice more. The precipitate was then mounted on filter paper, washed with a small amount of alcohol, and dried under a heat lamp. It was counted with a mica-window end-on counter under conditions of standard geometry. The weight of arsenate present in the precipitate was then determined volumetrically. The observed counts were corrected for decay. Self-scattering and self-absorption corrections were found to be negligible for the thicknesses of precipitate that were used.

The separation procedure was sufficient to separate all other radioactive nuclides present from the As^{77}, as was shown by half-life determinations on the precipitate. The measurements permitted a calculation of the total activity of the As^{77} produced per gram of bromide during the particular irradiation.

Measurements were made to determine the fraction of the As^{77} present as arsenite (AsIII) and as arsenate (AsV). A known weight of the irradiated sample, approximately 30 g., was dissolved in 100 ml. of solution containing known amounts of arsenite and arsenate carriers. After time for complete dissolution and equilibration, the arsenate fraction was removed by precipitation as $MgNH_4AsO_4.6H_2O$. This precipitate was separated by filtration, dissolved, reprecipitated, and prepared for counting in the manner previously described.

The filtrate containing the arsenite fraction was acidified to pH 2 with HCl, and the AsIII precipitated as As_2S_3 with hydrogen sulphide. The precipitate was filtered, dissolved in ammonium sulphide, and reprecipitated by acidification. The precipitate was removed and dissolved with HCl and $KClO_3$, which oxidized the arsenic to the pentavalent state. The arsenic was then precipitated and counted as $MgNH_4AsO_4.6H_2O$.

In all cases, the sum of the amounts of the As^{77} found in the AsIII and AsV fractions was equal to the total As^{77} content within experimental error. Attempts were made to detect As^{77} present as arsine by bubbling arsine through a freshly prepared solution of the irradiated bromide and then absorbing the gas on a filter paper impregnated with mercuric chloride solution. The paper was then counted but no detectable amounts of radioactivity were observed.

Experiments were carried out on the exchange of arsenic between arsenite and arsenate in the presence of high concentrations of bromide ion. Labeled arsenate ion was prepared using radioactive As^{76} produced by the (n, γ) reaction on sodium cacodylate (4). This was added to 100 ml. of a solution containing 30 g. of potassium bromide and a known amount of arsenite carrier. The solution was allowed to stand for 2 hours, and then the arsenite and arsenate fractions were separated and counted. The results indicated that at both high and low values of the pH, less than one per cent exchange had occurred.

The results obtained when irradiated samples of some bromides and bromide hydrates were dissolved in water are given in Table I. Lithium, sodium, potassium, and ammonium bromides each gave approximately 10% of the As^{77} activity in the AsV fraction, and the remainder appeared as AsIII. The monohydrate of lithium bromide gave 55% in the AsV fraction while the dihydrates of lithium and sodium bromides gave approximately 95% of the As^{77} in the AsV fraction.

The effect upon the distribution of As^{77} of the pH of the solution in which the irradiated solids were dissolved was determined. A Beckman pH meter, model N-2, was used to determine the pH values. The addition of large quantities of the solid bromides to the solutions tended to decrease the pH values. An attempt was made to keep the pH constant by the gradual addition of NaOH solution as the solid was dissolved. Table II

gives the pH range observed during the solution of the solid, and the percentage of As^{77} appearing in the AsV fraction.

The results show that in basic solutions, anhydrous sodium and lithium bromides and the dihydrate of lithium bromide give essentially the same distribution as they do in neutral solutions. The monohydrate of lithium bromide, however, shows a peculiar behavior in that the percentage of As^{77} appearing as AsV increases to a maximum at about pH 11, and then decreases at higher pH values.

DISCUSSION

The results in Table I indicate that the distribution of As^{77} between the trivalent and pentavalent states is markedly dependent upon the amount of water contained in the crystal. For 0, 1, or 2 moles of water per mole of bromide, the percentage of As^{77} appearing as AsV is about 10, 53, and 95 respectively. An increase in the amount of water favors the formation of the more highly oxidized form. This is probably to be correlated with the corresponding increase in the percentage of oxygen in the solid.

The results given in Table II indicate that for the anhydrous salts and for the dihydrate of lithium bromide, the same results are obtained when the solids are dissolved in solutions of high pH as when they are dissolved in water. For the anhydrous bromides and the dihydrate the results can be explained by assuming that two types of As^{77}-containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

species may be present, the first reacting with water to form AsIII and the second to form AsV, the ratio of the second to the first increasing when the water content of the solid is increased from 0 to 2 moles per mole of bromide. The valence state formed on solution appears to be independent of pH.

Although the percentage of the As^{77} appearing as AsV for lithium monohydrate is intermediate between the values found for the anhydrous salts and the dihydrate, the results of Table II cannot be explained by assuming that here the same two As^{77}-containing species are present in the solid, but in intermediate proportions. The maximum in the percentage of the As^{77} appearing as AsV which occurs at about pH 11 requires the presence of at least one species in the solid whose reactions on solution depend upon the pH of the solution in a rather complicated way. This species appears to be absent or present in only small proportions when the irradiated solid is the anhydrous bromide or the dihydrate.

There is no evidence concerning the exact identity of any of the species which have been postulated to occur in the irradiated solid. The two species assumed to be present in the irradiated anhydrous bromides and in the dihydrate could contain arsenic in the trivalent and pentavalent states respectively and undergo hydrolysis upon solution to form arsenite and arsenate. The third type of species, present in addition to the other two in irradiated bromide monohydrates, could represent an intermediate type formed only at intermediate water content. If there is only one species of this intermediate type, to explain the results of Table II, one would have to assume that it undergoes three competing reactions in solution. The first would involve a reaction with water to form AsIII, the second a reaction with hydroxyl ion to form AsV, and the third a reaction of higher order with respect to hydroxyl ion to form AsIII. Other schemes to explain the results of Table II can be devised if one assumes more than one species of this intermediate type.

The results obtained are not sufficient to allow any definite conclusions to be drawn as to the chemical forms of the As^{77} in these irradiated bromides. It can be stated, however, that As^{77} is present in more than one chemical form, and that for lithium bromide monohydrate, reactions on solution involving hydroxyl ions can occur.

REACTION OF DEUTERIUM ATOMS WITH ETHANE—MECHANISM OF METHANE EXCHANGE[1]

R. Berisford[2] and D. J. Le Roy

ABSTRACT

The reaction of deuterium atoms with ethane has been studied at 25° C. by the method of mercury ($^3P_1$) photosensitization. Methane formation takes place by the addition of D atoms to methyl radicals in the presence of a third body. From the dependence of methane exchange on third-body concentration the lifetime of the excited methane molecule is estimated to be of the order of 10^{-9} sec. The lifetime of the excited ethane molecule formed by the addition of a D atom to an ethyl radical is estimated to be considerably less than 10^{-9} sec.

INTRODUCTION

The reaction between ethane and atomic hydrogen (or deuterium) has been studied under a number of different conditions and the literature has been discussed extensively by Steacie (1). There is little doubt that the primary reaction in every case is

$$H \text{ (or D)} + C_2H_6 = C_2H_5 + H_2 \text{ (or HD)}. \quad [1]$$

Methane is the main product formed at the low pressures used in the discharge tube method of Wood and Bonhoeffer (1) and the hot filament method of Berlie and Le Roy (2). It is also an important product when the H (or D) atoms are produced by mercury photosensitization, even when the initial quenching is by ethane:

$$Hg(^3P_1) + H_2 = Hg(^1S_0) + 2H, \quad [2]$$

$$Hg(^3P_1) + C_2H_6 = Hg(^1S_0) + H + C_2H_6. \quad [3]$$

Presumably, the methane arises from methyl radicals formed in the atomic cracking reaction,

$$H + C_2H_5 = 2CH_3, \quad [4]$$

followed by

$$H + CH_3 = CH_4, \quad [5]$$

$$CH_3 + H_2 = CH_4 + H, \quad [6]$$

or

$$CH_3 + C_2H_6 = CH_4 + C_2H_5. \quad [7]$$

The primary purpose of the present investigation was the elucidation of the mechanism of methane formation, particular emphasis being placed on the role of inert gases on the extent of deuterization of the methane.

EXPERIMENTAL

Reagents

Heavy water (99.83%), obtained from Atomic Energy of Canada Limited, was used to produce deuterium by the method described by Kirshenbaum (3). Ethane, obtained from the Ohio Chemical and Manufacturing Company, was subjected to numerous trap-to-trap distillations in which only the intermediate portions were retained. Carbon dioxide, obtained from commercial Dry Ice, and propane (Ohio) were treated in the same way. The four deuterated methanes, CH_3D, CH_2D_2, CHD_3, and CD_4, were obtained

from Merck & Co., Ltd., Montreal. Their purity was said to be not less than 98.0, 96.0, 96.9, and 99.4%, respectively. We were unable to detect any foreign bands in their individual infrared spectra.

Reaction System

The total volume of the reaction system was 2780 cm.^{3}, and included a buffer volume, an all-glass circulating pump, and a cylindrical quartz cell 10 cm. long and 5 cm. in diameter. Resonance radiation was provided by a 4-watt U-shaped General Electric germicidal lamp. The mercury vapor concentration in the reaction cell was the equilibrium vapor pressure at room temperature. The ethane was measured accurately in a small calibrated volume before condensing it into the reaction system.

Analysis of Products

The non-condensable products, consisting of the various hydrogens and methanes, were passed through a trap containing silica gel cooled with liquid air. This removed all of the methanes and most of the hydrogens. The methanes were finally separated in a pure state by treating the desorbed gas with copper oxide at 250° C. and then passing it through a liquid-air trap.

The condensable gases were fractionated on a low-temperature still (4). A few of the ethane fractions were subjected to infrared and mass spectrographic analysis.

Infrared analyses of the methanes formed in the reaction were made with a Perkin-Elmer Model 12-C spectrometer with sodium chloride optics, modified as described previously (5). No CH_4 was found but each of the other four methanes was present. The fundamental vibration frequencies used are given in Table I.

Because of the small moments of inertia there was a considerable amount of overlapping of the bands, but of more significance was their susceptibility to pressure broadening. The observed extinction coefficient of any particular methane at one of its principal absorption frequencies was strongly dependent on the amounts of other methanes present, even when there was no overlapping of bands. This difficulty was overcome by deliberately broadening the rotational structure by the addition of large amounts of carbon dioxide. An example of the effect of carbon dioxide on optical density ($D = \log I_0/I_t$) is shown in Fig. 1. Calibration curves were obtained and analyses made using a standard pressure of 400 mm. of carbon dioxide in the absorption cell.

Under these conditions linear plots of D vs. P, the pressure in mm., were obtained for the individual methanes (except in the case of CD_4) and the values of q in the expression $D = qP$ are given in Table I; q has the units mm.$^{-1}$ and applies to the particular

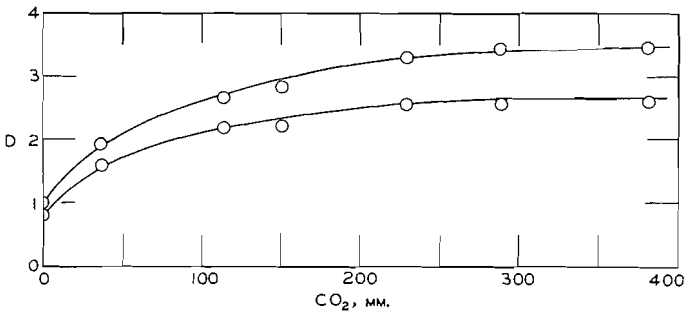

FIG. 1. Effect of carbon dioxide on the optical density, $D = \log I_0/I_t$, at 1306 cm.$^{-1}$ (upper curve) and 1235 cm.$^{-1}$ (lower curve) for a sample containing the four deuterated methanes.

optical cell used, which had a path length of 67 cm. The values of q, which are underlined in Table I, are for frequencies at which maxima occur; the remaining values indicate the magnitude of overlapping. Since D was not proportional to P for CD_4, the concentration of CD_4 in a mixture was obtained from the empirical curve of D vs. P after correcting the observed optical density at 996 cm.$^{-1}$ for the contribution due to CHD_3. The concentrations of CHD_3, CH_2D_2, and CH_3D were obtained by solving equations of the form $D = \sum q_i P_i$ for each of the appropriate frequencies.

Analytical results on three synthetic mixtures are given in Table II. Mass spectrographic analysis on sample No. 2 was done through the kindness of Dr. A. W. Tickner, Division of Applied Chemistry, National Research Council, Ottawa.

RESULTS AND DISCUSSION

The effect of the inert gas carbon dioxide on the relative yields of the deuterated methanes is shown in Table III. A comparison of the ethane consumed with the total methanes formed shows that these are the most important products. In a few instances analyses were made for higher products: 0.066 mm. of propane and 0.0040 mm. of butane were formed in experiment No. 6; 0.063 mm. of propane, 0.007 mm. of butane, and 0.006 mm. of hexane were formed in experiment No. 8. A mass spectrographic analysis of the residual ethane from experiment No. 12 showed that 0.36 mm. of C_2H_5D and 0.09 mm. of $C_2H_4D_2$ were formed.

It is evident from Table III that variations in the initial pressure of deuterium have

little or no effect either on the amount of total methane or on its isotopic composition. This suggests that the methyl radicals formed in [4′] do not, under the conditions of our experiments, form methane by the analogue of [6]:

$$D + C_2H_5 = CH_3 + CH_2D. \qquad [4']$$

This is further borne out by the fact that the analogue of [6] would yield only CH_3D and CH_2D_2 unless some source of CHD_2 and CD_3 radicals was provided. Reaction [7] can be eliminated since no CH_4 was produced, a fact which gives further support to the elimination of [6], since the rate constants reported for [6] and [7] are such that in the present experiments the abstraction by CH_3 radicals of D atoms from D_2 and of H atoms from C_2H_6 would proceed at approximately the same rate (6, 7).

The results in Table III show that high pressures of carbon dioxide cause an increase in the proportions of CH_3D and CH_2D_2 and a decrease in the proportions of CHD_3 and CD_4. It is evident, therefore, that reactions analogous to [5] require a third body. The following detailed mechanism is suggested:

$$D + CH_3 = CH_3D^*, \qquad [8]$$

$$CH_3D^* = CH_2D + H, \qquad [9]$$

$$CH_3D^* + M = CH_3D + M. \qquad [10]$$

Similar reactions involving $CH_2D_2^*$, CHD_3^*, and CD_4^* are assumed to occur. Defining α_1, α_2, α_3, and α_4 as the rate constants for the bimolecular formation, β_1, β_2, β_3, and β_4 for unimolecular decomposition, and γ_1, γ_2, γ_3, and γ_4 for bimolecular stabilization of these four excited molecules, expressions can be derived for the rates of formation of each of the stable deuterated methanes in terms of [4′]. The rate of [4′] will, of course, be equal to one half the total rate of formation of methane. Unimolecular decompositions of excited molecules yielding D atoms need not be taken into account, and the rate of formation of CD_4 will be given simply by $\alpha_4(D)(CD_3)$. Writing $\beta_i/\gamma_i = p_i$ and noting that the latter has the same units as M, the calculated percentage yields are as follows:

(i) $$\% CH_3D = 50[M/(p_1+M)],$$

(ii) $$\% CH_2D_2 = 50[(2p_1+M)/(p_1+M)].[M/(p_2+M)],$$

(iii) $$\% CHD_3 = 50[(2p_1+M)/(p_1+M)].[p_2/(p_2+M)].[M/(p_3+M)],$$

(iv) $$\% CD_4 = 50[(2p_1+M)/(p_1+M)].[p_2/(p_2+M)].[p_3/(p_3+M)].$$

If it is assumed that $\gamma_1 = \gamma_2 = \gamma_3 = Z$, in which Z is the collision frequency per unit concentration for the deactivating reactions, then the natural lifetimes, τ_1, τ_2, τ_3 of the activated species CH_3D^*, $CH_2D_2^*$, CHD_3^*, will be given by $\tau_1 = 1/(p_1Z)$, $\tau_2 = 1/(p_2Z)$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

$\tau_3 = 1/(p_3 Z)$. Lifetimes calculated in this way will apply, of course, only to decompositions which yield H atoms. The value of Z used, 4.3×10^{-10}, was based on that for a collision between CO_2 and CH_2D_2*, assuming a mean collision diameter of 4.42 Å, estimated from viscosity data. Taking into account reduced masses and mean collision diameters, M is given by the expression $M = (CO_2)+1.25(C_2H_6)+1.20(D_2)$; however, better correlation was obtained when the coefficient of the D_2 concentration was set at 0.6.

Since analytical errors in the determination of small percentages of CH_3D are emphasized when reciprocals are taken, the "best" value of p_1 was obtained by plotting equation (i) for various assumed values of p_1, as shown in Fig. 2. It was estimated that p_1 was approximately 60 mm. Using this value, equation (ii) was plotted for various assumed values of p_2, as shown in Fig. 3; p_2 was estimated to be approximately 85 mm. In a similar way p_3 was estimated to be approximately 50 mm. The uncertainty in p_3 was somewhat greater than that in p_2 and p_1, possibly because the analysis for CD_4 was dependent on that for CHD_3, as mentioned previously. Agreement between theory and

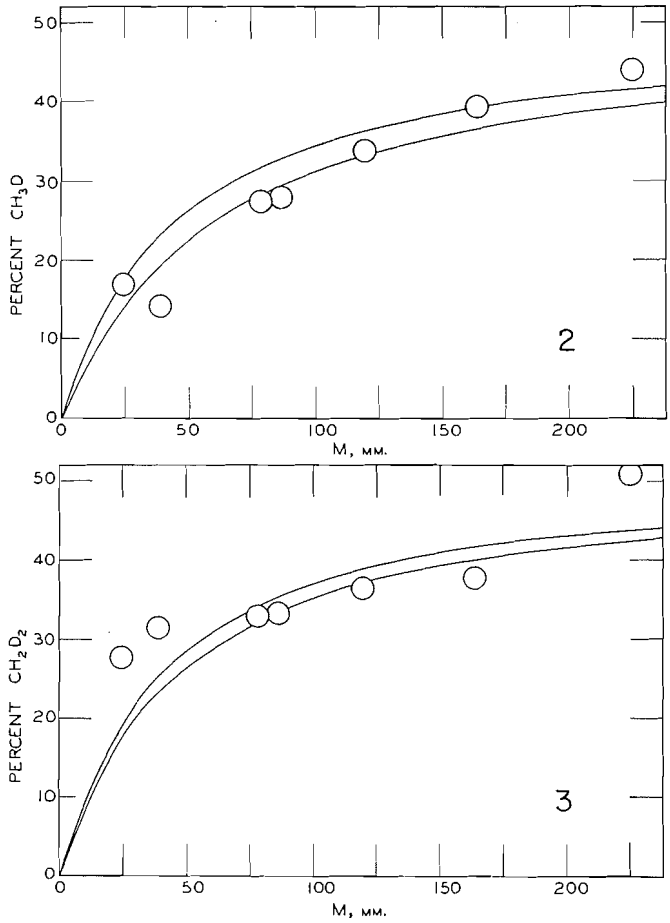

FIG. 2. Effect of third-body concentration on the proportion of CH_3D in the total methanes. Upper curve, equation (i) with $p_1 = 45$ mm.; lower curve, $p_1 = 60$ mm.

FIG. 3. Effect of third-body concentration on the proportion of CH_2D_2 in the total methanes. Upper curve, equation (ii) with $p_1 = 60$ mm., $p_2 = 85$ mm.; lower curve, $p_1 = 60$ mm., $p_2 = 95$ mm.

For personal use only.

experiment was not improved by postulating pressure-independent exchange reactions of the type $D + CH_3 = CH_2D + H$.

In view of the limited accuracy of the determination of the individual deuterated methanes there is no justification for assigning different lifetimes to the three activated molecules. About all that can be said is that the lifetimes are of the order of 10^{-9} sec., corresponding to a p of the order of 70 mm.

It is possible to obtain a simple expression for the percentage of deuterium in the total methanes on the assumption that $p_1 = p_2 = p_3 = p$. For $p = 70$ mm. this expression agrees reasonably well with the experimental results, the average deviation being less than 4%. This would, of course, have been the only criterion of the mechanism if the methane fraction had simply been burned and the deuterium content of the water determined, but it also has some merit in the present instance since values for the individual methanes are, to some extent, interdependent.

In order to further substantiate the mechanism it is necessary to take into account the H atoms liberated in reactions such as [9]. Since no CH_4 was found the H atoms must be consumed in one or more of reactions [1], [4], and [11]:

$$H + D_2 = HD + D \qquad [11]$$

Glasstone, Laidler, and Eyring (8) have calculated that at 300° K., k_{11} will be 1.5/7.3 times the rate constant for the conversion of para to ortho hydrogen. Using the data of Geib and Harteck (8, 9) for the para–ortho conversion, k_{11} would be 2×10^7 cm.^{3} mole^{-1} sec.$^{-1}$; using the expression $10^{13.7}\ e^{-7500/RT}$, as suggested by Trotman-Dickenson (10), k_{11} would be 3.3×10^7. At the same temperature k_1 is 3.7×10^7 (2). Thus k_{11} and k_1 are of similar magnitude. Furthermore, the concentration of D_2 was from 4 to 10 times that of C_2H_6. An additional factor accounting for the absence of CH_4 is the fact that one quarter of the total atom consumption is due to reaction [1], in which the substitution of an H for a D atom would not affect the relative amounts of the deuterated methanes.

The consumption of H atoms by [4] would result in less-extensive deuterization than predicted by the mechanism. The magnitude of the decrease depends on the ratio $k_4(H)/k_{4'}(D)$ and would be more important at low values of M. By assuming a reasonable magnitude for this ratio it was concluded that the true lifetime would probably be greater than 0.5×10^{-9} sec. It is unfortunate that the experimental accuracy did not permit the use of such criteria as plotting $(CHD_3)/(CD_4)$ vs. M.

Lavrovskaia, Mardaleishvili, and Voevodskii (11, 12) have suggested a mechanism for the exchange of radicals which, in the case of CH_3, would correspond to the reaction

$$CH_3 + D_2 = CH_3D + HD \qquad [12]$$

While their results are not directly comparable to ours because they did not investigate the deuterium content of their methane, their conclusion that deuterium atoms play no role in radical exchange must be taken with reservation in view of the dependence of deuterization on third-body concentration, clearly demonstrated in the present work.

The argument that reactions such as [8], [9], and [10] cannot account, in many cases, for the amount of deuterium found in the products hinges on the relative rates of [11] and of the primary reaction of the D atoms (reaction [1] in the present instance). If the former is greater than the latter there is no difficulty in accounting for the extent of deuterization; if the rates are comparable then the extent of deuterization could increase with D_2, as found by Lavrovskaia, Mardaleishvili, and Voevodskii, even if reactions analogous to [12] did not occur.

It is of interest to compare the present results with the possible lifetime of $C_2H_5D^*$, formed in the reaction

$$D + C_2H_5 = C_2H_5D^*. \qquad [13]$$

This reaction undoubtedly precedes [4′], but the lifetime of the excited molecule must be much less than 10^{-9} sec., as shown by the following considerations.

From quenching data for D_2 (13) and CO_2 (14) the observed rates of formation of methane were corrected for quenching by CO_2. The corrected rates showed no dependence on M and hence the formation of deuterized ethane must be attributed to reactions which are independent of pressure in the range used, presumably to the combination of methyl radicals. The lifetime of $C_2H_5D^*$ formed in [13] would be expected to be much less than that of the excited methanes, in spite of the increased number of degrees of freedom, since its energy content would be about 14 kcal. per mole greater than that required for breaking the C—C bond.

The authors wish to express their thanks to the National Research Council for supporting this research.

THE MASS SPECTRA OF THREE DEUTERATED BUTANOLS[1]

W. H. McFadden, M. Lounsbury, and A. L. Wahrhaftig[2]

ABSTRACT

The mass spectra of 1,1-dideutero-1-butanol, 1,1,1,3,3-pentadeutero-2-butanol, and 1,1,1,2,3,3-hexadeutero-2-butanol have been obtained using 70-volt ionizing electrons. Comparison of the cracking patterns of the deuterated butanols with those of the undeuterated compounds confirms certain known features of the mass spectra of alcohols and reveals further information regarding the formation of several rearrangement ions. The strong tendency for alcohols to break at bonds beta to the hydroxyl group has been attributed to charge localization on the oxygen and this feature is used to explain the formation of many of the rearrangement ions. It is postulated that a hydrogen atom may be transferred to the electron-deficient oxygen and that the resulting structure distributes its excess energy and charge to give the activated complexes leading to the observed ions.

INTRODUCTION

The mass spectra of some deuterated ethanols (1), propanols (2, 3, 4), and butanols (5, 6) have been previously reported. In addition to being a valuable aid in kinetic studies the cracking patterns have given considerable information about the behavior of alcohols under electron bombardment. In the mass spectra of the four isomeric butanols rearrangement* ions occur at mass/charge ratio† $m/e = 33$ ($CH_3OH_2^+$) for *n*-butanol and isobutanol and at $m/e = 31$ (CH_2OH^+) for *sec*-butanol and *tert*-butanol (7). With the exception of a small amount of a mass 33 ion formed from *n*-propanol these ions are not observed in the mass spectra of other alcohols. However, many higher alcohols produce ions by loss of uncharged groups having mass 31 or 33, a notable example being formation of the abundant ion with mass 55 from 3-methyl-1-butanol. Inspection of the mass spectra of the alcohols reported by the American Petroleum Institute (7) suggests that these ions may be formed as primary daughter ions. In addition, many ions are apparently formed by loss of similar rearrangement groups such as H_3O, H_2O, CH_3OH, CH_3CH_2OH. It is clear that an activated complex in which a highly stable molecule such as H_2O or CH_3OH is partially formed will be energetically favored. It is also likely that there is some stabilization obtained by the partial formation of such radicals as OH_2 and CH_3OH_2.

From previous research (8), we had available three deuterated butanols: 1,1-dideutero-1-butanol, 1,1,1,3,3-pentadeutero-2-butanol, and 1,1,1,2,3,3-hexadeutero-2-butanol (hereafter referred to as *n*-butanol-d_2, *sec*-butanol-d_5, and *sec*-butanol-d_6 respectively). In order to investigate the formation and significance of the rearrangement ions the mass spectra of the three deuterated butanols have been obtained, along with those of the undeuterated compounds.

EXPERIMENTAL

Preparation of the three deuterated butanols has been described elsewhere (8). Originally they were collected as small "center-cut" samples from a distillation column operating with approximately eight theoretical plates. They were stored two years at Dry-Ice

"Rearrangement ions" refers to ions formed from an activated complex in which the molecular configuration differs from that of the original molecule owing to intramolecular transfer of atoms or groups of atoms.
†*Since this paper makes no reference to doubly charged ions the word "mass" is frequently substituted for the expression "m/e".*

temperature and about six months at room temperature. Before introduction into the mass spectrometer they were further purified by processing through a gas–liquid chromatographic column to remove traces of water and other impurities.

The mass spectra were obtained using a 90°-deflection, 6-in.-radius mass spectrometer similar to one described previously (9). The alcohols were allowed to diffuse into the ion source through a capillary leak under their own vapor pressure. The electron-accelerating potential was 70 volts and the electron current to the ionization chamber was 40 μa. The positive ions were accelerated into the analyzer tube by a potential of 2000 volts and the mass spectrum was scanned magnetically. The ion current arriving at the collector was amplified and recorded with a Speedomax Pen Recorder, Type G.

RESULTS

The mass spectra of *n*-butanol-d_0, *n*-butanol-d_2, *sec*-butanol-d_0, *sec*-butanol-d_5, and *sec*-butanol-d_6 are presented in Table I. The ion abundances, in terms of mole per cent (i.e. total ion current normalized to 100%), are the averages of two runs appropriately corrected for background contributions. The normal residual corrections were insignificant except at $m/e = 28$ where residual nitrogen contributed from 5 to 10% of that peak. However, when a sample was admitted to the mass spectrometer considerable enhancement of background was observed, which was shown to be due to the previous alcohol sample. This memory effect was reduced by mass analyzing the samples several weeks apart and by baking and flushing the mass spectrometer tube during the intervening period. Where necessary, corrections were made for the previous sample by measuring the height of a suitable ion-current peak and calculating the contribution of the contaminant to the rest of the spectrum. The maximum possible error introduced by this procedure was too small to affect the conclusions reported.

The mass spectra have not been corrected for carbon or oxygen isotopic contributions nor has any assay been made to determine the hydrogen–deuterium isotopic purity of the samples. From previous work (8) it is believed that the isotopic purity is better than 97%, and inspection of the mass spectra presented in Table I appears to confirm this. For example, the abundance ratio of the ions at $m/e = 48$ and 47 obtained from *sec*-butanol-d_5 shows the maximum possible isotopic impurity to be 3% on carbon 1. This value for the isotopic impurity would be reduced by any contribution of the ions CD_3COH^+ or CD_3CHO^+ at $m/e = 47$.

DISCUSSION

A. General

Many outstanding features of the mass spectra of alcohols have led to the conclusion that dissociation of the parent molecule–ion occurs with the ion in an electronic state in which the electron removed from the molecule is one of the non-bonding electrons of the oxygen atom. This generalization was first suggested by Cummings and Bleakney as a result of appearance-potential studies for the ions from methanol and ethanol (10). The apparent localization of charge on the oxygen causes the oxygen to behave as a trivalent atom, and as a consequence it attempts to form a bond with atoms that approach within bond-length distances. Thus, it attempts to form an additional bond with the carbon to which it is already attached and as a result the other three bonds of that carbon are weakened. Breaking of any one of these bonds, with or without transfer of the charge to the hydrocarbon fragment, gives rise to the principal ions formed by simple bond rupture. In addition to this, the trivalent oxygen also attempts to form bonds with atoms or

groups that come in its vicinity as a result of vibrations and internal rotations. The complexes thus formed can give rise to the various rearrangement ions observed in the mass spectra of alcohols.

These suggestions are consistent with the theory of mass spectra of polyatomic molecules presented by Rosenstock and co-workers (11, 12, 13). According to this theory, the

excited parent ion distributes its excess energy among its various degrees of freedom until a particular configuration, the activated complex, is formed. This complex then dissociates, forming a daughter ion. The redistribution of excess energy can lead to a number of different activated complexes and in addition the daughter ions can decompose to give secondary ion products. The mass spectrum is thus the result of several competing unimolecular reactions. Studies of mass spectra of polyatomic molecules show that the charge is selectively localized at various sites but it is not always possible to determine a priori where the most probable location may be. The determining factor is most generally the relative magnitudes of the ionization potentials of the two fragments but experimental data to illustrate this point for alcohols are scarce. Calculations of the mass spectra have been made using the theory of Rosenstock *et al.* for methyl, ethyl, isopropyl, and *n*-propyl alcohols (14, 15). For these calculations, charge localization on the oxygen was assumed for determinations of the principal reactions and the calculated results are in agreement with the experimental observations.

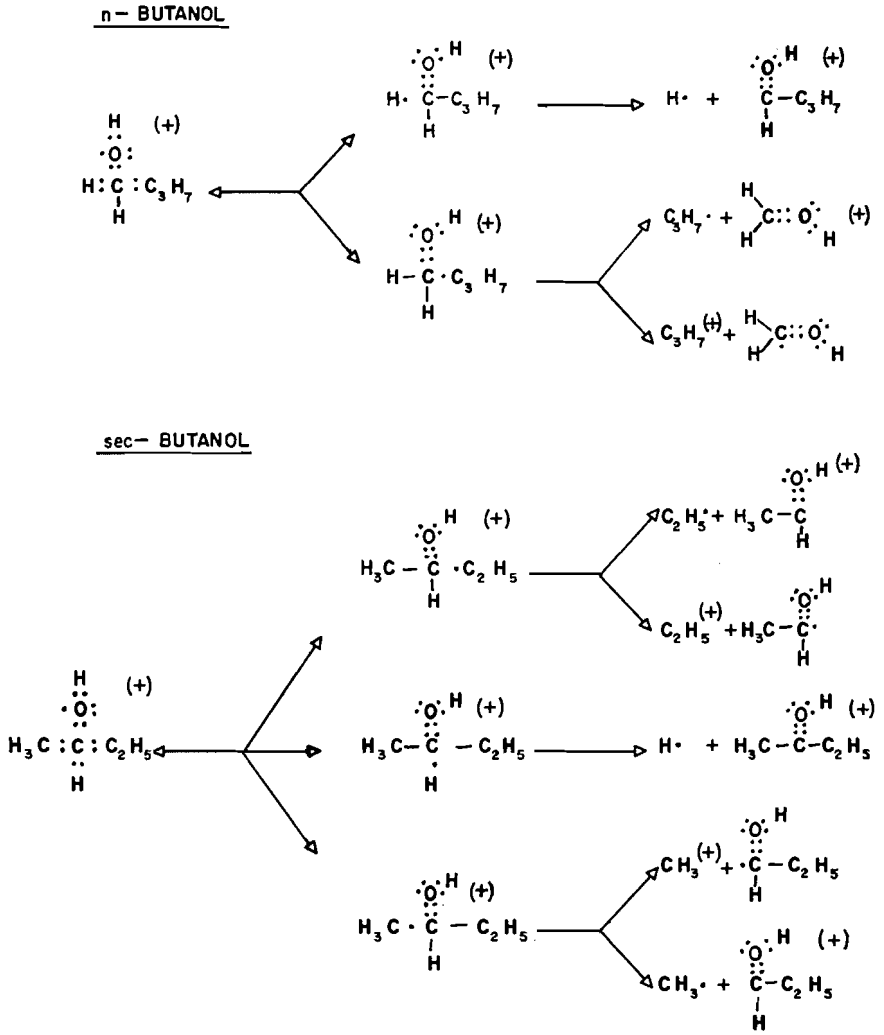

FIG. 1. Principal reactions leading to a simple bond break in *n*-butanol and *sec*-butanol.

B. Ions Formed by Simple Bond Rupture

The principal contribution of ions formed by a simple bond break to the mass spectra of alcohols arises from the rupture of bonds beta to the hydroxyl (i.e. the other bonds of the carbon to which the hydroxyl is attached). In Fig. 1 the ions formed by a simple bond break are shown for *n*-butanol and *sec*-butanol. An attempt has been made to show the important influence of charge localization by using the electron dot representation where appropriate. In Table II the data from which these reactions are deduced are shown. These data and previous experimental evidence (1, 2, 3, 4, 5, 6) indicate that this influence is not extended appreciably beyond bonds beta to the hydroxyl. During the period between ionization and decomposition the parent ion may resonate between the various structures illustrated and eventually dissociate to give the ions observed.

(*i*) *n-Butanol*

In the parent region the most abundant ion is that due to the loss of hydrogen. In Table II the mass spectrum of *n*-butanol-d_2 shows that this hydrogen is lost primarily from the carbon containing the hydroxyl for, when this carbon is deuterated, the largest ion in the parent region becomes the parent minus 2 mass units. This observation has

TABLE II

been previously noted for deuterated ethanols (1) and isopropanols (2, 3, 4). Loss of $CH_3\cdot$ from *n*-butanol-d_0 can occur by a simple bond break only from a delta bond and significantly it is found that it contributes only 0.26% of the total ionization. Loss of $CH_3CH_2\cdot$ from *n*-butanol-d_0 can occur by a simple bond break of a gamma bond and contributes only 2.2% of the total. From *n*-butanol-d_2 loss of $CH_3\cdot$ or of $CH_3CH_2\cdot$ is considerably smaller (0.06% and 0.76% respectively), which may indicate that these processes occur only partly by simple rupture of gamma or delta bonds. On the other hand loss of a propyl radical to form the ion CH_2OH^+ or loss of $\cdot CH_2OH$ to form a propyl ion both contribute a considerable fraction of the total ionization of *n*-butanol and the data obtained from the mass spectrum of *n*-butanol-d_2 confirm the expectation that these ions are formed by a simple beta bond break.

(*ii*) *sec-Butanol*

The most abundant ion in the parent region is that due to loss of hydrogen, as was also noted for *n*-butanol. Again the data of Table II demonstrate that this hydrogen is

primarily from the carbon containing the hydroxyl. Loss of $CH_3\cdot$ from *sec*-butanol contributes 7.6% of the total ionization and could occur by breaking a carbon–carbon bond beta or gamma to the hydroxyl. In the d_5 and d_6 *sec*-butanols the beta methyl group is deuterated and the mass spectra show conclusively that the methyl group lost is almost entirely from the beta position. Loss of $CH_3CH_2\cdot$ may also occur as a result of a simple bond break beta to the hydroxyl and contributes 38% of the total ionization. The data of Table II indicate this to be the principal reaction with no significant indication of intramolecular rearrangements.

C. Ions Formed by Intramolecular Rearrangement

In addition to the tendency to break bonds beta to the hydroxyl, the mass spectra of alcohols show a number of important ions which are formed by intramolecular rearrangement. The existence of ions such as $CH_3OH_2^+$ from *n*-butanol indicates the possibility of an activated complex in which the rearranged group has been partly or wholly formed. It is further suggested that for certain reactions such an activated complex may lose the rearranged group as a neutral fragment by transfer of the charge to the hydrocarbon matrix. It is obvious that loss of the groups H_3O, CH_3OH_2, etc. might occur in two steps (e.g. loss of CH_3OH_2 could be the result of loss of $\cdot CH_2OH$ followed by loss of H_2) but in a homologous series no general relationship is observed between the relative abundance of the ion due to loss of $\cdot CH_2OH$ and that due to loss of CH_3OH_2. If the latter occurred principally as a two-step process one would expect the ratio (parent $-$ CH_3OH_2)/(parent $-$ $\cdot CH_2OH$) to be approximately constant. In actuality this ratio varies randomly over a range of 0.25 to 20 for the 11 alcohols cited in Table III. Alternatively it might be suggested that, since loss of H_2O gives the most abundant ion (15.2%) in the mass spectra of *n*-butanol, formation of the ion $C_3H_5^+$ could be due to loss of H_2O followed by loss of $\cdot CH_3$. However, loss of H_2O leads to the ion $C_4H_8^+$ and the most reasonable secondary step is then $C_4H_8^+ \rightarrow C_2H_4^+ + C_2H_4$. The other possibility, loss of $CH_3\cdot$ followed by loss of H_2O, seems unreasonable since the ion formed by loss of $CH_3\cdot$ at $m/e = 59$ requires breaking of a delta bond and is only 0.26% abundant.

It may reasonably be concluded that in some of the cases the CH_3OH_2 fragment is lost as a unit even though it is inherently unstable as a separate molecule. This postulate

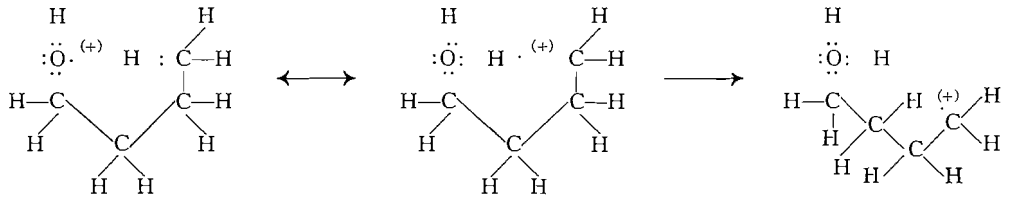
implies that both the rearrangement ion and the ion formed by loss of the rearranged group may result from the same activated complex. The appearance of the positive charge on either will be a statistical result of resonance between the various electronic configurations, and the ratio of the ion abundance of each species should be a function of the ionization potential of each fragment.

(*i*) *n-Butanol*

In order to explain the existence of the observed rearrangement ions it is suggested that an intramolecular rearrangement occurs whereby a hydrogen atom is transferred to the electron-deficient oxygen in the following fashion:



I II III

As a result of internal rotations and vibrations carbon-bonded hydrogen atoms will approach within bonding range of the oxygen and during this brief encounter establish equilibrium between structures I and II. As the molecule continues its internal motion the hydrogen may be transferred to the oxygen as shown. The resulting complex, III, would continue to distribute its excess energy and charge among the various degrees of freedom until a configuration was obtained which would lead to decomposition.

To demonstrate how a complex of this type can explain the formation of many of the rearrangement ions, specific examples are chosen for *n*-butanol. It is clear that the complex III could undergo a simple bond break to form the predominant ion $C_4H_8^+$ or the less predominant* H_2O^+. Comparison of the mass spectra of *n*-butanol-d_0 and *n*-butanol-d_2 (Table I) reveals that in the formation of H_2O^+ the hydrogen on carbon 1 is not involved to any significant extent ($<7\%$). A similar comparison for the ion formed by loss of H_2O ($C_4H_8^+$) leads to the same conclusion, i.e. that the hydrogen lost with the hydroxyl does not come from carbon 1. The mass spectrum of 1-deutero-1-butanol tabulated by Eliel and Prosser (6) confirms this conclusion and in addition the mass spectrum of their compound, 2-deutero-1-butanol, indicates that the hydrogen on carbon 2 is also not involved. These observations agree with the fact that for the rearrangements proposed, transfer of the hydrogens from carbon 3 or 4 is sterically more favorable. An alternative suggestion (16) is that the hydrogen on carbon 2 is lost after the hydroxyl, thus forming the stable ethylenic structure, but the data of Eliel and Prosser eliminate this possibility so far as *n*-butanol is concerned.

The ion $CH_3OH_2^+$, which is observed for very few alcohols and is significant only for *n*-butanol and isobutanol, could be formed from complex III by transfer of the H_2O group to the terminal methyl or alternatively by transferring another hydrogen to carbon 1. In the mass spectrum of *n*-butanol-d_2 there is an rearrangement ion of 1.32% abundance at mass 35 ($CHD_2OH_2^+$). This value is in agreement with the value of 1.27% contributed by the corresponding rearrangement ion ($CH_3OH_2^+$) formed from *n*-butanol-d_0. Since

**Although care was taken to remove H_2O from the samples it is not known whether H_2O has contributed significantly to the ions at m/e = 18 in Table I. For example, the 2.4% increase observed at this mass from sec-butanol-d_6 is probably about 40% from CD_3 and 60% from an H_2O impurity.*

For personal use only.

the position of the deuteriums has been retained in this ion it indicates that transfer of an additional hydrogen is the predominant mechanism. The data of Eliel and Prosser for 2-deutero-1-butanol indicate furthermore that approximately one-half of the time the extra hydrogen comes from the adjacent carbon, carbon 2. It is interesting to note that although the pentanols do not form the ion $CH_3OH_2^+$ to any significant extent, several show abundant ions due to loss of 33 mass units, and in the mass spectrum of 3-methyl-1-butanol (which is structurally similar to *n*-butanol) this ion is the largest peak. An important test of the mechanisms postulated here would be a study of deuterated forms of some of these pentanols.

Formation of the ion H_3O^+ could readily occur by transfer of a second hydrogen to the H_2O group on complex III. The data indicate that this hydrogen apparently comes from the adjacent carbon (carbon 1) about one-half of the time and a similar conclusion is reached regarding loss of H_3O to form the $C_4H_7^+$ ion. In the latter case there is at present no conclusive evidence to eliminate the possibility of two consecutive reactions contributing to this ion (e.g. loss of OH followed by loss H_2), but from the arguments presented earlier these would appear to be relatively unimportant.

(ii) sec-Butanol

The mass spectrum of *sec*-butanol contains a number of rearrangement ions similar to those observed from *n*-butanol but the data obtained from the deuterated analogues do not clearly indicate simple reaction mechanisms. Secondary butanol-d_0 produces the rearrangement ion CH_2OH^+ (7.7% abundance) at mass 31. Because of the possible contribution of the deuterated ethyl ions, $CD_2CH_3^+$ and $CH_2CD_3^+$, to the peaks observed at masses 31 and 32 the reaction mechanisms are not apparent but the data indicate that several patterns may be possible. For example, the appearance of the ion CD_2OH^+ (m/e = 33) in the mass spectrum of *sec*-butanol-d_5 indicates that approximately 25% of the time the hydrogen on the carbon containing the hydroxyl (carbon 2) is not involved. (The contributions of CDH_2OH^+ and $CDHOD^+$ to the mass 33 ion are relatively small.) In addition the peak observed at mass 32 from *sec*-butanol-d_6 could not be entirely due to the deuterated ethyl ion $CD_3CH_2^+$ and it is estimated that at least one-half of the observed abundance (4.4%) would be due to the ion $CDHOH^+$. This indicates that a significant number of events involve one of the hydrogens on carbon 4. The most plausible explanation of these observations seems to be that the ion CH_2OH^+ (or its deuterated analogues) arises from the daughter ions CH_3CHOH^+ (38%) and $CH_3CH_2CHOH^+$ (7.6%), which may be in equilibrium with their various structures

Such rearrangement ions could decompose to produce the various deuterated ions of CH_2OH^+ observed from *sec*-butanol-d_5 and *sec*-butanol-d_6. It is noteworthy that the equilibrium structures suggested might undergo a sufficient number of exchanges to give an ion with a deuterated hydroxyl. The ion abundance observed at mass 34 for both deuterated *sec*-butanols is too large to be explained as due to the C^{13} isotopic species or to a deuterated CH_3OH^+ analogue. In accordance with the foregoing postulates one may conclude that it is CD_2OD^+.

The formation of ions by loss of rearrangement groups such as CH_3OH_2, CH_2OH, cannot be deduced with any certainty because of the large expected contribution of secondary products from the abundant daughter ion CH_3CHOH^+. As indicated in Table I, the six ions with masses between 39 and 44 contribute 18% of the total ionization in the

For personal use only.

mass spectra of *sec*-butanol-d_0. In the mass spectra of the deuterated *sec*-butanols this 18% ionization is divided quite evenly between nine ions so that one cannot reasonably determine probable reaction paths.

Ions formed by the possible loss of H_2O cannot be readily studied from the mass spectra of the two deuterated *sec*-butanols because of the excessive contribution due to the ion formed by loss of CD_3. The mechanism of the loss of H_3O to form $C_4H_7^+$ (or deuterated analogues) can be partially deduced. The data indicate that for about 60% of the events only the hydrogens from carbon 2 or carbon 4 are involved ($m/e = 59$, *sec*-butanol-d_5) while the ion at mass 60 in the spectrum of *sec*-butanol-d_6 indicates that one hydrogen from carbon 4 is involved in about 40% of the events. The formation of the hydronium ion apparently involves the hydrogens from carbon 4 less than 10% of the time ($m/e = 20$, *sec*-butanol-d_6) whereas the single hydrogen from carbon 2 can be involved about 40% ($m/e = 20$, *sec*-butanol-d_5). The appearance of the fully deuterated hydronium ion at $m/e = 22$ may indicate that H_3O^+ arises primarily from the daughter-ion structures suggested to explain the observations on the deuterated analogues of CH_2OH^+. It would seem that loss of a hydrogen and subsequent gain of three deuteriums by the oxygen would be quite unexpected except in terms of a relatively simple exchange equilibrium.

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES

VI. DEGRADATION OF 4-*O*-METHYL-D-GLUCOPYRANURONOSYL-ALDOBIURONIC ACIDS TO 2-*O*-(4-*O*-METHYL-D-GLUCOPYRANOSYL)-GYCEROLS[1]

P. A. J. Gorin and A. S. Perlin

ABSTRACT

The configurations of glycosidic linkages in 4-*O*-methyl-D-glucopyranuronosyl-aldobiuronic acids can be determined by conversion to the derived 2-*O*-D-glucopyranosyl-glycerol hexamethyl ether, which is compared, by its infrared spectrum and specific rotation, with the sirupy hexamethyl ethers synthesized from 2-*O*-α- and 2-*O*-β-D-glucopyranosyl-glycerol. Thus, the configuration of 2-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-xylose was shown to be α, since it was degraded to 2-*O*-α-D-glucopyranosyl-glycerol hexamethyl ether. The configuration of 4-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-galactose was correlated with that of the former aldobiuronic acid, since both gave crystalline 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-glycerol penta-*p*-nitrobenzoate.

INTRODUCTION

Parts II and IV of this series (1, 2) describe a method for determining the configuration of reducing disaccharides by degradation to one of the two possible anomeric 2-*O*-glycopyranosyl-glycerols. The present paper demonstrates the feasibility of this approach for the 4-*O*-methyl-D-glucopyranuronosyl-aldobiuronic acids, except those linked glycosidically to the primary hydroxyl group of the reducing end-unit. Two readily obtainable aldobiuronic acids, 2-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-xylose (I) (3), from the wood of *Populus tacamahacca* Mill. (4), and 4-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-galactose (II), from Mesquite gum (5), were examined and each found to contain the α-glycosidic linkage.

Isolated from the wood, 2-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-xylose was converted to the D-xylitol derivative (III) by sodium borohydride reduction (6). The xylitol derivative was treated with diazomethane and the methyl ester formed was oxidized with 2.2 moles of lead tetraacetate (1) which preferentially oxidized the xylitol end-group to give 2-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-L-glyceraldehyde methyl ester. Reduction of the glyceraldehyde derivative with sodium borohydride (6, 7) afforded after purification by cellulose column chromatography (8) 2-*O*-(4-*O*-methyl-D-glucopyranosyl)-glycerol (IV) ($[\alpha]_D$ +125°). All of the above-described intermediates were not crystalline. The last-named compound was methylated with sodium hydroxide – methyl sulphate to yield its hexamethyl ether ($[\alpha]_D$ +123°), which gave an infrared absorption spectrum indistinguishable from that of the sirupy hexamethyl ether ($[\alpha]_D$ +132°) prepared from the known 2-*O*-α-D-glucopyranosyl-glycerol (1). By contrast, the fully methylated sirupy derivative of the known anomeric β-glucosyl-glycerol (9, 10) showed $[\alpha]_D$ −5° and gave an infrared absorption spectrum distinctly different from that of the α-derivative. A crystalline derivative suitable for characterization of other α-(4-*O*-methyl-D-glucopyranuronosyl)-aldobiuronic acids was provided by the complete *p*-nitrobenzoylation of 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-glycerol. This derivative may be prepared with perhaps as little as 10 mg. of the glycerol derivative and hence is more useful than the methyl ether for characterization of the α-anomer.

IV

The aldobiuronic acid from Mesquite gum, 4-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-galactose, was oxidized with 2 moles of lead tetraacetate. Reduction of the D-threose derivative with sodium borohydride afforded 2-*O*-(4-*O*-methyl-D-glucopyranuronosyl)-D-threitol (V), which was not crystalline. This compound was treated with diazomethane and the methyl ester was reduced with sodium borohydride. The material thus obtained proved to be a mixture containing the required sirupy 2-*O*-(4-*O*-methyl-D-glucopyranosyl)-D-threitol, which was obtained in poor yield after fractionation on a cellulose column. The comparatively low yield is probably due to the slow rate of lead tetraacetate oxidation of 4-substituted aldoses (10). The threitol portion was found to be cleaved preferentially by 1 mole of sodium periodate (11), since formaldehyde was formed in 98% yield. The resulting glyceraldehyde derivative was reduced to 2-*O*-(4-*O*-methyl-D-glucopyranosyl)-glycerol by sodium borohydride. Removal of trace amounts of impurity by fractionation on a cellulose column furnished a material having an $[\alpha]_D$ identical with that of the known α-anomer. Confirmation of the configuration was given by *p*-nitrobenzoylation of the glycerol derivative. The penta-*p*-nitrobenzoate formed was the α-anomer, since it had the same specific rotation, melting point, mixed melting point, and X-ray diffraction pattern as 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-glycerol penta-*p*-nitrobenzoate derived from the disaccharide obtained from *P. tacamahacca*.

EXPERIMENTAL

Optical rotations were measured at 27° C. Paper chromatography was carried out on Whatman No. 1 filter paper using *n*-butanol–ethanol–water (40:11:19 v/v) as solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(12) and ammoniacal silver nitrate (13) and *p*-anisidine hydrochloride (14) spray reagents. Solutions were concentrated at 50° C. under reduced pressure. Infrared absorption spectra were prepared by the potassium bromide window technique (15).

*2-O-α- and 2-O-β-*D*-Glucopyranosyl-glycerol Hexamethyl Ethers*

2-*O*-α-D-Glucopyranosyl-glycerol (2.26 g.) was dissolved in water (50 cc.) containing sodium hydroxide (20 g.), and methyl sulphate (18 cc.) was added dropwise to the stirred solution. The mixture was left overnight and the procedure repeated four times. It was then heated to 100° C. for 1 hour to destroy excess reagent, cooled, and brought to neutrality with sulphuric acid. The solution was evaporated to a solid which was extracted with ethanol. The extract was filtered and evaporated to a crust which was dissolved in water and extracted continuously with chloroform. Evaporation of the chloroform after drying with magnesium sulphate yielded a sirup which was extracted with light petroleum (b.p. 50–60° C.) (16). The petrol solution yielded the required hexamethyl ether (1.21 g.) as a sirup which had $[\alpha]_D$ +137° (*c*, 1.2, $CHCl_3$), +132° (*c*, 1.3, 2,4-lutidine), and n_D^9 1.4548. Calculated for $C_9H_{12}O_2(OCH_3)_6$: —OCH_3, 55.0%. Found: —OCH_3, 55.7%.

2-*O*-β-D-Glucopyranosyl-glycerol (145 mg.), using the same procedure, yielded the sirupy hexamethyl ether (60 mg.) which had $[\alpha]_D$ −8° (*c*, 1.2, $CHCl_3$), −5° (*c*, 1.1, 2,4-lutidine), and n_D^9 1.4532. Calculated for $C_9H_{12}O_2(OCH_3)_6$: —OCH_3, 55.0%. Found: —OCH_3, 55.3%.

*2-O-α-*D*-Glucopyranosyl-glycerol Hexamethyl Ether From 2-O-(4-O-Methyl-*D*-glucopyranuronosyl)-*D*-xylose*

The aldobiuronic acid (3.0 g.) was dissolved in water (50 cc.) and neutralized with aqueous sodium hydroxide. Sodium borohydride (1.0 g.) was added and after 2 hours excess reagent was destroyed with acetic acid. Sodium ions were removed with Amberlite IR-120 and the solution was filtered and evaporated to dryness. Boric acid was removed by repeated evaporations with methanol, the residue containing sirupy 2-*O*-α-(4-*O*-methyl-D-glucopyranuronosyl)-D-xylitol which was converted to its methyl ester (2.4 g.) using methanolic diazomethane.

The methyl ester (2.4 g.) obtained on evaporation was oxidized with 2.2 moles of lead tetraacetate for 20 hours in acetic acid (200 cc.) containing water (5 cc.). Most of the lead was removed by addition of 10% oxalic acid in acetic acid (15 cc.). The precipitate was filtered off and the solution evaporated to dryness. The 2-*O*-α-(4-*O*-methyl-D-glucopyranuronosyl)-L-glyceraldehyde methyl ester (contained in the residue) was reduced to 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-glycerol with sodium borohydride (1.0 g.) in water (50 cc.). After 18 hours the reaction mixture was worked up by the method described above. The sirupy product (1.79 g.) gave mainly a spot on a paper chromatogram with R_{rhamnose} 0.9 and small amounts of unidentified impurities. The mixture was fractionated on a cellulose column using *n*-butanol as solvent to yield a sirup having $[\alpha]_D$ +125° (*c*, 1.0, water) and which produced 4-*O*-methyl glucose and glycerol, identified chromatographically (17) (*p*-anisidine hydrochloride and ammoniacal silver nitrate sprays), on acid hydrolysis.

Methylation of a portion of the material (403 mg.) by the method described previously gave the hexamethyl ether (221 mg.) which had $[\alpha]_D$ +123° (*c*, 1.0, 2,4-lutidine), n_D^{10} 1.4552, and an infrared absorption spectrum indistinguishable from that of the known α-hexamethyl derivative, thus identifying it as the α-anomer. Calculated for $C_9H_{12}O_2(OCH_3)_6$: —OCH_3, 55.0%. Found: —OCH_3, 55.0%.

2-O-α(4-O-Methyl-D-glucopyranosyl)-glycerol Penta-p-nitrobenzoate

The glycerol derivative (85 mg.) was heated on a steam bath for 1 hour with *p*-nitrobenzoyl chloride (600 mg.) in pyridine (4 cc.) (18). The reaction mixture was added to excess aqueous sodium bicarbonate and stirring was continued overnight. The product was filtered off and recrystallized twice from ethyl acetate. Yield, 94 mg. The crystals had m.p. 207–209° C. and $[\alpha]_D$ +95° (*c*, 1.0, 2,4-lutidine). Calculated for $C_{45}H_{35}O_{23}N_5$: C, 53.31%; H, 3.48%. Found: C, 53.17%; H, 3.42%.

2-O-α-(4-O-Methyl-D-glucopyranosyl)-glycerol Penta-p-nitrobenzoate from 4-O-(4-O-Methyl-D-glucopyranuronosyl)-D-galactose

Partially degraded Mesquite gum (50 g.) was further hydrolyzed with strong acid by the method of Smith (5), and the aldobiuronic acids obtained by treatment of the mixed barium salts (16 g.) with Amberlite IR-120 were fractionated on a cellulose column using ethyl acetate – acetic acid – water (3:1:1 v/v) as solvent. The required 4-*O*-methyl-glucuronosyl-aldobiuronic acid (2.2 g.) was thus obtained.

The acid (0.88 g.) in methanol (200 cc.) was treated with excess ethereal diazomethane. The solution was evaporated to a sirup which was oxidized for 2½ hours with 2 moles of lead tetraacetate (2.11 g.) in acetic acid (200 cc.) and water (3 cc.). Lead was removed by addition of 10% oxalic acid in acetic acid (4.5 cc.); the solution was filtered and then evaporated to dryness.

Treatment of the methyl ester derivative contained in the residue with sodium borohydride (1.5 g.) in water (100 cc.) for 18 hours afforded the reduced material (0.52 g.) after the solution was worked up in the prescribed way. Two main spots were observed on the paper chromatogram using the silver nitrate spray. They had $R_{\text{galactose}}$ 2.0 and 2.3 respectively, and the mixture was fractionated on a cellulose column using *n*-butanol one-half saturated with water as solvent. The faster material isolated (125 mg.) gave $[\alpha]_D$ +80° (*c*, 2.0, water), and was considered to be the required 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-D-threitol. It gave spots corresponding to 4-*O*-methyl glucose and threitol on a paper chromatogram (*p*-anisidine hydrochloride and ammoniacal silver nitrate sprays) on acid hydrolysis, and consumed 1.9 moles of sodium periodate in 20 hours. Also, when oxidized with 1 molar portions of sodium periodate and lead tetraacetate, 0.98 and 0.87 moles of formaldehyde, respectively, were formed, as estimated by the chromotropic acid method (19).

Therefore, the threitol derivative (101 mg.) was oxidized with 1 mole of sodium periodate in water (10 cc.). After 18 hours the solution was treated with Amberlite IR-120, and after removal of the resin, barium carbonate was added to remove iodic and periodic acids. The insoluble material was filtered off, the filtrate evaporated to dryness, and the residue extracted with methanol. The methanolic solution was treated with sodium borohydride (25 mg.) and after it had been left for 3 hours the required 2-*O*-α-(4-*O*-methyl-D-glucopyranosyl)-glycerol was isolated. Yield, 82 mg. Minor impurities were shown to be present on a paper chromatogram and these were removed by fractionating the product on a cellulose column using *n*-butanol as solvent. The pure glycerol derivative (60 mg.) had $[\alpha]_D$ +125° (*c*, 1.0, water).

A portion (45 mg.) was characterized by conversion to its penta-*p*-nitrobenzoate derivative. Yield, 65 mg., m.p. 208–210° C., and $[\alpha]_D$ +94° (*c*, 0.8, 2,4-lutidine) after two recrystallizations from ethyl acetate. It was indistinguishable from the penta-*p*-nitrobenzoate derived from 2-*O*-α-(4-*O*-methyl-D-glucopyranuronosyl)-D-xylose by comparison of X-ray diffraction patterns; no depression of the melting point on mixing was observed. Calculated for $C_{45}H_{35}O_{23}N_5$: C, 53.32%; H, 3.48%. Found: C, 53.28%; H, 3.19%.

THE CONDUCTANCES OF AQUEOUS SOLUTIONS OF LITHIUM CHLORATE AT 25.00° C. AND AT 131.8° C.[1]

A. N. Campbell and W. G. Paterson[2]

ABSTRACT

The conductances, densities, and viscosities of aqueous solutions of lithium chlorate have been obtained over the complete range of concentration at 131.8° C. and up to saturation (and somewhat beyond) at 25.00° C. The curve of specific conductance versus concentration passes through a maximum which does not shift noticeably in composition with change in temperature. There are no minima on the curves of equivalent conductance versus concentration. The relative viscosity of the solutions decreases with rise in temperature; this is the reverse of the effect usually observed.

The experimental results have been compared with the calculated results, obtained by the use of the equations of Wishaw and Stokes and of Falkenhagen.

An extensive study of the conductances and viscosities of concentrated aqueous electrolytic solutions has been going on in this laboratory for several years. The salts suitable for this work are such as show a wide concentration range. The salts investigated have been: ammonium nitrate at 25°, 35°, 95°, and 180° C. (1, 2, 3, 4); silver nitrate at 25°, 35°, 95°, and 221.7° C. (1, 2, 3, 4); and lithium nitrate at 25° and 110° C. (5, 6).

The conductances of aqueous solutions of lithium chlorate over a wide range of concentration and at several temperatures are reported in the literature but, for various reasons, the work is either inadequate or erroneous. Kraus and Burgess (7) give data on conductance at a series of temperatures but they were primarily interested in the conductance of lithium chlorate on the addition of small amounts of water and their data are incomplete at 25° C. Accurate measurements have been made by Scatchard (8) and co-workers in the dilute range at 10° C. The investigations of Klotschko and Grigorjew (9) cover a wide range of concentrations at six different temperatures, one of which is 25° C. These authors prefer the specific to the equivalent conductance as a basis of theoretical interpretation. When their results are plotted against concentration, it becomes evident that there is a considerable scattering of points on the graph. Their results are too inaccurate to be of any value; for example, the specific conductance of their weakest solution at 25° C. yields a value of equivalent conductance greatly in excess of the limiting conductance as calculated from the sum of the limiting ionic conductances of lithium and chlorate ions. Further, when their curves of density or viscosity versus concentration are extrapolated to zero concentration, the values for the density or viscosity of pure water so obtained are considerably different from the accepted values.

EXPERIMENTAL PROCEDURE

Lithium chlorate was prepared and dried by the method of Campbell and Griffiths (10). Since lithium chlorate is exceedingly hygroscopic, it is not possible to make up solutions of defined concentration by weighing; all solutions must be analyzed. In view of the difficulties inherent in the direct determination of lithium or chlorate radical, the following simple and satisfactory procedure was adopted for arriving at lithium chlorate content. A weighed sample of solution was treated with excess concentrated sulphuric acid and evaporated to dryness in a Vycor dish; platinum cannot be used. The resulting

[1]*Manuscript received April 1, 1957.*

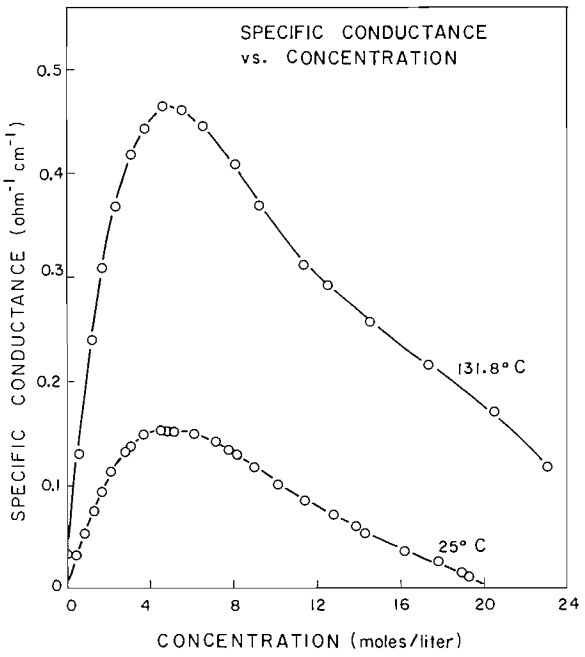

FIG. 1.

lithium sulphate was ignited to constant weight. The procedure was tested on sodium chlorate and it was found that an accuracy of 0.01% was attainable.

The density of each solution of lithium chlorate was determined and thus it was possible to plot a graph of weight per cent versus density of solution. Interpolation from this graph then became the analytical method used for the remainder of the research, with a consequent great saving of time.

Our technique of conductance measurements has been described previously (1, 2, 3, 4). In order, however, to keep down the voltage output of the audio-oscillator and avoid heating of the solution in the conductance cell, a simple triode-type amplifier was introduced in the telephone circuit.

For work at 131.8° C., where the vapor pressure of the solution exceeds 1 atm., the conductance cells were placed in a closed bomb; the technique has been described previously (4). The solvent water was distilled water having a specific conductance of less than 5×10^{-6} mhos and this is more than sufficiently low for work on concentrated solutions ($c > 0.01$ N).

The cell constants were obtained in the usual way. The standard potassium chloride solutions of Jones and Bradshaw (11) refer to 25° C. and it is not immediately obvious that cell constants obtained for 25° C. are good at other temperatures. Washburn (12), however, has shown how to calculate the cell constant at a temperature other than 25° C., from the value at 25° C. For cells constructed of Pyrex and platinum the change in cell constant is very slight. The correction for our cells for the change in temperature from 25° C. to 131.8° C. was about 0.03% and it was always applied.

Solutions were prepared from a concentrated stock solution, of known strength, by dilution with water. The exact concentration was then obtained from the density. Density was usually determined with a Weld pycnometer but for the anhydrous melt at

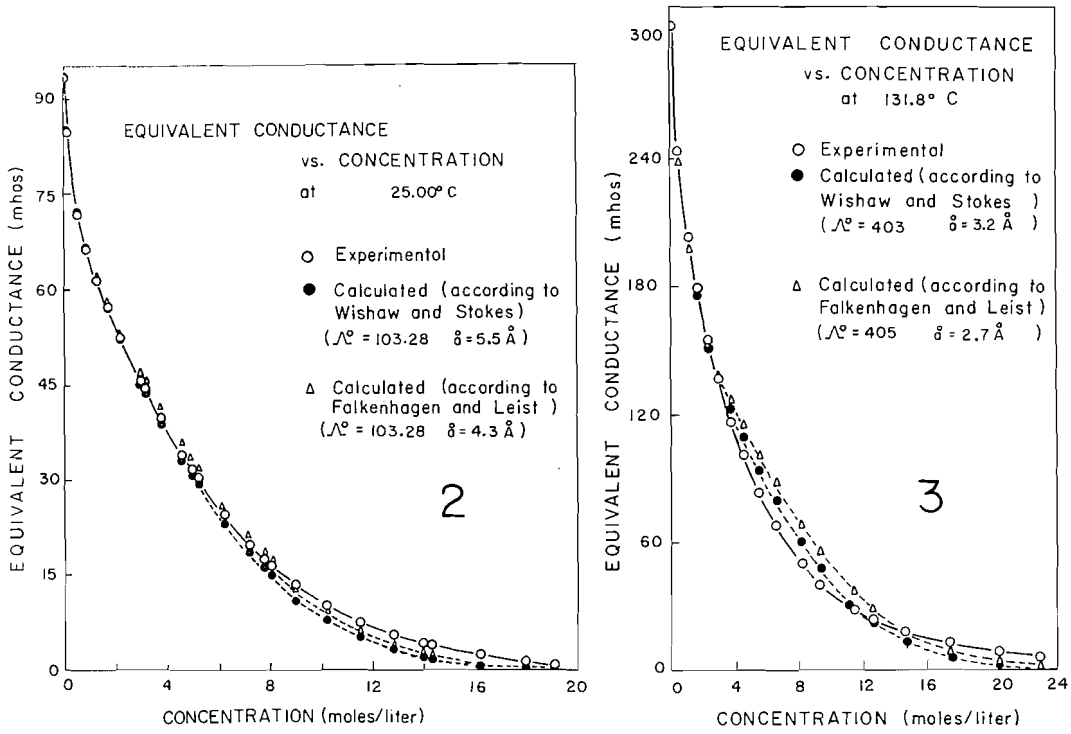

FIGS. 2 and 3.

131.8° C. a special type of filling and of pycnometer were used. This has also been described (4).

EXPERIMENTAL RESULTS

The experimental values of weight per cent, molarity, density, relative viscosity, specific conductance, and equivalent conductance, observed and calculated from the equations of Stokes and of Falkenhagen, are recorded in Tables I and II. The conductance measurements are limited to an accuracy of 0.1% and the density figures may be in error in the fourth decimal place. Plots of specific conductance and of equivalent conductance (observed and calculated) versus concentration at 25.00° C. and 131.8° C. are represented in Figs. 1 to 3. Fig. 4 is a plot of relative viscosity versus concentration at the two temperatures.

DISCUSSION OF RESULTS

The existence of maxima in the curves of specific conductance versus concentration is of interest, since it means that, for concentrations beyond that of the maximum, solutions containing more electrolyte have a lower conductance than solutions containing less electrolyte, that is, either the total number of ions is decreasing, or their mobility or both. For instance, the conductance at 131.8° C. of a 10 molar solution is the same as that of a 2 molar solution, despite a fivefold increase in electrolyte concentration. Such maxima are recorded only infrequently in the literature because of the lack of experimental investigations in the high concentration range.

The concentration corresponding to the maximum does not shift noticeably with

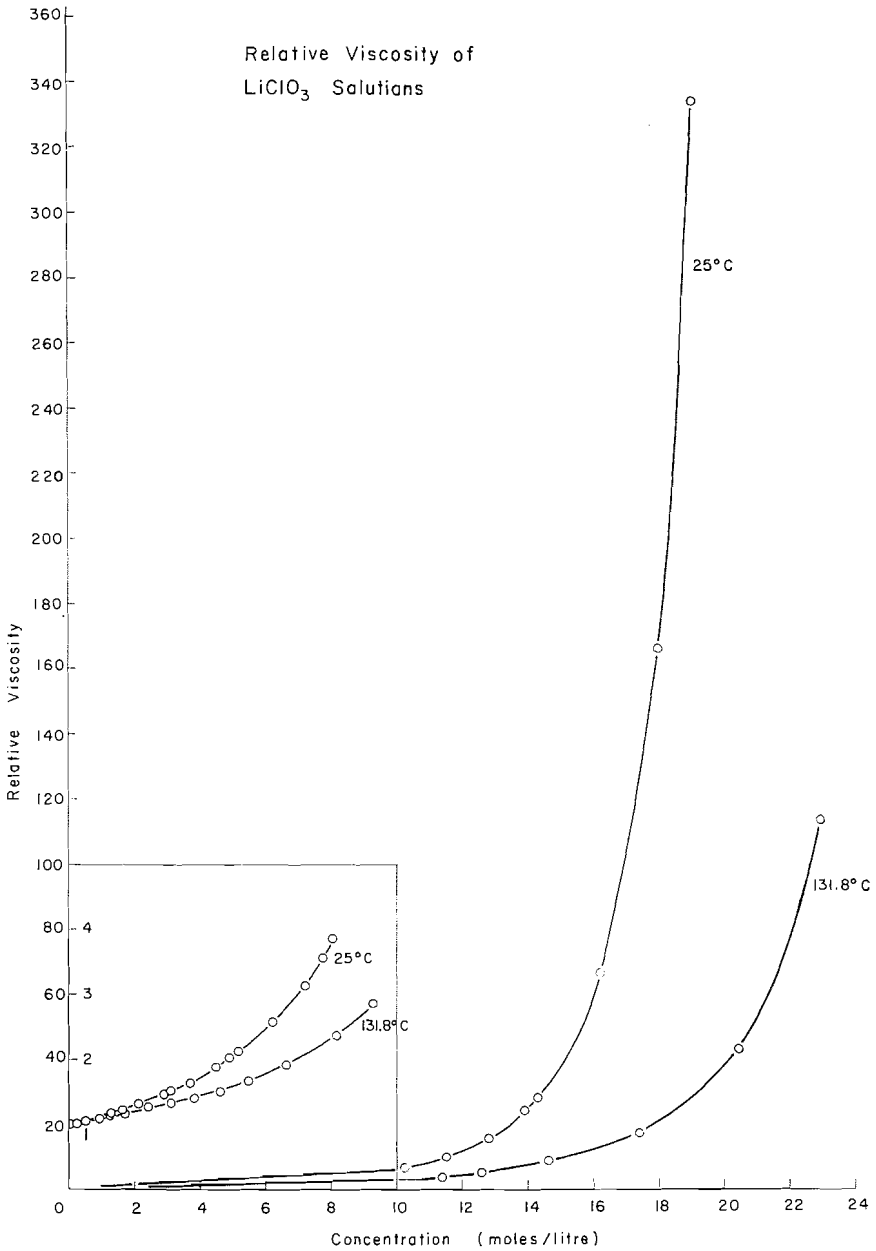

FIG. 4.

temperature, and this was observed by Klotschko and Grigorjew (9), who seek to connect this with the equilibrium diagram of the system lithium chlorate – water but there is, of course, no necessary connection whatever between the two. If it is assumed that strong electrolytes are completely ionized, no matter what the concentration, then the existence of the maximum points to a marked slowing down of the ions. Obviously, the electrical effects considered by the Debye–Hückel-Onsager theory will become very marked but the picture is complicated by changes in the hydration of the ions. At high concentrations,

all solvent molecules must be tightly held by ions; there will be little or no "free" water. This should produce, as it does, a very great increase in viscosity and this factor also tends to slow down the ions. The exact effect of viscosity on the motion of ions has not yet been formulated but it must be considerable, and is probably due in very concentrated solutions to interionic effects. Presumably, the effect is not measured simply by the bulk viscosity but there must be some connection.

The plots of equivalent conductance versus concentration (Figs. 2 and 3) show a progressive decrease in equivalent conductance with increasing concentration. At the higher temperature (131.8° C.) it was possible to cover the entire range of concentration up to anhydrous melt but no minimum is observed. Minima are found with electrolytes in solvents of relatively low dielectric constant and the meaning is discussed by Fuoss and Kraus (13). Their explanation is that non-conducting ion-pairs are first formed, followed, at high concentration, by conducting triple ions. It is apparent that, for all the salts investigated in this laboratory, no triple ions are formed. It is often contended that ion pairs cannot form in aqueous solution, because of the high dielectric constant of the medium but, in these very concentrated solutions, it becomes difficult to say what the medium is and therefore to state the dielectric constant. We think it unlikely that ion pairs will form in any lithium salt solution while there is still sufficient water present to preserve the very stable structure of the hydrated ion, but in very concentrated solutions, because of the proximity of the ions, formation of ion pairs must be considered probable. It should be pointed out that the last three figures of Table I refer to supersaturated solutions, which were easy to obtain.

The theory of extremely dilute solutions is well developed but there is no entirely satisfactory theory covering the conductance of concentrated solutions. The Debye–Hückel–Onsager theory has been extended by Fuoss and Onsager (14), by Wishaw and Stokes (15), and by Falkenhagen, Leist, and Kelbg (16). In every case, the extension consists in attributing to the ions a finite diameter, a, instead of considering them as mathematical points. In order to apply any of the above equations to more concentrated solutions, a viscosity correction must be used. Most authors, if they venture into this region at all, content themselves with dividing the calculated equivalent conductance by the relative viscosity. It has been suggested by Stokes (private communication) that it might be better to divide by some (fractional) power of the viscosity. Other workers, on the other hand, contend that because of the assumed complexity of concentrated solutions it is fruitless to pursue this line of investigation beyond, say, 0.1 N. It is our opinion, however, that solutions of moderate concentration are not so complicated in structure and that the Debye–Hückel–Onsager approach can be pursued further, if an appropriate viscosity correction can be found. It must be admitted that when the water content is reduced so low that there is not sufficient water present to hydrate the ions completely (notably in the present case of lithium chlorate) it is absurd to consider the ionic diameter as constant. It is therefore surprising that the equations of Wishaw and Stokes and of Falkenhagen to represent the general course of the equivalent conductance versus concentration curves rather well.

Papers proceeding from this laboratory have, since 1952, made extensive reference to the conductance equation of Wishaw and Stokes (15); no theoretical treatment is therefore necessary here. A somewhat similar equation is due to Falkenhagen and Leist (16); for uni-univalent electrolytes, the equation assumes the form:

$$\Lambda = \Lambda_0 \cdot \frac{\eta_0}{\eta} - \frac{e^2}{3\epsilon kT} \cdot \frac{\kappa}{1+\kappa a} \cdot \Lambda_0 \cdot \frac{\eta_0}{\eta} \cdot \frac{q}{(1+\sqrt{q})(1+\kappa a\sqrt{q})} - \frac{ne^2}{3\pi\eta_0} \cdot \frac{1000}{C\times 9\times 10^{11}} \cdot \frac{\kappa}{1+\kappa a} \cdot \frac{\eta_0}{\eta} \cdot$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The symbols have their usual significance, except that $q = \frac{1}{2}$ for 1:1 electrolytes, n is the number of ions of a given type per cubic centimeter, and C is the concentration in moles per liter. We have used both the equations of Wishaw and Stokes and of Falkenhagen and Leist to calculate Λ for the concentrations used by us. These results are compared with our experimental results in Tables I and II and graphically in Figs. 2 and 3.

Quite recently, Professor Falkenhagen, in a private communication, has stated the most recent form of his conductance equation as:

[1] $$\Lambda = \Lambda_0 - \Lambda_I - \Lambda_{II} \qquad \text{(general formulation)}$$

where Λ_I represents the relaxation effect and Λ_{II} the electrophoretic effect:

[2] $$\Lambda_I = \frac{e^2\Lambda_0}{GD_0kT} \cdot \frac{(2-\sqrt{2})\kappa}{(1+\kappa a)(1+\frac{1}{2}\sqrt{2}\,.\,\kappa a+\frac{1}{6}\kappa^2a^2)},$$

[3] $$\Lambda_{II} = \frac{e^2L}{27\pi\times 10^{11}\eta_0} \cdot \frac{\kappa}{1+\kappa a}.$$

The symbols have their usual significance except that L = Avogadro's number. We have used this equation to calculate Λ for lithium chlorate at 25.00° C. These results, for concentrations ranging from 0.0219 M to 6.199 M, are given in Table III. We have slightly altered å from 4.3 to 4.1 Å, for this purpose. The agreement is very good. Up to 0.5121

TABLE III

COMPARISON OF OBSERVED CONDUCTANCES AND THOSE CALCULATED BY FALKENHAGEN'S MOST RECENT EQUATION: LITHIUM CHLORATE SOLUTIONS AT 25.0° C.

$\Lambda^* = \Lambda_{calc}$ uncorrected for viscosity.
$\Lambda' = \Lambda_{calc}$ corrected for viscosity.

M, the discrepancy is negligible. After this, the error of the calculated quantity becomes increasingly positive and amounts to 4.76% of the observed result at 6.199 M. Beyond 6 M, the difference between the results of the two Falkenhagen equations is negligible, so there is no point in carrying the new calculations beyond this. Neither have we calculated for 131.8° C., with the more recent equation, because our complete ignorance of the value of Λ_0 at 131.8° makes it impossible to impose a fair test. According to Falkenhagen himself, his most recent equation is on sound theoretical ground as long as $Ka << 1$. Beyond this point, a viscosity correction must be introduced. It has always been the fashion to divide the calculated conductance by the relative viscosity and, if this is done, the following equation results:

$$\Lambda_c = (\eta_0/\eta)\{\Lambda_0 - \Lambda_I - \Lambda_{II}\}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Equations such as the above, however, must at best be described as "semi-empirical", since the exact form of the viscosity correction is not known. Falkenhagen and Leist (16) test the (original) equation by using the data for the conductance of lithium chloride solutions at 18° C. Using a value of å = 4.8 Å, they obtain very good agreement with the experimental data; at a concentration of 10 molar the experimental and calculated equivalent conductances differ by less than one mho. Some of the agreement may be fortuitous, since the equation is not really justified at such high concentrations, but it does indicate that dividing by the relative viscosity is at least an approximation to the truth. For our own results Stokes' suggestion of dividing by some power of the viscosity, other than one, can very well be met by using the power 1.05, that is, by dividing the calculated conductance by $(\eta/\eta_0)^{1.05}$; calculated and observed results then agree very well up to 6 *M*. Since, however, this is a purely empirical procedure, there being no reason to use this power, or any other, of the viscosity, except to force the calculated results into agreement with the observed values, we think it better to continue the older practice of simply dividing by the relative viscosity and to attribute deviations to shortcomings in the equation. Obviously, there must be many phenomena in concentrated solutions which are not covered by the Falkenhagen treatment, which must be oversimplified for very concentrated solutions.

The new equation of Falkenhagen yields better results than that of Wishaw and Stokes (15). In all such equations, the choice of å is quite arbitrary. For example, in calculating for lithium chloride, Falkenhagen and Leist use a value of å of 4.8 Å; the calculations of Wishaw and Stokes are based on å = 5.2 Å, and Fuoss and Onsager (14) use 4.31 Å in their calculations for the dilute region.

In order to calculate Λ, Λ_0 must be known and a reasonable value for å, the distance of closest approach of the ions, must be assumed. At 25.0° C., the only uncertain parameter is the latter quantity. Two series of calculations have been made (Wishaw–Stokes equation), using slightly different values of this parameter. To obtain a good fit with the Falkenhagen equation, significantly different values of å had to be used. At the higher temperature, the difficulty of not knowing Λ_0 is an additional handicap. For each value of å, we have used a slightly different value of Λ_0. Although Stokes maintains that å is temperature independent we have used a smaller value of å for the higher temperature.

Again, all equations assume constancy of å with increasing concentration. In fact, however, and assuming again that å is a real quantity, the distance of closest approach must decrease with increasing concentration, because a concentration is eventually reached where there is no longer sufficient water in the solution to maintain extensive hydration.

ACKNOWLEDGMENTS

We are indebted to Dr. E. M. Kartzmark for her assistance in the preparation of this paper and with the calculations. As in all work proceeding from this laboratory, most of the expense of the research was borne by a research fund supplied by the National Research Council.

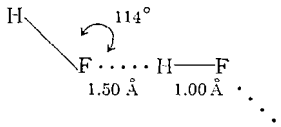
SPECTRE INFRAROUGE DE HF À L'ÉTAT CRISTALLIN[1]

PAUL A. GIGUÈRE ET NUMAN ZENGIN[2]

RÉSUMÉ

On a mesuré le spectre d'absorption infrarouge entre 300 et 5000 cm.$^{-1}$ de minces films de HF cristallisé à −180° C. La vibration fondamentale produit un doublet intense à 3420 et 3060 cm.$^{-1}$ et un second, plus faible, à 3590 et 3270 cm.$^{-1}$. Toutes les caractéristiques du spectre concordent avec les données actuelles sur la structure cristalline de HF: chaînes parallèles, en zigzag, de molécules reliées par des liaisons hydrogène asymétriques. On a également déduit les dimensions approximatives suivantes:



La haute polarité de la molécule et les fortes liaisons hydrogène se manifestent de plusieurs façons: largeur exceptionnelle des bandes (de 150 à 200 cm.$^{-1}$); grand espacement des diverses composantes de la fondamentale dans le cristal; abaissement considérable (quelque 700 cm.$^{-1}$) de la fréquence fondamentale en passant de la molécule libre au solide, résultant d'une diminution de la force de rappel de 8.8 à 6.3×10^5 dynes/cm.; fréquences de libration élevées (1000–1200 cm.$^{-1}$) et forces de rappel intermoléculaires allant jusqu'à 0.6×10^5 dynes/cm.

Les spectres infrarouges et Raman des cristaux moléculaires peuvent fournir des indications précieuses sur l'arrangement des molécules à l'état solide ainsi que sur les forces intermoléculaires. Cette information est particulièrement utile dans le cas des composés de l'hydrogène puisque la diffraction aux rayons X ne permet pas de localiser ces atomes avec précision. Jusqu'à présent on a étudié par ces méthodes les halogénures HCl, HBr et HI (1, 2, 3, 4) mais aucun travail n'est encore paru sur HF à l'état solide. La raison principale en est sans doute la difficulté que présente la manipulation de ce composé extrêmement corrosif. De plus sa tendance marquée à la fluorescence rend presque impossible l'étude de l'effet Raman dans les états condensés. Ainsi une étude récente du spectre Raman de l'acide liquéfié (5) n'a révélé aucune indication de la vibration fondamentale.

MÉTHODE EXPÉRIMENTALE

À cause de la grande réactivité de l'acide fluorhydrique, et en particulier de son action sur le verre, il a fallu des précautions spéciales pour préparer les échantillons. Le gaz, contenu dans un cylindre de fer, était censé pur à 99.9%.* Les seules traces d'impuretés susceptibles d'affecter les résultats (H_2O, 0.04%; H_2S, 0.02%; SO_2, 0.01%) étaient à peine visibles dans les spectres des films les plus épais. Le gaz était transféré sous pression réduite dans un réservoir de cuivre d'environ un demi-litre d'où il était admis par petites bouffées dans la cellule d'absorption. Celle-ci était en verre, du type courant (6); les parois internes étaient recouvertes d'un enduit résistant à l'acide fluorhydrique. À cette fin nous avons d'abord employé une couche suffisamment épaisse de vernis Glyptal qui offre une protection efficace mais finit par se détacher du verre après un certain temps. Par la suite nous y avons substitué la cire Halocarbon 15-00,† également inerte, qui adhère

indéfiniment au verre. Les fenêtres de la cellule étaient faites de disques de chlorure d'argent sauf pour les mesures au-delà de 25 μ où il fallut recourir à l'iodure de césium. Le disque central, sur lequel se condensait le film de HF, était fait des mêmes matériaux; dans le cas de l'iodure de césium un mince film de polyéthylène, suffisamment transparent jusqu'à 40 μ, empêchait l'attaque par l'acide fluorhydrique.

Les canalisations, réduites au minimum, étaient de cuivre rouge. Un robinet à pointeau en laiton permettait de contrôler le débit du gaz; un manomètre de Bourdon à capsule de cuivre indiquait la pression dans le réservoir. Le seul robinet en verre sur la cellule à absorption était lubréfié avec de la graisse Fluorolube MG.* La moindre attaque des parois par l'acide se traduisait par l'apparition dans les spectres de bandes d'absorption des fluosilicates. L'épaisseur des films, telle qu'évaluée d'après la quantité de gaz utilisé et l'étendue de la surface froide, dans l'hypothèse d'une condensation uniforme, variait entre 3 et 5 μ. Leur température n'a pas été mesurée avec précision mais elle devait être d'environ $-180°$ C. avec l'air liquide comme réfrigérant. Les spectres furent enregistrés au moyen d'un spectrographe de Perkin-Elmer, Modèle 12C à double passage. Suivant la région nous avons utilisé des prismes de LiF, NaCl et CsBr calibrés de la façon usuelle (7).

RÉSULTATS

Les bandes d'absorption infrarouges de HF cristallisé se divisent en deux groupes distincts: les fondamentales, de 2.8 à 3.5 μ (Fig. 1) et les vibrations du réseau, au-delà de 6 μ (Fig. 2). Le premier groupe comprend le doublet principal à 3420 et 3060 cm.$^{-1}$. Vu la largeur considérable de ces bandes et leur proximité relative il était difficile de déterminer avec plus de précision la position des maxima. Un second doublet beaucoup moins intense que le premier, à 3590 et 3270 cm.$^{-1}$ présente quelque difficulté d'interprétation. À première vue on pourrait l'attribuer à des combinaisons (somme-différence) des fréquences fondamentales avec une vibration du réseau de l'ordre de 200 cm.$^{-1}$. Cependant les intervalles de fréquence, soient 170, 150 et 210 cm.$^{-1}$ respectivement, ne concordent pas assez bien à cette fin. De plus on devrait s'attendre à trouver une bande semblable vers 2860 cm.$^{-1}$ alors qu'en fait on n'observe qu'un renflement à peine perceptible. Étant donnée la ressemblance générale, à des échelles différentes, des deux doublets il semble plus probable que nous avons affaire ici aux quatre composantes de la vibration fondamentale, puisqu'il y a quatre molécules de HF dans la maille cristalline (8). Normalement deux des composantes devraient être actives en infrarouge et deux en Raman. Cependant il n'est pas inconcevable que toutes quatre apparaissent en infrarouge, surtout si on considère la possibilité de désordre dans la structure du cristal (distribution statistique des liaisons hydrogène) qui détruit la symétrie des sites.

Quant à la bande très floue déjà mentionnée aux environs de 2860 cm.$^{-1}$, et visible seulement dans les échantillons les plus épais, elle peut provenir d'une combinaison d'une fondamentale avec une vibration de réseau ou encore de quelque impureté. Hornig (2) a trouvé une bande analogue à 2616 cm.$^{-1}$ dans le spectre de HCl crystallisé. L'ion H_3O^+ possède une faible bande à cet endroit dans les solutions aqueuses d'acides (9) mais comme nous n'avons pu déceler aucune trace d'absorption vers 1700 cm.$^{-1}$, cette explication se trouve éliminée. Il convient d'ajouter ici qu'aucune indication d'harmoniques ni de bandes de combinaison n'est apparue entre 4000 et 5000 cm.$^{-1}$ probablement parce que les films utilisés étaient trop minces.

Du côté des grandes longueurs d'onde outre une demi-douzaine de bandes extrêmement faibles provenant, semble-t-il, d'impuretés (SO_2, H_2S, etc.), on trouve quatre ou cinq

FIG. 2. Bandes de vibration du réseau cristallin de HF.

bandes assez fortes à 366, 547, 955–1010 et 1204 cm.$^{-1}$. La courbe médiane dans les figures 1 et 2 a été obtenue avec le même échantillon en sorte que les intensités relatives des deux groupes de bandes sont reproduites assez fidèlement. Pour attribuer sans équivoque ces bandes aux divers modes de vibration du réseau cristallin il faudrait connaître le spectre Raman de HF cristallin. À titre d'essai on peut assigner le doublet non résolu à 955–1010 cm.$^{-1}$ ainsi que la bande assez large à 1204 cm.$^{-1}$ à des rotations gênées ou librations. A priori ces fréquences semblent passablement élevées pour de tels modes mais cette situation s'explique par la petitesse du moment d'inertie de la molécule HF ainsi que par l'énergie relativement grande des liaisons hydrogène dans cette substance. Par ailleurs le pic aigu à 366 cm.$^{-1}$ est de fréquence appropriée pour une translation comme on le verra plus loin d'après les forces de rappel intermoléculaires. Enfin l'origine de la

forte bande asymétrique surmontée d'un pic aigu à 547 cm.$^{-1}$ demeure incertaine. Sa fréquence paraît trop élevée pour une translation et un peu basse pour une libration; son intensité est également trop grande pour une harmonique de ν_T. Il se peut qu'elle provienne de mouvements de torsion des chaînes.

DISCUSSION

L'analyse de ces résultats se trouve facilitée par l'étude très poussée de Hornig et son groupe (1, 2, 3, 4) sur les spectres infrarouges de HCl, HBr et HI ainsi que par la détermination par les rayons X de la structure cristalline de HF (8). Ainsi l'on sait que ce cristal orthorhombique contient quatre molécules par maille, avec la symétrie du groupe infini $D_{24}{}^{17}$, quoique la symétrie $D_{24}{}^{16}$ ne soit pas définitivement exclue. Les molécules, reliées par des liaisons hydrogène, forment des chaînes en zigzag quasi-infinies, coplanaires et parallèles au plan 100 (Fig. 3); l'angle entre les molécules adjacentes est de 120°. Une telle structure implique des liaisons hydrogène orientées selon une direction privilégiée, ce qui semble en contradiction avec la nature essentiellement électrostatique de ce genre de liaisons. Cependant Schneider (10) a démontré récemment, en se servant du concept d'orbitale équivalente (11), le rôle important que jouent dans la formation de la liaison hydrogène les "doublets libres" sur l'atome accepteur de proton. À cause de l'hybridation des orbitales du fluor (sp^3) les molécules de HF tendent donc à s'orienter mutuellement suivant un angle à peu près tétragonal.

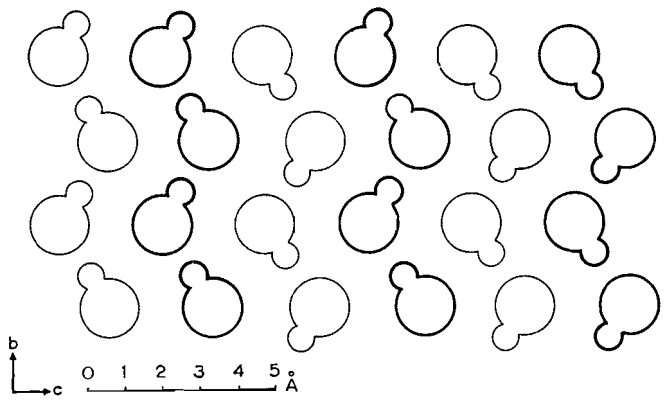

FIG. 3. Arrangement désordonné des chaînes de HF dans deux plans 100 successifs.

Les bandes fondamentales de HF cristallin sont d'abord remarquables par leur grande largeur: de 150 à 200 cm.$^{-1}$ à comparer avec 10 ou 20 cm.$^{-1}$ pour les autres halogénures HX. Cette caractéristique bien connue des composés contenant des liaisons hydrogène a suscité de nombreuses explications. Dans le cas de HF il n'est pas impossible que l'élargissement des bandes soit dû pour une part à un certain désordre dans le cristal. En effet l'analyse aux rayons X a montré la possibilité d'une distribution statistique des liaisons hydrogène, telle que représentée sur la figure 3. Les données présentes favorisent cette explication sans toutefois trancher la question; pour ce faire il faudra recourir à des méthodes plus puissantes telle la diffraction des neutrons. De toute façon ce désordre, s'il existe, ne conduit à aucune entropie résiduelle au zéro absolu puisqu'il ne fait intervenir que deux configurations différentes pour chaque chaîne (8). Contrairement aux autres halogénures d'hydrogène qui présentent à l'état solide des transitions du premier

For personal use only.

ou du second ordre, HF garde la même structure cristalline à toute température. Il est évident qu'à cause de la grande polarité de la molécule et des fortes liaisons hydrogène les molécules n'ont pas la liberté de se réorienter dans le cristal.

La fréquence élevée des vibrations fondamentales confirme sans équivoque que la liaison F—H · · · F est asymétrique dans HF à l'état solide contrairement au cas exceptionnel de l'ion HF_2^- (10). Un calcul approximatif basé sur la règle de Badger conduit, à partir d'une fréquence moyenne de 3300 cm.$^{-1}$, à une distance H—F d'environ 1.00 Å. Comme la diffraction aux rayons X a donné 2.49 Å pour la distance minimum entre deux atomes de fluor voisins, il s'ensuit que les liaisons hydrogène sont d'à peu près 1.50 Å dans ce cristal. Dans la vapeur la distance F—H · · · F dans les polymères est de 2.55 Å (12) tandis que dans la molécule libre la distance interatomique est de 0.917 Å (13). On voit donc que les liaisons hydrogène dans HF sont notablement plus courtes, et partant plus fortes, que dans H_2O (1.75 Å); dans cette dernière substance le passage de la vapeur au solide allonge la liaison O—H de 0.96 à 1.01 Å (14).

À la suite de l'analyse de Hornig on sait que dans les cristaux des composés polaires du type HX le rapport des intensités des deux composantes fondamentales I_x et I_y dans le spectre infrarouge varie suivant l'angle α entre molécules voisines d'après la relation

$$I_x/I_y = \tan^2\alpha/2.$$

Des mesures faites sur cinq spectres différents de HF nous ont donné pour le rapport d'intensité des deux bandes à 3420 et 3060 cm.$^{-1}$ les valeurs: 2.31, 2.32, 2.38, 2.42 et 2.48 qui correspondent à des angles allant de 113° à 115°. L'accord avec le valeur trouvée par diffraction des rayons X, 120.1° (8), est satisfaisant surtout si l'on songe à l'incertitude des mesures d'intensité dans le cas présent. Par ailleurs l'écart entre ces diverses valeurs de α est beaucoup moindre que pour HCl et HBr (2). La possibilité, mentionnée par Hornig, d'une orientation partielle des films est évidemment minime pour une substance aussi polaire que HF. De toute façon on n'a jamais observé de différence notable entre les spectres de films déposés sur AgCl et sur NaCl, du moins dans la région de 300 à 1000 cm.$^{-1}$. Notons que des mesures d'intensité faites sur le doublet secondaire à 3590 et 3270 cm.$^{-1}$ conduisent à un angle voisin de 100°, bien que la précision des mesures soit évidemment assez faible ici. Ce résultat renforce l'hypothèse des deux composantes fondamentales déjà invoquée pour ces bandes.

Forces de rappel

Les présents résultats permettent d'évaluer les forces de rappel tant pour la molécule que pour le cristal. Qualitativement l'existence de forces intermoléculaires considérables

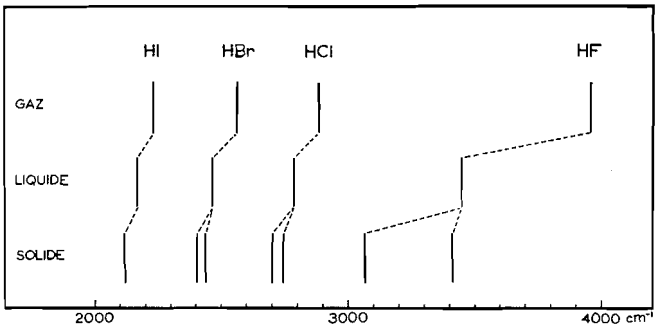

FIG. 4. Comparaison des fréquences de vibration des halogénures d'hydrogène dans les trois états physiques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

dans le cristal de HF se manifeste de trois façons: (*a*) un abaissement inusité de la vibration fondamentale en passant de la molécule libre, 3962 cm.$^{-1}$ (13) au cristal (Fig. 4); (*b*) la séparation extrêmement grande entre les composantes de la vibration fondamentale à l'état solide et enfin; (*c*) les valeurs très élevées des fréquences de libration. Ces observations sont en accord avec le caractère ionique marqué de la liaison H—F et les fortes liaisons hydrogène, 6.7 kcal./mole, selon Pauling (15), qui persistent même à l'état de vapeur.

Nous avons d'abord calculé les forces de rappel, tant principale que secondaires, à partir des quatre présumées composantes de la vibration fondamentale en supposant que le couplage entre les vibrations internes et externes des molécules dans le cristal est faible. Cette hypothèse est naturellement moins justifiable pour HF que pour les autres halogénures d'hydrogène mais elle tient encore en première approximation. En assignant arbitrairement les quatre fréquences comme suit:

$$\nu_1 = 3270 \text{ cm.}^{-1},$$
$$\nu_2 = 3060 \text{ cm.}^{-1},$$
$$\nu_3 = 3420 \text{ cm.}^{-1},$$
$$\nu_4 = 3590 \text{ cm.}^{-1},$$

on arrive aux valeurs suivantes (la notation est celle de Hornig):

$$f_{11} = 6.31\times10^5 \text{ dynes/cm.},$$
$$f_{12} = f_{34} = 0.65\times10^5 \text{ dynes/cm.},$$
$$f_{13} = f_{24} = 0.015\times10^5 \text{ dynes/cm.},$$
$$f_{14} = f_{23} = 0.36\times10^5 \text{ dynes/cm.}$$

Par contre, si on n'utilise que les deux composantes majeures on obtient des constantes assez voisines pour les deux forces principales, soient $f_{11} = 5.9$ et $f_{12} = 0.62\times10^5$ dynes/cm. Ces quantités demeurent sujettes à revision jusqu'à ce que les fréquences fondamentales dans le spectre Raman du cristal soient connues. Pour le moment il est intéressant de constater que la diminution de la force de rappel interne en passant de la molécule libre au cristal est énormément plus grande pour HF que pour les autres halogénures d'hydrogène (Tableau I). L'amortissement de la vibration de HF dans le cristal accroît son anharmonicité, laquelle se manifeste par un élargissement des bandes d'absorption.

Quant aux modes de libration des molécules dans le réseau cristallin, les fréquences trouvées ici soient 955, 1010 et 1204 cm.$^{-1}$ sont sans doute les plus hautes jamais rencontrées. Il est intéressant de les comparer à celles de la glace à 850 cm.$^{-1}$ (16). Hornig et

Osberg (2) ont évalué à 266 cm.$^{-1}$ la fréquence de ce mode dans HCl cristallin, ce qui est en harmonie avec une valeur moyenne de 1100 cm.$^{-1}$ pour HF. Nous avons utilisé cette dernière quantité pour calculer la constante secondaire f_{12} d'après la formule usuelle

$$f = 4\pi^2\nu^2 I/r^2$$

pour une oscillation perpendiculaire à la force de rappel; nous obtenons ainsi presque exactement le même résultat (6.4×10^5 dynes/cm.) que ci-haut. Enfin un calcul très grossier de la fréquence de translation gênée ν_T d'une molécule HF par rapport à ses voisines dans l'hypothèse d'un oscillateur harmonique conduit à une valeur d'environ 330 cm.$^{-1}$.

Des deux facteurs principaux qui affectent les vibrations d'une molécule dans le cristal soient (*a*) le champ de forces créé par l'ensemble des molécules dans leur position d'équilibre et (*b*) le couplage avec les molécules adjacentes, il est clair que le second est énormément plus important dans le cas de HF. La technique dite de dilution isotopique (3) a permis à Hornig de différencier ces deux facteurs dans des "cristaux mixtes" de HCl et DCl. Vu la largeur anormale des bandes d'absorption de HF il est peu probable que cette méthode puisse révéler suffisamment de détails sur les vibrations des molécules isolées ou des paires de molécules dans les mélanges.

ABSTRACT

The infrared absorption of thin crystallized films of HF at −180° C. was measured from 300 to 5000 cm.$^{-1}$. The fundamental vibrations give rise to a strong doublet at 3420 and 3060 cm.$^{-1}$ and a weaker one at 3590 and 3270 cm.$^{-1}$. These bands are remarkably broad owing to the presence of very strong hydrogen bonds. From the intensity ratio of the fundamental components the angle between neighboring HF molecules in the zigzag chains is calculated to be about 114°. Both the splitting of the fundamental components and the vapor–solid shift are unusually large in keeping with the high polarity of the molecule and the strong hydrogen bonds. The "internal" force constant $f_{11} = 6.31 \times 10^5$ dynes/cm. is much lower than for the free molecule, and the "external" force constants are higher, by an order of magnitude, than in the other hydrogen halide crystals. Some five lattice vibrations were found between 350 and 1200 cm.$^{-1}$.

THE INFRARED CARBONYL STRETCHING BANDS OF ACETOPHENONES SUBSTITUTED IN THE METHYL GROUP[1]

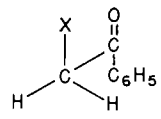
R. NORMAN JONES AND ERNEST SPINNER[2]

ABSTRACT

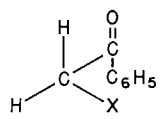
Measurements have been made of the positions and intensities of the C=O stretching bands in the infrared spectra of compounds of the types C_6H_5—CO—CH_2X, C_6H_5—CO—CHX_2, and C_6H_5—CO—CX_3 where X = —Cl, —Br, —I, —CN, —C_6H_5, and —OH. In most cases two bands are observed, and these are attributed to *gauche* and *cis* conformations associated with hindered rotation about the CO—CH_2X and CO—CHX_2 bonds. The relative positions and intensities of these bands are discussed in terms of the steric, electrical, and mass effects of the substituents.

INTRODUCTION

Rotational isomerism has been observed repeatedly in substances containing the groups —CO—CH_2X and CO—CHX_2 (1, 2, 3, 4, 5). Rotation of the CH_2X or CHX_2 group is restricted and the preferred conformations are those in which an H or X atom eclipses the oxygen atom when the molecule is viewed along the axis of the CO—CH_2X or CO—CHX_2 bond (I, II).



I (cis)



II (gauche)

Bellamy, Thomas, and Williams (4) have studied the C=O stretching bands in the infrared spectra of ω-chloroacetophenone, ω,ω-dichloroacetophenone, and ring-substituted derivatives of the former. In spectra measured in the liquid phase they observed two prominent maxima in the C=O stretching region, whereas a single band only was noted if the spectra were determined on material in the solid state. The relative intensities of the doublet peaks were temperature dependent, the lower frequency band becoming relatively more intense with rising temperature. In a later publication (5), Bellamy and Williams further established that the relative intensities of the two peaks varied with the solvent, the band at higher frequency increasing in relative intensity with change from a solvent of lower polarity (CCl_4) to one of higher polarity ($CH_3.CN$). By analogy with the influence of the C—X conformation on the C=O stretching bands of α-halogenated cyclohexanone derivatives (6, 7, 8, 9), Bellamy and collaborators assigned the doublet band of higher frequency to the *cis* form (I), and, from the temperature effect, they inferred that this is thermodynamically the more stable conformation.

This investigation extends these studies to acetophenone derivatives containing —Br, —I, —C≡N, —C_6H_5, and —OH substituents in the methyl group. The substitution effects on the integrated absorption intensities are also considered.

EXPERIMENTAL

The spectra were determined in carbon tetrachloride and chloroform solutions on a Perkin-Elmer model 112 double-pass single-beam spectrometer using a calcium fluoride prism at a computed spectral slit width (S') of 1.6 cm.$^{-1}$ (10). The absolute values reported for the positions of the band maxima are correct within ± 1 cm.$^{-1}$ and the reproducibility is accurate to ± 0.5 cm.$^{-1}$. The integrated absorption intensities were determined by method II of Ramsay (11, 12); integration was performed by the use of Simpson's Rule and extended out into the wings of the band to the point where the measured optical density was 0.01. Corrections for finite spectral slit width were not applied since the ratio of S' to the half band width ($\Delta\nu_{\frac{1}{2}}^{(a)}$) was less than 0.2 in all cases except phenacyl alcohol (10). For this compound $\Delta\nu_{\frac{1}{2}}^{(a)} = 8$ cm.$^{-1}$ and the finite slit error on the basis of Ramsay's calculations would amount to about 2%.

The compounds were obtained commercially, or prepared by standard methods, and purified by fractional crystallization, vacuum distillation, vacuum sublimation, or combinations of these techniques. The melting points, boiling points, and refractive indices were consistent with values reported in the literature.

RESULTS AND DISCUSSIONS

The positions and intensities of the C=O stretching bands in both solvents are listed in Table I.

Band Positions

The compounds containing the groups —CH_2Cl, —$CHCl_2$, —CH_2Br, —$CHBr_2$, —CH_2I, and —$CH_2.C_6H_5$ give two bands, designated ν_1 and ν_2. The compounds containing —$CH_2.CN$ and —$CH_2.OH$ show one band only, as do those containing —CCl_3 and —CBr_3 groups.

The doublet maxima noted for —CH_2Cl and —$CHCl_2$ agree with the observations of Bellamy and collaborators (4) on these compounds and the band positions in carbon

tetrachloride solution check with the amended values reported by these investigators in their later publication (5). In all cases where doublets are observed the band at higher frequency (ν_1) is relatively more intense in chloroform than in carbon tetrachloride solution, indicating that the ν_1 band is associated with the more polar structure. This is consistent with the assignment of the ν_1 band to the *cis* conformation I.

In any carbonyl compound, the C=O stretching frequency is determined by a combination of steric, electrical, and mass effects of the groups surrounding the C=O bond. These effects have been reviewed in a preceding publication (13). At present the relative importance of the different effects for a given structure cannot be evaluated quantitatively, though certain structures are encountered in which one or other of these effects can be recognized to exercise a dominating influence.

Substitution Effects in the gauche Conformation (Band ν_2)

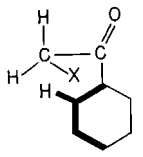
The band at lower frequency falls in the range 1694–1682 cm.$^{-1}$ in carbon tetrachloride solution and 1689–1678 cm.$^{-1}$ in chloroform. Except for the chlorinated compounds, the band lies below that of acetophenone, and the frequency diminishes in the sequence:

$-CH_2Cl$	>	$-CHCl_2$	>	$-CH_3$	>	$-CH_2Br$	>	$-CH_2.C_6H_5$	>	$-CH_2I$	>	$-CHBr_2$
(49.5)		(84)		(15)		(94)		(91)		(141)		(173)

Since electron withdrawal raises the C=O frequency, this sequence shows that the polar effect of the substituent is opposed by mass and/or steric effects that act to lower the frequency. If acetophenone itself is excluded, the above sequence approximates to one of increasing mass, as is indicated by the molecular weights of the groups given above in parenthesis.

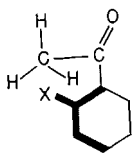
Although the mass effect may be predominant, the influence of the electrostatic and steric effects of the substituent is also apparent. The inductive effect should be strongest for chlorine; the increase in the ν_2 frequencies of the chloro compounds can be explained in this way, and it is consistent with the substitution effects of chlorine on the ν_1 band discussed below.

Steric effects should be most in evidence in the bromide and iodide. In these compounds (III) the *ortho* hydrogen atom of the benzene ring and *gauche* halogen atom appear to be in the same steric relationship as in the *ortho*-halogenated acetophenones in the *s-trans* configuration (IV), for which steric interaction effects have been demonstrated (13).



X = Br, I

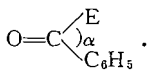
III



X = Br, I

IV

This steric strain can be released in a number of ways: (*a*) by a slight rotation of the methyl group about the CO—CH_2X axis; (*b*) by a slight rotation of the plane of the benzene ring about the 1,4-axis; (*c*) by increase in the angle α in



.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Of these effects (*a*) should have little effect on the ν_2 frequency and should be inoperative for the disubstituted derivatives, (*b*) should raise the C=O frequency by diminishing the resonance with the aromatic ring, and (*c*) should lower the frequency. In fact *ortho* bromination of acetophenone raises the C=O frequency by 11 cm.$^{-1}$ whereas bromination in the methyl group lowers it by 3 cm.$^{-1}$; the analogy between the steric conditions in these structures is therefore more apparent than real. The steric strain in IV would appear to be relieved largely by rotation of the whole acetyl group with respect to the ring, and the strain in III by opening of the R—CO—R angle.

Substitution Effects on the ν_1 Band

For the ν_1 band the C—O stretching frequency is in all cases greater than that of acetophenone, and diminishes in the series:

$$-CCl_3 > -CHCl_2 > -CH_2Cl > -CH_2CN > -CH_2Br > -CHBr_2 > -CBr_3 > -CH_2I > -CH_2.C_6H_5 > -CH_3.$$

Here the electronegativity of the substituent exercises the dominant influence. The trisubstituted groups $-CCl_3$ and $-CBr_3$ exhibit one band only, and since this lies well above that of acetophenone it is to be classified with the ν_1 series. For the chloro derivatives ν_1 increases with increasing substitution ($-CCl_3 > -CHCl_2 > -CH_2Cl$), whereas for bromination the sequence is reversed ($-CH_2Br > -CHBr_2 > -CBr_3$). The introduction of the first chlorine atom (in the *cis* position) changes the C=O frequency by +23 cm.$^{-1}$, while the further displacements on introduction of the second and third chlorine atoms in the *gauche* positions are +2 and +1.5 cm.$^{-1}$ respectively.* Although small, these additional positive shifts are significant, and they agree with the shifts produced by chlorination on the ν_2 band. The major shift induced by the *cis* C—Cl bond results largely from the direct dipole–dipole interaction across space, while the smaller shifts for the *gauche* C—Cl bonds are associated with the inductive effect acting through the bond system.

The "true" inductive effect of the *gauche* C—Cl bond on ν_1 must be somewhat greater than the 1 to 3 cm.$^{-1}$ actually observed. The *gauche* C—Cl bond will have a small dipole–dipole interaction with the C=O bond of opposite sign to that of the *cis* C—Cl bond. Furthermore the *gauche* C—Cl bond will have small steric and mass effects which will also act to lower the frequency. In the case of the bromo derivatives, these negative mass and steric effects are more important than the positive inductive effect of the *gauche* C—Br bond, and the reversed series is observed with the positive shift for $-CH_2Br$ (18 cm.$^{-1}$) exceeding that for $-CHBr_2$ (16 cm.$^{-1}$) and $-CBr_3$ (13 cm.$^{-1}$).

The low frequency of the single band in phenacyl alcohol suggests a *gauche* conformation, but more probably this molecule is stabilized in the *cis* conformation (V), with the hydrogen bonding being responsible for the excessive lowering of the ν_1 band. This band is symmetrical and very narrow ($\Delta\nu_{\frac{1}{2}}^{(a)} = 8$ cm.$^{-1}$), further evidence that only one molecular species is present.

Band Intensities

The integrated absorption intensity of the C=O stretching band in all types of carbonyl compounds varies over a comparatively small range between 1 and 5 intensity units.* Because the total range of intensity is so limited, it is difficult to evaluate the significance of small intensity changes associated with substitution effects. The situation is different with such bands as N—H stretch and C≡N stretch for which intensities have been observed to vary over a hundredfold range in various types of amines and nitriles (15, 16, 17).

Most of the ω-substituted acetophenones considered in this paper possess two carbonyl bands that overlap extensively. This overlap makes it impossible to evaluate the integrated absorption intensities of the ν_1 and ν_2 bands separately and only the total space integral under the complex band system can be obtained. The figures given in Table I are for this quantity.

In all cases, the integrated absorption intensity of this band system is greater in chloroform solution in carbon tetrachloride; this could indicate that the absorption of ν_1 is greater than that of ν_2, since the *gauche/cis* ratio is less in chloroform. However, the same solvent intensity effect is observed for the trichloro- and tribromo-derivatives and for acetophenone, itself, where the *gauche/cis* ratio is not involved. Most of the enhanced intensity in chloroform must therefore be attributed to a general solvent effect not dependent on the conformation.

In all cases, substitution diminishes the intensity of the carbonyl band system. The main features of these substitution effects are summarized in the series i–v listed below, where the groups are arranged in an order of diminishing band intensity. The sequence is the same in both solvents, though the quantitative differences are not.

(i) $-CH_3 > -CH_2I > -CH_2Br > -CH_2Cl$

(ii) $-CH_3 > -CH_2Cl > -CHCl_2 > -CCl_3$

(iii) $-CH_3 > -CH_2Br > -CHBr_2 > -CBr_3$

(iv) $-CH_3 > -CCl_3 > -CBr_3$

(v) $-CHCl_2 > -CHBr_2$

In series i–iii the intensity falls as the electronegativity of the functional group increases. Series iv and v, however, suggest that in the di- and tri-substituted compounds bromine is more effective than chlorine in lowering the band intensity. This effect is probably predominantly steric as it is only observed in the polysubstituted derivatives.

Substitution Effects on the gauche/cis Ratio

Because of the extensive overlap the integrated absorption intensities cannot be used to determine the equilibrium concentrations of the *gauche* and *cis* species. Some information about this equilibrium can be obtained from the ratio of the extinction coefficients at the peaks of the ν_1 and ν_2 bands. These are summarized in Table II.

The single peak of phenacyl cyanide shows little change in intensity or band width in the two solvents; from the position of the maximum (1709 cm.$^{-1}$ in CCl_4) it can be assumed that this compound exists exclusively in the *cis* conformation. The iodide shows a strong maximum at 1683 cm.$^{-1}$ in the same solvent, with a weak inflection at 1701 cm.$^{-1}$, and therefore exists predominantly, but not exclusively, in the *gauche* form. The iodide and nitrile represent the extremes of *gauche* and *cis* stabilized systems; the other compounds are listed in Table II in a sequence of increasing ratio of $\epsilon^{(a)}_{\nu_2,max}$ to $\epsilon^{(a)}_{\nu_1,max}$, and with some

**The unit of integrated absorption intensity employed here is 10^4 mole^{-1} liter cm.$^{-2}$. (See Ref. 18.)*

reservations this can be identified with the sequence of increasing *gauche/cis* equilibrium ratio.

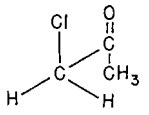
This series approximates to one of increasing stability of the *cis* form with increased electron-withdrawing effect of the X group. From III we might expect that with increase in the size of the X substituent, the increasing steric hindrance would raise the energy of the *gauche* forms, and so shift the equilibrium in favor of the *cis* conformation. In fact, the reverse appears to be true; in the iodide the equilibrium is greatly in favor of the *gauche* form, in spite of the steric hindrance associated with the large iodine atom. It is evident that we are dealing here with a complex interplay of factors which cannot be evaluated *a priori.*

VALIDITY OF THE ASSIGNMENTS

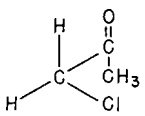
In assigning the ν_1 and ν_2 bands respectively to the *cis* and *gauche* conformations we have accepted the arguments advanced by Bellamy, Thomas, and Williams (4, 5). These in turn are based partly on an earlier generalization from this laboratory (6) that "*large positive shifts of the* C=O *stretching frequency on α-bromination in the cyclohexanone ring system in the chair configuration occur only when the bromine atom occupies an equatorial position*". This generalization was later extended to other halogens (Ref. 14, p. 478), while Corey and collaborators (7, 8, 9) have shown that conformational assignments based on this rule are consistent with those derived from thermodynamic considerations. Kumler and Huitric (19) have questioned some of Corey's conclusions because they conflicted with dipole moment data. The criticisms however were directed against Corey's assumption of a rigid chair configuration for the cyclohexanone ring in certain compounds, and not against the spectroscopic argument per se.

The existence of spectroscopic effects associated with conformational equilibria in compounds of this type was first recognized by Mizushima and co-workers (2) in chloroacetone. Initially these investigators assigned the C=O band of lower frequency to VI, which they considered thermodynamically more stable than the *gauche* structure VII. This was not consistent with the conclusions of Bellamy, Corey, and ourselves, since it required that the parallel alignment of C=O and C—Cl dipoles should produce

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.



VI



VII

a lesser spectral shift than the *gauche* arrangement. It was however in agreement with our observations in indicating greater thermodynamic stability for the *cis* conformation.

Recently Josien, Castinel, Chiurdoglu, and Vanlanduyt (20) in a reappraisal of Mizushima's data changed the assignment of the vapor-state carbonyl band of chloroacetone; this left the structural assignments for VI and VII unchanged, but indicated greater thermodynamic stability for VII over VI. This presented a complete reversal from the spectroscopic and thermodynamic behavior pattern developed by Bellamy, Corey, and ourselves for α-bromo ketones, and led Josien and collaborators to criticize our original interpretation of the α-halogenated cyclohexanone-type spectra.

The discussion of substitution effects earlier in this paper by no means fully explains the band shifts on the basis of the conformations associated with ν_1 and ν_2, but the situation is a good deal less satisfactory if the assignments are reversed. Without elaborating on this unnecessary detail, it can be noted, for example, that introduction of the first chlorine atom produces a positive displacement of $+23$ cm.$^{-1}$ for ν_1 while the additional displacements produced by the second and third chlorine atoms are $+2$ and $+1.5$ cm.$^{-1}$ respectively. If the ν_1 and ν_2 assignments are reversed this requires that the first (*gauche*) chlorine substituent produces the large displacement while the second (*gauche*) and the third (*cis*) substituents have only small effects. Difficulties of the same kind would be encountered in explaining the relatively small differences observed between mono- and di-halogenated substituents on the ν_2 band and such an assignment is quite untenable.

Finally, the recent re-examination of the spectrum of chloroacetone has led Bellamy and Williams (5) to reverse the assignments for the carbonyl bands of that compound, so that there is now complete consistency with the ω-substituted acetophenone spectra. With this change the conclusions from dipole moment measurements as well as the thermodynamic behavior of these compounds substantiate fully the hypothesis that large positive carbonyl shifts are associated with *cis*-bromination in the α-position.

ACKNOWLEDGMENTS

The acetophenone derivatives were prepared by one of us (E. S.) in the chemistry laboratories of the Manchester College of Science and Technology in connection with an investigation of their ultraviolet spectra. We wish to thank Dr. A. Burawoy for making them available to us for these studies.

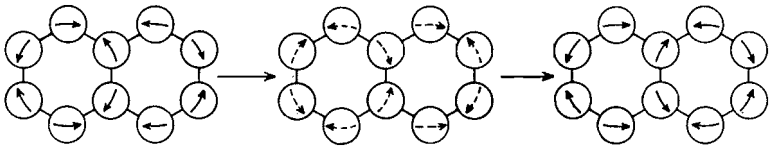
CLASSICAL APPROACH TO THE STRUCTURE OF CONDENSED-RING AROMATIC COMPOUNDS—A REJOINDER TO THE PROBLEM OF DIBENZO(*cd*,*mn*)PYRENE

LAKHBIR SINGH

According to the molecular-orbital treatment of the dibenzo(*cd*,*mn*)pyrene structure given by Lister (2), this molecule should be paramagnetic corresponding to two free electrons. It is a remarkable conclusion, as all other known hydrocarbons of this family including graphite are diamagnetic. The author of the present note, however, believes that the simple classical theory can still provide better guidance in such complicated problems. This approach can be considered reliable even today, as it is known that the earlier electronic theory was essentially correct in all its conclusions, "although expressed in a terminology which now seems old-fashioned" (1).

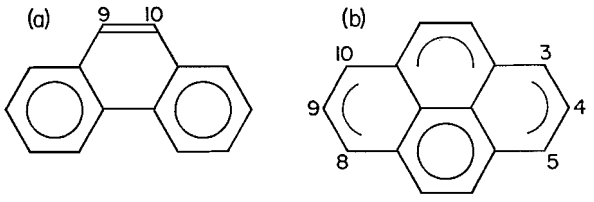
According to a new classical concept of the aromatic bond developed by the author (3), the π-electrons tend to form a continuous circular coupling round the benzene ring. However, the π-electron coupling in the condensed-ring aromatic compounds cannot be unique and stable, because the π-electrons on the carbon atoms which are common between two or three rings can complete the circular coupling (or the 'sextet') of only one of these rings at a time (4). Thus, the π-electron coupling in these complex molecules remains in a state of turmoil, which is responsible for their peculiar physical and chemical properties.

In naphthalene, each ring alternately becomes fully aromatic. Part of the time, the continuous aromatic coupling gets truncated in both the rings. The π-electrons at the α-positions, which do not form the continuous ring, return round these atoms to complete the π-electron coupling in the side ring. This side ring behaves more or less as a conjugated side chain (for half the time) and is the cause of greater reactivity of the napthalene



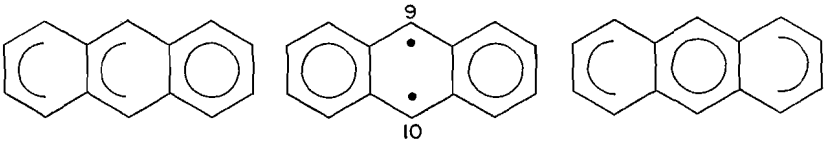
π-Electron coupling in naphthalene. The broken arrows represent the π-electrons on the lower side of the molecular plane.

molecule. In phenanthrene, most of the time a simple double bond remains in the middle ring, because of the greater tendency of the π-electrons to complete the sextets in the two outer rings. This explains the olefinic character of this C_9—C_{10} bond. In pyrene, however, a naphthalene type of coupling in the two middle rings also becomes equally



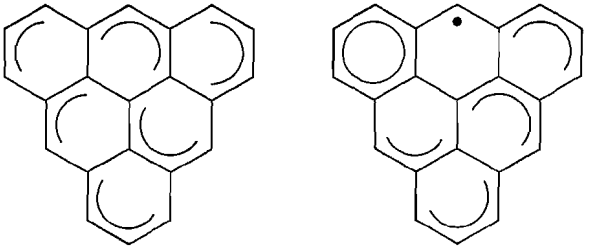
π-Electron coupling in phenanthrene (*a*) and pyrene (*b*).

effective. The transient π-electron coupling among three atoms in this molecule is supported by the reduction product 3,4,5,8,9,10-hexahydropyrene. The two π-electrons on the C_9 and C_{10} positions in the middle ring of anthracene remain uncoupled for part of the time. However, this molecule is not paramagnetic in spite of the abundant chemical evidence in favor of this partial free valence character at these two positions. This is owing to the fact that these π-electrons are not free in the usual sense of this term. They can be called free or uncoupled in a relative sense only. The π-electrons forming the



π-Electron coupling in anthracene.

aromatic bond couple on both sides of the molecular plane after each half revolution of these electrons round the carbon atoms (3). The π-electrons at the truncated ends of the aromatic bond couple after one full revolution around the carbon atoms (4) as in a simple covalent bond, while these partially free π-electrons in anthracene couple after one and a half revolutions. This situation arises only momentarily for each π-electron when it is on a C_9 or C_{10} atom. Under these circumstances the spin of the electron cannot be treated as free. These gradations in coupling are, however, reflected in the variations in chemical properties as shown by the benzene carbon atoms, the α-positions in naphthalene, and the C_9 and C_{10} positions in anthracene.



π-Electron coupling in dibenzo(*cd*,*mn*)pyrene.

On the basis of the above considerations, it can be predicted that the dibenzo(*cd*,*mn*)-pyrene hydrocarbon will not be paramagnetic. It may, however, have some free valence character of the anthracene type. The π-electron coupling in it can get truncated in many ways. The actual weight to these possibilities can be decided only after the chemical properties are known.

THE STRUCTURE OF MITRAPHYLLINE[1]

J. C. SEATON,[2] R. TONDEUR,[2] AND LÉO MARION

ABSTRACT

Mitraphylline ($C_{21}H_{24}O_4N_2$) contains a carbomethoxyl group, and on hydrolysis gives rise to mitraphyllic acid. Spectroscopic evidence shows that the alkaloid contains two chromophores, one characteristic of an oxindole and one corresponding to the grouping $CH_3OOC—C'=CH.OR$. On treatment with dilute mineral acid the alkaloid gives rise to mitraphyllal ($C_{19}H_{24}O_3N_2$), which is a hemiacetal that no longer contains the isolated double bond and the carbomethoxyl group originally present in the alkaloid. Reduction of mitraphyllal by the Wolff–Kishner reaction gives mitraphyllane ($C_{19}H_{26}O_2N_2$). The dehydrogenation of mitraphyllal produced 3,4-diethylpyridine and 3-ethyloxindole. The action of lithium aluminum hydride on mitraphylline under mild conditions gave rise to mitraphyllol by reduction of the carbomethoxyl group, and under more vigorous conditions to dihydrodesoxy-mitraphyllol by reduction of the oxindole carbonyl as well. This last product has the properties of an aromatic amine. On the basis of the new experimental evidence, a total structure of mitraphylline is derived.

Mitraphylline has been isolated from *Mitragyna rubrostipulacea* Havil. (= *Adina rubrostipulata* K. Schuman)[3] by Michiels (1), by Denis (2), and also by Raymond-Hamet (3). Michiels (4) also isolated it from *M. stipulosa* Kuntze (= *M. macrophylla* Hiern.). In all cases except one (5) the alkaloid has been isolated in the laevorotatory form. It has been assigned the formula $C_{21}H_{24(26)}O_4N_2$, and assumed to contain a carbomethoxyl group and one C-methyl group (6). Distillation of mitraphylline hydrochloride from zinc dust under reduced pressure yields a neutral substance $C_{10}H_9ON$, 3,4-diethylpyridine, and isoquinoline (6, 7). The same neutral substance has also been obtained from rhyncophylline (8) and uncarine-A (9). It has been converted to 3-ethyloxindole by hydrogenation (7). Wenkert and Reid (10) have suggested that it was probably spiro-3,3-cyclopropyloxindole, and the identity has since been established by Kondo *et al.* (11) by direct comparison with a synthetic specimen. A monoacetyl derivative has been reported (7). Mitraphylline gives a yellow color with tetranitromethane, forms an amorphous dibromide, and when hydrogenated over Adams' catalyst absorbs 3 moles of hydrogen, but over a palladium catalyst, it is reported to absorb only 1 mole (5).

Mitraphylline has now been re-examined and sufficient additional evidence obtained to make it possible for us to advance a total structure for the alkaloid. Although many references to mitraphylline in the literature (6) include an expanded formula showing a

[3]*The identity of this species seems to be controversial. Certain authors include it in the genus Mitragyna. Botanically, the two genera are very close, but it has been claimed that there are sufficient criteria to include the species in the genus Adina. The plant has been studied successively under several names. For a botanical description of the plant see J. Lebrun, Les essences forestières du Congo Belge, Publication INEAC, Vol. 2, p. 220, Brussels, 1939.*

carbomethoxyl group, the presence of such a group does not seem to have been demonstrated experimentally before. The analysis of mitraphylline and its degradative products confirm the formula $C_{21}H_{24}O_4N_2$. The base was hydrolyzed with potassium hydroxide to the crystalline mitraphyllic acid, $C_{20}H_{22}O_4N_2$. When re-esterified with methanol and hydrogen chloride the acid was partially reconverted to mitraphylline which, however, was contaminated with another product and could not be completely purified. Its X-ray powder diagram contained all the lines present in the X-ray diagram of pure mitraphylline, but a few additional faint lines were also present.

The ultraviolet spectrum of mitraphylline is identical with that of rhyncophylline, which has been shown to be made up of contributions from an oxindole chromophore and the grouping $CH_3O_2C—\acute{C}=CH.OR$ (12). The infrared absorption spectrum in chloroform shows a band at 3415 cm.$^{-1}$ indicative of an imino group, and in nujol mull it contains bands at 1725 and 1704 cm.$^{-1}$ attributable to an ester carbonyl and an oxindole carbonyl respectively, at 1626 and 755 cm.$^{-1}$ due to a benzene ring, and at 1105 cm.$^{-1}$ indicative of a cyclic ether. The intensity of the absorption at 1626 cm.$^{-1}$, however, is greater than that expected for a benzene ring, and it is probable that it also includes a contribution from a polarized double bond.

Hydrogenation of the alkaloid in acetic acid solution over a platinum catalyst yielded a hexahydroderivative $C_{21}H_{30}O_4N_2$. The absence of a band at 755 cm.$^{-1}$ in the infrared absorption spectrum of this product indicated that the benzene ring had been hydrogenated. The fact that the ultraviolet spectrum did not contain the usual absorption of an oxindole chromophore confirmed this, while the retention of the strong absorption at 239 mμ, due to the grouping $CH_3OOC—\acute{C}=CH.OR$, showed that the isolated double bond had not been affected (cf. 5). The presence of a band at 1626 cm.$^{-1}$ in the infrared spectrum of the product is also probably due to this double bond.

Reduction of mitraphylline with lithium aluminum hydride at room temperature gave rise to an alcohol, $C_{20}H_{24}O_3N_2$, that we propose to designate as mitraphyllol. Its infrared absorption spectrum contained a split oxindole carbonyl at 1730–1708 cm.$^{-1}$, and a band at 1654 cm.$^{-1}$ indicating that the enol–ether grouping was still present. The shift of the last absorption band from 1626 cm.$^{-1}$ (in the spectrum of mitraphylline) was to be expected because reduction of the ester to a primary alcohol group would remove the conjugation. The ultraviolet spectrum of mitraphyllol is that of a simple oxindole.

Under more vigorous conditions, the reduction of mitraphylline with lithium aluminum hydride produced dihydrodesoxy-mitraphyllol, $C_{20}H_{26}O_2N_2$. The infrared spectrum of this product showed no carbonyl absorption, but still contained a band at 1660 cm.$^{-1}$ due to the absorption of the enol–ether double bond. The ultraviolet spectrum was that of an aromatic amine, and indeed, dihydrodesoxy-mitraphyllol coupled with diazotized sulphanilic acid to form an indicator-type dye. Since this reduction of the oxindole carbonyl produced an amine and not an indole derivative it can be concluded that the 3-position of the oxindole system in the alkaloid must be disubstituted (13).

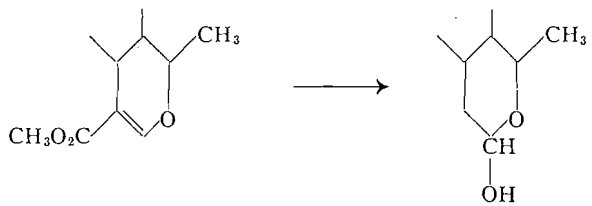
Acid hydrolysis of mitraphylline gave rise to a basic product (cf. 12) which could not be crystallized, but formed a crystalline picrate in methanol. The base regenerated from the picrate was a well-defined crystalline substance, $C_{20}H_{26}O_3N_2$, containing one methoxyl group. The presence of a methoxyl seemed to indicate that the expected aldehyde had, in the presence of methanol, been converted to a hemiacetal. That this was actually so became apparent when the crystalline base was obtained on treatment of the amorphous hydrolysis product with 1% methanolic hydrogen chloride. The ultraviolet spectrum of the crystalline product was that of a simple oxindole, thus indicating that the enol–ether

171537

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

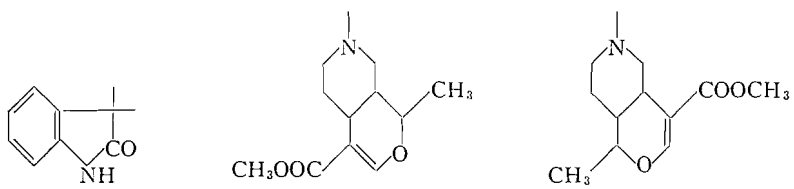
system was no longer present. The infrared absorption spectrum contained a split oxindole carbonyl band at 1695–1730 cm.$^{-1}$, bands at 1625 and 750 cm.$^{-1}$ due to the benzene ring, and three new bands at 1180, 1140, and 1060 cm.$^{-1}$ which are reported to be characteristic of an acetal (14). The crystalline product $C_{20}H_{26}O_3N_2$, for which we suggest the name methylmitraphyllal, gave on hydrolysis a base which could not be induced to crystallize. This base contained no methoxyl group, it slowly reduced Tollens' reagent, and could be methylated in almost quantitative yield to methylmitraphyllal. Its infrared spectrum contained no absorption attributable to an aldehyde, but did contain an absorption band in the hydroxyl region, and therefore the amorphous substance must be a hemiacetal and will be designated as mitraphyllal. Further evidence that mitraphyllal was a hemiacetal was provided by the Wolff–Kishner reduction, which yielded mitraphyllane ($C_{19}H_{26}O_2N_2$), an amorphous product isolated as its crystalline picrate. As expected, the infrared absorption spectrum of mitraphyllane in chloroform contained a peak at 3600 cm.$^{-1}$ indicating the presence of a hydroxyl group.

The formation of mitraphyllal and methylmitraphyllal is consistent with the presence in the alkaloid of the cyclic system I since hydrolysis of the ester and the enol–ether group followed by decarboxylation and cyclization would result in the formation of a hemiacetal II.



I II

Dehydrogenation of mitraphyllal with palladium–charcoal produced 3,4-diethylpyridine and 3-ethyloxindole. Hence the experimental evidence indicates the presence in the alkaloid of fragment III and either fragment IV or V. It was hoped to distinguish between IV and V by means of the dehydrogenation product of mitraphyllol, which was expected



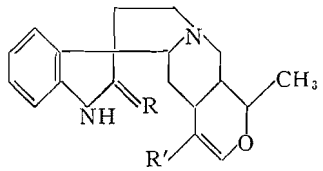
III IV V

to be 3-ethyl-4-isopropylpyridine. Unfortunately, this dehydrogenation either with selenium or with palladium produced 3,4-diethylpyridine. Biogenetically, however, structural element IV is more likely than V. Furthermore, structure IV occurs in a number of carboline alkaloids (15–18) whereas structure V has not yet been found. Also, IV definitely corresponds to the structure of rhyncophylline (12) and may legitimately be assumed to be present in mitraphylline.

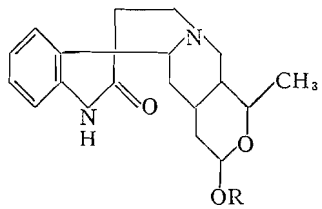
The biogenetic derivation of mitraphylline is probably similar to that suggested for rhyncophylline (12) involving the same starting materials. As for rhyncophylline, the α-position of the piperidine ring would be linked to the 3-position of the oxindole system,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

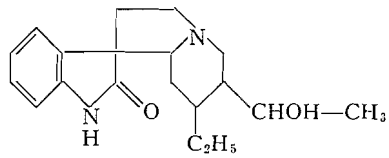
and therefore, the structure of mitraphylline must be that shown in formula VI (R = O, R′ = CO_2CH_3). On the basis of this formula, the structures of the various derivatives



VI (R = O; R′ = CO_2CH_3)
VII (R = O; R′ = CH_2OH)
VIII (R = H_2; R′ = CH_2OH)



IX (R = H)
X (R = CH_3)



XI

of mitraphylline became obvious. Thus mitraphyllol is represented by VII, dihydrodesoxymitraphyllol by VIII, mitraphyllal by IX, methylmitraphyllal by X, and mitraphyllane by XI.

Just as rhyncophylline is the oxindole analogue of corynantheine, mitraphylline is the oxindole analogue of the four stereoisomerides ajmalacine (δ-yohimbine, tetrahydroserpentine) (15), mayumbine (16), akuammigine (17), and tetrahydroalstonine (18).

EXPERIMENTAL

The ultraviolet spectra were determined in absolute ethanol, unless otherwise stated, on a Beckmann DU spectrometer. The infrared absorption spectra were recorded with a Perkin–Elmer double beam instrument model 21. The peaks are indicated by a wave number and the percentage absorption (in parenthesis). The compounds were dispersed in mulls in nujol unless otherwise mentioned. All melting points were taken on a microscope hot stage and are uncorrected.

Mitraphylline

The alkaloid was obtained from the bark of *Mitragyna rubrostipulacea* Havil.[4] Mitraphylline consisted of colorless needles, m.p. 275–276°, $[\alpha]_D^{24}$ −3° (*c*, 1.3 in chloroform), −39° (*c*, 2.4 in 0.1 *N* hydrochloric acid), pK_a 4.6 (by titration in 80% methylcellosolve with 0.02 *N* hydrochloric acid). Found: C, 68.60; H, 6.69; N, 7.59; OCH_3, 8.46; act. H, 0.29. Calcd. for $C_{21}H_{24}O_4N_2$: C, 68.46; H, 6.57; N, 7.60; 1 OCH_3, 8.41; 1 act. H, 0.27%. Ultraviolet absorption: shoulder at 280 mμ, log ε 3.18, λ_{max} 243 mμ, log ε 4.22, λ_{min} 224 mμ, log ε 4.02. Infrared absorption: 3260(32), 1725(85), 1704(84), 1626(74), 1105(74), 755(46). In chloroform: 3415(20), 1715(81), 1625(68).

The base formed a perchlorate that crystallized from alcohol–ether as long prismatic needles, softening at 214° and melting at 240°, $[\alpha]_D^{22}$ −26°±6 (*c*, 1 in 95% ethanol). A

[4]*Collected in the Northeast section of the Experimental Station (Mulungu) of the Institut pour l'étude agronomique du Congo (INEAC) in whose chemical laboratory the isolation of the alkaloids was carried out. The extraction of the bark was done in the plant of the Cooperative Congokina, Costermansville, Belgian Congo.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

hydriodide was also prepared that consisted, after crystallization from absolute methanol, of silky needles, m.p. 233–236°, $[\alpha]_D^{22}$ −13.5° (*c*, 1.2 in absolute ethanol). Found: C, 51.31; H, 5.14. Calcd. for $C_{21}H_{24}O_4N_2.HI$: C, 50.80; H, 5.08%.

Alkaline Hydrolysis of Mitraphylline

The base (0.35 g.) was refluxed for 1 hour in methanol (9 ml.) containing water (1 ml.) and potassium hydroxide (0.5 g.). The methanol was distilled off and the aqueous solution neutralized with dilute hydrochloric acid. The mixture was then extracted with chloroform, and the extract was dried and evaporated to dryness. The residual mitraphyllic acid (150 mg.) partially crystallized when benzene was added. After several recrystallizations from ethanol, it consisted of colorless prisms (45 mg.), m.p. 301° (decomp.). $[\alpha]_D^{22}$ +21.4° (*c*, 1.17 in pyridine). Found: C, 67.66; H, 6.28; N, 7.73. Calcd. for $C_{20}H_{22}O_4N_2$: C, 67.78; H, 6.26; N, 7.91%.

Esterification of Mitraphyllic acid

The acid (66 mg.) was refluxed for 10 minutes in a saturated solution of methanolic hydrogen chloride (3 ml.). The solvent was evaporated and the base liberated with ammonium hydroxide was extracted with chloroform. The extract was washed with water, dried, and evaporated to dryness. It left a residue (49 mg.) which was chromatographed on alumina (grade II). Elution with chloroform containing 1% methanol gave mitraphylline (28 mg.), which after crystallization from methanol, melted at 257–259° either alone or in admixture with pure mitraphylline. The X-ray powder photograph confirmed the identity with mitraphylline.

Acetylmitraphylline

Mitraphylline (190 mg.) was acetylated in pyridine (2 ml.) and acetic anhydride (0.5 ml.). The acetylated product (68 mg.) after crystallization from methanol–water, melted at 171–173°. $[\alpha]_D^{23}$ −6.2 (*c*, 1.0 in ethanol). Found: C, 67.33; H, 6.21; N, 6.54; $COCH_3$, 9.96. Calcd. for $C_{23}H_{26}O_5N_2$: C, 67.30; H, 6.39; N, 6.83; 1 $COCH_3$, 10.49%. pK_a 4.3 (by titration with 0.02 *N* hydrochloric acid in 80% methylcellosolve).

Hexahydromitraphylline

Mitraphylline (108 mg.) was hydrogenated in glacial acetic acid (10 ml.) over Adams' catalyst (50 mg.) at 28° and 755 mm. of mercury. The hydrogen absorbed (23.4 ml.) corresponded to the volume calculated (21.5 ml.) to reduce three double bonds. The catalyst was filtered and the filtrate made basic with sodium carbonate solution and extracted with chloroform. The extract was dried over sodium sulphate, evaporated to dryness, and the residue crystallized from acetone from which it separated as colorless prisms (60 mg.), m.p. 276° (decomp.). $[\alpha]_D^{25}$ +15.3° (*c*, 0.97 in ethanol). Found: C, 67.29; H, 7.96; N, 7.51. Calcd. for $C_{21}H_{30}O_4N_2$: C, 67.35; H, 8.09; N, 7.48%. Ultraviolet absorption: λ_{max} 237 mμ, log ε 4.05, λ_{min} 215 mμ, log ε 3.72. Infrared absorption: 1710(89), 1698(89), 1630(70), 1105(76), 1092(77).

Acid Hydrolysis of Mitraphylline

Mitraphylline (500 mg.) was refluxed with 8% hydrochloric acid (125 ml.) for 3.5 hours, and the cooled solution neutralized with sodium bicarbonate and extracted with ether. The extract was dried over sodium sulphate and evaporated to dryness leaving the crude amorphous mitraphyllal (490 mg.), which was dissolved in absolute methanol (20 ml.). Picric acid (500 mg.) was added and the solution boiled for 30 minutes and then concentrated. The picrate crystallized as yellow prisms which after recrystallization from

For personal use only.

methanol melted at 198–200° (decomp.). Found: C, 54.80; H, 5.03. Calcd. for $C_{20}H_{26}O_3N_2$. $C_6H_3O_7N_3$: C, 54.64; H, 5.11%. The base was regenerated on a basic resin (Amberlite IRA, 400) in methanol. The eluate on evaporation left a residue which crystallized from acetone in colorless prisms (methylmitraphyllal, 150 mg.) m.p. 224°, $[\alpha]_D^{25}$ −59.2° (*c*, 1.3 in ethanol). Found: C, 70.26; H, 7.49; N, 8.03; OCH_3, 8.43. Calcd. for $C_{20}H_{26}O_3N_2$: C, 70.15; H, 7.65; N, 8.18; 1 OCH_3, 9.05%. Ultraviolet absorption: shoulder at 780 mμ, log ε 3.18, λ_{max} 253 mμ, log ε 3.86, λ_{min} 228 mμ, log ε 3.33. Infrared absorption: 1730(94), 1696(81), 1625(56), 1183(74), 1140(71), 1060(88), 749(79).

Methylmitraphyllal

A solution of crude mitraphyllal (500 mg.) in 1% methanolic hydrogen chloride (50 ml.) was allowed to stand at room temperature overnight, refluxed for 30 minutes, and evaporated to dryness. Aqueous sodium carbonate was added to the residue and the mixture extracted with chloroform. The extract was dried over sodium sulphate, evaporated to dryness, and the residue was crystallized several times from acetone. The product (140 mg.) melted at 224° either alone or in admixture with a sample of methylmitraphyllal obtained as described above.

Hydrolysis of Methylmitraphyllal

Methylmitraphyllal (100 mg.) was refluxed with 1% hydrochloric acid (20 ml.) for 1 hour. The cooled solution was neutralized with sodium bicarbonate and extracted with ether. The extract was dried over sodium sulphate and evaporated to dryness. The residue consisted of the amorphous mitraphyllal, 95 mg. which contained no methoxyl group. Infrared absorption in chloroform: 3590(38), 3430(52), 1725(99), 1626(81). With Tollens' reagent mitraphyllal slowly formed a silver mirror. When treated with picric acid in methanol it gave an almost quantitative yield (150 mg.) of methylmitraphyllal picrate, m.p. 198–200° (decomp.).

Mitraphyllane

Mitraphyllal (100 mg.) trimethyleneglycol (2.5 ml.) and 95% hydrazine (250 mg.) were heated together at 150° for 1 hour. Potassium hydroxide (0.5 g.) was added and the excess of hydrazine evaporated while the temperature was increased to 200°. After 3 hours the mixture was cooled, water was added, and the solution extracted with ether. The extract was washed with water, dried over sodium sulphate, and evaporated to dryness. The residue was dissolved in methanol and a solution of picric acid (100 mg.) in methanol was added. The picrate was collected and recrystallized from methanol from which it separated in long yellow prisms (70 mg.) m.p. 167–169°. Found: C, 55.13; H, 5.48. Calcd. for $C_{19}H_{26}O_2N_2.C_6H_3O_7N_3$: C, 55.24; H, 5.38%. The base was regenerated on a basic resin (Amberlite IRA, 400) in methanol and was distilled at 0.1 mm. (air bath temperature 170–180°). It consisted of a colorless glass, 35 mg. $[\alpha]_D^{25}$ +39.3° (*c*, 0.89 in ethanol). Found: C, 72.42; H, 8.33. Calcd. for $C_{19}H_{26}O_2N_2$: C, 72.58; H, 8.34%. Ultraviolet absorption: shoulder at 280 mμ, log ε 3.21, λ_{max} 252 mμ, log ε 3.87, λ_{min} 229 mμ, log ε 3.60. Infrared absorption: 3200(55), 1707(92), 1625(61), 752(61). In chloroform: 3600(34), 3435(48), 1710(98), 1625(73).

Mitraphyllol

A solution of mitraphylline (500 mg.) and lithium aluminum hydride (400 mg.) in tetrahydrofuran (250 ml.) was allowed to stand at room temperature overnight. Water (3 ml.) was added, and after 30 minutes the precipitate was filtered off and washed with chloroform. The combined washings and filtrate were dried over sodium sulphate and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

evaporated to dryness. The residue was crystallized from acetone from which it separated as colorless prisms (170 mg.), m.p. 227°, $[\alpha]_D^{25}$ −79.7° (*c*, 0.79 in ethanol). Found: C, 70.16; H, 6.81; N, 8.07. Calcd. for $C_{20}H_{24}O_3N_2$: C, 70.56; H, 7.11; N, 8.23%. Ultraviolet absorption: shoulder 280 mμ, log ε 3.11, λ_{max} 252 mμ, log ε 3.88, λ_{min} 230 mμ, log ε 3.57. Infrared absorption: 3270(59), 1730(89), 1708(88), 1655(62), 1626(67), 750(61).

Dihydrodesoxy-mitraphyllol

Mitraphylline (200 mg.) and lithium aluminum hydride (200 mg.) in dioxane were refluxed under nitrogen for 3 hours. Water (2 ml.) was added to the cooled solution, and after 30 minutes, the precipitate was filtered off and washed with chloroform. The combined filtrate and washings were dried over sodium sulphate and evaporated to dryness. The residue, after crystallization from ether, consisted of colorless prisms (105 mg.), m.p. 173–174°, $[\alpha]_D^{25}$ −15.9° (*c*, 1.26 in ethanol). Found: C, 73.44; H, 8.08; N, 8.66. Calcd. for $C_{20}H_{26}O_2N_2$: C, 73.59; H, 8.03; N, 8.58%. Ultraviolet absorption: λ_{max}, 295 mμ, log ε 3.45, λ_{max} 243 mμ, log ε 3.83, λ_{min} 270 mμ, log ε 3.59. Infrared absorption: 3375(48), 3180(50), 1660(56), 1615(56), 745(78).

A few drops of diazotized sulphanilic acid were added to a solution of dihydroxy-mitraphyllol in hydrochloric acid. A red color developed immediately which turned to yellow when the solution was made alkaline. The red color returned on acidification. Neither mitraphylline nor mitraphyllol coupled with diazotized sulphanilic acid.

Dehydrogenation of Mitraphyllal

Mitraphyllal (200 mg.) was heated with palladium–charcoal (30%, 200 mg.) under dry nitrogen to 290° during 1 hour. A distillate was collected which was fractionated into two portions, I, boiling below 210°, and II, boiling above 210°. Fraction I was a colorless basic liquid which formed a picrate crystallizing from methanol in yellow plates, m.p. 140–141°, not depressed on admixture with an authentic specimen of 3,4-diethylpyridine picrate. Found: C, 49.21; H, 4.25. Calcd. for $C_9H_{13}N.C_6H_3O_7N_3$: C, 49.45; H, 4.43%. The infrared spectrum was identical with that of 3,4-diethylpyridine picrate. Fraction II (boiling higher than 210°) was crystallized from hexane. It consisted of colorless prisms, m.p. 101°, not depressed on admixture with a synthetic specimen of 3-ethyloxindole. The X-ray powder diagram was identical with that of the synthetic specimen.

ACKNOWLEDGMENTS

We acknowledge our indebtedness to Mr. R. Lauzon and Dr. R. Norman Jones for recording the infrared absorption spectra, and to Dr. Maria Przybylska for the preparation of the X-ray powder diagrams. Also to the Institut pour l'étude agronomique du Congo, Mukungu, Belgian Congo, for the work done in their laboratories.

HYDROLYSIS OF SULPHATE ACID ESTER IN UNSTABILIZED CELLULOSE NITRATES[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] BRIAN T. NEWBOLD, AND J. THOMAS

ABSTRACT

The rate of hydrolysis of the sulphate acid ester in unstabilized cellulose nitrates in acetone/water solution at 25° C. has been studied. The rate of hydrolysis in 90% acetone/water was too slow to produce a measurable increase in acidity during 24 hours. In 99% acetone/water solution the initial hydrolysis was very rapid and was followed by slower hydrolysis which was complete after 24 hours. Similar results were obtained with wood cellulose nitrates.

In the case of cotton cellulose nitrates, there was an indication that hydrolysis of the sulphate acid ester decreased as the nitrogen content increased. The rate of hydrolysis of the sulphate acid ester in both cotton and wood cellulose nitrates was very similar to that of the sulphate acid ester in cellulose acetate sulphate.

INTRODUCTION

It has been shown that the rate of hydrolysis of the sulphate ester of cellulose acetate sulphate depends on various factors of which the liquid medium is considered the most important (1). When cellulose acetate sulphate is dissolved in acetone the hydrolysis of the sulphate ester is rapid compared with that of the acetate ester. In 70% acetone the relative rates are reversed. At 25° C. or greater, the hydrolysis of the sulphate ester is complete after 24 hours (1). The solvolysis of both the sulphate ester and the acetate ester in acetic acid is well known (2). In water the cleavage of the acetate ester is more rapid than that of the sulphate ester (3).

Miles (4) has summarized the work done on the determination of sulphate ester in unstabilized cellulose nitrates by titration in acetone. The sulphate ester can be determined satisfactorily by titration in water, or analysis for calcium after ion exchange, or hydrolysis in acetone/water solution, or analysis for sulphate after treatment with 50% alcohol (5). Recently (6) the hydrolysis method for the determination of sulphate acid ester in acetone/water solution has been carefully studied.

The sulphate ester in unstabilized cellulose nitrate can be removed by prolonged boiling in water maintained just alkaline; the decomposition is most rapid when the boiling is carried out under slightly acid conditions (7). Spinks *et al.* (8) studied the sulphate content of unstabilized cellulose nitrate using $S^{35}O_4^=$ as a tracer, and found that it could only be removed at the expense of degradation and decomposition of the cellulose nitrate.

The object of the present work was to study the rate of hydrolysis of the sulphate acid ester in unstabilized cotton and wood cellulose nitrates in acetone/water solution.

EXPERIMENTAL

Cellulose Nitrate

The preparation of the cotton and wood unstabilized cellulose nitrates was carried out using the method mentioned in a recent publication (9). The cellulose nitrates were washed continuously for 48 hours with distilled water passed through an ion exchange column. Samples of cellulose nitrate were removed from the washing apparatus and dried

[1]*Manuscript received November 14, 1957.*
Contribution from Department of Chemistry, Laval University, Quebec, Que., with financial assistance from the Defence Research Board of Canada.
[2]*Present address: Lignosol Chemicals Limited, Quebec, Que.*

by centrifuging at 4000 r.p.m., for 5 minutes. Cotton cellulose nitrates could be dried by this method to approximately 35% moisture content and wood cellulose nitrates to about 45%. Samples were then set aside for moisture, nitrogen, and sulphate determinations (3). The per cent sulphate acid ester contents of the cellulose nitrates were determined by the hydrolysis method (6).

Hydrolysis of Sulphate Acid Ester in Unstabilized Cellulose Nitrates

The initial acidity of moist samples of cellulose nitrate in which there was no hydrolysis was determined by titration in 90% acetone/water solution, using the method recently described (6).

Hydrolysis experiments were performed on duplicate moist samples (2–3 g. dry weight) of cellulose nitrate dissolved in 99% acetone/water (700 ml.). Reagent grade acetone which contained 0.63% water, determined by an infrared absorption method, was used. The solutions were immediately placed in a constant-temperature bath controlled at 25°±0.1° C. The starting time of the experiments was taken when half the solvent had been added to the sample. Aliquots (100 ml.) were removed from the solutions at intervals and the hydrolysis stopped by dilution with distilled water (100 ml.). The increase in acidity was measured by titration with 0.01 *N* potassium hydroxide using a Macbeth pH meter.

The per cent hydrolysis was calculated directly by using the zero hydrolysis and 24-hour titers, expressed as milliliters per gram of cellulose nitrate. The 24-hour value represents the total sulphate content, because the sulphate acid ester is completely hydrolyzed. A typical example serves to illustrate the calculations involved. For a 12.1% unstabilized cotton cellulose nitrate containing 100% sulphate acid ester and 0.75% water, the zero hydrolysis titer was 5.19 ml./g. After 1 hour of hydrolysis, the titer was 11.50 ml./g. The 24-hour hydrolysis titer was 13.40 ml./g. Therefore, the percentage hydrolysis after 1 hour was $[(11.50-5.19)/(13.40-5.19)]\times 100 = (6.31/8.21)\times 100 = 77$.

RESULTS AND DISCUSSION

The difference in the rate of solvolysis of the sulphate acid ester and nitrate groups in unstabilized cellulose nitrate has been established by Gagnon *et al.* (5). In the present work, it was found that hydrolysis of the sulphate acid ester, RSO_4H, of cotton cellulose nitrate was effectively stopped by dissolving the moist cellulose nitrate in 90% acetone/water solution. The rate of hydrolysis was too slow to produce a measurable increase in acidity during 24 hours. Similar results were obtained for wood cellulose nitrates. Gagnon *et al.* (10) obtained similar results for the sulphate ester in cellulose acetate sulphate.

It was found that hydrolysis of the sulphate acid ester in unstabilized cotton cellulose nitrate could be carried out satisfactorily in 99% acetone/water solution at 25° C. In general, the initial hydrolysis of the sulphate acid ester is very rapid. For example, in one experiment, for an 11.7% N cotton cellulose nitrate containing 83% sulphate acid ester, the difference between the zero hydrolysis and 5-minute hydrolysis titers was 4.17, expressed as milliliters 0.01 *N* KOH per gram of cellulose nitrate. The difference for the 24-hour titer was 7.12 ml./g. The rate of hydrolysis slowed down considerably after 5 minutes. For instance, the difference between 5-minute and 1-hour hydrolysis titers was only 1.55 ml./g. In general, it can be said that the sulphate acid ester of unstabilized cotton cellulose nitrate is considerably hydrolyzed in the first hour.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The amount of sulphuric acid released by hydrolysis of low sulphate ester content cotton cellulose nitrates was very small. For a 13.3% N cellulose nitrate containing 46% ester, the sulphuric acid released after 24 hours was only 0.32%.

The rate of hydrolysis curves for the sulphate acid esters in four cotton cellulose nitrates, containing very similar amounts of water and sulphate ester, are shown in Fig. 1.

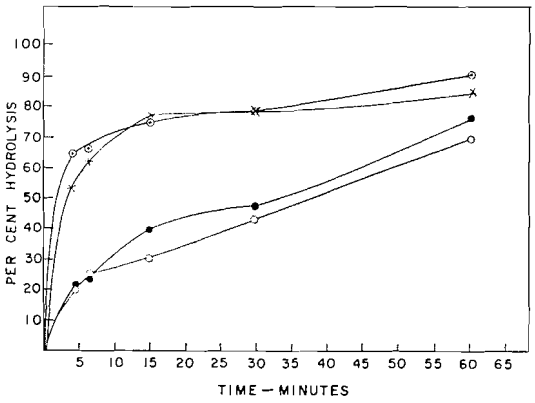

FIG. 1. Hydrolysis of the sulphate acid ester in cotton cellulose nitrates.

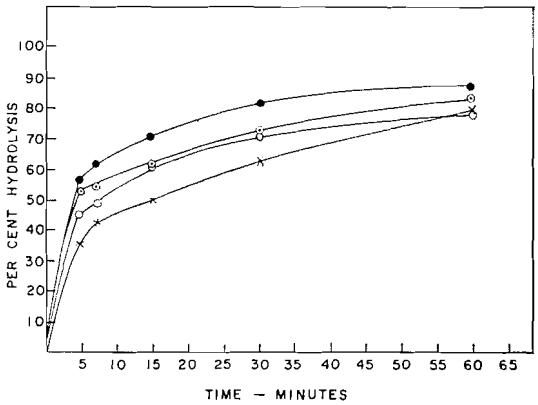

FIG. 2. Hydrolysis of the sulphate acid ester in wood cellulose nitrates.

Nitrogen, %	Sulphate acid ester, %	Sulphuric acid, %		Water concn., % vol.
		Grav.	Titrimetric	
⊙ 11.6	96	0.95	0.94	0.64
× 11.4	100	1.00	0.93	0.78
● 12.1	100	0.58	0.64	0.75
○ 11.9	100	0.69	0.75	0.77

There was 53% hydrolysis of sulphate ester in the first 5 minutes for a cellulose nitrate containing 11.4% nitrogen whereas there was only 20% hydrolysis for a 12.1% N cellulose nitrate. Similar results are shown for cellulose nitrates containing 11.6% and 11.9% nitrogen. Each curve represents the results obtained from duplicate hydrolysis experiments on the same cellulose nitrate sample. The hydrolysis values could be reproduced and the nitrogen contents were determined with good precision (9). It was very difficult to prepare cotton cellulose nitrates containing similar sulphate acid ester and water contents.

It appears that the rate of hydrolysis of the sulphate ester decreased as the nitrogen content increased (Fig. 1). This effect could be explained by the ester groups being sterically hindered by nitrate groups.

In the present work, hydrolysis experiments were also carried out on unstabilized wood cellulose nitrates. There was rapid initial hydrolysis of the sulphate acid ester, followed by slower hydrolysis up to 24 hours. For instance, in one experiment with a 12.8% N wood cellulose nitrate containing 55% sulphate acid ester and 1.26% water, the difference between zero and 5-minute hydrolysis titers was 3.00 ml./g. After 1 hour of hydrolysis, the difference rose to 6.30 and finally after 24 hours it was 8.10 ml./g.

The rate of hydrolysis curves for the sulphate esters of four wood cellulose nitrates containing similar sulphate ester and water contents are given in Fig. 2. The initial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

hydrolysis was very rapid. For example, for an 11.8% N wood cellulose nitrate, there was 53% hydrolysis of the sulphate acid ester in the first 5 minutes and the corresponding value after 1 hour was 80%.

Nitrogen, %	Sulphate acid ester, %	Sulphuric acid, %		Water concn., % vol.
		Grav.	Titrimetric	
⊙ 11.8	96	1.23	1.26	0.94
× 11.7	97	1.33	1.36	0.98
● 11.4	98	2.32	2.11	0.96
○ 10.8	97	1.71	1.65	1.00

There are similarities between these curves and those obtained for cotton cellulose nitrates (Fig. 1). However, the curves cannot be strictly compared because cotton and wood cellulose nitrates having the same nitrogen content contained different amounts of moisture.

There was no striking difference between the rates of hydrolysis of wood cellulose nitrates containing different amounts of nitrogen (Fig. 2) as was the case for cotton cellulose nitrates. This fact could possibly be explained by structural differences. Wood cellulose nitrates having similar sulphate ester and moisture contents could be prepared without difficulty in contrast to cotton cellulose nitrates.

The rate of hydrolysis curves for cotton and wood cellulose nitrates (Figs. 1 and 2) are similar in shape to those given previously (10) for the hydrolysis of cellulose acetate sulphate. In general, the hydrolysis of the sulphate ester in both unstabilized cotton and wood cellulose nitrates is very similar to that of the sulphate ester in cellulose acetate sulphate.

THE KINETICS OF THE THERMAL DECOMPOSITION OF ETHYL BROMIDE AND ETHYL BROMIDE-d_5[1]

ARTHUR T. BLADES

ABSTRACT

The kinetics of the pyrolysis of ethyl bromide and ethyl bromide-d_5 have been studied using the toluene carrier gas technique. Variation of the pressure in the range 0.6 to 4.4 cm. Hg reveals what is believed to be a legitimate pressure effect on the first-order rate constants. The Arrhenius rate expressions determined at 4 cm. Hg pressure are:

k(ethyl bromide) $= 8.5 \pm 1.6 \times 10^{12} e^{-52,200 \pm 300/RT}$ sec.$^{-1}$ (T = 523°–633° C.);

k(ethyl bromide-d_5) $= 2.1 \pm 0.4 \times 10^{13} e^{-54,840 \pm 300/RT}$ sec.$^{-1}$ (T = 531°–635° C.).

The differences in the two rate expressions are discussed.

INTRODUCTION

The thermal decomposition of alkyl bromides into the alkene and hydrogen bromide occurs more or less homogeneously and with few other detectable products. The effect of inhibitors on the rates of decomposition of the secondary and tertiary compounds is, in general, small, but with primary bromides the rates are reduced to a limiting value (1, 2, 3, 4, 5, 6, 7). While the order of reaction in the uninhibited pyrolysis is often obscure, the fully inhibited decomposition of all the compounds studied is believed to be unimolecular.

An example of such a decomposition is that of ethyl bromide into ethylene and hydrogen bromide. This reaction has long been known to be first order, but recent investigations of the pyrolysis by Goldberg and Daniels (2) reveal that, though the decomposition is first order, there is an induction period and the products both accelerate and retard the decomposition. They indicated that ethylene, *n*-hexane, and toluene (8) reduce the rate of decomposition to a limiting value at which the only significant reaction is the simple unimolecular decomposition:

$$C_2H_5Br \rightarrow C_2H_4 + HBr.$$

Recent studies of this decomposition in cyclohexene by Green, Harden, Maccoll, and Thomas (3) confirm this conclusion. An attempt to use the carbon isotope effect (9) to confirm the intramolecular nature of this reaction has been contested (10) on the grounds that the rate constants in the system were unusually high.

The present work was undertaken as a preliminary to a more intensive investigation of the carbon and hydrogen isotope effects in this decomposition.

EXPERIMENTAL

The toluene carrier-gas technique, in which the compound is decomposed in a large excess of toluene in a flow system, was used in this study. The apparatus was essentially a replica of that previously used (8); however, provision was made for the introduction of the toluene at higher pressures. This was achieved by the use of heated lines and a thermostatically controlled bath around both the toluene supply and the oil–mercury manometer. The ratio of toluene to ethyl bromide in the pyrolyzed gases was maintained as high as possible, consistent with the pressure and contact time requirements of each

[1]*Manuscript received March 7, 1958.*
Contribution No. 66 from the Research Council of Alberta, Edmonton, Alberta. This article is based on a paper presented at the 41st Annual Conference and Exhibition of The Chemical Institute of Canada, Toronto, May 26–28, 1958.

experiment. The reaction cell was 8 inches long and $\frac{3}{4}$ inch in diameter. Consideration for possible errors as a result of the heat load on the furnace dictated the use of contact times up to 2.2 seconds at the higher pressures. The products were condensed in a liquid nitrogen trap, and the rate constants were based on the titration of the hydrogen bromide with 0.1 N sodium hydroxide.

The commercial, ether-free ethyl bromide was distilled over phosphorus pentoxide on a 36-inch glass helix packed column; b.p. 36.1° C. at 70.2 cm. Hg. The deuterium compound, supplied by Merck and Co., was stated to be 99+% ethyl bromide-d_5 and was not further purified. The toluene was reagent grade and was distilled over sodium. All compounds were thoroughly degassed before use.

In investigating the temperature coefficients of the two pyrolyses, an attempt was made to carry out experiments on the two compounds under identical conditions so that relative rates might be plotted as a function of temperature. However, the results of such a plot indicated a difference in activation energy essentially the same as that from the individual rate expressions obtained from a least squares treatment of the data. The errors quoted are the indicated maxima from an average deviation in k of $1\frac{1}{2}$%.

RESULTS

Pressure Effect

The effect of pressure on the rate constants was investigated over the range 0.6 to 4.4 cm. Hg. Each first-order rate constant plotted in Fig. 1 represents a single analysis and must not be regarded as a limiting rate at zero conversion. No attempt was made to adjust conditions to produce uniform conversion and hence the precise shape of the curves is not too significant.

16	4.02	17	2.17	5.5	804.2	0.0256

Temperature Dependence

In investigating the temperature coefficient of the rate it was necessary to operate at a pressure of about 4 cm. Hg in order to obtain data in a region where errors due to non-first-order behavior would be no greater than the experimental error. The rate expressions calculated from the data in Table I were, for ethyl bromide:

$$k = 8.5\pm1.6\times10^{12}e^{-52,200\pm300/RT}\text{sec.}^{-1},$$

and for ethyl bromide-d_5:

$$k = 2.1\pm0.4\times10^{13}e^{-54,840\pm300/RT}\text{sec.}^{-1}.$$

The former compares very favorably with the previously reported expression (8) obtained by this technique,

$$k = 7.3\times10^{12}e^{-52,300/RT}\text{sec.}^{-1} \text{ at } p = 2.0\pm0.2 \text{ cm. Hg},$$

especially since the lower pressure would be expected to make the results 10% low.

An Arrhenius plot of the data is presented in Fig. 2 and a similar plot for the ratio of the rate constants is shown in Fig. 3.

DISCUSSION

The mechanism for the totally inhibited decomposition of many of the alkyl bromides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

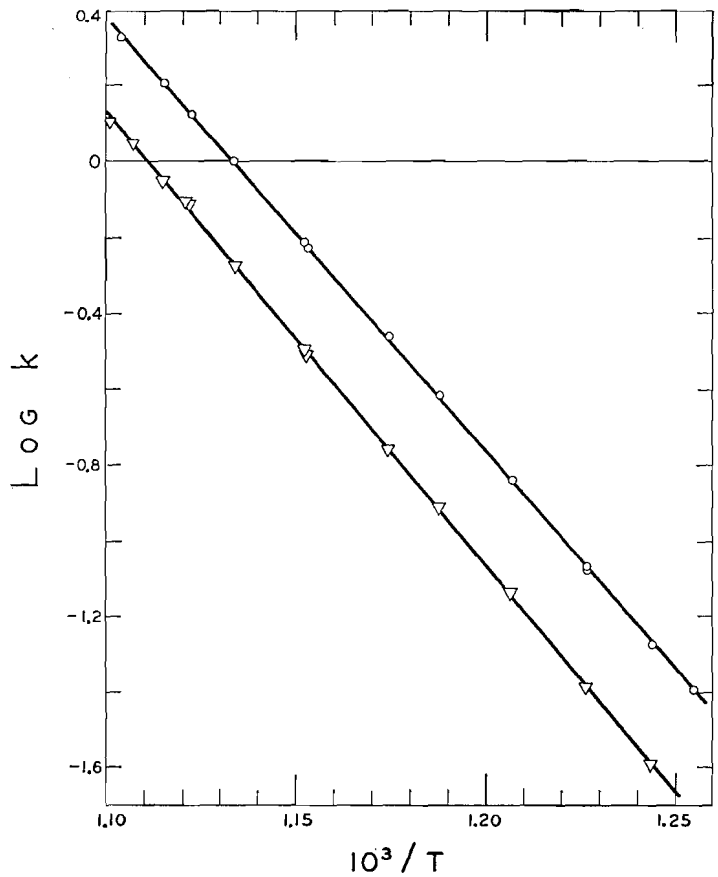

FIG. 2. Arrhenius plots for ○ ethyl bromide and ▽ ethyl bromide-d_5.

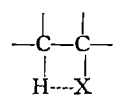
and chlorides is now generally accepted to involve the formation of a "four-centered" activated complex (8, 11).



Since this is such a relatively simple mechanism, it is particularly satisfying that highly accurate and reproducible rate expressions can be obtained by the use of the toluene carrier-gas technique. Hence the decomposition of ethyl bromide seems ideal for a careful study of isotope effects in intramolecular decomposition reactions.

The effect of pressure on the rate constants for the two compounds indicates a quasi-unimolecular reaction below about 4 cm. Hg for each of them. Although this effect occurs in an atmosphere largely composed of toluene, it is likely that the collision efficiencies of the toluene and the bromides are sufficiently similar so that the pressure would be much the same as for the decomposition of the pure gases. The limited pressure range of the data for this effect renders a calculation of the Hinshelwood-Lindemann degrees-of-freedom fruitless. It is noteworthy that the pressure effect for the ethyl chloride decomposition (12) becomes apparent around 1 cm. Hg pressure despite a considerably higher frequency factor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

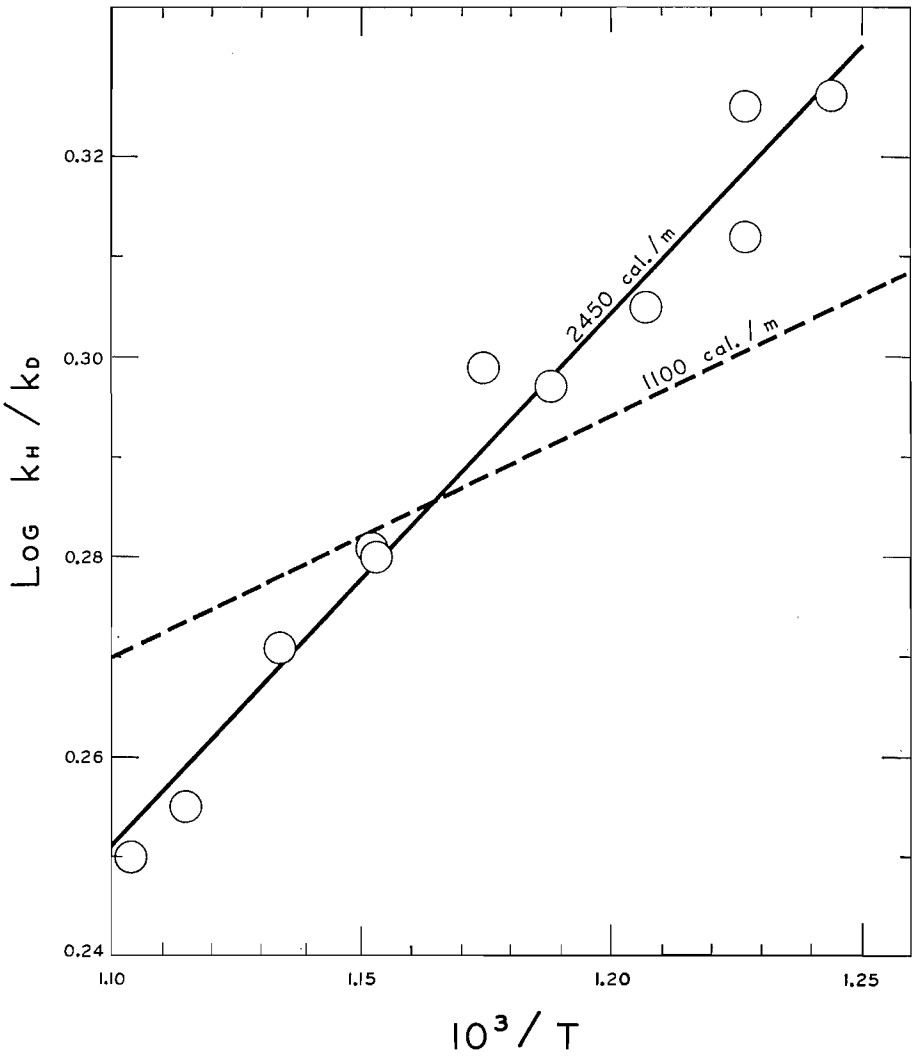


FIG. 3. Arrhenius plot for the ratio of rate constants for ethyl bromide and ethyl bromide-d_5.

The two Arrhenius rate expressions are interesting in two respects, namely, the large difference of 2600 cal./mole in the activation energies and the lower frequency factor for the hydrogen compound. Reference to the Bigeleisen (13) theory of the kinetic isotope effect suggests that the maximum difference in activation energy should be the difference in the zero-point energies in those vibrations associated with activation. Since a single carbon–hydrogen stretching frequency may account for only 1100 cal./mole, it is evident that other methyl group vibrations must be invoked to account for the observed activation energy difference.

The abnormal frequency-factor ratio of 0.4 cannot be so readily explained since the Bigeleisen theory predicts a frequency factor ratio between 1 and $\sqrt{2}$ and it would require an error of 1500 cal./mole in the activation energy difference to make the experimental rates consistent with a ratio of unity. A similarly anomalous ratio has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

observed in the relative rates of rearrangement of cyclopropane and cyclopropane-t_1 (14), and several possible explanations have been advanced which might be applicable here.

A classical rotational kinetic isotope effect occurs in these decompositions in addition to the effects discussed above. Since the activation step involves the conversion of an internal rotational degree of freedom into a less active vibration, a negative entropy of activation should result. For the ethyl bromide-d_5, however, the reduced moment of inertia about C—C bond will be almost twice as large as for the hydrogen compound, resulting in a greater entropy of internal rotation of about $(R \ln 2)/2$ and hence a greater change in entropy during activation. A maximum additional factor of $\sqrt{2}$ would be predicted for this kinetic isotope effect.

ACKNOWLEDGMENTS

REACTIVITY STUDIES ON NATURAL PRODUCTS

V. RATES OF BOROHYDRIDE REDUCTION OF SOME RING A AND B STEROID KETONES[1]

OWEN H. WHEELER[2] AND JOSÉ L. MATEOS[3]

ABSTRACT

The rates of reduction of 3-, 6-, and 7-cholestanone, coprostan-3-one, Δ^4- and Δ^5-cholesten-3-one, and $\Delta^{8(14)}$-ergosten-3-one with sodium borohydride in isopropanol have been measured. The proportions of α- and β-isomers formed were determined in most cases and the corresponding rates of equatorial and axial reduction obtained. Δ^4-Cholesten-3-one and 6- and 7-cholestanone are reduced at a slower rate and Δ^5-cholesten-3-one and $\Delta^{8(14)}$-ergosten-3-one at a higher rate than the saturated 3-ketosteroids.

Sodium borohydride has been used as a selective reducing agent in steroid chemistry and preparative reductions have been reported of a 3-keto group of both allo and normal steroids, in the presence of 11- (1), 12- (2), 17- (3), and 20-keto groups (4, 5), of a 3-keto group in the presence of both 11- and 20-keto groups (5), and of a 20-keto group in preference to an 11-keto group (6) and a Δ^4-3-keto system (7). Garrett and Lyttle (8) in a kinetic study found that under their conditions the 3-keto group of pregnan-3,20-dione was reduced instantaneously and the 20-keto group at a measurable rate. All these examples of selective reduction involve positions in the steroid molecule which are known to have quite different steric environments. In the present work the reactivities of some ring A and B ketosteroids (see Table I), which would be expected to have smaller differences, have been measured.

TABLE I

KINETICS OF BOROHYDRIDE REDUCTION*

	$k \times 10^4$	Ratio†
Cyclohexanone	565±3	1.4
Cholestan-3-one	397±7	1.0
Coprostan-3-one	434±6	1.1
Cholestan-6-one	241±6	0.60
Cholestan-7-one	111±2	0.28
Δ^4-Cholesten-3-one	54.8±1.2	0.14
Δ^5-Cholesten-3-one	1320±18	3.3
$\Delta^{8(14)}$-Ergosten-3-one	610±11	1.5

*In isopropanol at 25.0°. Rate constants in liter mole^{-1} sec.$^{-1}$.
†Ratio of rate constants to cholestan-3-one = 1.0.

The solvent used by Garrett and Lyttle was aqueous dioxan but this gave very fast and irreproducible results with our very reactive ketones. Recently Brown and co-workers (9, 10) have used isopropanol for kinetic studies and this proved suitable because of the stability of borohydride in this solvent, the solubility of the steroids, and their reasonably slow rates of reduction. Although cholestan-3-one and coprostan-3-one undergo bromination at different rates (11), their rates of reduction are very similar and only a little less than that of cyclohexanone and this is to be expected since there are no large steric or strain effects influencing addition to the exocyclic double bond. However 6- and

[1]*Manuscript received February 12, 1958.*
Contribution from the Instituto de Quimica, Universidad Nacional Autonoma de Mexico, Mexico 20, D.F.

7-cholestanone undergo reduction at a greatly reduced rate. The principal effect decreasing the rate of reduction of the 6-ketone will be steric hindrance from the axial methyl group at C-10 (12), and the 7-ketone is hindered from attack of borohydride ion by the 'eclipsing effect' of the α-hydrogen atom on C-15 (12). Moreover, the ketone groups of both these compounds will be subject to the inductive effect of the alkyl group of the adjacent ring which will depolarize and further deactivate the carbonyl group (13), as compared to that of cholestan-3-one. Selective reduction of a 3,7-diketone should be possible, since assuming no mutual interaction, one equivalent of borohydride would reduce only 22% of the 7-keto group.

In the case of Δ^4-cholesten-3-one resonance interaction in the α,β-unsaturated ketone system will reduce the charge on the ketone group and reduce its reactivity (12). However in the case of Δ^5-cholesten-3-one there is no loss of resonance energy on reduction, but hyperconjugative interaction will stabilize the borohydride reduction intermediate and lead to an increased rate of reduction. $\Delta^{8(14)}$-Ergosten-3-one also shows an increased rate of reactivity as compared to cholestan-3-one, but it seems unlikely that this can be electronic in origin since the double bond is so remote from the keto group. The double bond in ring C will produce small distortions in the conformation of the rings which will be transmitted to ring A and this is also distorted by the keto group (11). Reduction will reduce some of the distortion in this ring and is therefore favored.

The percentages of α- and β-alcohols formed were determined for five of the ketones (Table II) and the over-all rates of reduction have been divided into the rates of formation of these α- and β-isomers (Table III) resulting from quasi-equatorial and quasi-axial attack (14) (also termed 'exo' and 'endo' attack (15)). The percentage of equatorial isomers formed from cholestan-3-one and coprostan-3-one is similar to that from 4-methylcyclohexanone (14), agreeing with the previous suggestion that 3-ketosteroids are not subject to any large steric effects.

The reduction of cholestan-7-one gives a large amount of cholestane and, although the rate of 'equatorial' reduction is considerably less than that for cholestan-3-one, the rate of 'axial' reduction is only slightly reduced. This suggests that reduction of the 7-keto group by attack from the underside of the molecule is not particularly hindered, whereas reduction in the equatorial plane of the molecule is highly hindered. The principle factor seems to be the 'eclipsing effect' of the 15α-hydrogen atom (11), but the shielding of the methyl groups on carbons 10 and 13 will also decrease the rate of attack from the topside. The cholestane probably arises by steric repulsion, from the 7β-position, of the bulky carbonyl–borohydride reduction complex. Steric acceleration in the chromium trioxide oxidation of 7α-cholestanol, known to involve the attack of a chromium ester on the β-hydrogen atom, has also been observed (16).

The introduction of a double bond into a cyclohexanone ring will lead to a flattening of the ring (17). In the reduction of cholest-4-en-3-one the preferred transition state for reduction will be that leading to the formation of the equatorial alcohol, since this allows maximum interaction between the π-electrons of the double bond and the borohydride radical. β-Cholest-3-en-ol constitutes the major product and the decrease in rate is much greater for the formation of the α-alcohol.

The double bond in cholest-5-en-3-one also distorts the molecule and ring A is bent down from the equatorial planes of the other rings (18). However no large steric effects are introduced and since electronic interaction is much less than that for cholest-4-en-3-one the relative rates of equatorial and axial reduction increase equally.

A previous study of the reduction of cholest-4-en-3-one with sodium borohydride in aqueous methanol reported (19) that 74% of the β-isomer was formed. However in the present work 95% of the β-isomer was isolated and this is in agreement with the observations that cholesta-4,6-dien-3-one (20) and cholest-1-en-3-one (21) give essentially the β-isomer. In the present work 58% of cholestan-7β-ol was formed in the reduction of cholestan-7-one. However, the reduction of 3β-acetoxycholestan-7-one with sodium borohydride in aqueous methanol (14) was reported to give only 27% of cholestan-3β,7β-diol. The analysis was based on the assumption that the inseparable mixture of diols formed contained only cholestanediols. Cholestan-3β-ol was probably also formed.

EXPERIMENTAL

The ketones used were those prepared in a previous study (12).

Kinetics.—The ketone (*ca.* 0.6 g.) was dissolved in anhydrous isopropanol (90 ml.) in a flask which was allowed to equilibrate in temperature in a constant-temperature bath maintained at 25.0±0.1°. A solution (10 ml.) of sodium borohydride (98% purity, *ca.* 0.3 *N*) in isopropanol was added and the flask rapidly shaken. The halftime of addition was taken as zero time and aliquots (10 ml.) were withdrawn at definite times and added to excess potassium iodate (0.1 *N*) containing potassium iodide. The halftime of delivery of the pipette was taken as the time of sampling. Sulphuric acid (10 ml., 2 *N*) was added and the liberated iodine titrated with 0.1 *N* sodium thiosulphate using starch as indicator (9). The rate constants were calculated from a second-order rate plot and straight line graphs were obtained up to 90% reaction. Each experiment was repeated 3 or 4 times and the average results with their mean errors are given in Table I.

Isolation of products.—All the optical rotation measurements were carried out with chloroform solutions at 25°.

Cholestan-3-one.—A solution of 1.0 g. of this ketone in isopropanol (75 ml.) was mixed with sodium borohydride in isopropanol (75 ml., 0.3 *N*). After 24 hours at room temperature the solution was diluted with water and the cholestanols (1.0 g., m.p. 114–117°)

extracted with ether. The mixture was separated by chromatography on alumina into α-cholestanol (140 mg.), m.p. 180–182°, eluted with benzene and β-cholestanol (840 mg.), m.p. 135–138°, eluted with benzene–ether.

Coprostan-3-one.—Similar reduction of coprostanone (300 mg.) gave a mixture of coprostanols (205 mg.), m.p. 82–85°, which could not be separated by chromatography. Treatment with digitonine in ethanol gave a precipitate (110 mg.) corresponding to β-coprostanol (26.3. mg.), and evaporation of the mother liquor gave α-coprostanol, m.p. 118°.

Cholestan-7-one.—This ketone (500 mg.) was reduced as above and the oily product chromatographed on unwashed alumina using a proportion of 80/1. Hexane eluted cholestane (150 mg.), m.p. 77–79°. Hexane–benzene mixtures eluted successively cholestan-7α-ol (110 mg.), m.p. 74–77°, and cholestan-7β-ol (130 mg.), m.p. 114–115°.

Δ^4-*Cholesten-3-one.*—The crude product had $[\alpha]_D^{CHCl_3}$ 47.0°, corresponding to cholest-4-en-3β-ol, $[\alpha]_D$ 44°, 96%, and cholest-4-en-3α-ol, $[\alpha]_D$ 121°, 4%. It could be separated by chromatography on alumina, using hexane–benzene (4/1) as eluent, into the α-alcohol (5%), m.p. 84°, and the β-isomer (95%), m.p. 130–132°.

Δ^5-*Cholesten-3-one.*—The two isomeric alcohols formed could not be separated by chromatography, but were separated by digitonine treatment into cholesterol (83%), m.p. 148–149°, and epicholesterol (17%), m.p. 140–141°, which was recovered from the mother liquors.

ACKNOWLEDGMENT

The authors are grateful to Professor H. C. Brown for discussions on the procedure for the borohydride kinetics. The work was supported by grants from the Rockefeller Foundation, New York, and the Instituto Nacional de la Investigacion Cientifica, Mexico.

THE EFFECT OF ADDITION OF POTASH TO NICKEL CHROMITE CATALYSTS[1]

H. C. ROWLINSON[2]

ABSTRACT

Experiments are described on the dehydrogenation of butene-1 in the presence of steam, over three nickel chromite catalysts. These are: (*a*) pure nickel chromite, (*b*) nickel chromite pellets impregnated with potash from solution, and (*c*) a catalyst with potash added before the nickel oxide and chromium sesquioxide are combined. The oxidation state of the catalyst largely affects the products, for overreduction causes disruption of the hydrocarbons. The effect of the potash is to prevent this overreduction and thus to improve selectivity to butadiene. There is a difference between the behavior of catalysts with surface potash (type *b*) and those where the potash is distributed through the mass (type *c*). This difference is explained by the formation of large pores on reduction of type (*c*) catalysts.

INTRODUCTION

The use of potash as a promoter has been extensively studied (1) for iron – synthetic ammonia catalysts. In addition it is widely used to encourage the water–gas reaction on dehydrogenation catalysts, and recently its effects on Cr_2O_3–Al_2O_3 have been investigated (2) for several reactions. This work reports the effect of potash additions to a nickel chromite catalyst used for the dehydrogenation of butene-1, and represents part of a larger study of olefin dehydrogenation catalysts which contain nickel chromite. In particular, the difference is emphasized, in this case, between catalysts to which the KOH has been added to the bulk of the material, and those to which it is added by impregnation from solution.

EXPERIMENTAL

Preparation of Catalysts

Three different catalysts were prepared; those of pure $NiCr_2O_4$, those with 10 wt.% K_2O "built in", and those with the K_2O added on the surface. The nickel chromite was prepared from reagent grade Cr_2O_3 powder and $Ni(NO_3)_2.6H_2O$ crystals. Upon warming of the appropriate mixture, the nitrate dissolved in its water of crystallization, and the whole was mixed to a homogeneous mush. In those catalysts where the potash was to be "built in" it was added at this stage. This mixture was then heated to 900° C. for 3 hours, cooled, powdered, and pelleted with 2% graphite. The pellets used were cylindrical, $\frac{1}{8}$ in. × $\frac{1}{8}$ in. The pellets were then fired at 1050° C. for 4 hours before use, and in the absence of KOH were shown by X-ray spectrography to be the spinel $NiCr_2O_4$. Some of the pellets were then impregnated with a potash solution by immersion of 10 g. of pellets in 10 cc. of solution containing 0.3 g. of KOH. The pellets absorbed about 6 cc. in a few minutes at room temperature and thus contained approximately 0.125 wt.% of K_2O. They were dried by heating slowly to 600° C.

Reaction Conditions

The reactor was a stainless steel (type 446) tube of internal diameter $\frac{5}{8}$ in. and has been described elsewhere (3). A flow system was used with a bed volume of 10 cc. The butene-1 feed was diluted with 10 to 12 volumes of steam preheated to 600° C., and the product gases were collected over water, and analyzed in the mass spectrograph. Flow

rates of approximately 110 v/v per hr. were measured by a flow meter on the butene feed. Two estimates of the efficiency of the catalysts could thus be calculated: (*a*) percentage conversion, i.e., the mole percentage of butene that has decomposed, and (*b*) percentage selectivity, i.e., the mole percentage of the decomposed butene that is converted to butadiene. The butene in the product gas was normally the equilibrium mixture of 1- and 2-butene, although butene-1 was the feed.

RESULTS

1. Performance of the Catalysts

(*a*) *Nickel Chromite Unpromoted*

This catalyst was stable below about 590° C., and gave, for example, a conversion of 14% with a selectivity of 65% at 575° C. Above 590° C. the nickel chromite catalyst showed the phenomenon of "wildness" described by Reilly (4). This state allowed a cracking reaction to take over from the dehydrogenation, and thus caused a progressive increase in product gas, mainly H_2 and CH_4. The selectivity to butadiene fell effectively to zero, and there was a considerable lay-down of carbon.

(*b*) *Nickel Chromite Impregnated with Potash Solution*

It was not found possible to make this catalyst "wild". In addition, the selectivity to butadiene was greatly improved, as is shown by the results in Table I. The catalyst as prepared by heating in air had a great amount of surface chromate and dichromate; this

TABLE I

DEHYDROGENATION OF BUTENE-1 ON AN "IMPREGNATED" CATALYST (TYPE *b*)

Temp., ° C.	Conversion, %	Selectivity, %
587	13.1	90
613	15.5	85
613	17.7	82 feed <100 v/v per hr.
637	25.0	81
636	22.8	72 after air regeneration
630	21.6	78

was most easily shown by placing a pellet in cold water when the characteristic orange color was seen (2). Thus in the initial few minutes of the catalytic reaction the reduction of surface chromate took place with a consequent large production of CO_2. Finally it may be noted that there was very little lay-down of carbon on this catalyst. The amount of carbon lay-down was measured by burning it off with air and steam and collecting the CO_2 on "Ascarite". This burnoff was enacted every $\frac{1}{2}$ hour for the unpromoted catalyst (*a*) above, but in the presence of surface potash it was found that steam alone would restore the activity of the catalyst and even this treatment was needed only after several hours' use. Moreover, the use of air regeneration on the potash-promoted catalysts reduced its selectivity as is shown in the last two results in Table I.

(*c*) *Nickel Chromite with Potash Built In*

This catalyst also would not display "wildness", but two other characteristics distinguished it from the catalyst with potash on the surface. The first is its behavior in the initial half hour of activity. A typical plot of the rates of formation of product gas against time is given in Fig. 1. The first product is largely CO_2 and corresponds to the reduction of chromate; the subsequent rapid product-gas increase is mainly due to hydrogen formation and resembles a "wild" condition except that it tapers off to a performance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

roughly equivalent to that of the impregnated catalysts, e.g., a conversion of 22% and a selectivity of 78.1 at a temperature of 622° C. This state is quite stable.

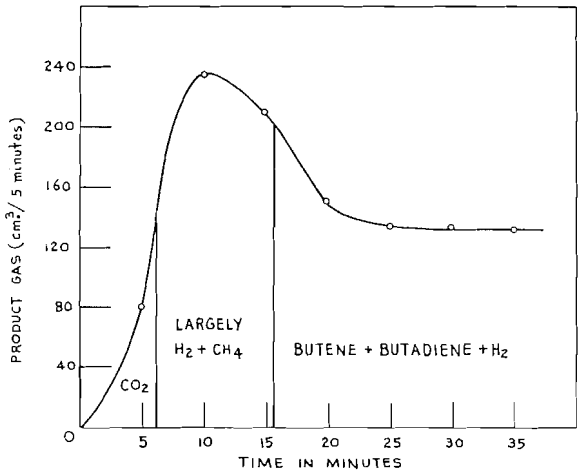

FIG. 1. Rates of product-gas formation against time for a "built-in" catalyst (type *c*). The rates are in cm.³ of gas produced over a 5-minute interval and are plotted at the end of each 5-minute interval.

The second difference between catalysts (*b*) and (*c*) is that on the latter there is considerable carbon lay-down. On a given catalyst sample the amount of this lay-down is independent of the time the catalyst is in use, and for most samples was of the order of 0.135 g. on 10 g. of catalyst (all samples contained 10 wt.% of K_2O). Experiments showed that all this carbon was laid down in the period between 5 and 15 minutes when the rate of product gas formation was large. Preliminary reduction of the catalyst with H_2 gas removed the first part of the rate of gas formation curve, but did not remove the second (large gas production) part, nor did it affect the lay-down of carbon.

2. Surface Area Measurements

Surface areas of the potash-promoted catalysts were measured by the standard B.E.T. nitrogen-adsorption method. To check that chemisorption was not occurring (5), the areas were remeasured with argon at liquid oxygen temperatures. The values of 16.2 Å² and 15.0 Å² were used for the cross-sectional areas of N_2 and A respectively (6, 7). The results of these measurements are given in Table II, and the terms "oxidized" and "reduced" are discussed below.

TABLE II

SURFACE AREAS OF POTASH PROMOTED CATALYSTS (m.²/g.)

	"Impregnated" catalyst (type *b*)		"Built-in" catalyst (type *c*)	
	With N_2	With A	With N_2	With A
Oxidized	2.19	2.20	0.672	0.646
Reduced	3.32	3.39	11.4	11.9

DISCUSSION

The most obvious effect of the addition of potash to nickel chromite catalysts is the prevention of "wildness". This state is believed to be due (3) to the reduction of nickel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

oxide to nickel metal, and it is the latter that is the disruptive catalyst. It is of interest that the tendency to "wildness" disappears also in potash-free catalysts containing more Cr_2O_3 and less NiO (at approximately 75 mole % and more of Cr_2O_3). However, in this latter case reduction still takes place during catalytic action as is shown by the heat output on regeneration with air (independent of carbon burnoff). Presumably it is the agglomeration of reduced metal "ions" into metallic particles that is prevented by the excess chromia. Thus, it can be concluded that in the promoted catalysts the presence of potash on the chromia prevents either the reduction of metal oxide or the formation of metallic particles. However, the addition of potash to pure NiO does not prevent the "wildness" of this catalyst which sets in at about 520° C.

The difference between catalysts with impregnated and "built-in" potash is an unusual one; there is, for example, no similar difference in the reduction of iron oxide for synthetic ammonia catalysts (8). A possible explanation is that the formation of potassium chromate in catalyst (*c*) leaves some NiO uncombined, and that the latter behaves in a "wild" manner until covered by carbon. This explanation must be rejected, for decreasing the percentage of NiO to zero does not affect the phenomenon illustrated in Fig. 1, nor the constant carbon lay-down. Thus, it seems most likely that there is a pore effect; the reduction of the potassium chromate in the case where the potash is distributed through the mass leaves a network of tiny pores in which the butene decomposes to carbon because the butadiene cannot diffuse out. This yields the large volume of H_2 observed, and explains the constant carbon lay-down. When the pores are full of carbon the catalyst behaves like a surface-promoted one. The surface areas appear to support this explanation. For these measurements, used catalyst samples were oxidized to remove the carbon, and surface areas measured in the oxidized state. Then the samples were reduced briefly at 600° C. with hydrogen, so that there could be no lay-down of carbon, and the areas of the reduced catalysts measured. There is an increase in area by a factor of approximately 15 on reduction of the catalyst with the "built-in" potash, whereas for the surface-promoted one the factor is 1.5. This difference must be ascribed to the formation of pores in the solid mass of the catalysts of type (*c*) due to the decrease in volume of K_2CrO_4 when reduced to Cr_2O_3 and K_2O.

THE CRYSTALLIZATION OF CALCIUM SULPHATE DIHYDRATE[1]

O. J. SCHIERHOLTZ

ABSTRACT

In this preliminary series of experiments, calcium sulphate dihydrate has been allowed to crystallize spontaneously from solutions of varying degrees of supersaturation, and induction periods and rate constants have been determined. The effect of crystal area, pH, and accelerators and retarders on this process has been examined. The degree of supersaturation has a direct effect on both the induction period and rate constant. Nucleation is affected markedly by pH. Salts having an ion in common with calcium sulphate function as accelerators. Retarders affect the induction period in proportion to their concentration, but show little, if any, effect on the rate of crystallization. The behavior of the various reagents under the conditions prevailing in these experiments is largely in accord with observations on the behavior of commercial plasters.

INTRODUCTION

The work described in this paper was undertaken because of the apparent conflict of explanations offered in the literature for some of the phenomena observed in the setting of commercial gypsum plasters, which involves the crystallization of calcium sulphate dihydrate. A clearer understanding of the function of accelerators and retarders would be of considerable value in the manipulation of commercial plasters for specific purposes.

The results of several previous studies (1, 2, 3) indicate that the hemihydrate dissolves to form a solution supersaturated with respect to the dihydrate, which then crystallizes out. Photomicrographic (1) and radioisotope (3) studies support this view, which has been discussed in relation to the theory of von Weimarn (2, 4). Some workers have suggested that the rate of solution of the hemihydrate is the controlling factor and that retarders function by affecting this rate of solution.

In this paper, the first of a series, the reactants were all in solution initially, thus eliminating any effects attributable to the surface of the hemihydrate or its rate of solution. The influence of such factors as the initial supersaturation, crystal surface area of the dihydrate, pH, and addition of accelerators and retarders was then determined. The effect of temperature was not investigated at this time, hence the calculation of activation energies has not been attempted.

EXPERIMENTAL

The first attempts to obtain solutions supersaturated with respect to calcium sulphate dihydrate were by dissolving hemihydrate at 10° C. and raising the temperature to 25° C. This was based on solubility data reported in the literature (5, 6). Because of difficulty in achieving complete, rapid solution of the hemihydrate, this method was abandoned in favor of the following.

The calcium required for any desired supersaturation was weighed out as calcium hydroxide, dispersed in a little water, the equivalent amount of standard sulphuric acid added, and the solution made to final volume of 150 cc. with water. After thorough stirring, the solution was filtered through Whatman No. 41H paper into an aluminum dish. All these operations were performed at 10° C. The temperature was then raised to 25° C. in about 15 seconds by immersion of the aluminum dish in warm water. The solution was transferred to a large scratch-free test tube, fitted with a mechanical stirrer, and

[1]*Manuscript received November 7, 1957.*
Contribution from: Department of Chemistry, Ontario Research Foundation, Toronto 5, Ontario.

suspended in a thermostat at 25° C. A 1-ml. sample was taken immediately for analysis followed by others at suitable intervals of time. The pH of these solutions was close to 4.5, as determined by Accutint papers. The glass electrode pH meter could not be used because of the tendency of calcium sulphate to crystallize on the electrode surface. Samples for analyses were pipetted through a cotton filter and titrated against standard disodium ethylenediaminetetracetate (7) using a microburette.

RESULTS AND COMMENT

A plot of the calcium content of the solution against time gave a logarithmic type of curve (Fig. 1). If c is the concentration at time t, and c_s the saturation concentration, then $\log_{10}(c-c_s)$ plotted against t will be linear provided the crystallization obeys first-order kinetics. For pure solutions of calcium sulphate, c_s was taken to be 1.53×10^{-2} moles liter^{-1} at 25° C. (6). In cases where additives were present, c_s was determined experimentally to a reasonable approximation.

The general type of curve obtained is shown in Fig. 2. Most of the experimental curves depart from linearity towards the end of the run. For purposes of analysis, the solid

line has been replaced by dotted lines at both ends of the curve, and the point where the dotted line intersects the line projected horizontally at the level of the original concentration was taken as the time t_0, the approximate starting point of the linear portion of the curve. Thus, the time interval preceding t_0 is taken as the induction period.

Fig. 3 illustrates the application of this method of analysis to the cases where the initial supersaturation was varied in the series 100%, 125%, 150%, and 175%. A curve for 135% has been omitted for clarity.

A. Effect of Supersaturation on the Course of Crystallization

Starting with any given supersaturation (Fig. 3) the crystallization process appears to follow a first-order rate law over a large percentage of the reaction. This is shown by the relative constancy of the first-order rate coefficients calculated for various time intervals during a typical experiment (Table I). It is also apparent that the process does not follow a second-order rate law. The first-order rate constants, calculated over the linear portions of the curves in Fig. 3, are given in Table II.

The ends of the curves in Fig. 3 deviate considerably, indicating a more complicated process in the early and final stages. The deviation in the final stages may reflect the

188	175.2	153	418	265	40	0.0072

lower solubility of larger crystals, but a more refined analytical method is required at these lower calcium concentrations to investigate this aspect with assurance.

Close control of nucleation experiments is difficult to achieve. Within one set of experiments, e.g. Fig. 3 or Fig. 6, the curves obtained are reasonably reproducible and change in a logical fashion with systematic change in conditions. Unfortunately, quantitative comparison between experiments performed at widely different times is poor. For example, Expt. 188 (Fig. 3) and Expt. 71 (Fig. 6) do not agree in rate coefficient although made under nominally the same conditions several months apart.

In general, however, the observed effect of supersaturation on rate coefficient appears to be in accord with von Weimarn's theory that the initial velocity of nucleus formation is proportional to the relative supersaturation. It is possible that the results obtained might be explained by assuming that the crystals are growing in one direction only, i.e. deposition on a constant surface area. However, much more experimental data is needed to substantiate this.

The crystals produced in this series of experiments were all mixtures of the acicular and twinned types (Fig. 4), as found by earlier workers. There was some variation in the proportion of the two types, but no regular trend was found, as would be expected if the supersaturation were the dominant influence.

B. Effect of Crystal Surface Area on Crystallization

In a series of experiments the area of crystal surface in contact with the crystallizing liquid was varied. Apparently calcium sulphate behaves normally in this respect. The results, shown in Table III, suggest that the area for crystal growth is substantially constant over the linear portion of the $\log_{10}(c-c_s)$ vs. time curve, which may be a consequence of the acicular nature of the crystals with growth occurring predominantly on one face and that the process is diffusion controlled with the film of solution immediately in contact with a growing face being only slightly supersaturated.

TABLE III

EFFECT OF CRYSTAL SURFACE AREA ON k

Expt. No.	Modification	Point of modification	k, min.$^{-1}$
188	None	—	0.0072
185	Crystals added	27% Crystallized	0.0113
192	Crystals crushed	30% Crystallized	0.0110
187	Crystals removed	27% Crystallized	0.0034

C. Effect of pH on Crystallization Rate

Most of the experiments reported in this paper were made at pH 4.5. However, a

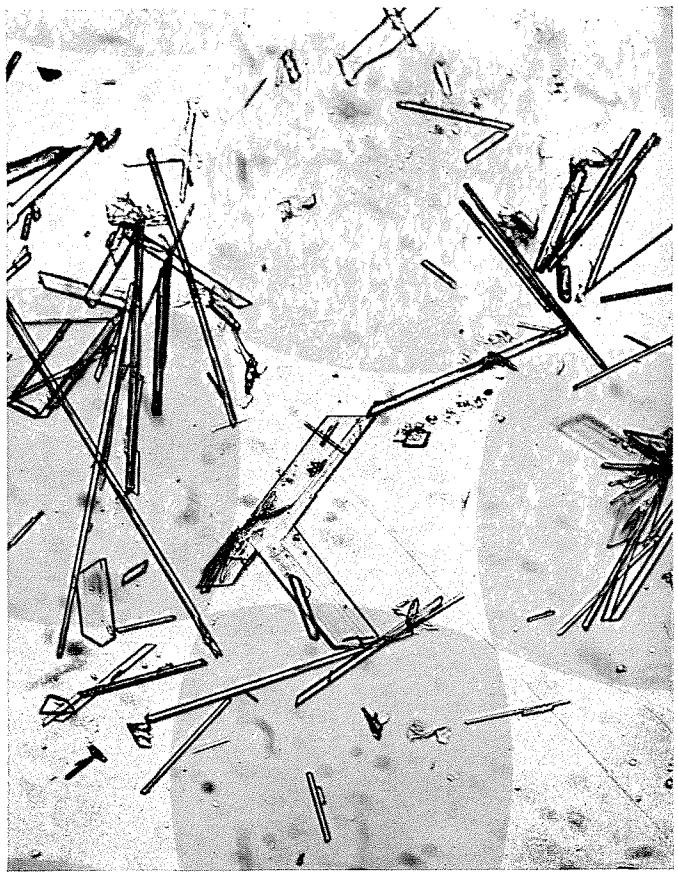

FIG. 4. Acicular and twinned types of crystals found throughout these experiments. 200 ×

number of experiments at higher pH gave rather striking results, shown in Table IV and Fig. 5. All pH adjustment was made by adding the required additional amount of calcium hydroxide.

TABLE IV

EFFECT OF pH ON t_0 AND k

Expt. No.	% Supersaturation	pH	t_0, min.	k, min.$^{-1}$
138	150	4.5	62	0.0051
170	150	5.5	314	0.0023
181	150	6.6	375	0.0017
191	175	4.5–6.6	42	0.0072
188	175	4.5	40	0.0072

It is apparent that the length of the induction period and, to a lesser extent, the rate constant are markedly affected as the pH approaches the neutral value. In Expt. 191, pH 4.5 was maintained until about 27% of the material had crystallized out and the normal rate for the prevailing conditions had been established. Adjustment of the pH to 6.6 at this stage had a negligible effect on the rate, giving further indication that the rate constant is determined by conditions existing at the end of the induction period.

D. Effect of Accelerators, Retarders, and Salts Having No Common Ion

A series of experiments were made, starting with pure calcium sulphate solution at 175% supersaturation, with the additions shown in Table V. The quantities of reagents were chosen arbitrarily, but were of such a magnitude as to clearly show their effects in these solutions. They are not particularly related to quantities used in commercial plasters.

TABLE V

EFFECT OF ADDITIONS ON t_0 AND k

Expt. No.	Addition	Concn. of addition, moles liter^{-1}	$c_s \times 10^4$ moles liter^{-1}	t_0, min.	k, min.$^{-1}$
72	K_2SO_4	(23×10^{-3})	112.4	6	0.0432
92	$CaCl_2$	(4.4×10^{-3})	139	6	0.0177
71	Control		153	50	0.0096
96	NaCl	(59×10^{-3})	195	60	0.0092
109	Retarder	(2.75×10^{-3})	153	98	0.0080
104	Retarder	(5.5×10^{-3})	153	182	0.0082

In the results shown in Table V and Fig. 6, the values of c_s were determined by experiment. These values for Expts. 92 and 96 agree well with values interpolated from the literature, although that for Expt. 72 is possibly 10 units lower than the corresponding value inferred from the literature. However, in this case the data are very scarce.

Inorganic salts added to a solution of calcium sulphate 175% supersaturated with respect to the dihydrate may affect the course of events by (*a*) changing c_s and thus the initial supersaturation, (*b*) by affecting nucleation in other ways, or (*c*) by affecting the rate constant other than through the change in initial supersaturation.

Salts containing a common cation or anion functioned as accelerators, producing a short induction period and high rate constant. The value of c_s is decreased, thus increasing the initial supersaturation, but extrapolation of the data of Table II by plotting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

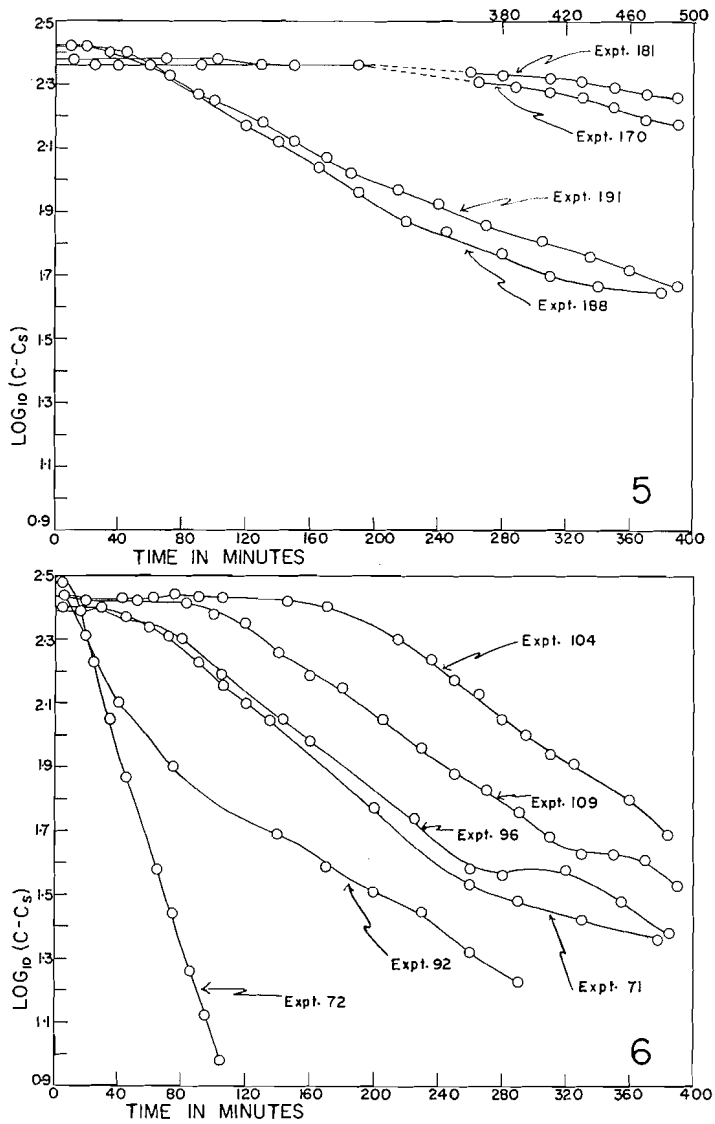

FIG. 5. Plot of $\log_{10}(c-c_s)$ versus time for various pH conditions.
FIG. 6. Plot of $\log_{10}(c-c_s)$ versus time for solutions containing various additives.

$\log_{10} k$ against (c_i-c_s), where c_i is the initial concentration, indicates that this would account for only part of the high k value found (0.0113 min.$^{-1}$ of 0.0432 min.$^{-1}$). This extrapolation involves the assumption that the same relation between initial supersaturation and k holds for both pure and salted solutions.

Salts having no ion in common with calcium sulphate showed little effect on the induction period or the value of k. The c_s value was markedly increased, hence the initial supersaturation reduced. Extrapolation of data, as above, indicates a k value of 0.0046 min.$^{-1}$ instead of 0.0092 min.$^{-1}$ for Expt. 96. Thus it might be argued that sodium chloride, for example, has an accelerating effect on the crystallization process which is offset by an increase in solubility of calcium sulphate. Sodium chloride did

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

not act as an accelerator in the same sense as did potassium sulphate, nor did it behave analogously to aluminum sulphate, which is widely used as an accelerator in commercial plaster.

Where retarders are present, the induction period is considerably greater and roughly proportional to the amount of retarder used. When crystallization finally begins, it proceeds at a rate not greatly different from that of the control sample. This behavior tends to support the view that retarders function by covering the nuclei as they form, until the supply of retarder is exhausted. Nucleation and subsequent crystallization then proceed unhindered. Evidently the retarder is not acting by interfering with diffusion.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to Dr. A. E. R. Westman, Dr. M. H. Jones, Dr. D. B. DeLury, and Dr. H. G. McAdie for helpful suggestions, and to Douglas Renton for his painstaking assistance on the experimental work.

THE SYSTEM KOH–K_2CO_3–H_2O AT LOW TEMPERATURES

I. PHASE EQUILIBRIA[1]

A. A. Lang and A. J. Sukava

ABSTRACT

Phase diagrams for the system KOH–K_2CO_3–H_2O were determined for 25°, 10°, 0°, −10°, −20°, −40°, and −60°. The stable hydrates of potassium hydroxide were the di- and tetra-hydrates; those of potassium carbonate were the sesqui- and hexa-hydrates. No compound formation between KOH and K_2CO_3 was detected.

INTRODUCTION

Very few data for the ternary system KOH–K_2CO_3–H_2O are found in the literature. It is known (1) that at 30° this system is univariant when the solution contains 55.14% potassium hydroxide and 2.05% potassium carbonate, the equilibrium solid phases being $KOH.2H_2O$ and $K_2CO_3.3/2H_2O$. The hydrate $K_2CO_3.6H_2O$ exists at −18° in equilibrium with a solution containing 8.80% potassium hydroxide and 36.11% potassium carbonate (2).

According to some of the older published data for the binary system KOH–H_2O (3, 4, 5, 6), anhydrous potassium hydroxide is stable above 143°. Below this temperature the successive stable forms are the mono-, sesqui-, di-, and tetra-hydrates at intervals down to a eutectic at −66°, at which point the tetrahydrate is in equilibrium with ice and a solution containing 30% potassium hydroxide. In partial contradiction, a more recent report (7) claims that potassium hydroxide hydrates with 5, 6, 8, and 18 moles of water also exist, and that the binary eutectic lies at −82.5° with the hexa- and octa-hydrates in equilibrium with a solution containing 31.2% potassium hydroxide.

Published data for the binary system K_2CO_3–H_2O show quite conclusively that the stable hydrates of potassium carbonate are the mono-, sesqui-, and hexa-hydrates. The hexahydrate exists down to a eutectic with ice at −36.5° (2, 8, 9, 10).

The results reported in the present paper arise from part of a study of some physical properties of aqueous solutions containing potassium hydroxide and potassium carbonate in the temperature range from 25° to −60°, a study which constitutes part of a more general investigation of the properties of alkaline battery electrolytes. Ternary phase-equilibrium data are presented for this temperature range.

EXPERIMENTAL

The temperature from 25° to −10° was kept constant to within ±0.02° with a Townson and Mercer X-27 bath. A Kelvinator refrigerating unit served as cooling equipment. Water and ethylene glycol – water solutions were used as bath liquids. A Townson and Mercer X-160/U bath was used for temperature control from −20° to −60°. This bath employed petroleum ether as bath liquid, with a Dry Ice – acetone cooling mixture surrounding the heat exchanger. It held the temperature constant to within ±0.05°.

The thermometers employed were mercury-in-glass and toluene-in-glass for the higher and lower temperatures respectively. These were calibrated against certified standards. The calibration and reading of the thermometers are considered the major sources of

error in the temperature measurements. By our estimation the maximum accuracy of these measurements probably varies from about ±0.05° at 25° to about ±0.5° at −60°, despite the more precise temperature control.

All the saturated solutions were prepared from reagent grade chemicals and distilled water. The mixtures were stirred in covered Pyrex vessels held in the temperature bath, with the stirring usually prolonged for 2 or 3 days to ensure equilibrium. Samples of liquid and wet solid phases were separated by suction through sintered-glass filters and weighed quantities of these were analyzed by titration with hydrochloric acid. The compositions of equilibrium solids were determined by the "wet residue" method.

RESULTS AND DISCUSSION

The analytical data and composition of equilibrium solids are given in Table I. Typical phase diagrams are shown in Figs. 1*a* and *b* and 2. Fig. 3 shows all the liquidus curves. Some of the univariant points, or isobaric triple points, were determined by direct analysis of the equilibrium solutions, while others were found by extrapolation as indicated.

The course and shape of the liquidus curves in Fig. 3 seem to suggest that the extrapolated values for the two equilibria, (i) $KOH.4H_2O$ – $K_2CO_3.6H_2O$ – saturated solution at −40° and (ii) $KOH.4H_2O$ – ice – saturated solution at −60°, probably lie in metastable regions. No attempt was made to investigate these small regions by actual experiment.

The narrow range of liquid composition in equilibrium with potassium hydroxide dihydrate at 25°, 10°, and 0° was not investigated. The solubilities of pure potassium hydroxide were obtained from existing literature (1) and are shown as such in the tables.

The data for −10° show that potassium carbonate sesquihydrate is readily obtained in metastable equilibrium at this temperature with solutions containing less than about 7% potassium hydroxide. The rate of transition of the potassium carbonate sesquihydrate to the stable hexahydrate was found to be very slow even at temperatures 10° to 15° below the known transition point (−6.2° (2)). Seeding with hexahydrate crystals was necessary to promote the transformation. These results are in agreement with those of other studies (2).

A special effort was made to detect the hydrates $KOH.5H_2O$ and $KOH.18H_2O$, which have been reported (7). According to this report, the range of existence of the pentahydrate is supposed to be from −43° to −62.5°, with equilibrium solutions ranging from 38.5 to 33.7% potassium hydroxide. That of the octodecahydrate is supposed to be from −32° to −75.5°, with solutions ranging from 22.5 to 30.2% potassium hydroxide. If these hydrates do indeed exist, as claimed, their presence should have been shown by our data for −40° and −60°, especially since the results of our analyses were usually reproducible to within ±0.2%. We found no such evidence. In particular, it would appear that steric effects would preclude the existence of a hydrate with 18 moles of water per mole of potassium hydroxide. It is noteworthy too that extrapolation of our ternary data to 0% potassium carbonate (to give the solubility curve for pure potassium hydroxide in water) will show a trend which supports the older arguments (3, 4, 5, 6) according to which the eutectic for the binary KOH–H_2O system lies at −66°, with the hydrate $KOH.4H_2O$ and ice in equilibrium.

It should also be noted that, since our data do not extend below −60°, the possible existence of a sharp ternary eutectic with a low concentration of potassium carbonate cannot be discounted on present evidence. Such a possibility might indeed offer at least a partial explanation of the −82.5° value reported as the eutectic temperature for the

$KOH–H_2O$ system (7). This seems the more likely, since reagent grade potassium hydroxide, unless intensively purified, is liable to contain a small percentage of carbonate, and since the investigators reporting this low eutectic point probably used such unpurified hydroxide. The possible absorption of atmospheric carbon dioxide by the potassium hydroxide solutions might also have been overlooked.

We recognize the obvious inadequacy of our data for the temperature range between $-20°$ and $-60°$. Plans are being made to complete these data at some future date, by investigating this system at $-30°$ and $-50°$.

THE POLARIZED FLUORESCENCE OF VERY THIN ANTHRACENE CRYSTALS[1,2]

J. FERGUSON[3] AND W. G. SCHNEIDER

ABSTRACT

The polarized fluorescence from anthracene sublimation flakes has been measured at 300°, 77°, and 4° K. A recording spectrometer was used to measure accurately the relative intensity of the two crystal polarizations and also to determine changes in the spectrum between 77° and 4° K. The polarization ratio (b/a) was found to decrease with increasing wavelength and measurements made at 77° and 4° K. indicate that there is more than one emitting level and that these have different polarization properties. The fluorescence arises from regions of weak absorption in the crystal and it is suggested that these regions occur in the neighborhood of imperfections. In addition the polarized fluorescence excited from anthracene sublimation flakes containing traces of tetracene has been determined and changes were found in the transfer efficiency between 77° and 4° K., again suggesting the presence of more than one emitting level. No depolarization of the tetracene fluorescence was observed at low temperatures.

INTRODUCTION

The optical spectra of crystalline anthracene are important for the development of a theory of molecular crystal spectra and also to help in the elucidation of the mechanism of photoconduction. The purpose of the present communication is to report new studies of the fluorescence emitted from crystals of anthracene both at room temperature and low temperatures and to re-examine the interpretation of the origin of this fluorescence. For this pure single sublimation flakes of anthracene were used as well as single flakes deliberately contaminated with tetracene.

Previous measurements of anthracene crystal fluorescence at low temperatures have been made by the following workers: Obreimov, Prikhot'ko, and Shabaldas (1), Pesteil and Barbaron (2), Tsujikawa and Kanda (3), and Sidman (4). All these authors noticed the development of "fine" structure at very low temperatures and Pesteil and Barbaron have measured some 115 of these "lines". Perhaps more important than the appearance of this structure is the polarization ratio, here defined as the ratio of the intensity of the fluorescence vibrating parallel to the b crystal axis to that vibrating parallel to the a axis. The earliest measurements of polarization ratio were made by Obreimov, Prikhot'ko, and Shabaldas (1) and with a rather crude visual method they obtained a b/a ratio of 5.5:1, measurements being made at room temperature and low temperatures. Ganguly and Chaudhuri (5) have made measurements at room temperature but as mentioned in our earlier communication (6) their result suffers from the use of large crystals and subsequent diminution of the polarization ratio by reabsorption. Pesteil (7) has reported polarization ratios for anthracene single crystal at room temperature, but these are referred to the axes of the optical indicatrix and two of these axes vary with wavelength.

In our earlier communication (6) we reported that the polarization ratio at room temperature is about 5:1 and suggested that the reason for this is because the emitting levels are predominantly those regions of the crystal where lattice symmetry is disturbed. The present work reports more fully these results and extends them to low temperatures.

EXPERIMENTAL

In order to measure quickly and accurately the fluorescence spectra a photomultiplier was used in place of the photocell compartment and cell block of a Beckman DU Spectrometer. The crystal and necessary optical accessories were placed on an optical bench running at right angles to the length of the spectrometer. The fluorescence was excited by a BTH high-pressure mercury lamp and two filters were used to obtain only 3650 Å radiation (Corning 9863 and 5860).

The power supply and amplifier were provided by a Photovolt Photometer No. 520M and a Varian G10 recorder was used in series. A constant-speed motor through a system of gears was used to drive the wavelength knob of the Beckman spectrometer at such a speed that the wavelength range 5000–4000 Å was covered in 5 minutes. Continuous recording of fluorescence spectra could therefore be made.

For room temperature measurements single anthracene sublimation flakes were mounted on a very clean silica disk. This disk was then placed over a pinhole so that it was possible to rotate the crystal centrosymmetrically through 180°. At first a Wollaston prism was used as an analyzer (placed between the crystal and the slit of the monochromator) but this was later replaced with a piece of polaroid equally satisfactory and more convenient.

For the low-temperature measurements a liquid-helium cell of the type described by Duerig and Mador (8) was used, minor modifications being made in the cell piece. The sublimation flakes were mounted on small silica disks and these fitted into copper pieces which slide into slots in the cell block at right angles to the light beam. A good portion of each crystal was selected and the remaining parts of the silica disk were painted over with Aquadag. In this way it was possible also to determine the absorption spectrum of each crystal. The cell was designed so that two crystals could be used in each assemblage of the apparatus. As it was not possible to rotate the crystals, the polaroid analyzer was rotated in order to obtain the two crystal polarizations. This necessitated a calibration of the spectrometer plus photomultiplier in order to compensate for slight changes in transmission of polarized radiation as the plane of polarization is changed.

A final calibration of the unit was obtained with a tungsten strip filament operated at known color temperature. In all cases the slit width of the spectrometer was kept constant during the recording of a spectrum and was normally about 0.2 mm.

Liquid nitrogen and liquid helium were used to cool the crystals. With liquid helium a small amount of helium gas (about 10^{-3} mm.) was momentarily introduced into the cell to act as thermal exchange gas to reduce the temperature of the sample to 4° K. No direct measurements of the temperature of the crystals were made.

The sublimation flakes were grown in a metal crucible in an atmosphere of carbon dioxide in the absence of light. The crystals grew on a filter paper placed over the mouth of the crucible and suitable ones were transferred to the silica disks with a sewing needle mounted in cork.

RESULTS

A. Room Temperature Measurements

Pure Anthracene

Fluorescence spectra from a number of single crystals were recorded. The spectra are similar to two reported elsewhere (9) and have not been included here. Only the polarization properties will be mentioned.

Fluorescence emitted normal to the *ab* plane is strongly polarized with maximum intensity (I_b) when the electric vector is parallel to the *b* crystal axis and minimum intensity (I_a) parallel to the *a* crystal axis. If the crystal is rotated and the intensity of the fluorescence is measured through an analyzer, held fixed, the resultant intensity will be given by $I_b\cos^2\theta + I_a\sin^2\theta$, where θ is the angle between the *b* crystal axis and the electric vector direction of the analyzer. The maximum and minimum correspond respectively to I_b and I_a and the ratio I_b/I_a is the polarization ratio.

Fig. 1(*a*) shows two such curves, one measured at 420 mμ, the other at 445 mμ (two maxima in the fluorescence spectrum). They represent typical results for thin anthracene sublimation flakes and correspond to polarization ratios of 5.3:1 (420 mμ) and 4.2:1 (445 mμ). This variation of polarization ratio with wavelength is important and will be discussed later.

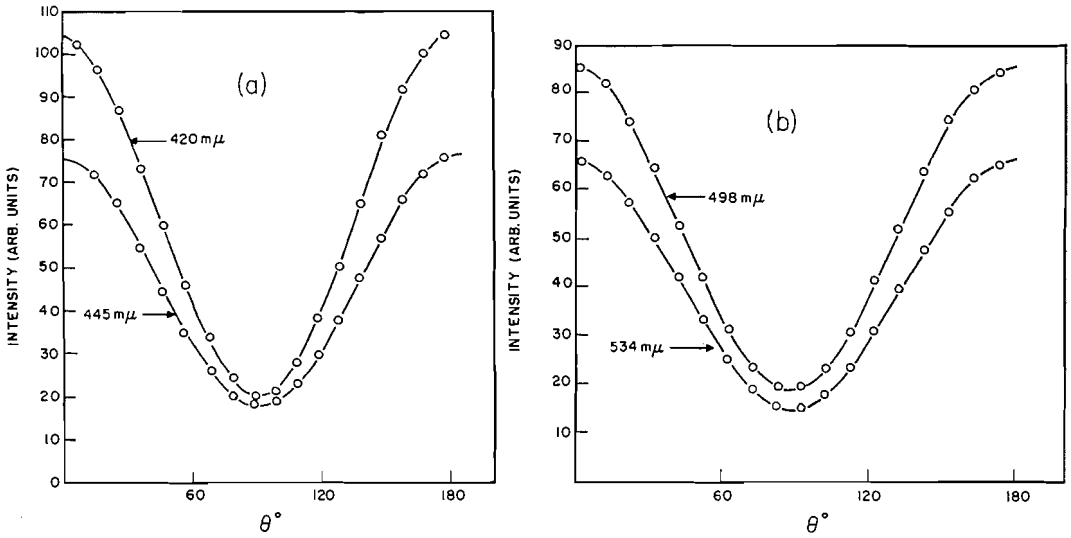

FIG. 1. Variation of fluorescence intensity as a function of θ, the angle between the electric-vector direction of the analyzer and the *b* crystal axis: (*a*) anthracene fluorescence spectrum, 420 and 445 mμ maxima; (*b*) tetracene fluorescence spectrum, 498 and 534 mμ maxima.

The measurements at room temperature can be summarized thus:

(*a*) Spectra emitted from different crystals, on the whole, are similar, showing only slight variations, mainly in the amount of reabsorption which depends on crystal thickness.

(*b*) The polarization ratio is not constant and decreases with increasing wavelength. For the 420 mμ maximum it is in the range 5.0:1–5.5:1.

(*c*) Even for very thin crystals the first maximum in the *a*-polarized spectrum (about 400 mμ) is less intense than the second maximum (about 420 mμ). There is thus evidence of an abnormal distribution of intensity in the *a*-polarized fluorescence.

Anthracene Containing Tetracene

When very small amounts of tetracene are included in anthracene the fluorescence of the latter is strongly quenched giving rise to the bright green-yellow fluorescence of the former (10).

The fluorescence from a single crystal of anthracene containing tetracene is also strongly polarized and Fig. 1(*b*) shows typical results obtained. The two curves are analogous to those of Fig. 1(*a*) and correspond to the first and second maxima in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

tetracene fluorescence spectrum. The polarization ratios are 4.5:1 and 4.4:1 respectively and unlike anthracene, therefore, the polarization ratio does not change with wavelength.

B. Low Temperature Measurements

Pure Anthracene

Obreimov, Prikhot'ko, and Shabaldas (1) conclude that "different crystals produce different fluorescence spectra. The lines in the spectrum differ in width and, perhaps, in relation to intensity. Curiously the widest bands were found in the spectrum of a crystal supposedly "blue" i.e., of a pure crystal. Spectra of green crystals are composed of narrow bands".

These conclusions were substantiated in the present work, although the poor dispersion of the spectrometer did not allow resolution of the spectrum into "lines", but indications of these were obtained in one or two favorable cases.

Because of the variation in the fluorescence spectra from different crystals it is necessary to include a number of spectra and these have been chosen to emphasize particular

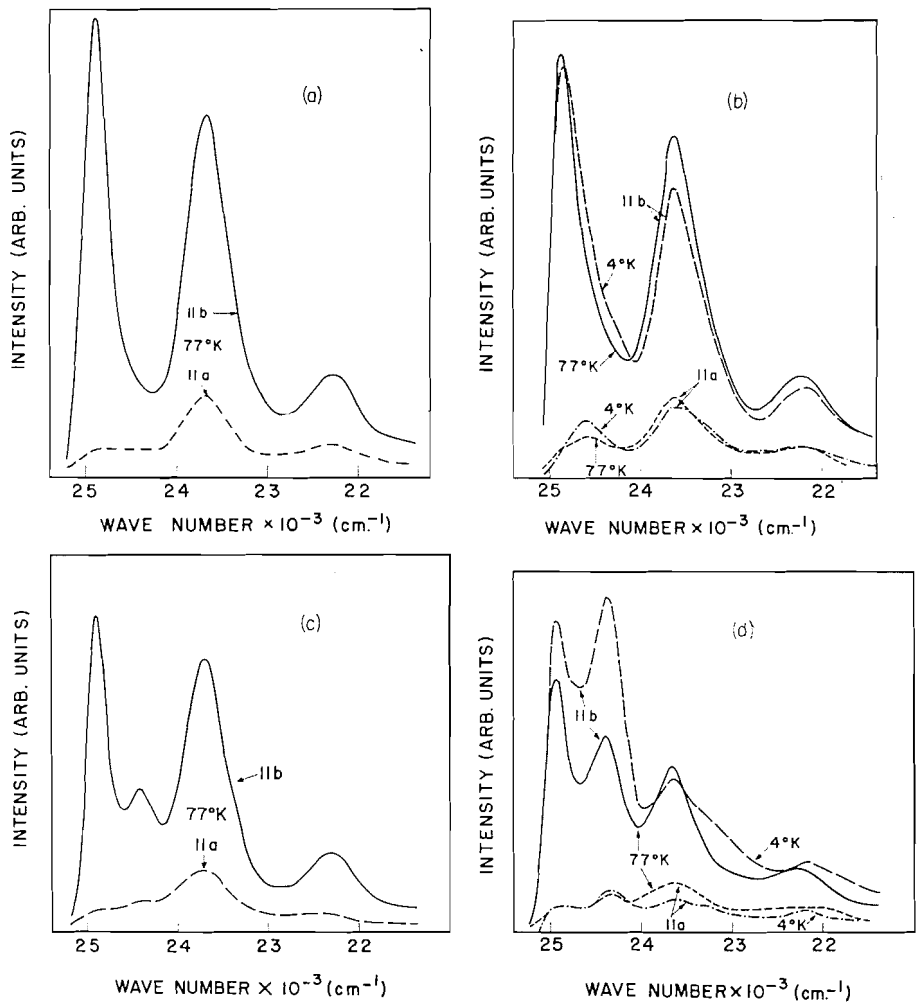

FIG. 2. Examples of the variation in the fluorescence spectrum excited from crystals about 0.2 μ thick.

For personal use only.

differences. The spectra shown in Fig. 2(*a*) were obtained at 77° K. As can be seen, the spectrum parallel to the *b* crystal axis is more intense than that parallel to the *a* crystal axis. In addition, the polarization ratio is not constant, but decreases with decreasing energy (increasing wavelength). As at room temperature the intensity distribution in the *a* polarization is abnormal and most of the intensity is carried in the second maximum.

Fig. 2(*b*) shows spectra obtained from another crystal, measured at 77° and 4° K. The effect of lowering the temperature is to alter slightly the intensity distribution in both crystal polarizations and decrease the over-all polarization ratio but not uniformly throughout the spectrum. The highest energy *b*-polarized band is broader than the similar band in Fig. 2(*a*) and the effect of lowering the temperature is mainly to increase the intensity of the low-energy side of this band.

Fig. 2(*c*) shows the spectrum of a crystal having an absorption spectrum nearly identical with that in Fig. 2(*a*). As can be seen from a comparison with Fig. 2(*a*) the fluorescence spectra are different. This crystal has a new maximum appearing at about 24,400 cm.$^{-1}$ in both polarizations. The measurements were taken at 77° K.

Fig. 2(*d*) shows an example of the marked changes that some crystals exhibit when cooled from 77° to 4° K. The spectrum at 77° K. is similar to that in Fig. 2(*c*) except for a redistribution of intensity.

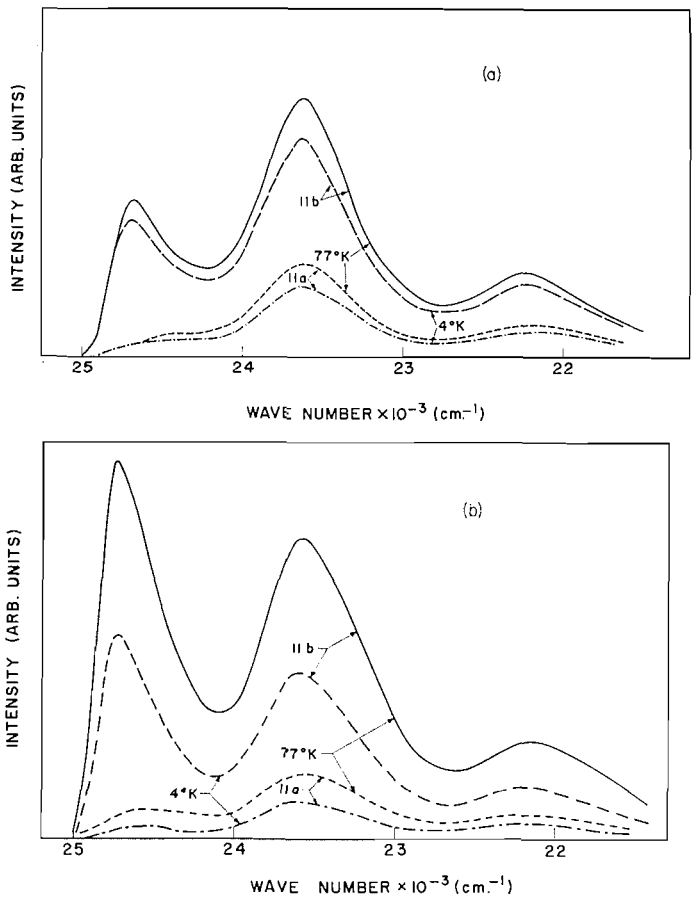

FIG. 3. Examples of the variation in the fluorescence spectrum excited from crystals 2–3 μ thick.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Examples of fluorescence spectra from thicker crystals are shown in Fig. 3. The individual variations in spectra are not so marked as with the thinner crystals and the bands are broader.

Anthracene Containing Tetracene

Because of the variation observed in the fluorescence of pure anthracene crystals it was decided to deliberately introduce tetracene in very small quantities and study the effect of temperature on both the anthracene and tetracene fluorescence, the latter

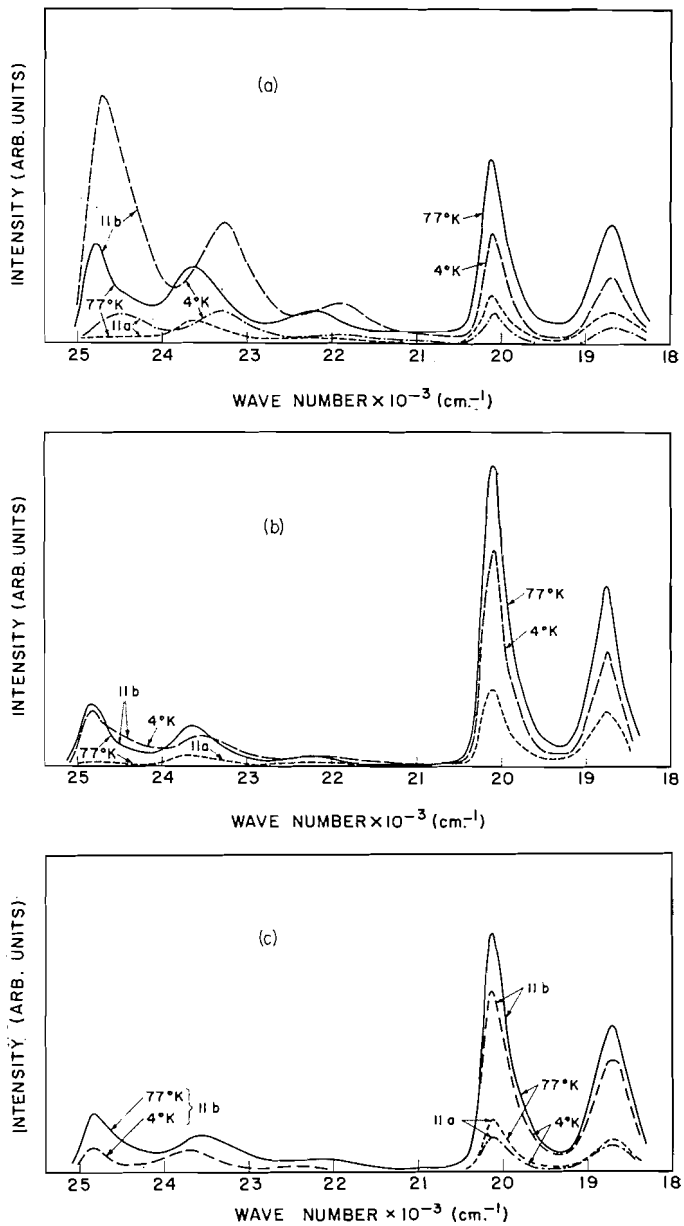

FIG. 4. Examples of the variation with temperature of the fluorescence spectrum of anthracene crystals containing traces of tetracene.

For personal use only.

acting as an "internal standard". Previous measurements with anthracene crystals containing tetracene at 20° K., by Sidman (11), were made on crystals in which the tetracene concentration was so high that nearly all of the fluorescence came from the tetracene, and the anthracene fluorescence was not photographed.

Fig. 4(*a*) shows a most marked effect of temperature on the transfer efficiency as well as a simultaneous alteration of the anthracene spectrum, observed with a crystal about 10^{-5} M./M. At 77° K. the anthracene emission amounts to 0.50 of the whole, while at 4° K. this fraction is 0.79.

Fig. 4(*b*) shows a result similar to that in Fig. 4(*a*), obtained with a crystal containing slightly more tetracene (about 2×10^{-5} M./M.). In this case the fraction of the energy emitted by the anthracene is 0.25 at 77° K. and 0.35 at 4° K. Again there is a change in the anthracene spectrum but it is less marked.

As well as a decrease in transfer efficiency at 4° K. some crystals showed an increase and Fig. 4(*c*) is an example of the fluorescence emitted from such a crystal. The fraction of energy emitted by anthracene is 0.32 at 77° K. and 0.18 at 4° K. Again there is a change in the anthracene spectrum.

Before proceeding with a discussion of the results we shall summarize the observations with pure anthracene crystals.

(1) Fluorescence spectra from different crystals are different, as reported earlier by Obreimov, Prikhot'ko, and Shabaldas (1). In addition it should be noted that the bands are sharper with very thin crystals (about 0.2 μ). For thicker crystals the bands are broader.

(2) In most very thin crystals a considerable rearrangement of the intensity occurs when the crystal is cooled from 77° to 4° K.

(3) As well as the rearrangement of the intensity which occurs between 77° and 4° there is a change between room temperature and 77° K. In both cases the effect is to decrease the fluorescence occurring at lower energies relative to that nearer the origin so that an approximate mirror-image intensity relation to the absorption spectrum is lost.

(4) The polarization ratio is not constant and at the high energy region of the spectrum it is greater than 7:1.

(5) The spectra are all displaced to lower energies at low temperatures but the displacement is not the same for each crystal, the thinnest crystals being displaced the least.

(6) The changes in intensity which occur in some crystals when they are cooled from 77° to 4° K. indicate the presence of more than one emitting level with different polarization properties, e.g. Fig. 2(*c*).

DISCUSSION

Craig (12) has extended the theory developed by Davydov (13) to include crystal-induced mixing of the $^1B_{2u}$ and $^1B_{3u}$ molecular states of anthracene. He showed that when second-order crystal-field perturbations are included in the crystal wave functions the polarization ratio for the 3800 Å anthracene system is reduced from 7:1 (*b*:*a*), given by first-order theory (identical with the oriented gas model), to about 3:1. A subsequent detailed measurement of the extinction coefficients of the *a*- and *b*-polarized absorption in anthracene single crystals at room temperature by Bree and Lyons (14) has substantiated the theory of Craig.

Although theory satisfactorily interprets the absorption spectrum, except in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

region of the *b*-polarized absorption edge (considered in a later publication), it predicts the wrong polarization ratio for the fluorescence spectrum. This quantity should be about 3:1 and furthermore it should be constant throughout the spectrum. The reason for this failure will now be discussed but first we must consider an interpretation of the fluorescence spectrum at low temperatures advanced by Sidman (4). Sidman has suggested that emission originates from trapped exciton levels postulated by Frenkel (15) and that these levels are observed both in absorption and fluorescence. The reasons advanced for this interpretation are: (*a*) the absorption in the *b*-polarized edge of the absorption spectrum (origin of the fluorescence spectrum) is weak because the transition is to a trapped exciton state and involves lattice relaxation around an excited molecule; (*b*) the condition $|D_{mk}| >> |J_{mk}|$ given by Frenkel is fulfilled.

As regards (*a*), such a non-vertical low probability transition should *increase* the decay-time of the fluorescence emission as the temperature is decreased to 4° K. because all of the emission comes from these levels at this temperature. However, Elliot, Liebson, and Ravilious (16) find the decay-time to be *decreased* by a factor easily explained by the reduced overlap between absorption and fluorescence spectra as the temperature is lowered. As the emission at very low temperatures has a decay-time only slightly changed from the room-temperature value we must not, therefore, look for an explanation for the weak absorption in the absorption edge in terms of a low-transition probability to these levels.

The condition $|D_{mk}| >> |J_{mk}|$ given by Frenkel for the formation of trapped excitons is an approximation made for the particular type of crystals that he considered, i.e. ionic crystals. Frenkel has made it clear that if the excitation energy remains on an atom or molecule in the lattice the others will adjust themselves to the new conditions and this will correspond to a smaller potential energy than for the case when the energy is transferred before the lattice relaxation takes place. Frenkel assumed that this change in energy is of the order of $|D_{mk}|$ (the change in energy of interaction between an atom or molecule and the surrounding ones when it is brought into an excited state), but the same assumption grossly overestimates the energy of relaxation of the lattice around an excited molecule such as anthracene where the interaction forces are of the van der Waals type. In view of this and the lifetime measurements we must look further than the trapped exciton treated theoretically by Frenkel.

As we are dealing with real crystals the crystal wave functions will be of two types: those having the symmetry of the 3-dimensional space group (or closely approximating this) and those which do not have this symmetry, i.e., surfaces and various imperfections. In the case of the experimental absorption spectrum the energy levels of the former case will dominate the over-all crystal absorption and good agreement is to be expected between theory and experiment. However, for fluorescence, the levels of lowest energy are important in view of the large mean free path of the exciton, and if crystal levels of the latter type exist with energy less than the former type then these will be expected to dominate the fluorescence process in spite of their low concentration. It should be pointed out here that the trapped exciton envisaged by Frenkel applies to the perfect lattice and transitions to and from these levels would be expected to have the same energy in different crystals, i.e., fluorescence spectra from different crystals should be identical. Fluorescence arising from imperfections of course corresponds to trapped excitons in the broad sense but not in the sense used by Frenkel.

In this communication we shall not attempt a quantitative calculation of the changes to be expected in the characteristics of the emission from surfaces and imperfections but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

shall limit ourselves to some qualitative conclusions. The two sets of molecules in the anthracene lattice are so oriented that the total interaction which determines the splitting between the two energy levels corresponding to a single molecular B_{2u} level is nearly zero, although some individual interactions are large. We might expect therefore that slight perturbations to the lattice structure will in some cases upset this balance and split the levels to a much greater extent than occurs in regions where the crystal symmetry approximates to the 3-dimensional space group. In other cases where the effect of the perturbation is larger it is probable that a very small number of anthracene molecules have energy levels lying below the level of the perfect lattice and, providing sufficiently low temperatures are used, these molecules will not be able to exchange their excitation energy with the neighboring molecules of the lattice and the fluorescence will show a fine structure as is observed when anthracene is an impurity in another lattice, e.g., in phenanthrene and in naphthalene (17). Such a model explains the appearance of fine structure which is seen at about 20° K. and also that the width of these "lines" varies from crystal to crystal.

Although the effect of imperfections on the energy levels must be somewhat complex, *in all cases the polarization ration will be changed from the crystal-induced value of 3:1 towards the oriented gas value of about 7:1.*

As well as emission arising from imperfections we must consider also the possibility of emission from exciton levels with wavenumber vector (k) greater than zero for the case that the level corresponding to $k = 0$ is not the one of least energy. Such an emission process requires the simultaneous creation of a phonon with wavenumber equal to the difference between the wavenumbers of the emitted photon and the exciton. The fluorescence arising in this manner will occur at lower energies than the optically allowed absorption to the level $k = 0$ as is observed; however, the polarization ratio in this case should be very close to the value in absorption. As the emission spectrum of the crystal is complex we must not overlook such a mechanism for at least a part of the total emission.

If the observations summarized at the end of the results section are now consulted it will be seen that these are consistent with the emission arising mainly from imperfections. It is possible to go further and deduce that some of these levels correspond to considerably distorted regions of the lattice. This must be so in order to explain the movement of intensity towards the origin of the fluorescence (e.g. Fig. 2(*c*)) and the subsequent loss of a mirror-image intensity relation to the absorption spectrum observed in solution (9). In such regions the potential energy surfaces of the excited state must lie more nearly over those of the ground state than is the case for the normal lattice. In addition, from the very high polarization ratio near the origin of the fluorescence the emission from these levels is mainly *b* polarized.

In principle we can distinguish between two types of imperfection that might be present in the crystals used but unfortunately no control over the presence of the second of these was possible. The two types are growth imperfections and those introduced into the crystal by mounting on silica. The latter must be important as the flakes adhere strongly to the silica surface and the strain involved must be considerable, particularly in thin crystals where the large variation in the fluorescence is no doubt explained in part by the imperfections introduced by mounting. In view of this it would be difficult to set up any satisfactory model to examine quantitatively the effect of imperfections.

The interpretation of the fluorescence from pure anthracene is substantiated by measurements made on crystals containing tetracene. Obviously the introduction of tetracene constitutes an imperfection and one that is a very efficient trap for anthracene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

excitation energy so it is necessary to keep the concentration very low in order to detect fluorescence from the anthracene. If the regions close to the included tetracene represent the only imperfections in the anthracene lattice we would not expect to find any change in the transfer efficiency when the temperature is changed from 77° to 4° K. provided the thermal degradation of the excess energy is not altered. However, the results shown in Figs. 4(*a*) and 4(*b*) indicate that there must be imperfections at considerable distances from the tetracene molecules. We can say this because the transfer efficiency is decreased in going from 77° to 4° and from earlier work (9) we know that the critical intermolecular distance for transfer of energy between anthracene and tetracene is about 44 Å so that in these crystals excitation energy must be trapped by anthracene (imperfections) at distances greater than 44 Å at the lower temperature. The striking feature about this process is that the fluorescence from the latter regions is markedly different in intensity distribution and energy from the fluorescence observed at 77° K., as can be seen.

It is possible therefore to detect more than one emitting level in these crystals, but it must not be assumed that these on the average are always located at considerable distances from the tetracene impurity and this is shown by Fig. 4(*c*). In this case where the transfer efficiency is increased between 77° and 4° K. most of the anthracene levels of lowest energy must lie within the critical distance from the tetracene so that energy trapped in these levels is transferred to the tetracene with higher efficiency. The anthracene fluorescence is again changed but this time in the opposite direction to the other crystals, as is expected, since the energy normally coming from the lowest levels is now transferred to the tetracene. In all of these cases the changes which take place with decrease of temperature are perfectly reversible.

In the crystals examined no anomalous behavior of the tetracene fluorescence was found when the temperature was reduced to 4° K. Sidman (11) has recently reported that the fluorescence from tetracene in anthracene is depolarized at 20° K., but in the crystals studied in the present work no such depolarization was detected and, in fact, the polarization ratio at 4° K. averages about 4:1. The concentration of tetracene was considerably lower by at least a factor of 100 than for the crystals used by Sidman, and in addition his crystals were large ones grown from the melt. Sidman (17) has also reported a similar depolarization of the fluorescence of anthracene in phenanthrene, again with crystals grown from the melt. Here again, however, measurements made at 20° K. with sublimation flakes of phenanthrene containing anthracene by Obreimov, Prikhot'ko, and Shabaldas (1) show that the anthracene fluorescence is strongly polarized. At present there seems no satisfactory explanation for the results reported by Sidman but it is possible that this will lie in the different method of preparation of the crystals.

While there appears to be considerable evidence for the presence of imperfections in anthracene sublimation flakes it must not be assumed that these will play such a dominant role in the emission from other molecular crystals. The significant quantity indicative of emission from imperfections is the polarization ratio and this must be measured both in absorption and emission for other crystals before the importance of imperfections can be estimated.

KINETIC LAWS FOR SURFACE REACTIONS IN FLOW SYSTEMS[1]

K. J. LAIDLER

ABSTRACT

A general differential equation is set up for the flow of reactant gases through a catalytic reactor, account being taken of changes in volume as the reaction proceeds and of the possibility that the catalyst surface is not completely available. Integrated solutions are given for three special cases and are presented in graphical form: (1) first-order reaction, the result being applicable whether the surface is completely available or not (Fig. 1); (2) second-order reaction with the surface completely available (Fig. 2); (3) second-order reaction with only a small fraction of the surface available (Fig. 3). The treatment is related to previous treatments of Hulburt, Thiele, and Wheeler.

INTRODUCTION

The general kinetic laws applicable to flow systems have been well worked out, but when the reactor contains a granulated porous catalyst certain complications arise. The object of the present paper is to develop the kinetic equations for such systems in forms that take into account these complexities. The main matters that give difficulty are:

(i) the question of the correct kinetic equations to use for systems of variable volume,
(ii) the corrections required when the reaction is accompanied by a volume change, and
(iii) the incomplete availability of the surface under certain conditions.

Of these (i) was treated many years ago by Benton (1), while (ii) has been discussed in detail by Hulburt (2). Various workers, in particular Thiele (3) and Wheeler (4), have discussed (iii). In the present paper all three factors will be considered together, and general kinetic equations will be developed which give the fraction of reaction occurring in a reactor as a function of the properties of the reaction system.

THEORETICAL

The Steady-State Equation

Benton's treatment leads to the conclusion that for a surface-catalyzed reaction of αth order the number of moles dn disappearing in time dt in an element of volume dV is given by

$$-dn = k_v c^\alpha \, dV dt, \qquad [1]$$

where c is the concentration of reactant in the slab and k_v is a rate coefficient. The exact form of k_v is considered later; it depends on certain characteristics of the catalyst granules, the diffusion constant within the pores, and in general on the concentration (not, however, when $\alpha = 1$ or when the catalyst surface is completely available).

Consider a thin slab of the reaction system, of volume $dV = Adx$, where A is the cross-sectional area and dx the thickness. If c is the concentration at the point x, and $c+dc$ that at $x+dx$, and if the volume of gas passing the point x per second is R, the steady-state equation for the slab is

$$Rcdt = (R+dR)(c+dc)\, dt + k_v c^\alpha \, dV dt. \qquad [2]$$

With the neglect of the term in $dVdcdt$ this equation reduces to

$$Rdc + cdR + k_v c^\alpha \, dV = 0. \qquad [3]$$

[1]*Manuscript received March 21, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.

In order to solve this, one must have an explicit expression for R as a function of the extent to which reaction has occurred.

The Volume Rate of Flow, R

If there is no change in the total number of molecules during the reaction, R is constant; the second term in Eq. [3] then drops out and the equation is readily integrated. Suppose, however, that the stoichiometry of the reaction is such that 1 mole of reactants gives rise to ν moles of products. Then if initially a volume V_1^* of gas contains n_1 moles of reactant molecules, after some reaction has occurred, there are n moles of reactants and $\nu(n_1-n)$ moles of product. The volume occupied by this is

$$V^* = V_1^*[\nu-(\nu-1)(n/n_1)]. \quad [4]$$

It is convenient at this stage to introduce the dimensionless variables

$$f = n/n_1 \quad [5]$$

and

$$\xi = V/V_0, \quad [6]$$

where n_1 is the number of moles of gas entering the reactor in the volume V_1, V_0 is the total volume of the reactor, and V is the volume that has been traversed at any time. Eq. [4] may then be written as

$$V^* = V_1^*[\nu-(\nu-1)f], \quad [7]$$

whence

$$R = R_1[\nu-(\nu-1)f], \quad [8]$$

where R is the volume rate of flow at any point and R_1 the volume rate of flow of the entering gas. From [8] it follows that

$$dR = -(\nu-1)\, R_1\, df. \quad [9]$$

The General Dimensionless Rate Equation

Since $c = n/V^*$ and $c_1 = n_1/V_1^*$ it follows that

$$c = c_1(V_1^*/V^*)(n/n_1) \quad [10]$$

$$= c_1\{f/[\nu-(\nu-1)f]\} \quad [11]$$

and that

$$dc = c_1\{\nu/[\nu-(\nu-1)f]^2\}df. \quad [12]$$

Introduction of these expressions into Eq. [3], and using Eqs. [8] and [9], gives rise, after some reduction, to

$$\{[\nu-(\nu-1)f\,]^\alpha/f^\alpha\}df+(k_v\, V_0\, c_1^{\alpha-1}/R_1)d\xi = 0. \quad [13]$$

This equation may be written as

$$\{[\nu-(\nu-1)f]^\alpha/f^\alpha\}df+bd\xi = 0, \quad [14]$$

where b is defined by

$$b = k_v\, V_0\, c_1^{\alpha-1}/R_1. \quad [15]$$

Equations [14] and [15] can be applied to the determination of the order of reaction and the activation energy without proceeding with the integrations. Suppose, for example, that c_i is varied and, by trial and error, R_i is simultaneously varied so as to keep the f–ξ relationship the same, i.e., so that the same fraction of reaction occurs in the reactor. If this is so it follows that the ratio $c_i^{\alpha-1}/R_i$ is unchanged; α can therefore be determined. If the reaction is of the first order it will not be necessary to change R_i in order to maintain b constant as c_i is varied; if it is of the second order R_i must be varied in proportion to c_i, and so on.

The procedure for determining the activation energy is similar. The temperature is varied, and either c_i or R_i varied so as to keep b constant (i.e., so that the extent of reaction remains the same). If R_i is varied its relationship with the temperature is the same as that of k_v, and the activation energy can therefore be obtained from an Arrhenius plot of log R_i against $1/T$. A similar procedure can be used for c_i.

In general, k_v, and therefore b, is a function of f, and the dependence is discussed later. In some situations, however, as when the surface is completely available to the reaction system (when the catalyst pores are sufficiently large) b is a constant. The parameter b can also be shown to be a constant for any first-order reaction whether the surface is completely available or not. The integrated form of Eq. [14] will first be considered for this case of constant b, after which the general dependence of b on f will be discussed, and an integrated solution obtained.

The Case in which b Is Constant

It does not appear to be possible to obtain an explicit general solution of Eq. [14], but solutions for certain special cases of interest are readily obtained. The solutions for $\alpha = 1$ and $\alpha = 2$ will be given.

The integrated form of Eq. [14] for $\alpha = 1$, subject to the boundary conditon $\xi = 0$, $f = 1$, is

$$\nu \ln f + (\nu - 1)(1 - f) + b\xi = 0. \qquad [16]$$

The fraction f_t of reactant remaining at the outlet of the reactor, when $\xi = 1$, is therefore defined by

$$\nu \ln f_t + (\nu - 1)(1 - f_t) + b = 0. \qquad [17]$$

Figure 1 shows $1 - f_t$, the fractional yield of product from the reactor, plotted against the parameter b, for various values of ν. This figure permits a graphical evaluation of b from the results of an experiment in a reactor. If it is known that the surface is completely available (see below) the rate constant k_v can then be calculated using Eq. [12].

The corresponding solutions for the second-order case ($\alpha = 2$) are

$$\nu^2(1 - 1/f) - 2(\nu - 1)\ln f - (\nu - 1)(1 - f) + b\xi = 0 \qquad [18]$$

and

$$\nu^2(1 - 1/f_t) - 2(\nu - 1)\ln f_t - (\nu - 1)(1 - f_t) + b = 0. \qquad [19]$$

Figure 2 shows $1 - f_t$ plotted against b for various values of ν.

It will now be shown that Eqs. [16] and [17] apply to any first-order reaction, whether the surface is completely available or not. If the surface is completely available the rate constant k_v is given by

$$k_v = k\rho_b S_g, \qquad [20]$$

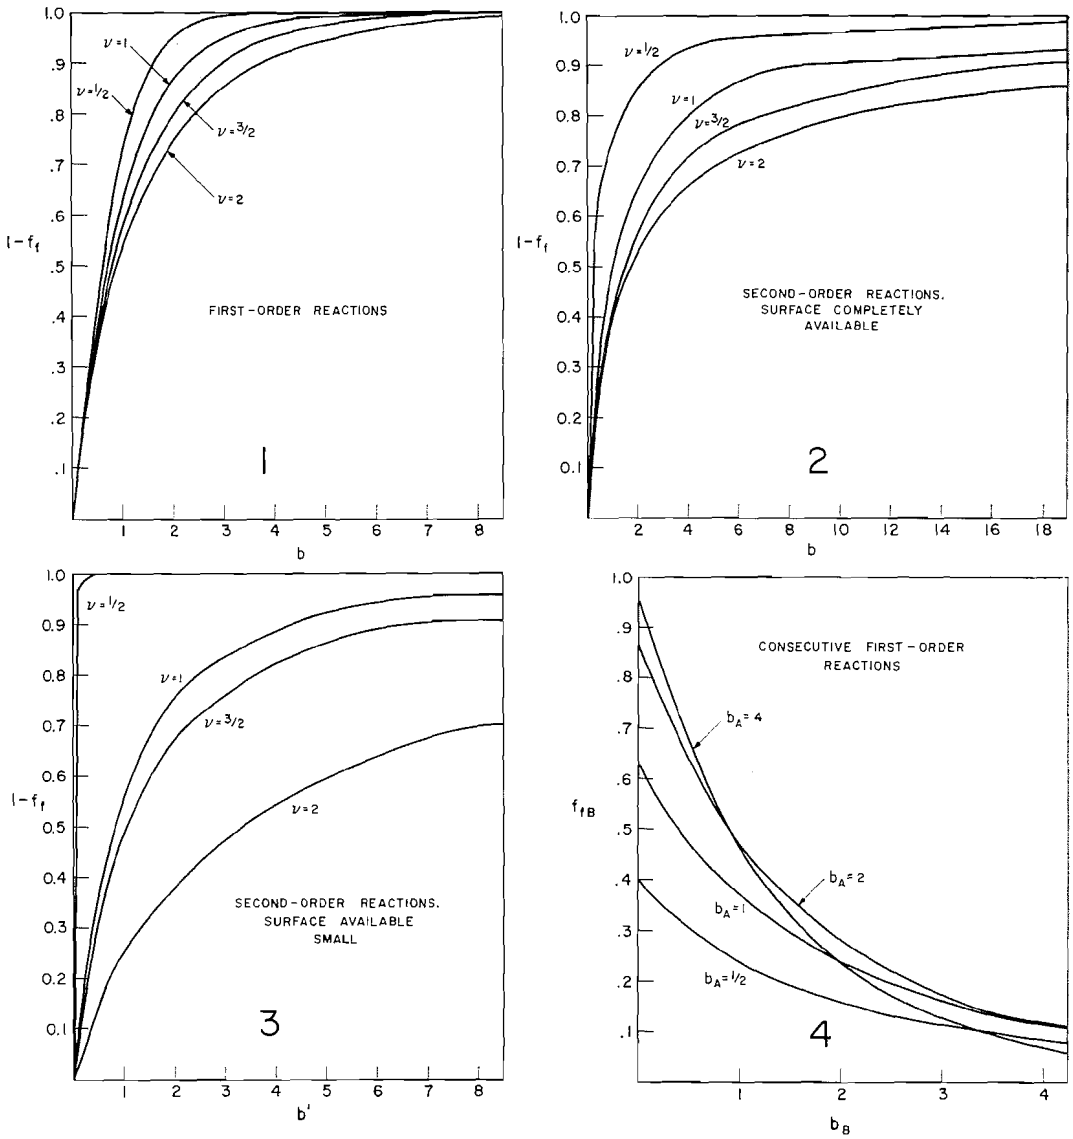

FIG. 1. The fractional yield of product plotted against the parameter b, defined by Eq. [15] in the text, for various values of ν. These curves apply to first-order reactions.

FIG. 2. The fractional yield of product plotted against b, for second-order reactions; these curves apply only when b is independent of f, i.e. when the surface is completely available.

FIG. 3. The fractional yield of product plotted against b', for second-order reactions in which the fraction of surface available is small.

FIG. 4. The fractional yield of an intermediate B, in the case of consecutive first-order reactions, plotted against the parameter b_A for various values of the parameter b_B.

where k is the intrinsic rate constant with respect to unit surface area, ρ_b is the bulk density of the catalyst (the mass per unit over-all volume), and S_g is the surface area per gram of catalyst. The parameter b is therefore in this case given by

$$b = k\rho_b S_g V_0 c_1^{\alpha-1}/R_1, \qquad [21]$$

so that if b is determined experimentally, in the manner indicated above, k can be calculated using the known characteristics of the system.

For personal use only.

If the surface of the catalyst is not completely available to the reaction system the treatment of Thiele (3) combined with that of Wheeler (4) leads to the result that for a first-order reaction

[22] $$k_v = k\rho_b S_g(\tanh h)/h,$$

where h is defined by

[23] $$h = L(2k/Dr)^{1/2}.$$

D is the diffusion constant for the reaction system, L the mean half-length of the pores, and r the mean radius of the pores. Wheeler (4) has proposed useful methods of estimating L and r in terms of easily-measured quantities, and has discussed the magnitude of D. When h is sufficiently small (less than 0.2) $(\tanh h)/h$ is close to unity, and Eq. [22] approaches Eq. [20]. Otherwise k_v is reduced to the fraction $(\tanh h)/h$, which is therefore the fraction of surface available. Wheeler (4) has shown how this fraction can be determined from the experimental data.

Eqs. [18] and [19], and indeed the corresponding equations for any reaction of other than the first order, apply only when the surface is completely available. In such cases k_v is always given by Eq. [20] and b is therefore constant. Otherwise k_v and b are functions of f and the integrated equations then assume different forms, some of which are discussed below.

The Case in which b Is a Function of f

Thiele's treatment (3) does not lead to explicit solutions for other than first-order reactions. However, a combination of Wheeler's (4) and Thiele's (3) procedures leads to the conclusion that the fraction of surface available is approximately

$$(\tanh h)/h,$$

where h is now defined by

[24] $$h = L(2k/rD)^{1/2}\, c^{(\alpha-1)/2}.$$

This reduces to Eq. [23] when $\alpha = 1$. The parameter b is now a function of c, and therefore of f.

General solutions again appear to be impossible. The integration may, however, be carried out for a second-order reaction in which the fraction of surface available is small; in this case $\tanh h \approx 1$, so that $(\tanh h)/h$ is approximately equal to $1/h$. When this is so, k_v is given by (with $\alpha = 2$)

[25] $$k_v = (k\rho_b S_g/L)(rD/2k)^{1/2}\, c^{-1/2}$$

and b by

[26] $$b = (k\rho_b S_g V_0 c_1/R_1 L)(rD/2k)^{1/2}\, c^{-1/2}.$$

Using Eq. [11] this becomes

[27] $$b = (k\rho_b S_g V_0 c_1^{1/2}/R_1 L)(rD/2k)^{1/2} f^{-1/2}[\nu-(\nu-1)f]^{1/2}.$$

Equation [14] then becomes, with $\alpha = 2$,

[28] $$\{[\nu-(\nu-1)\,f]^{3/2}/f^{3/2}\}df + b'\,d\xi = 0,$$

where

[29] $$b' = (k\rho_b S_g V_0 c_1^{1/2}/R_1 L)(rD/2k)^{1/2}.$$

Comparison of Eq. [28] with Eq. [14] shows that Eq. [28] corresponds to a system having

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

an apparent order of three halves. This is shown by the index to which f is raised and by the fact that, to maintain b' constant, the ratio $c_1^{\frac{1}{2}}/R_1$, viz. $c_1^{\alpha-1}/R_1$ with $\alpha=3/2$, must be kept constant.

The solutions of Eq. [28] take different forms according to the values of ν. The simplest case is when $\nu = 1$, and the solution using the boundary condition $f = 1$, $\xi = 0$ is

$$2(1-1/f^{1/2})+b'\xi = 0. \qquad [30]$$

The solution for $\nu = 1/2$ is

$$\sqrt{2}\left(\frac{3}{4}\ln\frac{\sqrt{(1-f)}+\sqrt{(2-f)}}{\sqrt{(2-f)}-\sqrt{(1-f)}}+\tfrac{1}{2}\sqrt{[(1-f)(2-f)]}-\sqrt{\frac{1-f}{2-f}}\right)+b'\xi = 0. \qquad [31]$$

That for $\nu = 3/2$ is

$$3/2\,\{\sqrt{2}+3/2.\sin^{-1}\sqrt{\tfrac{1}{3}}-\sqrt{[(3-f)/f]}-3/2.\sin^{-1}\sqrt{\tfrac{1}{3}f}-\tfrac{1}{6}\sqrt{[f(3-f)]}\}+b'\xi = 0 \qquad [32]$$

while for $\nu = 2$.

$$\sqrt{2}.\{10+3\pi-8\sqrt{[(2-f)/f]}-12\sin^{-1}\sqrt{\tfrac{1}{2}f}-2\sqrt{[f(2-f)]}\}+b'\xi = 0. \qquad [33]$$

The plots of $1-f_t$ against b' (for $\xi = 1$) are shown in Fig. 3 for the four values of ν.

Consecutive Reactions

It is frequently the case that reactions occur in two stages, and the treatment of the flow kinetics in such systems is of some interest. If the intermediate is the desirable product, for example, it is important to know the conditions under which it will be produced in maximum amounts.

Attention will be confined to the case of two consecutive first-order reactions, represented by the scheme

$$\mathrm{A} \xrightarrow{k_{v1}} \mathrm{B} \xrightarrow{k_{v2}} \mathrm{C}.$$

The rate equations are:

$$-dn_A = k_{v1}\,c_A\,dVdt, \qquad [34]$$

$$-dn_B = k_{v2}\,c_B\,dVdt - k_{v1}\,c_A\,dVdt, \qquad [35]$$

$$-dn_C = k_{v2}\,c_B\,dVdt. \qquad [36]$$

The steady-state equations for the slab of volume dV are, for A

$$Rc_A\,dt = (R+dR)(c_A+dc_A)dt+k_{v1}\,c_A\,dVdt, \qquad [37]$$

and for B

$$Rc_B\,dt = (R+dR)(c_B+dc_B)dt+k_{v2}\,c_B\,dVdt-k_{v1}\,c_A\,dVdt. \qquad [38]$$

With the neglect of terms of the type $d\,Rdcdt$ these equations reduce to

$$Rdc_A+c_A\,dR+k_{v1}\,c_A\,dV = 0, \qquad [39]$$

$$Rdc_B+c_B\,dR+k_{v2}\,c_B\,dV-k_{v1}\,c_A\,dV = 0. \qquad [40]$$

The corresponding equations for C need not be written down, since when solutions for A and B have been obtained that for C follows at once.

The fact that both reactions are of the first order does not necessarily imply that their

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

stoichiometry corresponds to the equation written above. In general 1 mole of A gives rise to ν moles of B, and 1 mole of B produces μ moles of C. If initially a volume V_1^* of gas contains n_{A_1} moles of A, after some reaction has occurred there are n_A moles of A, n_B moles of B, and n_C moles of C, and

$$n_A+(n_B/\nu)+(n_C/\nu\mu) = n_{A1}. \quad [41]$$

The total number of moles present is

$$\sum n = n_A+n_B+n_C, \quad [42]$$

and this, using Eq. [41], is equal to

$$\sum n = \nu\mu\, n_{A1}-(\nu\mu-1)n_A-(\mu-1)n_B. \quad [43]$$

The volume occupied by this is

$$V^* = V_1^*[\nu\mu-(\nu\mu-1)f_A-(\mu-1)f_B], \quad [44]$$

where f_A and f_B are defined by

$$f_A = n_A/n_{A1} \quad [45]$$

and

$$f_B = n_B/n_{B1}. \quad [46]$$

The volume rate of flow, R, at any point is therefore related to the initial rate by

$$R = R_1[\nu\mu-(\nu\mu-1)f_A-(\mu-1)f_B], \quad [47]$$

whence

$$dR = -(\nu\mu-1)R_1\, df_A-(\mu-1)R_1\, df_B. \quad [48]$$

The concentrations c_A and c_B are given by

$$c_A = c_{A1}(V_1^*/V^*)(n_A/n_{A1}) = c_{A1}f_B/[\nu\mu-(\nu\mu-1)f_A-(\mu-1)f_B] \quad [49]$$

and

$$c_B = c_{A1}(V_1^*/V^*)(n_B/n_{A1}) = c_{A1}f_B/[\nu\mu-(\nu\mu-1)f_A-(\mu-1)f_B]. \quad [50]$$

An explicit solution of these equations appears not to be possible in the general case. The solution for $\nu = \mu = 1$ is simple, however, and proceeds as follows. Under these circumstances

$$f_A = c_A/c_{A1}, \qquad f_B = c_B/c_{A1}, \quad [51]$$

$$R = R_1, \qquad dR = 0, \quad [52]$$

$$\xi = V/V_0. \quad [53]$$

Equations [39] and [40] become

$$R_1\, df_A+k_{v1}\, V_0 f_A d\xi = 0, \quad [54]$$

$$R_1\, df_B+k_{v2}\, V_0 f_B d\xi-k_{v1}\, V_0 f_A d\xi = 0. \quad [55]$$

The solution of [54], with the boundary condition $\xi = 0, f_A = 1$, is

$$f_A = e^{-b_A\xi} \quad [56]$$

where b_A is defined by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

[57] $$b_A = k_{v1} V_0/R_1.$$

This equation is equivalent to Eq. [16] with $\nu = 1$, as of course it must be as the law for the disappearance of A is independent of the subsequent fate of B.

Insertion of [56] into [55] gives

[58] $$df_B + b_B f_B \, d\xi - b_A e^{-b_A \xi} \, d\xi = 0$$

where b_B is defined by

[59] $$b_B = k_{v2} V_0/R_1.$$

The solution of [58], with the boundary condition $\xi = 0, f_B = 0$, is

[60] $$f_B = [b_A/(b_B - b_A)] (e^{-b_A \xi} - e^{-b_B \xi}).$$

Figure 4 shows f_{tB} (the fraction of B present at the outlet, when $\xi = 1$) as a function of b_B for various values of b_A.

DISCUSSION

The equations derived above, and the corresponding plots, are useful in the analysis of kinetic data for flow systems, particularly when it is desired to know the intrinsic activity k of the catalyst surface. A possible procedure is as follows:

(1) First determine the apparent order of the reaction, by varying concentrations and rates of flow in the manner described above.

(2) Investigate the extent to which the total surface area is utilized; this can be done by comparing the rates when the catalyst is in different states of granulation, and seeing whether the rate falls in line with the B.E.T. area or the number of pore mouths.

On the basis of the above tests it will in many cases be possible to conclude that the system belongs to one of the cases considered in Figs. 1 to 4. From a value of $1 - f_t$ it is then possible to determine b or b' and hence, using the appropriate expression for b or b', the value of k. The calculation of k of course requires a knowledge of the volume rate of flow, the bulk density, and the surface area per gram. In addition, if the surface is not completely available, it is necessary to determine (tanh h)/h in the manner suggested by Wheeler (4).

A variant of the above method is necessary if consecutive reactions are involved. A possible procedure is now to determine b_A, and hence k_1, from the disappearance of A. The values of b_B and k_2 can then be determined from the appearance of B, using Fig. 4. More complicated systems can be treated by suitable extensions of the above methods.

ACKNOWLEDGMENTS

THE NATURE OF THE CADMIUM IONS IN HYDROXIDE AND CARBONATE SOLUTIONS[1]

PHYLLIS E. LAKE AND J. M. GOODINGS[2]

ABSTRACT

The nature and concentration of the cadmium-containing ions in potassium hydroxide and potassium carbonate solutions have been studied polarographically. The co-ordination number for the hydroxide–cadmium complex is 4 and its dissociation constant 2×10^{-10}. The co-ordination number for the carbonate–cadmium complex is 3 and its dissociation constant 6×10^{-7}.

INTRODUCTION

From a study of the electrolytic oxidation of cadmium in carbonate and hydroxide solutions (1) it became apparent that cadmium must exist in solution as an intermediate step in the oxidation. According to Latimer (2) the solubility products of $Cd(OH)_2$ and $CdCO_3$ are 2×10^{-14} and 5×10^{-12} respectively. These data show that no appreciable concentration of cadmium can exist in these solutions as a simple Cd^{+2} ion.

The object of this work was to measure the concentration of cadmium in potassium hydroxide and potassium carbonate solutions in equilibrium with solid CdO, $Cd(OH)_2$, and $CdCO_3$ and to determine the nature and properties of the cadmium-containing ion.

The method used was that described by Lingane (3). After it was established that the reduction of the complexes was reversible, measurements of half-wave potential as a function of concentration of complexing ion were made. From these results co-ordination numbers and dissociation constants were calculated.

EXPERIMENTAL

Preparation of Saturated Solutions

Solutions of KOH ranging from 1 to 13 *N*, of K_2CO_3 ranging from 1 to 10 *N* (10 *N* is supersaturated but remained stable over a period of 8 months), and mixtures of the two having a total normality of about 7 and containing varying proportions of OH^- and CO_3^{-2} were prepared. One series of these solutions was saturated with CdO, another with $Cd(NO_3)_2.4H_2O$. Approximately one gram of the cadmium compound was added to each 500-ml. sample. The solutions were allowed to stand in contact with the solid, and shaken vigorously from time to time. One set of solutions was allowed to stand at each of the following temperatures: 0° C., 25° C., and 50° C. The $Cd(NO_3)_2.4H_2O$ was converted rapidly to either $Cd(OH)_2$ or $CdCO_3$ depending on the solution. The solid phase in contact with the mixed solutions was not analyzed but was probably a mixture of $Cd(OH)_2$ and $CdCO_3$. The brown CdO gradually became lighter in color and conversion to the hydroxide and carbonate occurred slowly. Samples of the clear liquid were removed from time to time and analyzed polarographically for cadmium. When two successive samples showed no change in diffusion current, the solutions were assumed to be saturated.

Analytical Technique

A Leeds and Northrup "Electrochemograph type E" was used for all the analyses. A drop time of 4 seconds and a polarizing rate of 50 mv./min. were used throughout. One arm of the H-shaped test cell contained the reference electrode, the other the test solution.

The center portion contained a fritted-glass disk and an agar plug. The reference electrode was saturated calomel and all potentials quoted in the tables are referred to this reference. Approximately 10-ml. samples were used. Oxygen-free nitrogen was bubbled through the cell for at least 10 minutes before the analysis was carried out. Approximately 0.005% gelatin was added to the test solution to avoid maxima.

A calibration curve of diffusion current vs. cadmium concentration was drawn covering the range 1×10^{-5} to 1×10^{-2} mole/l. of cadmium nitrate in a 1.5 *N* KNO_3 supporting electrolyte. Variation of the KNO_3 concentration from 1 normal to saturated had little effect (about 1% over the whole range) on the diffusion current and half-wave potential. Potassium nitrate was chosen as a supporting electrolyte, because nitrate ion does not form a complex with cadmium (4).

Cadmium concentrations in the test samples were determined as follows: after a solution had been saturated with cadmium a small amount of the clear liquid was pipetted off and stored at the temperature of the original solution to allow for settling of any suspended material. A sample for analysis was then pipetted from this second solution and allowed to come to room temperature. A part of this solution was titrated with standard 0.1 *N* HCl to determine the final OH^- and/or CO_3^{-2} concentration. The remainder was neutralized with concentrated nitric acid and diluted or concentrated to a convenient volume so that the KNO_3 concentration was 1–2 normal. Concentrated nitric acid was chosen in preference to dilute acid to avoid volume dilution of the original sample below polarographically detectable concentrations of cadmium. The neutralized solution was analyzed polarographically, and the cadmium concentration as Cd^{+2} ion was determined from the calibration curve.

Polarograms were drawn for all the unneutralized solutions at 25° C. in order to measure the effect of OH^- and CO_3^{-2} activity on half-wave potential.

Results

The dependence of cadmium concentration on KOH and/or K_2CO_3 concentration is shown in Figs. 1, 2, and 3. The half-wave potentials for these solutions (at 25°) are shown in Table I.

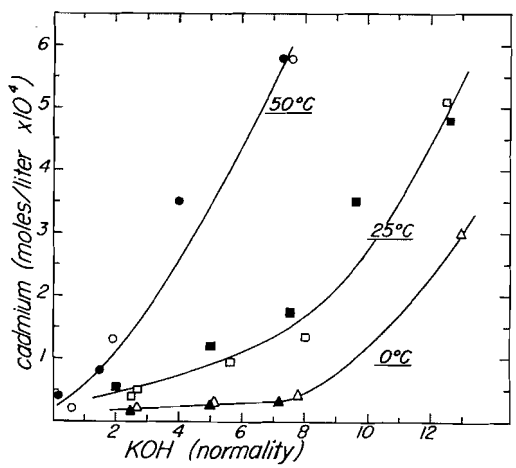

FIG. 1. Concentration of cadmium in potassium hydroxide solutions. (In all figures the open symbols refer to solutions saturated with respect to CdO, the closed symbols to solutions saturated with respect to $Cd(OH)_2$ and/or $CdCO_3$.)

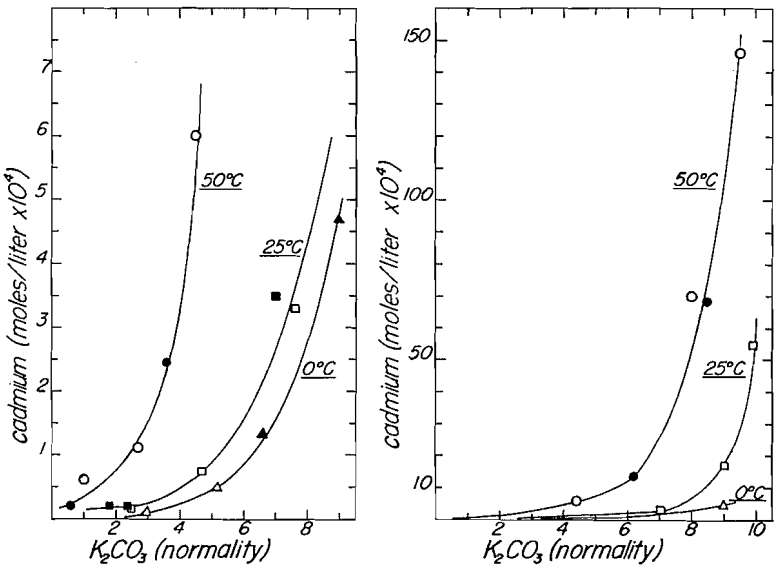

FIG. 2. Concentration of cadmium in potassium carbonate solutions.

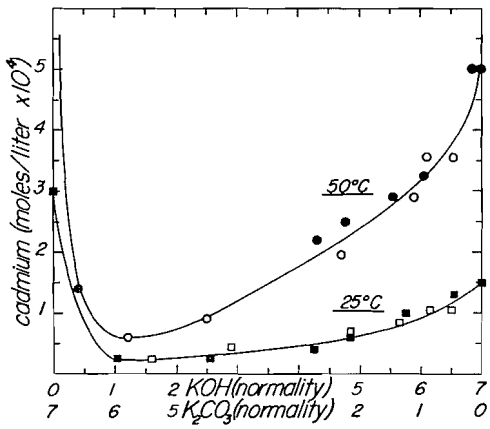

FIG. 3. Concentration of cadmium in mixed solutions.

No attempt was made to measure the rate of dissolution of the CdO, $Cd(OH)_2$, and $CdCO_3$, but the results indicate that a period of approximately two weeks was necessary to attain equilibrium at 25° C. and 4–6 weeks at 0° C.

Experimental Accuracy

The total error in determination of concentration of cadmium, considering variations in drop size from one capillary to another, and in temperature, error in regulating drop time, error in measuring i_d, and in construction and reading the calibration curve may amount to as much as ±10%. Errors in determining final OH^- and CO_3^{-2} concentration might be ±5%. Half-wave potential values were reproducible within ±5 mv.

DISCUSSION

Activities

Because of the high concentrations of K_2CO_3 and KOH used in the solubility determinations it was necessary to use activity instead of concentration and to take into account the liquid junction potentials before determining co-ordination numbers and dissociation constants.

The activity coefficients for the KOH solutions were determined using the data of Akerlof and Bender (5). Activity coefficients for K_2CO_3 were found in Landolt-Börnstein Tabellen (6).

Liquid Junction Potentials

The liquid junction potentials were calculated using both the Henderson and the Planck equations. In both cases the values obtained for the K_2CO_3 solutions were always <3 mv. and thus are within the limits of experimental error. Therefore no correction was made to the measured values of $E_{\frac{1}{2}}$ for the carbonate case. Liquid junction potentials calculated for KOH solutions were considerably larger (11–30 mv.) and could not be

neglected. Potentials corrected according to both the Planck and the Henderson equations are shown in Table II. It was felt that the "constrained diffusion junction" described by the Planck equation represented better the conditions present in the test cell; therefore, these corrections were used in the subsequent calculations.

Reversibility

Lingane (3, 7) has shown that if the dissociation of the metal ion complex and its reduction at the dropping electrode are rapid and reversible then the equation for a wave, at 25° C. in the presence of an excess of complex-forming substance, is

$$[1] \qquad E_{\text{d.e.}} = E_{\frac{1}{2}} - (0.0591/n) \log\{i/(i_d - i)\},$$

where i is the current and $E_{\text{d.e.}}$ the voltage of the dropping electrode at any time, $E_{\frac{1}{2}}$ is the half-wave potential, i_d the diffusion current, and n is the number of Faradays associated with the electrode process. From Eq. [1] it is evident that, for a reversible wave,

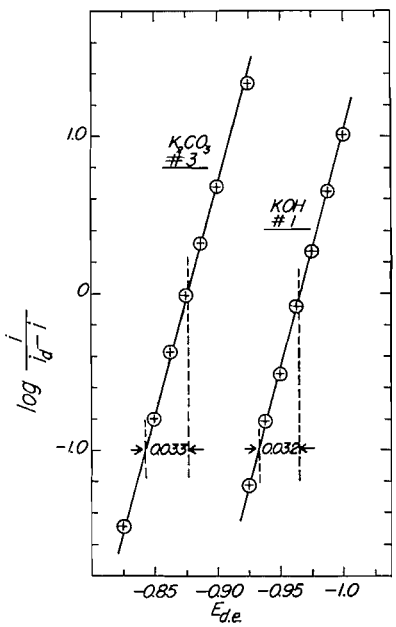

FIG. 4. Test for reversibility of reductions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

a plot of log $i/(i_d - i)$ against $E_{d.e.}$ will yield a straight line of slope $-0.0591/n$. The reversibility of the reductions was tested in this manner. Two examples are shown in Fig. 4. The points fall on straight lines of slopes -0.032 ± 0.003 and -0.033 ± 0.003 in good agreement with -0.030, the theoretical value for a reversible reduction where $n = 2$.

Co-ordination Number

The half-wave potential for reduction of a complex metal ion is independent of the concentration of the metal ion, but shifts with changing activity of the complexing ion according to the equation

$$[2] \qquad E_{\frac{1}{2}}/\log C_x f_x = -p\,(0.0591/n),$$

where p is the co-ordination number and C_x and f_x the concentration and activity coefficient of the complexing ion (3, 7). Since it is impossible to determine individual values for a_{OH^-} and $a_{CO_3^{-2}}$ the mean ion activities $a\pm$ were used in the following calculations.

In accordance with Eq. [2] the half-wave potentials for cadmium in caustic solutions (corrected for E_{lj} according to the Planck equation) are plotted against the log of the mean ion activity of KOH in Fig. 5. The slope of the line $E_{\frac{1}{2}}$ vs. log $a\pm$ is -0.108 ± 0.01. The theoretical slope for $n = 2$, $p = 4$ is -0.118. Since liquid junction potential corrections are so large the agreement is better than would be expected. The empirical formula for the cadmiate ion, then, is $Cd(OH)_4^{-2}$.

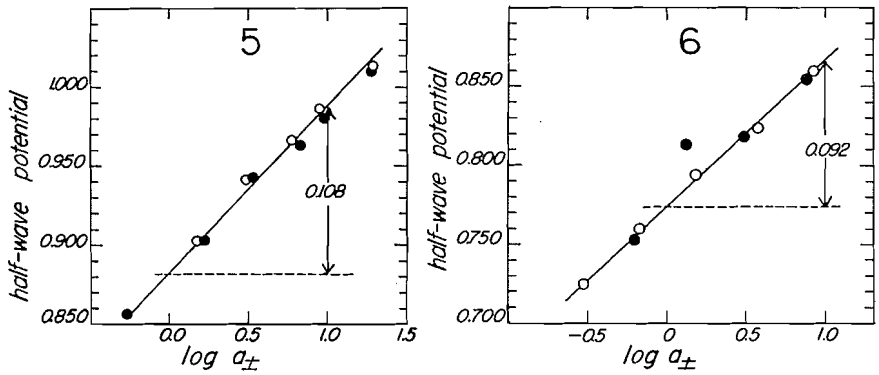

FIG. 5. Determination of p for cadmium complex in potassium hydroxide solutions.
FIG. 6. Determination of p for cadmium complex in potassium carbonate solutions.

Scholder and Staufenbiel (8) prepared and isolated disodium cadmiate ($Na_2Cd(OH)_4$) by refluxing a suspension of $Cd(OH)_2$ in concentrated NaOH solutions, but were unable to obtain the complex salt using hydroxide concentrations lower than 14 N. It appears, however, that the cadmiate ion exists in solution at concentrations as low as 1 normal with respect to hydroxide. This formula for the cadmiate complex is similar to that determined by e.m.f. measurements for the zincate ion ($Zn(OH)_4^{-2}$) (9).

The half-wave potentials for cadmium in carbonate solutions are plotted against log of the mean ion activity for K_2CO_3 in Fig. 6. The slope of the line is -0.092 ± 0.005, while the theoretical slope for $n = 2$, $p = 3$ is -0.090. Hence the co-ordination number for the carbonate complex is 3, and its empirical formula $Cd(CO_3)_3^{-4}$.

No evaluation of p can be made from the half-wave potentials for the mixed solutions because of present lack of knowledge of the activity coefficients in the mixed solutions. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

is interesting to note that, although the ionic strength of the solutions increases as the proportion of CO_3^{-2} ion increases, both the shift of $E_{\frac{1}{2}}$ and the solubility of cadmium decrease. That is, in the mixed solutions the effect of the hydroxide ion appears to be more important than that of the carbonate ion. This is consistent with the observation made previously (1) that after anodic oxidation of cadmium in similar mixed solutions, the final product is always pure $Cd(OH)_2$ if the hydroxide concentration is $\geqslant 0.7$ N.

Dissociation Constants

The half-wave potential for the reduction of a metal ion complex depends on the logarithm of the dissociation constant (K_c) and is more negative the smaller the value of K_c, that is, the more stable the complex ion. The approximate equation for the relation of $E_{\frac{1}{2}}$ to log K_c given by Lingane (3, 7) is

$$[3] \qquad (E_{\frac{1}{2}})_c - (E_{\frac{1}{2}})_s \cong (0.0591/n) \log K_c - p(0.0591/n) \log C_x f_x,$$

where $(E_{\frac{1}{2}})_c$ and $(E_{\frac{1}{2}})_s$ are the half-wave potentials for the complex and simple metal ions. Because of the wide variation of activity coefficients over the range of concentrations of KOH and K_2CO_3 used in this work, the activity coefficient f_x could not be neglected. The half-wave potential for a simple cadmium ion in 1.5 N KNO_3 is -0.0591 v. The liquid junction potential correction in this value is smaller than the experimental error. Using Eq. [3] the dissociation constants were calculated for both the hydroxide and carbonate complexes at a number of different concentrations of complexing ion. The results are shown in Table III. The dissociation constant of the cadmiate complex ($Cd(OH)_4^{-2} \rightleftharpoons Cd^{+2} + 4OH^-$) is $\sim 2\times10^{-10}$ and of the carbonate–cadmium complex ($Cd(CO_3)_3^{-4} \rightleftharpoons Cd^{+2} + 3CO_3^{-2}$) is $\sim 6\times10^{-7}$.

CONCLUSIONS

Cadmium can exist in finite concentrations in concentrated hydroxide and carbonate solutions in the form of complex ions $Cd(OH)_4^{-2}$ and $Cd(CO_3)_3^{-4}$ respectively. The hydroxide–cadmium complex is the more stable of the two.

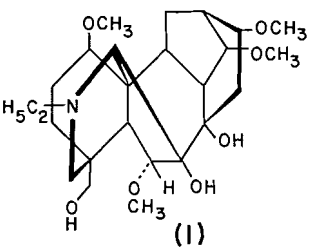
THE INTERRELATION OF DELPHELINE AND LYCOCTONINE[1]

O. E. Edwards, Léo Marion, and K. H. Palmer[2]

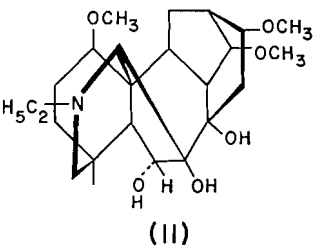
ABSTRACT

Lycoctonine has been converted to a derivative of delpheline, thus establishing a common diterpenoid skeleton and identical points of nuclear substitution for the two alkaloids.

The chemistry of the delphinium alkaloid lycoctonine is for the most part understandable on the basis of the diterpenoid structure I (1, 2, 3). Cookson and Trevett, in an excellent study of the reactions of the alkaloid delpheline, have shown that these find ready interpretation if the skeleton and position of nuclear substitution is the same as that of lycoctonine (4, 5). Hence demethylenedelpheline has been assigned structure II.



(I)



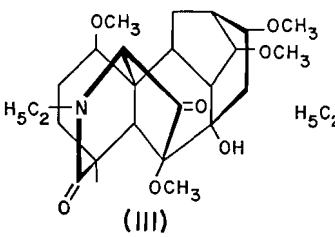
(II)

It was desirable to prove or disprove this suggested relationship. A number of routes involving conversion of lycoctonine and delpheline to a common degradation product seemed plausible. However, since delpheline was not readily available to us, we undertook instead to convert lycoctonine to a known delpheline derivative.

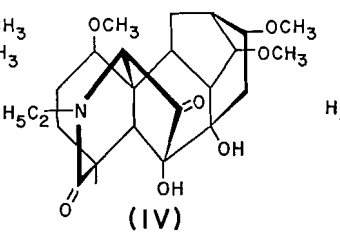
Three possible routes to this goal appeared promising:

(*a*) Interrelation through the monobasic dicarboxylic acid from delpheline (4) as suggested earlier (3).

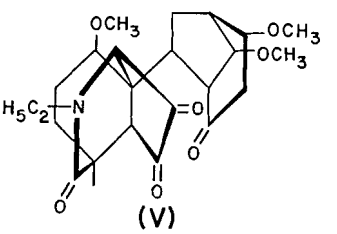
(*b*) Since the methoxyl α to the ketone carbonyl in the "desoxymethyleneiso" compound from lycoctonine can be hydrolyzed readily (6), the "desoxyiso" compound III should on similar treatment give IV. Cleavage of IV with periodic acid would lead to the triketone V possibly identical with dehydrodemethyleneoxodelpheline *seco*diketone (5).



(III)



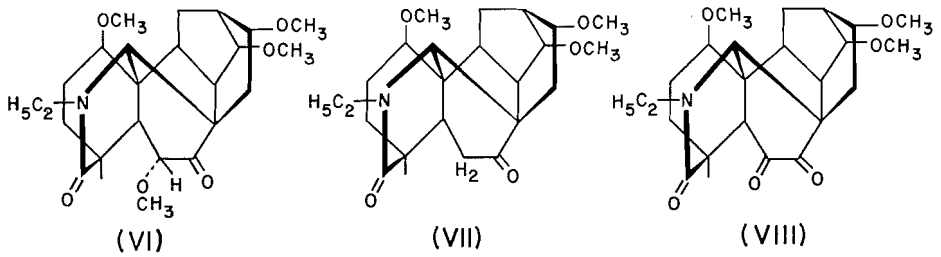
(IV)



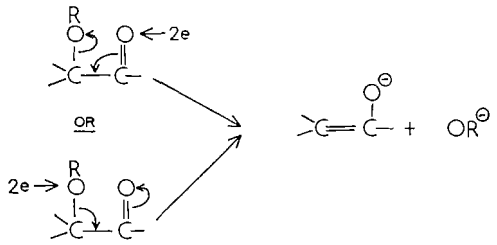
(V)

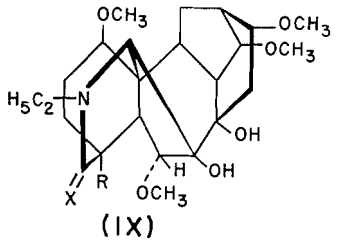
[1]*Manuscript received April, 1, 1958.*
Contribution from the Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada. Issued as N.R.C. No. 4780. Presented in part at the Ninth Seminar in the Chemistry of Natural Products, Fredericton, New Brunswick, October 23–25, 1957.
[2]*National Research Council of Canada Postdoctorate Fellow.*

(*c*) The reductive removal of the methoxyl α to the ketone carbonyl in anhydrodesoxylycoctonam VI would give VII, which could then be oxidized to the diketone VIII.[3] This is the structure suggested for dehydrodemethyleneoxodelpheline pinacone (4).



Since method (*c*) was attempted first and proved successful the others were not investigated. This approach became very attractive when we became aware of the reductive removal of alkoxy and aryloxy groups from the carbon α to a ketone by sodium amalgam (7, 8). The reduction probably proceeds by direct electron transfer from the metal surface, as illustrated.[4]





IX *a*, X = H_2, R = CH_2OH
IX *b*, X = H_2, R = CHO
IX *c*, X = H_2, R = CH_3
IX *d*, X = O, R = CH_3

In order to obtain compound VIII, lycoctonine (IX *a*) was oxidized to lycoctonal (IX *b*), which was then reduced to desoxylycoctonine (IX *c*). This was oxidized to desoxylycoctonam (IX *d*) by permanganate.[5] The conversion of IX *d* to anhydrodesoxylycoctonam VI was accomplished in high yield using the sulphuric acid in acetic acid technique (12). Treatment of an ethanol solution of VI with sodium amalgam gave an 80% yield of de(methoxy)anhydrodesoxylycoctonam (the keto lactam VII). This compound when treated in dioxane at 180° with selenium dioxide gave the α-diketone X.

The product had a melting point and X-ray powder diffraction pattern identical with those of the α-diketone from delpheline (4) and a mixed melting point with this compound showed no depression. The infrared spectra (nujol mull and in chloroform solution) were

[3]*We are grateful to Dr. Ragini Anet, who suggested this possible approach to the interrelation.*
[4]*A similar mechanism for reduction of α-ketols and α-haloketones has been put forward by Brewster (9) and in the case of α-acetoxy ketones by Rosenfeld (10).*
[5]*Modification of the procedure described earlier (11) led to improved results.*

superimposable except for small intensity differences. However, the rotation of our compound was $[\alpha]_D^{27}$ $-58\pm4°$ instead of the reported $-72°$ (4). The very kind co-operation of Professor R. C. Cookson in providing a sample of demethyleneoxodelpheline pinacone acetate enabled us to prepare sufficient delpheline α-diketone to remeasure the optical rotation. Samples of varying purity melting between 200° and 209° all had a rotation $[\alpha]_D^{27}$ $-60\pm4°$; hence we now consider the identity completely established.

The α-diketone proved to be a very sensitive compound, heating in order to concentrate a solution in ethanol or ethyl acetate being sufficient to cause a drop of 10° in the melting point. The selenium dioxide oxidation proved difficult to reproduce. The best result was obtained using an old sample of purified dioxane. Preliminary experiments on the acetoxylation of VII using lead tetraacetate in hot acetic acid gave poor yields of an amorphous acetate and were therefore abandoned.

Since the bulk of this reported work was completed[1] Carmack *et al.* (13) have converted delpheline into a known lycoctonine derivative, hence establishing the same relationship that we have proved.

The close relation between delpheline, deltaline (13), and lycoctonine and that between ajaconine, atidine, and atisine (14, 15) suggests that the great variety of delphinium and aconite alkaloids represent variations in substitution on relatively few modified diterpenoid skeletons.

EXPERIMENTAL

Unless otherwise stated, melting points (uncorrected) were determined on a micro-Kofler hot stage, rotations were measured in absolute ethanol, ultraviolet spectra in 95% ethanol, and infrared spectra using the nujol mull technique. The alumina[6] was standardized after Brockman (16).

Desoxylycoctonam

Desoxylycoctonine (1.739 g.) was dissolved in acetone (70 ml.) containing acetic acid (0.7 ml.), and to this was added finely powdered potassium permanganate (1 g.) in small portions (50 mg.). The last portion persisted for 3 hours. Excess oxidant was reduced by the addition of a saturated solution of sulphur dioxide in acetone (0.5 ml.) and the slurry was filtered. An acid–base–neutral separation of the residue left after evaporation of the acetone solution gave mainly neutral material (1.580 g.). This was chromatographed on an alumina column (activity 3, 31.6 g.).

Fractions	Eluting solvent	Wt., in mg.
1–2	Benzene	84.5
3–6	Benzene–chloroform (1:1)	749
7–8	Benzene–chloroform (1:3)	142.5
9–14	Chloroform	145
15–16	Methanol	225

Fractions 2–10 when crystallized from ether gave colorless tabular needles (865 mg.) of desoxylycoctonam. Melting point and mixed melting point with authentic material 166–168° C.

Anhydrodesoxylycoctonam (VI)

A solution of desoxylycoctonam (700 mg.) in glacial acetic acid (containing 0.1% v/v of sulphuric acid) (8 ml.) was heated at 80° C. for 70 minutes. The warm solution

[6]*Woelm brand neutral alumina.*

For personal use only.

was poured onto crushed ice, neutralized with an ice-cold solution of potassium hydroxide (20%), and extracted with chloroform. The extract after evaporation of the chloroform gave a white froth (700 mg.) which crystallized from ether–acetone or hexane–acetone in colorless square plates (0.318 mg.), m.p. 166–168° C. Chromatography on alumina (8 g., activity 2) of the mother liquors gave a further quantity (100 mg.) of anhydrodesoxylycoctonam after crystallization of the residue (201 mg.) obtained from the chloroform–benzene (1:1) eluate. $[\alpha]_D^{23}$ −8.4 (*c*, 1.48), $[M]_D^{23}$ −37; λ_{min} 2640 Å (log ϵ 1.16), λ_{max} 3040 Å (log ϵ 1.92). Infrared max. 1729 cm.$^{-1}$ (ketone), 1646 cm.$^{-1}$ (lactam). Found: C, 67.15; H, 8.22; OCH_3, 27.45. Calc. for $C_{25}H_{37}O_6N$: C, 67.17; H, 8.34; $4OCH_3$, 27.77.

De(methoxy)anhydrodesoxylycoctonam (VII)

Sodium amalgam (5%, 2.66 g.) was added to a solution of anhydrodesoxylycoctonam (400 mg.) in absolute ethanol (5 ml.), the mixture shaken for 3 hours, then filtered through Hyflo-Supercel, and diluted with water (15 ml.). The residue (0.39 g.) after evaporation of a chloroform extract of this solution crystallized from acetone–ether or acetone–hexane in long colorless needles (270 mg.), m.p. 158–159° C. A mixture with starting material melted at 145° C. The residue (120 mg.) obtained by evaporation of the mother liquors was dissolved in ethanol (1.5 ml.), 5% sodium amalgam (440 mg.) added, and the whole experiment repeated as above. A further amount (70 mg.) of VI was obtained after chromatography of the reaction product on alumina (activity 3). $[\alpha]_D^{23}$ −5° (*c*, 1.86), $[M]_D^{23}$ −21°, λ_{min} 2580 Å (log ϵ 1.35), λ_{max} 2810 Å (log ϵ 1.66). Infrared spectrum: 1725 cm.$^{-1}$ (ketone), 1646 cm.$^{-1}$ (lactam). Found: C, 69.00; H, 8.59; N, 3.23; OCH_3, 22.4. Calc. for $C_{24}H_{35}O_5N$: C, 69.12; H, 8.46; N, 3.36; $3OCH_3$, 22.33.

Acetoxylation of De(methoxy)anhydrodesoxylycoctonam

De(methoxy)anhydrodesoxylycoctonam (20 mg.) was dissolved in glacial acetic acid (1 ml.) and heated to 100°. A saturated solution of lead tetraacetate (44.5 mg.) in glacial acetic acid (1.39 ml.) was added and the mixture heated at 100° C. for 3 hours. After it was cooled, the excess lead tetraacetate was destroyed with sodium metabisulphite. A 5% methanolic solution of potassium hydroxide (5 ml.) was added and the resulting pale yellow solution heated under reflux for 2 hours. The bulk of the methanol was removed under reduced pressure, *N* sulphuric acid was added to give a pH of 5.0, and the solution was extracted with chloroform. The pale yellow residue from the chloroform (18 mg.) was chromatographed on alumina (activity 2) (400 mg.). Benzene and benzene–chloroform (9:1) eluted unchanged starting material. Chloroform–methanol (9:1) eluted only a small quantity of material (3 mg.). This was then acetylated as described by Cookson and Trevett for their ketol (4). The pale yellow neutral product (3 mg.) could not be crystallized but had a broad absorption band at 1730 cm.$^{-1}$ ($OCO.CH_3$) in the infrared spectrum.

Oxidation of De(methoxy)anhydrodesoxylycoctonam

Freshly sublimed selenium dioxide (400 mg.) was added to a solution of de(methoxy)-anhydrodesoxylycoctonam (52 mg.) in dioxan (2.5 ml.) contained in a Carius tube. The tube was sealed and heated at 180° C. for 2 hours. The contents of the cooled tube was filtered through Hyflo-Supercel, diluted with a solution of potassium hydroxide (20%), and the resultant pale yellow solution was extracted with chloroform. The residue after evaporation of the chloroform gave a pale yellow froth (54 mg.) which was dissolved in benzene and shaken with a globule of mercury for 15 minutes. The precipitate of black mercury selenide and the mercury were filtered off and the solution evaporated under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

reduced pressure to a pale yellow froth (52 mg.). This was chromatographed on an alumina column (1 g., activity 2) and the fractions crystallized from ether or acetone–hexane.

Fractions	Eluting solvent	Wt., in mg.	M.p.
1	Benzene	9.5	204–205° C.
2	Benzene–chloroform 9:1	7	204–205° C.
3–4	Benzene–chloroform 3:1	14.5	202–209° C.
5	Benzene–chloroform 2:1	5	205–209° C.
6	Benzene–chloroform 1:1	2	205–209° C.

Fractions 3 and 4 were combined and recrystallized from ether/acetone giving pale yellow needles, m.p. 211–213.5° C. A mixed melting point with these crystals and those of the α-diketone derived from demethyleneoxodelpheline pinacone (3) melted at 211–214.5° C. Fractions 1–6 were combined and recrystallized from acetone–ether or acetone–hexane giving pale yellow needles or prisms, m.p. 214–216° C. The compound had $[\alpha]_D^{27}$ $-58\pm4°$ (*c*, 0.4 in $CHCl_3$). Infrared max. (in CS_2) 1758 cm.$^{-1}$, 1722 cm.$^{-1}$ (α-diketone), and 1658 cm.$^{-1}$ (lactam); (in $CHCl_3$) 1756 cm.$^{-1}$, 1722 cm.$^{-1}$, and 1650 cm.$^{-1}$. Infrared max. (nujol mull) 1759(74.5), 1725(75), 1650(94), 1325(51), 1300(54), 1280(49), 1240(51), 1221(58), 1192(57), 1175(47), 1130(83), 1098(92), 1065 S (48), 1040(42), 1012(44), 990(46), 920(42). The X-ray powder diffraction pattern of the diketone (prisms) and the recrystallized α-diketone from delpheline (prisms) were completely superimposable (35 lines). Found: C, 66.89; H, 7.58. Calc. for $C_{24}H_{33}O_6N$: C, 66.80; H, 7.71. Further experiments using pure dry dioxane, acetic acid, acetic acid – acetic anhydride gave markedly lower yields.

Delpheline α-Diketone

Samples obtained from Professor Cookson or prepared from demethyleneoxodelpheline pinacone acetate (3) crystallized in needles from methanol–water, or as pale yellow prisms from ethyl acetate. The melting point could not be raised above 199° with these solvents if the solutions were concentrated by heat. The compound was readily eluted from a column containing a 20-fold ratio of alumina (activity 2) with benzene and benzene–ether, giving fractions melting between 207–211°. Recrystallization with heating lowered the melting point. A sample with melting point 209° had an $[\alpha]_D^{27}$ -60 ± 4 (*c*, 1.09 in $CHCl_3$). Another sample with melting point 202° had $[\alpha]_D^{27}$ -60 ± 3 (*c*, 0.80 in $CHCl_3$). Infrared max. (in $CHCl_3$) 1756 cm.$^{-1}$, 1722 cm.$^{-1}$ (α-diketone), and 1650 cm.$^{-1}$ (lactam). Infrared max. (nujol mull) 1759(73), 1725(71), 1650(92), 1325(46), 1300(48), 1280(42), 1240(46), 1220(52), 1192(51), 1175(39), 1130(80), 1098(89), 1065 S (39), 1040(35), 1012(38), 988(34), 920(38).

ACKNOWLEDGMENTS

We are grateful to Professor R. C. Cookson for his very kind co-operation in providing us with delpheline derivatives and to Dr. Ragini Anet for her valuable suggestion.[3] We wish to thank Dr. M. Przybylska for obtaining the X-ray powder diffraction patterns, Mr. R. Lauzon for taking the infrared spectra, and Mr. H. Seguin for the analyses.

VOLTAIC CELLS IN FUSED SALTS

PART IV. ELECTRODE POTENTIALS OF THE SYSTEMS: Tl/TlCl (KCl–NaCl), Cu/CuCl (KCl–NaCl), Cu/$CuCl_2$ (KCl–NaCl), Cr/$CrCl_2$ (KCl–NaCl), AND Cr/$CrCl_3$ (KCl–NaCl). REDOX POTENTIALS OF THE SYSTEMS: Pt/CuCl, $CuCl_2$ (KCl–NaCl), AND Pt/$CrCl_2$, $CrCl_3$ (KCl–NaCl)[1]

S. N. Flengas[2] and T. R. Ingraham

ABSTRACT

Using a Ag/AgCl (KCl–NaCl) reference electrode, the standard electrode potentials of the systems Tl/TlCl (KCl–NaCl), Cu/CuCl (KCl–NaCl), Cu/$CuCl_2$ (KCl–NaCl), Cr/$CrCl_2$ (KCl–NaCl), and Cr/$CrCl_3$ (KCl–NaCl) were measured and found to be: 0.650 volt at 680° C., and 0.250, −0.175, 0.755, and 0.423 at 700° C. respectively. The standard redox potentials of the systems Pt/$CuCl_2$, CuCl (KCl–NaCl), and Pt/$CrCl_3$, $CrCl_2$ (KCl–NaCl) were also measured at 700° C. and found to be 0.600 and 0.240 volt respectively. The effect of temperature on the electromotive forces of the above cells was measured and the heats of the cell reactions were calculated from the data.

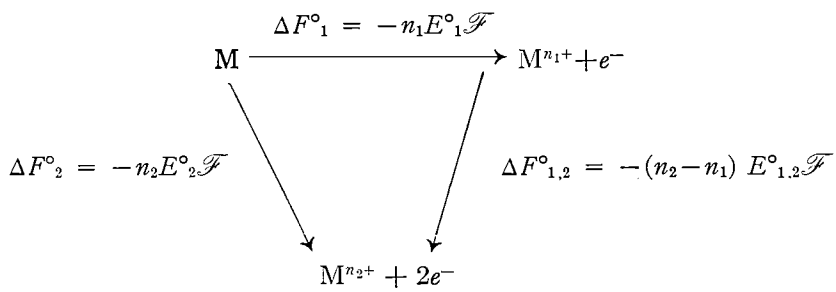
INTRODUCTION

In previous publications (1, 2, 3) in this series, standard potentials for several electrode systems in fused salts were reported. To make these measurements, an equimolar mixture of sodium and potassium chlorides was used as the solvent for the metal chloride in the system investigated, and a silver – silver chloride electrode, developed earlier in this work (1), was used as a reference in determining the electrode potential.

In the present investigation, the method has been applied to thallium, copper, and chromium. Both copper and chromium yield ions with two or more stable valency states at high temperatures. The potentials for each of the valence states and the associated redox potentials were determined.

These results are an additional contribution to the program in these laboratories of establishing an electromotive series of metals in molten salts at different temperatures.

When a metal, M, yields two positive ions, M^{n_1+} and M^{n_2+}, where $n_2 > n_1$, there are three standard potentials associated with the system. These are the potentials $E°_1$ and $E°_2$ of the electrodes M/M^{n_1+} and M/M^{n_2+} respectively, and the oxidation–reduction potential $E°_{1,2}$ of the system M^{n_1+}/M^{n_2+}. The relationship between these three potentials can be seen from the following cyclic diagram:



The equation relating these potentials is:

$$[1] \qquad n_2\, E°_2 - n_1\, E°_1 = (n_2 - n_1)\, E°_{1,2}.$$

[1]*Manuscript received March 11, 1958.*
Contribution from the Mines Branch Laboratories, Department of Mines and Technical Surveys, Ottawa.
[2]*National Research Council Postdoctorate Fellow, assigned to Mines Branch.*

When any two of the three potentials are known (i.e. one electrode potential $E°_1$, and the standard redox potential $E°_{1,2}$) the unknown electrode potential $E°_2$ can be calculated.

This method was applied to obtain the standard electrode potentials of the systems copper – cupric chloride and chromium – chromic chloride, neither of which could be measured directly because of the reactivity of the metals with their metal chlorides in solution.

EXPERIMENTAL

In the course of the experimental work, two different types of cells were used for determining potentials:

(a) Cells for Measurements of Metal Electrode Potentials

These were of the type

$$\begin{array}{c|c|c|c|c|c|c} \text{M} & & \text{MCl}_{n_1}\ (x_2) & & \text{AgCl}\ (x_1) & & \text{Ag} \\ (-) & | & \text{KCl–NaCl (1/1 mole)} & \| \quad \text{Asbestos fiber} \quad \| & \text{KCl–NaCl (1/1 mole)} & | & (+) \end{array}$$

where M was respectively thallium, copper, or chromium metal, and MCl_{n_1} was respectively TlCl, CuCl, or $CrCl_2$, at a mole fraction x_2.

The reaction in voltaic cells of this type is:

$$\text{M} + n_1\,\text{Ag}^+ = \text{M}^{n_1+} + n_1\text{Ag}.$$

The relationship between the electromotive force and the metal ion concentration in the cell is given by the Nernst equation in the form:

$$[2] \qquad E_{\text{cell}} = (E°_{\text{M}/\text{M}^{n_1+}} - E°_{\text{Ag}/\text{Ag}^+}) - (2.303RT/n_1\mathcal{F})\log(x_2/x_1{}^{n_1}),$$

where $E°_{\text{M}/\text{M}^{n_1+}}$ and $E°_{\text{Ag}/\text{Ag}^+}$ are respectively the standard electrode potentials of the half-cells Cu/CuCl, Cr/$CrCl_2$, or Ag/AgCl, under the conditions of the experiment. It will be observed that in equation [2], mole fractions are used in preference to activities. The simplification is justified, as will be shown by the subsequent data, when the activity coefficients or the complexity constants of the species involved in the cell reaction, or both, remain constant over the concentration range investigated. Thus, standard electrode potentials calculated from equation [2] will include the effects due to both activities and complex formation.

(b) Cells for the Measurement of Redox Potentials

These were of the type:

$$\begin{array}{c|c|c|c|c|c|c} \text{Ag} & & \text{AgCl}\ (x_1) & & \text{MCl}_{n_1}\ (x_2) & & \text{Pt} \\ (-) & | & \text{KCl–NaCl (1/1 mole)} & \| \quad \text{Asbestos fiber} \quad \| & \text{MCl}_{n_2} & | & (+) \\ & & & & \text{KCl–NaCl (1/1 mole)} & & \end{array}$$

where MCl_{n_1} was respectively CuCl or $CrCl_2$ at mole fraction x_2, and MCl_{n_2} was respectively $CuCl_2$ or $CrCl_3$ at mole fraction x_3.

The reaction in redox cells of this type is:

$$\text{Ag} + \text{M}^{n_2+} = \text{M}^{n_1+} + \text{Ag}^+$$

where $n_2 - n_1 = 1$.

The relationship between the redox electromotive force and the metal ion concentrations is given by the Nernst equation in the form:

$$[3] \qquad E_{\text{cell}} = (E°_{\text{Ag}/\text{Ag}^+} - E°_{\text{M}^{n_1+}/\text{M}^{n_2+}}) - (2.303RT/\mathcal{F})\log(x_1.x_2/x_3)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

where $E^{\circ}_{M^{n_1+}/M^{n_2+}}$ is the standard redox potential of the half-cells Pt/CuCl, $CuCl_2$, or Pt/$CrCl_2$, $CrCl_3$, under the conditions of the experiment.

It will be noted that here, as in equation [3], mole fractions are used in preference to activities.

Preparation of Materials

Anhydrous cuprous chloride was prepared by recovery from an aqueous solution in which cupric chloride was reduced with sulphurous acid (4). The anhydrous cuprous chloride was washed with glacial acetic acid, anhydrous ether, and absolute alcohol.

Anhydrous chromic (III) chloride was prepared from the corresponding hydrated salt of analytical grade, by heating at 600° C. in the presence of carbon tetrachloride vapor (5). The compound thus obtained was in the form of violet-colored "greasy" scales, which were very stable in air. Anhydrous chromous (II) chloride was prepared by hydrogen reduction of the anhydrous chromic (III) chloride (6) in a tubular furnace heated at 550° C. To observe the end of the reduction, the HCl produced during the reaction was dissolved in water and titrated with normal sodium hydroxide solution. When purified dry hydrogen was used, the product was pure white.

All of the compounds thus prepared were pelletized and kept in closed containers in a desiccator over sulphuric acid until they were used. Analysis of the various samples of the different batches indicated that for all of the materials, a purity of over 99% had been attained.

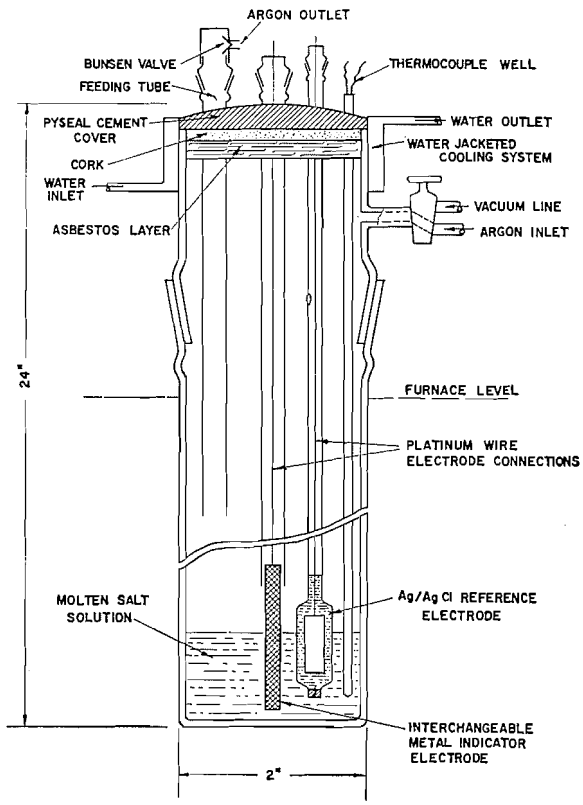


FIG. 1. All silica cell.

Apparatus and Procedure

The technique used to study the Tl–Ag, Cu–Ag, and Cr–Ag systems was essentially the same as that described in earlier papers of this series (1, 2, 3). Because the chlorides used in these experiments were reactive to both moisture and oxygen, the cell design was modified to permit evacuation to dehydrate the solvent salts before a run was begun. The modified apparatus is shown diagrammatically in Fig. 1. Slight improvements in the furnace design, over that used in previous work (1), have reduced temperature variations to ±2° C. at 900° C.

At the beginning of a run the cell was loaded with KCl–NaCl and heated for 12 hours under vacuum at 600° C. Purified argon was then introduced, the temperature increased to melt the salts, and the metal electrodes inserted into their respective positions. To protect the contents of the cell from air contamination, a small stream of argon was continuously introduced into the cell and released under a slight positive pressure through a Bunsen valve. Pellets of the metal chloride reagents were introduced, as required, through the feeding tube.

A pool of pure molten thallium metal (99.9%), copper wire of 99.99% purity or a block of 99.4% chromium metal were used as the indicator electrodes for the respective standard electrode potential measurements.

The indicator electrode for the measurement of redox potentials was a platinum tube 2 inches long and ½ inch I.D. After each addition of reagent, equilibrium was attained in 2–3 hours. In the absence of any form of stirring this was attributed either to the slow process of dissolution of the pellet in the fused-salt solvent or to the subsequent slow diffusion of the salt through the solution.

After equilibrium had been established in a cell, the potential measurements were reproducible to within one millivolt over a 2-day period.

RESULTS

The electromotive forces of the Tl–Ag, Cu–Ag, and Cr–Ag voltaic cells were measured first as a function of the metal ion concentration and then as a function of temperature. The results of the experiments in which the concentration of the metal ions was varied at constant temperature are shown in Table I.

From equation [2], it follows that when x_1 and x_2 are chosen so that the log term of this equation becomes zero, then:

$$[4] \qquad E_{cell} = E^{\circ}_{M/M^{n_1+}} - E^{\circ}_{Ag/Ag^{+}}.$$

When the electromotive forces of the cells were plotted against the log term $x_2/x_1^{n_1}$, as calculated from the data given in Table I, the results were well represented by straight lines, as shown in Fig. 2.

The slopes of the experimental lines for the Tl–Ag and Cu–Ag systems agree well with the theoretical value for a one-electron electrode process as calculated from equation [2] (0.191 and 0.196 respectively, as compared with the theoretical value 0.195 volt). That obtained with the Cr–Ag system corresponds to a two-electron electrode process (0.094, as compared with the theoretical 0.097 volt). In addition, the linearity of the curves in Fig. 2 shows that the activity coefficients or the complexity constants of TlCl, CuCl, and $CrCl_2$ in alkali chloride melt solution remain practically constant over the concentration range investigated.

The experimental standard electrode potentials for the copper, chromium, and thallium systems, as interpolated at log $(x_2/x_1^n) = 0$ on the curves in Fig. 2, are given in Table II.

TABLE I

ELECTROMOTIVE FORCES OF VOLTAIC CELLS AS A FUNCTION OF THE METAL ION CONCENTRATION AT THE INDICATOR ELECTRODE

(*a*) Tl (−) | TlCl (x_2) KCl–NaCl (1/1 mole) ‖ AgCl (x_1) KCl–NaCl (1/1 mole) | Ag (+)

Mole Fraction of AgCl (x_1)	Mole fraction of TlCl (x_2)	t,° C.	E_{cell} (volts)
6.235×10^{-2}	3.610×10^{-3}	680	0.875
6.235×10^{-2}	6.907×10^{-3}	680	0.822
6.235×10^{-2}	1.425×10^{-2}	680	0.752
6.235×10^{-2}	2.503×10^{-2}	680	0.724
6.235×10^{-2}	3.645×10^{-2}	680	0.690
6.235×10^{-2}	4.140×10^{-2}	680	0.685
6.235×10^{-2}	5.540×10^{-2}	680	0.658
6.235×10^{-2}	6.026×10^{-2}	680	0.655

(*b*) Cu (−) | CuCl (x_2) KCl–NaCl (1/1 mole) ‖ AgCl (x_1) KCl–NaCl (1/1 mole) | Ag (+)

Mole fraction of AgCl (x_1)	Mole fraction of CuCl (x_2)	t,° C.	E_{cell} (volts)
6.235×10^{-2}	1.080×10^{-3}	700	0.588
6.235×10^{-2}	3.961×10^{-3}	700	0.478
6.235×10^{-2}	1.296×10^{-2}	700	0.390
6.235×10^{-2}	2.372×10^{-2}	700	0.343
6.235×10^{-2}	3.912×10^{-2}	700	0.289

(*c*) Cr (−) | $CrCl_2$ (x_2) KCl–NaCl (1/1 mole) ‖ AgCl (x_1) KCl–NaCl (1/1 mole) | Ag (+)

Mole fraction of AgCl (x_1)	Mole fraction of $CrCl_2$ (x_2)	t,° C.	E_{cell} (volts)
6.235×10^{-2}	2.822×10^{-4}	703	0.861
6.235×10^{-2}	5.640×10^{-4}	703	0.834
6.235×10^{-2}	1.323×10^{-3}	703	0.802
6.235×10^{-2}	2.359×10^{-3}	703	0.781
6.235×10^{-2}	3.467×10^{-3}	703	0.761
6.235×10^{-2}	6.027×10^{-3}	703	0.738
6.235×10^{-2}	9.352×10^{-3}	703	0.715

In addition, the table also includes calculated (7) values for the standard potentials of the cell reactions in the absence of solvent. The significance of the differences between the experimental and calculated potentials will be discussed later in the text.

TABLE II

SUMMARY OF RESULTS

‡Obtained by extrapolation of low temperature data.

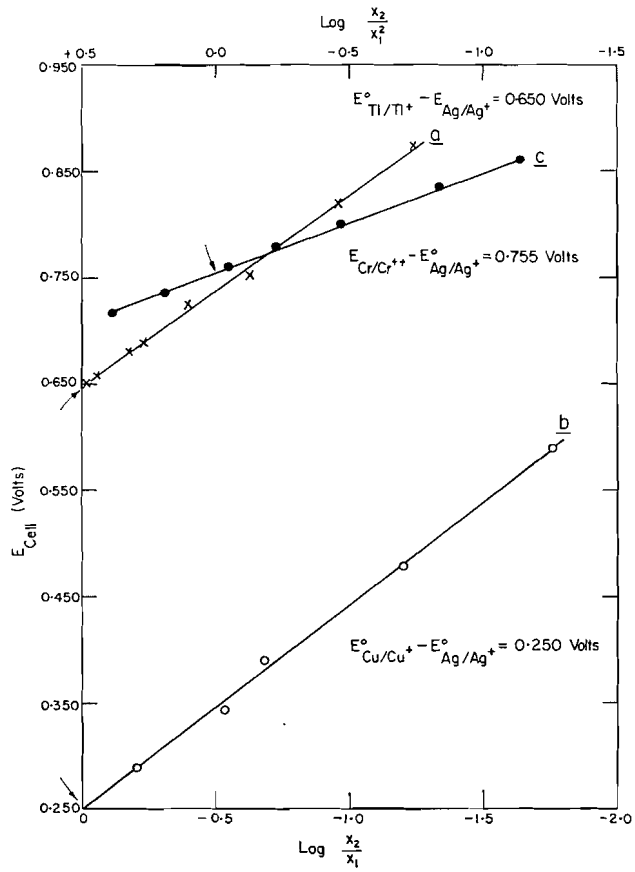

FIG. 2. Electromotive forces of the cells:

$$\begin{array}{ccccc} M & | & MCl_{n_1}\ (x_2) & \| & AgCl\ (x_1) \\ (-) & | & KCl\text{–}NaCl\ (1/1\ mole) & \| & KCl\text{–}NaCl\ (1/1\ mole) \end{array} \begin{array}{c|} \\ | \\ | \end{array} \begin{array}{c} Ag \\ (+) \end{array}$$

as a function of $\log(x_2/x_1^{n_1})$, at constant temperature.
M is (*a*) thallium, (*b*) copper, and (*c*) chromium (top scale). MCl_{n_1} is respectively TlCl, CuCl, and $CrCl_2$.

The effect of temperature change on the electromotive forces of the voltaic cells previously cited was next investigated. Because of the volatility of TlCl (b.p. 720° C.), measurements above 700° C. were not possible with the Tl–Ag voltaic cell.

The results for the Cu–Ag and Cr–Ag voltaic cells are given in Table III. Also included in Table III are values for the standard potentials at different temperatures, calculated from the data using equation [2].

From Table III it is readily seen that temperature has practically no effect on the standard potential of the Cu–Ag voltaic cell.

From the standard potentials of the Cr–Ag voltaic cell given in Table III, using the well-known equations,

$$[5] \qquad \Delta F^\circ = -n\,E^\circ\mathcal{F} = -2.303RT \log K$$

it was possible to calculate, for various temperatures, the equilibrium constants for the cell reactions given in Table II. The results of these calculations are shown in Fig. 3, where log K was plotted against the reciprocal of absolute temperature. The curve is linear over the temperature range investigated.

	989	0.759	0.754
	972	0.762	0.757

The best straight line through the experimental points was calculated by applying the least-squares method.

The heat of reaction (ΔH_r) in cells of this type is the difference between the heats of formation (ΔH_f) of the respective metal chlorides in the presence of the solvent, i.e.,

[6] $$\Delta H_r = \Delta H_{f\ (CrCl_2\ \text{in KCl–NaCl})} - \Delta H_{f\ (AgCl\ \text{in KCl–NaCl})}.$$

The heat of reaction was calculated from the slope of the straight line in Fig. 3, in accordance with the van't Hoff equation,

[7] $$d \ln K/dT = \Delta H_r/RT^2.$$

The value thus obtained is:

$$\Delta H_{r(Cr,Cr^{++})} = -42.46\pm0.5 \text{ kcal./mole.}$$

In the case of the Cu–Ag voltaic cell, where it was found that $dE/dT = 0$, the heat of reaction is equal to the free energy change and can be calculated directly from equation [5]. The result of the calculation is:

$$\Delta H_{r(Cu,Cu^+)} = -6.10 \text{ kcal./mole.}$$

Measurement of Redox Potentials

The electromotive forces of the Cu^+/Cu^{++} and Cr^{++}/Cr^{+++} redox cells were measured first as a function of the salt concentrations, and then as a function of temperature. The results of the experiments in which the concentration of the metal chlorides was varied at constant temperatures are shown in Table IV, and the plot of $\log(x_1.x_2/x_3)$ versus the electromotive forces is given in Fig. 4.

Following the same procedure as used previously, the standard redox potentials of the systems were obtained by graphical interpolation at zero log concentration. The results are grouped in the summary given in Table II.

It will be observed that the curves in Fig. 4 are effectively linear over the concentration range investigated, which again indicates that the activity coefficients or the complexity constants of the species involved in each of the reactions remain constant.

The slopes of the experimental lines for both redox systems agree well with the theoretical value for a one-electron reduction process (0.197 as compared with 0.195 volt) at this temperature.

The effect of temperature change on the electromotive forces of the two redox cells above was investigated next. The results are shown in Table V.

Also included in Table V are values for the standard redox potentials at different

(−)	AgCl (x_1)	MCl_{n1} (x_2)		(+)
	KCl–NaCl (1/1 mole)	MCl_{n2} (x_3)		
		KCl–NaCl (1/1 mole)		

as a function of $\log(x_1.x_2/x_3)$, at constant temperature.
M is (*a*) copper and (*b*) chromium, and MCl_{n1} and MCl_{n2} are respectively CuCl, $CuCl_2$, and $CrCl_2$, $CrCl_3$.

temperatures, as calculated from the data using equation [3]. From these values, by applying equations [5], the effective equilibrium constants for the redox cell reactions were calculated. The results of these calculations are shown in Fig. 5, where log K was plotted against the reciprocal of the absolute temperature. The curve is linear over the temperature range investigated. For each curve the best straight line was calculated by applying the least squares method.

The heat of reaction in cells of this type is best expressed by the equation:

$$[8] \qquad \Delta H_r = \Delta H_{f(MCl_{n_2})} + \Delta H_{f(AgCl)} - \Delta H_{f(MCl_{n_1})},$$

where ΔH_f is the heat of formation of the metal chlorides in the molten alkali chloride salt solution. These heats of reactions were calculated from the slopes of the straight lines in Fig. 5, in accordance with the van't Hoff equation, and the results are:

$$\Delta H_r(Cu^{++}, Cu^{+}) = -9.15 \pm 0.6 \text{ kcal./mole}$$

$$\Delta H_r(Cr^{+++}, Cr^{++}) = +11.84 \pm 0.5 \text{ kcal./mole}$$

Having established the standard metal electrode potentials of the systems Cu/CuCl (KCl–NaCl) and Cr/$CrCl_2$ (KCl–NaCl), and the standard redox potentials of the systems $CuCl_2$/CuCl (KCl–NaCl) and $CrCl_3$/$CrCl_2$ (KCl–NaCl), equation [1] was then applied to calculate the standard electrode potentials of the systems Cu/$CuCl_2$ (KCl–NaCl)

○ with increasing temperature, ● with decreasing temperature.

and $Cr/CrCl_3$ (KCl–NaCl), which are unobtainable by direct measurement. The results of these calculations were given previously in the summary of results in Table II. The heats of the cell reactions for these systems can be calculated by applying the equation, $\sum(\Delta H_r) = 0$, to a cyclic process similar to that used to derive equation [1]. The values thus obtained are:

$$\Delta H_{r(Cu,\ Cu^{++})} = +3.05 \text{ kcal./mole}$$

$$\Delta H_{r(Cr,\ Cr^{+++})} = -54.30 \text{ kcal./mole}$$

From the data in Table II it is also possible to calculate the free energies and the equilibrium constants of the following chemical reactions as they occur in the melt:

(1) $Cu + CuCl_2 = 2CuCl$

(2) $Cr + 2CrCl_3 = 3CrCl_2$

(3) $CuCl_2 + CrCl_2 = CrCl_3 + CuCl$

The results of these calculations are given in Table VI.

It can be readily deduced that reactions (1) and (2) will proceed effectively to completion, whilst with reaction (3) a chemical equilibrium between the reacting species will be attained.

TABLE VI

FREE ENERGIES AND EQUILIBRIUM CONSTANTS OF REACTIONS IN FUSED SALTS

Reaction at 700° C. in KCl–NaCl solvent	$\Delta F°$, kcal./mole	$K_{eq.}$
$Cu + CuCl_2 = 2CuCl$	−19.80	2.85×10^{4}
$Cr + 2CrCl_3 = 3CrCl_2$	−45.94	2.08×10^{10}
$CuCl_2 + CrCl_2 = CrCl_3 + CuCl$	− 8.30	7.33×10^{1}

DISCUSSION

It is of theoretical interest to compare the experimental electrode potentials, and the experimental heats of the cell reactions, with values calculated from thermodynamic data on the pure metal chlorides (8) without solvent. The calculations for the standard potentials are given in Table II. If the free energy change associated with the difference in standard potentials is attributed entirely to the formation of complexes in melts, the dissociation constants for these complexes can be calculated using the method previously (1) described. It must be emphasized that, in calculating dissociation constants, no assumption has been made about the structure of these compounds. Accordingly, these values could equally well represent the ratio of the activity coefficients. However, following the same procedure used previously (1, 2, 3), these values were calculated as "complex dissociation constants" and the results are:

$$K_d(\text{CuCl complex}) = 2.7\times10^{-1} \text{ at } 700° \text{ C.}$$
$$K_d(CuCl_2 \text{ complex}) = 2.9\times10^{-3} \text{ at } 700° \text{ C.}$$
$$K_d(CrCl_2 \text{ complex}) = 1.07\times10^{-2} \text{ at } 700° \text{ C.}$$
$$K_d(CrCl_3 \text{ complex}) = 4.14\times10^{-2} \text{ at } 700° \text{ C.}$$

From Table II it will be observed that in the case of TlCl, the small difference between the experimental and the calculated potential indicates almost ideal behavior.

Heats of the cell reactions calculated from existing thermodynamic data (8) on the pure metal chlorides are given in Table VII. In this table are also included values obtained experimentally in the present investigation in the presence of the KCl–NaCl solvent.

In Table VII, it will be observed that the experimental average heats of reactions are of the same order as the calculated ones.

The magnitude of the complex dissociation constants above, and the small difference between the heats of reaction, indicate that the over-all energy change which occurs when the metal ions are transferred from the solid or liquid phase of the pure metal chloride to an alkali chloride molten salt solvent is quite small.

THE STRUCTURES OF α- AND β-PARACHLORAL[1]

A. NOVAK[2] AND E. WHALLEY

ABSTRACT

The infrared and proton magnetic resonance spectra of α- and β-parachloral have been investigated and the dipole moment of α-parachloral has been determined. The results show that both isomers have the chair configuration of the ring and that α-parachloral has symmetry C_s with one axial and two equatorial CCl_3 groups and that β-parachloral has symmetry C_{3v} with three equatorial CCl_3 groups.

1. INTRODUCTION

Parachloral, the cyclic trimer of chloral, forms two stereoisomers that have been isolated by Chattaway and Kellett (1). The isomers have been designated α-parachloral, m.p. 116° C., and β-parachloral, m.p. 152° C. Their structures have not been investigated previously. In this paper the infrared and proton magnetic resonance spectra of these compounds (2) and the dipole moment of α-parachloral are used to determine the structures.

2. EXPERIMENTAL PROCEDURES AND RESULTS

α- and β-Parachloral were prepared from chloral hydrate and sulphuric acid as described by Chattaway and Kellett (1). They were purified by repeated crystallization from alcohol until their melting points were constant and in agreement with the values of Chattaway and Kellett.

The spectra were recorded with a Perkin–Elmer Infrared Spectrophotometer Model 21 equipped with a sodium chloride prism. The specimens were examined as mulls in nujol and hexachlorobutadiene, as solutions in carbon tetrachloride and carbon disulphide, and as solids in the form of thin crystalline layers between sodium chloride plates.

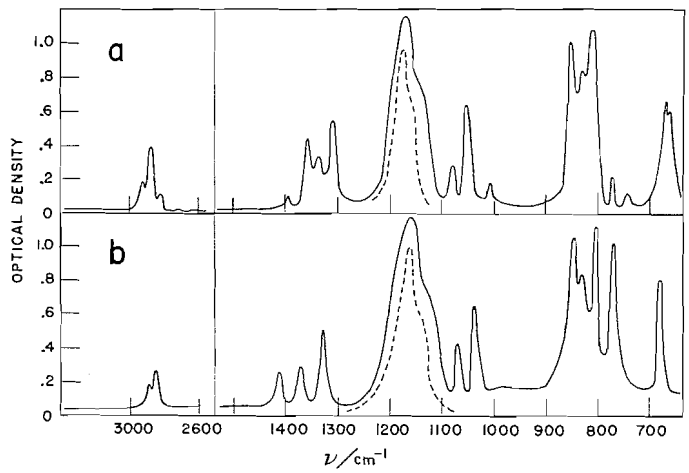

FIG. 1. Infrared spectra of solutions of (*a*) α-parachloral, (*b*) β-parachloral. Carbon tetrachloride solutions were used for the region 3600–1000 cm.$^{-1}$ and carbon disulphide solutions were used for region 1000–650 cm.$^{-1}$.

[1]*Manuscript received February 4, 1958.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 4792.
[2]*National Research Council of Canada Postdoctorate Fellow 1956–58.*

The infrared spectra of α- and β-parachloral in solution are shown in Fig. 1. The wave numbers of the absorption maxima or shoulders of both the solution and the crystalline spectra and their relative intensities are listed in Table I.

The solid and solution spectra show but little difference in the position and intensity of the bands. The 1336 and 809 cm.$^{-1}$ bands of α-parachloral in solution are split in the crystal, the separation of the components being about 8 cm.$^{-1}$. If there is more than one molecule in the unit cell of the crystal the splitting can readily be explained.

*The bands near 1160, 1140, and 1050 cm.$^{-1}$ are similar to bands in paraldehyde and higher homologues (3, 4); they are probably due to mainly-ring vibrations.

The proton magnetic resonance spectra of α- and β-parachloral in chloroform solution were very kindly measured for us by W. G. Schneider and H. J. Bernstein using a Varian V-4300 NMR Spectrometer.

The dipole moment of α-parachloral in cyclohexane solution has been determined by Dr. D. W. Davidson and Miss J. Taylor of this Division. Dielectric measurements were made with a Gross-type cell of about 5 pf capacitance, using a General Radio 716 C Capacitance Bridge and 716 P Guard Circuit. The frequency was 10 kc./sec. and the temperature 25.0±0.1° C. Eastman Kodak White Label cyclohexane was used and its dielectric constant was taken to be 2.0172 (5). The capacitance with pure solvent and with solution was measured by the substitution technique using a reiteration method, and a series of 10 measurements was made by each of two observers. The results were corrected for the small effect due to the combined influence of the switch and cable capacitance, which was determined by the same reiteration process. The refractive indices (n_{25}^{D}) were measured at 25.0±0.1° C. with a Spencer Abbé Refractometer. The results are summarized in Table II.

The dipole moment was calculated using Guggenheim's equation (6) to be 1.64 Debye units, with an error, allowing for systematic effects, of ±0.1 D.

3. DISCUSSION

If all the valency angles are tetrahedral there are four likely structures for the parachlorals, shown as I to IV in Fig. 2. Structures that contain more than one axial CCl_3 group either in the chair or in a boat configuration are much less likely on steric grounds. Structure I has symmetry C_{3v} and the other structures have symmetry C_s.

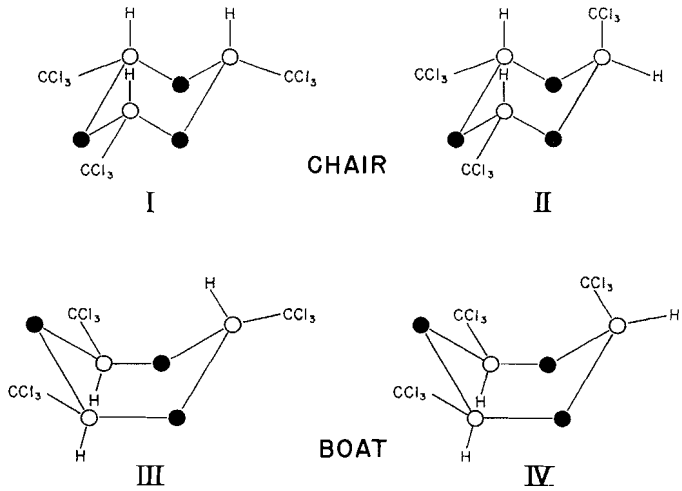

FIG. 2. Possible structures of the parachlorals. Black circles represent the oxygen, and white circles the carbon atoms.

m = Concentration of α-parachloral.
ϵ, n = Dielectric constant, refractive index of solution.
ϵ_0, n_0 = Dielectric constant, refractive index of pure solvent.

Proton Magnetic Resonance Spectra

The proton magnetic resonance spectrum (2) of β-parachloral in chloroform solution has only one peak. The three protons are therefore equivalent and the molecule has a C_3 axis. Hence, the structure is I (Fig. 2). The PMR spectrum of α-parachloral has two peaks with intensities in the ratio 1:2. Two of the three protons are therefore equivalent and the molecule has C_s symmetry. Hence the structure must be either II, III, or IV.

Dipole Moment

The dipole moments for the structures I, II, III, and IV, calculated by vector addition of the bond moments by taking the moments of the C—Cl, C—O, and C—H bonds to be 1.57 (7), 0.9, and 0.2 D. (8) respectively and the valence angles to be tetrahedral, are 2.74, 1.59, 0.60, and 2.91 D. respectively. The experimentally determined dipole moment is 1.64±0.1 D. and it shows that α-parachloral has structure II (Fig. 2).

Infrared Spectra

In both C_s and C_{3v} symmetries the normal modes of vibration of parachloral, the frequencies of which are expected in the region 3500–650 cm.$^{-1}$, may, to a first approximation, be divided into 9 C—H vibrations (3 stretching, 3 bending, and 3 wagging) and 18 skeletal stretching vibrations. The C—H vibrations are classified according to symmetry species in Table III. There are five infrared-active C—H vibrations for C_{3v} and nine for C_s symmetry. The skeletal stretching vibrations for C_{3v} symmetry can be represented (9) by $4A_1+2A_2+6E$; thus 10 of them are infrared-active. All 18 vibrations ($10A'+8A''$) are active for C_s symmetry. Some frequencies of the vibrations that are mainly to the peripheral groups will probably coincide; the number of the resolved bands in the spectrum is therefore expected to be smaller than the number of the active vibrations.

TABLE III

C—H VIBRATIONS OF PARACHLORAL

Approximate type of vibration	Expected frequency range	C_{3v}			C_s	
		A_1	A_2	E	A'	A''
3 C—H stretching	3100–2700 cm.$^{-1}$	1	0	1	2	1
3 C—H bending	1500–1200 cm.$^{-1}$	1	0	1	2	1
3 C—H wagging	1300–700 cm.$^{-1}$	0	1	1	1	2
Infrared active		+	−	+	+	+

C—H Vibrations

The stretching (ν) and bending (δ) modes of CH groups are particularly suitable for confirming the symmetry classes of the parachlorals, since the corresponding bands appear in the region where other fundamentals are not expected.

In the 3 μ region α-parachloral has three bands and β-parachloral has two bands. These are too strong to be combination bands or overtones so they are almost certainly ν(C—H) fundamentals. The numbers agree with the symmetries C_s and C_{3v} respectively.

In the 1500–1300 cm.$^{-1}$ region α-parachloral has four bands. Three are expected for C_s symmetry. One of the observed bands, 1395 cm.$^{-1}$, being very weak, is probably a combination band or overtone perhaps involving C—Cl vibration; they usually give bands about here (10). β-Parachloral has three bands. Two δ(C—H) bands are expected for C_{3v} symmetry. The strong 1330 cm.$^{-1}$ band is doubtless a δ(C—H) fundamental. The two bands at 1415 and 1367 cm.$^{-1}$ are of medium and nearly equal intensity; they are probably caused by Fermi interaction of a δ(C—H) fundamental with an overtone or combination frequency, probably the analogue of the 1395 cm.$^{-1}$ band of α-parachloral.

Thus the ν(C—H) and δ(C—H) bands confirm the C_s and C_{3v} symmetries for α- and β-parachloral, respectively. The ν(C—H) and δ(C—H) bands of β-parachloral are analogous to the bands at 2900 and 2830, and 1400 and 1345 cm.$^{-1}$ in the spectrum of paraldehyde (4); paraldehyde also has C_{3v} symmetry (3, 11, 12).

The wagging (γ) C—H modes are less straightforwardly assigned. For C_{3v} symmetry only one vibration, of species E, is infrared active. This may cause the 1075 cm.$^{-1}$ band in the spectrum of β-parachloral. A similar band associated with γ(C—H) has been observed near 1025 cm.$^{-1}$ in the spectrum of chloral (13). In the α-isomer three γ(C—H) bands are expected; the two bands near 1080 and 1007 cm.$^{-1}$ may be amongst them.

For personal use only.

Skeletal Stretching Vibrations

In the spectrum of β-parachloral there are nine strong or very strong bands near 1157, 1135, 1075, 1037, 845, 832, 807, 771, and 677 cm.$^{-1}$. If one of these, perhaps 1075 cm.$^{-1}$, is a γ(C—H) band there are eight skeletal stretching bands. This is close to the number expected for C_{3v} symmetry. The spectrum of α-parachloral in this region is very similar if one assumes that the bands at 1080 and 1007 cm.$^{-1}$ are γ(C—H) bands; the only other differences other than slight frequency shifts are that the 677 cm.$^{-1}$ band of β-parachloral is replaced by two very close bands at 671 and 668 cm.$^{-1}$ in α-parachloral and the 771 cm.$^{-1}$ band is replaced by two weaker bands at 770 and 745 cm.$^{-1}$. In both β- and α-parachloral the ring has the chair configuration so no major difference in the number of bands due to mainly-ring vibrations is expected and none is observed (Table I.) The splitting of the 677 and 771 cm.$^{-1}$ bands indicates that they are probably due mainly to peripheral groups.

The infrared spectra of β- and α-parachloral thus strongly support the assignment of structures I and II, respectively, to them.

The relative melting points agree with these structures. β-Parachloral has the more symmetrical structure and so it would be expected to pack better in its crystal and it has higher dipole moment. Both factors would tend to make β-parachloral have the higher melting point, and this is observed.

ACKNOWLEDGMENTS

We are indebted to Dr. D. W. Davidson and Miss J. Taylor for determining the dipole moment of α-parachloral and to Drs. W. G. Schneider and H. J. Bernstein for determining the proton magnetic resonance spectra.

ON THE NATURE OF SULPHUROUS ACID[1]

MICHAEL FALK[2] AND PAUL A. GIGUÈRE

ABSTRACT

Repeated attempts to detect by infrared spectrometry stable H_2SO_3 molecules in aqueous solutions of "sulphurous acid" or in frozen mixtures of SO_2 and H_2O have given only negative results. Sulphur dioxide dissolved in water exists mostly in the molecular state, the HSO_3^- and $HS_2O_5^-$ ions being formed in small amounts as a result of the equilibria

$$SO_2 + 2H_2O \rightleftharpoons HSO_3^- + H_3O^+ \text{ and } HSO_3^- + SO_2 \rightleftharpoons HS_2O_5^-.$$

There is very little interaction between SO_2 and H_2O molecules in condensed phases.

In spite of the major importance of aqueous solutions of sulphur dioxide in a multitude of industrial processes there remains a surprising uncertainty as to the nature of the equilibria between the molecular and ionic species in these solutions. Sulphur dioxide dissolves in water to the extent of about nine weight per cent at 25° C. and atmospheric pressure (1). The resulting solution possesses well-known acidic properties, conducts the electric current, and behaves as if it contained an acid, presumably H_2SO_3. However, although the ions H_3O^+, HSO_3^-, and SO_3^{--} are indeed present in the solution, the free acid itself has never been isolated or shown to exist. Nevertheless, its existence has been taken for granted by most chemists, the equilibria in the aqueous solutions being usually expressed as follows:

$$SO_2 + H_2O \rightarrow H_2SO_3;$$

$$H_2SO_3 + H_2O \overset{K_1}{\rightleftharpoons} H_3O^+ + HSO_3^-;$$

$$HSO_3^- + H_3O^+ \overset{K_2}{\rightleftharpoons} H_3O^+ + SO_3^{--}.$$

Assuming that these were the only equilibria involved, and that the first step is complete, i.e. that all the un-ionized sulphur dioxide in solution is combined to form H_2SO_3, the two ionization constants were calculated from electrical conductivity data to be $K_1 = 0.012$ to 0.017 (2, 3), and $K_2 = 10^{-7}$ to 10^{-6} (4, 5). The above assumptions, however, were soon proved incorrect, as evidence for the existence of unchanged SO_2 molecules in aqueous solution was obtained from ultraviolet absorption spectra (6, 7, 8, 9). Many workers attempted to calculate the ratio of H_2SO_3 to "free" SO_2 molecules in solution from the measurements of vapor pressures and electrical conductivities of the solution as a function of temperature and concentration, with widely divergent results (1, 2, 3, 10). These calculations appear to have relatively little merit, being based on such drastic assumptions as the use of Kohlrausch's law at fairly high concentrations, or the substitution of concentrations for activities. Because the individual concentrations of SO_2 and H_2SO_3 in solution were unknown, a convention was proposed by Lewis and Randall (11) setting arbitrarily the equilibrium constant

$$K = (H_2SO_3)/(SO_2)\ (H_2O) = 1.$$

With the advent of Raman spectroscopy, numerous studies were made of aqueous solutions of sulphur dioxide (12, 13, 14). In every case three Raman lines were detected,

[1]*Manuscript received March, 31, 1958.*

[2]*Holder of a Cominco Fellowship.*

corresponding to essentially unchanged SO_2 molecules. The only other species detected in some cases were the HSO_4^- and SO_4^{--} ions formed by slow oxidation of aqueous SO_2, a reaction difficult to prevent during long exposures. Recently an extensive Raman study by Simon and Waldmann (15, 16, 17) revealed for the first time in these solutions some lines due to bisulphite ions, HSO_3^-, in very low concentration, as well as pyrosulphite ions, $HS_2O_5^-$, pointing to the hitherto unsuspected equilibrium $HSO_3^- + SO_2 \rightleftharpoons HS_2O_5^-$. The concentration of the sulphite ions, SO_3^{--}, is certainly much too low to be detected spectroscopically, and the H_3O^+ ion does not give rise to a measurable Raman spectrum (18). None of the Raman lines detected in aqueous solutions by Simon and Waldmann could be attributed to H_2SO_3, although these authors continue to refer to the solutions as "sulphurous acid".

In the present work we have examined the infrared spectra of sulphur dioxide solutions in water in order to supplement the evidence for the absence of H_2SO_3 in solution. We have also studied the SO_2–H_2O mixtures in the solid state, where the formation of the compound H_2SO_3 might be favored.

EXPERIMENTAL

Aqueous Solutions of SO_2

The samples were prepared simply by squeezing between a pair of silver chloride windows a drop of aqueous solution of sulphur dioxide saturated at 25° and one atmosphere. Since a pressure cell was not available, evaporation of the dissolved sulphur dioxide could not be prevented and the spectra had to be recorded in small steps. A composite spectrum, based on several overlapping runs, is reproduced in Fig. 1, together with the spectrum of pure water in the same region. The spectra were obtained with a Perkin–Elmer model 12-C instrument, using NaCl and CsBr prisms; the background noise has

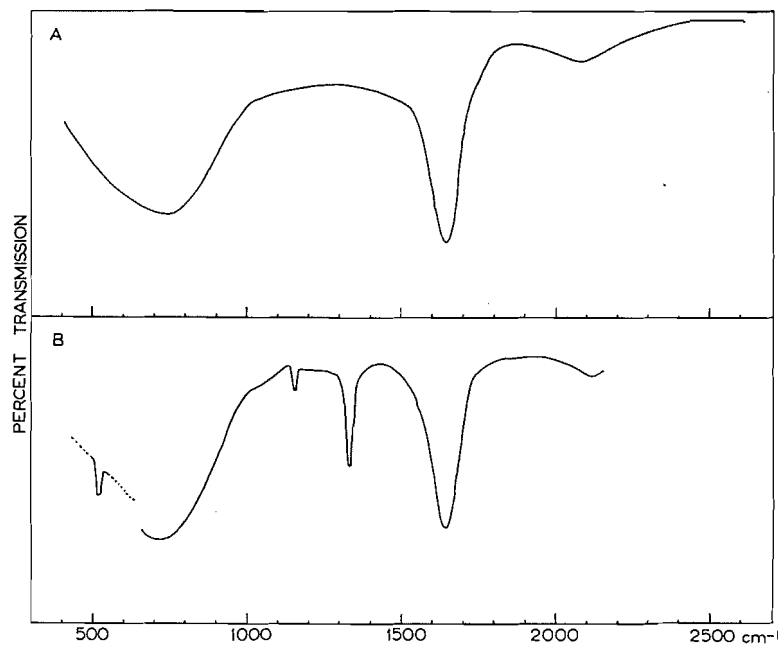

FIG. 1. A. Spectrum of a thin film of pure water in the region of NaCl and CsBr prisms. B. Spectrum of a thin film of solution of sulphur dioxide in water.

been smoothed out in replotting the spectra. In addition to the absorption bands of liquid water (ν_2 at about 710 cm.$^{-1}$, ν_2 at 1640 cm.$^{-1}$, $\nu_2 + \nu_R$ at 2120 cm.$^{-1}$, and ν_3 at 3400 cm.$^{-1}$), the spectrum of the solution contains three bands at 527, 1152, and 1334 cm.$^{-1}$, due respectively to the fundamental vibrations ν_2, ν_1, and ν_3 of the dissolved SO_2 molecules. These values are only slightly removed from the corresponding frequencies in pure liquid SO_2: 523, 1148, and 1338 cm.$^{-1}$ (19).

Solid Mixtures of SO_2 *and* H_2O

Various proportions of SO_2 and H_2O were mixed thoroughly by diffusion in the vapor phase, then condensed at liquid air temperature upon a silver chloride window in a conventional low-temperature infrared cell, and the absorption spectra recorded. The spectrum (in the range of the sodium chloride prism) of an equimolecular mixture is reproduced in Fig. 2. Included for comparison are the spectra of pure SO_2 and ice obtained in the same manner.

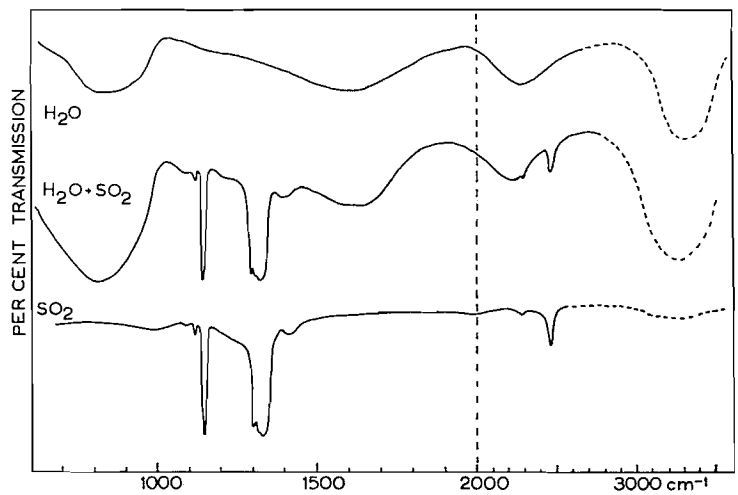

FIG. 2. Spectra in the region of NaCl prism of solid SO_2, solid H_2O, and their equimolecular mixture condensed at −190° C.

The spectrum of the mixture is essentially a superposition of the spectra of pure components. No new absorption bands appear and those of SO_2 and H_2O undergo no change of frequency, appearance, or intensity.* Variations in the composition and temperature of the deposits or irradiation with ultraviolet radiation from a Hanovia mercury lamp was without significant effect on the spectra. These results show clearly the absence of compound formation and, in particular, the absence of H_2SO_3 molecules which, if stable, would have been expected to form under these conditions. By contrast, the infrared spectra of solid mixtures of HCl or NH_3 with H_2O, condensed in an identical manner, have indicated clearly the formation of molecular compounds in those systems (21, 22).

Phase diagram studies of the SO_2–H_2O system have previously proved the existence of only one stable hydrate, $SO_2.6H_2O$ (23), apparently of the "gas hydrate" type (24). Such hydrates are characterized by very weak bonding with water, hence would have

**The shape of the ν_R band of ice appears changed somewhat in the spectrum of the mixture. It is not certain whether this effect is genuine, for the shape and intensity of the ν_R band in pure water and ice seems very sensitive to changes in film characteristics (20).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

an infrared spectrum practically identical with that of the pure components. The compound H_2SO_3, on the other hand, would give rise to a number of new absorption bands, quite different from those of SO_2. The closely related spectrum of the aqueous HSO_3^- ion contains Raman frequencies at 457, 586, 709, 1019, 1089, 1129, and 2532 cm.$^{-1}$ (15).

DISCUSSION

The present infrared spectra confirm the conclusion of earlier Raman investigations that sulphur dioxide molecules are not strongly hydrated in aqueous solution and do not form the compound H_2SO_3. The upper concentration limit of the latter, which could have escaped detection, is believed to be 0.2 *M* in the infrared spectra and about 0.1 *M* in the Raman work (Simon and Waldmann detected the strongest lines of the HSO_3^- and $HS_2O_5^-$ ions at concentrations below 0.1 *M*). Since the most concentrated solutions employed in our work contained some 8.3% SO_2, or 1.3 *M*, and those employed in the Raman study of Simon and Waldmann contained up to 17.2% SO_2, or about 3 *M* (under pressure), the upper limit for H_2SO_3 may be set at 1/30 of the sulphur dioxide concentrations. However, the actual concentration of H_2SO_3 may be expected to be very much smaller than that. Even in the solid phase, where the formation of the compound H_2SO_3 would be much more likely, it cannot be detected at all and the interaction of SO_2 and H_2O molecules appears to be very weak in all phases.

Therefore the un-ionized fraction of sulphur dioxide in "sulphurous acid" solutions exists as uncombined molecules. As for the ionic species, the electrical conductivity data indicate that the H_3O^+ ions are present at a concentration of about 0.1 *M* in a solution 1 *M* in sulphur dioxide (3). The anions, HSO_3^-, $HS_2O_5^-$, plus a much smaller amount of SO_3^{--}, must be present at the same total concentration, although the exact proportions are difficult to determine. Altogether some 10% of sulphur dioxide dissolved at n.t.p. is ionized.

Unstable H_2SO_3 molecules might be involved as short-lived intermediates in the formation of the HSO_3^- ions. However, these ions could also be formed by another mechanism such as

$$2H_2O \rightleftharpoons OH^- + H_3O^+; \; SO_2 + OH^- \rightleftharpoons HSO_3^-$$

suggested by Campbell and Maass (3) some time ago. In any event the over-all equilibrium is

$$SO_2 + 2H_2O \rightleftharpoons HSO_3^- + H_3O^+.$$

The term "sulphurous acid", like the analogous "carbonic acid" H_2CO_3, established by long tradition, will continue to be used. It should be understood, however, that these hypothetical compounds do not exist in detectable concentration even in solutions. In remarkable contrast to sulphur dioxide, selenium dioxide appears to react completely with water, forming the stable selenious acid, H_2SeO_3, both in solution and in the crystalline phase. We are now completing a similar investigation of selenious acid and expect to report the results shortly.

RÉSUMÉ

L'étude des spectres infrarouges confirme que les solutions aqueuses de SO_2 ne contiennent pas de quantités mesurables d'acide sulfureux, H_2SO_3. Dans ces solutions les molécules de SO_2 existent en majorité comme telles à côté de faibles concentrations des ions HSO_3^- et $HS_2O_5^-$ résultant des équilibres:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$$SO_2 + H_2O \rightleftharpoons HSO_3^- + H_3O^+$$

et

$$HSO_3^- + SO_2 \rightleftharpoons HS_2O_5^-.$$

Par ailleurs les spectres de mélanges solidifiés de SO_2 et H_2O n'indiquent pratiquement aucune interaction entre ces deux composés en phases condensées.

NOTES

PHYSICAL ADSORPTION IN THE BENZENE–POLYSTYRENE SYSTEM*

S. S. Barton and S. G. Mason

INTRODUCTION

Although the sorption of solvent vapors by solid polymers is usually considered as a solution process, McLaren and Cutler (1) found that when the water sorption isotherm of a water-soluble fraction of polyvinyl acetate was analyzed from the point of view of the Flory–Huggins equation, values of μ much larger than $\mu_{crit.}$ are required in the low pressure region. This phenomenon, indicating phase separation, was attributed to surface adsorption preceding solution formation at low relative pressures. On the other hand, Baughan (2) found that the sorption isotherm of benzene or polystyrene sheets fitted the Flory–Huggins equation over a benzene volume fraction of 0.07 to 0.57 with an interaction constant $\mu = 0.45$. It would appear in this case that the sorbed benzene formed a homogeneous solution with the polystyrene.

When the sorbate is not a solvent for the sorbent, the "adsorption" characteristics of the reaction can be more pronounced. The presence of strongly adsorbing sites in a polymer matrix which are saturated by initial quantities of sorbing (non-solvent) gases and vapors have been deduced by several workers (3, 4, 5).

As long as the concentration of solvent sorbate is not so high that the sorbate–sorbent complex loses its rigidity, then a certain amount of adsorption on active sites can be expected to occur in any solvent–polymer system at low relative pressures.

In the investigation described in this note, heats of sorption of small amounts of benzene on two samples of polystyrene were measured. The heats evolved were sufficiently high to be considered heats of physical adsorption, and have been taken as evidence that surface adsorption precedes solution in the benzene–polystyrene system.

EXPERIMENTAL

A conventional all-glass adsorption apparatus with mercury valves instead of stopcocks was used. Benzene vapor was measured into a calibrated volume from a reservoir containing thoroughly outgassed reagent grade benzene. The measured dose was then exposed to a fairly large (*ca.* 5 g.) sample of outgassed polystyrene, mounted in the reaction well of a large diphenyl ether isothermal calorimeter, operating at 26.9° C. (6, 7). Pressures were measured by conventional mercury manometers read to the nearest 0.5 mm.

The take-up of benzene as indicated by the falling pressure was initially rapid, but after 10–15 minutes became very slow. The slow take-up, when allowed to proceed, was observed to continue for many days. In each determination, the contribution from the slow take-up was made as small as possible by isolating the large calibrated volume from the polystyrene sample as soon as possible after the initial rapid sorption had taken place. Slow sorption could then only continue at the expense of the relatively small amount of benzene vapor in the dead space.

Heat was evolved during the initial rapid sorption, and shortly after the benzene pressure had become nearly constant, the rate of movement of the mercury thread in the

This investigation was conducted under Extra-Mural Grant No. 6 from the Defence Research Board.

dilatometer tube of the calorimeter again assumed the normal small positive drift indicating that any heat given off by the subsequent sorption was evolved too slowly to be detected by the calorimeter. The heat evolved during the rapid sorption was calculated by using the averages of the fore- and after-drifts to correct the total mercury displacement over the time of the rapid sorption. The corrected displacement figure was converted to calories by means of an electrically determined calibration constant.

Two different types of commercial polystyrene were used. Type A was in the form of a powder which passed No. 42 mesh and was supplied by Monsanto Canada Limited, who stated it to have a molecular weight of about 60,000. Type B was in the form of irregularly shaped particles of *ca.* 1.2×10^{-2} cc. The supplier, Dow Chemical Company (Midland, Mich.), stated it to have molecular weight about 270,000.

Two samples of Type A were used. Two series of heat and isotherm measurements were made on one sample and four series were made on the other. Between series, the sorbed benzene was removed by exhaustive pumping. Similarly, two samples of Type B were used in three series of measurements.

RESULTS AND DISCUSSION

Isotherms describing the "fast" adsorption of benzene on polystyrene are shown in Fig. 1. The ordinate, A_F, gives the amount of benzene adsorbed before the constant after-drift of the calorimeter was established. The slow sorption, which continued between measurements and did not affect the calorimeter, is not included. It was estimated that because of this slow sorption, the true benzene concentration in the condensed phase was about 4% higher than indicated by A_F. The relative pressure values are those observed at the end of each "fast" adsorption. No attempt was made to determine an equilibrium isotherm, since the time required, with the experimental arrangement used, would have been too long.

Fig. 1, which includes all of the isotherm points from the nine experiments, shows that within the rather large error encountered in the work it was possible to reproduce the different isotherms.

The shape of the isotherm is that of Type III or Type IV of the classification of Brunauer (8). Almost all of the benzene is sorbed over a very narrow range of pressure, and for equal amounts of sorption a higher pressure is required with Type A polystyrene than with Type B. This behavior is associated with adsorption in rather narrow size-distributions of pores (9). In fact, the present heat and isotherm data are best correlated by assuming that porous adsorption occurs. Pore radii were obtained by extrapolating the almost vertical, linear portions of each isotherm back to the pressure axis and substituting the value obtained into the simple Kelvin equation. Zero contact angle was assumed and values for the liquid density and surface tension of bulk benzene were used (10). The values obtained are given in Table I.

Fig. 2 shows the integral heat of adsorption (q_I) curves. The integral heat at any particular value of A_F is the sum of the individual amounts of heat, per gram of polystyrene, evolved up to that value of A_F.

At low values of A_F the heat curves are concave towards the A_F axis but become straight lines as A_F increases. The linear portion of the heat curve begins at roughly the same value of A_F as does the linear portion of the corresponding isotherm.

The differential heat of adsorption, q_d, is given by the slope of the integral curve. Fig. 2 shows that q_d falls fairly rapidly from an initial high value to a lower constant value as adsorption proceeds. Most of the adsorption takes place with constant q_d. Using q_L

= 8080 cal./mole as the heat of vaporization of benzene at 27.0° C. (6) and the constant q_d values, the quantity $q_d - q_L$, the net heat associated with the adsorption of benzene on the polystyrene pore structure, has been calculated.

TABLE I

PORE SIZES AND HEATS OF ADSORPTION

Polystyrene	p_0/p	Pore radius (Å)	q_d (cal./mole)	$q_d - q_L$ (cal./mole)
A	7.36	10.1	10310	2230
B	1.75	36.2	9059	979

Taking 5.7 Å as the molecular diameter of benzene (11), it is seen that the radius of the pores in the Type A polystyrene are of the order which should give a high proportion of double-wall adsorption (12) with the benzene molecule. Also, the radii of the pores in the larger granules of Type B polystyrene are sufficiently large so that co-operative, double-wall adsorption would be very much diminished. The net heat of adsorption in the smaller pores is seen to be nearly double the net heat of adsorption in the larger pores.

Although the heat and isotherm data agree when regarded as indicating the occurrence of porous adsorption, the very small size of the pores brings into question the applicability of the simple Kelvin equation, and thus throws doubt on the whole explanation presented (13). However, the reproducibility of the isotherms indicates strongly that polystyrene can maintain its surface structure through limited adsorption and desorption cycles, and the differential heat of adsorption is of the order of magnitude associated with physical adsorption.

One of the consequences of swelling and partial solution is that any pore system will be greatly changed as the swollen structure collapses on de-swelling. It is apparent that the

For personal use only.

amount of sorption in the experiments described was not sufficient to cause marked swelling of the polystyrene. The highest benzene volume fraction encountered here was 0.05, at the lower end of the range investigated by Baughan (2).

It is appreciated that the molecular weights of the samples were quite different. However, from the point of view adopted here, the effect of molecular weight on the amount of heat evolved or the shape of the "fast" isotherm should be of little consequence.

An alternative explanation which has been kindly suggested by the Referee does not involve capillary condensation but instead the transition from physical (surface) adsorption to solution near the surface of the substrate. In a theoretical treatment of this transition, Hill (14) has indicated that an intermediate region of sorption at an essentially constant pressure should be observed. It is possible that the nearly vertical portions in Fig. 1 may correspond to an equilibrium between benzene vapor and a saturated solution of polystyrene in benzene on the surface of the polymer. Since Type A polymer, being of lower molecular weight than Type B, is the more soluble of the two it may be expected that solution would occur at a lower relative vapor pressure for Type A. It is, however, difficult to account for the observed energies on this basis, since the (exothermic) heat of solution may be expected to increase with increasing molecular weight (15).

THE MECHANISM OF THE PYROLYSIS OF PRIMARY ALKYL BROMIDES*

Arthur T. Blades

Considerable literature has appeared in the last few years on the pyrolysis of alkyl bromides to form the corresponding olefin and hydrogen bromide (1, 2, 3, 4, 5, 6, 7, 8). With secondary and tertiary bromides this reaction appears to involve primarily a unimolecular split and the kinetics of these reactions can be studied reasonably well without inhibitors. With primary bromides the reaction involves free radicals and it is necessary to use an inhibitor to reduce the rates to a limiting value; this residual reaction is believed to be similar to that for the secondary and tertiary compounds. This communication refers to the uninhibited pyrolysis of ethyl and *n*-propyl bromides.

Agius and Maccoll (10) consider that the uninhibited pyrolysis of *n*-propyl bromide is a chain reaction initiated by a break into propyl radicals and bromine atoms. A plot of the "first order" data vs. $P_0^{\frac{1}{2}}$ indicated that a 3/2 order described the data much more adequately, and an appropriate chain mechanism was devised. These observations have been confirmed by Semenov, Sergeev, and Kapralova (7), who also note the catalytic effect of bromine and hydrogen bromide. More recently, Goldberg and Daniels (8) reported similar studies on ethyl bromide, and also indicated that a chain decomposition occurs. They stated that the rate became "first order" after an induction period but that the rate constants were pressure dependent. They also found that the reaction was greatly accelerated by the addition of one of the products (hydrogen bromide), and inhibited by the other product (ethylene). It is of interest to examine the data of Goldberg and Daniels to see whether it can be reconciled with the kinetics for *n*-propyl bromide proposed by Agius and Maccoll.

The order of decomposition of ethyl bromide was inferred by Goldberg and Daniels from a plot of the logarithm of the fraction of bromide remaining, against time. However, this is not a particularly good indicator of order, especially when an induction period is observed. The fact that the rate decreased with decreasing pressure suggests that some other order might fit the data more adequately. A replot of the k vs. P_0 data in Goldberg and Daniels' Fig. 2 as k vs. $P_0^{\frac{1}{2}}$ gives a reasonably straight line with an intercept at $k = 0.6$ sec.$^{-1}$. Since a first-order decomposition corresponding to a simple molecular split is proceeding simultaneously with the chain reaction, the intercept should correspond to this rate, and it is possible to predict a value of $k = 0.5$ sec.$^{-1}$ from the data on this uncatalyzed reaction (9). Therefore, a more realistic rate expression for ethyl bromide would be:

$$r = k[C_2H_5Br] + k_1[C_2H_5Br]^{3/2}.$$

This does not imply that the mechanism proposed by Goldberg and Daniels is incorrect but it appears that some alteration must be made in their mathematical treatment of it. Their steady-state approximations are that the bromine, bromine atom, and C_2H_4Br radical concentrations become stable. As pointed out by Hirschfelder (10), the stationary-state approximation can be applied only if the rate of destruction of intermediates is many order of magnitude greater than that of the over-all reaction. For bromine, with a bond energy of 45.5 kcal./mole, this condition is not fulfilled. Insofar as this argument vitiates the steady-state treatment, their suggestion that at high bromide pressures the concentration on the wall is independent of the pressure can no longer be accepted.

Since the bromine atoms are in quasi-equilibrium with the bromine, it seems equally unlikely that this concentration would be constant but it might vary roughly according to the $\frac{1}{2}$ power of the ethyl bromide pressure as suggested by the kinetics equation of Goldberg and Daniels:

$$r = k_a[C_2H_5Br] + k_d[C_2H_5Br]\,[Br] + k_b[C_2H_5Br_{wall}]\,[HBr_{wall}].$$

In the absence of analytical data on the bromine concentration, it is impossible to properly apply the stationary-state approximation. It is possible that the molecular reaction between bromine and ethylene might alter the concentration of the former substantially.

Since Agius and Maccoll have not investigated the effect of hydrogen bromide on the *n*-propyl bromide decomposition, examination must be confined to their kinetics data. A plot of first order "k" vs. $P_0^{\frac{1}{2}}$ in their Fig. 3 and plots of $p^{-\frac{1}{2}}$ vs. time in Fig. 5 indicate a purely 3/2 order for *n*-propyl bromide. Extrapolation of data on the purely

intramolecular decomposition of this compounds to 360° C. gives a value of $k = 0.3 \times 10^{-4}$ sec.$^{-1}$ (11). This small value has been lost in their rather large experimental error, but it is sufficiently large to be included in the rate expression:

$$r = k[C_3H_7Br] + k_1[C_3H_7Br]^{3/2}.$$

Their kinetics data are then not inconsistent with the same mechanism as has been proposed for ethyl bromide.

The observation of the catalytic effect of hydrogen bromide on this decomposition (7) completes the evidence that the decompositions of ethyl and *n*-propyl bromides are mechanistically identical. The mechanism proposed by Goldberg and Daniels is the more plausible for both compounds since it explains all of the experimental facts.

If this mechanism is correct, the theories advanced by Semenov (12) and by Maccoll and Thomas (1) to explain the difference in mechanisms of decomposition of *n*-propyl and isopropyl bromides must be modified to include the possibility of the rate of reaction between hydrogen bromide and the alkyl bromide being the mechanism-controlling factor.

GASEOUS AND LIQUID STATES OF AGGREGATION IN THE SUPERCRITICAL REGION

F. G. SMITH

A considerable amount of geological theory of formation of mineral deposits is dependent on the properties of water at supercritical temperatures and/or pressures. Consequently, geochemists and economic geologists are interested in physical theories of supercritical fluids, and in experimental studies of heterogeneous systems containing one or more such fluids. For example, if the volume of a liquid phase is kept constant as the temperature and pressure are increased to values above the critical temperature, and it can be shown that thermodynamic functions are continuous and uninflected, then we can extrapolate chemical properties of the liquid state into the supercritical region. There is a controversy in the geochemical literature regarding the appropriate term for designating a supercritical fluid, but it seems to be preferable to call it a liquid if it has the thermodynamic properties of a liquid, and a gas, if it has those of a gas.

In a review of data on the state of supercritical fluids of geological interest (1), it was emphasized that the liquid state is not limited by the critical temperature, but is limited

approximately by the critical volume in the supercritical region of temperature and pressure. X-Ray diffraction methods allow a positive discrimination between the two states of aggregation, but simpler procedures would be more useful.

The problem is simply that of showing whether the structure of the phase is more like the continuity in all dimensions characteristic of the ideal liquid state, or more like the discontinuity of the ideal gaseous state. Since an increase in the number of chemical bonds between components of a system involves a decrease of heat content and volume, thermodynamical expressions involving these terms can be used for discrimination. Mayer and Streeter (2) discussed the use of $\Delta H/\Delta T$ and $-\Delta V/\Delta P$ relations in locating phase transitions and in discriminating between anomalous first-order and diffuse transitions.

A related method that can be applied where PVT data are available consists of analyzing isobaric thermal expansion curves. Below the critical pressure, these curves have a first-order discontinuity at the boiling temperature, but above the critical pressure, they have a diffuse first-order discontinuity. The curve of dV/dT goes to $+\infty$ at the transition when the pressure is below the critical pressure, but goes to a finite value above it. The curve of d^2V/dT^2 goes through zero at the transition, both below and above the critical pressure.

In the one-component system H_2O, the above relations are shown at 200, 500, and 1000 bars in Fig. 1. The plotted curves were drawn through values of $\Delta V/10°$ calculated from experimental data by Kennedy (3). The characteristic curvatures of the dV/dT relation in the liquid and gaseous states, respectively, are clear, at least up to pressures of the order of 1000 bars. The temperature at which d^2V/dT^2 is zero is a function of the pressure, and is such that V is between 3.0 and 3.5 cc./g. In other words, the phase transition takes place in the supercritical region near, if not exactly at, the critical

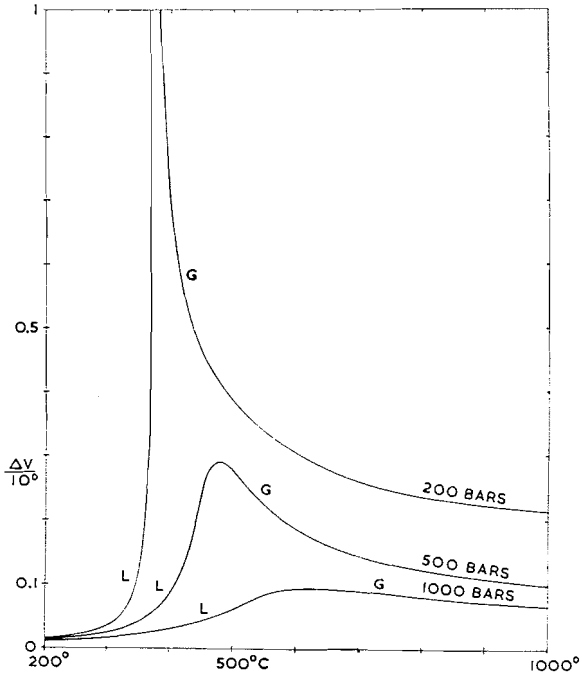

FIG. 1.

volume. There is no phase change at the critical temperature except in the special case when the pressure is exactly the critical value.

In summary, d^2V/dT^2 is positive in the liquid state and negative in the gas state, both below and above the critical pressure. In addition, the liquid–gas diffuse phase transition in the supercritical region is not at the critical temperature but near the critical volume.

ULTRASONIC ABSORPTION IN BUTYRIC ACID[1]

P. WHITE[2] AND G. C. BENSON

ABSTRACT

Ultrasonic absorption has been measured in pure butyric acid by a pulse technique from 0° to 40° C. and values of the relaxation frequency obtained. The activation energy of the relaxation process is shown to be 1.1 kcal./mole. These results are compared with published values for acetic and propionic acids and possible relaxation processes are discussed.

INTRODUCTION

Ultrasonic absorption measurements have been made in acetic and propionic acids over quite a wide range of temperature and at frequencies in the region of the relaxation frequency, but very little comparable information is available for other carboxylic acids. In the present paper, results are given for the absorption of ultrasound in pure butyric acid in a temperature range 0° C. to 40° C. and at frequencies from 1 to 9 Mc./second. A relaxation process has been shown to be present in acetic and propionic acids and until recently this was attributed to dimerization. Results obtained in acetic acid solutions have thrown doubt on this interpretation and it was thought that further experiments on carboxylic acids might help in deciding the mechanism of the relaxation process.

EXPERIMENTAL

Butyric acid was purified (1) and freshly distilled before use. The freezing points of samples used were in the range $-5.5°$ to $-5.7°$ C. measured using a Beckmann thermometer calibrated against a platinum resistance thermometer. Sound absorption measurements were carried out by a pulse technique at 1, 3, 5, 7, 9 Mc./second in an apparatus to be described in another publication (2).

RESULTS

Fig. 1 shows the measured value of attenuation in db./cm. with varying frequency at temperatures 0° C., 25° C., and 38.4° C. The absorption coefficient α was obtained from these values by dividing the ordinates of the graph by 8.686 (3).

For a single molecular process occurring with a relaxation time τ, the variation of absorption coefficient α with frequency ν is given by

$$\alpha = B\nu^2+[A\nu^2/\{1+(\nu/\nu_m)^2\}], \quad [1]$$

where A and B are constants and $\nu_m = 1/2\pi\tau$. Preliminary values of ν_m, A, and B were obtained by substitution of values of α at 1, 3, and 5 Mc./second in equation [1]. Further

It is usual to assume that the relaxation time is given by an expression

$$\tau = (D/T) \exp(\Delta E_a/RT), \quad [2]$$

where D is a constant and ΔE_a the activation energy associated with the relaxation process. Fig. 2 shows a graph of $\log(\nu_m/T)$ against $1/T$ for butyric acid, the activation energy being $\Delta E_a = 1.11$ kcal./mole.

DISCUSSION

A comparison of the above ν_m and ΔE_a values with those already published for acetic and propionic acids (5, 6) is made in Table II. The values shown for acetic and propionic acids at 0° C. were obtained by extrapolation of $\log(\nu_m/T)$ against $1/T$ graphs. Since acetic acid is normally solid at 0° C., the value 0.18 must be regarded as that for the supercooled liquid.

TABLE II

	ν_m at 0° C. (Mc./s.)	ν_m at 25° C. (Mc./s.)	ν_m at 40° C. (Mc./s.)	ΔE_a (kcal./mole)
Acetic acid	[0.18]	0.725	1.48	8.5
Propionic acid	[0.60]	2.36	4.61	7.5
Butyric acid	1.13	1.46	1.67	1.11

Since the values of ν_m are similar for the three acids, it is possible that a similar molecular process is responsible for the relaxation in all these cases. However, the comparatively large variation in ΔE_a values between propionic and butyric acids is then difficult to understand. The results indicate that the activation energy for the process decreases as the chain length increases. It has been suggested (5, 6, 7, 8, 9) that dimerization or polymerization through hydrogen bonds was responsible for relaxation in acetic and propionic acids. Piercy and Lamb (10) recently concluded that the higher of the two relaxation frequencies ($\geqslant 15$ Mc./second) which they obtained in dilute acetic acid solutions was caused by relaxation of the monomer–dimer equilibrium. These authors suggest that the earlier work on acetic and propionic acids produces relaxation frequencies corresponding to perturbation of an equilibrium other than dimerization.

Although the results presented are interesting per se, it appears that further experiments must be conducted before the true mechanism of the relaxation process is known.

NOTE ON THE RATE OF EVOLUTION OF HYDROGEN AT A MAGNESIUM ANODE[1]

J. H. GREENBLATT

ABSTRACT

Recent work on the mechanism of the anodic dissolution of magnesium is reviewed and additional data on the temperature dependence of the rate of hydrogen evolution at magnesium anodes during electrolysis is given. It is concluded that the results obtained and the literature on this subject are explained more logically by a kinetic mechanism involving initial solution of a univalent magnesium ion followed by subsequent reaction of this ion with water than by postulating self-corrosion with hydrogen evolved at local cathodes.

The problem of hydrogen evolution at a magnesium anode during electrolysis has received considerable attention recently (refs. 1–10) and it has been inferred from measurements of apparent valency and the ratio of reaction products that a kinetic mechanism postulating solution by a univalent ion followed by reaction of this ion with water satisfactorily accounts for the results (refs. 1–6). The basic mechanism put forward is the following (3).

$$Mg \rightarrow Mg^{+} + e \qquad [1]$$

$$2Mg^{+} + H_2O \rightarrow [Mg^{+}\,H_2O\,Mg^{+}] \rightarrow Mg^{++} + MgO + H_2 \qquad [2]$$

This mechanism explains in a logical manner the production of hydrogen and the one to one ratio between soluble and insoluble magnesium found when magnesium dissolves anodically in NaCl solutions (3). If the magnesium anode is being used in solutions containing reducible substances, such as perchlorates (1, 2), or if organic liquids that are electron acceptors are used as the anolyte (7), reduction products are obtained. The production of these can also be explained by the above mechanism.

A competing explanation to the kinetic mechanism is the assigning of the production of hydrogen and reduction products to local cathode activity as a result of self-corrosion on the magnesium anode (8, 9, 10). Although this would logically explain the production of these reduction products, it can only explain the one to one ratio of soluble to insoluble magnesium as a fortuitous event.

Recently Tomashov *et al.* (10) measured the rates of hydrogen evolution from anodes of cast technical (99.7%) magnesium and various other magnesium alloys at room temperature. They obtained a linear relation between the rate of hydrogen evolution and current density. In interpreting their findings, they ascribe the hydrogen evolution to self-corrosion and explain the linear relation as follows. Hydrogen is evolved at local cathodes that are filmed areas immediately adjacent to the active anode areas as the latter move forward during the solution process. This relates the amount of forward movement of the cathode surface to the movement of anodes over the surface as a result of dissolution of magnesium. Since the active surface is assumed proportional to the current density, the linear relationship is observed. Straumanis (8, 9) proposes an essentially similar mechanism involving the breakdown of the initial protective film with the uncovering of new cathodes. He devises a general equation for the "difference" effect, which simplifies to a linear relation between rate of hydrogen evolution and current density if the rate of formation of new cathodes is zero, or nearly so, if the overvoltage is constant and the polarization linear with current density.

[1]*Manuscript received March 12, 1958.*
Contribution from the Naval Research Establishment, Defence Research Board, Department of National Defence, Dartmouth, Nova Scotia.

The kinetic mechanism leads directly to a linear relation between the rate of hydrogen evolved and the current. If one assumes a steady state for which Mg^+ is being consumed as fast as it is produced and since $\frac{1}{2}$ mole of hydrogen gas is produced for each Mg^+ consumed, it is seen that

$$dH_2/dt = I/2F$$

is obtained, where I is the current and F the faraday.

In so far as Phelps (5) found by the rotogenerative technique that the anode areas on a corroding magnesium anode do not move over the surface as the current density is increased but merely become more intense, Tomashov's picture could be questioned. Also, the self-corrosion theory implies rate control as due to cathode area, which has been related to current density. At constant current density, or constant current, since Tomashov's work was done on samples all of the same area, rate control could be affected by other influences, such as temperature, which would affect the hydrogen overvoltage. Accordingly, rates of hydrogen evolution from anodes of pure (99.92%) magnesium and magnesium 1% manganese alloy were determined over the temperature range 0 to 75° C. to determine the effect of temperature and to determine if the temperature coefficient would give any further information as to the solution mechanism.

The rates were calculated from plots of gas evolved against time obtained by allowing the hydrogen evolved to expand into a partially evacuated volume with the pressure changes being continuously recorded. A 5% sodium chloride electrolyte was used and the cathode in the simple electrolysis cell was an Ag–AgCl electrode.

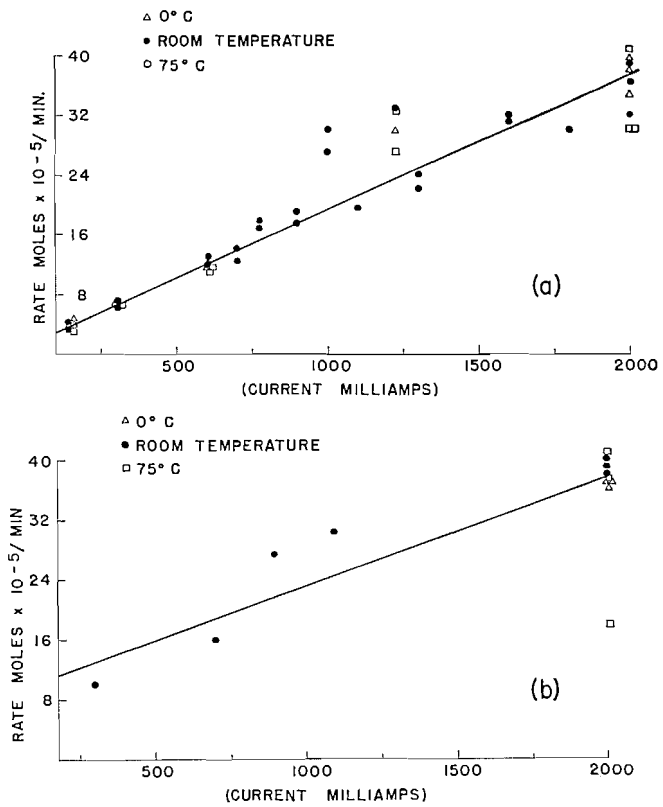

FIG. 1. Plot of the rate of evolution of hydrogen against current density for (*a*) pure magnesium and (*b*) magnesium 1% manganese alloy.

The electrode area in all cases was 23.8 cm.^{2}, and the current was varied over the range of 150 to 2000 ma. corresponding to a current density range of 0.0065 to 0.080 amp./cm.^{2}.

The results obtained are shown in Fig. 1. It is seen that at constant current (which is also equivalent to constant current density) the effect of temperature is negligible. This negligible temperature coefficient would be characteristic of the kinetic mechanism which involves essentially a free-radical mechanism, i.e., reaction between Mg^+ and water. A self-corrosion mechanism would be expected to yield a greater temperature difference because of variation of hydrogen overvoltage with temperature.

Thus, it would appear that again the kinetic mechanism explains more easily and straightforwardly the experimental results.

In passing, the rate values found agree well with Tomashov's. He lists values of 3.7, 7.3, and 16.8 ml. H_2/cm.^{2}/hr. at current densities of 10, 20, and 50 ma./cm.^{2} compared with 3.9, 7.4, and 16.1 ml. H_2/cm.^{2}/hr. at current densities of 12, 24, and 47 ma./cm.^{2}.

ANIONIC POLYMERIZATION OF α-METHYLSTYRENE

PART II. KINETICS[1,2]

D. J. WORSFOLD AND S. BYWATER

ABSTRACT

Dilatometric measurements have been made of the reaction rates in the reversible equilibrium anionic polymerization of α-methylstyrene initiated by sodium naphthalene in tetrahydrofuran solution, at temperatures of −10°, −40°, and −77°. The kinetic results and measurements made of the viscosity of the polymer conform with the mechanism of the reaction proposed by Szwarc *et al.*, modified by the large degree of reversibility found with this monomer at these temperatures.

The mechanism of the polymerization of certain vinyl hydrocarbons initiated by the complexes of sodium with polynuclear aromatic hydrocarbons in solution in some aliphatic ethers has recently been proposed by Szwarc *et al.* (1). They visualize an initial donation of an electron to the monomer followed by rapid dimerization of the radical ion formed to give a dicarbanion capable of growth by repeated monomer addition at both ends. In suitable solvents these carbanions are stable and no termination occurs and the chain ends remain active after the monomer has been consumed.

This latter property was made use of in demonstrating the reversible nature of the propagation step of polymerization (2). All polymers produced under these conditions should have a certain concentration of monomer in equilibrium with the active chain end (3), but in the case of α-methylstyrene this reaches appreciable amounts, even below room temperature, and profoundly changes the behavior of the system. It has been proposed that the chains are initiated rapidly and grow comparatively slowly at the expense of the monomer until the latter is reduced to its equilibrium concentration when the rate of the bimolecular forward reaction equals that of the unimolecular depolymerization. From such a scheme it is easily shown that the approach of the monomer concentration to the equilibrium concentration will, as a close approximation, follow a kinetic law first order in the initiator concentration and at a rate proportional to the excess concentration of the monomer over the equilibrium value. The polymerization of this monomer has a half-life time of the order of minutes, as opposed to seconds for other monomers, so it has been found convenient to make some kinetic measurements on this system to see if they are in accord with the scheme outlined above.

EXPERIMENTAL

The purification of the solvent (tetrahydrofuran) and the monomer have been described before (3). The method adopted for measuring the rates was dilatometric using an annulus-shaped dilatometer to minimize, as far as possible, the temperature effects inherent in reactions of this speed. The dilatometer and adjacent mixing vessel were evacuated, and the monomer and solvent condensed into the mixing vessel. The catalyst solution was formed from naphthalene solution on a sodium film under vacuum in an attached vessel. This solution was introduced into the mixing vessel by breaking a finely drawn tip by rotation of a ground joint after temperature equilibrium had been established. The reaction solution was then forced into the dilatometer under purified

nitrogen (3) and the dilatometer closed by a stopcock. The contraction was measured with a mercury thread in a calibrated tube. The catalyst concentration was measured at the end of the reaction in a Fisher Electrophotometer using the dilatometer as the optical cell. The filter used had a transmission maximum at 560 mμ. A separate calibration established that Beer's Law was obeyed over the concentration range used.

Two methods were employed in the calibration of optical density against catalyst concentration. In the first, a concentrated solution of sodium naphthalene of known concentration was added in small portions from a small burette to a solution of α-methylstyrene contained in a vessel incorporating the optical cell. A small initial blank was found due to trace impurities and subtracted from the subsequent additions; the whole operation was performed under vacuum. In the second method, the vessel incorporating the optical cell was attached by means of break seals to a small vessel containing sodium naphthalene solution, another containing monomer, a longer graduated tube containing a solution of the polymer anions, and one further side vessel directly joined in which sodium naphthalene solution was made. First the solution of sodium naphthalene was rinsed all round the vessel containing the cell. It was then drained back into the side vessel and the main body rinsed by condensing the solvent into it and allowing it to drain back. When the vessel was clean, the side arm was frozen and sealed off and removed. Next, the seal to the catalyst solution was broken and the catalyst rinsed into the main vessel and then this side arm was removed. The seal to the monomer was then broken and this distilled in. Knowing all the volumes and concentrations involved, the concentration of polymer anions was known, and the optical density was measured. The solution was then diluted by distilling solvent into the solution from the graduated side tube, and the optical density found over a range of concentration.

RESULTS

As expected, each individual run was pseudo first order up to 3 half-life times, some tailing off was observed in some runs after 90% reaction. Some typical first-order plots are shown in Fig. 1. The measurements were made at three temperatures, −10°, −40°, −77°, using in the first two a glycol–water thermostat (3), in the last a dry ice – acetone slush.

The dependence of the pseudo first-order rate constant on initiator concentration at −40° is shown in Fig. 2, and appears linear with a small intercept on the rate axis. This intercept is consistent with a small amount of catalyst destruction in raising the temperature from −40° to 25°, at which the optical readings were made, the reactive polymer chain end being extremely sensitive to trace impurities. On the other hand the effect may be real and due to variations in the activity of the ionic chain ends at their relatively high ionic concentration in a solvent of such low polarity.

The rates found at the other two temperatures are shown in Table I. The constant k is calculated from the expression

$$-d[\text{monomer}]/dt = k[\text{initiator}]\{[\text{monomer}]-[\text{monomer}]_e\},$$

where $[\text{monomer}]_e$ is the equilibrium concentration. The rate constants at the three temperatures do not give a good Arrhenius plot but demonstrate that the apparent activation energy, which in this case should correspond to that of the propagation step of polymerization, is of the order of 2 to 3 kcal.

In studies of the sodium naphthalene initiated polymerization of styrene and of butadiene, Szwarc *et al.* (4) have established that a linear relationship between the logarithms

TABLE I

PSEUDO FIRST-ORDER RATE CONSTANTS

Temp., ° C.	Catalyst concn., $\times 10^4$ moles liter^{-1}	k, liter mole^{-1}min.$^{-1}$
−10	11.8	84.5
−10	12.2	96.3
−10	13.9	85.3
−10	16.8	82.2
−10	23.6	74.1
−10	24.8	69.1
−77	16.4	20.6
−77	26.5	16.4
−77	28.2	11.2
−77	31.2	12.7
−77	50.2	14.1

of the ratio [monomer]/$\frac{1}{2}$[catalyst] and the intrinsic viscosity of the resulting polymer is achieved. This is due to the fact that the above ratio should be equivalent to the polymer chain length on the scheme suggested. The usefulness of this relation for determining molecular weights of sharply fractionated polymer samples is largely dependent on the sharp Poisson type distribution expected for the molecular weight distribution when the depolymerization reaction is not important, which for most monomers is normally true. For α-methylstyrene these conditions are more difficult to achieve because of the early onset of the depropagation reaction at temperatures above about −50° C. The calculated distribution for the equilibrium system diverges considerably from the Poisson type, and large divergences have been found for this monomer, at temperatures around 0° C.

In order to establish the Szwarc relationship, the reaction mixture, about molar in monomer and with variable catalyst, was mixed at 25°. This is above the ceiling temperature for this concentration and so no polymerization should occur. The catalyst

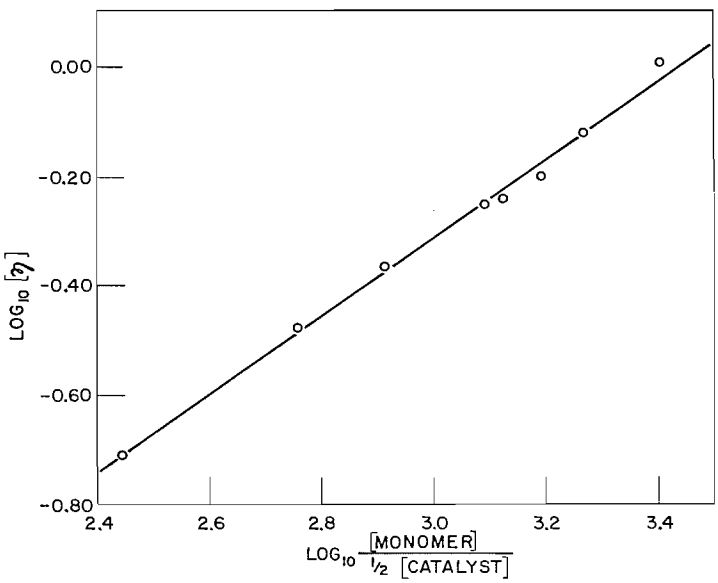

FIG. 3. Variation of intrinsic viscosity with calculated degree of polymerization.

concentration was found from the optical density, and then the reaction mixture placed in a bath at −80° C. The cooling should be rapid compared with the rate of polymerization, and at this temperature the reaction should be over 99% complete, and the resulting polymer should have a very sharp distribution. The reaction was killed after 7 half-life times with methanol at which point the influence of the depropagation should be small. The results are shown in Fig. 3 and are defined by $[\eta] = 1.16 \times 10^{-4}$ mol. wt.$^{0.714}$ by the method of least squares.

The kinetics of polymerization of α-methylstyrene catalyzed by sodium naphthalene appear therefore to conform to the scheme of Szwarc *et al.* (1) modified by the occurrence of a simultaneous depropagation reaction. The suggestion that the polymer chains grow by simultaneous addition of monomer to both ends of the chain is confirmed by preliminary results obtained in these laboratories which suggest that a very similar relationship is obtained between $[\eta]$ and molecular weight determined by light scattering and osmotic pressure measurements. Hence, the ratio Δ[monomer]/$\frac{1}{2}$[catalyst] does appear to correspond to the polymer chain length.

LYCOPODIUM ALKALOIDS

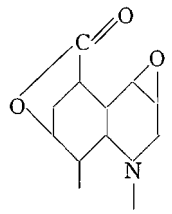
VII. THE REACTION OF ANNOTININE WITH PHENYL LITHIUM[1]

G. S. PERRY,[2] DAVID B. MACLEAN, AND R. H. F. MANSKE[3]

ABSTRACT

Annotinine, $C_{16}H_{21}O_3N$, reacted with phenyl lithium to yield diphenylannotinine, $C_{23}H_{33}O_3N$, containing two hydroxyl functions. Oxidation of diphenylannotinine by the Oppenauer procedure yielded a monohydroxyketone, $C_{28}H_{31}O_3N$, while oxidation with chromic acid yielded a dihydroxyketone, $C_{28}H_{31}O_4N$. A mechanism for the formation of these compounds is discussed in relation to the chemistry of annotinine.

Annotinine, $C_{16}H_{21}O_3N$, is known to contain an epoxide function, a lactone ring, and a tertiary nitrogen atom (1). The relationship of these groups to one another has been demonstrated by Wiesner *et al.* (2) and by MacLean and Prime (3). This relationship is represented in the partial formula below.



The structure of annotinine is now known (4, 5) but for the purposes of this paper the partial structure above suffices.

Some years ago we found that annotinine reacted readily with phenyl lithium to form diphenylannotinine, $C_{28}H_{33}O_3N$ (I), which was isolated at that time in an amorphous state. Diphenylannotinine did not dehydrate readily as would be expected of a diphenylcarbinol nor did it show any reactions characteristic of a compound containing an epoxide function. Our formula also differed from that of Meier and Marion (6), who proposed the formula $C_{28}H_{35}O_4N$ for the product of reaction of annotinine with phenyl lithium. Because of the anomalous behavior of diphenylannotinine and because of the difference between our results and those of Meier and Marion, we have investigated the reaction more thoroughly.

We have now obtained diphenylannotinine in crystalline form. This compound has a pronounced tendency to solvate, which may explain the formula of Meier and Marion and the difficulty in obtaining good analytical results for the base. Drastic oxidation of diphenylannotinine yielded traces of benzophenone, which indicated that both phenyl residues were attached to the same carbon atom. Oxidation by the Oppenauer procedure using potassium tertiary butoxide or aluminum isopropoxide yielded the monohydroxyketone, $C_{28}H_{31}O_3N$ (II). Both I and II were oxidized by chromic acid in acetic acid to the dihydroxyketone, $C_{28}H_{31}O_4N$ (III), which is apparently identical with the product iso-

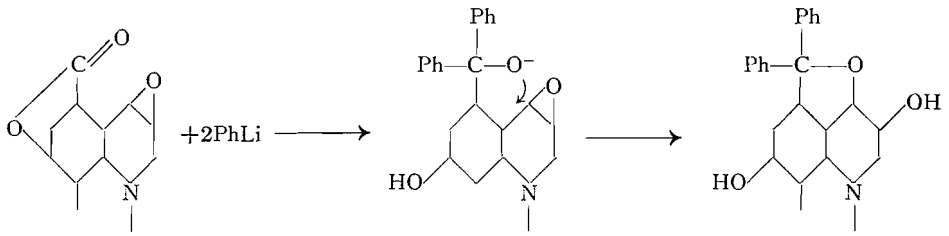
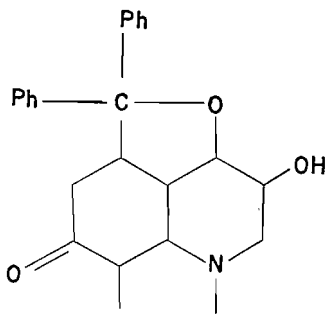
lated by Meier and Marion (6). Compounds I, II, and III analyzed for two, one, and two active hydrogens respectively. Neither I, II, nor III underwent reactions typical of a compound containing an epoxide function. Prolonged treatment of I, II, or III with boiling concentrated hydrochloric acid or alkali resulted in the recovery of starting material. Compound I was unaffected by further treatment with phenyl lithium or with lithium aluminum hydride in ether or tetrahydrofuran. It seemed apparent therefore that the epoxide function was no longer present in the molecule and in some way it must have been destroyed in the reaction with phenyl lithium.

A plausible explanation of these results is offered in the sequence represented below:

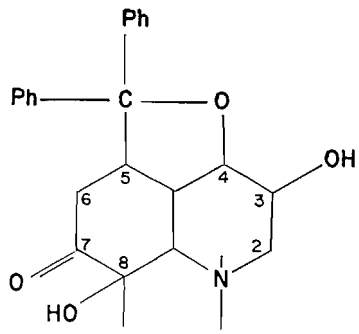


I

The formation of a new tetrahydrofuran ring results from nucleophilic attack of the intermediate tertiary alkoxide ion on the epoxide ring to yield a dihydroxy compound. This structure explains the lack of reactivity toward hydrochloric acid both as an addend to an epoxide ring and as dehydration agent toward a diphenylcarbinol. The oxidation by the Oppenauer procedure to give a single carbonyl group is not without precedent. Annotinine hydrate, which has hydroxyl groups in positions 3 and 7, yields only a C_7 ketone (2). The chromic acid oxidation is more unusual, for in this case a fourth oxygen is introduced. The fourth oxygen is apparently present as an hydroxyl group and could only be introduced at an activated position in the molecule. An indication that the carbonyl group provided the activation was afforded by a study of the behavior of acetylated diphenylannotinine toward the action of chromic acid. The acetylated compound was not affected by the oxidant under reaction conditions similar to those which oxidized diphenylannotinine. The infrared absorption spectrum of II and III tends to support the proposition that III is an α-hydroxyketone. The carbonyl absorption of II was at 1706 cm.$^{-1}$ while in III the absorption was at 1722 cm.$^{-1}$. A shift in this direction and of this magnitude is consistent with an α-hydroxyketone structure with the hydroxyl group in an axial conformation relative to the carbonyl. Compounds II and III are therefore assigned the following structures:



II



III

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Position "8" is favored over position "6" as the site of the new hydroxyl function because the hydroxyl is obviously tertiary, and Wiesner *et al.* (4) have shown that position "6" is a methylene group in annotinine.

Diphenylannotinine failed to undergo elimination of its diphenylcarbinol grouping on treatment with potassium tertiary butoxide and it yielded the same ketone on treatment with potassium tertiary butoxide or aluminum isopropoxide in the presence of cyclohexanone. This contrasts with the behavior of diphenyldesoxodihydroannotinine (7). This difference in reactivity in the two series may be the result of the greater rigidity of the ring system imposed by the new tetrahydrofuran ring in diphenylannotinine.

EXPERIMENTAL

Diphenylannotinine

A solution of phenyl lithium, prepared from 1.2 g. lithium and 14.5 g. bromobenzene in 100 ml. of anhydrous ether, was treated over a period of 15 minutes with 3.0 g. of annotinine in 70 ml. of ether–benzene. The initial precipitate of a white solid soon disappeared and the mixture was refluxed for 1½ hours after the addition of annotinine. The mixture was decomposed in ice water, the organic layer separated, and the aqueous layer extracted with several portions of fresh ether. The combined extract was dried and concentrated. The residue was dissolved in benzene, adsorbed on alumina, and eluted with benzene until no more diphenyl, a by-product, was obtained. The column was then eluted with two volume per cent methanol in benzene. From this eluate 5.0 g. of a pale yellow residue was recovered which crystallized from benzene. The recovered crystals possessed a double melting point at 128° and 236° C., neither of which was particularly sharp. These crystals were apparently highly solvated, since they lost 21% of their weight on drying at 118° C. at 0.5 mm. The dried crystals, which were submitted for analysis, melted at 236° C. Calc. for $C_{28}H_{33}O_3N$: C, 77.93; H, 7.71; N, 3.25; act. H (2), 0.46. Found: C, 78.85, 78.83; H, 7.65, 7.69; N, 3.30; act. H, 0.56, 0.58%.

Recrystallization of the above sample from ether yielded a compound which had a single sharp melting point at 236°. Found: C, 77.97, 77.99; H, 7.68, 7.70%.

The infrared spectrum (nujol) contained a strong band in the hydroxyl region at 3400 cm.$^{-1}$ but only weak absorption in the aromatic region at 1600 cm.$^{-1}$. In carbon bisulphide there were two absorption bands in the hydroxyl region at 3603 cm.$^{-1}$ and 3460 cm.$^{-1}$. The three typical bands for a monosubstituted benzene were found at 3080 cm.$^{-1}$, 3052 cm.$^{-1}$, and 3021 cm.$^{-1}$.

The hydrochloride was prepared by the addition of concentrated aqueous hydrochloric acid to an acetone solution of the base from which it immediately crystallized. Recrystallization from acetone–methanol yielded a compound melting at 292–293° C. This compound was apparently a very stable hydrate and gave satisfactory analytical results only after drying over boiling xylene for 1 hour. Calc. for $C_{28}H_{33}O_3N.HCl$: C, 71.87; H, 7.27%. Found: C, 71.84, 71.51; H, 7.40, 7.27%.

The original base was regenerated from the salt by treating an aqueous suspension of the salt with ammonia and extracting with ether.

The methiodide of diphenylannotinine was prepared by heating under reflux, for 6 hours, a mixture of diphenylannotinine and methyl iodide in acetone. The crystals which separated on cooling were filtered from the mother liquor and recrystallized from ethanol. They melted at 257° C. with decomposition. Calc. for $C_{29}H_{33}O_3NI$: C, 60.73; H, 6.28%. Found: C, 60.77, 60.98; H, 6.17, 6.37%.

Diphenylannotinine was recovered unchanged after prolonged treatment with boiling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

concentrated hydrochloric acid, with phenyl lithium in ether, and with lithium aluminum hydride in ether.

Oxidation of Diphenylannotinine with Chromic Acid

A solution of 0.7 g. of diphenylannotinine in 3 ml. of glacial acetic acid was mixed with a solution of 0.4 g. of chromic acid anhydride in 5 ml. of glacial acetic acid containing just enough water to effect solution. There was an immediate separation of a dark brown sludge, which soon dissolved, whereupon the mixture was poured into excess ammonia in 100 g. of ice and exhaustively extracted with chloroform. The combined chloroform extracts were dried, filtered through a pad of alumina, and taken to dryness to yield 0.38 g. of a viscous yellow oil which crystallized in contact with methanol. After several recrystallizations from methanol, the compound consisted of fine needles which melted at 242° C. Calc. for $C_{28}H_{33}O_4N$: C, 75.15; H, 7.43; N, 3.13; act. H (2), 0.44%. Found: C, 75.60, 75.36; H, 7.05, 6.81; N, 3.49; act. H, 0.42, 0.48%.

The infrared absorption spectrum (nujol) had a band in the carbonyl region at 1722 cm.$^{-1}$ and in the hydroxyl region at 3300 cm.$^{-1}$.

The starting material was recovered after treatment of this compound with boiling concentrated hydrochloric acid or alcoholic potassium hydroxide. Acetic anhydride converted this substance into an acetate from which the original base was recovered upon alkaline hydrolysis.

Oppenauer Oxidation of Diphenylannotinine

Diphenylannotinine, 1.0 g., was added to a suspension of 0.6 g. of potassium tertiary butoxide in an anhydrous mixture of 3.0 g. of cyclohexanone and 35 ml. of toluene. The mixture, which became bright yellow, was refluxed for $\frac{1}{2}$ hour. The mixture was cooled, poured on ice, the organic layer separated, and the aqueous layer extracted several times with toluene. The combined toluene extracts were extracted with three 25-ml. portions of 10% hydrochloric acid. The combined acid extracts were washed once with ether, then basified with ammonia, and exhaustively extracted with chloroform. The combined chloroform extracts were dried, concentrated, and then adsorbed on a column of alumina. Elution with two volume per cent methanol in chloroform yielded, after evaporation of the solvent, 0.61 g. of a crystalline product. After recrystallization from methanol it melted at 244–245° C. A mixture of this with the oxidation product derived from chromic acid treatment was completely liquid at 213° C. Calc. for $C_{28}H_{31}O_3N$: C, 78.29; H, 7.28; N, 3.26; act. H (1), 0.27. Found: C, 77.84, 77.81; H, 7.42, 7.45; N, 3.04, 3.02; act. H, 0.23%.

The infrared absorption spectrum (nujol) had a strong band in the carbonyl region at 1706 cm.$^{-1}$ and weak hydroxyl absorption at 3300 cm.$^{-1}$. In carbon bisulphide there was a single band in the hydroxyl region at 3595 cm.$^{-1}$.

This compound was unaffected after prolonged treatment with boiling aqueous hydrochloric acid.

Oxidation with aluminum isopropoxide as catalyst and cyclohexanone as the hydrogen acceptor also yielded compound II above.

Oxidation of $C_{28}H_{31}O_3N$ with Chromic Acid

To a solution of 0.8 g. of compound II in 5 ml. of glacial acetic acid there was added a solution of 0.7 g. of chromic acid anhydride in 8.0 ml. of glacial acetic acid containing just enough water to effect solution. After 5 minutes the reaction mixture was poured into excess ammonia in ice and extracted with chloroform. The dried extracts were filtered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

through a pad of alumina and then concentrated to yield 600 mg. of a viscous oil which crystallized in contact with methanol. After several recrystallizations from methanol it melted at 241–242° C.; a mixture of this with the starting material was completely liquid at 219° C. while a mixed melting point determination with III showed no depression. The infrared spectra of III and this product were identical.

Acetylation of Diphenylannotinine and Its Attempted Oxidation with Chromic Acid

A solution of 0.5 g. of diphenylannotinine in 10 ml. of acetic anhydride was refluxed for 2 hours, cooled, and shaken with ice water to hydrolyze excess acetic anhydride. The solution was then made alkaline with sodium hydroxide and exhaustively extracted with chloroform. The dried extracts were concentrated, adsorbed on a column of alumina, and the column was eluted with chloroform to yield 0.300 g. of a glassy solid which failed to crystallize. The compound was very soluble in ether and petroleum ether. Its infrared spectrum had no bands in the hydroxyl region but contained strong bands in the acetyl region at 1746 $cm.^{-1}$ and at 1240 $cm.^{-1}$.

The above compound 0.27 g. was dissolved in glacial acetic acid and treated with chromic acid in the manner described previously. After 10 minutes the excess chromic acid was destroyed and the solution was worked up in the usual fashion. The recovered product, 0.2 g., had an infrared spectrum identical with that of the starting material.

The product from chromic acid treatment was hydrolyzed with aqueous alcoholic alkali to yield diphenylannotinine identified by its infrared spectrum.

Oxidation of Diphenylannotinine with Potassium Dichromate in Sulphuric Acid

Diphenylannotinine (1.5 g.) was added to a mixture of 5.0 g. of potassium dichromate in 20 ml. of 50% sulphuric acid. The mixture was directly steam-distilled until oily droplets no longer appeared in the distillate. Water was added continuously throughout the distillation to maintain the original concentration. The distillate was ether-extracted, the extracts dried, and concentrated to yield 30 mg. of residue. The residue was partitioned between ether and aqueous sodium bicarbonate. The ether layer yielded a viscous yellowish oil which had an infrared spectrum identical with that of benzophenone. The oil was treated with a hot solution of 2,4-dinitrophenylhydrazine to yield a yellow solid which melted at 231–235° and did not depress the melting point of authentic benzophenone 2,4-dinitrophenylhydrazone. The infrared spectra of the two hydrazones were identical.

The bicarbonate phase yielded, after acidification and extraction, benzoic acid identified by its melting point and mixed melting point with an authentic sample.

The acidic solution in the reaction mixture was basified with ammonia and extracted with chloroform. From the chloroform extracts there was isolated 20 mg. of a compound identical with III.

A SPECTROPHOTOMETRIC DETERMINATION OF RHODIUM WITH TIN (II) BROMIDE[1]

S. S. Berman and R. Ironside

ABSTRACT

Rhodium salts react with a solution of tin (II) bromide in hydrobromic acid to produce an intense yellow color suitable for a spectrophotometric determination of rhodium. The method described is relatively simple and is the most sensitive for this metal published to date. Several factors influencing the intensity and stability of the colored species, whose nature is unknown, are described. Since the other platinum metals and base metals interfere it is necessary to isolate the rhodium prior to its determination. However, a fair estimation of rhodium can be made even when equivalent quantities of iridium are present. The procedure may be adapted, with a small loss in sensitivity, to determine rhodium in solutions which have been fumed with sulphuric acid.

INTRODUCTION

Relatively few spectrophotometric procedures have been proposed for the determination of rhodium. Of the four methods that have been developed usefully, the most satisfactory from the point of view of stability and tolerance of diverse ions is that employing tin (II) chloride as the reagent. This method, first noted in 1913 (1) and recently re-examined by several researchers (2, 3), suffers from a lack of sensitivity, an important drawback with regard to rhodium, which in all known commercial deposits of the platinum metals is present in relatively small proportions. The most sensitive method, employing sodium

TABLE I

Sensitivity of spectrophotometric methods for rhodium

hypochlorite (4), cannot be applied to solutions of rhodium in sulphuric acid, a medium in which rhodium is quite often found. A comparison of the sensitivities of these procedures and that described below is shown in Table I.

Berman and McBryde (7) noted the formation of a yellow color when tin (II) chloride in hydrobromic acid was added to solutions containing rhodium. However, this color was reported as unstable and attempts to develop a precise determination for rhodium were unsuccessful. The writers have succeeded in finding a set of conditions under which this color is quite stable, lending itself to a simple and sensitive determination of the metal. This was done primarily by the addition of a relatively large quantity of perchloric acid to the system prior to the addition of the reagent. The spectral curve produced is shown in Fig. 1. The absorption peak is at 427 mμ and the curve appears to be identical with that found by Berman and McBryde.

EXPERIMENTAL

Apparatus and Solutions

Absorption measurements were made with a Beckman Model DU quartz spectrophotometer and matched 1.00-cm. Corex-glass cells. Spectral curves and studies of the stability of the species under various conditions were made with a Beckman Model DK-1 recording spectrophotometer.

A standard rhodium solution was prepared by dissolving very pure sodium chlororhodate in 0.1 *M* hydrochloric acid. This solution was standardized gravimetrically with thiobarbituric acid (8) and found to contain 2.03 mg. of rhodium per milliliter of solution. A 5-ml. aliquot of this solution was diluted to 1000 ml. with 0.1 *M* hydrochloric acid and so contained 10.15 μg. of rhodium per milliliter of solution.

The reagent was a 20% w/v solution of tin (II) oxide dissolved in concentrated hydrobromic acid (about 40% HBr). The hydrobromic acid was redistilled before use to remove any impurities.

All other chemicals used were of analytical reagent grade.

Development of the Method

The Reagent

Preliminary experiments with the tin (II) chloride–hydrobromic acid reagent of Berman and McBryde showed that, aside from the colored species being unstable, there was formed, at room temperature, a second absorption peak at 470 mμ which slowly disappeared. This was identical with that formed using tin (II) chloride alone as the reagent and was presumably due to the high chloride concentration in the reagent. To eliminate this reaction a chloride-free reagent was prepared. This was first done by dissolving pure tin in concentrated hydrobromic acid and later by the much quicker method of dissolving tin (II) oxide in concentrated hydrobromic acid. In both these cases it is assumed that the product corresponds to a solution of tin (II) bromide in hydrobromic acid.

The intensity of the colored species was found to increase with the quantity of reagent used. However, it was noted that when more than two milliliters of reagent were used the reagent blank when measured against distilled water slowly increased in absorbancy. This, coupled with the fact that the reagent blank itself begins to absorb very strongly below 400 mμ, led to the acceptance of 2 ml. as the optimum quantity of reagent.

Effect of Hydrobromic Acid

When more than 0.5 ml. of hydrobromic acid was added to the sample the absorbancy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

increased with the concentration of this acid. However, the time required to achieve maximum absorbancy was also increased. This was accompanied by a decrease in the stabilities of the colored species and the reagent blank. Except in the case of fumed sulphuric acid samples (which will be described later) no hydrobromic acid, aside from that present in the reagent, was added to the system in the final procedure.

Effect of Perchloric Acid

The addition of concentrated perchloric acid (70–72%) had the effect of stabilizing the system. Maximum absorbancy was attained within 20 minutes when 8 to 10 ml. of this acid were added to the system prior to the addition of the reagent. A precipitate sometimes formed on the addition of the reagent if the solution did not contain a few milliliters of water. This precipitate dissolved rapidly when the solution was diluted to volume. The formation and dissolution of the precipitate did not appear to affect the absorbancy of the solution. The color was stable for at least 3 hours.

It was also noted that when perchloric acid was absent the colored species was not only unstable but the rate of attainment of maximum absorbancy and the subsequent decrease in absorbancy was photosensitive.

Recommended Procedure

Transfer the solution containing the rhodium to a 25-ml. volumetric flask and dilute to about 5 ml. with water. Add 10 ml. of concentrated perchloric acid followed by 2 ml.

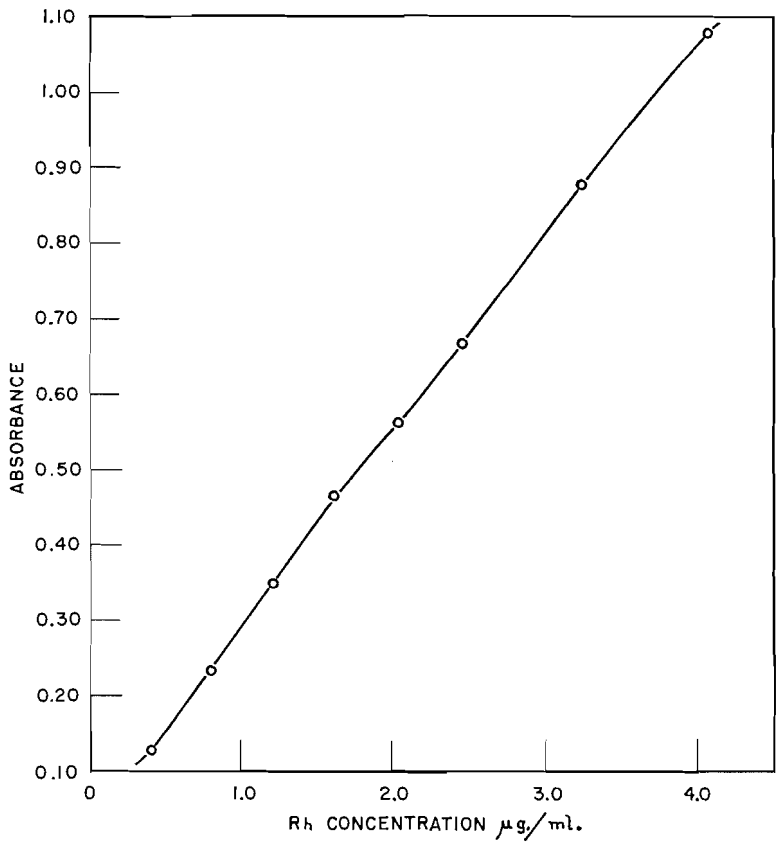

FIG. 2. Absorbance of Rh solutions at 427 mμ.

For personal use only.

of the tin (II) bromide reagent. Dilute to volume with water. After 20 minutes measure the absorbancy at 427 mμ using a reagent blank for comparison.

Precision Attainable

The mean absorbancy of five replicate samples each containing 50.8 μg. of rhodium in a final volume of 25 ml. was 0.562. The mean deviation of these results was 0.001 or 0.2%.

Adherence to Beer's Law

The colored solutions adhere to Beer's law for concentrations ranging from 0.8 to 1.6 p.p.m. However, measurements were made over a range from 0.4 to 4.0 p.p.m. and excellent precision was attained in all cases. The deviations from Beer's law are illustrated by Fig. 2.

The recommended range for this procedure is 0.4 to 4 p.p.m. when measurements are made using 1-cm. cells.

The Determination of Rhodium in Solutions after Fuming with Sulphuric Acid

Quite often in the analysis of the platinum group metals, sulphuric acid is introduced into the system at one stage or another and the resulting solution taken to fumes of the acid. Also, in the case of rhodium, sulphuric acid is apt to be present, since it is the only single mineral acid capable of attacking this metal quantitatively. For this reason an investigation of the applicability of the procedure described above to such solutions was carried out.

Preliminary experiments with unfumed samples containing sulphuric acid showed that the presence of this acid decreased the absorbancy of the system. It was found that maximum stability accompanied by minimum reaction time occurred when 8 ml. of perchloric acid and 1 ml. of reagent were used. Under these conditions a difference of 1 ml. of concentrated sulphuric acid resulted in about a 1% change in absorbancy.

Samples were prepared by fuming solutions containing rhodium and 2 ml. of concentrated sulphuric acid.

When these samples were treated as described above in the recommended procedure no color was evident at first. A yellow color slowly formed when the sample was left standing but this never became very intense. Attempts to increase the rate of color formation by heating the sample were only partially successful.

It was found that if the fumed solution was diluted to about 5 ml. with water, 0.5 ml. of concentrated hydrobromic acid added, and the solution boiled vigorously for 5 minutes, the color developed within 8 minutes of the addition of the reagent and the absorbancy was identical with that of a similar solution that contained 2 ml. of sulphuric acid but which had not been fumed.

The following procedure was found to be quite satisfactory for samples containing between 1 and 2 milliliters of concentrated sulphuric acid. Cool the rhodium solution after fuming and add 5 ml. of water and 0.5 ml. of concentrated hydrobromic acid. Boil this solution vigorously for at least 5 minutes then allow it to cool. Add 8 ml. of concentrated perchloric acid followed by 1 ml. of the reagent. Transfer to a 25-ml. volumetric flask and dilute to volume. After 8 minutes measure the absorbancy at 427 mμ against a reagent blank containing the same quantity of sulphuric acid as the sample.

Five replicate samples, each containing 50.8 μg. of rhodium which had been fumed with 2 ml. of concentrated sulphuric acid, gave a mean absorbancy of 0.503. The mean deviation of these results was 0.001 or 0.2%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Effect of Diverse Ions

The other platinum metals and base metals usually associated with the platinum metals interfere. Surprisingly, of the platinum metals iridium produced the least interference. A solution containing 46.4 μg. of iridium, when treated as described above, produced a colorless solution which showed no absorption peaks in the visible region. The presence of 9.3 and 46.4 μg. of iridium in solutions containing 50.8 μg. of rhodium reduced the absorbancies by about 2 and 6% respectively. It is apparent that a fair estimation of rhodium can be made even when equivalent quantities of iridium are present.

The exact intensities of the interferences of the other metals were not ascertained, as in all probability, in practice, they will depend on the history of the sample in question.

THE EXTENT OF THE ABNORMAL RECOMBINATION OF CYANISOPROPYL FREE RADICALS FROM 2,2′-AZO-BIS-ISOBUTYRONITRILE[1]

M. TALÂT-ERBEN AND A. N. ISFENDIYAROĞLU

ABSTRACT

The extent of the abnormal recombination of cyanisopropyl radicals to yield the ketenimine intermediate has been investigated at 80° C. in toluene. It is found that 54.4% of the radicals recombine this way. This value is 75% higher than that reported previously. This result makes it possible to estimate a better value for the molar extinction of intermediate, and suggests the possibility that in the decomposition of the latter both free-radical and molecular processes are co-operative.

INTRODUCTION

Talât-Erben and Bywater (3) have shown that a ketenimine intermediate is formed in the thermal decomposition of 2,2′-azo-bis-isobutyronitrile, and estimated the extent of the corresponding radical recombination to be approximately 30% of the total. This result was used to estimate the molar extinction coefficient of intermediate at maximum absorption at 287 mμ. Moreover, they used the same result to calculate the branching ratios of the two recombinations, and came to the conclusion that a decomposition step of intermediate into free radicals would be experimentally undistinguishable from a molecular process, since both assumptions give for $k_1 t_{max}$ values which are too close to be discernible. However, the above statements cannot be considered as conclusive, since the distribution ratio of the original hydrolytic product of ketenimine in toluene and 1 *N* HCl was unknown, so that there is no proof that the extraction of the product was complete. Therefore, it would be of interest to undertake a redetermination of the branching ratio under more precisely controlled experimental conditions.

EXPERIMENTAL

The azo-compound* (Westville Laboratories, Monroe, Connecticut) was recrystallized from benzene; m.p. 103° C. dec. The thermal decomposition was carried out at 80° in toluene (C.P.), in a thermostat controlled to about 0.2°, under a stream of purified nitrogen, with continual shaking. Azo-compound (1.6 to 1.9 g.) was decomposed in 50 cc. of toluene. After a definite time the solution was cooled quickly to stop the reaction, and transferred quantitatively into a separatory funnel. Fifty cubic centimeters of 1 *N* HCl were added, and the two phases were stirred rigorously for at least 20 minutes, then the emulsion-like mixture was left until the phases disengaged completely. The acid layer which contained the nitrile (II) was collected in a filter flask. The extraction was repeated at least three times with fresh portions of HCl. During extraction the ketenimine (I) hydrolyzes to the corresponding substituted amide (II), and passes into the aqueous phase. This hydrolytic step is a fast reaction owing to the unstable character of ketenimine group, as shown by Stevens and French (2).

$(CH_3)_2C{=}C{=}N{-}(CH_3)_2CN$ (I)

$(CH_3)_2CH.CO.NH.C(CH_3)_2CN$ (II)

$(CH_3)_2CH.CO.NH.C(CH_3)_2.CO.NH_2$ (III)

$(CH_3)_2CH.CO.NH.C(CH_3)_2.CO.OH$ (IV)

[1]*Manuscript received April 29, 1958.*
Contribution from the Faculty of Mining Engineering, Technical University of Istanbul, Istanbul, Turkey.
**Kindly supplied by Dr. S. Bywater of the National Research Council.*

The distribution ratio of (II) in toluene and 0.95 N HCl was found to be 1.17×10^{-2}. Therefore, after three extractions the amount left in toluene must be completely negligible; this was proved to be the case by additional extractions. The HCl extract was evaporated at 48° under reduced pressure, until all HCl was removed. The residue from evaporation, which consisted of an equimolecular mixture of (IV) and ammonium chloride, was dissolved in about 50 cc. of distilled water, and titrated against 0.1 N NaOH, potentiometrically. The fact that the end point in the neutralization was unaffected by the presence of ammonium chloride buffer has been established by titration of an authentic sample consisting of an equimolecular mixture of (IV) and NH_4Cl. This made it possible to cancel a separation step which would cause material losses. The authentic sample of (IV) had been prepared in a previous work (3) and had a melting point of 150° C. The neutralization point was taken as the inflection point of the clear S-shaped curve of the titration diagram. To check that under these conditions the hydrolysis of (II) to (IV) was complete, and that no detectable amount of (III) was ever formed, a definite amount of an authentic sample of (II) was subjected to the same conditions; the amount (in moles) of the acid formed was equal to that of the original nitrile with a great accuracy. The sample used in this experiment as well as in the determination of the distribution ratio was prepared in a previous work (4), and had a melting point of 105° C.

RESULTS AND DISCUSSION

Experiments were performed with reaction times of 25, 60, 104, 130, 180, and 240 minutes, at least two runs for each reaction time. The amount of (IV) expressed as the molar fraction of the initial amount of the azo compound changed with the reaction time in a manner very similar to that of the change of optical density with time as given in reference (3). The results are shown in Fig. 1. The maximum occurs at a point corresponding to a yield of 20.0%. This must be $1/e$th of the actual fraction of cyanisopropyl radicals that combine to form the ketenimine intermediate; this branching is thus found to be 54.4%. This result is about 75% higher than that reported in reference (3). Accordingly, the conclusion (1) that free radicals are not involved in the formation of the intermediate or in its decomposition cannot be maintained.

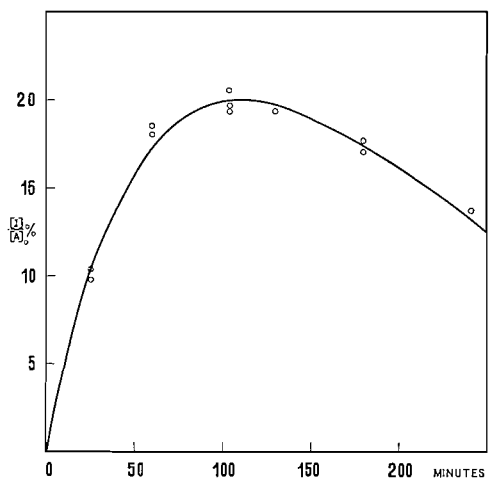

FIG. 1. Actual amounts of hydrolytic product of the intermediate as a fraction of the initial amount of azo compound versus reaction time. The curve has been calculated by using the reaction scheme of reference (3), assuming $k_4 = k_1$ and $k_3/(k_2 + k_3) = 0.544$.

For personal use only.

By comparison of the actual amount of intermediate extracted in the form of one of its hydrolytic products in this work with the optical density data of Table I of reference (3), it is possible to predict a better value for the molar extinction of (I), namely 46 at 320 mμ. This would correspond to a molar extinction of about 150 at maximum absorption at 287 mμ, assuming that the shape of the absorption curve given by the oily fraction (3) is characteristic of the intermediate. On the other hand, in the assumption that the latter decomposes to regenerate free radicals rather than by a molecular process, $k_1 t_{max}$ would now have to be 1.5; this value would be experimentally distinguishable from the value 1.0 corresponding to the molecular decomposition. The observed value, which is in the range 1.0 to 1.2, suggests that at most both mechanisms are co-operative, with the molecular process predominating.

A MASS SPECTROMETRIC STUDY OF NORMAL OXYGEN AND OXYGEN SUBJECTED TO ELECTRICAL DISCHARGE[1,2]

J. T. HERRON[3] AND H. I. SCHIFF

ABSTRACT

A mass spectrometric study was made of oxygen activated by microwave and by a-c. glow discharge. Appearance potential curves for normal oxygen at masses 16 and 32 indicated the occurrence of multiple electron impact processes. The change in the curves when the oxygen was activated could be interpreted by assuming the presence of O-atoms in the ^3P ground state, and O_2 molecules in the $^1\Delta_g$ excited state. No evidence was obtained for the presence of ozone up to pressures of 2 mm. Hg. The recombination coefficient of O-atoms on pyrex was found to be 1.1×10^{-4}. Only one oxygen atom in 21 was ionized before recombining in the mass spectrometer ion source. The rate constant for the reaction of O-atoms with N_2O is less than 1×10^{-8} cm.^{3} mole^{-1} sec.$^{-1}$, and several orders of magnitude less than this for the reaction $O(^3P) + N_2O \rightarrow 2NO$. The reaction of O-atoms with NO_2 was much faster than with NO, but no evidence was found for the formation of NO_3.

INTRODUCTION

When oxygen is subjected to electrical discharge at about 1 mm. Hg pressure, its chemical activity is greatly enhanced. The literature on the nature of the active species has recently been reviewed by Linnett and Marsden (1). They conclude that most of the oxygen is present as normal molecules and atoms. However, it may be inferred from a recent study of the thermal decomposition of ozone (2) that this compound might also be present in appreciable quantities under these conditions. The presence of ozone has also been postulated by Barth and Kaplan (3) to explain their observation of the Herzberg oxygen bands in discharges containing small quantities of nitrogen, and by Ford and Endow (4) to explain the mechanism of the NO_2 photolysis. Moreover there seem to be no compelling reasons for excluding the presence of electronically or vibrationally excited oxygen molecules.

This paper reports a mass spectrometric study of activated oxygen and some preliminary measurements of its reaction with the oxides of nitrogen. New species were identified by their mass-to-charge ratios and by their appearance potentials. To determine the appearance potentials of new species at masses 16 and 32, it was necessary to compare ionization-efficiency curves for normal and activated oxygen. The curves obtained for normal oxygen appeared to have features not previously reported. These curves are therefore also discussed.

EXPERIMENTAL

Apparatus

The mass spectrometer and the method used to measure appearance potentials have been described previously (5). Oxygen was found to reduce seriously the lifetime of the tungsten filament used as a source of electrons in the mass spectrometer. Carbon filaments were found to last longer and to give smaller CO^+ and CO_2^+ ion currents in the presence of oxygen. (For a discussion of the use of carbon filaments in mass spectrometers see ref. 6.) The only difficulty encountered with these filaments was some instability in

electron emission caused by poor contact between the carbon and the lead wires. This difficulty was finally overcome by evaporation of gold onto the ends of the filament, which were then held by a pair of miniature screw clamps. The maximum emission from these filaments was limited by evaporation of the carbon. However, the ionizing current could be increased to values comparable to those obtained with tungsten filaments of similar dimensions by the use of a reflector shield.

Two types of electrical discharges were used, a 60-cycle glow discharge and a microwave electrodeless discharge. The glow discharge was produced in a U-shaped pyrex tube 20 mm. in diameter and 80 cm. long. The electrodes were made of 1S grade aluminum rated to have a purity of 99.5%; aluminum of lower purity was found to undergo rapid attack in an oxygen discharge. To increase the electrode life further the entire discharge tube was immersed in a water bath. The activated oxygen was withdrawn from the center of the discharge and travelled a distance of 30 cm. to the sampling leak of the mass spectrometer.

The electrodeless discharge was excited in a quartz tube, 13 mm. in outside diameter, which passed through a slot in a resonance cavity box. Power was supplied by a "Raytheon" diathermy unit operating at 2450 Mc./sec. The activated gas was pumped from the discharge over the mass spectrometer leak through 13-mm. pyrex tubing, the length of which was varied between 10 and 50 cm.

Procedure

Oxygen was flowed continuously through the discharge and over the sampling leak of the mass spectrometer. "Bone-dry" tank oxygen of 99.90% purity was used without further purification, since several experiments performed with fractionally distilled oxygen and with oxygen produced by pyrolysis of potassium permanganate gave identical results. The oxygen pressure was varied from 0.1 to 2 mm. Hg. The mass flow rate at 1 mm. Hg pressure was 25 μM./sec.; the corresponding linear flow rate was 490 cm./sec. Provision was also made for adding water vapor to the oxygen stream.

Other gas inlets were located between the discharge and the sampling leak for introduction of calibrating gases for appearance potential studies and for the nitrogen oxides. The oxides of nitrogen were purified by the method of Nightingale *et al.* (7) and the mass spectrometer conditioned for NO_2 analysis by the method suggested by Friedel *et al.* (8).

The presence of mercury vapor was avoided, since it produced a deposit of mercuric oxide on the walls which deactivated the oxygen. A mirror of mercury was deposited on the walls of a trap located above the rotary pump to prevent attack of activated oxygen on the pump oil.

RESULTS AND DISCUSSIONS

Normal Oxygen

The O_2^+ ionization efficiency curve for normal oxygen was determined in the presence of argon as the calibrating gas. The partial pressure of argon was adjusted to make the ion currents at mass numbers 40 and 32 equal when the electron energy was 60 ev. The O_2^+ curve had a smaller slope and a longer 'tail' portion than the A^+ curve, which suggested that it resulted from several ionizing processes, such as the production of O_2^+ with vibrational excitation. The present instrument was incapable of resolving energies comparable to the spacing between vibrational levels.

Fig. 1 shows a typical set of experimental points through which several straight lines have been drawn. The A^+ curve has been adjusted to make the 'linear' portion parallel

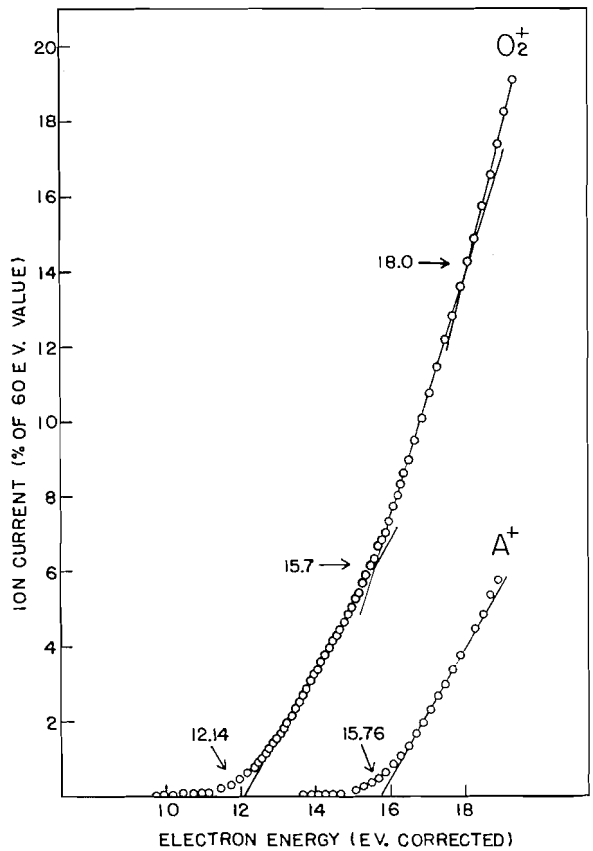

FIG. 1. Ionization efficiency curve for O_2^+ from normal oxygen.

to the lowest straight line of the O_2^+ curve. The average value of the ionization potential of O_2 obtained by extrapolation of seven such curves was 12.23±0.07 ev. A value of 12.10 ev. was obtained from a single attempt to use the extrapolated voltage difference method (9) with the adjusted A^+ curve. This method was not felt to be reliable for extrapolation of composite curves since the values obtained are very sensitive to the adjustment applied to the calibrating gas curve. However Warren (9) has used this method to obtain a value of 12.20±0.03 ev. for the ionization potential of O_2, but gave no details of the measurements. Hagstrum (10) obtained a value of 12.2±0.2 ev. using electron impact, and Watanabe reports a value of 12.075±0.010 ev. from photoionization measurements (11).

The intersections of the straight lines drawn through the O_2^+ curves gave appearance potentials of 15.7±0.5 and 18.0±0.5 ev. Herzberg (12) lists the electronic excitation energy of the $^4\pi_u$ and $^4\Sigma_g^-$ states of the O_2^+ ion as 3.95 ev. and 6.00 ev. respectively, although he indicates some uncertainty in these values. The appearance potential of these excited molecular ions formed by electron impact from ground state $^3\Sigma_g^-$ O_2 molecules can then be calculated to be 16.1 and 18.2 ev. The observed appearance potentials agree with these figures within the combined uncertainty of the spectroscopic and electron impact values.

The ionization efficiency curves obtained at mass 16 for normal oxygen indicated that

For personal use only.

O^+ is formed by several processes. Three "linear" portions could be drawn through the lower part of the curves and appearance potentials obtained from their intersections. Since the assignment of these "linear" portions is somewhat arbitrary, averages were taken of a large number of independent measurements. These average values and the processes which can be associated with them are shown in Table I and can be seen to be in substantial agreement with those reported by Hagstrum (13) and Thorburn (14). A portion of a typical curve is plotted as filled circles in Fig. 4.

TABLE I

POSSIBLE ELECTRON IMPACT PROCESSES IN NORMAL AND ACTIVATED OXYGEN

Process	Observed appearance potential				
	Normal oxygen			Activated oxygen	Calc.
	Hagstrum	Thorburn	This work

Activated Oxygen

The mass spectra of normal and activated oxygen were compared over the pressure range 0.1 to 2.0 mm. Hg. Table II shows the ion currents observed at masses 16, 32, and 48 at various pressures and using both types of discharge. Small ion currents were also observed at masses 28 and 44, which were probably due to reaction of oxygen with the filament or with carbon-containing impurities in the ion source. The change in the ratio of ion intensities at mass 16 to those at mass 32, from about 0.08 to 0.03, was

TABLE II

MASS SPECTRA OF NORMAL AND ACTIVATED OXYGEN

observed when the tungsten filament was replaced by a carbon filament as a source of electrons in the mass spectrometer. This change may be due to the greater extent of pyrolysis of O_2 to O-atoms on the tungsten filament. This interpretation is supported by the longer 'tail' portion of the O^+ appearance potential curve obtained with the tungsten filament. The last column of the table shows the percentage change in the ratio of ion currents at masses 16 and 32 when the oxygen was activated. Appearance potentials were determined at these mass numbers to identify the new species present in the activated gas.

Ozone

(*a*) *Normal Oxygen*

The ion current at mass 48 in the mass spectrum of *normal* oxygen might be due to ion–molecule reactions occurring in the mass spectrometer ion source. This would agree with the observed second-order dependence of the O_3^+ ion current on pressure (cf. Table II). The possible ion–molecule reactions are listed in Table III along with the calculated heats of reaction.

TABLE III

POSSIBLE REACTIONS FOR THE FORMATION OF O_3^+ IN NORMAL OXYGEN

Process	ΔH, kcal./mole
$O_2^+(X^2\pi_g) + O_2 \rightarrow O_3^+ + O$	107.1
$O_2^+(a^4\pi_u) + O_2 \rightarrow O_3^+ + O$	16.0
$O_2^+(A^2\pi_u) + O_2 \rightarrow O_3^+ + O$	−4.0
$O_2^+(b^4\Sigma_g^-) + O_2 \rightarrow O_3^+ + O$	−31.8
$O_2^+(X^2\pi_g) + O \rightarrow O_3^+$	−10.1
$O^+ + O_2 \rightarrow O_3^+$	−42.6

The reaction $O_2^+ + O_2 \rightarrow O_3^+ + O$ is exothermic only if the O_2^+ ion is in the second or third excited state. Since Franklin has found* that only exothermic ion–molecule reactions are observable, this does not appear to be a likely source of O_3^+ ions. The analogous reaction $H_2^+ + H_2 \rightarrow H_3^+ + H$ is approximately thermally neutral and has been used to explain the H_3 ions observed in the mass spectrum of hydrogen (15).

The last two reactions shown in Table III are energetically possible, but probably require third-body stabilization. No other example of such a simple ion–molecule addition reaction has been reported.

There remains the possibility of O_3 being formed directly on the mass spectrometer filament, although the mechanism for such a reaction is not apparent. This problem can only be solved by measuring the appearance potential of the O_3^+ ion. Attempts are currently being made to improve the sensitivity of the instrument to permit such measurements.

(*b*) *Activated Oxygen*

No increase in the ion current at mass 48 was observed when the oxygen was activated. A previous mass spectrometric study of pure ozone (16) showed that the ion current at mass 48 from pure ozone is at least 0.13 times as large as the ion current at mass 32 from pure oxygen at the same pressure. From the detection limit of the mass spectrometer it can be concluded that ozone is not present in activated oxygen in concentrations greater than 0.02% up to pressures of 2 mm. Hg.

**Private communication.*

In a recent study of the pyrolysis of ozone at several hundred millimeters Hg pressure, Benson and Axworthy (2) obtained rate constants for the reactions:

$$M + O_3 \underset{k_2}{\overset{k_1}{\rightleftarrows}} M + O_2 + O$$

$$O + O_3 \xrightarrow{k_3} 2O_2.$$

These rate constants can be used to calculate the steady-state concentration of ozone, which would be expected for the experimental conditions used in the present study. The time required to reach a steady-state condition can also be shown to be the same order as the time required for the activated gas to pass from the discharge to the mass spectrometer leak. At 300° K. and 1 mm. Hg pressure the calculated steady-state concentration of ozone is 0.29%, which is at least an order of magnitude above the detection limit of the mass spectrometer. However, Benson and Axworthy's value for k_2, when the third body is O_2, is only an estimate, and might be responsible for part of the discrepancy.

This discrepancy cannot be explained by heterogeneous destruction of ozone on the walls of the tubing connecting the discharge and the mass spectrometer. Harteck and Dondes (17) have shown that ozone decomposition does not occur directly on glass but only indirectly by the recombination of the O-atoms in equilibrium with the ozone. The low recombination coefficient of O-atoms observed in this work precludes this as an important mechanism for ozone disappearance.

The presence of effective catalysts for ozone decomposition such as Hg or H_2O vapors was also carefully avoided. However, McGrath and Norrish (18) have postulated a rapid reaction between vibrationally excited O_2 and O_3 in the flash photolysis of ozone. Any ozone formed in the present study might have been rapidly destroyed by the excited O_2 (see below) found to be present in activated oxygen.

Since k_3 has an activation energy of 6.0 kcal./mole it might be argued that the steady-state ozone concentration might be lower than the calculated value, since the gas issuing from the discharge is considerably above room temperature. However, no ozone was detected when the activated gas was flowed through a 50-cm. length of tubing. The gas should then have been at 300° K. for a sufficient time to reach the steady-state concentration corresponding to this temperature.

There remains the possibility that the ozone was destroyed in the ion source. Although the sensitivity of the mass spectrometer in detecting ozone was determined using pure ozone, it is possible that at low ozone concentrations decomposition might occur more rapidly on the hot walls of the ion source. A single experiment performed with an ion source designed to prevent collisions of molecules with the metal walls did show a small increase in ion intensity at mass 48 when the oxygen was activated. However, since the mass spectrometric sensitivity for ozone with this source has not yet been determined, no estimate could be made of the ozone concentration. Further studies with this source are now in progress.

Excited Oxygen Molecules

Fig. 2 shows a typical set of curves obtained when the ion intensities at masses 40 and 32 were plotted against the electron energy. The apparent electron-energy scale was shifted to make the linear portion of the argon curve extrapolate to the spectroscopic ionization potential of argon. The argon curves obtained when the discharge was excited coincided with those obtained in the absence of the discharge. The curves at mass 32 did

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

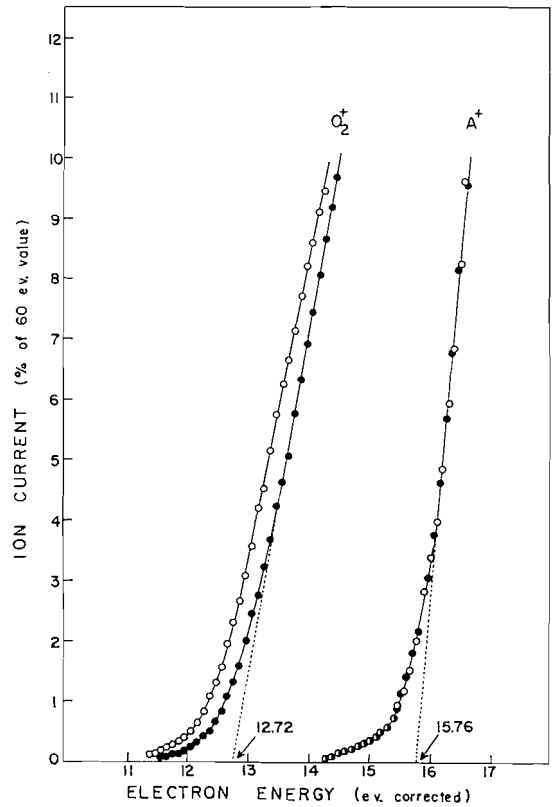

FIG. 2. Ionization efficiency curves for O_2^+ and A^+. Filled circles correspond to normal gas, open circles to activated gas.

not coincide, which suggested the presence of new species. When the difference ΔO_2^+, between the two curves, was plotted as a function of electron energy, the curve shown in Fig. 3 was obtained. The slope of the argon curve was adjusted to make it parallel to the ΔO_2^+ curve. The average of four determinations, one using xenon as the calibrating gas, indicated that the new species had an ionization potential 1.00 ± 0.03 ev. lower than normal oxygen.

Herzberg reports the excitation energy of the $^1\Delta_g$ state of oxygen to be 0.98 ev. (19). The new species may therefore be oxygen in this electronically excited state. It is unlikely that it could be oxygen in the ground state with only this amount of vibrational energy, although McGrath and Norrish (18) have proposed a long lifetime for vibrationally excited oxygen.

The concentration of excited molecules can be estimated at about 10% from a comparison of the initial slopes of the ΔO_2^+ curves and the O_2^+ curves for normal oxygen. The estimate is based on the assumption that the ionization cross sections for excited and normal oxygen are identical and that their ionization probabilities increase with excess electron energy in the same way.

Foner and Hudson (20) also obtained evidence for an excited molecular species in activated oxygen. They analyzed their ionization-efficiency curves by a mathematical procedure and obtained a value of 0.93 ± 0.10 ev. for the excitation energy. They suggested that the excited molecules were in the $^1\Delta_g$ state and estimated their concentration to be between 10 and 20%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Several authors (21, 22, 23) have suggested the formation of excited molecules by O-atom recombination. However, it is unlikely that the excited molecules detected in this work were formed in this way. Measurements of the rate of atom recombination (see below) indicated that only a negligible proportion of the atoms would recombine during the time required for the activated gas to pass from the discharge to the mass spectrometer leak. Since the atom concentrations were of the order of 10%, appreciable quantities of excited molecules could not be formed by this mechanism. It is much more likely that they are excited by the discharge.

Oxygen Atoms

Fig. 4 shows a typical ionization efficiency curve for O^+ ions formed by electron impact with oxygen activated by the microwave discharge. Similar curves were obtained when the a-c. glow discharge was used to excite the gas. The inset in the figure shows a magnified view of the lower portion of the curve. The first appearance potential was obtained by linear extrapolation of this portion of the curve. The energy scale was corrected using krypton as the calibrating gas. The average value obtained for the appearance potential was 13.90±0.05 ev. However, in view of the ambiguities involved in the "linear" extrapolation method, the value is probably not accurate to better than ±0.2 ev.

The ionization potential of ground state $^3P_2$ oxygen atoms is 13.615 ev. (24). Since

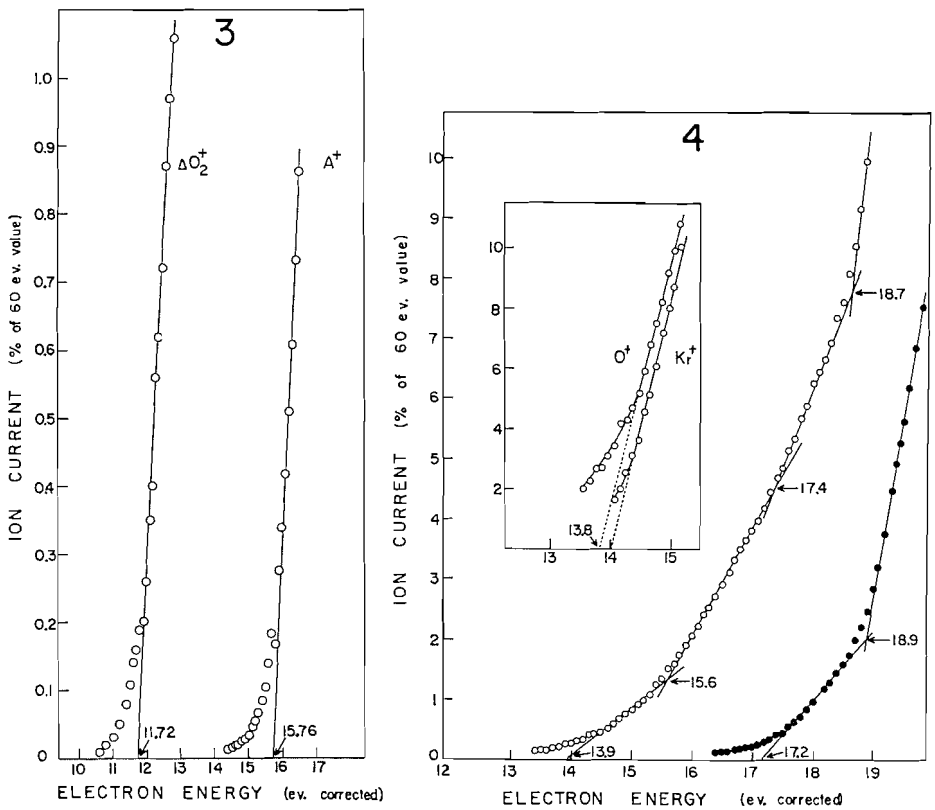

FIG. 3. Ionization efficiency curves at mass 32 for new species and at mass 40 for argon.

FIG. 4. Ionization efficiency curves for O^+ ions. Filled circles correspond to normal gas, open circles to activated gas. Inset shows lower portion of activated gas curve and curve for Kr^+ from krypton. NOTE: The numbers along the ordinate in the insert should read .2, .4, .6, .8, and 1.0.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

appearance potentials obtained by linear extrapolation tend to be somewhat higher than the corresponding spectroscopic values, the agreement between these values can be considered as satisfactory evidence for the existence of ground-state atoms in activated oxygen.

Since no appearance potentials were ever observed below the ionization potential of $^3P_2$ atoms, it can be concluded that metastable atoms cannot be present in appreciable quantities.

Linear portions could also be ascribed to the O^+ ionization efficiency curves for activated oxygen. Although it was not always possible to locate all the breaks in the curve for a single experiment, average values for five higher appearance potentials could be obtained from a large number of experiments. These values are given in Table I. The appearance potentials at 15.7 and 18.0 ev. agree, within the estimated experimental uncertainty, with the values calculated for electron impact on $^1\Delta_g$ molecules in activated oxygen. The calculated values for ionization of ^3P O-atoms to excited O^+ states are somewhat outside the experimental uncertainty of the observed appearance potentials. These processes undoubtedly occur and add to the difficulty in identifying the breaks in the ionization efficiency curves.

Concentration of Oxygen Atoms

The O-atom concentration was determined by "titration" with NO_2 as originally suggested by Spealman and Rodebush (25). NO_2 was introduced into the activated oxygen stream through a mixing jet. The amount of NO_2 remaining after a reaction time of 0.5 seconds was determined as a function of initial NO_2 concentration, as shown in Fig. 5. For low NO_2 concentrations most of the NO_2 is consumed.

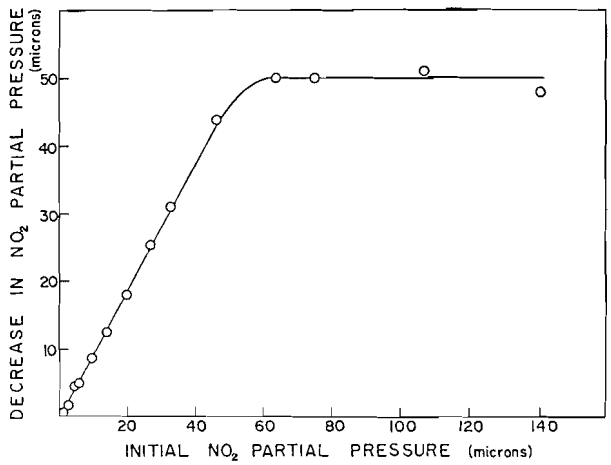

FIG. 5. Titration of O-atoms with NO_2.

This indicates that the reaction:

$$NO_2 + O \rightarrow NO + O_2 \qquad [1]$$

is very much faster than reaction:

$$NO + O + M \rightarrow NO_2 + M \qquad [2]$$

at these pressures.

Above a partial NO_2 pressure of 60 μ all the O-atoms are consumed by reaction [1]. This agrees with the observation that the chemiluminescence associated with reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

[4] disappears above this pressure. The amount of NO_2 consumed at the "plateau" was therefore taken as a measure of the O-atom concentration.

The atom concentrations produced by both types of discharges varied from 4 to 12 mole %. The presence of water vapor in the oxygen stream greatly enhanced the atom concentration. For example, in one experiment, the atom concentration increased immediately from 4.8 to 8.6% upon addition of 0.6% water vapor. The rapidity of the change suggests that water vapor increases the discharge efficiency and does not simply act as a "poison" against wall-catalyzed recombination.

The O-atom concentration could not be estimated from the relative change in the O^+ and O_2^+ ion intensities caused by activation of the gas. Under certain conditions the O_2^+ ion intensity actually increased when the discharge was excited, although the ion intensity of argon (used here as a monitoring gas) was unaltered. This observation cannot be explained by the production of $^1\Delta_g$ molecules unless these have a much larger ionization cross section than normal oxygen. The ionization efficiency curves shown in Fig. 2 indicate that this is not the case.

Dissociation of molecules into atoms should cause a decrease in the O_2^+ ion intensity. Recombination of atoms in the ion source might not be expected to cause an increase in O_2^+ ion current above the value obtained for the undissociated gas. However, atoms will pass through the mass spectrometer leak faster than molecules, since the flow is largely non-viscous. Recombination in the ion source could then lead to a net increase in O_2^+ ion intensity relative to the monitoring gas.

An estimate can be made of the extent of atom recombination in the ion source. In a typical experiment at 0.53 mm. Hg pressure the O_2^+ ion current increased from 6820 (arbitrary units) to 7020 when the discharge was excited, the O^+ ion intensity increased from 201 to 217, while the A^+ ion intensity remained constant at 404. The O^+ ion intensity due to O-atoms was therefore:

$$217-(7020/6820\times 201)=10.$$

According to the additivity principle of ionization cross sections proposed by Stevenson and Otvos (26), oxygen atoms should have half the ionization cross section of oxygen molecules. The atom concentration for this experiment, obtained by NO_2 titration, was 6%. The ion intensity expected if no recombination had occurred in the ion source would then be:

$$0.5\times(6820+201)\times 0.06=210.$$

Thus, only 1 atom in 21 is ionized before recombining on the wall. This can be compared with LeGoff's calculation (27) that a molecule experiences an average of 50 collisions with the walls of a Nier-type source before being ionized or removed by the pump.

Recombination Coefficient of Oxygen Atoms

If it is assumed that atoms recombine exclusively on the walls, the recombination coefficient of O-atoms could also be determined by the NO_2 titration technique. The NO_2 was introduced successively at several positions along the tube connecting the discharge to the mass spectrometer leak. The O-atom concentration could then be measured as a function of time. The recombination coefficient on pyrex was found to be 1.1×10^{-4}, which agrees with the value of 1.2×10^{-4} reported by Linnett and Marsden (1).

Reactions of Activated Oxygen with Nitrogen Oxides

N_2O

The N_2O was introduced through an inlet jet. No change in mass spectrum was observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

when the oxygen was activated. The largest ion currents in the mass spectrum of pure N_2O occur at mass numbers 28, 30, and 44. This made detection of the possible reaction products, N_2 and NO, very difficult. Moreover, small changes in the parent peak were also difficult to measure, since the background CO_2^+ ion current changes when the oxygen is activated. The uncertainties in measuring these ion intensities were estimated to be about 5%. On this basis, an upper limit for the second-order rate constant for the reaction of N_2O with O-atoms can be placed at 1×10^8 cm.^{3} mole^{-1} sec.$^{-1}$.

The rate constant for the reaction

$$N_2O + O \rightarrow 2NO \qquad [3]$$

must be several orders of magnitude less than this, since no chemiluminescence was detected from the subsequent reaction

$$NO + O \rightarrow NO_2 + h\nu \qquad [4]$$

for reaction times 100 times as long as those used in the mass spectrometer measurements. The limit of detection of the chemiluminescence is also many times lower than that of the mass spectrometer.

This is in agreement with the results of Kaufman *et al.* (28), who studied the thermal decomposition of N_2O and, by an indirect calculation, estimated $k_3 = 1\times10^{11}\ e^{-15,500/RT}$ cm.^{3} mole^{-1} sec.$^{-1}$. Zelikoff and Aschenbrand (29) have proposed reaction [3] as an important step in the photolysis of N_2O at 1849 Å and at 1470 Å. This can only be reconciled with the present observations if oxygen atoms are present in excited states. This has recently been suggested by the same authors (30).

NO *and* NO_2

Reaction times of 0.02 and 0.5 seconds were used with these reactants. The only reaction products detected when either of these oxides was reacted with activated oxygen was the other oxide. No ion current at mass 62, corresponding to NO_3^+, was ever observed. The ratio of NO to NO_2 was always high, regardless of the reactant or reaction time. This would indicate that reaction [1] is much faster than reaction [2]. However, if these were the only important reactions, the ratio $[NO]/[NO_2]$ would be expected to equal k_1/k_2 [M], and should be independent of initial reactant concentration. This was not found to be the case. For example, when NO_2 was used as the reactant, the ratio of concentrations increased from 34 to 460 as the initial NO_2 concentration was increased from 0.4 to 10%. Apparently other important reactions are also occurring. These reactions are being investigated in more detail.

THE REACTIONS OF DIMETHYL- AND TRIMETHYL-AMINES WITH ATOMIC HYDROGEN[1]

Z. M. GEORGE, A. N. WRIGHT,[2] AND C. A. WINKLER

ABSTRACT

The reactions of hydrogen atoms with dimethyl- and trimethyl-amines produced mainly methane, together with relatively large quantities of ethane and small amounts of hydrogen cyanide. Dimethylamine was also a product of the trimethylamine reaction.

The reactions of hydrogen atoms with dimethyl- and trimethyl-amines have never been directly investigated. It was of particular interest to determine whether these reactions, like the corresponding reactions of ethylenimine and N-methylethylenimine (1), and of methyl- and ethyl-amines (2), would yield hydrogen cyanide as a product.

EXPERIMENTAL

The apparatus and techniques employed were similar to those described in the earlier papers (1, 2) from this laboratory. The total pressure of atomic and molecular hydrogen in the reaction system was 0.80 mm., with a molecular hydrogen flow rate of 7.6×10^{-5} mole per second. The hydrogen atom concentration was 5.7% at 60° C., and 4.2% at 275° C., as estimated from the amounts of reaction when ethyl chloride and hydrogen bromide were used as reactants at these temperatures (3).

RESULTS AND DISCUSSION

Figs. 1A and 2A show that both dimethyl- and trimethyl-amines react with hydrogen atoms to produce hydrogen cyanide. For both amines, the rates of production of hydrogen cyanide were linear at low flow rates of amine and increased with temperature, while at higher flow rates they passed through maxima beyond which they eventually decreased to zero.

Analyses for products other than hydrogen cyanide were made for the reactions at 60° C. The results are shown in Figs. 1 and 2, B and C. As with methylamine and ethylamine (2), free ammonia was recovered only when the total amount of base recovered exceeded the total amount of hydrogen cyanide, and conversely free hydrogen cyanide was recovered only when its amount exceeded the total recovery of base. A small amount of substance was recovered from the dimethylamine reaction which gave titration for neither base nor cyanide and defied infrared identification (cf. ref. (2)).

The maximum amounts of dimethyl- and trimethyl-amines reacted were less than the estimated hydrogen atom concentration and the amounts of reaction decreased at higher amine flow rates. As in the methylamine reaction, methane was the main product of the reactions and its amount passed through a maximum with increase in flow rate of amines. The amount of ethane produced attained a constant value in both reactions at relatively high flow rates.

The non-condensables, which consisted mainly of nitrogen and methane, were estimated mass spectrometrically for the dimethylamine reaction, and by gas chromatography (molecular sieve 5A, mesh 30–70, temperature 50° C.) for the trimethylamine reaction.

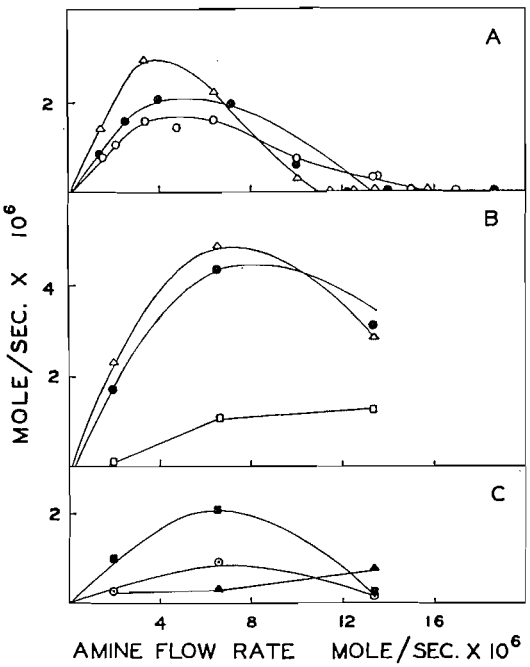

FIG. 1. Dimethylamine – hydrogen atom reaction. A—HCN production: ○ 56±5° C. ● 180±6° C. △ 284±4° C.
B and C—Amine reacted and products formed at 56±5° C.: ● Dimethylamine reacted. △ Methane. □ Ethane. ■ HCN. ⊙ "No titer". ▲ NH_3.

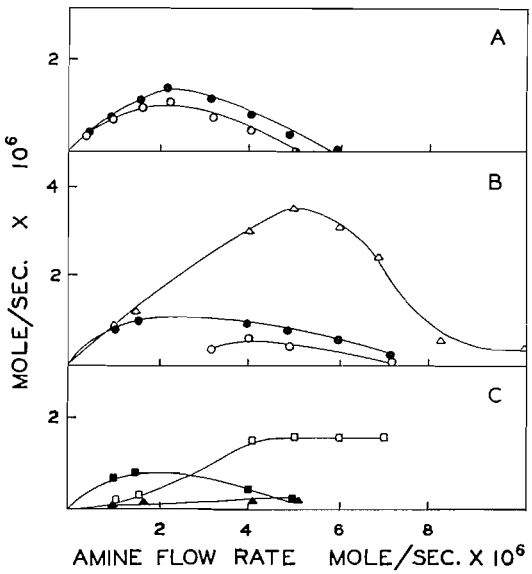

FIG. 2. Trimethylamine – hydrogen atom reaction. A—HCN production: ○ 56±3° C. ● 275±5° C. B and C—Amine reacted and products formed at 56±3° C.: ● Trimethylamine reacted. △ Methane. ○ Nitrogen. □ Ethane. ■ HCN. ▲ NH_3.

At flow rates beyond which no hydrogen cyanide was formed, the trimethylamine–hydrogen atom reaction yielded some dimethylamine, as shown by chromatographic separation (silica gel column at 50° C.) of trimethylamine from mixtures of the condensable products from which ethane and ammonia had been removed by distillation. The "recovered" trimethylamine was found to be approximately 35% dimethylamine. A series of experiments conducted with about 1% hydrogen atoms at very high flow rates of trimethylamine produced no liquid (4); the reactions appeared to follow the same course as with 5.7% hydrogen atom concentration.

Mechanisms similar to those suggested previously for the reactions of hydrogen atoms with methyl- and ethyl-amines (2) may be postulated to explain the main features of the corresponding reactions with dimethyl- and trimethyl-amines. The primary process in both reactions is probably hydrogen atom abstraction, i.e. for dimethylamine,

$$(CH_3)_2NH + H \rightarrow (CH_3)_2\dot{N} + H_2 \qquad \Delta H = -9 \text{ kcal.} \qquad [1a]$$

and

$$(CH_3)_2NH + H \rightarrow CH_3NH\dot{C}H_2 + H_2 \qquad \Delta H = -9 \text{ kcal.} \qquad [1b]$$

and for trimethylamine,

$$(CH_3)_3N + H \rightarrow (CH_3)_2N{-}\dot{C}H_2 + H_2 \qquad \Delta H = -9 \text{ kcal.} \qquad [1c]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The radicals formed in these reactions could react further with hydrogen atoms to form activated dimethylamine and trimethylamine molecules containing about 85 kcal. of excess energy, and these could dissociate

$$(CH_3)_2NH^* \rightarrow CH_3 + CH_3NH \qquad \Delta H = -20 \text{ kcal.} \qquad [2a]$$

$$(CH_3)_2NH^* \rightarrow CH_4 + CH_3N \qquad \Delta H = -17 \text{ kcal.} \qquad [2b]$$

and

$$(CH_3)_3N^* \rightarrow CH_3 + (CH_3)_2N \qquad \Delta H = -12 \text{ kcal.} \qquad [2c]$$

$$(CH_3)_3N^* \rightarrow CH_4 + CH_3{-}N{-}CH_2 \qquad \Delta H = -11.9 \text{ kcal.} \qquad [2d]$$

The dimethylamine radical formed in reaction [2*c*] could react with another hydrogen atom or a trimethylamine molecule to produce an activated dimethylamine molecule which could dissociate as in [2*a*] or [2*b*], but might be deactivated by collision to appear as the dimethylamine observed in the products from the trimethylamine reaction. The CH_3NH radical produced in [2*a*] could react further with hydrogen atoms to produce activated methylamine (2), followed by its dissociation to yield CH_3N radicals from which hydrogen cyanide might be formed as outlined previously,

$$CH_3N \rightarrow HCN + H_2 \qquad \Delta H = -48 \text{ kcal.} \qquad [3]$$

The only plausible reason for a decrease in hydrogen cyanide production at high flow rates of dimethyl- and trimethyl-amine appears to be recombination of CH_3N radicals, or their reaction to produce C_2H_6 and N_2, before they suffer decomposition to hydrogen cyanide.

Formation of methane as the main product of the reaction of hydrogen atoms with dimethyl- and trimethyl-amines is readily explained by reaction of methyl radicals with hydrogen atoms and hydrogen abstraction from the amines by methyl radicals. The decrease and final levelling out of methane production at high flow rates of trimethylamine might be attributed to the replacement of methyl radical – hydrogen atom reaction by the slower abstraction reactions and increased recombination of methyl radicals to form ethane, as the supply of hydrogen atoms is depleted by increased extents of the primary reactions. The apparent decrease in the amount of amine reacted at higher flow rates of amines could be attributed to the stabilization by collision of the activated amines which otherwise decompose by reactions [2*a*] to [2*d*].

PREDICTION OF SOME THERMODYNAMIC PROPERTIES EMPLOYING THE ISOELECTRONIC PRINCIPLE[1]

P. SMITH AND C. N. R. RAO

ABSTRACT

An empirical method for predicting standard enthalpies and free energies of formation of isoelectronic molecules bearing in turn the groupings —F, —OH, —NH_2, and —CH_3 is proposed and used. It appears to be accurate to about ±10 kcal. $mole^{-1}$ or better depending on the procedure employed.

INTRODUCTION

There have been a number of useful empirical correlations between the different properties of bonds in similar molecules (1, 2, 3, 4, 5). Similar to these are the regular trends noticed in the case of the thermodynamic properties of related substances (6, 7, 8). The present paper gives a method whereby thermodynamic trends have been applied in predicting some thermodynamic quantities. Of particular interest was the prediction of the thermodynamic properties of the hypothetical substance H_2O_3, a postulated product (9) when dissociated water vapor is condensed at low temperatures.

BASIS OF THE METHOD

It is to be expected that regularities in thermodynamic quantities would be particularly evident between molecules of similar electronic structure, in harmony with the corresponding correlations of other molecular properties with electronic structure for isoelectronic molecules (10). In view of the comparative plenty of thermodynamic data on sequences of isoelectronic molecules bearing in turn the isoelectronic groupings[2] —CH_3, —NH_2, —OH, and —F attention here has been confined to them. The most convenient variable with which to relate these thermodynamic quantities[3] proved to be the atomic number of the non-hydrogen atom in the —X group,[2] owing to the paucity of data on other possible parameters for the range of molecules covered.

In general no smooth regularities are obtained if ΔH_f° or ΔF_f° values, for substances either in their standard states at 25° C. or as gases in their standard states at 25° C., are plotted against atomic number. To circumvent this difficulty these quantities were amended before use so as to relate to similar processes of formation from X_2. For example, ΔH_f° values for the HX sequence show no smooth trend with atomic number variation, but ΔH° values for the synthetic processes of the type

$$\tfrac{1}{2}H_2+\tfrac{1}{2}X_2 = HX \qquad [1]$$

do. To distinguish the value of ΔH° for step [1] with all substances in their standard states at 25° C. from that with all substances as gases in their standard states at 25° C., the former is denoted by $\Delta H_f^{\circ *}$ and the latter by $\Delta H_f^{\circ **}$. Similar notation is used for ΔF values. Fig. 1 illustrates the success achieved for this series. As might have been

[2]*These will be denoted by the general symbol —X.*

[3]*All thermodynamic data used in this paper relate to 25° C. unless stated otherwise. All data are taken from the usual standard sources (11, 12) except for the values given in the Appendix and some of the values listed in Tables I and II for comparison purposes.*

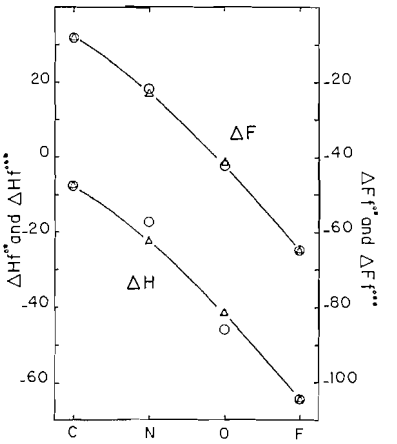

FIG. 1. $\Delta H°$ and $\Delta F°$, in kcal. mole^{-1}, for the reaction, $\frac{1}{2}H_2 + \frac{1}{2}X_2 = HX$ as a function of X. ○, $\Delta H_f°*$ or $\Delta F_f°*$; △, $\Delta H_f°**$ or $\Delta F_f°**$.

expected, the two sequences involving the all-gas-phase synthetic reaction, so reducing the effects of intermolecular forces, give the smoothest trends (which are the ones drawn). But the other two sets of points, relating to $\Delta H_f°*$ and $\Delta F_f°*$, deviate from their corresponding all-gas-phase plots by no more than ± 5 kcal. mole^{-1}, suggesting that $\Delta H_f°*$ and $\Delta F_f°*$ plots might be adequate for the many other possible sequences where gas-phase data are often lacking.

This conclusion is borne out by Fig. 2, which shows smooth trends in $\Delta H_f°*$ and $\Delta F_f°*$ for the synthetic process

$$C_6H_6 + \tfrac{1}{2}X_2 = C_6H_5X + \tfrac{1}{2}H_2. \qquad [2]$$

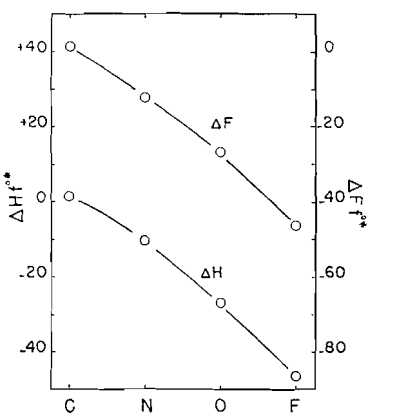

FIG. 2. $\Delta H°$ and $\Delta F°$, in kcal. mole^{-1}, for the reaction $C_6H_6 + \frac{1}{2}X_2 = C_6H_5X + \frac{1}{2}H_2$ as a function of X.

Figs. 3 and 4 indicate similar trends in $\Delta H_f°*$ for a variety of different processes. The data in these last cases are not complete. For this same reason $\Delta F_f°*$ plots are not even attempted.

PREDICTIONS

From Figs. 3 and 4 estimates of the unknown $\Delta H_f°$ values may be made. These are given in Table I together with similarly predicted values taken from Fig. 5. All estimates

Fig. 5 and not presented in Table I, together with any related $\Delta F_f°$ data that could be deduced by this method. All predictions in Table II refer to the substances in the gaseous state because they are derived from all-gas-phase plots. The trends in Figs. 3 and 4 were taken as non-linear; those in Fig. 5 and Table II were less similar to one another and so were drawn as straight lines by the method of least squares. It is unlikely that the estimated values are uncertain by more than about ± 10 kcal. mole^{-1}. This uncertainty limit is supported by the size of the trend irregularities present in Figs. 1 to 5.

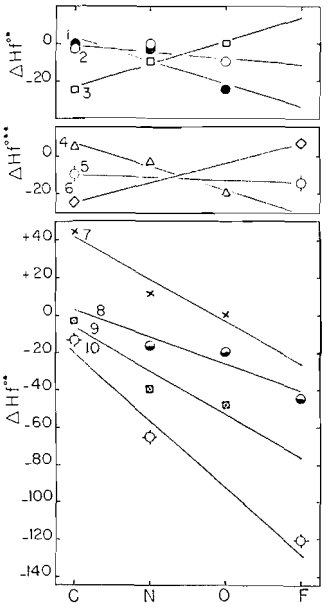

FIG. 5. $\Delta H°$, in kcal. mole^{-1}, for the reactions:

1, $\frac{1}{2}C_2H_6 + \frac{1}{2}X_2 = XCH_3$
2, $\frac{1}{2}N_2H_4 + \frac{1}{2}X_2 = XNH_2$
3, $\frac{1}{2}H_2O_2 + \frac{1}{2}X_2 = XOH$
4, $C_2H_6(g) + \frac{1}{2}X_2(g) = XC_2H_5(g) + \frac{1}{2}H_2(g)$
5, $\frac{1}{2}Cl_2(g) + \frac{1}{2}X_2(g) = XCl(g)$
6, $\frac{1}{2}O_2(g) + X_2(g) = X_2O(g)$
7, $CH_3COOH + \frac{1}{2}X_2 = CH_3COX + \frac{1}{2}H_2O_2$
8, $HCHO + \frac{1}{2}X_2 = XCHO + \frac{1}{2}H_2$
9, $CH_3COOH + \frac{1}{2}X_2 = XCH_2COOH + \frac{1}{2}H_2$
10, $CO + X_2 = COX_2$ as a function of X.

TABLE II

ESTIMATES OF STANDARD ENTHALPIES AND FREE ENERGIES OF FORMATION AT 25° C.

Compound	$\Delta H_f°$, kcal. mole^{-1}	$\Delta F_f°$, kcal. mole^{-1}
$NH_2Cl(g)$	0	—
$HOCl(g)$	-29^a	—
$(NH_2)_2O(g)$	+9	+29
$(HO)_2O(g)$	−35	-24^b
$C_2H_5F(g)$	−50	−40

[a] A recent calculation (17) of the bond dissociation energy $D°$(HO—Cl) at 25° C. gives a value for $\Delta H_f°$ HOCl(g) of -21 ± 3 kcal. mole^{-1}.

[b] Bray (18) has estimated $\Delta F_f°$ H_2O_3(aq.) and $\Delta H_f°$ 0° K. H_2O_3(g) to be not greater than −10 and −17 kcal. mole^{-1} respectively. The method used is not clear.

For personal use only.

The agreement between the estimates by this method and the compared values given in Tables I and II is not against this assessment of the error. In the case of acetyl fluoride the two values listed in Table I are 15 kcal. mole^{-1} apart. This is probably, to some extent, because the normal boiling point of acetyl fluoride is only 4° C. below 25° C. (15); also the estimated value is obtained by extrapolation and not interpolation.[4] It is possible that the predicted data given in Table II are uncertain to only ±5 kcal. mole^{-1}, being derived from all-gas-phase plots which are also of small slope.

DISCUSSION

The trends observed in Figs. 1 to 5 appear nearly linear. The processes involved are of the types

$$RH+\tfrac{1}{2}X_2 = RX+\tfrac{1}{2}H_2, \quad [3]$$

$$\tfrac{1}{2}RR+\tfrac{1}{2}X_2 = RX, \quad [4]$$

$$E+\tfrac{1}{2}X_2 = EX, \quad [5]$$

where RH and RR are compounds and E is an atom or a molecule. These are not all that are possible. For example, [3] added to [4], taking RR as H_2, gives

$$RH+X_2 = RX+HX. \quad [6]$$

The fact that $\Delta H°$ for the reaction

$$\tfrac{1}{2}X_2(g) = X\cdot(g) \quad [7]$$

also shows a nearly linear trend (19), namely 42, 30±2, 26, and 18 kcal. mole^{-1} for methyl (11), amino (5), hydroxyl (11), and fluorine (20) respectively, implies, for example, that $\Delta H°$ for the process

$$RX(g) = R\cdot(g)+X\cdot(g), \quad [8]$$

namely $D°$(R—X), shows a similar variation with X, by virtue of the linear relation applying for [3]. This must also be so for the quantity ($\Delta H_f°$ X·(g) $-\Delta H_f°$ RX(g)) inasmuch as R· is fixed within a series. A difficulty in employing this type of dependence to estimate unknown values of $\Delta H_f°$ and unknown bond dissociation energies is the uncertainty (5) in some of the values of $\Delta H_f°$ X·(g). This could be avoided by using plots of $\Delta H_f°$ values for one complete sequence, RX(g), versus that for another, incomplete sequence R′X(g). It is of course implied above that $D°$(R—X) versus $D°$(R′—X) plots should be nearly linear also, although such plots are generally less convenient to use than the $\Delta H_f°$ RX, R′X correlations because the $D°$ values often have to be calculated from $\Delta H_f°$ data.

The fact that bond dissociation energies of isoelectronic bonds of the first row halogen-type radicals show nearly linear changes with atomic number can be appreciated qualitatively in terms of the similarity of bonding involved, as pointed out by others (19). A quantitative explanation is, so far, lacking, although the tentative, approximate formula treatment by Mulliken would appear to show promise (22). The approach used in Figs. 1 to 5 may be regarded as a limited extension to the empirical formula used by Pauling (23) for the value of $\Delta H_f°$ in kilocalories for a compound in its standard state, containing n_N and n_O atoms per molecule of nitrogen and oxygen respectively,

[4]*At the time this method was first developed $\Delta H_f°$ for liquid fluorobenzene was not known. Using the available data in Fig. 2 gave a predicted value of −38±5 kcal. mole^{-1} in agreement with the since reported (16) figure of −34.75±0.3 kcal. mole^{-1}, now plotted in Fig. 2.*

For personal use only.

$$-\Delta H_f^\circ = 23.06 \sum(x_A - x_B)^2 - 55.1\ n_N - 24.2\ n_O, \quad [9]$$

where x_A and x_B are the electronegativities of atoms A and B making bond A—B in the compound and the summation is taken over all bonds. The present use of $\Delta H_f^{\circ **}$ or $\Delta H_f^{\circ *}$ values instead of the unamended ΔH_f° data eliminates the n_N and n_O correction terms that allow for the multiple bond character of the bonds in N_2 and O_2 and, in case [3] for example, it follows that

$$-\Delta H_f^{\circ **} = 23.06[(x_R - x_X)^2 - (x_R - x_H)^2], \quad [10]$$

where x_R and x_X are the electronegativities, on the Pauling scale, for the atoms that make the R—X bond. Now x_X varies linearly (23) with atomic number, being 2.5, 3.0, 3.5, and 4.0 respectively for C, N, O, and F. This makes equation [10] predict trends of $-\Delta H_f^{\circ **}$, or $-\Delta H_f^{\circ *}$, with atomic number much more strongly parabolic than those observed. This difference is emphasized by the fact that, from [4] for example,

$$\Delta H_f^{\circ **}\ RX(g) = D^\circ(R—X) - \tfrac{1}{2}[D^\circ(R—R) + D^\circ(X—X)] \quad [11]$$

shows a nearly linear dependence upon x_X, whereas the simple Pauling definition of electronegativity assumes a linear dependence upon $(x_X - x_R)^2$. However, the Pauling electronegativity values are based upon bond energy term data and not bond dissociation energies, so the discrepancy is not unexpected.

HYDROGEN BONDING IN THE AMINE HYDROHALIDES

I. GENERAL ASPECTS[1, 2]

BERNADETTE CHENON[3] AND C. SANDORFY

ABSTRACT

The infrared spectra of 17 amine hydrohalides have been measured in the solid state, in aqueous solutions, and in their conjugate amine. Their NH^+ stretching and scissoring bands are discussed.

The stretching bands of hydrogen-bonded aliphatic and aromatic amine hydrohalides fall into the same part of the spectrum. In the solid state, the hydrogen bonds are of type N^+—H- - -X^-. The aliphatic amine salts usually exhibit many sharp bands, while the aromatic amine salts have broad but composite bands. Tertiary amine salts show a hypsochromic shift in the order hydrochloride, hydrobromide, hydriodide; primary and secondary aliphatic amine salts show a slight bathochromic shift in the same order. Primary and secondary aromatic amine salts behave less regularly, although in most cases the shift is hypsochromic. These facts can be explained qualitatively by considering the charge distribution in the ionized amino groups and the contribution of electrostatic and delocalization effects to the energy of the hydrogen bonds.

The anharmonicity of the potential surface which causes the appearance of strong combination bands may lead to the broadening of bands or to many sharp bands. There is no parallelism in this latter case between shift and broadening of the bands.

The assignment of a strong band which appears in many cases near 2000 cm.$^{-1}$ is discussed.

The above-mentioned characteristic band shifting is absent in the spectra of aqueous solutions and it is concluded that in this case hydrogen bonding is not of the N^+—H- - -X^- but of the N^+—H- - -O type.

INTRODUCTION

The problem of hydrogen bonding has been the subject of hundreds of publications since the notion was introduced by Moore and Winmill in 1912 (1) and since the fundamental work of Bernal and Fowler in 1933 (2), and the field has been reviewed on several occasions (3, 4, 5, 6, 7).

The most conspicuous changes in the infrared spectrum of a compound due to hydrogen bonding are the shift of the X—H stretching bands to lower wave numbers, their increased intensity, their remarkable broadness, and their splitting to two or more components in many cases. Recently a comprehensive interpretation of these phenomena was attempted by Bratož and Hadži and we shall refer to their theory frequently below (8).

The wave mechanical aspect of the hydrogen-bond problem was reviewed by Coulson (9), who considers electrostatic, delocalization, repulsion, and dispersion force contributions to the energy of the hydrogen bond. This article too will be taken as one of the bases of our discussion.

Infrared spectra of amine salts exhibit all the main characteristics of spectra of hydrogen-bonded species to a large though varying degree. Electrostatic forces should be very strong in this case, since the proton donor and the proton acceptor are here both ions with net charges. Delocalization may also be an important factor, since the ionization potential of a halide ion is very low. As Lord and Merrifield have pointed out, the amine salts constitute a test case for every theory of hydrogen bonding (10). These authors as well as Rundle and Parasol (11) have already discussed a certain number of hydrohalide spectra.

We have measured the infrared spectra of the hydrochlorides, hydrobromides, and hydriodides of 17 amines among which primary, secondary, and tertiary aromatic and aliphatic amines were represented. The spectra were measured in the solid state, in aqueous solution, and in the conjugate amine if the latter was a liquid.

EXPERIMENTAL

A. Preparation of the Substances

Hydrochlorides

Hydrogen chloride gas was obtained by the action of sulphuric acid on dry sodium chloride. The gas was led through sulphuric acid and anhydrous calcium chloride and then into a solution of the amine in anhydrous ether. (One part by volume of amine in three parts of ether.)

Hydrobromides

Hydrogen bromide was obtained by the action of bromine on xylene. The gas was led through cold xylene and calcium sulphate and then into a solution of the amine in anhydrous ether.

Hydrochlorides and hydrobromides obtained by this method were filtered and washed with anhydrous ether. This was done in nitrogen atmosphere whenever the salt was hygroscopic. The products were recrystallized twice or three times from absolute alcohol by slow addition of anhydrous ether.

Hydriodides

Solutions of the amines in ether were extracted with 47% hydriodic acid in several successive operations. The latter was then evaporated under vacuum on a water bath. (This operation lasted at least two hours.) The product was washed several times in anhydrous ether, then dissolved in absolute alcohol, and recrystallized in the same way as the hydrochlorides and hydrobromides. Hydriodides are much less hygroscopic than the two other salts.

The preparation of the following compounds presented certain difficulties.

N-Methyl-diphenylamine Hydrochloride

The product was oily and crystallized by friction. This product was used although it was probably not of a high degree of purity.

The hydrochloride and hydrobromide of *N*,*N*-dimethylaniline were prepared at 0° C. Since they are very hygroscopic and somewhat unstable they were kept in a desiccator over potassium hydroxide and phosphorous pentoxide.

If prepared by the general methods given above the hydrochloride and the hydrobromide of tri-*n*-butylamine are non-recrystallizable oils. In order to prepare the hydrochloride the gas was led through a third desiccant and the pure amine was used instead of a solution in ether. The white product, very hygroscopic, was recrystallized under nitrogen atmosphere.

Pure ethylamine hydriodide was obtained from a commercial sample by heating it gently with potassium hydroxide bulbs. The gaseous amine was led into 47% hydriodic acid.

B. Measurement of the Spectra

The infrared spectra were measured on a Perkin–Elmer model 112 single beam double pass instrument with a sodium chloride prism.

The spectra were taken in three different media: in the solid state, in aqueous solution, and dissolved in the conjugate amine if the latter was a liquid. The cells were filled under nitrogen atmosphere whenever the compounds were hygroscopic.

The spectra of the solids were taken in a perfluorinated paraffin oil manufactured by Hooker-Electrochemical Co. of Niagara Falls, N.Y., and labelled "fluorolube T-45". Hydrogen atoms in this oil are replaced by fluorine and chlorine in the proportion 3:1. Nujol was unsuitable because of the importance of the CH_3 and CH_2 absorption region for the present study. In many cases, however, the spectra were measured in both nujol and fluorocarbon oil and the bands not covered by the nujol bands did not show any noticeable change. We shall assume, therefore, that the influence of the halogenated mulling agent on the spectra is negligible.

The KBr pellet technique was avoided, since under the pressure applied for preparing the pellets conditions for hydrogen bonding might change.

Amine hydrohalides are usually extremely soluble in water. In the present case concentration was as high as 400 mg./ml., that is, about 1 to 3 mole/liter. The salts of diphenylamine are insoluble in water and those of *N*-methyl-diphenylamine undergo decomposition in water.

With solutions of the salts in their amine the concentration was about 100 mg./ml., that is, of the order of 0.3 to 1 mole/liter.

The compounds not listed in Table III are either unstable or insufficiently soluble in their amine for the purpose of measuring their infrared spectra.

In many cases, when a saturated solution of a salt in its amine was prepared, a solid smear resulted. In other cases such a smear was prepared by using the conjugate amine as a mulling agent. This gave very intense spectra and was used for the determination of the NH_3^+ and NH_2^+ scissoring bands, which are often weak.

We have not attempted at this stage to make quantitative measurements of intensity or extinction coefficients.

RESULTS

A. Aliphatic Compounds

I. Spectra in the Solid State (Fluorocarbon Oil)

Stretching bands due to NH_2 and NH groups between 3500 and 3100 cm.$^{-1}$ have completely disappeared. (Table I. Strong bands are indicated by the use of italics.)

Stretching bands due to the protonated amino groups appear between 2800 and 2300 cm.$^{-1}$ (first region). In addition, prominent bands appear in some salts near 2000 cm.$^{-1}$ (second region) and the scissoring bands are in the 1600–1500 cm.$^{-1}$ region (third region). We shall not be concerned in this paper with bands at lower frequencies.

First Region

Primary aliphatic amine hydrohalides (Figs.* 1, 2, 3, 4) give a series of usually well-separated, sharp, or medium broad bands in the first region. Their number varies between four and nine. In certain instances, notably tertiary butylamine and cyclohexylamine salts, these bands are remarkably sharp and well resolved. (Table I. Shoulders are not listed in the tables. Thus the number of bands is often higher than may appear from the tables. See the figures.)

There are probably more bands which coincide with the CH_3 and CH_2 bands between 3000 and 2800 cm.$^{-1}$ and which we cannot separate out in the spectra reported here.

**The region occupied by the atmospheric CO_2 band is left empty on the figures. In Fig. 18, it is approximately subtracted from the spectrum.*

Work is going on in this laboratory in order to measure these under higher resolution.

There is, in general, a slight bathochromic shift in the order hydrochloride, hydrobromide, hydriodide, the latter having the lowest frequency. The shift amounts to 10 to 50 cm.$^{-1}$ but it could not be measured more accurately with the sodium chloride prism which was used. Band overlapping often makes it difficult to follow a band from one salt to another. The slight bathochromic shift in the above-mentioned order seems to be, however, the general rule.

Secondary aliphatic amine hydrohalides show essentially the same phenomena as the primary ones, that is, many bands (perhaps somewhat less well-resolved) between 2800 and 2400 cm.$^{-1}$ with a slight bathochromic shift from hydrochloride to hydrobromide to hydriodide (Figs. 5 and 6).

Tertiary aliphatic amine hydrohalides behave differently (Figs. 7 and 8). We find four to seven bands which are fairly well resolved in the case of triethylamine hydrohalides but less well resolved in tri-*n*-butylamine hydrohalides. Here there is a hypsochromic effect in the order hydrochloride, hydrobromide, hydriodide, and the bands become sharper in the same order. The shift is about 150 cm.$^{-1}$ from one halide to the next in the series in the case of the tri-*n*-butylamine salts and about 80 cm.$^{-1}$ for triethylamine salts. (It is not easy to see from the tables the relation between the bands of one salt and another in the series when large shifts occur. Therefore we have marked by an asterisk the approximate "center of gravity" of the bands.)

Second Region

Most hydrohalides of primary amines have one or two strong bands between 2200 and 1800 cm.$^{-1}$. These bands are strong and fairly sharp, their intensity diminishing from hydrochloride to hydrobromide to hydriodide. There is a pronounced bathochromic shift along the halide series in the same order, although in this region the shift is somewhat greater than the corresponding shift for the bands of the first region, and amounts to 30–100 cm.$^{-1}$.

In *n*-butylamine and *sec*-butylamine hydrohalides these bands are weak.

The only band we find in this area for hydrohalides of secondary and tertiary amines is for piperidine, which has three weak bands in the second region.

Third Region

In this part of the spectrum where the scissoring bands are expected we find two bands for hydrohalides of primary amines near 1600 cm.$^{-1}$ and 1510 cm.$^{-1}$. There is a regular bathochromic shift of 10 to 20 cm.$^{-1}$ in going from hydrochloride to hydrobromide and from hydrobromide to hydriodide.

Hydrohalides of secondary amines show one band near 1590 cm.$^{-1}$ with a shift in the same sense as for the primary amines, but greater in going from hydrobromide to hydriodide.

There are bands in this area for some tertiary compounds but they are unlikely to be of similar origin.

II. Spectra in Aqueous Solutions

It is important to point out that there is practically no difference between the spectra of hydrochlorides, hydrobromides, and hydriodides in aqueous solution. There is some variation of frequency in the cases of ethylamine, piperidine, and tri-*n*-butylamine but it is irregular. In all other cases the three give virtually identical spectra (Table II).

Because of the strong water absorption only the lower bands of the first region may be observed. They are somewhat broader than in the solid state but not very broad. These

bands are always located above 2500 cm.$^{-1}$ (except for the bands for piperidine), that is, at higher frequencies than for the solids.

There is a water absorption region at about 2125 cm.$^{-1}$ and this becomes stronger when the salts are dissolved in water so the latter may have a band there.

III. Spectra of Amine Salts Dissolved in Their Amine (*Table III*)

These solutions exhibit one or two fairly sharp and strong bands between 2700 and 2450 cm.$^{-1}$. In the case of the three primary amines the bands are at about the same place as in aqueous solution; in the case of di-*n*-butylamine amine they are closer to those in the solid. The slight bathochromic shift observed in solid becomes irregular. The bands are at about the same place with slight variations. None of the tertiary aliphatic amine salts is sufficiently soluble in its amine.

There are bands, too, between 2100 and 2000 cm.$^{-1}$ but they are weak and broad. The other parts of these spectra cannot be used because of heavy amine absorption.

IV. Spectra Taken as Solid Smears of the Salts in Their Amine (Table IV)

There is a close resemblance between these spectra and the corresponding spectra of the pure salt in the solid phase. This resemblance includes the location of the bands and the significant hypsochromic shifts in the tertiary amine salts and other aromatic salts; however, the small bathochromic shift in primary and secondary aliphatic amine salts loses its regularity.

This general similarity again shows that the fluorocarbon oil used as a mulling agent for the measure of the spectra in solid state has no significant effect on the spectra.

B. AROMATIC COMPOUNDS

I. Spectra in the Solid State

First Region

In the primary and secondary amine hydrohalides two broad bands are observed (Table I) (Figs. 9 and 10). These are in the same general part of the spectrum as the more numerous bands of the aliphatic compounds. It is, however, quite clear from the appearance of the bands that none of them is simple. On the contrary, a great number of peaks and inflections shows that they are composed of several bands superimposed.

In the tertiary amine hydrohalides (Figs. 11, 12, 13) there is only one broad band which is quite clearly composite as well. This band shifts towards higher frequencies by about 100 to 200 cm.$^{-1}$ going from hydrochloride to hydrobromide to hydriodide; thus it moves in the same direction as the aliphatic tertiary amine salts. The broadness of the bands diminishes in the same order.

The bathochromic shift described previously in the aliphatic primary and secondary amine hydrohalides in the series hydrochloride, hydrobromide, and hydriodide is not observed in the primary and secondary aromatic amine salts; there is instead a hypsochromic shift. For aniline the shift is hypsochromic by about 40 cm.$^{-1}$ but only the band at higher frequency undergoes the shift. The hypsochromic effect is well pronounced in the case of diphenylamine salts (by about 100 cm.$^{-1}$ in each case) and there are other weaker bands around the main band. In the case of *N*-methylaniline the hypsochromic

shift is large between hydrochloride and hydrobromide but negligible between hydrobromide and hydriodide. There are weaker bands here too.

The general tendency is thus for the hypsochromic shift with aromatic compounds.

Second Region

There are always weak overtone and combination bands between 2000 and 1600 cm.$^{-1}$ in the spectra of aromatic compounds (12) and it is necessary to distinguish from these the bands which are due to NH^+ absorption.

Hydrochlorides of aniline and pyridine show two bands between 2100 and 2000 cm.$^{-1}$ which are stronger than bands in the same region of the respective amine. The three salts of diphenylamine give two bands whose intensity diminishes from hydrochloride to hydrobromide and from hydrobromide to hydriodide and which shift towards lower frequencies in the same order.

The other compounds have no band in this region.

Third Region

Two well-known vibrations of the benzene nucleus appear at almost exactly the place where the NH_3^+ and NH_2^+ scissoring vibrations should be and thus the observation of the latter is difficult (Table I).

Aniline hydrohalides have a band near 1565 cm.$^{-1}$ and another at 1518 cm.$^{-1}$. Secondary amine hydrohalides have a band between 1580 and 1540 cm.$^{-1}$. These bands all shift bathochromically in going from hydrochloride to hydrobromide to hydriodide.

The tertiary amine salts have no band in this region.

For personal use only.

II. Spectra of Aqueous Solutions

Hydrohalides of aniline, *N*-methylaniline, *N*,*N*-dimethylaniline, and pyridine are well soluble in water. The one band which can be observed is always higher than 2650 cm.$^{-1}$, higher than in the solid, and higher also than the corresponding bands of the aliphatic compounds (Table II).

III. Spectra of Hydrohalides Dissolved in Their Amine

Salts of aniline, *N*-methylaniline, and pyridine could be studied under these conditions. In the case of aniline the bands are 40 to 50 cm.$^{-1}$ higher than in the solid phase (Table III). The hypsochromic shift is slight in the case of the aniline salts, and also in the case of *N*-methylaniline salts but is quite pronounced in the pyridine salts.

IV. Spectra of the Hydrohalides in Solid Smears in Their Amine (Table V)

As is the case with the aliphatic amines under the same conditions, these spectra resemble those of the corresponding salts in the solid phase. The hypsochromic effect in the series hydrochloride to hydriodide is clearly observed for the tertiary compounds. However for aniline only the first band is hypsochromic and the second one is slightly bathochromic, for *N*-methylaniline the first band is stationary and the second is bathochromic.

The scissoring bands show a regular bathochromic shift. Heacock and Marion (13) have shown that the scissoring bands are of appreciable value for identification purposes and they gave data for many amines, usually of more complicated structure. We have tabulated further data in Tables I, IV, and V.

DISCUSSION

Number and Appearance of Bands

There is a formal analogy between $-CH_3$, $\rangle CH_2$, and $\rightarrow CH$ groups on one hand and the $-NH_3^+$, $\rangle NH_2^+$, $\rightarrow NH^+$ groups on the other hand.

CH_3 groups have an antisymmetric and a symmetric stretching vibration, the former being degenerate. CH_2 groups have two non-degenerate stretching vibrations, and CH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

groups have one (14). Consequently we might expect two stretching bands for NH_3^+ or three if the C_{3v} symmetry is diminished and the degeneracy removed. This removal of the degeneracy might be caused by lower symmetry of the crystal lattice. For NH_2^+ we expect two stretching bands and for NH^+ one.

Unfortunately the free NH_3^+, NH_2^+, and NH^+ stretching frequencies are not known because of the difficulty of dissolving amine salts in non-polar solvents. Even if this were possible association by hydrogen bonding could still persist. Since the introduction of a positive charge distributed between the nitrogen and the hydrogens must weaken the N–H links we can estimate that these stretching frequencies would fall in the range 3200–3000 cm.$^{-1}$. In the solid state and in the very concentrated solutions all hydrogens should participate in hydrogen bonding except, perhaps, in a few cases of steric hindrance. This is actually what Donohue found by X-ray methods in the case of some complex amine salts (15).

While for amines the shift due to hydrogen bonding amounts to less than 100 cm.$^{-1}$ (16, 17) for their hydrohalides the shift is several hundred wave numbers showing the strength of the hydrogen bonds formed by the latter.

The main point is that we do not find three, two, or one bands, as expected on grounds of the above-mentioned formal analogy, but many more. Only in the case of some of the aromatic amine hydrohalides, such as the aniline and pyridine salts, does the rule seem to be followed; in these two compounds we find, respectively, two and one broad regions of absorption, each region, however, being composed of many bands.

In general, in the amine hydrohalides examined, there is no direct relationship between the number of bands in the first region and the number of hydrogen atoms linked to the nitrogen. It is apparent furthermore that with the aromatic compounds the bands are usually broad, while with aliphatic compounds they are usually sharp.

Although aromatic compounds give broad bands, multiple peaks and inflections reveal that they are composed of about as many component bands as we find for aliphatic compounds.

Plumb and Hornig (18) investigated ammonium fluoride crystals by both infrared and X-ray methods at room and liquid-air temperatures. They reported that "the most striking features of the NH_4F spectrum are the sharp lines and the large number of bands, shoulders, and general spectral detail" in the spectrum, especially in the low temperature spectrum. Between 3300 and 2500 cm.$^{-1}$ they found 11 peaks. The NH_4F molecule has a high symmetry, the true site symmetry being C_{3v}, but as far as the ammonium ion and its nearest neighbors are concerned the arrangement is tetrahedral (T_d). Long range interactions or coupling between the various ammonium ions may lower the symmetry but these effects are probably small as the latter are separated by a heavy atom. Thus Plumb and Hornig conclude that most of the bands are combination bands.

Amine hydrohalides may be regarded as substituted derivatives of ammonium salts. For most of them the symmetry in the crystal is probably lower and thus we might expect the degenerate stretching vibration to split in the case of primary amine salts. This, however, would not explain the many bands observed.

The striking resemblance between the spectra taken in the solid phase and in a smear in the conjugate amine of the hydrohalide, where crystallization would be at most partial and where there would be a high degree of disorder, shows that the crystal structure has generally little to do with the appearance of a great number of bands in the NH^+ stretching region. It seems likely therefore, that most of these bands are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

combinations. This is in accordance with observations and suggestions of Plumb and Hornig (18) and Bratož and Hadži (8).

We have to answer, however, the following two questions:

1. Why are the bands well separated for aliphatic amine salts and melted together for aromatic amine salts?
2. What are the strong bands near 2000 cm.$^{-1}$ (second region) which appear in many cases?

The broadness of the bands is probably the key problem of theories of hydrogen bonding. The first views on this subject were that it arises from the broadening of the energy levels by intermolecular interaction (5, 19).

This early interpretation was later recognized as insufficient. Predissociation theories have been proposed by Stepanov (20, 21) and by Cannon (22). More recently it has been suggested (Lippincott and Schroeder (23) and Batuev (24)) that movement of the end atoms may constantly vary the potential under which the vibrations of the bonded hydrogen occur, and that this could be the cause of the broadening of the bands.

The unusual anharmonicity of vibrations involving hydrogen bonding has been recognized for a long time. In particular, the pronounced anharmonicity of the bands of amine hydrohalides was pointed out by Lord and Merrifield (10).

Bratož and Hadži (8) have made anharmonicity the central phenomenon in their attempt to interpret by a single theory all the characteristic properties of hydrogen bonds. According to them, intermolecular interactions would account for the moderate broadness of weakly bonded stretching bands and that of the bending bands, but to explain the large bathochromic shift and great broadness found with strong hydrogen bonds we must suppose that the part of the potential surface relevant to the stretching vibrations is highly anharmonic. This anharmonicity would account for the unusual strength of the combination bands. Bratož and Hadži have shown, too, that the effect of the displacement of the two heavy end atoms is precisely to increase anharmonicity.

In the present case there does not seem to be any reason to believe that the displacement of the end atoms affects the band width differently in the aromatic and aliphatic cases.

The fact that the absorption in the first region for aliphatic amine salts consists of a series of well-separated bands, while in the aromatic compounds the bands are broad and composite, may be connected with the availability and frequency of vibrations which combine with the NH^+ stretching vibrations. The width of the individual bands may then be related to the extent of intermolecular interactions. We should like to point out that Stark effects acting on each ion due to the electric field created by the others must be an important factor here.

It is generally believed that strong hydrogen bonds give large shifts and broad bands and that the two go together. Plumb and Hornig have pointed out (18), however, that this is not necessarily so, although it is usually the case. Our results show quite clearly that shift and broadness do not necessarily go together. Aromatics and aliphatics give bands in the same part of the spectrum but the former are broad and the latter sharp.

We may conclude that pronounced anharmonicity, which gives unusual strength to combination bands, need not lead to very broad bands; it can lead also to a great number of sharp bands. This depends on the frequencies of the vibrations combining with the NH^+ stretching vibrations but also on the width of the individual bands.

Thus we have to explain why, as seems to be the case, band broadening is greater in the case of aromatics than in the case of aliphatics. Intermolecular influences which are mainly responsible for it are unlikely to differ much between the two types. One reason may be the different charge distribution which would give more positive charge to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

hydrogen in the aromatic and tertiary cases (see the next section). Disordering in the crystal structure may be another reason for band broadening.

If we suppose that the potential surface of a hydrogen bond has two minima (see text below) and if we consider the stretching vibration as the beginning of the dissociation of a bond followed by the formation of another, we can treat this vibration as a chemical reaction and speak of an activation energy corresponding to the maximum which separates the two minima. This maximum should be lower for aromatic derivatives because for them the increasing of the N—H distance is linked with a partial return to trigonal hybridization and coplanarity and thus to a relative gain of stability, hence in this situation the bond would be more sensitive to intermolecular influences. This argument may be valid even if there are not two pronounced minima in the potential surface but only one minimum and one point of inflection as is probably the case. As in a chemical reaction there is no direct relationship between activation energy and energy of a reaction, so in the case of hydrogen bonding broadness and shift may not be directly related even if both depend on the anharmonicity of the potential surface.

Location of the Bands and Band Shifts

As we saw in the previous paragraph the hydrogen-bonded NH^+ frequencies fall into the same general spectral area for both aromatic and aliphatic amine salts. This is somewhat astonishing in view of the fact that aliphatic amines are strong basis and aromatic amines are weak basis. This is a fact we have to explain. Furthermore, as we have mentioned above, when we go from hydrochloride to hydrobromide to hydriodide we observe a significant hypsochromic shift for tertiary compounds, whether aliphatic or aromatic. For primary and secondary amine salts there is a somewhat less systematic hypsochromic shift for the aromatic compounds and a slight but systematic bathochromic shift for the aliphatic ones.

The existence of these regular shifts is a proof that the hydrogen bonds are actually of the N^+—H- - -X^- type. This applies to the solids and solutions and smears in the conjugate amines.

There is, furthermore, the appearance of the strong band (or bands) near 2000 in the case of most aliphatic primary amine salts as well as those of piperidine and pyridine. This band was first described by Randall, Fuson, Fowler, and Dangl (25) in the case of amino-acids and amino-acid hydrochlorides, and it was mentioned also by Thompson, Nicholson, and Short (26). It was clear to these authors that this band must be related to the protonated amino groups. Its assignment remained, however, an open question.

In addition to the difference in basicity between aliphatic and aromatic amines there is another simple fact we must take into account: in tertiary amine salts there are as many hydrogens as halide ions but in secondary and primary ones there are twice and three times as many, respectively. This fact may be useful especially in the absence of a knowledge of the crystal structure. It is very likely that with the secondary and primary amine hydrohalides more than one hydrogen is bonded to one halide ion.

It is generally considered that the energy of a hydrogen band comes from four different sources: attractive electrostatic forces, delocalization energy, dispersion forces, and repulsion between the interpenetrating electron clouds.

This fragmentation of the energy is of course somewhat artificial. The various contributions could correspond to the influence on the total energy of different fragments of the potential function which we find in the Hamiltonian for the system and do not represent separate physical phenomena. This language is, however, convenient for a discussion of hydrogen bonds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

For example, Lippincott and Schroeder (23, 27) and Finch and Lippincott (28) have shown that a satisfactory potential function for hydrogen-bonded systems can be set up by taking the sum of the above-mentioned contributions, and Coulson and Danielsson (29, 30) and Tsubomura (31) have introduced the notion of ionic and covalent character of hydrogen bonds. In his wave mechanical treatment of the O—H- - -O system Tsubomura considered the following five valence bond structures:

A O—H- - -O
B O^- H^+- - -O
C O^+ H^-- - -O
D O^- H—O^+
E O H^- O^+

Structures A, B, and C represent almost entirely the electrostatic effect. Structures D and E imply a charge transfer, thus a delocalization effect. Their weight, which is insignificant at large distance, increases rapidly (to as high as 11%) as the distance becomes shorter, as during a stretching vibration. Thus delocalization would explain a part of the energy of the hydrogen bond and a good part of the intensity of the related vibrational band.

In the case of amine hydrohalides we may write the following set of structures in analogy with those of Tsubomura (X = Cl, Br, or I):

A N^+—H- - -X^-
B N H^+- - -X^-
C N^{++} H^-- - -X^-
D N H—X
E N^+ H^- X

If we wish to consider this set of structures as a basis for a valence-bond calculation it is necessary that the nuclear skeleton and also the internuclear distances should be approximately the same.

Here structures B and D would represent the free amine and the acid HX, if the H—X distance was allowed to readjust to its normal value.

Let us assume that the distances are the same for all structures and that it is justified to make a qualitative valence-bond argument.

Structure A has certainly by far the highest weight. With its two opposite charges it should imply a much stronger hydrogen bond than structure A in the case of the O—H- - -O system.

If we wish to compare the hydrohalides of aliphatic and aromatic amines we, of course, have to consider the entire molecules, not only the N^+—H- - -X^- portion.

In the aromatic case the formation of the hydrohalide stabilizes the system but little because of the loss of the resonance energy due to conjugation between the approximately $2p_z$ lone pair of the nitrogen and the π-electrons of the benzene ring. The nitrogen which had approximately trigonal hybridization in the free amine will have approximately tetrahedral hybridization in the salt. Thus the energy of structure A will be relatively high. In the case of aliphatic amines there is no similar loss of resonance energy and structure A is relatively more stable.

For the aromatic hydrohalides the energies of structures B and D are stabilized relative to the energy of structure A, since they do not involve a loss of resonance energy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

In the aliphatic compounds, on the other hand, this stabilization of B and D relative to A will not occur, so that B and D will contribute less to the wave function for the hydrogen-bonded species in the aliphatic case than in the aromatic case.

To sum up, for the aliphatic amine salts structure A involves a stronger hydrogen bond and the latter is overwhelmingly electrostatic in character. Structures B and D are probably not negligible but much less important. For the aromatic salts, A involves a weaker hydrogen bond but resonance with B and D increases its stability so that the bonds are of about the same strength in both cases and the corresponding infrared NH^+ stretching bands are at about the same part of the spectrum. In the aromatic case appreciable delocalization should occur because of structure D. We have supposed in this argument that structure C is unimportant. Additional delocalization may arise because of structure E.

The qualitative valence–bond argument given above may be stated in a more chemical manner. For the aliphatic amine hydrohalides, which are strong basis, the attachment of the proton to the nitrogen can be considered as complete and the positive charge centered on the nitrogen. Therefore structure A is a good approximate representation of the system.

On the other hand, for aromatic amine salts, which arise from weak basis, the proton may not be firmly bound to the nitrogen and the positive charge may be divided between the nitrogen and the hydrogen. This implies greater weight for B and D with more delocalization.

We have now to explain the characteristic shifts from Cl^- to Br^- to I^- described in the previous section.

Our reasoning with the use of structures A, B, and D applies strictly only to tertiary amine hydrohalides where there is one hydrogen for every halide ion. Structure B should be relatively more important for them, while for primary and secondary amine salts we must suppose that structure B is less important because the positive charge is distributed among the nitrogen and three or two hydrogens. Now structure B should be more important in hydrochlorides than in hydrobromides and hydriodides, because HCl has a higher ionic character in its valence–bond description than HBr and HI (3). This would explain the large hypsochromic shift observed in this order with both aromatic and aliphatic tertiary amine hydrohalides. This tendency may be accentuated in some cases by steric effects.

Since the order of electroaffinities for the halogens is (32)

Cl	3.78 ev.,
Br	3.54 ev.,
I	3.24 ev.,

structure D, which implies delocalization, should be most important for hydriodides. Thus, whether we will observe a bathochromic or a hypsochromic shift in the series hydrochloride to hydriodide will depend upon the relative weights of structures B and D in the wave function. With tertiary amine hydrohalides we have a hypsochromic shift because structure B always has a weight which is appreciable and greater than D. This gives the strongest hydrogen bond with Cl^-. With primary and secondary *aromatic* amine hydrohalides structure B is still important (as it does not involve a loss of resonance energy) but less so than for tertiary amine salts because the fraction of positive charge on one hydrogen will be less. Therefore we still usually obtain hypsochromic shifts,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

although less systematically, because of the more comparable weights of B and D. With primary and secondary *aliphatic* amine hydrohalides structure A predominates, while B and D are less important than in the aromatic case. D is more important than B, since the fraction of positive charge on one hydrogen is very small. This gives a slight bathochromic shift, the strongest hydrogen bond being formed with I^-.

As we have seen, the regularity of the slight bathochromic shift is lost in solution or smear in the conjugate amine. This is understandable too from the above argument, since the relative weights of structures B and D may be sensitive to environment.

Assignment of the Band near 2000 cm.$^{-1}$

Our next problem is the assignment of the band in the 2000 cm.$^{-1}$ area.

The following interpretations may be considered:

1. An unusually strong combination band which is a sum of the scissoring frequency and a lower internal or lattice frequency.

2. An unusually strong difference band between a stretching band and some low-lying frequency.

3. One could argue that the antisymmetric and symmetric stretching vibrations may be very far apart, the band near 2000 cm.$^{-1}$ corresponding to the latter.

4. We could assume a double minimum potential surface and a resulting splitting of the stretching bands (8, 33, 34).

There might be two reasons why the potential surface should exhibit two minima. The one would be a coupling of two (or three) vibrations where two (or three) hydrogen bonds end at the same halide ion. The other would be due to the fact that, as Plumb and Hornig (18) pointed out, there must be a point of relative stability when the hydrogen approaches the halide ion during the vibration, as this vibration can be considered the beginning of dissociation

$$R{-}NH_3^+X^- \rightleftarrows NH_3 + HX, \text{ etc.}$$

The following facts are relevant. The band at 2000 cm.$^{-1}$ always shifts bathochromically the hydriodides giving the lowest frequencies and the shift is about twice as large in most cases as for the upper bands.

We do not find this band with tertiary amine hydrohalides. The only exception is pyridine.

The band is most prominent in the spectra of aliphatic primary amines and it is interesting to note that it seems to be strong when the upper bands are well resolved, sharp bands. We find it too, however, in the spectra of piperidine, diphenylamine, pyridine, and aniline salts, but in piperidine salts it is much weaker. In pyridine and aniline it is absent or weak except for the hydrochloride. There may be some doubt whether in the latter cases the band is of the same origin. In diphenylamine salts the bands in this part of the spectrum are strong and behave like the corresponding bands in the case of the aliphatic primary amine salts.

It is usually not a single band. One can distinguish shoulders on the band contour or find two or more bands.

Now it is interesting that this band exhibits always downward shift in going from hydrochloride to hydriodide, even if the upper bands shift in the opposite direction as in the case of the diphenylamine salts. The scissoring bands behave in the same way. This would favor an interpretation of this band as an unusually strong combination of the scissoring band and a vibration which should have a frequency of about 400 cm.$^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Against this assignment is the fact that, as Bratož and Hadži have pointed out, the part of the potential surface involving the scissoring vibration is only moderately anharmonic. It is possible, however, that the lower frequency may be very anharmonic. This assignment is compatible with the fact that tertiary amine salts which do not have a scissoring band near 1600 cm.$^{-1}$ do not have the band near 2000 cm.$^{-1}$ either. In some of the aromatic cases (like pyridine or aniline) the supposed lower frequency may combine with benzene ring vibrations, which are always present in the same part of the spectrum, instead of with the NH_2^+ or NH_3^+ scissoring vibration.

The second interpretation (difference band) is more likely from the point of view of anharmonicity; however we must suppose again that the lower vibration is also very anharmonic if we hope to explain the fact that the band near 2000 cm.$^{-1}$ is usually much stronger than any of the higher bands. In the most typical cases, for instance that of tertiary butylamine and cyclohexylamine salts, the frequencies of the upper bands are nearly equidistant, the spacing being of the order of 100 cm.$^{-1}$. Thus these would be difference bands between the "real" stretching frequency and the overtones of a vibration of frequency 100 cm.$^{-1}$, and the band near 2000 cm.$^{-1}$ would be a difference band between the former and some very anharmonic vibration of frequency 800–700 cm.$^{-1}$. This interpretation offers no obvious reason for the absence of the band in the case of tertiary amine salts unless the lower vibration is linked to the presence of two or three hydrogens on the nitrogen atom, nor does it explain its characteristic shifting.

The third interpretation, that the upper bands are the antisymmetrical stretching band and combination bands and that the band near 2000 cm.$^{-1}$ is the symmetrical stretching band, would explain the observed strength of the latter band, since it would now be a fundamental; however it seems unlikely in view of the large separation between the two fundamentals. This separation is very large with cumulative double-bond systems but these bear little resemblance to the present case.

The general appearance of the spectra would indicate strongly an interpretation by a potential surface having two minima. The assumption of two minima because of the coupling of two of more N^+—H vibrations through a common halide ion is very unlikely because of the large weight of the latter. The other reason for the two minima (see 4 above) is more likely but this would not explain such a large splitting and it would also not explain either the absence of the band in the spectra of tertiary amine salts or the characteristic shifting of the band near 2000 cm.$^{-1}$.

More work is clearly needed but in our opinion and at the present stage the first assignment, that is, a combination between the scissoring band and a very anharmonic band near 400 cm.$^{-1}$, seems to be the most likely.

Aqueous Solutions

The spectra taken in aqueous solutions give bands which have higher frequencies than those taken in solid phase. The difference amounts to about 50–100 cm.$^{-1}$ (Table II). The case of pyridine salts seems to be exceptional; the higher frequency band lies near 2400 cm.$^{-1}$ in solid and near 2850 cm.$^{-1}$ in aqueous solution and they are very broad in both media.

It is even more important that in every case hydrochlorides, hydrobromides, and hydriodides have their bands at about the same place and we do not find the characteristic shifts found in other media. The slight variations observed in certain cases do not show any regularity.

We conclude from this that in aqueous solutions the hydrogen bonds are no longer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

of the N^+—H- - -X^- type but of the N^+—H- - -O type. The water molecules might form hydrogen bonds of this type or with the halide ions or between themselves, and we can imagine other more complicated cases in these very concentrated solutions.

CONCLUSIONS

The above discussion refers to the general features we observed. Almost every amine and its salts would deserve a special study and we hope to discuss some related special problems in a second publication. This applies in particular to certain observations on amine solutions of the hydrohalides. The following facts, however, seem to be well established.

The location of the NH^+ stretching bands of the hydrogen-bonded amine hydrohalides at about the same part of the infrared spectrum for both aliphatic and aromatic molecules indicates that the energy of these hydrogen bonds comes mainly from electrostatic forces but that the charge distribution is different for the two categories and that delocalization makes a greater contribution to hydrogen bond energy in the case of the aromatic hydrohalides than in the case of the aliphatic hydrohalides.

The same factors allow a consistent qualitative explanation of regular hypsochromic or bathochromic shifts in the series hydrochloride → hydrobromide → hydriodide and of differences observed in the shifting of primary, secondary, and tertiary amine salts.

Our observations confirm the idea that the broadness of the bands is related to anharmonicity but they show too that anharmonicity might lead to broad regions of absorption and to a series of sharp bands as well, and also that shift and broadness do not necessarily go together.

Crystallographic studies would be highly desirable in order to supplement spectroscopic evidence related to the problem of hydrogen bonding in the case of amine hydrohalides.

RÉSUMÉ

Les spectres infrarouges des sels halogènes de dix-sept amines ont été mesurés à l'état solide, en solution aqueuse et en solution à l'amine même. Les vibrations de valence et de déformation des groupements NH_3^+, NH_2^+, NH^+ ont été étudiées.

Les vibrations de valence des sels des amines aliphatiques et aromatiques qui prennent part dans des associations par liaison hydrogène se trouvent dans la même partie du spectre. Les liaisons hydrogène sont du type N^+—H- - -X^-. Les composés aliphatiques ont généralement plusieurs bandes minces tandis que les composés aromatiques possèdent de vastes régions d'absorption composées de plusieurs bandes. Chez les sels des amines tertiaires les bandes se déplacent vers les ondes courtes dans l'ordre: chlorhydrate, bromhydrate, iodhydrate; chez les sels des amines aliphatiques primaires et secondaires les bandes se déplacent légerèment vers les grandes ondes. Chez les sels des amines aromatiques primaires et secondaires on observe moins de régularité mais le déplacement s'effectue généralement vers les ondes courtes. Ces faits s'expliquent qualitativement au moins si l'on prend en considération la répartition des charges dans les groupements amino ionisés, et les contributions des effets électrostatique et de délocalisation à l'énergie des liaisons hydrogène.

L'anharmonicité de la surface de potentiel qui fait apparaître des tons de combinaison forts peut conduire à l'élargissement des bandes ou à beaucoup de bandes minces. La grandeur du déplacement et l'élargissement des bandes ne vont pas toujours de pair ici.

On discute l'attribution d'une bande forte qu'on trouve près de 2000 $cm.^{-1}$ en beaucoup de cas.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Les déplacements caractéristiques observés en solide ne se reproduisent pas en solution aqueuse. On en conclut que là la liaison hydrogène n'est pas du type N^+—H- - -X^- mais du type N^+—H- - -O.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Prof. Lucien Piché, Head of this Department, for his constant interest in this work.

We wish to thank Prof. D. Patterson and Prof. H. Favre for many helpful discussions.

Mrs. N. Iliesco contributed to this work at its early stage, a fact that we would like to acknowledge here.

Special thanks are due to Dr. K. Lenore McEwen for helpful discussions and help in preparation of the manuscript.

We acknowledge, too, a stimulating discussion with Dr. D. S. McClure, from Radio Corporation of America, Princeton, New Jersey.

The National Research Council of Canada and Imperial Oil Limited of Sarnia supported our research work with grants. We should like to express to them our appreciation.

NOTES

THE POLAROGRAPHIC REDUCTION OF DIAZOTIZED AROMATIC AMINES*

R. M. ELOFSON

INTRODUCTION

The polarographic activity of diazotized aromatic amines was first reported by Elofson and Mecherly (5), who made use of it in amperometric titrations. Later Elofson and co-workers (6) reported on the polarography of diazotized amines and employed their limiting currents for analytical purposes. By comparing the total wave height with that for hydroquinone, which should have a nearly identical diffusion coefficient, it was concluded that four electrons were involved in the over-all reduction. Further support for this conclusion was cited in the fact that phenylhydrazine is produced by electrolytic reduction of diazotized amines (8) at a mercury electrode. It was therefore concluded that the net reduction occurring at a dropping mercury electrode could be described by [1].

$$ArN_2^+ + 4H^+ + 4e \rightarrow ArNHNH_3^+ \qquad [1]$$

Almost simultaneously, Atkinson and co-workers (1) reported on the detailed polarographic reduction of diazotized amines, finding that the reduction took place in two main steps, one at potentials below -0.3 volts vs. S.C.E. and a larger wave at more negative potentials. From the results of coulometric analyses performed at stirred mercury pool electrodes they concluded that only one electron was involved irrespective of whether reduction took place at the first or second plateau. No material other than phenylmercuric chloride and diphenylmercury could be isolated during the coulometric analysis. In a subsequent paper, Atkinson *et al.* (2) reported that two electrons were involved when coulometric analyses were performed at the second plateau.

Kochi (7), in a later investigation, corroborated the results of Atkinson, although he did not specify the pH at which his measurements were made.

In view of the above discrepancies and the difficulty in reconciling markedly different diffusion coefficients for diazonium ions and for hydroquinone, it was deemed desirable to reinvestigate this problem.

EXPERIMENTAL

The polarograms described in this paper were obtained with a Leeds and Northrup Electrochemograph, type E. A saturated calomel electrode was used as an anode. The temperature of the electrolysis cell was maintained at 0° C. to 2° C. At $h = 60$ cm. the capillary constants were $m = 2.62$ mg./sec. in air and $t = 3.63$ seconds at zero applied potential in 0.2 N HCl.

RESULTS

In their first paper, Elofson and Mecherly (5) noted that the lower wave was not proportional to concentration above about 4×10^{-4} M. Some results of a detailed investigation concerned with the effect of concentration of a diazotized amine in acid solution on its polarograms are illustrated in Figs. 1 and 2. It is evident that the total

Contribution No. 70 from the Research Council of Alberta, Edmonton, Alberta. Prepared for presentation at the Annual Conference of the Chemical Institute of Canada at Vancouver in June 1957.

current was proportional to the concentration to at least 2.8×10^{-3} M. On the other hand, the limiting current for the first wave reaches a constant value at a diazotized amine concentration of above 1×10^{-3} M. Very similar results were obtained in solutions buffered to pH 6.

The data in Table I illustrate the effect of varying height of the mercury column on the limiting currents. It can be seen that while the total current is very nearly proportional to the square root of the height, the magnitude of the lower wave is directly proportional to the height. This observation and the fact that the lower wave reaches a constant value indicates that the first wave is an adsorption wave. The second is diffusion controlled (4, 9).

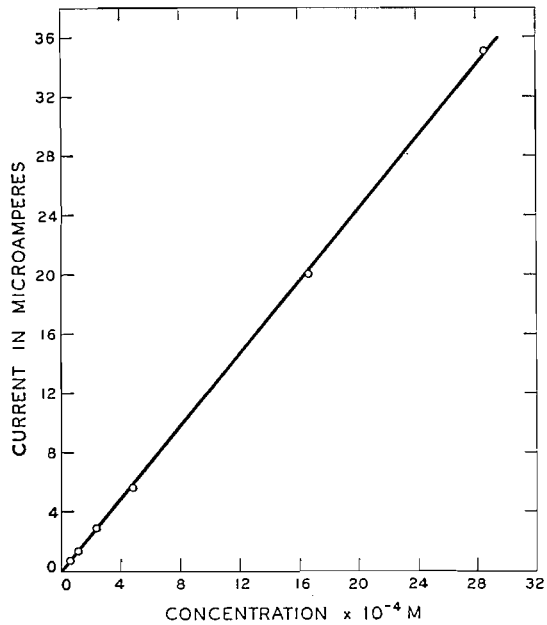

FIG. 1. Relation between total limiting current and concentration of *p*-anisidine diazo in 0.2 *N* hydrochloric acid.

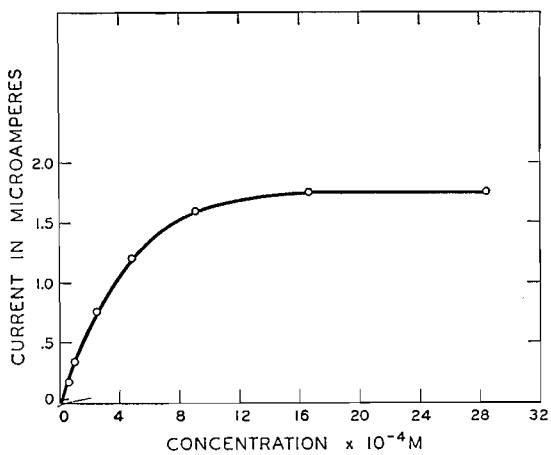

FIG. 2. Relation between limiting current for the first reduction wave and concentration of *p*-anisidine diazo in 0.2 *N* hydrochloric acid.

TABLE I

LIMITING CURRENTS FOR *p*-ANISIDINE DIAZO FOR VARYING HEIGHTS OF MERCURY

(Concentration, 2.4×10^{-4} *M* in 0.2 *N* HCl)

Height of mercury, cm.	Limiting current		First wave	Total wave
	First wave μa.	Total wave μa.	Height	Square root of height
28	0.38	1.76	0.068	1.66
56	0.74	2.58	0.066	1.70

In order to determine the value of '*n*' in the electrode reaction, *p*-methoxybenzenediazonium chloride (*p*-anisidine diazo) was selected because of its good thermal stability and low rate of coupling in side reactions (3). The work of McClure and Lowry (8) and Ruetschi and Trumpler (10) clearly indicated that only acidic solutions would actually yield hydrazines because of side reactions. Furthermore, the work of both of the above groups of workers showed that acidic solutions of benzenediazonium salts in the presence of mercury decompose to form mercuric salts according to [2].

$$ArN_2Cl + Hg \rightarrow ArHgCl + N_2 \qquad [2]$$

Coulometric analyses with stirred mercury pools were found in agreement with Atkinson (1, 2) and Kochi (7) to yield mainly phenylmercuric salts with apparent values of '*n*' less than one at either the first or second plateau. Both McClure and Lowry (8) and Ruetschi and Trumpler (10) found that rapid stirring was conducive to formation of phenylmercuric salts.

Coulometric analyses were then carried out in an ice bath in a microcell of the design shown in Fig. 3. Thermal decomposition of the diazotized amine was found to be negligible during the time required for an electrolysis. A correction was applied for the amount of the diazotized amine with mercury at zero applied potential.

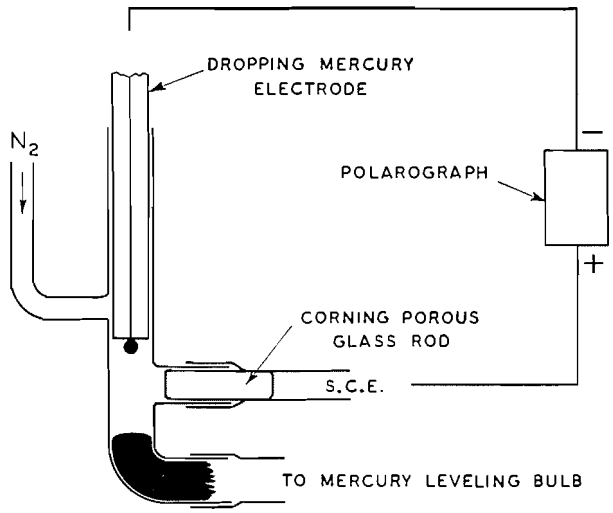

FIG. 3. Microcoulometer for controlled potential electrolyses of diazotized aromatic amines.

At a cathodic potential of −0.55 volts on the first plateau, with 0.6 ml. of 0.001 *M* solution, '*n*' was, in agreement with the results of previous workers, found to be 1.0. At −1.1 volts on the second plateau, three analyses gave a mean value for '*n*' equal to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

4.1 with 0.6 ml. of 0.001 *M* solution. The solutions electrolyzed at −1.1 volts gave positive tests for the hydrazine when treated with ammonium molybdate in 5% sulphuric acid. Positive tests for the hydrazine could not be obtained when the electrolyses were carried out with stirred pool electrodes. In more concentrated solutions, 0.005 *M*, the value of '*n*' approximated four but it was difficult to obtain good measurements because the droplets would not coalesce and these droplets trapped an appreciable fraction of the cell solution. Nevertheless, confirmation of the high current efficiencies obtained by Ruetschi and Trumpler in large scale electrolyses was indicated.

DISCUSSION

The experiments described herein clearly support the claim that the over-all reaction of diazotized aromatic amines at a dropping mercury electrode involves a 4-electron reduction. The first wave in the polarographic reduction is due to an adsorption phenomenon which results from the 1-electron reduction to a free radical (1, 2, 6) according to [3], which is evidently stabilized at the mercury electrode.

$$ArN_2^+ + e \rightarrow ArN_2. \qquad [3]$$

This mechanism is also favored from the constitution of the tar isolated by Kochi (7). The stability of the adsorption complex is the principal factor which determines the potential at which the adsorption current occurs. It is therefore to be expected that the half-wave potentials for the first reduction waves of a number of diazotized aromatic amines would not correlate with electron densities in the usual way (7). It would seem desirable to correlate the half-wave potential with adsorptivities of the free radicals on the mercury electrode at various potentials.

ON THE DECOMPOSITION FLAME OF OZONE AT HIGH PRESSURE*

R. Sandri

The theory of the decomposition flame in ozone–oxygen mixtures has been developed in an earlier paper of this series (1). In another paper (2), the author has shown that this theory can also be applied to high relative concentrations of ozone (up to 100%). The results were found in good agreement with measurements made by Lewis and Elbe (3) and by Streng and Grosse (4) at atmospheric pressure.

DISCUSSION

The experiments described herein clearly support the claim that the over-all reaction of diazotized aromatic amines at a dropping mercury electrode involves a 4-electron reduction. The first wave in the polarographic reduction is due to an adsorption phenomenon which results from the 1-electron reduction to a free radical (1, 2, 6) according to [3], which is evidently stabilized at the mercury electrode.

$$ArN_2^+ + e \rightarrow ArN_2. \qquad [3]$$

This mechanism is also favored from the constitution of the tar isolated by Kochi (7). The stability of the adsorption complex is the principal factor which determines the potential at which the adsorption current occurs. It is therefore to be expected that the half-wave potentials for the first reduction waves of a number of diazotized aromatic amines would not correlate with electron densities in the usual way (7). It would seem desirable to correlate the half-wave potential with adsorptivities of the free radicals on the mercury electrode at various potentials.

ON THE DECOMPOSITION FLAME OF OZONE AT HIGH PRESSURE*

R. Sandri

The theory of the decomposition flame in ozone–oxygen mixtures has been developed in an earlier paper of this series (1). In another paper (2), the author has shown that this theory can also be applied to high relative concentrations of ozone (up to 100%). The results were found in good agreement with measurements made by Lewis and Elbe (3) and by Streng and Grosse (4) at atmospheric pressure.

For personal use only.

In order to test further the validity of the formulae and to provide some assistance for experimental work, calculations have now been made predicting decomposition flame velocities at high pressures.

The formulae which have been derived for the ozone flame velocity V_0 do not contain the pressure p but only the initial relative concentration of ozone y_{30}, the initial temperature T_0, and the flame temperature T_f. For mixtures containing up to 50% ozone, T_f is practically independent of p and consequently V_0 is also independent of it. For higher values of y_{30}, however, the flame temperature becomes so high that dissociation of molecular oxygen into atomic oxygen in the "burned" gas begins to play an important role. Then, since higher pressure decreases the degree of dissociation, T_f and consequently V_0 increase appreciably with pressure. This increase is greater for higher initial temperature.

Table I shows flame velocities in pure ozone, computed for various pressures and for initial temperatures of 195° K. (temperature of dry ice) and 300° K. The corresponding flame temperatures were calculated by thermodynamic methods, using the data of the N.B.S. Circulars C461 and C564.

PEROXIDES IN THE COMBUSTION OF ISOBUTANE[1]

G. W. TAYLOR[2]

ABSTRACT

A survey has been made of the nature of the peroxides occurring in the combustion of isobutane below and above the lower cool-flame limit. The peroxides were resolved and partially identified by paper chromatography. Below the cool-flame limit, the peroxide is found to be mostly *tert*-butyl hydroperoxide, with some hydrogen peroxide, but as the cool-flame limit is approached the proportion of *tert*-butyl hydroperoxide declines, while that of hydrogen peroxide increases. In addition, peroxides identified as aldehyde and acid peroxides increase as the cool-flame limit is approached. No *tert*-butyl hydroperoxide appears to survive the cool flame, although copious quantities of aldehyde peroxide and hydrogen peroxide remain.

INTRODUCTION

The nature and role of the peroxides occurring in the products of the non-catalyzed thermal oxidation of hydrocarbons has been the subject of considerable debate, and the problem has been complicated by the absence of a reliable analytical technique, capable of identifying peroxides in the amounts usually prevailing in the study of combustion reactions. The possible occurrence of various types of peroxides in combustion reactions has recently been considered by Tipper (1). While several unequivocal identifications have been claimed, these are for the most part confined to exceptional cases, for example the low-temperature combustion of acetaldehyde (2).

A paper chromatographic method of resolving some peroxide mixtures has recently been briefly described, and applied in the analysis of the cool-flame combustion products of ethyl benzene (3). The application of this technique has now been extended over a further range of peroxides and its use in the analysis of the combustion products of isobutane is the subject of the present paper.

Isobutane is a rather exceptional fuel, in that it possesses nine primary hydrogen atoms and only one tertiary hydrogen atom. That this latter atom is the initial point of attack by oxygen has been demonstrated by Batten, Gardner, and Ridge (4). Further, the hydroperoxide derived from isobutane, *tert*-butyl hydroperoxide, is unique among the lower alkyl hydroperoxides in its thermal stability. From the point of view of the possible identification of alkyl hydroperoxide in a hydrocarbon oxidation product, the combustion of isobutane thus appears particularly attractive. Batten, Gardner, and Ridge analyzed their combustion products in some detail and, apart from the inevitable gaseous product, found formaldehyde, a smaller amount of higher aldehyde, acetone, a little acid, and peroxides. The peroxides were further examined by polarography with successive removal of various components. Hydrogen peroxide was removed by reaction with

titanous chloride and ammonia. Formaldehyde peroxide (and, the authors conclude, higher aldehyde peroxide also) was removed by reaction with mercury. The residual peroxide was assumed on the basis of its polarogram to be alkyl hydroperoxide. From this procedure, the authors concluded that alkyl hydroperoxide, probably *tert*-butyl hydroperoxide, could form more than 50% of the total peroxide.

An examination of their polarograms immediately reveals that the identification of the peroxide is by no means unequivocal, as the authors themselves make clear. Nevertheless, the occurrence of *tert*-butyl hydroperoxide and hydrogen peroxide appeared highly probable, the former compound especially in the induction period.

The present work entirely confirms the conclusions of Batten, Gardner, and Ridge by providing identifications which can be open to very little uncertainty.

EXPERIMENTAL

Isobutane, a gift from the British Petroleum Company Limited, contained 0.5% *n*-butane as the sole detectable impurity. Oxygen was obtained from a cylinder and was used without further treatment.

The reaction was studied using a flow system similar to that already described (3). The reaction vessel was a pyrex cone, 15 cm long, 2.5 cm maximum diameter. The fuel to oxygen ratio was 1 to 1, total pressure atmospheric. The products were passed through a trap at −80° C. At the end of a run the trap was allowed to warm up, isobutane evaporating off. The residual liquid was used in the identification of peroxides. Drops of liquid were paper chromatographed as previously described. The solvent system used was butanol–ether–water (10:10:1). The chromatograms were developed with aqueous acidified potassium iodide solution. The unknown chromatograms were compared with those of standards run on the same paper.

The standard peroxides, whose R_F values are shown in Table I, were: methoxy hydroperoxide and dimethoxyperoxide (formaldehyde peroxides); α-hydroxyethyl hydroperoxide and α,α'-dihydroxydiethyl peroxide (acetaldehyde peroxides); *tert*-butyl hydroperoxide, and hydrogen peroxide. Aldehyde peroxide was made by desiccating an aqueous mixture of aldehyde and hydrogen peroxide containing a drop of sulphuric acid, over concentrated sulphuric acid. The end product of the formaldehyde mixture was a mildly explosive, insoluble solid, shown by Rieche and Meister (5) to be tetraoxymethylene diperoxide. This contained a little material soluble in water, which was dimethoxyperoxide. A compound which was almost certainly methoxy hydroperoxide was obtained only as an intermediate in the initial stage of the reaction. A similar sequence occurred in the acetaldehyde reaction, but here polymer was not obtained. The end product was a hygroscopic, very explosive oil. In addition, butyraldehyde and caproaldehyde were shaken with hydrogen peroxide; some reaction occurred producing compounds of R_F value 0.99–1.0. In general, pure peroxides were not isolated, aqueous solutions being adequate for the present purpose.

RESULTS

The oxidation of isobutane was studied at 250, 330, 360, and 370° C. A cool flame appeared at about 350° C.

(*a*) *At 250° C, total flow 0.4 ml per sec, run time 195 minutes.*—A trace of aqueous product, strongly peroxidic, remained in the trap. The R_F values of the peroxides were 0.99 and 0.50. A smudge, of maximum density at 0.85, also was formed. The component of R_F 0.99 strongly predominated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

(*b*) *At 330° C, total flow 2.0 ml per sec, run time 30 minutes.*—The product was similar to the above. The proportion of material of R_F 0.99 was somewhat decreased, while that of R_F 0.50 increased. The smudge was also denser.

(*c*) *At 360° C, total flow 2.0 ml per sec, run time 15 minutes. Weak cool flame.*—The degree of oxidation was considerably increased, and an appreciable volume of liquid product was formed. The R_F values of the peroxides were 0.50 and 0.9; the latter spot was actually a streak, extending between 0.95 and 0.7. The component of R_F 0.99 was almost certainly absent.

(*d*) *At 370° C, total flow 2.0 ml per sec, run time 30 minutes. Bright cool flame.*—The product was treated as in (*c*). No component of R_F 0.99 was present, although the density of the 0.7–0.95 smudge was considerably increased. The component of R_F 0.50 was also present.

DISCUSSION

A comparison of the R_F values of the unknown peroxides with the R_F values of the standards shows that the unknown peroxide of R_F 0.50 is almost certainly hydrogen peroxide. It is interesting that this compound is a product of the low-temperature reaction, as it has generally been assumed to be characteristic more of a high-temperature reaction. The possibility that the hydrogen peroxide detected is actually a result of decomposition of organic peroxide during the analysis is ruled out by the fact that spots, not streaks, were obtained in the chromatography of the standards.

The spot of R_F 0.99 exactly matches that of *tert*-butyl hydroperoxide. The identification of this component as *tert*-butyl hydroperoxide is strongly substantiated by the conditions of its appearance. It is a product of the induction period, that is, a primary product, and disappears as the degree of reaction increases, that is, as the cool-flame limit is crossed. This behavior is exactly the reverse of that of aldehydes—and hence, aldehyde peroxides—which are the predominant products of cool-flame reactions (e.g. propane (6) and hexane (7)). It is improbable, therefore, that the fast-moving peroxide is a higher aldehyde peroxide possibly derived from the preferential combustion of the trace of *n*-butane in the starting material.

The material of R_F 0.7–0.95 was a minor component below the cool-flame limit, but increased markedly as the limit was crossed. A comparative study of the cool-flame oxidation of a wide variety of hydrocarbons and ethers showed that this material is a characteristic product of all the oxidations. A comparison of its chromatographic behavior with that of the standards suggests that its composition is complex, and it is believed that the material is a mixture of aldehyde and acid peroxides not completely resolved. The presence of alkyl hydroperoxides is not ruled out, but the conditions of its occurrence would appear to preclude the presence of alkyl hydroperoxides.

TABLE I

R_F VALUES OF STANDARD PEROXIDES

Peroxide	R_F
Hydrogen peroxide	0.50
Methoxyhydroperoxide	0.65
Dimethoxyperoxide	0.82
α-Hydroxyethyl hydroperoxide	0.73
α,α′-Dihydroxydiethyl peroxide	0.95
tert-Butyl hydroperoxide	0.99

It is concluded, therefore, that in the oxidation of isobutane, the peroxide products are hydrogen peroxide, *tert*-butyl hydroperoxide, and aldehyde peroxides. *Tert*-butyl hydroperoxide is the predominant product of the induction period, along with some hydrogen peroxide. As the cool-flame limit is passed, the yield of *tert*-butyl hydroperoxide suffers a catastrophic decline while the yields of aldehyde peroxides and hydrogen peroxide increase.

This behavior appears to substantiate the conclusions of Batten, Gardner, and Ridge. The decline in their total peroxide after the induction period was ended (in contrast with the present data) is probably a result of consumption of reactant in their static apparatus.

This work was done while the author was in the Department of Physical Chemistry in the University of Cambridge, England. He is indebted to Prof. R. G. W. Norrish, F.R.S., for inspiration and encouragement.

THE REACTIONS OF ACTIVE NITROGEN WITH CYCLOPROPANE, CYCLOBUTANE, AND CYCLOPENTANE[1]

N. V. KLASSEN,[2] M. ONYSZCHUK,[3] J. C. MCCABE,[4] AND C. A. WINKLER

ABSTRACT

Cyclopropane, cyclobutane, and cyclopentane in order of increasing reactivity with active nitrogen yielded hydrogen cyanide and ethylene as the major products. The relative proportions of ethylene to hydrogen cyanide increased with number of carbon atoms in the reactant and with increase of temperature.

Alkenes have been found (1) to react with active nitrogen more rapidly than do the corresponding alkanes, to yield a larger proportion of unsaturated hydrocarbons (other than the initial reactant) relative to hydrogen cyanide in the products. It was of interest to determine whether cycloalkanes, in their reactions with active nitrogen, would resemble the corresponding *n*-alkanes or their olefin isomers, and whether the ease of reaction would depend upon the relative stabilities of the cycloalkane rings.

EXPERIMENTAL

The apparatus, experimental techniques, and analytical methods were essentially the same as those described in previous papers (2, 3, 4). A molecular nitrogen flow of 58 micromoles/second at a pressure of 1.5 mm Hg was used in the cyclopropane and cyclobutane reactions, while in the cyclopentane reaction the molecular nitrogen flow was 100 micromoles/second at a pressure of 1.8 mm Hg. In a brief examination of the atomic hydrogen reaction with cyclopentane and ethylene the flow of hydrogen was 120 micromoles/second at a pressure of 0.95 mm Hg.

Cyclopropane of 99.5% purity was used after a single bulb-to-bulb distillation. A limited supply of cyclobutane of approximately 99% purity was obtained through the courtesy of Dr. W. D. Walters, University of Rochester. The cyclopentane used had a refractive index $n_D^{20} = 1.4062$ ($n_D^{20} = 1.4064$ for highly purified cyclopentane (5)). Low temperature fractionation failed to reveal any lower molecular weight impurities.

Analyses for HCN, $(CN)_2$, and NH_3 were made by standard titration methods (6, 7), while mass-spectrometric and gas-chromatographic methods were used for other condensible and the non-condensible products.

RESULTS

Active nitrogen appeared to react only slowly with cyclopropane, since the purple-pink reaction flame completely filled the reaction vessel, even at high reactant flow rates. The flow rate of active nitrogen was taken to be equal to the maximum flow rate of hydrogen cyanide produced in the reaction of ethylene with active nitrogen at temperatures above 250° C (1) and found to be 3.9 micromoles/second.

The recovery of HCN increased as cyclopropane flow rate increased at all temperatures (Fig. 1), hence complete consumption of active nitrogen did not take place except, perhaps, at high flow rates at 350° C. The recoveries of C_2H_4 and C_2H_2 were much smaller than that of HCN (Fig. 1), and C_2H_6 was detected only in trace amounts.

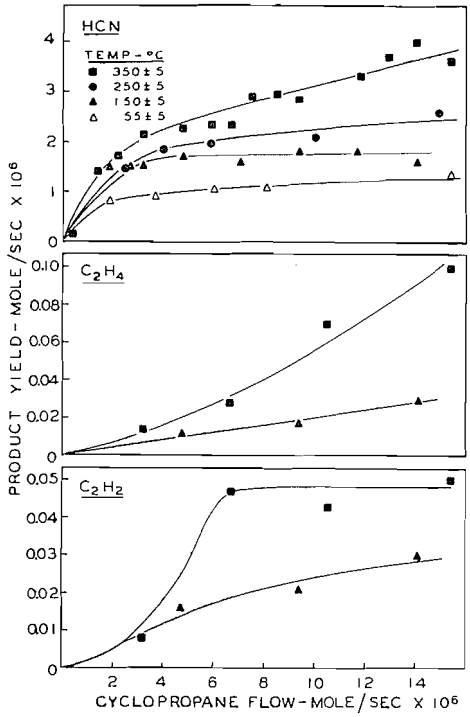

FIG. 1. Relation of cyclopropane flow rate to product yields.

At high flow rates cyclobutane reacted with a relatively intense peach-colored flame in a small volume around the hydrocarbon inlet, from which it might be inferred that cyclobutane was considerably more reactive than cyclopropane. This is confirmed by the much higher conversion to HCN (Fig. 2). Complete reaction of the active nitrogen (the flow rate of which was 5.2 micromoles/second) appeared to be attained only above 250° C and 5 micromoles/second cyclobutane flow, when the production of HCN became independent of reactant flow rate.

The yields of other products in relation to cyclobutane flow rate are also shown in Fig. 2. Propane was detected among the products, but in even smaller amounts than propylene.

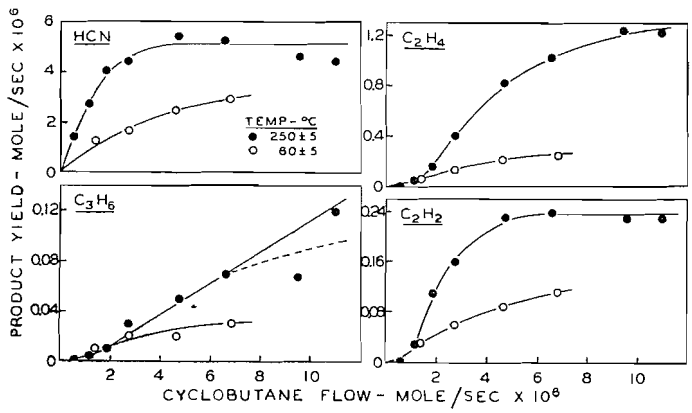

FIG. 2. Relation of cyclobutane flow rate to product yields.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Cyclopentane reacted with active nitrogen with a reddish-violet flame that was concentrated near the hydrocarbon inlet at all but the lowest flow rates, i.e. the reaction appeared to be quite fast. The limiting production of HCN (Fig. 3) was essentially equal to the active nitrogen flow rate of 13 micromoles/second. The largest observed ratio of C_2H_4 to HCN was 0.7, but this ratio would undoubtedly have increased at still higher cyclopentane flow rates (not readily attainable because of back diffusion from the reaction vessel).

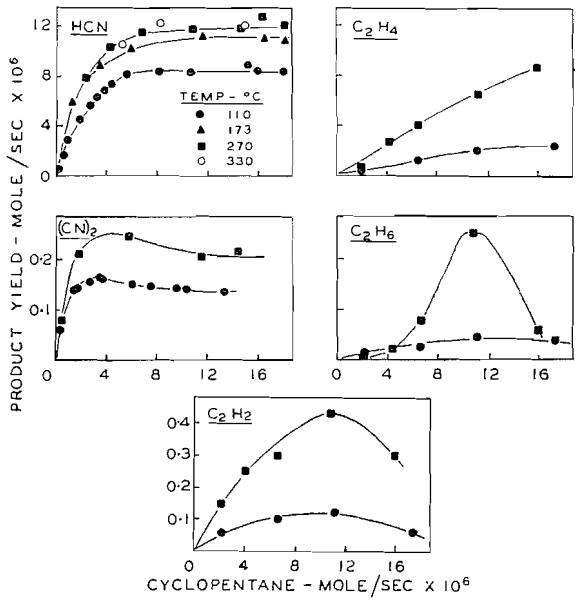

FIG. 3. Relation of cyclopentane flow rate to product yields.

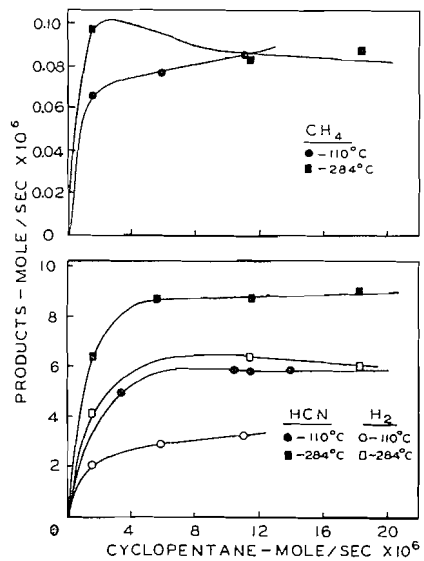

FIG. 4. Relation of cyclopentane flow rate to yields of methane and hydrogen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The recoveries of $(CN)_2$, C_2H_6, and C_2H_2 showed maxima with cyclopentane flow rate. Ammonia and C_3 and C_4 hydrocarbons were detected in amounts less than 1% of the HCN.

In another series of experiments, with an active nitrogen flow of 9.7 micromoles/sec the productions of CH_4, H_2, and HCN were found to be related to cyclopentane flow, as shown in Fig. 4. Mass-spectrometric and gas-chromatographic analyses indicated that no product in excess of 1% of the HCN remained undetected.

To obtain information about the possible effect of atomic hydrogen on the cyclopentane – active nitrogen reaction, the relative rates of the H atom reactions with cyclopentane and ethylene were examined at 284° C. With the results shown in Table I.

TABLE I

DATA FOR THE REACTIONS OF HYDROGEN ATOMS WITH CYCLOPENTANE AND ETHYLENE AT 284° C

cyclo-C_5H_{10} input	C_2H_4 input	Argon input	C_2H_6 yield	C_2H_4 yield	C_2H_4 destroyed
12.95[a]	—	—	0.170	0.120	—
13.65	—	—	0.170	0.200	—
—	12.65	—	0.920	11.05	1.60
—	13.50	—	1.250	11.95	1.55
—	12.90	11.95	0.920	11.40	1.50
—	13.05	12.00	0.900	11.55	1.50
13.30	12.45	—	0.520	12.10	*ca.* 0.45[b]
13.20	12.85	—	0.420	12.45	*ca.* 0.45[b]

[a]All values refer to flow rates in micromoles/second.

[b]It was assumed that approximately 0.08 micromoles/second of ethylene was produced by reaction of hydrogen atoms with cyclopentane.

Since the hydrocarbon flow (13 micromoles/second) was in large excess over the H atom flow (estimated from the H atom – hydrogen iodide reaction to be about 6 micromoles/second (8)), the reaction of H atoms should have been confined largely to their initial attack on the hydrocarbon. The results obtained with a mixture of ethylene and argon indicate that physical effects in the apparatus used do not invalidate direct comparison between the reactions of hydrocarbon mixtures and the reactions of pure hydrocarbons. Hence, it may be inferred from Table I that ethylene was destroyed three times more slowly when mixed with an equal amount of cyclopentane than when it reacted alone. Therefore, the rates of the reactions of atomic hydrogen with ethylene and cyclopentane are of the same order at 284° C, and any hydrogen atoms produced in the cyclopentane – active nitrogen reaction at 270° C would be expected to react to a large extent with cyclopentane.

TABLE II

KINETIC CONSTANTS FOR THE REACTIONS OF ACTIVE NITROGEN WITH CYCLOALKANES

Cycloparaffin	Temp., ° C	k, liter $mole^{-1}sec^{-1} \times 10^{-5}$	E, kcal $mole^{-1}$	P, $\times 10^4$
Cyclopropane	50	0.8	3.2	0.6
	150	2.5		
	250	5.1		
	350	9.1		
Cyclobutane	60	1.2	4.6	4.7
	250	18.		
Cyclopentane	110	2.4	5.3	8.8
	270	19.

Values of the second-order rate constants for the initial attack of active nitrogen on cyclopropane, cyclobutane, and cyclopentane are shown in Table II. The calculations were made for conditions of incomplete consumption of both cycloalkane and active nitrogen.

DISCUSSION

As in previous papers, it will be assumed that atomic nitrogen is the main chemically reactive species in active nitrogen (9).

It would seem that the reactions of cyclopropane, cyclobutane, and cyclopentane with nitrogen atoms can be explained by similar mechanisms, the initial steps of which are analogous to the primary reaction suggested previously (1) for the reaction of active nitrogen with saturated hydrocarbons, i.e.,

$$\text{cyclo-}C_5H_{10} + N \rightarrow HCN + H_2 + C_4H_7; \quad \Delta H = -10 \text{ to } -40 \text{ kcal.} \qquad [1]$$

$$\text{cyclo-}C_4H_8 + N \rightarrow HCN + H_2 + C_3H_5; \quad \Delta H = -58 \text{ kcal} \qquad [2]$$

$$\text{cyclo-}C_3H_6 + N \rightarrow HCN + H_2 + C_2H_3; \quad \Delta H = -29 \text{ kcal} \qquad [3]$$

An obvious alternative to reaction [1] which would permit a ratio for C_2H_4 to HCN of 0.7, but which would seem to be forbidden by its endothermicity, is the reaction

$$\text{cyclo-}C_5H_{10} + N \rightarrow HCN + 2C_2H_4 + H; \quad \Delta H = +14 \text{ kcal.} \qquad [4]$$

The reaction

$$\text{cyclo-}C_5H_{10} + N \rightarrow HCN + C_2H_4 + C_2H_5; \quad \Delta H = -25 \text{ kcal} \qquad [5]$$

is also a possible alternative to reaction [1]. However, it should be followed by very rapid reaction of C_2H_5, and subsequently CH_3 radicals with active nitrogen to form HCN (1, 10, 11). The attack of nitrogen atoms on cyclopentane almost certainly has a higher activation energy than the radical–nitrogen atom reactions, and more nitrogen atoms should therefore be consumed in the primary step at higher temperatures and cyclopentane flow rates. Consequently, the radicals should suffer correspondingly less destruction and, contrary to the experimental results, the yields of ethane and methane should increase steadily with temperature and cyclopentane flow. Hence it may be concluded that reaction [5] is also of relatively little, if any, importance in the cyclopentane–active nitrogen reaction.

The unsaturated radicals formed in reactions [1], [2], and [3] should be attacked rapidly by nitrogen atoms in reactions such as

$$C_4H_7 + N \rightarrow HCN + C_2H_4 + CH_2 \qquad [6]$$

$$C_3H_5 + N \rightarrow HCN + C_2H_4 \qquad [7]$$

$$C_2H_3 + N \rightarrow HCN + CH_2 \qquad [8]$$

together with the reactions

$$CH_2 + N \rightarrow HCN + H \qquad [9]$$

$$CH_2 + N \rightarrow CN + H_2. \qquad [10]$$

If some of the CH_2 produced in reactions such as [6] or [8] is in the triplet state, the reaction

$$CH_2^* + N \rightarrow CN + 2H \qquad [11]$$

might occur to an appreciable extent.

The large amounts of C_2H_4 formed in the cyclopentane reaction at 270° C can be explained if the previous reactions are accompanied by

$$\text{cyclo-}C_5H_{10} + H \rightarrow \text{cyclo-}C_5H_9 + H_2 \quad [12]$$

and

$$\text{cyclo-}C_5H_{10} + CN \rightarrow \text{cyclo-}C_5H_9 + HCN, \quad [13]$$

followed by

$$\text{cyclo-}C_5H_9 + N \rightarrow HCN + 2C_2H_4. \quad [14]$$

The present study has shown that the attack of cyclopentane by H atoms at 270° C and high cyclopentane flow rates is quite probable even in the presence of considerable ethylene.

The maxima in the production of CH_4 and C_2H_6 from cyclopentane at the higher temperatures may be explained if it is assumed that these arise mainly from CH_3 radicals, and that the radicals are produced as suggested previously (1, 12),

$$C_2H_4 + N \rightarrow HCN + CH_3. \quad [15]$$

The extent of reaction [15] should pass through a maximum with flow rate of cyclopentane, since it is in competition with reaction [1], and this maximum should be more pronounced at higher temperatures, as observed, since the activation energy of reaction [1] (5.3 kcal/mole) appears to be higher than that of reaction [15] (3 kcal/mole (13)). The maximum should be less pronounced for methane than for ethane production, as observed, if methane production resulted mainly from reaction of CH_3 radicals with cyclopentane, while ethane was produced by their recombination.

Recovery of acetylene in small amounts from the three hydrocarbon – N atom reactions may be explained as in an earlier paper (1), i.e. reaction of N atoms with $N \cdot C_2H_4$ complexes to bring about recombination of N atoms and production of triplet ethylene which then decomposes to yield acetylene. Cyanogen probably resulted from the recombination of CN radicals formed in reactions such as [10] and [11].

The large value of the C_2H_4: C_3H_6 ratio in the cyclobutane reaction and the increase of this ratio with temperature indicate that propylene was formed in secondary processes, perhaps by the hydrogenation of C_3H_5 radicals. Similarly, the small quantities of ethylene recovered from the cyclopropane reaction could have resulted from hydrogenation of C_2H_3 radicals, perhaps by abstraction from the parent hydrocarbon.

It is interesting to note that, of the three reactions studied, the cyclopropane reaction appears to have the lowest activation energy. This might be due to greater delocalization of carbon–carbon bond orbitals in cyclopropane (greater *p*-character), thus facilitating the approach of an electrophilic reagent such as a nitrogen atom. A similar situation exists in the ethylene – active nitrogen reaction which also has a low activation energy.

THE REACTIONS OF ACTIVE NITROGEN WITH CHLOROMETHANES[1]

S. E. Sobering[2] and C. A. Winkler

ABSTRACT

Cyanogen chloride and chlorine were the only gaseous products observed in the reaction of active nitrogen with carbon tetrachloride at 110° and 420° C. The product yields tended towards limiting values at higher reactant flow rates, and increased with increase of temperature at all flow rates. The reactions of active nitrogen with chloroform and dichloromethane at 260° and 420° C yielded hydrogen chloride, hydrogen cyanide, and cyanogen, in addition to cyanogen chloride and chlorine. The behavior of the product yields with reactant flow rates and temperature was similar to that of the products from carbon tetrachloride.

The reactions of active nitrogen with methyl-, ethyl-, propyl-, isopropyl-, and vinyl-chlorides have been discussed in earlier papers from this laboratory (1, 2). The present paper reports the results obtained in a similar study with carbon tetrachloride, chloroform, and dichloromethane, to examine the effect of different extents of halogen substitution.

EXPERIMENTAL

The apparatus and experimental procedures were essentially the same as those used in the previous studies of active nitrogen reactions (3). Standard analytical methods (4, 5, 6) were adapted without serious difficulty to the products of the reactions after they had been given appropriate preliminary separation by low-temperature distillation and chemical absorption (7).

RESULTS AND DISCUSSION

The reaction flames for the three reactions were quite bright, with an orange tint that became progressively less marked with decrease in the number of halogen atoms in the reactant molecule.

A small amount of greenish-brown polymer was formed during each of the reactions. With carbon tetrachloride, but not with the other chloromethanes, a trace of white solid was also deposited. This solid resembled hexachlorethane in its solubility in ether and in its tendency to sublime when heated. Although no chemical analyses of the polymers were made, owing to the difficulty in obtaining sufficient material, they did not behave, when heated, as if they were pure materials such as cyanuric chloride or paracyanogen. Traces of free carbon appeared to be formed in the chloroform and dichloromethane reactions.

With CCl_4, the flow rate of molecular nitrogen was 39 micromoles/second (operating pressure = 1 mm) and that of active nitrogen was estimated to be 9.3 micromoles/second, from the maximum HCN production from ethylene at 425° C (2, 3). The only gaseous products were Cl_2 and CNCl, the yields of which changed with flow rate of CCl_4 in the manner shown in Fig. 1. The ratio of Cl_2 yield to CNCl yield decreased steadily from about 3:1 to a limiting value of 1.5:1 as the flow rate of CCl_4 was increased over the range used.

With $CHCl_3$, a new pumping system was used, and the active nitrogen flow rate was estimated as 14.6 micromoles/second, with a molecular flow of 180 micromoles/second at a pressure of 1.65 mm. The gaseous products were HCl, CNCl, and Cl_2 in comparatively

large amounts, together with lesser amounts of HCN and $(CN)_2$. In Fig. 2, which depicts the relations of product yields to $CHCl_3$ flow rates, the total HCN + $(CN)_2$ yields consisted of approximately 40% HCN and 60% $(CN)_2$.

With CH_2Cl_2, the operating conditions were identical with those used for $CHCl_3$. The major products were HCl, HCN, and CNCl, production of which varied with flow rate of CH_2Cl_2 as indicated in Fig. 3. Much smaller quantities of Cl_2 (Fig. 3) and $(CN)_2$ (maximum 0.4 micromoles/second) were produced.

The reactions of active nitrogen with the three chloromethanes of the present study resemble the reaction with methyl chloride studied previously (1) in color and behavior of the reaction flames, in tendency for slight polymer formation, in exothermicity, and in production of HCl and HCN as products when possible. It should be noted that the methyl chloride reaction yielded only HCl and HCN (and hydrogen) as major products; CNCl and Cl_2 were entirely absent.

There seems to be little doubt that the active nitrogen – CCl_4 reaction occurred by

$$N + CCl_4 \rightarrow [N \cdot CCl_4] \rightarrow CNCl + Cl_2 + Cl; \quad \Delta H = -24 \text{ kcal.}$$

The alternative decomposition of the collision complex to yield CN radicals seems unlikely, since no significant quantity of cyanogen was formed.

The observed increase in Cl_2: CNCl ratio with decrease of CCl_4 flow rate suggests that, with excess N atoms, reactions occur of the type

$$N + N \cdot CCl_4 \rightarrow N_2 + CCl_4^*,$$

followed by decomposition of the excited CCl_4 to yield chlorine and perhaps CCl_3, dimerization of which would yield the traces of hexachlorethane that appeared to be formed.

The products from the reaction of chloroform with active nitrogen can be semi-quantitatively explained by the scheme

$$\begin{aligned} N + CHCl_3 \rightarrow [N \cdot CHCl_3] &\rightarrow CNCl + HCl + Cl; \quad \Delta H = -48 \text{ kcal} \\ &\rightarrow HCN + Cl_2 + Cl; \quad \Delta H = -29 \text{ kcal} \\ &\rightarrow CN + HCl + Cl_2; \quad \Delta H = -18 \text{ kcal,} \end{aligned}$$

in which the first reaction occurs to at least three times the extent of the other two combined. However, compared with the proportions inferred from such a mechanism, there appears to be an excess of HCl and deficiency of chlorine in the products. This might result from reactions such as

$$Cl + CHCl_3 \rightarrow HCl + CCl_3; \quad \Delta H = -12 \text{ kcal}$$

followed by

$$CCl_3 + N \rightarrow CNCl + 2Cl; \quad \Delta H = -35 \text{ kcal.}$$

Other reactions that would lead to loss of chlorine at the expense of HCl production might be suggested, e.g.

$$N + N \cdot CHCl_3 \rightarrow N_2 + CHCl_3^*$$

and subsequent decomposition of the excited $CHCl_3$ to yield HCl and other products such as CCl_2, or free carbon, traces of which were observed.

The dichloromethane – active nitrogen reaction may be represented similarly to that of chloroform:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$$N + CH_2Cl_2 \rightarrow [N \cdot CH_2Cl_2] \rightarrow HCN + HCl + Cl; \quad \Delta H = -54 \text{ kcal}$$
$$\rightarrow CNCl + HCl + H; \quad \Delta H = -27 \text{ kcal}$$
$$\rightarrow CN + 2HCl; \quad \Delta H = -24 \text{ kcal.}$$

Since reaction of CN radicals with parent reactant appears not to have been appreciable (no optimum in $(CN)_2$ yield), and the amount of cyanogen formed was trivial, the third reaction must have been relatively unimportant. From the relative proportions of HCN and CNCl formed it may then be inferred that the first reaction was the predominant mode of attack.

Again, the rate of chlorine production was relatively low and HCl production relatively high. This suggests consumption of chlorine in reactions such as

$$Cl + CH_2Cl_2 \rightarrow HCl + CHCl_2$$

and HCl production in reactions such as

$$H + CH_2Cl_2 \rightarrow HCl + CH_2Cl,$$

or

$$N + [N \cdot CH_2Cl_2] \rightarrow N_2 + CH_2Cl_2^*$$

followed by

$$CH_2Cl_2^* \rightarrow 2HCl + C.$$

As with chloroform, this last possibility is supported by the apparent formation of traces of free carbon.

REACTIONS OF ALKOXY RADICALS

V. PHOTOLYSIS OF DI-*t*-BUTYL PEROXIDE[1]

GARNETT MCMILLAN AND M. H. J. WIJNEN[2]

ABSTRACT

The photolysis of di-*t*-butyl peroxide has been investigated over the temperature range 25° to 79° C. As reaction products were observed: acetone, *t*-butyl alcohol, methyl *t*-butyl ether, *i*-butylene oxide, ethane, methane, and carbon monoxide. The following reactions, involving the *t*-butoxy radical, have been studied:

$$(CH_3)_3CO \rightarrow CH_3COCH_3 + CH_3 \quad [2]$$

$$(CH_3)_3CO + CH_3 \rightarrow (CH_3)_3COCH_3 \quad [5]$$

$$(CH_3)_3CO + DtBP \rightarrow (CH_3)_3COH + R \quad [6]$$

An activation energy difference of $E_2 - E_6 = 3$ kcal has been obtained.

INTRODUCTION

Previous work (1, 2, 3) on the photolysis of di-*t*-butyl peroxide has established that the primary process consists of the breakage of the O—O bond, thus producing two *t*-butoxy radicals. It could also be shown that the *t*-butoxy radical is relatively unstable and decomposes according to reaction [2]:

$$(CH_3)_3CO \rightarrow CH_3COCH_3 + CH_3. \quad [2]$$

As most recent values for the activation energy of reaction [2] have been reported 11.2±2 (3) and 13.2±2.4 (4) kcal.

Such a value for E_2 would, however, indicate that especially at low temperatures the *t*-butoxy radical might survive long enough to take part in abstraction and recombination reactions. While the formation of *t*-butyl alcohol through hydrogen abstraction by *t*-butoxy radicals has been reported frequently (5, 6) no information was available regarding the activation energy for the abstraction of a hydrogen atom from di-*t*-butyl peroxide. In the photolysis of di-*t*-butyl peroxide a considerable amount of ethane is produced by recombination of methyl radicals, originating from reaction [2]. It seemed, therefore, likely that especially at low temperatures some methyl *t*-butyl ether might be produced via recombination reactions, although this compound had thus far not been reported among the reaction products.

In order to clear these questions the photolysis of di-*t*-butyl peroxide has been studied again.

EXPERIMENTAL

The apparatus is essentially the same as described previously (7). As a rule, a Hanovia S-500 medium pressure arc was employed as light source. The light intensity was varied by inserting wire-gauze screens between arc and cell. In some runs, marked as such in Table I under intensity, a BH-6 lamp, made by General Electric, was used. The effective light output of the BH-6 lamp is about three times that of the Hanovia S-500 arc.

After the photolysis, the reaction products and the excess di-*t*-butyl peroxide were cooled down to about −175° C. At this temperature CO, CH_4, and C_2H_6 were removed

[a]Open spaces indicate that, under the given conditions, this compound was formed in amounts too small to allow its determination by mass-spectrometer analysis.

NOTE: Unless marked by *, data for *i*-butylene oxide are somewhat high owing to the presence of small amounts of methyl ethyl ketone.

by Toepler pump and sampled for mass-spectrometer analysis after their total volume had been measured. The liquid products were then separated from the excess undecomposed di-*t*-butyl peroxide by gas chromatography. A 6-ft-long general-purpose column C, obtained from Perkin–Elmer, was used. The column was operated at room temperature, using helium at a pressure of 10 lb as carrier gas. Under these conditions all reaction products come over within 25 minutes after introduction of the sample, while di-*t*-butyl peroxide is retained up to 67 minutes. The reaction products, thus separated from di-*t*-butyl peroxide, were trapped out and analyzed by mass spectrometer. In this way it was possible to determine the relative ratios in which the liquid products were formed although no absolute values are obtained.

It has been established previously (2, 5) that the ratio $(2R_{C_2H_6}+R_{CH_4})/R_{CH_3COCH_3}$ is equal to unity in the thermal and photolytic decomposition of di-*t*-butyl peroxide. This is easily understood if one realizes that one methyl radical is formed for every acetone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

molecule produced by the thermal decomposition of the *t*-butoxy radical, according to reaction [2]. Taking into account that some methyl radicals are produced by secondary photolysis of acetone a more correct figure for the observed rate of acetone production is obtained by $R_{CH_3COCH_3} = 2(R_{C_2H_6}-R_{CO})+R_{CH_4}$. It is thus possible to calculate the rate of acetone production from the rates of methane, ethane, and carbon monoxide production. Since the relative ratio of acetone to other liquid products is determined by mass spectrometer, the rates of formation of all other products may be calculated.

In several runs a known amount of *i*-butane was added to the liquid products before mass-spectrometer analysis. Accurate data could thus be obtained for the production of acetone and other liquid products. In all instances data thus obtained for $R_{CH_3COCH_3}$ agreed with those calculated via the formula $R_{CH_3COCH_3} = 2(R_{C_2H_6}-R_{CO})+R_{CH_4}$.

It was not possible to discriminate by mass spectrometer between methyl ethyl ketone and *i*-butylene oxide, since the only available peak, yielding good resolution is *m/e* 72, common to both compounds. It was, however, possible to stop trapping of the reaction products, leaving the gas chromatography apparatus, before the appearance of methyl ethyl ketone. In this way, accurate data for the production of *i*-butylene oxide were obtained. These data indicated that peak *m/e* 72 was mainly due to the presence of *i*-butylene oxide. Since neither of these two compounds are of extreme interest in the present discussion, data reported in Table I for *i*-butylene oxide have been calculated on the assumption that no methyl ethyl ketone was formed.

The conversion has been kept below 5% of the starting material. The di-*t*-butyl peroxide used in this investigation was obtained from Shell Chemical Corporation and was distilled under reduced pressure, a small middle fraction being retained. Gas chromatographic analysis indicated it to be more than 99% pure.

RESULTS AND DISCUSSION

Data, obtained by photolyzing di-*t*-butyl peroxide at different temperatures and light intensities are reported in Table I. The following reactions have been considered to explain the formation of acetone, *t*-butyl alcohol, methyl-*t*-butyl ether, *i*-butylene oxide, ethane, and methane:

$$(CH_3)_3COOC(CH_3)_3 + h\nu \rightarrow 2(CH_3)_3CO \quad [1]$$

$$(CH_3)_3CO \rightarrow CH_3COCH_3 + CH_3 \quad [2]$$

$$2(CH_3)_3CO \rightarrow (CH_3)_3COH + (CH_3)_2\overset{\diagdown\ \diagup}{CH_2CO} \quad [3]$$

$$CH_3 + (CH_3)_3CO \rightarrow CH_4 + (CH_3)_2\overset{\diagdown\ \diagup}{CH_2CO} \quad [4]$$

$$CH_3 + (CH_3)_3CO \rightarrow (CH_3)_3COCH_3 \quad [5]$$

$$(CH_3)_3CO + DtBP \rightarrow (CH_3)_3COH + (CH_3)_3COOC(CH_3)_2CH_2 \quad [6]$$

$$(CH_3)_3COOC(CH_3)_2CH_2 \rightarrow (CH_3)_3CO + (CH_3)_2\overset{\diagdown\ \diagup}{CH_2CO} \quad [7]$$

$$2CH_3 \rightarrow C_2H_6 \quad [8]$$

$$CH_3 + DtBP \rightarrow CH_4 + (CH_3)_3COOC(CH_3)_2CH_2 \quad [9]$$

However, in addition to the reaction products mentioned above, also carbon monoxide and traces of methyl ethyl ketone were observed. Table I clearly shows that acetone is the most abundant reaction product and it seems logical to accept, as other authors (3) did, that CO and $C_2H_5COCH_3$ are formed by secondary photolysis of acetone. The following reactions are therefore added:

$$CH_3COCH_3 + h\nu \rightarrow CH_3 + CH_3CO \quad [10]$$
$$CH_3 + CH_3CO \rightarrow CH_3COCH_3 \quad [11]$$
$$CH_3 + CH_3CO \rightarrow CH_4 + CH_2CO \quad [12]$$
$$CH_3CO \rightarrow CH_3 + CO \quad [13]$$
$$R + CH_3COCH_3 \rightarrow CH_2COCH_3 + RH \quad [14]$$
$$CH_3 + CH_2COCH_3 \rightarrow C_2H_5COCH_3 \quad [15]$$

The following equations may be derived from this mechanism:

$$R_{CH_3COCH_3} \times R^{\frac{1}{2}}_{C_2H_6}/R_{CH_3OC(CH_3)_3} = k_2k_8^{\frac{1}{2}}/k_5 \quad [I]$$

and

$$R_{(CH_3)_3COH}/R^2_{CH_3COCH_3} = k_3/k_2^2 + k_6/k_2[DtBP]/R_{CH_3COCH_3}, \quad [II]$$

where R_x is the rate of production of the compound x.

Owing to secondary reactions involving acetone, $R_{CH_3COCH_3}$ is not correctly given by measuring the observed rate of acetone production. Some of the originally formed acetone decomposed to give CO and methyl radicals, some reacted to form methyl ethyl ketone. The amount of methyl ethyl ketone is, however, smaller than 1% of the originally formed acetone and may therefore be neglected. The amount of acetone decomposed to CO and methyl radicals is given by the rate of CO production. In calculating equations [I] and [II] the rate of acetone production by reaction [2] is therefore given by the sum of the *observed* rate of acetone production and the rate of production of carbon monoxide. At room temperature a constant value was obtained for equation [I], indicating $k_2k_8^{\frac{1}{2}}/k_5 = 5.1 \pm 0.5 \times 10^8$ in molecules$^{\frac{1}{2}}$/(sec$^{\frac{1}{2}}$ cc$^{\frac{1}{2}}$). Equation [I] involves the reaction products: acetone, ethane, and methyl *t*-butyl ether. Acetone and ethane are the major reaction products in the photolysis of di-*t*-butyl peroxide. Methyl *t*-butyl ether is, however, formed in trace amounts only. As a matter of fact, the largest amount of ether observed did not exceed 3×10^{-3} ml of gas at n.t.p. This undoubtedly explains why this product was not observed by previous investigators. With increasing temperature, the production of ether decreases, mainly owing to an increased decomposition of the *t*-butoxy radical into acetone and methyl radicals via reaction [2]. The results obtained for $k_2k_8^{\frac{1}{2}}/k_5$ show, therefore, considerable scatter at 55° C, as indicated in Table II. At 79° C the amount of ether produced was too small to allow its determination by mass-spectrometer analysis.

TABLE II

RATIOS OF RATE CONSTANTS

Temperature, ° C	$10^{19}k_6/k_2$	$10^{-8}k_2k_8^{\frac{1}{2}}/k_5$, molecules$^{\frac{1}{2}}$/(cc$^{\frac{1}{2}}$ sec$^{\frac{1}{2}}$)
25	0.72	5.1
55	0.45	21±6
79	0.32	—

It is obvious that an activation energy, determined from data at two temperatures only, should be taken with the utmost reservation. It is nevertheless interesting to point out that our data indicate a value of 9±2 kcal for the activation energy of reaction [2]. This value agrees within experimental error with data obtained by Volman and Graven (3), who reported $E_2 = 11.2 \pm 2$ kcal.

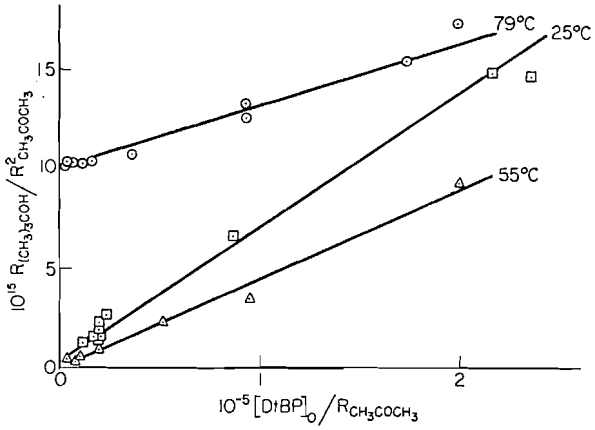

FIG. 1. Plot of $10^{15}R_{(CH_3)_3COH}/R^2_{CH_3COCH_3}$ versus $10^{-5}[DtBP]_0/R_{CH_3COCH_3}$ at various temperatures.

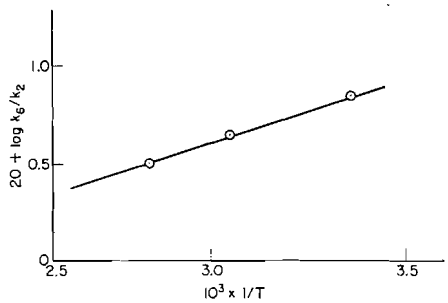

FIG. 2. Plot of $20+\log k_6/k_2$ versus $10^3\times 1/T$.

Equation [II] is plotted in Fig. 1 for the temperatures 25, 55, and 79° C. The origin on the ordinate has been displaced by 10 units for the data at 79° C. Values obtained for k_6/k_2 from Fig. 1 are given in Table II. A plot of log k_6/k_2 in Fig. 2 gives an activation energy difference of $E_2-E_6 = 3$ kcal.

No intercepts are observed when plotting equation [II] (Fig. 1) for the temperatures 55° and 79° C. It is difficult to decide whether the intercept observed at 25° C is real. The absence of an intercept would prove that reaction [3], the disproportionation of two *t*-butoxy radicals, would not occur. It may, however, be concluded that $k_3/k_2^2 \leqslant 0.5 \times 10^{-15}$ in molecules^{-1}/(sec^{-1} cc^{-1}). From this conclusion it is possible to calculate the maximum amounts of *t*-butyl alcohol and *t*-butylene oxide formed by reaction [3]. Such calculations indicate that *t*-butyl alcohol is mainly, if not only, formed by abstraction reaction [6] rather than by disproportionation of *t*-butoxy radicals. These calculations also indicate that, even at 25° C, *i*-butylene oxide is mainly, if not only, formed by decomposition of the $(CH_3)_3COO(CH_3)_2CH_2$ radical as suggested by reaction [7].

A value of 11.3 kcal has been reported (8) for the activation energy of reaction [9], the abstraction of a hydrogen atom from di-*t*-butyl peroxide by methyl radicals. Accepting our value of $E_2-E_6 = 3$ kcal and $E_2 = 11.2\pm$ kcal, as reported by Volman and Graven, the data indicate that less energy is required for the abstraction of a hydrogen atom from di-*t*-butyl peroxide by *t*-butoxy radicals than for the similar reaction by methyl radicals. A similar observation has been made regarding the case of abstraction reactions by methoxy and methyl radicals (9).

THE EXTRACTION OF PLUTONIUM FROM NEUTRON-IRRADIATED URANIUM BY URANIUM TRICHLORIDE AND BY MAGNESIUM CHLORIDE[1]

D. E. McKenzie,[2] W. L. Elsdon, and J. W. Fletcher

ABSTRACT

The extraction of plutonium from neutron-irradiated uranium by uranium trichloride and by magnesium chloride has been examined in the temperature range 1150° to 1250° C. The results of the uranium trichloride experiments have been used to evaluate the standard free-energy change of the equilibrium reaction $UCl_3 + Pu \leftrightharpoons PuCl_3 + U$. These free-energy values have been used to predict the plutonium extraction in the magnesium chloride experiments on the assumption that the uranium trichloride, continuously formed from the non-equilibrium reaction $3/2MgCl_2 + U \rightarrow UCl_3 + 3/2Mg$, rapidly established the above equilibrium with the plutonium in the uranium. Agreement between predicted and experimental results supports this assumption.

A preliminary study of the kinetics of the $MgCl_2$–U reaction showed that the initial rate of reaction is controlled by the distillation of magnesium metal from the reaction zone.

INTRODUCTION

In previous papers, the separation of plutonium from neutron-irradiated uranium by volatilization (1) and by liquid silver extraction (2) was described. Another possible technique for achieving this important separation is by reaction of plutonium with molten inorganic salts, as represented in the following equilibrium expression,

$$MX + Pu \leftrightharpoons PuX + M.$$

The plutonium salt formed by the reaction enters the salt phase and is thus separated from the uranium metal. This method has been examined by a number of investigators (3, 4) using uranium fluorides. The present paper describes an investigation of the extraction of plutonium by uranium trichloride and by magnesium chloride.

High-temperature thermodynamic data may be used to predict the distribution of plutonium between the salt and metal phases. From the data on the free energy of formation, the standard free-energy change accompanying the reactions may be calculated for a given temperature. These values may be used to obtain the equilibrium constant for that temperature. Using the mass-action expression for the equilibrium constant, the distribution of plutonium between the two phases may be calculated.

Since only estimated values for the free energies of formation of liquid uranium and plutonium chlorides are available (5, 6), the distribution equilibria are a useful check on the reliability of the available data for these compounds. Besides testing the available thermodynamic data, the above calculations have been reversed to give, from the experimental data, new equilibrium constants, and hence, standard free-energy changes accompanying the reactions. A similar procedure has been used by Buyers to determine the free energy of formation of plutonium trifluoride (7). These new values have been used to predict the distribution of plutonium in the experiments with magnesium chloride.

EXPERIMENTAL

Materials and Apparatus

The neutron-irradiated uranium was cut from natural uranium fuel rods which had been irradiated in the NRX reactor and allowed to decay for 3 years. The concentration

of plutonium in this material was 0.025%. Uranium trichloride was prepared from uranium metal by passing hydrogen chloride over the hydride (8). Considerable care to exclude moisture and air was required to obtain a pure product. Anhydrous magnesium chloride was obtained by carefully heating C.P. grade ammonium magnesium chloride hexahydrate in a current of dry hydrogen chloride to remove water, followed by further heating in vacuum to remove ammonium chloride. Magnesium analyses of the product gave 25.67 and 25.35% Mg, calculated 25.54%. The chlorides were stored and handled in a dry nitrogen atmosphere.

The uranium and salt, contained in an alumina crucible ("Triangle" recrystallized alumina, Morganite Carbon Products Canada Limited, 195 Eastern Ave., Toronto 2, Ontario), were heated by a tungsten wire coil surrounded by thermal and radiation shields. The assembly was mounted in a glass bulb which could be evacuated by diffusion and mechanical pumps (1). Temperatures were measured with a platinum, platinum – 10% rhodium thermocouple which was coiled in the heating zone as a seat for the crucible containing the charge. The thermocouple was calibrated to give the temperature of the charge by melting various pure metals in the apparatus. The temperature measurements were accurate to ±5° C.

Procedure and Analyses

For an experiment, the uranium was etched in acid to remove approximately 25% of its weight for a reference solution, then washed in water and acetone. Weighed amounts of the chloride and of neutron-irradiated uranium, in an alumina crucible, were placed in the apparatus. The glass bulb was pumped down to a pressure of 10^{-5} mm Hg or less and then the crucible was heated to 300° C for further degassing. After admitting welding grade argon to a pressure of 1 atmosphere, the charge was heated to temperature. The salt and uranium were contacted for 30 minutes in all runs except those where time was the variable to be studied.

After contacting, the charge was cooled in an argon atmosphere, separated from the crucible, and the salt phase dissolved or washed away from the metal billet. In each experiment the complete phase was dissolved for analysis. The solutions were analyzed for uranium (9) and magnesium (10) spectrophotometrically; plutonium was determined using standard radiochemical procedures. Plutonium recoveries of 95% or better were obtained in all runs.

RESULTS AND DISCUSSION

The Extraction of Plutonium with Uranium Trichloride

On contacting the liquid phases of uranium trichloride and neutron-irradiated uranium the following equilibrium is established:

$$UCl_3 + Pu \leftrightharpoons PuCl_3 + U.$$

The literature values of thermodynamic data listed in Table I were used to calculate the equilibrium constants for the above equilibrium. The distribution of plutonium between salt and metal was then predicted on the assumptions that plutonium behaves ideally in molten neutron-irradiated uranium and that the product plutonium trichloride dissolves to form an ideal solution in uranium trichloride. Evidence at higher temperatures for the former assumption has been obtained in previous work (1, 3), while the isomorphism of the trichlorides and the proximity of plutonium and uranium in the actinide series are supporting evidence for the validity of the latter.

The extraction of plutonium was examined for various U/UCl_3 mole ratios (Table II)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

and also at various temperatures (Table III). The proportions of the original plutonium remaining in the salt and in the metal phase are listed in the tables. The calculations using the thermodynamic data give directly the proportion of the original plutonium remaining in the uranium phase and these are listed in the last column of each table.

TABLE I

THERMODYNAMIC DATA FOR UCl_3 AND $PuCl_3$

Compound	Reference No.	$(\Delta F - \Delta H_{298})/T$(calories/degree) 500° K	1000° K	1500° K	ΔH_{298} (kcal)	Melting point (° K)
UCl_3	5	53.51 (s)	51.65 (s)	49 (l)	−213.5	1108
$PuCl_3$	6	54 (s)	53 (s)	50 (l)	−229.3	1033

Although the calculated values (Table II) for plutonium remaining in the uranium phase are close enough to the experimental values to be useful in making predictions, the experimental results at 1200° C are consistently lower (i.e. less plutonium in the uranium phase) than the predictions. Also, in Table III, there is excellent agreement for experiments at 1160° C but the data show a trend of increasing extraction with temperature, which is the reverse of that predicted by the thermodynamic data. In view of these discrepancies and the fact that the thermodynamic data were estimated, it seemed worth while to use the experimental data and the assumptions of ideality to calculate equilibrium constants and standard free-energy changes accompanying this reaction. The results of these calculations are shown in Table IV. The table shows for each temperature the "average" value for the equilibrium constant from which the standard free-energy

change for that temperature has been evaluated. This $\Delta F°$ is then compared with the previous estimate of Brewer *et al.* (5, 6). (For this comparison the estimates are listed to three significant figures although Brewer *et al.* give only two.)

As a test of the internal consistency of the data, a plot of log K vs. $1/T$ should yield a straight line. This plot is shown in Fig. 1. Although the result at 1250° C is low, the other data are reasonably consistent and may be represented, approximately, by the equation $\log K = 5.96 - (5.42 \times 10^3/T)$. From the slope of this line the enthalpy change accompanying the reaction $UCl_3 + Pu \leftrightharpoons PuCl_3 + U$ at about 1220° C is calculated to be 24.8 kcal.

The Reaction of Uranium Metal and Magnesium Chloride

Molten magnesium chloride in contact with molten uranium reacts according to the following equation:

$$3/2MgCl_2 + U \rightarrow UCl_3 + 3/2Mg.$$

Since magnesium chloride has a higher free energy of formation (i.e. more negative) than uranium trichloride, it would be expected that the reaction proceeds because the experiments were performed under conditions which permitted continuous distillation of magnesium from the reaction zone. It might be anticipated, further, that the initial rate of reaction will depend upon the surface area of uranium exposed to the salt. As the reaction proceeds, however, the rate will decrease owing to the accumulation of the reaction product, uranium trichloride, in the salt phase. These general expectations have been found to be correct.

The initial reaction rates have been measured using both neutron-irradiated uranium and natural uranium at a number of temperatures; the data are summarized in Table V and plotted as log rate (grams of U reacted/hr cm² U surface) vs. $1/T$ in Fig. 2. The results have been treated by the least squares method to give the equation: log rate (grams of U reacted/hr cm² U surface) $= 4.76 - (7.16 \times 10^3/T)$. From the slope of this line an activation energy of 32.8 kcal has been calculated for the rate-controlling step of the initial process. This activation energy may be compared with the value of 32.3 kcal per mole, the heat of vaporization of magnesium metal at 1200° C (11). This agreement is good evidence that the initial rate of the reaction of uranium metal and magnesium chloride is controlled by the distillation of magnesium metal from the reaction zone.

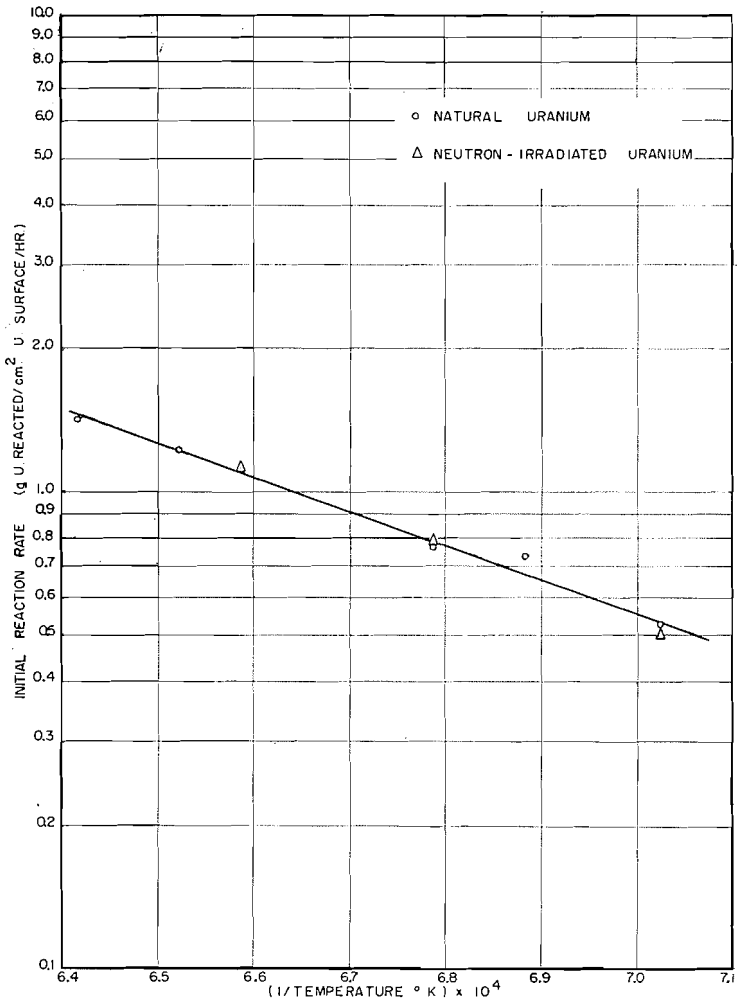

FIG. 2. The effect of temperature on the initial rate of reaction between magnesium chloride and uranium metal.

The Extraction of Plutonium in the Magnesium Chloride Experiments

For these experiments, the following reactions occur on contacting magnesium chloride with molten neutron-irradiated uranium:

$$3/2MgCl_2 + U \rightarrow UCl_3 + 3/2Mg \quad [1]$$

$$3/2MgCl_2 + Pu \rightarrow PuCl_3 + 3/2Mg \quad [2]$$

$$UCl_3 + Pu \leftrightharpoons PuCl_3 + U. \quad [3]$$

The experiments were performed under a pressure of one atmosphere of argon and at a temperature above the boiling point of magnesium metal. Thus, since the temperature of the glass bulb surrounding the reaction crucible was considerably below the melting point of magnesium, the magnesium continuously distilled from the reaction zone and equilibrium with respect to reactions [1] and [2] was not reached. To calculate the extraction of plutonium using thermodynamic data, it was assumed that reaction [3], which does no involve tvolatile components, was in equilibrium at all times, and that uranium trichloride was dissolved in an inert diluent, magnesium chloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

On this basis, the equilibrium constants, calculated from the expression derived for the uranium trichloride experiments, were used to predict the extraction of plutonium in the magnesium chloride experiments. At the conclusion of an experiment the concentration of uranium trichloride in the salt phase was determined (by chemical analysis) and substituted into the mass-action expression to calculate the plutonium distribution, again, assuming ideal solution behavior in the salt and metal phases.

The extraction of plutonium has been examined at three temperatures (Table VI) and for various times (Table VII). The tables show the mole fraction of uranium trichloride in the salt and the proportions of original plutonium in the salt and in the metal at the end of each experiment. The latter is compared with the calculated value for plutonium remaining in the uranium.

TABLE VI

EFFECT OF TEMPERATURE ON EXTRACTION OF PLUTONIUM BY MAGNESIUM CHLORIDE

Contacting time = 30 minutes

Temperature (° C)	Wt U (g)	Wt $MgCl_2$ (g)	Final UCl_3 in salt		Pu distribution (% original)		
					Exptl.		Calc.

1245	9.268	1.788	7.2	0.15	91.8	8.0	5.3

TABLE VII

EFFECT OF CONTACTING TIME ON EXTRACTION OF PLUTONIUM BY MAGNESIUM CHLORIDE AT 1200° C

Time (min)	Wt U (g)	Wt $MgCl_2$ (g)	Final UCl_3 in salt		Pu distribution (% original)		
					Exptl.		Calc.
			% Original U	Mole fraction	Salt	U	U
10	9.941	1.028	1.7	0.06	56.2	40.3	22.8
30	9.315	1.045	2.5	0.10	84.3	18.0	16.7
60	10.174	1.126	3.4	0.12	90.0	10.9	12.5
120	9.170	1.026	6.5	0.21	92.9	6.1	6.6

The reasonable agreement of the calculated and experimental results for contacting times of thirty minutes or longer provides some support for the assumptions used in making the calculations. Thus, the distribution of plutonium can be predicted from the concentration of uranium trichloride in the salt phase by assuming that the reaction between plutonium and uranium trichloride is at equilibrium even though magnesium chloride and uranium are still reacting. The results for the first experiment listed in Table VII indicate that this assumption does not hold for contacting times of less than thirty minutes.

Two additional experiments were performed at 1140° C and an argon pressure of 100 p.s.i.g. The objective in these experiments was to prevent the formation of uranium trichloride by preventing the distillation of magnesium metal. The data are summarized in Table VIII. While the application of pressure to this system did not completely prevent distillation, the results show that the rate of distillation was reduced, since there was considerably less uranium trichloride formed than in other 30-minute experiments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

(e.g. Table VI). Similarly, it would be expected that the rate of reaction between magnesium chloride and plutonium would be reduced below that for experiments at one atmosphere pressure. However, the reduction in the rate of this reaction would not be expected to influence the extraction equilibrium, since it is assumed that this equilibrium is controlled by the uranium trichloride concentration. The reasonable agreement between calculated and experimental results in these experiments provides additional support for this assumption.

CYCLOHEXANE COMPOUNDS

II. SYNTHESIS AND STRUCTURE OF TWO STEREOISOMERIC 3-AMINO-1,2-CYCLOHEXANEDIOLS[1,2]

R. A. B. Bannard and L. R. Hawkins

ABSTRACT

The stereoisomeric 1-ethoxy-2,3-epoxycyclohexanes were prepared from 1-ethoxycyclohexene-2 via 1-ethoxycyclohexene-2 bromohydrin. Ammonolysis of the lower- and higher-boiling oxides furnished 1α-ethoxy-2β-hydroxy-3α-aminocyclohexane and 1α-ethoxy-2α-hydroxy-3β-aminocyclohexane respectively. In a similar manner, 1α-methoxy-2β-hydroxy-3α-aminocyclohexane and 1α-methoxy-2α-hydroxy-3β-aminocyclohexane were obtained from 1-methoxycyclohexene-2 via 1-methoxycyclohexene-2 bromohydrin and the stereoisomeric 1-methoxy-2,3-epoxycyclohexanes. Ether cleavage of 1α-ethoxy- and 1α-methoxy-2β-hydroxy-3α-aminocyclohexane gave 3α-amino-1α,2β-cyclohexanediol hydrobromide, from which the free base was obtained. 3β-Amino-1α,2α-cyclohexanediol was prepared similarly from 1α-ethoxy- and 1α-methoxy-2α-hydroxy-3β-aminocyclohexane. The stereochemistry of the 3-amino-1,2-cyclohexanediols, 1-alkoxy-2-hydroxy-3-aminocyclohexanes, and 1-alkoxy-2,3-epoxycyclohexanes has been elaborated.

In 1947 Mousseron and co-workers (1, 2, 3) prepared an ethoxyaminocyclohexanol of unknown structure by ammonolysis of 1-ethoxy-2,3-epoxycyclohexane, and in 1952, McCasland *et al.* (4) obtained a similar substance, m.p. 132–134°, in the same manner as Mousseron *et al.* (1, 2, 3). The compound was characterized as the N-*p*-nitrobenzoyl derivative, m.p. 201–203°, and was converted on ether cleavage with hydrobromic acid

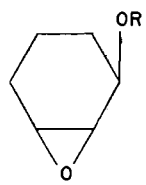
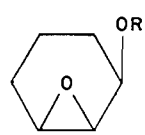
Contribution from Defence Research Chemical Laboratories, Ottawa, Canada. Issued as D.R.C.L. Report No. 273. Presented in part at the 41st Annual Conference of the Chemical Institute of Canada, Toronto, May 26–28, 1958.
[2]*For Part I of this series see reference 12.*

to an aminocyclohexanediol hydrobromide, m.p. 167–168°. The N-*p*-nitrobenzoyl derivative of the latter compound (m.p. 182–183°) rapidly consumed 1 mole of periodate, thus showing the aminediol to be a 3-amino-1,2-cyclohexanediol. McCasland *et al.* (4) did not assign a stereochemical structure to the substance but pointed out that of the four possible structures (I to IV) only I and II are probable, since oxide ring opening usually yields *trans*-oriented products (5, 6). The present communication describes the synthesis and assignment of structure to two isomeric 3-amino-1,2-cyclohexanediols and to the 1-alkoxy-2,3-epoxycyclohexanes and 1-alkoxy-2-hydroxy-3-aminocyclohexanes used as intermediates in their preparation.

Mousseron *et al.* (1, 2, 3) and McCasland *et al.* (4) had prepared 1-ethoxy-2,3-epoxycyclohexane, either by peracid oxidation of 1-ethoxycyclohexene-2, or by the action of aqueous alkali on 1-ethoxycyclohexene-2 chlorohydrin (V or VI; R = C_2H_5, X = Cl). The chlorohydrin, which was obtained (1, 3, 4) by interaction of monochlorourea (7, 8) and 1-ethoxycyclohexene-2, was considered by McCasland *et al.* (4) to possess structure VI (R = C_2H_5, X = Cl). No proof was submitted in support of this structure nor was it demonstrated that the chlorohydrin thus obtained consists of a mixture of isomers. In 1942 Moir (9), McRae (10), and co-workers studied the reaction between 1-methoxycyclohexene-2 and monochlorourea, and found that a mixture of isomeric chlorohydrins (V or VI; R = CH_3, X = Cl) was formed together with 1-methoxycyclohexene dichloride. It did not prove possible to separate the isomeric chlorohydrins from each other or completely from the dichloride by fractional distillation. The chlorohydrin mixture on treatment with aqueous alkali yielded a mixture of stereoisomeric 1-methoxy-2,3-epoxycyclohexanes (VII and VIII; R = CH_3), demonstrating the presence of at least two isomeric chlorohydrins in the mixture. Somewhat later, but prior to the work of Mousseron *et al.* (1, 3) and McCasland *et al.* (4), Fenton (11) showed that 1-ethoxycyclohexene-2 on treatment with monochlorourea led to a mixture of isomeric chlorohydrins (V or VI; R = C_2H_5, X = Cl) which in turn gave two stereoisomeric 1-ethoxy-2,3-epoxycyclohexanes (VII and VIII; R = C_2H_5). Fenton (11) did not make it clear whether or not 1-ethoxycyclohexene dichloride was present in the chlorohydrin mixture. Repetition of Fenton's work revealed that 1-ethoxycyclohexene dichloride is indeed present. Numerous attempts to separate the chlorohydrin–dichloride mixture by fractional distillation proved fruitless (see Table III).



(VII)



(VIII)

The presence of dichlorides in the 1-alkoxycyclohexene-2 chlorohydrins detracts from their usefulness for preparation of the corresponding oxides, since both the *trans*-, or lower-boiling, oxide (VII) and the *cis*-, or higher-boiling, oxide (VIII) were contaminated with chlorinated substances (10). Furthermore, the fact that the isomeric chlorohydrins are not readily separable makes them impractical as intermediates for preparation of

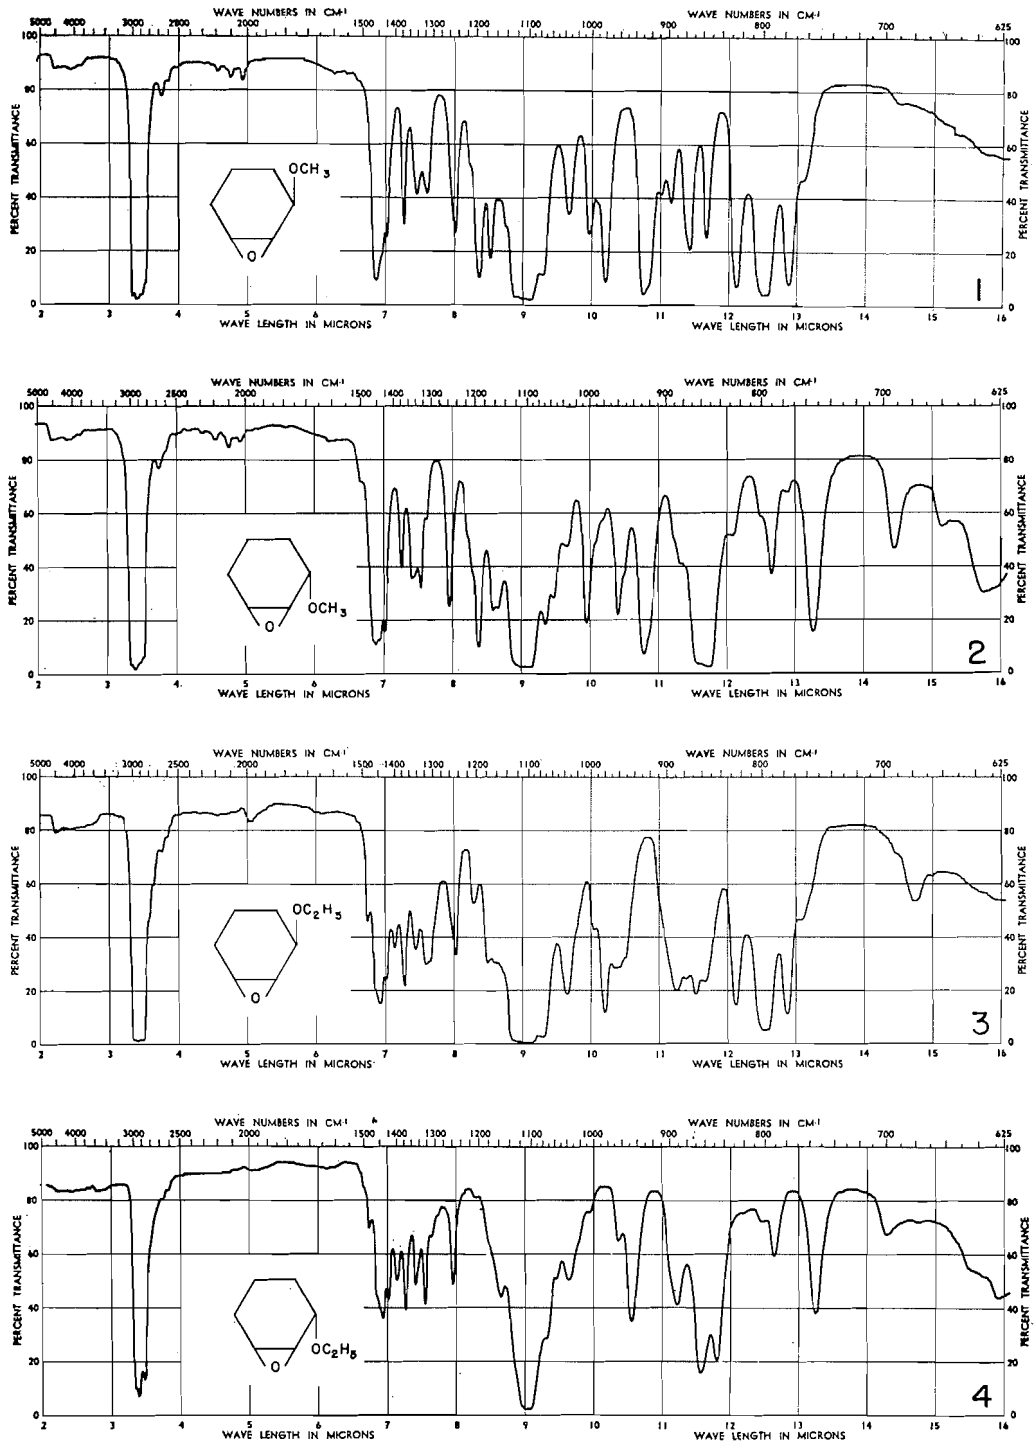
the 1-ethoxy-2-hydroxy-3-aminocyclohexanes by direct ammonolysis (12) because it has been found in the present investigation that separation of the resultant stereoisomeric amines is too laborious. Attention was therefore turned to preparation of the corresponding bromohydrins in the hope that either or both disadvantages characteristic of the chlorohydrins would be eliminated.

For many years the structures of the 1-methoxy-2,3-epoxycyclohexanes remained unassigned. Recently, however, it has been shown by Lemieux, Kullnig, and Moir (13) via proton magnetic resonance spectroscopy on the 1,3-dimethoxy-2-acetoxycyclohexanes resulting from acetylation of the products of methanolysis of the 1-methoxy-2,3-epoxycyclohexanes, that the lower-boiling isomer (the so-called α-isomer (10)) has the *trans*-configuration and the higher-boiling isomer (the so-called β-isomer (10)) the *cis*-configuration. This work, however, still left unsettled the configurations of Fenton's 1-ethoxy-2,3-epoxycyclohexanes. It will be demonstrated in the sequel that in this case also, the lower-boiling oxide is the *trans*-isomer and the higher-boiling oxide the *cis*-isomer.

1-Methoxy- and 1-ethoxycyclohexene-2 were prepared by modification of the method of Gogek *et al.* (14). 1-Methoxycyclohexene-2 on treatment with N-bromosuccinimide in aqueous suspension (cf. Guss and Rosenthal (15)) gave a mixture of isomeric 1-methoxycyclohexene-2 bromohydrins (V or VI; R = CH_3, X = Br) in 77% yield, uncontaminated with the corresponding dibromide. In a similar manner the mixed 1-ethoxycyclohexene-2 bromohydrins (V or VI; R = C_2H_5, X = Br) were obtained in 85% yield also free of dibromide. It did not prove possible to separate the isomeric bromohydrins by fractional distillation. However, the bromohydrin mixtures proved much superior to the chlorohydrin–dichloride mixtures as intermediates for preparation of the stereoisomeric 1-alkoxy-2,3-epoxycyclohexanes (VII and VIII).

1-Methoxycyclohexene-2 bromohydrin (V or VI; R = CH_3, X = Br) on treatment with aqueous sodium hydroxide gave an 84% yield of the stereoisomeric *dl*-1-methoxy-2,3-epoxycyclohexanes (VII and VIII; R = CH_3), which were readily separated by fractional distillation and were free of halogenated material (cf. McRae *et al.* (10)). On the basis of refractive index and infrared spectra of the various fractions (see Table V) it was estimated that the yield of *trans*-, or lower-boiling, oxide is 63% and that of the *cis*-, or higher-boiling, oxide is 19%. Thus, the percentages of *trans*- and *cis*-oxide in the mixture are 77% and 23% respectively, suggesting the same percentage composition for the 1-methoxycyclohexene-2 bromohydrin mixture. In a similar manner the stereoisomeric *dl*-1-ethoxy-2,3-epoxycyclohexanes (VII and VIII; R = C_2H_5) were obtained in 88% yield. The yield of *trans*-oxide was estimated to be 70.5% and that of the *cis*-oxide 17.5%, giving a distribution of 80% *trans*- and 20% *cis*-oxide in the mixture. It is evident from Table IV that fractionation of the 1-ethoxy-2,3-epoxycyclohexanes was not as clean cut as with the corresponding methoxy compounds. This result was unexpected in view of the difference in boiling points of the isomers and the high reflux ratio used.

The spectra of the 1-methoxy- and 1-ethoxy-2,3-epoxycyclohexanes are shown in Figs. 1 to 4. These substances give a strong band at 1100 cm^{-1} characteristic of the unsymmetrical C—O—C stretching vibration in aliphatic ethers (16). Absorption due to the symmetrical ring stretching vibration of the oxirane ring was observed in the characteristic 1250 cm^{-1} region (16). In each case, the *trans*-isomer showed a medium intensity band at 1245 cm^{-1} and the *cis*-isomer showed a similar band at 1255 cm^{-1}. It is possible to use the bands at 1245 and 1255 cm^{-1} as criteria of purity of the oxides but the change in intensity of these bands is not sufficiently great to permit accurate quantitative



FIGS. 1–4. Infrared spectra of the 1-alkoxy-2,3-epoxycyclohexanes.

estimation of the compositions of mixtures—the refractive index gives a more sensitive method. However, there are a number of bands in the region 690–1380 cm^{-1} which show great differences in intensity as the composition of mixtures of the *trans*- and *cis*-oxides change, some of which could undoubtedly be used for quantitative estimation by means of a suitable calibration curve. The *trans*-oxides show prominent characteristic bands at 775, 795, 800, 825, 980, 1200, and 1380 cm^{-1}, whereas the *cis*-oxides show prominent characteristic bands at 690, 755, 790, 845, 865, and 1325 cm^{-1}. The forerun of each oxide contained a trace of carbonyl impurity as shown by the appearance of a weak band at 1675 cm^{-1}. This carbonyl impurity could be due to the presence of a trace of *cis*-bromohydrin in the predominantly *trans*-oriented bromohydrin mixture (17), since the action of alkali on the former would lead to ketone rather than epoxide (18, 19).

Ammonolysis of *dl*-1β-methoxy-2α,3α-epoxycyclohexane* (VII; R = CH_3) with aqueous ethanolic ammonia by Hawkins and Bannard's method (12) gave *dl*-1α-methoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = CH_3), m.p. 107–108°, in 84% yield, uncontaminated with its isomer X (R = CH_3), as shown by paper chromatography. In a similar manner, ammonolysis of *dl*-1α-methoxy-2α,3α-epoxycyclohexane (VIII; R = CH_3) produced *dl*-1α-methoxy-2α-hydroxy-3β-aminocyclohexane (X; R = CH_3), m.p. 94°, in 75% yield, uncontaminated with its isomer IX (R = CH_3). The two 1-methoxy-2-hydroxy-3-aminocyclohexanes (IX and X; R = CH_3) were shown to be distinctly different by comparison of their infrared spectra, paper chromatographic behavior (see Table VI), a mixed melting-point determination (m.p. 72–92°), and preparation of their hydrobromides, and N-acetyl, N-*p*-nitrobenzoyl, and N-phenylthiourea derivatives listed in Table I.

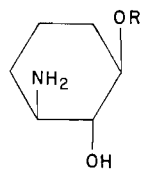
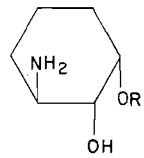
[a]McCasland *et al.* (4) report m.p. 201–203°.

**The system of nomenclature used to describe the configurations of the 1-alkoxy-2,3-epoxycyclohexanes and compounds obtained on scission of the oxirane ring conforms to that used by Lemieux, Kullnig, and Moir (13).*

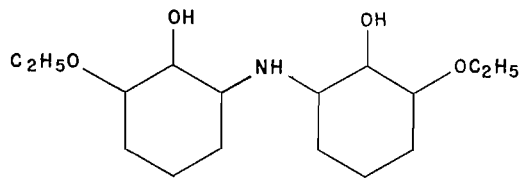


(IX)



(X)

Ammonolysis of *dl*-1β-ethoxy-2α,3α-epoxycyclohexane (VII; R = C_2H_5) gave *dl*-1α-ethoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = C_2H_5), m.p. 134.5–135.5°, in 77% yield, uncontaminated with its isomer X (R = C_2H_5). In one experiment in which an ammonia/oxide ratio of less than 20:1 was used, a small amount of the secondary amine α,α-bis-(2β-hydroxy-3α-ethoxycyclohexyl)amine (XI) was obtained and isolated as the hydrobromide, m.p. 313–314° (cf. Hawkins and Bannard (12)). Ammonolysis of *dl*-1α-ethoxy-2α,3α-epoxycyclohexane (VIII; R = C_2H_5) furnished *dl*-1α-ethoxy-2α-hydroxy-3β-aminocyclohexane (X; R = C_2H_5), m.p. 133–134°, in 89% yield, uncontaminated with its isomer IX (R = C_2H_5). The two 1-ethoxy-2-hydroxy-3-aminocyclohexanes (IX and X; R = C_2H_5) were shown to differ from one another by comparison of infrared spectra, paper chromatographic behavior (see Table VI), a mixed melting-point determination (m.p. 116–118°), and preparation of their hydrobromides and N-acetyl, N-*p*-nitrobenzoyl, and N-phenylthiourea derivatives given in Table I.



(XI)

It is evident from the melting points of the N-*p*-nitrobenzoyl derivatives of the *dl*-1-ethoxy-2-hydroxy-3-aminocyclohexanes (Table I) that McCasland *et al.* (4) obtained *dl*-1α-ethoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = C_2H_5). This result was anticipated in view of the fact that the *trans*-oxide greatly predominates in the mixture of stereoisomeric oxides resulting from the action of alkali on the 1-ethoxycyclohexene-2 bromohydrins, implying that a similar situation would prevail in the case of the corresponding chlorohydrins. A similar result (i.e. predomination of *trans*-oxide) would also be expected when the oxide is prepared by peracid oxidation of 1-methoxycyclohexene-2 (1, 2, 3, 4,), since Henbest and Wilson (20, 21) have found that peracid oxidation of cyclic allylic esters or ethers yields predominantly the *trans*-oxide. It thus seems certain that Mousseron *et al.* (1, 2, 3) obtained the same compound as McCasland *et al.* (4) but in a less pure condition.

Ether cleavage of *dl*-1α-methoxy-2β-hydroxy-3α-aminocyclohexane or *dl*-1α-ethoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = CH_3 or C_2H_5) with 47% hydrobromic acid gave *dl*-3α-amino-1α,2β-cyclohexanediol hydrobromide, m.p. 168–169°, in 90% yield,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

which was converted to the free base I, m.p. 151°, in 87% yield. In a similar manner, ether cleavage of *dl*-1α-methoxy-2α-hydroxy-3β-aminocyclohexane or *dl*-1α-ethoxy-2α-hydroxy-3β-aminocyclohexane (X; R = CH_3 or C_2H_5) gave *dl*-3β-amino-1α,2α-cyclohexanediol hydrobromide, m.p. 165.5–167°, in 70% yield, which was converted to the free base II, m.p. 104–105°, in 95% yield. The two aminediols were shown to be quite different by a mixed melting-point determination with their hydrobromides (m.p. 145–150°), comparison of their infrared spectra and paper chromatographic behavior (see Table VI), and preparation of the N-*p*-nitrobenzoyl, N-phenylthiourea, and triacetyl derivatives listed in Table II.

*Contains 1 molecule of ethanol of crystallization.

The data presented above establish the stereochemical identity of the 1-alkoxy-2-hydroxy-3-aminocyclohexanes (IX; R = CH_3 or C_2H_5) resulting from ammonolysis of the α- or lower-boiling 1-alkoxy-2,3-epoxycyclohexanes (VII; R = CH_3 or C_2H_5) and necessarily also show the stereochemical equivalence of the two oxides. Similarly the stereochemical identity of the 1-alkoxy-2-hydroxy-3-aminocyclohexanes (X; R = CH_3 or C_2H_5) resulting from ammonolysis of the β- or higher-boiling 1-alkoxy-2,3-epoxycyclohexanes (VIII; R = CH_3 or C_2H_5) has also been demonstrated and the stereochemical equivalence of the two oxides follows. Furthermore, it has been clearly shown that the α- and β-oxides differ from one another since they lead to distinctly different aminocyclohexanediols. The aminediols were shown to be 3-amino-1,2-cyclohexanediols, since the N-*p*-nitrobenzoyl derivative in each case rapidly consumed 1 mole of periodate at 25° (22). However, reaction was so rapid at this temperature that the relative rates of oxidation of the two isomers could not be observed with sufficient accuracy to permit stereochemical assignment to the diols. Repetition of the oxidation with sodium metaperiodate at 3°, however, gave the results shown in Fig. 5. Comparison of the $t_{\frac{1}{2}}$ values makes it clear that the diol group in the aminediol resulting from ammonolysis of the β-oxides must be assigned the *cis*-configuration II and the diol group in the aminediol from ammonolysis of the α-oxides must possess the *trans*-configuration I, since the N-*p*-nitrobenzoyl derivative of the former is oxidized 7.5 times more rapidly than that of the latter (23, 24, 25).

The N-phenylthiourea derivatives of the aminediols were prepared in the expectation that determination of relative rates of cleavage of the isomers with periodate would lead to confirmation of the structures assigned above. However, the periodate cleavage of these derivatives proved abnormal in that even the N-phenylthiourea derivative of

○ 3β-*p*-Nitrobenzamido-1α,2α-cyclohexanediol

trans-2-aminocyclohexanol reacted rapidly with periodate. Thus, these derivatives cannot be used to protect an amine function during diol scission with periodate.

Ionophoretic migration of *cis*-1,2-diols in borate buffer is generally considered to be associated with formation of ionized chelated complexes (25, 26) and has been used to deduce the structure of cyclitols (27). The ionophoretic mobilities of the N-*p*-nitrobenzoyl and N-phenylthiourea derivatives of the aminediols I and II in 0.1 *M* sodium tetraborate were determined. In each case (see Table VII) the derivative arising from the β- or higher-boiling 1-alkoxy-2,3-epoxycyclohexanes exhibited ionophoretic mobility, while the derivative obtained from the α- or lower-boiling 1-alkoxy-2,3-epoxycyclohexanes did not migrate, thus leading to the conclusion that derivatives obtained by oxide ring scission of the former compounds contain a *cis*-1,2-diol group (I), whereas derivatives obtained similarly from the latter compounds contain a *trans*-1,2-diol group (II). This result confirms the structural assignment made on the basis of relative rates of periodate cleavage of the aminediol N-*p*-nitrobenzoyl derivatives.

It is assumed throughout that opening of the oxirane ring under the basic conditions used is accompanied by Walden inversion at the reactive carbon atom (i.e. C_3) (4, 5, 6, 14, 28, 29), and that ether cleavage is not attended by Walden inversion (see Gogek *et al.* (14) and references there cited, also Lemieux, Kullnig, and Moir (13)). Assignment of structure I to the *trans*-diol leads to structure IX (R = CH_3 or C_2H_5) for the 3-amino-1-alkoxy-2-hydroxycyclohexanes derived from the α-oxides and hence to the *trans* structure VII (R = CH_3 or C_2H_5) for the latter, in agreement with the conclusion reached by Lemieux, Kullnig, and Moir (13) in the case of the α-methoxy oxide (VII; R = CH_3). In a similar manner, assignment of structure II to the *cis*-diol leads to structure X (R = CH_3 or C_2H_5) for the 3-amino-1-alkoxy-2-hydroxycyclohexanes derived from the β-oxides and hence to the *cis* structure VIII (R = CH_3 or C_2H_5) for the latter.

Lemieux, Kullnig, and Moir (13) have pointed out that both 1-methoxy-2,3-epoxycyclohexanes (VII and VIII; R = CH_3) show a preference for attack at position 3 by nucleophilic reagents and suggest that such preference is probably an electronic effect of the presence of the electronegative alkoxyl group, rather than a steric effect. This suggestion receives support from the results reported above on ammonolysis of the 1-methoxy- and 1-ethoxy-2,3-epoxycyclohexanes (VII and VIII; R = CH_3 or C_2H_5).

EXPERIMENTAL*, †

trans-1,2-Dibromocyclohexane

trans-1,2-Dibromocyclohexane was prepared by the method of Snyder and Brooks (30).

1-Methoxycyclohexene-2

1-Methoxycyclohexene-2 was prepared by the method of Gogek *et al.* (14), with the method of isolation modified as follows. After the solution of *trans*-1,2-dibromocyclohexane (3.88 g, 1.60 moles), sodium (90.0 g, 3.9 g-atoms), and absolute methanol (1100 ml) had been heated under reflux for 10 hours, the precipitated sodium bromide was collected by suction filtration and washed with anhydrous ether (6×50 ml). The filtrate and washings were distilled on the steam bath first at atmospheric pressure and finally at 25–30 mm pressure until a semisolid mushy residue remained. The residue was treated with water (200 ml) and the solution was extracted with ether (3×50 ml). The extracts were combined with the earlier distillates and the solution was fractionated slowly at atmospheric pressure using a 20-inch vacuum-jacketed Stedman column, yielding 134 g (74.8%) of 1-methoxycyclohexene-2 as a colorless mobile fragrant liquid, b.p. 138–139°, n_D^{25} 1.4513–1.4518. Gogek *et al.* (14) report a 60% yield of substance, b.p. 139°. Berlande (31) has reported n_D^{20} 1.4530.

1-Ethoxycyclohexene-2

1-Ethoxycyclohexene-2 was prepared by the same method as described above for 1-methoxycyclohexene-2. Yield, 58.5%, b.p. 153–154°, n_D^{25} 1.4490. Berlande (31) has reported b.p. 156°, and n_D^{20} 1.4585. Fenton (11) reported b.p. 153–153.5°.

1-Ethoxycyclohexene-2 Chlorohydrin

1-Ethoxycyclohexene-2 chlorohydrin was prepared by the method of Fenton (11) using monochlorourea as the source of hypochlorous acid. From 378 g (3.0 mole) of 1-ethoxycyclohexene-2, 358 g of colorless to pale yellow liquid, b.p. 108–113° at 11–13 mm pressure, n_D^{25} 1.4784–1.4794, was obtained. Fenton (11) reported b.p. 105–120° at 20 mm pressure and McCasland *et al.* (4) reported b.p. 110–117° at 12 mm. Refractionation at 1–2 mm pressure of 770 g of chlorohydrin prepared by the above method gave the fractions indicated in Table III.

TABLE III

FRACTIONATION OF 1-ETHOXYCYCLOHEXENE-2 CHLOROHYDRIN

Fraction No.	B.p. (° C)	Weight (g)	Refractive index n_D^{25}	Analysis[a]

1-Ethoxycyclohexene-2 Bromohydrin

N-Bromosuccinimide (178 g, 1.00 mole), 1-ethoxycyclohexene-2 (132 g, 1.05 mole),

*All melting points and boiling points are uncorrected.
†Microanalyses by Micro-Tech Labs., Skokie, Ill., and J. G. Helie, of these laboratories.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

and water (500 ml) were mixed at 25° in a 1-liter three-necked flask equipped with a "trubore" stirrer and thermometer (12). Stirring was continued until the N-bromosuccinimide dissolved (20 minutes) and a heavy colorless layer of bromohydrin separated, during which time the temperature rose to 75°. The two-phase system was allowed to cool to room temperature, the bromohydrin layer was separated, and the aqueous phase was extracted with ether (2×100 ml). The extracts and bromohydrin were combined and the ether removed by distillation *in vacuo*. The residue was kept overnight at 4°, after which the precipitated succinimide was removed by filtration. The filtrate was fractionated *in vacuo* yielding 190 g (85.2%) of 1-ethoxycyclohexene-2 bromohydrin as a colorless oil, b.p. 87.5–91.5° at 0.3 mm, n_D^{25} 1.5018–1.5025. Calc. for $C_8H_{15}O_2Br$: C, 43.07; H, 6.78; Br, 35.82%. Found: C, 42.95; H, 6.82; Br, 35.82%.

1-Methoxycyclohexene-2 Bromohydrin

1-Methoxycyclohexene-2 bromohydrin was prepared in exactly the same manner as described for 1-ethoxycyclohexene-2 bromohydrin. Yield, 161 g (77.0%) of colorless oil, b.p. 94–97° at 1 mm, n_D^{25} 1.5120–1.5131. Calc. for $C_7H_{13}O_2Br$: C, 40.22; H, 6.27; Br, 38.22%. Found: C, 40.08; H, 6.35; Br, 37.98%.

dl-1β-Ethoxy-2α,3α-epoxycyclohexane and dl-1-α-Ethoxy-2α,3α-epoxycyclohexane (VII and VIII; R = C_2H_5)

1-Ethoxycyclohexene-2 bromohydrin (234 g, 1.05 mole) was treated with aqueous sodium hydroxide (120 g, 2.94 moles, 300 ml) at 25° with mechanical stirring. The temperature rose to 35° and the lower bromohydrin layer was replaced by a supernatant layer of colorless oxide. The mixture was heated at 75° for 1 hour with continuous stirring, and cooled to room temperature; the oxide layer was then separated and the aqueous phase extracted with ether (3×100 ml). The combined oxide and ether extracts were dried over anhydrous magnesium sulphate, after which the ether was removed *in vacuo*. The colorless residue was fractionated at 10 mm pressure using a Podbielniak Whirling Heli-Band column, employing diphenylmethane as "chaser" during the final stage of fractionation, giving the results shown in Table IV.

TABLE IV

FRACTIONATION OF 1-ETHOXY-2,3-EPOXYCYCLOHEXANES

Fraction No.	B.p. (° C)	Refractive index n_D^{25}	Weight (g)	Analysis*	
				% C	% H
1	55.5–56.0	1.4484	84.2	67.52	10.01
2	56.0–56.5	1.4491	21.6	67.80	10.14
3	56.5–64.5	1.4520	2.3	67.63	9.91
4	64.5–65.5	1.4554	23.0	67.81	10.11
			131		

*Calc. for $C_8H_{14}O_2$: C, 67.58; H, 9.92%.

From Table IV it is clear that the 1-ethoxy-2,3-epoxycyclohexanes were obtained in 88.0% yield. Fraction 1 is pure *trans*-oxide, since the infrared spectrum of this compound showed the characteristic oxirane band at 1245 cm^{-1}, and fraction 4 is pure *cis*-oxide, since its infrared spectrum showed the characteristic oxirane band at 1255 cm^{-1}. Fractions 2 and 3 are mixtures of the two oxides, since both the above-mentioned bands were present in the infrared spectra. Mixtures of the pure oxides gave a linear relationship between refractive index and percentage composition and the yields of the two

oxides were estimated. The yield of *trans*-oxide is 105 g (70.4%) and that of *cis*-oxide is 26.3 g (17.6%), i.e. the mixture consists of 80% *trans*-oxide and 20% *cis*-oxide. Fenton (11) reported b.p. 82–84° at 20 mm for *trans*-oxide and 97–100° at 20 mm for *cis*-oxide. McCasland *et al.* (4) gave b.p. 79–82° at 15–16 mm and n_D^{25} 1.4530 for the oxide mixture resulting from peracid oxidation of 1-ethoxycyclohexene-2, and Mousseron *et al.* (3) gave b.p. 77–78° at 12 mm and n_D^{25} 1.4493 for a similar product.

dl-1β-Methoxy-2α,3α-epoxycyclohexane and dl-1α-Methoxy-2α,3α-epoxycyclohexane (VII and VIII; R = CH_3)

1-Methoxycyclohexene-2 bromohydrin (146 g, 0.70 mole) was treated with aqueous sodium hydroxide (84.0 g, 2.04 mole, 200 ml), as described for the preparation of the corresponding ethoxy compounds, yielding, after subsequent manipulation as described above, the fractions shown in Table V.

TABLE V

FRACTIONATION OF 1-METHOXY-2,3-EPOXYCYCLOHEXANES

Fraction No.	B.p. (° C)	Refractive index n_D^{25}	Weight (g)	Analysis*	
				% C	% H
1	54–55	1.4512	55.0	65.69	9.52
2	55–65	1.4520	0.7	65.82	9.57
3	65–69	1.4545	1.9	65.80	9.66
4	69–71	1.4585	17.4	65.71	9.56
			75		

*Calc. for $C_7H_{12}O_2$: C, 65.58; H, 9.44%.

From Table V it is evident that the yield of 1-methoxy-2,3-epoxycyclohexane mixture is 83.8%. Fraction 1 is pure *trans*-oxide and fraction 4 is pure *cis*-oxide, while fractions 2 and 3 are mixtures (infrared spectra). As in the case of the corresponding ethoxy compounds the composition of mixtures was estimated on the basis of refractive index. The yield of *trans*-oxide is thus 56.5 g (63.2%) and that of *cis*-oxide 17.4 g (19.4%), i.e. the mixture consists of approximately 77% *trans*-oxide and 23% *cis*-oxide. McRae *et al.* (10) have reported b.p. 67–69° at 15 mm and n_D^{20} 1.4532 for the *trans*-oxide and b.p. 75–85° at 12 mm and n_D^{20} 1.4603 for the *cis*-oxide.

dl-1α-Methoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = CH_3)

dl-1β-Methoxy-2α,3α-epoxycyclohexane (12.8 g, 0.100 mole) was heated for 1 hour at 100° in a stainless-steel bomb with 28% aqueous ammonia (135 ml, 2 moles) and absolute ethanol (60 ml) (12). The solution was evaporated to dryness *in vacuo* and the resultant buff-colored amine was sublimed at 110–120° at 1 mm, yielding 12.1 g (83.5%) of colorless *dl*-1α-methoxy-2β-hydroxy-3α-aminocyclohexane, m.p. 107–108°. Calc. for $C_7H_{15}O_2N$: C, 57.90; H, 10.41; N, 9.65%. Found: C, 57.52; H, 10.39; N, 9.58%.

dl-1α-Methoxy-2α-hydroxy-3β-aminocyclohexane (X; R = CH_3)

dl-1α-Methoxy-2α,3α-epoxycyclohexane (15.0 g, 0.117 mole) was ammonolyzed with aqueous ethanolic ammonia under the conditions described for 1β-methoxy-2α,3α-epoxycyclohexane, yielding 12.8 g (75.3%) of *dl*-1α-methoxy-2α-hydroxy-3β-aminocyclohexane as colorless feathery needles, m.p. 94°, after recrystallization from ethanol–ether. Calc. for $C_7H_{15}O_2N$: C, 57.90; H, 10.41; N, 9.65%. Found: C, 57.47; H, 10.39; N, 9.58%.

dl-1α-Ethoxy-2β-hydroxy-3α-aminocyclohexane (IX; R = C_2H_5)

dl-1β-Ethoxy-2α,3α-epoxycyclohexane (31.1 g, 0.219 mole) was ammonolyzed with aqueous ethanolic ammonia under the conditions described for *dl*-1β-methoxy-2α,3α-epoxycyclohexane, yielding 26.8 g (77.0%) of *dl*-1α-ethoxy-2β-hydroxy-3α-aminocyclohexane as colorless platelets, m.p. 134.5–135.5°, after recrystallization from ethanol–ether. McCasland *et al.* (4) report m.p. 132–134° for this compound. Calc. for $C_8H_{17}O_2N$: C, 60.35; H, 10.76; N, 8.80%. Found: C, 60.67; H, 10.93; N, 8.72%.

In one experiment in which the ammonia–oxide ratio was less than 20:1 a small amount of α,α-bis-(2β-hydroxy-3α-ethoxycyclohexyl)amine was obtained, and isolated as the hydrobromide, m.p. 313–314°. Calc. for $C_{16}H_{32}O_4NBr$; C, 50.27; H, 8.44; N, 3.66; Br, 20.9%. Found: C, 50.36; H, 8.47; N, 4.12; Br, 20.93%.

dl-1α-Ethoxy-2α-hydroxy-3β-aminocyclohexane (X; R = C_2H_5)

dl-1α-Ethoxy-2α,3α-epoxycyclohexane (16.1 g, 0.113 mole) was ammonolyzed with aqueous ethanolic ammonia under the conditions described for *dl*-1β-methoxy-2α,3α-epoxycyclohexane, yielding 16.0 g (88.8%) of *dl*-1α-ethoxy-2α-hydroxy-3β-aminocyclohexane as fine colorless needles, m.p. 133–134°, after recrystallization from ethanol–ether. Calc. for $C_8H_{17}O_2N$: C, 60.35; H, 10.76; N, 8.80%. Found: C, 60.51; H, 10.83; N, 8.73%.

Derivatives of the dl-1-Alkoxy-2-hydroxy-3-aminocyclohexanes

The *dl*-1-alkoxy-2-hydroxy-3-aminocyclohexanes reported above were characterized as their hydrobromides and N-acetyl, N-*p*-nitrobenzoyl, and N-phenylthiourea derivatives. The hydrobromides and N-phenylthiourea derivatives were prepared by standard methods. The N-*p*-nitrobenzoyl derivatives were prepared by Leffler and Adams' procedure (32). The N-acetyl derivatives were obtained by treating the alkoxyaminocyclohexanols with a 10% excess of acetic anhydride at room temperature, followed by evaporation to dryness *in vacuo*, and recrystallization from ethanol–ether. Yields, melting points, and analytical data for the derivatives are given in Table I.

dl-3α-Amino-1α,2β-cyclohexanediol Hydrobromide

(*a*) *From dl-1α-Ethoxy-2β-hydroxy-3α-aminocyclohexane* (IX; R = C_2H_5)

dl-1α-Ethoxy-2β-hydroxy-3α-aminocyclohexane (60.0 g, 0.377 mole) was heated under reflux for 1½ hours with 48% hydrobromic acid (230 ml, 2.0 moles). Most of the excess acid was removed by distillation *in vacuo* but no attempt was made to distill to dryness (cf. McCasland *et al.* (4)). The residue was treated with ether (300 ml) and ethanol (75 ml) and evaporated *in vacuo* to small volume. This operation was repeated, after which 300 ml of ether was added, followed by just sufficient ethanol to produce a clear solution. When the solution was allowed to stand at 4°, *dl*-3α-amino-1α,2β-cyclohexanediol hydrobromide separated as colorless to light-grey rosettes. Yield, 73.1 g (91.4%), m.p. 168–169°. McCasland *et al.* (4) report m.p. 167–168°. Calc. for $C_6H_{14}O_2NBr$: C, 33.98; H, 6.65; N, 6.61; Br, 37.68%. Found: C, 33.89; H, 6.71; N, 6.66; Br, 37.64%.

(*b*) *From dl-1α-Methoxy-2β-hydroxy-3α-aminocyclohexane* (IX; R = CH_3)

dl-1α-Methoxy-2β-hydroxy-3α-aminocyclohexane (35.0 g, 0.241 mole) was subjected to ether cleavage under the conditions described above. Crystallization of the product from ethanol–ether furnished 46.3 g (90.5%) of *dl*-3α-amino-1α,2β-cyclohexanediol hydrobromide as colorless to light-grey rosettes, m.p. 167.5–169°. Admixture of this substance with that obtained in (*a*) above did not depress the melting point. The two samples gave identical infrared spectra, and moved with the same speed in paper chromatograms (R_F 0.40, see Table VI).

For personal use only.

dl-3α-Amino-1α,2β-cyclohexanediol (I)

dl-3α-Amino-1α,2β-cyclohexanediol hydrobromide (60.0 g, 0.283 mole) was dissolved in a solution of sodium hydroxide (11.8 g, 0.286 mole in 100 ml water). Evaporation to dryness *in vacuo* gave a light-tan crystalline residue, which was sublimed at 140° at 0.5 mm to free it from inorganic material. Recrystallization of the sublimate from absolute ethanol yielded 32.4 g (87.4%) of *dl*-3α-amino-1α,2β-cyclohexanediol, m.p. 151°, as colorless prisms. Calc. for $C_6H_{13}O_2N$: C, 54.93; H, 9.99; N, 10.68%. Found: C, 55.05; H, 10.11; N, 10.71%.

dl-3β-Amino-1α,2α-cyclohexanediol Hydrobromide

(*a*) *From dl-1α-Ethoxy-2α-hydroxy-3β-aminocyclohexane* (X; R = C_2H_5)

dl-1α-Ethoxy-2α-hydroxy-3β-aminocyclohexane (14.0 g, 0.88 mole) was subjected to ether cleavage under the conditions described for its isomer. Crystallization from ethanol–ether gave 13.0 g (69.8%) of *dl*-3β-amino-1α,2α-cyclohexanediol hydrobomide as colorless rosettes, m.p. 165.5–167°. Calc. for $C_6H_{14}O_2NBr$: C, 33.98; H, 6.65; N, 6.61; Br, 37.68%. Found: C, 34.31; H, 6.86; N, 6.79; Br, 37.36%.

(*b*) *From dl-1α-Methoxy-2α-hydroxy-3β-aminocyclohexane* (X; R = CH_3)

dl-1α-Methoxy-2α-hydroxy-3β-aminocyclohexane (5.30 g, 0.0365 mole) was subjected to ether cleavage under the conditions described for *dl*-1α-ethoxy-2β-hydroxy-3α-aminocyclohexane. Crystallization from ethanol–ether gave 5.40 g (69.8%) of colorless rosettes, m.p. 165.5–167°. Admixture of this substance with the compound isolated from (*a*) above caused no depression in melting point. The two samples likewise gave identical infrared spectra and moved with the same speed in paper chromatograms (R_F 0.43, see Table VI).

dl-3β-Amino-1α,2α-cyclohexanediol (II)

dl-3β-Amino-1α,2α-cyclohexanediol hydrobromide (14.0 g, 0.066 mole) was converted to the free base by passing a 5% aqueous solution through Amberlite IRA-400 resin in the hydroxide form. Evaporation to dryness *in vacuo* followed by recrystallization from benezene gave 5.90 g (95.3%) of *dl*-3β-amino-1α,2α-cyclohexanediol, m.p. 104–105°, as colorless prisms. Calc. for $C_6H_{13}O_2N$: C, 54.93; H, 9.99; N, 10.68%. Found: C, 55.02; H, 10.00; N, 10.77%.

Derivatives of the dl-3-Amino-1,2-cyclohexanediols

The *dl*-3-amino-1,2-cyclohexanediols were characterized as their N-*p*-nitrobenzoyl, N-phenylthiourea, and triacetyl derivatives. The same methods were used as in preparation of derivatives of the 1-alkoxy-2-hydroxy-3-aminocyclohexanes, except that in preparation of the triacetyl compounds, a 10-fold excess of acetic anhydride was used. Yields, melting points, and analytical data for the derivatives are given in Table II.

N-Phenylthiourea Derivative of dl-trans-2-Aminocyclohexanol

The same method was used as for preparation of the N-phenylthiourea derivatives of the *dl*-1-alkoxy-2-hydroxy-3-aminocyclohexanes. Yield, 93%, m.p. 144.5°. Calc. for $C_{13}H_{18}N_2SO$: C, 62.37; H, 7.25; N, 11.19; S, 12.80%. Found: C, 62.09; H, 7.22; N, 11.29; S, 12.69%.

Paper Chromatography of the 3-Amino-1,2-cyclohexanediols and Derivatives

For paper chromatography 2% solutions of the compounds in water, ethanol, or acetone were applied to unwashed Whatman No. 1 paper (7.5 λ spots). The chromatograms were developed overnight in a glass tank by the descending technique using *n*-butanol – acetic acid – water (25:6:25) as developer. The air-dried chromatograms were sprayed with bromcresol green for detection of the free amines and with ammoniacal

silver nitrate (33) for detection of the N-*p*-nitrobenzoyl derivatives of the aminediols. R_F values are given in Table VI.

Periodate Oxidation of dl-3α-p-Nitrobenzamido-2β,3α-cyclohexanediol and dl-3β-p-Nitrobenzamido-2α,3α-cyclohexanediol

(*a*) *At 25° C*

A 40-mg sample of each aminediol *p*-nitrobenzoyl derivative was treated with 0.1053 *N* paraperiodic acid (20.00 ml) at 25°. Iodometric titrations with sodium arsenite (22) revealed that 0.95 mole of paraperiodic acid was consumed per mole of *cis*-diol derivative in 60 minutes and 0.96 mole of paraperiodic acid was consumed per mole of *trans*-diol derivative in 90 minutes.

(*b*) *At 3° C*

A 20-mg sample of aminediol derivative was dissolved in 50 ml of water at room temperature and the solution was cooled to 3°. At time zero, sodium metaperiodate (10.00 ml, 0.0300 *N*) at 3° was pipetted into the solution, which was stirred constantly in a constant temperature bath at 3°±0.1°. The reaction was allowed to proceed for a specified length of time, after which further reaction was stopped by addition of sodium bicarbonate (2 g, A.R.), sodium arsenite (25.00 ml, 0.0200 *N*), and potassium iodide solution (1 ml, 20%). The consumption of periodate was determined by back-titration with 0.0100 *N* iodine (22) and the quantity of aminediol derivative oxidized calculated. Results are shown in Fig. 5.

Electrophoresis of 3-Amino-1,2-cyclohexanediol Derivatives on Glass Paper

The aminediol derivatives (1% solution in acetone) were spotted on 63×380 mm strips of glass fiber paper (H. Reeve Angel and Co., Inc.) together with D-glucose and 2,3,4,6-tetramethyl-D-glucose as reference compounds. The strips were placed in a water-cooled closed strip-type apparatus (E.C. Apparatus Co., Model No. 401) con-

THE REACTION OF CYANOGEN BROMIDE WITH THE SODIUM SALTS OF CARBOXYLIC ACIDS

II. THE REACTION OF CYANOGEN BROMIDE WITH THE SODIUM SALTS OF ALIPHATIC ACIDS[1]

D. E. Douglas[2] and Anna Mary Burditt[3]

ABSTRACT

Cyanogen bromide reacts with the sodium salts of lower aliphatic acids at 250–300° C to form an α-keto isocyanate as the primary product. The latter undergoes subsequent pyrolytic decomposition to a nitrile and carbon dioxide. A mechanism is proposed to account for the observed interchange of labelled carbon atoms between the CN group of the cyanogen bromide and the carboxyl group of the salt in the over-all reaction.

INTRODUCTION

In the heterogeneous reaction between cyanogen bromide and sodium benzoate at 250–300° C, it was shown, by the use of carbon-14-labelled reactants, that an interchange of carbon atoms between the CN group of the cyanogen bromide and the carboxyl group of the benzoate occurs according to the following over-all reaction (1):

$$CNBr + RC^*OONa \rightarrow RC^*N + CO_2 + NaBr. \qquad [1]$$

Preliminary experiments with sodium salts of several aliphatic acids and cyanogen bromide under similar conditions (2) seemed to indicate that a different mechanism was in operation, since a significant portion of carbon dioxide carbon originated in the aliphatic carboxyl group. In a more detailed investigation, however, which is described in this communication, it was established that the interchange of carbon atoms in accordance with reaction [1] occurs also when R is aliphatic (R = CH_3, C_2H_5—), although other simultaneously occurring pyrolytic reactions tend to obscure this reaction.

Although the sodium salts of several aliphatic acids were employed in this study, the most significant observations were made with sodium propionate as a reactant. Upon reaction with cyanogen bromide at 250–300° C under the conditions described previously, the latter salt yielded, in addition to the expected propionitrile, carbon dioxide and sodium bromide, two other compounds. Dipropionamide collected as a sublimate in the cooler part of the apparatus.[4] The other product was collected along with propionitrile in the cold trap attached to the pyrolysis tube. Unlike a nitrile, this compound reacted readily with ammonia under anhydrous conditions. The latter material possessed the properties of propionylurea, forming carbon dioxide and acid upon alkaline hydrolysis. In an experiment in which sodium acetate was the starting material, the nitrile fraction was passed through a mixture of glass and fuller's earth at 300° C. The formation of some carbon dioxide afforded additional evidence that the primary product of the reaction of cyanogen bromide with the sodium salt of an aliphatic acid is a compound yielding nitrile and carbon dioxide on pyrolysis, and forming monoacylurea with anhydrous ammonia. This primary product is an α-keto isocyanate, on the basis of the foregoing evidence.

[3]*Present Address: Faculty of Medicine, Queen's University, Kingston, Ontario.*
[4]*Zappi and Bouso (3) have reported the formation of monoamides in the reaction of sodium acetate and sodium propionate with cyanogen chloride.*

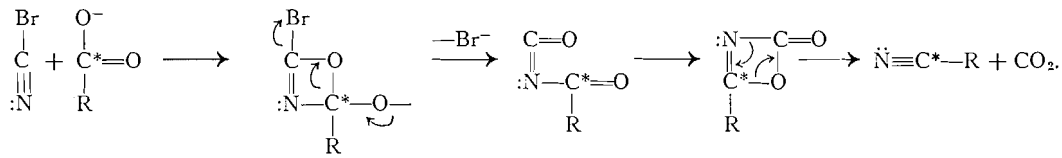
The reaction of cyanogen bromide with the sodium salt of an aliphatic acid may therefore be summarized as follows:

$$CNBr + RCOONa \rightarrow RCONCO + NaBr$$

$$RCONCO \rightarrow RCN + CO_2.$$

Only with lower aliphatic acids and under high vacuum is it possible for some of the α-keto isocyanate to escape complete pyrolysis. In the previously investigated reaction of sodium benzoate with cyanogen bromide, benzoyl isocyanate is undoubtedly formed initially, but it immediately pyrolyzes because of its low volatility.

To explain the observed interchange of carbon atoms between the CN group of the cyanogen bromide and the carboxyl group, the following mechanism is postulated:



An investigation of the pyrolysis of pure propionyl (isocyanate-C^{14}) should confirm this mechanism.

EXPERIMENTAL

The apparatus and procedure have already been described in detail (1). Approximately one millimole of the aliphatic acid sodium salt was weighed out and was suspended on a mixture of 0.5 g each of ignited fuller's earth and pulverized glass (40 mesh) by evaporation of a slurry of these materials in water. When a C^{14}-labelled sodium salt was employed, a known amount of activity was added to the weighed sample of inactive sodium salt in solution, before the latter was mixed with the fuller's earth and glass. After evaporation of the slurry, the mixture was transferred to the U-tube of the pyrolysis apparatus, and was heated in a Wood's metal bath to the appropriate temperature. The pyrolysis tube was connected, through a spiral trap cooled in liquid nitrogen, to a high-vacuum line. Slightly more than the equivalent quantity of cyanogen bromide was allowed to diffuse through the contents of the U-tube, while the latter was evacuated continuously. The carbon dioxide which collected in the spiral was converted to barium carbonate after fractionation with dry ice – acetone. The nitrile fraction was partially separated from unreacted cyanogen bromide by distillation on the vacuum line, and was reduced in ethereal solution with lithium aluminum hydride for characterization and radioassay. After decomposition of the lithium aluminum complex with dilute sulphuric acid, the amine was distilled from the mixture, after the latter had been rendered alkaline with sodium hydroxide, in a semimicro-Kjeldahl apparatus. The distillate was collected in excess dilute hydrochloric acid. The amine hydrochloride remaining after evaporation of this solution was recrystallized from an appropriate solvent. Ethanol was employed for ethylamine hydrochloride, and chloroform for propylamine and higher amine hydrochlorides. Known amounts of the hydrochlorides were plated on stainless-steel planchets for radioassay. Stearonitrile was plated directly, after purification by high-vacuum sublimation. Barium carbonate was plated on aluminum disks from a slurry. Appropriate self-absorption corrections were applied where necessary (4). Counting was performed with a helium and alcohol flow-type geiger counter with an approximately 2π geometry.

Pyrolysis of Nitrile Fraction from an Experiment with Sodium Acetate

Sodium acetate (4 millimoles) was suspended on powdered glass (40 mesh), and this mixture was placed in the U-tube of the apparatus previously described. Cyanogen bromide in slight excess was passed through the U-tube while the latter was evacuated continuously. Carbon dioxide was fractionated with dry ice – acetone and converted to barium carbonate. Yield of $BaCO_3$ 0.2227 g (28% based on acetate). The liquid remaining in the spiral trap was recycled through a mixture of fuller's earth and powdered glass at 304° C under high vacuum. An additional quantity of carbon dioxide was formed during pyrolysis, yielding 0.0945 g of barium carbonate.

Alkaline Hydrolysis of Propionylurea

The liquid reaction product from two experiments in which sodium propionate-1-C^{14} was allowed to react with cyanogen bromide under the conditions previously described was treated with ammonia in ether under anhydrous conditions. To the solid obtained from this reaction was added carrier propionylurea (5), the mixture was homogenized by crystallization, and the solid was sublimed under high vacuum. To a solution of the sublimate (5.15 mg) was added carrier propionylurea (25.9 mg) and the whole was evaporated to dryness in a bomb tube. The residue was hydrolyzed with saturated barium hydroxide solution (4 ml) at 100° C in the sealed tube overnight. A quantitative yield (52.7 mg) of barium carbonate was obtained, of specific activity 22,850 counts/minute millimole. The specific activity of the material before hydrolysis was 32,800 counts/minute millimole. A small portion of the initial activity was present in the acid recovered from the hydrolysis.

PAPER CHROMATOGRAPHY OF AMINE HYDROCHLORIDES AND OTHER COMPOUNDS

The amine hydrochlorides obtained from the lithium aluminum hydride reduction of the product nitriles were chromatographed on Whatman No. 1 filter paper by the ascending technique. For comparison, authentic samples of amine hydrochlorides were run in adjacent positions. Butanol saturated with 25% aqueous acetic acid was the developing solvent. The amines were detected with ninhydrin (6).

Propionylurea could not be distinguished from propionamide when these substances were chromatographed with the butanol – acetic acid – water medium as both had R_f values of 0.74. To facilitate detection on paper, these compounds were labelled with carbon-14 by synthesis from propionic acid-1-C^{14}. The developed chromatograms were placed in contact with Eastman No-Screen X-Ray film.

Dipropionamide-1-C^{14} with butanol–water as the developing solvent had an R_f of 0.91. Several unidentified spots with R_f values less than 0.74 appeared faintly on radioautographs of chromatograms of the nitrile fraction from the sodium propionate – cyanogen bromide reaction after this fraction had been treated with anhydrous ammonia. α-Cyanopropionic acid and α-isocyanopropionic acid were shown to be absent by chromatography of these substances for comparison.

RESULTS AND DISCUSSION

Data for typical experiments are presented in Tables I and II. It is evident that a significant portion of the carbon dioxide carbon is derived from the cyanogen bromide molecule. Simultaneously occurring pyrolytic reactions, other than the formation of an α-keto isocyanate and its decomposition to a nitrile and carbon dioxide, may explain in part the distribution of radioactivity among the products. Moreover, the formation and

pyrolysis of a part of the α-keto isocyanate by a route other than the postulated one, could also account for this distribution of activity. Such reactions as decarboxylation

and dehydration as well as the formation of free aliphatic acid in the presence of traces of hydrogen bromide are all possible under the experimental conditions employed, and one or more of these is probably responsible for the observed formation of a diamide. Variation in reaction conditions from one aliphatic acid to another is in part the result of the decreasing volatility of the intermediate α-keto isocyanate with increasing molecular weight. Thus, this intermediate was present in the nitrile fractions from the sodium acetate and propionate reactions, but with higher acids, and especially with benzoic acid, the α-keto isocyanate could have only a momentary existence in the hot zone of the pyrolysis apparatus. The postulated formation of an α-keto isocyanate in the reactions investigated offers a logical explanation of the observed interchange of carbon atoms between cyanogen bromide and the carboxyl group through the mechanism described earlier in this communication.

ACKNOWLEDGMENT

The authors wish to thank Dr. Karl Wiesner for his helpful criticism and advice.

STUDIES ON THE MECHANISMS OF CYCLIZATION OF RING A OF STEROIDS DURING THE REFORMATSKY REACTION[1]

R. D. H. HEARD,[2] G. A. BALLA, J. R. JAMIESON,[3] AND P. ZIEGLER[4]

ABSTRACT

The Reformatsky reaction of 3,5-*seco*-5-ketocholestan-3-oic acid methyl ester with methyl bromoacetate yielded 2-carbohydroxycholestenone, cholestenone, and 4-carbomethoxycholestenone. The appearance of these products indicated that cyclization of ring A proceeded along two different paths; this conclusion was confirmed by the use of methyl bromoacetate-1-C^{14} and -2-C^{14}.

One of the earliest successful attempts (1) at introduction of radioactive carbon 14 into ring A of the steroid nucleus involved the Reformatsky reaction of 3,5-*seco*-5-ketocholestan-3-oic acid methyl ester (I*b*) with carboxyl-labelled methyl bromoacetate. In these experiments, the crude Reformatsky products were cyclized, hydrolyzed, and decarboxylated by conventional methods to provide cholestenone-3-C^{14} (XI*) in 32% yield. The molar radioactivity count of XI* was found to be the same as that of the carboxyl-labelled methyl bromoacetate used, and largely on the basis of this finding the conclusion was reached that the reaction proceeded entirely through the intermediates III*, IV*, and V*. This sequence of reactions was postulated by Turner (1) to involve abstraction of a proton from III* at position 2, followed by transannular ring closure and elimination of methoxide ion to give the keto-lactone IV*. The latter, in turn, would then lose a proton at position 4 and be transformed readily into the stable anion V*. It was also pointed out that removal of a proton, alpha to the carbomethoxy group in III*, would lead to a less stable four-membered oxygen intermediate; the latter, after hydrolysis and dehydration, would be expected to decarboxylate yielding inactive cholestenone (XI). There is considerable evidence in support of Turner's view that Reformatsky reactions of δ-ketoesters can provide intermediate lactones of the type III. Thus, it was shown (2) that methyl β-(1-methyl-2-ketocyclohexyl)propionate and ethyl bromoacetate reacted under the usual Reformatsky conditions to yield 21% of 2-keto-3-carboxy-10-methyl-$\Delta^{1,9}$-octahydronaphthalene. The isolation of this acid by extraction from the crude reaction products with 2% ammonium hydroxide can only be explained by assuming the formation of an intermediate six-membered lactone. Similarly, 1-tetralone-2-β-propionic acid methyl ester on treatment with methyl bromoacetate and zinc provided 1-acetic acid methyl ester-3,4-dihydronaphthalene-2-β-propionic acid (3). It has been known for long that γ-ketoesters undergo Reformatsky reactions to yield γ-lactones. Ethyl levulinate, for example, was found to afford amongst other products the lactone of β-hydroxy-α,β-dimethyladipate, when condensed with methyl α-bromopropionate (4). Ethyl β,β-dimethyllevulinate and ethyl bromoacetate produced over 50% of δ-carbethoxy-β,β,γ-trimethyl-γ-valerolactone (5).

The studies to be described herewith were undertaken to determine more conclusively the mechanisms of ring closure during the Reformatsky reaction of the δ-ketoester I*b*.

The experiments were usually carried out in refluxing benzene using tracer amounts of C^{14}-labelled methyl bromoacetate, and the products, from which zinc salts were removed by washings with dilute mineral acid, were finally chromatographed on neutral alumina. Elution from the column with hexane–benzene separated four different compounds. The first fraction consisted of cholestenone (XI* or XI•), identified by melting point, optical rotation, ultraviolet absorption, and comparison with an authentic specimen of XI. Regardless of whether methyl bromoacetate-1-C^{14} or -2-C^{14} was employed, the crystals of cholestenone proved to be radioactive. The second compound obtained from the alumina failed to crystallize and was not radioactive; it was saponified to give I*a*, and therefore represented unreacted starting material. The third fraction was a crystalline solid which was radioactive, both when methyl bromoacetate-1-C^{14} and -2-C^{14} were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

used. It analyzed correctly for a carbomethoxycholestenone, and on the basis of the following evidence could be quite definitively assigned the structure of 4-carbomethoxycholestenone (X* or X•). The material exhibited maximum absorption in the ultraviolet region at 243.5 mμ (log ε = 4.14), characteristic of an α,β-unsaturated ketone. The known fact (2) that the presence of a carbomethoxy group in cross-conjugation with an α,β-unsaturated ketone does not affect the latter's absorption maximum in the ultraviolet should be noted in this case. Examination in the infrared region showed bands at 5.74 μ and at 5.95 μ, representative of the carbonyl group of an ester and a Δ^4-3-ketone respectively. The compound did not give a coloration with alcoholic ferric chloride solution and failed to react with sodium in benzene; this evidence, indicative of the absence of an active hydrogen, can be accommodated by 4-carbomethoxycholestenone (X), but not by its isomer VII. While the unknown compound, assigned structure X, was resistant to alkaline hydrolysis, probably because its resonance structures do not permit nucleophilic attack at the exocyclic carbon atom attached to C-4, it readily provided cholestenone on acid treatment. The isomer VII on the other hand would be expected to saponify in the normal fashion, since resonance in this system does not prevent carbonium ion formation at the exocyclic carbon atom attached to C-2; in fact, it was found that 2-carbomethoxycholestenone (VII) saponified readily under mild conditions. That the unknown compound was indeed 4-carbomethoxycholestenone (X) was shown conclusively by the tracer technique. It was found that acid hydrolysis of the carbomethoxycholestenone, obtained with methyl bromoacetate-2-C^{14}, gave rise to radioactive cholestenone (XI•); however, the acid hydrolysis of the intermediate obtained with methyl bromoacetate-1-C^{14} provided inactive cholestenone (XI).

The fourth and last compound eluted from the column of alumina was found to contain twice the radioactivity count of XI• (or XI*) and X• (or X*) obtained in the same experiment. It was therefore assumed that 2 moles of acetate had been incorporated into its structure. Since cholestenone could not be derived from it by acid or alkaline treatment, this compound was not examined further.

In one Reformatsky reaction, using inactive reagent, the crude products were analyzed for the presence of Δ^4-3-ketone by ultraviolet spectrophotometry, both before and after treatment with cold dilute acid. Since the two assays showed the presence of 30–35% of Δ^4-3-ketone, it was concluded that cyclization and elimination of bromozinc methoxide occurred during the Reformatsky reaction, and not on acidification or chromatography on alumina. That Dieckmann type cyclizations occur during Reformatsky reactions with δ-keto esters has previously been reported (6, 7, 8). It was of interest to note that these analytical figures agreed well with the amounts of Δ^4-3-ketones (XI plus X) usually isolated from the chromatograms. The reaction products were then separated into neutral and acidic constituents by washing with dilute sodium carbonate solution; the two fractions contained 23% and 8% of Δ^4-3-ketones respectively. The acid fraction was crystallized to yield a compound, m.p. 126–128° C, giving an intense green color with ferric chloride solution. It was assigned structure VIII on the basis of this evidence and because it provided cholestenone (XI) on pyrolysis. Methylation of VIII afforded the corresponding methyl ester (VII), which also produced a green coloration with ferric chloride solution and showed an ultraviolet absorption maximum at 244.5 mμ (log ε = 4.21). Elemental analyses for VII (and its 2,4-dinitrophenylhydrazone) were not entirely satisfactory, probably because of contamination with traces of cholestenone. On mild saponification, VII yielded VIII.

A careful examination of these results proves that, under the experimental conditions used, two different mechanisms of cyclization are operative. When the Reformatsky

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

reaction was carried out with methyl bromoacetate-1-C^{14}, the cholestenone (XI*) and the 4-carbomethoxycholestenone (X*), isolated from the column of alumina, were both radioactive. Since acid hydrolysis of X* yielded inactive XI, the reaction path leading to X* must be different from that leading to XI*. In other words, 4-carbomethoxycholestenone (X) is not the precursor of the cholestenone eluted from the chromatograms. The sequence of reactions leading to the formation of X is postulated to proceed by a Dieckmann cyclization of the Reformatsky ester II, via the intermediate IX. The isolation of 2-carbohydroxycholestenone (VIII) from the alkaline washings of the reaction products and the demonstration of its facile decarboxylation indicate that VIII is the precursor of the cholestenone eluted from the chromatogram. The isolation of the acid VIII lends support to Turner's hypothesis (1) of the formation of the intermediate lactonic ester III. Dieckmann cyclization of the Reformatsky ester II via VI (in the opposite sense as was postulated before) would be expected to provide VII. But since VII failed to appear amongst the isolated reaction products, the second mechanism of cyclization is believed to proceed via the intermediates III, IV, V, and VIII. In conclusion, it should be noted that the two different cyclization reactions occur to the same extent, as judged by the yields of X and XI.

EXPERIMENTAL

All melting points have been corrected. The optical rotations were determined in chloroform solution, the ultraviolet spectra in ethanol (unless otherwise stated), and the infrared spectra, obtained by Dr. R. N. Jones, of the National Research Council, Ottawa, in carbon disulphide. Microanalyses were carried out by Mr. E. Thommen, Basel, Switzerland.

Methyl bromoacetate-1-C^{14} and -2-C^{14} were kindly prepared by Dr. B. Belleau; the radioactivity counts of these reagents are not known. The radioactivities of the steroids were determined in the flow Q-gas counter (Nuclear Instrument and Chemical Corporation) and are expressed in counts per minute per milligram.

Cholestenone-4-C^{14} (XI) and 4-Carbomethoxycholestenone-4-C^{14} (X*)*

3,5-*seco*-5-Ketocholestan-3-oic acid (I*a*; 5 g; 12.3 millimoles) was treated with an ethereal solution of diazomethane, the ether was evaporated, and the residual oil dried *in vacuo*. Absolute anhydrous benzene (50 ml), a crystal of iodine, activated zinc (2.5 g), and methyl bromoacetate-2-C^{14} (3.8 g; 25 millimoles) were added to the dried residue. The mixture was refluxed for 3.5 hours, during which time a white, crystalline precipitate formed and gradually the solution turned brown. More activated zinc (1.5 g) was added during the first ½ hour of refluxing. After it had been cooled, the mixture was diluted with ether and dilute hydrochloric acid, the solvent extract was washed five times with dilute acid, then with water, dried over sodium sulphate, filtered, and evaporated to dryness. The yellow, oily residue (4.65 g) could not be crystallized; it was methylated with diazomethane and subsequently chromatographed on activated alumina (100 g), using 200 ml portions of eluant.

Fractions 5–11 were combined to yield, after recrystallization from ether–methanol, 650 mg (14%) of cholestenone-4-C^{14} (XI*), m.p. 79–80°, $[\alpha]_D^{19}$ +89.9°, showing maximum ultraviolet absorption at 242.5 mμ (log ε = 4.18) and counting at 3200.

Fractions 12–19 could not be crystallized; they were saponified for 2 hours with 5% methanolic potassium hydroxide to yield, after working up, 930 mg (19%) of crystals, m.p. 155°, giving no depression on mixed melting point with authentic 3,5-*seco*-5-ketocholestan-3-oic acid (I*a*). This recovered starting material was not radioactive.

Fractions 20–32 were crystallized from ether–hexane to provide 850 mg (16%) of 4-carbomethoxycholestenone-4-C^{14} (X*), m.p. 154° and $[\alpha]_D^{19}$ +89.4°; this compound gave no coloration with tetranitromethane or alcoholic ferric chloride, did not react with sodium in benzene, but developed a purple color with the Zimmermann reagent; it showed an ultraviolet maximum at 243.5 mμ (log ϵ = 4.14) and in the infrared region its maxima were at 5.75 μ and 5.95 μ. Anal. Calc. for $C_{29}H_{46}O_3$: C, 78.68; H, 10.47; OCH_3, 7.01. Found: C, 78.89; H, 10.48; OCH_3, 6.90.

Fractions 33–47, crystallized from ether–hexane, yielded 650 mg (10%) of material, m.p. 155°, and gave marked depression on mixed melting point with *Ia* and X*. This material gave no color reactions with alcoholic ferric chloride, tetranitromethane, or the Zimmermann reagent and was transparent through the ultraviolet range of the spectrum. Its radioactivity count was 6800. Attempts at conversion of this compound to cholestenone by vacuum distillation, saponification, or acid hydrolysis failed. Microanalyses indicated the presence of one methoxy group and the formula $C_{31}H_{50}O_5$.

2,4-Dinitro-phenylhydrazone of X

Compound X (100 mg) and 2,4-dinitro-phenylhydrazine (300 mg) were refluxed for 15 minutes in 95% ethanol (30 ml). The hot solution was then treated with concentrated hydrochloric acid (2 ml) and refluxed for an additional 15 minutes. After it had been cooled, the precipitate was filtered off, washed with ethanol, then with hexane, and dried. The orange hydrazone had m.p. 198–200°. Anal. Calc. for $C_{35}H_{50}O_6N_4$: C, 67.50; H, 8.09; N, 9.00. Found: C, 67.49; H, 8.35; N, 9.25.

Acid Hydrolysis of 4-Carbomethoxycholestenone-4-C^{14} (X)*

Compound X* (200 mg) was refluxed for 15 hours in glacial acetic acid (12.5 ml) and concentrated hydrochloric acid (3 ml). The solution was then diluted with water, extracted with ether, and the solvent extract washed twice with water, three times with dilute sodium carbonate, and again with water. The ether solution was dried, then evaporated to yield 170 mg of an oily residue which on crystallization from ether–methanol gave 147 mg (85%) of cholestenone-4-C^{14} (XI*), m.p. 79–80°, and counting at 4000.

Saponification of 4-Carbomethoxycholestenone (X)

The ester X (200 mg) was refluxed for 2 hours in 5% methanolic potassium hydroxide (20 ml). After addition of water, most of the methanol was evaporated *in vacuo* and the residue was extracted with ether. The solvent extract, washed with water to neutrality,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

yielded, after drying over sodium sulphate, filtration, and evaporation of the ether, 172 mg of material; this was crystallized from methanol to give unreacted starting material, m.p. 153–154°, no depression on mixed melting point with X.

Cholestenone-3-C^{14} (XI) and 4-Carbomethoxycholestenone-C^{14} (X*)*

The experimental procedure employed was the same as that described for the preparation of X• and XI•, except that different quantities of reagents were used and that carboxyl-labelled methyl bromoacetate was substituted for the corresponding methylene-labelled compound.

The dry residue obtained after methylation of *Ia* (3 g; 7.4 millimoles) was reacted with zinc (2 g), a crystal of iodine, and methyl bromoacetate-1-C^{14} (2.28 g; 14.9 millimoles) in benzene (35 ml). Chromatography of the products yielded 245 mg (9%) of cholestenone-3-C^{14} (XI*), m.p. 79–81°, counting at 1.5×10^4 min^{-1} mg^{-1}; 1.02 g (34%) of non-radioactive starting material (*Ia*), m.p. 153–154°; 205 mg (8%) of 4-carbomethoxycholestenone-C^{14} (X*), m.p. 154° and counting at 1.4×10^4 min^{-1} mg^{-1}; 160 mg (4%) of material, m.p. 154–155°, counting at 2.4×10^4 min^{-1} mg^{-1}.

Acid Hydrolysis of 4-Carbomethoxycholestenone-C^{14} (X)*

Compound X* (100 mg), m.p. 154° and counting at 1.4×10^4 min^{-1} mg^{-1}, was refluxed for 15 hours with glacial acetic acid (7.5 ml), concentrated hydrochloric acid (4 ml), and dioxane (2 ml). The solution was diluted with water and extracted with ether, the solvent extract was washed successively with water, dilute carbonate, and again with water. The neutral ethereal solution was dried over sodium sulphate, filtered, and evaporated to yield 98 mg of an oily residue, which was chromatographed on 5 g of alumina, using 10-ml portions of eluant. The fractions, obtained with benzene–hexane (3:7, 1:1, and 4:1), were crystallized from ether–methanol to provide 70 mg of cholestenone (XI), m.p. 80° and counting at 80 min^{-1} mg^{-1}. This very low activity could not be removed either by vacuum distillation of a sample of this cholestenone or by repeated crystallization from ether–methanol; it is attributed to slight contamination. Further elution of the alumina column with benzene and ether yielded 27 mg of residue. This material was crystallized from ether–hexane to give unreacted starting material, m.p. 149–152°, with a radioactivity of 1.5×10^4; it did not give a depression on mixed melting point with X*.

Quantitative Analysis for α,β-Unsaturated 3-Ketones in the Products of the Reformatsky Reaction by Ultraviolet Spectrophotometry

3,5-*seco*-5-Ketocholestan-3-oic acid (*Ia*; 3 g; 7.4 millimoles) was methylated with ethereal diazomethane and the ether evaporated. The residue, after thorough drying *in vacuo*, was then dissolved in anhydrous benzene (30 ml) and treated with zinc (2 g), a crystal of iodine, and methyl bromoacetate (2.28 g; 14.9 millimoles). This mixture was refluxed gently for 2 hours, then cooled. A sample (0.1 ml), pipetted out of the solution, was evaporated to remove the benzene, and then dissolved in anhydrous ether (100 ml). This ethereal solution showed an ultraviolet maximum at 243 mμ ($\log I_0/I_x = 1.44$). On the basis of molecular weight (400) and extinction coefficient (15,000), 0.96 g of Δ^4-3-ketone was calculated to be present.

The benzene solution was then diluted with ether and cold dilute hydrochloric acid, the aqueous layer was discarded, and the solvent extract washed with water. Again a sample (0.25 ml) was pipetted out of the ether–benzene extract (72 ml), the solvents were evaporated, and the residue from the sample dissolved in ethanol (100 ml). This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

solution exhibited an ultraviolet maximum at 242 mμ (log $I_0/I_x = 1.2$); it was therefore calculated that 0.92 g of Δ^4-3-ketone was contained in the crude acidified Reformatsky reaction products.

The ether–benzene extract, after dilution with more ether, was washed three times with portions (30 ml) of 5% sodium carbonate solution, then with water until the washings were neutral. A sample (0.54 ml) of the neutral solvent phase (135 ml) was evaporated *in vacuo* and the residue dissolved in ethanol (100 ml). The alcoholic solution showed a maximum in the ultraviolet at 242 mμ (log $I_0/I_x = 1.05$), indicating that 0.7 g of Δ^4-3-ketone was present in the neutral solvent extract.

The carbonate washings were acidified immediately, extracted with ether, and the solvent extract washed several times with water; it was dried over sodium sulphate, filtered, and finally evaporated to dryness to yield an oily residue (275 mg). A small part (3 mg) of this residue was dissolved in 100 ml of ethanol; the resulting solution showed an ultraviolet maximum at 242 mμ (log $I_0/I_x = 0.93$), which demonstrated the presence of 230 mg of Δ^4-3-ketone in the acid fraction.

Isolation of 2-Carbohydroxycholestenone (VIII)

The acid fraction (275 mg), obtained in the preceding experiment, was crystallized from ether–hexane to yield 100 mg of material, m.p. 118–121°; recrystallization from ether gave m.p. 126–128° (the melted crystals resolidified on cooling, then remelted at 75–85°). This substance gave a yellow color with tetranitromethane, an intense green with alcoholic ferric chloride, but was negative in the Zimmermann test. It exhibited a maximum absorption in the ultraviolet at 242 mμ (log $\epsilon = 4.23$).

The mother liquor of this acid fraction on standing in aqueous ethanol gave cholestenone (XI), m.p. 81–82°, no depression on mixed melting point with authentic XI. It was therefore concluded that VIII decarboxylated partially during extraction and/or isolation procedures.

Pyrolysis of VIII

Distillation of VIII, m.p. 126–128°, *in vacuo* (0.1 mm) at 185–193° provided a distillate which readily crystallized from ether–methanol to yield quantitatively cholestenone (XI), m.p. 78–80°.

2-Carbomethoxycholestenone (VII)

Compound VIII was methylated with ethereal diazomethane, the ether solution washed with water, dried over sodium sulphate, filtered, and the filtrate evaporated *in vacuo*. The residue crystallized with difficulty from aqueous methanol to give a substance (VII) of m.p. 91–93°; recrystallization from methanol gave m.p. 102–104° and $[\alpha]_D^{19}$ +91°. This material produced a green color with ferric chloride solution, showed an ultraviolet maximum at 244.5 mμ (log $\epsilon = 4.21$), and exhibited carbonyl absorption bands in the infrared region at 5.73 μ and at 5.96 μ. Anal. Calc. for $C_{29}H_{46}O_3$: C, 78.68; H, 10.47. Found: C, 79.07; H, 10.95.

2,4-Dinitro-phenylhydrazone of VII

A solution of VII (40 mg) and 2,4-dinitro-phenylhydrazine (150 mg) in ethanol (35 ml) was refluxed for ½ hour. After cooling, concentrated hydrochloric acid (2 ml) was added and the solution was then kept at 20° for several hours. The precipitate which had formed was filtered off, washed with ethanol and hexane, and dried *in vacuo*. The orange crystals had m.p. 213–215°. Anal. Calc. for $C_{35}H_{50}O_6N_4$: C, 67.50; H, 8.09; N, 9.00. Found: C, 66.68; H, 7.91; N, 8.92.

Saponification of 2-Carbomethoxycholestenone (VII)

Compound VII (75 mg) and potassium carbonate (50 mg) were dissolved in methanol (15 ml) and water (1 ml). The solution, after standing at 20° for 48 hours, was diluted with water and extracted with ether. The solvent extract provided a neutral fraction (22 mg) which failed to crystallize; the acid fraction (50 mg), obtained from the aqueous carbonate phase, crystallized from ether, giving material of m.p. 124–125°. This substance (VIII) gave no depression on mixed melting point with VIII.

THE SOLUBILITY OF ALUMINUM HYDROXIDE IN ACIDIC AND BASIC MEDIA AT 25° C[1, 2]

K. H. GAYER, L. C. THOMPSON, AND O. T. ZAJICEK

ABSTRACT

The solubility of $Al(OH)_3$ was measured in NaOH and $HClO_4$ solutions. Possible reactions of $Al(OH)_3$ in dilute NaOH and $HClO_4$ solutions are indicated along with the calculated constants. The amphoteric hydroxide was found to be more acidic than basic. The isoelectric point of $Al(OH)_3$ was determined to be pH 7.7.

HISTORICAL

The amphoteric nature of aluminum hydroxide has been studied by other investigators, but owing to incomplete data the extent of its amphoterism is still not entirely determined. Its isoelectric point has not been previously determined.

A number of equilibrium constant values are tabulated below:

Source	Equilibrium constant	Value
Heyrovsky (1)	Solubility product	1.06×10^{-33} at 25° C
Heyrovsky (1)	Ion product of aluminic acid	35×10^{-14} at 25° C
Kruyt and Troelstra (2)	Solubility product	1.00×10^{-32} at 25° C
Wood (3)	Acid dissociation constant	6.30×10^{-13} at 25° C
Slade (4)	Acid monobasic dissociation product approx. constant	1×10^{-10}

Hildebrand (5), in his study on the solubility of aluminum hydroxide, claimed that it dissolved as an acid. This claim was supported by the slight break in the solubility curve corresponding to the addition of another equivalent of base. Heyrovsky (6) stated that aluminum hydroxide dissolves in alkalies as follows:

$$Al(OH)_3 + OH^- \leftrightarrows Al(OH)_4^-.$$

Joseph (7) in plotting equivalent conductance against the ratio of sodium hydroxide to aluminum hydroxide obtained no sharp breaks or irregularities and, therefore, concluded that aluminate ion AlO_2^- occurs.

EXPERIMENTAL

Procedure

The general procedure is similar to that used by Garrett and Heiks (8).

Preparation of Reagents

The preparation of conductivity water is that of Gayer and Woontner (9).

Aluminum hydroxide.—Aluminum hydroxide was precipitated from aluminum chloride by means of sodium hydroxide. The precipitate was washed several times beyond that required to give a negative flame test for sodium for both the solid and the supernatant liquid. A sample of the precipitate was dried for 2 days at 50° C. Following this, it was ignited at 500° C. From the weight loss, the empirical formula was calculated to be

[1]*Manuscript received April 8, 1958.*

$Al_2O_3 \cdot 3H_2O$. An X-ray diffraction powder pattern showed the material to be crystalline. The three major d values, in order of decreasing intensity, were found to be 4.62, 4.27, and 2.20 Å.

Aluminum chloride.—Baker and Adamson reagent grade aluminum chloride crystals were used to prepare the hydroxide. Standard aluminum solutions: 1.76 g of aluminum alum was dissolved in distilled water and made up to 1 liter. The standard solution contained 0.1 mg of aluminum per milliliter. From this solution spectrophotometric determinations of aluminum were made by diluting to make solutions of 2, 4, 8, 12, 16, 20, 24, and 28 γ/ml. The standard curve was prepared by means of the Beckman Model B spectrophotometer.

Chloroform.—Reagent grade chloroform was used for the extraction of the aluminum quinolate.

8-Hydroxyquinoline.—Twenty grams of hydroxyquinoline was dissolved in 60 ml of glacial acetic acid and diluted to 1 liter with distilled water.

Colorimetric analyses.—The aluminum analyses were made with a Beckman Model B spectrophotometer using the method of Sherrington and Gentry (10). The absorbance was measured at 400 mμ against a reagent blank.

pH.—A Beckman Model G pH meter was used to determine the equilibrium values of the hydrogen and hydroxyl ion activities.

Δ_{OH} = initial moles of base − equilibrium moles of base,
= base consumed by Al.

THE DATA

The data are collected in Tables I and II. The values for the activity coefficients for NaOH and $HClO_4$ are given by Robinson and Stokes (11).

From the amounts of sodium hydroxide consumed and from the ratio of consumed sodium hydroxide to dissolved aluminum, it can be concluded that a major portion of the sodium hydroxide is simply adsorbed.

Δ_{H^+} = initial moles of acid − equilibrium moles of acid.

In view of the constancy of the equilibrium constant values and the relatively small amounts of solid dissolved, we believe that the following reaction is predominant in the concentrations of sodium hydroxide from 0.0008 molal to 0.08 molal.

$$Al(OH)_3\,(s) + OH^- = H_2AlO_3^- + H_2O.$$

The form $H_2AlO_3^-$, rather than $Al(OH)_4^-$, was chosen since it is felt that the equation tends to better emphasize the acid-base character of the reaction. For the equation written,

$$K = a_{H_2AlO_3^-}/a_{OH^-} = M_{H_2AlO_3^-}\cdot\gamma_{H_2AlO_3^-}/a_{OH^-}.$$

According to the Debye–Hückel limiting law, the activity coefficients for 1–1 electrolytes should be equal at equal ionic strengths; hence,

$$\gamma_{H_2AlO_3^-} = \gamma_{OH^-} = \gamma_{NaOH}$$

and

$$K = M_{H_2AlO_3^-}\cdot\gamma_{NaOH}/a_{OH^-} = 2.98\times10^{-1}$$

$$\Delta F^\circ = 720 \text{ cal/mole}.$$

Using the above equilibrium constant and K_w, the ionization constant for water at 25° C, the ionization constant for the following reaction was calculated:

$$Al(OH)_3\,(s) = H^+ + H_2AlO_3^-$$

$$K = 2.98\times10^{-15}.$$

Taking into consideration (1) the amount of acid consumed to the amount of aluminum hydroxide dissolved and (2) the fair constancy of the equilibrium constants over limited ranges of acid, we can probably conclude that in very low acid concentrations from 0 to 2×10^{-4} molal, reaction [1] below predominates and in acid concentrations from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

2×10^{-4} molal to 2×10^{-3} molal, and possibly higher, reaction [3] predominates. In view of the drift in values of K_2, the range of reaction [2] cannot be determined. At most, we can only conclude that it probably occurs simultaneously with reaction [3] in the intermediate concentration of acid near 2×10^{-4} molal.

$$Al(OH)_3\,(s) + H^+ = Al(OH)_2^+ + H_2O \qquad [1]$$

$$Al(OH)_3\,(s) + 2H^+ = Al(OH)^{+2} + 2H_2O \qquad [2]$$

$$Al(OH)_3\,(s) + 3H^+ = Al^{+3} + 3H_2O \qquad [3]$$

$$K_1 = a_{Al(OH)_2^+}/a_{H^+} = M_{Al(OH)_2^+}\cdot\gamma_{Al(OH)_2^+}/a_{H^+}.$$

As before,

$$\gamma_{Al(OH)_2^+} = \gamma_{HClO_4}$$

and

$$K_1 = M_{Al(OH)_2^+}\cdot\gamma_{HClO_4}/a_{H^+} = 2.52$$

$$\Delta F_1^\circ = -550 \text{ cal/mole.}$$

Since K_2 was not constant, no attempt was made to select a representative value for it.

$$K_3 = a_{Al^{+3}}/a_{H^+}^3 = M_{Al^{+3}}\cdot\gamma_{Al^{+3}}/a_{H^+}^3.$$

From the Debye–Hückel limiting law, the activity coefficient of a 1–3 electrolyte may be replaced by the cube of that for a 1–1 electrolyte; hence,

$$K_3 = M_{Al^{+3}}\cdot\gamma^3_{HClO_4}/a_{H^+}^3 = 1.10\times10^9$$

$$\Delta F_3^\circ = -12{,}300 \text{ cal/mole.}$$

Using the value obtained for K_3 above and the cube of K_w, the ionization constant for water at 25° C, the solubility product constant for the following reaction was calculated:

$$Al(OH)_3\,(s) = Al^{+3} + 3OH^-,$$

$$K = 1.10\times10^{-33}.$$

For an amphoteric hydroxide, the isoelectric point will represent the minimum solubility. Plotting the logarithm of the reciprocal of the solubility against pH gives a curve with a maximum at pH 7.7.

A STUDY OF SILVER NITRATE SOLUTIONS IN GAS CHROMATOGRAPHY[1]

M. E. Bednas and D. S. Russell

ABSTRACT

Silver nitrate, dissolved in some organic solvents, has formed a relatively specific medium for the gas chromatographic separation of olefins. Columns formed from ethylene glycol and glycerin solutions of silver nitrate are comparable, but those formed from the polyethylene glycol solutions are considerably less effective. These silver nitrate solutions were stable below 65° C, but began to decompose slowly at 85° C.

An aspect of gas chromatography which has received little attention in the literature has been the use of liquid phases which react with components of the sample to form unstable complexes. A solution of silver nitrate in ethylene glycol has been used to form a column of this type. It is relatively specific for olefins, retaining ethylene and propylene, for example, much longer than such higher-boiling paraffins as *n*-pentane and *n*-hexane.

The existence of unstable complexes of this type has been demonstrated by Francis (1), who isolated a compound from propylene and silver nitrate. This proved to be stable at room temperature and normal pressure, but decomposed reversibly to silver nitrate and propylene at reduced pressures or at higher temperatures. The use of silver nitrate in a gas chromatographic column was first reported by Bradford *et al.* (2). They found that a saturated solution of silver nitrate in ethylene glycol on a support of kieselguhr gave excellent separations for traces of ethane in ethylene. Tenney (3) has clearly illustrated the selective effect of silver nitrate for normal olefins from pentene-1 through to nonene-1.

The moisture which is sometimes present in ethylene glycol and similar solvents, or that which these solvents absorb from samples containing traces of water, is subsequently eluted during the chromatographic process and frequently interferes with the determination. To circumvent this problem van de Craats (4) has suggested the use of benzyl cyanide as a solvent for silver nitrate, but has not included any data on this column.

The papers referred to above have not considered the temperature stability of these columns. Keulemans (5) states that the temperature should be kept below 40° C, since above this temperature the transient adducts with silver nitrate are not formed, and the solution is not stable.

This present study was undertaken to pursue this temperature stability further and to obtain comparative results for columns of ethylene glycol, polyethylene glycol, and glycerin solutions of silver nitrate.

EXPERIMENTAL

Apparatus

A commercial chromatographic unit, the Fisher-Gulf Partitioner, was employed. The columns consisted of $\frac{1}{4}$-inch copper tubing wound into a coil 6 inches in diameter. A thermistor serves as a detector. Both the detector and the column are contained in

[1]*Manuscript received May 22, 1958.*

the same air bath, which can be controlled at the following steps, 50°, 65°, 85°, 100°, 120°, and 140° C. It can also be used at its ambient temperature (27° C) but without control. In this case the drift was less than 1% of full scale deflection at full sensitivity over a period of 20 minutes. The peaks are recorded on a conventional strip-chart recorder, fitted with a ball-and-disk integrator.

In these experiments helium was the only carrier gas used.

Reagents

Silver nitrate, Mallinckrodt Analytical Reagent.
Ethylene glycol, Eimer and Amend.
Triethylene glycol (mol. wt. 200), Carbide and Carbon, "Carbowax".
Polyethylene glycol (mol. wt. 400), Carbide and Carbon, "Carbowax".
Glycerin, Baker and Adamson.

Preparation of Columns

Approximately 30 g finely pulverized silver nitrate was added slowly to 20 ml glycerin (or glycol) in a beaker while stirring vigorously with a magnetic stirrer. In some cases the beaker was placed in warm water to hasten the solution of the salt. Care was taken to keep the temperature below 50° C. After several minutes stirring the undissolved silver nitrate was separated by centrifuging for a few minutes.

Exactly 17 ml of this saturated solution was then added to 39 g (100 ml) 30–60 mesh firebrick to give a packing which contained about 40% solvent by weight. The usual care was taken to ensure a uniform mixture. The resulting material appeared to be quite dry and flowed readily.

Sufficient $\frac{1}{4}$-inch diameter copper tubing was degreased and filled with the prepared packing. Approximately 6 ml of packing was required to fill 1 foot of tubing. The tubing was carefully filled while it was suspended by one end, being shaken at intervals to produce a uniform bed. The ends were plugged with glass wool and the tubing was wound to form a coil 6 inches in diameter.

RESULTS

Columns were prepared as described containing relatively saturated solutions of silver nitrate in ethylene glycol, polyethylene glycol, and glycerin. The relative retention times

which were obtained from the solutions of ethylene glycol and glycerin are given in Tables I and II. It will be observed that the *cis*- and *trans*-butene-2 are well separated as are the isobutene and the butene-1. These two pairs have been difficult to resolve with most other columns (2, 6, 7, 8, 9, 10). Their chromatograms are shown in Figs. 1 and 2.

TABLE I

RELATIVE RETENTION TIMES FOR $AgNO_3$ – ETHYLENE GLYCOL COLUMN

11-ft column
50° C
Flow rate, 25 ml/minute
Corrected retention time for ethylene, 4.5 minutes

	Retention time (ethylene = 1.00)	
n-Pentane (and lighter alkanes)	0	(Not retained)
trans-Butene-2	0.56	
trans-Pentene-2	0.89	
Ethylene	1.00	
Isobutene	1.19	
Propylene	1.22	
cis-Butene-2	2.0	
Butene-1	2.35	
Pentene-1	2.8	
cis-Pentene-2	2.95	
Hexene-1	4.2	
Heptene-1	6.1	
Octene-1	8.9	

TABLE II

RELATIVE RETENTION TIMES FOR $AgNO_3$ – GLYCERIN COLUMN

11-ft column
50° C
Flow rate, 20 ml/minute
Corrected retention time for ethylene, 4.5 minutes

	Retention time (ethylene = 1.00)	
n-Pentane (and lighter alkanes)	0	(Not retained)
trans-Butene-2	0.31	
Isobutene	0.75	
Propylene	0.91	
Ethylene	1.00	
cis-Butene-2	1.17	
Pentene-1	1.32	
Butene-1	1.42	
Ethylene dichloride	3.3	
Butadiene	6.0	
Cyclopentene	9.8	
Isopropanol	40.	
n-Propanol	60.	

The retention time for *cis*-butene-2 relative to that of *trans*-butene-2 is given in Table III for the three columns. The proportion of the silver nitrate on the firebrick is also given to demonstrate the relation between the silver nitrate concentration and the efficiency of the separation. This relation was also borne out when more dilute solutions were used and again when some of the silver nitrate was found to be decomposed in the column. With columns containing no silver nitrate (or those in which the silver nitrate was completely reduced), all olefins and paraffins containing four carbon atoms or less were not retained at all (i.e. not separated from air).

TABLE III

SELECTIVITY FOR *cis*- AND *trans*-BUTENE-2

Column	Column length, ft	% $AgNO_3$ on fire-brick	Ratio *cis/trans* 27° C	50° C		
1. $AgNO_3$ – ethylene glycol	11	24.	4.1	3.6		
2. $AgNO_3$ – polyethylene glycol	11	8.3	—	1.8		
3. $AgNO_3$ – glycerin	11	24.	4.7	4.1		
4. Formamide	6				1.18	(0° C)
5. Dimethylsulpholane	50	($\frac{3}{8}$ inch diam.)			1.17	(0° C)
6. Alumina	7				1.21	(60° C)
7. Tri-isobutylene	6				0.90	
8. Acetonyl acetone	6				0.86	(20° C)
9. $AgNO_3$ – ethylene glycol	6				0.32	
10. $AgNO_3$ – ethylene glycol ($AgNO_3$ completely decomposed)	11	*cis*- and *trans*-Butene-2 not retained				
11. Ethylene glycol	11	*cis*- and *trans*-Butene-2 not retained				

The concentration of silver nitrate found in solutions prepared as described is given in Table IV and may be regarded as relatively saturated solutions at room temperature.

TABLE IV

SOLUBILITY OF $AgNO_3$

Glycerin	95 g/100 ml solution
Ethylene glycol	85 ,, ,,
Triethylene glycol (mol. wt. 200)	48 ,, ,,
Polyethylene glycol (mol. wt. 400)	32 ,, ,,

The *cis–trans* ratios of five other columns are also included in Table III, columns 4–9, as calculated from results reported by other workers. The values reported by Bradford *et al.* (2), columns 7, 8, 9, gave ratios which were less than unity and indicate that the *cis*-butene-2 was eluted before the *trans*-butene-2. Our observations in the case of the silver nitrate – ethylene glycol column have not confirmed this fact. If, however, the values for *cis* and *trans* are interchanged in Bradford's report a *cis–trans* ratio of 3.1:1 is obtained, which is in agreement with the authors' findings.

The authors have employed "two-stage" columns (8) in an attempt to separate paraffins as well as olefins on one column. This consisted of a silver nitrate – glycerin column for separating the olefins, in series with a dinonyl phthalate column for separating the paraffins. Little success was achieved.

As an alternative, we suggest that a silver nitrate – glycerin column be employed for analysis of the olefins, and the paraffin fraction collected for subsequent analysis on a dinonyl phthalate or similar column.

Stability of Silver Nitrate Columns

The instability of the silver nitrate solutions seriously limits the use of the column to lower temperatures. It was therefore considered desirable to obtain further information concerning the temperature at which the decomposition begins, and its rate. Glycerin was also compared as a solvent in the hope that it might prove superior to ethylene glycol.

An ethylene glycol – silver nitrate column was heated to 100° C for 16 hours, and then tested for its efficiency at 35° C. No appreciable separation of *cis*- and *trans*-isomers took place, although the same column had previously shown a *cis–trans* ratio of 3.6:1

For personal use only.

(column 1, Table III). The packing was recovered from the column and the organic phase was diluted with water. Upon titration with chloride this solution indicated the presence of little or no silver ion. The original titration for silver was obtained, however, if the packing was first digested with dilute nitric acid. From the examination of similar columns, it was found that the efficiency of the column was directly related to the concentration of silver ions present.

Ethylene glycol – silver nitrate and glycerin – silver nitrate packings were prepared on firebrick as described and kept in closed bottles. These bottles were stored in a controlled oven for periods of several days, when small samples were removed and titrated with chloride. The results which were obtained are illustrated in Fig. 3.

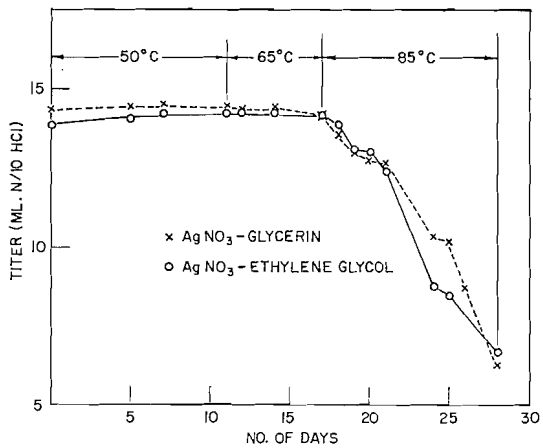

FIG. 3. Thermal stability of columns.

Both column materials were stable at least up to 65° C but decomposed slowly at 85° C. Subsequently a silver nitrate – ethylene glycol column has shown no change in relative retention times after 12 days at 65° C. It has been used intermittently at various temperatures not exceeding 65° C for 6 months, with no significant change in the relative retention times.

CONCLUSIONS

It may be concluded that the ethylene glycol and glycerin columns may be used safely up to 65° C and even at 85° C for short periods without serious damage. The glycerin – silver nitrate column had no distinct advantages, although it did show slightly better separations than its ethylene glycol counterpart. Polyethylene glycol proved less suitable probably owing to its more limited solubility of silver nitrate.

One noteworthy characteristic of these columns is their use for separating the paraffins as a group from the olefins.

THE LIMITING CONDUCTANCE OF POTASSIUM IODATE AND OF IODATE ION AT 25.00° C[1]

A. N. CAMPBELL AND E. BOCK[2]

ABSTRACT

Measurements have been made of the equivalent conductance of solutions of potassium iodate, at 25.00° C, at concentrations ranging from 0.8×10^{-4} to 16×10^{-4} *N*. From this the limiting equivalent conductance of potassium iodate is found to be 114.41 mhos and that of iodate ion 40.91 mhos. The experimental technique is described. The ionic conductances of chlorate, bromate, and iodate ions are compared.

INTRODUCTION

We are beginning, in this laboratory, an investigation of the conductances of very dilute solutions at temperatures above 25.00° C, in order to know the limiting conductances, both equivalent and ionic, above 25° C. This again has a bearing on our work on concentrated solutions, which has been appearing over the last 8 years (1, 2, 3, 4, 5, 6, 7, 8). We have already published one paper on the limiting conductances of ammonium chloride, ammonium bromide, and ammonium nitrate, at 35.00° C (9). Since then, however, we have refined our techniques and we intend this paper to be a statement of the experimental method to be used throughout the series, although, of course, as the temperature of measurement is raised further precautions will have to be taken to obtain constancy of temperature, to prevent distillation or even boiling, etc.

As a preliminary exercise, we have determined the limiting conductance of potassium iodate and of iodate ion, at 25.00° C. Apart from three rather early measurements by Harkins and Pearce (10) nothing has been done on iodate ion, although the limiting conductances of chlorate and bromate, at 25° C, have been determined with great accuracy (11, 12).

EXPERIMENTAL PROCEDURE

The electrical circuit for work of this kind is now standard. We are indebted to the International Nickel Company and to the Imperial Oil Company for the provision of a Jones bridge. The signal is amplified by a tuned amplifier. The detector is a cathode ray oscillograph; it is thus possible to differentiate between resistance and capacity imbalance. Measurements were made at the standard frequency of 1000 but measurements were also made at other frequencies to show that the apparent resistance did not vary with the frequency, as it should not if the true resistance is being measured.

Our conductance cell, of silica, is identical with that used by Shedlovsky (13). The thermostat is a double-jacketed, completely enclosed oil bath, containing 16 gal of mineral oil; the air over the bath is stirred and heated to a temperature slightly above that of the bath. Temperature is determined by a platinum resistance thermometer, and Mueller bridge.

The thermometer was obtained from the National Research Council and calibrated by them. We use a large toluene mercury regulator and thyatron control (14). The variation of temperature does not exceed 5×10^{-3} ° C. The potassium iodate was a Fisher certified reagent of the very highest purity and we felt that nothing would be gained by an additional recrystallization. Moreover, as the impurities in the salt—less than 0.01% in total—were ionic in nature, the error introduced into the conductance value

[1]*Manuscript received June 12, 1958.*
Contribution from the Chemistry Department of the University of Manitoba, Winnipeg, Manitoba.
[2]*Holder of a C.I.L. Fellowship, 1957–58.*

will be proportional to the difference in conductance of the salt investigated and the impurities; an error a great deal less than 0.01%. The salt was dried at 150° C and kept over P_2O_5 in a desiccator until needed. As for conductance water, we began by using an ion-exchange column, employing MB-3 (Fisher) ion-exchange resin. We found, however, that, although the issuing water had a very low conductance at first (2×10^{-7} mhos), this increased with time. It appears that something is extracted from the material of the column which subseqently undergoes chemical change with production of an electrolyte. The increase in conductance is small but, since the water conductance correction is considerable (about 10% of the whole for the most dilute solution used) in these very dilute solutions, it must be constant and known with accuracy. We therefore simply use the water from an electric still, from which we remove dissolved gases with bubbling nitrogen. This water has a conductance of 4.5×10^{-7} to 7×10^{-7} and it does not change with time, when preserved in a silica container. The conductance cell was subjected to a prolonged steaming operation until we were convinced, from experimental measurement, that the conductance of water stored in it did not change with time. All measurements are carried out in an atmosphere of nitrogen.

The balance used is a single-pan semimicro type, having a sensitivity of 0.01 mg. Since we do not possess a microbalance, it is not possible to make up the most dilute solutions by introducing the very small weights of dry salt directly into the cell. We have therefore used a weight burette for the purpose of obtaining a solution of known concentration. The cell constant was determined in the usual way with 1/100 demal potassium chloride. As a final test of technique, we determined some of the conductances of potassium chloride at 25.0° C (at various concentrations) and we obtained exact agreement with the results of Shedlovsky and of Gordon (13, 15).

The only previous work on potassium iodate at 25.00° C is that of Harkins and Pearce (10), who report the conductances at three rounded-off concentrations, viz., 0.2×10^{-3}, 0.5×10^{-3}, and 1×10^{-3}. From these figures, they state the limiting conductance to be 114.37 mhos, in close agreement with our figure but we do not see what justification they can have for this, since they presumably (no details are given) only made three determinations plotted. And then, again presumably, they plotted Λ versus $\sqrt{c}$, and drew a straight line, more or less at random, through the three points. Yet when such a plot is constructed the extrapolated value of Λ_0 comes to 114.20 mhos.

EXPERIMENTAL RESULTS

Our results are contained in the following table.

TABLE I

THE SPECIFIC AND EQUIVALENT CONDUCTANCES OF AQUEOUS SOLUTIONS OF POTASSIUM IODATE AT 25.00° C

Concentration, in moles/liter $\times10^4$	Specific conductance $\times10^6$, in mhos	Equivalent conductance, in mhos
0.86082	9.78064	113.62
2.05973	23.30996	113.17
3.14043	35.45545	112.90
4.69655	52.85967	112.55
6.58631	73.90498	112.21
8.66525	96.93815	111.87
10.81886	120.72765	111.59
12.92765	143.92353	111.33
14.11540	157.96544	111.19
15.64277	173.66603	111.02
16.88694	187.24239	110.88

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

When the above results are plotted in the form of Λ versus $\sqrt{c}$, and the best straight line drawn (by the method of least squares), it is seen that no single determination deviates from the line by more than 1/100%. The slope of the line (85.91) is very close to the theoretical Debye–Hückel slope (86.51) but is somewhat less; this is what is usually found. When the line is extrapolated to zero concentration, Λ_0 results as 114.41. Taking the limiting conductance of potassium ion to be 73.50 (15, 16) at 25.00° C, the limiting conductance of iodate ion results as 40.91.

DISCUSSION

Since the limiting conductances of chlorate, bromate, and iodate ions are now known with accuracy, there is some interest in comparing them with the dimensions of the crystallographic ions (17), thus:

TABLE II

COMPARISON OF LIMITING IONIC CONDUCTANCES WITH DIMENSIONS OF CRYSTALLOGRAPHIC IONS

Ion	Limiting conductance	Edgelength of tetrahedral ion
ClO_3^-	64.6	2.33 Å
BrO_3^-	55.74	2.73 Å
IO_3^-	40.91	3.35 Å

The ratio of conductances is 1.58:1.36:1 and that of edgelength 1.44:1:1.71 iodate, with the largest (crystallographic) ion size, has the smallest ionic conductance, but the agreement is obviously not quantitative. Indeed, similar calculations with other ions (notably the bromide ion) show that sometimes an ion may even have a greater apparent size and yet have a greater conductance. It is well known that Stokes' law does not apply to the motion of particles as small as the smaller ions. Stokes and Robinson (18) consider the problem of how large an ion must be in order that Stokes' law may be obeyed and assign a lower limit. Nevertheless though quantitative agreement with Stokes' law is not to be expected here, if the crystallographic dimensions were true measures of the sizes of the ions in solution qualitative agreement should exist.

Differences in solvation may account for the discrepancy although other explanations are possible.

DIACETYLENE: PREPARATION, PURIFICATION, AND ULTRAVIOLET SPECTRUM[1]

K. K. Georgieff and Y. Richard

ABSTRACT

Diacetylene was prepared by the reaction of 1,4-dichloro-2-butyne with sodium hydroxide. Three modifications of procedure were tried to determine which gave the highest yield and purest product. Evidence that the by-product is 2-chloro-2-butene-3-yne is presented. Several methods for purifying the diacetylene were investigated. The ultraviolet spectrum with molar extinction coefficients is given.

INTRODUCTION

A sample of very pure diacetylene was required for polymerization and spectroscopic studies. In recent years most investigators have prepared it by the dehydrochlorination of 1,4-dichloro-2-butyne with sodium hydroxide (1, 2, 3, 4, 5) but only one (4) appears to have reported that the product is not entirely pure. However, no indication of the nature of the impurity was given.

RESULTS

Several modifications of the dehydrochlorination were tried to determine which gave the highest yield and purest product. The yields were highest when 40% aqueous sodium hydroxide solution (285% of theory) was added to a 25% solution of 1,4-dichloro-2-butyne[2] in ethyl alcohol at 65–75° over a period of 1 hour (1) and the product was swept out of the reaction flask with a stream of hydrogen. However, a small percentage of a by-product having a parent peak of 86 in its mass spectrum, as well as tarry high polymers, also formed. When the procedure was reversed and the dichlorobutyne in alcohol was added to the sodium hydroxide, the yield of diacetylene was substantially lower and the fractionated product contained about the same concentration of the same impurity. When pure dichlorobutyne was added to 43% sodium hydroxide solution at 115°, the yield was still lower but the relative amount of the above impurity was lower. Some acetylene and methyl acetylene also formed and were detected by their mass spectra.

From the ratio of the 87 to the 86 mass peak, the spectrum indicates that the impurity contains four carbon atoms and the ratio of the 86 to the 88 peak is in good agreement with the known ratio of Cl_{35} to Cl_{37}. It would thus appear that its empirical formula is C_4H_3Cl. It also has a strong absorption at 224 to 245 mμ in the ultraviolet and its extinction coefficients are of a higher order than those of diacetylene, indicating two conjugated ethylenic groups or an ethylenic together with an acetylenic. From the above evidence, there would appear to be little doubt that this compound formed, even in the presence of a large excess of sodium hydroxide, by the incomplete dehydrochlorination of the dichlorobutyne and could theoretically have the structure I, II, or III.

$$CH_2Cl—C\equiv C—CH_2Cl + NaOH \rightarrow NaCl + H_2O + CH_2=CCl—C\equiv CH \quad [I]$$

$$\text{or } CHCl=CH—C\equiv CH \quad [II]$$

$$\text{or } CH_2=CH—C\equiv C—Cl \quad [III]$$

To establish its identity, its infrared spectrum was obtained and a comparison made of the out-of-plane vibrations of its olefinic hydrogens with those of four compounds

closely related with I, II, and III, as shown in Table I. The band assignments previously published for monovinylacetylene (6, 7, 8) and 2-chloro-1,3-butadiene (9, 10) were assumed. Since only a fragmentary spectrum for 1-chloropropene-1 appears to have been previously published (10), it was first necessary to obtain samples of 1- and 2-chloropropene-1 (from K. & K. Laboratories, U.S.A.) and purify them by distillation in a Podbielniak column. Their purity was checked with the mass spectrometer.

TABLE I

ASSIGNMENT OF INFRARED BANDS (cm^{-1})

Out-of-plane vibrations of olefinic hydrogens	CH_3—CH=CHCl	CH_3—CCl=CH_2	CH_2=CH—CCl=CH_2	CH_2=CH—C≡CH	Our impurity
CH_2=CH—			974 (9, 10) 924	972 (8) 924	
CH_2=CCl—		938 929 881	878		919 862 853
R—CH=CHX (*trans*)	932				
R—CH=CHX (*cis*)	766 754				

Our impurity showed a band of medium intensity at 919 cm^{-1} and a strong doublet at 862 and 853 cm^{-1}. Both 2-chloro-1,3-butadiene and 2-chloropropene-1 show absorptions in the same regions whereas 1-chloropropene-1 shows absorption at 932 and a doublet at 766 and 754 cm^{-1}, which, in accordance with the correlations established by Kitson (10), could be attributed to *cis*- and *trans*-isomers. There is little spectral evidence in support of structure III. Neither is it probable on chemical grounds. It would thus appear that the structure of our impurity is I, CH_2=CCl—C≡CH. The shift of the chlorine atom from the 1-carbon to the 2-position is reminiscent of that of chlorobutadiene (11).

PURIFICATION

Attempts to remove the 2-chloro-2-butene-3-yne by the high vacuum, fractional distillation – condensation technique (8, 12) using distilling temperatures from −60 to −95° failed. So did distillation from solvents such as ethyl acetoacetate and methyl isobutyl ketone, as well as conventional, simple distillation at 277 mm mercury absolute. Fractional recrystallization was abandoned owing to great experimental difficulties imposed by the necessity of keeping the sample very cold and away from oxygen. Attempts to remove the impurity by partially polymerizing the sample at −6 to +13° in the absence of air and catalyst increased its concentration, thus indicating that the diacetylene polymerized more rapidly. Diluting the diacetylene with 10 to 15 volumes of hydrogen and passing it rapidly through a solution of sodium hydroxide in amyl alcohol at 138° reduced the chloro impurity from 1.5 to 0.2% but only 10–20% of the diacetylene was recovered. The remainder polymerized to tar. Gas chromatography, on the other hand, was found to produce high purity diacetylene with high recoveries. A tube (20 ft long × ¼ inch O.D.) filled with Johns-Manville C-22 firebrick (35–50 mesh) which was impregnated with 33% tricresyl phosphate was employed. Using a diacetylene vapor sample of about 5 ml (measured at 760 mm), a hydrogen flow of 67 ml per minute, and a tube temperature of 65°, the recovery was at least 93% per pass. After one or two passages through the tube, no 2-chloro-2-butene-3-yne could be detected by the mass spectrometer.

It is well known that the loss of diacetylene is substantial if it is handled by the usual laboratory techniques owing to its volatility and ease of polymerization. However, it was found that by using the high-vacuum, low-temperature-distillation technique (8, 12), such loss was reduced to a negligible value. By storing the samples (whether pure or impure) at -50 to $-78°$ under vacuum, losses due to polymerization were very small, even after 1 year without a stabilizer. The preferred procedure was to distill the diacetylene into a glass tube, cool it with liquid nitrogen, evacuate to a pressure of at least 10^{-4} mm mercury, and seal the tube. However, when the sample contained dissolved gas (usually air), it was first necessary to degas it several times by successively warming it to -20 to $0°$, cooling with liquid nitrogen, and pumping off the gas.

ULTRAVIOLET SPECTRUM

The ultraviolet spectrum of diacetylene vapor has been published by Price and Walsh (13) for the 1000 to 2000 Å region and by Woo and Chu (14, 15, 16) for the 2068 to 2970 Å region. Our spectrum was obtained with a Beckman DK-2 spectrophotometer on samples dissolved in iso-octane. There was general agreement with Woo and Chu's spectrum but there was a shift in our peaks of 7 to 9 mμ towards the lower wave lengths and some differences in the relative intensities of the maxima were apparent. The curve is given in Fig. 1 and the molar extinction coefficients in Table II. Our values are of the same order of magnitude as those obtained by Armitage *et al.* (17) on substituted diacetylenes.

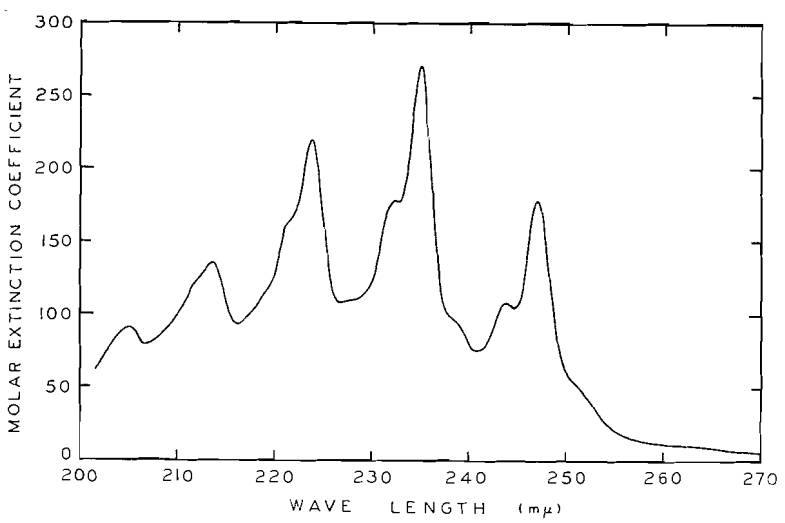

FIG. 1. Ultraviolet spectrum of diacetylene in iso-octane.

TABLE II

ULTRAVIOLET SPECTRUM OF DIACETYLENE

CONCN. = 7 TO 30 $\times 10^{-4}$ MOLES PER LITER IN ISO-OCTANE

λ_{max}, mμ	ϵ_{max}	λ_{max}, mμ	ϵ_{max}	λ_{max}, mμ	ϵ_{max}
~205	~90	223.8	222	244	110
211.3sh	117	232.5	180	247.1	180
213.5	136	234.9	270	251.5	55
221.5sh	168	238.5	101		

Extinction values were also obtained on a Beckman DU instrument and were generally 10 to 20% lower than those above. In contrast to those obtained with the DK-2, they were found to decrease rapidly with increase in concentration of diacetylene even at low optical densities (i.e. 0.1 to 0.3). A similarly great deviation from the Beer–Lambert–Bouger absorption law was noted previously with monovinylacetylene and other acetylene polymers (8).

ACKNOWLEDGMENTS

SOME CHEMISTRY OF 2,6-DIETHYLANILINE[1]

P. M. G. BAVIN[2] AND J. M. W. SCOTT[3]

ABSTRACT

Orientation in the nitration and bromination of amides derived from 2,6-diethylaniline has been shown to be dependent on the acidity of the reaction medium, as found previously for the 2,6-dimethyl homologues.

The acidity of the reaction medium is known to influence the orientation of substitution products of many amines (1, 2, 3, 4, 5, 6, 7) and their derivatives, particularly anilides and sulphonamides (8, 9, 10, 11). Derivatives of 2,6-dimethylaniline (*m*-2-xylidine) have proved to be of more than usual interest (9, 10), so that the opportunity has been taken to examine some of the chemistry of 2,6-diethylaniline.

2,6-Diethylaniline was recently prepared for the first time (12). It forms nicely crystalline salts with hydrochloric, hydrobromic, and perchloric acids which, as expected for the salts of weak bases (13), are partly hydrolyzed in water. With benzaldehyde it reacts smoothly to form a Schiff's base and readily forms amides with acetic anhydride, benzoyl chloride, and *p*-toluenesulphonyl chloride. The acetamide (X) is very resistant to acid hydrolysis so that the toluenesulphonamide (I) was preferred as an intermediate.

Nitration of (I) in the presence of nitrous acid (7, 10) gave an excellent yield of pure 4-nitro derivative (II), the structure of which was proved by conversion to the known 4-nitro-2,6-diethylphenol (IV) and 2,6-diethyl-1,4-benzoquinone (V). In sulphuric acid, nitration gave a rather lower yield of the 3-nitro derivative (VI), its structure being assumed by elimination. The acetamide (X) readily yielded a dinitro compound, almost certainly (VII), and considerable difficulty was encountered in obtaining the 3-nitro derivative (VIII).

Bromination of the acetamide (X) in sulphuric acid gave the 3-bromo derivative (IX), the structure of which is assumed by analogy with previous work on the dimethyl homologue (9). In acetic acid or chloroform, the 4-isomer (XII) was obtained. This compound, the structure of which is also assumed by analogy (9), has been shown to be formed by the rearrangement of the *N*-bromoacetamide (14). Bromination of the sulphonamide (I) in sulphuric acid, chloroform, or acetic acid gave products which were not obtained pure by repeated crystallization and whose infrared spectra showed them to be essentially identical. Removal of the tosyl group followed by acetylation gave almost pure (XII), showing that bromination had occurred predominantly in the 4 position.

Aniline, the toluidines, and related compounds are very much more reactive than their salts so that the small concentration of free amine present in sulphuric acid largely controls the orientation in nitration in this medium (1, 2, 3, 4, 5, 6, 7). Derivatives of 2,6-dialkylaniline (alkyl is methyl or ethyl) offer a more complex problem. The proximity of the ortho substituents twists the amide group out of the plane of the aromatic ring,* thereby greatly reducing mesomerism between the ring and the nitrogen (10, 15, 16).

**Reducing mesomerism between the ring and the nitrogen will increase the basicity of the latter, but the compression caused by the ortho substituents may nullify or even out-balance this effect ((17), pp. 214–223).*

X	H	H
XI	NO_2	H
XII	Br	H
XIII	NH.Ac	H

This lowers the reactivity of the 4 position but leaves it more reactive than the 3 position (10). Since in sulphuric acid 3-derivatives are usually obtained, it appears that the protonated and unprotonated forms differ but little in reactivity at the 3 position.

The sulphonamides (I) and (XIV) and their *N*-nitroso derivatives are probably insufficiently reactive to undergo nitrosation (cf. (7)) so that (XV) has been suggested (10) as the reactive species in nitration in the presence of nitrous acid.

As expected, nitration of (I) and bromination of (X) are completely analogous to reactions of the dimethyl homologues (9, 10). That bromination of (I) in sulphuric acid gives rise to predominantly the 4-isomer may be due to the low basicity of the sulphonamide group and the greater selectivity of bromination compared with nitration (18).

It was hoped initially to confirm the structures of the bromination products by comparison of their infrared spectra with those of the corresponding nitro compounds. This hope was not realized, only approximate similarities being observed.

EXPERIMENTAL

2,6-Diethylaniline was supplied as a reddish liquid and used without purification.

Melting points are uncorrected. Most of the nitration products turned brown in light and were crystallized in covered flasks. Nitration conditions were essentially those used by Wepster for the dimethyl homologues (10).

2,6-Diethylaniline hydrochloride crystallized from dilute hydrochloric acid as colorless needles, m.p. 175–179° with decomposition. Calc. for $C_{10}H_{16}NCl$: C, 64.68; H, 8.69%. Found: C, 64.48; H, 8.44%. Crystalline salts were also formed with perchloric and hydrobromic acids but these were not characterized. The free amine separated as an oil when the salts were dissolved in warm water.

N-Benzal-2,6-diethylaniline.—On the gentle warming of a mixture of the amine (2 g.) with benzaldehyde (4 g.), water started to separate almost at once. Ethanol (2 ml.) was added and the mixture boiled under reflux for 10 minutes. The Schiff's base was obtained as a pale yellow solid by pouring the mixture into an excess of cold dilute sodium bisulphite solution. Two crystallizations from hexane afforded yellow prismatic needles (2.6 g.), m.p. 54–55°. Calc. for $C_{17}H_{19}N$: C, 86.03; H, 8.07; N, 5.90%. Found: C, 86.20; H, 8.08; N, 5.88%.

N-(2,6-Diethylphenyl)-benzamide was prepared by shaking the amine (2 g.) with benzoylchloride (3 ml.) and a solution of sodium hydroxide (5 g.) in water (10 ml.). The solid product was crystallized twice from toluene, affording slender needles (2.2 g.), m.p. 236–237°. Calc. for $C_{17}H_{19}NO$: C, 80.57; H, 7.56; N, 5.53%. Found: C, 80.73; H, 7.42; N, 5.66%.

N-(2,6-Diethylphenyl)-acetamide (X) was prepared by adding acetic anhydride (200 ml.) dropwise to the amine (100 g.) cooled in an ice bath. The reaction, which was rapid and exothermic, was completed on the steam bath. Addition of 10% sulphuric acid (500 ml.) and crushed ice precipitated the amide. Crystallization from ethanol (200 ml.) afforded white needles (110 g.), m.p. 139–140°, raised to 141–142° by two crystallizations from toluene. (Lit. m.p. 135–136°, (12).) Calc. for $C_{12}H_{17}NO$: C, 75.35; H, 8.96; N, 7.32%. Found: C, 75.56; H, 8.71; N, 7.46%.

N-(2,6-Diethylphenyl)-p-toluenesulphonamide (I).—The amine (150 g.) was dissolved in dry pyridine (500 ml.) and *p*-toluenesulphonyl chloride (210 g.) added slowly while the mixture was cooled with an ice–salt bath. Next morning, the mixture was poured onto crushed ice and the pyridine neutralized with dilute hydrochloric acid. Crystallization from methanol–acetone (Norite) afforded yellowish prisms (265 g.), m.p. 130–132°. An analytical sample was obtained as well-defined colorless prisms, m.p. 132–133°, after two crystallizations from benzene. Calc. for $C_{17}H_{21}NO_2S$: C, 67.31; H, 6.98; N, 4.62%. Found: C, 67.45; H, 6.98; N, 4.49%.

N-(4-Nitro-2,6-diethylphenyl)-p-toluenesulphonamide (II).—A mixture of the amide (I) (30 g.), acetic acid (100 ml.), fuming nitric acid (40 ml.), and sodium nitrite (2 g.) was boiled under reflux for 1 hour. Pouring onto ice precipitated a gum which soon crystallized. Successive crystallizations from methanol (Norite) and benzene–hexane afforded the nitroamide as pale yellow needles (22–25 g.), m.p. 140–141°. Calc. for $C_{17}H_{20}N_2O_4S$: N, 8.04%. Found: N, 8.18%.

4-Nitro-2,6-diethylaniline (III).—The nitroamide (II) (10 g.) was stirred overnight with sulphuric acid (30 ml.) containing water (4 ml.). Pouring onto ice precipitated the pale yellow amine sulphate, which was decomposed to the amine by neutralization with dilute ammonia solution. Two crystallizations from methanol gave long bright yellow needles of the amine, m.p. 137–138°. Calc. for $C_{10}H_{14}N_2O_2$: N, 14.42%. Found: N, 14.59%.

N-(4-Nitro-2,6-diethylphenyl)-acetamide (XI) was prepared by acetylating the amine (III). It crystallized from benzene–hexane as pale yellow needles, m.p. 195–196°. Calc. for $C_{12}H_{16}N_2O_3$: N, 11.96%. Found: N, 11.71%.

N,N-Diacetyl-2,6-diethyl-1,4-phenylenediamine (XIII).—The nitroamine (III) was reduced with hydrazine and palladized charcoal, giving the diamine as a colorless oil. Acetylation followed by two crystallizations from acetone–toluene afforded the bisamide as slender needles, m.p. 216–217°. Calc. for $C_{14}H_{20}N_2O_2$: N, 11.28%. Found: N, 11.30%.

4-Nitro-2,6-diethylphenol (IV).—To a cold (0–5°) solution of the nitroamine (III) (3 g.) in 50% sulphuric acid (40 ml.) was added sodium nitrite (2 g.). The mixture was left for 1 hour at room temperature and, after addition of urea to destroy excess nitrous acid, was maintained at 60° for 1 hour. During this time the phenol separated as a reddish solid. Attempted purification through the intensely yellow sodium salt was not successful but two crystallizations from methanol (Norite) afforded slightly reddish needles, m.p. 131–133° with decomposition. (Lit. m.p. 130–131° with decomposition (19).)

2,6-Diethyl-1,4-benzoquinone (V) was prepared by oxidizing the nitrophenol (IV) with lead tetraacetate, as described previously (19). It was obtained as bright yellow needles, m.p. 36–38°, by low temperature crystallization from pentane. (Lit. m.p. 35° (19); 39° (20).)

Attempts to oxidize the nitroamine (III) to the quinone, using chromic acid or lead tetraacetate, were not successful.

N-(3-Nitro-2,6-diethylphenyl)-p-toluenesulphonamide (VI).—A mixture of acetic acid (50 ml.), fuming nitric acid (4.5 ml., d. 1.5), and sulphuric acid (50 ml.) was added dropwise to a vigorously stirred suspension of the amide (I) (32 g.) in acetic acid (250 ml.) containing sulphuric acid (120 ml.). The addition required ½ hour during which time the temperature rose to 45°. After 6 hours the product was isolated by pouring the mixture onto crushed ice. Crystallization from aqueous ethanol (Norite) afforded buff prisms (17–26 g.), m.p. 149–151°. An analytical sample was obtained as pale yellow prisms after several crystallizations from benzene–hexane, m.p. 152–153°. Calc. for $C_{17}H_{20}N_2O_4S$: N, 8.04%. Found: N, 8.13%.

N-(3-Nitro-2,6-diethylphenyl)-acetamide (VIII).—Hydrolysis of the once-crystallized amide (VI) with 90% sulphuric acid gave the amine as a yellow oil. Acetylation followed by crystallization from methanol and then benzene–hexane afforded the acetamide as almost colorless needles, m.p. 153–154°. Calc. for $C_{12}H_{16}N_2O_3$: N, 11.96%. Found: N, 12.01%.

N-(3,5-Dinitro-2,6-diethylphenyl)-acetamide (VII) was commonly obtained when the acetamide (X) was nitrated in a mixture of acetic and sulphuric acids. It crystallized from toluene as pale yellow needles, m.p. 206–208° with some decomposition (capillary determination). On the hot stage, with a rapid rate of heating, the melting point was 211–212°. Calc. for $C_{12}H_{15}N_3O_5$: C, 51.24; H, 5.35; N, 14.94%. Found: C, 51.31; H, 5.31; N, 14.94%.

On a few occasions the mononitro compound (VIII) was obtained by nitrating (X) but reliable conditions for its preparation by this method were not found. Attempts to dinitrate the sulphonamide (I) were not successful, probably owing to hydrolysis.

N-(3-Bromo-2,6-diethylphenyl)-acetamide (IX) was prepared by shaking the acetamide (X) for several hours with a mixture of 98% sulphuric acid (400 ml.) and bromine (20 g.), during which time hydrogen bromide was steadily evolved. The product was isolated by pouring onto crushed ice, crystallization from benzene giving white needles (18 g.), m.p. 157–160°, raised to 161–162° by two crystallizations from methanol. Calc. for $C_{12}H_{16}NOBr$: C, 53.34; H, 5.18%. Found: C, 53.12; H, 5.95%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

N-(4-Bromo-2,6-diethylphenyl)-acetamide (XII) was obtained when the acetamide (X) was brominated in chloroform or acetic acid. It crystallized from methanol or benzene–hexane as long white needles, m.p. 181–182°. Addition of the 3-isomer (VII) depressed the melting point. Calc. for $C_{12}H_{16}NOBr$: C, 53.34; H, 5.97; N, 5.18; Br, 29.58%. Found: C, 53.30; H, 5.85; N, 5.13; Br, 30.25%.

Bromination of the sulphonamide (I) in chloroform (with or without addition of potassium carbonate), acetic acid, or sulphuric acid gave impure products having almost identical infrared spectra. Repeated crystallization from various solvents (methanol, acetone, ethyl acetate, benzene) gave white needles having melting points in the range 115–144°. Calc. for $C_{17}H_{20}NO_2SBr$: C, 53.41; H, 5.27%. Found: C, 53.58, 53.29; H, 5.25, 5.35%. Hydrolysis with 90% sulphuric acid gave, after acetylation, the 4-bromo-acetamide (XII), obtained after one crystallization from methanol.

INFRARED SPECTRA

The infrared spectra were obtained using potassium bromide disks and solutions in carbon disulphide or chloroform, and were calibrated against the spectrum of "Polystyrene".

The 1600–2000 cm.$^{-1}$ region, generally useful in orienting benzene derivatives (21, pp. 54–70), proved to be of little value as the acetamides showed strong carbonyl absorption at about 1650 cm.$^{-1}$. Comparison of the bands in the 700–1200 cm.$^{-1}$ region failed to reveal useful correlation with structure, and comparison of some of the spectra with those of the dimethyl homologues was also valueless.

ACKNOWLEDGMENTS

The authors are grateful to the Ethyl Corporation for generous samples of 2,6-diethylaniline and to Dr. B. M. Wepster for samples of certain derivatives of 2,6-dimethylaniline and for friendly correspondence. One of them (P. M. G. B.) is deeply indebted to Dr. F. A. L. Anet for his encouragement and interest.

MICROCALORIMETRIC AND KINETIC STUDIES OF THE α-CHYMOTRYPSIN – HYDROCINNAMIC ESTER – HYDROCINNAMIC ACID SYSTEM[1]

WILLIAM J. CANADY[2] AND KEITH J. LAIDLER

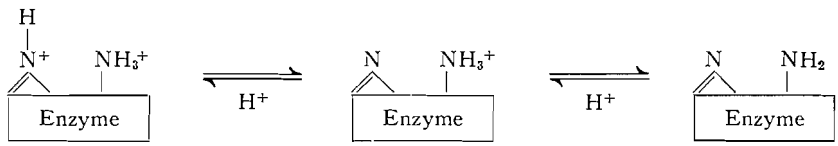
ABSTRACT

Using a microcalorimeter of the Tian–Calvet type the heat of binding of hydrocinnamic acid to α-chymotrypsin has been measured in aqueous solution over a range of pH values. The heat evolved was found to vary from about 5 to about 28 kcal per mole as the pH was varied from 5.1 to 7.8. In order to see whether these heats are due to the binding of the inhibitor at the active center of the enzyme, heats were also measured at pH 7.1 by a kinetic method, the inhibitor constant being determined over a range of temperatures; the heat calculated in this way was consistent with the microcalorimetric value. The kinetic work also gave rise to entropies of binding of the inhibitor and the substrate (methyl hydrocinnamate); these entropies are negative, the significance of which is discussed in terms of the mode of binding. It is suggested that the results are best explained on the hypothesis that the active center of the enzyme contains, in addition to the ordinary acidic and basic sites, a negatively charged group that interacts electrostatically with the anion of hydrocinnamic acid.

INTRODUCTION

A considerable amount of evidence has now accumulated regarding the nature of the active center in the enzyme chymotrypsin, and about the mechanisms of the reactions catalyzed by the enzyme. Since these matters have recently been reviewed and discussed (1) only the most important points will be referred to here. The work with DFP (2) and with other inhibitors (3, 4) has shown the enzyme to contain one active center per molecule. The pH dependence of the rate (5, 6) shows that the active center contains two ionizing groups, the active form of the enzyme being the one in which one of these groups is acidic and the other basic. A study of the kinetics of the hydrocinnamic acid hydrolysis in 20% methanol solution over a range of pH values and substrate concentrations (5) has shown that the pK's of the ionizing groups in the active center of the enzyme are 7.2 and 8.0, and that these groups are *not* involved in the formation of the enzyme-substrate complex but only in the subsequent steps.

The DFP work, although not entirely unequivocal, does on the whole point towards the fact (7) that the imidazole group of histidine is involved in the reaction. This group presumably corresponds to the pK value of about 7.2. The identity of the group having a pK of 8.0 (or perhaps higher, as suggested in a footnote later) is unknown, but the group might be an ω-amino group. If this is the case the ionization of the enzyme is as represented below:



As far as reaction mechanisms are concerned, it is undoubtedly the case that a Michaelis complex is formed initially. This complex appears to be formed without the participation of the ionizing groups, and the binding may involve van der Waals and other weak

forces. By analogy with the reaction with DFP and other irreversible inhibitors, it can be concluded with reasonable certainty that the enzyme is acylated at its imidazole site during the subsequent breakdown of the complex. Evidence that this is the case has been provided by the transient-phase studies of Gutfreund and Sturtevant (8, 9).

One aspect of enzyme kinetic studies that has so far been largely neglected is that involving detailed studies of the binding of inhibitors to enzymes. A few measurements of K_i values have been made, but usually at only one pH, and few ΔH and ΔS values are known for any enzyme–inhibitor system. Such studies can provide valuable information regarding reaction mechanisms, and may indeed reveal features of the active centers of enzymes that cannot be revealed by studies with substrates. The present investigation has been carried out with the object of learning about the mode of binding of the inhibitor hydrocinnamic acid to the enzyme α-chymotrypsin, over a range of pH values. Two kinds of measurement have been made. In the first place, heats of binding of the inhibitor to the enzyme have been measured directly, using a very sensitive microcalorimeter. Secondly, partly in order to see whether the heats evolved are really due to the binding of the inhibitor at the active center of the enzyme, heats of binding were also measured by a kinetic method, the inhibitor constant being measured over a range of temperatures.

Our determinations of heats of binding by microcalorimetry are, we believe, the first in which this technique has been applied to an enzyme–substrate or enzyme–inhibitor system. The results of the measurements will be seen below to provide additional knowledge of the nature of the active center and of its interaction with substrates and inhibitors.

EXPERIMENTAL

Microcalorimetry

The microcalorimeter employed is of the conduction type of Tian (10), as modified by Calvet (11, 12), and our techniques with it have been described elsewhere (13, 14). The measurements were made at 25.0° C.

The hydrocinnamic acid was supplied by Eastman Kodak and was recrystallized from hot water; m.p. 48.5° C. A solution of hydrocinnamic acid of concentration 5×10^{-2} M in $M/15$ Sørensen's phosphate buffer (15) was used throughout all of the experiments. The enzyme used was a three-times-crystallized sample of α-chymotrypsin, supplied by the Worthington Biochemical Corporation. Immediately before each experiment a fresh chymotrypsin solution of 2×10^{-4} M was made up in Sørensen buffer of the desired pH. Ten milliliters of the enzyme solution was placed in the main calorimeter cell, and 0.5 ml of the inhibitor solution was placed in the capillary bulb. After a suitable time for temperature equilibration the capillary bulb was broken, and a small rubber bulb connected to the far end of the capillary was gently squeezed to ensure mixing. A blank was run at the same time by adding inhibitor solution to a plain buffer solution of the same pH as the buffered enzyme solution. The difference between the values obtained with the blank and the enzyme is the heat evolved by the combination of inhibitor with enzyme. The final pH of the reaction mixture was checked after the heat was measured. This value was recorded as the pH at which the heat was evolved.

Kinetics

The methyl ester of hydrocinnamic acid was prepared by refluxing the acid with an excess of methanol, a few drops of concentrated sulphuric acid being used as catalyst. The product was dissolved in ether and washed with 5% sodium bicarbonate solution

For personal use only.

and with water. It was purified by fractional distillation, the middle 20% being collected; the boiling point was 236.5° C at atmospheric pressure. The enzyme employed was the same three-times-crystallized sample used for the calorimetric investigations. The buffer employed was the Sørensen's phosphate buffer previously used in the calorimetric determinations, but at the much lower concentration of 1.7778×10^{-4} *M*. The concentration of enzyme was approximately 1×10^{-5} *M*. The same enzyme solution was always used throughout a complete set of runs. The procedure was to measure initial reaction rates over a range of substrate and inhibitor concentrations. The range of substrate concentrations employed was 0.89×10^{-3} *M* to 2.65×10^{-3} *M*, the upper limit being imposed by the low solubility of the substrate in water. The inhibitor concentration was varied from 0.659×10^{-3} to 5.27×10^{-3} *M*. In order for the ionic strength to be maintained constant all solutions were 0.1 *M* in sodium chloride. Runs were carried out at 10.0°, 15.0°, 20.0°, 25.0°, and 30.0° C, and at a pH of 7.10.

The course of the reaction was followed by potentiometric titration, using a Radiometer Automatic Titrator as a pH meter. As the reaction proceeded small amounts of 2×10^{-2} *M* sodium hydroxide were added from a syringe micropipette in order to neutralize the hydrocinnamic acid liberated and to maintain the pH constant at 7.10. The sodium hydroxide was conveyed directly to the surface of the solution by means of a bent hypodermic needle. The reaction mixture was stirred by means of a magnetic stirrer, and the temperature maintained constant by circulation of thermostatically controlled water through an outer jacket.

RESULTS

Microcalorimetry

The heats evolved per mole are shown in Table I, and a plot of ΔH against pH is given in Fig. 1.

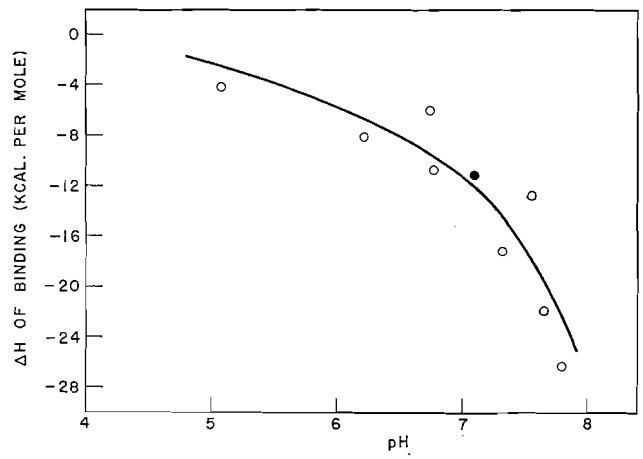

FIG. 1. Plot of ΔH of binding against pH, for the α-chromotrypsin – hydrocinnamic acid system.

Kinetics

The rates obtained at a variety of temperatures, substrate concentrations, and inhibitor concentrations are shown in Tables II and III.

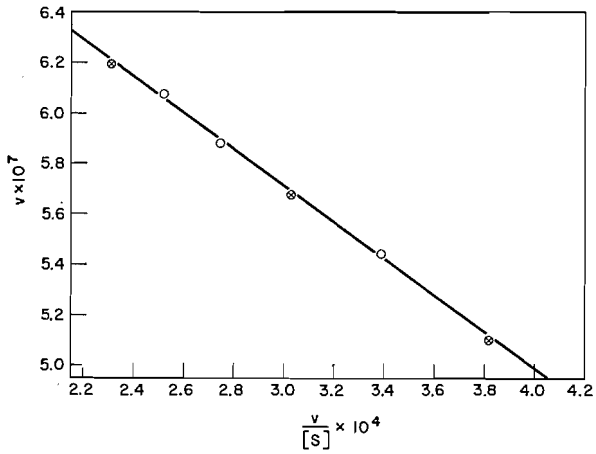

FIG. 2. Plot of v against $v/[S]$ for the hydrolysis of hydrocinnamic ester. The points with crosses represent duplicate runs.

the over-all kinetic behavior is consistent with the above mechanism; in the present treatment the above mechanism will therefore be assumed. The validity of this mechanism can be demonstrated, as first shown by Eadie (16), by plots of $v/[S]$ against v. A representative plot of this kind is shown in Fig. 2. From the slope and intercepts may be obtained the values of k_2 and $\bar{K}$; the latter is the reciprocal of the conventional Michaelis constant and is defined by

$$[1] \qquad \bar{K} = 1/K_m = k_1/(k_{-1}+k_2).$$

As referred to above there is good evidence that $k_{-1} \gg k_2$, so that $\bar{K}$ is simply the equilibrium constant for the formation of the complex.

The values of K_i were obtained from plots of v_0/v against [I]; v is the inhibited rate and v_0 the uninhibited rate. The rate equation for competitive inhibition is

$$[2] \qquad v = k_2\bar{K}[E]_0[S]/(1+\bar{K}[S]+K_i[I])$$

and from this it follows that

$$[3] \qquad v_0/v = 1+\{K_i[I]/(1+\bar{K}[S])\}.$$

The slopes of the plots were found to be proportional to $1/(1+\bar{K}[S])$; examples of such plots are shown in Fig. 3, and the lines are seen to meet the ordinate at a value of unity. The results confirm that the inhibition is indeed competitive; from the slopes, $\bar{K}$ being known, the K_i values were calculated.

Each value of $\bar{K}$ was obtained from about ten kinetic runs, every other one being made in duplicate. The values of K_i were also obtained from about ten runs. All values were calculated using the method of least squares.

Table IV shows the $\bar{K}$ and K_i values obtained in the above manner. In Fig. 4 the natural logarithms of $\bar{K}$ and of K_i are plotted against the reciprocal of the absolute temperature. The ΔH values calculated from the least-square slopes are given in Table V, together with the corresponding free energies and entropies. The second column shows the values corresponding to $\bar{K}$ and therefore related to the binding of the ester, the third column the values corresponding to K_i and related to the binding of the acid.

TABLE V

SUMMARY OF THERMODYNAMICAL RESULTS FOR THE BINDING OF ESTER AND ACID

	pH = 7.10 Ester	Acid	
ΔG	− 4.55	− 3.78	kcal per mole
ΔH	−11.2	−11.0	kcal per mole
ΔS	−22.2	−24.3	e.u.

DISCUSSION

The result of greatest interest from the present standpoint is the fact that the heat corresponding to K_i, namely 11.0 kcal per mole, agrees quite closely with that obtained in the microcalorimetric studies. This is shown in Fig. 1, in which the heats are plotted against the pH; the open circles represent the calorimetric results, the closed circle the kinetic value obtained as described above. Since the microcalorimeter was being used at its very highest sensitivity there may well be an error of 10% or more in the calorimetric heats, and this largely accounts for the difference between the kinetic heat and the calorimetric ones. Additional reasons for differences are:

(1) the much higher enzyme concentration that had to be used in the calorimetric work (2×10^{-4} M as compared with 1×10^{-5} M),

(2) the fact that the kinetic work was done in 0.1 M sodium chloride solution.

In view of the similarity of the kinetic and calorimetric values there is no reason to doubt that the microcalorimetric values do correspond to the interaction between the active centers and the inhibitor. Further work to confirm this is, however, necessary, and is now being carried out at other pH values.

Other points that are worthy of comment are as follows. The close similarities between the ΔH, ΔS, and ΔG values for esters and inhibitor are consistent with the conclusions, strongly suggested by the pH studies in 20% methanol (5), that*

(*a*) $\bar{K}$ is actually an equilibrium constant,

(*b*) the binding between enzyme and substrate does not involve the ionizing groups on the enzyme.

Conclusion (*b*) suggests that the enzyme–substrate binding probably involves van der Waals forces between enzyme and substrate (1), and these forces are expected to remain practically the same if the ester is replaced by the acid.

**It should be mentioned that recent work (17, 18) indicates the pH behavior in aqueous solution to be slightly but significantly different from that in 20% methanol as used by Laidler and Barnard (5) and other workers. The pH optimum is 7.8 in 20% methanol but 8.4 in pure water. Stein and Laidler (17) are currently carrying out a detailed study of the influence of methanol on the kinetics of the reaction, with particular reference to the binding of irreversible inhibitors such as DFP, while Gill and Laidler (18) are studying the pH dependence in aqueous solution and are extending the present work on the binding of hydrocinnamic acid.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

A further insight into the nature of the inhibition is provided by a comparison of K_i at 25° C and at various pH values, as follows:

pH = 7.1	K_i = 592	Present work
pH = 7.8	K_i = 182	Neurath and Gladner (19)
pH = 7.9	K_i = 33	Huang and Niemann (20)
pH = 7.9	K_i = 33–50	Foster and Niemann (21)

Although the conditions (ionic strength, nature of buffer, etc.) are not the same in all cases, it seems clear that the inhibitor is much less strongly bound at the higher pH values.

The microcalorimetric studies have shown that the binding becomes more exothermic as the pH is raised; together with the K_i values, this implies that the ΔS of binding becomes considerably more negative with increasing pH. The ΔS of binding at pH 7.8 is in fact approximately -80, as compared with the value of -24.3 at pH 7.1.

Since the pK of hydrocinnamic acid is 4.66 (22) it is clear that the acid is almost entirely in the anionic form at all of the pH values of the present investigation. The variations in the thermodynamic quantities for the binding of the inhibitor must therefore be attributed to changes in the state of ionization of the enzyme. It is postulated that the enzyme possesses at its active center, in addition to the acidic and basic groups responsible for the actual hydrolysis of the substrate, a negatively charged group. This group must be largely neutralized at the pH of 7.1 (this follows from the close similarity of the thermodynamical values for the ester and the acid). At the values of 7.8–7.9, however, it must be assumed that this group is largely in the negatively charged form. As a result the binding of the acid anion is much less strong, and there is a large negative entropy of binding owing to the repulsion between the two charged groups.

ACKNOWLEDGMENTS

The authors are very much indebted to Dr. H. M. Papée, for very considerable help with the microcalorimetric determinations.

The work was supported by a grant from the Defence Research Board.

THE SEPARATION OF SATURATED AND UNSATURATED FATTY ACID ESTERS BY GAS–LIQUID CHROMATOGRAPHY[1]

B. M. Craig and N. L. Murty[2]

ABSTRACT

Fatty acid methyl esters are separated according to chain length by using washed silicone grease supported on 20–40 mesh C_{22} firebrick. By using a plasticizer on the firebrick support the same esters are separated according to both chain length and degree of unsaturation. Together the two procedures can be used to determine the component fatty acids in fats and oils. Nearly parallel linear relations are obtained for saturated, monoethenoid, diethenoid, and triethenoid methyl esters when the logarithm of emergence time is plotted against the carbon number of the fatty acid.

INTRODUCTION

The development of gas–liquid partition chromatography by Martin and James (1, 2) has provided a new and powerful tool for semimicro- and micro-analyses. The rapid extension of this method to fats and oils by Martin and James (1, 2, 3), Cropper and Heywood (4, 5), Dijkstra *et al.* (6), Van de Kamer *et al.* (7), Ray (8) and the improvements developed by these workers have made possible the separation of small quantities of fatty acid esters. These separations are based on chain length and include separation of esters of odd-numbered acids and branched-chain acids. Silicone grease and Apiezon grease with or without stearic or other saturated acids have been the preferred liquid phases supported on Celite or crushed firebrick. A further development has been fractionation on the basis of unsaturation in a series of esters such as stearic, oleic, linoleic, and linolenic acids. This has been accomplished by Orr and Callen (9) and by Lipsky and co-workers (10) using commercial plasticizers as liquid phases. The first used by Orr and Callen (9) is Reoplex 400, which is a commercial plasticizer and is a polyoxyalkalene adipate. The plasticizers used by Lipsky are adipic esters of diethylene glycol and the adipic ester of diethylene glycol cross-linked with pentaerythritol.

In this laboratory gas–liquid chromatography has been used with silicone and Apiezon liquid phases for the analysis of fats and oils. Reoplex 400 was found to "bleed" extensively, particularly at temperatures over 200° C. Attempts were then made to synthesize plasticizers which would effect the separation of stearic, oleic, linoleic, and linolenic acids but which would not "bleed". A number of these have been synthesized and tested and the results are given in this paper.

EXPERIMENTAL

Silicone Column

Dow–Corning High Vacuum stopcock grease was dispersed in ethyl acetate by means of an Ultra-Turrax high speed stirrer, then precipitated out by addition of methyl alcohol and treated as described by Cropper and Heywood (4, 5). The washed silicone grease was dispersed in ethyl acetate in a round-bottom flask. C_{22} firebrick (Johns Manville) was added to the suspension (a mixture of 20–30 and 30–40 mesh 1:1 (w/w)), and the solvent evaporated at 80–90° C under vacuum in a laboratory rotary evaporator.

The silicone grease was applied in a 1:4 ratio (w/w) with the crushed firebrick, and was packed in a copper column $\frac{1}{4}$ inch in diameter by 12 feet in length.

Plasticizer Columns

Two plasticizers were synthesized using a dibasic acid and diethylene glycol containing 1% by weight of diglycerol to provide cross-linking. The dibasic acids were adipic and succinic and details are given for preparation of the succinic plasticizer. A mixture of 24.0 g succinic acid, 21.2 g of diethylene glycol, 0.5 g of diglycerol, and 0.2 g of *p*-toluenesulphonic acid in a round-bottom flask was heated at 130° C/2 mm for 2 hours with occasional shaking. A clear sirupy solution resulted. The plasticizer was dissolved in ethyl acetate, washed three times with water, dried over anhydrous sodium sulphate, filtered, and the solvent removed under reduced pressure. The plasticizer was dissolved in ethyl acetate and applied to 20–40 mesh C_{22} firebrick in a 1:4 ratio (w/w) as outlined for the silicone column.

Two columns, copper tubing $\frac{1}{4}$ inch by 6 feet long, using succinic and adipic plasticizers, respectively, were coupled in series, with the succinic as the fore column. Initial tests indicated that the succinic plasticizer gave a more effective separation of the esters of stearic and oleic acids and the adipic column of the esters of linolenic and arachidic acids.

Apparatus

The gas–liquid chromatographic unit of conventional design was constructed in the laboratory. Four Gow–Mac filaments were employed with two in each of the reference and sample detectors and the bridge was operated at 150 ma. Helium was used as the carrier gas and the recorder was operated at the 2.5-mv range. The apparatus was controlled at a temperature of 210° C. The silicone column was operated at a flow rate of 100 cc per minute and the plasticizer columns at 70 cc per minute, as measured by a soap bubble unit on the outlet tube. The sample sizes varied from 3 to 15 μl, depending on the particular oil, and injection was made with a precision syringe.

The materials used in the study were the methyl esters of the fatty acids from tallow, soybean oil, lard, and herring oil, which were kindly supplied by the research laboratory of Canada Packers Limited, Toronto, Canada.

RESULTS AND DISCUSSION

Figure 1, which reproduces actual recorder charts, gives the curves that resulted for lard, tallow, soybean oil, and herring oil esters with the plasticizer column and for lard and herring oil esters with the silicone column. The position of peaks representing C_{10}, C_{12}, C_{14}, C_{16}, and C_{18} saturated acids, labelled 1, 2, 3, 4, and 5, respectively, were determined by calibration with a known synthetic mixture of these acids.

The separation of palmitic, stearic, oleic, linoleic, and linolenic methyl esters in soybean oil are comparable to those obtained by Lipsky (10) using a commercial plasticizer. The plasticizer used in the present work "bled" slightly during the first runs but little or not at all at later stages and operation of the column for a period of 3 weeks indicated no decreased efficiency. The present columns using a 1:4 ratio of liquid phase have a limited capacity, e.g. approximately 10 mg of soybean esters on 20 g of column packing before evidence of overloading is indicated.

The tallow esters on a silicone column showed C_8, C_{10}, C_{12}, C_{14}, C_{15}, C_{16}, C_{17}, and C_{18} acids as well as peaks between C_{14} and C_{15} and C_{16} and C_{17}, which may have been branched-chain acids. The tallow esters from the plasticizer column showed additional peaks which may be due to unsaturated acids of various chain lengths. Herring oil esters

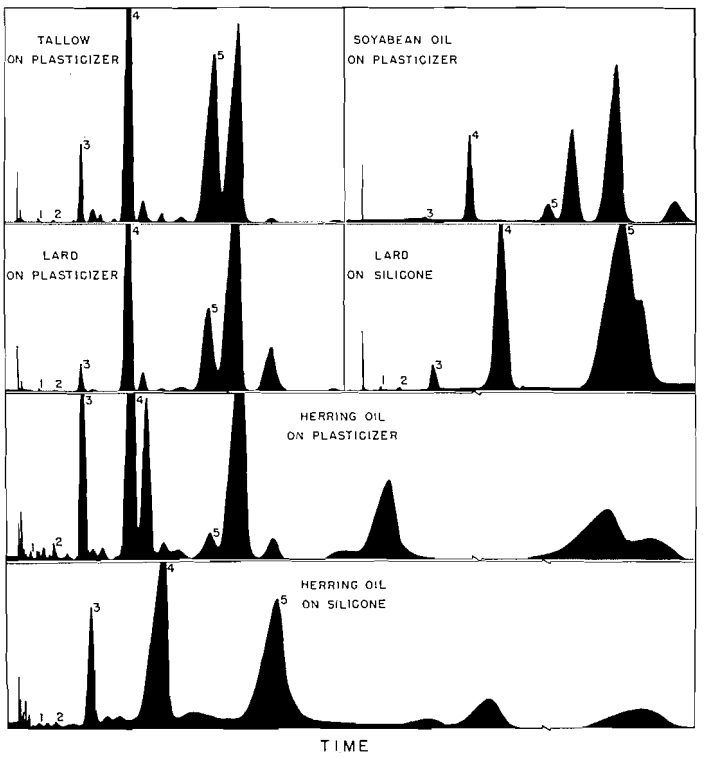

FIG. 1. Gas–liquid chromatographic separations of methyl esters of fats and oils on silicone and plasticizer columns. The numbers 1, 2, 3, 4, and 5 refer to the saturated C_{10}, C_{12}, C_{14}, C_{16}, and C_{18} acids. Peaks following these are odd-numbered or branched-chain in the case of silicone columns or unsaturated from the plasticizer column.

also showed odd-numbered fatty acids, C_9, C_{11}, C_{13}, and C_{15}, in addition to the expected even-numbered series on a silicone column. The lard esters showed even-numbered members from C_{10} to C_{20} on a silicone column and a number of unsaturated acids in each group on the plasticizer column.

Some separation of saturated and unsaturated acids took place on the silicone column within a group such as the C_{18} acids. The separation was the reverse of that accomplished by the plasticizer column in that the less unsaturated acids are retained more strongly by the liquid phase. This was proved by coupling a silicone column to a plasticizer column. The separation on the plasticizer then offset the silicone column, single peaks being obtained for each chain length. The same results were obtained with columns using Apiezon "M" as a liquid phase coupled to a plasticizer column.

The logarithm of the emergence time (time from the air peak to the sample peak) has been plotted against number of carbon atoms (Fig. 2). Peaks representing the saturated acids C_{12}, C_{14}, C_{16}, and C_{18} were plotted first and the linear relation for chain length against logarithm of retention time was established. Other peaks from various curves were plotted on the same line according to retention time only. The odd-numbered acids and compounds thought to be branched-chain acids are also represented, both from the silicone and the plasticizer columns.

The "monoethenoid" relation was made up by moving the points representing the peaks following those of palmitic, stearic, and arachidic acids, e.g. palmitoleic, oleic, and

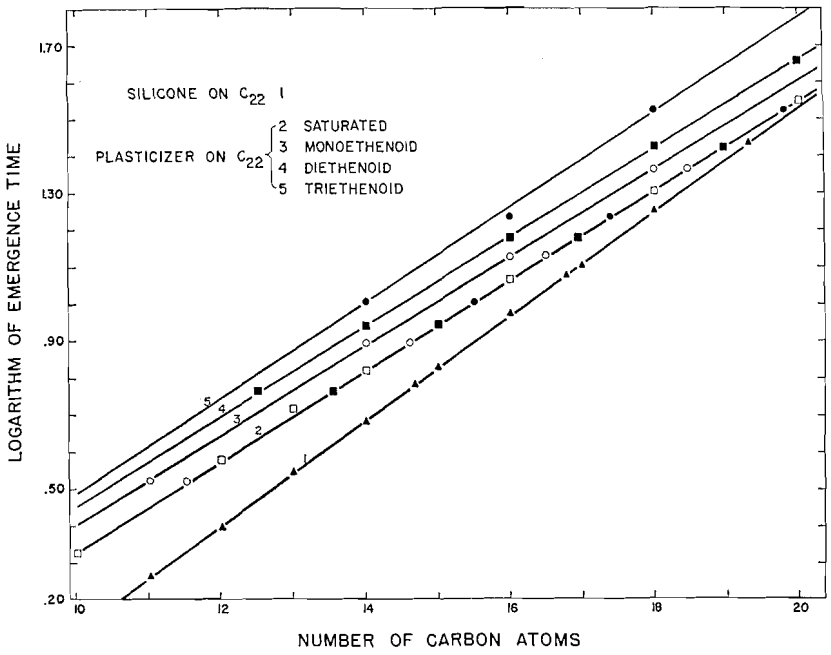

FIG. 2. Logarithm of emergence time plotted against carbon number for saturated, monoethenoid, diethenoid, and triethenoid acids from plasticizer columns and for acids from silicone column.

eicosenoic acids, to correspond to the appropriate carbon numbers. As expected, a linear relation was obtained, since the presence of one double bond would presumably have the same influence on each chain length.

The same procedure was followed for the diethenoid acids, giving a family of linear relations which are essentially parallel. The linear relation for triethenoid does not seem to be parallel to the other relations but further work needs to be done on polyethenoid acids with polyester columns to establish the slope of this line in relation to the less unsaturated acids.

Since these linear relations were established by using known esters and fatty acid esters of oils of known composition, the system is applicable for analysis of any other oil if similar conditions of temperature, flow rate, column size, and packing are used. The present system of plasticizers alone is inadequate, since the dienoic C_{16} acid has the same emergence peak as the C_{17} acid. Similarly, linolenic acid and arachidic acid examined in other oils show a simultaneous emergence. Such difficulties could be resolved by collecting the fractions from the silicone column and applying these in turn to a plasticizer column, a procedure which would require the initial separation of larger quantities of fatty acid esters.

The research on separation of saturated and unsaturated fatty acids is being continued to find liquid phases which give a more efficient separation particularly of such sequences as stearic–oleic and linolenic–arachidic acids. Preliminary results on quantitative measurements of unsaturated acids such as linoleic and linolenic which are presently done by spectrophotometric analysis indicate that the chromatographic method is equally reliable and requires considerably smaller samples.

THE ANALYSIS OF NUCLEAR MAGNETIC RESONANCE SPECTRA

IV. FOUR NUCLEI: AB_3[1]

R. J. Abraham, J. A. Pople,[2] and H. J. Bernstein

ABSTRACT

The proton magnetic resonance spectrum of methyl mercaptan has been analyzed on the basis of the nuclear grouping AB_3. The spectrum calculated for $J/\nu_0\delta = 0.324$ agrees very well with that observed.

1. INTRODUCTION

This series of papers presents detailed methods of analysis of complex nuclear magnetic resonance spectra which arise when signal separations due to chemical shifts are of the same order as the spin-coupling constants. In Part I (1), the quantum mechanical methods for setting up the problem for nuclei of spin $\frac{1}{2}$ were reviewed and a notation set up for classifying groups of nuclei which gave characteristic spectra. In this paper, we shall be concerned with four nuclei of spin $\frac{1}{2}$, three of which (type B) are in equivalent chemical positions. This means that they have the same chemical shift and the same coupling constants with the fourth nucleus (type A). According to the notation of Part I, this is described as an AB_3 group if the chemical shift is of the same order as the coupling constant. It should be noted that some groups may give spectra of this type even though the B-nuclei may not be equivalent at any one instant. If the nuclei are rearranging positions rapidly (compared with the width of the spectrum in frequency units), they will become effectively equivalent, the chemical shifts and coupling constants being replaced by mean values. An important source of AB_3 spectra is likely to be methyl groups where internal rotation carries out this rapid interchange. An example of this sort is the proton spectrum of CH_3SH at 40 Mc/sec, which is analyzed in Section 3.

2. GENERAL THEORY FOR AB_3

We shall adopt the general method and notation outlined in Part I (1). This involves the construction of matrices of the Hamiltonian using a set of basic functions chosen according to the symmetry of the nuclear group. It is necessary to combine the two spin functions of the A-nucleus with the six functions for three equivalent nuclei B_3. The latter were tabulated by McConnell, McLean, and Reilly (2) and consist of four symmetrical functions

$$[2.1] \qquad (\alpha\alpha\alpha),\ (\alpha\alpha\beta+\alpha\beta\alpha+\beta\alpha\alpha)/\sqrt{3},\ (\beta\beta\alpha+\beta\alpha\beta+\alpha\beta\beta)/\sqrt{3},\ (\beta\beta\beta)$$

and two degenerate pairs

$$[2.2] \qquad (\alpha\alpha\beta+\alpha\beta\alpha-2\beta\alpha\alpha)/\sqrt{6},\ (\alpha\alpha\beta-\alpha\beta\alpha)/\sqrt{2}$$

and

$$[2.3] \qquad (\beta\beta\alpha+\beta\alpha\beta-2\alpha\beta\beta)/\sqrt{6},\ (\beta\beta\alpha-\beta\alpha\beta)/\sqrt{2}.$$

Contribution from the Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada. Issued as N.R.C. No. 4853.
[2]*Department of Theoretical Chemistry, Cambridge, England.*

Using the group C_3, we shall call [2.1] A-functions and [2.2] and [2.3] E-functions. (The symbol A here refers to the symmetry and not to the A-nucleus.)

The next step is to construct symmetry basic functions for the complete group of four nuclei and work out the matrix of the Hamiltonian, making use of the simplifications that no mixing occurs between functions with a different total spin-component or between functions of different symmetry. Since all E-states are doubly degenerate, it is unnecessary to repeat calculations for both components, so we only consider one component of each and finally double the intensities of E-transitions. Accordingly, we shall deal only with the E basic functions $(\alpha\alpha\beta-\alpha\beta\alpha)/\sqrt{2}$ and $(\beta\beta\alpha-\beta\alpha\beta)/\sqrt{2}$.

The set of basic functions obtained by combining [2.1]-[2.3] with the functions α and β for the A-nucleus are given in Table I, together with the corresponding matrix elements of the Hamiltonian. ν_0 is the basic radio frequency employed, σ_A, σ_B, the screening constants of the two sets of nuclei, and J the A–B coupling constant. Terms involving the coupling constant between different B-nuclei are omitted, as it is known that they do not affect the observed spectrum (2). The suffix attached to each basic function gives the value of the total spin-component in the z-direction.

The determination of energies and stationary-state wave functions involves the solution of four 2×2 secular equations. We define the chemical shift δ as

$$\delta = \sigma_B - \sigma_A \qquad [2.4]$$

and introduce new positive quantities D_+, D_0, D_-, D'_0 and angles θ_+, θ_0, θ_-, θ'_0 between 0 and π, such that

$$\begin{aligned}
D_+ \cos 2\theta_+ &= \tfrac{1}{2}\nu_0\delta + \tfrac{1}{2}J \\
D_+ \sin 2\theta_+ &= \sqrt{3}\,J/2 \\
D_0 \cos 2\theta_0 &= \tfrac{1}{2}\nu_0\delta \\
D_0 \sin 2\theta_0 &= J \\
D_- \cos 2\theta_- &= \tfrac{1}{2}\nu_0\delta - \tfrac{1}{2}J \\
D_- \sin 2\theta_- &= \sqrt{3}\,J/2 \\
D'_0 \cos 2\theta'_0 &= \tfrac{1}{2}\nu_0\delta \\
D'_0 \sin 2\theta'_0 &= \tfrac{1}{2}J.
\end{aligned} \qquad [2.5]$$

TABLE I

BASIC FUNCTIONS AND MATRIX ELEMENTS OF THE HAMILTONIAN FOR FOUR NUCLEI AB_3

	Function $ABBB$	Diagonal matrix elements	Off-diagonal matrix elements
A_2	$\alpha\alpha\alpha\alpha$	$\nu_0(2-\frac{1}{2}\sigma_A-\frac{3}{2}\sigma_B)+\frac{3}{4}J$	
$1A_1$	$\alpha(\alpha\alpha\beta+\alpha\beta\alpha+\beta\alpha\alpha)/\sqrt{3}$	$\nu_0(1-\frac{1}{2}\sigma_A-\frac{1}{2}\sigma_B)+\frac{1}{4}J$	$\sqrt{3}\,J/2$
$2A_1$	$\beta\alpha\alpha\alpha$	$\nu_0(1+\frac{1}{2}\sigma_A-\frac{3}{2}\sigma_B)-\frac{3}{4}J$	
$1A_0$	$\alpha(\beta\beta\alpha+\beta\alpha\beta+\alpha\beta\beta)/\sqrt{3}$	$\nu_0(-\frac{1}{2}\sigma_A+\frac{1}{2}\sigma_B)-\frac{1}{4}J$	J
$2A_0$	$\beta(\alpha\alpha\beta+\alpha\beta\alpha+\beta\alpha\alpha)/\sqrt{3}$	$\nu_0(\frac{1}{2}\sigma_A-\frac{1}{2}\sigma_B)-\frac{1}{4}J$	
$1A_{-1}$	$\alpha\beta\beta\beta$	$\nu_0(-1-\frac{1}{2}\sigma_A+\frac{3}{2}\sigma_B)-\frac{3}{4}J$	$\sqrt{3}\,J/2$
$2A_{-1}$	$\beta(\beta\beta\alpha+\beta\alpha\beta+\alpha\beta\beta)/\sqrt{3}$	$\nu_0(-1+\frac{1}{2}\sigma_A+\frac{1}{2}\sigma_B)+\frac{1}{4}J$	
A_{-2}	$\beta\beta\beta\beta$	$\nu_0(-2+\frac{1}{2}\sigma_A+\frac{3}{2}\sigma_B)+\frac{3}{4}J$	
E_1	$\alpha\alpha(\alpha\beta-\beta\alpha)/\sqrt{2}$	$\nu_0(1-\frac{1}{2}\sigma_A-\frac{1}{2}\sigma_B)+\frac{1}{4}J$	
$1E_0$	$\alpha\beta(\beta\alpha-\alpha\beta)/\sqrt{2}$	$\nu_0(-\frac{1}{2}\sigma_A+\frac{1}{2}\sigma_B)-\frac{1}{4}J$	$-\frac{1}{2}J$
$2E_0$	$\beta\alpha(\alpha\beta-\beta\alpha)/\sqrt{2}$	$\nu_0(+\frac{1}{2}\sigma_A-\frac{1}{2}\sigma_B)-\frac{1}{4}J$	
E_{-1}	$\beta\beta(\beta\alpha-\alpha\beta)/\sqrt{2}$	$\nu_0(-1+\frac{1}{2}\sigma_A+\frac{1}{2}\sigma_B)+\frac{1}{4}J$	

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

The D-quantities are given directly by

$$[2.6] \qquad \begin{aligned} D_+ &= +\tfrac{1}{2}\{(\nu_0\delta)^2+2J(\nu_0\delta)+4J^2\}^{\frac{1}{2}} \\ D_0 &= +\tfrac{1}{2}\{(\nu_0\delta)^2+4J^2\}^{\frac{1}{2}} \\ D_- &= +\tfrac{1}{2}\{(\nu_0\delta)^2-2J(\nu_0\delta)+4J^2\}^{\frac{1}{2}} \\ D'_0 &= +\tfrac{1}{2}\{(\nu_0\delta)^2+J^2\}^{\frac{1}{2}}. \end{aligned}$$

The wave functions and energies of all states are now easily evaluated in terms of these quantities and it is possible to find the transition energies and intensities as outlined in Part I. These are given in Table II. A symbol such as $2A'_1$ is used for the state which reduces to the basic function $2A_1$ in the limit of large chemical shifts. The table is based on the assumption that $\sigma_B > \sigma_A$. If $\sigma_B < \sigma_A$ the spectrum is inverted, i.e. transition 1 is now $J+D_1$ to high field of $\gamma_0(1+\sigma_A/2-\sigma_B/2)$ instead of to low field etc.

TABLE II

TRANSITION ENERGIES AND INTENSITIES FOR FOUR NUCLEI AB_3

	Transition	Origin*	Energy (relative to $\nu_0(1-\frac{1}{2}\sigma_A-\frac{1}{2}\sigma_B)$)	Intensity
1.	$2A'_1 \rightarrow A_2$	A	$J+D_+$	$[\sqrt{3}\sin\theta_+-\cos\theta_+]^2$
2.	$2A'_0 \rightarrow 1A'_1$	A	$-\frac{1}{2}(\nu_0\delta)+D_+ +D_0$	$[-2\sin\theta_0\cos\theta_+ +\cos\theta_0\cos\theta_+ +\sqrt{3}\cos\theta_0\sin\theta_+]^2$
3.	$2E'_0 \rightarrow E_1$	A	$\frac{1}{2}J+D'_0$	$2[\cos\theta'_0-\sin\theta'_0]^2$
4.	$2A'_{-1} \rightarrow 1A'_0$	A	$-\frac{1}{2}(\nu_0\delta)+D_0+D_-$	$[2\sin\theta_0\cos\theta_-+\cos\theta_0\cos\theta_- \sqrt{3}\cos\theta_0\sin\theta_-]^2$
5.	$E_{-1} \rightarrow 1E'_0$	A	$-\frac{1}{2}J+D'_0$	$2[\cos\theta'_0+\sin\theta'_0]^2$
6.	$A_{-2} \rightarrow 1A'_{-1}$	A	$-J+D_-$	$[\cos\theta_-+\sqrt{3}\sin\theta_-]^2$
7.	$1A'_{-1} \rightarrow 1A'_0$	B	$-\frac{1}{2}(\nu_0\delta)+D_0-D_-$	$[\sqrt{3}\cos\theta_0\cos\theta_-+\sin\theta_-\cos\theta_0 +2\sin\theta_-\sin\theta_0]^2$
8.	$1E'_0 \rightarrow E_1$	B	$\frac{1}{2}J-D'_0$	$2[\cos\theta'_0+\sin\theta'_0]^2$
9.	$1A'_0 \rightarrow 1A'_1$	B	$-\frac{1}{2}(\nu_0\delta)+D_+-D_0$	$[2\cos\theta_0\cos\theta_++\sin\theta_0\cos\theta_+ +\sqrt{3}\sin\theta_0\sin\theta_+]^2$
10.	$1A'_1 \rightarrow A_2$	B	$J-D_+$	$[\sqrt{3}\cos\theta_++\sin\theta_+]^2$
11.	$2A'_0 \rightarrow 2A'_1$	B	$-\frac{1}{2}(\nu_0\delta)-D_++D_0$	$[\sqrt{3}\cos\theta_0\cos\theta_+-\cos\theta_0\sin\theta_+ +2\sin\theta_0\sin\theta_+]^2$
12.	$2A'_{-1} \rightarrow 2A'_0$	B	$-\frac{1}{2}(\nu_0\delta)-D_0+D_-$	$[2\cos\theta_0\cos\theta_--\sin\theta_0\cos\theta_- +\sqrt{3}\sin\theta_0\sin\theta_-]^2$
13.	$E_{-1} \rightarrow 2E'_0$	B	$-\frac{1}{2}J-D'_0$	$2[\cos\theta'_0-\sin\theta'_0]^2$
14.	$A_{-2} \rightarrow 2A'_{-1}$	B	$-J-D_-$	$[\sqrt{3}\cos\theta_--\sin\theta_-]^2$
15.	$1A'_{-1} \rightarrow 2A'_0$	Comb.	$-\frac{1}{2}(\nu_0\delta)-D_0-D_-$	$[-\sqrt{3}\sin\theta_0\cos\theta_--\sin\theta_0\sin\theta_- +2\cos\theta_0\sin\theta_-]^2$
16.	$1A'_0 \rightarrow 2A'_1$	Comb.	$-\frac{1}{2}(\nu_0\delta)-D_+-D_0$	$[-2\cos\theta_0\sin\theta_+-\sin\theta_0\sin\theta_+ +\sqrt{3}\sin\theta_0\cos\theta_+]^2$

*Based on $\sigma_B > \sigma_A$.

The shape of the spectrum (apart from scale factors) is a function only of the magnitude of the dimensionless parameters $J/(\nu_0\delta)$. Some spectra calculated for a series of values of this ratio are illustrated in Fig. 1. (The labelling of transitions assumes $\sigma_B > \sigma_A$ and $J > 0$. If $J < 0$, the appearance of the spectrum is unaltered, but the transitions would have to be renumbered.) Numerical values of the transition energies are given in Table III for a series of values of $J/(\nu_0\delta)$. The scale is adjusted so that the chemical shift is one unit.

One useful feature to note is that the spin-coupling constant is given directly by the separation between lines 3 and 5.

3. METHYL MERCAPTAN

As an example of an AB_3 spectrum we have measured the proton spectrum of CH_3SH at 40 Mc/sec. The sample of the liquid at room temperature was sealed in a spinning tube of 0.5 mm o.d. Spectra were obtained with a Varian V-4300 High Resolution Spectrometer equipped with field stabilizer. The side-band technique was used to obtain signal separations. The resonance spectrum of CH_3SH is reproduced in Fig. 2. This pattern clearly resembles the reverse of the calculated spectrum of Fig. 1 for $J/\nu_0\delta = 0.5$. The reversed spectrum corresponds to $\sigma_B < \sigma_A$ but the numbering remains the same as in Table II. The positions of the lines are easily fitted into the formulae of Table II and a good fit is obtained for

$$J = 7.85 \text{ cycles/sec}$$

$$\nu_0(\sigma_A - \sigma_B) = 24.25 \text{ cycles/sec.} \qquad [3.1]$$

Calculated transition energies and intensities using these parameters (adjusted to give agreement for line 6) are given in Table IV. The observed intensities are peak heights normalized so that the sum of the observed and theoretical intensities for the A lines are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

equal and also those for the B lines. As expected, the agreement between observed and calculated intensities is much better for the well-resolved A lines than for the overlapping B lines.

SECOND-ORDER UNIMOLECULAR KINETICS IN THE THERMAL DECOMPOSITION OF HYDROGEN PEROXIDE VAPOR[1]

W. FORST

ABSTRACT

The thermal decomposition of hydrogen peroxide vapor has been reinvestigated by the static method as a function of initial pressure at pressures up to 22 mm Hg, and in the presence of inert gas (helium, oxygen, and water) up to 100 mm Hg. In each case the apparent first-order rate constant increased linearly with pressure. It is demonstrated that under the present experimental conditions the pyrolysis of hydrogen peroxide shows behavior typical of an elementary unimolecular reaction in its low-pressure, second-order region. The reaction was accompanied by a heterogeneous decomposition which in the presence of foreign gas became inhibited. Helium was used as inhibitor over the temperature range 430–470° C, which permitted calculating the activation energy for activation with peroxide and with helium. The results can be satisfactorily accounted for by assuming a critical energy of 47–50 kcal and five effective classical oscillators for activation with peroxide and three with helium, provided deactivation occurs on every collision. Kinetic evidence against this assumption is briefly discussed.

INTRODUCTION

The thermal decomposition of hydrogen peroxide vapor has received close attention recently (1, 2, 3). The pressure dependence of the first-order rate constant observed by Giguère and Liu (1) suggested that under their experimental conditions the reaction behaved much like a unimolecular decomposition in its low-pressure, second-order region. As considerable interest attaches to such behavior, experimental verification appears worth while.

THEORETICAL

The general Lindemann mechanism for unimolecular reactions may be written in the form (4)

$$\mathrm{A}+\mathrm{M} \xrightarrow{a_i} \mathrm{A}_i^*+\mathrm{M}$$

$$\mathrm{A}_i^*+\mathrm{M} \xrightarrow{b_i} \mathrm{A}+\mathrm{M}$$

$$\mathrm{A}_i^* \xrightarrow{c_i} \text{products},$$

where the subscript i represents energy states of A from critical energy to infinity, the asterisk denotes a molecule of reactant possessing energy in excess of the critical amount, and M represents a molecule of reactant, product, or an inert gas. To avoid needless confusion of symbols, the notation used throughout is essentially that of Johnston (ref. 4 and later papers). From the above scheme the observed (apparent) first-order rate constant is given by

$$[\mathrm{I}] \qquad k = \frac{\text{Rate}}{[\mathrm{A}]} = \sum_i \frac{a_i c_i [\mathrm{M}]}{b_i[\mathrm{M}]+c_i},$$

where square brackets indicate concentrations.

[1]*Manuscript received June 6, 1958.*
Contribution from the Department of Chemistry, Laval University, Quebec, Que. This work was supported by the Office of Scientific Research of the U.S. Air Force under Contract No. AF 18(600)-492. Based on a paper presented at the 41st Annual Conference and Exhibition of the Chemical Institute of Canada, Toronto, May 26–28, 1958.

If $b_i[M] < c_i$ for all i this expands to

[II] $$k = [M]\left\{\sum_i a_i - \sum_i \frac{a_i b_i}{c_i}[M] + \sum_i a_i\left(\frac{b_i}{c_i}\right)^2[M]^2 - \ldots\right\}.$$

At the low-concentration limit

[III] $$b_i[M] \ll c_i \qquad \text{for all } i,$$

so that the second and higher terms in the bracket of [II] will be small compared with the leading term, and hence

[IV] $$k = \sum_i a_i[M] = a[M],$$

where a is the second-order constant for activation and [M] a properly weighted sum of the concentrations of reactant, product, and inert gas. Equation [IV] means that as long as the inequality [III] is satisfied, the plot of observed first-order rate constant k vs. [M] will be a straight line passing through the origin, i.e. the reaction will be second order. If the reaction is accompanied by a first-order heterogeneous reaction, there will be a finite intercept H on the k-axis, and [IV] becomes

$$k = a[M]+H.$$

If the inequality [III] is not satisfied, that is, if the pressure is not low enough, the second and higher terms in the bracket of [II] will not vanish and the plot of k vs. [M] will show a curvature.

The over-all reaction in the decomposition of hydrogen peroxide is

$$H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2,$$

so that [IV] becomes in the presence of one inert foreign gas X

[V] $$k = a_1[H_2O_2]+a_2[H_2O]+a_3[O_2]+a_4[X].$$

Stoichiometry requires

$$[H_2O] = \tfrac{1}{2}[O_2] = [H_2O_2]_0 - [H_2O_2],$$

and it follows that

[VI] $$k = a_1[H_2O_2]_0+a_4[X]-(a_1-a_2-\tfrac{1}{2}a_3)([H_2O_2]_0-[H_2O_2]),$$

where the subscript zero refers to initial concentration. Define relative efficiency R_M of gas M with respect to reactant

$$R_M = a_M/a_1,$$

and the relative efficiency of products $\bar{R}$

$$\bar{R} = a_2/a_1+a_3/2a_1.$$

Substitution of $\bar{R}$ into [VI] yields

$$k = a_1[H_2O_2]_0+a_4[X]-a_1(1-\bar{R})\{[H_2O_2]_0-[H_2O_2]\},$$

which at zero time reduces to

[VII] $$k_0 = a_1[H_2O_2]_0+a_4[X],$$

so that [VI] can be written in the form (5)

[VIII] $$k = -\frac{1}{[H_2O_2]}\cdot\frac{d[H_2O_2]}{dt} = \frac{d\log[H_2O_2]}{dt} = k_0-a_1(1-\bar{R})\{[H_2O_2]_0-[H_2O_2]\}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

This treatment makes it clear that the simple relationship implied by [IV], i.e. that at the low-concentration limit the observed first-order rate constant k is a linear function of [M], is true only for k_0. Equation [VIII] shows that $k = k_0$ only when $\bar{R} = 1$, which in general need not be the case. Hence the proper way to test experimental data for accordance with the predictions of the theory is to calculate k_0 from initial rate, or from a plot of $d \log[H_2O_2]/dt$ vs. $[H_2O_2]_0 - [H_2O_2]$.

EXPERIMENTAL

Apparatus

The apparatus was essentially the same as that described previously (1, 6). The reaction was followed manometrically, the pressure being measured by means of a transducer, and recorded by a recording potentiometer (6). A decade resistor was incorporated in the transducer input circuit to permit adjustment of input voltage. Power source was a standard 12-v automobile storage battery of 70-amp-hr capacity which gave input voltage stable to better than one part in one thousand during the course of a run if care was taken to keep the transducer at a reasonably constant temperature (78–80° C).

The reaction vessel was a 2-liter spherical Pyrex flask properly conditioned with hydrogen peroxide (6). Temperatures were measured by an electronic resistance thermometer calibrated against a certified platinum resistance thermometer; the readings refer to the temperature of the outside wall of the reaction vessel. Temperature was constant to better than 0.1° during the course of a run, and to about ±0.2° for nonconsecutive runs. Hydrogen peroxide vapor was obtained by evaporating liquid 99%+ hydrogen peroxide at 75° C. As is usual in this type of work, difficulties were encountered in preparing hydrogen peroxide reservoirs free of catalytic activity. In one particular instance, when the usual treatments with hot fuming sulphuric acid and hot concentrated peroxide failed, hydrofluoric acid was tried as a last resort (7). This treatment was apparently successful, judging from the absence of oxygen streamers at 70° C under vacuum. However, this peroxide gave gas-phase decomposition rates that were clearly out of line, showing a steady daily drift toward higher values, until after a week and 50 runs they settled at 50% above the normal value. When a new peroxide reservoir, which did not receive the hydrofluoric acid treatment, was substituted, results returned to normal. The only explanation seems to be that the above treatment produced some volatile fluorosilicate capable of triggering off the gas-phase decomposition of peroxide.

Procedure for a Typical Experiment

Hydrogen peroxide was evaporated into a 5-liter mixing flask heated to 120° C, and this procedure was followed by the addition of a second gas in the required amount, the total pressure not exceeding 100 mm Hg. Five minutes was allowed for mixing, and then two consecutive runs were made on the same mixture. This procedure was followed also in the case of experiments with peroxide only. Immediately before an experiment the transducer input voltage was checked and the recorder zero adjusted. The mixture was then rapidly introduced through a scratched stopcock into the reaction vessel up to the required pressure as displayed on the recorder, the stopcock was closed, and the recorder rapidly switched to the lowest range 0–1 mv. This was necessary in order to magnify as far as possible the pressure increase accompanying the reaction, which in the presence of excess foreign gas was quite small. The time interval between introduction of one-half of the mixture (= zero time) and the actual start of the pressure–time record was about 10 seconds, so that a small extrapolation was necessary to obtain initial pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The chart speeds used were generally high, i.e. such that the tracing showed small curvature, a condition that made extrapolation easier. Tracings which did not permit an unambiguous extrapolation were discarded. Initial rate was obtained by drawing a tangent to the pressure–time curve at zero time by means of a simple tangentimeter* of the type described by Latshaw (8). The decomposition was followed only long enough to obtain a pressure–time tracing convenient for evaluation.

RESULTS

The results are summarized in Figs. 1, 2, and 3; the captions are self-explanatory. Each experimental point represents the average of two consecutive runs. All straight lines were fitted to the equation

$$k_0 = m+n[\mathrm{X}]$$

by the method of least squares. Standard deviation was calculated for the slope and intercept of the straight-line portion of the peroxide plot at 431.5° C, the complete equation being

[IX] $$k_0 = (1.28\pm0.18)\times10^{-3}+(23.6\pm1.7)\times10^{-5}[\mathrm{H_2O_2}]_0.$$

Values of the parameters m and n for foreign-gas experiments are summarized in Table I.

TABLE I

LEAST-SQUARES FIT OF FOREIGN-GAS EXPERIMENTS TO EQUATION $k_0 = m+n[\mathrm{X}]$

Temp., ° C	[X]	$m\times10^3$ ($\mathrm{sec^{-1}}$)	$n\times10^5$ ($\mathrm{mm\ sec^{-1}}$)
431.5	H_2O	2.73	17.7
431.5	O_2	2.49	3.47
431.5	He	2.45	2.52
439.6	He	4.28	3.25
448.4	He	6.82	4.25
458.4	He	8.94	6.66
468.5	He	13.2	11.0

While all of the experiments reported there were evaluated from initial rates in the manner described, three experiments on pure peroxide were performed with the object of applying equation [VIII]. The decomposition was followed to completion for 12 half-lives (~30 minutes) and the results were replotted as $\log[\mathrm{H_2O_2}]$ vs. time. As will be shown later, in this case $\bar{R} = 0.83$ so that this plot should exhibit a curvature, which two of them in fact did. The curvature was of the right order of magnitude but in opposite directions; the third run yielded a straight line for all practical purposes. It was concluded that the data were not accurate enough to sustain the test of equation [VIII], or that complications arise if the reaction is allowed to proceed too far. For this reason it was considered safer to interpret the results on the basis of initial rate measurements only. However, it seems doubtful if equation [VIII] is useful even for data of very high accuracy because the curvature of the log(concentration) vs. time plot is very slight (unless $\bar{R}$ is very much different from unity) and consequently the difficulty of estimating accurately the small difference in slope of the tangents is considerable.

As noted previously (6), the concentration of hydrogen peroxide vapor evaporating from the liquid is subject to fluctuations, and is always less than the concentration of the

For personal use only.

liquid itself; in addition, some decomposition occurs during the mixing time. These losses amount to about 5–10% for the two runs immediately following the mixing period, but the effect on the gas-phase decomposition rate is much less than expected, very likely because $\bar{R} = 0.83$, i.e. the collision efficiency of the products water and oxygen is quite close to the efficiency of the reactant itself. Consequently no correction was applied to hydrogen peroxide concentrations or partial pressures as determined from pressure measurements.

DISCUSSION

Basis of the interpretation of the results is equation [VII] which predicts a linear dependence of $[H_2O_2]_0$ on k_0 for $[X] = 0$, or of $[X]$ on k_0 for $[H_2O_2]_0 = \text{const}$. Inspection of Figs. 1, 2, and 3 shows that such is indeed the case for all foreign-gas experiments, and

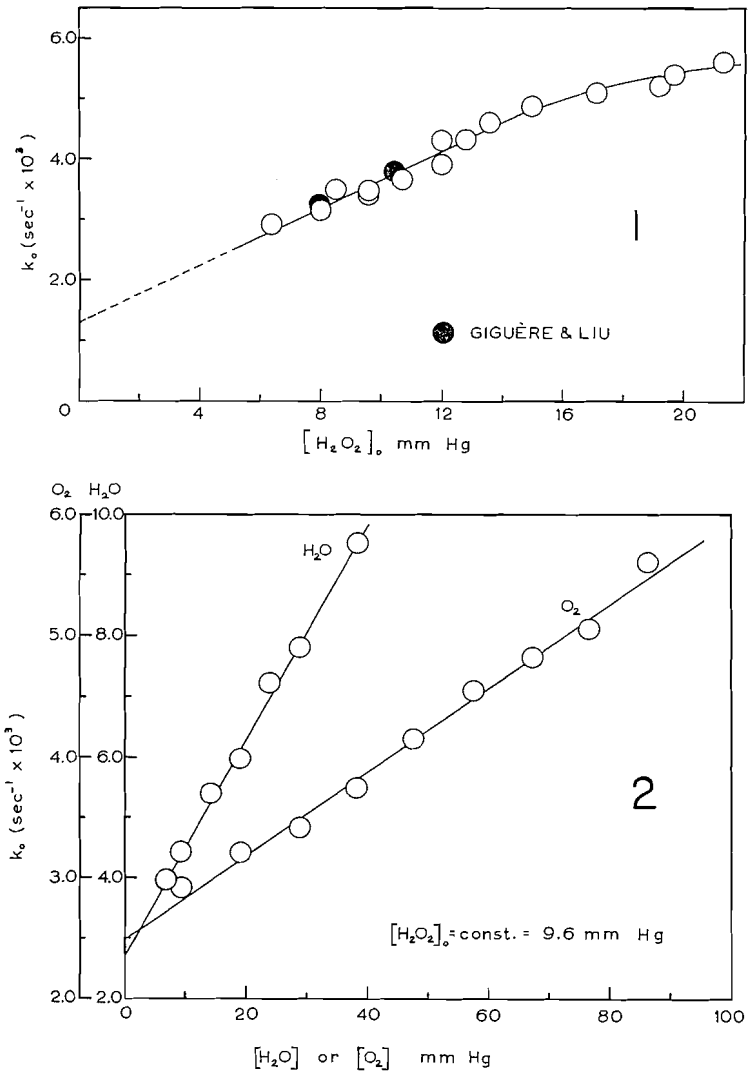

FIG. 1. Results at 431.5° C. Observed first-order rate constant k_0 plotted against initial pressure of hydrogen peroxide. Included for comparison are two points obtained by extrapolation of Giguère and Liu's results (1).

FIG. 2. Results at 431.5° C. Observed first-order rate constant k_0 plotted as a function of partial pressure of water or oxygen, with initial partial pressure of peroxide fixed at 9.6 mm Hg.

for pure peroxide up to about $[H_2O_2]_0 = 15$ mm Hg. In an elementary unimolecular reaction this agreement would be sufficient proof that the reaction is in its second-order region, but the thermal decomposition of hydrogen peroxide cannot be an elementary reaction: if, as is generally conceded (1, 2), the initial step consists of a rupture of the O—O bond, it is obvious that the final products, oxygen and water, can be formed only after a more or less complex series of secondary reactions. However, by assuming a reasonable mechanism, it is easy to demonstrate that the kinetics of the gas-phase peroxide decomposition can nevertheless be simple enough to show all the essential features of an elementary unimolecular reaction.

A reasonable mechanism has been proposed by Giguère and Liu (1). It will be used here with the exception of their reaction [3]

$$2HO_2 \rightarrow H_2O_2 + O_2, \qquad [3]$$

because there is evidence, from the hydrogen–oxygen reaction, that it occurs as a first-order surface reaction (9, 10), the rate of which would be small on a clean Pyrex surface. Elimination of reaction [3] from the Giguère–Liu mechanism increases the steady-state concentration of HO_2 but has no influence on the kinetics and simplifies the algebra considerably. The reaction scheme to consider is then

$$A + M \xrightarrow{a_i} A_i^* + M$$

$$A_i^* + M \xrightarrow{b_i} A + M$$

$$A_i^* \xrightarrow{c_i} 2OH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$$OH+A \xrightarrow{k_2} HO_2+H_2O \qquad [2]$$

$$OH+HO_2 \xrightarrow{k_4} H_2O+O_2, \qquad [4]$$

where A represents hydrogen peroxide and the remaining symbols have their usual significance. When the usual steady-state assumption is made, the rate of disappearance of hydrogen peroxide is

$$-\frac{d[A]}{dt} = \sum_i a_i[A][M]+\sum_i \frac{a_i c_i[A][M]}{b_i[M]+c_i}-\sum_i \frac{a_i b_i[A][M]^2}{b_i[M]+c_i}.$$

If $b_i[M]<c_i$ for all i, the fractions following the summation signs may be expanded in powers of [M], and the expression for the observed first-order rate constant becomes, after some rearrangement,

$$k = -\frac{1}{[A]}\frac{d[A]}{dt} = 2[M]\left\{\sum_i a_i-\sum_i \frac{a_i b_i}{c_i}[M]+\sum_i a_i\left(\frac{b_i}{c_i}\right)^2[M]^2-\ldots\right\},$$

which is identical with [II], except for the factor 2. Consequently at the low-pressure limit

[IV′] $$k = 2\sum_i a_i[M] = 2a[M],$$

[VII′] $$k_0/2 = a_1[H_2O_2]_0+a_4[X],$$

relations analogous to [IV] and [VII]. In a similar way, it can be shown that when the pressure is high enough, $c_i \ll b_i[M]$ for all i, and

$$-\frac{d[A]}{dt} = \sum_i \frac{a_i c_i}{b_i}[A],$$

i.e. the reaction is first-order, as indeed a unimolecular reaction should be. With this demonstration the interpretation of Figs. 1, 2, and 3 in terms of equation [VII] becomes reasonably legitimate. The appearance of the factor 2 in [VII′] makes no essential difference in the arguments of this discussion.

According to equation [VII] the slopes of the straight lines in Figs. 1, 2, and 3 represent the second-order rate constant for activation; from this the relative efficiency R_M of gas M with respect to peroxide may be calculated. The results at 431.5° C are $R_{H_2O} = 0.75$, $R_{O_2} = 0.15$, $R_{He} = 0.11$. The relative efficiency of products $\bar{R}$ is then $\bar{R} = 0.75+\frac{1}{2}\times 0.15 = 0.83$, and is thus different from unity, although not sufficiently so to cause an appreciable curvature of the log(concentration) vs. time curves (see Experimental). The values for R_M reported here are comparable with efficiencies obtained in other unimolecular rate studies (11, 12), and are particularly notable for an apparent lack of correlation between the energy transfer efficiency R_M and the number of vibrational degrees of freedom (note that R_M for helium and oxygen are practically equal).

The straight line for pure peroxide (Fig. 1) does not pass through the origin; since the heterogeneous decomposition of hydrogen peroxide is known to be the first order (13), there is good reason to identify the intercept on the k-axis of the peroxide plot as representing the heterogeneous component of the reaction. On this basis, a simple calculation shows the reaction to be 65% homogeneous at 431.5° C and 10 mm Hg, compared with the estimate of 80% made by Giguère and Liu (1) for the same temperature and pressure. Presence of a heterogeneous component in the reaction requires that the inter-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

cepts m in foreign-gas experiments be equal to $a_1[H_2O_2]_0+H$, i.e. there should be $m = (3.55\pm0.34)\times10^{-3}$ sec^{-1}, as determined from equation [IX] for $[H_2O_2]_0=9.6$. Comparison with the values listed in Table I for m at 431.5° C makes it at once apparent that this is not so; in fact, calculation shows that

$$m \approx a_1[H_2O_2]_0, \text{ i.e. } H \approx 0.$$

It is therefore necessary to assume that the heterogeneous reaction becomes inhibited in the presence of foreign gas, unless one is willing to make the implausible assumption that all foreign-gas experiments contain a very large systematic error in a_1 or $[H_2O_2]_0$, or both. The effective elimination of the heterogeneous reaction in foreign-gas experiments seems to be supported by the observation that reproducibility was much better in the presence of a foreign gas.

At this point it appears profitable to consider the heterogeneous decomposition of hydrogen peroxide in more detail. The sensitivity of the reaction to minute changes in surface conditions is notorious, which excludes a diffusion-controlled process. The rate-controlling process must be a reaction of absorbed species, and as such would be expected to show sensitivity to anything adsorbed on the surface, including adsorbed gases. Since adsorption of foreign gas on the surface reduces the number of surface sites available for reaction, the reaction becomes inhibited. This is apparently what happens in the case of helium, oxygen, and water. Oxygen and water are known for their inhibiting effects in other reactions (14) but a similar effect for an inert gas like helium does not seem to have been observed before. It would appear that appreciable pressures of foreign gas are needed for effective inhibition, because the amount of products (water and oxygen) formed in the course of the reaction is not sufficient for detectable self-inhibition.

If the inhibitor is strongly adsorbed, it can be shown (15) that the fractional reduction in rate of a unimolecular surface reaction is given by

$$v/v_0 = 1/K_c c_g,$$

where v = inhibited rate, v_0 = rate in absence of inhibitor, c_g = concentration of inhibitor in the gas phase, K_c = equilibrium constant for adsorption of inhibitor. For a non-localized adsorbed layer, such as would be the case with an inert gas, the expression for K_c is (16)

$$K_c = c_a/c_g = (F_a/F_g)e^{\epsilon/kT},$$

where c_a = concentration of adsorbed inhibitor, F_a, F_g = the corresponding partition functions per unit area and per unit volume, respectively, ϵ = heat of adsorption of inhibitor. Hence

$$v/v_0 = (F_g/F_a c_g)e^{-\epsilon/kT}.$$

If ϵ is small, v/v_0 will be almost temperature-independent, meaning that such inhibitor will be almost equally effective at all temperatures. The value of ϵ for helium is a few hundred calories per mole (17), which makes helium a particularly interesting inhibitor. For helium at 431.5° C,

$$H = m-a_1[H_2O_2]_0 = (0.18\pm0.16)\times10^3 \text{ sec}^{-1},$$

i.e. inhibition is very nearly complete. With a rise in temperature, v/v_0 for helium is not likely to change much; actually, inhibition is likely to become more complete, considering that temperature affects the homogeneous rate much more than the heterogeneous one owing to the difference in activation energies (~50 and 10 kcal, respectively (1)). It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

seems therefore quite safe to assume that in the presence of helium $H = 0$ at temperatures above 431.5° C.

This conclusion lends a particular significance to helium experiments over a range of temperatures, as it becomes possible to obtain as a function of temperature a_1, the second-order rate constant for activation with peroxide (from the intercept m of the corresponding straight line), and a_4^{He}, the second-order rate constant for activation with helium (from slope n), and consequently also the corresponding activation energies. It would have been naturally more desirable to obtain a_1 and the corresponding activation energy more directly from peroxide experiments, but this was not possible. With rising temperature the peroxide decomposition becomes too fast to measure at higher pressures, so that the useful pressure range over which the reaction is accessible to study at higher temperatures with the present equipment is much too narrow. In addition, the effect of self-heating becomes appreciable (1).

The slopes n and intercepts m of Table I have been recalculated in terms of concentrations in moles/liter, and the results summarized in Table II. This table also includes a_1 values from oxygen and water experiments; although inhibition in these two cases does not appear quite as complete as in the case of helium, H is nevertheless roughly zero within experimental error. The data of Table II are plotted in Fig. 4 as the usual Arrhenius plot of log (rate constant) vs. reciprocal absolute temperature. The equation of each line and the standard deviation for slopes and intercepts have been calculated by the method of least squares.

The activation energy for activation with peroxide is seen to be 48.1±2.9 kcal, compared with Giguère and Liu's value of 48±3 kcal (1). Considering the wide difference

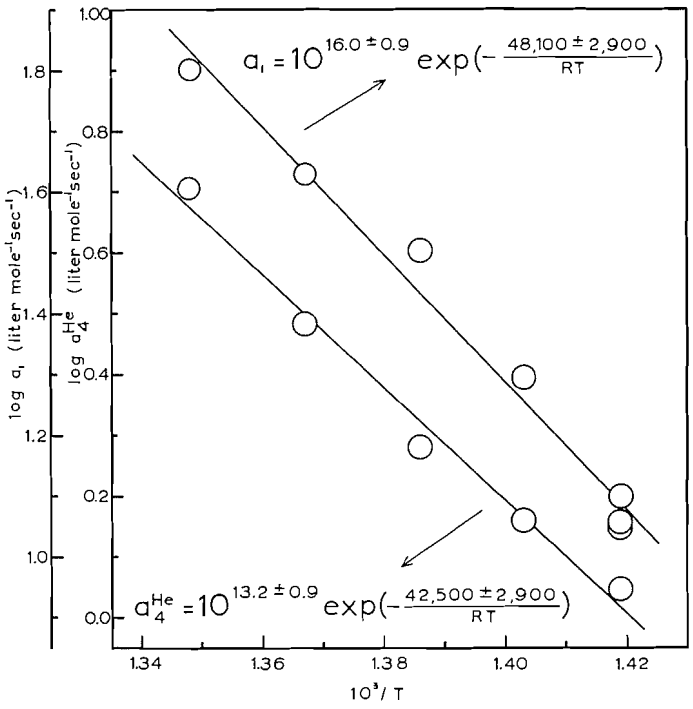

FIG. 4. Arrhenius plot for second-order rate constants for activation with peroxide (a_1) and with helium (a_4^{He}). Included is the least-squares equation of each line.

TABLE II

TEMPERATURE DEPENDENCE OF SECOND-ORDER RATE CONSTANTS FOR ACTIVATION

Temp., ° C	a_1 (liter mole^{-1} sec^{-1})	$a_4^{H_2O_2}$ (liter mole^{-1} sec^{-1})
431.5	12.5 (water)	—
431.5	11.4 (oxygen)	—
431.5	11.2 (helium)	1.11
439.6	19.8	1.44
448.4	31.9	1.91
458.4	42.4	3.04
468.5	63.3	5.08

between the two methods used for eliminating the contribution of the homogeneous reaction, this agreement is gratifying, although the closeness of the agreement is undoubtedly a coincidence. The activation energy for activation with helium is 42.5±2.9 kcal, so that, within experimental error, it equals the activation energy for activation with peroxide, as indeed in the first approximation it should because the activated state is the same in either case, namely H_2O_2*. Hence for the purpose of further discussion the two equations may be written with sufficient accuracy as

[X] $$a_1 = 10^{15} \exp(-45{,}000/RT) \text{ liter mole}^{-1} \text{ sec}^{-1},$$

[XI] $$a_4^{He} = 10^{14} \exp(-45{,}000/RT) \text{ liter mole}^{-1} \text{ sec}^{-1}.$$

It will be noted that the pre-exponential factors are larger than the kinetic collision number by a factor of 10^{-3} to 10^{-4}. If the mechanism for hydrogen peroxide decomposition proposed in this discussion is accepted, it follows from equation [VII'] that the values of the rate constants a_1 and a_4^{He} given by equations [X] and [XI] should be halved. Of course this will not affect the value of the activation energy, but will make a difference of 0.3 in the power of the pre-exponential factor.

Assuming that a non-linear molecule containing N atoms may be represented by an array of $s = 3N-6$ lightly coupled classical oscillators, one obtains from statistical mechanics (18)

[XII] $$a = Z \exp(-E_c/RT \sum_{r=0}^{r=s-1} \frac{1}{r!}\left(\frac{E_c}{RT}\right)^r,$$

which for $E_c \gg sRT$ reduces to

[XIII] $$a = Z \frac{(E_c/RT)^{s-1} \exp(-E_c/RT)}{(S-1)!},$$

where Z is the kinetic collision number; the experimental activation energy E_A is related to the critical energy E_c by the equation

$$E_A = E_c-(s-3/2)RT.$$

When the values of Z and E_c are substituted in [XIII], the value of a may be adjusted to fit experimental results expressed by equations [X] or [XI] by selecting a proper value for the parameter s. The results of these calculations are given in Table III for the two extremes of the temperature range. The best fit at either temperature seems to be for helium, $s \sim 3$, $E_c \sim 47$ kcal; for peroxide, $s \sim 5$, $E_c \sim 50$ kcal. If a_1 (equation [X]) and a_4^{He} (equation [XI]) are halved, the fit is essentially the same at either temperature. Having regard to the number of normal modes in hydrogen peroxide (six), the number of effective oscillators involved seems reasonable. If E_c may be identified with the strength

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

of the O—O bond, and if the latter is taken as 48 kcal (1), the values found for E_c are probably as close as one could expect. These results at the same time justify the approximation $E_c \gg sRT$ involved in [XIII].

TABLE III

NUMBER OF CLASSICAL OSCILLATORS EFFECTIVE IN ACTIVATION BY PEROXIDE AND HELIUM

$T = 431.5°$ C; $a_1 = 10.9$ (equation [X]); $a_4^{He} = 1.1$ (equation [XI])				$T = 468.5°$ C; $a_1 = 54.3$ (equation [X]); $a_4^{He} = 5.4$ (equation [XI])			
		Calc. from [XIII]				Calc. from [XIII]	
s	E_c	a_1	a_4^{He}	s	E_c	a_1	a_4^{He}
2	45.7	0.06	0.08	2	45.8	0.49	0.64
3	47.1	0.4	0.5	3	47.3	2.9	3.8
4	48.5	1.8	2.3	4	48.8	12.4	16.1
5	49.9	6.3	8.2	5	50.3	41.9	54.5
6	51.3	19.0	24.7	6	51.8	119.7	155.4

It is well to bear in mind that equation [XII] is derived for equilibrium. When [XII] is applied to a unimolecular reaction, it is implied that

$$b_i = Z,$$

or that deactivation occurs on every collision (19, 20), a proposition which has been challenged recently (12, 21, 22). In the argument against deactivation on every collision it is tacitly assumed that the distribution function $\sum_i P_i$ defined by

$$\text{[XIV]} \qquad \sum_i P_i = \sum_i \frac{A_i^*}{A} = \sum_i \frac{a_i}{b_i}$$

has a constant value independent of the nature of foreign gas (21); it is then shown that if deactivation occurred on every collision the efficiency of a foreign gas relative to reactant would be equal to the ratio of the corresponding collision numbers. As collision numbers at a given temperature do not vary much from gas to gas, the relative efficiency of all gases should not be far from unity, a consequence which is not observed.

The weakness of this argument concerns the assumed nature of the distribution function in [XIV]. The reason why this function should not depend on the nature of foreign gas is by no means obvious; actually, it would seem reasonable to assume that $\sum_i A_i^*$ could be affected by the energy transfer efficiency of the foreign gas, and hence $\sum_i P_i$ need not be a fixed quantity for all gases. In the absence of any detailed knowledge of $\sum_i P_i$ it appears that kinetic arguments alone cannot decide whether deactivation occurs on every collision or not. As a case in point, one might take equation [XIII] where an explicit form for $\sum_i P_i$ is assumed. E_A and s are experimental quantities independent of any assumption; s is an adjustable parameter, and Z a quantity about which information is desired. Clearly, unless s is known, no information can be obtained about Z. In the absence of precise knowledge of either s or Z the problem degenerates into a case of one equation and two unknowns.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Prof. P. A. Giguère for his continued interest in this work.

NOTES

POLYOXYETHYLENEGLYCOL ETHERS. PART II*

B. A. GINGRAS AND C. H. BAYLEY

Further to the work described in Part I (1), the three ethers $C_8H_{17}O(CH_2CH_2O)_6H$, $C_{16}H_{33}O(CH_2CH_2O)_6H$, and $C_{16}H_{33}O(CH_2CH_2O)_6C_{16}H_{33}$ have been obtained from the reaction between the mono- or di-potassium salt of the hexaoxyethyleneglycol and the appropriate alkyl chloride.

The first two ethers, with terminal hydroxyl groups, are soluble in water and in the usual organic solvents. Their infrared spectra show the typical absorption of the hydroxyl at 3 μ and the broad aliphatic ether band in the 8–9 μ region. A medium band at 13.9 μ is indicative of the paraffin chain.

The last ether, lacking a hydroxyl group, behaves like a saturated hydrocarbon, being hydrophobic and soluble in organic solvents only. Its infrared spectrum is almost identical with that of the corresponding monoether except in the region of the hydroxyl absorption.

EXPERIMENTAL

n-Octylhexaoxyethyleneglycol Ether

Metallic potassium (5.9 g, 0.15 g-atom) was added in small pieces to hexaoxyethyleneglycol (42.4 g, 0.15 mole) and the mixture was stirred and heated at 130° C. After the potassium metal had reacted completely, 1-chlorooctane (25 g, 0.17 mole, b.p. 180° at 758 mm, reported in literature, 181.5° at 765 mm) (2) was added dropwise, the stirring being continued for a further 3 hours. The mixture was then cooled, diluted with acetone, and the potassium chloride was removed by filtration.

The residue was fractionally distilled under reduced pressure, and the fraction of b.p. 150°–180° at 0.1 mm (50 g) was collected. This, when distilled, gave hexaoxyethyleneglycol (b.p. 156° at 0.02 mm, 33 g) and *n*-octylhexaoxyethyleneglycol ether (b.p. 180° at 0.07 mm, 195° at 0.3 mm, n_D^{25} 1.4499, 12.7 g, 20%). The product remained yellowish even after several distillations and it was best purified by chromatography through a silica gel column. A mixture of ethyl ether and methanol, 4:1, eluted the colorless liquid in quantitative yield. Calculated for $C_{20}H_{42}O_7$: C, 60.91%; H, 10.66%. Found: C, 60.39%; H, 10.68%.

Preparation of Hexaoxyethyleneglycol Mono- and Di-hexadecyl Ethers

The reaction was carried out as above using hexaoxyethylene–glycol (25.4 g, 0.09 mole), metallic potassium (3.5 g, 0.09 g-atom), and 1-chlorohexadexane (25 g, 0.1 mole, m.p. 12°, reported in literature 12°) (3). At the end, acetone was added to the cooled mixture and the potassium chloride removed by filtration. From the filtrate separated white crystals of hexaoxyethyleneglycol dihexadecyl ether which was recrystallized from absolute alcohol to a constant m.p. 50° C (7 g, 19%). Calculated for $C_{44}H_{90}O_7$: C, 72.33; H, 12.33. Found: C, 72.33; H, 12.40.

Issued as N.R.C. No. 4835.

The residue (24 g) was chromatographed in three portions through silica gel and there was obtained from elution with ethyl ether – methanol 9:1 mixture hexadecylhexaoxyethyleneglycol ether (18.9 g, 43%), which after recrystallization from *n*-hexane had m.p. 37° C. Calculated for $C_{28}H_{58}O_7$: C, 66.40; H, 11.46. Found: C, 66.66; H, 11.58.

SEPARATION OF CARBOHYDRATES ON COCOANUT CHARCOAL COLUMNS

F. W. BARTH AND T. E. TIMELL

Chromatographic separation on columns of charcoal–Celite has been widely used for resolving mixtures of oligosaccharides (1, 2, 3, 4, 5, 6) and methylated monosaccharides (7, 8, 9). Although Celite alone has been used for separating sugars (10), its addition to the charcoal has usually only served the purpose of increasing the rate of flow of the eluate through the columns. The commonly used mixture has been that originally suggested by Whistler and Durso (1), consisting of equal parts of Darco G-60 and Celite 535 (4, 6, 9), although "activated charcoal" (3, 11) and "animal charcoal" (8) have also been employed. Recently Jermyn (6) has advocated the use of cellulose powder instead of Celite in order to obtain faster flow. Andrews, Hough, and Powell (12) have suggested the use of very short columns, supported on a sintered plate in a Büchner funnel. This technique obviates the need for the addition of Celite, which is stated to have a tendency to contaminate the fractions obtained.

In the course of an investigation on the constitution of a polysaccharide from milkweed floss (13) it was noticed that cocoanut charcoal (a product of Fisher Scientific Co., Fair Lawn, N.J.), 50–200 mesh, pretreated with 6 *N* hydrochloric acid, water, anhydrous ethanol, and again water, was an excellent material for separating both uronic acids and methylated monosaccharides. The rate of flow, even through long columns, was very rapid. The fractions obtained were very pure and the separations were sharp. When a mixture of uronic acids, obtained on partial hydrolysis of milkweed floss (13), was added to the top of a cocoanut charcoal column (4×12 cm) and eluted with 4, 7, and 15% aqueous ethanol, respectively, three main fractions were obtained, namely a chromatographically pure aldotriouronic acid (0.20 g), 2-*O*-(4-*O*-methyl-D-glucopyranosyluronic acid)-D-xylopyranose (1.30 g) and 4-*O*-methyl-D-glucuronic acid (0.45 g), the latter in admixture with some aldobiouronic acid. Addition of a mixture of sugars obtained from the methylated, reduced, and hydrolyzed aldobiouronic acid (0.57 g) to a similar column (2×10 cm) and elution with 10 and 15% aqueous ethanol gave pure 3,4-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose, respectively. When a mixture of galactose, glucose, and 4-*O*-methyl-D-glucose was treated similarly, elution with 1.5% ethanol yielded the neutral sugars, while the 4-*O*-methyl-D-glucose was eluted with 5% ethanol.

The residue (24 g) was chromatographed in three portions through silica gel and there was obtained from elution with ethyl ether – methanol 9:1 mixture hexadecylhexaoxyethyleneglycol ether (18.9 g, 43%), which after recrystallization from *n*-hexane had m.p. 37° C. Calculated for $C_{28}H_{58}O_7$: C, 66.40; H, 11.46. Found: C, 66.66; H, 11.58.

SEPARATION OF CARBOHYDRATES ON COCOANUT CHARCOAL COLUMNS

F. W. BARTH AND T. E. TIMELL

Chromatographic separation on columns of charcoal–Celite has been widely used for resolving mixtures of oligosaccharides (1, 2, 3, 4, 5, 6) and methylated monosaccharides (7, 8, 9). Although Celite alone has been used for separating sugars (10), its addition to the charcoal has usually only served the purpose of increasing the rate of flow of the eluate through the columns. The commonly used mixture has been that originally suggested by Whistler and Durso (1), consisting of equal parts of Darco G-60 and Celite 535 (4, 6, 9), although "activated charcoal" (3, 11) and "animal charcoal" (8) have also been employed. Recently Jermyn (6) has advocated the use of cellulose powder instead of Celite in order to obtain faster flow. Andrews, Hough, and Powell (12) have suggested the use of very short columns, supported on a sintered plate in a Büchner funnel. This technique obviates the need for the addition of Celite, which is stated to have a tendency to contaminate the fractions obtained.

In the course of an investigation on the constitution of a polysaccharide from milkweed floss (13) it was noticed that cocoanut charcoal (a product of Fisher Scientific Co., Fair Lawn, N.J.), 50–200 mesh, pretreated with 6 *N* hydrochloric acid, water, anhydrous ethanol, and again water, was an excellent material for separating both uronic acids and methylated monosaccharides. The rate of flow, even through long columns, was very rapid. The fractions obtained were very pure and the separations were sharp. When a mixture of uronic acids, obtained on partial hydrolysis of milkweed floss (13), was added to the top of a cocoanut charcoal column (4×12 cm) and eluted with 4, 7, and 15% aqueous ethanol, respectively, three main fractions were obtained, namely a chromatographically pure aldotriouronic acid (0.20 g), 2-*O*-(4-*O*-methyl-D-glucopyranosyluronic acid)-D-xylopyranose (1.30 g) and 4-*O*-methyl-D-glucuronic acid (0.45 g), the latter in admixture with some aldobiouronic acid. Addition of a mixture of sugars obtained from the methylated, reduced, and hydrolyzed aldobiouronic acid (0.57 g) to a similar column (2×10 cm) and elution with 10 and 15% aqueous ethanol gave pure 3,4-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose, respectively. When a mixture of galactose, glucose, and 4-*O*-methyl-D-glucose was treated similarly, elution with 1.5% ethanol yielded the neutral sugars, while the 4-*O*-methyl-D-glucose was eluted with 5% ethanol.

An acidic solution of 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose could also be easily resolved after the acid had been removed by washing the column with water.

The adsorptive power of cocoanut charcoal appears to be somewhat greater than that of Darco G-60, as elution with larger quantities of water is necessary for complete removal of neutral sugars (14). Addition of 1–2% aqueous ethanol usually achieves the same result much more rapidly. The use of gradient elution (6, 8) would probably improve the resolution obtainable with this type of adsorbent.

QUENCHING AND VIBRATIONAL-ENERGY TRANSFER OF EXCITED IODINE MOLECULES

C. ARNOT AND C. A. MCDOWELL

Recent studies (1, 6) of the quenching of the fluorescence spectrum of iodine by foreign gases have led to rather different values for the quenching efficiencies of simple molecules. Polanyi's (1) results were summarized in Table I, page 127 of Can. J. Chem., **36**, 1958, and are here reproduced.

	p, mm	I_0/I_p	I_p'/I_p	$Z_p\times10^{-8}$	$\delta\times10^{-8}$	$\delta p/Z_p$	$\epsilon\times10^{-8}$	$\epsilon p/Z_p$
H_2	9.6	3.15	0.78	2.78	0.17	0.59	0.16	0.55
D_2	8.3	3.88	0.80	1.69	(0.17)	(0.83)	(0.55)	(2.7)

$\tau = 10^{-8}$ second, I_2 pressure 0.43 mm.

The values listed above for δ, the quenching constant, were obtained from data obtained by Wood (2) for hydrogen, the same value being used for deuterium. Wood studied the fluorescence excited by sunlight and not monochromatic Hg 5461 Å, and his intensity measurements were made by a visual comparative method. The iodine pressure in Wood's experiments was 0.20 mm, as opposed to Polanyi's 0.43 mm. As neither the values of δ nor ϵ were corrected by Polanyi for the reduction of the lifetime from the "ideal mean lifetime" by self-quenching, the effect of self-quenching differs in the two experiments.

Eliashevich (3) corrected his results for self-quenching, using data obtained by Stern and Volmer (4). Assuming a value of 10^{-8} second for the "ideal mean lifetime", Eliashevich

An acidic solution of 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose could also be easily resolved after the acid had been removed by washing the column with water.

The adsorptive power of cocoanut charcoal appears to be somewhat greater than that of Darco G-60, as elution with larger quantities of water is necessary for complete removal of neutral sugars (14). Addition of 1–2% aqueous ethanol usually achieves the same result much more rapidly. The use of gradient elution (6, 8) would probably improve the resolution obtainable with this type of adsorbent.

QUENCHING AND VIBRATIONAL-ENERGY TRANSFER OF EXCITED IODINE MOLECULES

C. ARNOT AND C. A. MCDOWELL

Recent studies (1, 6) of the quenching of the fluorescence spectrum of iodine by foreign gases have led to rather different values for the quenching efficiencies of simple molecules. Polanyi's (1) results were summarized in Table I, page 127 of Can. J. Chem., **36**, 1958, and are here reproduced.

	p, mm	I_0/I_p	I_p'/I_p	$Z_p\times10^{-8}$	$\delta\times10^{-8}$	$\delta p/Z_p$	$\epsilon\times10^{-8}$	$\epsilon p/Z_p$
H_2	9.6	3.15	0.78	2.78	0.17	0.59	0.16	0.55
D_2	8.3	3.88	0.80	1.69	(0.17)	(0.83)	(0.55)	(2.7)

$\tau = 10^{-8}$ second, I_2 pressure 0.43 mm.

The values listed above for δ, the quenching constant, were obtained from data obtained by Wood (2) for hydrogen, the same value being used for deuterium. Wood studied the fluorescence excited by sunlight and not monochromatic Hg 5461 Å, and his intensity measurements were made by a visual comparative method. The iodine pressure in Wood's experiments was 0.20 mm, as opposed to Polanyi's 0.43 mm. As neither the values of δ nor ϵ were corrected by Polanyi for the reduction of the lifetime from the "ideal mean lifetime" by self-quenching, the effect of self-quenching differs in the two experiments.

Eliashevich (3) corrected his results for self-quenching, using data obtained by Stern and Volmer (4). Assuming a value of 10^{-8} second for the "ideal mean lifetime", Eliashevich

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

deduced that the lifetime was reduced to 3.3×10^{-9} second at the concentration of iodine of 0.17 mm which he used. Polanyi's work can therefore be compared only with that of Eliashevich if a similar correction is made. Polanyi interpreted his results in terms of the extension of the Stern–Volmer relationship put forward by Roessler (5), which does not take into account self-quenching.

Polanyi obtained sufficient data to calculate quenching constants for hydrogen and deuterium, although for some reason he preferred to use Wood's results, which were obtained with nothing like the same precision. He states values for I_0/I_p and I_p'/I_p. The ratio of the total fluorescence intensity in the absence and in the presence of added gas (R_1), from which the quenching probability can be found, is equal to $I_0/(I_p+I_p')$.

The values of this ratio were then determined from Polanyi's data:

[1] $$R_1 = I_0/(I_p+I_p') = (I_0/I_p)/\{1+(I_p'/I_p)\}$$

Hydrogen: $I_0/I_p = 3.15$, $I_p'/I_p = 0.78$ Hence $R_1 = 3.15/1.78 = 1.77$.

Deuterium: $I_0/I_p = 3.88$, $I_p'/I_p = 0.80$ Hence $R_1 = 3.88/1.80 = 2.16$.

Polanyi's results were then interpreted in terms of the scheme put forward by Arnot and McDowell (6). Equation 24 in that paper shows:

[2] $$R_1 = (k_F+k_s[\mathrm{M}]+k_q[\mathrm{X}])/(k_F+k_s[\mathrm{M}]).$$

Rearranging,

[3] $$k_q/k_F = (R_1-1)\{1+(k_s/k_F)[\mathrm{M}]\}/[\mathrm{X}].$$

A value of 2.0×10^5 liters mole^{-1} was used for the ratio of self-quenching and fluorescence rate constants. The only other published quantitative data for self-quenching is that of Stern and Volmer (4), who found a value of 0.08 mm for the "self-quenching half pressure". On the basis of the Stern–Volmer relationship, $I_0/I = 1+\beta p$, where β is identified with k_s/k_F, this quenching half-pressure is equivalent to a value of $1/p$ for k_s/k_F, i.e. 2.25×10^5 liters mole^{-1} (1 mm Hg = 5.53×10^{-5} moles liter^{-1} at 17° C).* This value is in agreement with the value we obtained.

Substituting in equation [3]

Hydrogen: $R_1-1 = 0.77$, $k_s/k_F = 2.0\times10^5$ liters mole^{-1}, $[\mathrm{I_2}] = 0.43\times5.35\times10^{-5}$ moles liter^{-1}, $[\mathrm{M}] = 9.6\times5.35\times10^{-5}$ moles liter^{-1}

Hence $(1+k_s/k_F[\mathrm{I_2}]) = 5.60$ and $k_q/k_F = 8.4\times10^3$ liters mole^{-1}.

Deuterium: $R_1-1 = 1.16$, $(1+k_s/k_F[\mathrm{I_2}]) = 5.60$, $[D_2] = 8.3\times5.35\times10^{-5}$ moles liter^{-1}

Hence $k_q/k_F = 1.46\times10^4$ liters mole^{-1}.

Rearrangement of equation 23 in paper by Arnot and McDowell (6) yields the result

[4] $$k_T/k_F = \frac{(R_2-1)(1+[\mathrm{M}]k_s/k_F)-([\mathrm{X}]k_q/k_F)}{(1-R_3/Z)[\mathrm{X}]}.$$

Substituting for hydrogen the following values: $R_2 = 3.15$, $R_3 = 0.78$, $(1+[\mathrm{M}]k_s/k_F) = 5.60$, $k_q/k_F = 8.4\times10^3$ liters mole^{-1}, $[\mathrm{H_2}] = 9.6\times5.35\times10^{-5}$ moles liters^{-1}, $Z = 4$, we calculate

$$k_T/k_F = 1.9\times10^4 \text{ liters mole}^{-1}.$$

**Conversion factor of 1 mm = 5.35×10^{-5} moles liter^{-1} has been used here as temperature at which Polanyi's work was carried out was deduced to be ca. 27° C from his iodine pressure.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

For deuterium the following values have to be substituted in equation [4], namely: $R_2 = 3.88$, $R_3 = 0.80$, $(1+[M]k_s/k_F) = 5.60$, $k_q/k_F = 1.46\times10^4$ liters mole^{-1}, $[D_2] = 8.3\times5.35\times10^{-5}$ moles liter^{-1}. These yield the result $k_T/k_F = 2.7\times10^4$ liters mole^{-1}. The theoretical rate constants for collisions between iodine molecules and added gas molecules can be calculated from the expression:

$$[5] \qquad k = (N_0/100)\,(r_1+r_2)^2[8RT(1/M_1+1/M_2)]^{\frac{1}{2}} \text{ (liters mole}^{-1}\text{ sec}^{-1}\text{)},$$

where M_1 and M_2 are the molecular weights of the colliding species. Values of $\gamma_{I_2} = 2.7$ Å and $\gamma_{H_2} = \gamma_{D_2} = 1.1$ Å were used.

$N_0 = 6.023\times10^{23}$ molecules mole^{-1}, $R = 8.318\times10^8$ ergs/degree, $T = 300°$ K, $M_{I_2} = 254$, $M_{H_2} = 2$, $M_{D_2} = 4$, $\gamma_{I_2} = 2.7\times10^{-8}$ cm, $\gamma_{D_2} = \gamma_{H_2} = 1.1\times10^{-8}$ cm. We thus calculate

$$k_{H_2} = 4.9\times10^{11} \text{ liters mole}^{-1}\text{ sec}^{-1}$$

and

$$k_{D_2} = 3.5\times10^{11} \text{ liters mole}^{-1}\text{ sec}^{-1}.$$

On the basis of the "ideal mean lifetime" τ being 10^{-8} sec, then $k_F = 1/\tau = 10^{-8}$ sec^{-1}, and the theoretical values of k_T/k_F calculated are:

H_2 4.9×10^3 liters mole^{-1}
D_2 3.5×10^3 liters mole^{-1}.

Polanyi's experimental results interpreted this way yield values of k_T/k_F that are 3.9 times the theoretical value for H_2 and 7.7 the theoretical value for D_2 and are thus of the same order of magnitude as those found by Arnot and McDowell (6) for the quenching by other gases.

We are grateful to the National Research Council for a grant-in-aid of this research.

CONDUCTANCES OF CONCENTRATED AQUEOUS SOLUTIONS OF MIXED ELECTROLYTES[1]

A. N. CAMPBELL, E. M. KARTZMARK, AND A. G. SHERWOOD

ABSTRACT

Equivalent conductances, viscosities, and densities were determined for solutions equimolar in two of the three salts lithium nitrate, ammonium nitrate, and silver nitrate. The three possible combinations of two salts were each studied at 25° C and at 35° C.

The observed conductances and viscosities were compared with those of the single salt solutions at the same total ion concentration. The conductances were lower than the mean of the conductances of the single salt solutions. The viscosities were also lower than the mean viscosities.

INTRODUCTION

Work in this laboratory has, for the past 8 years, been devoted to providing reliable data on the conductances of concentrated solutions of lithium, of silver, and of ammonium nitrates, and of lithium chlorate in aqueous solutions, and also, in the case of lithium nitrate, in alcohol and alcohol–water mixtures. Recently, the accumulated data have assumed an added interest with the appearance of conductance equations which purport to be valid well into the region of finite concentration. These equations are being tested and are showing encouraging results.

It was considered that a study of mixtures of electrolytes in concentrated solution would be interesting as an extension of our general scheme of work. Accordingly the nitrates of lithium, of silver, and of ammonium were investigated in pairs in aqueous solution. The conductances, viscosities, and densities of solutions, equimolar in each salt, were determined at 25° C and at 35° C.

Onsager and Fuoss (1) have extended the calculations of the Debye–Hückel–Onsager limiting law to include a mixture of ions in solution but their treatment cannot be extended, except as a qualitative analogy, to concentrated solutions. It was first observed by Bray and Hunt (2) that the conductance for a given total concentration of ions is not additive. They studied solutions of sodium chloride and hydrogen chloride and attempted to explain their results as due to incomplete dissociation.

Onsager's theory predicts that the faster ion (H^+ in the case mentioned above) will be slowed down, and the slower ion accelerated, in the mixture. This was shown to be true, experimentally, by Longsworth (3) when he determined the transference numbers of the individual ions in mixed aqueous solutions of potassium chloride and hydrogen chloride.

According to Onsager and Fuoss, of the two effects tending to retard the motion of ions in solution, only the relaxation effect will have a different value in mixed solutions from that in a solution of the single salt of the same concentration. Onsager and Fuoss have compared calculated data for solutions of sodium chloride and hydrogen chloride

[1]*Manuscript received June 3, 1958.*
Contribution from the Chemistry Department, University of Manitoba, Winnipeg, Manitoba.

with the experimental values of Bray and Hunt, and the calculated data for mixtures of barium chloride and hydrogen chloride and of potassium chloride and hydrogen chloride (all at 25° C) with the experimental values of Bennewitz, Wagner, and Küchler (4). The comparison indicates that the Onsager–Fuoss treatment is valid as a limiting law, i.e. at extreme dilution. The work of Krieger and Kilpatrick (5) on the conductance of mixed solutions of lithium chloride and potassium chloride in dilute solution also leads to the same conclusion, viz. that the Onsager–Fuoss treatment is valid for very dilute solutions.

Few measurements have been made on concentration solutions. Van Rysselberghe and Nutting (6) measured conductances of mixtures of sodium and potassium halides and nitrates, in solutions whose total concentration was 1.0 molal. They observed that the mixture rule was most nearly correct when the component salts had similar conductances. Van Rysselberghe, Grinnel, and Carson (7) measured conductances of binary mixtures of two–one, two–two, and one–one electrolytes with common anions and with concentrations ranging from 0.5 to 9.0 *N*. They found the departure from the mixture rule to be much larger for higher valence ions.

EXPERIMENTAL PROCEDURE

Our technique has been frequently described and need not be repeated here (8). All solutions were equimolar with respect to the two component salts. A dry box was introduced for the manipulation of the hygroscopic lithium nitrate. The weight concentration was known to within ±0.002%. We have recently found it convenient to adopt the thyratron relay system of temperature control, as described by Swinehart (9), in

by the mixture rule from the Λ values of the individual salts in solutions of the same concentration. The mixture rule applied to conductance gives:

$$\Lambda_{mix} = x_1\Lambda_1 + x_2\Lambda_2,$$

where x_1 and x_2 are the mole fractions of salts 1 and 2 respectively and Λ_1 and Λ_2 are the equivalent conductances of the single salts at the same concentration. Since all solutions were equimolar in the two salts ($x_1 = x_2 = 0.5$), this amounts merely to taking the average of the conductances of the two single salt solutions. The values for the single salt solutions were obtained by interpolation from the previous results of this laboratory (8), and from the results for lithium nitrate at 35° C, obtained for the first time in this study and given in Table IV.

In column 7 are listed the differences between the calculated and observed equivalent conductances. Column 8 shows the increase in relative viscosity of each solution over

Fig. 1, a graph of equivalent conductance vs. concentration, is typical of the six sets of data. Fig. 2 illustrates graphically the relation among the viscosity of the mixed solutions, the viscosity of the single salt solutions, and the viscosity of the mixed solutions as calculated by the mixture rule, for the case of lithium nitrate – ammonium nitrate at 25° C. It can be seen from the tables of data that this type of graph is common to all the solutions, except the lithium nitrate – silver nitrate solutions at 35° C where the calculated and observed viscosities almost coincide; this graph is shown as Fig. 3. The data for lithium nitrate solutions at 35° C are given in Table IV; the graph of equivalent conductance appears in Fig. 1, and the viscosity plot in Fig. 3.

DISCUSSION OF RESULTS

The equivalent conductances of the mixed solutions were in all cases less than the values calculated by the mixture rule. If Λ_A, Λ_B, and Λ_M are the equivalent conductances of solutions of A, of B, and of an equimolar mixture of the two respectively, all at the same total ion concentration, then:

$$\Lambda_M < (\Lambda_A + \Lambda_B)/2.$$

This means that if in a solution of A one half of the A cations are replaced by B cations (the anion remaining the same), the resulting conductance will be lower than the mean conductance of the two single salt solutions. The deviations from the calculated conductances do not seem to be caused by any single ion. The deviation is large when the difference in conductances of the single salt solutions is large, and the mixture rule is more nearly applicable when the difference in conductance is small. This is in agreement with the observations of Van Rysselberghe and Nutting (6).

It is possible that differences in hydration may be concerned. For example, suppose one half of the lithium ions be replaced by ammonium ions. Since the ammonium ions are hydrated to a smaller extent than are the lithium ions, the remaining lithium ions have more water available for hydration and would therefore behave as if they were in more dilute solution. In general then, the more highly hydrated ion will be in effect in a more dilute solution. An increase in solvation and hence of the effective radius of the ion would, in the sense of Stoke's law, cause a decrease in the mobility of the ion. The increase in equivalent conductance observed on dilution of a salt solution (despite a possible increase in hydration) is due to a decrease in the interionic forces. When hydrated ions are replaced by less hydrated ions of the same charge, the number of ions presumably remains the same and the interionic forces are only slightly altered. Hence, in the case considered, the remaining lithium ions being more highly hydrated, their mobility will decrease. The contribution of the ammonium ion to conductance will be little affected, since it is only slightly hydrated. Hence it appears that the hydration effect would operate in the direction of lowering the conductance of the mixture below the value calculated by the mixture rule.

No hydration data are available for the silver ion, but from consideration of ion size and charge the primary hydration number should lie between those of sodium and potassium. Robinson and Stokes (10) from diffusion experiments assign the following values for the hydration numbers: $NH_4^+ = 0.0$; $K^+ = 0.4$; $Na^+ = 0.7$; $Li^+ = 2.3$. The nature of the experiments permits only of the determination of differences in hydration numbers but this is sufficient to show that the order of increasing hydration is $NH_4^+ < K^+ < Ag^+ < Na^+ < Li^+$. Since this is also the order of decreasing conductance, the argument developed for the lithium nitrate – ammonium nitrate solutions is consistent with our observations.

A consideration of the dielectric constant of mixed solutions leads to the same conclusion. No measurements of dielectric constant in mixed solutions have been made but certain theoretical deductions are possible. Hasted, Ritson, and Collie (11) offer the following equation to represent the change in dielectric constant of the medium with concentration of electrolyte:

$$D = D_0 + 2\bar{\delta}\sqrt{c}.$$

According to this equation, D is linear in $\sqrt{c}$. Determinations by these authors suggest that $\bar{\delta}$, the proportionality factor, is larger for smaller and more highly charged ions; this is due to the rigid orientation of the water molecules of the hydration sheath. Strict obedience to the linear equation is observed only up to a concentration of 2 molar. This is due to the inclusion of all the water molecules in the fields of the ions; the highest possible orientation of water molecules has been attained and further addition of ions can have little effect. In replacing lithium ions by ammonium ions, which are less highly hydrated, more water molecules are made available to the strong fields of the remaining lithium ions and so their power of depressing the dielectric constant is increased. Hence the dielectric constant of the mixed solution will be lower than that calculated from the mixture rule. The lower dielectric constant will increase the interionic forces and increase the tendency toward ion pair formation resulting in a lower conductance than the calculated value.

In all cases but one, the viscosities of the mixtures were lower than the values calculated by the mixture rule. The one exception, lithium nitrate – ammonium nitrate solutions at 35° C, occurs where the viscosities and conductances of the two single salt solutions are almost the same. If the viscosity were the sole factor determining conductance, this would imply that an increase in equivalent conductance would occur. Since this is not so, it is obvious that the viscosity effect is exceeded by other effects. It is difficult, however, to see why the viscosity of the solutions of two salts should be lower than the value calculated by the mixture rule. The lowering of dielectric constant, with the consequent strengthening of the interionic forces, tends to increase the viscosity. This is in agreement with the observation made by Kraus (12) in his discussion of the viscosity – dielectric constant relation. The increased hydration of the lithium ion should also increase viscosity. It therefore appears that some other factor or factors must cause this effect in mixed solutions.

SOME THERMODYNAMIC CONSIDERATIONS OF THE EFFECTS OF STRESS ON METAL ELECTRODE POTENTIALS[1]

E. A. FLOOD

ABSTRACT

It is shown that the change in thermodynamic potential of a solid when elastically strained by the application of the principal stresses p_x, p_y, and p_z is given by the equation

$$\mu-\mu_0 = \tfrac{1}{3}\int_{0,T}^{p_x+p_y+p_z} v\,d(p_x+p_y+p_z)+\phi(q-q_0),$$

where v is the volume per unit mass and $\phi(q-q_0)$ is the shear strain work done on unit mass of the solid, at T and $(p_x+p_y+p_z)$ constant, as the relative values of p_x, p_y, and p_z vary, i.e., as the values of the principal stresses vary from their mean.

INTRODUCTION

Many modern authors of scientific papers assume that the work done upon a system constitutes a measure of the change of Gibbs free energy of the system concerned, quite regardless of how this work is done and regardless of its relation to the pertinent equilibrium conditions. Of course, it is well known that when a solid or liquid is in equilibrium with its vapor that work may be done on or by the system at constant temperature without change in the Gibbs free energy of the system, i.e., without change in the thermodynamic potential of the substance concerned.

The variation in thermodynamic potential of a substance corresponding to given variations in the various variables of the system will depend upon how these variables are involved in particular equilibrium conditions. Accordingly, in order to calculate the changes of potential which accompany given changes in the variables of a system it is essential that the mathematical operations correspond with the idealized experimental conditions.

THERMODYNAMIC POTENTIALS

The condition that a system be in reversible equilibrium with externally applied forces is that the heat absorbed during any change shall be equal to the increase in energy of the system plus the maximum work that the system can do against the externally applied forces. Thus to be in reversible equilibrium with its surroundings the work done *on* a system during a specified change will be the same as that done *by* the system during the exact reverse of the specified change. This is the oldest of the thermodynamic conditions for equilibrium and is, of course, the Carnot–Kelvin condition that a system have no tendency to change its state spontaneously. It will be noted that while both the energy and entropy changes of a system depend only on the initial and final states, the reversible work done and the net heat absorbed ($\int T\,dS$) depend upon how the change is carried out, i.e., upon the path of integration.

The Carnot–Kelvin condition for equilibrium was expressed by Gibbs in the more concise form $(\delta S)_E \leqslant 0$ or $(\delta E)_S \geqslant 0$, leading to similar expressions using the various other thermodynamic functions, the enthalpy, Helmholtz free energy, Gibbs free energy, etc.

[1]*Manuscript received June 13, 1958.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4878.

The general condition that the various parts of an isolated system be in reversible equilibrium with one another with respect to heat transfer, as between its parts, is that the temperature of its parts shall be the same. If matter may interdiffuse between these parts independently of heat it is also necessary that the thermodynamic potentials of the various kinds of matter in these different parts of the system shall be the same.

Processes in which a given mass of material in "state 1" disappears, while at the same time an equal mass appears in "state 2", the natures and states of the masses, all their respective intensive variables, etc., remaining constant during the transformation, are essentially displacement processes. The condition that such processes be reversible is that the total thermodynamic potentials or displacement potentials of the masses in the two states shall be equal. Where the only externally applied forces involved are the temperature and hydrostatic pressures and we write $F = E - TS + pv$, the condition that the process be reversible is that $\Delta F = 0$ or that $\mu_1 = \mu_2$,* where the thermodynamic potential $\mu = (\partial F/\partial \mathrm{m})_{T,p}$. That this is equivalent to the Carnot–Kelvin equilibrium condition may readily be demonstrated as follows. Let the mass δm_1 disappear by reversible introduction into a reference system while at the same time the mass δm_2 appears as in a typical Washburn thermodynamic engine. If the nature and state of mass m_1 remain unchanged, the entropy and volume per unit mass remain unchanged. The condition that the mass m_1 be in reversible equilibrium with the externally applied forces requires that the decrease in energy δE_1 shall be equal to the heat evolved less the work done on the system by the external forces. If the only external force is the hydrostatic pressure p_1 the work done on the system is $p_1 \delta v$. Thus as the mass δm_1 disappears we have $-\delta E_1 = -T\,\delta S_1 + p_1 \delta v_1$, and similarly as δm_2 appears we have $\delta E_2 = T\,\delta S_2 - p_2 \delta v_2$ and the net effect of the operation is that the energy of the mass may have changed while a quantity of heat has been absorbed or rejected and work done by or on the system. If this work is the maximum work that can be done, the process as a whole is reversible and we can write $\delta F = T\,\delta S - W_{\mathrm{rev}}$. Evidently if $F_1 = E_1 - TS_1 + p_1 v_1$ and $F_2 = E_2 - TS_2 + p_2 v_2$ per unit masses then for the process as a whole $\Delta F = F_2 - F_1 = E_2 - E_1 - T(S_2 - S_1) + p_2 v_2 - p_1 v_1 = 0$, when $p_2 = p_1$ or when

$$\int_{p_0}^{p_2} v_2\, dp = \int_{p_0}^{p_1} v_1\, dp.$$

Thus the condition that $\Delta F = 0$ for such displacement processes at constant T and p is equivalent to the Carnot–Kelvin equilibrium condition. Thus for such processes the condition for equilibrium is that $F_1 = F_2$ or that $\mu_1 = \mu_2$ and the condition that equilibrium be preserved as F_1 and F_2 are changed is that $dF_1 = dF_2$. Hence when the temperature is constant the equilibrium condition equation is $v_1\, dp_1 = v_2\, dp_2$. Evidently in the process above

$$E_2 - E_1 = \delta E = T \int_{S(v_1)}^{S(v_2)} dS - \int_{v_1,\,T}^{v_2} p\, dv = T(S_2 - S_1) - (p_2 v_2 - p_1 v_1),$$

and $p_2 = p_1$ or if phase changes are involved

$$\int_{p_0}^{p_1} v_1\, dp = \int_{p_0}^{p_2} v_2\, dp.$$

Let us consider a case where the equilibrium between δm_1 and the reference system involves only the external pressure p_1 and T as before, but where E_1' and S_1' may differ

The subscripts refer to the "phases" or to the separate bodies of matter, not to the components as is the common convention in this respect.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

from E_1 and S_1, owing to the action of some other forces (such as the presence of a gravitational field), which are not directly involved in the displacement work terms. Thus let E_1' and S_1' be given by

$$E_1'-E_1 = T\int_{x_0,T,p_1}^{x} dS-\int_{x_0,T,p_1}^{x} p\,dv-\int_{x_0,T,p_1}^{x} f(x)\,dx$$
$$= T(S_1'-S_1)-p_1(v_1'-v_1)-\phi(x_1p_1)+\phi(x_0,p_1)$$

where

$$-\int_{x_0,T,p_1}^{x} p\,dv-\int_{x_0,T,p_1}^{v} f(x)\,dx$$

is the work done by the system on changing its position from x_0 to x in a scalar potential field.*

As before, the condition for reversibility is that

$$E_2-E_1' = T(S_2-S_1')-(p_2v_2-p_1v_1')+\phi(x)-\phi(x_0)$$

and we can write,

$$F_1' = E_1'-TS_1'+p_1v_1' = E_1-TS_1+p_1v_1-\phi(x)+\phi(x_0),$$
$$F_2 = E_2-TS_2+p_2v_2,$$

or,

$$F_1'' = E_1'-TS_1'+p_1v_1'+\phi(x),$$
$$F_2'' = E_2-TS_2+p_2v_2+\phi(x_0),$$

and the condition for reversible equilibrium in such processes is again that $\Delta F = 0$.† This leads to the well-known equation for equilibrium in an isothermal potential field $v\,dp = -d\phi(x)$.

* $$\int_{x_0,T,p}^{x} f(x)\,dx = \int_0^m \frac{\partial}{\partial m}\int_{x_0,T,p}^{x} f'(x)d\,x\cdot d\,m$$

where $f'(x)$ is the force function per unit mass thus providing for variation in f with m, T, and p being constant.

†*We can derive F_1' from F_2' by integrating in two steps first from p_2 to p_1 at T and x_0, and second, from x_0 to x at p_1 and T so that*

$$F_1' = F_2'+\int_{p_2,x_0,T}^{p_1,x,T} d\,F$$

and during the first step

$$\int_{p_2,x_0,T}^{p_1} d\,F = \int_{p_2,x_0,T}^{p_1} d\,E-T\int_{p_2,x_0,T}^{p_1} d\,S+\int_{p_2,x_0,T}^{p_1} p\,dv+\int_{p_2,x_0,T}^{p_1} v\,dp$$
$$= \int_{p_2,x_0,T}^{p_1} v\,dp = \int_{p_2,x_0,T}^{p_1}\frac{\partial F}{\partial p}\,dp$$

while in the second step

$$\int_{x_0,p_1,T}^{x} d\,F = \int_{x_0,p_1,T}^{x} d\,E-T\int_{x_0,p_1,T}^{x} d\,S+\int_{x_0,p_1,T}^{x} p\,dv$$
$$= -\int_{x_0,p_1,T}^{x} f(x)\,dx = \int_{x_0,p_1,T}^{x}\frac{\partial F}{\partial x}\,dx.$$

Evidently the condition that $\Delta F = 0$ or that $F_1' = F_2'$ is that

$$\int_{p_2,x_0,T}^{p_1} v\,dp-\int_{x_0,p_1,T}^{x} f(x)\,dx = 0 = \int_{p_2,x,T}^{p_1} v\,dp-\int_{x_0,p_2,T}^{x} f(x)\,dx.$$

If we suppose that the equilibrium between the mass m_1 and the reference system necessarily involves an electric charge so that as δm_1 is forced into the reference system, reversibly, a definite electric charge is carried with it thus leaving the remaining mass with, say, a net negative charge, as in an electrolytic equilibrium where the mass is in equilibrium with positively charged ions in solution; in this case, we must write $F = E - TS + pv + \epsilon c$ where ϵ is the e.m.f. and c the charge. This leads directly to the relation

$$d\epsilon = -v\,dp/c$$

$$\epsilon - \epsilon_0 = -\frac{1}{n\mathfrak{F}}\int_{p_0}^{p} v\,dp$$

where n is the number of charges carried by the ion, $\mathfrak{F}$ is Faraday's constant, v the volume per mole, etc. Thus the potential difference between two incompressible metal electrodes which differ only in hydrostatic state of stress is $\epsilon - \epsilon_0 = -[v/n(\mathfrak{F})](p - p_0)$. Thus the electrode becomes more negative (more electropositive or less noble) as the hydrostatic pressure p increases. Of course, the electrode becomes positive (more noble) when the hydrostatic pressure p is negative.*

When the stresses acting on the electrode are not hydrostatic stresses, the situation is somewhat more complex. When the contractions $\partial x/x$, $\partial y/y$, etc., are linear functions of the normal stresses p_x, p_y, etc., and the material is isotropic, the volume change is given by the change of the sum of the normal stresses. Accordingly a definite work term is involved for given values of $(p_x + p_y + p_z)$. However, in the general case it is only when the shape remains constant that a reversible equilibrium and a definite work term can be associated with the positive or negative changes in volume which accompany the addition or removal of elements of mass. In this case, if xyz be an element of volume v, then $\delta v = yz\,dx + zx\,dy + xy\,dz$, and we can write,

$$\delta E = T\delta S - p_x yz\,dx - p_y zx\,dy - p_z xy\,dz + \mu\delta m.$$

We can integrate this equation holding T and p_x, p_y, p_z, the principal stresses, constant and obtain a definite work term only if dx, dy, and dz are related to one another in a constant manner. In this case we can write $y = a_y x$, $z = a_z x$, where a_y and a_z are constants and obtain

$$\begin{aligned}\delta E &= T\delta S - (p_x + p_y + p_z)a_y a_z x^2\,dx + \mu\delta m,\\ &= T\delta S - \tfrac{1}{3}(p_x + p_y + p_z)\delta v + \mu\delta m,\\ &= T\delta S - \bar{p}\delta v + \mu\delta m.\end{aligned}$$

This leads to

$$\epsilon - \epsilon_0 = -\frac{1}{n\mathfrak{F}}\int_{\bar{p}_0}^{\bar{p}} v\,dp$$

where $\bar{p} = \tfrac{1}{3}(p_x + p_y + p_z)$.

If, however, p_x, p_y, and p_z, the principal or normal stresses, are of relatively large magnitudes and differ from one another appreciably, shear strain energies are necessarily involved. The work term associated with the shear strain energy is not involved in the displacement work and accordingly we must add the corresponding work term to the displacement or Gibbs potential, as done above in the case of a gravitational potential

Since an electric charge on a thin wire gives rise to an appreciable mechanical stress, a term taking this into account explicitly may be necessary. The term is equivalent to $\partial\mu_1/\partial q.\delta q$ where δq is the increased charge associated with the greater ϵ.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$\phi(x)$. This work term is always positive when taken from the unsheared state, i.e., work done on the body at constant temperature as an angular deformation occurs at constant $(p_x+p_y+p_z)$, while the relative values of p_x, p_y, and p_z change. In this case we should write $F = E_{q_0}-TS+\bar{p}v+\epsilon c+\phi(q)$, where $\phi(q)$ is the shear strain energy per unit mass

$$=\int_{q_0,T,v}^{q}\phi\, dq$$

($\phi(q)$ for elastic deformations of isotropic bodies obeying Hooke's Law is $1/12M\,[(p_x-p_y)^2+(p_y-p_z)^2+(p_z-p_x)^2]$ where M is the modulus of rigidity).

Accordingly the electrode potential $\epsilon-\epsilon_0$ as a function of stress becomes,

$$\epsilon-\epsilon_0 = -\frac{1}{n\mathfrak{F}}\int_{\bar{p}_0}^{\bar{p}} v\, d\bar{p}-\int_{q_0,T,\bar{p}}^{q}\phi\, dq. \qquad [1]$$

Evidently purely compressional or dilational strain energies are not explicitly involved in the final formulae, since they are already contained in the E, TS, and pv terms. For elastic solids obeying Hooke's Law we can write approximately,

$$\epsilon-\epsilon_0 = -(v/n\mathfrak{F})(\bar{p}-\bar{p}_0)-(v/12M)[(p_x-p_y)^2+(p_y-p_z)^2+(p_z-p_x)^2]$$
$$\delta\epsilon = -(v/3n\mathfrak{F})(p_x+p_y+p_z)-(v/12M)[(p_x-p_y)^2+(p_y-p_z)^2+(p_z-p_x)^2],$$

where $\delta\epsilon$ is the voltage difference between an electrode under no stress and one with normal stresses p_x, p_y, and p_z expressed in suitable units. Thus the shear strain energy always makes the electrode more electropositive (i.e. less noble), while the displacement work terms make the electrode more electropositive when $p_x+p_y+p_z$ is positive and makes the electrode less electropositive (i.e. more noble) when the sum of the pressures or normal stresses is negative. For small positive or negative values of p_x, p_y, and p_z, the shear strain potential will be negligible, while at very large values of the stresses the shear strain potential may be dominant. If the electrode is strained beyond its elastic limit and the stress released, a term of the type $\phi(q)$ will remain so that the strained metal will in general be more electropositive (i.e. less noble) than in the unstrained state; however, in this case the magnitude of $\phi(q)$ cannot be calculated in any very simple manner. In general, in the absence of competing chemical reactions of the electrode, electrolyte, etc., lack of reversibility will tend to reduce the magnitude of the difference $\epsilon-\epsilon_0$, i.e. to reduce the magnitude of the electrical work the cell can do.

If the stress p_x arises as a result of the application of a constant force while p_y and p_z correspond to the constant hydrostatic pressure of the electrolyte, the stress p_x will vary as material dissolves or deposits on the electrode. There can be no true equilibrium in this case. However, in the case of an electrode of reasonably large diameter the variation of p_x due to dissolution or deposition will be very small, especially when the electrolyte concentrations are small. If the electrode is reasonably uniform so that all parts of it, including the surface layer, are in thermodynamic equilibrium with one another, equation 1 should hold reasonably well for small changes in stress. If the surface of the electrode which controls the ionic equilibrium consists of largely detached particles of metal so that little of the applied stress is sustained by these surface particles, the observed $\epsilon-\epsilon_0$ will be much less than that calculated. It is also possible that the outer layer, due, say, to work hardening, may be of much greater rigidity than that of the interior material and consequently that the stress sustained by the surface material is appreciably greater than that estimated from the applied force. In this case the observed $\epsilon-\epsilon_0$ may be greater than that calculated from equation 1.

The general trend of the relevant data reported in the literature, that we have seen, appears to be consistent with the views expressed above (cf. Fryxell, R. E. and Nachtrieb, N. H. J. Electrochem. Soc. **99**, 495 (1952)).

A somewhat similar problem has been discussed by Gibbs. In the paragraph following Equation (397) of his "Equilibrium of heterogeneous substances" he appears to have made a slip (!!) when he states, "the fluids in equilibrium with the solid are all supersaturated with respect to the substance of the solid, except when the solid is in a state of hydrostatic stress". This statement is only generally correct when the mean of the principal stresses of the solid is equal to or greater than the hydrostatic stress of the fluid.

APPENDIX

The basic relations may be generalized as follows:

$$dE = T\,dS - \sum P_i\,dV_i + \sum f_j\,dx_j$$

where the terms $\sum P_i dV_i$ are all work terms which are necessarily associated with the reversible addition or removal of material, its nature and state remaining constant during the process, the terms $\sum f_j\,dx_j$ are work terms which are not associated directly with the addition or removal of the material, its nature and state remaining constant.

Thus we can write,

$$\begin{aligned} dE &= T\,dS - \sum P_i\,dV_i + \left[\sum \frac{\partial}{\partial m}\int_{x_{j0}}^{x_j} f_j\,dx_j + \mu_0\right] dm \\ &= T\,dS - \sum P_i\,dV_i + \mu\,dm. \end{aligned}$$

The nature of the work terms $\sum P_i\,dV_i$ are assumed to be such that the integration of the equation holding T, the P_i's, and μ constant has a definite meaning and corresponds to an ideal physical process. Thus we can write,

$$E = TS - \sum P_i\,V_i + \mu m$$

and

$$F = E - TS + \sum P_i\,V_i = \mu m.$$

Evidently,

$$\left(\frac{\partial F}{\partial m}\right)_{T,P_i,x_j} = \left(\frac{\partial E}{\partial m}\right)_{S,V_i,x_j} = \mu$$

$$\left(\frac{\partial F}{\partial x_1}\right)_{T,P_i,m,x_2\ldots} = \left(\frac{\partial E}{\partial x_1}\right)_{S,V_i,m,x_2\ldots} = f_1$$

The condition that the μ's be the same for two separate bodies of matter is equivalent to the condition that in any transfer of matter between the two bodies, $\delta E = 0$ when S and V_i's are constant, and that $\delta E = T\delta S - \text{work}_{(\max)}$ or that $\delta F = 0$, when T and P_i's are constant.

Similar relations hold for other thermodynamic functions, thus all of the equilibrium conditions are contained in the Carnot–Kelvin condition for reversibility.

MICROCALORIMETRY OF THE ADSORPTION OF WATER VAPOR ON SODIUM CHLORIDE[1]

HENRY M. PAPÉE[2] AND KEITH J. LAIDLER

ABSTRACT

Using a microcalorimeter of the Calvet type, measurements have been made of the heats of adsorption of water vapor on microcrystals of sodium chloride, the rate of heat production being followed as a function of time. With crystals of surface areas between 1 and 15 square meters per gram it was found that three distinct processes occurred, in the following order: (1) simple adsorption of water on the surface, (2) decrease in the surface area, and (3) penetration of water into the lattice. During the second stage no adsorption could be detected. On crystals with larger surface areas there was considerable overlapping of the three phenomena, but the general mechanisms appear to be the same.

INTRODUCTION

Detailed studies of the surface enthalpies of sodium chloride crystals have been made by Benson and his co-workers (1, 2, 3), who measured the heat evolved on the solution in water of sodium chloride crystals of high surface area. The mechanism of the adsorption of water vapor on sodium chloride is a matter of considerable importance in connection with the precipitation of rain (4, 5, 6, 7), and in order to gain further knowledge of this phenomenon a microcalorimetric investigation has been made of the heat liberated when water vapor is allowed to come into contact with sodium chloride crystals of various surface areas.

EXPERIMENTAL

Materials

The sodium chloride employed was C.P., and crystals having large specific surface areas were prepared using a special apparatus and technique developed by Young and Morrison (8; cf. also ref. 2, where the same method was employed). The essential feature of the procedure is that vapor is swept from the surface of molten sodium chloride in a turbulent stream of nitrogen and is carried into an electrostatic precipitator, where the small particles are collected. Care was taken to avoid conditions that would lead to the formation of metallic sodium and of sodium nitrate (3), and tests of purity revealed the absence of contamination. The samples of salt were kept at all times in a desiccator, and all manipulations with the material were carried out at 25.0° C in an atmosphere of dry nitrogen of less than one per cent relative humidity.

In some experiments the work was done directly with samples prepared in the electrostatic precipitator. In other cases samples were prepared by controlled sintering, under vacuum at 240° C, of samples prepared in this way. Samples of low areas (from 1 to 2 $m^2 g^{-1}$) were obtained by grinding optical crystals and sieving them to -200 mesh.

Surface areas were measured by the Brunauer–Emmett–Teller method, involving the adsorption of nitrogen at relative pressures below 0.15. Tests showed that the surface areas of the samples remained constant over considerable periods of time.

All samples were heated for 12 hours at 150° C under vacuum.

Microcalorimetry

The heat measurements were carried out in a microcalorimeter of the Tian–Calvet type (9), and the general procedures were as described in previous papers (10, 11)

[1]*Manuscript received May 26, 1958.*

dealing with work with this instrument. A special device which allowed the adsorption to take place under high vacuum was designed and constructed; it is shown schematically in Fig. 1, and further details are given on p. 264 of ref. 12. Essentially it consists of two connecting cells, each one of which is fitted into a silver thimble in the microcalorimeter block. One cell contains the salt and the other, the water and a heat exchanger. When the connections between the two cells are opened the vapor diffuses into the salt, and measurements are made of both the heat evolved in the salt cell and of the heat absorbed in the water cell. The manipulations with the cells could be made from outside the calorimeter by the turning of insulated rods.

Prior to being filled with salt the interior container was outgassed under high vacuum for 5 hours at 250° C, and the whole vacuum circuit was evacuated for 5 hours, after which it was filled with dry nitrogen. The subsequent operations were carried out in a dry box in which the relative humidity was below one per cent. The sodium chloride was introduced into the cell and its weight determined by difference.

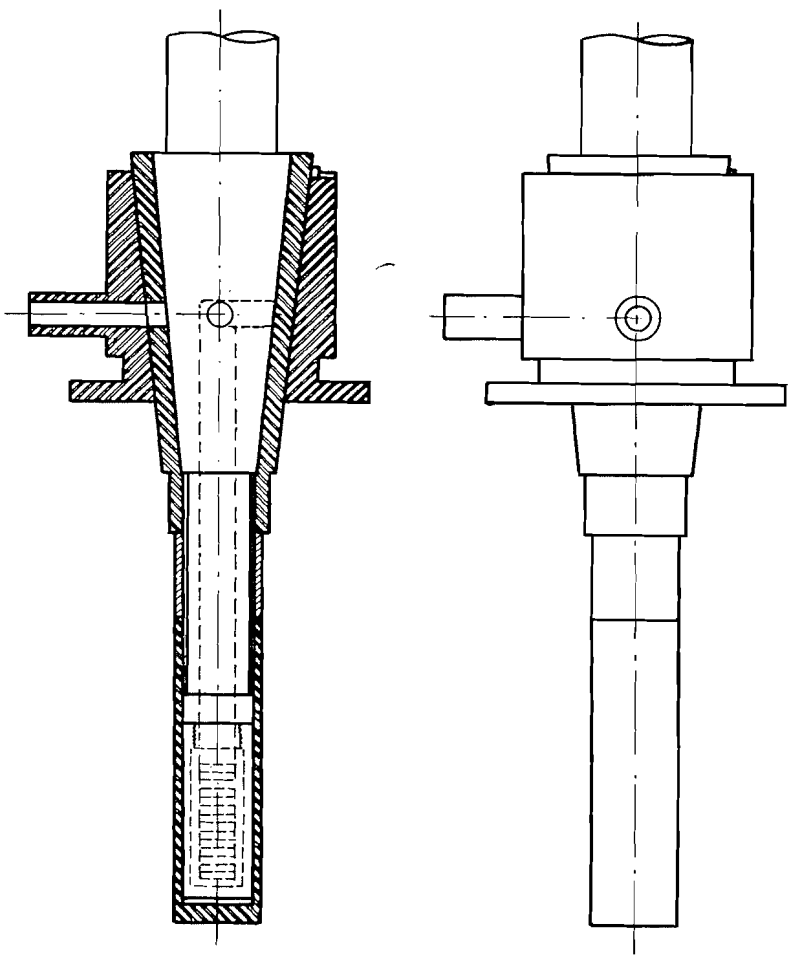

FIG. 1. Schematic representation of a high-vacuum cell for the adsorption studies. At the left is shown a section, at the right an outside view twisted through 90°. Two cells of this type are connected together by thick polythene tubing and inserted into the microcalorimeter block. The turning of valves required to connect and disconnect the two cells is performed by turning an insulated rod which comes out through the top of the apparatus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

After the introduction of the vacuum circuit into the microcalorimeter the water-containing cell was evacuated, left for 10 minutes, and the operation repeated three times. This cell was then sealed off, and the salt-containing cell was pumped down for 4 hours, using a diffusion pump. After the pump was disconnected the salt cell was sealed off and the water cell put into communication with the interconnecting bridge. The whole assembly was then left overnight to attain thermal equilibrium.

On the following day zero readings were taken over a period of several hours, and the cells then put into communication with one another. Separate recordings were made of the heat evolved in the salt cell and of the heat absorbed in the water cell. The values were corrected using results from blank experiments in which the salt container was empty but in which all other operations were identical.

All heat measurements were carried out at $25.00 \pm 0.01°$ C, and the runs were continued for a considerable number of hours in each case. The calorimeter records the rate of heat evolution (Q/t) as a function of time,* and heats are determined by mechanical integration using a planimeter. The values quoted in the present paper are 'thermochemical' calories, equal to 4.1840 joules. The instrument was calibrated electrically.

General Procedure

Two series of experiments were carried out, as follows:

Series 1.—In this group of measurements calorimetric measurements were made using different weights of a given sample of sodium chloride, the surface area being 19.68 $m^2 g^{-1}$.

Series 2.—In this series the work was done with salt samples weighing from 0.4 to 2.0 g but with specific surface areas ranging from 1 to 20 $m^2 g^{-1}$.

Work was done with various degrees of connection between the two cells, and it was found that the most useful results, in which the separate stages were distinctly revealed, were obtained when the rate of diffusion was moderate.

RESULTS

When the rate of diffusion of water vapor into the salt cell is caused to be small, points of discontinuity are observed in the record of Q/t against t for the salt cell, as shown schematically in Fig. 2. By comparing the records for the salt cell and the water cell, and using the known heat of vaporization of water, it is possible to estimate the amount of water that interacts with the salt during each of the separate processes.

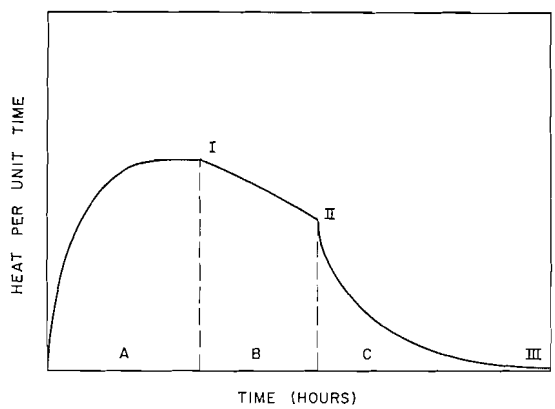

FIG. 2. Schematic plot of rate of heat production against time, showing the two inflection points observed on the microcalorimetric records.

**This is very close to the truth because of the slowness of the process.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

Fig. 2 shows that Q/t at first increases progressively with time until finally a steady value is obtained. This first process is ended by a point of discontinuity after which Q/t decreases gradually until a second point is reached. This second point could be detected only when larger crystals, with surface areas below 15 $m^2\ g^{-1}$, were used. Such points of discontinuity were well defined when the surface area was between 1 and 15 $m^2\ g^{-1}$, but difficult to detect in samples of areas of about 20 $m^2\ g^{-1}$; this was the case in experiments of series 1.

The process can therefore be regarded as occurring in three stages, corresponding to the areas A, B, and C in Fig. 2. Heats corresponding to the three stages were determined by measuring the appropriate areas.

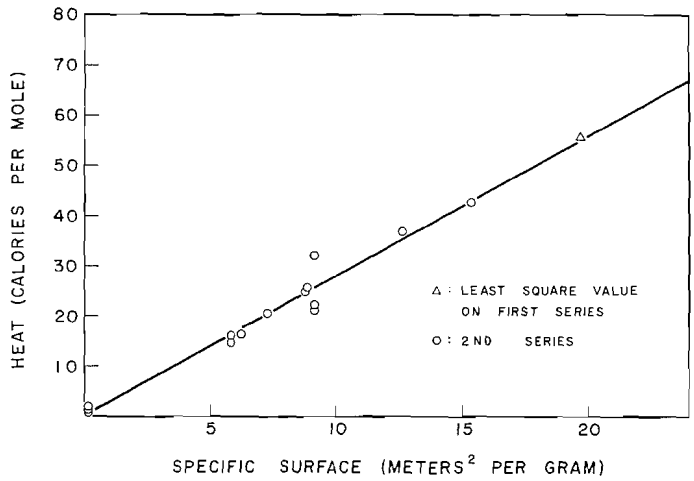

FIG. 3. Plot of heat evolved up to the first inflection point (area A in Fig. 2) against the specific surface area.

TABLE I

HEATS CORRESPONDING TO THE VARIOUS STAGES

Figure	Stage	Series of experiments	Cell	Slope
3	A	1 and 2	Salt	2.77 ± 0.06 (cal $mole^{-1}$)/($m^2\ g^{-1}$) = 0.047 ± 0.001 cal m^{-2}
4	A	1 and 2	Water	-0.75 ± 0.02 (cal $mole^{-1}$)/($m^2\ g^{-1}$) = -0.0128 ± 0.0003 cal m^{-2}
5	A + B	2	Salt	$5.91+0.08$ (cal $mole^{-1}$)/($m^2\ g^{-1}$) = 0.101 ± 0.001 cal m^{-2}
6	A + B	2	Water	-0.76 ± 0.02 (cal $mole^{-1}$)/($m^2\ g^{-1}$) = -0.0130 ± 0.0003 cal m^{-2}
7	C	1	Salt	3.93 ± 0.03 (cal $mole^{-1}$)/($m^2\ g^{-1}$) = 0.0673 ± 0.0005 cal m^{-2}
8	C	1	Water	-1.34 ± 0.17 (cal $mole^{-1}$)/($m^2\ g^{-1}$) = -0.023 ± 0.003 cal m^{-2}

The results are summarized in Figs. 3–10, and in Tables I and II. The figures show plots of heats against either the surface area or the weight of sample, and it is to be seen that reasonably linear behavior is found in both cases. Figs. 3, 5, 7, and 9 refer to the cell in which the salt is contained, and therefore are concerned with heat evolution; Figs. 4, 6, 8, and 10 show results for the cell from which the water was evaporating, and heat is therefore absorbed. The lines in Figs. 3–10 all appear to pass through the origin, and least-square calculations were made in such a way that the line was forced to go through the origin. The resulting slopes, and the standard deviations, are given in Table I. In the case of stage C in the second series of experiments it was found that there was no relationship between the heat and the surface area, but only between the heat and the weight of the sample.

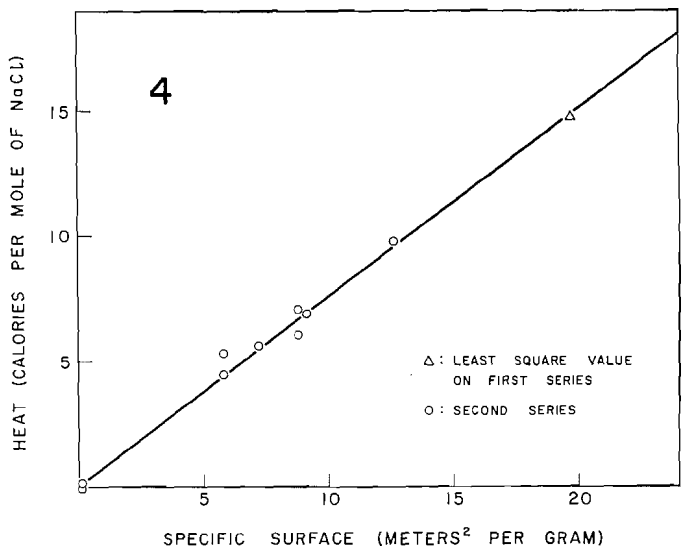

FIG. 4. Plot of heat absorbed up to the first inflection point against the specific surface area, for the cell from which the water was evaporating.

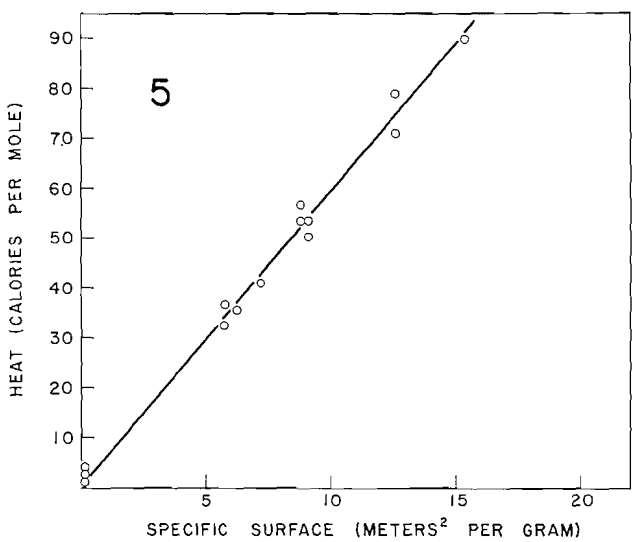

FIG. 5. Plot of heat evolved up to the second inflection point (areas A and B in Fig. 2) against the specific surface area.

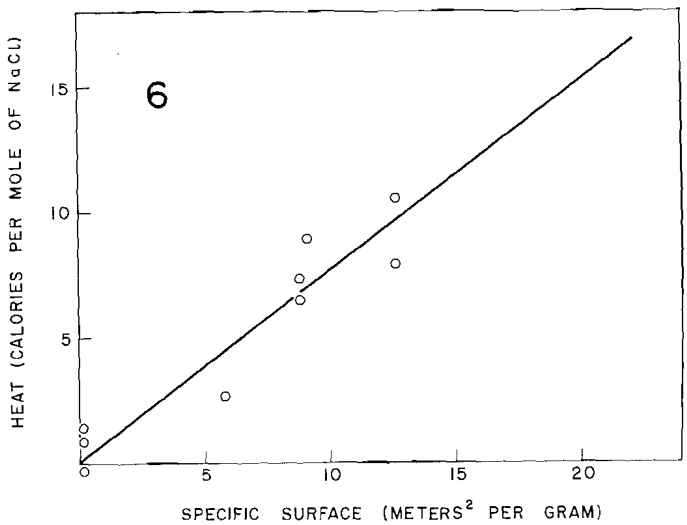

FIG. 6. Plot of heat absorbed up to the second inflection point, for the cell from which the water was evaporating.

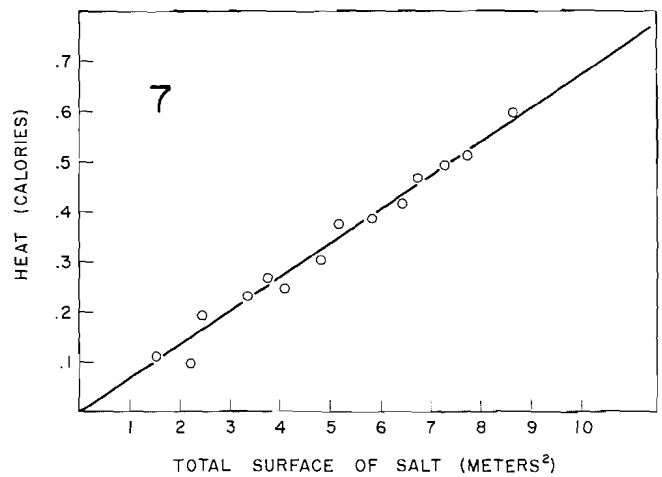

FIG. 7. Plot of heat evolved after the second inflection point (area C in Fig. 2) against the total surface area.

Table II summarizes the main results of the investigation, and shows, for each of the three stages A, B, and C, the heats evolved in the salt cell and absorbed in the water cell.

DISCUSSION

The most striking result of the present investigation is that during stage B there is, within the experimental error, no heat absorbed in the water cell. This means that there is no evaporation of water during the process and therefore no uptake of water by the salt. Stage B thus represents simply a change in the nature of the surface of the salt. The picture that therefore emerges is that the three stages are as follows:

Stage A.—Adsorption of water on the surface of the salt.

Stage B.—Change in the surface area of the salt. Presumably the salt crystals to some extent coalesce, with a decrease in surface area, and during this process there is no uptake of water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

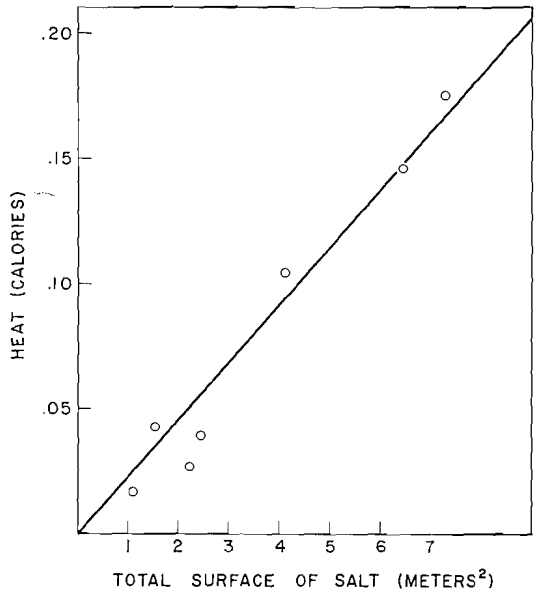

FIG. 8. Plot of heat absorbed after the second inflection point against the total surface area, for the cell from which the water was evaporating.

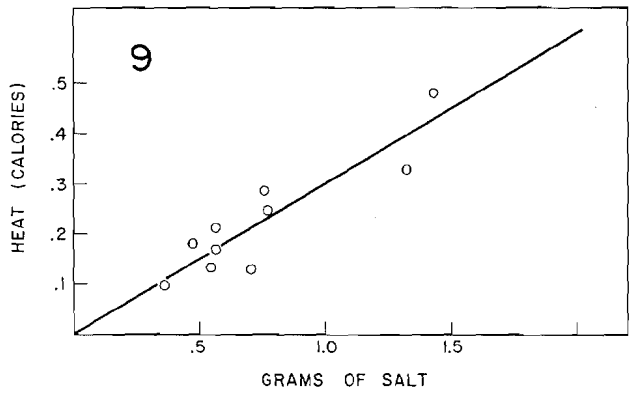

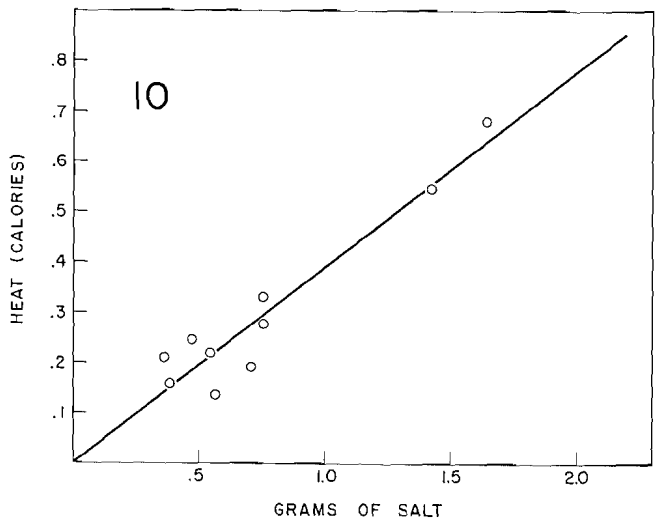

FIG. 9. Plot of heat evolved after the second inflection point against weight of salt.

FIG. 10. Plot of heat absorbed after the second inflection point against weight of salt, for the cell from which the water was evaporating.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Stage C.—Penetration of water into the crystal lattice, and condensation of additional water on the surface.

It is unlikely, however, that the stages are to be distinguished sharply. Thus the heat evolved in the salt cell during stage A is equal to about 36 kcal per mole of water, and this is too large to correspond to a simple physical adsorption; presumably some change in the surface is occurring at the same time.

It is significant that during stages A and B the heat evolution is proportional to the surface area; the heats per unit area were found to be uninfluenced by whether the material was prepared by electrostatic precipitation, by sintering, or by grinding. However, the magnitude of the heat evolved in stage C is proportional to the total weight of the sample and not to the surface area. These facts are consistent with the mechanisms proposed above for the three stages. During stage C the crystals are considered to have undergone a pronounced change in surface area, and the heat is therefore independent of the initial areas.

The amount of water evaporated in stage A, estimated from the heat absorption and the latent heat of evaporation, is found to be about one twelfth of that required to form a monolayer.* The significance of this may well be that this is the amount required to induce the crystals to undergo a structural change in which a decrease of surface occurs.

It is of interest to compare the results obtained in the present work with the value of Benson *et al.* (3) for the total surface energy of sodium chloride. Their value is

$$0.0659 \text{ cal m}^{-2}.$$

This value is seen from Table II to be greater than the value for stage A (0.047 cal m^{-2}) but less than the sum of the values for stages A and B (0.101 cal m^{-2}). This result further suggests that stages A and B are not sharply separated from one another, although it would appear that all of the surface has been broken down by the end of stage B.

ACKNOWLEDGMENTS

The authors are indebted to Mr. T. W. Zawidzki for preparing the sodium chloride of high surface area, and for help in many other ways. They are also indebted to Drs. G. C. Benson and J. A. Morrison of the National Research Council for the use of their electrostatic precipitator and for much help and valuable advice. Thanks are also due to Professor M. Proulx for the preparation of Fig. 1.

The work was performed under a contract between the U.S. Air Force Cambridge Research Center and the University of Ottawa.

**This estimate is based on a value of 10.6 Å² for the area occupied by each water molecule; a monolayer would therefore consist of 9.43×10^{18} molecules or 2.82×10^{-4} g of water per square meter. The heat absorbed in the water cell during stage A was 1.28×10^{-2} cal per square meter of salt. This corresponds to the evaporation of 2.33×10^{-5} g of water.*

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

IV. SUR LA RÉACTION DE CES SELS AVEC LA 2,5-DIHYDROXY-*p*-BENZOQUINONE ET LA SYNTHÈSE DE LA 3-HYDROXY-2,5-BISPHENYL-*p*-BENZOQUINONE[1]

P. BRASSARD[2] ET P. L'ÉCUYER

RÉSUMÉ

L'accumulation des fonctions phénoliques sur l'anneau de la *p*-benzoquinone rend la molécule particulièrement apte à la copulation avec les sels de diazonium au détriment de l'arylation. La réaction de la 2,5-dihydroxy-*p*-benzoquinone avec ces sels donne, en solution aqueuse et en présence d'un excès de 25% de la quantité stoechiométrique d'hydroxyde de potassium, la 2,5-dihydroxy-3-phénylazo-*p*-benzoquinone. Lorsqu'on effectue la réaction en présence d'au moins deux fois la quantité calculée de la base, on isole la 2,5-dihydroxy-3-phényl-6-phénylazo-*p*-benzoquinone. La 2,5-dihydroxy-3,6-bis-(*o*-tolyl)-*p*-benzoquinone est la seule 2,5-dihydroxy-3,6-bisaryl-*p*-benzoquinone que nous avons réussi à synthetiser par cette réaction. Au cours de nos travaux nous avons synthétisé la 3-hydroxy-2,5-bisphényl-*p*-benzoquinone selon un autre procédé décrit dans la partie expérimentale.

INTRODUCTION

La synthèse de la 2,5-dihydroxy-3,6-bisphényl-*p*-benzoquinone ou acide polyporique (1) et de ses dérivés naturels, l'atromentine (2) et la leucomélone (3) a été, jusqu'à présent, l'objet d'un certain nombre de travaux. Fichter (4) a d'abord réalisé la préparation de l'acide polyporique et Kögl (5) celle du diméthyléther de l'atromentine avec des rendements respectifs de 0.14 et 1.28%. Adams (6), Asano et Kameda (7), Kvalnes (8), Ghigi (9) et Fieser et Oxford (10) publièrent d'autres synthèses de l'acide polyporique, et Akagi (3) réalisa celle de la leucomélone.

Il est relativement difficile d'obtenir la 2,5-dichloro- et les 2,5-bisaryl-*p*-benzoquinones (11), les intermédiaires indispensables à la préparation des 2,5-dihydroxy-3,6-bisaryl-*p*-benzoquinones. Pour cette raison, il nous a semblé opportun de tenter d'obtenir directement ces dernières à partir de la 2,5-dihydroxy-*p*-benzoquinone en utilisant une technique analogue à celle qu'a suivie Neunhoffer (12) pour l'arylation de la 2-hydroxy-1,4-naphtoquinone avec les sels de benzène-diazonium.

La 2,5-dihydroxy-*p*-benzoquinone se prépare avec grande facilité par la méthode de Jones et Shonle (13), mais l'accumulation des fonctions phénoliques sur l'anneau de la quinone rend la molécule particulièrement apte à la copulation avec les sels de diazonium au détriment de l'arylation.

Lorsqu'on fait réagir une solution aqueuse du chlorure de diazonium avec de la 2,5-dihydroxy-*p*-benzoquinone dissoute dans de la potasse contenant 25% d'hydroxyde de potassium en excès de la quantité stoechiométrique et qu'ensuite on acidifie légèrement le mélange (pH = 5) par l'addition d'acide acétique, une certaine quantité de substances indésirables précipitent. Si on filtre alors et acidifie fortement le filtrat (pH = 2) avec de l'acide chlorhydrique on obtient la 2,5-dihydroxy-3-arylazo-*p*-benzoquinone. Il est nécessaire d'employer un excès de 25% de la quantité calculée d'hydroxyde de potassium, car autrement le rendement diminue considérablement.

Influence de la température de réaction et de la concentration d'hydroxyde de potassium

Lorsqu'on effectue la réaction du sel de diazonium avec la 2,5-dihydroxy-*p*-benzoquinone en présence de deux fois la quantité théorique d'hydroxyde de potassium, on isole de la même façon que précédemment, une autre classe de composés, soit les

[1]*Manuscrit reçu le 9 juin, 1958.*
Contribution du Département de Chimie, Université Laval, Québec, P.Q.
[2]*Adresse actuelle: Chemisches Institut der Universität, Zürich, Suisse.*

2,5-dihydroxy-3-aryl-6-arylazo-*p*-benzoquinones. En élevant la température de réaction de 50 à 85°, et en augmentant en même temps la concentration de la base jusqu'à un excès de 200%, on obtient encore les mêmes substances. Le seul effet de ces variations croissantes de la température et de la concentration de la base est de faire baisser proportionnellement les rendements (Tableau I).

TABLEAU I

INFLUENCE DE LA TEMPÉRATURE DE RÉACTION ET DE LA CONCENTRATION D'HYDROXYDE DE POTASSIUM

Réaction du chlorure de benzène-diazonium (0.1 mole) avec la 2,5-dihydroxy-*p*-benzoquinone (0.05 mole) en solution aqueuse (600 ml)

Température	% d'excès de KOH	Rendement, en %
45–50°	100	28
45–50°	150	18
45–50°	200	11
80–85°	100	20

Influence du substituant dans le sel de diazonium

Dans la synthèse des dihydroxyarylazoquinones comme dans la préparation des 2-hydroxy-3-aryl-1,4-naphtoquinones en milieu alcalin, la réactivité des sels de diazonium semble être l'inverse de celle qui se manifeste lors de la réaction normale avec la *p*-quinone en l'absence de base. Dans ce dernier cas la stabilité du sel de diazonium favorise l'arylation de la quinone non-hydroxylée. Par contre, lors de la réaction avec la 2-hydroxy-1,4-naphtoquinone d'après la méthode de Neunhoffer, l'*o*-toluidine diazotée donne un rendement de 65%, tandis que le chlorure de *p*-chlorobenzène-diazonium n'en fournit plus qu'un de 40%.

Nous avons observé la même relation dans la réaction des sels de diazonium avec la 2,5-dihydroxy-*p*-benzoquinone en milieu alcalin. Les meilleurs résultats ont été obtenus avec la *m*-toluidine diazotée tandis que le rendement est nul avec la chlorure de *p*-chlorobenzène-diazonium.

Dans un cas seulement, il nous a été possible de synthétiser une 2,5-dihydroxy-3,6-bisaryl-*p*-benzoquinone par cette réaction. C'est en utilisant un sel de diazonium particulièrement instable, le chlorure d'*o*-methylbenzène-diazonium, et en employant des quantités équimoléculaires de la quinone et du réactif diazoique. Nous avons alors obtenu la 2,5-dihydroxy-3,6-bis-(*o*-tolyl)-*p*-benzoquinone avec un rendement de 32%.

Enfin nous avons synthétisé la 3-hydroxy-2,5-bisphényl-*p*-benzoquinone, à partir de la 2,5-bisphényl-*p*-benzoquinone, en suivant la façon de procéder décrite dans la partie expérimentale.

PARTIE EXPÉRIMENTALE*

2,5-Dihydroxy-3-phénylazo-p-benzoquinone

On diazote de la façon habituelle de l'aniline (9.3 g, 0.10 mole) dissoute dans une solution diluée d'acide chlorhydrique (25 ml d'acide concentré dans 100 ml d'eau). On ajoute lentement (l'opération doit durer 5 minutes), la solution du sel de diazonium à une solution de 2,5-dihydroxy-*p*-benzoquinone (7.0 g) et d'hydroxyde de potassium (20.0 g) dans l'eau (500 ml) tout en maintenant la température entre 45 et 50° et en agitant vigoureusement. On continue d'agiter pendant 20 minutes à la même température. On

**Les points de fusion ont été pris à l'aide de l'appareil de Johns.*

For personal use only.

dilue alors à environ 1 litre, et on acidifie à pH = 5 avec de l'acide acétique. On filtre, on rend le filtrat fortement acide par l'addition d'acide chlorhydrique et on essore le précipité. Après deux cristallisations dans le dioxane, la 2,5-dihydroxy-3-phénylazo-*p*-benzoquinone (6.2 g, 51% de la théorie), aiguilles rouges, contient du dioxane de cristallisation. Elle perd ce dioxane par séchage sous vide à 60° en se transformant en une poudre rouge vif qui se décompose entre 220 et 225°. Calculé pour $C_{12}H_8O_4N_2$: C, 59.02%; H, 3.30%; N, 11.46%. Trouvé: C, 59.0%; H, 3.3%; N, 11.2%.

2,5-Dihydroxy-3-(o-tolylazo)-p-benzoquinone

On opère exactement comme précédemment. Après deux cristallisations dans le dioxane on obtient 8.4 g (65% de la théorie) de 2,5-dihydroxy-3-(*o*-tolylazo)-*p*-benzoquinone pure sous la forme d'aiguilles brun-rouge. Après avoir éliminé le dioxane de cristallisation par chauffage sous-vide à 60° pendant 3 heures, la substance devenue pulvérulente est de couleur rouge foncé et se décompose entre 225 et 228°. Calculé pour $C_{13}H_{10}O_4N_2$: C, 60.46%; H, 3.90%; N, 10.81%. Trouvé: C, 60.7%; H, 3.8%; N, 10.7%.

2,5-Dihydroxy-3-phényl-6-phénylazo-p-benzoquinone

On procède comme pour la préparation de la 2,5-dihydroxy-3-phénylazo-*p*-benzoquinone sauf qu'on utilise 40.0 g d'hydroxyde de potassium au lieu de 20.0 g. On essore 6.9 g de produit brut. Par cristallisation dans le dioxane on obtient 4.5 g (28%) de 2,5-dihydroxy-3-phényl-6-phénylazo-*p*-benzoquinone pure sous la forme de fines aiguilles orangées. Elle se sublime au-dessus de 200°. P.f. 256–257°. Calculé pour $C_{18}H_{12}O_4N_2$: C, 67.49%; H, 3.78%; N, 8.85%. Trouvé: C, 67.7%; H, 4.0%; N, 8.9%.

2,5-Dihydroxy-3-(m-tolyl)-6-(m-tolylazo)-p-benzoquinone

On suit le même mode opératoire que pour la préparation précédente. On obtient ainsi 11.5 g de produit brut, qui après cristallisation dans le dioxane, donne 8.4 g (48% de la théorie) de 2,5-dihydroxy-3-(*m*-tolyl)-6-(*m*-tolylazo)-*p*-benzoquinone pure sous la forme d'aiguilles rouge-brun. Elle contient du dioxane de cristallisation. Elle le perd par chauffage sous vide à 60° et se transforme en une poudre brune qui se sublime au-dessus de 200°. P.f. 224–225°. Calculé pour $C_{20}H_{16}O_4N_2$: C, 68.95%; H, 4.63%; N, 8.04%. Trouvé: C, 69.2%; H, 4.6%; N, 8.0%.

2,5-Dihydroxy-2,6-bis-(o-tolyl)-p-benzoquinone

En procédant comme pour la synthèse de la 2,5-dihydroxy-3-phénylazo-*p*-benzoquinone, mais en employant 30.0 g d'hydroxyde de potassium au lieu de 20.0 g, on obtient une substance que l'on cristallise une première fois dans un mélange de dioxane et d'éthanol (1:1) et une deuxième fois dans un peu de dioxane. La 2,5-dihydroxy-3,6-bis-(*o*-tolyl)-*p*-benzoquinone pure se présente sous la forme d'aiguilles jaunes. On se débarrasse des molécules de solvant de cristallisation par chauffage sous vide à 60°. Transformée en une poudre brun-pâle, la 2,5-dihydroxy-3,6-bis-(*o*-tolyl)-*p*-benzoquinone se sublime au-dessus de 200°. P.f. 243–244°. Calculé pour $C_{20}H_{16}O_4$: C, 74.98%; H, 5.03%. Trouvé: C, 75.1%; H, 5.0%.

3-Hydroxy-2,5-bisphényl-p-benzoquinone

On laisse reposer, pendant 24 heures, un mélange d'anhydride acétique (100 ml), de 2,5-bisphényl-*p*-benzoquinone (10.0 g) et d'acide perchlorique à 40% (10 gouttes). On verse alors le mélange dans 1000 ml d'eau froide, on essore le précipité, on le dissout dans le méthanol (100 ml), on ajoute de l'acide chlorhydrique concentré (5 ml) et on bout à reflux pendant 1 heure. On refroidit la solution, on la rend alcaline par l'addition d'une solution diluée d'hydroxyde de sodium et on dilue avec de l'eau à environ 500 ml.

For personal use only.

Le 1,3,4-trihydroxy-2,5-bisphényl-benzène s'oxyde alors spontanément à l'air. Après quelques minutes on filtre et avec de l'acide chlorhydrique dilué on acidifie à pH = 3. La 3-dihydroxy-2,5-bisphényl-*p*-benzoquinone cristallise dans le dioxane en longues aiguilles rouges qui contiennent des molécules de solvant. Elle effleurit à l'air pour donner une poudre rouge qui se sublime au-dessus de 200° sans fondre. Le rendement pour les trois étapes est excellent. Calculé pour $C_{18}H_{12}O_3$: C, 78.25%; H, 4.38%. Trouvé: C, 78.3%; H, 4.1%.

REMERCIEMENTS

LIGHT ABSORPTION STUDIES

PART XI. ELECTRONIC ABSORPTION SPECTRA OF NITROBENZENES[1]

W. F. Forbes

ABSTRACT

The spectra of nitrobenzenes are discussed in terms of previously proposed hypotheses relating electronic interactions and ultraviolet absorption spectra.

INTRODUCTION

In previous parts of this series it was proposed that *B*- and *C*-bands of a large number of benzene derivatives are determined mainly by mesomeric and steric interactions and only to a lesser extent by other factors. These hypotheses, which, if true, have important implications, are consistent with a large body of data. For example, whenever primary mesomeric interactions or steric effects are assumed to operate, the spectral changes are normally much larger than the spectral changes which are ascribed to other interactions, such as field effects, inductive effects, and various types of solvent–solute interactions. The present purpose is to extend these hypotheses to nitrobenzenes. The substituent in nitrobenzene possesses a negative mesomeric effect. However, this negative mesomeric effect is greater in nitro-compounds than in the previously studied acetophenones and benzoic acids, and other interactions may also play a different part.

The spectra of nitrobenzenes have recently been described by a number of workers (for example, 1, 2, 3, 4, 5), and the spectra have been noted to cause anomalous effects (6, 7; cf. also the greater ethylenic stretching frequency at 1600 cm^{-1} in nitrobenzenes (8*a*), and the absence of the usual correlations for C–H bending vibrations in the region 1000–650 cm^{-1} (8*c*)).

ULTRAVIOLET ABSORPTION SPECTRA

Nitrobenzene

The ultraviolet absorption spectra of nitrobenzene in different solvents are listed in Table I.

A broad symmetrical absorption band, structureless even in the gas phase (3), occurs near 260 mμ, which is classified as the *B*-band, by analogy with the *B*-band near 240 mμ in acetophenones. The bands are of comparable intensity and undergo parallel changes on alteration of the dielectric constant or polarity of the solvent. The nitrobenzene band at 260 mμ will also be shown to be highly susceptible to steric effects, causing hypsochromic shifts and reduced absorption intensities, which represents a characteristic property of the *B*-band in acetophenones and benzoic acids (11).

Next, no appreciable concentration dependence could be discerned for various nitrobenzene solutions. This indicates that nitrobenzene is apparently not appreciably associated in solution within the investigated concentration range (see Table I). The observed bathochromic wavelength displacement with increased dielectric constant of the solvent is parallel, but more pronounced for nitrobenzene than for acetophenone. This suggests increased solvent stabilization of the excited state relative to the ground state and may be related to the greater contribution of dipolar excited states in nitrobenzene (cf. also ref. 3). Change of pH of the solution does not cause any additional wavelength shift,

*This series of papers.

which emphasizes the importance of the dielectric constant, compared with the presence or absence of hydrogen ions in determining the location of the *B*-band. On the other hand, media of high acidity, such as sulphuric acid (see Table I and ref. 3), have a marked effect on the spectrum.

Further, the *B*-band of nitrobenzene lies at considerably longer wavelength than that of acetophenone. Since the *B*-band of monosubstituted benzenes is predominantly determined by mesomeric interaction (cf., for example, ref. 12), it follows that in the absence of other considerations the nitro-group would be expected to exert a greater negative mesomeric interaction than the acetyl-group and in this way nitrobenzene absorbs at longer wavelength. It may be noted that the large mesomeric effect of the nitro-group can be used to explain the large frequency shift of the C–H bending vibration in nitrobenzene (13), and also the extremely high intensity of the R–NO_2 stretching vibration (8*f*) and the enhanced intensities of the aromatic bands at 1600–1500 cm^{-1} for nitrobenzenes (8*b*), since absorption intensities in the infrared region are probably largely proportional to resonance interaction (14, 15).

The *C*-band in nitrobenzene is identified only with difficulty. This is explained by the hypothesis (11) that a large mesomeric effect causes a low intensity *C*-band. There is little doubt that this band corresponds to the band in benzene at *ca.* 260 mμ (9, 11).

Para-Substituted Nitrobenzenes

The ultraviolet absorption spectra of some para-substituted nitrobenzenes are listed in Table II.

Para-disubstituted compounds provide a good method of studying mesomeric interactions because inductive-type interactions and steric effects may be assumed to be small (12) for a number of compounds of this type, and if the para-substituent is electron donating, a large mesomeric interaction would be expected. The data for this type of

*This series of papers.

compound, as discussed in the following paragraph, are in fact consistent with the hypothesis that a mesomeric type of interaction predominantly determines the spectra and that inductive and other types of interactions are again only of secondary importance (cf. Introduction). To investigate this mesomeric interaction, the data in Table II are first divided into two groups. The first group comprises the earlier values in Table II which do not show any appreciable mesomeric interaction. This is either because acid conditions prevent mesomeric interaction, as for *p*-nitroaniline in acid solution, or alternatively because primary mesomeric interaction may be negligible, as for *p*-dinitrobenzene, where by analogy with the electron-withdrawing properties of the nitro-group in the ground state, neither of the two nitro-substituents would be expected to act effectively as an electron donor in the electronic excited state.

For the latter type of example, moreover, both para-substituents will also tend to deactivate the benzene ring, that is, cause a withdrawal of π-electrons from the benzene

ring. This latter deactivation is also suggested by other data. For example, the carbonyl stretching frequencies in dilute chloroform solution for *p*-nitrobenzaldehyde (λ_{max} 1721 cm^{-1} (8*d*)) and *p*-nitroacetophenone (λ_{max} 1700 cm^{-1} (12)) are considerably displaced from those of benzaldehyde (λ_{max} 1709 cm^{-1}) and acetophenone (λ_{max} 1691 cm^{-1}) (12). This indicates that at least some of the conjugation, which causes the initial shift to lower frequency in aromatic carbonyl compounds, because of the aromatic nucleus, is no longer available. Although this argument again is evidently applicable only to the ground state, it is not unreasonable to assume that a similar deactivation occurs in the electronic excited state. Consequently, the carbonyl stretching frequencies data indirectly support the hypothesis. The supposed absence of mesomeric interaction may also be related to Hammett's observation (20) that for nitrobenzenes two different substitution constants must be used (cf. also ref. 21). Further, ultraviolet data indicate a reduced force constant in the N-nuclear bond for compounds like *p*-dinitrobenzene, since an increased extinction coefficient, as is observed in the early examples of Table II relative to nitrobenzene, may be ascribed to a reduced force constant. A number of similar examples have previously been discussed (22) and the relation between a reduced force constant and an increased extinction coefficient *in the absence of primary mesomeric interaction* has previously been suggested as a "secondary" effect in electronic spectra (22) and this hypothesis accounts well for the observed spectral changes. For example, the para-formyl group is assumed to decrease the double-bond character of the N-nuclear bond and in this way decreases the force constant of this bond, and hence increases the molecular

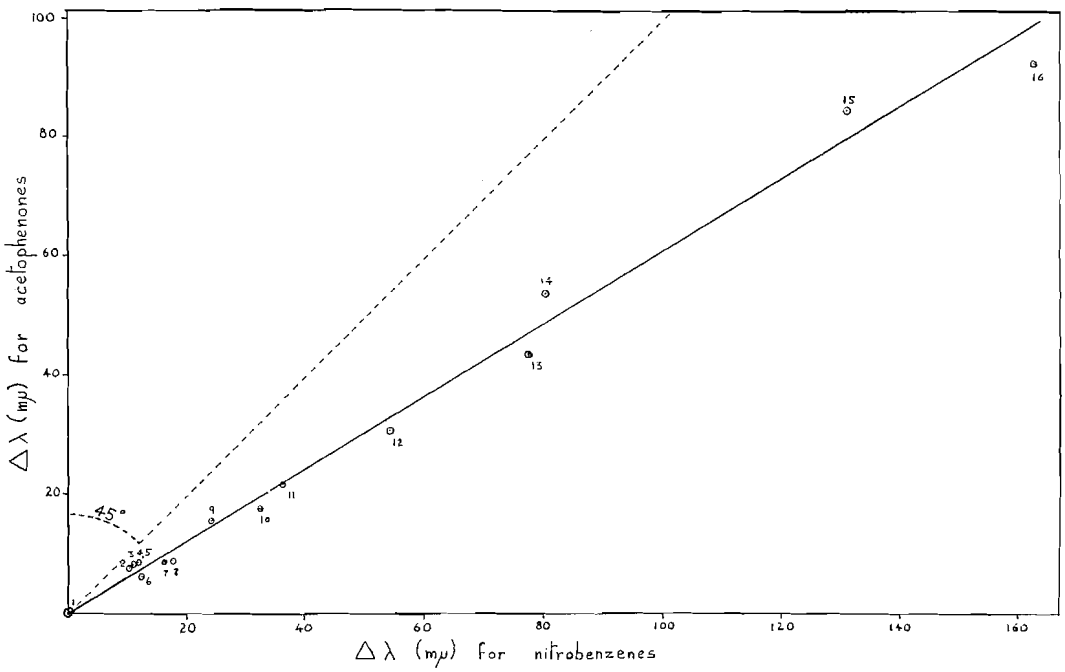

FIG. 1. Wavelength shifts ($\Delta\lambda$) of the *B*-band obtained on introducing a para-substituent in nitrobenzene and acetophenone. 1—H (gas phase); 2—Me (gas phase); 3—Et (gas phase); 4—*i*-Pr (gas phase); 5—*t*-Bu (gas phase); 6—H (hexane); 7—F (iso-octane, hexane); 8—H (ethanol); 9—Me (iso-octane, hexane); 10—Cl (95% ethanol, ethanol); 11—Br (95% ethanol, ethanol); 12—I (95% ethanol, ethanol); 13—OH (aqueous acid); 14—NH_2 (hexane, naphtha); 15—NH (ethanol); 16—OH (aqueous base). Values obtained from Table II, ref. 3, and previous papers in this series.

extinction coefficient. This decreased force constant may incidentally explain the relatively more pronounced *C*-band in compounds like *p*-nitroacetophenone (see Table II and ref. 11) compared with the *C*-band in nitrobenzene.

For the second group of data in Table II the primary mesomeric interaction which predominantly affects the electronic excited state is supposed to be the main factor determining the maximal wavelength of the *B*-band. In support of this hypothesis the following may be cited. First, an increased dielectric constant in the para-substituted nitrobenzenes, where primary mesomeric interaction is supposed to occur, causes bathochromic displacements parallel, but usually more pronounced, to those observed for nitrobenzene itself (see Tables I and II). This suggests that both changes are related to one and the same, mesomeric, interaction. Next, Fig. 1 shows that the wavelength displacements, and consequently the energy changes, for acetophenones and nitrobenzenes tend to be directly proportional to each other whenever mesomeric interaction is assumed to determine the *B*-band. This again is consistent with the hypothesis that both wavelength displacements are proportional to one electronic interaction, which is predominantly mesomeric in character.

The slope of the straight line obtained in Fig. 1 also indicates that mesomeric interaction is greater in nitro-compounds. This is ascribed to increased resonance contributions of dipolar excited states in nitrobenzene because of the greater negative mesomeric effect of the nitro-group. Two additional points may be noted. First, although the concept of resonance structures is implied in this discussion, molecular orbital theory provides, at least qualitatively, a similar picture (cf. ref. 9). Secondly, intensity values (ϵ) of para-substituted compounds compared to intensity values of unsubstituted compounds (ϵ_0) are less suitable than wavelength changes in the study of mesomeric interactions. This follows not only because overlapping of bands may interfere with the quantitative estimation of absorption intensities, but also because intensity values are more sensitive to other, secondary, interactions, such as slight changes in the force constant of the N-nuclear bond caused by solvent–solute interactions.

Meta-Substituted Nitrobenzenes

The spectra of meta-substituted nitrobenzenes are listed in Table III.

In meta-substituted nitrobenzenes primary mesomeric interaction between the meta-substituents is theoretically impossible and hence the observed *B*-bands would be expected to correspond to the *B*-bands of the two monosubstituted parent compounds. This explanation is taken to account for the frequent occurrence of two distinct *B*-bands in a meta-disubstituted benzene derivative. This is illustrated by some of the data in Table III, and the band assignment is also supported by a number of unpublished data. One of the *B*-bands, the nitrobenzene *B*-band, is usually identified without difficulty for the compounds listed in Table III. The second *B*-band is ascribed to benzenoid absorption involving the non-nitro substituent. It may be noted in passing that Doub and Vandenbelt sometimes designate this second *B*-band as a "secondary primary band" (7). For example, the maximal absorption at 251.5 mμ for *m*-nitrophenol is assumed to be a secondary primary band, whereas we would ascribe this absorption to phenolic *B*-band absorption.

However, the observed *B*-bands will not necessarily correspond closely to the *B*-bands of the mono-substituted parent compounds, since a secondary interaction also occurs between the two substituents in meta-substituted compounds. This interaction has previously been discussed in general terms (25), and we will therefore at present consider

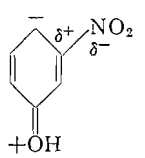
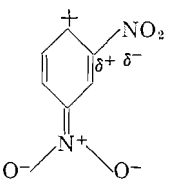
Table IV shows that a meta-nitro substituent indeed affects the absorption band, usually giving rise to an appreciable displacement. This displacement is positive or negative, presumably depending on the dipolar forms contributing to the electronic excited state. In this way, a nitro-group apparently exerts a negative wavelength displacement on chromophores like acetophenone or nitrobenzene, but a positive wavelength displacement on chromophores like anisole or phenol. The different effect of the nitro-group in meta-disubstituted benzene derivatives may be rationalized by assuming that either structure I or II may preferentially contribute to the electronic excited state. Assuming structures of this type, one may visualize the way in which the formation of a positive or negative charge near the *m*-nitro-group may have opposite effects, as illustrated for *m*-nitrophenol and *m*-dinitrobenzene. The relatively large extinction coefficients, which are noted in the *B*-band of the meta-substituted nitrobenzenes listed in Table IV, are again tentatively ascribed to a reduced force constant caused by the electron-withdrawing effect of the nitro-substituent (cf. ref. 22).



I



II

The nitrobenzene *B*-band is evident in most of the compounds listed in Table III, and is subject to the usual secondary interactions. One of these, the buttressing effect, would be expected to occur in meta-substituted nitrobenzenes (cf. ref. 26), and this effect would be expected to be greatest for *m*-dinitrobenzene. In this way, the buttressing effect may contribute to the variation in the observed wavelength displacement (see Table IV). The *C*-band in meta-substituted nitrobenzenes usually becomes more pronounced, an observation which has previously received an explanation (11).

*This series of papers.

The ortho-effect of alkyl groups in nitrobenzenes has previously been ascribed to steric inhibition of resonance (1) and it was noted that the decreased intensity of absorption is qualitatively in agreement with the increased size of the substituent, i.e. *t*-butyl > *i*-propyl > methyl. For alkylnitrobenzenes in iso-octane solution a hypsochromic shift is also observed compared with the wavelength of maximal absorption in the meta-isomers. This is explained by assuming that in certain ortho-isomers not only does the alkyl group fail to contribute to mesomeric interaction between the two substituents,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

but the vicinal alkyl-group also causes the nitro-group to twist about the C–NO_2 axis. Consequently, absorption in the ortho-isomer occurs at shorter wavelength, and with decreased absorption intensity (cf. ref. 25, 27).

By considering the two types of *B*-bands in ortho-isomers (cf. preceding section), we can further relate changes in the *B*-bands with the ease of dislodging a particular group from the plane of the benzene ring. For example, in *o*-nitrophenol (basic solution) the band corresponding to nitrobenzene occurs at λ_{max} 282 mμ, ϵ = 4300, similar in intensity to the band in *m*-nitrophenol, which occurs at λ_{max} 291 mμ, ϵ = 4500. The other *B*-band, which occurs in the meta-isomer at λ_{max} 251.5 mμ, ϵ = 11,000, and which is ascribed to the phenolate ion, occurs in the ortho-isomer only as an inflection at 250 mμ, ϵ = 5000. This suggests that the $-O^-$ substituent is more readily dislodged from the plane of the benzene ring than the nitro-group.

The ease of dislodging a particular group from the plane of the benzene ring may also depend on the solvent. This is illustrated in Fig. 2 for the spectrum of *o*-nitrobenzoic acid.

Fig. 2 shows that the nitrobenzene *B*-band in aqueous medium is more pronounced

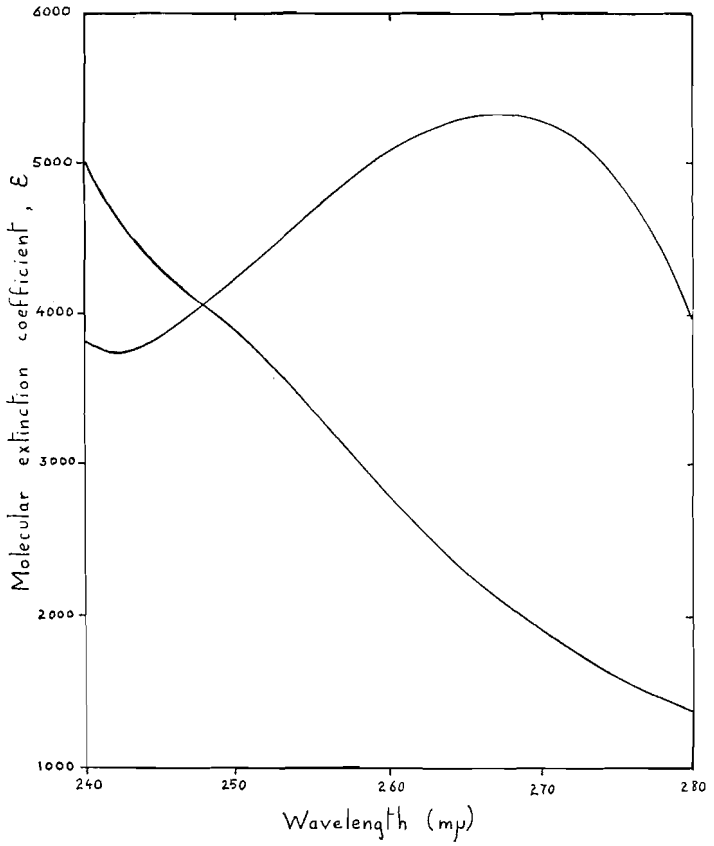

FIG. 2. The *B*-band (nitrobenzene band) of *o*-nitrobenzoic acid in 1—water; 2—cyclohexane containing 2% ether. Strictly speaking, for comparison purposes, the spectrum should have been determined in acidified aqueous solution, since in water the molecule will actually absorb as the anion and not as the undissociated acid. (We are grateful to a referee for drawing our attention to this.) However, in fact, the spectrum in acidified water also shows a similar maximum (see Table V) undergoing only the usual displacement associated with the change from neutral to acidic medium (cf. ref. 25).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

and, as such, more readily recognized. This has some application from an analytical point of view (see next section). It can be explained by assuming that in aqueous solution the nitrobenzene band is strengthened at the expense of benzoic acid coplanarity. This explanation may be related to the appreciable wavelength displacement observed for nitrobenzene absorption on passing from hexane to ethanol and water, since this also suggests solvent–solute interaction between the nitro-group and the solvent. In terms of the previously proposed classification of steric effects (cf. ref. 12 and references cited there), this observation implies that *in aqueous solutions ortho-substituted nitrobenzenes will more frequently give rise to type I steric effects* (that is, an intensity decrease without appreciable wavelength displacement will be observed), *whereas in hexane media other steric effects will often be observed.*

As expected, steric interactions in ortho-substituted nitrobenzenes are also evident from a number of other physical data (cf. also ref. 5). For example, while the characteristic Raman frequency of the nitro-group is around 1367 cm^{-1}, in nitrobenzene the interaction of the nitro-group with the aromatic nucleus causes a frequency drop to 1341 cm^{-1}. In *o*-nitrotoluene some of this interaction is destroyed, and absorption again occurs at higher frequency (1345 cm^{-1}). In nitromesitylene the interaction is almost completely destroyed and the frequency occurs at 1363 cm^{-1}, close to the frequency of the unconjugated nitro-group (28; cf. also refs. 29, 30). This latter absorption may be compared with the ultraviolet absorption of nitromesitylene (1), which also indicates the virtual absence of conjugation.

Apart from steric interactions, the operation of other forces, especially intermolecular hydrogen bonding, would be expected to be evident in ortho-substituted nitrobenzenes. Examples of intermolecular hydrogen bonding may be provided by the nitrobenzene *B*-bands of nitrophenol and nitroanisole. In ethanol, the meta-isomers absorb maximally within 3 mμ (see Table III), whereas the corresponding ortho-isomers show a bathochromic shift of 14.5 mμ for the phenol (see Table V). It may be noted that this wavelength displacement is qualitatively similar to the displacement observed in the corresponding acetophenones (11) and that intramolecular hydrogen bonding in nitrobenzenes is also suggested from infrared data (cf. refs. 8*d*, 31).

The *C*-band of ortho-substituted nitrobenzenes again is normally more pronounced than that of the corresponding para-isomers, but tends to disappear in compounds where steric inhibition of resonance is large (11).

APPLICATIONS

Since the negative mesomeric effect is large for a nitro-group, the mesomeric interaction in nitrobenzene will be large, and will not be too easily inhibited by steric interactions. Consequently the prerequisite for a type I steric effect is available; namely, the electronic excited state, where mesomeric interaction is presumed to be greater than in the ground state, remains frequently at a similar energy level for the prevalent conformations in both the sterically hindered compounds and reference compounds, and hence no appreciable wavelength displacements are observed. Steric effects of type I are in fact often observed, and are found to be more probable in aqueous solution, where solvent–solute interactions are assumed to further facilitate the mesomeric interaction.

Thus, the characteristic nitrobenzene band near 260 mμ will often be evident in aqueous solution, even in a reasonably complex molecule. Conversely, the occurrence of a band near 260 mμ under those conditions, for a compound containing a nitro-group, indicates the presence of the nitrobenzene chromophore. It should be noted, however, that for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

ortho- or meta-substituted nitrobenzene chromophores more than one band may occur in this region, and that for certain para-substituents the band may be considerably displaced towards longer wavelength (cf. Table II).

If a definite absorption band occurs near 260 mμ, the absorption intensity of the band can also be used to estimate steric effects. This type of spectral analysis has recently been employed in the discussion of the structures of 2-carboxy-4,5-dimethoxy-2′-nitrobiphenyl and 2-carboxy-4,5-dimethoxy-2′-nitro-3′-methylbiphenyl (26) and of (+)6,6′-dinitro-2,2′-di-(2,4-dimethylbenzoyl)biphenyl (32). Qualitative spectral investigation of the nitro-group is also possible in the infrared region (8*e*, 33), since the nitro-group causes characteristic bands near 1550 cm^{-1} and in the region 1360–1300 cm^{-1}. Lastly, the *B*-band in the ultraviolet region appears to be well suited to the quantitative determination of compounds containing a nitrobenzene chromophore. This is so, because the extinction coefficients obey Beer's law fairly accurately and in additon the absorption is not particularly sensitive to slight changes in pH. In this way, the method may offer advantages, for example, in the study of reaction mechanisms involving a nitro-substituent.

EXPERIMENTAL

The ultraviolet absorption spectra were determined in quartz cells using a Unicam SP500 spectrophotometer. For each compound at least two independent sets of observations were made. Some of the spectra, for example the acetophenone spectra used in constructing Fig. 1, have already been described in previous parts of this series. Little disagreement was found between our values and those reported elsewhere in the literature. The estimated precision of our values for extinction coefficients is $\pm 5\%$ or better. On theoretical grounds the use of oscillator strengths, *f*, would be preferred, but for practical reasons we have not used this quantity so far (cf. also Wepster (5), who has found a reasonably linear relationship between ϵ_{max} and *f*). The estimated precision of our values for the maximal wavelengths is ± 0.5 mμ.

The nitrobenzenes were purified from the commercially available compounds. Solvents also were purified by standard methods.

ACKNOWLEDGMENTS

The author gratefully acknowledges the assistance of Mr. J. C. Dearden, Miss Rosemarie Gosine, and Mr. J. F. Templeton in the experimental work, and in the preparation of the diagrams (Mr. J. C. Dearden).

Lastly, it is a pleasure to thank the National Research Council of Canada for grants supporting this work.

LIGHT ABSORPTION STUDIES

PART XII. ULTRAVIOLET ABSORPTION SPECTRA OF BENZALDEHYDES[1]

J. C. Dearden and W. F. Forbes

ABSTRACT

The electronic spectra of benzaldehydes in the region 220–360 mμ are recorded and discussed in terms of previously stated hypotheses. The formyl group is shown to endow benzene derivatives with spectral properties similar to those of the acetyl group in acetophenones, except that steric interactions are slightly modified.

INTRODUCTION

The ultraviolet absorption spectra of benzaldehydes are of interest because they provide additional examples in the study of the various interactions which determine electronic spectra. The spectra would be anticipated to be related to the previously studied spectra of acetophenones (1, 2, 3), benzoic acids (4), and nitrobenzenes (5), since in all these compounds a negative mesomeric effect operates.

The spectra of some of the benzaldehydes have previously been recorded (6, 7, 8, 9, 10), but, whenever it proved convenient, spectra were redetermined in order to obtain data under near-identical conditions. The terminology employed in this paper is identical with that employed in previous parts of this series.

THE SPECTRUM OF BENZALDEHYDE

The absorption maxima of benzaldehyde in different solvents are listed in Table I.

TABLE I

ABSORPTION MAXIMA OF BENZALDEHYDE IN DIFFERENT SOLVENTS*

		B-Band		*C*-Band

Benzaldehyde in cyclohexane solution appears to show a slight concentration dependence, which may be caused by intermolecular hydrogen bonding (11). Unfortunately, the changes in the extinction coefficients are not sufficiently large to permit any conclusions at this stage. None of the *C*-bands listed in Table I shows concentration dependence within the accuracy of the experiments. Extinction coefficients are also altered on changing the solute concentration for dioxane solutions (see Table I), and some aspects of these spectral changes will be examined in a separate study. It is noticeable, however, that some interaction occurs between solvent and solute in solvents other than cyclohexane, as witnessed by the spectral changes occurring in various solvents. In particular, the characteristic doublet, observed in cyclohexane and to a small extent in ether solution, disappears in all other solvents.

This doublet is more pronounced for both *B*- and *C*-bands on reducing the temperature (12). In acetophenone, in the gas phase and in heptane, the spectrum is also reported to be slightly unsymmetrical at the *B*-band maximum and shows a small shoulder at about 7 mμ to the red of the peak. Again in all other solvents, this maximum was found to be symmetrical and the shoulder was absent. For nitrobenzenes, the *B*-band is structureless, even in the gas phase, and quite symmetrical about the maximum (13). An explanation involving hydrogen bonding cannot perhaps be ruled out completely, at least at this stage (cf. 14), but seems improbable. Any complete explanation for this fine structure effect must take into account the above and also the following observations:

(i) The fine structure occurs for all benzaldehyde *B*-bands described in this paper, with the exception of the band at 225 mμ for *m*-nitrobenzaldehyde, which exhibits no fine structure (see following sections). For this compound, the benzaldehyde band is considerably displaced.

(ii) The fine structure disappears for certain *C*-bands (see following sections).

(iii) In the *B*-band of *o*-hydroxybenzaldehyde the fine structure is slightly different inasmuch as the longer wavelength peak is more pronounced (see Table V). This is the only *B*-band for which this different band shape was noted.

The occurrence of the doublet for solutions of benzaldehyde in hexane is also of some practical importance, since it frequently allows the identification of the benzaldehyde

band, not only in simple benzaldehydes (see following sections) but also in more complicated molecules (cf. 15).

Finally in this section it may be noted that the maximal absorption of the *B*-band for benzaldehyde normally occurs at longer wavelength than for acetophenone. This prompts the speculation that benzaldehyde exists, at least at room temperature, with a larger proportion of planar or near-planar conformations. This hypothesis also correlates with the known lesser susceptibility of benzaldehydes to steric interactions (cf. 1, 16). On the other hand, the carbonyl stretching frequency of benzaldehyde lies at 1709 cm^{-1} (mean integrated absorption intensity, $A = 2.56$ $mole^{-1}$. liter. $cm^{-2} \times 10^{-4}$), whereas the corresponding frequency for acetophenone under identical conditions occurs at 1691 cm^{-1} ($A = 2.20$), that is, at shorter frequency or longer wavelength (2). This wavelength shift therefore is in the reverse order from that observed in the ultraviolet spectra. An explanation of these observations may be provided if it is remembered that steric effects in the *B*-band are predominantly caused by interactions between vicinal atoms in the electronic excited state (cf. 2, 16, 17), and consequently the observed opposite wavelength displacements may represent a previously discussed type of steric effect in which ground and excited states are displaced in opposite directions compared with a non-hindered reference compound (cf. Fig. 2 in Part VII (2) of this series). Although the positions of the maximal wavelengths are displaced in opposite directions for the vibrational and electronic spectra, the integrated absorption intensities (A) of the vibrational spectra relate to the wavelength changes in the electronic spectra. This is as anticipated, since the integrated absorption intensities have been related to the resonance energies of conjugation (18), which also predominantly determine the *B*-band in electronic absorption spectra. This hypothesis, incidentally, is consistent with the observation that in sulphuric acid the two compounds absorb at identical maximal wavelength in the ultraviolet region and with similar absorption intensity. That is, it is assumed that the increased solvent–solute interaction in this solvent overcomes the steric interactions between the methyl-group and the ortho-hydrogen atoms in acetophenone.

THE SPECTRA OF PARA-SUBSTITUTED BENZALDEHYDES

The spectra of para-substituted benzaldehydes are listed in Table III and wavelength displacements compared with benzaldehyde are also related to similar wavelength displacements obtained in the acetophenone and nitrobenzene series (see Table III and Fig. 1).

Most of the values in Table III are for hexane solution, but some of the values are for ethanolic solution. In compiling the wavelength shifts for Fig. 1, the mean maximal wavelength was used. This introduces an uncertainty, since the maximum of the hypothetical "unresolved" band may not exactly coincide with this mean. However, this uncertainty does not appear to introduce any appreciable deviation from the observed relations, since Fig. 1 shows that the wavelength displacements are approximately proportional to each other, indicating that the electronic interactions are comparable for the compounds under investigation. An exception is provided by the hydroxy-compounds in alkaline ethanol, which appear to show a relatively smaller wavelength displacement for the benzaldehyde. This effect may tentatively be ascribed to the relative absence of steric interactions in benzaldehydes (see previous section), since, in this way, the alkaline medium will tend to overcome steric interactions in acetophenones and nitrobenzenes.

Table III shows that the *B*-bands of all para-substituted benzaldehydes obtained by us possess fine structure in hexane solution, except the *B*-band of *p*-nitrobenzaldehyde.

Partly because of this, the *B*-band of *p*-nitrobenzaldehyde is assigned to nitrobenzene absorption. On the other hand, the spectrum of *p*-carboxybenzaldehyde shows the typical benzaldehyde doublet. The former assignment, indicated in Table III by square brackets, also receives support, since this band not only shows the absence of the characteristic benzaldehyde doublet, but also shows the characteristic properties of nitrobenzene absorption. For example, the *B*-band of *p*-nitrobenzaldehyde in aqueous solution undergoes an appreciable bathochromic wavelength displacement to 266 mμ, that is, to the wavelength associated with nitrobenzene absorption in aqueous solution (5) (see Table III). These assignments therefore suggest the absence of any appreciable interaction between two electron-withdrawing substituents in para-disubstituted benzene derivatives. Further, the assignments for para-substituted benzaldehydes may be rationalized in terms of competing mesomeric interactions, the suggested order of mesomeric interaction being $-NO_2 > -CHO > -COOH$; and this order is supported by the relative locations of the maximal absorption for nitrobenzene, benzaldehyde, and benzoic acid

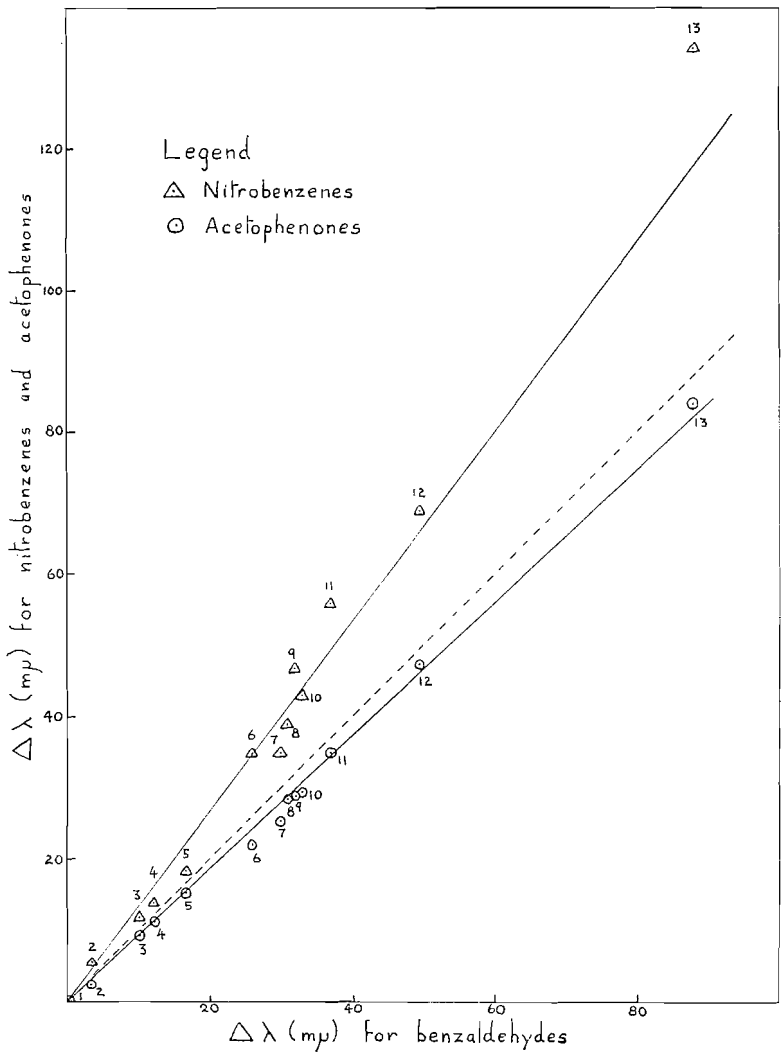

FIG. 1. Wavelength displacements ($\Delta\lambda$) in the *B*-band obtained on introducing para-substituents in benzaldehyde, acetophenone, and nitrobenzene. Values in hexane unless otherwise stated. 1—H; 2—F; 3—Me; 4—Cl; 5—Br; 6—I (in ethanol); 7—I; 8—MeO; 9—MeO (in ethanol); 10—OH; 11—OH (in ethanol); 12—NH_2; 13—OH (in alkaline ethanol) (values from Table III).

(3). This order is again suggested by the *B*-bands of ortho-substituted benzaldehydes (see Table V), since for example the fine structure of the *B*-band of *o*-carboxybenzaldehyde points to this band being due to benzaldehyde absorption. This in turn suggests that the carboxyl-group is preferentially dislocated.

Whenever the para-substituent can act as electron donor, appreciable interactions occur in para-substituted benzaldehydes and the resulting displacements to longer wavelength are shown in Fig. 1 to be directly proportional to corresponding displacements in the acetophenone and nitrobenzene series. This suggests that the displacements are proportional to one "basic" electronic interaction, which acts along the extremities of a conjugated system and which is characteristic for each substituent. This interaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

has already been associated with the mesomeric effect of a substituent, although in its assignment of the order for halogens the interaction affords a different order from that usually accepted for the mesomeric interactions of the halogens (17).

The slope of the line in Fig. 1 relating wavelength displacements in para-substituted acetophenones and benzaldehydes is less than tan 45°, whereas the slope of the line relating wavelength displacements for nitrobenzenes and benzaldehydes is greater than tan 45° (see Fig. 1). This confirms the expected order of mesomeric effect, that is $-NO_2 > -CHO$, and also suggests a mesomeric electron-withdrawing ability $-CHO > -COCH_3$. This latter observation should be related with the fact that benzaldehyde absorbs maximally at longer wavelength than acetophenone.

The *C*-band for each of the compounds listed in Table III could normally be identified only with difficulty. It disappeared in compounds where there is appreciable interaction between the two para-substituents. These tendencies have previously been noted and discussed (3).

THE SPECTRA OF META-SUBSTITUTED BENZALDEHYDES

The spectra of *m*-substituted benzaldehydes and the displacements due to the meta-substituent in benzaldehydes, acetophenones, and nitrobenzenes are listed in Table IV.

Table IV shows that the effect of substituents on the location of the benzaldehyde *B*-band is usually small and similar for benzaldehydes, acetophenones, and nitrobenzenes.

Table IV also shows that meta-substituted benzaldehydes may give rise to two distinct *B*-bands. One of these *B*-bands is the expected benzaldehyde band, somewhat modified

TABLE IV

because of the secondary short-range interaction of the non-formyl substituent (5, 22). The second *B*-band corresponds to the absorption of the other substituent, with the formyl group acting as the secondary substituent. These latter bands are again indicated by square brackets. Thus, for example, in the spectrum of *m*-nitrobenzaldehyde in cyclohexane two bands occur, one at λ_{max} 225 mμ ascribed to benzaldehyde absorption and a much weaker absorption at *ca.* 245 mμ ascribed to nitrobenzene absorption. This assignment may be questioned on the grounds that the benzaldehyde band is appreciably displaced and also because the band does not show the doublet characteristic of benzaldehyde absorption in inert media. On the other hand, a nitro-group normally gives rise to appreciable changes in the spectra of meta-disubstituted benzene derivatives (5). Also, our assignment receives support from the spectrum of *m*-nitrobenzaldehyde in ethanol (see Table IV). There, the presence of ethanol would be expected to displace the nitrobenzene absorption to longer wavelength and this is in fact observed.

Steric effects in meta-substituted benzaldehydes would not be expected to be significant, since the formyl group is relatively small. However, the fairly low extinction coefficient for the *B*-band of *m*-iodobenzaldehyde may be caused, at least partly, by a buttressing interaction. Similarly, the unusual wavelength displacement, as shown in Table IV, for *m*-iodonitrobenzene compared to those for *m*-iodoacetophenone and *m*-iodobenzaldehyde also points to the operation of a buttressing effect in this type of compound (cf. 23).

The *C*-bands, as anticipated, are well defined for meta-substituted benzaldehydes (cf. 3).

THE SPECTRA OF ORTHO-SUBSTITUTED BENZALDEHYDES

The spectra of ortho-substituted benzaldehydes are listed in Table V, together with the spectra of ortho-substituted acetophenones.

All the *B*-bands, with the exception of that of *o*-nitrobenzaldehyde, occur as doublets. The *B*-band of *o*-nitrobenzaldehyde at 247 mμ is again assigned to nitrobenzene absorption, as indicated by square brackets in Table V. This is confirmed by the absorption of this compound in ethanol, which, as anticipated, occurs in the more polar solvent at longer wavelength at 252 mμ (ϵ = 4700) (21). The greatly reduced absorption intensity of the band, particularly in ethanolic solution, compared with the corresponding band in the meta-isomer, is ascribed to the increased steric interaction between the two vicinal substituents in *o*-nitrobenzaldehyde.

Information concerning the nature of the ortho-effect can also be obtained by comparing the spectra of *o*-substituted benzaldehydes with the spectra of *o*-substituted acetophenones (see Table V). At least three interpretations may be advanced for the observed ortho-effects and the data assist in deciding between these. The first interpretation is to ascribe the ortho-effect to intramolecular hydrogen bonding; a second interpretation (cf. 22) is to ascribe the ortho-effect to steric interaction between vicinal atoms or groups *with the molecule occupying only one ground state* (6); a third interpretation is to assume that the ortho-effect may also sometimes be caused by the molecule existing in more than one conformation, for example an *s-cis* and *s-trans* conformation, which however do not all contribute to the observed absorption (16).

Examination of Table V shows that an explanation based on intramolecular hydrogen bonding is consistent with the observed similarity of the *B*-bands for the *o*-hydroxy and *o*-methoxy derivatives of benzaldehyde and acetophenone. On the other hand, hydrogen bonding would not account for the generally decreased absorption intensities in the

For personal use only.

acetophenone series, nor in particular would it account, for example, for the spectrum of *o*-chloroacetophenone, where the molecular extinction coefficient is reduced to a much greater extent than in the corresponding benzaldehyde. Therefore, steric interactions evidently also determine the ortho-effects and intramolecular hydrogen bonding is not the sole explanation for the observed ortho-effects. Experiments to differentiate between the two types of steric effects will be reported separately.

The *C*-bands show the usual changes (3), although it may be noted that in *o*-tolualdehyde and in salicylaldehyde the *C*-band does not occur as a doublet (see Table V).

EXPERIMENTAL

The benzaldehydes were obtained commercially or prepared by standard methods as described in the literature. The physical constants, after purification, of the compounds not previously reported in this series are listed in Table VI.

The ultraviolet absorption spectra were determined in specially calibrated quartz cells of various path lengths using a Unicam SP 500 spectrophotometer. Dioxane–water mixtures were prepared as previously described (11). For each compound at least two independent sets of observations were made. Where previous data are available, our data compare well with the published values. For the *m*- and *p*-aminobenzaldehydes the purified solutions in ether were directly diluted with cyclohexane to about 2% ether. This procedure avoided polymerization, which otherwise occurred. The spectrum was determined on each solution, and the concentration was subsequently obtained by evaporating to dryness and weighing the residue.

LIGHT ABSORPTION STUDIES

PART XIII. THE ELECTRONIC ABSORPTION SPECTRA OF RING-SUBSTITUTED ANILINES[1]

W. F. Forbes and I. R. Leckie

ABSTRACT

A spectral analysis of benzene derivatives in terms of steric and electronic interactions is extended to ring-substituted anilines.

INTRODUCTION

In previous parts of this series spectral analyses were carried out for substituted acetophenones, benzaldehydes, and nitrobenzenes, that is, for compounds in which one substituent possesses a *negative* mesomeric effect. The purpose of the present communication is to consider in greater detail the effect of the amino group on the electronic spectra, that is, the effect of a group which possesses a *positive* mesomeric effect.

Systematic investigations of the electronic spectra of anilines have also recently been carried out by Wepster (1) and by Klevens and Platt (2). The emphasis of our work will be to relate the available data to the hypotheses developed for other benzene derivatives in this series and, whenever convenient, we have also redetermined the reported data, in order that data would be obtained under near-identical conditions.

THE ANILINE SPECTRUM

The absorption maxima of aniline for different solvents in the region 220–300 mμ are listed in Table I.

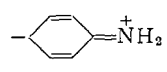
TABLE I

Main absorption maxima of aniline in different solvents

Solvent	*B*-Band		*C*-Band		Source
	λ_{max} (mμ)	ϵ_{max}	λ_{max} (mμ)	ϵ_{max}	
Vapor phase	229		*ca.* 280		*, †
Cyclohexane	233–234	9000	286	1900	*
Ethanol	234–235	8000	284–285	1700	*
Water	230	8000	278	1400	*
0.1 *N* HCl	202	7500	247 252 258	150 170 150	*
N NaOH	230	8400	279	1400	*
Ether	238	10,000	288	1900	*
Cyclohexane containing 3% ether	234	9000	285	1800	*

*This series of papers.
†ϵ_{max} values not determined.

The two bands listed in Table I are described as *B*- and *C*-bands, implying that these bands correspond to the similar bands in acetophenone, benzaldehyde, and nitrobenzene (cf. 3, 4, 5). Consequently the corresponding electronically excited states may be visualized as involving dipolar resonance forms of type I.



I

[1]*Manuscript received June 16, 1958.*
Contribution from the Memorial University of Newfoundland, St. John's, Newfoundland.

The *B*-band of aniline appears to be symmetrical and shows no fine structure if the spectra are determined in solution. Some fine structure occurs in cyclohexane for the *C*-band, but this is not evident in other solvents, for example in ether or water. In the vapor phase, fine structure is shown by both *B*- and *C*-bands. Further, in cyclohexane both *B*- and *C*-bands do not show any appreciable concentration dependence within the investigated concentration range (2×10^{-3} to 3.36×10^{-4} moles/liter for the *B*-band, and 1×10^{-2} to 3.36×10^{-4} moles/liter for the *C*-band). This may be related to information deduced from infrared data, which suggests that aniline in carbon tetrachloride solution occurs as the monomer up to a concentration of 10^{-2} moles/liter (6).

The data in Table I also show that although no appreciable spectral change occurs between the spectra in ethanol and cyclohexane, a more pronounced spectral change occurs between the spectra in cyclohexane and aqueous solution. Analogous wavelength displacements are observed for the spectrum of N,N-dimethylaniline in hexane, ethanol, and water (7), and this therefore suggests that the observed spectral changes are not caused by hydrogen bonding involving the nitrogen-linked hydrogen atoms. In addition, it has previously been shown that if an aqueous solution of aniline is examined within a temperature range sufficient to affect any hydrogen bonding present, no spectral changes are observed (8). Searching for a possible explanation of the spectral changes, one may note that the reduced extinction coefficient between ethanol and water for N,N-dimethylaniline, which is not observed for aniline, may be tentatively ascribed to steric interaction. Ungnade has previously pointed out (see footnote 17 of ref. 7) that it is necessary to assume a hydrate, involving the unshared electron pair, in aromatic amines in order to account for the basic properties of these substances, and that the formation of such hydrates is subject to steric effects. Consequently, the most probable explanation of the wavelength displacement is provided by assuming that in aqueous solution the molecular species $C_6H_5NH_3OH$ contributes appreciably to the observed absorption. However, this species must surely involve some form of hydrogen bonding, although it may not be the same type of hydrogen bond as will be described below. The aniline or N,N-dimethylaniline molecule presumably in some way accepts the proton of the water molecule by means of the non-bonding electrons of the nitrogen atom. It has been suggested that by partially isolating the $2p_z$ electrons of the nitrogen atom in this way, the hydrogen bond reduces the interaction between the $2p_z$ electrons and the benzene ring and thus the absorption band is displaced to shorter wavelength (9).

In aqueous solution, the equilibrium

$$C_6H_5.NH_3OH \rightleftharpoons C_6H_5.NH_3^+ + OH^-$$

may also be sufficiently displaced to the right to contribute to the observed wavelength displacements. However, within the investigated concentration range, this effect does not appear to be important. That is, the *B*-band in aqueous solution was found to be unchanged within the concentration range 2×10^{-3} to 3.25×10^{-4} moles/liter and the *C*-band was found to be unchanged within the concentration range 10^{-2} to 3.25×10^{-4} moles/liter. In acidic media, there occurs a hypsochromic wavelength displacement which may be related to the non-availability of the unshared *p*-electrons in the electronic excitation. That is, the non-bonded electrons are now predominantly involved in the nitrogen–hydrogen bond, and are consequently unable to participate in the transitions leading to the *B*-band. This wavelength displacement is incidentally quite characteristic for aniline and ring-substituted anilines (see Tables I, II, III, and IV), and may therefore be used in the identification of an amino substituent. No appreciable wavelength displacement occurs in weakly basic media (see Table I).
