VOLUME 36 JANUARY 1958 NUMBER 1

Symposium on The Structure and Reactivity of Electronically-Excited Species

A REPORT ON A SYMPOSIUM HELD BY THE PHYSICAL CHEMISTRY DIVISION OF THE CHEMICAL INSTITUTE OF CANADA[1]

K. J. LAIDLER AND D. A. RAMSAY

A symposium on the structure and reactivity of electronically-excited species was held at the University of Ottawa under the auspices of the Physical Chemistry Division of the Chemical Institute of Canada on September 5th and 6th, 1957. A number of invited papers were presented, most of these having previously been printed in full and distributed to the participants in advance of the meeting. The sessions were devoted to brief presentations of these invited papers, to presentations of additional work, and to general discussions. A number of the invited papers are being published in the present issue of the Canadian Journal of Chemistry; in this paper we give a general account of the meeting, emphasizing the main matters that were discussed and the main conclusions that were drawn. The papers will be discussed under two main headings, the first dealing with the structures of electronically-excited species and the second with their reactivities.

THE STRUCTURES OF ELECTRONICALLY-EXCITED SPECIES

During recent years considerable efforts have been devoted to the detailed study of the electronic spectra of simple polyatomic molecules. The rapid development of the subject may be seen from the following chronological list of molecules, ions, and free radicals for which rotational and vibrational analyses have been carried out:

Prior to 1940	H_2CO, CO_2^+
1940 to 1950	CS_2, CO_2^+, SO_2, NO_2, ClO_2
1950 to 1957	C_2H_2, HCN, CS_2, H_2CO, CS_2^+, $C_4H_2^+$  NH_2, HCO, CH_3, HNO

[1]*Manuscript received October 3, 1957.*
Contribution from the Department of Chemistry, University of Ottawa, and the Division of Pure Physics, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4538.

There is therefore available at the present time fairly detailed knowledge of the structures of these species in their ground and excited states, and a number of them were discussed at the symposium.

Shapes of Excited Species

An introductory paper dealing with the structures of electronically-excited species was presented by G. Herzberg (National Research Council, Ottawa), who pointed out that the symmetry species and shapes of molecules in electronically-excited states are often considerably different from the corresponding properties in the ground states. For example, C_2H_2, HCN, and CS_2 are linear in their ground states but non-linear in their first electronically-excited states. The free radicals NH_2 and HCO are non-linear in their ground states and linear in their low-lying excited states.

Additional examples of changes of molecular shape or molecular symmetry accompanying an electronic transition were afforded by subsequent papers presented at the meeting. G. W. Robinson and V. E. DiGiorgio (Johns Hopkins University, Baltimore, Md.) presented conclusive evidence that formaldehyde is non-planar in its low-lying excited state, and K. Allison and A. D. Walsh (Queen's College, Dundee) showed that a similar deviation from planar symmetry may occur in one or two of the electronic states involved in Rydberg transitions of formaldehyde. G. W. King (McMaster University, Hamilton, Ont.) discussed the absorption spectrum of glyoxal, and showed that while there is probably very little change in molecular geometry during the transition there is a change of molecular symmetry. In the general discussion period Walsh advanced the idea that NH_2 may not be quite linear in its low-lying excited state. The potential-energy curve may have a small potential maximum in the 180° configuration, and this may account for the negative anharmonicity in the bending vibrations.

The experimental data which have accumulated on the shapes of molecules in electronically-excited states have provided striking support for the general accuracy of the extensive predictions made by Walsh in 1953. The general usefulness of these predictions was underlined by the discussions at the meeting.

Theoretical Treatments of Excited States

R. S. Mulliken (University of Chicago) dealt with the molecular orbital method for computing the energies of electronically-excited states. He suggested that we may be at the dawn of a new era of structural chemistry in which it will be possible to make detailed and reliable calculations of energies and other properties. He presented the results of some recent calculations on CO, N_2, C_2H_2, and several molecules of the AB_2 type, and compared the results with experimental data wherever available. The possibility that certain excited states of AB_2 molecules may have unsymmetrical configurations was discussed, and supporting evidence was cited in the case of the ClO_2 molecule, in which the antisymmetric stretching vibration appears to be excited with considerable intensity in the absorption spectrum.

J. W. Linnett (Oxford University) discussed an apparent discrepancy in viewpoint between simple molecular orbital theories as developed by Walsh and hybridized orbital theories as developed by Pauling. According to the former viewpoint the simplest electronic transition may be regarded as due to the transfer of an electron from one orbital to another, and may be accompanied by a considerable change in molecular geometry. According to the latter viewpoint the shapes of molecules are determined by hybridized groups of electrons, e.g. sp^2, sp^3, rather than by individual electrons. The change of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

shape that may accompany an electronic transition should therefore be regarded as indicating a change of hybridization. By considering possible electron distributions in simple molecules such as N_2, CO, and C_2H_2, Linnett showed that the two methods of approach may differ merely in viewpoint rather than in fundamental concepts.

Multiplicities of Excited States

Considerable discussion centered on the question of the multiplicities of the excited states of various molecules. A. E. Douglas (National Research Council, Ottawa) presented some preliminary results on Zeeman effects which strongly suggested that the excited state of the near ultraviolet bands of CS_2 is a triplet and not a singlet as had previously been assumed. G. W. Robinson and V. E. DiGiorgio discussed some very weak bands of formaldehyde which showed a doublet spacing that does not change appreciably with either vibrational excitation or isotopic substitution. They assigned these bands to a singlet–triplet system and suggested that the rather large doublet spacing may be due to a coupling between the electron spin and residual unquenched orbital angular momentum in the molecule. Further work is clearly required, both theoretically and experimentally, on (1) the Zeeman effect in polyatomic molecules, and (2) spin–orbit coupling in polyatomic molecules.

In connection with the multiplicity problem mentioned above some headway might be made if the theoreticians were to form a more definite view about the f values to be expected for "allowed" and "forbidden" transitions, and if the experimentalists were to begin to measure the integrated intensities of various band systems. It would be valuable to have order of magnitude f values from both points of view.

Theoretical work on the intensity of the $^1A_2 \leftarrow {}^1A_1$ bands of formaldehyde was presented by J. A. Pople and J. W. Sidman* (Cambridge University). The bands are forbidden by the electronic selection rules, and electronic–vibration interaction is usually invoked to explain the existence of the perpendicular bands. This explanation, however, cannot account for the appearance of parallel bands, and Pople and Sidman suggested that the intensity of these bands may be due to an electronic–rotational interaction. They calculated an approximate f value, and thus provided a challenge to the experimentalists to obtain the measured value.

Excited States of Ions

An interesting method for obtaining information regarding the excited states of molecular ions was described in a paper by D. C. Frost and C. A. McDowell (University of British Columbia, Vancouver, B.C.). An essentially monoenergetic source was used in a mass spectrometer, and discontinuities in the curves of ion current *versus* electron energy were observed; these discontinuities yielded information concerning the energies of the excited states of the ions. This approach provides a valuable complement to the usual spectroscopic methods, there being very little spectroscopic information available on the electronic spectra of polyatomic ions. The only spectra obtained so far have been in emission, and the only ions for which detailed analyses have been carried out are CO_2^+, CS_2^+, and $C_4H_2^+$. No absorption spectrum of a molecular ion, whether diatomic or polyatomic, has yet been observed in the gas phase.

The spectra of molecular ions have frequently been investigated in the solid phase, and a paper was presented by J. W. Sidman on the emission and absorption spectra of the nitrite ion in the crystalline state at low temperatures. Information was derived

concerning the vibrational and lattice frequencies for both the ground and excited states, and the results were compared with the predictions made by Walsh for 18-electron AB_2 systems.

Interaction between Electronic and Vibrational Motions

Two of the papers at the symposium described the rather complex interaction between electronic and vibrational motions in polyatomic molecules. M. H. L. Pryce and U. Öpik (Bristol University) and H. C. Longuet-Higgins and R. A. Sack (Cambridge University) dealt with the dynamical Jahn–Teller effect; this paper was concerned with the vibronic energy levels of a non-linear molecule in a doubly-degenerate electronic state which is split in first order by a doubly-degenerate vibrational mode. Theoretical patterns were presented showing the vibrational structures and intensity distributions expected for bands involved in transitions between a Jahn–Teller distorted state and a non-degenerate electronic state. These predictions should prompt experimentalists to obtain data on transitions of this type.

The second paper along these lines was presented by K. Dressler and D. A. Ramsay (National Research Council, Ottawa) and dealt with the Renner effect in linear polyatomic molecules. This work was concerned with the complex vibronic patterns that may arise as the result of the interaction between electronic orbital angular momentum in a linear polyatomic molecule and the angular momentum associated with the bending vibrations. The analysis of the spectrum of NH_2 suggests that the vibronic levels of a hypothetical Π state split into two groups, half of the levels correlating with the vibronic levels observed in the excited state and the other half with vibrational and rotational levels of the ground state. The interpretation of the experimental results involves a considerable extrapolation of the theory originally developed by Renner, and necessitates further theoretical investigations.

The problem of the transfer of electronic and vibrational energies in weakly coupled systems was discussed both theoretically and experimentally in papers by J. N. Murrell (Cambridge University and University of Chicago) and by D. S. McClure (R.C.A. Laboratories, Princeton, N.J.). The general problem of energy transfer is now being attacked using a variety of experimental techniques, such as ultrasonics, flash photolysis, shock waves, and fluorescence quenching, and information is being obtained concerning the probabilities for the conversion of energy from one form to another.

An important problem of interest to spectroscopists, photochemists, and theoreticians concerns the probability of predissociation in polyatomic molecules. Recent spectroscopic work has shown that the probability of predissociation in a polyatomic molecule depends not only on energy and symmetry considerations, as in a diatomic molecule, but on additional quantum numbers that have no counterpart in a diatomic molecule. Recent work on the ultraviolet spectrum of HCN has shown that the probability of predissociation in the non-linear excited state increases with the quantum number for rotation about the axis of least inertia of the molecule. In the linear excited state of HCO the Σ vibronic levels associated with the various vibrational modes have been found to be stable; the Π, Δ, . . . vibronic levels, on the other hand, are predissociated. Theoretical investigation of these new empirical rules is needed.

THE REACTIVITY OF ELECTRONICALLY-EXCITED SPECIES

The section of the symposium devoted to reactivity was introduced by E. W. R. Steacie (National Research Council, Ottawa), who outlined the role played by electronically-excited species in reaction mechanisms, and gave a brief history of the subject

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

of reaction mechanisms with special reference to excited states. He pointed out that in the early days of chain reactions excited species, or 'hot' molecules, were introduced in order to explain certain features of the mechanisms, and that in some cases their introduction was without basis. As time goes on, however, we are learning more and more about the detailed nature of the reactions involving these excited species, and in some cases can make reliable identifications of the species. On the whole rather more is known about the part played by electronically-excited species in flames, but knowledge of their role in thermal, photochemical, and photosensitized reactions is rapidly being gained.

H. Eyring (University of Utah, Salt Lake City) gave a broad review of the subject of reactions of electronically-excited species, and emphasized the importance of treating the reactions theoretically in terms of potential-energy surfaces. He discussed from a theoretical standpoint certain processes involving argon ions, and also the interpretation of the mass spectrum of propane.

Theoretical Treatments

Several papers in the symposium were devoted to the theoretical treatment of reactions involving electronically-excited species. R. A. Marcus (Polytechnic Institute of Brooklyn) presented a theory of unimolecular reactions of electronically-excited molecules. He dealt with the process of excitation of a molecule in its ground state to vibrationally-excited states of the electronically-excited molecule, and also the unimolecular breakdown of the molecule formed. The course of this reaction is represented by a motion on a potential-energy surface, the reaction being the passage over a saddle point. Marcus's final expression for the rate of the reaction involves an activation energy that is independent of the frequency of the absorbing light, and a frequency factor that depends on the frequency of the light. The frequency factor for the unimolecular decomposition of an electronically-excited species will in general be smaller than 10^{13} sec.$^{-1}$, the value typical for molecules in their ground states. A second paper by Marcus dealt with the potentialities and limitations of the flash photolysis method for studying the chemical reactions of excited states.

The decomposition of an electronically-excited molecule was also treated by B. Stevens* (Princeton University). It has been concluded by Sponer and Teller that whereas an optical transition in a symmetrical molecule excites the totally symmetric vibrations, it is the non-totally symmetric vibrations that are usually responsible for the dissociation processes. The unimolecular breakdown of an electronically-excited molecule therefore involves an internal redistribution of vibrational energy, and the rate depends on the magnitude of coupling of the optically active (symmetrical) and dissociative (non-symmetrical) vibrations; this coupling will be a function of the anharmonicity and hence of the energy. The implications of this were worked out in some detail by Stevens, who pointed out that the rate of the dissociation process will vary very considerably with the amount of optical energy given to the molecule. If the amount of energy is small there will be little coupling between the two types of vibration, and therefore a low probability of unimolecular dissociation; as the energy is increased the probability of transfer from the optically active to the dissociative vibrations becomes greater, and the rate of reaction is therefore greater.

A paper by E. K. Gill and K. J. Laidler (University of Ottawa) dealt for the most part with the nature of the reaction

$$Hg^*(^3P_1) + O_2(^3\Sigma_g^-) \rightarrow Hg(^1S_0) + O_2^*.$$

In the past there has been some discussion as to the electronic nature of the oxygen

Now at Esso Research and Engineering Co., Linden, N.J.

formed in this reaction. Gill and Laidler considered both the experimental evidence and the potential-energy surfaces, and showed that both lead to the conclusion that the oxygen formed is in the $^3\Sigma_u^+$ state. This is the highest electronically-excited state of oxygen for which there is enough energy available in the excited mercury, so that in the reaction there has been a minimal transfer of electronic to vibrational energy. The experimental evidence for this conclusion is that inert gases increase the rate of ozone production in this reaction, which they could hardly do if the excitational energy of the oxygen were to a considerable extent vibrational energy; the inert gases would then readily bring about deactivation. The theoretical treatment of the reaction involves the use of the potential-energy surfaces, and when these are constructed it is seen that there is an easy path for the formation of the $^3\Sigma_u^+$ oxygen.

Experimental Studies of Simple Systems

A number of the papers presented at the symposium dealt with experimental studies of reactions of a very simple type; many of them dealt with reactions involving three atoms, reactions that are very simple to treat theoretically. H. E. Gunning* (Illinois Institute of Technology, Chicago) presented the results of a number of experiments on photosensitization by isotopic mercury atoms. The procedure was to excite Hg^{202} ($^3P_1$) atoms in natural mercury vapor, and to cause them to react with substrates that form solid mercury compounds when the photosensitization process occurs. The solid mercury compounds formed were examined to see whether they were enriched in the Hg^{202} isotope. Such enrichment is evidence for the primary formation of the mercury compound. One group of substances used consisted of halides such as hydrogen chloride, methyl chloride, and carbon tetrachloride; these formed Hg_2Cl_2 on photoexcitation, and there was enrichment of the isotope in every case. It therefore follows that the excited mercury reacts directly with the abstraction of a halogen atom. Three substances which form HgO were studied: water vapor, nitrous oxide, and oxygen. There was very slight isotope enrichment in the case of H_2O, but no enrichment at all with nitrous oxide and oxygen.

During the presentation of his paper Gunning referred to the fact that his more recent results had indicated quite different quenching cross-sections for Hg^{198} and Hg^{202} in their $^3P_1$ states. In the discussion period Shuler pointed out that this was a very surprising result since isotopes would be expected to react at approximately the same rate. There was considerable discussion on this point, but no definite conclusions were drawn.

The chemiluminescence in the system atomic sodium plus atomic hydrogen was discussed in a paper by J. D. McKinley, Jr.,† and J. C. Polanyi‡ (Princeton University), the procedure being to allow atomic sodium to diffuse into a mixture of atomic and molecular hydrogen. The results indicated that the reaction giving rise to luminescence is either $Na+Na+H \rightarrow NaH+Na^*$ or $Na+H+H \rightarrow H_2+Na^*$. In the former case the collision yield is 4×10^{-3}, in the latter case 1×10^{-5}; these figures are based on Bodenstein's method of calculating rates of termolecular collisions.

Two papers dealt with the quenching of the iodine fluorescence spectrum, one by C. L. Arnot and C. A. McDowell (University of British Columbia) and the other by J. C. Polanyi (University of Toronto). When iodine vapor is excited by the green mercury line at 5461 Å there is produced a $^3\Pi$ electronically-excited state of iodine in the 26th vibrational level. On collision with foreign molecules these excited iodine molecules may undergo a transition to the 25th and the 27th vibrational levels, and new fluorescence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

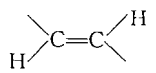
bands appear corresponding to transitions from these levels to ground electronic states. In addition there is the possibility of a direct fluorescence of the electronically-excited molecule in the 26th vibrational state, and it is possible to compare the rate constants for vibrational energy transfer (k_t) with those for fluorescence (k_f), for various added gases. Some ratios of rate constants obtained by Arnot and McDowell are as follows:

Added gas	He	Ne	A	O_2
k_t/k_f (liter mole^{-1})	5.31×10^4	2.69×10^4	1.64×10^4	1.5×10^4

On the assumption that the fluorescence lifetime for the excited iodine is 10^{-8} second, these ratios are approximately ten times as great as would be calculated using the collision theory. There are two possible reasons for this discrepancy: the lifetime of the excited iodine may be less by a factor of ten or so, or the rate constants for the transfer processes may indeed be ten times greater than the collision frequencies. In the discussion of this paper Mulliken pointed out that data are probably available for making a calculation of the lifetime of the excited iodine molecule, so that it should be possible to resolve this problem. In Polanyi's investigation of the system the results were somewhat different; transfer in the case of hydrogen molecules, for example, occurred in one out of every four collisions.

Work on the reaction between nitric oxide and oxygen atoms was described by T. M. Sugden and E. M. Bulewicz (Cambridge University) and by F. Kaufman (Aberdeen Proving Ground, Maryland). When small amounts of nitric oxide are added to a system containing oxygen atoms, such as a flame, a greenish continuum is emitted, and this was studied by Sugden and Bulewicz over a range of temperatures and compositions. It has for some time been believed that the continuum is due solely to the process $NO+O \rightarrow NO_2+h\nu$, and that the intensity of the continuum may be used as a measure of the oxygen-atom concentration in a flame. However, the results of Sugden and Bulewicz showed that nitric oxide catalyzed the combinations of free radicals in flames, and that the intensity of the continuum is determined by more complicated processes than a simple combination of NO and O. The intensity may therefore not be used as a measure of oxygen atom concentrations. Various other reactions giving rise to the formation of NO_2* were considered. Kaufman's work provided rate constants for the reaction $O+NO+M \rightarrow NO_2+M$.

G. J. Minkoff (Imperial College, London) dealt with the mechanism of the thermal decomposition of acetylene, with special references to the role played by electronically-excited states of acetylene. It was pointed out that the relatively large reaction rates observed at the beginning of the induction period are not consistent with previous mechanisms involving the intervention of stable dimers, and that in order to explain the kinetics it is necessary to postulate that a diradical is produced on the surface; this diradical then undergoes a polymerization in the gas phase, with some chain ending occurring on the surface. Minkoff postulated that at lower temperatures the triplet diradical formed is in the *trans* configuration



and that this readily undergoes polymerization. At higher temperatures the *cis* form is produced to a greater extent and, owing to the proximity of the hydrogen atoms, readily undergoes dehydrogenation. There was considerable discussion about the nature of the excited states of acetylene, and G. W. King indicated that his work with Ingold showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

the triplet state of acetylene to be normally in the *trans* form. Mulliken pointed out that the *cis* and *trans* forms should not differ very much in energy.

Elementary Processes in Flames

In addition to that of Sugden and Bulewicz, referred to above, there were two papers dealing with reactions in flames. A paper by H. P. Broida and K. E. Shuler (National Bureau of Standards, Washington) described additional work by these authors on the study of flame temperatures and energy distributions. Their work involved the addition of iron to various flames and a study of the electronic states of the iron, a number of iron lines being examined. The general conclusion was that iron is a good thermometer in that if there is equilibrium in the flame the iron lines provide a reliable temperature for the flame; if on the other hand there is not equilibrium this fact is readily revealed.

T. Carrington (National Bureau of Standards, Washington) described investigations on the electronically-excited ($^2\Sigma^+$) OH radicals in oxyacetylene flames burning at atmospheric and reduced pressures. The results indicate that these electronically-excited radicals are quenched at practically every collision. This is of some interest since non-equilibrium populations of rotational levels of the excited radicals had been observed spectroscopically in certain flames and discharges, and the results have often been assumed to indicate a persistence of the initial rotational distribution. It has been assumed that the OH radicals remain in the excited state for the normal radiative lifetime of the electronic transitions (6×10^{-6} second), and therefore undergo at atmospheric pressure about a thousand collisions before radiating. Carrington's discovery that the quenching efficiency is very high indicates, however, that this cannot be so: the electronically-excited radicals have no chance to undergo a series of collisions. The non-equilibrium distribution cannot therefore be due to the persistence of the rotational levels, and must correspond to the distribution existing when the OH radicals are initially formed. A possible mechanism for the production of abnormal populations of OH* in flames and in discharges through water vapor was suggested by Broida; his explanation is based on the idea, due originally to Niira, that electronically-excited H_2O^* dissociates into OH* ($^2\Sigma^+$) with excess rotational energy. In flames, according to Broida, the excited H_2O is produced in the reaction

$$C + O + H_2O \rightarrow CO + H_2O^*.$$

Reactions of More Complex Molecules

Several papers dealt with reactions involving polyatomic molecules, including the one by Stevens discussed above. J. Heicklen and W. A. Noyes, Jr., (University of Rochester) and H. Okabe (National Research Council, Ottawa) dealt with reactions involving electronically-excited ketone molecules. Heicklen and Noyes showed that the primary processes for simple ketones, such as acetone, are essentially as follows:

(1) The initial absorption of radiation gives rise to a singlet-excited ketone, the vibrational energy of which depends upon the wave length.

(2) Some of the initially excited molecules dissociate, the number depending upon the wave length and the pressure. Others lose vibrational energy by collision to reach the lowest vibrational level of the upper singlet state.

(3) Molecules in the lowest vibrational level in the singlet state may either fluoresce or be converted into a triplet state which rapidly passes into its lowest vibrational level.

(4) Phosphorescence may occur from the lowest vibrational level of the triplet state, but dissociation may occur if molecules are raised to higher vibrational levels of this state.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

There are therefore two methods of dissociation, one of which depends on wave length but only slightly on temperature, the other only slightly on wave length but greatly on temperature. Some work with biacetyl, $CH_3COCOCH_3$, was described, and it was shown that at 4358 Å the decomposition is due to collision between two triplet-excited biacetyl molecules:

$$2CH_3COCOCH_3^* \rightarrow CH_3COCOCH_3 + CH_3CO + CO + CH_3.$$

When a mixture of acetone and biacetyl is irradiated at 3130 Å the light is absorbed solely by the acetone, but fluorescence of biacetyl has been observed. This is attributed to reactions involving transfer of electronic energy on collision, as follows:

$$CH_3COCH_3^* + B \rightarrow CH_3COCH_3 + B^*.$$

A paper on the fluorescence and photolysis of hexafluoroacetone, CF_3COCF_3, was presented by H. Okabe (National Research Council). The excitation of hexafluoroacetone vapor by light of wave length 3130 Å gives rise to strong fluorescence. The variation of the fluorescence efficiency with pressure and the addition of foreign gases suggest that the fluorescence may be principally from the lowest vibrational level of the short-lived singlet-excited state. It is proposed that the molecule is raised to the upper vibrational levels of a singlet-excited state, and subsequently deactivated to the lowest vibrational level of that state, from which it fluoresces. The molecule in the higher vibrational level can dissociate into C_2F_6 and CO. The over-all reaction scheme proposed to explain the results is as follows:

$$\begin{aligned}
CF_3COCF_3 &\xrightarrow{h\nu} CF_3COCF_3^{*n} \\
CF_3COCF_3^{*n} &\rightarrow C_2F_6 + CO \\
CF_3COCF_3^{*n} &\rightarrow CF_3COCF_3 \text{ (internal conversion)} \\
M + CF_3COCF_3^{*n} &\rightarrow CF_3COCF_3^{*0} + M \\
CF_3COCF_3^{*0} &\rightarrow CF_3COCF_3 + h\nu \\
CF_3COCF_3^{*0} &\rightarrow CF_3COCF_3 \text{ (internal conversion)}
\end{aligned}$$

Here $*n$ denotes the nth vibrational level of the singlet excited state, *0 the lowest vibrational level.

In the discussion period the possibility that the singlet-excited state may pass into a triplet-excited state by internal conversion was discussed in some detail.

THE LOWER EXCITED STATES OF SOME SIMPLE MOLECULES[1]

R. S. MULLIKEN

ABSTRACT

The present and prospective rapidly increasing usefulness of good LCAO-MO calculations on the electronic states of simple molecules in the interpretation of observed excited states is pointed out. As examples, the observed and predicted states of, in particular, the $\pi^3\pi$ configurations of N_2 and CO are compared with those of C_2H_2 and HCN and with those of CO_2 and CS_2. Further, the results of LCAO-SCF calculations on CO_2 and on O_3 are surveyed, and it is shown how these can be helpful in interpreting and understanding the ground and excited states of AB_2 (expecially AO_2) molecules in general. A new interpretation of the so-called $d\ ^3\Pi$ state of CO as a case $b\ \pi_u^3\pi_g$, $^3\Delta_u$ state is proposed. Tentative interpretations of some of the ultraviolet absorption spectra of C_2H_2, HCN, and of a number of AB_2 molecules are reviewed or suggested, including some discussion of the shapes of excited states. The AB_2 discussion is a revision of one given earlier. Finally, following up a suggestion of Coon, it is pointed out that there exists strong evidence for slightly unequal A—O distances in certain excited states of ClO_2 and SO_2.

INTRODUCTION

Experience shows that any antibonding MO is much stronger in its effects than its corresponding bonding MO. For example, two H atoms in the $\sigma_g1s\ \sigma_u1s$ state repel, two He atoms ($\sigma_g1s^2\ \sigma_u1s^2$) repel, and two coplanar CH_2 groups in C_2H_4 in its first excited states (configuration . . . $(x+x)(x-x)$ in LCAO symbolism) twist to become perpendicular.[2] Further examples are found in molecules AB_2, where as soon as all bonding (and non-bonding) MOs are filled (as in CO_2, NO_2^+, N_3^-, etc.), addition of further electrons causes bending (as in NO_2, O_3, SO_2, ClO_2, excited CS_2, etc.); this gives relief (with energy-lowering) from otherwise strong antibonding. The writer has discussed the double-bond case (8) and the AB_2 cases (9),[3] and A. D. Walsh (16) has treated the AB_2 and a variety of other cases in a comprehensive series of papers which have given marked impetus to the study of the shapes of excited molecules.

Meanwhile new spectroscopic and other data and theoretical LCAO-MO electronic structure computations provide a basis for increased (though not yet thorough) insight into this field. Some of the new evidence and conclusions are reviewed below, in a discussion of some simple linear molecules, and of AB_2 molecules in general. Emphasis is placed first on observed and computed excited electronic states of the prototype molecules CO, N_2, C_2H_2, and CO_2 all of which if or when linear have a lowest or second-lowest excited configuration of the type . . . $\pi^3\pi$. Attention is then given to the low excited states and non-Rydberg spectra of CO_2 and C_2H_2. Finally, a comparison between theoretical computations on the forms and energies of the LCAO-MOs of CO_2 (180°) and O_3 (120°) throws light on the energies and shapes of the spectroscopically known excited states of CO_2, NO_2, and so on. In some excited states of AB_2 molecules, there is evidence of further loss of symmetry ($C_{2v} \rightarrow C_s$) in addition to bending; this can be understood as giving additional relief from antibonding.

This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.

This work was assisted by the office of Ordnance Research under Project TB2—0001(505) of Contract DA-11-022-ORD-1002 with the University of Chicago.

[2]*See Mulliken (8). In C_2H_4, the twisting is distinctly assisted by hyperconjugation in the twisted form. This is strong enough so that $C_2H_4^+$, even though no antibonding electron is present, probably is only barely or not quite stable toward twisting (10, 17).*

[3]*The acute-angled O_3 model reluctantly adopted there was forced by the then available knowledge of the infrared spectrum. It does not affect the essential features of the paper.*

THE LOW EXCITED ELECTRONIC LEVELS OF CO, N_2, AND CO_2

To begin, let us consider theory and experiment for the lowest excited configurations of CO and N_2, then of CO_2. The ground states of N_2 and CO may be described as:

[1] N_2: $(\sigma_g 1s)^2\,(\sigma_u 1s)^2\,(3\sigma_g)^2\,(2\sigma_u)^2\,(1\pi_u)^4\,(3\sigma_g)^2$, $^1\Sigma_g^+$;
CO: $(1\sigma)^2\,(2\sigma)^2\,(3\sigma)^2\,(4\sigma)^2\,(1\pi)^4\,(5\sigma)^2$, $^1\Sigma^+$.

Leaving aside the four inner electrons, the theoretically computed forms and energies (i.e. ionization energies or term values) of the ground-state MOs and of the two atomic-valence-shell excited MOs are described in LCAO approximation in Table I. Especially notable are the considerable hybridization in the σ MOs and the resulting strength of bonding in the lowest energy of these, with corresponding weakness of bonding in the last occupied MO, and great strength of antibonding in the excited σ MO. Similar characteristics are found for all other molecules on which theoretical LCAO-MO SCF computations have been made (e.g. CO_2 and O_3, Table V).

TABLE I

FORMS OF N_2 AND CO MOLECULAR ORBITALS*

*Based on: C. W. Scherr (J. Chem. Phys. **23**, 569 (1955)) for N_2, R. C. Sahni (Trans. Faraday Soc. **49**, 1 (1953)) for CO.

†The symbols s; h; h' mean 2s; a 2s, 2pσ hybrid with strong end toward the other atom and positive; and a 2s, 2pσ hybrid with weak end toward the other atom and positive (cf. Fig. 1); x and z refer to 2px and 2pz, together comprising 2pπ. The symbols B and b mean strongly or weakly bonding, A and a mean strongly or weakly antibonding.

‡Rough weighted average term values based on excitation energies to various states.

§Observed; calc. is (a).

Theoretically computed energies (N_2), and observed energies and other data (CO, N_2), are given in Table II for the various *states* of the two lowest excited *configurations*. It should be noted that this table incorporates the most recent spectroscopic results and their interpretation, and includes a new identification of the d state of CO as a $^3\Delta_u$ state (cf. Table II footnote). A study of Table II gives confidence that LCAO-MO computations on simple molecules can predict correctly the energy order of the various states of a $\pi^3\pi$ configuration, and even roughly quantitatively the positions of the lower-energy excited states. However, the predicted energy of the $\pi_u^3\,\pi_g$, $^1\Sigma_u^+$ state of N_2 is certainly too high, since the actual energy can surely not exceed the (vertical) 17.5 ev. required to remove a $1\pi_u$ electron entirely. We may nevertheless reasonably conclude from the very high computed value that the vertical energy of the actual state must be rather close to the π_u ionization limit. This is true for the observed state b' identified in Table II as $\pi_u^3\,\pi_g$, $^1\Sigma_u^+$; its vertical energy is roughly 14 or 15 ev. The theory also shows that this one

*The CO state d here identified as $^3\Delta$ (Hund's case b) has hitherto been called d $^3\Pi_i$ (Hund's case a), following an analysis by Gerö and Szabo (Ann. Physik, **35**, 597 (1939)) of the d → a emission bands. Although their data are not adequate for a conclusive judgment, the reported structure seems to be entirely compatible with $^3\Delta(b) \rightarrow {}^3\Pi(a)$, and not with $^3\Pi(a) \rightarrow {}^3\Pi(a)$. See G. Herzberg and T. J. Hugo (Can. J. Phys. **33**, 757 (1955)) and Tanaka, Jursa, and Leblanc (J. Chem. Phys. **26**, 862 (1957)), and references there given, for sources of the above data on CO. Because of some uncertainty in the vibrational numbering, ω_e may be somewhat larger, and r_e and the energy somewhat smaller, for d $^3\Delta$.*

†*For sources of the data on N_2, see R. S. Mulliken, in Proceedings of the Conference on Aeronomy (held at Cambridge, Mass., in June, 1956), (Pergamon Press, Ltd., London, 1957), and references there given. Values in brackets are estimated (not observed). Energy values in parentheses are vertical values from LCAO-MO theoretical computations by C. W. Scherr (J. Chem. Phys. **23**, 569 (1955)). Observed energy values are non-vertical; the vertical values would be about 0.5 ev. higher for the $\sigma^{-1}\pi^*$ states, about 1.5 ev. higher for the $\pi^{-1}\pi^*$ states.*

state must be much more ionic in character than all the other $\pi_u^3\,\pi_g$ states, justifying the identification in Table II with an observed state of much larger r_e and smaller ω_e than the others. Further, the theory shows that this $^1\Sigma_u^+$ state is the *only* one of the $\pi_u^3\,\pi_g$ states to which spectroscopic transition from the ground state is allowed by the selection rules (analogously for $\pi^3\,\pi^*$, $^1\Sigma^+$ of CO), but that this one transition should be intense (V, N type). The state identified in Table II with $^1\Sigma_u^+$ is the lowest-energy $^1\Sigma_u^+$ state of N_2 to which an intense transition occurs.[4]

The good agreement of theory and experiment for CO and N_2 lends strong credence to the LCAO-MO theoretically predicted energy order and rough quantitative locations of the states of the excited configurations . . . $1\pi_g^3\,2\pi_u$, . . . $1\pi_g^3\,3\sigma_g$, and . . . $1\pi_g^3\,3\sigma_u$ for linear CO_2 (cf. Table III). The negative computed ϵ values (term values) for $3\sigma_g$ and $3\sigma_u$ (see Table V) of course cannot be taken literally. They may, however, reasonably be interpreted to mean that the actual (necessarily positive) ϵ values for these MOs are small. The computed negative values probably signal a characteristic breakdown of the usual LCAO-MO approximation, based on free-atom Slater AOs, for high-energy LCAO-MOs. Further, such small-ϵ LCAO-MOs should probably be, as it were, dissolved and replaced by Rydberg MOs. Borderline cases between LCAO and Rydberg MOs are known. For example, the LCAO-MO $\sigma_u 1s$ (i.e., $1s_a - 1s_b$) of H_2 is nearly identical in form and

[4]*There should also be another high-energy $^1\Sigma_u^+$ state of (approximately) V type, corresponding to the configuration $\sigma_g^{-1}\sigma_u^*$. Presumably this is present at somewhat higher energies, but possibly the b′ state is $\sigma_g^{-1}\sigma_u^*$ and the $\pi_u^{-1}\pi_g$ V state is at higher energies, or possibly the situation is more complicated and involves mixing of two or more $^1\Sigma_u^+$ states.*

‡But perhaps slightly unsymmetrical.

**Polarization expected for absorption transition from ground state (*f* means forbidden).

must be identified with the Rydberg (or united-atom) MO $2p\sigma_u$. Again, the C—H antibonding a_1 excited LCAO-MO for CH_4 (or NH_3, or H_2O) strongly resembles and must be identified with the Rydberg MO 3*s*.

We may now conclude that: (1) the $^1\Sigma_u^+$ state of $\pi_g^3\,\pi_u$ for linear excited CO_2 is to be expected only at much higher energies than the others of this configuration, and (2) the $^3\Pi_g$ and $^1\Pi_g$ states of $\pi_g^3\,\sigma_g$ and the $^3\Pi_u$ and $^1\Pi_u$ states of $\pi_g^3\,\sigma_u$ are to be expected only at high energies close to the π_g ionization limit (13.8 ev.), and well above all the $\pi_g^3\,\pi_u$ states except the $^1\Sigma_u^+$. Point (2) makes it fairly certain that Walsh (16) was right in assuming the $3\sigma_g$ MO of CO_2 to be less firmly bound than the $2\pi_u$, reversing the order assumed by the present writer (9) in his 1942 diagram of the orbital energies of AB_2 molecules for apex angle 180°.[5]

Let us next consider the predicted levels of linear and bent CO_2 (Table III) in relation to the observed absorption spectra above 1600 Å. For bent CO_2 (C_{2v} symmetry), the π_g MO of $\pi_g^3\,\pi_u$ must split into an a_2 and a b_2 MO, and the π_u into an a_1 and a b_1.[6] The partial configuration $\pi_g^3\,\pi_u$ thus gives rise to *four* partial configurations yielding four singlet and four triplet states. The latter must be correlated with the several linear-molecule $\pi_g^3\,\pi_u$ states in the manner shown in Table III if we assume that the a_1 excited MO becomes rapidly lower than b_1 on bending, as is indicated by both empirical (9, 16) and now also theoretical (cf. Table V) evidence. It can then be predicted that some of

[5]*The writer in 1942 thought $3\sigma_g$ might be lower because of the large amount of $2s_C$ in it, if strongly antibonding; but Mulligan's LCAO-MO computations show it to be nevertheless of high energy.*

[6]*The orbital notation follows the internationally approved recommendations (J. Chem. Phys.* **23**, *1997 (1955)).*

these states should be bent, others linear (Table III). There seems to be little doubt that the observed rather weak absorption system with maximum near λ1475 (cf. Table III) represents a transition to a bent $^1\Delta_u B_2$ state, as proposed by Walsh.

The interpretation of the observed second rather weak CO_2 system with maximum near λ1330 then presents a puzzle; Walsh has identified it as the transition to the $^1\Sigma_u^+$ of $\pi_g^3\,\pi_u$ or to the corresponding $^1B_2$ state, but this identification must apparently be rejected because (*a*) the transition is too weak, and (*b*) its upper state should surely be considerably higher in energy in view of Point (1) in the second preceding paragraph. The state in question might conceivably be identified with $^1\Pi_g$ of $\pi_g^3\,\sigma_g$, but this seems to be excluded by (*a*) Point 2 of the second preceding paragraph, and (*b*) the fact that the molecule in this state is expected to be linear, in which case there should be only one relatively strong band in the system, instead of the large number actually observed. A rather plausible identification would be with a transition to a strongly bent $b_1\,a_1^2\,a_1$, $^1B_1$ or $b_1^2\,a_1\,a_1$,$^1A_1$ upper state corresponding to a $^1\Sigma_g^-$ or $^1\Delta_g$ state of the linear-molecule configuration $1\pi_u^3\,2\pi_u$, although one would have expected such a state to be distinctly higher in energy, since the ionization potential of $1\pi_u$ is 3.6 volts higher than that of $1\pi_g$ (cf. Table V).

In the doubtless analogous case of the weak near-ultraviolet CS_2 absorption spectrum, rotational and vibrational analysis seems to show conclusively that the lowest excited singlet level is a bent $^1B_2$ (equilibrium angle about 140° according to Dr. B. Kleman), with rotational perturbations attributable to the predicted (cf. Table III) nearby $^1A_2$ state. Direct transitions to the latter state, being electronically forbidden, should be weaker than to the $^1B_2$. According to a private communication from Dr. Kleman, the bands at the high-frequency end of the near-ultraviolet CS_2 absorption look like a separate system; if so, this might be analogous to the λ1330 CO_2 system.

[*Added after the conference.*—Dr. A. E. Douglas reported at the conference that the low-frequency end of the near-ultraviolet CS_2 spectrum shows a pronounced Zeeman effect, indicating that the excited state is a triplet state. The high-frequency end, which shows no definite evidence of a Zeeman effect, might then have a singlet upper state. These results can be understood without radical revision of the preceding discussion if the upper state of the weak low-frequency bands is the lowest $^3A_2$ of Table III, related to $^3\Delta_u$ of the linear case; its rotational perturbations would be attributed to the second (or possibly both) of the low $^3B_2$ states of Table III. The stronger high-frequency region could then be explained by transitions to the bent $^1B_2$ state related to $^1\Delta_u$ of the linear case. Additional weak transitions to other states listed in Table III might possibly also be present in the observed structure. This revision of the earlier interpretation of the near-ultraviolet CS_2 absorption spectrum is not unreasonable in view of the relatively strong spin–orbit coupling in the sulphur atom (analogous singlet–triplet transitions should be very much weaker and very difficult to observe in CO_2). However, the fact that no indication whatever of the presence of triplet fine structure has been noted in any of the band lines by Liebermann or by Kleman, in spite of the use of high resolution, seems difficult to reconcile with a triplet state for the upper state of the low-frequency near-ultraviolet bands.]

On the basis of the preceding discussion and Table III, it seems fairly safe to conclude (*a*) that the lowest singlet excited states of CO_2 are a bent $^1B_2$ and $^1A_2$ with vibrational zero levels near 7 ev., and (*b*) that the lowest triplet states are corresponding bent $^3B_2$ and $^3A_2$ states near 5–5.5. ev. (Walsh (16) attributes a well-known emission system observed in carbon monoxide flames to a transition from a higher triplet level to one of

these.) With respect to the higher excited levels, the present survey suggests that considerably more study, both experimental and theoretical, is needed. Similar remarks apply to CS_2.

THE LOW EXCITED LEVELS OF ACETYLENE

The ground-state electron configuration of C_2H_2 should be closely analogous to that of N_2 (cf. [1]) except for the C—H bonding properties of the σ MOs:

$$[2] \qquad C_2H_2\colon\ (\sigma_g 1s_C)^2\,(\sigma_u 1s_C)^2\,(2\sigma_g)^2\,(2\sigma_u)^2\,(3\sigma_g)^2\,(1\pi_u)^4,\ {}^1\Sigma_g^+.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{HC, CH}\ \ \text{HC, CH}\ \ \text{CC}\ \ \ \text{CC}$$

The capital letters under the last four MOs indicate their probable major bonding characteristics. For spectroscopic purposes, the major difference from N_2 is that $3\sigma_g$, because of its strong C—C bonding function, must be less easily excited than $1\pi_u$, the reverse of what is true for N_2.[7] Hence for linear excited C_2H_2, the $(3\sigma_g)\,(1\pi_u)^4\,1\pi_g$ states, unlike N_2 (Table II), are doubtless definitely above all except perhaps the highest $({}^1\Sigma_u^+)$ of the $(3\sigma_g)^2\,(1\pi_u)^3\,1\pi_g$ states, so that we need consider only the latter. In Table IV, the observed and computed $\pi_u^3\,\pi_g$ states of N_2, and the corresponding computed states for *linear* C_2H_2 (14),[8] are compared. From our experience on CO and N_2 as discussed above, we may place confidence in these computed values for linear C_2H_2 so far as the energy order of the states is concerned, and also very roughly quantitatively. The foregoing considerations furnish a basis for the correlations given in Table IV of these linear-molecule with bent-molecule states of excited C_2H_2, and give some guidance as to the energy order for the bent-molecule states.

Now let us assume, with Walsh (16), that $1\pi_u$ splits into two MOs differing little in energy, namely a_1 and b_1 for C_{2v} (*cis*) symmetry, or b_u and a_u for C_{2h} (*trans*) symmetry, and that $1\pi_g$ splits into one MO whose energy does not change with bending (a_2 for *cis*, b_g for *trans*) and another whose energy decreases strongly with bending (b_2 for *cis*, a_g for *trans*).[9] This assumed behavior on bending is analogous to what happens in AB_2 molecules, where it is definitely known that the low-energy π MOs $1\pi_u$ (bonding) and $1\pi_g$ (non-bonding) split only slightly with bending, while the high-energy antibonding $2\pi_u$ splits very strongly (cf. Table V). The MOs a_2 or b_g from π_g and b_1 or a_u from π_u are antisymmetric to the plane of bent C_2H_2 and necessarily remain strongly bonding and antibonding, respectively, during bending. For C_{2v} (*cis*-bent) C_2H_2, the correlations in Table IV are formally identical with those for CO_2 (Table III) except for the MO labels (a_2 replaces b_2, a_1 replaces b_1, and vice versa, because the configuration here is $\pi_u^3\,\pi_g$ instead of $\pi_g^3\,\pi_u$). For C_{2h} (*trans*-bent) C_2H_2, which has no analogue for CO_2, the correlations are similar, but the selection-polarization rules for allowed spectroscopic transitions from the ground state are distinctly altered. Ingold and King, and Innes, in their thorough analyses of the observed weak absorption band system near λ2200, find transitions only to *trans*-bent ${}^1A_u$ excited molecules (see Table IV) (4, 5). The absence of transitions to *cis*-bent molecules can be explained by the spectroscopic forbiddenness of ${}^1A_2 \leftarrow {}^1\Sigma_g^+$, but there is

[7] *The writer estimates that the ionization potential of $3\sigma_g$ is 20–21 volts, whereas the observed minimum ionization potential of C_2H_2, which must belong to $1\pi_u$, is only 11.3 volts.*

[8] *For further calculations, see Serre (15) and references given there.*

[9] *Ingold and King, on the other hand, assume that $\pi_u b_u$ and $\pi_g a_g$ (or $\pi_u b_1$ and $\pi_g a_2$) both become nearly nonbonding and nearly equal in energy in bent C_2H_4. This results in a very different pattern of predicted excited levels. A consequence is that the lowest ${}^1B_u$ of bent C_2H_2 should be rather far (perhaps 3 ev.) below the lowest ${}^1A_u$ (cf. Fig. 3 on p. 2715 of their papers (4)). Since the transition to this state should then lie in the visible, and be relatively strong, their assumption about the nature of these MOs seems improbable (but see below). However, they are in agreement with Table IV and with Walsh that the configuration of the ${}^1A_u$ upper level of the λ2200 system is $a_u b_u^2 a_g$.*

*See Fig. 1 for explanation of atomic orbital symbols describing the form of each MO. The symbols B, b, N, a, A respectively mean strongly bonding, weakly bonding, essentially non-bonding, weakly antibonding, and strongly antibonding. Computed quantities based on I. Fischer-Hjalmars (Arkiv. för Fysik, **11**, 529 (1957)) for O_3, and J. F. Mulligan (J. Chem. Phys. **19**, 347, 1428 (1951)) for CO_2. The "observed" ϵ values for the occupied MOs of CO_2 are ionization potentials based on Rydberg series (including the latest unpublished results of Y. Tanaka on $2\sigma_g$) and the CO_2^+ spectrum (for $1\pi_u$). For the unoccupied MOs of CO_2, the ϵ values are approximate average term values appropriate to excited states. Ozone is at the left, carbon dioxide at the right.*

no reason to suppose that *cis*-bent $^1A_2$ molecules cannot exist, although perhaps (4) they may have somewhat higher energy.

Comparing with CO_2, it seems relevant that the intensity of ^1A_u (*trans*) $\leftarrow {}^1\Sigma_g^+$ in acetylene ($f = 10^{-4}$, cf. Table IV footnote), whose analogue $^1A_2 \leftarrow {}^1\Sigma_g^+$ in CO_2 is forbidden, is much less than that of the observed $^1B_2 \leftarrow {}^1\Sigma_g^+$ λ1475 system of CO_2 ($f = 0.004$). This seems reasonable, since $^1A_u \leftarrow {}^1\Sigma_g^+$ of C_2H_2 must acquire its intensity from $^1\Pi_u A_u \leftarrow {}^1\Sigma_g^+$ transitions (through some weak mixing of higher-configuration $^1\Pi_u A_u$ states with our $^1\Sigma_u^- A_u$), while $^1B_2 \leftarrow {}^1\Sigma_g^+$ of CO_2 can acquire its intensity mainly from the predictedly very intense $(\pi^3\pi,\ {}^1\Sigma_u^+)^1B_2 \leftarrow {}^1\Sigma_g^+$ transition (by admixture of $(\pi^3\pi,\ {}^1\Sigma_u^+)^1B_2$ into $(\pi^3\pi,\ {}^1\Delta_u)^1B_2$ on bending).

It can now be predicted that there should be absorption transitions $^1B_2$(*cis*) $\leftarrow {}^1\Sigma_g^+$ and ^1B_u (*trans*) $\leftarrow {}^1\Sigma_g^+$ for C_2H_2, and that these should be much stronger than the ^1A_u (*trans*) $\leftarrow {}^1\Sigma_g^+$ λ2200 system. It seems likely that these predicted transitions can be identified with the rather plentiful confusion of bands, which are relatively weak but stronger than the λ2200 system, extending from near λ2000 for a few hundred angstroms toward shorter wavelengths.[10] A detailed study of these bands, if feasible, would be of great interest. Comparisons with recent work of Herzberg and Innes (3) on HCN will also be valuable; here again, the linear-molecule predicted states of $\pi^3\pi$ configuration should be similar to those of N_2 or CO.

[*Added after the meeting.*—At λ1520 occurs the origin of the first Rydberg transition

[10]*See the extensive discussion in Walsh's paper (16). Further, on the basis of unpublished results, Dr. P. G. Wilkinson estimates a total f value of very roughly 10^{-3} for the bands between λ1900 and λ1550. But Dr. T. M. Dunn of University College, London (private communication), estimates an f value five or ten times larger for these bands. He also estimates a larger f value for the "λ2200" system, and furthermore estimates that the intensity maximum of this system is near λ1900 rather than λ2200.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

of C_2H_2. This is an intense transition (f = 0.13 according to Moe and Duncan (7)). On the basis of the vibrational structure (essentially only two or three quanta of the C—C stretching vibration) and the appearance of the bands, the excited state here, hence presumably the $^2\Pi_u$ ground state of $C_2H_2^+$, is definitely linear. A report on this transition and on the next group of strong bands near λ1340, going beyond previous work of W. C. Price (12), is in course of preparation by Dr. P. G. Wilkinson. Wilkinson's analysis indicates the presence of a very close group of three upper electronic states for the λ1340 group, of which two seem to be Rydberg states with a nearly but not quite linear configuration, while the third appears to be a non-Rydberg state in which the molecule is *trans*-bent, perhaps to 120°, *and twisted.* (Price assigned this whole group of bands to a single Rydberg transition.) The most likely identification of this bent and twisted state is with the transition to the high-energy ^1B_u state of Table IV which corresponds to the linear-molecule $\pi_u^3\,\pi_g$, $^1\Sigma_u^+$ state. The high intensity (f about 0.17 according to Moe and Duncan for the group of three electronic transitions near λ1340; more or less equally shared by all three) and the energy (9.25 ev., as compared with 12.85 ev. for the supposedly analogous $^1\Sigma_u^+$ of N_2—cf. Table IV) tend to support this identification. However, it is evident that our theoretical understanding is still incomplete. A possibility not considered in Table IV, which perhaps may be important, is that for linear acetylene there exist low excited $^3\Pi_u$ and $^1\Pi_u$ states of configuration $\pi_u^3\,\sigma_u$ involving a strongly antibonding σ_u MO analogous to $3\sigma_u$ of N_2 (cf. Table I) but lower in energy, to which might correspond bent states one of which could be (or could be mixed into) the λ1340 bent upper state. Final conclusions must await further experimental and theoretical study.

In seeking to interpret the four electronic absorption systems of HCN and DCN which Herzberg and Innes (3) observe below λ2000, a qualitative theoretical consideration indicates an electron configuration

[3] $$\underset{\text{CN}}{(1s_N)^2}\,\underset{\text{CH}}{(1s_C)^2}\,\underset{\text{C=N}}{(3\sigma)^2\,(4\sigma)^2\,(1\pi)^4\,(5\sigma)^2}$$

in which the last σ MO (5σ) and the π MO may have about equal ionization potentials, or the 5σ even somewhat less than the 1π. This is in marked contrast to acetylene (cf. [2] and text above) where there seems to be no doubt that the last σ MO ($3\sigma_g$) is very much more tightly bound than the $1\pi_u$ MO. The excited states of HCN for the molecule if it were linear should then resemble closely those of N_2 and CO (cf. Table II) in that the configuration $\sigma^{-1}\pi^*$ would be involved in giving rise to the lowest excited states. On this basis, the bent upper state of Herzberg and Innes' α system might be identified with the $^1A''$ state corresponding to the linear-molecule $\sigma^{-1}\pi^*$, $^1\Pi$ state, while the β, γ, and δ system upper states could be correlated with some of the other states corresponding to $\sigma^{-1}\pi^*$ and $\pi^{-1}\pi^*$. In favor of this identification is the fact that Herzberg and Innes find a considerable increase in the C—H distance in the α upper level, which does not seem to be understandable (and is not found in the λ2200 system of C_2H_2) in terms of any state correlated with a pure $\pi^{-1}\pi^*$ linear-molecule configuration. In $\sigma^{-1}\pi^*$, the C—H distance could be increased if the 5σ MO is somewhat C—H bonding. The interpretation suggested here is open to objections, but may at least point toward some possibilities which should be explored.]

Because of the definite conclusions as to the energy order and other characteristics of the $\pi_u^3\,\pi_g$ states of linear C_2H_2, the correlations and interpretations proposed here are somewhat different from those of Walsh. They also differ considerably from those of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Ingold and King (4). The present interpretation is in harmony with the observation of a ^1A_u lowest excited state of moderately high energy. It does not, however, offer any explanation as to why the molecule is bent to just 120° in this state. Complete LCAO-MO theoretical calculations on C_2H_2 and HCN, for various geometrical forms and electronic states, should be exceedingly helpful in giving better answers and increased understanding.

THE LOWER-ENERGY EXCITED LEVELS AND SPECTRA OF BENT AB_2 MOLECULES

As is well known, AB_2 molecules with up to 16 valence-shell electrons (CO_2, etc.) are linear in their ground states, but those with more are bent. Recent microwave and other spectroscopic work now affords reliable information on angles and internuclear distances for many of these (cf. Table VI). The bent form of the 17–19 electron molecules can be explained if (*a*) the linear form is stabilized by the net effect of the predominantly bonding and non-bonding MOs occupied by the first 16 electrons, (*b*) the next two electrons go into an MO ($4a_1$) whose energy decreases rapidly with bending, (*c*) the next electron goes into an MO which is little affected by bending (cf. ClO_2). The increased bending in 20-electron molecules like F_2O and Cl_2O may presumably be attributed to decreased s–p hybridization in the halogen outer atoms and other quantitative changes. Recent LCAO-MO theoretical calculations on the electronic structures of CO_2 and O_3, for the experimentally known internuclear distances in each case, throw a great deal of light on the forms of all the MOs involved. A survey of the results, including a simplified rough description of the computed form and energy of each MO occupied in the ground state, as well as of the forms of all valence-shell-AO excited MOs, is presented in Table V (see also Fig. 1). The table has a number of points of interest. In studying it, however, one should keep in mind that the computed results, while good, are only approximate.[11] The reliability of the computed ϵ values can be judged by a comparison of observed and computed values for CO_2—see also Tables II and III. The approximate forms of the MOs are probably fairly reliable in most cases.

The following points are especially relevant here. (1) The linear-molecule $1\pi_u$ and $1\pi_g$ MOs split and change in energy relatively little as a result of bending. (In comparing ϵ values of bent O_3 and linear CO_2 in Table V, it should be kept in mind that the larger nuclear charge on the central atom in O_3 causes a general increase in ϵ values.) (2) The first excited MO $2\pi_u$ of CO_2 splits very strongly to give a $4a_1$ MO whose ϵ in O_3 is as large as the MOs corresponding to $1\pi_g$, and a $2b_1$ MO whose ϵ should not change on bending. We have thus a theoretical explanation of the highly angle-sensitive $4a_1$ MO which is known empirically. One notes that, although the $2\pi_u$ MO is strongly antibonding, and the $2b_1$ remains so, the $4a_1$ for a 120° angle is only weakly antibonding. The very large ϵ of $4a_1$ at 120° is a result which comes out of the theoretical calculation and which perhaps cannot be fully explained in qualitative terms, although it can be partially attributed to the decreased antibonding. (3) The linear-molecule MOs $3\sigma_g$ and $3\sigma_u$ are very high in energy, and go over into even higher energy (at least for the $3\sigma_g$) bent-molecule MOs $5a_1$ and $4b_2$. The thus-indicated ϵ values are so small that, contrary to earlier assumptions (9), these MOs probably may be left out of consideration in the explanation of observed absorption spectra except perhaps at short wavelengths in the vacuum ultraviolet.

The theoretical computations permit considerable improvements in both the writer's and Walsh's AB_2 diagrams with respect to the energies of the various MOs, and give new

[11] *Besides the approximations inherent in the LCAO–MO SCF method, the computations on* O_3 *and* CO_2 *did not specifically take into account the 1s electrons. Further, many of the integrals involved were approximated. On the other hand, the results for* N_2 *in Table I are based on a complete exact LCAO–MO SCF computation.*

*See Table V (ozone) for approximate forms of MOs. The symbols x, y, f respectively refer to transitions polarized perpendicular to the molecule plane, parallel to the B–B axis, or forbidden; w means weak, s, strong. The predicted changes in apex angle α and A—B distance r are based on the bending and bonding properties of the MOs involved.

†*Ground-state data: for* NO_2, *cf. G. E. Moore (J. Opt. Soc. Am.* **43**, *1045 (1953)) and G. R. Bird (J. Chem. Phys.* **25**, *1040 (1956)); for* NO_2^- *(in crystal), M. R. Truter (Acta Cryst.* **5**, *132 (1952)); for* O_3, *cf. R. H. Hughes (J. Chem. Phys.* **24**, *1313 (1956)); for* SO_2, *S. R. Polo and M. K. Wilson (J. Chem. Phys.* **22**, *900 (1954)); for* ClO_2, *J. D. Dunitz and K. Hedberg (J. Am. Chem. Soc.* **72**, *3108 (1950). Spectroscopic data*: NO_2 *absorption, L. Harris and G. W. King (J. Chem. Phys.* **2**, *51, (1934)) and G. Wilse Robinson (report at Ohio State University Spectroscopic Conference (1957)); for* NO_2 *absorption intensities, T. C. Hall and F. E. Blacet (J. Chem. Phys.* **20**, *1745 (1952)) and Harris and King (loc. cit.); for* NO_2 *fluorescence spectrum (probably* $2b_1 \rightarrow 4a_1$*; smaller f (longer lifetime) in emission may be explained by lower transition probability at larger angle), D. Neuberger and A. B. F. Duncan (J. Chem. Phys.* **22**, *1693 (1954)). Note that* $2b_1 \leftarrow 1a_2$ *in* NO_2 *should give rise to two non-intersystem transitions of which an identification is given here for one. For* NO_2^- *in* $Na^+NO_2^-$ *crystal: see W. G. Trawick and W. H. Eberhardt (J. Chem. Phys.* **22**, *462 (1954)), J. W. Sidman (J. Am. Chem. Soc.* **79**, *2669, 2675 (1957)); Sidman's work shows that the λ3500 system is an allowed one in spite of its weakness and confirms the x polarization found by Trawick and Eberhardt. The f values for* NO_2^- *are based on aqueous solution data of H. L. Friedman (J. Chem. Phys.* **21**, *319 (1953)); the λ2900 solution band is apparently much weaker or possibly absent in the crystal, while the λ2100 solution band shows a double peak, and possibly part or most of the f value may belong to a different (charge-transfer) transition.* O_3*: calculated frequencies (not given above) and f values, I. Fischer-Hjalmars (loc. cit. Table V); absorption bands, cf. survey by H. Sponer and E. Teller (Revs. Modern Phys.* **13**, *75 (1941)) and more recent literature. It is here assumed that the very weak reported infrared system is due to impurities (perhaps* O_4*) or is an intersystem transition. Evidence that the bands near λ3500 form a system distinct from the stronger region near λ2550 has also been disregarded.* CF_2 *emission, P. Venkateswarlu (Phys. Rev.* **77**, *676 (1950)), absorption, R. K. Laird, E. B. Andrews, and R. F. Barrow (Trans. Faraday Soc.* **46**, *803 (1950)).* SO_2*: λ3800 system, Russell et al. (ASTIA AD81060), Coffmann et al. (ASTIA AD95806), with J. B. Coon; λ2900 system, N. C. Metropolis (Phys. Rev.* **60**, *295 (1941)) and see P. A. deMaine (J. Chem. Phys.* **26**, *1036 (1957)) for* CCl_4 *solution data from which f value has been computed. The λ2900 system and a stronger absorption region near λ2000 also appear in fluorescence.* ClO_2*: J. B. Coon and E. Ortiz (J. Molecular Spectroscopy (In press, 1957) and Phys. Rev.* **96**, *845A (1954)). In a private communication, J. B. Coon gives* $f = 1.7\times10^{-7}$ *and* 4.3×10^{-3} *respectively for the* SO_2 *λ3800 and λ2900 systems. See also text "added after the meeting".*

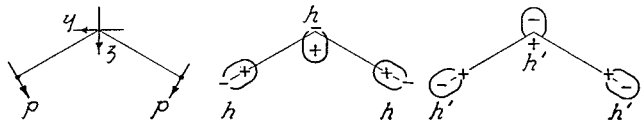

FIG. 1. Schematic diagram to indicate forms of atomic orbitals used in describing O_3 molecular orbitals in LCAO approximation. For any atom, s means $2s$ and x means $2px$, while h and h' respectively refer to various in-plane sp hybrids directed *more or less* toward or away from the center but whose exact forms and orientations vary from case to case. For the middle atom, y and z mean $2py$ and $2pz$ with positive end in the direction shown. For the outer atoms, p means an in-plane $2p$ AO directed *approximately* perpendicular to an O—O bond. The x AO's are antisymmetric to the molecular plane, while all others are symmetric. Double symbols in the descriptions (e.g. sh or $p-s$) are used where hybridization is somewhat minor in importance (e.g. sh means a mixture of s and h, $p-s$ a mixture of p and $-s$). *Capital letters* are used in a few cases to indicate rather strong predominance in the total LCAO-MO.

Fig. 1 applies also to CO_2 if the apex angle is increased from 120° to 180° with the O atom orbitals retaining their orientations to the CO axes; the x and the p_O and z_C AOs now become π AOs.

insight into the forms of the MOs. In combination with new experimental data of the last few years, they have led the writer to review earlier attempts to interpret the electronic absorption spectra of triatomic oxides, and to propose, in Table VI, identifications of known spectra above about λ2000. In this effort, he is indebted to Professors G. W. Robinson, J. B. Coon, and W. H. Eberhardt for suggestions and for information on their current work.

The assignments of observed band systems to MO transitions for the several molecules are to a large extent mutually consistent and consistent with theoretical requirements and expectations (listed under "Predictions"). However, there seem to be some discrepancies which are difficult to explain, and the identifications must therefore still be considered provisional. These difficulties will now be mentioned and commented on briefly.

(1) The SO_2 λ3800 system is so weak that one is tempted to attribute it to a singlet–triplet transition, but if this is correct, the corresponding singlet–singlet transition should be nearby at somewhat shorter wavelengths. Although the λ2900 system fulfills this specification, its $\Delta\alpha$, Δr characteristics are so different as to rule out such a relation. The much stronger bands near λ2000 are too far away. Thus one is left with the assignments in the table. The low intensities of the assigned SO_2 bands, and the fact that we have ignored the strong bands near λ2000 whereas for NO_2 and NO_2^- we have included strong bands at short wavelengths in the assignments, are not entirely satisfactory.

[*Added after the meeting.*—Dr. A. E. Douglas reported at the meeting that the SO_2 λ3800 system shows a pronounced Zeeman effect. This supports its interpretation as a singlet–triplet transition rejected above, but does not answer the contrary argument given above. Douglas finds no Zeeman effect in the λ2900 system; if λ3800 is actually a singlet–triplet transition, λ2900 is probably $2b_1 \leftarrow 4a_1$ (it will be noted that the experimental data in Table VI which would contradict this appear with a ?) and $2b_1 \leftarrow 1a_2$ is probably represented by strong bands near λ2000.]

In the case of *ozone*, the assignments are definitely tentative and need further study (see footnote on O_3 in Table VI). For *all* the molecules, additional non-Rydberg transitions besides those considered in Table VI, involving excitation from the deeper occupied MOs (and possibly also to higher excited MOs), are of course to be expected at shorter wavelengths, and a number of such transitions have certainly been observed. There seems, however, to be no reason why d hybridization for S and Cl in SO_2 and ClO_2 should markedly affect the long wavelength spectra. It should make the MOs $1a_2$ and $3b_2$ somewhat bonding, and strengthen the bonding MOs on the whole.

For personal use only.

(2) The identification of the visible NO_2 bands as $2b_1 \leftarrow 4a_1$ seems to be supported by the work of Robinson (13) and of Eberhardt, but the observed intensity ($f = 0.003$) is higher than expected, and also higher than for the transition identified as $4a_1 \leftarrow 3b_2$ which one might expect to be rather strong. An *alternative identification* would be to attribute the visible bands to $4a_1 \leftarrow 3b_2$, the bands with λ_{max} at about 2350 to $2b_1 \leftarrow 1a_2$, and to suppose that the $2b_1 \leftarrow 4a_1$ bands are present among the visible bands but too weak to be noticed. It should be noted that $4a_1 \leftarrow 3b_2$ is possible only for NO_2 among the molecules in Table VI, since in the others the $4a_1$ shell is filled in the ground state.

(3) While $4a_1$ in NO_2 should be more or less halfway down from $2b_1$ toward $3b_2$ and $1a_2$, as one sees by interpolation between CO_2 and O_3 in Table V, it should in the other molecules (judging from the O_3 calculated results in Table V) be close to $1a_2$ and $3b_2$, and the latter should have ϵ values near 15 ev., while $2b_1$ is expected to have ϵ near 5 ev. Hence the $2b_1 \leftarrow 4a_1$ and $2b_1 \leftarrow 1a_2$ spectra of NO_2^-, O_3, SO_2, and ClO_2 might be expected to have frequencies corresponding to about 10 ev., instead of being in the range 3–6 ev. as observed according to Table VI. However, since an examination of Table V excludes any possibility of alternative MOs which could give smaller predicted excitation energies, we must apparently conclude that the MO identifications are not essentially at fault.

Granting this, it would seem that theoretical calculations based more directly on *electronic states* may be needed to account for the observed spectra. In general, the energies of electronic states can be estimated only roughly by the assumption of a definite fixed orbital energy ϵ for each excited MO. "Configuration interaction" often strongly affects excitation energies. Reorganization when excitation from one to another particular MO involves a large change in charge distribution can also cause energy lowering. When *degenerate* MOs are involved, there are often a number of states covering a wide energy spread, as for example in the $\pi^3\pi$ states of Tables II–IV. While it is true that in bent AB_2 molecules there are no degenerate MOs, one may expect a partial persistence of the widely spread groupings of states that would exist for the degenerate-MO configurations of these molecules if linear. In fact the discussion given above of the excited states as a point of departure was based on this premise. In applying the same approach to the excited states of, say, NO_2 and O_3, one would first compute the energies of the linear-molecule states, then consider what happens on bending. For NO_2, $\pi_g^4\,\pi_u$, $^2\Pi$ would yield the ground state . . . $1a_2^2\,3b_2^2\,4a_1$, $^2A_1$ and the low excited state . . . $1a_2^2\,3b_2^2\,2b_1$, $^2B_1$, while the several states $^4\Pi_g$, $^2\Pi_g$, $^2\Pi_g$, $^2\Phi_g$, and $^2\Pi_g$ of $\pi_g^3\,\pi_u^2$ would give a number of other excited states. For O_3, one would start with the states of $\pi_g^4\,\pi_u^2$ and $\pi_g^3\,\pi_u^3$. In general, *it is important to consider states as well as orbitals.*

A final point of considerable interest which emerges from some of the data on SO_2 and ClO_2 is the probability that these molecules become slightly unsymmetrical (C_s instead of C_{2v} symmetry) when excitation to a $2b_1$ MO occurs. This MO (cf. Table VI) is inescapably antibonding, but its antibonding effect would be expected to be smaller for an unsymmetrical structure—just as, conversely, a bonding electron in a delocalized MO can give stronger total bonding than one localized between two nuclei. The evidence for an unsymmetrical upper state for the ClO_2 band system, first brought to the writer's attention by J. B. Coon (2),[12] and for the λ3800 and λ2900 SO_2 systems, consists in the fact that the (for C_{2v} antisymmetric) frequency ν_3 is more strongly excited in the upper state than could otherwise reasonably be understood; further, that this frequency shows an

[12]*Earlier, Lotmar (6) gave evidence for an unsymmetrical upper state (cf. p. 780) for the* SO_2 *bands near λ2000, in the fact that* $\Delta v_3 > 0$ *seems to occur in fluorescence. However, later work raises some questions as to this evidence (1).*

For personal use only.

exceptionally large positive anharmonicity (cf. x_{33} values in Table VI). If we assume that these upper states *are* unsymmetrical, then in terms of the coordinate Q_3 associated with ν_3 under C_{2v} symmetry, one has a double minimum problem.[13] If the asymmetry is *only slight*, so that the hump between the two minima is very low, the ν_3 vibration levels should still be fairly evenly spaced, as for C_{2v} symmetry. However, the resulting broadened potential curve should result in (*a*) diminishing the effective force constant for small ν_3 vibrations but introducing strong positive anharmonicity, (*b*) permitting transitions $\Delta v_3 = 2, 4 \ldots$ to occur much more strongly than would be possible by Franck–Condon considerations if there were a single minimum. (Also, $\Delta v_3 = 1, \ldots$ can now occur if the transition is *y* or *z* polarized, but probably only very weakly.) The expected results agree with what is observed. For *larger* asymmetry, the situation would change to resemble ordinary inversion doubling as in NH_3; one should then observe strong *negative* anharmonicity, but $\Delta v_3 > 0$ should still occur readily.

One is tempted to connect unsymmetry of an AB_2 excited state with photodissociation into AB + B. Minimum-energy dissociation of AB_2 into AB + B may be effected, with or without initial asymmetry, by suitable simultaneous excitation of the vibrational coordinates Q_1 and Q_3 (and in general also Q_2). The main importance of initial asymmetry for direct photodissociation would be in softening the usual Franck–Condon inhibitions against $\Delta v_3 > 0$. The diffuseness of the high-frequency regions of some AB_2 absorption systems (e.g. the ClO_2 system) may well be due to direct dissociation of this sort at a saddle-point or a saddle-asymptote of the vibrational energy and/or to vibrational predissociation of vibrational levels near and above such a saddle-point, or above such a saddle-asymptote. In other cases, predissociation into a different electronic state having a lower vibrational saddle-point or saddle-asymptote may occur.

EQUIVALENT ORBITALS AND THE SHAPES OF EXCITED SPECIES[1]

J. W. LINNETT

ABSTRACT

The electron distributions in the ground states of C_2H_2, HCO, and NH_2, and in one excited state of each species, have been considered by transforming the simple molecular orbitals into equivalent ones. In the light of these considerations, the shapes and dimensions of the above species in these states have been discussed. It is found that a considerable degree of understanding can be achieved though there is uncertainty in the interpretation in some cases.

INTRODUCTION

The object of this paper is to discuss some ways in which the shapes of molecules and radicals in their ground and excited states are decided by their electronic structures. The molecule C_2H_2 and the radicals HCO and NH_2 will be considered as examples. An extensive treatment of this type of problem has been given by Walsh (10), his approach being that of *simple* molecular orbital (M.O.) theory. This method, in its simple form, implies that the total energy can be represented to a satisfactory approximation by the sum of a number of one-electron energies of values corresponding to the orbitals that are occupied. Clearly this is an overapproximation, for interelectronic effects arising both from their charge and from the consequences of the Pauli principle (i.e. effects of multiplicity) are ignored. To some extent, of course, in drawing diagrams in his papers, Walsh has taken account of these effects, for the graphs of energy against angle are not computed from a number of one-electron calculations but are derived on a more empirical basis.

Simple M.O. theory, because interelectronic effects are ignored, is clearly an oversimplification. This may be particularly serious in the discussion of shapes, for these are, to a large extent, decided by the mutual effects of electrons on one another. For example, methane is tetrahedral because the Pauli principle requires that four electrons with parallel spins in the $2s$ and three $2p$ orbitals of carbon will be, with greatest probability, at the corners of a regular tetrahedron (11). Moreover charge effects favor this shape also. Also NH_3 is pyramidal because of the presence of the lone pair and of the interaction of this with the bonding pairs (7). Consideration of shapes should therefore include interelectron effects as well as one-electron effects, and consequently the simple M.O. procedure is not wholly satisfactory.

The approach used in this paper will be that based on the representation of the molecular wave function in terms of equivalent orbitals which are linear combinations of the basic one-electron molecular orbitals, for these allow an easier appreciation of the electron distribution, and a more reasonable assessment of the effects of electron interactions. This procedure has been used previously by the author to discuss the bonding in the ground and some excited states of the diatomic molecules and ions formed by carbon, nitrogen, and oxygen (5). Equivalent orbitals of this type are to be preferred when electron distributions are being considered (4). It was found that the force constants and bond lengths correlated well with the number of electrons concentrated in the internuclear region, providing the types of orbitals that were occupied were taken into account.

For the diatomic molecules it was shown (5) that the wave function could be transformed in part from an M.O. description to an equal equivalent orbital description, the

Contribution from Inorganic Chemistry Laboratory and Queen's College, Oxford University, Oxford, England. This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.

equivalent orbitals being atomic orbitals if the L.C.A.O. (linear combination of atomic orbitals) approximation was being used for the molecular orbitals. Let us consider a diatomic molecule AB and the orbitals π_1 (bonding) and π_2 (antibonding). There are two degenerate π_1 orbitals, which may be designated π_1^+ and π_1^-, involving $e^{+i\phi}$ and $e^{-i\phi}$ respectively where ϕ is the azimuthal angle. To a first approximation one may write for the molecular orbitals expressions of the type

$$[1] \qquad \begin{aligned} \pi_1^+ &= a.2p\pi_A^+ + b.2p\pi_B^+, \\ \pi_2^+ &= a'.2p\pi_A^+ - b'.2p\pi_B^+, \end{aligned}$$

where a, b, a', and b' are all positive. Suppose that two electrons having parallel spins occupy π_1^+ and π_2^+, and, for the moment, that these are the only two electrons in the molecule. To satisfy the Pauli principle the wave function must be

$$[2] \qquad \begin{vmatrix} \pi_1^+(1).\alpha(1) & \pi_2^+(1).\alpha(1) \\ \pi_1^+(2).\alpha(2) & \pi_2^+(2).\alpha(2) \end{vmatrix},$$

where α is the spin function. The above function can easily be shown to be identical with

$$[3] \qquad \begin{vmatrix} 2p\pi_A^+(1).\alpha(1) & 2p\pi_B^+(1).\alpha(1) \\ 2p\pi_A^+(2).\alpha(2) & 2p\pi_B^+(2).\alpha(2) \end{vmatrix}.$$

So one may equally describe the electrons as being in the atomic orbitals $2p\pi_A^+$ and $2p\pi_B^+$ or as being in π_1^+ and π_2^+. On this basis one may describe the ground state (G.S.) of O_2 either as $\sigma_g^2.\sigma_u^2.\pi_u^4.\sigma_g^2.\pi_g^2$ or as $2s_A.\overline{2s_A}.2s_B.\overline{2s_B}.2p\pi_A^+.2p\pi_B^+.2p\pi_A^-.2p\pi_B^-.(\overline{\pi_u^+}.\overline{\pi_u^-}.\sigma_g.\overline{\sigma_g})$. In the second of these the presence of an electron with a β spin function in the orbital $2s_A$ is represented by $\overline{2s_A}$, while, if the spin wave function is α, the bar sign is omitted (5). This type of procedure will now be used to consider the shape and binding in some polyatomic molecules and radicals in both ground and excited states.

THE GROUND AND EXCITED STATES OF ACETYLENE

Ingold and King (3) have shown that the absorption band system of acetylene in the neighborhood of 2200 Å is due to a transition to an excited state in which the acetylene molecule is bent, having a *trans* configuration and a center of symmetry. They also bring forward good evidence for believing that the bond between the two carbon atoms is probably a three-electron bond and that the symmetry of the state is ^1A_u.

The electronic structure of the ground state of acetylene is analogous to that of nitrogen, which may be represented by $\sigma_g^2.\sigma_u^2.\pi_u^4.\sigma_g^2$. This is equivalent to $2s_A.\overline{2s_A}.2s_B.\overline{2s_B}.(\pi_u^+.\overline{\pi_u^+}.\pi_u^-.\overline{\pi_u^-}.\sigma_g.\overline{\sigma_g})$ and corresponds to a configuration of maximum probability in which each nitrogen nucleus and K-electron core is surrounded by two approximately tetrahedral sets of electrons, there being five in each set, three in the bond region and two on the internuclear axis, both these being outside the bond region and at opposite ends of the molecule (5). The configuration of maximum probability is therefore reminiscent of Baeyer's interpretation of the triple bond. In acetylene the first four electrons of the set $\sigma_g^2.\sigma_u^2.\pi_u^4.\sigma_g^2$ serve to bond the hydrogen atoms to the carbon, and the remaining six the two carbon atoms to one another, the spatial configuration of the electrons being satisfactory for doing this with a linear arrangement of the four nuclei. For N_2, a relatively small excitation of this system can be achieved by transferring one electron from the π_u to a π_g molecular orbital. Only singlet states will be considered here since it is certain that the excited state observed by Ingold and King is a singlet. There are several singlet states described by $\sigma_g^2.\sigma_u^2.\pi_u^3.\sigma_g^2.\pi_g$. They are:

$$\left.\begin{array}{l}\sigma_g\cdot\overline{\sigma_g}\cdot\sigma_u\cdot\overline{\sigma_u}\cdot\pi_u^{+}\cdot\overline{\pi_u^{+}}\cdot\pi_u^{-}\cdot\sigma_g\cdot\overline{\sigma_g}\cdot\overline{\pi_g^{+}} \\ \text{or}\quad 2s_A\cdot\overline{2s_A}\cdot 2s_B\cdot\overline{2s_B}\cdot\overline{2p\pi_A^{+}}\cdot\overline{2p\pi_B^{+}}\cdot(\pi_u^{+}\cdot\pi_u^{-}\cdot\sigma_g\cdot\overline{\sigma_g})\end{array}\right\}\ {}^1\Delta_u$$

$$\left.\begin{array}{l}\sigma_g\cdot\overline{\sigma_g}\cdot\sigma_u\cdot\overline{\sigma_u}\cdot\pi_u^{+}\cdot\pi_u^{-}\cdot(\overline{\pi_u^{+}}\cdot\overline{\pi_g^{-}}+\overline{\pi_u^{-}}\cdot\overline{\pi_g^{+}})\cdot\sigma_g\cdot\overline{\sigma_g} \\ \text{or}\quad 2s_A\cdot\overline{2s_A}\cdot 2s_B\cdot\overline{2s_B}\cdot(\overline{\pi_u^{+}}\cdot\overline{\pi_g^{-}}+\overline{\pi_u^{-}}\cdot\overline{\pi_g^{+}})\cdot(\pi_u^{+}\cdot\pi_u^{-}\cdot\sigma_g\cdot\overline{\sigma_g})\end{array}\right\}\ {}^1\Sigma_u^{-}$$

[4]

$$\left.\begin{array}{l}\sigma_g\cdot\overline{\sigma_g}\cdot\sigma_u\cdot\overline{\sigma_u}\cdot\pi_u^{+}\cdot\pi_u^{-}\cdot(\overline{\pi_u^{+}}\cdot\overline{\pi_g^{-}}-\overline{\pi_u^{-}}\cdot\overline{\pi_g^{+}})\cdot\sigma_g\cdot\overline{\sigma_g} \\ \text{or}\quad 2s_A\cdot\overline{2s_A}\cdot 2s_B\cdot\overline{2s_B}\cdot(\overline{\pi_u^{+}}\cdot\overline{\pi_g^{-}}-\overline{\pi_u^{-}}\cdot\overline{\pi_g^{+}})\cdot(\pi_u^{+}\cdot\pi_u^{-}\cdot\sigma_g\cdot\overline{\sigma_g})\end{array}\right\}\ {}^1\Sigma_u^{+}$$

For all these the bonding group is $(\pi_u^{+}\cdot\pi_u^{-}\cdot\sigma_g\cdot\overline{\sigma_g})$ so that the bond length would be expected to be about $0.92\times1.40 = 1.29$ Å (cf. Linnett (5), Table 3 (1.40) and Figure 1 (0.92)). No ${}^1\Delta_u$ state has been identified for N_2 but the state designated j (Herzberg (1)) is described as ${}^1\Sigma_u^{+}$ (about 100,000 cm.$^{-1}$ above the G.S.) and the state a' (probably 60,000 cm.$^{-1}$ above the G.S.) is probably ${}^1\Sigma_u^{-}$. The first of these (j) has $r_0 = 1.28$ Å while the second (a') has $r_e = 1.28$ Å. It seems possible therefore that j and a' are to be identified with the corresponding two states described just above.

The three states just described differ in the non-bonding group of two electrons with parallel spins, one in a π_u (bonding) and one in a π_g (antibonding) orbital. The differing groups are:

[5]

$${}^1\Delta_u:\quad \pi_u^{+}\cdot\pi_g^{+}\qquad\qquad (\text{and } \pi_u^{-}\cdot\pi_g^{-})$$

$${}^1\Sigma_u^{-}:\ (\pi_u^{+}\cdot\pi_g^{-}+\pi_u^{-}\cdot\pi_g^{+})$$

$${}^1\Sigma_u^{+}:\ (\pi_u^{+}\cdot\pi_g^{-}-\pi_u^{-}\cdot\pi_g^{+})$$

For the situation in which electrons 1 and 2 occupy the above orbitals the above become, using $\pi_u^{+} = \pi_u\cdot e^{+i\phi}$ and $\pi_g^{-} = \pi_g\cdot e^{-i\phi}$, etc.:

[6]

$${}^1\Delta_u:\ \{\pi_u(1)\cdot\pi_g(2)-\pi_u(2)\cdot\pi_g(1)\}\{\cos(\phi_1+\phi_2)\pm i\sin(\phi_1+\phi_2)\}$$
$$\text{or}\ \{2p\pi_A(1)\cdot2p\pi_B(2)-2p\pi_A(2)\cdot2p\pi_B(1)\}\{\cos(\phi_1+\phi_2)\pm i\sin(\phi_1+\phi_2)\}$$

$${}^1\Sigma_u^{-}:\ \{\pi_u(1)\cdot\pi_g(2)-\pi_u(2)\cdot\pi_g(1)\}\{\cos(\phi_1-\phi_2)\}$$
$$\text{or}\ \{2p\pi_A(1)\cdot2p\pi_B(2)-2p\pi_A(2)\cdot2p\pi_B(1)\}\{\cos(\phi_1-\phi_2)\}$$

$${}^1\Sigma_u^{+}:\ \{\pi_u(1)\cdot\pi_g(2)+\pi_u(2)\cdot\pi_g(1)\}\{\sin(\phi_1-\phi_2)\}$$
$$\text{or}\ \{2p\pi_A(1)\cdot2p\pi_A(2)-2p\pi_B(1)\cdot2p\pi_B(2)\}\{\sin(\phi_1-\phi_2)\}$$

(When considering the symmetry of these last expressions it must be remembered that the bonding group $\pi_u^{+}\cdot\pi_u^{-}$ has the symmetry represented by a negative sign so that the symmetry of the whole group of electrons is the reverse of the symmetry of the pair considered in the expressions [6].) The probability distribution for this non-bonding group in the ${}^1\Delta_u$ state is independent of ϕ_1 and ϕ_2, one electron being on each nitrogen atom. For the ${}^1\Sigma_u^{-}$ state there is one electron on each atom so placed that the highest probability is when the two are in the same plane (i.e. $(\phi_1-\phi_2) = 0$ or π). The ${}^1\Sigma_u^{+}$ state is an ionic state, there being a high probability of both electrons being simultaneously on A or on B. This means that the electron pattern of the ${}^1\Delta_u$ state may be summarized as $sp^3(\sigma\pi^2)$; $sp^2(\sigma)$.* The first group, $sp^3(\sigma\pi^2)$, forms a set like that for a conventional

*The symbolism used here has been described by the author elsewhere (5) and signifies a set of one spin which employs an sp^3 group of orbitals from each atom, the bonding group consisting of three electrons in a σ and two π orbitals, and a second set of the other spin which employs an sp^2 group of orbitals from each atom, the bonding group consisting of one electron in a σ orbital. The atomic orbitals used are given outside the brackets and the bonding orbitals inside the brackets. In addition the orbitals occupied by electrons of one spin are given before the semicolon and those occupied by electrons of the other spin are given after the semicolon.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

triple bond, which has been described above. The second group, $sp^2(\sigma)$, of five electrons involves in the configuration of maximum probability a triangular arrangement round each atom, one electron being between the nuclei (5). In the $^1\Delta_u$ state the plane of the triangular group round one atom is independent of the plane of the group round the other atom (probability independent of ϕ_1 and ϕ_2). For the $^1\Sigma_u^-$ state the electron pattern is also $sp^3(\sigma\pi^2)$; $sp^2(\sigma)$, but the triangular planes of the electrons of the $sp^2(\sigma)$ set tend to lie in the same plane (maximum when $(\phi_1-\phi_2) = 0$ or π). For the $^1\Sigma_u^+$ state the electron pattern is $sp^3(\sigma\pi^2)$; $sp(p^2)^{\frac{1}{2}}(\sigma)$, this being an ionic state.

Consideration of acetylene differs from that of nitrogen in that the location of the protons must also be examined. These protons will be in a particular spatial relation to one another and to the rest of the molecule. For this reason the electronic pattern of the $^1\Delta_u$ states will not be well suited to holding the protons since the electrons of the $sp^2(\sigma)$ set on the two atoms do not tend to have any particular spatial relation with respect to one another with the result that the electron cloud will tend to be too diffuse for binding. In the $^1\Sigma_u^-$ state the two sets are separately well suited to bonding the protons but in different places. The $sp^3(\sigma\pi^2)$ set would tend to bind them in a linear form on the CC axis, but the $sp^2(\sigma)$ set will tend to bind them in a non-linear planar form, either *cis* or *trans*. So this state unmodified is not suited to binding the two protons. However if the electrons of the $sp^3(\sigma\pi^2)$ set, which are outside the central bond region, are displaced towards the directions of the electrons of the $sp^2(\sigma)$ set, two electron pair CH bonds could be formed. But, if this happened without any modification of the $\sigma\pi^2$ group in the central bond region, the electron configuration round each carbon atom would become very unbalanced and this is improbable on the grounds of both charge and spin correlation. The unevenness of the distribution can be remedied to some extent by moving an electron out of the bond region so that the $sp^3(\sigma\pi^2)$ set becomes $sp^2p^{\frac{1}{2}}(\sigma\pi)$, one tetrahedral position on each carbon atom being occupied by only one electron. On this basis, this excited state of acetylene would be expected to be planar and non-linear (probably *trans* because of charge repulsion effects), involving an ordinary electron pair CH bond and a CC bond having three electrons in the bond region (even though it is derived from a state of N_2 having four electrons in the bond region). All these features are observed by Ingold and King, the CC and CH bond lengths being 1.383 and 1.09 Å respectively, the corresponding vibration frequencies being consistent with these values. Moreover, the bending frequency for the excited state is higher than that in the ground state, which would be anticipated for this structure (cf. Walsh (10)). This is the electronic structure suggested by Ingold and King for the excited state, for the $^1\Sigma_u^-$ state of the linear molecule correlates with the ^1A_u state of the bent one and the orbital occupation would also be that expected. The orbitals of *trans* HCCH will now be considered briefly.

The possible molecular orbitals of *trans* HCCH are of the symmetries represented by a_g, a_u, b_g, and b_u; a and b represent orbitals symmetric and antisymmetric to the twofold symmetry axis, and g and u those that are symmetric and antisymmetric to the center respectively. The four singlet excited states which correlate with the $^1\Delta_u$ (^1A_u and ^1B_u), $^1\Sigma_u^-$ (^1A_u), and $^1\Sigma_u^+$ (^1B_u) states are:

$$
\begin{aligned}
&^1A_u\colon a_g\cdot\overline{a_g}\cdot b_u\cdot\overline{b_u}\cdot a_g\cdot\overline{a_g}\cdot \;\vdots\; a_u\cdot b_u\cdot\overline{b_u}\cdot\overline{a_g}\\
&^1A_u\colon a_g\cdot\overline{a_g}\cdot b_u\cdot\overline{b_u}\cdot a_g\cdot\overline{a_g}\cdot \;\vdots\; a_u\cdot\overline{a_u}\cdot b_u\cdot\overline{b_g}\\
&^1B_u\colon a_g\cdot\overline{a_g}\cdot b_u\cdot\overline{b_u}\cdot a_g\cdot\overline{a_g}\cdot \;\vdots\; a_u\cdot\overline{a_u}\cdot b_u\cdot\overline{a_g}\\
&^1B_u\colon a_g\cdot\overline{a_g}\cdot b_u\cdot\overline{b_u}\cdot a_g\cdot\overline{a_g}\cdot \;\vdots\; a_u\cdot b_u\cdot\overline{b_u}\cdot\overline{b_g}
\end{aligned}
\qquad [7]
$$

The orbitals to the right of the dotted line correlate with the $\pi_u^3\cdot\pi_g$ group of the linear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

molecule. The two derived from the $\pi_u^+.\pi_u^-$ group of two electrons with the same spin are in all cases the $a_u.b_u$ pair. The pair derived from the $\pi_u.\pi_g$ set with the other spin differs in the four cases. In the first ^1A_u state it is a $b_u.a_g$ and both these orbitals are concentrated in the plane of the molecule. For the second ^1A_u state both the orbitals ($a_u.b_g$) are concentrated out of the plane of the molecule, the molecular plane being a node. Electrons in these two orbitals are clearly not suited to binding the protons in the molecular plane. With the two ^1B_u states the orbital pairs are $a_u.a_g$ and $b_u.b_g$. In both cases one orbital is concentrated in the molecular plane and the other has that plane as a node. This group will not be suited for binding the atoms in a planar arrangement. So the only state of this set of four which would be expected to provide strong binding for the atoms in a planar arrangement is the first ^1A_u state. This correlates with the $^1\Sigma_u^-$ state, which has just been discussed as providing a suitable basis for the binding, if a modification occurs which leads to the molecule becoming non-linear. The whole interpretation is therefore entirely self-consistent as between the electronic structures of the linear and bent forms (9), and also as between the electronic structure and the observed shape and dimensions.

THE NH_2 RADICAL

The lowest state of a linear NH_2 radical would be expected to be a $^2\Pi$ state having the orbital occupation $\sigma_g.\overline{\sigma_g}.\sigma_u.\overline{\sigma_u}.\pi_u^+.\overline{\pi_u^+}.\pi_u^-$. The orbitals occupied by the electrons of one spin form the set $\sigma_g.\sigma_u.\pi_u^+.\pi_u^-$, which will involve contributions from the $2s$ and three $2p$ orbitals of the nitrogen atom. Therefore it will be expected that there will be a tetrahedral group of four electrons round the nitrogen atom. The orbitals occupied by electrons of the other spin form the set $\overline{\sigma_g}.\overline{\sigma_u}.\overline{\pi_u^+}$, which will involve contributions from the $2s$ and two $2p$ orbitals of the nitrogen atom. Therefore it will be expected that there will tend to be a triangular group of three electrons round the nitrogen atom. Neither of these sets is in fact suitable for binding the atoms in a straight line. However they are both well suited to binding the two protons in directions which are at about 110° with respect to one another. A suitable mutual orientation of the triangle and the tetrahedron can achieve this simultaneously. In fact, NH_2, in the ground state, is found to be non-linear (8), though the angle ($103\frac{1}{3}°$) is smaller than would be expected from the above arguments. Presumably the explanation for this lies in the polarization of the electron cloud round the nitrogen atom as a result of the presence of the protons. Such polarization always tends to cause a reduction in interbond angles (6). The electronic structure then becomes $a_1.\overline{a_1}.b_2.\overline{b_2}.a_1.\overline{a_1}.b_1$ (cf. Walsh (10)).

The two members of the degenerate pair of the $^2\Pi$ ground state of linear NH_2 pass, on bending the molecule in a particular plane, into the configurations $a_1.\overline{a_1}.b_2.\overline{b_2}.a_1.\overline{a_1}.b_1$ and $a_1.\overline{a_1}.b_2.\overline{b_2}.a_1.b_1.\overline{b_1}$. As has been said, the consequence of this, for the ground state, is that the set of four of one spin and the set of three of the other both tend to cause the HNH angle to be about 110°. Moreover, in the ground state, these effects operate in the same plane for both spin sets. In the excited state, the set of four electrons is similar, but the set of three would here tend to bend the molecule in a plane at right angles to that in which the set of four would tend to bend it. The experimental data indicate that the best compromise between these two effects results in the molecule having the lowest energy when it is linear.

THE HCO RADICAL

This is isoelectronic with the NO molecule, which, in the ground state, has the structure $\sigma_1.\overline{\sigma_1}.\sigma_2.\overline{\sigma_2}.\pi_1^+.\overline{\pi_1^+}.\pi_1^-.\overline{\pi_1^-}.\sigma_3.\overline{\sigma_3}.\pi_2^+$. One group of orbitals ($\sigma_1.\sigma_2.\pi_1^+.\pi_1^-.\sigma_3.\pi_2^+$) is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

that characteristic of an ordinary double bond, $sp^3(\sigma\pi)$, and the other group $(\overline{\sigma_1}.\overline{\sigma_2}.\overline{\pi_1^+}.\overline{\pi_1^-}.\overline{\sigma_3})$ is that characteristic of an ordinary triple bond, $sp^3(\sigma\pi^2)$. On passing to a consideration of HCO it is clear that there is no direction from the carbon atom in which two electrons, one from each set, tend to be concentrated. An electron pair CH bond can however be achieved in the same manner as that discussed for the excited state of HCCH, namely by modifying the $sp^3(\sigma\pi^2)$ group to one of $sp^2p^{\frac{1}{2}}(\sigma\pi)$ so that the electrons not in the CO bond region are concentrated off the CO axis. However it would seem that, as with acetylene, this can only be done at the expense of weakening the CO bond; in this case, from a five-electron to a four-electron one. The observed length is 1.20 Å(2), which may be compared with 1.23 for H_2CO, 1.16 for CO_2 and COS, and 1.13 for CO. It is not clear just how the observed lengths should be interpreted. The length is nearer to that in H_2CO than that in CO but it is not certain what allowance should be made for the absence of one proton and one electron compared with H_2CO. A possibility is that the electronic structure is intermediate between that in which the CH bond is an electron pair bond and the CO a four-electron one, and that in which the CH is essentially a one-electron bond and the CO a five-electron bond. This would explain why the CO bond is somewhat shorter than that in H_2CO, why the molecule is bent, but it would suggest that the CH might be somewhat weak. Information on this is not available.

Of the excited state observed by Herzberg and Ramsay (2) three structural features are known: (*a*) the molecule appears to be linear; (*b*) the CO bond length (1.18) is a little smaller than that in the ground state, though still considerably longer than that in CO; (*c*) the CH valence vibration suggests a strong CH bond analogous to those in the ground states of HCN and HCCH.

The lowest state of linear HCO is a Π state and therefore doubly degenerate. If the molecule is bent in a particular plane, these members of the doubly degenerate pair pass into the states $a_1'^2.a_2'^2.a_3'^2.a_1''^2.a_4'^2.a_5'$ and $a_1'^2.a_2'^2.a_3'^2.a_1''^2.a_4'^2.a_2''$ since the degenerate members of the Π pair of orbitals pass into an a' and an a'' orbital (cf. Walsh (10)). The situation appears to be somewhat similar to that in NH_2. That is, for the ground state, both sets of electrons have configurations tending to cause the molecule to bend in the same plane, while, for the excited state, the two sets have configurations tending to cause the molecule to bend in different planes, with the result that the best compromise (i.e. lowest energy) is achieved when the molecule is linear. In this linear configuration the structure of the set of five electrons having the same spin will probably be $sp^3(\sigma\pi^2)$, since this tends to concentrate an electron on the OC axis for binding the hydrogen atom. The other set must remain $sp^3(\sigma\pi)$. However, this will mean that, in the linear excited state, there will be a greater concentration of electrons in the CO bond region than in the bent ground state. This accounts for the CO bond being shorter in the excited than in the ground state, as is observed. However, the strength of the CH bond is surprising.

SUMMARY

From the above discussion it can be seen that considerations of the above kind, which involve transforming the molecular orbitals into orbitals more localized in particular, and if possible separate, regions of space, enable one to draw conclusions about the electron distribution in different states. As a consequence, certain properties of the ground and excited states can be understood. The application of these ideas has been most successful for the states of acetylene involved in the transition observed by Ingold and King. The interpretation of the states of NH_2 and HCO is however less certain in the present state of our understanding of electron configurations.

THE NATURE OF FORMALDEHYDE IN ITS LOW-LYING EXCITED STATES[1]

G. W. Robinson and V. Erdmanis DiGiorgio

ABSTRACT

Long path length, high resolution spectra in the near ultraviolet of H_2CO and D_2CO at −78° C. have been obtained, and further strong evidence in support of a non-planar excited state is presented. The double-headed bands to the long wavelength side of the singlet–singlet system are shown to belong to the singlet–triplet transition. A vibrational analysis and partial rotational analysis shows the excited triplet state to be very similar to the excited singlet state. The larger C—O stretching frequency in the triplet state may characterize the multiplicity of these states in the simple aliphatic aldehydes and ketones. It is found that the C—O bond order in both states is very nearly 1.5, and striking similarities between the bonding in these states and the C—O bonding in formic acid are pointed out. The similarity between the singlet and triplet excited states may not extend to chemical behavior because of spin correlation rules, but there are no general reasons why the triplet state should be more reactive than the singlet.

INTRODUCTION

Recently an extensive body of experimental evidence has indicated that a rather large difference in geometry exists between the ground and excited state structures of most simple polyatomic molecules. In many instances, even the symmetry properties of the equilibrium configurations are different. For example, acetylene, while linear in its ground state, has a non-linear *trans* configuration in its low-lying excited state (15). Ethylene has a planar structure in the ground state with a very high barrier for internal rotation, but in its low-lying $^1B_{1u}$ state, as well as in its Rydberg states, the molecule exhibits an equilibrium configuration in which the CH_2 groups are no longer coplanar, and the barrier for internal rotation is more nearly that expected for a carbon–carbon single bond (37, 38). The molecules NH_2 (9, 29), HCO (14), and probably NO_2 (31) are bent in the ground state but linear in their low-lying excited states, while for CS_2 (16) and quite likely HCN and CO_2 (34, 35), the opposite holds true. The ammonia molecule has a low-lying electronic state which has a planar configuration (1), and formaldehyde, the topic of this paper, is non-planar in its low-lying excited states (3, 30).

Such changes in geometry are to be expected if the *bonding* electron configuration is changed by the electronic transition. For similar reasons, chemical properties are expected to be quite different in the ground as compared with the excited states of such molecules.

The formaldehyde molecule is an excellent testing ground for the study of these effects. An intimate knowledge concerning the low-lying excited states has intrinsic interest since the molecule is a simple example of a group of molecules on which a considerable number of photochemical investigations have been made (27). Furthermore, the long wavelength system is a prototype of n–π^* transitions which have attracted a great deal of theoretical and experimental interest. Finally, evidence presented here indicates that certain of the long wavelength absorption bands are associated with a singlet–triplet transition in the molecule, so that now the possibility exists of studying in detail the rotational–vibrational structure of a triplet state in a polyatomic molecule.

The first part of the paper discusses in a qualitative way the electronic, structural, and chemical properties of the low-lying excited states of formaldehyde based on the

Work supported in part by the Office of Ordinance Research, U.S. Army, under Project No. TB2-0001 of Contract No. DA-36-034-ORD-2169.

results of recent spectroscopic investigations. The second part treats briefly the experimental techniques and gives some details concerning the more recent investigations of the singlet–singlet as well as the singlet–triplet systems.

THE GROUND STATE

The absence of inversion doubling in addition to the observed statistical weights of the rotational sublevels definitely shows that the ground state has the well-known planar Y-shaped structure of point group C_{2v} (12). In spite of the large amount of work on formaldehyde and its isotopically substituted species, zero-point vibrations cause some uncertainty to exist in the structural determination (7).

The electronic structure of the ground state has been discussed by Mulliken (23), McMurry and Mulliken (22), and more recently by Walsh (36). The 12 valence electrons are situated in the six lowest-lying molecular orbitals which in approximate order of energy are*

$$(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2(2b_2)^2(2b_1)^0(4a_1)^0 \ {}^1A_1.$$

Roughly, the nature of these orbitals with respect to molecular bonding is

$1a_1$	$2s$ oxygen, non-bonding
$2a_1$	CH_2, bonding
$1b_2$	CH_2, bonding
$3a_1$	CO, σ bonding
$1b_1$	CO, π bonding
$2b_2$	$2p_y$ oxygen, lone pair non-bonding
$2b_1$	CO, π antibonding
$4a_1$	CO, σ antibonding.

The orbitals $2b_1$ and $4a_1$ are the first two excited orbitals.

Since the low-lying transitions in the molecule are localized in the CO bond, an alternative and fairly useful description regards formaldehyde as a perturbed linear molecule with symmetry axis along the CO direction. In the linear limit the a_1 orbitals correlate with σ-orbitals as does $1b_2$. The pairs $1b_1$ and $2b_2$ as well as $2b_1$ and $3b_2$ (not listed) become degenerate in this limit to form π-orbitals. The correlation diagram will resemble very closely that given by Walsh (35) for HAB molecules except an additional low-lying σ-orbital must be added. The available electrons fill all orbitals up to and including the first π-orbital, which holds four electrons, and the electronic symmetry is thus $^1\Sigma^+$ (perturbed).

THE NEAR ULTRAVIOLET TRANSITIONS

The lowest-lying electronic states in formaldehyde result from excitation of an electron from the non-bonding $2b_2$ orbital into the $2b_1$ excited orbital which is CO antibonding. A triplet state $^3A_2$ and a singlet state $^1A_2$ result. The presence of the antibonding π-electron in both states is expected to cancel approximately the bonding power of a bonding π-electron so that essentially *a three-electron bond results*. The CO linkage is expected to be about intermediate in length between a single and double bond. The HCH angle should be smaller† while the C—H distance should be larger than these same parameters in the ground state. The force constants and vibrational frequencies are well known to change in a similar way (3).

*The notation throughout is that suggested by Mulliken (25).
†The opposite is actually observed.

The most interesting effect of the decreased bond order is the lack of stability of the planar equilibrium configuration in these excited states (3, 30), the out-of-plane angle lying about midway between zero degrees and the out-of-plane angle for a tetrahedral structure (55°). Thus, strictly speaking, the electronic wave functions do not transform as representations of C_{2v}, but this is still a good approximation since the molecular orbitals do not feel very strong perturbative effects of the hydrogens. For this reason and for simplicity of discussion we prefer to retain the C_{2v} nomenclature throughout. In those instances where effects arise owing to the slight deviation from C_{2v} symmetry, the appropriate C_s description will be given in parentheses.

Because of the non-planar equilibrium configuration of the excited states, inversion doubling occurs (3, 30). The extremely low observed barriers for inversion indicate that a very small amount of energy stabilization is gained through mixing of carbon $2s$ and $2p_x$ orbitals in the non-planar molecule. The doubling of vibrational levels, many of which are not observed, introduces some uncertainty into the determination of excited state fundamentals.

The chemical properties of these states are quite different from those of the ground state, but *there are no general reasons why the triplet state should be more reactive than the singlet* since both exhibit nearly identical electronic structures. Both have two free valences and may be appropriately described as diradicals. The conservation of electron spin angular momentum (13) may under certain conditions allow one species to be more reactive than the other. For example, it would be predicted that the triplet states, but not the excited singlet states, of aldehydes and ketones would react very rapidly with O_2 ($^3\Sigma_g^-$ ground state), since in the latter case the reaction intermediate can not be produced in its singlet ground state. Such reactions of excited polyatomic molecules have not been discussed to a great extent in the past, but may in certain cases be important as evidenced from recent work (28).

Transitions to the $^{1,3}A_2$ excited states can be observed in absorption, while emission has been observed only for the singlet–singlet transition. These transitions are formally forbidden under the strict C_{2v} selection rules but occur through mixing with nearby electronic states. The strong type-B ($\perp$) bands are actually allowed by the non-planar selection rules (3) but could gain intensity through mixing with the $^1B_2$ state at $\sim$7 ev.

The weaker type-A ($\parallel$) bands are of a kind $^1A_1(^1A') \rightarrow {}^1A_2(^1A'')$ in the total vibronic sense and are strictly forbidden under the C_{2v} as well as the C_s selection rules. These transitions may gain intensity through mixing with a neighboring A_1 state (3), but there is an alternative way of understanding this apparent anomaly.* In the perturbed linear description of formaldehyde, three excited states would result from excitation of an electron to the first excited π-orbital, Σ^+, Σ^-, and Δ, the last probably lying lowest.

*NOTE ADDED IN PROOF.—*According to a paper soon to be published by J. A. Pople and J. W. Sidman, the mixing of A_1 and A_2 electronic states arises through a rotational-electronic interaction. That vibrationally-induced mixing does not occur to give a $\parallel$-type zero–zero band is clear, since there is no fundamental with a_2 symmetry. The viewpoint taken by us that formaldehyde can be considered a perturbed linear molecule with inherent mixing of the originally degenerate electronic states is exactly equivalent to the theory of Pople and Sidman. This was pointed out to us by Professor H. C. Longuet-Higgins in a private discussion. The interaction is the electronic analogue of the coriolis type rotational-vibrational interactions which cause mixing of approximately degenerate vibrational states of different symmetries in polyatomic molecules. The mixing gives rise to vibrational angular momentum which can interact with the rotational angular momentum to produce anomalies in the subband positions and intensities. In the present problem, electronic orbital angular momentum about the C—O axis arises from the interaction. In the absence of spin the perturbation can be detected through intensity anomalies, but in the triplet state, Hund's case-a coupling can occur, and subband positions as well as intensities are affected. The as yet incomplete experimental observations seem to bear out these concepts quite well, but it should be remembered that the observed $\parallel$-type bands could occur in an electric quadrupole transition.

The $^1\Delta$ state correlates with the $^1A_2$ state in the non-linear molecule, and the long wavelength spectrum could be described as a highly perturbed $^1\Sigma^+ \leftrightarrow {}^1\Delta$ transition for which $\Delta K = 0, \pm 1$. Type-C ($\perp$) bands were not observed even though some effort was made to find them. These would be Franck–Condon forbidden since they require excitation of b_2 vibrations in the excited state.

The singlet–triplet transition becomes allowed probably through a spin–orbit perturbation. The orbital part of the perturbation operator transforms as representations of the rotational subgroup $\mathbf{C}_2$, and because of symmetry, matrix elements are non-zero only for certain pairs of interacting electronic states (20). According to these selection rules, the $^3A_2$ state can mix with $^1B_1$, $^1B_2$, and $^1A_1$ states through perturbations by the x, y, and z components, respectively, of the spin–orbit operator. The observed bands resemble double-headed parallel bands having an irregular subband structure (see Fig. 3). Until a complete rotational analysis of these bands is obtained, however, the exact nature of the perturbing state will not be known. At present, it would appear that the z component of the perturbation operator is the one responsible for the mixing. This result is in disagreement with previous theoretical and experimental investigations (21).

EMISSION SPECTRUM

In formaldehyde, as in the higher aldehydes and ketones, the fluorescence and discharge emission spectra are identical (32), and their existence indicates the presence of relatively stable excited states in these molecules. It is well established (3, 30) that *the triplet state is not involved to an observable extent in emission*, and all observed bands have now been explained solely on the basis of the $^1A_2 \rightarrow {}^1A_1$ transition. A good reproduction of the very sharp electrodeless discharge spectrum can be found in the literature (30). As in most polyatomic systems, transitions occur from only a few of the lowest-lying vibrational levels in the excited electronic state. In H_2CO, under the conditions of discharge tube excitation, emission occurs strongly from the vibronic ground level and also from the level in which one quantum of ν_2' has been excited. Much weaker transitions occur from $2\nu_2'$ and also from the 0^- member of the first inversion doublet. The only ground state fundamentals which are involved are ν_4'' and ν_2'', this being in qualitative agreement with the predictions of the Franck–Condon principle.

The vanishingly small emission intensity from the $1^\pm$ inversion doublet in H_2CO is strong evidence in favor of predissociation in this region of the potential energy surface (4). This would set an upper limit to the dissociation energy,

$$H_2CO(^1A_1) \rightarrow H(^2S) + CHO(^2A'),^* \qquad E_{diss} \leqslant 28728 \text{ cm.}^{-1} \text{ (82.1 kcal./mole).}$$

A few remarks about the photolysis of H_2CO at 3650 Å (10) should be made. At dry ice temperature the absorption coefficient is negligible, the 3650 Å Hg line falling between two singlet–triplet bands. However, at temperatures where photochemical experiments must be performed to avoid polymerization, i.e. $T > 100°$ C., there is considerable hot band structure from the $^1A_1 \rightarrow {}^1A_2$ transition in this region. The analysis of the spectrum shows that the primary photochemical process would populate high rotational sublevels of 0^+ or $0^+ + \nu_2'$, these final states lying somewhat higher than 82 kcal./mole. It is therefore probable that the previously reported upper limit of 78 kcal./mole is slightly low. It should be mentioned that in these low-lying regions of the excited state

**The $^2A'$ state is probably the electronic ground state of* CHO *(35). The minimum additional energy needed to produce electronically excited* CHO *is about 10,000 cm.$^{-1}$ (14). See, however, Refs. (4) and (14).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

potential energy surface, the predissociation is so relatively weak that the rotational fine structure in absorption can be resolved to at least 0.1 cm.$^{-1}$. Even so, the transition probability for predissociation may still be a factor of 10^4 greater than that for the radiative transition. The intermediate dissociative state through which these predissociation processes occur is no doubt the first excited C—H antibonding triplet state since this state would correlate with the correct dissociation products.

The report (11) of two emitting levels, presumably $^1A_2$ as well as $^3A_2$, in acetone is puzzling and may indicate that the complex nature of the potential surfaces in the larger molecules is more advantageous to triplet state population prior to emission.

THE ABSORPTION SPECTRUM

In order to resolve the rotational structure in the weak singlet–triplet transition, collision broadening and hot band overlapping must be reduced to a minimum. To accomplish this, multiple pass techniques at −78° C. were employed both for H_2CO and for D_2CO. The gain in resolution above that obtained under ordinary conditions is striking, the limitation apparently being instrumental resolving power, in this case 250,000.

A multiple pass cell similar to the one described by Bernstein and Herzberg (2) was capable of giving path lengths of up to about 50 meters. The cell was cooled with dry ice, and at this temperature, formaldehyde pressures of 30 mm. Hg could be used. This pressure furnishes more than the necessary meter-atmosphere absorbing path for observation of the singlet–triplet bands. The procedure is also the most convenient for observation of the singlet–singlet system, since it was found that the vapor pressure of the gas over the polymer kept at room temperature is adequate. The rate of polymerization on the mirror surfaces was finite yet sufficiently slow so as not to cause difficulties.

The lack of hot band structure not only aids in the rotational analysis but also permits an unambiguous vibrational analysis to be made. For example, the photographs shown in Fig. 1 leave no doubt as to the hot band nature of the α-band at 27021 cm.$^{-1}$, and also they conclusively show the singlet–triplet bands to be temperature insensitive.

The Singlet–Singlet System

The very nice work of Brand (3) on the vibrational analysis of the emission and absorption systems quite strongly indicates a non-planar excited state. At about the same time, the rotational analysis of the α-band in emission was completed (30, 33) and showed a negative inertial defect, $\Delta = I_C - I_A - I_B$, in the excited state, proving beyond doubt the non-planar structure. The analysis will be published elsewhere (33), but the results are listed in Table I. The structural parameters, except for the HCH

angle and possibly the C—H distance, do lie about midway between Sp^2 and Sp^3 structures, but these must be considered tentative because of the lack of CD_2O data as well as the effect of zero-point vibrations.

The once puzzling 127 cm.$^{-1}$ spacing in the excited state is simply a result of inversion through a very low potential barrier. The first two intense $\perp$-bands of the absorption system are transitions from the ground vibronic state to the 0^- and 1^- members of the inversion doublets, and Brand assigned the weak $\parallel$-bands in this region to similar transitions involving 0^+ and 1^+. Since high dispersion plates taken of the gas at $T >$ 100° C. did not show clearly the presence of 0^+, there was some doubt about this interpretation (30), but the validity of Brand's assignment is completely borne out by a study of the spectrum at $T = -78°$ C. (see Fig. 2). The band marked 0^+, highly overlapped by the ^pP-branches of the A-band (0^-), should have the same lower state as the A-band and the same excited state as the α-band. A partial rotational analysis (19) shows that this is indeed the case. Incidentally, from these analyses an improved value of the out-of-plane bending fundamental in the ground state can be obtained (Table II). The barrier for inversion can be calculated to be ~650 cm.$^{-1}$ (3) from the positions

TABLE II

FUNDAMENTAL FREQUENCIES (cm.$^{-1}$) IN THE GROUND AND EXCITED STATES OF H_2CO AND D_2CO

	H_2CO			D_2CO		
	$^1A_1$	$^1A_2$	$^3A_2$	$^1A_1$	$^1A_2$	$^3A_2$
0^-	—	127	30	—	69	
1^+	—	530	537	—	387	448
1^-	—	951	779	—	669	
2^+	—		1171	—		889
2^-	—			—		
ν_1	2780	2851		2056	2077	
ν_2	1738	1177	1251	1700	1174	1249
ν_3	1503	1321		1106		1086
ν_4	1164.7	683	643	938		
ν_5	2874			2160		
ν_6	1280	899		990	735	

of the doublets, but the value is expected to be very approximate because of the inadequacies of the simple theories for low barriers. This is evidenced by the lack of agreement between barriers computed from CH_2O and CD_2O data. The absence of higher inversion doublets than $1^\pm$ in both H_2CO and D_2CO is caused by the fact that above the barrier the vibrational wave functions are approximately orthogonal with those in the ground electronic state.

In addition to ν_2' and the inversion doublets, the frequencies ν_1', ν_3', and ν_6' also occur weakly in combinations with these. Therefore all fundamentals except ν_5' may be approximately obtained and these are given in Table II along with the ground state values. The C—O stretching frequency 1177 cm.$^{-1}$ is very nearly the same as that observed for C—O in carboxylic acids, and may indicate similar three-electron bonding configurations in the two cases. The otherwise unexplained large value of ν_1' gives further evidence of this.*

**The similarity between the properties of the* CHO *bonding in the* $^1A_2$ *state of formaldehyde and the ground state of formic acid is quite striking:*

	H_2CO ($^1A_2$)	HCOOH
C—H stretch	2855 cm.$^{-1}$	2943 cm.$^{-1}$
C—O stretch	1177 cm.$^{-1}$	1180 cm.$^{-1}$
C—O bond length	1.32 Å	1.312 Å

The "three-electron" nature of the C—O *bond in* HCOOH *is further evidenced by recent microwave work (18).*

PLATE III

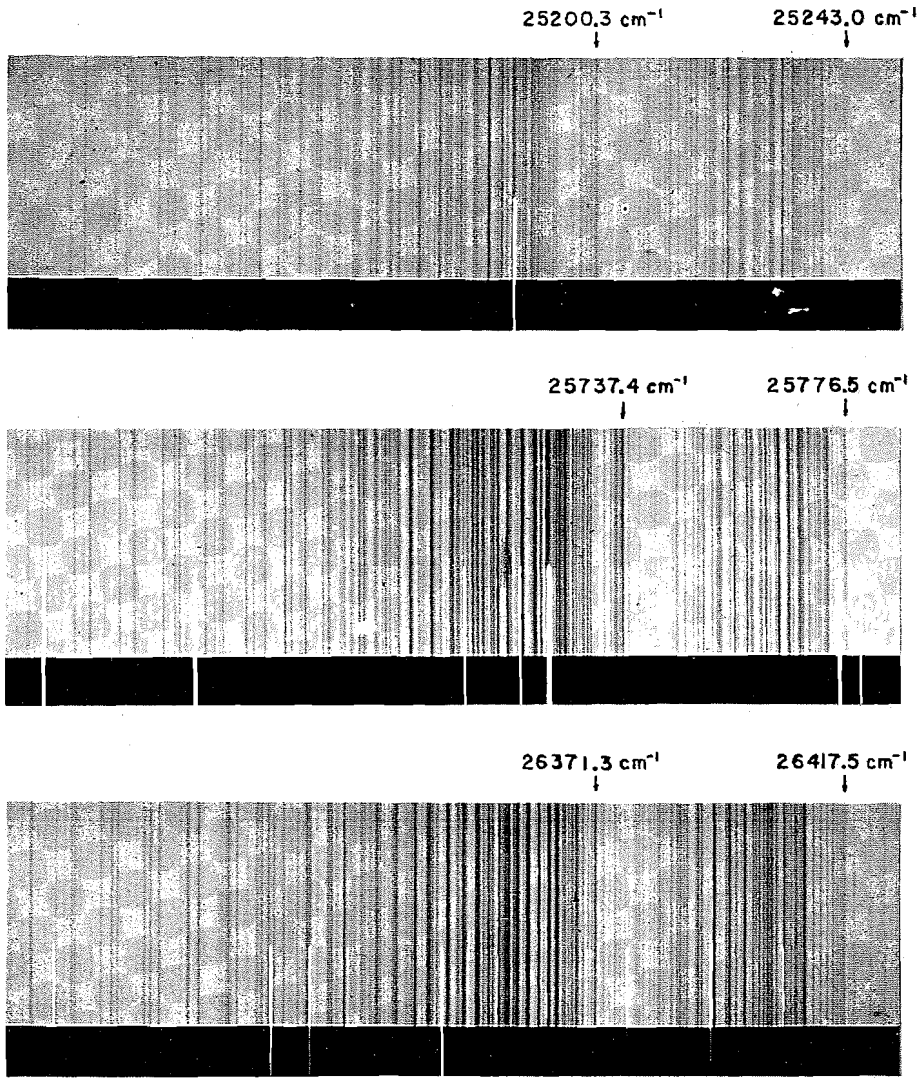

FIG. 3. Some singlet–triplet bands of H_2CO. Spectra taken at −78° C., 0.8 meter-atm. path. The doublet spacing does not change with vibrational excitation nor with isotopic substitution.

Table III lists all bands and their assignments. Since the vibrational pattern can be easily followed down to $\lambda \approx 2500$ Å it is safe to say that *the spectrum in the region 2500 Å $\leqslant \lambda \leqslant$ 3700 Å is caused by a single electronic transition.*

TABLE III

VIBRONIC BANDS OF SINGLET–TRIPLET TRANSITIONS OF H_2CO AND D_2CO

Assignment	H_2CO			D_2CO		
	λ_{air}	ν_{vac}	Int.	λ_{air}	ν_{vac}	Int.
0^+	3967.10	25200.2	m	3948.11	25321.4	w
1^+	3884.32	25737.3	s	3879.53	25769.0	s
2^+	3790.94	26371.2	m	3814.14	26210.8	m
$0^+ + \nu_2$	3775.15	26481.5	w	3762.47	26570.7	w
$1^+ + \nu_3$				3722.60	26855.3	w
$1^+ + \nu_2$	3704.56	26986.1	m	3700.43	27016.2	s
4^+				3689.06	27099.5	ww
$2^+ + \nu_2$	3618.98	27624.2	w	3641.32	27454.7	s
$0^+ + 2\nu_2$	3604.52	27735	w	3597.52	27789.0	w
$1^+ + \nu_2 + \nu_3$				3558.22	28095.9	w

The Singlet–Triplet Transition

The singlet–triplet bands with origins at approximately 3950 Å in H_2CO and D_2CO have been known for some time, being observed independently by Brand (3), Cohen and Reid (5), Coon (6), and Robinson (30). A reproduction of three of these bands in the H_2CO spectrum is given in Fig. 3. The bands are temperature insensitive (Fig. 1), are different in appearance from the usual parallel or perpendicular bands (compare Fig. 2), and do not fit into the established vibronic pattern of the 3650 Å system. These facts indicate that the bands belong to another electronic system, almost certainly to $^1A_1 \rightarrow {}^3A_2$ since they are weak and lie to the long wave-length side of the *lowest predicted* singlet–singlet transition.

High resolution (resolving power $\approx$250,000) photographs were obtained of the H_2CO and D_2CO systems at high and low temperatures. In all, nine D_2CO and eight H_2CO bands were found, many of which lay under hot band structure on the high temperature plates. The bands are "double-headed", *the doublet spacing being about 40±3 cm.$^{-1}$ in all bands of both isotopic species.* Since the magnitude of the spacing does not change on isotopic substitution, and is not highly dependent on vibrational excitation, this is strong evidence that it arises from an electronic, and not a rotational or vibrational origin. The doubling probably is caused by "case-*a*" coupling (13) of electron spin and partially quenched electron orbital angular momentum along the "symmetric top" axis. The electronic angular momentum then couples with the component of rotational angular momentum in this direction to give the observed irregular subband structure. The rotational analysis of the bands is in progress and thus far it has been possible to establish that the constant $\frac{1}{2}(B+C)$ for the $^3A_2$ state is very nearly identical but slightly larger than that of the $^1A_2$ state. This shows, as expected, that the C—O bond distance is quite similar in the two states.

The observed bands measured from the low frequency member of the doublet are listed, together with their vibrational assignments, in Table III. Some temperature sensitive bands of H_2CO, have been observed by Coon (6) at very long path-lengths and moderate dispersion. The observed effects of inversion doubling show that the excited state is non-planar, and from Coon's bands, some of which are analogous to the α-band in the singlet–singlet system, one can calculate the inversion splitting to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

$0^+ - 0^-$ 30 cm.$^{-1}$
$1^+ - 1^-$ 242 cm.$^{-1}$

which means that the barrier for inversion is somewhat higher in the triplet state than in the singlet state.

The triplet state fundamentals which have been observed are tabulated in Table II along with the singlet state values. The C—O stretching fundamental ν_2' is about 75 cm.$^{-1}$ larger than ν_2' in the excited singlet state. Since this difference is expected to remain fairly constant among the aliphatic aldehydes and ketones, it may provide a good check as to the multiplicity of the excited state in the many instances where only the coarse structure of the spectrum can be resolved.

In conclusion we would like to thank Professor G. H. Dieke for the use of the 21-ft. grating spectrograph on which much of this work was done. We also wish to extend our appreciation to Mr. Maclyn McCarty for helping with the calculations.

EXCITED STATES OF THE MOLECULAR IONS OF HYDROGEN FLUORIDE, HYDROGEN IODIDE, WATER, HYDROGEN SULPHIDE, AND AMMONIA[1]

D. C. Frost and C. A. McDowell

ABSTRACT

The ionization of the molecules of hydrogen fluoride, hydrogen iodide, water, hydrogen sulphide, and ammonia, by essentially monoenergetic electrons, has been studied in a mass spectrometer. The various excited states of the molecular ions of these compounds have been observed and the corresponding energy levels of the ions have been measured. The results are interpreted in terms of the electronic structures of these molecules as given by molecular orbital theory.

INTRODUCTION

The analysis of visible or ultraviolet spectra yields information about the excited states of molecules and free radicals. Almost all of our present data have been obtained in this way. And though a vast amount of such information is available, little of this refers to saturated molecules. There are obvious reasons why this is so, and it will undoubtedly be some time before sufficient spectroscopic data are available to permit the excited states of many saturated molecules to be evaluated. It is now possible, however, to use electron impact methods to obtain some of this much desired information. Recently a new electron impact technique (5, 6) has been used to study the ionization of molecules. This method utilizes essentially monoenergetic electrons with an energy spread of $\sim$0.1 ev., and so it is now possible to determine accurately the energies of the excited states of many molecular ions. These data are now available for molecular ions of nitrogen (6), methane (7), the alkyl halides (7), and several other molecules. In this paper we shall describe some new results for the molecular ions of hydrogen fluoride, hydrogen iodide, water, hydrogen sulphide, and ammonia.

Besides yielding values for the energy levels of the excited states of the various molecular ions, the present studies are of interest for other reasons. They enable the molecular orbital theories of the electronic structures of these molecules to be assessed. Furthermore, it is known from self-consistent field molecular orbital theories (8, 13, 14, 17, 21), that Koopmans' theorem indicates to a good approximation that the energy of an electron in a given molecular orbital is equal to minus the ionization potential referring to the removal of an electron from that orbital; and it follows that once the several ionization potentials of a molecule are known, the energies of the various molecular orbitals are likewise known. The determination of the energies of the molecular orbitals of molecules is important, for by this means there are available further data for the more detailed assessment of the reliability of self-consistent field molecular orbital calculations. As was mentioned earlier, optical spectroscopic studies have not so far yielded much of the desirable information for saturated compounds, and it is perhaps for such molecules that the present studies are particularly important in that now there have become available data which cannot as yet be provided by any other experimental method.

EXPERIMENTAL

The Metropolitan-Vickers M.S.I. mass spectrometer, modified as previously described (6, 7), was used to determine the ionization potentials. As the tube of this instru-

ment and the inlet system are largely made of glass, a new gas introduction system had to be provided so that we could study hydrogen fluoride. The new inlet system was made from copper and it extended through a metal–glass seal down into the ionization chamber. At the extremity of the copper inlet tube a small teflon tube was added to provide insulation between the inlet tube and the ion source. A diagram of the inlet system is shown in Fig. 1. It will be noted that only metal gas valves with teflon diaphragms were used.

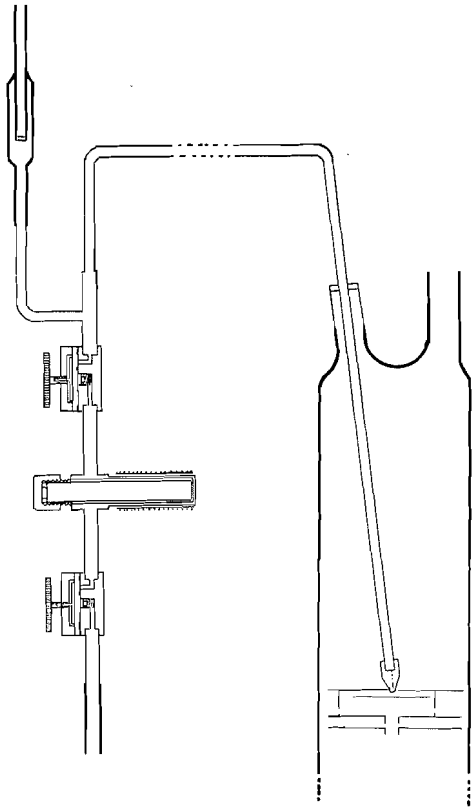

FIG. 1. All-metal inlet system for introducing hydrogen fluoride into mass spectrometer.

The hydrogen fluoride was prepared by heating a dry sample of potassium hydrogen fluoride. The reaction vessel was a copper-lined brass cylinder which could be heated electrically (see Fig. 1).

The hydrogen iodide was prepared by the combination of hydrogen and iodine vapor over a platinized asbestos catalyst in a high vacuum system, the gas being purified by repeated fractionation.

The other compounds used were prepared by normal chemical methods and highly purified before use.

Krypton was used as a calibration gas for all the studies. The ionization potential of krypton was taken as 112914.5 $cm.^{-1}$ (1) or 13.997 v., taking 8066.83 $cm.^{-1}$ equal to 1 v. (2).

EXPERIMENTAL RESULTS

The ionization efficiency curve for hydrogen fluoride is shown in Fig. 2. This shows clearly that there are two ionization processes, one producing the HF^+ ion in its ground

TABLE I

VERTICAL IONIZATION POTENTIALS OF HYDRIDES

Compound	Ionization potential (v.)	Electronic state of ion
Hydrogen fluoride	15.77±0.02	$^2\Pi_{3/2,1/2}$
	16.91±0.10	$^2\Sigma$
Hydrogen iodide	10.44±0.04	$^2\Pi_{3/2}$
	11.14±0.04	$^2\Pi_{1/2}$
	13.27±0.10	$^2\Sigma$
Water	12.60±0.01	$^2B_1$
	14.35±0.03	$^2A_1$
	16.34±0.06	$^2B_2$
Hydrogen sulphide	10.45±0.03	$^2B_1$
	12.46±0.03	$^2A_1$
	14.18±0.04	$^2B_2$
	16.07±0.05	?
Ammonia	10.40±0.02	$^2A_1$
	15.31±0.04	$^2E_{3/2,1/2}$

gen iodide. Here it is evident that there are three ionization processes. We shall show later that the first two are observed because the spin-orbital components of the $^2\Pi$ ground state of the HI^+ ion have been resolved. The other process refers to the formation of the $^2\Sigma$ first excited state of the HI^+ ion. The values of the ionization potentials for hydrogen iodide are given in Table I. Fig. 4 shows the ionization efficiency curve for the water molecule. The three ionization processes result from the formation of the H_2O^+ ion in its ground $^2B_1$ state, and its two excited states, the $^2A_1$ and $^2B_2$ states. The corresponding ionization potentials are given in Table I. In the case of hydrogen sulphide,

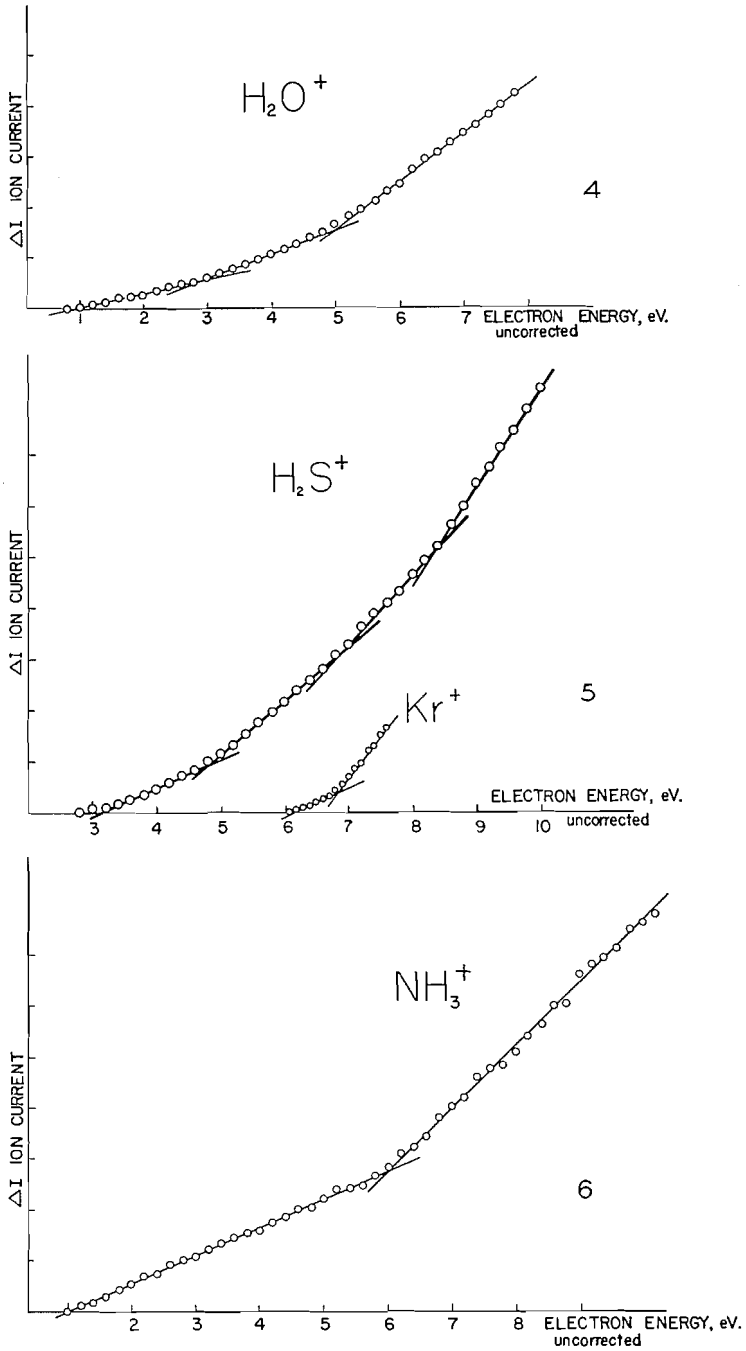

FIG. 4. The ionization efficiency curve for the formation of the H_2O^+ ion.
FIG. 5. The ionization efficiency curve for the formation of the H_2S^+ ion.
FIG. 6. The ionization efficiency curve for the formation of the NH_3^+ ion.

for which the ionization efficiency curve is shown in Fig. 5, besides the processes due to the formation of the H_2S^+ ion in its $^2B_1$ ground state and its $^2A_1$ and $^2B_2$ excited states, an extra ionization process is observed. The origin of this is not clear. The four observed

ionization potentials are listed in Table I. Fig. 6 shows the ionization efficiency curve for ammonia. Here there are clearly two ionization processes. The first refers to the formation of the NH_3^+ ion in its $^2A_1$ ground state, and the second to the formation of the NH_3^+ ion in its first excited ^2E state. The corresponding ionization potentials are listed in Table I.

DISCUSSION

Hydrogen Fluoride

The electronic structure of hydrogen fluoride can be represented by the molecular orbital formula

$$K\ (2s\sigma)^2\ (2p\sigma)^2\ (2p\pi)^4,\ ^1\Sigma^+ \qquad [1]$$

in which the orbitals are written in order of decreasing ionization energy from left to right. The first ionization potential which we have observed to occur at 15.77 ev. will refer to the removal of an electron from the $(2p\pi)$ orbital to form an HF^+ ion in its $^2\Pi_i$ state. This state has two components, $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$, but for fluorine compounds our apparatus cannot resolve these (3). The first excited state of the HF^+ ion will be formed by the removal of an electron from the $(2p\sigma)$ orbital of equation (1) to yield the $^2\Sigma$ state of the ion. The process which we have observed to occur at 16.91 ev. obviously is due to the formation of the HF^+ ion in its first $^2\Sigma$ excited state.

Recently Johns and Barrow (12) reported the observation of the ultraviolet spectra of the DF^+ and HF^+ ions. They concluded that the observed bands were due to transitions between a lower A-state and an upper B-state. The A-state was assumed to arise from the combination H^+ (or D^+) $+F(^2P)$ and was assumed to be the $A\ ^2\Sigma^+$-state. These spectroscopic studies indicate that the $A\ ^2\Sigma^+$-state of the HF^+ ion is 16.88 ev. above the ground $^1\Sigma_g^+$ state of hydrogen fluoride. Our results indicate clearly that the ionization potential which we observe at 16.91 v. is due to the formation of the HF^+ ion in its first excited state, i.e. the $A\ ^2\Sigma^+$ state, and the ionization potential due to the formation of the HF^+ ion in its ground state is 15.77 v. The ground state we take to be the $^2\Pi_i$ state in agreement with the molecular orbital formula [1] and with the spectroscopic data for the molecular ions HCl^+, HI^+, and HBr^+, all of which are known (10) to have $^2\Pi_i$ ground states. It follows, therefore, that bands due to the transitions $A\ ^2\Sigma^+$—$X\ ^2\Pi_i$ and $B\ ^2\Sigma^+$—$X\ ^2\Pi_i$ are still to be found for the DF^+ and HF^+ ions. Our results indicate that the former bands should be found in the near infrared.

Hydrogen fluoride, being a simple molecule with only 10 electrons, has recently been the subject of several extensive theoretical studies. Mueller (16) has reported the results of both a molecular and an atomic orbital treatment, while Kastler (13) has made a very detailed study of this compound from the valence bond standpoint. A self-consistent field molecular orbital treatment using Roothaan's (21) method has been carried out by Duncan (3), and more recently by Hamano (9). Hurley (11) has recently given a detailed discussion of the ground state of this molecule using the method of "atoms in molecules".

With the exception of Duncan's work, nearly all the other authors have chosen either the dissociation energy of the hydrogen fluoride molecule or its dipole moment as data for assessing the accuracy of their calculations. Above, we have mentioned that ionization potentials may be more useful data for comparing the validity of theoretical calculations. Duncan calculated that the first ionization potential of hydrogen fluoride should be 11.3 v. This is very much less than our experimentally determined value of 15.77 v. An examination of Duncan's calculation shows that the method used is probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

not the best one, and a detailed treatment of the hydrogen fluoride molecule recently carried out by Dr. J. A. R. Coope of this laboratory, using a method analogous to Hurley's "atoms in molecules" treatment, leads to a theoretical value for the first ionization potential which is in very good agreement with the experimental one.

Hydrogen Iodide

The hydrogen iodide molecule may be represented by the molecular orbital equation

$$KLMN\ (5s\sigma)^2\ (5p\sigma)^2\ (5p\pi)^4,\ {}^1\Sigma_g^+. \qquad [2]$$

From this equation it follows that it would require least energy to remove an electron from the non-bonding $(5p\pi)$ orbital, thus forming an ion with the structure . . . $(5p\sigma)$ $(5p\pi)^3$ and so presumably in a ${}^2\Pi_i$ state with spin-orbital components ${}^2\Pi_{3/2}$ and ${}^2\Pi_{1/2}$. Some years ago Price (19) obtained spectroscopic evidence to substantiate this, and also the fact that of the two spin-orbital components, the ${}^2\Pi_{1/2}$ was the upper one. Price observed a Rydberg series for hydrogen iodide with a limit at 89,130 cm.$^{-1}$, i.e. there is an ionization potential at 11.049 v. This limit Price assigned to the ${}^2\Pi_{1/2}$ level of the HI^+ ion. From considerations of the magnitude of the spin-orbital coupling separations of halogen atoms, Price concluded that the ${}^2\Pi_{3/2}$ level of the HI^+ ion should lie about 0.66 ev. below the ${}^2\Pi_{1/2}$ level, i.e. the ionization potential referred to this level should be $11.049-0.66 \approx 10.39$ v. Price was unable to find any Rydberg series which could be satisfactorily established as going to this limit. Our experimental results, shown as the ionization efficiency curve for the HI^+ ion in Fig. 3, do, however, clearly indicate the formation of the HI^+ ion in both the ${}^2\Pi_{3/2}$ and the ${}^2\Pi_{1/2}$ states, as well as an excited state above these. The separation of the spin-orbital components, ${}^2\Pi_{3/2}$ and ${}^2\Pi_{1/2}$, of the ground state of the HI^+ ion we find to be 0.70 ev., a value which is in excellent agreement with that estimated by Price (19), and also with the value we observed earlier for the separation of the spin-orbital components ${}^2E_{3/2}$ and ${}^2E_{1/2}$ of the ground state of the CH_3I^+ ion (3). That this interpretation of the first two processes in the ionization efficiency curve of the HI^+ ion is correct is supported by the photoionization studies of Watanabe (24), who found the first ionization potential of HI to be 10.38 ± 0.02 v. The value which we observed in our experiments is 10.44 ± 0.04 v.

The third ionization process observed at 13.27 v. for the HI^+ ion is obviously to be ascribed to the formation of this ion in its ${}^2\Sigma$ excited state. This state would arise by the removal of an electron from the $(5p\sigma)$ orbital of HI to form the HI^+ ion with the electronic structure . . . $(5p\sigma)^1\ (5p\pi)^4$. It will be recalled that we observed the formation of the HF^+ ion in the corresponding state. It is of interest to compare the value of 13.27 v. for the ionization potential of HI, referring to the production of the HI^+ ion in its ${}^2\Sigma$ excited state, with that of 11.22 v. observed for the formation of the CH_3I^+ ion in its ${}^2A_1$ excited state. Both these states arise by the removal of an electron from the σ-orbitals concentrated mainly along the X—I bond. It is, therefore, to be expected that the corresponding ionization potentials will vary as binding energies of the electrons in these X—I σ-orbitals. The dissociation energies of the X—I bonds can be taken as a rough measure of the binding energies of the electrons in the σ-type orbitals under discussion. The dissociation energy of the hydrogen iodide molecule is 70.44 kcal. mole^{-1} (9), whereas the dissociation energy of the C—I bond in methyl iodide is 52.6 kcal. mole^{-1} (15). This difference reflects that found for the ionization potentials referring to the removal of an electron from the σ-type orbitals along the X—I bonds in these two compounds.

Water

The ionization efficiency curve for the water molecule is shown in Fig. 4. Here there are obviously three different ionization processes occurring at 12.60±0.01, 14.35±0.03, and 16.34±0.06 v. It is interesting to note that in early experiments Sugden and Price (22), using a simple ionization tube, found evidence for ionization processes in water at similar voltages. These they attributed to the formation of the water molecule in various excited states. Their technique was, however, rather simple, and as they did not have any means of making mass analysis, they could not be certain that the different ionization processes observed did, in fact, refer wholly to the formation of excited states of the molecular ion species.

The electronic structure of the water molecule in terms of molecular orbital theory can be written as (18, 4):

$$(1a_1)^2\ (2a_1)^2\ (1b_2)^2\ (3a_1)^2\ (1b_1)^2,\ ^1A_1 \qquad [3]$$

Recent self-consistent field molecular orbital calculations by Ellison and Shull (4) have shown that this is the correct order of the orbitals and that the $(1b_1)$ is a pure $2p_x$ orbital of oxygen, the main bonding orbitals being the $(1b_2)$ and $(3a_1)$ orbitals, though $(2a_1)$ has some bonding character also.

This molecular orbital formula for water indicates that the first three states of the H_2O^+ ion should be the $^2B_1$, $^2A_1$, and $^2B_2$ states. These we assume to be those associated with the ionization processes observed at 12.6, 14.35, and 16.34 v. This identification is supported by Ellison and Shull's calculations, which give the energies of the $(1b_1)$, $(3a_1)$, and $(1b_2)$ orbitals for a H—O—H valence angle of 105° as −11.79, −13.20, and −18.35 ev., values which are in reasonable agreement with those which we have determined experimentally. The present assignment agrees with that suggested earlier by Sugden and Price (22). It should perhaps be pointed out that there is no doubt about the accuracy of the identification of the ground state of the H_2O^+ ion as a $^2B_1$ state. It may also be noted that the presently reported value for the first ionization potential of the water molecule is in excellent agreement with the spectroscopic value of 12.56± 0.01 v. obtained by Price (20) from a Rydberg series in the far ultraviolet spectrum of water.

Hydrogen Sulphide

Hydrogen sulphide has the same symmetry, i.e. C_{2v}, as the water molecule and it was of interest to see if the excited states of the molecular ion bore any relation to those observed for the water molecule. The ionization efficiency curve for the formation of the H_2S^+ ion is shown in Fig. 5. This curve is reminiscent of that for the water molecule, though the uppermost ionization process was not observed in that case.

The electronic structure of hydrogen sulphide can be represented by the following molecular orbital formula:

$$(1a_1)^2\ (2a_1)^2\ (1b_2)^2\ (3a_1)^2\ (1b_1)^2\ (4a_1)^2\ (2b_2)^2\ (5a_1)^2\ (2b_1)^2,\ ^1A_1 \qquad [4]$$

The first 10 electrons are in orbitals which approximate to the minor shell $1s^2\ 2s^2\ 2p_x^2\ 2p_y^2\ 2p_z^2$ structure of the sulphur atom. The last eight, in valence shell molecular orbitals, correspond to the last eight electrons in the molecular orbital formula for the water molecule.

From this equation it follows that the first three ionization processes observed for the H_2S^+ ion are due to the formations of the $^2B_1$, $^2A_1$, and $^2B_2$ states of the ion. These we

identify with the ionization potentials observed at 10.45±0.03, 12.46±0.03, and 14.18±0.04 v. It is of interest to note that Sugden and Price (22) observed ionization processes in hydrogen sulphide at 10.5, 12.2, and 14.0 v. and gave a similar interpretation. Again there is no doubt about the accuracy of our identification of the first ionization potential. This refers to the removal of an electron from the $2p_y$ orbital of the sulphur atom. Our value of 10.45 v. is to be compared with the spectroscopic value of 10.47 v. obtained by Price (20) and the result of 10.46 v. obtained by Watanabe (24) from photoionization experiments.

Ammonia

The ionization efficiency for ammonia (Fig. 6) shows the presence of an excited state of the NH_3^+ ion at 4.91 ev. above the first ionization potential. The identification of the two states of the NH_3^+ ion is apparent from the molecular orbital formula for ammonia. Ammonia belongs to the symmetry group C_{3v} and so its molecular orbital formula is:

$$(1a_1)^2\ (2a_1)^2\ (1e)^4\ (3a_1)^2,\ ^1A_1. \qquad [5]$$

The first ionization potential observed at 10.40±0.02 v. obviously refers to the energy required to remove an electron from the non-bonding ($3a_1$) orbital to form a NH_3^+ ion in its $^2A_1$ ground state, assuming that the C_{3v} symmetry is retained in the ion. This value of 10.4 v. for the first ionization potential of ammonia is confirmed by the photoionization work of Watanabe (24), though Walker and Weissler (23) report that their photoionization studies showed that ionization set in at 10.07 v.

The second ionization process which we observed to occur at 15.31±0.02 v. is identified as being due to the formation of the first excited state of the NH_3^+ ion, i.e. the ^2E state, by the removal of an electron from the ($1e$) degenerate orbital of the ammonia molecule. This ($1e$) orbital of ammonia is the main bonding orbital and it spans the three N—H bonds. It is interesting to note that Walker and Weissler (23) found evidence for a second ionization process setting in a little above 15 ev. They were, of course, not able to identify the cause of this, but our results at least show that at this energy there lies the first excited state of the NH_3^+ ion and so Walker and Weissler's observation is at least partly due to the formation of this excited state of the NH_3^+ ion.

ACKNOWLEDGMENT

We wish to thank the National Research Council of Canada for grants in support of this work.

THE ELECTRONIC SPECTRA OF CRYSTALLINE TOLUENE, DIBENZYL, DIPHENYLMETHANE, AND BIPHENYL IN THE NEAR ULTRAVIOLET[1]

ROBERT COFFMAN[2] AND DONALD S. MCCLURE[3]

ABSTRACT

The electronic absorption spectra of single crystals of toluene, dibenzyl, diphenylmethane, and biphenyl have been photographed at 20° K. using polarized light in the range 3000 to 2500 Å. The fluorescence spectrum of biphenyl has also been examined. This is the first time that the excited states of biphenyl analogous to the B_{2u} state of benzene have been observed. The main features of the spectra are similar for all four compounds, and the differences may be understood in terms of the weak coupling between the benzene rings of the "double molecules".

I. INTRODUCTION

According to current theory the π-electronic states of the dibenzyl molecule should closely resemble those of the toluene molecule. Any slight differences would have to be ascribed to a mechanical or electronic coupling between the rings in dibenzyl. The electronic component of this coupling should be small because the $-CH_2-CH_2-$ link between the benzene rings is not a conjugative link. Greater differences are expected between toluene and diphenylmethane since only one $-CH_2-$ group separates the rings in the latter. Finally with no intervening "insulating group", as in biphenyl, the spectra may differ greatly.

This series of molecules has been investigated before (2), but only with the aid of solution spectra, and no clear results have been obtained. We have obtained the spectra of single crystals at 20° K. with polarized light. Under these conditions a wealth of detail is observed. In the present article, the experimental results are described, and partial vibrational analyses of the spectra are given. One of us has interpreted further details of the spectra in terms of the electronic and vibrational coupling energies between the benzene rings. This work is reported in the article following this one (12).

An especially interesting discovery made during the course of this work is the existence of a weak, sharp transition in biphenyl. In previous studies of this molecule, only strong continuous absorption regions have been found.

II. EXPERIMENTAL

The polarized spectra of single crystals were obtained using a large Hilger quartz prism instrument. The details have been described previously (10). The spectra were observed at 20° K. At 77° K. they are quite broad and very few details may be resolved. Helium temperatures would probably have given sharper lines than 20° K., and would permit a more precise analysis, which would have been advantageous in several cases.

The biphenyl crystals were flakes grown from the vapor. They had the cleavage plane, the *ab* plane, most fully developed. From the order of interference determined with a quartz wedge in the polarizing microscope, and the value $\Delta n = 0.097$ for the birefringence on the *ab* plane (18), the thickness of the crystals was found. They were usually between

2 and 5 μ thick, and several millimeters across. A complete structure analysis of the biphenyl crystal does not exist. It is known to have the space group C_{2h}^5 with two molecules per unit cell, and to have the long molecular axis nearly coinciding with the c axis (3, 15). Since $\beta = 94.5°$, the long axis is nearly perpendicular to the ab plane. We therefore expected to be able to observe only the short-axis polarized transitions. We found a polarization ratio of $I_a/I_b = 1.0$ for short-axis transitions. The two molecules per unit cell must be nearly at right angles to each other if we are correct. Krishnan (9) and Dhar (4), using diamagnetic anisotropy and X-ray analysis respectively, obtained values for the molecular orientation parameters which would result in a polarization ratio $I_a/I_b = 1/3.89$ for short-axis transitions and would give appreciable intensity along the a axis for long-axis transitions. Our results are in disagreement with theirs in both respects.

Dibenzyl crystals were grown by cooling a melt held between quartz plates pressed together. Large areas having many crystals all aligned in the same way could be made by remelting most of the crystal and letting it grow again from a small unmelted bit. The value of the birefringence was obtained as approximately 0.13 by measuring the retardation and thickness on some moderately thick crystals grown in the above manner. This number could then be used for the thinner crystals, whose thickness could not be measured directly. The crystal plane developed in these crystals is the ab plane. A very precise X-ray structural study has been made by Jeffrey (8). The theoretical polarization ratio for a short-axis transition in the molecule is $I_a/I_b = 0.65$. No large polarization effects were therefore expected, or found.

Crystals of toluene were grown by allowing the liquid to solidify between quartz plates in a temperature gradient established over a liquid nitrogen bath. Diphenylmethane crystals were grown by allowing the melt to solidify between quartz plates. Its melting point is 26° C., but crystals grew well at 20° C. The diphenylmethane crystals were examined in the polarizing microscope and an area showing uniform orientation of the dielectric axes and low retardation was masked off and used for the experiments. The toluene crystals were examined in the dewar at 77° K. between crossed polaroids. A magnified image of the crystal mass was projected onto a white card, and a large uniformly oriented area was selected. The dielectric axes of this area were oriented vertically and horizontally and the image of the crystal was projected onto the slit of the spectrograph. The areas used were about one millimeter across.

The vapor spectra of these molecules are very complex. That of biphenyl is continuous (1). We examined the vapor spectrum in a 3 meter path after finding the sharp crystal spectrum, but could detect no sharp absorption bands. The spectrum of toluene vapor reported by Ginsburg and Robertson (7) was helpful in the analysis of the crystal spectrum. Robertson and Matsen (17) have reported the spectrum of diphenylmethane, but few details were given. No reports of the spectrum of dibenzyl vapor have been published to our knowledge.

III. RESULTS AND INTERPRETATION

Microphotometer tracings of the absorption spectra obtained are shown in Figs. 1–4. There is no marked dichroism arising from intermolecular interactions, but in the cases of toluene and diphenylmethane there are strong differences between the oppositely polarized spectra arising from molecular orientation. Several plates of the biphenyl spectrum appeared to show a crystal dichroism in the first strong band amounting to 4 cm.$^{-1}$. This is probably real, but since the bands are about 10 cm.$^{-1}$ wide it is hard to be certain of it.

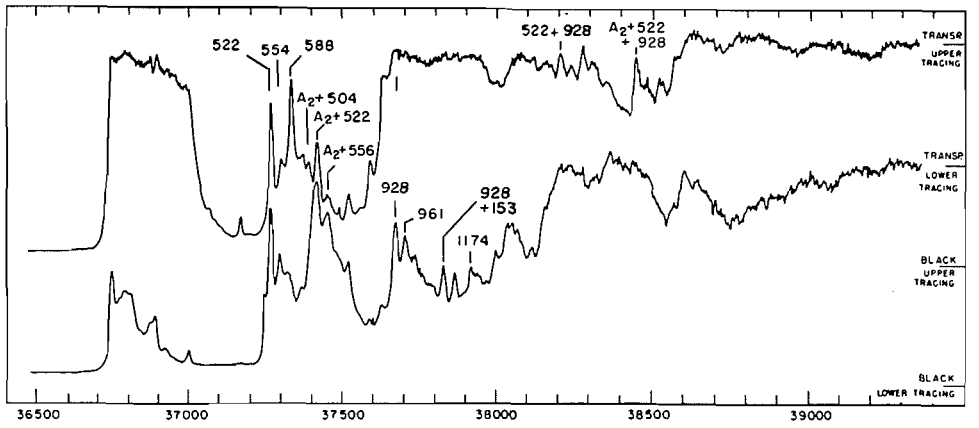
TOLUENE MONO-ORIENTED CRYSTAL ABSORPTION (POLARIZED), 20° K.

FIG. 1. Polarized absorption of oriented toluene crystals at 20° K. Some of the more important features are noted on the microphotometer tracing and others may be identified by reference to Table I.



POLARIZED ABSORPTION OF MONO-ORIENTED CRYSTALS OF DIPHENYLMETHANE AT 20 °K.

FIG. 2. Polarized absorption spectrum of diphenylmethane crystal at 20° K. The designation A_2 in the figure is to be interpreted as 2Δ, and equals approximately 150 cm.$^{-1}$.

A. Toluene

The observed lines and their interpretation are given in Table I and the spectrum is illustrated in Fig. 1. The agreement with Ginsburg's analysis of the vapor (7) is excellent if one takes the first strong band of the crystal spectrum, 37155 cm.$^{-1}$, as the 0–0 band. This is 322 cm.$^{-1}$ to the red of the 0–0 band of the vapor. There is a weak band at 37054, 101 cm.$^{-1}$ to the red of the 0–0 band. This is undoubtedly the same sort of band as is found in crystalline benzene, naphthalene, phenanthrene, etc., and probably serves as the origin of fluorescence, although the fluorescence spectrum was not studied. Other than this, there

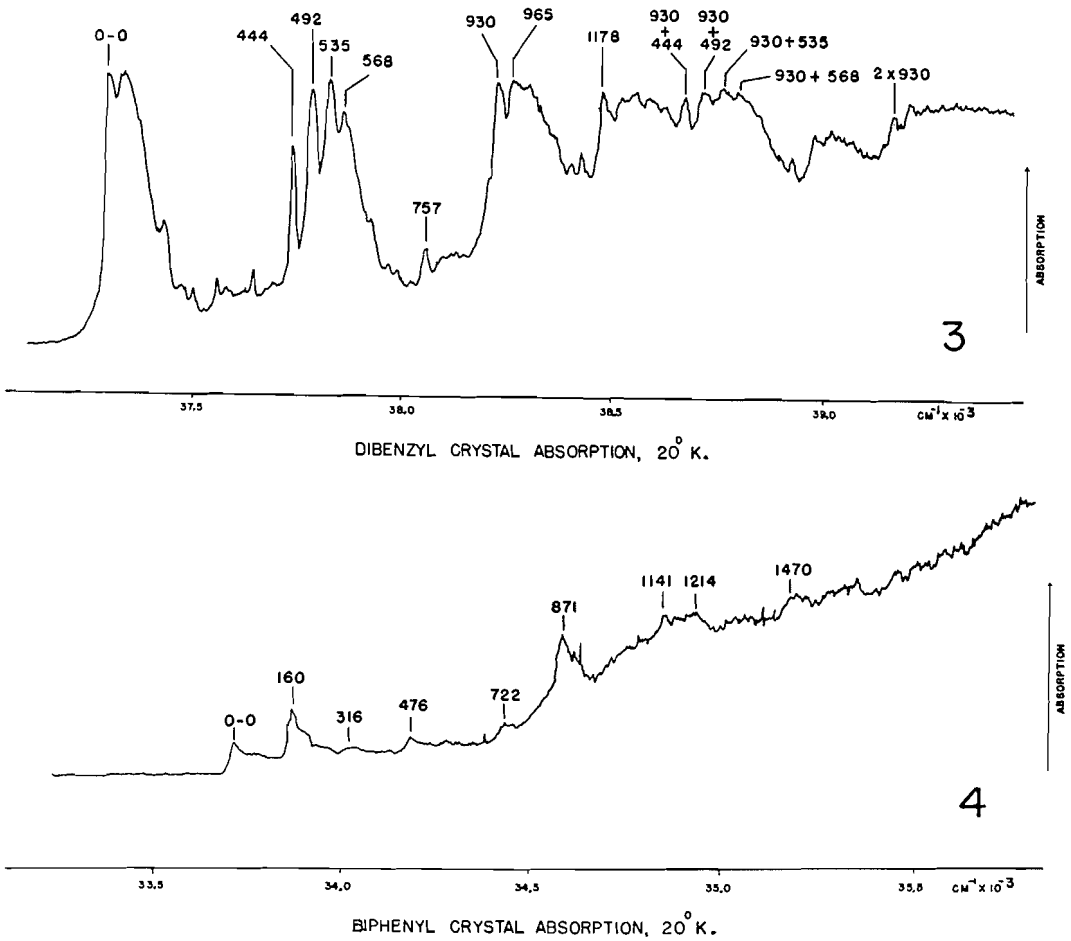

FIG. 3. Absorption spectrum of dibenzyl crystal at 20° K., *ab* plane. The polarized spectrum is the same along the *a* and *b* axes.

FIG. 4. Absorption spectrum of single biphenyl crystal, *ab* plane, at 20° K. The spectra are identical along the two axes except as noted in the text. The background appearing at higher frequencies is probably the long-axis transition giving rise to the well-known continuous absorption of this molecule.

are no distinct crystal effects. The 0–0 band components are at the same energy, so the intermolecular resonance energy is very small.

The most interesting feature of the spectrum is the region where the vibrations analogous to e_{2g} of benzene appear. The 456 and 528 cm.$^{-1}$ peaks respectively represent the a_1 and b_1 components of this motion in point group C_{2v}. The a_1 vibrational addition should be polarized in the same way as the 0–0 band, along the short axis in the molecular plane, while the b_1 band should be polarized along the ring-methyl direction, or long axis. These facts enable one to determine approximately how the toluene molecules are oriented in the crystal. The oriented gas model (fixed, but non-interacting molecules) can be used with confidence here because of the demonstrated absence of strong intermolecular resonance. The polarization of the 528 cm.$^{-1}$ band shows that the long axis is confined to one direction in the projection of the crystal plane we have studied. The polarization of the 456 cm.$^{-1}$ band shows that the short axis prefers the same direction by a factor of about 2. At least two molecules and probably four are needed per unit cell.

TABLE I

POLARIZED ABSORPTION SPECTRUM OF A TOLUENE CRYSTAL AT 20° K.

The frequency of each band is given, with a probable error of 3 cm.$^{-1}$, in column 1. The intensity in column 2 is indicated by vs = very strong, s = strong, m = medium, w = weak, vw = very weak, sh = shoulder on a stronger band. Most bands are polarized about twice as strongly in one of the crystal directions as in the other. This is indicated by 0 in column 3. The departures from the 2:1 ratio are indicated by + and −. Frequency differences from the 37155 cm.$^{-1}$ band are given in column 4, and the analysis of these differences in column 5. The vibration frequencies used in column 5 are from Ginsburg's work (see Ref. 7). The error given in column 6 is positive if the assigned combination is greater than the observed frequency. Positive deviations could be caused by anharmonicity.

39310	m	0	2155	1189+965	−1

Much fine structure appears on the plates, and also in the tracings. This may be evidence for excitation of the methyl group motions.

B. Dibenzyl

Of the three double molecules the spectrum of this one, illustrated in Fig. 3, should bear the most similarity to that of toluene, and should therefore be the easiest to understand. Table II shows the positions of the bands observed and the remarkable similarity of the prominent vibrational intervals to those of toluene. Since no dichroism was observed at the 0–0 band, 37296 cm.$^{-1}$, there must be very little intermolecular resonance. The fluorescence of this crystal could not be observed, possibly because traces of stilbene could not be entirely removed. The stilbene absorption, however, is too weak to interfere with the dibenzyl absorption. A few very weak bands to the red of the 0–0 band remain uninterpreted. Again, of chief interest is the region from 450 to 600 cm.$^{-1}$ from the origin.

The appearance of four bands instead of two in this region is direct evidence for either vibrational or electronic coupling between the rings. The analysis of these bands appears in the following paper.

The totally symmetric frequencies in the rest of the spectrum are very close to those of toluene, as expected. There is evidence that some of these bands are doubled, an indication of vibrational coupling between rings. The 930 cm.$^{-1}$ peak is as sharp as the 929 peak in toluene, so there is probably very little interaction here. But the analogue of the toluene

975 cm.$^{-1}$ peak appears to be split into 959 and 1004 cm.$^{-1}$. The analogue of 1190 cm.$^{-1}$ in toluene appears to be 1178+1196 cm.$^{-1}$ in dibenzyl. The 750 cm.$^{-1}$ peak is sharp and not split in dibenzyl.

C. Diphenylmethane

The spectrum of a diphenylmethane crystal is considerably more complex than those of toluene and dibenzyl (see Fig. 2). Table III gives the observed bands for two directions of polarization labelled *w* (weakly absorbing) and *s* (strongly absorbing). The crystals studied were in every case too thick to resolve the structure near the origin in the *s* polarization. In the *w* direction, structure could be resolved throughout the entire spectrum. The fact that great differences are observed in the spectra of the two polarizations is very fortunate, since it makes a detailed interpretation possible. We have not obtained accurate intensity measurements, however, and cannot take full advantage of this fact. In the following paper, it will be shown that both the molecular shape and an approximate crystal structure could be obtained from accurate spectral intensity data.

The spectrum may be analyzed, as shown in Table III, if one assumes that there are two origins separated by 150 cm.$^{-1}$, and two superposed spectra nearly identical to dibenzyl spectra. The occurrence of two spectra is interpreted as a result of electronic resonance between the two rings. The details of this interpretation are given in the following paper.

D. Biphenyl

The biphenyl absorption spectrum observed on the *ab* plane of a crystal 5.0 μ thick at 20° K. is shown as a tracing in Fig. 4, and the observed features are listed in Table IV. As is well known, the solution and vapor spectra of biphenyl are entirely diffuse, but sharp bands appear in the crystal spectrum. They have the same strength in both the *a* and the *b* directions. These bands are very weak compared to the continuous absorption.

The order of magnitude of the f-number associated with the weak transition is about 0.001, whereas the solution spectrum of the strong absorption band yields an f-number of 0.44.

TABLE IV

ABSORPTION SPECTRUM OF A SINGLE CRYSTAL OF BIPHENYL AT 20° K.

The interpretation of the frequency differences, measured from 33714 cm.$^{-1}$, may have to be modified as mentioned in the text. Frequencies of polarized Raman lines are given when they are close to an excited state interval (Fruhling, Ref. 6). p = polarized.

The first band which can be seen in the spectrum of the 5 μ crystal is as strong as the other bands of the spectrum; yet because of the high symmetry of the molecule, it is not necessarily the true electronic origin of the weak transition. Therefore we studied the absorption of thicker crystals and the fluorescence. In a 50 μ crystal at 77° K., broad absorption appears beginning at about 33200 cm.$^{-1}$, 510 cm.$^{-1}$ to the red of the first sharp band. There is a diffuse maximum at 33310 cm.$^{-1}$.

Pesteil (14) has reported the fluorescence spectrum of biphenyl crystal at 2° K. We studied the spectrum at 77° K. merely to be sure that impurities were not present in our samples and to verify the main features of Pesteil's data. He reports the first fluorescence band to lie at 33340 cm.$^{-1}$. This coincides within the rather large limit of error with our 33310 cm.$^{-1}$ absorption maximum. The band which Pesteil calls the origin of the electronic system is at 32480 cm.$^{-1}$ and is a weak band. We found this to be the first strong band of the spectrum; this is our main disagreement with Pesteil, but the different crystallographic plane used by Pesteil (*ac* plane) and the difference in temperature may explain it. The intervals measured from the 32480 cm.$^{-1}$ band to the other fluorescence bands agree very well with the Raman bands (6), as Pesteil shows.

The origins of progressions in symmetric vibrations in absorption and fluorescence are 1232 cm.$^{-1}$ apart, and the band where weak absorption and weak fluorescence coincide lies 860 cm.$^{-1}$ above the fluorescence origin and 374 cm.$^{-1}$ below the absorption origin. The 860 cm.$^{-1}$ interval is very nearly equal to an infrared frequency (16). Furthermore, a weaker band reported by Pesteil at 32610 cm.$^{-1}$ in fluorescence is 730 cm.$^{-1}$ from the 33340 cm.$^{-1}$ band. The 730 cm.$^{-1}$ interval also appears in the infrared. It seems quite likely therefore that the fluorescence spectrum is a forbidden transition which appears principally through the action of the 860 cm.$^{-1}$ vibration. The forbidden 0–0 band at 33340 cm.$^{-1}$ appears weakly because of the perturbations from the crystal field. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

33714 cm.$^{-1}$ band is interpreted as the origin of an allowed transition. The 374 cm.$^{-1}$ difference between these two origins may be interpreted in terms of the interaction between the two benzene rings, as is done in the following paper. It would be difficult to call the 1232 cm.$^{-1}$ interval a 1–0+0–1 interval with 860 cm.$^{-1}$ the 1–0 band and 374 cm.$^{-1}$ the 0-1 band because these two frequencies are not comparable in magnitude. A difference of only 10-20% would be expected if this were to be the interpretation.

There is an alternative interpretation of the weak 33340 cm.$^{-1}$ band which must be considered. Similar weak absorption bands have been observed before in molecular crystals such as phenanthrene (11) and naphthalene (13). There is no possibility of interpreting these in terms of an intramolecular resonance. They must be interpreted as fluorescence from the same electronic state as the absorption. The energy separation has not been fully interpreted, but is only present in pure molecular crystals, not in diluted crystals or in other types of solution.

A rigorous experiment to decide between these alternatives would be to use a crystal which is transparent in the region where biphenyl absorbs, and to examine the polarized solid solution spectra of biphenyl in this solvent. We have not done this experiment but instead used a 3-methylpentane glass as the solvent for absorption and emission. The absorption at 77° K. in this glass is continuous, and the point where $\epsilon = 100$ is at approximately 35600 cm.$^{-1}$. The fluorescence bands are quite broad, and the onset of the first one was estimated to be at 34000 cm.$^{-1}$. There is thus a difference of 1600 cm.$^{-1}$ between the onset of absorption and emission. It appears therefore that the gap is not less than in the crystal.

Another difference between biphenyl and the other crystals mentioned is that there is no strong emission beginning from the weak absorption band. As we have pointed out, only very faint emission occurs here, whereas in naphthalene and phenanthrene, the strong allowed band begins here. Therefore the emission observed from biphenyl must be coming from a state different from the state absorbing at 33714 cm.$^{-1}$. We conclude that there is good evidence for the existence of two excited electronic levels, 33340 and 33714 cm.$^{-1}$.

The analysis of the vibrational intervals in the absorption spectrum of biphenyl is given in Table IV. The interpretation of this analysis is not so obvious as in the case of the other molecules we have discussed. In the other cases, the vibrations which were excited in the transition were all analogous to the ones in the toluene spectrum. Even though the excited state of biphenyl can be considered to be derived from the B_{2u} state of benzene and is closely related to it, there must be enough differences to change the vibrational overlap integrals so as to favor other vibrations.

The spectrum may be understood if it is compared to the Raman spectrum (6). There is a line at 161 cm.$^{-1}$ which appears only in the solid and whose nature is not known. It is quite possible that the prominent 160 cm.$^{-1}$ band in the absorption spectrum corresponds to a vibration mode similar to the 161 cm.$^{-1}$ Raman line.

A polarized Raman line at 324 cm.$^{-1}$ corresponding to a totally symmetric vibration could well be the ground state counterpart of the 316 cm.$^{-1}$ interval seen in absorption. Another polarized line of 731 cm.$^{-1}$ could be the analogue of the 722 cm.$^{-1}$ absorption band. The strong 871 cm.$^{-1}$ absorption band has no analogue in the Raman spectrum, however. It is therefore interpreted as the combination 160+722. Other probable associations of Raman and absorption bands are noted in Table IV.

There is an interesting similarity between the types of vibrations excited in the biphenyl spectrum and those excited in the stilbene spectrum (5). These two molecules are similar in that their benzene rings are conjugated, while in dibenzyl and diphenylmethane they

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

are not. In both stilbene and dibenzyl the symmetric C—C stretching modes derived from ν_{16}, e_{2g}, 1584 cm.$^{-1}$, and ν_{13}, e_{1u}, 1485 cm.$^{-1}$, of benzene are excited while the frequencies in the neighborhood of 1000 cm.$^{-1}$ analogous to the ν_2, a_{1g}, 992 cm.$^{-1}$, breathing mode of benzene are much less strongly excited. With the unconjugated molecules, exactly the opposite occurs. A simple explanation of this is that polar structures contribute more to the excited states of the conjugated molecules, and these structures, in order to exist, must shrink some bonds and expand others in just the way required to excite the symmetric partners of the degenerate vibrations.

Both stilbene and biphenyl have strongly excited low frequency vibrations. In stilbene these may be explained in terms of totally symmetric bending modes, but there are no such modes in biphenyl, and it does not seem possible to explain the 160 cm.$^{-1}$ interval as a totally symmetric molecular vibration. The lowest such mode should be the vibration of one ring against the other, and this could hardly be below 300 cm.$^{-1}$. (Perhaps the polarized 324 cm.$^{-1}$ line is this mode.) Because the absorption intensity in this transition is very low, it may be that the 160 cm.$^{-1}$ interval represents a non-totally-symmetric vibration which mixes in some other electronic state. But, if our B_{1u} assignment of the 33714 cm.$^{-1}$ state is correct, the 160 cm.$^{-1}$ vibration must be g in order to induce such mixing, and no g vibration of biphenyl could be this low. A possibility is that it represents the addition of a 374+160 = 534 cm.$^{-1}$ frequency to the forbidden electronic origin at 33340 cm.$^{-1}$. The value 534 cm.$^{-1}$ is in the range of the benzene-like e_{2g} vibration. It would have to be the antisymmetric a_1 component since a short-axis transition must be produced (see following paper).

IV. CONCLUSIONS

In all four molecules studied the spectra are produced by transitions closely related to the $^1A_{1g} \rightarrow {}^1B_{2u}$ transition of benzene appearing at 2600 Å. In the spectra of toluene, dibenzyl, and diphenylmethane, the same types of ring vibrations are excited during the transitions. This fact is of importance in analyzing the spectra of the latter two molecules. Quite different types of vibrations are excited in the biphenyl transition. Some of these vibrations are the highest frequency C—C stretching vibrations of the rings, similar to those excited by electronic transitions in stilbene, anthracene, and other conjugated aromatic molecules.

The low temperature spectra under our conditions of high resolution have revealed several important details about the excited electronic states of four related molecules. In each case the magnitude of the electronic and vibrational interactions between the benzene rings of the double molecules may be deduced from the spectra. Details of these interactions are discussed in the following paper.

ENERGY TRANSFER IN MOLECULAR CRYSTALS AND IN DOUBLE MOLECULES[1]

DONALD S. MCCLURE[2]

ABSTRACT

The theory of the transfer of electronic energy between two molecules, or between two parts of a "double molecule", is discussed for the case in which vibrational quanta are present. The results are obtained for two limiting cases of weak and strong electronic interaction. Some of the phenomena occurring in the intermediate region are discussed qualitatively. With the aid of these results the spectra of biphenyl, diphenylmethane, and dibenzyl have been analyzed, and the electronic energy exchange parameter has been determined for each. These data are compared with similar data on durene crystal and the paracyclophanes. The electronic energy exchange parameter is given approximately correctly by considering the interaction of electronic transition dipoles except for very close and for very distant molecules.

I. INTRODUCTION

Two kinds of weakly coupled systems in which energy transfer processes have been observed are molecular crystals and "double molecules", i.e. molecules consisting of two identical parts coupled through a weakly conjugating linkage. Recently, high resolution single crystal spectra of several double molecules have been obtained (2). The spectral data are analyzed in this paper and compared with existing information on molecular crystals and other double molecules. Our main purpose is to show what the actual values of these energy transfer parameters are and to make them available for theoretical work.

Vibrational as well as electronic energy transfer has been observed. Effects of intermolecular coupling on vibrations have been observed in infrared spectra of single crystals as well as in electronic spectra. Our main interest in vibrational coupling in this paper will be in the way it interacts with the electronic coupling. This interaction may take any form from a minor splitting of vibrational levels to a major change in the geometry of the system.

Some of the theory of electronic states of weakly coupled systems has been reviewed by Craig (3), who applies it to molecular crystals. In this theory the interaction between the units of the molecular crystal occurs by way of an excitation transfer without necessarily any electron transfer. The intermolecular potential is usually expanded in a multipole series and the leading term is evaluated to determine the interaction energy. In this way Craig (3) calculated the spectrum of the anthracene crystal using the dipole–dipole term and Fox and Schnepp (5) calculated the spectrum of the benzene crystal using the octupole–octupole term. Longuet-Higgins and Murrell (6) have developed a theory which is applicable to "double molecules", since the potential for interaction between the parts is not expanded in a multipole series and allowance is made for electron transfer processes. The energy states of biphenyl, for example, were calculated.

II. ELECTRONIC SPLITTING IN BIPHENYL, DIPHENYLMETHANE, AND DIBENZYL

Schematic representations of the spectra of toluene and the related double molecules are shown in Fig. 1, after the work of Coffman and McClure (2). The original spectra were taken at 20° K. with polarized light and single crystals. Only in the case of biphenyl

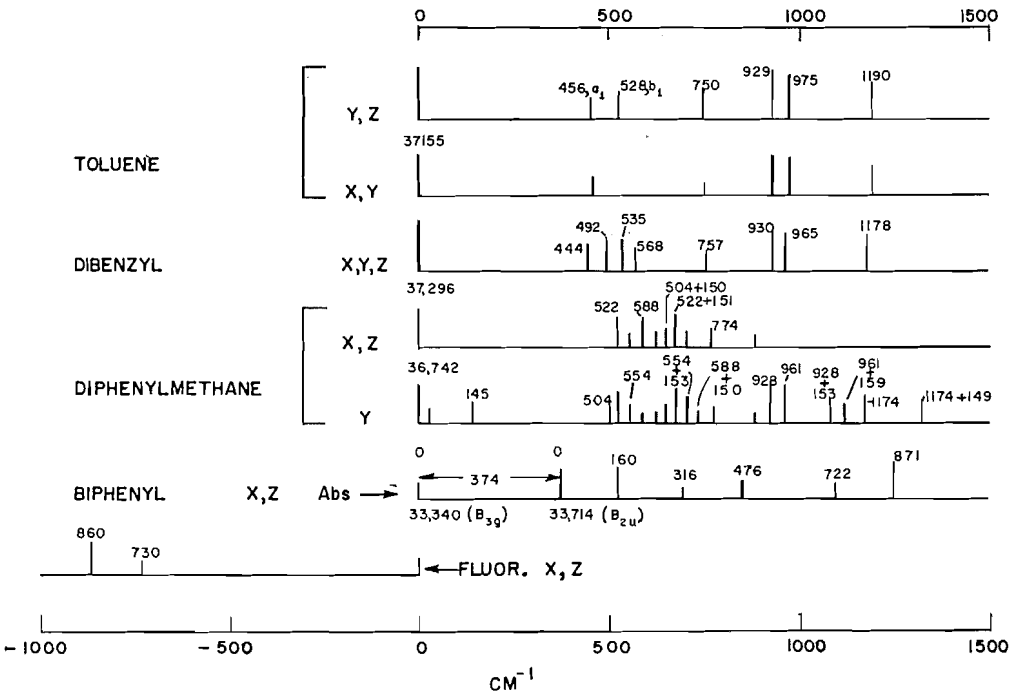

FIG. 1. Schematic drawings of the spectra of toluene and some related double molecules. Vibration frequencies measured from the electronic origins are given.

is it possible to observe the electronic splitting directly, as indicated in the analysis on Fig. 1. In the other two cases, it is possible with the aid of the toluene spectrum for comparison to find the approximate value of the electronic splitting. The molecular shapes and the coordinate systems to be used in the following discussion are shown in Fig. 2.

A. Analysis of the Spectra of Double Molecules

Some simple quantum mechanical problems must be considered first before proceeding to the spectroscopic data. The electronic and vibrational states of double molecules may be written to a first approximation as products of the wave functions of the separate parts. For the ground state $\psi^n = \psi_1^0\psi_2^0$, and for the excited states, corresponding to the mth excited state of the parts,

$$\left.\begin{matrix}\psi_S^m \\ \psi_A^m\end{matrix}\right\} = \frac{1}{\sqrt{2}}(\psi_1^0\psi_2^m \pm \psi_1^m\psi_2^0). \qquad [1]$$

The subscript S goes with the + sign and A with the − sign. The double molecules we are considering have symmetry elements, some of which interchange rings. ψ_S and ψ_A will behave oppositely under such symmetry operations, i.e. one will change sign and the other not. The ± property itself may be considered as a symmetry element in the following general discussion.

In each case the excited state is like the B_{2u} state of benzene and therefore in the individual rings there is a node across the ring passing through the point of substitution. This transition is forbidden in benzene, but allowed in toluene. However the vibrational electronic interaction mechanism active in benzene still induces an appreciable transition moment in toluene as well as in the double molecules under consideration. Our most

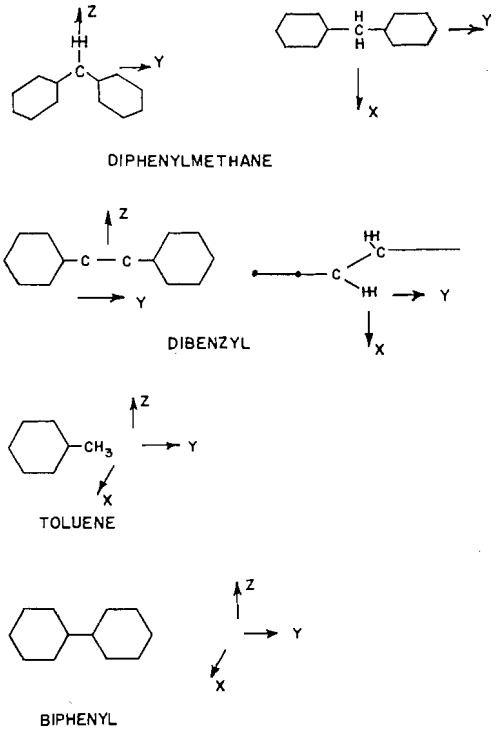

FIG. 2. Coordinate systems and symmetry properties of toluene, dibenzyl, diphenylmethane, and biphenyl. The rings of diphenylmethane are drawn to indicate the foreshortening due to rotation about the C—CH_2 bond.

interesting results will be obtained by analyzing the spectrum in the region where the perturbing vibration appears. In benzene this is an e_{2g} mode of 521 cm.$^{-1}$ which splits in toluene into an a_1 at 456 cm.$^{-1}$ and a b_1 at 528 cm.$^{-1}$ in the excited state. Note that the a_1 mode is lower, since it involves motion of the attached methyl group, while in the b_1 vibration there is a node at the methyl group.

The following problems must now be solved in order to interpret the spectra.

1. Splitting of the Vibrationless Transition in Double Molecules

The hamiltonian for the double molecule may be written as $H_1+H_2+H_{12}$, where H_1, H_2 are the hamiltonian functions for toluene and H_{12} is an interaction potential. Using the wave functions given earlier, the energy of the S state is $D+\Delta$, and of the A state $D-\Delta$, relative to the unperturbed energy as zero. Here D is the displacement of the center of gravity due to the interaction potential, i.e.,

$$D = \int (\psi_1^0 \psi_2^m)^2 H_{12}\, d\tau \qquad [2]$$

and Δ is half the splitting, i.e.

$$\Delta = \int \psi_1^0 \psi_2^m H_{12} \psi_1^m \psi_2^0\, d\tau. \qquad [3]$$

The transition moment is

$$\left.\begin{matrix}\mathbf{M}_S \\ \mathbf{M}_A\end{matrix}\right\} = \frac{\mathbf{M}_1 \pm \mathbf{M}_2}{\sqrt{2}} \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

for the S and A states. The vector sum is zero for one of the states in the case of dibenzyl, since it corresponds to a g-state. In diphenylmethane both states may have non-zero components for certain geometries. The displacement, D, will be neglected in later calculations since it does not affect the spectrum.

2. Splitting of Symmetric Vibronic States

Vibrations which are totally symmetric in toluene form two vibrations in the double molecule. They will have different energies because of the mechanical and electronic coupling between the two rings. One can write four product-type vibronic wave functions corresponding to the presence of one vibrating ring and one electronically excited ring in the double molecule. It is important to realize that the ring containing the electronic excitation may or may not contain the vibrational excitation. Another important distinction, discussed in detail by Simpson and Peterson (9), is related to the first. One must distinguish two limiting cases: (1) the electronic interaction between the parts of the molecule results in a splitting which is small compared to the vibrational intervals, (2) the electronic interaction produces a splitting much larger than the vibrational intervals. These are called the weak and the strong coupling cases, respectively. We may now list the wave functions, the first order energies, and the transition probabilities from the ground state for these two limiting cases. This information is given in Table I. It has been assumed throughout that the electronic and vibrational wave functions of each part of the double molecule are exactly the same as those of the related single molecules.

TABLE I

WAVE FUNCTIONS, ENERGIES, AND TRANSITION PROBABILITIES FOR WEAK AND STRONG COUPLING

State	Symm.	Wave function	First order energy	Transition probability
Ground	S	$\psi_1^0\psi_2^0X_1^{00}X_2^{00}$	0	—
m-Electronic	S A	$1/\sqrt{2}.[\psi_1^m\psi_2^0X_1^{m0}X_2^{00} \pm \psi_1^0\psi_2^mX_1^{00}X_2^{m0}]$	$E_m \pm \Delta$	$(\mathbf{M}_1 \pm \mathbf{M}_2)/\sqrt{2}$
Weak coupling:				
m-elect.	S A	$1/\sqrt{2}.[\psi_1^m\psi_2^0X_1^{m0}X_2^{0a} \pm \psi_1^0\psi_2^mX_1^{0a}X_2^{m0}]$	$E_m + V_a^0 \pm \Delta$	$\begin{cases} 0 \\ 0 \end{cases}$
+ a-vibr.	S A	$1/\sqrt{2}.[\psi_1^m\psi_2^0X_1^{ma}X_2^{00} \pm \psi_1^0\psi_2^mX_1^{00}X_2^{ma}]$	$E_m + V_a^m \pm \Delta$	$\begin{cases} (\mathbf{M}_1 \pm \mathbf{M}_2)S_{1a}/\sqrt{2} \\ \end{cases}$
Strong coupling:				
m-elect.	S A	$1/2.[\psi_1^m\psi_2^0 + \psi_1^0\psi_2^m][X_1^{S0}X_2^{Sa} \pm X_1^{Sa}X_2^{S0}]$	$E_S + V_a^S \pm v$	$\begin{cases} (\mathbf{M}_1+\mathbf{M}_2)S_{1a} \\ 0 \end{cases}$
+ a-vibr.	A S	$1/2.[\psi_1^m\psi_2^0 - \psi_1^0\psi_2^m][X_1^{A0}X_2^{Aa} \pm X_1^{Aa}X_2^{A0}]$	$E_A + V_a^A \pm v$	$\begin{cases} (\mathbf{M}_1-\mathbf{M}_2)S_{1a} \\ 0 \end{cases}$

Notes to table:
m = mth excited electronic state of one ring.
a = ath vibrational mode.
ψ_1^m = electronic wave function of ring 1 in state m.
X_1^{ma} = vibrational wave function of ring 1 in electronic state m and vibrational state a.
Δ = electronic coupling energy.
v = vibrational coupling energy.
V_a^m = vibrational energy of ath mode in mth electronic state.
S = Symmetric under ring interchange.
A = Antisymmetric under ring interchange.
E_m = energy of mth electronic state.
$\mathbf{M}_1$ = transition moment of one ring from 0 to m.
$E_S = E_m + \Delta$, $E_A = E_m - \Delta$.
S_{1a} = Franck–Condon overlap integral; a-vibr., ring 1.

The qualitative results are these. In the weak coupling limit, the electronic splitting Δ is very small. If it is considered to be zero there are two vibronic states: one having a vibrational quantum in the unexcited ring with its ground state frequency, V_a^0; and the other having a vibrational quantum in the excited ring, with the frequency V_a^m, determined by the force constants of the excited state. Only the second of these states has a non-vanishing transition probability from the ground state. This is a result of vibrational overlap. Two vibronic states separated by 2Δ arise from each one when the first order electronic energy coupling is added.

In the strong coupling limit, there are two widely separated electronic states of the double molecule. In this limit 2Δ is much larger than the vibrational energies. The vibration frequencies V_a^S and V_a^A are characteristic of the force constants of the excited states S and A. The mechanical coupling v between the rings is considered to be small and splits each vibration into a symmetric and an antisymmetric mode. The symmetry of each state is determined by the product of the vibrational and the electronic symmetry, since it is possible to separate the electronic and vibrational wave functions in the strong coupling limit. One of the A states, $S \cdot A$, and one of the S states, $A \cdot A$, have zero transition probability from the ground state because the vibrational overlap factor, $S_{1a} - S_{2a}$, is zero.

Real cases of course fall into the intermediate region. We will not attempt to solve the intermediate coupling problem here, but will only point out those features of it which are important for analyzing the spectra at hand. Intermediate coupling must begin to be considered when the two classes of weak coupling states interact appreciably. This occurs when the value of Δ approaches $V_a^0 - V_a^m$, the difference in energy of a vibration in the ground state and in the mth excited state. These energy differences are of the order of 100 cm.$^{-1}$. In the examples to be discussed later, values of Δ less than and greater than this figure are found. We expect the vibrational intervals to become altered when Δ is in the region of $V_a^0 - V_a^m$.

Simpson and Peterson pointed out that the splitting energy, Δ, in the weak coupling region is proportional to the band intensity of the individual vibronic bands undergoing the interaction, while in the strong coupling limit Δ is proportional to the full electronic band intensity. In the intermediate region the Δ value depends upon matrix elements of electronic interaction between different vibronic states, and so will have a value larger than in the weak coupling limit. The Δ value will begin to increase rapidly when the interacting systems are close enough so that these second order matrix elements become large, that is when Δ is of the order of V_a^m.

Thus we may distinguish two important cases of the intermediate coupling region: (1) $\Delta \approx V_a^0 - V_a^m$ and (2) $\Delta \approx V_a^m$.

In the first region in which $\Delta \approx V_a^0 - V_a^m$, mixing must occur between the two S states, and between the two A states. The transition probabilities are therefore no longer zero and finite respectively, but all four states must have a finite transition probability. The spectrum for small Δ should appear as a lower doublet at $E_m + V_a^m \pm \Delta$ and a weak doublet at higher energies $E_m + V_a^0 \pm \Delta$, since V_a^0 is usually greater than V_a^m. By the time Δ has reached $V_a^0 - V_a^m$, there should be four lines of roughly equal spacing, and having intensities determined only by the orientation of the vectors $\mathbf{M}_1$ and $\mathbf{M}_2$. Thus if the molecular geometry permitted $\mathbf{M}_1 + \mathbf{M}_2$ to equal $\mathbf{M}_1 - \mathbf{M}_2$ all four lines would be of equal intensity.

As the second region is approached there should be no large changes in relative in-

tensity of the four vibronic lines. Somewhere between the second region and the strong field limit, the intensity of two of the lines must decrease. The spectrum now consists of a pair of widely spaced doublets, and one component of each must lose its intensity.

3. Degenerate Vibration in the Excited State

The degenerate vibration is split in the molecule even without energy exchange. One of its components acts like an ordinary totally symmetric vibration while the other induces a forbidden transition by vibrational–electronic interaction. The problem thus reduces to a treatment of the non-totally-symmetric vibration. This vibration induces a transition in the half-molecule, independent of energy transfer. The degenerate vibrations of most interest are derived from the benzene e_{2g} mode. In toluene this becomes a_1 and b_1 (C_{2v}). We will continue to use a and b to designate the totally symmetric and non-symmetric components, respectively.

The energy levels are not appreciably affected by the vibrational mixing of excited states, and the transition probabilities are enhanced in the double molecule to the same extent as in the single molecule.

A possible effect could arise from the fact that vibrational mixing, if it is to produce any enhancement of intensity, must occur between states in weak coupling and states in strong coupling. The result is that the overlap factor, which causes two of the weak coupling states to have zero transition probability, is no longer as effective, and these two states could have a finite transition moment. The induced moment for this case is the moment induced in the single molecule times a vibrational overlap integral, $(X_1^{0a} \cdot X_1^{s0})$. This is similar to the Franck–Condon overlap integral, and may sometimes have an appreciable value. It is probably not an important source of intensity, however, compared to the intermediate coupling effects discussed in Section *2*. The conclusion is therefore that vibrationally induced transitions will act no differently from the direct transitions in the double molecules, and all the considerations of Section *2* apply equally to both.

We may now proceed to the analysis of the spectra.

B. Dibenzyl

The important features of the spectrum of dibenzyl are shown in the diagram of Fig. 1. No splitting of the 0–0 band could be observed, and a direct measure of the coupling between the benzene rings cannot be made. The appearance of four bands related to the e_{2g} vibration of benzene is of considerable interest, however, and permits some estimate to be made of the ring–ring interaction. The interpretation of these bands as arising from the mode related to e_{2g} of benzene seems well justified if one compares the spectrum with that of toluene, diagrammed in Fig. 1 and shown in detail in the preceding paper (2).

The dibenzyl molecule in the crystal has the symmetry C_i, but it is very close to C_{2h}, and selection rules based on C_{2h} are found to be closely obeyed. If we let the ring-interchanging operation defining S and A be the C_2 axis, then the pure electronic state related to B_{2u} of benzene, or A_1 of toluene, will become $A_u(S)$ and $B_g(A)$. Transitions to the A_u state are expected to be as strong as in toluene, and those to the B_g state are forbidden. If a dipole–dipole interaction potential is assumed (Sec. III), one predicts that the B_g state lies below the A_u state.

In the weak coupling limit we would expect to have a spectrum similar to that of toluene. Only two bands would appear in the e_{2g} region. These would correspond to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

a_1 and b_1 vibrations observed in toluene. The vibronic state containing the a_1 vibration would be $S(A_u)$, the same as the pure electronic transition, while the vibronic state containing the b_1 vibration would be $A(B_u)$. The polarizations would be z and y respectively, in analogy with toluene.

The presence of four bands of comparable intensity can be interpreted by assuming an appreciable excursion into the intermediate coupling region where the vibronic states containing ground state vibrational quanta may gain intensity. If we refer to Table I, and let a and b represent the a_1 and b_1 toluene-type vibrations we would expect the following levels, whose total energies are given to the right, to appear with appreciable intensity:

$$S(A_u) \quad E_m+V_a{}^0+\Delta, \qquad S(A_u) \quad E_m+V_a{}^m+\Delta,$$
$$A(B_u) \quad E_m+V_b{}^0-\Delta, \qquad A(B_u) \quad E_m+V_b{}^m-\Delta,$$

where m represents the B_{2u} type excited state. We know the approximate values of the vibrational quanta to be close to the following values for toluene:

$$V_a{}^0 = 521 \text{ cm.}^{-1}, \qquad V_a{}^m = 456 \text{ cm.}^{-1},$$
$$V_b{}^0 = 622 \text{ cm.}^{-1}, \qquad V_b{}^m = 528 \text{ cm.}^{-1}.$$

The intervals are measured in the spectrum from the electronic S level at $E_m+\Delta$. If we subtract this from the energy formulas for the vibronic levels and substitute the vibrational quanta we obtain a set of theoretical intervals which must be compared to the measured ones. By making the band assignments which appear to be the most consistent we obtain the list of comparisons:

Theor.		Exptl.
521	→	535
$622-2\Delta$	→	568
456	→	444
$528-2\Delta$	→	492

The values for 2Δ are 54 and 36, with an uncertainty of about 14, considering the mismatch of the two intervals which do not involve Δ. We will use $2\Delta = 45\pm14$ cm.$^{-1}$.

C. Diphenylmethane

Neither the true molecular shape nor the crystal structure of this compound is known. The single crystal spectra are strongly polarized, however, and some information about energy transfer within the molecule may therefore be obtained. The spectrum is diagrammed in Fig. 1.

One assumption which seems unlikely to be wrong is that diphenylmethane has a twofold symmetry axis bisecting the C—CH_2—C angle. The angle of rotation ϕ of the phenyl groups about the C(ar)—CH_2 axis is unknown. The C—CH_2—C angle may be assumed to be close to 112°. The molecular geometry and the coordinate system to be used are shown in Fig. 2.

The spectrum in the e_{2g} region has the eight bands which would be predicted for a molecule having no more than C_2 symmetry. Only four would be permitted for C_{2v} symmetry. In the two configurations corresponding to C_{2v}, the phenyl planes are perpendicular or parallel to the C—CH_2—C plane. It is clear then that the angle of rota-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

tion, ϕ, of the phenyl groups around the C—C bond is between 0° and 90° (ϕ will be measured from the perpendicular position).

As in the case of dibenzyl there is no clear evidence for a forbidden electronic origin. In case $\phi = 0$ (C_{2v} geometry) the forbidden transition would be $A_1 \rightarrow A_2$ and the allowed one $A_1 \rightarrow B_2$ (x-polarized). In C_2 geometry with $0° < \phi < 90°$, the A_2 excited state becomes an A state having a transition moment along the z-axis. The B_2 state becomes a B state and gradually loses its x-moment and gains a y-moment as ϕ increases. If a dipole–dipole interaction between the two rings is assumed, the energy of the A and B states as a function of the angle ϕ may be found. The energies are

$$[5] \qquad E\begin{pmatrix} A \\ B \end{pmatrix} = \pm \frac{2M^2}{R^3} (2.308\sin^2\phi - 1),$$

where M is the transition moment in one ring. Both the energies and the transition moments of states A and B are plotted in Fig. 3 as a function of angle. It can be seen

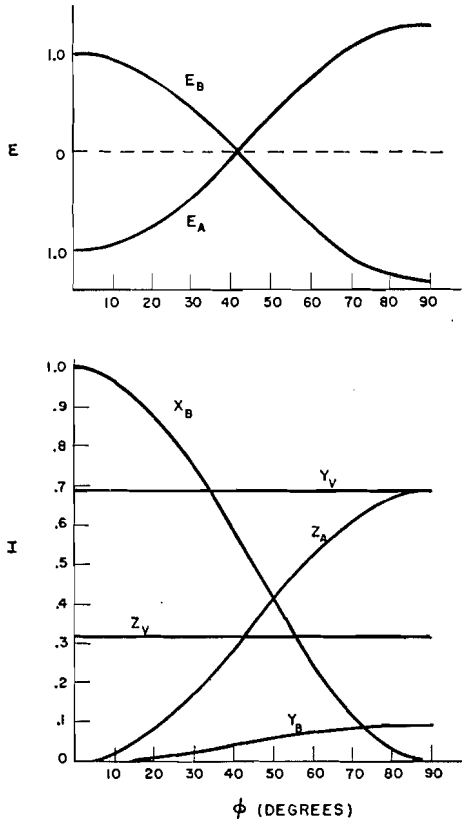

FIG. 3. Upper part: Energies of the A and B electronic states of diphenylmethane as a function of the angle of rotation ϕ.
Lower part: X_B, Y_B, Z_A—probabilities of short-axis transitions in the rings of diphenylmethane along molecular axes (see Fig. 2). Y_V, Z_V—probabilities of long-axis transitions (vibration-induced) along molecular axes.

that the higher state always has the higher transition moment, and that the two states coincide at $\phi = 41°$. The transition moments for vibronic transitions of the a_1-type toluene vibrations have the same polarization properties as the electronic origins, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

may therefore be read from Fig. 3. The induced transition moments due to the b_1-type toluene vibrations have polarizations independent of the angle ϕ. These are also plotted in Fig. 3. The intensity of the y-component of the vibrationally induced transition is the same as the vibration-induced intensity in toluene times $\sin^2 56°$. That of the z-component is proportional to $\cos^2 56°$. Further deductions from Fig. 3 may be made after examining the spectrum again.

The region of the spectrum corresponding to the e_{2g} vibration of benzene has its first band at 504 cm.$^{-1}$ from the allowed origin. This is somewhat higher than in toluene, where the first such band is at 456 cm.$^{-1}$. This suggests that the vibration modes of diphenylmethane are not as strictly comparable to those of toluene and benzene as in the case of dibenzyl. Nevertheless we will proceed with a similar analysis since the other prominent vibration frequencies, 928, 961, and 1174 cm.$^{-1}$, are very close to the dibenzyl frequencies 930, 965, and 1178 cm.$^{-1}$.

The bands of the e_{2g} region fall into two groups: 504 to about 580, and 649 to about 700 cm.$^{-1}$. If the second group are to be interpreted as vibrations of a character similar to the first, they must contain an electronic component which results in an energy about 150 cm.$^{-1}$ higher than that of the first group.

This is true not only for the e_{2g} region, but the entire spectrum may be analyzed as a superposition of two nearly identical spectra displaced from each other by 150 cm.$^{-1}$. The three totally symmetric frequencies, 928, 961, and 1174 cm.$^{-1}$, are found repeated at 153, 159, and 149 cm.$^{-1}$ respectively. This is within experimental error of 150 cm.$^{-1}$ because the bands here are somewhat broad. The band analogous to the 750 cm.$^{-1}$ band of toluene seems to be present at 774 cm.$^{-1}$ in diphenylmethane but its high frequency counterpart would fall too close to 928 cm.$^{-1}$ to be distinguishable from it.

A detailed analysis of the vibrational structure in the e_{2g} region may be made. It appears necessary to assume $\phi = 30°$ (approximately) and that the energy of the A state lies below that of the B state. It is also reasonable to identify each vibronic state by means of its strong coupling symbol, because the electronic splitting is large enough to separate two groups of vibronic levels into the states which ultimately go over into strong coupling states. Thus the symmetric and antisymmetric electronic and vibrational wave functions are represented by ψ_S, ψ_A, X_S, X_A respectively. The superscript a or b is added to X in order to indicate the type of vibrational mode. The analysis is shown in Table II.

The analysis is not entirely satisfactory because $X_A{}^a$ must be assumed to lie above

TABLE II

ANALYSIS OF DIPHENYLMETHANE SPECTRUM IN 400–700 cm.$^{-1}$ REGION

State	Symmetry	Intensity and polarization, calc.	Assignment	Polarization observed

Notes to table: M = direct vibronic transition moment,
M_i = vibrationally induced moment.

It is assumed that intermediate coupling causes enough mixing of states that transitions forbidden in the limiting cases are as strong as the allowed transitions.

$X_A{}^b$. Also the states $\psi_S X_A{}^a$ and $\psi_A X_S{}^a$, which are mixed in the intermediate region, do not have the correct polarization. The relationship between the polarization of a vibration in the first group of bands (superposed on the A origin) and the same frequency in the second group (superposed on the B origin) is correct in all cases, and the absolute polarizations, arising from the assumption that the A state is the lower one, are correct in three cases. Even though certain details do not seem entirely correct, it appears that the splitting between the A and B states, 2Δ, is almost certainly 150 cm.$^{-1}$.

The higher frequency electronic origin could be the band at 145 cm.$^{-1}$ from the first origin. Both origins are much stronger in one component than the other, and in fact the spectrum in one polarization has not been resolved because the crystals used have been too thick.

The diagram of Fig. 3 shows that in order to obtain strong absorption to both the A and B electronic origins in one polarization for ϕ between 20° and 60°, the molecular y-axis must be in the weakly absorbing direction of the crystal, and the x and z axes must both lie in the strongly absorbing direction. For values of ϕ near 80–90°, the x direction could be the weakly absorbing direction with y and z in the strong direction. We do not have good intensity measurements, so cannot say definitely what the molecular configuration is. It should be possible, however, to determine a molecular and a crystal structure from such measurements.

D. Biphenyl

In the experimental observations on the biphenyl crystal, the light was propagated parallel to the long molecular axis. Thus the only π–π transitions which could be observed are along the short axis. This was advantageous in that interference from the very strong long-axis polarized transition $^1A_{1g} \rightarrow {}^1B_{2u}$ was eliminated, and only the weak short-axis transitions could be seen. Using the diagram of Fig. 2 and Herzberg's notation for the group D_{2h}, the states of biphenyl derived from the B_{2u} state of benzene are B_{1u} and B_{3g}. Transitions are permitted from the ground state to the B_{1u} state, but not to the B_{3g} state. The allowed transition should have about the same intensity as the corresponding toluene transition. According to the intensity estimates made from the photographic plates they are approximately the same.

Both fluorescence and absorption have been observed, and direct observation of the two electronic states was therefore possible. The absorption beginning at 33714 cm.$^{-1}$ is interpreted as the $A_g \rightarrow B_{1u}$ transition. According to Pesteil (7), the fluorescence begins at 33340 cm.$^{-1}$ with a series of weak bands, and a series of strong bands begins at 32480 cm.$^{-1}$. The transition moment of the strong bands is along the long axis of the molecule. Our fluorescence experiments (2) essentially confirmed Pesteil's results but did not go as far as his. A broad band having its maximum at about 33310 cm.$^{-1}$ appeared in the absorption spectrum of a crystal 50 μ thick. We think that this is the absorption corresponding to the 33340 cm.$^{-1}$ fluorescence.

The interval between 33340 cm.$^{-1}$ and the strong fluorescence band 32480 cm.$^{-1}$ is 860 cm.$^{-1}$. This is equal to a known infrared absorption band. Its symmetry properties are not known, however. The interpretation is that a 860 cm.$^{-1}$ vibration makes a forbidden transition, whose origin is 33340 cm.$^{-1}$, allowed through vibrational–electronic interaction. The long-axis polarization of the fluorescence is reasonable, since the strongest nearby transitions which may be mixed in by vibration are long-axis polarized. The origin at 33340 cm.$^{-1}$ is interpreted as the $A_g \rightarrow B_{3g}$ transition made allowed by the unsymmetrical crystal field. Since the corresponding allowed $A_g \rightarrow B_{1u}$ transition is the 33714 cm.$^{-1}$ absorption, the B_{1u}–B_{3g} separation is 374 cm.$^{-1}$.

E. Paracyclophanes

Cram, Allinger, and Steinberg (4) have published the solution spectra of the paracyclophanes, a series of molecules in which two benzene rings are linked together in both para positions by $(CH_2)_n$ groups. The spectra look very similar to a *p*-xylene spectrum when the benzene rings are separated by at least $(—CH_2—)_4$ at both positions. If the rings are any closer a new and weaker band appears to the red. Table III gives the energy difference between the two bands for the compounds studied. These values of ΔE are only approximate because of the breadth of the bands.

TABLE III

INTERACTION ENERGIES BETWEEN BENZENE RINGS

Paracyclophanes						
m	*n*	C_1–C_1'	C_4–C_4'	*R* (separation of ring centers)	ΔE (calc.)	ΔE (obs.)
2	2	1.54	1.54	1.54	632	2400
2	3	1.80	2.26	2.03	278	2700
2	4	2.12	3.16	2.64	126	1600
3	3	2.52	2.52	2.52	142	2800
3	4	2.84	3.41	3.12	78	1950
3	6	3.50	5.27	4.39	28	~0
4	4	3.73	3.73	3.73	44	~0

Other molecules	R_1 (ring center)	R_2 (nearest points)	ΔE_1	ΔE_2	ΔE (obs.)
Biphenyl	4.25	1.45	30	760	374
Diphenylmethane (ϕ = 30°)	4.88	2.56	18	120	150
Dibenzyl	6.66	3.94	8	37	45±14
Durene crystal	6.45		29.6		<5

The weaker absorption band to the red is most probably the forbidden transition of the two which would be expected in the 2600 Å region of the double molecules. If the benzene rings are exactly parallel, this transition is rigorously forbidden in the pure electronic spectrum. Since it is always quite broad, it is probable that it only appears through vibrational–electronic interaction.

Some of the energy differences given in Table III are very large compared to those found for the singly linked double molecules of the previous section. The total intensity of the absorption per ring to both upper states is about right for the $A_g \rightarrow B_{2u}$ transition in *p*-xylene, so that the large splitting is not caused by admixtures of higher excited benzene-like π states. Cram, Allinger, and Steinberg have also calculated the ring–ring distances in these compounds assuming that the bond angles and distances are as nearly "normal" as possible. They point out that the large spectral changes only occur when the rings are closer than the Van der Waals packing distance of 3.40 Å. The distances between corresponding para and para-prime positions in some of these molecules are given in Table III.

F. Molecular Crystals

Crystal structure data are available for benzene and durene, but for very few other crystals containing principally benzene rings. Fox and Schnepp (5) have published an interpretation of the benzene spectrum as observed by Broude, Medvedew, and Prikhotjko (1). The spectrum of the durene crystal in absorption and fluorescence has been studied by Schnepp and McClure (8). There are two molecules per unit cell in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

this crystal and from its geometry some splitting is expected. No dichroism could be found, however, and the splitting must be under 5 cm.$^{-1}$.

III. INTERPRETATION OF THE DATA

A detailed interpretation of the data derived in this article would be of considerable value in learning about the outer parts of the wave functions of the systems considered. The energy transfer phenomena depend predominantly upon the shape of the wave functions in their outer regions. As our main purpose was to establish some valid numbers, only a rudimentary treatment based on the dipole–dipole interaction will be attempted here. An equation similar to eq. [5] is used.

All that is needed to carry out this treatment is a knowledge of the geometry, and the strength of the transition in the individual molecules, or parts of molecules. From the integrated absorption band one may obtain the magnitude of the transition moment (in cm.) through the equation

$$M^2 = 3.97\times10^{-20}\int\epsilon d\nu/\nu,$$

where ϵ is the molar extinction coefficient to base 10. The value of M for toluene is found to be 0.10 Å, and this number may be used in calculations on other compounds containing benzene rings. The full electronic transition moment has been used. The results of the calculations are shown in Table III.

Some of the paracyclophane splitting energies are greater by an order of magnitude than that predicted from the excitation exchange energy. In the two cases, the 3,6 and 4,4 compounds, where no splitting could be observed in the solution spectra, small splittings were calculated. The smallest splitting distinguishable in the solution spectra is roughly 500 cm.$^{-1}$. In the spectrum of the 4,4 compound, some spreading out of the vibrational structure is observable in the solution spectra, and in the low-temperature polarized crystal spectra one expects to see clear evidence for the ring–ring interaction.

The paracyclophanes, which have the very large splittings, all have their benzene rings separated by less then the "packing thickness" of 3.40 Å. Since below this distance there must be considerable π–π overlapping, it is reasonable to find that the dipole–dipole energy does not account for all of the splitting.

For the other double molecules, the dipole–dipole energy gives somewhat better values for the splitting. Taking the distance of separation from the nearest points of the benzene rings gives better values than using the separation of the ring centers. As pointed out by Schnepp and McClure (8), the durene crystal should have an observable dichroic splitting according to the dipole–dipole model. This is the one case in Table III where an overestimate of the interaction energy certainly occurs.

In the calculations for Table III the full electronic moment has been used. Simpson and Peterson (9) have recently shown that one must use only the individual vibronic band moments in the limit of very weak coupling, and the full electronic moment only in strong coupling. The overestimate of the durene energy is probably explainable in this way, as it is a very weakly coupled system.

In diphenylmethane the coupling seems to require use of the full electronic moment. The use of point dipoles is obviously a poor approximation for such closely coupled rings, and the full geometry of the system should be used. This statement also applies to the other molecules where large coupling energies are involved.

The numbers in Table III are believed to be well deserving of further theoretical study.

DIABATIC REACTIONS[1]

HENRY EYRING, GEORGE STEWART, AND RANSOM B. PARLIN

ABSTRACT

The fundamentals of diabatic reactions are briefly reviewed. The two important types of radiationless transitions at the crossover region of two potential surfaces are considered kinetically and rate formulations are given. The first type involves an appreciable activation energy in excess of the heat of reaction. The second does not. The reaction velocity is formulated using the absolute rate theory where the transmission coefficient is interpreted in terms of the Landau–Zener probability approximation. The over-all rate of a sequence of reactions is treated in accordance with the principle that resistances in series are additive. If the second in a sequence of two reaction steps involves a negative activation energy and is slow because of failure to cross to the new surface the resultant repeated passage through the crossover region requires a special formulation of the transmission coefficient, which is given. Whether this transmission coefficient influences the over-all rate or not depends on whether or not it belongs to the rate-determining step.

Quenching reactions are classified in terms of the number of free valences involved, an electron being excited from a saturated molecule conferring radical-like properties on the excited molecule. Excited odd-electron molecules will attract at considerable distances without appreciable activation energy.

The transmission coefficient is discussed in terms of recruitment factors for cases in which the products of a reaction are out of equilibrium.

Hot positive ions resulting from mass spectrographic reactions are indicated as another example of diabatic reactions, and a procedure for treating these by the activated complex theory is briefly mentioned.

Most chemical reactions at low temperatures proceed adiabatically, in the Ehrenfest sense, and so involve no crossing over from one potential energy surface to another (2). Diabatic reactions induced by radiation or by fast particles (2, 3) pass from one surface to another either by absorbing radiation or by a radiationless transition at the crossover region of two potential energy surfaces, or else by spontaneous emission of radiation (5). The Einstein transition probabilities are given by the well-known relations (1, 7)

$$[1] \qquad A_{m\to n} = \frac{8\pi h\nu_{mn}^2}{C^3} B_{m\to n} = \frac{32\pi^3\nu_{mn}^2}{3C^3\hbar} \int \psi_m^* \sum_i e_i \mathbf{r}_i \psi_n d\tau,$$

where the symbols have their usual meaning. A most useful relation for the probability

of continuing along one of the dotted curves in Fig. 1 instead of following along a full curve is given by the approximate relationship

$$P = \exp(-4\pi^2\epsilon_{12}^2/hv|S_1-S_2|) \quad [2]$$

due to Landau (4) and Zener (11).

In equation [2], $2\epsilon_{12}$ is the distance between the upper and lower full curves along a vertical line passing through the intersection of the dotted lines. The value of ϵ_{12} is $\int\psi_m^* H^{(1)}\psi_n d\tau$, where ψ_m and ψ_n are the eigenfunctions of H_0 corresponding to the crossing lines and $H^{(1)}$ is the perturbation which shifts the system to the full-lined non-crossing energy surfaces; v is the velocity of approach along the reaction coordinate and S_1 and S_2 are the respective slopes of the two dotted lines. For complicated intersecting surfaces a more exact solution than [2] should be found, but in any case appropriate averages of the parameters in [2] are required to give a mean value for the probability $\bar{P}$. The reaction velocity for passing from surface 2 to surface 1 is

$$v = \prod_i C_i(\mathfrak{H}kT/h)\exp(-\Delta F^{\ddagger}/RT). \quad [3]$$

We will write $\mathfrak{H} = \mathfrak{H}_1\mathfrak{H}_2$, where

$$\mathfrak{H}_2 = 2\bar{P}(1-\bar{P}) \quad [4]$$

and $\mathfrak{H}_1$ will be discussed subsequently. The velocity of the back reaction is

$$v_b = \prod_b C_b(\mathfrak{H}kT/Kh)\exp(-\Delta F^{\ddagger}/RT), \quad [5]$$

where C_b is the concentration of the bth product molecule and K is the equilibrium constant. The other symbols have the same values as in [3].

In Fig. 2 we have a second common type of surface crossing. Here the crossover point is at a lower value of the energy than the final state on surface 2 (to the right of b). In this case we have a specific rate constant at a which we call k_a and at b there is a specific rate constant k_b. The over-all rate is then

$$v = \prod C_i/(k_a^{-1}+k_b^{-1}) = \prod C_i k_a k_b/(k_a+k_b). \quad [6]$$

Again the velocity of the back reaction is

$$v_b = \prod_b (C_b/K)[k_a k_b/(k_a+k_b)]. \quad [7]$$

The rate constants k_a and k_b are each to be calculated as if the other rate-limiting process were absent. More generally, a sequence of any number of reactions has an over-all rate constant equal to the reciprocal of the sum of the reciprocals of the individual rates each calculated as though it were the only rate-determining step. This result is in accordance with the principle that resistances in series are additive (6). In [7] we have $k_b = \mathfrak{H}_b(kT/h)\exp(-\Delta F_b^{\ddagger}/RT)$, where $\mathfrak{H}_b \approx 1$ and $k_a = \mathfrak{H}_a(kT/h)\exp(-\Delta F_a^{\ddagger}/RT)$. We now take $\mathfrak{H}_a = \mathfrak{H}_1\mathfrak{H}_2$, where

$$\mathfrak{H}_2 = \{1-[1-2\bar{P}(1-\bar{P})]^{\nu\tau}\}(\tau\nu)^{-1}. \quad [8]$$

Here τ is the lifetime of the complex which vibrates ν times per second along the reaction coordinate if the only escape of the complex is back to surface 2, that is,

$$1/\tau = (kT/h)\exp[-(\Delta F_b^{\ddagger}-\Delta F_a^{\ddagger})/RT]. \quad [9]$$

The term in [8] which is raised to the power $\nu\tau$ expresses the probability of not transi-

For personal use only.

tioning in $\nu\tau$ tries so that the quantity in brackets expresses the chance of transitioning in $\nu\tau$ vibrations. Consequently $\mathfrak{H}_2$ is the average chance of transitioning per vibration. $\Delta F_a^{\ddagger}$ and $\Delta F_b^{\ddagger}$ are the standard free energies in going from the initial state to the activated states a and b, respectively. $\mathfrak{H}_1$ is the fraction of activated complexes moving from right to left, at equilibrium, which were formed from reactants. $\mathfrak{H}_1$ is discussed subsequently.

TYPE REACTIONS

The reverse of each quenching process is an excitation so that by the principle of microscopic reversibility discussing one is equivalent to discussing the other. When molecules collide there is a tendency for the compressed electron orbits to be promoted as they are promoted in the united atom. Thus, at some interatomic distance one expects a crossing of the non-excited state with the corresponding excited state, as seen in Figs. 1 and 2. Our figures and discussion apply as well to quenching within a molecule as to quenching by collision. In internal quenching the lower surfaces, instead of being flat, turn up like a parabola. This only changes the detailed partition functions to be used but does not modify the above formal considerations.

It is convenient to classify the types of quenching reaction in terms of the number of free valences involved. When an excited saturated molecule is quenched by a second saturated molecule, we have the hole from which the electron was ejected conferring radical-like properties on the excited molecule. Thus the activation energy for collision of such a pair should not exceed a few calories in analogy to the radical reactions $H+H_2 \rightarrow H_2+H$ with 8 calories activation energy, or the reaction $H+Cl_2$ with about 2 calories. The lowering of the activation energy due to the polar nature of the excited molecule leads us to expect low values approaching zero for the activation energy of barrier crossing leading to quenching. At room temperature each 1.3 calories activation energy yields a decrease in the apparent collision cross section by a factor of 10. Such a process is represented in Fig. 1. If the quencher or the excited molecule possesses an odd number of electrons in addition to being excited, two molecules will attract at considerable distance without appreciable activation energy, thus leading to large apparent cross sections. Fig. 2 exemplifies this situation.

THE CHEMICAL BOND AND ACTIVATION ENERGY

An electronic orbital behaves like a fluid sphere or rod of high surface tension which, like any fluid, seeks the lowest possible level of potential energy consistent with minimum surface area. Thus, if there are holes of low potential energy lying in two adjacent atoms and if in addition there is an available electron which by occupying the holes jointly can lower its energy, then the atoms will be drawn together by the electronic orbital, thus forming a chemical bond. Minimum curvature for the orbital means minimizing the kinetic energy, much as minimizing surface area lowers total surface energy for a fluid. Laidler (3) has compiled tables listing a variety of quenching cross sections and explained many of them in terms of the types of potential surfaces which cross. A crossing of surfaces with different multiplicities leads to slow reaction rates because of a small k_a. It is interesting that the observed cross sections are all near enough to ordinary kinetic theory values to preclude activation energies larger than a few calories. Since, however, with competing reactions only the fast reactions are exhibited, we naturally miss such quenching reactions as are relatively slow.

It is natural to expect that the rare gases would be poor quenchers of excited saturated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

molecules or even of excited mercury, not being able to complex with them, whereas excited radicals such as O*H, which can form coordination complexes even with saturated structures, should be quenched by most molecules including the rare gases. The efficiency of the rare earths and transition elements in picking up excitation in the carbon arc is understandable in terms of their unfilled shells, which when excited complex with even saturated molecules making k_a large. Even what Laidler (3) classifies as physical quenching where no new chemical species emerges might well be described as a chemical isomerization in which an excited isomer with its unsaturated valences by being quenched (or by emitting light) changes over into the completely or at least more completely saturated isomer. In this important sense all quenching processes are chemical reactions, each passing through its peculiar activated complex. The quenching molecule, when it emerges unchanged, has served like any other catalyst in providing a changed reaction path, in this case by yielding a crossing of potential surfaces.

Table I lists some of the quenching cross sections found in compilations such as those of Laidler (3). Gases like H_2 and D_2 have quenching cross sections larger than kinetic theory values if they react readily with $Hg(^3P_1)$, thus avoiding a multiplicity change, or if they overcome the multiplicity restriction, by having a long lifetime, τ, for the complex, as is probably true for $Na(^2P)$. $Cd(^3P_1)$, in spite of reacting with the hydrogens, is probably slowed down by a slow multiplicity change.

TABLE I

CROSS SECTIONS, Å²

	$Hg(^3P_1)$	$Cd(^3P_1)$	$Na(^2P)$
H_2	8.6, 6.0	0.67, 3.54	7.4
D_2	8.4, 11.9	0.19, 1.80	
	Unsaturated hydrocarbons		
C_2H_2	23	22	
C_2H_4	48, 26	24.9	44
C_3H_6	31	29	52
C_4H_8-1	33.5	35.2	58
C_4H_8-2	29	30.6	58
C_6H_6	41.9, 59.9	28.4	75
	Saturated hydrocarbons		
CH_4	0.059	0.012	0.11
C_2H_6	0.42	0.024	0.17
C_3H_8	1.6	0.012	0.2
n-C_4H_{10}	4.1	0.064	0.3
n-C_5H_{12}	8.6	—	—

n-C_7H_{16}	24	—	—
	Odd electron		
NO	24.7	—	—
	Halogens		
I_2	—	—	40
Br_2	—	—	100

The unsaturated hydrocarbons with their π electrons attract at large distances and then complex strongly enough that $k_a \gg k_b$ because of a long lifetime, τ_1, of the complex or else by an increase in the transition per vibration, $2\bar{P}(1-\bar{P})$. It is interesting that for the quenching of $Na(^2P)$, where chemical changes in the unsaturated hydrocarbons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

do not occur, the quenching cross sections are nevertheless greater than for $Hg(^3P_1)$ and $Cd(^3P_1)$, where H_2 is liberated. One must conclude that long lifetimes, τ, contrive to make $k_a \gg k_b$ and that this is independent of whether there are subsequent chemical changes or not. This indication that the rate-determining step is the "physical quenching" whether or not this is followed by a chemical reaction is interesting in connection with Zemansky's (10) evidence that oscillators which most nearly matched their quantum to the 5.03 kcal. for the change $Hg(^3P_1) \rightarrow Hg(^3P_0)$ were most efficient in the quenching process.

Table I indicates also that for saturated hydrocarbons the rate-determining step for quenching seems to yield roughly similar cross sections whether chemical reactions follow as for $Hg(^3P_1)$ or $Cd(^3P_1)$ or whether they do not as for $Na(^2P)$. This suggests again that the rate-determining step is low for methane because $2\bar{P}(1-\bar{P})$ and/or τ are low. Larger molecules would be expected to complex more readily with the excited atoms and so increase τ and, therefore, the quenching cross section, as is observed. The remaining cases are also in accord with the view that in quenching the rate-determining step is usually without an activation energy and is governed by τ and $2\bar{P}(1-P)$ whether or not it is followed by a subsequent chemical reaction.

THE TRANSMISSION COEFFICIENT, THE CONNECTIVITY OF STATES, AND THE RECRUITMENT FACTORS

We have discussed at some length $\mathfrak{H}_2$, which we will call the diabatic factor in the transmission coefficient $\mathfrak{H}_a = \mathfrak{H}_1\mathfrak{H}_2$. The factor $\mathfrak{H}_1$ is the additional factor required to correct an equilibrium reaction rate expression for non-equilibrium conditions. Ideally we should consider every possible quantum state of a reacting system as a separate species and proceed by the methods made familiar in dealing with chain reactions. Such a procedure yields the set of equations

$$[10] \qquad dc_i/dt = \sum_j (k_{j\rightarrow i}\, c_j - k_{i\rightarrow j}\, c_i),$$

where there are as many equations as there are quantum states. In the general case the k's are functions of the concentrations of various species, the temperature, which isotope is involved, and the radiation density. At equilibrium we have $dc_i/dt = 0$ for all species. In a steady state, dc_i/dt can be taken as zero to a good approximation only for certain intermediates which exist at very low concentrations in the reaction sequence. For those states considered to maintain an equilibrium distribution in spite of the reaction we assume

$$[11] \qquad d\ln c_i/dt = d\ln \textstyle\sum_k c_k/dt = -d\ln \sum_l c_l/dt.$$

This is, of course, a great simplification and never quite true. In [11] $\sum_k c_k$ gives the total concentration of a particular reactant while $\sum_l c_l$ is the concentration of a product; c_i is the concentration of the particular species in the ith quantum state. When one observes that the products of a reaction are out of equilibrium as chemiluminescent spectra often show, it follows by the principle of detailed balance that for the reverse reaction the reacting species would not be withdrawn from the reservoir of states in such a way as to maintain equilibrium exactly. To this extent a mean $\mathfrak{H}_1$ is not exactly true but is still a useful approximation. However, molecular beam experiments such as those of Taylor and Datz (9) will require something better than a mean $\mathfrak{H}_1$ and will be revealing the detailed structure of potential energy surfaces. The various isotopic reactions may have nearly equal mean values of $\mathfrak{H}_1$, in spite of markedly fluctuating transmission coefficients for various states of the activated complex.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

As indicated in equation [10], a particular state recruits its occupants from all other states. We define the recruitment factor for the j to i state with reference to equation [10] as

$$f_{j\to c} = k_{j\to c} c_j^0 / \sum_j k_{j\to i} c_j^0, \qquad [12]$$

where the zero subscript refers to the equilibrium concentration and $\sum_j f_{j\to i} = 1$. Clearly the f's are expressible in terms of partition functions alone. In order that $\mathfrak{H}_1$ should be unity, it is clear that every activated complex corresponding to crossing from reactant to product should recruit only from reactants, since $\mathfrak{H}_1$ is the total recruitment from reactant over recruitments from both reactants and from products. However, if it recruits equally from reactants and products, $\mathfrak{H}_1$ is still one-half. In pathological cases such as in the reaction $H_2 \rightarrow 2H$, the activated complex states moving in the direction reactants to products recruit largely from products. This yields a correspondingly low value for $\mathfrak{H}_1$.

MASS SPECTROGRAPHIC REACTIONS

The activated complex theory has been applied to reactions in the mass spectrograph (8). When an electron knocks another electron out of a molecule and makes a positive ion, this constitutes a Franck–Condon transition from the low potential surface for the molecule up to the surface corresponding to the ion. If the electron removed were completely localized in one bond in the ground state, and if there were no electronic reorganization in the positive ion, then only one bond length would be too short after the transition and the stored up energy would either break the weakened bond or would be insufficient to do so. Instead, the bonds finally broken bear little relation to the bond which must have been the source of the displaced electron. Another way of looking at the situation is that the equilibrium structure of the positive ion usually differs greatly from that of the neutral molecule in many bonds. The result is that, typically, ionization creates a positive ion with several electron volts of energy scattered over many degrees of freedom and only as the Lissajous motion of the mass point concentrates the dissociation energy in a bond does one get dissociation.

Thus, ionization creates a hot positive ion which usually has sufficient energy to break a variety of bonds each with a specific rate constant. The appearance potentials fix the activation energy for the corresponding reactions and the vibration frequencies can be estimated so that one can calculate a corresponding set of rate constants. Thus, for an assumed energy in the molecule, one can calculate the percentage of each of the possible products formed during the time the positive ion stays in the mass spectrograph. If the distribution function of number of ions against energy stored in the ion can be measured, or assumed, or calculated one can predict the mass spectra for a molecule. Much remains to be learned about such measurements and calculations, but enough success has been achieved to indicate that the outlined procedure is on the right track. Hot positive ions with their mobile structure and enormous reactivity seem to constitute one more diabatic province at least partly understood. Characteristically the energy left in electronically excited states crosses over and becomes available as vibrational energy promoting reaction on the lowest state of the positive ion. Molecules like the aromatic hydrocarbons which tend to fluoresce in solution possess groups of states which do not cross effectively with other states and, as would be expected, yield larger percentages of parent ions.

We wish to express our appreciation to the National Science Foundation for their support of this research.

REACTIONS INVOLVING ELECTRONICALLY-EXCITED OXYGEN[1]

E. KERRY GILL AND K. J. LAIDLER

ABSTRACT

The various electronically-excited states of oxygen atoms and molecules are briefly considered. Certain reactions involving some of these electronically-excited species are then discussed with reference to the experimental evidence and to the potential-energy surfaces on which they occur. In the case of the mercury-photosensitized formation of ozone from oxygen it is concluded that both experimental evidence and theoretical arguments point to the fact that the oxygen molecule initially formed is in an excited $^3\Sigma_u^+$ state. Consideration is also given to the mechanism of formation of O_2^* in the carbon monoxide flame and in other flames. The reactions

$$O+O_3 \rightarrow 2O_2^*$$

and

$$O_2^*+O_3 \rightarrow 2O_2+O$$

are also discussed briefly.

INTRODUCTION

A considerable number of electronically-excited states of oxygen molecules and atoms are known to exist, and spectroscopic data have provided detailed information about many of them. Several of these excited species are known to be involved in chemical reactions, either as reactants or as products. The purpose of this paper is to refer to a few of the more common reactions of this type, to discuss the evidence for the nature of the species involved, and to consider detailed reaction mechanisms from the standpoint of the method of potential-energy surfaces.

ELECTRONIC STATES

The electronic states of O and O_2 will be mentioned only very briefly, since this matter has been fully discussed elsewhere (14, 15). According to the Wigner–Witmer correlation rules two atoms of oxygen in their ground states (^3P_g) can produce, on combination, 18 different electronic species of the molecule, while one ground state atom plus one in the first excited level (^1D_g) can give an additional 18 species. Only a few of these are stable or relatively abundant, and Fig. 1 shows the potential-energy curves for those states of the molecule that have been observed spectroscopically. The $^1\Sigma_u^-$ and $^3\Delta_u$ states ($^3\Delta_u$ not drawn) have been detected by Herzberg (16).

The ground state of O_2 ($^3\Sigma_g^-$) and the first two excited states ($^1\Delta_g$ and $^1\Sigma_g^+$) have the electronic configuration

$$KK(\sigma_g 2s)^2(\sigma_u 2s)^2(\sigma_g 2p)^2(\pi_u 2p)^4(\pi_g 2p)^2$$

and dissociate to normal ^3P_g atoms as shown in the figure. Additional excited states are formed by the transfer of an electron from the bonding ($\pi_u 2p$) orbital to the antibonding ($\pi_g 2p$) orbital to give

$$KK(\sigma_g 2s)^2(\sigma_u 2p)^2(\sigma_g 2p)^2(\pi_u 2p)^3(\pi_g 2p)^3.$$

This configuration could produce the states $^1\Sigma_u^+$, $^1\Sigma_u^-$, $^1\Delta_u$, $^3\Sigma_u^+$, $^3\Sigma_u^-$, and $^3\Delta_u$, of which $^1\Sigma_u^-$, $^3\Sigma_u^+$, $^3\Sigma_u^-$, and $^3\Delta_u$ have been observed. $^3\Sigma_u^-$ dissociates into $O(^3P_g)+O(^1D_g)$, the rest into ground-state $O(^3P_g)$ atoms.

[1]*Manuscript received August 16, 1957.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada. This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.

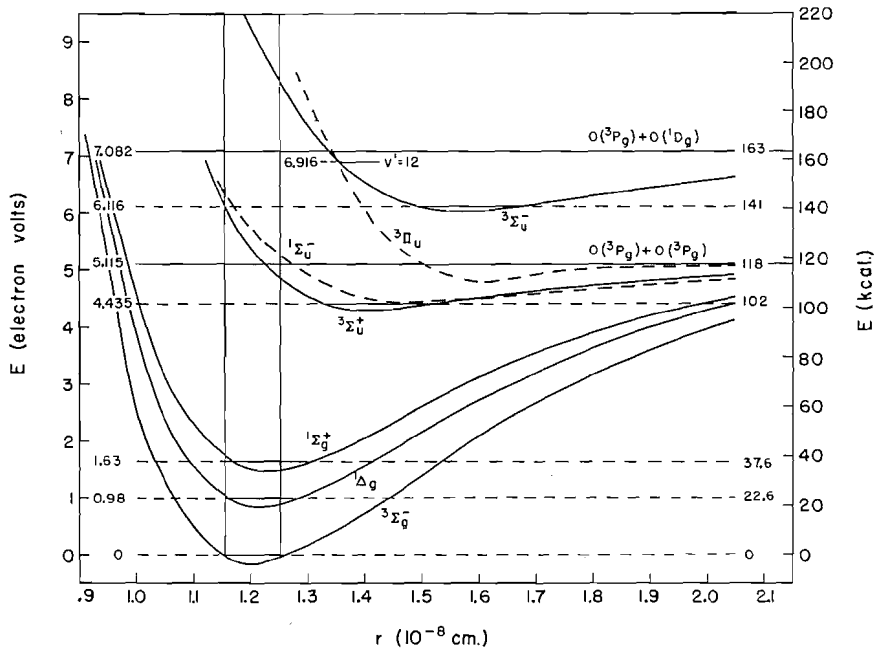

FIG. 1. Potential-energy curves for the ground and excited states of the oxygen molecule.

Fig. 1 also includes a $^3\Pi_u$ curve recently proposed by Wilkinson and Mulliken (34) to account for the predissociation of $O_2(^3\Sigma_u^-)$ into ^3P_g atoms.

THE REACTION $Hg^*(^3P_1) + O_2(^3\Sigma_g^-) \rightarrow Hg(^1S_0) + O_2^*$

Molecular oxygen is an effective quencher for the 2537 Å mercury line, the quenching cross-section being very large (29, 35). This quenching process involves the transition from the $^3P_1$ state of Hg to the $^1S_0$ state, a transition that occurs with an energy liberation of 4.88 ev. or 112.5 kcal. Ozone is produced during the quenching, and it is of interest to consider the state of the oxygen after it has reacted with the excited mercury atom.

In the first place, there is abundant evidence that the reaction is

[1] $$Hg^*(^3P_1) + O_2(^3\Sigma_g^-) \rightarrow Hg(^1S_0) + O_2^*,$$

where O_2^* is an excited state of oxygen, the nature of which is discussed below. The reasons for preferring this reaction to

[2] $$Hg^*(^3P_1) + O_2 \rightarrow HgO + O$$

and

[3] $$Hg^*(^3P_1) + O_2 \rightarrow Hg(^1S_0) + 2O(^3P_g)$$

are briefly as follows. Reaction [2] is exothermic by at least 64 kcal. (32) and is therefore energetically possible; however if it were followed by $O+O_2 \rightarrow O_3$ there would be one molecule of ozone formed from each Hg* atom.† Experimentally at least seven molecules are formed (3, 32), and the reaction $HgO+O_2 \rightarrow Hg+O_3$ is too endothermic to be useful. Reaction [3] can be excluded as being slightly endothermic.

†*Since the* Hg *is converted into* HgO *there can be no re-excitation to* Hg*. *If reaction* [1] *occurs re-excitation is possible and large yields can result.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

According to the correlation rules $Hg^*(^3P_1)$ and $O_2(^3\Sigma_g^-)$ can combine to give the linear complex HgO_2 in Σ and Π states with singlet, triplet, and quintet multiplicities. Energetically, since 4.88 ev. is available, the O_2^* could be in any one of the four lowest electronic states, namely $^3\Sigma_g^-$ (ground), $^1\Delta_g$, $^1\Sigma_g^+$, and $^3\Sigma_u^+$. All of these states are permitted by the correlation rules, as may be seen as follows:

$$Hg(^1S_0) + O_2^*(^3\Sigma_g^- \text{ or } ^3\Sigma_u^+) \rightarrow HgO_2(^3\Sigma),$$
$$Hg(^1S_0) + O_2^*(^1\Delta_g) \rightarrow HgO_2(^1\Sigma, {}^1\Pi, {}^1\Delta),$$
$$Hg(^1S_0) + O_2^*(^1\Sigma_g^+) \rightarrow HgO_2(^1\Sigma).$$

The question now to be decided is which of these four electronic states of O_2 is actually formed. Various suggestions have previously been made. Mitchell (25) suggested that, since the ground state of oxygen has a vibrational level at 4.86 ev., which corresponds closely to the energy released, this state will actually be formed; in other words, the electronic energy of the mercury will pass almost entirely into vibrational energy of the oxygen. However, recent work has indicated (23, p. 105) that this resonance factor, arising from the matching of energy levels, is not an important one. Volman (33), on the basis of his results (32) on the effect of foreign gases on ozone production, suggested that the oxygen produced was either vibrationally excited $^3\Sigma_g^-$ or a singlet state, and argued against its being the $^3\Sigma_u^+$ state. Finally one of us (see p. 101 of Ref. 23) has tentatively suggested that the most probable process is the one involving the least loss of electronic energy, and from this it follows that the $^3\Sigma_u^+$ state is the one that should be produced.

In the following two subsections we re-examine this problem from both the experimental and theoretical points of view, and conclude that the $^3\Sigma_u^+$ state is probably produced.

Influence of Foreign Gases

The reactions subsequent to reaction [1] and leading to ozone production are

[4] $$O_2^* + O_2 \rightarrow O_3 + O$$

and

[5] $$O + O_2 + M \rightarrow O_3 + M + \text{k.e.}$$

where M is a third body required to carry off the excess energy. Volman's discussion (33) of the probable state of the O_2^* produced in reaction [1] is based on the effects of foreign gases added to the system. A number of such gases were found to increase the rate of ozone production in the mercury-photosensitized reaction, the order of effectiveness being

$$He > A > N_2 > CO_2.$$

These gases play a role in reaction [5] as well as in the reactions

[6] $$Hg^*(^3P_1) + M \rightarrow Hg(^1S_0) + M^*$$

and

[7] $$O_2^* + M \rightarrow O_2 + M^*.$$

This behavior of foreign gases is to be contrasted with their effects on the unsensitized photochemical formation of ozone from oxygen at 1849 Å (32). The foreign gases were in this case found to reduce the role of ozone formation, their order of effectiveness as retarders being the same as above. At this wavelength oxygen dissociates into two normal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

^3P atoms (27, p. 246), either by a direct transition to a repulsive state of O_2 or by a predissociation from the $^3\Sigma_u^-$ state:

[8] $$O_2 + h\nu \xrightarrow{1849\ \text{Å}} O(^3P) + O(^3P)$$

Subsequent processes are

[9] $$O + O_2 + M \rightarrow O_3 + M$$

and

[10] $$O + O + M \rightarrow O_2 + M.$$

The reactions occurring in the sensitized and unsensitized reactions may thus be compared as follows:

Sensitized reaction (accelerated by foreign gases)		Unsensitized reaction (retarded by foreign gases)	
I	$Hg^*(^3P_1) + O_2(^3\Sigma_g^-) \rightarrow Hg(^1S_0) + O_2^*$	VI	$O_2 + h\nu \xrightarrow{1849\ \text{Å}} O(^3P) + O(^3P)$
II	$O_2^* + O_2 \rightarrow O_3 + O$	VII	$O + O_2 + M \rightarrow O_3 + M$
III	$O + O_2 + M \rightarrow O_3 + M$	VIII	$O + O + M \rightarrow O_2 + M$
IV	$Hg^* + M \rightarrow Hg + M^*$		
V	$O_2^* + M \rightarrow O_2 + M^*$		

It is to be noted that in the sensitized reaction M catalyzes the production of ozone as far as III is concerned and inhibits it in IV and V. In the unsensitized reaction M is a catalyst in VII and an inhibitor in VIII.

In the sensitized reaction the foreign gases catalyze the formation of ozone, the inert gases being the most effective. Evidently their effect on III overrides that on IV and V. But if, as Volman asserts, the energy of O_2^* is largely vibrational, these gases would readily bring about deactivation, and no over-all accelerating effect would result. In our view the simplest explanation of the facts is that the excitation energy of O_2^* is largely electronic in nature. If this is the case the quenching to lower electronic states will occur only with difficulty, and hardly at all with the inert gases (20). In order for the ozone-producing reaction II to occur readily the O_2^* must have at least 94 kcal. of energy. If this O_2^* is in the $^3\Sigma_u^+$ state, even if it is in its ground vibrational level it still has more than this amount of energy. In the case of the three lower known electronic states, however, quenching by the foreign gases to the ground vibrational state would produce a molecule having insufficient energy to produce ozone. The facts are therefore completely explained if the $^3\Sigma_u^+$ state is formed, but not if any of the lower states are formed.

We may now consider whether these ideas are also consistent with the facts regarding the unsensitized formation of ozone by 1849 Å radiation, the mechanism for which is given above. To explain the retardation by foreign gases it must be supposed that their effect on reaction VIII is more important than on VII. This is probably due to the relative rates of the reactions; reaction VIII presumably has no activation energy, while Dainton and Kimberley (2) by an indirect method have concluded that VII has an activation energy of 4.3 kcal. Furthermore, in the thermal decomposition of ozone, which probably occurs by the mechanism

[11] $$O_3 + M \rightleftarrows O_2 + O + M,$$

[12] $$O + O_3 \rightarrow 2O_2,$$

[13] $$2O + M \rightarrow O_2 + M,$$

Griffith and McKeown (10) found that He, A, N_2, and CO_2 catalyzed the decomposition;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

this indicates that the last reaction is influenced by M more than is VII. Reaction VIII has not been included in the scheme for the sensitized reaction since there will be a much smaller concentration of oxygen atoms than in the unsensitized process; the over-all rate is very much less.

Volman (33) based his conclusion that O_2^* is *not* in the $^3\Sigma_u^+$ state upon the *relative* effects of the foreign gases, and made no mention of the important fact that increasing their concentration increases the rate. It is of interest that the results indicate the order of the effects of the gases to be the same on III as on VIII.

The conclusion of the present subsection is that the O_2^* produced in reaction [1] is in the $^3\Sigma_u^+$ state, and it would be of interest to have direct spectroscopic evidence of this. In the meantime we will now show that the same conclusion is suggested by the theoretical considerations.

Potential-Energy Surfaces

It is instructive to discuss the mechanism of reaction [1] using the method of potential-energy surfaces. Fig. 2 shows a schematic representation of the surfaces, the method

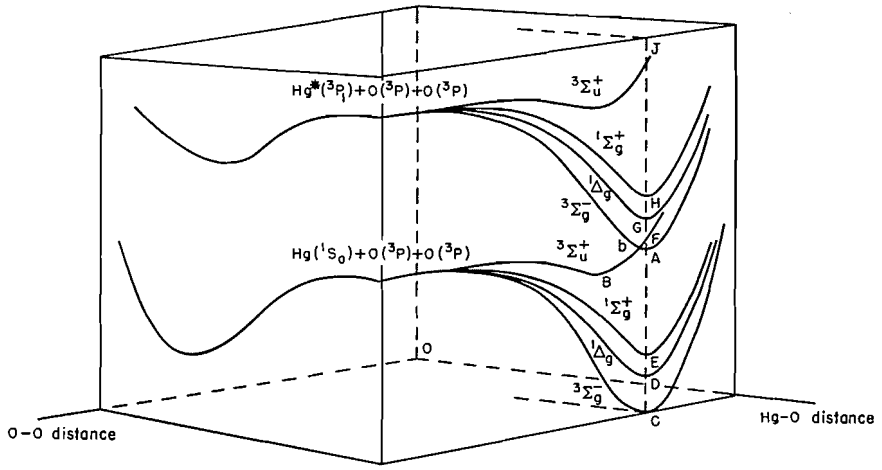

FIG. 2. Potential-energy surfaces for the Hg—O—O system.

employed being that previously used by one of us (20, 21, 22, 23, 24). Point A represents the initial state of the reaction, with $Hg^*(^3P_1)$ and $O_2(^3\Sigma_g^-)$ separated from one another. Points B, C, D, and E represent possible final states, corresponding to Hg ($^1S_0$) together with O_2 in its ground state (point C) or some excited state. Points A, B, C, D, and E are the entrances to valleys that proceed into the cube from the right-hand face.

Consider first the possibility of a transition from A to B, corresponding to the process

$$[14] \qquad Hg^*(^3P_1) + O_2(^3\Sigma_g^-) \rightarrow Hg(^1S_0) + O_2^*(^3\Sigma_u^+).$$

When the potential-energy curves are constructed accurately, using the spectroscopic data, the form of the curves in the region of the points A and B is as shown in Fig. 3. It is to be seen that the crossing point b lies at about the ground vibrational level of the $O_2(^3\Sigma_g^-)$ curve, so that the transition can easily occur even at considerable separations between Hg* and O_2. The potential-energy surfaces therefore confirm our deductions from the experimental results that the O_2 formed will be in the $^3\Sigma_u^+$ state, corresponding to the least transfer of electronic energy into other forms. The fact that the transition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

can occur at large separation is consistent with the very large quenching cross-section observed for the reaction (29, 35).

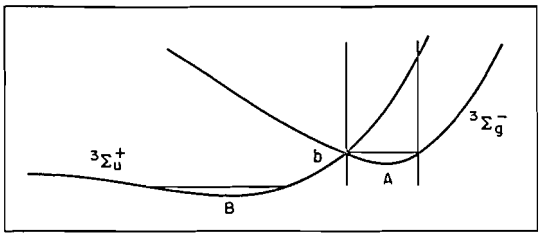

FIG. 3. Enlarged version of a portion of Fig. 2.

If for any reasons the transition to *B* did not occur, the conclusion from the surfaces is that the next most likely possibility is a transition to *E*; failing that, transitions to *D* and *C* could occur. In other words, the system "cascades" through the various electronic states. The evidence for this is as follows. Fig. 4 shows a schematic potential-energy profile through the line *CAJ* in Fig. 2. In this diagram the valley starting at *A*

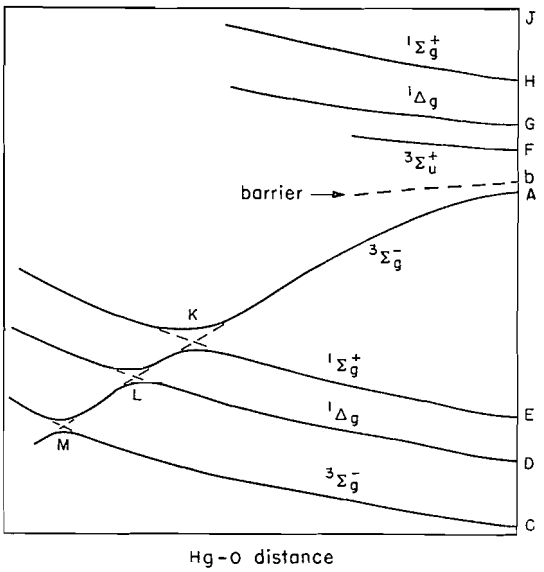

FIG. 4. Potential-energy profile through *CAJ* in Fig. 2. The designations refer to the state of the oxygen molecule.

is represented as going down as the Hg—O distance is decreased; this corresponds to attraction between Hg* and O_2. A number of valleys will start from the points *C*, *D*, *E*, *F*, *G*, and *H*; some of these will correspond to repulsive states and will therefore slope upwards. The dotted line starting at *b* represents the top of the barrier separating the valleys *A* and *B*; this line should not be in the plane of this profile but slightly above it (i.e. corresponding to larger O—O separations).

With regard to the valleys starting at *A*, *C*, *D*, and *E* there is some choice of multiplicities, and it will be assumed that those curves represented in Fig. 4 all correspond to the same multiplicity. The non-crossing rule then provides for resonance splittings, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

shown at K, L, and M. At the point K a system proceeding in the direction AK may undergo a transition and end up at E. Failing such a transition the next possibility is a transition at L, the system ending up at D. Failing that the oxygen will be in the ground state, at C. These latter possibilities, however, are very unlikely. Although the curves shown in Fig. 4 are only schematic it does not seem to be possible, by modifying the form of the curves, to arrive at conclusions other than those reached above.

To summarize, our conclusion from the potential-energy surfaces is that the order of probabilities for the formation of oxygen in reaction [1] is

$$^3\Sigma_u^+ > {}^1\Sigma_g^+ > {}^1\Delta_g > {}^3\Sigma_g^-.$$

The conclusion that the $^3\Sigma_u^+$ state is the most likely confirms our deduction from the experimental evidence based on the effects of foreign gases on ozone production.

THE REACTIONS $O(^3P) + CO(^1\Sigma_u^+) \rightarrow CO_2^*(^3\Pi)$ AND $CO_2^*(^3\Pi) + O_2 \rightarrow CO_2 + O_2^*$

The reactions

[15] $$O(^3P) + CO(^1\Sigma_u^+) \rightarrow CO_2^*(^3\Pi)$$

and

[16] $$CO_2^*(^3\Pi) + O_2 \rightarrow CO_2 + O_2^*$$

are believed to take place in the carbon monoxide flame. Since the mechanisms and other features of the reactions have recently been discussed (9, 23) only a brief discussion will be given here.

The luminosity of the carbon monoxide flame is too great to be attributed to thermal radiation alone, so that the presence of electronically excited species is to be expected. The ground state of CO_2 is $^1\Sigma_g^+$ (26) and the first excited states probably $^3\Pi$ and $^1\Pi$ in that order. Spectroscopic observation of the flame shows no evidence of any excited CO, and it is therefore believed that CO_2 is formed as above. Since CO is a singlet in its ground state, reaction with a normal (triplet) oxygen atom will necessarily produce excited $CO_2^*(^3\Pi)$, whereas CO_2 ($X\ ^1\Sigma_g^+$) can be formed directly only from an atom in a singlet state:

[17] $$O^*(^1D) + CO(^1\Sigma_u^+) \rightarrow CO_2(X\ ^1\Sigma_g^+).$$

The presence of O atoms in the reaction has been confirmed by Gaydon (6, 7). It is found (8, 11) that $O(^3P)$ atoms do not react with CO on every collision, but the reaction between $O(^1D)$ and CO is much more rapid (28).

If the CO_2 formed in [15] were in the ground state, the process would be exothermic by 126.7 kcal., whereas the actual heat liberated is lower than this by the energy of excitation and is probably about zero (7). The spectral continuum of the flame has been attributed (7) to the association reaction

[18] $$CO + O \rightarrow CO_2^* \rightarrow CO_2 + h\nu.$$

At the same time, the banded structure of the spectrum is due to the Schumann–Runge system

[19] $$O_2^*(^3\Sigma_u^-) \rightarrow O_2(^3\Sigma_g^-).$$

Hornbeck (17) observed that with increasing O_2/CO ratio, the intensity of the continuum decreased while that of the banded structure increased. This would be explained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

by the fact that an increase in O_2 pressure will increase the amount of O_2^* formed in [16] and consequently the intensity of the Schumann–Runge bands. But also the CO_2^* ($^3\Pi$) is brought to the ground state by this radiationless transition and less will be at hand to give the continuum reaction [18] (23, p. 72).

The possibility of physical quenching in [16], with the oxygen remaining in its ground state, is not forbidden by the correlation rules, but consideration of the disposition of the potential-energy surfaces involved (9) shows that it is very unlikely since the $^3\Sigma$ surface lies much below the others with no apparent connection between them.

Two excited electronic states of oxygen have been detected in the flame; one is the $^3\Sigma_u^-$ state which, by passing to the lowest state, gives the Schumann–Runge bands. This state can be formed via triplet complexes, and if ionic surfaces are involved, the process would be (Ref. 23, p. 101):

[20] $$CO_2^*(^3\Pi) + O_2(^3\Sigma_g^-) \rightarrow CO_2O_2(^3\Sigma, {}^3\Pi) \rightarrow CO_2^+O^-O(^3\Sigma, {}^3\Pi) \rightarrow CO_2(^1\Sigma_g^+) + O_2^*(^3\Sigma_u^-).$$

The other state is the $^1\Sigma_g^+$, which can be produced via singlet complexes:

[21] $$CO_2^*(^3\Pi) + O_2(^3\Sigma_g^-) \rightarrow CO_2O_2(^1\Sigma, {}^1\Pi) \rightarrow CO_2^+O^-O(^1\Sigma, {}^1\Pi) \rightarrow CO_2(^1\Sigma_g^+) + O_2^*(^1\Sigma_g^+).$$

THE REACTION $O(^3P) + O^*(^1D) + M \rightarrow O_2^*(^3\Sigma_u^-) + M$

The fact that the Schumann–Runge bands have been observed in the hydrogen (1, 5, 31), carbon monoxide (18), and ammonia (19) flames suggests that there may be a reaction such as

[22] $$O(^3P) + O^*(^1D) + M \rightarrow O_2^*(^3\Sigma_u^-) + M$$

common to all of these flames, by which the $O_2^*(^3\Sigma_u^-)$ is produced (Ref. 23, p. 75). The metastable O^* (^1D) may be produced thermally, from the dissociation of one of the reaction intermediates such as $OH^*(^2\Sigma^+)$, or perhaps, in the case of the CO flame, from

[23] $$CO_2(^1\Sigma^+) \rightarrow CO(^1\Sigma^+) + O^*(^1D).$$

THE REACTIONS $O + O_3 \rightarrow 2O_2^*$ AND $O_2^* + O_3 \rightarrow 2O_2 + O$

The reactions

[24] $$O + O_3 \rightarrow 2O_2^*$$

and

[25] $$O_2^* + O_3 \rightarrow 2O_2 + O$$

are believed to occur in the photochemical decomposition of ozone. The primary process of the scheme must be

[26] $$O_3 + h\nu \rightarrow O_2 + O.$$

From thermal data, ΔH for [26] is 24.1 kcal. corresponding to a wavelength of about 11,800 Å, which would be the infrared limit for a possible dissociation (Ref. 29, p. 144). Shorter wavelengths supply energy for the following reactions:

		ΔH (kcal.)	λ (Å)	
[27]	$O_3 + h\nu \rightarrow O_2(^3\Sigma_g^-) + O(^3P)$	24.1	11,800	I.R.
[28]	$O_3 + h\nu \rightarrow O_2^*(^1\Delta_g) + O(^3P)$	47.1	6,200	
[29]	$O_3 + h\nu \rightarrow O_2^*(^1\Sigma_g^+) + O(^3P)$	62	4,600	Visible
[30]	$O_3 + h\nu \rightarrow O_2(^3\Sigma_g^-) + O^*(^1D)$	70	4,000	
[31]	$O_3 + h\nu \rightarrow O_2^*(^1\Sigma_g^+) + O^*(^1D)$	108	2,600	U.V.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Consequently, it has been suggested (30) that the O atom of [26] is ^3P when absorption takes place in the visible region, and ^1D when in the ultraviolet.

The experimental work of Forbes and Heidt (4, 12) showed a range of values for the quantum yield ϕ and a complex dependence of ϕ on ozone concentration, total pressure, light intensity, etc. Heidt (13) concluded that activated molecules must play a part in the reaction and found it necessary to postulate an energy chain:

[32] $$O_3 + h\nu \longrightarrow O_2^* + O,$$

[33] $$O + O_3 \longrightarrow 2O_2^*,$$

[34] $$O + O_2 + M \longrightarrow O_3 + M,$$

[35] $$O \xrightarrow{\text{walls}} \tfrac{1}{2}O_2,$$

[36] $$O_2^* + O_3 \longrightarrow 2O_2 + O,$$

[37] $$O_2^* + M \longrightarrow O_2 + M.$$

The rather complicated expression for ϕ that results gives the correct dependence of ϕ on light intensity, pressure, and so forth.

Whether or not the O_2 of [32] is electronically excited depends upon the wavelength used, as seen above. ΔH for reaction [33] is $(-92.3+2E_e)$ kcal. where E_e is the excitation energy of each O_2^* in [33]. Consequently, each oxygen molecule could be in the $^1\Sigma_g^+$ state and the reaction still be exothermic. Now ΔH for reaction [36] is $(25.7-E_e)$ kcal. so that in order for it to be exothermic, $E_e \geqslant 25.7$ kcal. or 1.12 ev.; i.e. O_2^* is $^1\Sigma_g^+$ or a vibrationally excited form of a lower state.

Ozone absorbs weakly in the visible and strongly in the ultraviolet region. The electronic term level of the $^1\Sigma_g^+$ state of O_2 is 38 kcal., which, according to Heidt, corresponds roughly to the difference in energy between the long wave limits of the ultraviolet and visible absorption spectra of O_3, 3500 and 6500 Å (Ref. 27, p. 396). If this also corresponds to the energy difference between two electronic levels of O_3, the upper one of which dissociates spontaneously to O_2+O, then reaction [36] may be expected to be very efficient if the O_2^* is $^1\Sigma_g^+$. It is therefore assumed that this is the electronic state involved.

PRIMARY PROCESSES IN REACTIONS INITIATED BY PHOTOEXCITED MERCURY ISOTOPES[1]

HARRY E. GUNNING[2]

ABSTRACT

A study has been made of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in natural mercury vapor, with a number of substrates which form solid mercury compounds in mercury photosensitization. Some data are also given for reactions initiated by $Hg^{198}6(^3P_1)$ atoms. The solid mercury compounds formed were examined for enrichment in the isotope initiating the reaction. Such enrichment would be evidence for the primary formation of the mercury compound.

Three HgO-forming substrates were studied: water vapor, nitrous oxide, and oxygen. The Hg_2Cl_2-forming substrates studied included hydrogen chloride, methyl chloride, methylene chloride, chloroform, carbon tetrachloride, isopropyl chloride, and boron trichloride. One Hg_2Br_2-forming substrate was examined—isopropyl bromide.

Among the HgO-forming substrates only water vapor gave enrichment in Hg^{202} in the HgO product. The Hg^{202} content of the oxide was found to vary from 32 to 35%, depending on reaction conditions, compared to a natural abundance of 29.6%. With water vapor – butadiene mixtures, oxides containing as high as 90% Hg^{202} were obtained. Similar enrichment factors were obtained for $Hg^{198}6(^3P_1)$ reactions.

Hydrogen chloride and the alkyl chlorides yielded calomels containing a maximum of 45% Hg^{202}. Methyl chloride gave similar enrichment factors in Hg^{198} for the $Hg^{198}6(^3P_1)$ reaction. The calomel formed in the boron trichloride reaction showed no enrichment.

Addends such as butadiene and benzene, when added to hydrogen chloride, increased the Hg^{202} enrichment from 45% to 60%.

For those reactions which yield mercury compounds enriched in the initiating mercury isotope, evidence is presented for a single primary process. Failure to obtain pure isotopes is attributed to exchange reactions with adsorbed natural mercury during recovery of the enriched mercury from the product. It is postulated that the addends react with the mercury product and reduce chemisorption of natural mercury on the product.

The significance of these findings in the mechanisms of the reactions studied is discussed.

INTRODUCTION

Mercury-$6(^3P_1)$ photosensitization has been extensively employed as a photochemical technique for the study of free radical reactions in the gas phase. Little, however, is known about the nature of the primary process in such reactions. The situation is complicated by the fact that mercury is polyisotopic, consisting of an even-mass group of isotopes of zero nuclear spin, Hg^{196}, Hg^{198}, Hg^{200}, Hg^{202}, Hg^{204}, together with two odd-mass isotopes, Hg^{199} and Hg^{201}, of nuclear spin 1/2 and 3/2 respectively. These isotopes may differ markedly, one from another, in the efficiency of energy transfer in the collision of the photoexcited isotope with the substrate, and also in the nature of the primary reaction. The problem would clearly be simplified by studying the mechanism of reactions initiated by the $6(^3P_1)$ state of a single mercury isotope. Through a systematic investigation of monoisotopic mercury-photosensitization the importance of nuclear spin and related factors could be assessed.

In many mercury-photosensitized reactions solid compounds of mercury are formed. Thus HgO is a product in the reaction of Hg $6(^3P_1)$ atoms with H_2O, O_2, and N_2O, while Hg_2Cl_2 is formed with alkyl chlorides as substrates, and Hg_2Br_2 with the alkyl bromides. If the solid mercury compound is formed exclusively in the primary process, the product

[1]*Manuscript received August 16, 1957.*
Contribution from the Department of Chemistry, Illinois Institute of Technology, Chicago 16, Illinois
This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.
This work was supported by the U.S. Atomic Energy Commission under Contract AT(11-1)-43.
[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*

should contain only that mercury isotope which has been excited. If the isotope is photo-excited in natural mercury vapor (Hg^N), any enrichment in that isotope in the solid mercury product will be evidence for primary formation of the product.

Experiments in monoisotopic mercury-photosensitization are performed in general by exposing the substrate gas, presaturated with Hg^N, to the resonance radiation from a quartz electrodeless discharge containing a trace of the mercury isotope to be studied. The even-mass isotopes will emit a single hyperfine component at 2537 Å, and this component will be absorbed by the same isotope in the Hg^N vapor in the reaction cell.

Owing to the small separation in the hyperfine components of the 2537 Å line, *ca.* 0.01 Å, the optical conditions for the unique excitation of a single mercury isotope in Hg^N vapor are very critical. Broadening effects in both emission and absorption must be minimized. An experimental and theoretical study of this problem has recently been made by Osborn, McDonald, and Gunning (3). These authors showed that the lamp must be operated at constant temperatures below 30° C., and that the substrate gas pressure in the reaction system must be kept low to reduce pressure-broadening effects in absorption. Under these conditions it was shown that the observed absorption could be calculated on the assumption that the emission line was a Doppler type, of width determined by the lamp wall temperature, modified by self-absorption, and that the absorption line was a pure Doppler line.

In this paper the results of a number of exploratory studies on various substrates will be presented. The majority of the photosensitizations have been carried out with $Hg^{202}6(^3P_1)$ atoms. However, some data are reported for $Hg^{198}6(^3P_1)$ atoms. Among the HgO-forming substrates, H_2O, N_2O, and O_2 have been studied. The results on a number of calomel-forming substrates will be reported. These include HCl, CH_3Cl, CH_2Cl_2, $CHCl_3$, CCl_4, i-C_3H_7Cl, and BCl_3. Data on one Hg_2Br_2-forming substrate, i-C_3H_7Br, will also be given.

EXPERIMENTAL

The details of the lamp assembly have already been described (2). The quartz electrodeless discharge tubes were 6 mm. I.D. and 25 cm. in length. The excitation was maintained by a 2450 Mc. oscillator. In all runs the lamps were maintained at constant temperature, ±0.1° C., by a sheath of thermostated cooling water. The lamp temperatures used varied slightly with various substrates, within the 25–30° C. range. A number of shapes and sizes of quartz cells were employed in the studies. It was shown that cell dimensions did not influence the enrichments obtained. Most of the data on HCl and the alkyl halides were obtained using ribbon-type quartz cells, with windows 0.1 cm. apart. The data on HgO-forming substrates were obtained with quartz spiral reaction cells with the lamp placed concentric with the coils of the cell. The cells were attached to the reaction system with spherical joints.

A conventional flow system was employed with manometers placed at exit and entrance points to measure the pressure drop across the cell. Flow rates were measured with calibrated capillary flow meters. The stream of substrate gas was presaturated with Hg^N by allowing it to pass through an operating, umbrella-type, mercury diffusion pump.

During the irradiation the solid mercury product deposited in and downstream from the radiation zone. At the end of the run, the product was removed by solution in hydrochloric acid. The acid solution was partially neutralized with sodium hydroxide, and the mercury recovered by deposition on gold wire. The isotopic composition of the mercury was determined *in vacuo* by resonance radiation absorbiometry. This method has already been described (2).

The particular experimental procedures employed with each substrate will be described in forthcoming publications.

RESULTS

The Reaction of Water Vapor with $Hg^{202}6(^3P_1)$ *Atoms*

Separate studies on the Lorentz-broadening effect of added substrate gas on the contour of the absorption line indicated that total foreign gas pressures should not exceed 50 mm. (3). All runs were therefore performed below 50 mm. pressure.

A large number of runs was carried out with water vapor alone, and in the presence of nitrogen and helium as carrier gases. The percentage of Hg^{202} found in the oxide product varied from 32 to 35%, compared to the natural abundance of 29.6%.

The addition of butadiene to the water vapor stream was found to have a remarkable effect on the enrichments obtained. Some of the preliminary data have already been published (6). Only the basic findings will be noted here. Thus with the progressive addition of higher mole percentages of butadiene to the water vapor, it was found that the enrichment increased markedly, reaching a maximum value of 90% Hg^{202} with a 4:1 mole ratio of water vapor to butadiene.

The Reaction of Water Vapor with $Hg^{198}6(^3P_1)$ *Atoms*

Several experiments have been done on the irradiation of flowing butadiene – water vapor mixtures, presaturated with Hg^N, with a Hg^{198}-electrodeless discharge. Here the photoexcitation process is complicated (3) by the fact that the 201*b* component in absorption is separated from the 198 component by only 0.0011 Å. The Doppler half-width of the emission line is calculated to be 0.0024 Å. Hence the emission line from the Hg^{198} source should simultaneously excite both Hg^{198} and Hg^{201} atoms. In the absorbiometric method of analysis (2), the Hg^{198} source was operated under the same conditions as in the reaction. Hence the analytical data will yield the total enrichment in $Hg^{198}+Hg^{201}$.

For butadiene – water vapor mixtures over the range of 35–45 mole per cent butadiene, the fractional enrichment in $Hg^{198}+Hg^{201}$ was found to vary from 3.21 to 3.13. If the emission line did not appreciably overlap the 201*b* component, these data would correspond to a change in Hg^{198} concentration from the natural abundance of 10.0% to 31.3–32.1%. By analogy with the Hg^{202} reaction, it is expected that high purity Hg^{198} should be obtainable with lower concentrations of butadiene in the stream, using an Hg^{198} source, operated at 0° C.

The Reaction of $Hg^{202}6(^3P_1)$ *Atoms with Nitrous Oxide and Oxygen*

Both nitrous oxide and oxygen form HgO in mercury photosensitization. Enrichment in Hg^{202} in the oxide product would of course be evidence for formation of HgO in the primary process. A large number of runs have been made with these substrates over the pressure range from 0 to 100 mm. In all cases the HgO formed had the normal abundance of Hg^{202}.

The Reaction of $Hg^{202}6(^3P_1)$ *Atoms with Hydrogen Chloride and the Alkyl Halides*

Hydrogen chloride and the alkyl chlorides were found to form deposits of calomel in mercury photosensitization. X-Ray examination of these deposits showed them to consist of Hg_2Cl_2, together with traces of $HgCl_2$.

The calomel was removed from the reaction vessel by solution in concentrated hydrochloric acid. Repeated tests showed that mercury did not detectably dissolve under these conditions. The acid solution was neutralized with sodium hydroxide, and the mercury

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

was recovered by plating on gold. The isotope analysis was done as with the HgO-forming substrates.

Hydrogen chloride was found to form an enriched calomel, containing a maximum of 45% Hg^{202}. The highest yields were obtained at substrate pressures less than 50 mm., and at high flow rates. The low pressures were necessary to eliminate Lorentz broadening effects. The effects of flow rate will be discussed in a later paper.

Free radical acceptor addends such as butadiene, propylene, and benzene were found to increase markedly the enrichment in Hg^{202}. Benzene and butadiene were found to increase the enrichment to 60% Hg^{202}. Propylene was somewhat less effective, yielding calomels containing a maximum of 52% Hg^{202}.

Of the alkyl chlorides, methyl and isopropyl chlorides were the most thoroughly studied. These compounds behaved similarly to hydrogen chloride in that maximum enrichments of 45% were obtained for the pure substrates. The addition of butadiene was found to be almost ineffective in increasing the enrichment in contrast to the hydrogen chloride reaction.

Among the simple alkyl chlorides, it was found that increasing the length of the alkyl chain did not markedly change the enrichment.

The series CH_3Cl, CH_2Cl_2, $CHCl_3$ and CCl_4 was studied in order to determine the effect of increasing chlorine substitution on the Hg^{202} enrichment. The first three members of the series all gave maximum enrichments in the 43–45% range. In proceeding from CH_3Cl to $CHCl_3$ progressively lower pressures had to be used since the Lorentz broadening cross section of the substrate molecule increased with increasing chlorine substitution. Carbon tetrachloride did not form measurable yields of calomel.

One Hg_2Br_2-forming substrate, isopropyl bromide, was studied in order to determine the influence of the type of halogen on the enrichment. The Hg_2Br_2 was found to be enriched to a maximum of 35% Hg^{202}—a markedly lower value than obtained with the chlorides.

Several experiments were done with boron trichloride as the calomel-forming substrate. While good yields of calomel were obtained, no enrichment was detected.

The Reaction of Methyl Chloride with $Hg^{198}6(^3P_1)$ *Atoms*

In this reaction a maximum enrichment factor of 1.5 was obtained, corresponding to an increase in Hg^{198} concentration from 10.0 to 15.0%. As in the case of the reaction of water vapor with $Hg^{198}6(^3P_1)$ atoms, part of this enrichment could be attributed to Hg^{201}.

The Effect of Product Recovery Techniques on Enrichment

It is well known that mercury vapor tends to adsorb readily on its own solid compounds. In the formation of HgO and Hg_2Cl_2 during monoisotopic photosensitization, it was found that appreciable adsorption of Hg^N occurred on the surface of the solid mercury product. It was therefore possible that exchange reactions could occur during the recovery of the product by solution in hydrochloric acid. The importance of exchange reactions was clearly demonstrated by the following experiment: An HgO, 88% enriched in Hg^{202}, was prepared from the reaction of $Hg^{202}6(^3P_1)$ atoms with a water–butadiene mixture. The HgO was recovered by solution in 1:5 acid by volume. After analysis the mercury was dissolved in dilute nitric acid, the oxide was precipitated with base, and the oxide was then redissolved in 1:5 acid. A tiny globule of natural mercury was added to the solution in hydrochloric acid and let stand for an hour. The mercury metal was removed by filtration, and the mercury in the solution was recovered by plating on gold. Analysis showed that the mercury contained only 42% Hg^{202}. Several similar experi-

ments were performed with enriched mercury samples, and it was concluded that exchange was occurring between dissolved Hg^N and the Hg^{202++} ions present in the acid solution.

The exchange reaction between Hg^N (dissolved) and Hg^{202++} was found to increase in rate at higher acid concentrations. These exchange reactions are now being systematically studied.

DISCUSSION

From the data presented here on the reactions of single isotopes, photoexcited in natural mercury vapor, with hydrogen chloride and some simple alkyl halides, it would appear likely that the primary reaction:

$$Hg^i6(^3P_1) + RX \rightarrow Hg^iX + R \quad [1]$$

occurs to an appreciable extent. The fact that the mercury recovered in the Hg^iX product is not a pure isotope might be attributed to one or more of the following factors:

(*a*) The emission line is sufficiently broad to cause photoexcitation of more than one isotopic species.

(*b*) Two primary processes are operative: the isotopically-specific process [1] above, together with

$$Hg^i6(^3P_1) + RX \rightarrow Hg^i + R + X. \quad [2]$$

The X atoms formed in [2] could form Hg^NX by reaction with the Hg^N always present in the reaction cell.

(*c*) Many secondary exchange reactions could occur which would reduce enrichment in the final product. Thus secondary gas-phase reactions of the type

$$Hg^iX + Hg^N \rightarrow Hg^NX + Hg^i \quad [3]$$

could account for the observed enrichments.

(*d*) Exchange reactions could occur in the recovery of the mercury from the product, owing to the presence of adsorbed Hg^N in the product.

The fact that essentially pure Hg^{202} can be obtained from the water–butadiene reaction would indicate that only Hg^{202} isotopes are being photoexcited. This conclusion is further substantiated by the work of Osborn, McDonald, and Gunning (3), on the shapes of the emission and absorption lines.

Sufficient evidence is not yet available to determine the importance of factors (*b*) and (*c*). However, from the data now known, the fact that pure isotopes are not recovered in the mercury product can be reasonably explained by factor (*d*). Thus in the recovery of mercury from the HgX product, it is necessary to dissolve the product in concentrated hydrochloric acid. It has already been shown that Hg^{i++} ions exchange with dissolved Hg^N in acid solution. The rate of the exchange increased markedly with increased acid concentration. The high enrichments obtained in the water reaction were possible only because of the fact that the HgO can be dissolved in dilute acid. The extent to which the exchange reaction would be important would also depend upon the amount of adsorbed Hg^N on the mercury product. Semiquantitative data have now been obtained in this laboratory which indicate that Hg^N adsorbs much more strongly on Hg_2Cl_2 than it does on HgO.

From the foregoing it can be seen that our findings can be explained on the assumption that (1) there is a single primary process and (2) exchange reactions in product recovery cause reduction in enrichment.

The lower maximum enrichment found for isopropyl bromide, compared to the alkyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

chlorides, may be due to differences in Hg^N adsorption in the product. A more reasonable explanation, however, would be that direct photolysis of the bromide is occurring, with the formation of Hg^NBr from the reaction of Br atoms with the Hg^N present.

The role of butadiene in increasing the enrichment in the hydrogen chloride reaction with photoexcited Hg^{202} and Hg^{198} atoms, an effect much more evident in the water reaction, was at first thought to arise from the suppression of secondary calomel formation. Thus if Cl atoms are formed in the primary process, they would be expected to add rapidly to butadiene, thereby reducing the formation of Hg^NCl. While this possibility has not been eliminated, an alternative explanation is that the butadiene polymer, formed by the interaction of butadiene with R radicals from the primary process, deposits on the calomel product, and protects it from Hg^N adsorption. It has been noted that a thin film of butadiene polymer does indeed form over the calomel (4).

For hydrogen chloride and the alkyl halides studied, our data are consistent with the assumption that reaction [1] is the only primary process operative. The normal mercury-$6(^3P_1)$-photosensitized decomposition of methyl chloride has been studied by Masson and Steacie (1). These authors conclude that reaction [2] is the primary process. It should be emphasized that their conclusions are not in disagreement with ours, since they investigated the reaction at 72–328° C., whereas our work was done at 25–30° C. It would be expected that higher temperatures would favor reaction [2] over reaction [1]. In the reaction of methyl chloride with $Hg^{202}6(^3P_1)$ atoms (5), at 30° C., no hydrogen chloride was detected among the products. This is important evidence that reaction [2] does not occur to an appreciable extent under these conditions.

In the chlorinated methane series, no change of maximum enrichment was observed in methyl chloride through chloroform. In the carbon tetrachloride reaction the quantum yield of calomel formation is apparently very small, since the quantities of calomel obtained were insufficient for analysis, in the same exposure period used for the other chlorinated methanes.

The absence of enrichment in the boron trichloride reaction would indicate that the primary process involves scission into BCl_2+Cl. This reaction is currently under study in this laboratory as a method for synthesizing B_2Cl_4.

Among the three HgO-forming substrates studied—water vapor, nitrous oxide, and oxygen—only water vapor was found to give enrichment. The absence of enrichment in the nitrous oxide reaction would be evidence in favor of the primary cleavage into N_2+O. In the oxygen reaction HgO can be eliminated as a primary product.

A detailed study of the reaction of $Hg^{202}6(^3P_1)$ atoms with water vapor and water vapor–butadiene mixtures will be published shortly (7). The data obtained would favor the primary process:

$$HOH + Hg^{202}6(^3P_1) \rightarrow Hg^{202}OH + H. \qquad [4]$$

The marked effect of added butadiene on the enrichment may be due in part to a suppression of the reaction:

$$Hg^{202}OH + H \rightarrow Hg^{202} + HOH \qquad [5]$$

by virtue of the rapid reaction of H atoms with butadiene. It appears more likely, however, that the butadiene prevents the reduction of HgO by H atoms at the wall. The removal of H atoms should increase the over-all quantum yield of HgO formation, without changing the isotopic composition of the mercury. The butadiene must also serve to eliminate exchange reactions. In this connection it should be noted that HgOH has free radical character. Hence there may be a direct addition reaction between HgOH

For personal use only.

and butadiene. The resulting compound may protect the mercury compound from exchange reactions in product recovery.

CONCLUSIONS

In this paper it has been shown how the technique of monoisotopic photosensitization may be employed to give important information on the primary process in mercury-photosensitized reactions wherein solid mercury compounds are formed as products. Quantum yields are currently being measured for a number of the reactions discussed in this paper. From these data, taken in conjunction with the enrichment values, it should be possible to determine the absolute rate of the primary, isotopically-specific process.

Photosensitization with natural mercury is a complex process owing to the polyisotopic character of natural mercury. The odd-mass isotopes of finite nuclear spin probably differ markedly from the even-mass isotopes in their quenching reactions. Through detailed studies on monoisotopic photosensitization considerable information should be obtained on the factors which determine the nature and rate of primary processes in collisions of the second kind.

ACKNOWLEDGMENTS

The author is deeply indebted to a number of his present and former graduate students whose work is discussed here. He would especially like to thank Dr. C. Cameron McDonald, Dr. Kenton R. Osborn, Mr. Richard Pertel, Mr. John A. Poole, and Mr. John McDowell.

SOME EFFECTS OF INTRAMOLECULAR VIBRATIONAL ENERGY TRANSFER IN COMPLEX FLUORESCENT MOLECULES[1]

B. STEVENS[2]

ABSTRACT

The effects of intramolecular redistribution of vibrational energy on both the fate of an excited complex molecule and the appearance of its electronic spectra are discussed in terms of a three-dimensional energy surface. It is suggested that continuous absorption be used as a criterion for the application of classical methods to intra- and inter-molecular vibrational energy transfer in those cases where fluorescence emission is observed.

INTRODUCTION

The selection rules require that comparatively few vibrations of a polyatomic molecule are excited during an electronic transition (13) and that if the transition is allowed these are totally symmetric (8). Since totally symmetric vibrations lead to the simultaneous rupture of more than one bond if excited sufficiently, it is concluded that normal dissociation into two fragments is brought about by non-totally symmetric vibrations, the ground state energy of which is preserved during the electronic transition (25). If a forbidden transition to the fluorescent state is observed owing to the excitation of a non-totally symmetric vibration as in benzene (26) and naphthalene (24), this vibration is rarely excited sufficiently to cause direct dissociation. Thus the normal photodissociation of polyatomic molecules involves an internal transfer of energy from totally symmetric to non-totally symmetric vibrations.

THE THREE-DIMENSIONAL ENERGY SURFACE

Let us make the generalization that the majority of vibrations of a complex molecule will not be excited during an electronic transition but will be associated with dissociation along one coordinate, whilst the few optically excited vibrations require a much higher energy for a dissociation which produces more than two fragments; these will be referred to as optically inert or dissociative vibrations and optically active vibrations respectively. The energy of the former will be related to the vapor temperature T, whilst that of the latter will be determined by the energy $hc\bar{\nu}$ of the absorbed quantum.

If the vibrations of the excited n-atomic molecule are assumed to be harmonic, its total vibrational energy V is given by

$$\begin{aligned} V &= hc[\bar{\nu}_1(v_1+\tfrac{1}{2})+\bar{\nu}_2(v_2+\tfrac{1}{2})+ \ldots +\bar{\nu}_{3n-6}(v_{3n-6}+\tfrac{1}{2})] \\ &= V_A+V_D, \end{aligned}$$

where v_i and $\bar{\nu}_i$ are the level and frequency of the ith vibration and V_A and V_D are the energy sums of optically active and optically inert vibrations respectively. If we now consider the molecule as a single harmonic oscillator we may write

$$V = k\alpha^2/2 = k(\alpha_A{}^2+\alpha_D{}^2)/2,$$

where k has the dimensions of a force constant and α is a vibrational amplitude with optically active and dissociative components α_A and α_D related to V_A and V_D respectively; these components have the properties

$$V_A, \alpha_A = f(\bar{\nu}); \qquad V_D, \alpha_D = f(T).$$

The energy surface of the excited n-atomic molecule may now be represented as a circular paraboloid of radius α at height V above its minimum, with mutually perpendicular horizontal coordinates α_A and α_D. This is shown in Fig. 1 as a series of isoenergetic con-

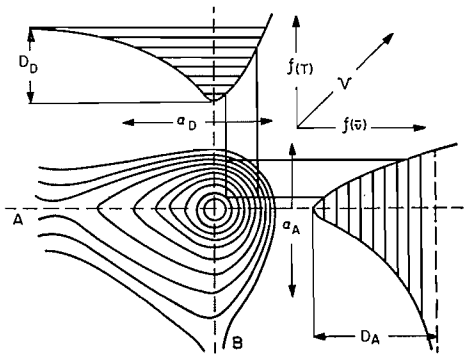

FIG. 1. Three-dimensional energy surface for a complex fluorescent molecule.

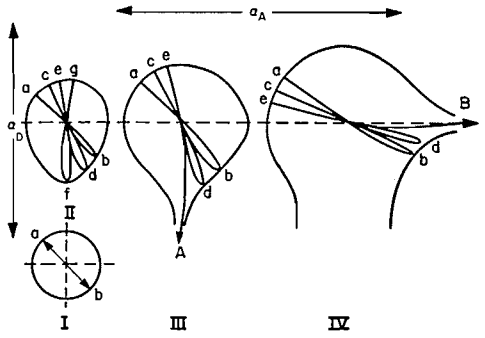

FIG. 2. Isoenergetic contours for four types of vibrational levels recognized in Fig. 1.

tours in which the effects of anharmonic forces are taken into consideration; cross sections showing the variation of surface energy along each coordinate are drawn at the top and to the right of the figure. The effects of anharmonic forces along the α_D coordinate leading to normal dissociation at A when $V \geqslant D_D$ may be expected to be more pronounced than those along the α_A coordinate which requires that $V \geqslant D_A \gg D_D$ for dissociation into several fragments to take place at B.

THE EFFECT OF INTRAMOLECULAR VIBRATIONAL ENERGY TRANSFER ON EMISSION AND PHOTODISSOCIATION

Four types of energy contour recognized in Fig. 1 are shown in Fig. 2. The behavior of the potentially fluorescent molecule in each of the corresponding vibrational levels at pressures so low that collisional perturbation is negligible is discussed below.

(*a*) The lowest vibrational levels produced by the absorption of a frequency $\bar{\nu}$ close to the frequency $\bar{\nu}_0$ of the 0,0 band at the lowest possible vapor temperatures (see Fig. 1) are comparatively free from anharmonic effects and may be represented by contour I of Fig. 2. If we may assume that both vibrational components are in phase at the instant of transition, the vibrational excursion is represented by the line *ababa* . . . and little or no redistribution of energy between the vibrational components takes place during the lifetime τ of the excited molecule. Since $V_A = hc(\bar{\nu}-\bar{\nu}_0) \sim 0$, the characteristic fluorescence spectrum will be emitted.

In benzene the 0,0 band is not observed and higher vibrational levels are produced by the absorption of a frequency greater than $\bar{\nu}_0$. Owing to the high symmetry of this molecule these levels will also have the properties of contour I and the absence of vibrational energy redistribution results in the appearance of the well-known resonance emission (14, 16) originating from the level $V_A = hc(\bar{\nu}-\bar{\nu}_0)$. At higher pressures V_A is collisionally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

reduced to a minimum and the simpler fluorescence spectrum is observed (7); in view of the discussion of contour II below, an increase in either T or $\bar{\nu}$ should produce the same effect. Similar remarks apply to the naphthalene emission spectrum in which progressions from the vibrationally excited upper state are observed at low pressures (24).

(*b*) An increase in either $\bar{\nu}$ or T produces intermediate vibrational levels (Fig. 1) with $V < D_D$ which are represented by contour II of Fig. 2. These are characterized by an increased anharmonicity along the dissociative coordinate α_D, and the initial vibrational excursion may be imagined to precess along *abcde* until it is stabilized along *efgfe* . . . with $V_A \sim 0$ and $V_D = CT + hc(\bar{\nu} - \bar{\nu}_0)$, where C is the molecular heat capacity.[3] If this precession is stabilized within the time interval τ, the virtual independence of the fluorescence spectrum of T and $\bar{\nu}$ at low pressures where $\tau < 1/Z$ is understood (21).

(*c*) Higher vibrational levels with $D_D < V < D_A$ produced by a further increase in T or $\bar{\nu}$ or both have the hypothetical contour III (Fig. 2). Here the precession *abcde* representing the transfer of optically excited vibrational energy allows dissociation at A to compete with fluorescence emission. The probability d of dissociation will depend on the speed of the precession and on the barrier width at A, both of which increase with the over-all energy V. Since $V = f(\alpha_A, \alpha_D)$, the equivalence of thermal and optical contributions to d is evident (19, 20).

(*d*) Contour IV of Fig. 2 corresponds to the highest vibrational levels of the excited molecule with $V > D_A$. Two dissociative possibilities exist and the path followed may be expected to depend on the relative magnitudes of the optically and thermally excited vibrational components. The production of more than two fragments at B requires that $hc(\bar{\nu} - \bar{\nu}_0)$ be greater than CT for the precession to follow the direction *abcde* as shown, and in this respect it is interesting to note the production of C_2H_2 when benzene vapor is photolyzed by the Al spark (1855–2000 Å) (32), whereas at longer wavelengths the principal non-condensible product is H_2 (17, 23). A thermally induced dissociation into three or more fragments would not be expected owing to the much larger probability of normal dissociation at A as the molecule is collisionally activated in its ground state; the absorption of a sufficiently energetic quantum produces this type of level directly and allows both modes of disruption to compete. The variation of the primary photodissociation process with the frequency of absorbed radiation has been previously recognized (18); it appears from this discussion that the controlling factor is the relative magnitude of $V_A(\bar{\nu})$ and $V_D(T)$ rather than $\bar{\nu}$ alone.

THE EFFECT OF INTRAMOLECULAR VIBRATIONAL ENERGY TRANSFER ON THE APPEARANCE OF ELECTRONIC SPECTRA

Beyond a certain frequency limit the discrete absorption spectrum of a diatomic molecule becomes diffuse owing to the onset of predissociation. The lifetime of the excited molecule is reduced by a transition to a dissociated state with the result that the corresponding line width b given by

$$b = h/2\pi\tau$$

is increased. b approaches the separation of vibrational levels as τ is reduced to the order of a vibrational period and the spectrum becomes continuous at shorter wavelengths.

The absorption spectra of polyatomic gases exhibit similar characteristics ranging from sharp bands at long wavelengths, through a diffuse region, to a continuum in the

[3]*It is not suggested that the energy is transferred to the inactive vibrations because these are anharmonic; the anharmonicity allows the internal redistribution of the energy* $hc(\bar{\nu} - \bar{\nu}_0)$ *amongst all vibrations, of which those referred to as inactive are by far the more numerous.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

direction of higher frequencies (12, 29, 30); the structure at longer wavelengths fades into a continuous background as the temperature is increased (2, 10, 11) and shows a tendency to disappear completely as the molecule becomes more complex. It has been suggested that continuous absorption is due to predissociation in this case also (1, 27), but whilst this is probably true for simpler molecules which cannot be excited to fluorescence in this region, the following arguments suggest that this is not a unique interpretation in the case of more complex systems.

(*a*) As the complexity of a conjugated molecule increases, its absorption spectrum shifts towards the red (5). Since an energy corresponding to approximately 4000 Å is required to break the weaker bonds, absorption in the visible region should be discrete if dissociation alone is responsible for continuous absorption. The structureless bands of organic dyes do not support this criterion.

(*b*) To produce the necessary line broadening τ must be reduced to the order of a few vibrational periods in which case fluorescence emission would no longer be observed. A number of organic vapors can be excited to fluorescence by absorption in the continuous region (19, 29), which in several cases extends over the whole range; it is found moreover that the rate of dissociation is sufficiently slow to compete with emission when the wavelength of absorbed radiation varies by several hundred Å (18, 19).

(*c*) Fluorescence spectra in general exhibit less structure than the corresponding absorption spectra. Since the energy range of the observed emission rarely exceeds 20 kcal., dissociation of the ground state following emission is extremely unlikely (16).

It has been pointed out that the spacing of vibrational levels in polyatomic molecules decreases very rapidly with increasing vibrational energy (15); furthermore, as an increase in molecular complexity usually lowers molecular symmetry, a larger number of vibrations are electronically excited, which, together with a closer spacing of rotational levels due to larger moments of inertia, may well account for the appearance of continuous spectra in these cases (16). The remainder of this discussion will be concerned with the additional hypothesis that the diffuse and continuous spectra of complex molecules are due in part to line broadening.

To produce an appreciable effect, the broadening of vibration–rotational lines must be due to a process taking place within a few vibrational periods following the absorption act, yet allowing fluorescence emission to take place after an interval of approximately 10^{-8} second. This process must be intramolecular since continuous spectra are observed at low pressures (7, 30), and to account for continuous emission it must also take place in the ground state. If we consider that the line width b is determined by the lifetime θ of the individual vibronic states rather than by the lifetime τ of the electronically excited molecule, then such a process could be the internal redistribution of vibrational energy (22). If θ is of the order of 10 vibrational periods, b is approximately 5 cm.$^{-1}$, which, in view of the already close spacing of the numerous vibration–rotational lines, is sufficient to produce a continuous aspect.

A complex molecule has been defined as one in which the probability W of internal energy transfer exceeds $1/\tau$ (22). Since $\theta = 1/W$ and W increases both with molecular complexity and total vibrational energy V, θ has the range of values

$$\tau \geqslant \theta(T, \bar{v}) \geqslant 10^{-13} \text{ second.}$$

Thus we may expect discrete absorption only if this produces vibrational levels with the properties of contour I (Fig. 2), i.e. for simpler molecules at low vapor temperatures in the long-wave region. At shorter wavelengths, higher temperatures, or for more complex

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

molecules with larger heat capacities, absorption produces vibrational levels with the contour II, the lifetime θ of the initially formed vibronic state is reduced by internal energy redistribution, and the structure fades into a continuous background. This is the behavior observed.

The continuous nature of emission spectra is similarly explained if the surface in Fig. 1 is used to represent the molecular ground state. The energies of the vibrational components following emission are given by

$$V_A = hc(\bar{\nu}_0 - \bar{\nu}^*),$$

$$V_D = hc(\bar{\nu} - \bar{\nu}_0) + CT,$$

where $\bar{\nu}^*$ is the frequency of emitted radiation. The dependence of V_D on the frequency $\bar{\nu}$ of absorbed radiation arises from the transfer of the optically excited vibrational energy to this component prior to emission. Discrete fluorescence spectra will be observed only if the lowest vibrational levels of the ground state represented by contour I are produced. This requires that both V_A and V_D be small, as is the case at low temperatures for simple molecules with lower heat capacities when both the absorbed and emitted radiations have frequencies close to $\bar{\nu}_0$. These are the conditions under which the discrete emission spectra of benzene (14, 16), toluene (3), benzonitrile (3), fluorobenzene (4), aniline (30), naphthalene (24, 31), and anthracene (28) are observed. Since $\bar{\nu}$ is usually greater than $\bar{\nu}_0$, V_D is larger in the ground state following emission than in the upper state following absorption, with the result that fluorescence spectra are often less discrete than the corresponding absorption.

Thus diffuseness in the electronic spectra of polyatomic fluorescent molecules and of diatomic molecules may be considered as having a common origin if it is accepted that the lifetime of the vibronic states determines the width of vibration–rotational lines. In the former case intramolecular vibrational energy transfer reduces the lifetime of the initially formed vibronic state by changing the energies of the optically active and inactive components, but need not necessarily lead to dissociation. The internal energy transfer requires that a number of isoenergetic vibrational combinations be available for each vibrational level, in which case the levels themselves will be sufficiently closely spaced to account for the observed continuum. The criterion of continuity is largely one of resolution and its appearance may be due to both factors discussed, in which case there is some justification for the following conclusions:

(*a*) Where absorption in the continuous region excites fluorescence, the internal redistribution of vibrational energy is sufficiently rapid for thermal equilibrium to be established between the numerous oscillators within the interval τ (9), and the concept of vibrational temperature (6) is valid.

(*b*) The spacing of vibrational levels in a molecule excited by absorption in its continuous region is sufficiently close for the collisional removal of vibrational energy to be treated as a process of accommodation (6, 20).

(*c*) This classical treatment of vibrational energies cannot be applied to polyatomic molecules excited by absorption in the discrete region.

STUDIES OF CHEMICAL REACTIONS OF EXCITED SPECIES USING INTENSE LIGHT SOURCES[1]

R. A. MARCUS

ABSTRACT

The use of measurements of the products of flash photolysis as a means for studying the reactions of electronically-excited molecules is discussed. With intense light sources the problem of isolating these reactions from others involving free radicals is simplified. The flash sources also have their limitations, and misleading information which can result from the presence of inert gases is noted. A diagnostic test is proposed for detecting the effects (if any) of a possible adiabatic temperature rise of the flash.

Some recent studies in the author's laboratory are summarized. Evidence is presented that in the flash photolysis of acetone acetyl radicals arise from an excited molecule. Several deactivation processes are described and compared with results from fluorescence studies.

INTRODUCTION

The study of the chemical products of photochemical systems using low light intensities has yielded a considerable body of knowledge about the reactions of free radicals and some information about the behavior of electronically-excited molecules (13, 18). The short-lived species are produced in these systems in a well-defined way at a definite temperature. At the usual wavelengths employed there is no formation of ions which result from many other sources of radiation, nor are there the high temperatures which accompany the use of shock waves for producing these intermediates. Various methods of production and observation of unstable chemical species have been the subject of a recent symposium (19) and survey (10).

A number of detailed investigations have served to point up some of the information which can be derived about the electronically-excited molecules by these low light intensity techniques and at the same time have revealed their limitations. The experimental results show that the problem of distinguishing between the reactions of excited states and reactions involving free radicals is frequently a matter of some difficulty. Several such examples will be discussed.

In the method of flash photolysis, an intense light source is used, such as a flash lamp (11, 12), a spark (7), or an exploding wire (14). In these systems the concentration of the free radicals is so high that radical–radical reactions are usually favored over all others unless the radical is "hot". The reaction products thus become a more direct measure of the primary photochemical steps and of the reactions of the resulting electronically-excited molecules. However, since low intensity light sources have certain compensating features, the two techniques provide complementary rather than alternative approaches for the investigation of the reactions of excited states.

The study of unstable species and their reactions, by spectroscopic observations of the flashed system, has been reviewed recently (12). We shall be principally concerned here, instead, with flash studies based on a determination of reaction products.

EXAMPLES OF LOW LIGHT INTENSITY STUDIES—THEIR FINDINGS AND LIMITATIONS

In the photolysis of acetone, Noyes and his collaborators have shown that traces of oxygen (*ca.* 0.02 mm.) can quench the fluorescence of a long-lived electronically-excited acetone molecule (3) and can inhibit ethane formation at low light intensities (8, 9). A considerable amount of information was obtained about the latter process, but it is difficult to separate the reactions of oxygen with the excited molecules from those with the methyl radicals. However, from the rate constant estimated in the above study it can be computed that 10 mm. of oxygen will not react with methyl radicals under the usual flash photolysis conditions, thereby permitting the reaction with excited molecules to be studied in the absence of competing free radical processes.

Another important reaction of excited states is unimolecular dissociation. Some evidence described later suggests that acetyl radicals, but not carbon monoxide, may arise from the unimolecular dissociation of an excited acetone molecule which can be quenched by acetone at moderate pressures. This unimolecular reaction undoubtedly has some temperature coefficient, but its amount has not been definitely established. Complicating features occur, such as an increasing dissociation of acetyl radicals themselves with increasing temperature. The study of this system with intense light sources will serve to eliminate the latter reaction and permit an assessment of the temperature dependence of the former. Recently, flash experiments have provided some information on this process (17).

The photolysis of perfluoroacetone has been recently shown to result in the formation of carbon monoxide from an excited perfluoroacetone molecule (2). The unimolecular reaction rate constant was studied as a function of temperature. Since no perfluoroacetyl compound could be detected, it was not certain whether the dissociation first resulted in a short-lived perfluoroacetyl radical or whether there was a direct split into carbon monoxide. Supplementing this study by one employing flash photolysis could serve either to detect the radical or to place a lower limit on the latter's unimolecular rate constant, of the order of 10^6 sec.$^{-1}$ or so (depending on the light intensity).

SOME LIMITATIONS OF FLASH PHOTOLYSIS

While flash photolysis experiments have much to offer, they also have their limitations, whose importance depends upon the purpose for which they are being used. One problem is that of obtaining sufficiently monochromatic light by filters without reducing the intensity unduly and without having to use an inordinate number of flashes. Again, depending upon the flash time, there may be a more or less appreciable departure from steady-state conditions for the transient species. This situation will complicate the mathematical treatment of certain reaction schemes but not that of others. This problem will be analyzed in detail elsewhere.

Computation of variations in the light absorbed accompanying changes in the experimental conditions can be a difficult problem. It was not one in the present study, however, (except at wavelengths below 2000 Å where the absorption of acetone was not proportional to pressure at the pressures employed). The type of light source used in this study serves to alleviate the difficulty. Calculation of absolute quantum yields is a more formidable problem, partly because of the polychromatic nature of the light.

The reaction temperature may be uncertain because of some increase caused by the flash. Its amount can be reduced by increasing the heat capacity of the gaseous system, i.e. by adding large amounts of inert gas. This procedure, we shall see, has resulted in

misleading information when excited states are present. An alternative way is simply to investigate the effects of reducing the intensity and, thereby the temperature rise, of the flash. At these high light intensities, the quantum yields of products would probably not vary with light intensity if no temperature change occurs. Thus, when no intensity effect is found, this is evidence that either temperature changes do not occur or that if they do, their effect on the reaction products is negligible.

STUDIES IN THE FLASH PHOTOLYSIS OF ACETONE

The flash apparatus used in the present experiments (14) was of a standard type, but the customary flash lamp was replaced by an exploding wire. It proved to be convenient, cheap, and reproducible within several per cent. It was found that the light intensity could be easily varied in a known way merely by changing the distance from this line source, a long thin wire, to the axis of a parallel, cylindrical quartz reaction vessel (14). On the other hand, in any experimentation where an extremely large number of flashes is required, a flash lamp is preferable since it can be automatically flashed many times. In most of the experiments reported below the number of flashes varied between one and three, and the total per cent decomposition was about 0.1%. The flash period was fairly long, about 300 μsec.

Preliminary Studies with Unfiltered Light

In some preliminary experiments (15) using light containing radiation of wavelengths near 1900 Å, ethane, carbon monoxide, and methane were measured. No hydrogen was formed. The ratio of ethane to carbon monoxide was greater than one, averaging about 1.25 and indicating the presence of biacetyl.

Using 400 mm. carbon dioxide, the ethane to carbon monoxide ratio fell to about 0.95. Traces of biacetyl (0.1 to 0.7 mm.) also reduced the ratio to slightly below unity, even though they were present in too small an amount to absorb the radiation. When the 1900 Å light was removed by interposing a cellophane filter, these amounts of biacetyl had no effect at all on the products, showing that the electronically-excited molecule which it quenched arises from light in the 1900 Å region.

In the experiments in this and in the following sections the ratio of methane to carbon monoxide was about 0.1. There is evidence from these studies that this methane is not formed from a disproportionation between methyl and acetyl radicals. For example, the acetyl radicals could be reduced to zero concentration by addition of carbon dioxide, without appreciably affecting the methane to carbon monoxide ratio. Instead, the methane appears to arise either from a primary photochemical act or from the collision of a hot methyl radical with acetone. If the primary photochemical step is indeed the origin of the methane at high light intensities, the photolysis of mixtures of acetone and acetone-d_6 should result in the formation of methane and methane-d_4, but not any other deuterated methanes. Such experiments are in progress.

A methane to carbon monoxide ratio of 0.1 has also been obtained in experiments made with a fairly intense light source (1). These authors detected ketene.

In an earlier flash photolysis study using unfiltered radiation (5), Khan, Norrish, and Porter photolyzed acetone to high conversions and in the presence of 480 mm. carbon dioxide. This gas was added to reduce the temperature rise. Their ratio of methane to carbon monoxide was the same as ours but their ethane to carbon monoxide ratio was about 0.9. This is quite consistent with our subsequent results on the deactivating effects of carbon dioxide and of traces of biacetyl. It also serves to indicate the limitations of using inert gases to reduce the temperature rise when excited states are present.

Studies with Filtered Light

In these experiments (16), a cylindrical cellophane filter was employed. It surrounded the reaction vessel and was protected from the exploding wire by a concentric close-fitting quartz tube. The quantum yields of carbon monoxide and ethane, or more precisely the ratios of each of these products to the acetone pressure, were independent of light intensity when it was varied by a factor of five. The quantum yield of carbon monoxide was constant over a range of acetone pressures varying from 7 to 160 mm. (though there may be a 15% drop at high pressures, ~220 mm.). The yield of ethane decreased markedly with increasing acetone pressure, as in Fig. 1. This curve lies approximately between the curve found by Herr and Noyes at 3130 Å and their curve at 2537 Å

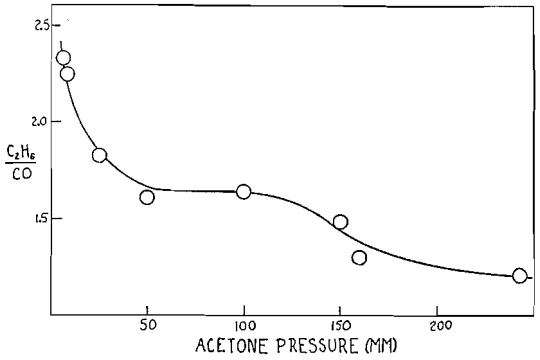

FIG. 1. Plot of ethane to carbon monoxide ratio vs. acetone pressure at room temperature. The point at 100 mm. is the mean of 1.62, 1.65, 1.66.

(4). These authors used low light intensities and worked at constant absorbed intensity to reduce the effects of changing the relative amounts of the secondary free radical reactions as the radical concentration varies. The shape of our curve suggests the presence of two excited acetone states.

Since our yields were independent of the light intensity, either the temperature of the system in these experiments is that of the room or temperature effects can be neglected. We can compare these results, then, with some obtained in fluorescence studies made at a definite temperature.

Acetone has been shown to fluoresce from two excited states, both of which can be quenched by acetone molecules (3). No fluorescence enhancement was reported at any pressure. At 50° C. the quenching occurs appreciably at acetone pressures of about 150 mm. for both states. Studies as detailed as this do not appear to have been reported for 25° C., but the behavior of total fluorescence with pressure is about the same at 25° C. and 50° C. (6). Purely for the present purposes of discussion, it will be assumed that this behavior is also the same for each state at the two temperatures.

From the photolysis studies, in conjunction with those of Herr and Noyes and the foregoing results, it is inferred that the excited state which yields acetyl radicals and is deactivated in the low pressure region of Fig. 1 is probably not responsible for the fluorescence, although the one deactivated in the higher pressure range may be. Carbon monoxide also does not appear to be a product of either fluorescing excited state, unless the fluorescence behavior at 25° C. and 50° C. is rather different.

Studies in Progress

Studies in progress in this laboratory include the effects of added hydrocarbons, of oxygen, and of increased temperature on the lifetime of the excited acetone molecules.

CONCLUSIONS

The determination of the chemical reaction products of flash photolysis is particularly suited for studying the reactions of electronically-excited molecules. It is shown that the addition of inert gases, for purposes of reducing the possible temperature rise of the flash, has led to misleading information. These gases can deactivate excited molecules and so change the reaction scheme. A preferable procedure, it is suggested, is to test for the effects of any temperature rise, and a diagnostic test is proposed.

Results obtained on the flash photolysis of acetone in several studies in this laboratory are described.

CHEMILUMINESCENCE IN THE SYSTEM ATOMIC SODIUM PLUS ATOMIC HYDROGEN[1]

J. D. McKinley, Jr.[2] and J. C. Polanyi[3]

ABSTRACT

When atomic sodium is diffused into a mixture of atomic and molecular hydrogen, a weak chemiluminescence is observed in the gas phase. Visible emission consists of the sodium D lines. The total intensity of the emission, $\sim 5 \times 10^{11}$ photons/second, indicates that only one in 5×10^4 of the sodium atoms entering the reaction vessel is involved in luminescent reaction. In order to account for the rapid fall-off in intensity of the flame away from the nozzle it is necessary to suppose that some non-luminescent reaction is removing sodium atoms in the gas phase. Preliminary experiments suggest that the non-luminescent reaction is $Na + H + H_2 \rightarrow NaH + H_2$, and the luminescent reaction either $Na + Na + H \rightarrow NaH + Na^*$ with collision yield 4×10^{-3} or $Na + H + H \rightarrow H_2 + Na^*$ with collision yield 1×10^{-5}.

This study of chemiluminescence in the gas phase was undertaken to obtain quantitative information concerning the efficiency of energy transfer into an electronic degree of freedom. It is frequently supposed that "energy matching" is important in processes of this type, although there is little direct experimental evidence for this supposition.

The luminescence of sodium vapor in the presence of atomic hydrogen was observed by Bonhoeffer (4), by Mohler (12), and recently by Aynard (1). The technique in every case was to pass dissociated hydrogen from a Wood's tube over hot sodium. Both Bonhoeffer and Mohler found that the luminescence consisted exclusively of the sodium D lines. Aynard, however, found the 3302–3303 Å sodium lines as well and attributed this discrepancy to the fact that earlier workers used wet hydrogen.

In the above investigations it was not possible to distinguish between surface reactions and gas phase reactions. In the present work we have avoided this ambiguity by operating under diffusion flame (13) conditions. The reaction can be confined in this way to the gas phase, and rates can be calculated from the observed diameter of the luminescent flame. This information was supplemented by measurements of emission intensity.

EXPERIMENTAL

The apparatus (Fig. 1) consisted of two separately controlled hydrogen flow systems, one carrying sodium vapor from a saturator, S, into the reaction vessel through a nozzle (0.05 mm. radius), and the other bringing atomic hydrogen from the discharge tube, W, into the reaction vessel.

In each system, cylinder hydrogen flowed through a "Deoxo" catalytic purifier and then through towers of magnesium perchlorate, ascarite, and again magnesium perchlorate. Hydrogen flows were regulated by needle valves and measured with calibrated capillary flow meters.

Prior to an experiment cubes of A.R. sodium, from which the outer layer of oxide had been cut away under benzene, were introduced into the saturator. By moving the sliding furnace, F_1, it was possible to distill the sodium in three stages along the length of the

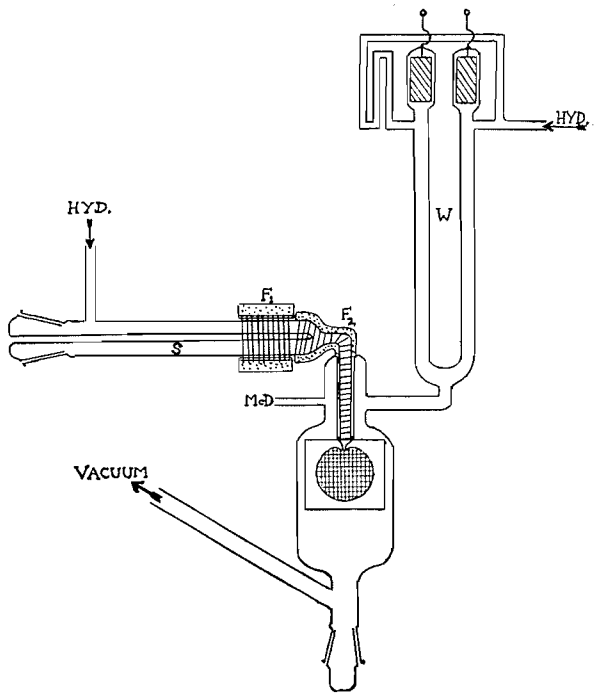

FIG. 1.

saturator. The last distillation resulted in a clean sodium mirror on the walls of the saturator just short of the heating coil F_2. F_2 was continued between the double walls of the central tube of the reaction vessel as far as the internal seal directly above the nozzle. By means of F_2 the central tube and the nozzle were kept at about 350° C. to prevent condensation of sodium.

The pressure of sodium at the nozzle was determined by the temperature of F_1. Since the total pressure in the saturator could be measured on a McLeod gauge (not shown in Fig. 1) the molar flow of sodium into the reaction vessel was calculable using the relationship

$$\text{molar flow of Na} = (\text{vapor pressure of Na in the saturator/total pressure in saturator}) \times \text{molar flow of } H_2 \text{ in saturator.}$$

In order to show that the vapor pressure of sodium in the saturator was the equilibrium pressure corresponding to the temperature of F_1, separate experiments were performed in which a copper gauze cylinder was suspended inside the reaction vessel to catch the sodium issuing from the nozzle in given time at known hydrogen flow rate and known F_1 temperature. The sodium thus collected was washed off the gauze with alcohol, and titrated against standard HCl. The results showed that the hydrogen stream was within 5% of being saturated with sodium. (The copper gauze was found to be necessary since deposition of the sodium on the pyrex vessel resulted in a substantial loss through combination with the glass.)

The hydrogen stream leading to the Wood's tube could be diverted through a water bubbler prior to the flow meter in order to observe the effect of using wet hydrogen.

The current passing through the discharge tube was in the region of 50 ma. at 15,000 volts (0.75 kw.). The percentage decomposition of the hydrogen in the region of the nozzle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

was *ca.* 30%; this was determined in separate experiments by a calorimetric method (9, 14). Typical rates of flow through the saturator and Wood's tube were 3×10^{-5} and 5×10^{-6} moles/second respectively; total pressure in the saturator was *ca.* 6 mm. and total pressure in the Wood's tube and reaction vessel 0.4–0.5 mm.

The region of luminescence could be observed through a plane pyrex window in the reaction vessel.

RESULTS AND DISCUSSION

With pressures of sodium at the nozzle tip from 2.5×10^{-3} to 1.5×10^{-2} mm. (F_1 *ca.* 260°–300° C.), and a rate of inflow of sodium of *ca.* 5×10^{-8} moles/second, an orange-colored luminescent flame was observed centering on the nozzle. The intensity of the emission was such as to be weakly visible in a partially darkened room. The luminescence was weaker at points further from the nozzle, fading into darkness well short of the walls.

After 10 minutes of operation under flame conditions a white deposit began to obscure the window. The deposit was formed in a ring around the reaction vessel along a length corresponding to the flame region. The deposit, a fine powder, could easily be distinguished from the metallic sodium-mirror obtained when the Wood's discharge tube was switched off. This white salt-like deposit is almost certainly sodium hydride.

Concurrently with the appearance of the white deposit a diffuse orange glow was observed at the walls of the reaction vessel. The glow was most intense in its upper region, i.e. at the level of the nozzle, where the deposit of sodium hydride was thickest. This secondary glow obscured the emission from the flame and made photography of the flame impossible. A photograph (*f* 2.5 camera, Eastman Kodak 103aF plates, 25-minute exposure) taken through an interference filter transmitting the sodium D line showed only the secondary luminescence. The flame emission could, however, be weakly detected on the same plate by microdensitometry.

A spectroscopic examination of the luminescence showed only the D line radiation 5890–5896 Å ($3^2P \rightarrow 3^2S$) and the H_α line at 6560 Å (the latter probably originating in scattered light from the Wood's tube). A glass lens focused the luminescence on the slit of a small Hilger constant deviation glass prism wavelength spectrometer, similar to the D-186 (focal length 286 mm., *f* 11) with camera attachment. The dispersion was *ca.* 70 Å/mm. at 5900 Å. Spectrograms were taken on Eastman Kodak I-F plates with 2 hours' exposure. It now seems unlikely that any light entered the spectrometer after the first 30–40 minutes, owing to the formation of the sodium hydride film on the window. The greater part of the light after the first 10 minutes must have come from the secondary emission. With the spectrometer we used we would have been unable to observe the sodium $4^2P \rightarrow 3^2S$ emission at 3302–3303 Å had it been present.

In view of the rapid deposition of NaH and consequent secondary luminescence, observations had to be of a kind that could be completed in the first 5 to 10 minutes after the flame had been started in a clean reaction vessel: namely visual observation and photometric observation.

By visual observation it was found that the size of the flame could be increased either by increasing the pressure of sodium at the nozzle or by decreasing the pressure of atomic hydrogen, which suggests that the luminescent reaction, or its rate-determining reaction, involves these two species.

The fact that the flame falls short of the vessel walls is proof that one of the reagents involved in the luminescence, or its rate-determining reaction, is more plentiful at the nozzle than away from it. This reagent is in all probability sodium.

We have therefore to account for an observed chemiluminescence in the gas phase,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

and consumption of some (or all) of the atomic sodium in the gas phase. Our further observations lead us to believe that these two effects arise from different reactions.

Experiments made with an R.C.A. 5819 photomultiplier tube calibrated against a 200 watt bulb of known color temperature showed that the total hemispherical emission from the flame was *ca.* 5×10^{11} photons/second when the inflow of sodium was 2.4×10^{16} molecules/second. Thus approximately one sodium atom in 5×10^{4} is involved in chemiluminescent reaction.

If the luminescent reaction were to account for the total consumption of sodium, then the ratio of the sodium pressure at the nozzle to that at the edge of the flame (ignoring the gradient due to flow) would be $1/[1-(5\times10^{4})^{-1}] = 1/[1-(2\times10^{-5})]$. In fact (see below) this ratio is *ca.* 1/0.3, from which we conclude that a non-luminescent gas-phase reaction is responsible for the bulk of the sodium consumption.

The true pressure of sodium at the limit of the visible flame can be estimated, since it must be approximately the same as the pressure at the nozzle *when the limit of the flame is at the nozzle*, i.e. when the first trace of flame, right at the nozzle tip, is observed. As already noted, the first luminescence was observed with $F_1 \simeq 260°$ C., i.e. *ca.* 2.5×10^{-3} mm. pressure of sodium at the nozzle. We therefore take this to be the pressure, p_R, of sodium at the edge of the flame.

The flame diameter was found to be 3.8 cm. ($\pm10\%$) in an experiment carried out under the following conditions: H_2 flow through the saturator 3×10^{-5} moles/second, H_2 flow through the Wood's tube 5×10^{-6} moles/second, H flow from Wood's tube 4×10^{-6} moles/second, pressure of H_2 in the saturator 6.5 mm., pressure of sodium in the saturator and at the nozzle 0.0074 mm. (F_1 at 284° C.), pressure of H_2 in Wood's tube and reaction vessel 0.4 mm., pressure of H in reaction vessel 0.04 mm.

No change in flame diameter was observed when the water saturator was switched into the hydrogen stream supplying the Wood's tube. This indicates that the gas-phase chemiluminescence proceeds at the same rate, and presumably by the same mechanism, whether or not water vapor is present. A faster chemiluminescent reaction, for example, would be expected to give a larger flame since it would have an appreciable rate at lower pressures of sodium. (It is not likely that the switch to wet hydrogen would have any instantaneous effect on the H atom concentration in the reaction vessel—time would be needed for water to be adsorbed on the wall.) Some other explanation must therefore be found for the discrepancy between Aynard's results and those of Bonhoeffer and Mohler.

We propose the following reaction scheme:

$$Na + H + H_2 \rightarrow NaH + H_2, \qquad [1]$$

$$Na + Na + H \rightarrow NaH + Na^*, \qquad [2]$$

$$Na + H + H \rightarrow H_2 + Na^*, \qquad [3]$$

in which [1] is the non-luminescent reaction consuming sodium, and either [2] or [3] or both are responsible for the observed luminescence. At a distance r from the nozzle the stationary state requirement is then

$$\delta\, d^2p_{Na}(r)/dr^2 - k_1\, p_{Na}p_H p_{H_2} = 0 \qquad (i)$$

if we ignore the very small amount of sodium that may be consumed by reaction [2]. $p_{Na}(r)$ is the sodium pressure within the interval dr; δ is the diffusion constant of atomic sodium in hydrogen (3.14 cm.^{2}/second (8)). This is a termolecular analogue to the well-known diffusion flame equation (Reference 4). Integration gives

$$k_1 = \delta(\ln p_R/p_0)^2/[p_H\, p_{H_2}(R-r_0)^2], \qquad (ii)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

where p_R is the pressure of sodium at the edge of the flame, p_0 is the pressure of sodium at the nozzle, R is the radius of the flame, and r_0 is the radius of the nozzle. Inserting the values listed above gives $k_1 = 1.5\times10^{16}$ cc.^{2} moles^{-2} seconds^{-1}.

This rate constant is only significant as an order of magnitude for k_1, in view of the approximate manner in which p_R was estimated. However, $k_1 \backsim 1\times10^{16}$ cc.^{2} moles^{-2} seconds^{-1} is in good agreement with rate constants obtained for other atomic combination reactions. Farkas and Sachsse (7) obtained $k = 3.4\times10^{16}$ cc.^{2} moles^{-2} seconds^{-1} for H + H + H_2, in quite good agreement with an earlier value of $k = 9\pm2\times10^{15}$ cc.^{2} moles^{-2} seconds^{-1} for the same reaction, due to Steiner and Wicke (17). In addition various workers (5, 6, 15, 16) have obtained (with accuracies to $\pm5\%$) $k \simeq 1\times10^{16}$ cc.^{2} moles^{-2} seconds^{-1} for I + I + M, depending on the nature of M, which is some inert gas; and for Br + Br + A, $k = 2.5\times10^{15}$ cc.^{2} moles^{-2} seconds^{-1} (18).

As an alternative to reaction [1] we have considered the bimolecular reaction

$$Na_2 + H \rightarrow NaH + Na, \qquad [4]$$

$\Delta H = -31$ kcal./mole so that the reaction would be non-luminescent ($3^2P \rightarrow 3^2S$ for sodium requires 48 kcal./mole). However, in order for this reaction to affect the concentration of *atomic* sodium appreciably, it would be necessary for molecular sodium to be replenished by a termolecular reaction, most probably (since H_2 is the most abundant "third body")

$$Na + Na + H_2 \rightarrow Na_2 + H_2. \qquad [5]$$

The minimum rate constant for [5] can be obtained by setting up a stationary state equation in which [5] determines the rate of consumption of sodium. Integration gives $k_5 \geqslant 3\times10^{17}$ cc.^{2} moles^{-2} seconds^{-1}, which is improbably high and would seem to rule out this possibility.

Another possible reaction involving sodium consumption,

$$Na + H_2 \rightarrow NaH + H, \qquad [6]$$

is endothermic and must be very slow since hydrogen is used as an "inert" carrier gas in sodium flame experiments (2, 13, 19).

We therefore consider that on the present evidence reaction [1] is the most likely non-luminescent reaction responsible for the consumption of sodium.

The luminescent reaction

$$NaH + H \rightarrow H_2 + Na^* \qquad [7]$$

is energetically possible ($\Delta H \simeq -56$ kcal./mole) and may be the explanation of the secondary luminescence at the wall. However, there are two reasons for supposing that it is not of major importance in the gas phase (possibly owing to appreciable activation energy). In cases where luminescence arises from reaction among the products formed in a diffusion flame one would not expect to observe, as we did under all flow conditions, the maximum emission at the tip of, or in, the nozzle. Observations on other low-pressure diffusion flames indicate that it is the initial reaction that occurs in this region. If reaction [7] nonetheless accounts for the luminescence, it must be extremely fast, in which case [1] will be the rate-determining reaction for luminescence. Evidence against this comes from our experiments with a photomultiplier tube. We attempted to vary separately the pressure of atomic sodium, atomic hydrogen, and molecular hydrogen. The luminescent intensity was found to be strongly dependent on the first two variables and only weakly on the third. This would not be the case if reaction [1] was determining the rate of luminescent reaction. We conclude that reaction [7] is not the principal luminescent reaction.

For personal use only.

Calculation of the total number of collisions Na + Na + H in the flame and Na + H + H in the flame leads to values of the collision yields for the two luminescent reactions, [2] and [3], in the case that either [2] or [3] predominates. Recent experimental evidence (5) indicates that Bodenstein's method (3) of calculating rates of termolecular collision is as good as any at present available. Accordingly we write

$$\frac{\text{rate of bimolecular collision}}{\text{rate of termolecular collision}} = \frac{\text{mean free path}}{\text{mean molecular diameter}}. \qquad \text{(iii)}$$

The total number of bimolecular collisions Na + H in the flame per second is

$$Z^{\text{Tot.}}_{\text{Na,H}} = Z_{\text{Na,H}}\, p_{\text{H}}\, 4\pi\, N_0 \int_{r_0}^{R} p_{\text{Na}}(r).r^2.dr, \qquad \text{(iv)}$$

where $Z_{\text{Na,H}}$ is the rate of collision at a concentration of 1 mole/cc. So that the total numbers of termolecular collisions are

$$Z^{\text{Tot.}}_{\text{Na,Na,H}} = \frac{Z_{\text{Na,H}}\, Z_{\text{Na,NaH}}\, p_{\text{H}}\, 4\pi\, \sigma_{\text{Na,NaH}}\, N_0}{\bar{c}_{\text{Na}}} \int_{r_0}^{R} (p_{\text{Na}}(r))^2.r^2.dr \qquad \text{(v)}$$

$$= 1.3\times10^{14}\ \text{seconds}^{-1},$$

$$Z^{\text{Tot.}}_{\text{Na,H,H.}} = \frac{Z_{\text{Na,H}}\, Z_{\text{H,NaH}}\, p_{\text{H}}{}^2\, 4\pi\, \sigma_{\text{H,NaH}}\, N_0}{\bar{c}_{\text{H}}} \int_{r_0}^{R} p_{\text{Na}}(r).r^2.dr \qquad \text{(vi)}$$

$$= 4.5\times10^{16}\ \text{seconds}^{-1}.$$

Since the total luminescence is $\backsim 5\times10^{11}$ photons/second, the luminescent collision yield in the case that reaction [2] predominates is $5\times10^{11}/1.3\times10^{14} \simeq 4\times10^{-3}$, and in the case that reaction [3] predominates $5\times10^{11}/4.5\times10^{16} \simeq 1\times10^{-5}$. If both reactions [2] and [3] contribute appreciably to the luminescence these figures are still substantially correct, and in *any* case they represent upper limits for the luminescent collision yields of these reactions.

Table I shows the extent of "energy matching" for the two luminescent reactions under discussion (cf. Kaplan (10) and Aynard (1)).

TABLE I

No.	Reaction	$-\Delta H$, kcal./mole
[2]	$Na + Na + H \rightarrow NaH(v = 0, J = 0) + Na^* 3^2P$	0±1.5*
[3] *a.*	$Na + H + H \rightarrow H_2(v = 0, J = 0) + Na^* 3^2P$	54.5
b.	$Na + H + H \rightarrow H_2(v = 1, J = 0) + Na^{**} 4^2P$	5.2
c.	$Na + H + H \rightarrow H_2(v = 1, J = 5) + Na^{**} 4^2P$	0.2
d.	$Na + H + H \rightarrow H_2(v = 5, J = 0) + Na^* 3^2P$	1.9
e.	$Na + H + H \rightarrow H_2(v = 5, J = 3) + Na^* 3^2P$	0.2

**A. G. Gaydon (Dissociation energies, Dover Publications, 1950) gives D(Na—H) ≈ 47 kcal. G. Herzberg (Spectra of diatomic molecules, D. Van Nostrand, 1950) gives D(Na—H) ≈ 50.5 kcal.; spectroscopic constants for H_2 were taken from Herzberg.*

If one considers all the quantized degrees of freedom of the products to be simultaneously equally available, then a case can always be made for perfect energy matching —certainly to the accuracy to which the energy terms are known. Some additional criterion is therefore required, the simplest being to suppose that the greater the number of degrees of freedom among which the energy must be distributed the less likely is the process. On this basis reaction [2] is favored as against reaction [3].

Magee and Ri (11), in a theoretical study of reaction [3] according to the semiempirical method, calculate a potential energy surface across which [3] proceeds adiabatically (activation energy $E = 6.5$ kcal./mole) in competition with the non-luminescent reaction [8] on a lower surface ($E = 0$ kcal.),

$$Na + H + H \rightarrow H_2 + Na^*, \quad E = 6.5 \text{ kcal./mole}; \qquad [3]$$

$$Na + H + H \rightarrow H_2 + Na, \quad E = 0 \text{ kcal./mole}. \qquad [8]$$

Making reasonable assumptions about the magnitudes of the transmission coefficients ($\kappa_3/\kappa_8 = 1/0.1$) they calculate that at 200° C. 15 sodium atoms are excited electronically for 1000 which gain only thermal energy. Since $\kappa_8 = 0.1$, this leads to a collision yield of 1.5×10^{-3} at 200° C., or 3×10^{-5} at room temperature, for luminescence due to reaction [3], in good agreement with our figure of *ca.* 1×10^{-5}. It is not possible to say how far this agreement is real until the kinetics of the luminescence have been properly elucidated, preferably over a range of temperatures.

ACKNOWLEDGMENTS

We are indebted to Mr. C. Sadowski of the University of Toronto for assistance with the calculations. We should also like to thank Professor A. G. Shenstone of the Physics Department, Princeton University, for the loan of a spectrograph.

THE QUENCHING OF THE IODINE FLUORESCENCE SPECTRUM[1]

C. ARNOT AND C. A. MCDOWELL

ABSTRACT

The quenching of the iodine fluorescence spectrum by various inert gases and oxygen has been studied with a view to obtaining information on the efficiencies of vibration energy transfer processes in this system. Preliminary results here presented are in agreement with earlier work of Rössler and Eliaschevich and indicate that the transfer processes are very efficient. A kinetic scheme is proposed to account for the various possible quenching and transfer processes and it is shown that this is in agreement with experimental results.

INTRODUCTION

The fluorescence spectrum of iodine vapor excited by the green mercury line 5461 Å was first investigated by Wood (6) (see Fig. 1). It consists of a series of bands stretching from 5461 towards the red. The excited state was shown by Mulliken (2) to be a $^3\Pi_{0_u}$ state which is split into levels by Λ doubling; these two levels behave almost like two independent $^1\Sigma$ states and only one of them (designated by Mulliken as $^3 0_u^+$) combines with the ground state.

On excitation with the narrow green line (Hg 5461) the iodine molecules are raised to the 26th vibrational level (6) of this $^3 0_u^+$ state and the fluorescence bands are produced by the transitions back to the ground state $26' \rightarrow 0''$, $26' \rightarrow 1''$, $26' \rightarrow 2''$, $26' \rightarrow 3''$, etc. The resonance spectrum has been extended as far as the 39th member at 9097 Å (6). The bands under these conditions have only a doublet structure (6).

It has been established that the quenching mechanism by foreign gases is by induced predissociation (3); the iodine molecule is induced by the foreign gas to pass into a repulsion potential energy state.

Transfer of the excited iodine molecule from the 26th vibrational level to other vibrational levels occurs with certain foreign gases, and new fluorescence bands originating from these levels are then observed (see Fig. 2). Rössler (4) showed that the vibrational quantum number only changes by 1 or 2 on these transfer collisions and so molecules are only transferred to the 24th, 25th, 27th, and 28th vibrational levels of the excited state. Change of rotational state also occurs in these transfer collisions and the bands lose their doublet structure and are broadened.

Transfer bands have, in general, only been observed with the rare gases, as the quenching action is much stronger with other gases, and the fluorescence intensity is weakened to a much larger extent.

EXPERIMENTAL

Materials

The rare gases were spectroscopically pure samples provided by the British Oxygen Company. The iodine was purified by sublimation.

Apparatus

The light source was a high intensity low pressure mercury arc with water-cooled electrodes, operated at 25 amp., 180 volts, which was made to a design by Stoicheff (5).

This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.

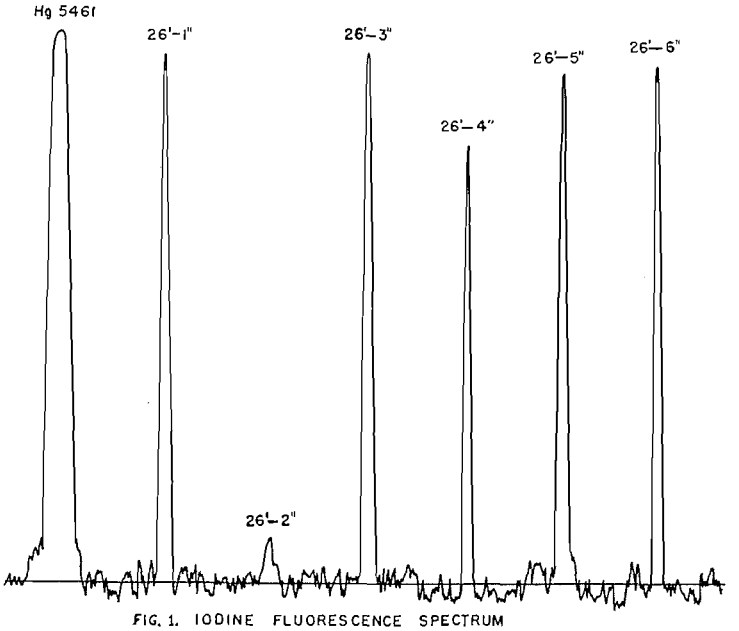

FIG. 1. IODINE FLUORESCENCE SPECTRUM

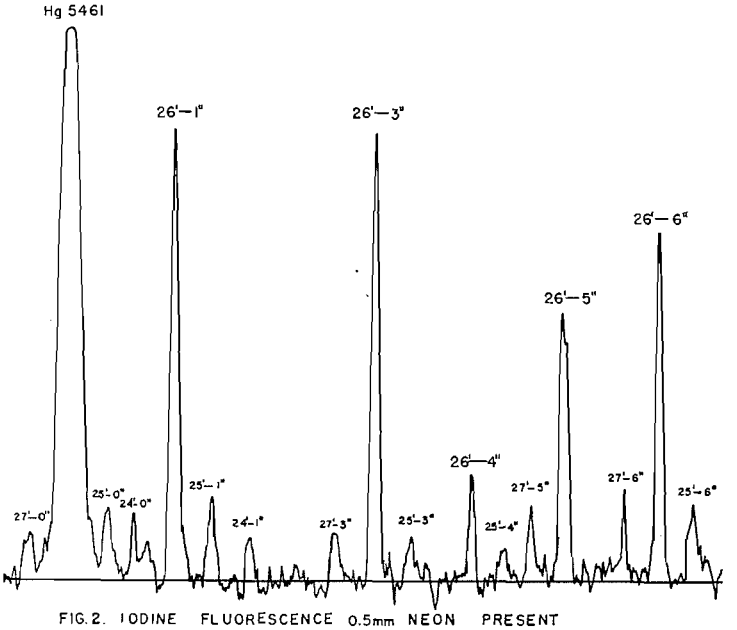

FIG. 2. IODINE FLUORESCENCE 0.5mm NEON PRESENT

FIG. 1. A portion of the fluorescence spectrum of the iodine molecule.
FIG. 2. A portion of the fluorescence spectrum of iodine showing transfer bonds caused by adding 0.5 mm. of neon.

The fluorescence vessel was a glass tube 70 cm. long and 2.5 cm. in diameter with an outer jacket 4.0 cm. in diameter to contain the filter solution. An optical flat at one end of the tube served as a viewing window and the other end of the tube led to a dibutyl phthalate manometer for measuring foreign gas pressure, a gas-introduction apparatus, and vacuum pumps.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

The fluorescence was photographed using a prism spectrograph having a dispersion of 33 Å per mm. The photographic plates were Kodak Scientific Plates type IIaF, which are sensitive to 7000 Å, thus allowing the first 19 bands of the resonance series to be studied. The plates were analyzed using a Hilger microphotometer, the blackening of the plates being recorded on a Leeds and Northrup recorder. The filter solution was a 0.5 *M* $NdCl_3$ solution, which eliminated the yellow mercury lines 5770 and 5790 Å.

The fluorescence tube and arc were mounted side by side and surrounded by a magnesium oxide reflector to cut down exposure times. A set of calibration marks was put on each plate by means of a Hilger calibrated step filter. Under these conditions an exposure time of 2 minutes was satisfactory.

Iodine crystals were contained in a small glass bulb. The system was evacuated with the iodine bulb maintained at a temperature of −80° C. The iodine was then kept at 0° C. while the pumping was continued, and then the system was isolated and the iodine allowed to come to equilibrium with its vapor at 0° C.

Exposures were made of the fluorescence in the absence of foreign gas and at various pressures of foreign gas, the gas being admitted by expansion from a small volume.

For self-quenching data the iodine was allowed to warm up and exposures were made at various iodine pressures, the pressure being measured on a Pirani gauge.

RESULTS AND DISCUSSION

Transfer bands were observed only on the plates with helium, neon, argon, hydrogen, and in some cases oxygen as foreign gas. Of these the intensities of the argon ones were very small and difficult to measure accurately. Even with He or Ne as foreign gas the intensities of the transfer bands were small and could not be accurately measured, as their density of blackening fell in the toe of the calibration curve for the photographic emulsion. With the other foreign gases added (O_2, N_2, Kr, and Xe) the quenching action was stronger.

The data obtained were interpreted in the light of the following kinetic scheme:

M = iodine molecule in ground state
M* = iodine molecule in 26th vibrational level of excited state
M_n^* = iodine molecules in any other level of excited state
X = foreign gas molecules

activation: $$M + h\nu \overset{k_a}{\rightleftharpoons} M^* \quad [1]$$

fluorescence: $$M^* \overset{k_{f_1}}{\rightleftharpoons} M + h\nu \quad [2]$$

$$\overset{k_{f_2}}{\rightleftharpoons} M + h\nu$$

$$\overset{k_{f_3}}{\rightleftharpoons} M + h\nu$$

we shall write $$\sum_n k_{f_n} = k_F$$

self-quenching: $$M^* + M \overset{k_s}{\rightleftharpoons} M + M \quad [3]$$

quenching: $$M^* + X \overset{k_q}{\rightleftharpoons} M + X \quad [4]$$

collisional transfer to some other vibrational level: $$M^* + X \overset{k_{t_1}}{\rightleftharpoons} M_1^* + X \quad [5]$$

$$\overset{k_{t_2}}{\rightleftharpoons} M_2^* + X$$

$$\sum_n k_{t_n} = k_T$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

back-transfer to 26th level:
$$M^*+X \overset{k_t}{\rightleftharpoons} M^*+X \quad [6]$$
$$M^*+X \overset{k_t}{\rightleftharpoons} M^*+X$$

fluorescence from collisionally excited levels:
$$M^* \overset{k_f}{\rightleftharpoons} M+h\nu \quad [7]$$
$$M_2^* \overset{k_f}{\rightleftharpoons} M+h\nu$$

self-quenching:
$$M_n^*+M \overset{k_s}{\rightleftharpoons} M+M \quad [8]$$

quenching:
$$M_n^*+X \overset{k_q}{\rightleftharpoons} M+X \quad [9]$$

Without foreign gas this scheme leads to the following expression for the intensity of the band of the fluorescence spectrum:

$$F_{0_n} = k_{f_n}[M^*].$$

Since $F_0 = \sum_n F_{0_n}$,

we get
$$F_0 = k_F k_a[M]/(k_F+k_s[M]) \quad [10]$$

and
$$F_{0_n} = k_{f_n} k_a[M]/(k_{f_n}+k_s[M]); \quad [11]$$

hence
$$1/F_{0_n} = k_F/k_a k_{f_n}[M]+k_s/k_{f_n}k_a. \quad [12]$$

A plot of $1/F_{0_n}$ against $1/[M]$ yields an intercept/slope ratio equal to k_s/k_F, and so the self-quenching efficiency of iodine can be determined.

With foreign gas present and where no transfer bands are observed, the above kinetic scheme leads to the following expression for the intensity of the nth band of the spectrum:

$$F_n = k_{f_n}[M^*]$$
$$= k_{f_n}k_a[M]/(k_F+k_s[M]+k_q[X]) \quad [13]$$

and
$$F_{0_n}/F_n = k_F+k_s[M]+k_q[X]/(k_F+k_s[M]) \quad [14]$$
$$= 1+(k_q/k_F)[X]/\{1+(k_s/k_F)[M]\}. \quad [15]$$

From a plot of F_{0_n}/F_n against $[X]$, k_q/k_F can be calculated for each of the foreign gases studied.

Where transfer bands are observed, all the processes 1–9 have to be considered and we can deduce an expression for the over-all kinetic scheme in the following way:

Let R_1 be the ratio of the total fluorescence intensities before and after the addition of foreign gas at a concentration X.

Let R_2 be the ratio of intensities of fluorescence originating from the 26th vibrational level before and after the addition of foreign gas at a concentration X.

Let R_3 be the ratio of intensity of fluorescence from levels other than the 26th level when foreign gas at a concentration X is present.

At equilibrium, $d[M^*]/dt = 0$ and $d[M_n^*]/dt = 0$.

Hence
$$k_a[M] = k_F[M^*]+k_s[M^*][M]+k_q[M^*][X]+k_T[M^*][X]-[X]\sum_n k_{t_n'}[M_n^*], \quad [16]$$

also
$$k_T[M^*][X] = [X]\sum_n k_{t_n'}[M_n^*]+k_F\sum_n[M_n^*]+k_s[M]\sum_n[M_n^*], \quad [17]$$

assuming
$$\sum k_{f_m} = \sum k_{f_l} = \sum k_{f_n} = k_F.$$

Processes involving collisional transfer of energy between the 24th, 25th, 27th, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

28th vibrational levels have been disregarded since these only lead to the iodine molecule being in a state in which processes identical to those in its previous state can occur and here we are considering the *summation* of intensities originating from these collisionally excited states.

Assuming that $$k_{t_1'} = k_{t_2'} = k_{t_3'},$$

i.e. assuming $$\sum_n k_{t_n'} = Zk_{t_n'} = k_{T'},$$

it follows, therefore, that $k_{t_n'} = k_{T'}/Z$, where Z is the number of occupied levels, i.e. $k_{t'}$ is independent of the vibrational level for back transfer to the original state;

then $$\sum_n k_{t_n'}[M_n^*] = k_{t_n'}\sum_n[M_n^*] = (k_{T'}/Z)\sum_n[M_n^*],$$

then, from [2], $$R_3 = k_F[M_n^*]/k_F[M^*] = k_T[X]/([X]k_{t_n'}+k_F+k_s[M]+k_q[X]) \quad [18]$$

and also, from [2],

$$\sum_n[M_n^*] = k_T[M^*][X]/([X]k_{t_n'}+k_F+k_s[M]+k_q[X]) = [M^*]R_3. \quad [19]$$

Hence $$[X]k_{t_n'}\sum_n[M_n^*] = k_{t_n'}[X][M^*]R_3 = (k_{T'}/Z)[X][M^*]R_3$$

and, substituting in [1], we get

$$k_a[M] = k_F[M^*]+k_s[M^*][M]+k_q[M^*][X]+k_T[M^*][X]-(k_{T'}/Z)[X][M^*]R_3, \quad [20]$$

and the intensity of fluorescence from the 26th level at the concentration of foreign gas

$$[X] = k_F[M^*] = k_Fk_a[M]/(k_F+k_s[M]+k_q[X]+k_T[X]-(k_{T'}/Z)[X]R_3). \quad [21]$$

Since $$F_0 = k_Fk_a[M]/(k_F+k_s[M]),$$

therefore $$R_2 = \{k_F+k_s[M]+k_q[X]+k_T[X]-(k_{T'}/Z)[X]R_3\}/(k_F+k_s[M]). \quad [22]$$

Assuming the probability of back transfer equals the probability of transfer, i.e. $k_T = k_{T'}$, then the following expression is obtained for R_2:

$$R_2 = \frac{1+(k_s/k_F)[M]+(k_q/k_F)[X]+(k_T/k_F)[X](1-R_3/Z)}{1+(k_s/k_F)[M]}. \quad [23]$$

k_T/k_F can be determined from R_1 in the following manner. If we consider that M* is an iodine molecule in any vibrational level of the excited state, then transfer processes may be neglected as they only lead to an excited molecule which undergoes exactly the same processes as in its previous state, i.e. fluorescence, self-quenching, and quenching. We thus obtain the same equation as previously for quenching processes, i.e.

$$R_1 = F_0/F = 1+(k_q/k_F)[X]/\{1+(k_s/k_F)[M]\}. \quad [24]$$

It follows from equation [24] that a plot of F_0/F against the concentration of quenching gas X should be linear with an intercept of unity on the F_0/F axis. In Figs. 3 and 4

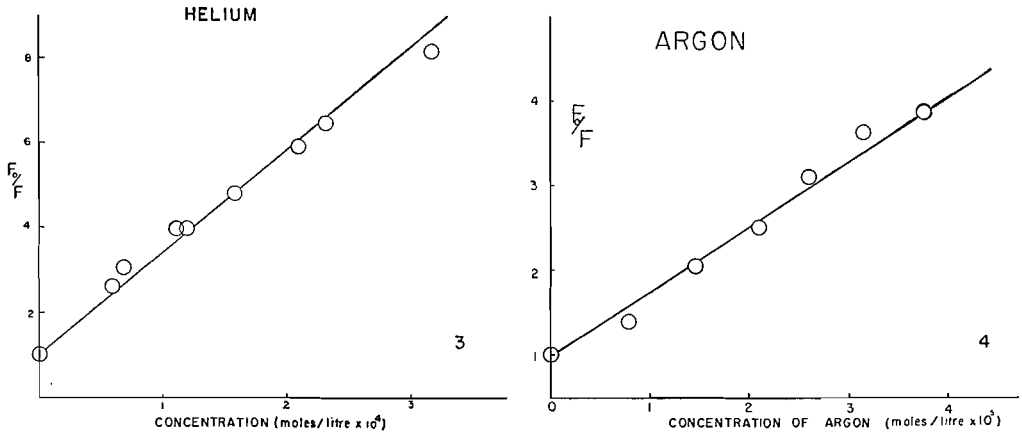

FIG. 3. Plot of F_0/F for the quenching of the fluorescence spectrum of iodine by helium.
FIG. 4. Plot of F_0/F for the quenching of the fluorescence spectrum of iodine by argon.

we show graphs of F_0/F against the concentration of the quenching gas for helium and argon; it will be seen that these are linear and that both intercept the F_0/F axis at unity in agreement with the requirements of equation [24]. It has been found that equation [24] is also obeyed by the gases listed in Table I.

From the slope of the straight line resulting from plotting equation [24] one can calculate the ratio $(k_q/k_F)/\{1+(k_s/k_F)[\mathrm{M}]\}$. Knowing the concentration of the iodine in the experiments and having previously determined k_s/k_F from self-quenching experiments with iodine using self-quenching bands where self-absorption is negligible, one can calculate values for k_q/k_F for each quenching gas studied.

Similarly, by plotting R_2 against the concentration of quenching gas X, one can determine (see equation [23]) the ratio

$$(1-R_3/Z)(k_q/k_F+k_T/k_F)/\{1+(k_s/k_F)[\mathrm{M}]\},$$

and knowing the concentration of iodine in the experiments and having determined R_3 (see definition above), k_q/k_F, and k_s/k_F, one can calculate k_T/k_F, the transfer coefficients, since Z is known, being the number of occupied levels of the excited iodine molecule. The values obtained for the coefficients k_T/k_F for the different gases studied are given in Table I.

TABLE I

COEFFICIENTS FOR THE TRANSFER OF VIBRATIONAL ENERGY IN EXCITED IODINE MOLECULES (T = 20° C.)

Gas	k_T/k_F, liters mole^{-1} experimental	k_T/k_F, liters mole^{-1} theoretical
Helium	5.31×10^4	3.23×10^3
Neon	2.69×10^4	1.66×10^3
Argon	1.64×10^4	1.39×10^3
Oxygen	1.5×10^4	1.37×10^3

The theoretical values quoted for the quenching coefficients in Table I were calculated from the equation

$$k_T/k_F = \frac{p_T N(r_1+r_2)^2}{1000} 8\pi RT\left(\frac{1}{M_1}+\frac{1}{M_2}\right)^{\frac{1}{2}} \qquad [25]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

using the following values for the parameters:

$N = 6.023 \times 10^{23}$ molecules liter^{-1}, $r_{He} = 0.98$ Å,
$r_{I_2} = 2.72$ Å, $r_{Ne} = 1.18$ Å,
$r_A = 1.46$ Å, $r_{O_2} = 0.47$ Å;
M_1 = mass of the iodine molecule;
M_2 = mass of the quenching molecule.

The value taken for the lifetime of the excited $^3\Pi_{0_u}$ state of the iodine molecule was $\tau = 10^{-3}$ second and the theoretical values were computed for a pressure of 1 cm.

The experimental data in Table I, which must only be regarded as preliminary, indicate that the transfer of energy in the system studied must be very efficient. Though our data are in agreement with the results of Rössler (4) and Eliaschevich (1), there is, of course, still to be explained the discrepancy between the experimental and theoretical values. It could be that the value of 10^{-8} second assumed for the lifetime of the excited iodine molecule is too short and it should be of the order of 10^{-7} second. Were this so, then the experimental values would be more nearly in agreement with the theoretical ones, which would now be 10 times larger.

ACKNOWLEDGMENTS

The earlier part of this work was carried out in the Department of Inorganic and Physical Chemistry, University of Liverpool, Liverpool 7, England, and we are grateful to Professor C. E. H. Bawn, C.B.E., F.R.S., for providing laboratory facilities. The remainder of the work and the analysis of the photographic plates was carried out in the Department of Chemistry, University of British Columbia, Vancouver 8, B.C. This latter portion was supported by grants from the National Research Council of Canada whom we should like to thank.

QUENCHING AND VIBRATIONAL-ENERGY TRANSFER OF EXCITED IODINE MOLECULES[1]

J. C. POLANYI[2]

ABSTRACT

Quenching of I_2^* ($^3\Pi_{0u}^+$) ($v' = 26$) is shown to take place to the exclusion of vibrational-energy transfer in iodine at pressures up to 19 mm. A possible quenching mechanism involving sensitized predissociation of the collision partner is described. Vibrational transfer in collisions with H_2 and D_2 is found to occur at less than every gas kinetic collision. Arguments on general grounds are put forward to support this result, which conflicts with that of earlier workers. Increase in the mass of the isotope is found to bring about increased efficiency of vibrational transfer.

INTRODUCTION

Franck and Wood (1) were the first to observe that the resonance spectrum of iodine vapor excited by the mercury green line is transformed into the complete band spectrum when foreign gases are added. Absorption of the narrow green line obtained from a water-cooled mercury discharge gives rise to the electronic transition $^3\Pi_{0u}^+ \leftarrow {}^1\Sigma_g^+$ resulting for the most part in I_2^* ($v' = 26$; $J' = 35$, 34, 29, and 28) (2, 3). Collisions between I_2^* and added gas may result either in quenching or in transfer to new vibrational and rotational levels of the excited $^3\Pi$ state.

The latter phenomenon is the origin of the effect observed by Franck and Wood. They were able to show that the changes in vibrational quantum number (v') were restricted to ± 1 or ± 2, with roughly equal probability, the changes in rotational quantum number to ± 2. It was clear that if the "transferred spectra" could be compared for a series of foreign gases, relative efficiencies in taking up single vibrational quanta of a known size would be calculable. Eliaschevich (4) made use of this method with H_2 and N_2 as the foreign gases. Rössler (5) performed similar experiments using the inert gases. Both workers calculated the probability of vibrational transfer on the assumption that the lifetime of I_2^* ($^3\Pi$) is 1×10^{-8} second. The calculated number of successful collisions was in every case greater (up to $100\times$) than the number of collisions obtained when the collision cross-section from kinetic theory was used. Rössler found that the transfer probability increased with the atomic weight of the inert gas.

It is generally supposed (see for example Pringsheim (6)) that the effect of increasing iodine pressure is the same as that of adding foreign gas, but there is to the writer's knowledge no experimental evidence for this. Wood and Speas (7) and also Pringsheim (8) investigated the self-quenching of iodine fluorescence at elevated pressures, but did not examine the fluorescent spectrum.

The present work was undertaken in the first place to ascertain the probability of vibrational-energy transfer in collisions I_2^* ($^3\Pi$) ($v' = 26$) $+ I_2$. Secondly it was hoped to obtain an independent check on the large transfer probabilities reported by Eliaschevich and Rössler. At the same time information was sought concerning the effect on transfer probability of a change in mass of the colliding partner in a case where other factors (such as polarizability) remained constant. Hydrogen and deuterium were therefore chosen as foreign gases.

EXPERIMENTAL

In the early part of this work an attempt was made to observe the fluorescence using a Raman-type apparatus (see for example Stoicheff (9)). A greatly increased fluorescence intensity was obtained in this way but the method was abandoned because of the considerable self-absorption in the important region of the spectrum up to $v'' = 3$.

The apparatus used is shown in Fig. 1. At first the source was a water-cooled mercury-discharge lamp but it was found that a sufficiently narrow green line could be obtained

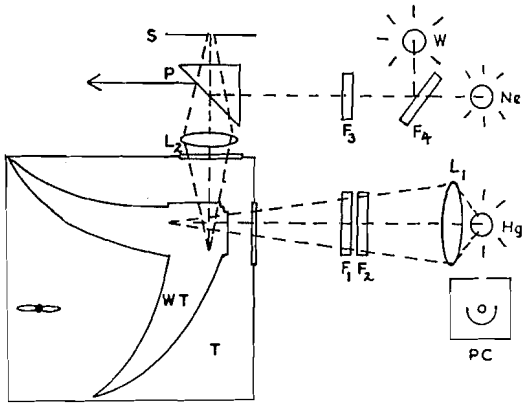

FIG. 1.

using a Mazda medium pressure 250 watt concentrated mercury arc. This lamp was started in a closed container and then operated in the open under an air blower. In this way the discharge was operated at the lowest practicable mercury pressure. The photocell (PC) was a WL930 used to keep a check on the constancy of the mercury lamp intensity.

Condenser lens L focused the light beam on a point about 1.55 cm. inside the double-horned Wood's fluorescence tube (WT), as close as possible to the exit window so as to minimize self-absorption. The Wood's tube shown in the figure was a sealed tube containing only crystals of iodine purified by resublimation. In the experiments where foreign gases were added a Wood's tube was used with a tap which was connected through a fine capillary to minimize absorption of iodine in the tap grease. This tube also differed from the sealed tube in that the ends of the conical limbs were connected to one another by an S shaped length of 6 mm. glass tubing. After the foreign gas had been introduced one limb of the S would be cooled while the other was heated so that the convecting gas would mix with the iodine vapor (for 10–15 minutes). The Wood's tube was immersed in a thermostated water-bath (T). The temperature was controllable to $\pm 0.1°$ C.

The filters F_1 and F_2 consisted of a Baird Multilayer filter with peak transmission at the mercury green line, and a Kodak Wratten No. 77 filter (2% transmission at the yellow line). The fluorescent light was focused by L_2 onto the slit S of a Steinheil spectroscope with three large glass prisms (*ca.* $f/10$), dispersion approximately 40 Å/mm. in the yellow. When the fluorescent spectrum was being observed, prism P was removed in the direction of the arrow (Fig. 1). With P in front of the slit the neon lamp (Ne) or the standard tungsten-filament lamp (W) could be photographed for calibration purposes. (F_3 was a sheet of frosted glass, F_4 a half-silvered mirror.) The neon spectrum was used both for wavelength calibration and for density vs. log exposure calibration. In the latter case a rotating sector not shown in Fig. 1 (Jarrel Ash, J.A. 1660; $I_0/I = 2$) was placed in front of the spectrograph slit. The tungsten lamp was a standard lamp of known color

temperature; it was used for calibrating the plates for variation in sensitivity with wavelength.

Hydrogen and deuterium were kindly supplied by Dr. P. M. Gundry, Princeton University. The gases had been purified by passage through a palladium thimble.

RESULTS

Fig. 2*a* is the fluorescent spectrum of iodine at 0.43 mm. pressure, photographed on a Kodak 103 aF plate (used for all spectra of Fig. 2) at a 6.5 minute exposure. Fig. 3*a* is the microdensitometer trace of this plate. The spectrum corresponds to that reported by Rank (3) for the iodine emission $^3\Pi_{0u}^+ \rightarrow {}^1\Sigma_g^+$; $v' = 26 \rightarrow v'' = 0, 1, (2), 3 \ldots$. Using a sensitized lN plate and 8.75-hour exposure we were able to photograph this spectrum as far as $v' = 26 \rightarrow v'' = 37$ (8830 Å). The rotational structure of the bands could not be resolved. The possibility that some of the fluorescence originated in $v' = 27$ and $v' = 25$ owing to absorption from wings of the mercury green line cannot be ruled out since the positions of the bands and their relative intensities would not be appreciably different if this were the case. However, the mercury green line did not appear significantly broadened in photographs of the source; promotion to 27′ and 25′ would consequently be expected to be slight.

Fig. 2*b* is the fluorescent spectrum of iodine at 19.2 mm. pressure (84° C.), with 4 hours'

exposure. The first band, at 5460 Å, as in all these plates, also contains reflected green light from the mercury discharge lamp. In plate 2*b* the amount of scattered light appears greater relative to the fluorescence since the latter has been much reduced by quenching. Some scattered yellow light (5770 and 5780 Å) from the mercury lamp appears at *Y* on trace 3*b* of plate 2*b*, obscuring the $v' = 26 \rightarrow v'' = 5$ transition.

Three significant changes have occurred in the fluorescent spectrum. The bands are now broader relative to their height. Five new bands have appeared (marked *X* in Fig. 3*b*) at the positions of the missing bands in the low pressure spectrum. Two anti-Stokes bands have appeared, separated from the resonance band by a space approximately equal to the separation between the normal bands, $26' \rightarrow 0''$, $26' \rightarrow 1''$, etc. (these anti-Stokes lines are not shown in 2*b* or 3*b*).

All three changes can be accounted for by supposing (cf. Loomis' (10) detailed analysis of Wood's low pressure spectrum) that the fundamental series of doublets originates in $v'' = 0$ and has no anti-Stokes members. At an elevated temperature the series of doublets originating in $v'' = 1$ and $v'' = 2$ will become important. With the dispersion used in the present work the various orders of the new series of doublets will almost coincide with the orders of the fundamental series. The slight difference in wavelength between the doublets of the new series and those of the fundamental series will result in the observed broadening of the spectral bands. Thus the origin of the first new series $29' \rightarrow 1''$ at 18,341 cm.$^{-1}$ overlaps heavily with the origin of the fundamental series $26' \rightarrow 0''$ at 18,311 cm.$^{-1}$. The anti-Stokes doublets of -1 and -2 order are a part of the series originating in $v'' = 1$ and $v'' = 2$ respectively.

The appearance of the new bands *X* can be explained as follows. It is known that the fundamental series $26' \rightarrow 0''$, $1''$, $2''$ . . . has practically identical doublet intensities to the series $27' \rightarrow 0''$, $1''$, $2''$ . . . and $28' \rightarrow 0''$, $1''$, $2''$ . . . . This is probably due (cf. Pringsheim (6), p. 156) to the relatively high values, v', of the eigenfunctions for all the upper levels (26, 27, 28) resulting in a great number of maxima near the turning points, which are all at nearly the same internuclear separation. It follows from the Franck–Condon principle that the transition probabilities depend largely on the eigenfunctions of the lower states determined by v''. This being the case the transitions $29' \rightarrow 0''$, $1''$, $3''$, $4''$ . . . (but not $2''$, $7''$, $9''$, $14''$, and $16''$) should be observed. Of these, $29' \rightarrow 3''$ will fall very close to the position of the missing line $26' \rightarrow 2''$. The other four new doublets are similarly accounted for by transitions $29' \rightarrow 8''$, $10''$, $15''$, and $17''$.

This leaves no lines unaccounted for and leads us to conclude that vibrational-energy transfer (the Wood effect) does not take place as a result of $I_2^* + I_2$ collisions to any extent even at this high pressure of iodine. The same was found to be true at intermediate pressures of iodine.

Figs. 2*c* and 2*d* are the fluorescent spectra of iodine at 0.43 mm. pressure in the presence of 9.6 mm. of hydrogen and 8.3 mm. of deuterium respectively. The exposure time was 35 minutes in each case. Four new bands are visible between the $v'' = 1$ and $v'' = 3$ bands of the original series. The positions and relative intensities of these bands identify them as arising from transitions $25' \rightarrow 1''$, $24' \rightarrow 1''$, $28' \rightarrow 3''$, $27' \rightarrow 3''$ (in order of increasing wavelength). Immediately to the long wavelength side of $v'' = 3$ of the original series is $25' \rightarrow 3''$. It is evident that the addition of hydrogen or deuterium has the effect of bringing about "transferring" collisions in which $I_2^*(v' = 26) \rightarrow I_2^*(v' = 28, 27, 25, 24)$, i.e. the iodine molecule may lose or gain either one or two quanta.

To interpret the densitometer traces (Figs. 3*c* and 3*d*) it is necessary to assume (see above) that the probability of a transition $v' \rightarrow v''$ is determined, in this region of high v', by v'' alone. The density plot is first converted to an intensity plot making use of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

calibration marks on the plate, and the area under each band is integrated graphically. The areas obtained for bands having the same v'', but different v', should then be in the ratio of the populations of the v' levels from which they originate. The areas obtained for the bands $28' \rightarrow 3''$, $27' \rightarrow 3''$, $25' \rightarrow 3''$ were the same to within $\pm 10\%$, indicating that a collision results in a change of vibrational quantum number of ± 1 or ± 2 with equal probability. This was the case for both H_2 and D_2.

A closer analysis of the data requires that one take into account that a new vibrational level may be partially converted by further collisions back to the original level. This may be significant for H_2 and D_2 since the quenching probability (which must be distinguished from the vibrational-transfer probability) is low. Rössler (5) (following Eliaschevich's (4) extension of the Stern–Volmer (11) treatment of quenching curves) took this "compound transfer" into account and derived the relationship

$$[1] \qquad I_0/I_p - 1 - \delta\tau p = \epsilon\tau p(1 - B.I_p'/I_p),$$

where I_p and I_0 are the fluorescent intensities of a particular band ($v' \rightarrow v''$) with and without the addition of a pressure p mm. of gas, I_p' is the intensity of some new band arising from vibrational transfer when gas is added: $(v'+1) \rightarrow v''$, $(v'-1) \rightarrow v''$, etc., δ and ϵ are quenching and vibrational-transfer constants such that the probabilities of quenching and transfer are given by δp and ϵp, τ is the mean life of I_2^* ($^3\Pi_{0u}^+$) ($v' = 26$) which we take to be 1×10^{-8} second in conformity with earlier workers, and B is an empirical constant which allows for the fact that the probability of a change in the vibrational quantum number by ± 1 may not be exactly the same as that by ± 2. Rössler found B to be ~ 0.85, only weakly dependent on the ratio of double to single jumps. We have adopted the same value.

The quenching constant δ comes from the expression

$$[2] \qquad Q = 1/(1+\delta p\tau),$$

where Q is the over-all quenching, i.e. the total intensity of the fluorescence in the presence of p mm. of added gas divided by the intensity in the absence of added gas. We have taken Q from the quenching curve for hydrogen obtained by Wood (12).

Q for deuterium is not known. However, we have provisionally calculated ϵ for deuterium on the basis that Q is the same as for hydrogen. This amounts to the assumption that the factor governing the relative quenching efficiencies of hydrogen and deuterium will be the collision duration. If this is the case, then Q at any pressure p must be the same for the two gases since the increased collision duration for D_2 will be exactly offset by the decreased number of collisions. Rössler found that the relative quenching efficiences of the inert gas series could be accounted for in terms of three variables: collision duration, polarizability, and effective cross section. Polarizability will not vary between H_2 and D_2. The effective cross section varies by only 10% from one member to the next of the inert gas series, making a negligible contribution to the variation in Q.

Table I lists the values used for the various quantities in equation [1] (I_0/I_p and I_p'/I_p are mean values) and the values obtained for the vibrational-transfer probability per

collision, $\epsilon p/Z_p$. Z_p is the number of collisions per second suffered by I_2^* at a pressure p of added gas, calculated using $r_{I_2} = 2.7$ Å and $r_{H_2} = r_{D_2} = 1.1$ Å.

DISCUSSION

In the previous section it was observed that quenching collisions $I_2^* + I_2$ take place to the exclusion of vibrational-transfer collisions even up to a pressure of 19.2 mm. of iodine. The question arises as to whether this is a specific effect due to the fact that the colliding partners are both iodine molecules.

It has been established (13) that the quenching of iodine resonance radiation excited by the mercury green line is due almost entirely to predissociation. According to the potential-energy diagram for iodine given by Mathieson and Rees (2) predissociation in normal quenching involves a transition from $^3\Pi_{0u}^+$ ($v' > 24$) to $^3\Sigma_u^+$ (0_u^-) $\rightarrow {}^2P_{3/2} + {}^2P_{3/2}$, normal atoms. Mulliken (14) has suggested that the transition may also be to $^1\Sigma_u^-$ (0_u^-).

In the present case, which involves self-quenching of iodine vapor, it is possible that the process is one in which the $^3\Pi_{0u}^+$ excited iodine molecule transfers its electronic energy to the ground-state I_2 collision partner, which is consequently excited to the lower repulsive state $^3\Pi_{1u}$ and dissociates into normal atoms. This could be characterized as *sensitized predissociation* by analogy with sensitized fluorescence. The transition $^3\Pi_{1u} \leftarrow {}^1\Sigma_g^+$ has actually been observed as a weak absorption in the red. The energy required is about 13 kcal./mole less than that liberated by the Hg-green-line fluorescence of I_2 in falling to the zero vibrational level of the ground state. The 13 kcal. would most probably remain in the quenched iodine molecule as vibrational energy ($v'' \simeq 23$):

$$I_2^* (^3\Pi_{0u}^+)(v' = 26) + I_2 (^1\Sigma_g^+)(v'' = 0) \rightarrow I_2 (^1\Sigma_g^+)(v'' \simeq 23) + I_2\dagger (^3\Pi_{1u}) \rightarrow I_2 + 2I.$$

On the evidence at present available the self-quenching of iodine fluorescence could equally well be due to a collisional transfer of I_2^* ($^3\Pi_{0u}^+$) into the $^3\Sigma_u^+$ (0_u^-) repulsive state, in precisely the same way that the inert gases quench the fluorescence. However, in view of the high efficiency observed for self-quenching it is of interest to note that this quenching is unique in having two reaction paths open to it:

$$I_2^* + I_2 \rightarrow I_2 + I + I \quad \text{(sensitized predissociation)},$$

$$I_2^* + I_2 \rightarrow I + I + I_2 \quad \text{(collisional predissociation)}.$$

In view of uncertainty in the value of δ, and probable error in obtaining I_0/I_p and I_p'/I_p, the value obtained for $\epsilon p/Z_p$ for hydrogen (vibrational-transfer probability per collision) could be in error by a factor of $\times 2$. With these limits of error our conclusion, taking $\tau = 1 \times 10^{-8}$ for I_2^*, is that on the average one to four collisions are needed between I_2^* ($v' = 26$) and hydrogen molecules to bring about a transfer of one or two quanta of vibrational energy into rotational or kinetic energy of H_2.

Eliaschevich (4) obtained a transfer efficiency $25\times$ our highest figure. Though significant differences in experimental technique exist between the two pieces of work they do not seem to account for the large discrepancy between our results and his. Eliaschevich appears to have used the peak height on an intensity vs. λ plot as a measure of band intensity, whereas we have used the integrated area under the band. Self-absorption would be somewhat greater in his experiments, though he used a lower pressure of I_2 (0.17 mm. compared with 0.43 mm.), owing to a 15 cm. long emission path compared with 1–1.5 cm. in our experiments. Our vibrational-transfer probabilities were measured at almost $10\times$ the pressure of H_2 that he used (1.1 mm. compared with 9.6 mm.). It is not expected that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

appreciable Lorentz pressure-broadening would occur even at the higher pressure of hydrogen.

As regards the correct lifetime (τ) to be used for I_2^* $^3\Pi$, Rabinowitch and Wood (13) point out that there is an analogy between $^3\Pi \rightarrow {}^1\Sigma$ for I_2^* emission, and $^3P \rightarrow {}^1S$ for Hg* emission. The Hg* $^3P_1$ lifetime is known to be $\sim 1 \times 10^{-7}$ second (Cd* $^3P_1$ and Zn* $^3P_1$ are respectively $\sim 2 \times 10^{-6}$ and 1×10^{-5} second). The assumption of 10^{-8} for the lifetime of I_2^* seems therefore to be a poor one. If a value of 3×10^{-7} were taken for the lifetime of I_2^*, then even for the case of Xe, for which Rössler obtained the highly improbable effective-collision-radius $r_{I_2} = 20$ Å, vibrational transfer would not occur at more than every gas kinetic collision. According to our results and using $\tau = 3 \times 10^{-7}$ seconds H_2 would have a collision efficiency for vibrational transfer of 1 collision in 55, and D_2 of 1 collision in 11. This seems more plausible than Eliaschevich and Rössler's collision efficiencies, which are $\gg 1$. As is well known, sound-dispersion data, which relate to changes in vibrational quantum number in the region $v \simeq 0$, give collision efficiencies $\ll 1$. "Third-body" data (see for example I + I + argon (15)), which refer to the removal of vibrational quanta in the region $v \sim \infty$, i.e. at the point of dissociation, can best be interpreted on the basis that the collision efficiency is 1. It would be remarkable if the intermediate case for which $v \simeq 26$ (approximately halfway to dissociation) were to have a collision efficiency $\gg 1$.

The value of $\epsilon p/Z_p$ for deuterium has been included in order to show that if, as seems likely, the ratio of quenching probabilities per collision for D_2 and H_2 is the same as the ratio of the collision durations, $\sqrt{(m_{D_2}/m_{H_2})} = 1.4$, then the ratio of the vibrational-transfer probabilities per collision will be approximately 5:1 (deuterium : hydrogen). Increasing vibrational-transfer efficiency with increasing mass of the colliding partner is in agreement with Rössler's work on I_2^* + inert gases. However, in the present case the difference is unambiguously associated with a change in mass.

The accuracy of these results could be greatly improved if heterochromatic microdensitometry were replaced by direct photometry. An attempt by the author to do this failed as a result of inadequate technique: the individual lines could be detected using a 10-stage photomultiplier tube, but the signal to noise ratio was too poor for accurate measurement. With a chopped light-beam and 14-stage photomultiplier these difficulties could probably be overcome.

ACKNOWLEDGMENTS

The author wishes to thank Dr. G. Herzberg of the Division of Pure Physics, National Research Council, Ottawa, and Prof. A. G. Shenstone of the Department of Physics, Princeton University, for their kindness in providing him with spectrographs and with all possible assistance. He is indebted to the David Sarnoff Research Laboratories, Radio Corporation of America, for the use of their recording microdensitometer.

EXCITED STATES OF ACETYLENE AND THEIR ROLE IN PYROLYSIS[1]

G. J. MINKOFF

ABSTRACT

Previous theories of acetylene pyrolysis are reviewed in the light of recent work by Minkoff, Newitt, and Rutledge. It is shown that the relatively large rates observed at the beginning of the induction period do not agree with mechanisms involving the intervention of comparatively stable dimers. The required kinetic form is obtained, however, if a triplet diradical is produced on the surface in a bimolecular process, followed by gas phase polymerization, with some chain ending on the surface. The detailed mechanism closely resembles Flory's scheme for liquid phase vinyl polymerization. The shape of the radical is discussed, and it is suggested that the *trans*-configuration leads to polymerization, while the *cis* facilitates dehydrogenation.

There has recently been some interest in the reactions of atoms or molecules in excited states (12, 14), and particularly of unsaturated molecules in triplet states. The purpose of this communication is to examine the role played by acetylene, and its polymers, in triplet states, during the pyrolysis of acetylene at temperatures below 500° C., particularly in view of the failure of mechanisms based on ground state molecules and radicals (21). In fact, there has been considerable controversy not only over the proposed mechanisms, but also over the experimental results. As a consequence of some recent work at temperatures below 525° C. (15), it has been possible to select those results which are most likely to be free of unexpected complications, and to propose a simple mechanism to account for most of the observations.

1. REVIEW OF PREVIOUS WORK

The main difficulties indicated in the literature are threefold; the first are concerned with the nature of the products, the second with the effect of surfaces, and the third is related to the effect of nitric oxide and the role of radicals. These will be considered in turn.

Confusion has often arisen regarding the products, since it is frequently stated, for example, that benzene is the main product of pyrolyzing acetylene. The latter result is only obtained under special conditions; the main reaction at low temperatures (i.e. below 500° C.) is polymerization to polycyclic and substituted aromatic compounds (see Ref. 15 for detailed references). Above 7–800° C., this is almost entirely superseded by decomposition to carbon and hydrogen (2). Products in the intervening region vary continuously from hydrogen and methane down to lower aromatics, including benzene, depending mainly on the temperature, but also on other factors. In particular Minkoff, Newitt, and Rutledge have shown that even at low temperatures, polymerization can be replaced by decomposition to carbon and hydrogen when halogen compounds or some metals are added to acetylene.

The elucidation of the mechanism has also been hindered by the differing reports of the effect of packing the reaction vessel with glass or other supposedly inert materials. Schlapfer and Brunner (19), and Frank-Kamenetsky (7), found the rate to be unaffected by increasing the surface-to-volume ratio. Pease (17), however, found the rate to be reduced by *ca.* 30%; Minkoff, Newitt, and Rutledge reported a weaker, but still inhibitory, influence of surface, while Silcocks (20) (who observed reaction to occur at unusually

[1]*Manuscript received August 16, 1957.*
Contribution from the Chemical Engineering Department, Imperial College, University of London, London, England. This paper was presented at the Symposium on the Structure and Reactivity of Electronically-Excited Species held at the University of Ottawa, Ottawa, Canada, September 5 and 6, 1957.

low temperatures) stated that the rate of reaction was considerably increased by packing the vessel. The treatment of the surface can also influence the rate in some circumstances (15, 24) but not in others (7). The different influences could be explained to some extent if both the chain initiation and chain termination were surface dependent, though to different extents. Any modifications of the surface would then have an over-all effect on the rate, which would depend on the relative activity of the surface to each of the two steps.

Random effects cannot be excluded, but the reported surface effects show some correlation with the amount of permanent gases (mostly hydrogen) detected, this being a possible measure of the decomposition reaction. Thus, in the absence of hydrogen, Pease found packing to inhibit the rate; Minkoff, Newitt, and Rutledge, who found only small inhibition, detected approximately 2–3% hydrogen, while the acceleration observed by Silcocks was associated with the isolation of considerable amounts of hydrogen.

Contradictions also exist regarding the presence of radicals. For example, Paneth and Hofeditz (16) found no positive evidence, so that if any radicals participate in the reaction, they may have unusual properties. On the other hand, Minkoff, Newitt, and Rutledge have confirmed the findings of Burnham and Pease (4) and of Frank-Kamenetzky (7), who observed that nitric oxide can almost completely inhibit the polymerization, and that after the nitric oxide has been used up, the reaction proceeds at the normal rate. While this indicates the presence of radicals, there is a sharp contrast with the normal effect of nitric oxide on hydrocarbon pyrolysis (see Ref. 21), since in the latter case, the rate gradually diminishes as more nitric oxide is added; however, some residual reaction is always observed, which the nitric oxide does not inhibit. A further complication is that exactly this behavior was reported for acetylene pyrolysis by Robertson, Magee, Fain, and Matsen (18); however, their measure of the rate was based on the instantaneous concentration of benzene, which occurred as an intermediate. This clearly was not indicative of the required rate, since the results obtained by this method are the only ones which do not give linear plots of log rate against $1/T$ (15). In view of the recent work of Jach and Hinshelwood (11), it is not impossible that the uninhibited reaction was induced by the Freon which was present in the system as an internal standard for the infrared absorption. Presumably, these observations will be of value when a deeper understanding of the reaction has been obtained.

2. KINETIC FEATURES

Most workers agree that the polymerization is, essentially, kinetically of the second order, although an induction period is usually observed (7, 15, 20). It has usually been assumed that the induction period represents the formation of a comparatively stable dimeric intermediate, and its accumulation to a steady state concentration when the rate of formation equals the rate of decomposition. The radicals formed by the decomposition are then supposed to catalyze the polymerization. Various suggestions have been made regarding the nature of the dimer, which has been said to be vinyl acetylene, cyclobutadiene, etc. Clearly, this scheme is formally of the Semenoff degenerate branching chain type, and the rate should therefore increase considerably from an initially very small value. This does not agree with the recent observation (15) that the initial rate, instead of being extremely low relative to the maximum value, is usually 30–50% of the latter. Another difficulty is that, while the initial rate and the maximum rate are both proportional to the square of the initial pressure (15), the length of the induction period is independent of the initial pressure (7, 15) below 500° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

A more satisfactory explanation is provided by a slow, bimolecular initiation, followed by a series of comparatively rapid bimolecular addition steps. The molecularity of the initiation step is indicated not only by the dependence of the initial rate on the square of the initial pressure, but also by the similarity of the initial and maximum rates. The relatively small difference between the latter implies that both sets of reactions contribute to the total rate of disappearance of acetylene, throughout the time during which second order kinetics are observed, and both must therefore be second order reactions. It is in fact shown later that the observed kinetic form closely resembles that of liquid phase polymerizations, which have similar mechanisms.

3. IDENTIFICATION OF CHAIN CARRIERS

Only two types of chain carriers can readily be formed from acetylene. One involves the fission of a C—H bond (I), while the other is formed by the "opening" of one of the triple bonds (II):

$$\underset{\text{(I)}}{CH{\equiv}C-} \qquad\qquad \underset{\text{(II)}}{-CH{=}CH-}$$

(No distinction is made at this stage between monomeric and polymeric radicals of each category.) Bimolecular collisions of two acetylene molecules seem at first sight to lead to —CH=CH—CH=CH— (II) rather than to CH≡C—CH=CH— (I), but, once formed, either radical would be able to propagate the polymerization chain. Considerations of the heats of formation (in the absence of activation energies) favor the formation of radical II. Thus, for radical I, the bond energy of the acetylenic C—H has been estimated as being 121 kcal. (25). With regard to II, the energy required to 'open one of the triple bonds' has been variously estimated as being in the region of 30 to 60 kcal. (cf. (5, 26)). A value of 50 kcal. will thus be assumed as being reasonably high. The conversion of the triple C—C bond into a double C—C bond probably implies (see below) a change of bonding orbitals in the C—H bonds from sp to sp^2. According to Walsh, the consequent total weakening requires 20–30 kcal. If this value is added to the 50 kcal. deduced previously, the heat of formation of II from acetylene has an upper limit of *ca.* 80 kcal. and a lower limit of 50 kcal. This is at least 40 kcal. less than is required to form I. The conclusion that C_2H— is more difficult to form than —C_2H_2—, in the absence of an excess of energy, is supported by a number of observations. The lack of effect of ethyl radicals when lead tetraethyl is added suggests that the energy of hydrogen abstraction is high, and this agrees with the lack of effect of oxygen, and with the shortness of extra chains produced by acetyl (or methyl) radicals from the pyrolysis of diacetyl, and of methyl radicals from the photolysis of acetone (23). Furthermore, the negative results of Paneth and Hofeditz suggest II rather than I. The results of photochemical experiments are not directly applicable. Nevertheless, it is clear that when sufficient energy is available to form C_2H—, polymerization proceeds readily; this can occur, for example, in the presence of $Cd(^1P_1)$ (2288 Å, 124 kcal.) or of $Hg(^3P_1)$ (2537 Å, 112 kcal.) (22). However, polymerization is also observed when triplet cadmium atoms (3261 Å, 87 kcal.) are used; Steacie and Le Roy attempted to overcome the difficulty by suggesting that since the heat of formation of cadmium hydride is 15.5 kcal., the reaction

$$Cd(^3P_1) + C_2H_2 \rightarrow CdH + C_2H-$$

can proceed if $D_{C-H(C_2H_2)}$ is not greater than 103 kcal. Since this estimate is much lower than that of other workers, a preferable explanation is that a triplet acetylene diradical is formed, which is responsible for the polymerization.

4. THE MULTIPLICITY AND NATURE OF THE RADICAL

The end of the previous paragraph introduced the possibility that the diradical is in the triplet state; this was necessary in the photochemical system because the multiplicity of the triplet cadmium atoms cannot be lost, but must be passed to another atom or molecule (cf. 14).

Since the triplet state, for any configuration, lies energetically lower than the corresponding singlet, the former would be more readily formed at a given temperature, were it not for the Wigner–Witmer spin conservation rules. These prohibit, in simple systems at least, the direct conversion of a singlet into a triplet. However, this restriction can be overcome by perturbing the fields of the system undergoing transition; this could be effected particularly well by a surface. If the suggestion is correct, then the bimolecular initiation reaction will become a surface process. If the polymerization is now visualized as a successive lengthening of the carbon skeleton of the diradical (II), by incorporation of acetylene molecules, then the formation of stable compounds can occur in two ways (other than by mutual destruction of carriers). One of these consists of passing the triplet multiplicity to an acetylene molecule

$$M_m^* + A \rightarrow Prod_m + A^*;$$

this is exactly parallel to the concept of chain transfer in liquid phase polymerization (3, 6); the regeneration of the chain carriers is thus ensured. The other process represents the spontaneous, unimolecular, conversion of a triplet chain carrier into a stable molecule. Again, this would be very slow in the gas phase, because of spin conservation restrictions, but it will readily occur on the surface.

The mechanism thus introduces a partial dependence on the surface of both chain initiation and termination, as was required by the consideration of the effect of surfaces. The apparent irregularities in the latter may further be explained by the difference in kinetic order of the two processes, in view of the fact that the comparisons are usually carried out under only one set of conditions by each worker.

5. MECHANISM

Formally, the mechanism can be represented as follows:

$$\textit{Initiation} \quad A + A \xrightarrow{\text{surface}} \begin{cases} A^x + A^x \\ A^x + A \\ A_2^x \end{cases} \quad \begin{cases} A = C_2H_2 \\ A^x = -C_2H_2- \\ A_2^x = -C_4H_4- \end{cases} \tag{1}$$

$$\textit{Polymerization} \quad A^x + A \longrightarrow A_2^x \tag{2}$$

$$A_n^x + A \longrightarrow A_{n+1}^x \tag{$n+1$}$$

$$\textit{Chain Transfer} \quad A_n^x + A \longrightarrow A^x + M_n \qquad (M_n = \text{stable product}) \tag{3}$$

$$\textit{Termination} \quad A_m^x + A_n^x \longrightarrow \text{Products} \tag{4}$$

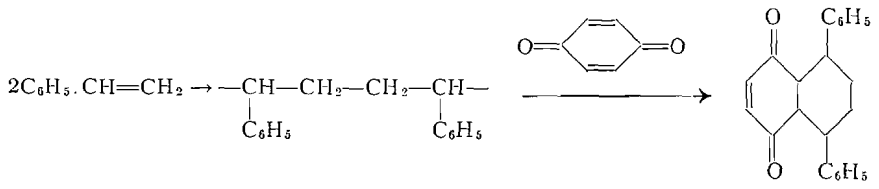
$$A_n^x \xrightarrow{\text{surface}} M_n \tag{5}$$

Regarding the initiation reaction, it is not at present possible to decide whether this results in one or more entities, but this does not affect the remainder of the discussion.

Apart from the inherent simplicity, the mechanism is supported by a number of considerations. Thus, it is very similar to the simplified scheme which Flory (6) proposed in 1937 to account for "vinyl" type polymerization in the liquid phase (see Ref. 1, 3 for later refinements). The main steps were: (*a*) formation of a dimeric divalent radical, (*b*) comparatively long polymerization chains, (*c*) chain transfer, similar to reaction (3), and (*d*) chain termination, involving interaction of two chain carriers. (The order of the

last reaction had little effect on the kinetic form deduced.) With some simplifications, graphs of concentration (C) against time have been deduced by the author for various possible ratios of chain termination to chain propagation. In every case, the initial rate is of the same order of magnitude as the maximum rate. From the diagram in Flory's paper, values of $1/C$ have been deduced, and plotted against time; the resulting graphs are identical in form with those reported for acetylene polymerization by Minkoff, Newitt, and Rutledge.

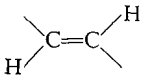
In the liquid phase system, direct evidence has been obtained of the formation of the dimeric radical, by the isolation of an addition compound with a molecule of benzoquinone inhibitor (13):



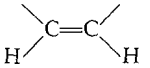
Under these conditions, Bamford and Dewar suggested that there was no need to invoke a triplet state. However, this point of view does not necessarily apply to the gas phase, particularly in view of the need for making the reaction mechanism sensitive to surface.

6. THE SHAPE OF THE TRIPLET STATE

The use of —CH=CH—CH=CH— as a chain carrier is not new (20), but it is only when this radical is considered as a triplet that the effect of surfaces, and of tests for radicals, can be reasonably explained. A further refinement is to predict the conditions leading to polymerization, and to decomposition. This is made possible by Ingold and King's analysis of the U.V. absorption spectrum of acetylene (10), which indicates that the triplet diradical is likely to have the *trans* configuration in the lower state, and the *cis* in a higher one:



trans



cis

It seems probable that during polymerization the carbon skeleton retains the *trans* shape. To some extent, this is supported by the "staggered" configuration of diacetylene in its upper, singlet, state (Dr. Callomon, private communication). Comparatively long carbon skeletons would then be formed in preference to small cyclic ones. At higher temperatures, however, sufficient energy becomes available for the *cis* configuration to be of importance, thus facilitating both the elimination of molecular hydrogen, and the formation of benzene in considerable amounts (cf. the textbook methods of making benzene by passing acetylene through a red-hot tube).

It is also possible that the effect of halogenated compounds and of metals can be explained in a similar way, by postulating that the change from *trans* to *cis* is facilitated by the free electrons in the metal surfaces, or by the strong electronegativity of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

halogen atoms. Once the C_2 molecules (or radicals) have been formed in the gas phase, they readily react with acetylene and form carbonaceous deposits (9).

This explanation of the role of halogens seems to be at least as probable as mechanisms based on the so-called affinity of halogen atoms for hydrogen. The latter are difficult to reconcile with the relative bond dissociation energies of 121 kcal. for C—H in acetylene and of 102 kcal. for HCl and even lower for HBr (8).

CONCLUSION

The mechanism presented in this communication explains the greater part of the effects reported below 500° C., and particularly that of surfaces. It has the advantage of treating the polymerization of acetylene in a manner analogous to that generally accepted for vinyl polymerization reactions, and it provides a simple explanation of the change from polymerization to decomposition at low temperatures. More experimental work on the latter aspect would be desirable.

The author acknowledges valuable discussions with Dr. V. Griffing, Dr. G. W. King, Prof. D. M. Newitt, and Dr. P. V. Rutledge.

THE FLUORESCENCE AND ITS RELATIONSHIP TO PHOTOLYSIS IN HEXAFLUOROACETONE VAPOR[1]

HIDEO OKABE[2] AND E. W. R. STEACIE

ABSTRACT

Hexafluoroacetone vapor, when excited at 25° C. by light of wavelength 3130 Å, gives rise to fluorescence. The fluorescence spectrum starts at about 3470 Å and extends to almost 6000 Å with a maximum at about 4200 Å, independent of pressure over the range 3 mm. to 170 mm. No fine structure is observed. Oxygen has almost no effect on the spectrum, contrary to the cases of acetone and biacetyl vapor, where oxygen causes a marked change. The absorption follows Beer's law between 5 mm. and 50 mm. of hexafluoroacetone pressure and the absorption coefficient has been measured.

The fluorescence efficiency decreases slightly with the addition of less than 1 mm. of oxygen and there stays constant up to an oxygen pressure of 30 mm., indicating that the fluorescence may be principally from the short-lived singlet excited state. The fluorescence efficiency increases with pressure of hexafluoroacetone or with the addition of inert gases such as perfluorobutane, perfluoropropane, hexafluoroethane, or carbon dioxide. The present results may be compared with those of the photolysis, where it was found that the quantum yield of the decomposition decreases with increasing pressure and with added inert gases. A close relationship between the fluorescence and the photolysis suggests itself. A mechanism is proposed to explain the results, which assumes that the molecule is raised to the upper vibrational levels of a singlet excited state, and subsequently deactivated to the lowest vibrational levels of the same state, from which it fluoresces. On the basis of this mechanism it seems possible to correlate the photolysis with the fluorescence.

INTRODUCTION

The photolysis and fluorescence of ketones have been studied extensively for many years (1).

While most photochemical reactions seem to involve principally the dissociation of molecules, in some cases both the dissociation and the fluorescence take place concurrently, when excited species are formed by the absorption of the radiation. In a few cases it seems possible to explain the results in terms of a mechanism which correlates both phenomena (2, 3).

The photolysis of hexafluoroacetone has been studied mainly by Ayscough and Steacie (4). They found that the mechanism of the photolysis by light of wavelength 3130 Å seems to be unusually simple over a wide range of temperatures. By investigating the effect of pressure and of various inert gases on the primary photochemical yields they concluded that the photolysis proceeds by way of an electronically excited species with a considerable lifetime. They found that the photochemical yields decreased with increase of pressure and with the addition of inert gases, which indicates that the excited molecules are deactivated effectively by collision. Since the photochemical yields were always considerably less than unity over the range of pressures studied, the possibility of fluorescence may be suggested as another way of energy dissipation. The study of fluorescence, if it is found, is of interest in order to arrive at a further understanding of the primary process. The present work was undertaken to investigate the hitherto unknown fluorescence of hexafluoroacetone and to correlate it with the photolysis data.

EXPERIMENTAL

Hexafluoroacetone hydrate was supplied by Dr. Leitch of this laboratory, to whom we are greatly indebted. It was dehydrated by phosphorus pentoxide, degassed and stored in a blackened bulb behind a mercury cutoff. The fluorocarbons were supplied by E. I. duPont de Nemours and Company. They were purified by trap to trap distillation in the vacuum line, a middle portion being retained, dried by phosphorus pentoxide, and stored behind a mercury cutoff. Oxygen was prepared by heating potassium permanganate and by passing it through liquid nitrogen traps.

The light source was a Hanovia S-500 lamp operated with a Sorensen regulator. The radiation passing through a 10 mm. hole was collimated by a quartz lens of 100 mm. focal length, and passed through the color filter combination of 3 mm. Corning No. 9863, 50 mm. path length of 0.178 M nickel chloride solution, and 30 mm. path length of 0.0025 M potassium chromate solution. The wavelength of the radiation was mainly 3130 Å. That light transmitted by the cell was focused by another quartz lens of 150 mm. focal length on a G.E. 935 photocell and the light intensity measured by galvanometer deflection. The fluorescent radiation was measured at right angles to the incident radiation. After removal of scattered ultraviolet radiation by a Corning No. 738 filter, the fluorescent radiation was focused by a quartz lens on the 1P21 photomultiplier tube of a Farrand photometer. The photocurrent was measured on a galvanometer. A correction for the background radiation, amounting to less than 3%, was applied. It was found that both the fluorescence and the transmission amplifier circuits were stable and reproducible during the run. The intensity of the light source sometimes fluctuated over a long period of time and it was necessary to correct this occasionally during a run by changing the secondary voltage.

The cell employed was similar to that of Hunt and Noyes (5) except that it was made of Pyrex with quartz windows in order to facilitate the replacement of the windows, which were attached to the cell by Apiezon W cement. The cell was T shaped with an internal diameter of 40 mm. and length of 150 mm. The stem of the T was 40 mm. in diameter and tapered down to 10 mm.

A Toepler-type expansion bulb was used for mixing the reactants. Oxygen was stored in a 5 liter bulb and was dosed into the cell by means of a 20 cc. mercury Toepler pump.

Most spectrograms were taken with a Hilger $f/4$ quartz spectrograph. Eastman Kodak 103a-B plates were employed with Kodak D-19 developer. The vacuum line, free of stopcocks, followed the customary design used in this laboratory.

The following measurements were carried out for hexafluoroacetone: (1) I_t^0, the light transmitted by the empty cell; (2) I_t, the transmitted light with the gas in the cell; (3) I_f, the intensity of the fluorescence emerging from the center of the cell; and (4) I_f^0, the intensity of scattered radiation, which was very small and virtually constant so that it was not measured each time.

The fluorescence efficiency, Q, proportional to the absolute quantum yield of fluorescence, was calculated from the following equation:

$$Q = (I_f - I_f^0)/(I_t^0 - I_t).$$

RESULTS

It was found that hexafluoroacetone gives strong fluorescence when excited by light of wavelength 3130 Å. The spectrum starts at about 3470 Å and extends to 6000 Å with a maximum at about 4200 Å (Fig. 1). The main features follow:

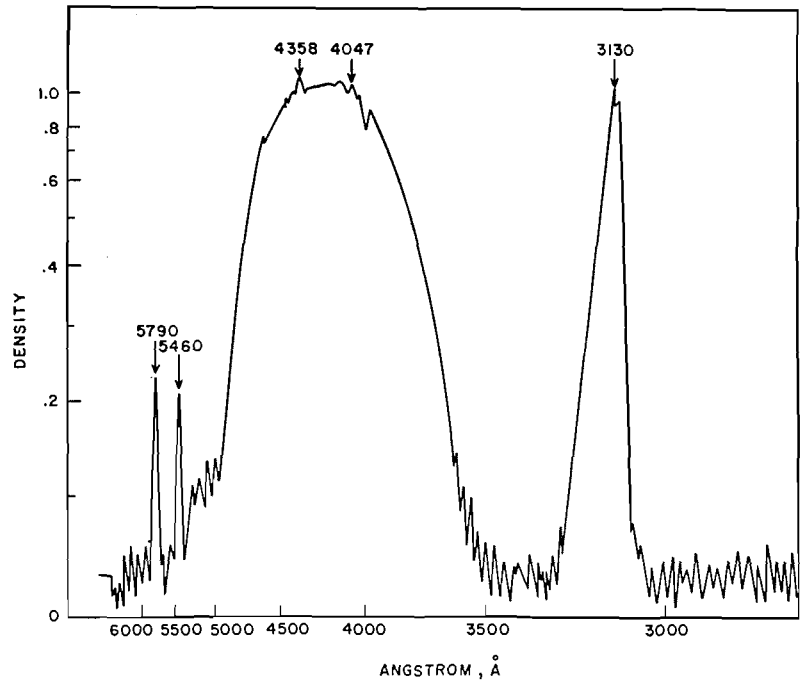

FIG. 1. Microdensitometer tracing of the fluorescence spectrum of hexafluoroacetone vapor excited by light of 3130 Å, using a Kodak 103a-B plate.

(1) The spectrum was independent of pressure of hexafluoroacetone from 3 mm. to 170 mm. at room temperature.

(2) No fine structure was observed with a Hilger high aperture glass spectrograph with a reciprocal linear dispersion of 80 Å/mm.

(3) The same spectrum was also obtained by exciting with light of wavelength 2800 Å or shorter.

(4) Oxygen had almost no effect on the spectrum.

The absorption followed Beer's law well between 5 mm. and 50 mm. and the calculated absorption coefficient k from the equation $I_t = I_t^0\ 10^{-kcd}$, where I_t^0 is the incident intensity, I_t the radiation transmitted, c the concentration in moles per liter, and d the distance in centimeters, was 6.80. The absorption coefficient is about 2.4 times greater than that of acetone at 3130 Å (6). The fluorescence efficiency Q was measured at 25° C. with various pressures of hexafluoroacetone and is given in Table I. It may be seen from

TABLE I

THE VARIATION OF THE FLUORESCENCE EFFICIENCY WITH HEXAFLUOROACETONE PRESSURE AT 3130 Å

P (mm.)	Q	P (mm.)	Q
1.75	6.9	17.0	7.81
4.7	7.7	21.5	8.19
7.3	6.51	25.5	8.31
11.9	7.21	30.5	8.91
15.4	7.40	37.5	8.36

the table that Q increases with pressure and reaches almost a maximum at about 20 mm. of pressure. This is quite contrary to the case of acetone, where Q decreases with pressure (6, 7), but is similar to biacetyl phosphorescence excited by light of wavelength 3650 Å (8). Fig. 2 shows the effect of oxygen pressure on the fluorescence efficiency Q of

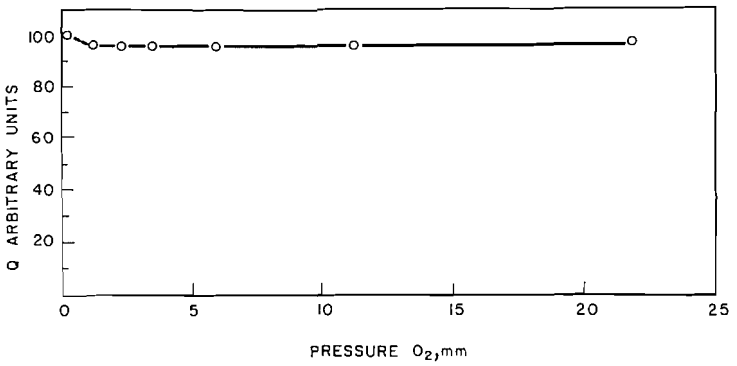

FIG. 2. Variation of fluorescence efficiency of 20 mm. hexafluoroacetone with oxygen pressure at 3130 Å.

20 mm. hexafluoroacetone at 25° C. As is seen from the curve, Q decreases slightly but definitely somewhere in the region below 1 mm. of oxygen pressure and there stays almost constant with further addition of oxygen. This is in marked contrast to acetone (6, 7) or biacetyl (9, 10, 11), where the emission decreased sharply to an almost negligible value with increasing oxygen pressure. The absorption of hexafluoroacetone was also measured and no change was observed with added oxygen.

In order to correlate the photolysis results with the fluorescence, the same inert gases used in the photolysis experiments were added to hexafluoroacetone and the fluorescence efficiency measured. Fig. 3 illustrates the effects of perfluorobutane, perfluoropropane, hexafluoroethane, and carbon dioxide on the fluorescence efficiency Q with 10 mm. of

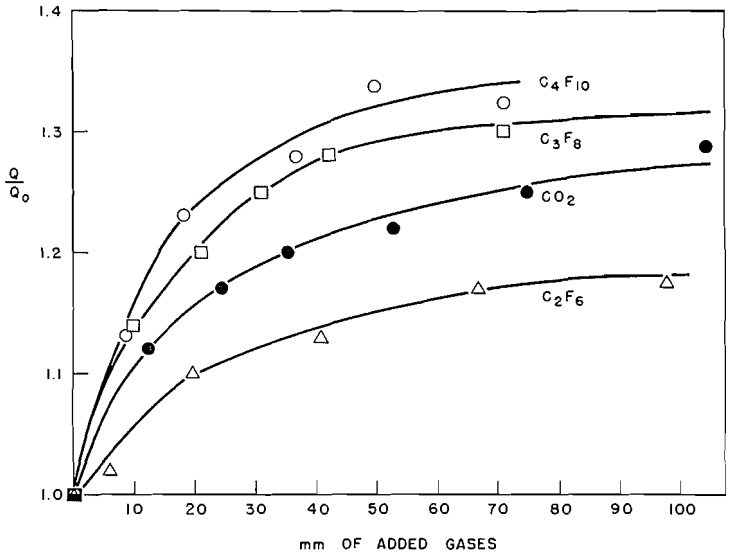

FIG. 3. Variation of fluorescence efficiency of 10 mm. hexafluoroacetone with pressure of added inert gases at 3130 Å.

For personal use only.

hexafluoroacetone at 25° C. It can be seen from the curves that in every case there is an increase of Q with added gases. The order in which the gases increase Q is as follows: perfluorobutane > perfluoropropane > carbon dioxide > hexafluoroethane. Perfluorobutane increases the fluorescence efficiency by almost 30%, and hexafluoroethane by 17% over the range covered. If smaller pressures of hexafluoroacetone were used, a more pronounced effect of added gas would be expected. Apparently neither of the added gases is as effective as hexafluoroacetone itself in increasing the fluorescence efficiency. The intensity transmitted by the empty cell I_t^0 was frequently checked by freezing down the mixtures with liquid nitrogen. No change of absorption occurred in the presence of the added gases. The photolysis data (4) show that the decomposition is reduced by the addition of inert gases and that the efficiency of reduction follows the same order as the efficiency of fluorescence increase, except that the order of carbon dioxide and hexafluoroethane is reversed. This suggests related mechanisms for the fluorescence and the photochemical decomposition.

DISCUSSION

The striking simplicity of the over-all photochemical process at 3130 Å in hexafluoroacetone was reported by Ayscough and Steacie (4). They found that hexafluoroethane and carbon monoxide are the only products and that the quantum yield of decomposition is always less than unity and strongly dependent on pressure and the addition of inert gases. These facts led them to postulate the formation of a long-lived electronically excited molecule as an intermediate, which decomposes by a first order process unless deactivated by collision. Since the quantum yield of dissociation is always less than unity, the energy must be dissipated by some process other than dissociation. These steps may be the internal conversion or the fluorescence or both. No details of this process are known.

The present work revealed the existence of strong fluorescence extending from 3470 Å to 6000 Å with a maximum at about 4200 Å, independent of pressure studied, with incident radiation of 3130 Å. The fluorescence does not seem to originate from perfluorobiacetyl as acetone fluorescence does from biacetyl, because (1) the CO to C_2F_6 ratio is always unity indicating that no CF_3CO radical is formed, (2) no perfluorobiacetyl was found mass-spectrometrically after the sample was photolyzed, (3) the fluorescence spectrum starts almost from the end of the absorption band, and has no resemblance to that of biacetyl fluorescence, and (4) the fluorescence intensity does not change with time, whereas the acetone fluorescence does, owing to the accumulation of reaction product (biacetyl) (5).

The absorption band of the vapor lies between 2450 and 3550 Å (4). Since fluorescence and absorption overlap, the 0–0 band would lie in the region of overlap. This band may tentatively be assigned to 28570 cm.$^{-1}$ (3500 Å). This would be the 0–0 band for the transition in absorption and presumably for the transition in fluorescence from a singlet excited state. By excitation at 3130 Å the molecule will be raised to high vibrational levels, Y_n, of a singlet excited state (see Fig. 4). Since no resonance fluorescence was observed, the molecule must be deactivated rapidly to the lowest vibrational levels, Y_0, of the singlet excited state before it fluoresces. Oxygen has almost no effect on the fluorescence efficiency as well as on the spectrum. By analogy with the cases of acetone and biacetyl, in which the fluorescence from a singlet excited state is not quenched by added oxygen, whereas the phosphorescence from a triplet state is strongly quenched by oxygen (6, 7, 10, 11), it may be assumed that the fluorescence is mainly from the singlet excited state of hexafluoroacetone although no direct evidence has been found.

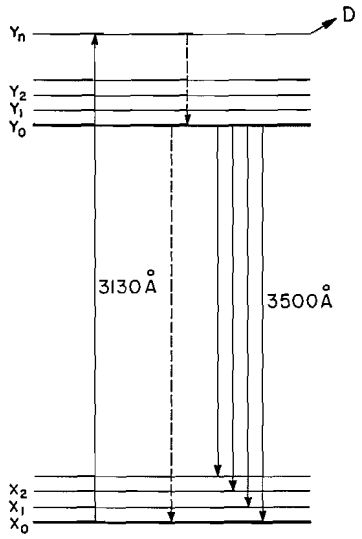

FIG. 4. Energy level diagram of hexafluoroacetone, where X_i is the ith vibrational level of the ground state, Y_i is the ith vibrational level of the singlet excited state, and D is the decomposition process. The full line represents the absorption or fluorescence process and the broken line represents the internal conversion or deactivation process.

The measurement of lifetime of hexafluoroacetone fluorescence is highly desirable in this respect.

It may be of interest to compare acetone and hexafluoroacetone with benzene and fluorobenzene. It was found that benzene shows both fluorescence and phosphorescence, whereas fluorobenzene shows only fluorescence at 77° K. (12). This was attributed to the more rapid transition from the singlet excited to the ground state compared to the radiationless transition to the triplet state in fluorobenzene, relative to that in benzene. This may be the case with acetone and hexafluoroacetone, although integrated extinction coefficients have not been compared in both cases.

From the foregoing discussion, the following process may be written:

[1] $$X+h\nu = Y_n,$$

[2] $$Y_n = C_2F_6+CO,$$

[3] $$Y_n = X,$$

[4] $$Y_n+X = Y_0+X,$$

[5] $$Y_0 = X+h\nu^*,$$

[6] $$Y_0 = X,$$

where X designates the ground state and Y_0 and Y_n, 0th and nth vibrational levels of the singlet excited state of hexafluoroacetone. Either or both steps [3] and [6] may be included. The following equation may be obtained from the above steps:

[7] $$\frac{1}{\phi} = 1+\frac{k_3}{k_2}+\frac{k_4}{k_2}(X),$$

where ϕ is the quantum yield of decomposition and (X) is hexafluoroacetone concentration. The validity of equation [7] may be tested by plotting $1/\phi$ against (X) from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

photolysis data (4). The plot corresponding to various temperatures gives a series of straight lines with an intercept of unity. This indicates that $k_3 = 0$, that is, there is no first order step other than the decomposition. Therefore the following equations will be obtained:

[8] $$\frac{1}{\phi} = 1+\frac{k_4}{k_2}(\mathrm{X})$$

and

[9] $$\frac{1}{aQ} = \frac{k_5+k_6}{k_5}+\frac{k_2(k_5+k_6)}{k_4k_5}\frac{1}{(\mathrm{X})},$$

where Q is the fluorescence efficiency and a is the ratio of quantum yield of fluorescence to the fluorescence efficiency. Since a is not known, each individual constant can not be obtained. The process may be compared to that for biacetyl when excited by 3650 Å radiation where step [3] should be included since the intercept is always greater than unity (2).

Fig. 5 illustrates the relation between $1/Q$ and $1/(\mathrm{X})$. It may be seen that equation [9] is approximately obeyed. At pressures lower than 5 mm., the plot deviates considerably from linearity, indicating that some other process must be considered. However, the data are not extensive and accurate enough to warrant further discussion of this process.

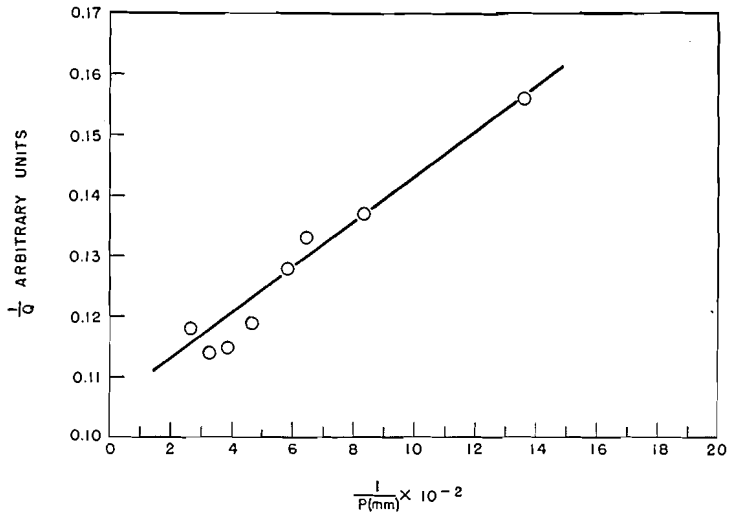

FIG. 5. The dependence of the reciprocal of the fluorescence efficiency on the reciprocal of the hexafluoroacetone pressure at 3130 Å.

The mechanism for hexafluoroacetone fluorescence seems to follow that for biacetyl green phosphorescence excited by light of 3650 Å, but not that for acetone fluorescence excited by light of 3130 Å. It indicates that the self-quenching process $\mathrm{Y}_0 + \mathrm{X} = 2\mathrm{X}$ is small and relatively unimportant compared to the deactivation process [4]. It also follows from the mechanism that

[10] $$\frac{aQ}{\phi} = \frac{k_4k_5}{k_2(k_5+k_6)}(\mathrm{X}).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

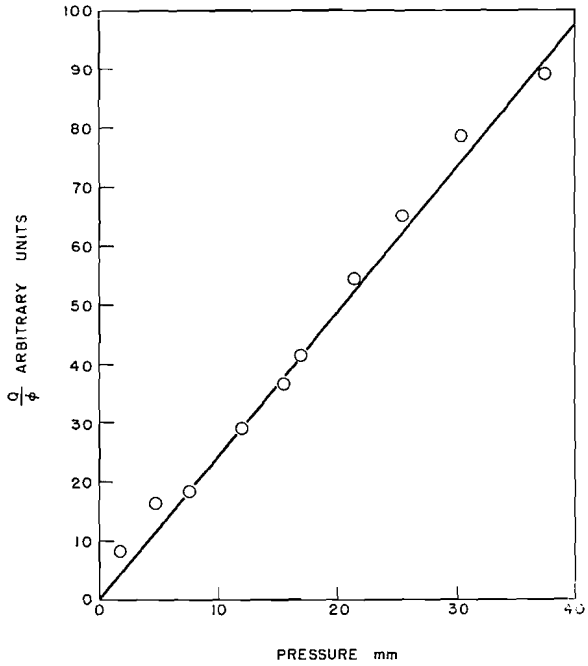

FIG. 6. The dependence of the ratio of the fluorescence efficiency, Q, and the photochemical yield, ϕ, on the pressure of hexafluoroacetone at 3130 Å.

Fig 6 shows the relation between Q/ϕ and (X), the pressure of hexafluoroacetone. The values for photochemical decomposition are taken from Ayscough and Steacie's data (4). As can be seen, a plot of Q/ϕ vs. pressure gives a straight line which passes through the origin. This indicates that the decomposition results almost exclusively from a first order step, and the fluorescence, from a second order step. The positive intercept on the Q/ϕ axis observed with biacetyl (2), indicating that dissociation results from the collision of two excited molecules, does not appear with hexafluoroacetone.

The close relationship between the photolysis and the fluorescence may be seen further from the effect of inert gases.

The hexafluoroacetone has the great advantage that it is possible to compare the effect of inert gas on the photolysis and the fluorescence simultaneously; since firstly it is possible to measure the primary photochemical yields even in the presence of added gas, and secondly the fluorescence yields are large enough to measure, thus making it possible to compare both directly.

In the presence of inert gas, the following step must be added:

[11] $$Y_n + M = Y_0 + M,$$

where M designates inert gases. The following equations may be derived:

[12] $$\frac{1}{\phi} = 1+\frac{k_4}{k_2}(X)+\frac{k_{11}}{k_2}(M),$$

[13] $$\frac{\phi_0}{\phi} = 1+\frac{k_{11}}{k_2+k_4(X)}(M),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

[14] $$\frac{aQ}{\phi} = \frac{k_4k_5}{k_2(k_5+k_6)}(\mathrm{X})+\frac{k_5k_{11}}{k_2(k_5+k_6)}(\mathrm{M}),$$

and

[15] $$\frac{Q}{Q_0}\frac{\phi_0}{\phi} = 1+\frac{k_{11}}{k_4(\mathrm{X})}(\mathrm{M}),$$

where (M) represents added inert gas concentration, and ϕ_0 and Q_0, the quantum yield of decomposition and the fluorescence efficiency, respectively, with 10 mm. hexafluoroacetone without added inert gas in the cell. It was shown (4) that ϕ_0/ϕ plotted against (M) gives a series of straight lines. Fig. 7 shows the relation between $(Q/Q_0)(\phi_0/\phi)$ and

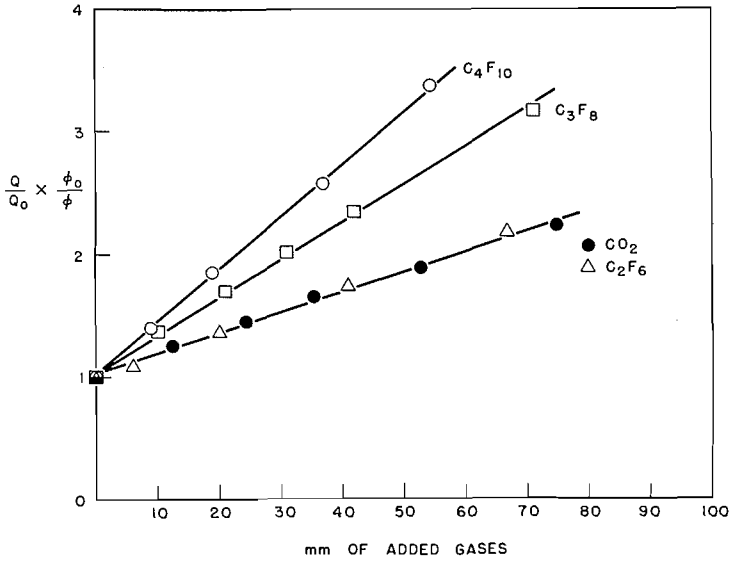

FIG. 7. The dependence of the ratio of the fluorescence efficiency and the primary photochemical yield on the pressure of added inert gases at 3130 Å.

(M). In this figure ϕ_0/ϕ values were taken from the points on the straight line corresponding to each pressure of added inert gas at 78° C., the only temperature for which data are available. It may be seen that a series of straight lines is obtained for each added gas. The slopes of the lines give the rates of deactivation by inert gases relative to that by hexafluoroacetone. The relative rates are 1, 0.42, 0.31, 0.17, and 0.17 for CF_3COCF_3, C_4F_{10}, C_3F_8, C_2F_6, and CO_2 respectively. These values are lower than those obtained from the photolysis data, although their relative orders are the same with the exception of that for CO_2. This is probably due to the fact that ϕ_0/ϕ values are obtained at 78° C. whereas Q/Q_0 values are at 25° C.

The authors wish to thank Mr. G. Ensell for the construction of the cell.

REACTION OF AMINO ALCOHOLS WITH CARBON DISULPHIDE[1]

A. F. McKay, M. Skulski, and D. L. Garmaise

ABSTRACT

ω-Amino alcohols possessing five or more methylene units between the amino and hydroxyl groups on condensation with carbon disulphide gave good yields of 1,3-di-(ω-hydroxyalkyl) thioureas. These symmetrically disubstituted thioureas on oxidation gave the corresponding 1,3-di-(ω-hydroxyalkyl) ureas.

The investigation of the reaction of carbon disulphide with amino alcohols (1) has been extended to the longer chain ω-amino alcohols. The ω-amino alcohols having five or more methylene units between the amino and hydroxy groups combine with carbon disulphide to give 1,3-di-(ω-hydroxyalkyl) thioureas (II). A series of these symmetrical thiourea derivatives II have been prepared and their properties are listed in Table I. 1,3-Di-(5-hydroxypentyl)-thiourea (II, $n = 5$) was isolated as an oil and it was converted directly into the corresponding urea without further purification. The 1,3-di-(5-hydroxy-

$n = 5$–11 III

pentyl)-, 1,3-di-(6-hydroxyhexyl)-, and 1,3-di-(7-hydroxyheptyl)-thioureas were oxidized in alkaline solution with hydrogen peroxide into the corresponding symmetrical urea derivatives III. 1,3-Di-(11-hydroxyundecyl)-thiourea was not oxidized under the same conditions but it was converted into 1,3-di-(11-hydroxyundecyl)-urea by refluxing with ethanolic silver nitrate solution (2).

Other urea derivatives prepared for characterizing the amino alcohols were 1-(α-naphthyl)-3-(6-hydroxyhexyl)-urea, 1-phenyl-3-(7-hydroxyheptyl)-urea, and 1-(α-naphthyl)-3-(11-hydroxyundecyl)-urea.

EXPERIMENTAL[2]

5-Aminopentanol-1

5-Aminopentanol-1 (b.p. 119–120° C. at 17 mm.; m.p. 26–28° C.; n_D^{16} 1.4608) was prepared in 45.5% yield by the method of Putokhin (3). The previously reported (3) physical constants are m.p. 26° C., d_4^{17} 0.9488, and n_D^{17} 1.4618.

6-Aminohexanol-1

6-Aminohexanol-1 was prepared by a modification of Wallach's method (4). Metallic sodium (150 g., 6.52 moles) was added to a refluxing solution of caprolactam (30 g., 0.26 mole) in freshly distilled absolute ethanol (1500 cc.) at a sufficient rate to maintain vigorous reflux. The reaction was complete in 1½ hours. The reaction mixture was steam distilled and the distillates were collected in 1 liter fractions. These fractions were acidified with hydrochloric acid and then evaporated to dryness. The first two fractions gave an impure hydrochloride melting at 215–235° C., yield 5.85 g. (16.25%). These crystals were considered to be impure hexamethylenimine hydrochloride, which Wallach reported (4) to melt at 236–237° C. The remaining distillate fractions gave a yellowish colored hydrochloride melting at 63–64° C., yield 28.91 g. (70.9%). This crude material (23.63 g., 0.15 mole) in absolute methanol (500 cc.) was passed through IRA-400 resin (1000 cc. of resin in the hydroxyl form previously washed with methanol) at a rate of 5 cc. per minute. The column of resin was washed with methanol (2500 cc.) and the eluate and washings were taken to dryness *in vacuo* under nitrogen. The product was distilled *in vacuo* under nitrogen. A crystalline product (b.p. 137–139° C. at 20 mm.) was obtained, yield 13.10 g. (42.1%). This crystalline product appeared to be dimorphous with one form melting at 57–58° C. and the other at 75–78° C. Wallach (4) reported a melting point of 55–56° C. Both forms gave one spot with a R_f value of 0.54 when chromatographed on Whatman No. 1 paper with butanol: acetic acid: water (4: 1: 5) solvent.

A sample (0.15 g., 0.001 mole) of 6-aminohexanol-1 was treated with α-naphthylisocyanate (0.218 g., 0.001 mole) in dry benzene (10 cc.). This suspension was refluxed for 1 hour. The gummy precipitate of 1-α-naphthyl-3-(6-hydroxyhexyl)-urea was removed by filtration and then crystallized from boiling acetone (5 cc.). A crop of colorless needles (m.p. 140–141° C.) was obtained, yield 0.265 g. (71.8%). The melting point was not changed by further crystallization. Anal. Calc. for $C_{17}H_{22}N_2O_2$: C, 71.30; H, 7.69; N, 9.78%. Found: C, 71.39; H, 7.83; N, 9.97%.

7-Aminoheptanol-1

Cycloheptanone oxime (b.p. 129–130° C. at 23 mm.) was prepared in 94.4% yield by the method of Pearson and Bruton (5). It was then converted into enantholactam (b.p. 148–150° C. at 10 mm.) in 82% yield by the method of Eck and Marvel (6).

Enantholactam (75.95 g., 0.6 mole) was converted into 7-aminoheptanol-1 hydrochloride by the method described above for the preparation of 6-aminohexanol-1. The first two distillates yielded a brownish oil (20 g.), which is probably impure heptamethylenimine hydrochloride. The residue from distillate fractions 3–7 was obtained as

[2]*All melting points are uncorrected. Microanalyses were performed by Micro Tech Laboratories, Skokie, Illinois.*

brownish needles melting at 67–75° C., yield 25.06 g. This crude 7-aminoheptanol-1 hydrochloride was dissolved in water (500 cc.) and the solution passed through a column of IRA-400 resin (600 cc. of resin in the hydroxyl form) at a rate of 5 cc. per minute. The column was washed with water (3500 cc.) and the eluate and washings were evaporated to dryness *in vacuo* under nitrogen. A crystalline distillate (b.p. 123° C. at 5 mm.; m.p. 48–53° C.) was obtained from the residue, yield 23.5 g. (29.9%). Wallach (4) reported a melting point of 48–50° C. for 7-aminoheptanol-1. A sample of the 7-aminoheptanol-1 (0.67 g., 0.0051 mole) in dry benzene (10 cc.) was treated with phenylisocyanate (0.61 g., 0.0051 mole). The product (m.p. 79.5–83° C.) was recovered by filtration, yield 1.25 g. (97%). One crystallization from acetone raised the melting point to 87–88° C. Anal. Calc. for $C_{14}H_{22}N_2O_2$: C, 67.16; H, 8.86; N, 11.20%. Found: C, 67.03; H, 8.71; N, 11.22%.

11-Bromoundecanoic Acid

11-Bromoundecanoic acid (m.p. 48° C.) was prepared in 69.9% yield from 11-undecanoic acid by the method of Ashton and Smith (7). The reported (7) melting point is 49.25° C.

11-Aminoundecanoic Acid

The patent procedure (8) for the preparation of 11-aminoundecanoic acid from 11-bromoundecanoic acid gave a 78.4% yield of product melting at 182–185° C. The reported (9) melting point of 11-aminoundecanoic acid is 186–187° C.

11-Aminoundecanoic acid (47 g., 0.23 mole) in 3.5 *N* methanolic hydrogen chloride solution was allowed to stand at room temperature for 16 hours. After most of the methanol was removed *in vacuo*, the crude methyl ester hydrochloride (m.p. 158–161° C.) was recovered by filtration, yield 51.1 g. (86.8%). One crystallization from methanol raised the melting point to 159.5–160.5° C. Anal. Calc. for $C_{12}H_{26}ClNO_2$: C, 57.24; H, 10.14; Cl, 14.09; N, 5.56%. Found: C, 57.33; H, 10.25; Cl, 14.35; N, 5.50%.

11-Aminoundecanol-1

Methyl 11-aminoundecanoate hydrochloride (m.p. 158–161° C.) (22.2 g., 0.088 mole) in methanol (400 cc.) was passed through a column of IRA-400 (OH) resin (400 cc. of resin previously washed with methanol) at a rate of 5–7 cc. per minute. The eluates and washings were evaporated to dryness *in vacuo* under nitrogen. The residue of crude methyl 11-aminoundecanoate melted at 70–85° C., yield 16.2 g. (85.3%). Pellets of metallic sodium (28 g., 1.2 moles) were added to the crude methyl ester (16.2 g., 0.075 mole) in absolute ethanol (500 cc.) at a rate to maintain the alcoholic solution at gentle reflux. After the solution cooled it was diluted with water (250 cc.) to decompose the excess sodium ethoxide. The methanol was removed *in vacuo* under nitrogen and the residual aqueous solution was extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated to dryness. A residue (m.p. 74–78° C.) of yellowish crystals was obtained, yield 4.0 g. (28.3%). This crude 11-aminodecanol-1 was purified by solution in warm methanol (13.5 cc./g.), and filtration and dilution of the filtrate with water (10 cc.). The final product melted at 71–73° C.

A sample (0.187 g., 0.001 mole) of 11-aminoundecanol-1 in dry benzene on treatment with α-naphthylisocyanate (0.169 g., 0.001 mole) gave 0.286 g. (80.2%) of crude 1-α-naphthyl-3-(11-hydroxyundecyl)-urea (m.p. 126–130° C.). Crystallization from acetone–benzene solution raised the melting point to 131° C. Anal. Calc. for $C_{22}H_{32}N_2O_2$: C, 74.11; H, 9.05; N, 7.86%. Found: C, 73.73; H, 9.05; N, 7.84%.

The aqueous filtrate from the chloroform extraction gave 16.5 g. of material melting at 197–205° C. This is considered to be the crude sodium salt of 11-aminoundecanoic acid. On treatment with concentrated hydrochloric acid solution it gave 11-aminoundecanoic acid hydrochloride (m.p. 148–149° C.). The latter material did not depress the melting point of a known sample of 11-aminoundecanoic acid hydrochloride (m.p. 148–149° C.).

Reaction of Amino Alcohols with Carbon Disulphide

The amino alcohol (0.05 mole) in absolute alcohol (25 cc). was added dropwise over a period of 20 minutes to a stirred solution of carbon disulphide (0.025 mole) at 5° C.

After the reaction mixture had remained at room temperature for several hours, it was refluxed for 9 to 15 hours. The colored alcoholic solution was treated with Norite A and filtered. The product was recovered by evaporating the filtrate to dryness *in vacuo* under nitrogen. The crystals were purified by crystallizing from a suitable solvent such as ethyl acetate. The properties of the symmetrical 1,3-di-(ω-hydroxyalkyl) thioureas prepared in this manner are given in Table I.

1,3-Di-(ω-hydroxyalkyl) Ureas

Method A

The 1,3-di-(ω-hydroxyalkyl) ureas with the exception of 1,3-di-(11-hydroxyundecyl)-urea were prepared in the manner described below for 1,3-di-(7-hydroxyheptyl)-urea.

To 1,3-di-(7-hydroxyheptyl)-thiourea (3.04 g., 0.01 mole) in alcoholic sodium hydroxide solution (34 cc. containing 0.8 g. of sodium hydroxide) hydrogen peroxide (5.08 cc. of 7.6 molar solution; 0.03 mole) was added dropwise at a temperature of 25–28° C. After the solution had been left at room temperature for 4 hours, it was diluted with water (250 cc.). The crystals (m.p. 121–122° C.) were recovered by filtration and dried, yield 2.77 g. (86.3%). One crystallization from absolute ethanol raised the melting point to 122–122.5° C.

Method B

1,3-Di-(11-hydroxyundecyl)-thiourea was converted in 88.3% yield into 1,3-di-(11-hydroxyundecyl)-urea (m.p. 128–129° C.) by the method of Kjaer *et al.* (2). Two crystallizations from ethyl acetate – ethanol (1:1) solution along with one treatment with Norite A raised the melting point to 134.5–136° C.

THE INFRARED SPECTRA OF MALONATE ESTERS[1]

R. A. ABRAMOVITCH[2]

ABSTRACT

The infrared spectra of a number of malonate esters have been examined. Most of them exhibit two ester carbonyl stretching bands which have been shown not to be due to enolization and conjugate chelation or to association. The influence of α-substituents is discussed, as well as the reason for the splitting of the band.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

During the course of another investigation diethyl 1-methyl-2-cyanoethylmalonate was prepared and its infrared spectrum examined. Two bands were observed at 1742 and 1730 cm.$^{-1}$ respectively which could only be attributed to the carbonyl groups of the ester functions. This was surprising, since Bellamy (5) states that diethyl malonate is essentially normal in its carbonyl frequency. The original authors (24), however, had only measured the spectrum up to 1750 cm.$^{-1}$. Bender and Figueras (7) remarked that diethyl malonate had an unusually broad (25 cm.$^{-1}$) band at 1740 cm.$^{-1}$, and indeed Felton and Orr (10) have recently shown that diethyl malonate exhibits two C=O stretching peaks at 1757 and 1740 cm.$^{-1}$ (in carbon tetrachloride solution). These authors ascribe the splitting either to symmetric and antisymmetric coupling of the two C=O stretching vibrations or to their resonance coupling with an overtone. In view of current interest in the splitting of carbonyl stretching frequencies the spectra of the malonate esters were examined in greater detail.

Vibrational coupling between carbonyl groups (16*a*) has been observed in a number of cases: diacyl and diaroyl peroxides (9), carboxylic acid anhydrides (23), and N,N-diacylamines (1). Recently, it has been suggested that glycidic esters dimerize in non-hydrogen-bonding solvents and that vibrational coupling then occurs between the carbonyl stretching motions of the two ester groups in the dimer (19). It should be pointed out, however, that whereas anhydrides exhibit two Raman bands corresponding to those found in the infrared (16*a*), the malonates, with one exception, show only one Raman shift in this region (18).

Preliminary examinations of some available malonates seemed to indicate that an α-hydrogen was necessary for two bands to appear, which would have pointed towards enolization with subsequent hydrogen bonding as the reason for the second peak. Thus, diethyl diethylmalonate and diethyl 2,2-*trans*-hydrind-5-enylmalonate only showed one band, though the former compound also had a very poorly-defined shoulder on the higher frequency side. Again, Felton and Orr (10) report only one band for diethyl *iso*propylidenemalonate though tetraethyl ethylenetetracarboxylate shows two. There is a large body of chemical evidence indicating that malonate esters have no appreciable enol content (3). In any case, had the second peak been due to a chelated carbonyl group its frequency should have been lower, and not higher, than the normal ester carbonyl stretching frequency. To examine the possibility of enolization and hydrogen bonding, diethyl ethyldeuteromalonate was prepared and compared with diethyl ethylmalonate; if enolization was taking place the position of the hydrogen-bonded carbonyl band would be altered on deuteration. Another possibility considered was that, when

the α-carbon atoms carried two substituents other than hydrogen, steric inhibition of vibrational coupling might occur and this could account for the single band observed in some cases. To investigate this, the spectra of diethyl *tert*-butylmalonate and di-*tert*-butylmalonate were recorded. Finally, a number of α-mono- and di-substituted malonates were examined in which the substituents varied in size and in electron attracting or repelling character.

EXPERIMENTAL

Most of the diethyl malonates used in this study were commercial samples purified by repeated fractional distillation when required. The author wishes to acknowledge gratefully the following gifts of specimens: diethyl 2,2-*trans*-hydrind-5-enylmalonate from Dr. H. B. Henbest; a sample of diethyl 1-acenaphthylmalonate from Dr. R. A. Heacock; and a sample of diethyl 1,1-dimethylprop-2-ynylmalonate from Dr. K. Mackenzie.

Di-*tert*-butylmalonate was prepared according to Backer and Homan (4). Diethyl bis-(2-cyanoethyl)-malonate was prepared according to Bruson and Riener (8) and had m.p. 62°. Diethyl *p*-nitrobenzylidenemalonate, m.p. 94°, was obtained from *p*-nitrobenzaldehyde and diethyl malonate in the presence of piperidine (17). Diethyl *tert*-butylmalonate was prepared in low yield by the action of *tert*-butylbromide on diethyl sodiomalonate (13). Diethyl 1-methyl-2-cyanoethylmalonate was prepared by the action of diethyl malonate on allyl cyanide in ethanolic sodium ethoxide (2).

Diethyl Ethyldeuteromalonate

Diethyl ethylmalonate (5 g., n_D^{23} 1.4150, redistilled, b.p. 212–214°) in absolute ethanol (20 ml.) containing sodium ethoxide (prepared from 0.615 g. sodium) was kept at room temperature overnight and then taken to dryness under vacuum to remove all traces of

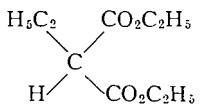
(5 cc.). Extraction with carbon tetrachloride and working up as above gave only a trace of a high boiling product, which proved to be diethyl diethylmalonate, b.p. 222° (I.R. spectrum identical with that of an authentic specimen but different from that of either diethyl ethylmalonate or diethyl ethyldeuteromalonate).

Infrared Spectra

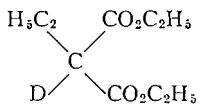
A Grubb-Parsons double-beam spectrometer, type S4, with a sodium chloride prism, was used. The measurements were carried out at slow chart speeds over the 6 μ range (at faster chart speeds the second band may be difficult to detect or appears only as a poorly defined shoulder) though they were carried out from 2 to 15 μ for some individual compounds. Points of interest other than in the 6 μ region are mentioned in the discussion. The frequency scale was calibrated by ammonia vapor bands (accuracy ± 3 cm.$^{-1}$ in the 6 μ region). Carbon tetrachloride and chloroform were analytical reagent grade, thoroughly dried before use. The measurements were carried out at a slit schedule of 1.5 mm. A variable-path cell was used to study the effect of dilution so that when the concentration of the solution was halved, for example, the cell thickness was doubled. The results are summarized in Tables I, II, and III. The relative intensities of the spectral bands are shown in parentheses, *i.e.* (vs) very strong, (m) medium, (w) weak, (sh) shoulder, (br) broad.

DISCUSSION

Most of the compounds examined exhibit two bands in the 5.6–5.9 μ region, with the notable exception of three of these: diethyl diethylmalonate ($\Delta\nu_{\frac{1}{2}}$ 46 cm.$^{-1}$, liquid film), diethyl ethylphenylmalonate, and diethyl 2,2-*trans*-hydrind-5-enylmalonate. The first two of these do have an indistinct shoulder, the first on the high and the second on the low frequency side of the peak respectively, whereas the third gives a broad band ($\Delta\nu_{\frac{1}{2}}$ 45 cm.$^{-1}$). In agreement with the chemical evidence (3), the presence of double peaks in compounds such as diethyl bis-(2-cyanoethyl)-malonate, diethyl *p*-nitrobenzylidene-malonate, and tetraethyl ethylenetetracarboxylate (10), in which no hydrogen atom is present *alpha* to the carbonyl groups, makes the hypothesis that the double peaks are due to enolization and conjugate chelation untenable. In support of this conclusion is the fact that the replacement of an α-hydrogen by a deuterium atom makes no apparent difference to the positions of the two bands in this region. This is seen particularly well when the spectra of diethyl ethylmalonate (I) and diethyl ethyldeuteromalonate (II) in carbon tetrachloride solutions are compared:

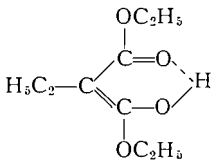


I

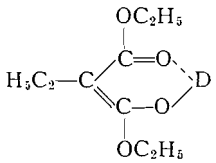


II

If enolization with consequent conjugate chelation had occurred, it would be expected that the positions of these carbonyl peaks would be shifted somewhat, which is not the case:



Ia



IIa

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Finally, the positions of the two peaks are not in agreement with those expected for chelated and unchelated carbonyl groups (22). On the other hand, some of the malonates which have an α-hydrogen atom do show a weak shoulder at 1700–1712 cm.$^{-1}$ when in solution, whereas those that do not have an α-hydrogen atom (with the exception of diethyl dibromomalonate, which is also abnormal in other respects) do not have this shoulder. This may be evidence of a very small extent of enolization, though other explanations are possible. Gordy (12) attributes a very weak band at 6.12 μ in the spectrum of ethyl malonate to the presence of a very small quantity of enol.

Dilution has no effect on either the position or the intensity of the double peaks (Table II), which means that end-to-end association of molecules, should it exist in the condensed state, is not the cause of the splitting of the C=O band (20). Also, Morris and Young (19) showed that, in a solvent such as chloroform (which was the solvent used in our dilution experiments), their suggested glycidic ester anti-parallel dimers dissociated into single molecules, so that our results indicate the absence also of such an association in the case of malonate esters as the cause of the two carbonyl peaks. It would be interesting to see if the positions and relative intensities of the peaks showed any temperature dependence. There is practically no shift in the positions of the bands on passing from the pure liquid to the solution spectra.

The absence of a second clear-cut peak in the cases of diethyl diethylmalonate and diethyl ethylphenylmalonate does not seem attributable to steric inhibition of vibrational coupling or dipole–dipole interaction between the two carbonyl groups, since when a single large group is present, as in the cases of diethyl *tert*-butylmalonate and diethyl 1-acenaphthylmalonate, as well as in di-*tert*-butylmalonate, the two bands still appear. The positions and the frequency differences between the two bands ($\Delta\nu$ = 11–25 cm.$^{-1}$) do, however, vary with the nature of the α-substituents (the influence of α-substituents is discussed in greater detail below), and a possible explanation is that, in the cases where only a single band or a band and an indistinct shoulder (only approximate position can be obtained) are observed, the two peaks are insufficiently resolved because $\Delta\nu$ is too small. The unusually large band widths at half maximal intensity ($\Delta\nu_{\frac{1}{2}}$) observed support this view.

The variation to a greater or lesser extent of the position of the peaks with the nature of the α-substituent makes it unlikely that resonance coupling of a C=O stretching vibration with an overtone should be the cause of the splitting, though it does not eliminate it as a possibility. Also, the absence of a clear-cut steric effect seems to rule out dipole–dipole interaction as the cause, since this would probably necessitate having the dipoles parallel to each other. A likely explanation for the double peaks seems, on the present evidence, to be symmetric and anti-symmetric coupling of the two C=O stretching vibrations, which would not, presumably, require such restricted steric conditions as would dipole–dipole interaction. Another possible answer, which would also fit in with some of the effects observed with α-halogeno substituents, would be some form of rotational isomerism, e.g. III $\rightleftharpoons$ IV:

III IV

Confirmation (or otherwise) of this possibility might be obtained from an examination

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

of the temperature dependence, if any, of the spectra (14). It is hoped to investigate this soon. The vibrational coupling hypothesis would fit in with the positions of the double peaks rather well. Thus, ethyl acetate absorbs at 1748 cm.$^{-1}$, and the introduction of an electron-withdrawing substitutent *alpha* to the carbonyl group raises the C=O stretching frequency by increasing the double-bond character of the carbonyl group. The ester band in ethyl cyanoacetate is at 1754 cm.$^{-1}$ and a similar (though somewhat lesser) effect to that of the cyano group is to be expected by the introduction of an α-ethoxycarbonyl group, as in diethyl malonate, in which the common ester stretching frequency should be *ca.* 1750–1752 cm.$^{-1}$. Splitting of the C=O band precludes the observation of this effect, though two things can be noted: (i) the mean position of the two components (1751 cm.$^{-1}$) is higher than that of the band for ethyl acetate, and (ii) the C=O band is split into two components, one at a frequency higher, and the other at a frequency lower, than the common value expected had no splitting occurred. Such behavior is typical of groups undergoing vibrational coupling (16*a*).

In view of the splitting of the C=O band it is rather difficult to correlate the nature of the α-substituent with its effect on the stretching frequency. It is clearly not justifiable to consider the influence of the substituent on the position of either one of the bands, and the only way is to consider the mean of the two peaks. The use of this frequency in any correlation is of a rather doubtful nature, however, since $\Delta\nu_{C=O}$ varies from one substituent to another and, though vibrational coupling is the most likely explanation of the splitting, other possibilities have not been completely ruled out, as mentioned above. In the case of the monocarboxylic acids and esters, lengthening of the alkyl chain causes a slight fall in the C=O frequency, as in ethyl propionate (1740 cm.$^{-1}$) compared with ethyl acetate (1744 cm.$^{-1}$) (see Table III). This is in line with the electron-repelling character of the methyl group. A similar, though weaker, effect takes place when one of the α-hydrogen atoms in diethyl malonate (1751 cm.$^{-1}$) is replaced by an ethyl group (1750 cm.$^{-1}$), and a still larger fall (in the mean position) occurs when it is replaced by an *n*-propyl group (1745 cm.$^{-1}$). When both α-hydrogen atoms are replaced by ethyl groups the mean frequency falls still further to 1744 cm.$^{-1}$. With a single *n*-butyl substituent the frequency rises slightly to 1747 cm.$^{-1}$ and with a single α-*tert*-butyl substituent it *rises above* the mean value for diethyl malonate, to 1754 cm.$^{-1}$. It appears, therefore, that a steric effect *is* in operation with α-alkyl substituents, and that it acts in opposition to the inductive and hyperconjugative effect of these groups. The nature of this steric effect is not clear (rotational isomerism?), and though it does not inhibit the splitting of the band it seems to raise the mean C=O stretching frequency. (*This, of course, obtains only if the use of the mean of the two frequencies is valid.*) The very slight increase caused by an α-phenyl group (1752 cm.$^{-1}$) could be due either to its –I effect or to its steric effect, and in the ethylphenyl derivative the frequency falls to 1745 cm.$^{-1}$. The –I effect of the α-acetamido group is seen in the increase to 1753 cm.$^{-1}$, whereas the effect of $\alpha\beta$-unsaturation in diethyl *p*-nitrobenzylidenemalonate (1731 cm.$^{-1}$) and in diethyl *iso*-propylidenemalonate (1726 cm.$^{-1}$) is clear. The influence of α-halogens is not straightforward. As is well established, in general, halogenation of the alkyl group *alpha* to a carbonyl raises the C=O frequency, the magnitude of the shift increasing with the increasing dipole moment of the C—X bond (viz. F > Cl > Br > I) (16*b*) (Table IV).

Further, Jones *et al.* (15) showed that while an equatorial bromine atom *alpha* to a keto group in steroidal *cyclo*hexanones causes an increase in the C=O frequency of 13–19 cm.$^{-1}$ by virtue of a Coulombic field effect which outweighs its inductive effect, introduction of a second bromine atom at the same α-carbon atom to form a *gem*-dibromide produces no, or only a slight, further increase, which can be associated with residual

inductive effects (6). Diethyl chloromalonate shows the expected strong increase in frequency (1760 cm.$^{-1}$); in diethyl bromomalonate the increase is still larger (1761 cm.$^{-1}$), which is the reverse of the order expected on the basis of electronegativity (Table IV) (see also Ref. 16*c*). Furthermore, the introduction of a second bromine atom to give diethyl dibromomalonate *lowers* the frequency to 1758 cm.$^{-1}$. It seems likely that the governing factor which produces the first increase is connected with the size of the halogen atom (Br > Cl) and that the second bromine introduced interferes sterically or otherwise with the first bromine–carbonyl interaction. It may be worth noting in this connection that the ratio of the intensities of the two carbonyl peaks is reversed on passing from the monochloro- and monobromo-malonates, to the dibromo-malonate.

The spectrum of diethyl ethyldeuteromalonate was interesting in that no C—D stretching band could be detected. This is not altogether surprising, for two reasons: (i) in most aliphatic hydrocarbons no peak attributable to the stretching vibration of a tertiary C—H bond can be discerned (16*d*), especially in this case, where only one such group exists in the molecule so that its contribution to the integrated absorption intensity on the basis of Francis' equation (11) would be very small; (ii) the force constant of the α-tertiary C—H bond in malonates would be expected to be rather weak and the band would, therefore, be shifted towards the long wave-length region. It may be possible that the additional shift in the same direction caused by substituting deuterium for hydrogen would move the band close to the carbonyl region, where it could not be detected. The presence of the C—D linkage in this compound is readily detected in the 'bending' region of the spectrum, and by a comparison of the spectrum with those of diethyl ethylmalonate and diethyl diethylmalonate over this range. In Table V the abbreviations h = high, l = low, and e = approx. equal intensities have been used to compare very roughly the relative intensities of corresponding peaks in the three compounds.

Some of the peaks present in diethyl ethylmalonate are shifted to lower frequencies

in the deutero compound and the ratio of intensities of some peaks is altered considerably. The spectrum of the deutero compound falls in very nicely as a mixture of parts of the ethyl and parts of the diethyl spectra, as expected.

An interesting reaction was observed when diethyl ethyldeuteromalonate was treated with sodium ethoxide in absolute ethanol (slight heat evolved), kept overnight, and the mixture taken to dryness and treated with water. Instead of the expected diethyl ethylmalonate there was obtained a very small amount of diethyl diethylmalonate, identical in boiling point and infrared spectrum with an authentic specimen. In view of the repeated purifications to which the diethyl ethyldeuteromalonate was subjected, it is unlikely that any diethyl compound was present in it before the sodium ethoxide treatment. The reaction probably involves a disproportionation, as *no* diethyl ethylmalonate was isolated from the product. That the ethyl group should have come from the sodium ethoxide or the alcohol used seems unlikely.

HYDROGEN ABSTRACTION REACTIONS OF DIPHENYLPICRYLHYDRAZYL[1]

A. G. Brook, R. J. Anderson, and J. Tissot Van Patot

ABSTRACT

The stable free radical diphenylpicrylhydrazyl (DPP·) has been found to react quantitatively with ammonia and hydrazine forming nitrogen and diphenylpicrylhydrazine, and less cleanly with hydroxylamine forming diphenylpicrylhydrazine and nitrous oxide. The reactions of DPP· with a variety of amines are not clean, in part owing to the formation of complexes of the amines with the reaction product diphenylpicrylhydrazine. Preliminary investigations of the reactions of DPP· with mercaptans have shown that these otherwise clean reactions have a variable stoichiometry, dependent on the concentration and other reaction conditions.

The stable free radical diphenylpicrylhydrazyl (DPP·), while not in general a powerful dehydrogenating agent, nevertheless shows considerable facility in removing hydrogen atoms attached to a nitrogen atom in a variety of compounds (3). In order to study this behavior further we have investigated the reactions of DPP· with a number of simple compounds having N—H bonds, and also with some mercaptans.

The ability of the radical to abstract hydrogen atoms from nitrogen is evidently a general reaction but a marked variation in the "cleanliness" of the reactions was noted. It was found that DPP· quantitatively converted both ammonia and hydrazine to nitrogen, being itself reduced to diphenylpicrylhydrazine (DPPH), according to the following equations:

$$3\text{DPP}\cdot + \text{NH}_3 \rightarrow 3\text{DPPH} + \tfrac{1}{2}\text{N}_2$$

$$4\text{DPP}\cdot + \text{N}_2\text{H}_4 \rightarrow 4\text{DPPH} + \text{N}_2$$

These reactions occurred relatively rapidly at room temperature and could be followed by collection of the gas evolved, and also by observing the disappearance of the characteristic intense purple color of the radical. The DPPH formed could be isolated practically quantitatively. Typical results are summarized in Table I. Attempts to partially dehydrogenate ammonia to give hydrazine failed, and the volume of gas collected indicated that complete oxidation of one-third of the ammonia occurred.

DPP· also reacts rapidly with hydroxylamine but the reaction is not as clean as those above, nor is the stoichiometry as clearly defined. Dilute solutions of the reagents can be "titrated" against one another to a clear orange-brown end point formed as the purple color of the radical disappears. From such experiments the molar ratio of DPP· to hydroxylamine was found to lie between 2.88 and 2.98. From larger runs in more concentrated solutions, carried out to afford reasonable quantities of reduction products and gas for examination, the molar ratio varied from 2.5 to 3.1. The major reduction product again was DPPH, isolated in 89% yield, and the gas was shown by its infrared absorption spectrum to be nitrous oxide. The most reasonable equation representing these data is as follows:

$$6\text{DPP}\cdot + 2\text{NH}_2\text{OH} \rightarrow 5\text{DPPH} + \text{N}_2\text{O} + \text{DPPOH?}$$

However, no product corresponding to 1-hydroxy-1-picryl-2,2-diphenylhydrazine (DPPOH), a known compound (6), was detected although small amounts of other products were isolated by chromatography of the reaction mixture. Since the ratio of DPP· to hydroxylamine and the amount of gas evolved in most cases corresponded fairly well to that predicted by the above equation it seems probable either that any DPPOH formed decomposed during the working up of the reaction or that other reactions are also occurring to a small extent. In support of this reasoning is the fact that more DPP· was converted to DPPH (89%) than is predicted by the equation (83%). These results are listed in Table II.

DPP· also reacts with a variety of amines but the nature of the reaction is not clear. Titration of very dilute (0.0005 *M*) solutions of the radical and methylamine to an orange end point indicates a molar ratio of radical to amine of 2.0, and the same ratio seems to hold for isopropylamine and *n*-butylamine also. Of the amines investigated only methylamine evolves significant quantities of gas, which by the absence of any characteristic infrared spectrum appears to be nitrogen. However the volume of gas evolved varied markedly with the solvent (see Table II).

From relatively large scale runs in concentrated chloroform solution the main reduction product isolated from all the amines investigated was DPPH, in amounts corresponding to 50–75% of the DPP· originally present. The remaining products were either intractable tars or amorphous solids which had variable and wide melting point ranges which recrystallization failed to improve. All that can be definitely stated about the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

reactions of the radical with these primary amines is that one of the amino hydrogens is readily abstracted by DPP· and that the resulting radical then apparently reacts in a variety of ways, in part with a second equivalent of DPP· and perhaps also with the solvent.

We also investigated to some extent the reaction between DPP· and diethylamine but the stoichiometry of the reaction could not be definitely extablished. In non-polar solvents the reactions were extremely slow while in polar solvents the reaction mixture became a muddy brown-black color as the reaction proceeded instead of the typical clear orange-brown color. Work-up of these reaction mixtures yielded as major products DPPH and a black solid which at about 115°–120° turned red and then melted at 172° as if it were pure diphenylpicrylhydrazine. It was shown that this latter material was a 1:1 complex of diphenylpicrylhydrazine and diethylamine.

The reactions of the radical with amines were much slower than those with the other reagents previously described. This led to the interesting observation that the rates of reduction of DPP· were much more rapid in polar solvents such as methanol or ethanol than in non-polar solvents such as benzene or chloroform, and furthermore, that in the polar solvents the final reaction mixtures were usually an opaque muddy brown color while in the non-polar solvents the reaction mixtures were a clear orange or orange-brown color. It was found that the intensity of this muddy brown color could be markedly changed by dilution, especially with a non-polar solvent, so that the system became clear orange-brown, or that this color could be turned to muddy brown by the addition of more amine solution. These observations are explained if a complex is formed between diphenylpicrylhydrazine and the amine which can dissociate into its components depending on the polarity of the medium and the concentration of the solution.

$$\mathrm{DPPH} + \mathrm{R_2NH} \rightleftarrows \mathrm{DPPH.R_2NH}$$

Such a complex was actually isolated in the case of diethylamine. It is obvious that such complex formation will completely confuse any stoichiometric determinations which may depend on the color of end points.

That the rate of a homopolar reaction should be dependent on the polarity of the medium is not unreasonable, since in these reactions the most probable means for transfer of a hydrogen atom from donor to acceptor is through formation of a complex between the amine and stable free radical (3). Such complexes involving the picryl group of DPP· would be expected to be more readily formed and to be more stable in polar solvents, as are the well-known complexes of amines with polynitroaromatic compounds (8). If hydrogen transfer depends on the formation of such complexes, it is not surprising that dehydrogenation occurs more rapidly in a medium favorable to their formation. Nor is it surprising that DPPH forms similar complexes in polar solvents.

We have also investigated briefly the reactions of DPP· with thiophenol and butyl mercaptan. These reagents react rapidly with the radical but, unlike in the other reactions studied, the molar ratio of DPP· to mercaptan varied markedly, being dependent on the concentration of the solutions and their order of addition. This was particularly noticeable with thiophenol, for in very dilute solution, when the radical was added to the thiophenol, the mole ratio was approximately 1.0 but in concentrated solution with the reverse order of addition the mole ratio was between 1.9 and 2.0. With butyl mercaptan there appeared to be less dependence on the order of addition and the mole ratio varied from 1.0 to 1.15 over a range of concentrations. These results can be explained by assuming the following reactions to be occurring:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

(*a*) DPP· + RSH → DPPH + RS·

(*b*) 2RS· → RSSR

(*c*) DPP· + RS· → DPPSR

The over-all stoichiometric ratio of the reaction depends on the relative importance of reactions (*b*) and (*c*), which depend strongly on concentration and on the various species present in the reaction mixture. In dilute solution, where DPP· is added to thiophenol, reaction (*b*) evidently occurs almost to the exclusion of (*c*), but in concentrated solution, where RS· radicals are being formed in the presence of DPP·, coupling of the unlike radicals occurs (reaction *c*) almost exclusively. When the reactions were worked up it was found that a mixture of compounds was obtained from which DPPH could be separated by chromatography and recrystallization. No success was achieved in isolating the thio derivative DPPSR.

With butyl mercaptan reaction (*c*) was evidently slower than (*b*), since the molar ratio varied over a much smaller range and appeared to be less dependent on the concentration of the reagents or the order of addition. In accord with this, relatively high yields (75%) of DPPH were isolated from the reactions. The kinetics of this reaction, in excess butyl mercaptan, have been reported (7).

It is obviously impossible to speculate at this stage as to the nature of the intermediate radicals produced during the dehydrogenation of hydrazine, ammonia, or hydroxylamine, but it is apparent from the last two cases that dimerization occurs at some stage. It is hoped that further insight into these reactions may be gained by kinetic studies on some of the simpler systems. It is obviously desirable to work with these relatively clean systems, since much of the work reported here is disappointing because of the difficulties found in isolating crystalline products in good yield, thus leaving the conclusions as to the processes occurring in many of the reactions rather speculative.

EXPERIMENTAL

All yields of diphenylpicrylhydrazine (DPPH) are based on the moles of diphenylpicrylhydrazyl (DPP·) reduced.

Materials

DPP· was prepared according to the method of Goldschmidt and Renn (4) as modified by Poirier *et al.* (6). The purple solid was dried *in vacuo* for several hours at 80° to remove the complexed chloroform (5). Anhydrous hydrazine (1) and anhydrous hydroxylamine (2) were prepared by published procedures. All solvents were purified and the liquid amines were distilled. Methylamine solutions were usually prepared by treating a mixture of the appropriate organic solvent and 30% aqueous methylamine solution with sodium hydroxide pellets to remove the bulk of the water. The supernatant liquid was decanted and dried over anhydrous sodium sulphate and then standardized against standard acid using methyl orange indicator. In some cases methylamine was prepared by liberating the amine from methylamine hydrochloride with alkali. Tank ammonia was used. All solutions were freshly prepared and frequently standardized.

Bulk Reactions of DPP·

A. Hydrazine

To 25 ml. of methanol containing 0.00125 mole of hydrazine was added 1.97 g. (0.0050 mole) of DPP· in 25 ml. of chloroform. The violet color of the radical disappeared as the solution successively became violet-red, amber, and finally orange-brown over a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

period of about 1 hour. Evaporation of the solution to dryness gave 1.97 g. (100%) of DPPH, m.p. 171°–172° (dec.), identified by mixed melting point with an authentic specimen. Recrystallization from 1:2 chloroform–ethanol failed to raise the melting point. If more than 4 equivalents of DPP· were added the solution remained purple and unchanged free radical could be recovered.

B. Ammonia

To 25 ml. of methanol containing 0.0013 mole of ammonia was added 1.54 g. (0.0039 mole) of DPP· in 25 ml. of chloroform. After 1 hour the solution was orange-brown and 1.54 g. (100%) of red DPPH, m.p. 171°–172° (dec.), was isolated.

C. Hydroxylamine

To 5.0 g. (0.00634 mole) of DPP· in 35 ml. of chloroform was added in 0.2 ml. aliquots a total of 5.7 ml. (0.00412 mole) of a 0.723 *M* solution of hydroxylamine in methanol. The reaction mixture was stirred magnetically and the reaction vessel was connected to a mercury-filled gas burette so that any gas evolved could be collected and measured. Gas was steadily evolved and the color changed from purple to orange-brown regularly until about 5.5 or 5.7 ml. of hydroxylamine solution had been added. No significant changes on further additions of hydroxylamine occurred. Toward the end of the addition a red solid precipitated from the reaction mixture. About 20 ml. of gas was evolved, which was shown by its infrared absorption spectrum to be nitrous oxide. This spectrum also contained absorption bands due to chloroform vapor so that a comparison was made with a gas sample made up of chloroform vapor and authentic nitrous oxide, which proved to be identical in every respect. The precipitate was filtered off and shown to be 2.52 g. (50.5%) of DPPH, m.p. 171°–172° (dec.). The filtrate was placed on a 3×25 cm. chromatography column of activated alumina and was eluted with several hundred milliliters of chloroform. Evaporation of this eluate to dryness followed by recrystallization from chloroform–ethanol gave an additional 1.96 g. (39.2%, total 89.7%) of DPPH, m.p. 171°–172° (dec.). A black band remained on the column which was eluted with ethanol to give an intense red colored solution. On evaporation to dryness this yielded 0.24 g. of a green-black solid which appeared to decompose at about 88° and which frothed at 120°. It was insoluble in dry benzene or chloroform but was soluble to give an intensely red solution in ethanol or ethyl acetate. It could not be recrystallized from these solvents or solvent pairs, since only gums were formed.

D. Methylamine

To 3.5 g. (0.0089 mole) of DPP· in 25 ml. of chloroform was added an excess (0.0087 mole) of methylamine in 5 ml. of chloroform. The color of the solution changed very slowly over 1–1.5 hours until it became orange-brown. About 25 ml. of gas was evolved. The infrared spectra showed absorption characteristic only of chloroform and methylamine vapors, as shown by comparison of a spectrum made up of these two substances; hence it seems likely that the major part of the evolved gas was nitrogen. To guard against the possibility that the excess of methylamine was responsible for the gas evolved, other runs with a deficiency of methylamine were made. Spectra of the gas evolved in these runs showed only the presence of chloroform and a trace of methylamine, neither of which would account for the volume of gas evolved.

The filtrate from this run was chromatographed on alumina and eluted with chloroform. A total of 2.24 g. (64%) of DPPH, m.p. 171°–172° (dec.), was isolated together with small traces of intractable gums and amorphous solids which could not be purified by crystallization.

E. n-Butylamine and Isopropylamine

When 14.2 g. (0.036 mole) of DPP· in 100 ml. of ethanol was treated with 1.85 g. (0.025 mole) of *n*-butylamine the color changed from purple to a muddy brown-black color over a period of 1 hour. Only a trace (1–2 ml.) of gas was evolved. A black precipitate weighing 7.75 g. (55%) of crude DPPH, m.p. 164°–172° (dec.), was filtered off and recrystallized from ethanol–chloroform to yield 6.5 g. (46%) of pure DPPH, m.p. 170°–172° (dec.). The filtrate from the original precipitate was evaporated to dryness, dissolved in chloroform, and chromatographed on alumina to yield an additional 0.9 g. (6%) of DPPH, m.p. 170°–172° (dec.), 0.42 g. of a dark solid, m.p. 205°–207° (dec.), which decomposed on attempted recrystallization from chloroform, and some tars which could not be induced to crystallize.

To 39.4 g. (0.1 mole) of DPP· in 300 ml. of diethyl ether was added 2.95 g. (0.05 mole) of isopropylamine. Over a period of several days the reaction mixture became brown. The suspension was filtered and 31.1 g. of solid was collected. Concentration of the filtrate yielded an additional 2.65 g. of solid. Aliquots of this 33.75 g. of solid were chromatographed on alumina. Elution with benzene of a 5-g. sample led to the isolation of 4.15 g. (83% of sample, 71% yield) of DPPH, m.p. 171°–172° (dec.), whose color was red-brown rather than the characteristic red. Elution with ethanol yielded a second fraction, 0.25 g. of brown-black amorphous material which melted at 184°–200° (dec.). Recrystallization from ethanol–petroleum (b.p. 90°–100°) failed to improve the melting range.

F. Diethylamine

To 0.5 g. (0.00126 mole) of DPP· in 25 ml. of 95% ethanol was added 0.00069 mole of diethylamine in 5 ml. of ethanol. The solution turned brown over 24 hours and a reddish brown after 48 hours. Red crystals were slowly deposited over 4 weeks and were filtered to yield 0.27 g. (54%) of DPPH, m.p. 171°–172° (dec.), identified by mixed melting point. The filtrate was evaporated to dryness and the resulting red-brown gum was redissolved in benzene and chromatographed on alumina. Two fractions were obtained, one of which was 0.04 g. (8%) of crude DPPH, m.p. 154°–170° (dec.), and the second, 0.02 g., melted at 77°–115° (dec.).

Alternatively, 5.00 g. (0.0127 mole) of solid DPP· was treated with about 10 ml. of diethylamine, the excess amine acting as solvent. There was immediate effervescence, the mixture became warm, and the suspension turned brown. After 1 hour 50 ml. of chloroform was added to dissolve the solid which was present. The solution was concentrated and cooled and a total of 0.58 g. (11%) of black crystalline solid was filtered off. This material started to change color at 90° and by 115° was bright red. It finally melted at 171°–172° (dec.), and a mixed melting point with DPPH was not depressed. This material was identical in behavior to the 1:1 complex of DPPH and diethylamine described below.

The remainder of the filtrate was evaporated to dryness under reduced pressure to yield a red gum. Chromatography on alumina yielded 2.0 g. (40%) of DPPH, m.p. 170°–172° (dec.).

Preparation and Identification of DPPH–Diethylamine Complex

To a red solution of 1.00 g. (0.00252 mole) of DPPH in 70 ml. of acetone was added 10 ml. (0.10 mole) of diethylamine. To this dark opaque solution was added 800–900 ml. of water and after it was cooled to 4° for 16 hours, 0.71 g. (61%) of black crystals was filtered off. This material began to change to red at 100° and by 120° was completely bright red. It then melted at 170°–172° (dec.). This material was similar in all respects

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

to that described above and a mixed melting point was not depressed. This material is the 1:1 complex of DPPH and diethylamine as shown below.

A 0.40-g. (0.00085 mole) sample of the black complex was heated at 120°–140° for 20 minutes while air was passed over the solid and then bubbled into a known amount of standard acid. The acid was then back-titrated with base, which showed that 0.00084 mole of diethylamine had been collected. The residue, which was a light red solid, weighed 0.33 g. (0.00084 mole) and was shown to be DPPH, m.p. 170°–172° (dec.), by its melting point which was not depressed when admixed with authentic DPPH. Thus the black solid is a 1:1 complex of DPPH and diethylamine, and the diethylamine was recovered in 99% yield. A second experiment gave identical results.

When a small sample of the black complex was dissolved in a few milliliters of chloroform an opaque brown solution was obtained. On dilution, the solution gradually became a clear orange-brown color characteristic of solutions of DPPH. Addition of more diethylamine converted the color back to the opaque brown color. Similarly if the opaque brown solution was shaken with concentrated hydrochloric acid, the solution became a clear orange-brown or red color, depending on the concentration.

When solutions of the complex of approximately the same concentration were made up in ethanol, acetone, and chloroform, the more polar solvents produced darker, browner solutions. Addition of a polar solvent, e.g. ethanol, to the chloroform solution produced an even darker solution, indicating that the opaque brown color was intimately associated with the polar medium.

Titration Experiments with DPP·

A. With Hydroxylamine

Dilute standard solutions of DPP· and hydroxylamine (0.002–0.005 *M*) in benzene or in ethylene glycol monomethyl ether were prepared. Known volumes of the hydroxylamine solution were titrated with the DPP· solution to an end point where a permanent pale purple color persisted. Several runs gave the following values for the molar ratio of DPP· to hydroxylamine: 2.97, 2.88, 2.98, 2.96. Evaporation of these solutions to dryness gave impure material melting at 145–170° (dec.).

B. Methylamine

Similar experiments to those described above carried out in ethanol solution gave the following values for the molar ratio of DPP· to methylamine: 1.91, 2.05, 2.07, 1.97.

C. Thiophenol

To 0.75 g. (0.0019 mole) of DPP· in 10 ml. of chloroform was added slowly a 0.374 *M* solution of thiophenol in ethanol. The color changed rapidly from purple to opaque brown to clear red-brown during the addition of 2.6 ml. (0.00097 mole) (mole ratio 2:1) of the thiophenol solution. Evaporation to dryness and recrystallization from 1:3 chloroform–ethanol yielded 0.30 g. of orange-red solid which appeared to be identical in all respects to DPPH except that the material melted at 132–134° with decomposition. A similar behavior has been previously described (7). Recrystallization failed to improve the melting point markedly. The material was chromatographed on alumina, and elution with benzene and then 1:1 benzene–chloroform yielded the following fractions, with their respective melting points: (1) 0.09 g. (12%), 172–173° (dec.), identified as DPPH by mixed melting point; (2) 0.05 g., 160–164° (dec.); (3) 0.03 g., 150–153° (dec.); (4) 0.05 g., 131–139° (dec.). Recrystallization failed to improve the melting points of the impure fractions.

When an identical run to that above was carried out except that the DPP· was dis-

solved in 100 ml. of chloroform and 50 ml. of ethanol, and the thiophenol solution was diluted 20-fold, 72 ml. (0.00133 mole) of thiophenol (mole ratio 1.43:1) was required to produce a clear orange-brown end point. The products isolated were similar to those described above, and DPPH was obtained in 14% yield.

When approximately 0.01 *M* solutions of the reagents were titrated against one another the mole ratios of radical to mercaptan were 1.09–1.16 when thiophenol was added to DPP·, and 1.00 when the DPP· was added to the thiophenol solution.

D. Butyl Mercaptan

To 0.20 g. (0.0005 mole) of DPP· in 25 ml. of chloroform was added 0.00061 mole of butyl mercaptan in 25 ml. of ethanol. The color changed from purple through opaque red-brown to clear orange-red over a few seconds. The solution was concentrated to yield, after recrystallization, 0.15 g. (75%) of DPPH, m.p. 169–172° (dec.), identified by mixed melting point.

When dilute (0.02 *M*) solutions of DPP· and butyl mercaptan were titrated against one another as described above the moles of radical per mole of mercaptan varied between 1.0 and 1.15, depending on the concentration, but the ratio did not seem to depend on the order of addition of the reagents.

Gas Evolution Experiments

In experiments in which gas evolution was quantitatively determined, the 50 ml. reaction vessel, equipped with magnetic stirrer and maintained at constant temperature by a water bath, was connected by capillary tubing to a 50-ml. burette filled with mercury which was attached to a mercury levelling bulb. The general procedure was as follows. In experiments in which it was established that nitrogen was evolved, all solutions were presaturated with nitrogen. The DPP· dissolved in the major portion of the solvent (concentration approximately 10 ml. per g.) was placed in the reaction flask, the system was closed off, and the solution was stirred and allowed to reach equilibrium. Then the hydrogen donor solution (sufficiently concentrated that the volume added was not more than 20% of the total volume of the system) was admitted from a 5-cc. burette which was attached to the reaction vessel through a ground-glass joint. The mercury levelling bulb was continually adjusted to maintain atmospheric pressure in the reaction flask.

The hydrogen donor solutions were added in arbitrary amounts in the cases of hydrazine and ammonia, after which the volume of gas evolved was measured, or else the hydrogen donor solution was added dropwise until a clear orange-brown end point was obtained, and significant changes in the volume of gas evolved ceased.

Tables I and II summarize the results obtained from a variety of hydrogen donors.

EXCHANGE BETWEEN THALLOUS AND THALLIC IONS IN THE PRESENCE OF SULPHATE ION[1]

D. R. WILES

ABSTRACT

The rates of the exchange reaction between thallous and thallic ions have been measured as a function of sulphate ion concentration, at constant acidity. At high sulphate concentrations, the results agree with those of Brubaker and Mickel, indicating second- and higher-order dependence of the rate on sulphate ion concentration. At low sulphate concentrations, pure first-order dependence on sulphate is found. The inhibitive effect found in some systems is absent. A bridge-transfer mechanism is suggested.

INTRODUCTION

The exchange between thallous and thallic ions in aqueous solution has been studied during the past several years by a number of workers, under a variety of conditions (1, 2, 3, 4, 5). It has generally been found that any change in the nature or number of ligands attached to one or other of the exchanging ions has a distinct effect on the rate of the exchange reaction. This effect amounts, in the case of most of the anionic ligands studied (e.g. hydroxyl, nitrate), to a positive catalysis of the reaction. In other cases (e.g. chloride and cyanide) the exchange rate is markedly decreased at low concentrations of the anion and very greatly increased at higher concentrations.

The present work is an investigation of the nature of the kinetics of the thallous–thallic exchange in perchloric acid solutions containing varying small concentrations of sulphate ion. This work is complementary to that of Brubaker and Mickel (1), who have reported recently on this exchange in somewhat stronger sulphate solutions.

EXPERIMENTAL

Thallous perchlorate was crystallized from a solution of reagent grade thallous nitrate to which had been added a considerable excess of perchloric acid. Crystallization was repeated once from strong perchloric acid, and once from water. Ferric ion was added to the solution of these crystals, and precipitated as hydroxide with ammonia. The thallous perchlorate was twice more crystallized from water, dried for 1 hour at 105°, and dissolved in water to make a stock solution 0.100 molar in thallous ion. This solution showed no darkening on neutralization, which indicated negligible contamination by thallic ion.

The thallic perchlorate solution was prepared from reagent grade thallic oxide which had, in turn, been purified of thallous ion by repeated precipitation with ammonia and redissolution in excess perchloric acid. The purified thallic oxide was dissolved in an excess of perchloric acid, to make a stock solution 0.100 molar in thallic ion, and 4.7 molar in excess acid. Radioactive Tl^{204} in the form of a solution of thallic nitrate was added at an early stage in the purification. Failure to show turbidity on addition of iodide to an aliquot of this stock solution set the limiting concentration of thallous ion at $\ll$0.004 molar, i.e. $\ll$4%. In both these preparations, heating of solutions was kept to a low minimum because of the danger that some chloride ion might be formed as a decomposition product of perchloric acid. Analysis of the solutions was done by precipitation of thallous chromate, which was dried and weighed as such. All other reagents were reagent grade, and were used with no further purification.

Exchange measurements were done by using the radioactive tracer as thallium(III) and observing its appearance in the thallous state. Separation of the thallous ion from the reaction mixture was done by the method of Prestwood and Wahl (5) using sodium chromate as precipitating agent, in an alkaline cyanide medium to prevent precipitation of thallic species. The thallous chromate precipitate was filtered onto tared filter disks, dried, weighed, and mounted on cards with cellulose tape. Counting of these radioactive samples was done with an end-window proportional counter, using a flowing methane–argon gas mixture.

Solutions for exchange measurements were made up to 0.010 M in each of thallic and thallous species, and 3.12 M in total acid (i.e. $[H_2SO_4]+[HClO_4] = 3.12$).* Solutions were made complete but for the thallous ion, and allowed to come to equilibrium with the constant temperature bath before addition of the thallous solution.

The errors involved in this type of work are very difficult to assess. Constancy in the weights of the samples counted made correction for back-scattering and self-absorption unnecessary. Observed activities in these samples are estimated to be in error by no more than 5%. The standard deviation of the measured specific activities of the "infinite time" samples was ±2%. It is thus likely that individual rate measurements are, in general, accurate to about ±10%, and internally consistent to ±5%.

RESULTS AND DISCUSSION

The results of the kinetic studies of the exchange are given in Table I.

Data plotted for the complete range of sulphate concentrations studied are shown in Fig. 1. These data show that the over-all dependence on sulphate concentration is

TABLE I

[a]*The values of* $[SO_4^{=}]$, $[H^+]$, *and* μ *were computed using the data of Smith (6) for the dissociation of* H_2SO_4. *For values of* $[SO_4^{=}] < 0.05$ *the variations in* $[H^+]$ *and* μ *are* $\leqslant 2\%$, *and are likely insignificant.*

[b]*Rate* $(R) = [Tl(III)][Tl(I)]/([Tl(III)] + [Tl(I)])$. $0.693/t_{\frac{1}{2}}$. *For the concentrations used in the present work,* $R = 5\times10^{-3}$. $0.693/t_{\frac{1}{2}}$.

Consideration of H_2SO_4 as effectively monobasic, for purposes of determining ionic strength, was based upon widely used but evidently inapplicable dissociation data. The author is very grateful to Dr. C. H. Brubaker for drawing attention to work by Smith (6), who has measured the concentration of the various species in sulphuric acid solutions over a wide range of ionic strength. At the ionic strengths used in the present work, Smith indicates a value of 1.3 for the dissociation constant of the bisulphate ion. The present work was, unfortunately, completed without reference to the more recent values. Values of the sulphate concentration reported in this paper were recalculated in accordance with Smith's data. Only at sulphate concentrations of greater than 0.1 M will the ionic strength and acidity vary significantly from the intended 3.12 M.

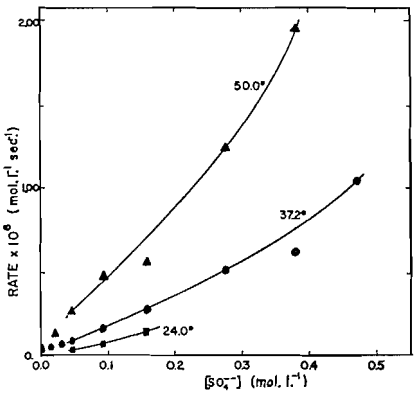

FIG. 1. Thallous–thallic exchange rates.

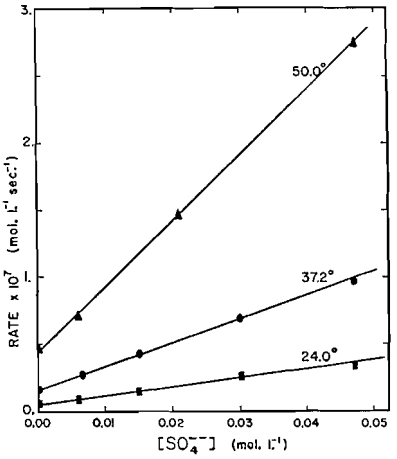

FIG. 2. Thallous–thallic exchange rates at low sulphate concentration.

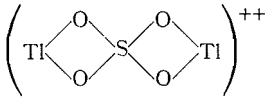
greater than the first order. This is in agreement with the results of Brubaker and Mickel (1) and indicates that more than one ligand takes part in the rate-determining step.

In Fig. 2 are plotted the exchange data for low values of the sulphate concentration. In this range, the dependence is linear, and the participation of only one sulphate group is indicated at these low sulphate concentrations.

Perhaps the most significant characteristic of the present rate curves is that they do not show the strong negative effect (inhibition) on the exchange found in the chloride (3) and cyanide (4) systems. The sulphate system seems in this respect more to resemble the nitrate (5) system.

From the above results and from the known (1) first-order dependence on each of Tl(III) and Tl(I), it can be inferred that the activated complex contains one ion of each of thallous, thallic, and sulphate. Following the suggestions of Taube (7) and others, in other cases, it seems reasonable that the actual activated complex might well be a bridge type of structure:



in which case the transfer of two electrons arises from the transfer of a sulphate radical from one thallium atom to the other. This same bridge-transfer mechanism would very likely also be applicable in the case of the more highly complexed species at higher sulphate concentrations.

It is important to point out that the above mechanism is not the only one consistent with the kinetics. Others might be: rapid dissociation of the thallic sulphate complex into a thallous ion and a neutral sulphate radical, dissociation of the bridge structure without transfer of sulphate, direct transfer of electrons by barrier penetration, and still others. The bridge-transfer mechanism seems to be the most attractive of these.

ACKNOWLEDGMENTS

The author is grateful to Drs. R. W. Dodson and J. Halpern for helpful comments, and to the National Research Council for financial support.

THE SYSTEMS Li_2SO_4–K_2SO_4–H_2O AND Li_2SO_4–Na_2SO_4–H_2O AT 25° C.[1]

A. N. CAMPBELL AND E. M. KARTZMARK

ABSTRACT

The 25° isotherm of the system Li_2SO_4–K_2SO_4–H_2O shows the existence of the double salt, $Li_2SO_4.K_2SO_4$, whereas that of the system Li_2SO_4–Na_2SO_4–H_2O yields no double salt but extensive solid solution of lithium sulphate in sodium sulphate. On the other hand, a study at 39.5° C. of the latter system shows that the double salt, $Li_2SO_4.Na_2SO_4$, does form at this temperature, accompanied as before by solid solution of lithium sulphate in sodium sulphate. The transition temperature for the reaction

$$Li_2SO_4.H_2O + Na_2SO_4 = Li_2SO_4.Na_2SO_4 + H_2O$$

is 29.3° C. A further transition, of unknown nature, occurs between 49° and 57°.

This paper is the second stage in our study of the system containing the radicals Li_2, Na_2, K_2, Cl_2, SO_4, and water. Our first paper (1) dealt with the system LiCl–NaCl–KCl–H_2O at 25° C. The corresponding system involving the sulphates is Li_2SO_4–Na_2SO_4–K_2SO_4–H_2O. The component ternary systems are Li_2SO_4–Na_2SO_4–H_2O, Li_2SO_4–K_2SO_4–H_2O, and Na_2SO_4–K_2SO_4–H_2O. The system Na_2SO_4–K_2SO_4–H_2O has been investigated by various workers. A complete bibliography is given by Hamid (2). A double salt, glaserite or Penny's salt, is formed, having the composition $3K_2SO_4.Na_2SO_4$. This double salt, however, while it is incapable of forming solid solutions with potassium sulphate, does so, at 25°, to some extent with sodium sulphate. Thus, according to Hamid, the two isothermally invariant ternary solutions, at 25°, are in equilibrium respectively with pure double salt and potassium sulphate and with Glauber's salt and the solid solution of sodium sulphate in double salt.

The systems Li_2SO_4–K_2SO_4–H_2O and Li_2SO_4–Na_2SO_4–H_2O have not previously been investigated, although Nacken (3) has investigated the equilibrium diagram of the anhydrous systems Li_2SO_4–K_2SO_4 and Li_2SO_4–Na_2SO_4. He finds that the former system gives rise to the congruently melting compound $Li_2SO_4.K_2SO_4$ and the latter to the compound $Li_2SO_4.Na_2SO_4$, which cannot exist in equilibrium with the melt. Scacchi (4) and Traube (5) have also obtained $Li_2SO_4.Na_2SO_4$ by crystallization of hot solutions of lithium and sodium sulphates.*

EXPERIMENTAL TECHNIQUE

The technique of solubility determinations is too well known to merit description here but something must be said about the methods of analysis. The only really practical method of determining sulphate radical, viz. barium sulphate precipitation, is notoriously unreliable, particularly in solutions containing alkali ions. Although we used this method we thought it necessary to support it by the use of a purely physical method and for this purpose we chose viscosity. All density and viscosity determinations were made on solutions containing 10 or 20 g. total anhydrous salt in 100 ml. of solution.

[1]*Manuscript received September 13, 1957.*
Contribution from the Chemistry Department, University of Manitoba, Winnipeg, Manitoba.

*NOTE ADDED IN PROOF.—*A paper by L. Cavalca and M. Nardelli (Gazz. chim. ital. **82**, 394–405 (1952)) has just come to hand, in which they have studied the system Li_2SO_4–Na_2SO_4–H_2O at 27° and 45.6° C. They agree with us in finding that the double salt $Na_2SO_4.Li_2SO_4$ does not exist at 27° though it does at 45.6° C. In addition, however, they claim the existence of a double salt $Na_3Li(SO_4)_2.6H_2O$. The existence of such a salt would require that the tie-lines intersect in the body of the diagram and this we feel to be impossible. We point out, in this connection, that prolonged and vigorous stirring is necessary to ensure the attainment of equilibrium.*

DISCUSSION

The results of Table II are plotted in Fig. 1. It is obvious that the expected double salt, $Li_2SO_4.K_2SO_4$, is stable at 25° C., although the solution is not congruently saturating; the pure anhydrous double salt decomposes when treated with water to give a mixture of double salt and potassium sulphate. The figure also shows some solid solubility of lithium sulphate in potassium sulphate and of lithium sulphate in double salt.

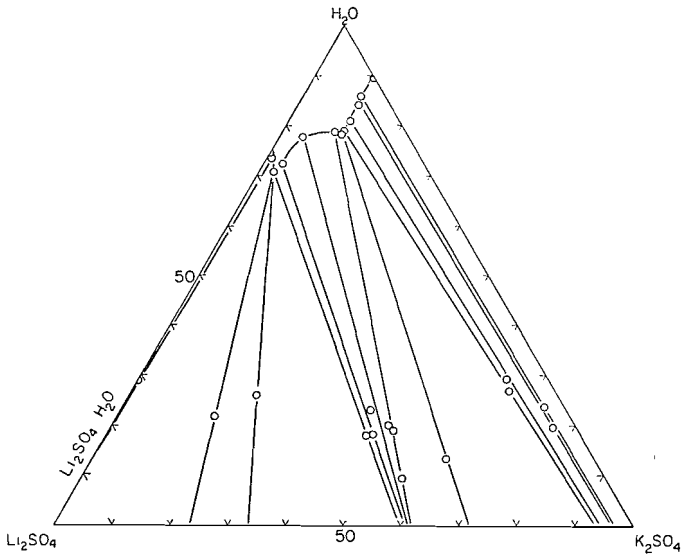

FIG. 1. The system Li_2SO_4–K_2SO_4–H_2O at 25° C.

The figures of Table IV are plotted in Fig. 2. Rather surprisingly, no double salt forms at 25° C. but there is extensive solid solubility of lithium sulphate in sodium sulphate,

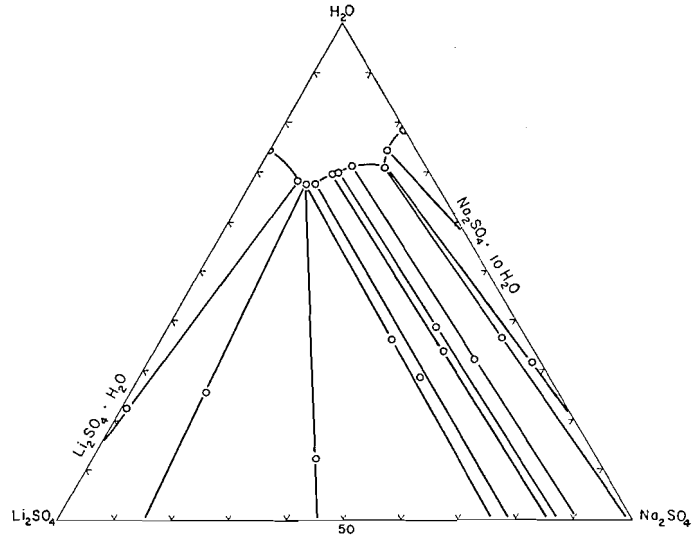

FIG. 2. The system Li_2SO_4–Na_2SO_4–H_2O at 25° C.

to the extent of, say, 25% lithium sulphate by weight. Because of the difference in crystal structure of lithium sulphate and β-Na_2SO_4, and of the difference in ionic radii of the lithium and sodium ions (6), this result surprised us and we verified it with some care. In one case, a very small solid phase was vigorously stirred with solution for 3 weeks, to ensure true equilibrium, before analysis. We have therefore no doubt of the fact, however surprising it may be. According to Nacken (3), solid α-Na_2SO_4 dissolves extensively in solid α-Li_2SO_4 at temperatures between 600° C. and 850° C., while α-Li_2SO_4 does not dissolve at all (in the solid state) in α-Na_2SO_4. We now find that, in the neighborhood of room temperature, Li_2SO_4 dissolves extensively in β-Na_2SO_4. The question of whether β-Na_2SO_4 dissolves in (anhydrous) β-Li_2SO_4 cannot be answered by this study, because the equilibrium lithium sulphate solid phase is always the monohydrate.

Since the literature indicated, beyond all reasonable doubt, that the double salt, $Li_2SO_4.Na_2SO_4$, does form from hot solution, there must be a transition temperature for the reaction:

$$Li_2SO_4.H_2O + Na_2SO_4 = Li_2SO_4.Na_2SO_4 + H_2O.$$

Accordingly, a dilatometric experiment was carried out, using a bulb charged with a moist equimolar mixture of lithium and sodium sulphates and *m*-xylene as indicator fluid. A marked expansion was observed at 30.0° C. and a less distinct expansion between 49.6° C. and 56.6° C. This was checked by determination of total solubility of an equimolar mixture of lithium and sodium sulphates. The results were:

Temperature, ° C.	Total solubility in wt. %
25	29.0
28.5	32.1
31.4	32.8
39.8	33.3
50.1	34.0
60.3	34.0
67.7	32.3

When the above figures are plotted as total solubility versus temperature, sharp breaks are observed at 29.3° C. and 57.5° C. We did not pursue further the question of the nature of the higher temperature transition.

way, it is apparent that the double salt, $Li_2SO_4.Na_2SO_4$, does indeed form although the region of its existence in contact with solution is small. Like the corresponding lithium–potassium double salt, it is incongruently saturating. The fact that the double salt of lithium–sodium is not stable at room temperature may account for some of the crystallographic difficulties encountered by Traube (5).

PHOTOLYSIS OF ACETONE IN THE PRESENCE OF METHYL-d_3 ACETATE[1]

M. H. J. WIJNEN

ABSTRACT

The photolysis of acetone in the presence of CH_3COOCD_3 has been carried out over the temperature range 151° to 274° C., at different ratios of acetone to methyl acetate and at different light intensities. As activation energies for the abstraction reactions

$$CH_3 + CH_3COOCD_3 \rightarrow CH_4 + CH_2COOCD_3 \quad [2]$$

and

$$CH_3 + CH_3COOCD_3 \rightarrow CH_3D + CH_3COOCD_2 \quad [3]$$

were obtained $E_2 = 10 \pm 0.5$ kcal. and $E_3 = 14 \pm 1$ kcal.

INTRODUCTION

Direct photolysis of CH_3COOCH_3 (5) and CH_3COOCD_3 (6), recently undertaken at this laboratory, indicated a considerable difference in activation energy between the abstraction of a hydrogen atom from the acetyl group and the abstraction of a hydrogen or deuterium atom from the methoxy group in methyl acetate by methyl radicals. In order to study these abstraction reactions in a relatively simple system, acetone was photolyzed in the presence of CH_3COOCD_3.

EXPERIMENTAL

The apparatus and technique were mainly the same as described elsewhere (7). The storage vessels containing acetone and methyl acetate were separated from the reaction vessel by mercury cutoffs. In order to prevent absorption by methyl acetate, the light of the S-500 medium pressure arc was filtered through Corning filter 9700, transparent above 2600 Å. The trideuteromethyl acetate was obtained from New England Nuclear Corporation. Mass spectrometric analysis showed it to contain at least 98% of CH_3COOCD_3. The acetone was obtained from Celanese Chemcel plant and was distilled once *in vacuo* before use.

RESULTS AND DISCUSSION

The results of the experiments carried out at various temperatures for various mixtures of acetone and methyl acetate are given in Table I.

The use of acetone as a source of methyl radicals to study hydrogen abstraction reactions is well established. The following reactions are, therefore, proposed to explain the methane and ethane formation when acetone is photolyzed in the presence of CH_3COOCD_3 at temperatures above 140° C.:

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3 \quad [1]$$

$$CH_3 + CH_3COOCD_3 \rightarrow CH_4 + CH_2COOCD_3 \quad [2]$$

$$CH_3 + CH_3COOCD_3 \rightarrow CH_3D + CH_3COOCD_2 \quad [3]$$

$$2CH_3 \rightarrow C_2H_6 \quad [4]$$

The following equations may be derived from this reaction mechanism:

$$R_{CH_4}/(R^{\frac{1}{2}}_{C_2H_6}[Ac]) = k_1/k_4^{\frac{1}{2}} + k_2/k_4^{\frac{1}{2}}[MeAc]/[Ac] \quad [I]$$

$$R_{CH_3D}/(R^{\frac{1}{2}}_{C_2H_6}[MeAc]) = k_3/k_4^{\frac{1}{2}} \quad [II]$$

$$R_{CH_4}/R_{CH_3D} = k_2/k_3 + k_1/k_3[Ac]/[MeAc] \quad [III]$$

The results obtained for $k_3/k_4^{\frac{1}{2}}$ via equation [II] are given in Table I. Within experimental error constant values were obtained for $k_3/k_4^{\frac{1}{2}}$ at constant temperatures. A plot of log $k_3/k_4^{\frac{1}{2}}$ against $1/T$ in Fig. 2 gives an activation energy difference of $E_3-\frac{1}{2}E_4 = 14\pm1$ kcal.

Equation [I] is plotted in Fig. 1. The data show good agreement with the proposed reaction mechanism. The intercepts of the lines in Fig. 1 give values of $k_1/k_4^{\frac{1}{2}}$. These values may also be obtained by photolysis of acetone alone. At three temperatures, runs were carried out photolyzing acetone alone. Values thus obtained are indicated on the ordinate of Fig. 1 and coincide within experimental error with the intercepts obtained by plotting equation [I].

From the slopes of the lines in Fig. 1 we obtain the values of $k_2/k_4^{\frac{1}{2}}$ reported in Table II. A plot of log $k_2/k_4^{\frac{1}{2}}$ against $1/T$ is shown in Fig. 2, together with data obtained for $k_2/k_4^{\frac{1}{2}}$ by direct photolysis of CH_3COOCD_3 (6). From the slope of this plot an activation energy of $E_2 = 10\pm0.5$ kcal. is obtained, assuming $E_4 = 0$ kcal. Plots of equation [III] at 208° and 274° C. give the following values for k_2/k_3 and k_1/k_3: $k_2/k_3 = 23$ and $k_1/k_3 = 54$ at 208° C., $k_2/k_3 = 8$ and $k_1/k_3 = 37$ at 274° C. Small errors in the determination of R_{CH_3D} at low temperatures have a large effect on the ratio R_{CH_4}/R_{CH_3D} and prevent plotting equation [III] at temperatures below 208° C.

Values obtained for the different ratios of rate constants are summarized in Table II.

As activation energy for reaction [2] is obtained $E_2 = 10\pm0.5$ kcal. An activation energy of 10.2 kcal. has been reported by Ausloos and Steacie (1) for the following reaction:

$$CH_3 + CH_3COOH \rightarrow CH_4 + CH_2COOH. \qquad [5]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

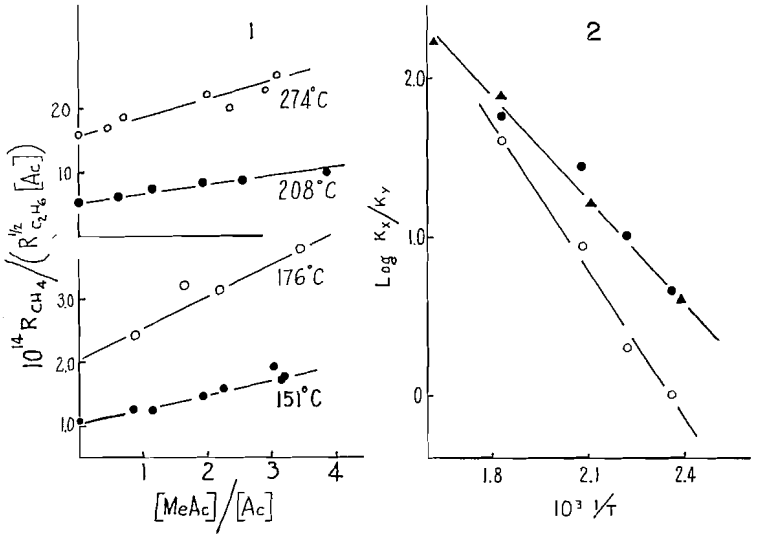

FIG. 1. Plot of $10^{14} R_{CH_4}/(R^{1/2}_{C_2H_6}[Ac])$ versus [MeAc]/[Ac] at various temperatures.
FIG. 2. Plot of $14 + \log k_3/k_4^{1/2}$ (○) and of $12.7 + \log k_2/k_4^{1/2}$ (●, ▲) against $10^3\,1/T$. Data marked by ● are reported in this work, those marked by ▲ were obtained by direct photolysis of CH_3COOCD_3.

TABLE II

RATIOS OF RATE CONSTANTS

Temp., ° C.	$10^{13}\,k_2/k_4^{1/2}$ in molecules$^{1/2}$/sec.$^{1/2}$ cc.$^{1/2}$	$10^{14}\,k_3/k_4^{1/2}$ in molecules$^{1/2}$/sec.$^{1/2}$ cc.$^{1/2}$	k_1/k_3	k_2/k_3
151	2.3	1.0	—	—
176	5.0	2.0	—	—
208	14.0	8.8	54	23
274	30	41.3	37	8

Since in both reactions, [2] and [5], the hydrogen is abstracted from the acetyl group, these values may be considered to be in good agreement.

The experimentally determined activation energy of 14±1 kcal. for the abstraction of a D-atom from the methoxy group in methyl acetate seems high. A direct comparison of the difference in activation energies between the abstraction of a hydrogen from the acetyl and from the methoxy group in methyl acetate is not possible owing to the different hydrogen isotopes in these groups.

Differences in activation energies between the abstraction reactions of H- and D-atoms by methyl radicals have been observed in the case of acetone, where values of 9.7 kcal. (3) were reported for E_6 and 11.3 kcal. (2) for E_7.

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3 \quad [6]$$

$$CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_2COCD_3 \quad [7]$$

This difference in activation energies seems mainly caused by the difference in zero point energies between the C—H and C—D bonds, since CH_3 and CD_3 radicals have been suggested (4) to abstract hydrogen atoms with, within experimental error, similar activation energies.

Accepting therefore for the reaction

$$CH_3 + CH_3COOCH_3 \rightarrow CH_4 + CH_3COOCH_2, \quad [8]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

an activation energy of 12.5±1 kcal., our results indicate that the abstraction of a hydrogen atom from the acetyl group requires less energy than the abstraction of a hydrogen atom from the methoxy group in methyl acetate.

It is interesting to compare these results with results obtained in the direct photolysis of CH_3COOCH_3 (5). As activation energy for the hydrogen abstraction by methyl radicals was obtained a value of 10 kcal., in agreement with the value of E_2 obtained in the present work. Among the reaction products were found large amounts of methyl propionate, probably formed by the reaction

$$CH_3 + CH_2COOCH_3 \rightarrow C_2H_5COOCH_3. \qquad [9]$$

No evidence could be obtained for the formation of ethyl acetate, indicating that most hydrogen was abstracted from the acetyl group, rather than from the methoxy group in methyl acetate.

These results confirm the conclusion drawn in this work that less energy is required for the abstraction of a hydrogen atom from the acetyl group than from the methoxy group in methyl acetate by methyl radicals.

In addition to the reaction products given in Table I, trace amounts of CD_3H, CO_2, and occasionally CD_4 were observed at 273° C. These products may originate from the thermal decomposition of the CH_2COOCD_3 radical.

Accepting as collision diameters of CH_3 and CH_3COOCD_3 3.5 and 6×10^{-8} cm., respectively, we calculated the steric factor ratios and obtained:

$$P_2/P_4^{\frac{1}{2}} = 1.5\times10^{-3} \text{ and } P_3/P_4^{\frac{1}{2}} = 5\times10^{-3}.$$

These values are of the order of magnitude generally observed in hydrogen abstraction reactions by methyl radicals.

ACKNOWLEDGMENTS

The author acknowledges many helpful discussions with Dr. H. D. Medley during the progress of this work. Special thanks are due to Messrs. R. W. Jarrett and R. H. Guedin for calculation and interpretation of the mass spectrometer data.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART I. INTRODUCTION[1,2]

W. F. Forbes and J. F. Templeton

ABSTRACT

Hydrogen bonding, which is known to give rise to dimer formation in benzoic acids and similar compounds, may affect solution spectra by intermolecular and by intramolecular bond formation. Generally environmental factors affecting absorption spectra can be conveniently divided into three types: intermolecular hydrogen bonding between solute molecules only; intermolecular hydrogen bonding between solute and solvent molecules; and environmental effects not involving the formation of hydrogen bonds.

Distinct evidence for these types of interaction is deduced from ultraviolet spectra, and various implications of the spectral analyses are discussed.

INTRODUCTION

Hydrogen bonding has been previously mentioned in this series as a possible cause of certain anomalous spectra (13, 14, 15, 17). Intramolecular hydrogen bonding has previously been used to explain certain features of the ultraviolet spectra of *o*-hydroxyacetophenone and salicylic acid (9, 10). Intermolecular hydrogen bonding would be expected to occur in organic compounds like benzoic acid, firstly because dimer formation in benzoic acids is a well-known phenomenon in infrared spectroscopy (2, 11, 22, 26) and secondly because certain changes in ultraviolet absorption spectra on alteration of the solvent have been ascribed to intermolecular hydrogen bonding (5, 6, 7, 30, 31, 33). Further, the dependence of a number of ultraviolet spectra on solution concentration has been noted by several workers (1, 19, 25, 28, 29, 34).

Intermolecular hydrogen bonding, for which there is therefore some evidence, may be conveniently divided into two types. Intermolecular hydrogen bonding may occur between solute molecules only or may occur between solvent and solute molecules. The former, intermolecular hydrogen bonding between solute molecules only, may be a function of the concentration. Consequently, it may be susceptible to independent investigation, particularly since examples can be selected which largely eliminate intramolecular hydrogen bonding and steric effects. Monosubstituted benzenes and especially benzoic acids provide a satisfactory starting point. The latter have also previously been discussed in this series (18) and it was found that although dimer formation was anticipated, the *B*-bands could as a first approximation be satisfactorily related without considering the effect of hydrogen bonding. The present communication may thus be considered as an extension of this previous study.

The effect of intermolecular hydrogen bonding between solvent and solute molecules and other environmental effects may be investigated by choosing examples in which again steric and intramolecular hydrogen bonding effects are small, and which further do not show the concentration changes ascribed to solute–solute hydrogen bonding. Such examples are available and these will be examined separately.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP 500 spectrophotometer. Intensity readings at different concentrations were

[1]*Manuscript received June 24, 1957.*
Contribution from the Memorial University of Newfoundland, St John's, Newfoundland.
[2]*This paper may also be considered as Part IX of a series of studies on light absorption, Part VIII of which appeared in Can. J. Chem.* **35**, *1049 (1957).*

obtained by using quartz cells of various path length, so that for different concentrations the optical density readings remained similar. For most of the compounds the concentration dependence was determined at least in duplicate over similar concentration ranges and was found to be qualitatively similar.

Compounds were purified by standard methods as described in the literature. Dioxane was purified by the method of Hess and Frahm (24), that is, by refluxing the dioxane with hydrochloric acid in a stream of nitrogen for 12 hours, removing the hydrochloric acid by treatment with potassium hydroxide, and then refluxing the dioxane with sodium for 10 hours. The distilled material, obtained in about 50% yield, was stored under nitrogen. Generally, purification was deemed adequate when additional processing resulted in no further measurable changes in the absorption intensity. Aqueous dioxane solvent mixtures were made up by mixing together the corresponding volume percentages. For example, 75% aqueous dioxane was obtained by mixing 75 volumes of purified dioxane with 25 volumes of distilled water.

The maximal wavelengths and absorption intensities are recorded in Tables I, II, and III. The concentration range was chosen to keep optical density readings between 0.3 and 0.7. Also, since no direct comparison of concentration dependences is intended at present, the reported values are mostly uncorrected. However, care was taken to use well-matched, carefully cleaned, cells, since some pairs of cells gave rise to differences in ϵ of up to 6% on interchanging the cells. For each concentration the observed extinction coefficients were within 2%. Band shapes for the benzoic acid spectra were found to be similar and consequently ϵ_{max} values may be used as measures of the actual absorption intensities.

Errors in a number of earlier determinations (cf. 19) were caused by the following:

(i) Solvents, if kept in some polyethylene bottles, frequently deteriorate on standing. Consequently all-glass bottles were used in preparing and storing solutions. The transmission density was checked for each solvent immediately before use. Further, the cells in each calibrated set were checked against each other before use.

(ii) Difficulties in solvent purification did not permit the determination of density readings in the longer cells without altering the sensitivity. This was particularly pronounced for dioxane. To obtain values for the 4 cm. cells at 230 mμ without altering the sensitivity, about five redistillations were required. As a general rule, the optical density reading in a 1 cm. cell at 250 mμ was 0.5 or less against air; if not, the dioxane was redistilled.

THE DEPENDENCE OF ELECTRONIC ABSORPTION SPECTRA ON CONCENTRATION (INTERMOLECULAR HYDROGEN BONDING BETWEEN SOLUTE MOLECULES ONLY)

For investigating hydrogen bonding and related effects *between solute molecules only*, hexane is a suitable solvent, because of its inactive nature and low dielectric constant. Consequently the main factor influencing the spectra may be the hydrogen bonding between solute molecules, and the intensity change with concentration in hexane as shown in the last examples of Table I may be provisionally assumed to represent a measure of this intermolecular hydrogen bonding.

Using this hypothesis, the data summarized in Table I are in agreement with results deduced by other methods. Thus, diphenyl, aniline, phenol, acetophenone, *p*-methylacetophenone, and methyl benzoate in cyclohexane solution do not show an appreciable intensity increase on increasing the concentration. For diphenyl, acetophenones, and methyl benzoate, this may be related to the inability of these compounds to form a hydrogen bond; and the reported absence of association for acetophenones (27), as

**Three concentrations only are reported in this and subsequent tables; intermediate values were obtained at intermediate concentrations.*

judged from infrared and Raman spectral studies, may also be noted in this connection. Aniline also does not exhibit any appreciable concentration dependence, which is perhaps surprising, since the presence of association is suggested from infrared data (21). At least two explanations, however, may be proposed for the discrepancy. In the first place, the change in the amount of intermolecular hydrogen bonding may be small or negligible within the concentration range under investigation, but may be more pronounced in a different concentration range. This suggestion receives strong support since pyrrole and related compounds do not show any appreciable stretching vibration changes, which may be ascribed to hydrogen bonding (21), below a concentration of 10^{-2} moles per liter. By contrast, the present concentration range lies between 10^{-6} and 10^{-2} moles per liter. Secondly, the sensitivity of the method may generally not be sufficient to discern a change, which nevertheless actually occurs.

At this stage the significance of the data may be discussed. For all the early examples listed in Table I an intensity change of between 1 and 5% does in fact occur on increasing the concentration by a factor of 40, whereas a similar intensity change does not occur for some of the compounds listed in Table II. Since this change occurs for all the examples in Table I and also frequently occurs independently of the solvent (see, for example, the spectrum of methyl benzoate in ethanol and in cyclohexane as listed in Table II), it is unlikely to be associated with weak intermolecular hydrogen bonding. Moreover, if we take the accuracy of each ϵ value to be $\pm2\%$ (cf. Experimental), practically all these values are within experimental error. However, the fairly general occurrence of the trend (see Table I) suggests that the slight intensity increase is real. The most probable explanations are therefore that the intensity increase is caused by van der Waal's forces of molecular interaction or merely by errors inherent in the experiments (cf. 3, 4, 12).

Table I also shows that for benzoic acids the situation is different. Apart from the small increase discussed in the previous paragraph, many benzoic acids in cyclohexane solution when the concentration is increased give rise to a more pronounced increase in the observed absorption intensity. Since the changes occur at different wavelengths, they cannot be ascribed to any phenomenon associated with a particular wavelength. Simi-

larly, the previously discussed small intensity increase is not confined to a limited wavelength range; compare the early examples in Table I, which occur between 227 and 286 mμ. Further, Ungnade and Lamb (34) have noted that similar changes to those described for the *B*-band of benzoic acid occur in the *C*-band of benzoic acid in cyclohexane solution. For example, they report a maximal absorption at 274 mμ, $\epsilon = 1050$ at a concentration of 0.0805×10^{-3} moles per liter, whereas at a concentration of 10.27×10^{-3} moles per liter this absorption occurs at 276 mμ, $\epsilon = 1120$ (34). Lastly, it will be shown in a later section that this intensity decrease is less pronounced for more polar solvents, and this observation again is consistent with the initial assumption which relates these intensity changes to intermolecular hydrogen bonding.

Another example of appreciable intensity change is provided by the concentration dependence of the *C*-band in phenols (28). This dependence has been ascribed to intermolecular hydrogen bonding (28), but possibly for similar reasons as have been mentioned for aniline, no appreciable spectral changes under the conditions of the present experiment are observed.

CONCERNING THE INTERPRETATION OF THE INTENSITY DECREASE

The observed intensity changes in Table I are apparently not accompanied by any large wavelength change. With this in mind, the possible factors causing the observed changes may now be briefly discussed at a more fundamental level. One possible explanation is that intermolecular hydrogen bonding (or generally association), by withdrawing part of the electronic cloud from the carboxyl group, increases the planarity of the molecule (cf. 18). The resulting decreased steric hindrance could account for the increased absorption intensity, and would be expected to give rise to a bathochromic shift (cf. 13, 18).

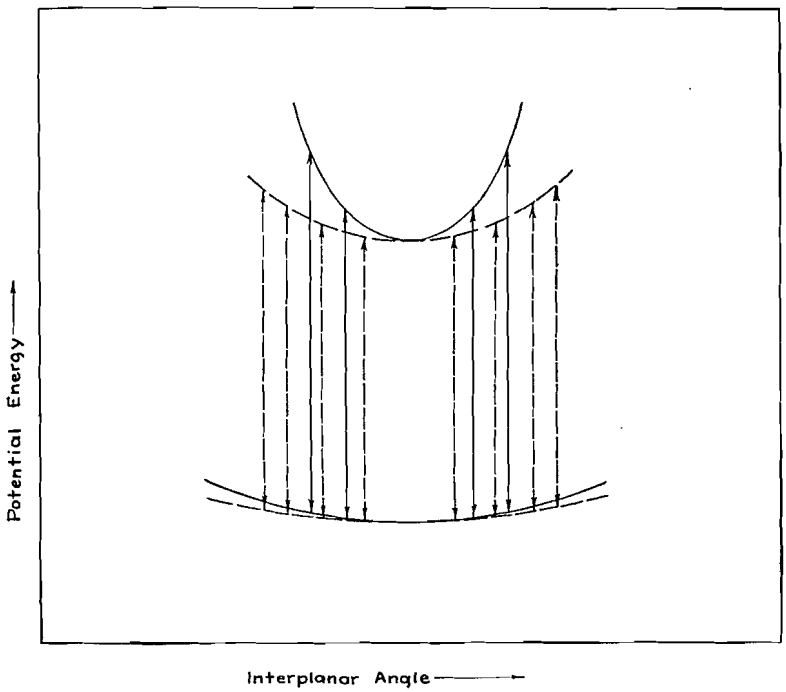

FIG. 1. Schematic representation of potential energy curves and electronic transitions for benzoic acid in the monomeric form (full lines) compared to benzoic acid in the dimeric form (dashed lines).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Another, not necessarily alternative, interpretation is to assume that association decreases the force constant of twist about the bond linking the carboxyl group to the benzene ring. This might be expected to cause an effect as illustrated in Fig. 1. (Fig. 1 is, of course, an idealization since, for example, it is not certain that the energy level minima of ground and excited states occur at similar interplanar angles.) As shown in the diagram, the decreased force constant is assumed to flatten the energy level curves of the ground and excited states and thereby increases the absorption intensity. This follows, because the proportion of molecules in positions favorable for electronic excitation will be increased. At the same time, the wavelength of maximal absorption normally undergoes a bathochromic shift.

A third explanation is that increased association (involving non-bonded electrons of the carbonyl group) increases the energy of excitation, because of the greater amount of energy required to excite partially bound electrons. Since this greater energy would cause a hypsochromic shift, this is probably not the predominant factor for the compounds studied (see Table I).

The hypothesis that association causes the observed changes, chiefly by varying the force constant, receives support from a number of other independent observations. Thus, in the first place, a smaller force constant—assuming the explanation proposed for the *C*-band (17)—would frequently produce similar changes in both *B*- and *C*-bands. This is in fact observed for benzoic acid.

Next, a similarly altered force constant would be anticipated on introduction of an electron-withdrawing substituent in a molecule in a position such that the main mesomeric interaction remains approximately constant. This is found to be correct. For example, *m*-terphenyl (λ_{max} 252 mμ, ϵ = 44,000) absorbs at the same maximal wavelength as diphenyl (λ_{max} 252 mμ, ϵ = 18,000), but rather surprisingly with more than twice the absorption intensity of diphenyl (23). This suggests that an effect analogous to the above-mentioned association occurs; more precisely, the third phenyl ring may be supposed to weaken the force constant for the central bonds and in this way cause the intensity increase.

Another example may be provided by the previously noted, but unexplained, similarity between the spectra of nitrobenzoic acids and nitrobenzene (18). There, the electron-withdrawing effect of both substituents in nitrobenzoic acids can be supposed to deactivate the benzene nucleus sufficiently to prevent any primary mesomeric interaction. This explains the absence of any appreciable mesomeric interaction between the two substituents in *p*-nitrobenzoic acid as indicated by the lack of any significant wavelength shift. Further, according to the present hypothesis, a secondary effect may now operate which will tend to reduce the force constant of the N-nuclear bond, and thus be responsible for the increased absorption intensity (λ_{max} 258 mμ, ϵ = 11,000) in *p*-nitrobenzoic acid. The meta-isomer absorbs with approximately the same intensity (λ_{max} 255 mμ, ϵ = 7500) as nitrobenzene (λ_{max} 258 mμ, ϵ = 8500), but in this compound a buttressing effect may account for a reduced absorption intensity (16). In the ortho-isomer, steric interactions certainly inhibit the conjugation between the nitro-group and the benzene ring and only an inflection appears at approximately 255 mμ, ϵ = 3500.

A similar explanation may also be used to explain more fundamentally the increased absorption intensity of phenyl benzoate (λ_{max} 230 mμ, ϵ = 15,000) compared with benzoic acid (λ_{max} 227 mμ, ϵ = 11,000; cf. (18)), and other "anomalous" spectral changes. These will be discussed in more detail in a separate communication.

THE EFFECT OF INTERMOLECULAR HYDROGEN BONDING BETWEEN SOLUTE AND SOLVENT MOLECULES ON ELECTRONIC ABSORPTION SPECTRA

It has been shown that definite spectral changes, which may be ascribed to association, are observed for benzoic acids in cyclohexane solution. If hydrogen bonding does occur and is responsible for these changes, one would expect that the concentration dependence would normally be greatest in hexane solution. This follows because, in solvents which are able to form a hydrogen bond with the solute molecules, a competitive hydrogen bonding may occur. This in turn presumably reduces the association occurring between solute molecules only, since generally the same substituent of the solute molecule would be involved in both solute–solute and solute–solvent hydrogen bonding. In the limit, as the solute–solvent interaction becomes increasingly more important, no concentration dependence would be observed. Therefore, it might be anticipated that, in the absence of special considerations, concentration dependence varies with the solvent. If concentration dependence occurs in an inert solvent, it may be expected to decrease in the solvent order hexane > ethanol > water.

This hypothesis has been investigated and some of the results are listed in Table II. The data can again be divided into two groups. There are the earlier values in Table II,

TABLE II

CONCENTRATION DEPENDENCE OF ABSORPTION MAXIMA IN DIFFERENT SOLUTIONS
(Concentration, $c = 6.5\times10^{-6}$–10^{-5} moles/l.; cell lengths in brackets)

		$40c$ (1 mm.)		$4c$ (10 mm.)		c (40 mm.)

**Hydrochloric acid has been added to the aqueous solution to avoid ionization, which evidently occurs in the pure aqueous medium as shown by the wavelength displacement to 223 mμ (cf. 34).*

where concentration dependence for both cyclohexane and ethanolic solution is small or absent. As mentioned before, the smallness of these intensity changes renders any conclusions based on them extremely doubtful. However, the indication is, as noted previously, that for some of these compounds changing the solvent does not materially affect the concentration dependence. This in turn indicates that this concentration dependence is not caused by hydrogen bonding. It may also be noted that Raman spectral studies (32) for methyl benzoate in ethanol afford no evidence for hydrogen bonding between methyl benzoate molecules.

For benzoic acid in ethanolic solution the expected decreased concentration dependence is observed. This concentration dependence unfortunately is so small that no decision

can be made concerning its reality. For aqueous solutions of benzoic acid ionization of the acid alters the spectrum (34) and consequently no decision can be made about dimerization. Addition of acid to both aqueous and ethanolic solution apparently inhibits concentration dependence, but the acid—apart from preventing ionization—may clearly also affect the hydrogen bonding. Similar changes are also observed for a number of substituted benzoic acids (20).

These observations are of interest for at least two reasons. First, they support the previous hypothesis, ascribing the spectral changes for benzoic acid in hexane solution to intermolecular hydrogen bonding. If this is so, the smaller concentration dependence or complete absence thereof provides at the same time evidence that hydrogen bonding occurs between solute and solvent molecules. This latter phenomenon is also well established from other physical data. Secondly, the smaller concentration dependence may throw light on the relative strengths of the hydrogen bonding involved. Thus, if *no* concentration dependence is observed in ethanolic solution, it may be supposed that the monomeric acids are under these conditions preferentially stabilized by hydrogen bonds, which are probably more important than the hydrogen bonds making up the benzoic acid dimer (cf. 34). Unfortunately, on the basis of the present data, remembering their qualitative nature (cf. Experimental), no definite decision can be made. There is, however, some indication that in *both* ethanolic *and* aqueous solution intermolecular hydrogen bonding between benzoic acid molecules is entirely inhibited (see Table II for the spectra of benzoic acid in ethanol and water when HCl has been added; cf. also (34)); that is, that any observed concentration dependence in aqueous or ethanolic solution should be ascribed to a changed degree of dissociation for the benzoic acid molecules rather than to dimerization.

THE EFFECT OF OTHER ENVIRONMENTAL FACTORS ON ELECTRONIC ABSORPTION SPECTRA

Under this heading we may group together a variety of other environmental factors which by means of a mechanism other than hydrogen bonding affect the absorption spectra. Their existence is almost self-evident from theoretical considerations, but clear-cut examples of their spectral effects are not always available. At present, we shall confine ourselves to discussing only one example, linking this with other spectral phenomena which also point to these environmental factors as a means of affecting spectra. Additional examples will be discussed in other parts of this series as they arise in the course of discussion.

The example chosen is the spectrum of acetophenone in dioxane–water mixtures and the relevant data are recorded in Table III. Dioxane–water mixtures were chosen partly because the dielectric constant of such solutions is known, and it was in this way hoped to find a relation between the dielectric constant of a solution and one of its characteristic spectral properties. The results show that for acetophenone in various solvent mixtures no concentration dependence is observed. This confirms the expectation that acetophenone under these conditions does not associate with itself (cf. 27). On changing the dielectric constant of the solvent, however another type of change is observed, namely a distinct wavelength shift in the *B*-band of acetophenone. This wavelength shift may either be caused by intermolecular hydrogen bonding of the type discussed in the previous section, or it may be caused by other forces acting on the molecule.

The following suggest that "other" factors also contribute to the observed spectral changes:

TABLE III

ABSORPTION MAXIMA OF COMPOUNDS IN SOLUTIONS OF VARYING DIELECTRIC CONSTANT

Compound	Solvent	Concentration range	λ_{max}, mμ	ϵ_{max} and percentage deviation
Acetophenone	Dioxane	4×10^{-4} to 1×10^{-5}	239	*12,700±3%
	75% aqueous dioxane	4×10^{-4} to 1×10^{-5}	241	12,300±2%
	50% aqueous dioxane	4×10^{-4} to 1×10^{-5}	243	12,200±2%
	25% aqueous dioxane	4×10^{-4} to 1×10^{-5}	244	12,300±2%
	Water	4×10^{-4} to 1×10^{-5}	244.5	12,100±2%
Acetophenone (*C*-band)	Dioxane	4×10^{-3} to 1×10^{-4}	277	*1010±3%
	75% aqueous dioxane	4×10^{-3} to 1×10^{-4}	277	1060±2%
	50% aqueous dioxane	4×10^{-3} to 1×10^{-4}	278	1120±2%
	25% aqueous dioxane	4×10^{-3} to 1×10^{-4}	278	1200±2%
	Water	4×10^{-3} to 1×10^{-4}	277	1240±2%
Nitrobenzene	Dioxane	8×10^{-4} to 2×10^{-5}	258	8200±2%
	50% aqueous dioxane	6×10^{-4} to 1.5×10^{-5}	264	7800±2%
	Water	8×10^{-4} to 2×10^{-5}	266	7850±2%

*ϵ *values within any particular concentration range are* ±2%.

(i) The location of maximal wavelength changes for the *B*-bands of both acetophenone and nitrobenzene with increase of dielectric constant (see Table III). Wavelength displacements of similar magnitude were observed on altering the solvent from ethanol to water by Ungnade (33), who tentatively ascribes these wavelength displacements to hydrogen bonding. However, if hydrogen bonding were exclusively responsible for the spectral change, one would expect almost every dioxane–water solvent mixture to have sufficient water molecules to ensure suitably solvated structures for all the acetophenone molecules present. It would follow that maximal wavelengths would be expected to alter appreciably on addition of a small amount of water to pure dioxane as solvent; after which addition of water to the solvent mixture should not cause any further spectral change. In fact, the addition of water progressively alters the wavelength of maximal absorption, and there is no indication of any break in the curve relating maximal wavelengths and dielectric constant of the solvent mixtures.

(ii) Infrared data (27) for acetophenone in various solutions failed to show any band doubling, such as would be expected if more than one molecular species were present in solution. Such band doubling *is* observed for various substituted amines and has been ascribed to hydrogen bonding (21).

(iii) It is well known that changing the solvent affects the general shape of an absorption curve in many cases. In one instance at least, an investigation has been carried out to determine whether these changes are due to intermolecular hydrogen bonding. Coggeshall and Lang (8), using the temperature effects in isooctane and ethanolic solutions, conclusively showed that the spectral differences between the two solutions for aniline and phenol do not depend on stable hydrogen bonded complexes.

In concluding this section it should be noted that apart from the existence of other environmental factors, little else can as yet be ascertained about these forces, from electronic absorption spectra. Consequently, no attempt has been made to explain their effects on the *C*-band, which apparently are different from the effect of these forces on the *B*-band (see Table III). For similar reasons steric effects have not been investigated, although steric effects will almost certainly affect such molecular interaction. Finally, the nature of the molecular interaction itself, which probably includes a polar solvent

For personal use only.

effect and the possibility of a change in the molecular entity concerned (for example, benzoic acids in different solvent media), has not been fully elucidated, and the problem evidently requires further consideration.

THE ELECTRIC MOMENTS OF SOME N,N′-DISUBSTITUTED PIPERAZINES[1]

M. V. George and George F Wright

ABSTRACT

The establishment of significant orientation polarizations for a series of symmetrically N-substituted piperazines including N,N′-dichloro-2,5-↑↓-dimethylpiperazine, which was prepared anew, confirms the report of Partington and contradicts that of Hassel. The existence of these moments is not compatible with the postulation of a favored chair conformation especially in consideration of the proton magnetic resonances of N,N′-dimethylpiperazine and N,N′-diformylpiperazine. On the other hand the experiments favor the postulation of flexible conformation for these piperazines.

According to several reviews (8, 2) the "chair" form of six-membered alicyclic compounds is the expected conformation. The reported zero dipole of N,N′-dichloropiperazine (1) is cited in support of this opinion. This evidence seems to be at variance with the report (14) that piperazine and diphenylpiperazine in benzene have moments of 1.47 D. and 0.85 D. respectively. The experimental data kindly furnished to us by Professor Partington seem to be unequivocal. In order to resolve the apparent contradiction we have examined the polarization of a series of piperazines by methods which have been described previously (15, 16). The results are included in Table I.

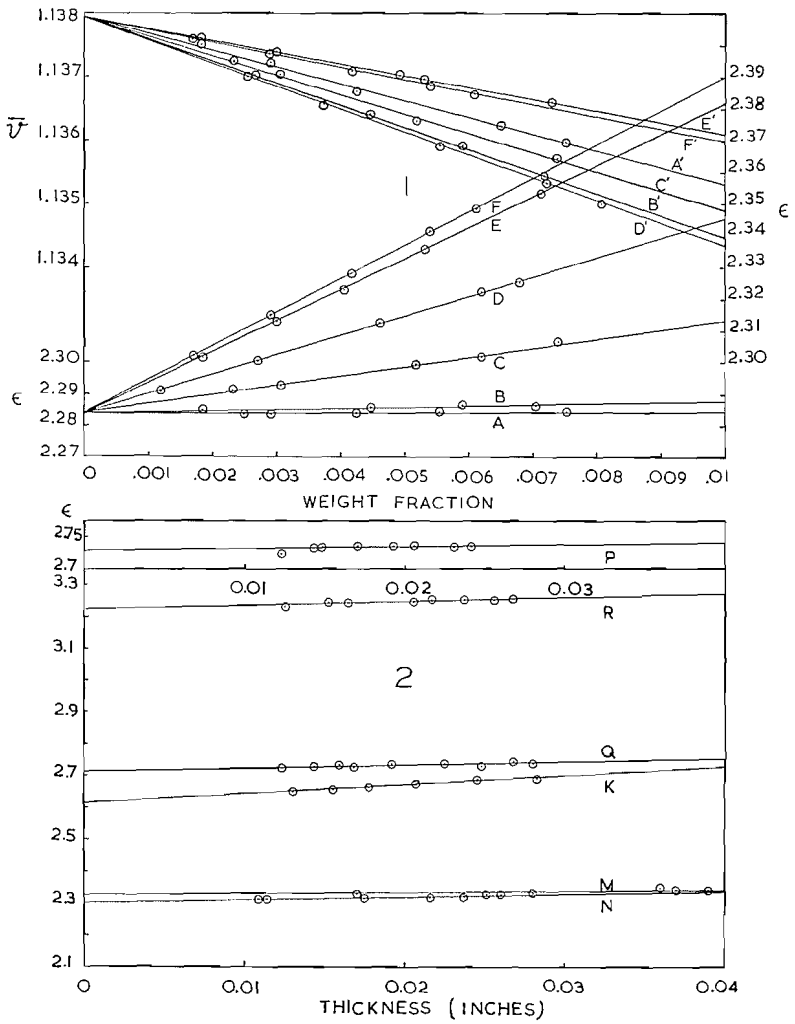
The values for solutions in benzene are derived by determination of $d\epsilon/d\omega$ (lines marked with unprimed letters, Fig. 1) and $d\bar{V}/d\omega$ (lines marked with primed letters in Fig. 1). Specifically, the dielectric constants (ϵ) and specific volumes ($\bar{V}$) of N,N′-dichloro-2,5-↑↓-dimethylpiperazine are recorded with respect to weight fractions ω for a series of solutions along lines A and A′, Fig. 1. Extrapolation to zero weight fraction gives values conforming closely with $\epsilon = 2.2840$ and $\bar{V} = 1.13795$ for pure benzene at 20°. Therefore calculation for total solute molecular polarization by the method of Halverstadt and Kumler (8) is justified.

In order to calculate the moment of this substance the distortion polarization must be evaluated. Since the additive group refraction (8.6 cc.) derived from the N–Cl linkage in a few liquid chloramines (17) is probably unreliable we have chosen to determine P_{E+A} from the dielectric constant of solid dichlorodimethylpiperazine obtained by extrapolation of apparent ϵ versus pellet thickness (line M, Fig. 2) to zero thickness where "edge effect" is minimal. The distortion polarization by this method (15, 16) is 40.4 cc. in contrast to 44.9 cc. calculated from group refractions. The electric moment calculated from $P_T - (P_{E+A})$ is 0.66 D. while that from $P_T - R_D$ (calc.) is 0.47 D. While the higher value should be considered the more reliable, neither moment conforms with the zero value stipulated for N,N′-dichloropiperazine by Andersen and Hassel (1).

Since these authors did not report experimental details we have redetermined the dielectric constants and specific volumes of benzene solutions containing dichloropiperazine. These values (lines B and B′, Fig. 1) justify the calculation of total molecular solute polarization as 46.3 cc. Unfortunately the distortion polarization (P_{E+A}) cannot be determined directly because the substance explodes in the pellet press. The damage attests to the energy of the N–Cl linkage.

In the absence of the experimental value we have calculated the moment of dichloropiperazine by use of the additive group refraction, and also by correcting the latter R_D by a factor derived from the additive versus the experimental distortion polarization of the dimethyl homologue. The moment (Table I) may be 0.85 D. or 0.71 D.,

[1]*Manuscript received July 23, 1957.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.



FIGS. 1 and 2.

depending on whether the corrected or the uncorrected additive refraction is applied. Despite the uncertainty one may affirm that the moment of N,N′-dichloropiperazine is not zero, as was reported previously (1). Moreover in view of the low group moment (*ca.* 0.3 D.) which has been assigned to the N–Cl linkage (23, 11) the conformation of atoms in this substance must exist largely in the flexible (so-called boat) form rather than the chair form.

In order to exclude the possibility that the presence of substituent methyl groups might vitiate the comparison between the two dichloropiperazines described above we have determined P_T and P_{E+A} for 2,5-↑↓-dimethylpiperazine from $d\epsilon/d\omega$ (line S, Fig. 3), $d\bar{V}/d\omega$ (line T, Fig. 3), and $d\epsilon/d$(thickness) (line N, Fig. 2). Although we used dioxane solutions the calculated moment (1.55 D.) compares favorably with the 1.47 D. reported by Martin (14) for piperazine in benzene. Furthermore the experimental P_{E+A} (Table I) is reasonably close to the calculated R_D for 2,5-↑↓-dimethylpiperazine. A similar comparison (from line P, Fig. 2) justifies Martin's calculated R_D for diphenylpiperazine. Thus correlations among the distortion polarization of piperazines seem to be reliable.

In view of Martin's small moment (0.85 D.) for N,N′-diphenylpiperazine it seemed worth while to examine an N-alkyl-disubstituted piperazine. Examination of N,N′-dimethylpiperazine in benzene ($d\epsilon/d\omega$, line V and $d\bar{V}/d\omega$, line U, Fig. 3) shows that its

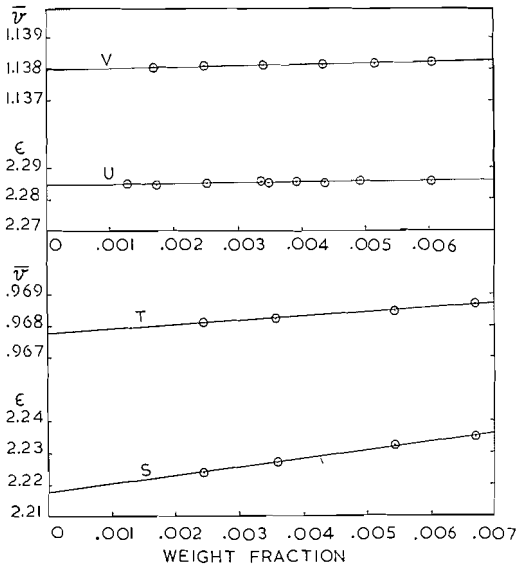

FIG. 3.

moment is low (0.59 D.). The difference between the diphenyl and dimethyl analogues is not unexpected (μ for aniline, 1.58 D., versus μ for trimethylamine, 0.86 D. in benzene), but closer correlation to define constellar differences is not justified without an elaborate study in which temperature and solvent are varied (15).

However it may be noted that a zero moment would be expected for a symmetrical

conformation since the methyl groups would be opposed either in axial or equatorial positions. Since their algebraic sum ought then to be zero, the existence of a real moment belies the postulation of a crown conformation.

Inherent in arguments of this sort is the assumption that a chair conformation, because of its essential stability, contributes so largely to the state of atomic arrangement in a six-membered cyclic molecule that the latter may be described as a static chair form. Such a form, if it is centrosymmetrical, will not be oriented in the electrical field. However, any activated deviation from this centrosymmetry will be observable by fields of frequency higher than those of atomic motion within the molecule. Undoubtedly for this reason Partington has suggested (14) that the observed moments of piperazines are due to axial–equatorial disposition of N,N′-substituents of chair conformations. The *e–a* constellation in IV (Fig. 4) would contribute to orientation polarization while the symmetrical *e–e* conformation, V, or the alternative *a–a* form would not make a contribution.

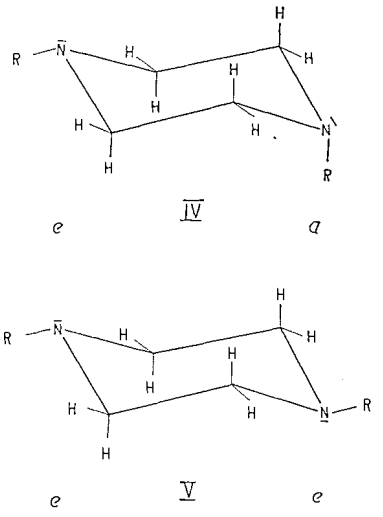

FIG. 4.

The transition from V *e–e* to V *a–a* may be expected to involve an activation energy which is not much less than the 3.6 kcal. specified (3) for the free energy difference between the *a–a* and *e–e* forms of 1,4-dimethylcyclohexane, and this activation energy should not be very different from the free energy difference between Partington's unsymmetrical form, IV, and his symmetrical V *e–e*. In these circumstances the amount of IV should not be great enough to account for the moments observed by Partington and ourselves. Moreover the transition rate from V to IV ought to be of the order of 0.0005 c.p.s. at ordinary temperatures, according to the energies that are involved. For our evaluation of transition rates we are greatly indebted to Dr. H. W. Patton and Mr. J. H. Chaudet of the Tennessee Eastman Company (Division of Eastman Kodak Co.), who determined proton magnetic resonances at 40 Mc. for several of these piperazines.

These workers have reported to us the information that N,N′-dimethylpiperazine shows two simple peaks about 6 cycles apart in the vicinity of 98 c.p.s. relative to water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

at 25°. They attribute the peak at the higher field position to the protons of the two N-methyl groups, which therefore are equivalent. The peak at the lower field position must be due to the methylene protons. Since these methylene protons in a static six-membered ring ought to be non-equivalent, Patton and Chaudet have cooled the sample to −5° C. in an attempt to separate the peak at lower field position, but without success. Therefore the transition rate must be faster by several orders of magnitude than the modulatory frequency at which resonance is measured. It follows that a chair conformation does not describe N,N′-dimethylpiperazine adequately.

For further variation in the piperazine substituents we have included N,N′-diformylpiperazine as a typical amide. The dielectric constants and specific volumes of its benzene solution are shown as D and D′, Fig. 1. The distortion polarization has been evaluated by the pellet technique (R, Fig. 2). Calculation of P_{E+A} discloses the presence of a high (7.7 cc.) atom polarization if the bond additivity calculation of P_E is reliable. The reliability of the calculated electronic polarization is attested in this instance by the close agreement (Table I) between calculated and observed molecular refractions of the analogous dimethylformamide.

Therefore the atom polarization of diformylpiperazine, specified by pellet measurement, probably is genuine, but one may doubt that it is related to the piperazine ring. More likely this distortion by the external electric field involves the formyl groups. It may be seen in Table I that substances like 2,5-dimethylpiperazine and N,N′-diphenylpiperazine do not display appreciable atom polarization. On the other hand *bis*-N,N′-β-cyanoethylpiperazine (moment calculations from F, F′, Fig. 1, and K, Fig. 2) and *bis*-N,N′-cyanoethyl-2,5-↑↓-dimethylpiperazine (calculations from E, E′, Fig. 1, and Q, Fig. 2) both seem to have atom polarizations comparable in magnitude with that of diformylpiperazine. Presumably the cyano groups, like the formyl group, can be distorted appreciably by a weak electric field at 500 kc. The phenomenon should and will be investigated more thoroughly. At present it is relatively unimportant because it does not affect appreciably the moment (2.72 D.) of diformylpiperazine.

The moment angle of the formylamino group is not known, but it is probably low. Indeed a low formylamino moment angle is exemplified by the value of 1.51 D. found (Table I) for methyldiformamide. Now if N,N′-diformylpiperazine is considered in the sense of two opposed units of dimethylformamide (Table I, 3.82 D.) in which the formyl moment angles are low, then the observed moment (2.72 D.) seems to be high if a symmetrical chair conformation is assumed. In such a structure the formyl groups would be opposed either in axial or equatorial positions. Thus they would largely cancel each other unless random rotation of the formyl group were restricted. Evidence that this restriction does not exist is presented below in order to confirm that the chair conformation for diformylpiperazine is improbable.

The proton magnetic resonance spectrum of N,N′-diformylpiperazine in water at 25° shows the same simplicity as that of N,N′-dimethylpiperazine. The weaker (−115 c.p.s. with respect to water) of two simple peaks has been attributed to the formyl protons, so the stronger peak, at +1.5 c.p.s., must be due to the methylene protons. There is no tendency toward splitting of the peak when the solution of diformylpiperazine is chilled almost to its freezing point. This behavior is different from that of dimethylformamide (19, 24). If the spectrum reported for this latter substance is revised to compare with a 40 Mc. field, a formyl-proton peak exists at −120 c.p.s. and two methyl-proton peaks occur at +80 and +88 c.p.s. relative to water, the respective areas being

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

1:3:3. However the rigidity is lost when the sample in the field is heated to 117°, at which temperature only a single peak at about 84 c.p.s. is observed.

It is apparent that the spectrum of diformylpiperazine at 25° resembles that of dimethylformamide at 117°, where the latter is presumed to have free, rapidly rotating methyl groups. Of course diformylpiperazine cannot have this generalized positioning of protons because of its cyclic structure. However an oscillatory motion of the six-membered ring would account for the single methylene peak that Patton and Chaudet observed if this oscillation were more rapid than that of the proton resonance frequency.

But in this circumstance the ring oscillation frequency ought to exceed 100 c.p.s. by at least an order of magnitude. Clearly this rate is incompatible with the oscillation of a "chair" ring for which the transition rate should not exceed 0.01 c.p.s., assuming a rather low transition energy of 2 kcal. The transition rate from "chair" to rigid "boat" is even more unfavorable according to the calculated energies (3). Consideration of Patton and Chaudet's results suggests that the transition energy must not exceed 300 cal. in order to attain a rate of about 1000 c.p.s., at which the substituent proton positions would not be discernible by the N.M.R. modulatory frequency.

It is widely accepted that the crown form of cyclohexane is more stable than is the flexible form (13), although some refinement of calculation suggests that the higher free energy attributed to the flexible form may be exaggerated (9). In fact the electron diffraction patterns of 1,2-dichlorocyclohexane and 1,1,2-trichlorocyclohexane have been interpreted in favor of the flexible form at not-too-elevated temperatures (5). Actually it might be expected that substituent groups would affect profoundly the shape of the ring to which they are attached, and Oosterhof (18, 9) has shown that the dipole moment of 1,4-cyclohexanedione is best explained in terms of a flexible form. This opinion is supported by solid dielectric studies to be reported from the Toronto laboratory, which show that this substance does not have an abnormal atom polarization.

Recently Kumler and Huitric have classified those cyclic types which may be expected to be flexible (12). The inclusion of piperazines among these classes is reasonable. A flattened tetrahedral aspect for the nitrogen atoms should permit the flexibility that is indicated for 1,4-cyclohexanedione. The potential energy barrier due to methylene hydrogen interaction should be significantly less than that postulated for cyclohexane. In this circumstance a transition energy of 300 cal., largely involving compensated bond rotations, may indeed account satisfactorily for the absence of axial and equatorial proton positions in the N.M.R. spectrum. Therefore piperazines are thought to be in flexible conformation.

Within this definition we question whether the term "conformation" is an appropriate description of the saturated six-membered ring of atoms when it is considered in its flexible aspect. These terms imply the existence, during time intervals greater than those of molecular collision rate, of definite static structures. But the flexible ring will assume an infinity of forms and certainly cannot be defined in less than six static structures. None of these six will be equivalent when substituents of different complexity are present. In such circumstances the difficulties of "conformational analysis" are apparent. Perhaps they are not unsurmountable if the use of a static model is abandoned in favor of a dynamic one.

The authors wish to thank the National Research Council and the Defence Research Board of Canada for funds in support of this research and Mrs. Westland, Mr. Podleschka,

and the Tennessee Eastman Company, Division of Eastman Kodak Company, for extensive experimental aid.

EXPERIMENTAL*

Purification of Solvents

Benzene was washed with concentrated sulphuric acid until the acid layer was colorless and then was dried and distilled by the sodium benzophenone technique (15). The specific volume and dielectric constant were 1.13795 and 2.284 at 20° C. respectively. Dioxane was refluxed with concentrated hydrochloric acid (5 ml./l.) for 6 hours, then neutralized, dried with sodium hydroxide, then refluxed, and finally distilled by the sodium benzophenone technique. The specific volume and dielectric constant at 20° C. were 0.96770 and 2.2175 respectively.

N,N'-Dichloro-2,5-↑↓-dimethylpiperazine

Repeated vacuum sublimation of commercial 2,5-↑↓-dimethylpiperazine gave flakes, m.p. 117–117.5° C. A solution of 5 g. (0.044 mole) in 20 ml. of water was added slowly with stirring to an excess of fresh sodium hypochlorite solution at 0° C. The white precipitate was filtered off, washed with cold water, and dried, 5.8 g. (72%), m.p. 81.5–82° C. Vacuum sublimation raised the melting point to 83.8° C. with 64% recovery. The density at 20° C. was found by flotation to be 1.394. Calc. for $C_6H_{12}Cl_2$: C, 39.4; H, 6.61; N, 15.3. Found: C, 39.7; H, 6.61; N, 15.8.

N,N'-Dichloropiperazine

This compound, prepared in 68% yield, m.p. 71–71.5° C. (21), was crystallized from ether–ethanol (2: 1, 15 ml./g.) and this was vacuum sublimed, m.p. 72° C.

N,N'-Diformylpiperazine

The reported procedure (20) gave a 91.5% yield, m.p. 125–126° C. Repeated crystallization from absolute ethanol (10 ml./g.) raised the melting point to 127.5° C. The density was determined by air displacement to be 1.391.

N,N'-Bis-[2-cyanoethyl]-2,5-↑↓-dimethylpiperazine (25)

To a suspension of 5.71 g. (0.05 mole) of 2,5-↑↓-dimethylpiperazine in 10 ml. of dioxane was added 0.25 cc. of benzyltrimethylammonium hydroxide (40% aq., Triton B) and then 7.18 g. (0.135 mole) of pure acrylonitrile with stirring during 1 hour. The temperature was maintained below 30° C. After subsequent stirring for 8 hours the system was diluted with 20 ml. of water and was extracted with methylene chloride. The methylene chloride extract was dried by magnesium sulphate and then evaporated, leaving 4.1 g. (38%), m.p. 140° C. Crystallization from absolute ethanol (50 ml./g.) using decolorizing charcoal raised the melting point to 147° C. The density (air displacement) was 1.163. Calc. for $C_{12}H_{20}N_4$: C, 65.4; H, 9.16; N, 25.4. Found: C, 65.5; H, 9.05; N, 25.7.

N,N'-Bis-[2-cyanoethyl]piperazine

The detail for preparation of the substance was not reported (6) so it was synthesized essentially as described above, yielding a brown mass which was distilled under reduced pressure. The fraction boiling at 174–176° C. at 6–7 mm. pressure solidified on cooling, and was purified by crystallization from ether (25 ml./g.), m.p. 62–63° C., 59.9% yield. Density determined by air displacement was 1.119.

Melting points have been corrected against reliable standards (see Wright, G. F. Can. J. Technol. **34, 89 (1956)).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

N,N'-Dimethylpiperazine

The substance was prepared (22) in 40% yield, b.p. 131–132° C. (758 mm.), D_4^{20} 0.861, n_D^{20} 1.4477.

Polarizations of Solutions

Dielectric constants and specific volumes were determined as described previously (16) except that a matching signal of 60 c.p.s. or 120 c.p.s. was read from an oscilloscope instead of a zero beat between V.F.O. and F.F.O. The polarization was calculated by the method of Halverstadt and Kumler (8).

Polarization of the Solids

The method outlined previously (15) was used, the only alteration being the use of a gold amalgam (4.0 g. Hg + 1.5 g. Au). The densities have been determined either by the flotation method (4) or by an air-displacement method. The density of N,N'-diphenylpiperazine by the latter method was 1.158 at 20° C.

Density of Solids by Air Displacement

In order to avoid the errors due to solubility and chemical reactions which are likely to occur when density is determined by flotation an apparatus has been redesigned (shown cross-sectionally in front and top elevations in Fig. 5) for greater precision than

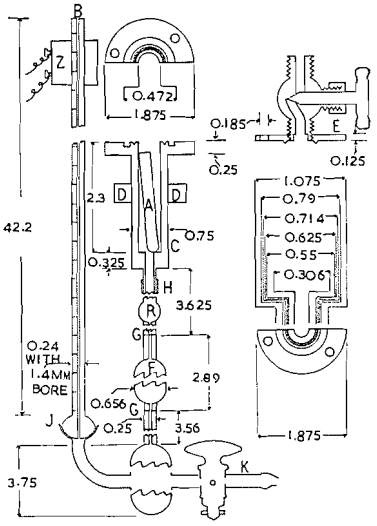

FIG. 5.

was required in the original one (7). The displacement of air by a finely-ground 0.3–1.0 g. sample in weighing tube A is measured by the change in pressure measured in manometer B after a 6-volt buzzer has reduced the column of mercury to a constant height. The brass chamber C, held by clamping block D, is equipped with a flange in which a seating V groove and a sealing square groove (containing a Parker O ring, 0.125 in. width, 0.8125 in. I.D., and 1.0625 in. O.D.) are cut. The V groove matches a V tongue in the flange E which is mated to C by three 10–32 machine screws. This flange, which is equipped for closure by a $\frac{1}{4}$ inch I PS Hoke valve, must be seated carefully with repeated symmetry tests by insertion of feeler stock between the flanges. When properly seated the volume of C, containing the empty sample tube, can be measured to a precision of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

0.04% by compressing air (by means of a levelling bulb, not shown) in front of mercury which fills the bulb F, the volume of which between two fiduciary marks G, G is previously known. A glass–metal seal H connects C and F, via a 2 cc. bulb R above the fiduciary mark. This bulb may be reduced in size to obtain proper volume relationship in the system. With attention to barometric pressure the change in manometric height is determined upon compression when the sample is included inside of C.

Thereupon the density is determined according to the relationship $d = W/L$, where L is the volume occupied by weight W of the sample. Then $L = M - PN/dp_2$, where P is the barometric pressure, dp_2 is the pressure difference (cm. Hg) observed when volume N of bulb F is filled with mercury, after brass chamber C containing the sample is rendered airtight. M is the volume of C containing the empty sample tube and is defined as $M = PN/dp_1$, where dp_1 is the observed pressure difference when mercury fills F without a sample in airtight chamber C.

Both the 12/2 ball joint J attaching the manometer and the stopcock K leading to the levelling bulb must be clamped tightly during the determination. The O ring but not the tongue and groove should be lightly greased in order to ensure airtightness when the flanges are connected. In order to avoid strain on the glass–metal seal during the closure operation the massive brass clamp D must secure C rigidly to the retort stand. Ordinary burette clamps suffice for the remainder of the apparatus.

The method is more arduous than a determination of density by flotation, but it is less subject to error than is the flotation method. For example the flotation of ferric acetylacetonate in aqueous calcium chloride has led to an erroneous value of 1.41 (15). The density by air displacement is 1.382 ± 0.002. A revised flotation in which the medium was hexane plus 1,2-dibromoethane saturated with the ferric compound gave a value of 1.381 ± 0.008. The value is decreased by either method when a crystal contains impenetrable faults, so the sample should be ground finely before analysis.

Polarization Values

Experimentally determined values for $d\epsilon/d\omega$ (α) and $d\bar{V}/d\omega$ (β) for the various piperazine derivatives are recorded as follows: N,N′-dichloro-2,5-↑↓-dimethylpiperazine, $\alpha = 0.05$, $\beta = 0.265$; N,N′-dichloropiperazine, $\alpha = 0.35$, $\beta = 0.355$; methyldiformamide, $\alpha = 2.88$, $\beta = 0.307$; N,N′-diformylpiperazine, $\alpha = 6.14$, $\beta = 0.368$; N,N′-*bis*-cyanoethyl-2,5-↑↓-dimethylpiperazine, $\alpha = 9.62$, $\beta = 0.180$; N,N′-*bis*-cyanoethylpiperazine, $\alpha = 10.61$, $\beta = 0.205$; 2,5-↑↓-dimethylpiperazine, $\alpha = 2.65$, $\beta = 0.140$; N,N′-dimethylpiperazine, $\alpha = 0.11$, $\beta = 0.034$.

The extrapolated values for ϵ from pellet measurements are listed as follows: N,N′-dichloro-2,5-↑↓-dimethylpiperazine, 2.325; N,N′-diformylpiperazine, 3.22; N,N′-*bis*-cyanoethyl-2,5-↑↓-dimethylpiperazine, 2.714; N,N′-*bis*-cyanoethylpiperazine, 2.615; 2,5-↑↓-dimethylpiperazine, 2.306; and N,N′-diphenylpiperazine, 2.730.

CRITICAL CONCENTRATION EFFECTS IN POLYMER–POLYMER–SOLVENT SYSTEMS[1]

C. C. Bigelow and L. H. Cragg

ABSTRACT

In various ternary systems of the type polymer A – polymer B – solvent S, a dip or peak has been observed in the $[\eta]$–c_B curve at the critical concentration of polymer B. ($[\eta]$ is the intrinsic viscosity of A in mixed solvent consisting of B and S, and c_B is the concentration of B in this mixed solvent.) It is shown that such a critical concentration effect is most likely to occur when the solvent is poor for polymer B, and will be the larger the poorer the solvent.

Evidence is also presented in support of the hypothesis that if, as is usual, the two polymers repel each other, the effect is a dip if the solvent is good for polymer A and is a peak if the solvent is sufficiently poor for polymer A.

Critical concentrations of polystyrene, polyvinyl acetate, and polymethyl methacrylate (five different samples) have been measured in this way in 12 different ternary systems. These observed critical concentrations are in good agreement with values calculated using the equation previously described, according to which the critical concentration of a polymer is inversely proportional to its intrinsic viscosity in the solution.

INTRODUCTION

In a recent paper (1) we presented evidence to show that a critical concentration can be determined in suitable viscometric experiments with ternary systems of the type polymer A – polymer B – solvent S. ("Critical concentration" here means the concentration of polymer at which the equivalent sphere of a given polymer molecule just touches the equivalent spheres of all of its nearest neighbor molecules of like kind.) If the intrinsic viscosity $[\eta]$ of Polymer A is measured first in pure S and then in a series of mixed solvents (solutions of polymer B in S) successively richer in polymer B, and if these intrinsic viscosities are plotted against c_B, the concentration of polymer B in the mixed solvent, then the resulting curve may exhibit a discontinuity at or very near the concentration calculated to be the critical concentration (c_{crit}) of polymer B in the solution. In four of the five experiments of this type that were reported, the discontinuity took the form of a dip, the curve having the general shape indicated in Fig. 1.

A qualitative explanation of this behavior was proposed, and an equation for calculating critical concentrations was developed with the aid of the Flory-Fox treatment of intrinsic viscosity. According to this equation, the critical concentration of polymer B should be inversely proportional to its intrinsic viscosity in pure solvent S (more strictly, to its reduced viscosity at $c_B = c_{crit}$, but since c_{crit} is very small, this reduced viscosity will differ little from the intrinsic viscosity). This conclusion was tested in experiments with the ternary system polystyrene – polymethyl methacrylate – solvent in which the intrinsic viscosity of polymer B (polymethyl methacrylate in this system) was varied, first by using samples of different molecular weight with the same solvent (*m*-xylene), and then by using two different solvents with the same sample of polymer. The observed critical concentration varied as predicted, and the values agreed remarkably well with the calculated values. (The observed critical concentration is taken to be the concentration c_B at which the discontinuity occurs or, more precisely, the concentration corresponding to the bottom of the dip or the top of the peak.)

In this paper we report and discuss the results of further study of this critical concentration phenomenon.

PROCEDURE

In the experiments to be reported here, we have (with a few exceptions noted in Table III) used the first of the two methods for determining critical concentrations that were described in the earlier paper (1). This was partly because this "intrinsic viscosity method" is more trustworthy (though much more time-consuming) than the other, but mainly because we were interested in the nature, as well as in the location, of the discontinuity in the $[\eta]$ vs. c_B curve.

Special care was taken in determining intrinsic viscosities. Both η_{sp}/c and $(\ln \eta_r)/c$ were plotted against c_A on a common plot and the curves were extrapolated to a common point at $c_A = 0$ to obtain $[\eta]$. When, as in almost all cases, these curves were straight lines, $[\eta]$ was evaluated by the method of least squares.

RESULTS AND DISCUSSION

I. The Nature of the Discontinuity

(*a*) In all of the experiments reported in the earlier paper, the solvent S was a poor one for polymer B. (By a "poor" solvent we mean here one in which the polymer has a relatively low intrinsic viscosity.) If the explanation of the critical concentration "dip" proposed in the previous paper is correct, a system in which the solvent S is poor for polymer B (and good for polymer A) should give a greater effect than one in which the solvent is good for polymer B (and good for polymer A). In a solvent that is good for it, the molecules of polymer A will be loosely coiled and the effective volume of an isolated molecule will be relatively large. As the critical concentration of polymer A is approached, molecules of polymer B will begin to crowd in on the molecule on all sides; and further increase in concentration will cause contraction of the polymer A molecule or of the polymer B molecules or both (assuming that the two polymers repel each other, as is true of most polymer pairs). If the solvent is poor for polymer B, its molecules will be more tightly coiled, and the density of segments of B in the immediate neighborhood of the A molecule will be higher than if the solvent is good for polymer B. The repulsive forces causing the molecule of A to shrink (and hence its intrinsic viscosity to decrease) will therefore be greater. Conversely, if the solvent is good for polymer B the contraction in volume of the molecule of polymer A (and therefore the decrease in $[\eta]$) might well be so slight as to be undetectable, partly because of the much lower density of B segments at the critical concentration, and partly because such contracting as would occur would be shared by the B molecules.

The validity of these speculations was tested in experiments with the systems listed in Table I. The results are shown graphically in Fig. 3. Toluene and benzene are both *poor* solvents for polyvinyl acetate; experiments 6 and 8 should therefore give measurable effects. Toluene and *m*-xylene are both *good* solvents for polystyrene; in experiments 7 and 9, therefore, the discontinuity should be very small or undetectable. As

TABLE I

TERNARY SYSTEMS IN EXPERIMENTS 6 TO 9
(For identification of polymer samples see Table V)

Experiment	Polymer A	Polymer B	Solvent S
6	PS-3	PV-1	Toluene
7	PV-1	PS-3	Toluene
8	PS-3	PV-1	Benzene
9	PM-4	PS-3	*m*-Xylene

can be seen, unmistakable "dips" do occur in the $[\eta]$–c_B curves for experiments 6 and 8 (and they occur at the calculated critical concentrations, indicated by the arrow) but there is no sign of a "dip" in the curves for experiments 7 and 9.

(*b*) In experiment 5 of the earlier paper (1) the discontinuity in the $[\eta]$–c_B curve was a peak rather than a dip (see Fig. 2 of this paper). In this experiment polymer A was

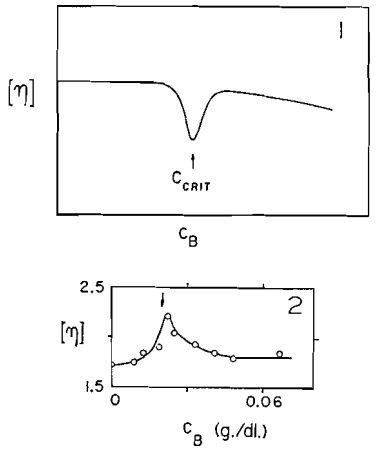

FIG. 1. Viscometric critical concentration effect: idealized curve.
FIG. 2. A critical concentration peak. (System: polystyrene – polymethyl methacrylate – butanone.)

polystyrene, polymer B was polymethyl methacrylate, and the solvent was butanone. This solvent is a poor one for *both* polymers. The shape of the discontinuity was a surprise, but it can be plausibly accounted for in terms of our molecular explanation. If the solvent is a very poor one for the A polymer (as butanone is for polystyrene in experiment 5) the segments of a polymer A molecule will much prefer one another's company to that of solvent molecules, and the polymer molecule will coil up tightly. If the dislike of polymer A for polymer B is less than its dislike of the solvent S, then the fairly uniform environment, consisting of solvent molecules and polymer B segments, that is attained near the critical concentration will be a more favorable environment for the polymer A molecule than pure solvent S. The molecule will therefore expand and $[\eta]$ will increase. Further, as c_B is increased, $[\eta]$ will continue to increase until the critical concentration is reached, after which interpenetration of the two kinds of polymer molecules begins to make the environment within and without the polymer A molecule more nearly the same. Then the molecule of polymer A will begin to contract again, for the mixed solvent is still a poor solvent for the polymer.

One might therefore expect to find a peak with systems in which the solvent S is poor for both polymers and is so poor for polymer A that the mutual repulsion of polymer A segments and solvent S molecules would exceed that of polymer A segments and polymer B segments.

We therefore investigated three additional systems, in which the solvent was at the same time poor for both polymers. These systems are described in Table II and the results obtained with them are shown graphically in Fig. 4. In two of the three experiments (10 and 11) a peak was indeed obtained— and at or very near the concentration calculated to be the critical concentration. In the third (experiment 12) no discontinuity of any kind was observed. This may be because the polymer A – solvent repulsion was not appreciably greater than the polymer A – polymer B repulsion.

TABLE II

SYSTEMS IN WHICH THE SOLVENT IS POOR FOR BOTH POLYMERS

Experiment	Polymer A	Polymer B	Solvents
10	PS-3	PV-1	Butanone
11	PS-3	PM-5	Ethyl acetate
12	PM-5	PS-3	Ethyl acetate

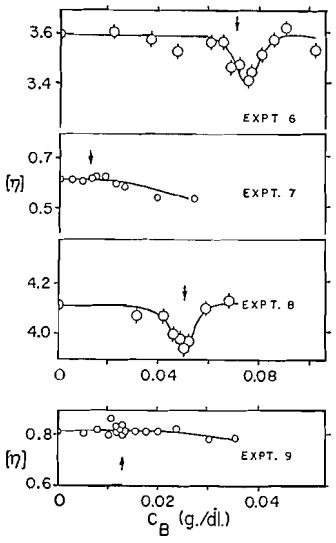

FIG. 3. Effect of goodness of solvent for polymer B. The solvent is poor for B in experiments 6 and 8 and good for B in experiments 7 and 9. (The arrows point to the calculated critical concentrations.)

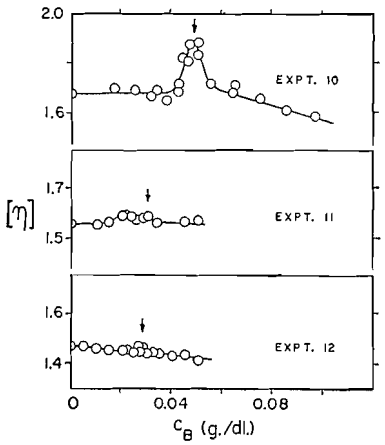

FIG. 4. Critical concentration effects with systems in which the solvent is poor for both polymers. (Arrows indicate calculated critical concentrations.)

(*c*) The success that our hypothesis has had in explaining and predicting experimental findings makes it seem highly probable that the critical concentration effects we have been studying are due to polymer–polymer and polymer–solvent interactions and to their relative magnitudes. So far we have dealt with systems in which the two polymers would be expected to repel each other (see for example the polymer incompatibility studies of Dobry and Boyer-Kawenoki (2) and of Kern and Slocombe (3)). The magnitude of the dip should be greatest when the solvent is good for polymer A and poor for polymer B and when the two polymers repel each other strongly. The magnitude of the effect should be less when the two polymers are more alike than are polystyrene and polyvinyl acetate, or polystyrene and polymethyl methacrylate. A number of experiments have been done which seem to support this idea. The systems investigated are listed in Table III. In all of them the solvent is a poor one for the solvent polymer (polymer B).

In five of the eight experiments (13, 14, 15, 21, and 22) the critical concentration effect, if any, was too small to manifest itself by an unmistakable discontinuity. In each of the other three experiments (16, 19, and 20) a dip was indicated, each time at or near the concentration calculated to be the critical concentration (see Fig. 5). These dips were, however, very small ones, definitely smaller than those observed in systems in which the two polymers were more different chemically. (It is interesting to note

that with two quite different systems—see experiments 19 and 20—critical concentration effects were observed when the two polymers were two different samples of the same polymer. These experiments provide direct evidence that molecules of the same polymer repel each other and, when crowded close together, cause each other to shrink. Such behavior was postulated on theoretical grounds and some of its consequences discussed by Weissberg, Simha, and Rothman (4). Indeed, they derived an expression for the concentration at which this shrinkage should occur (in a binary system)—though they did not call it a critical concentration—and their expression has the same form as ours.)

II. The Location of the Discontinuity: The Critical Concentration

Although these experiments have been concerned primarily with the nature (shape and magnitude) of the discontinuity, they contribute further evidence that the discontinuity does indeed occur at a critical concentration. In the first paper, proof that a critical concentration effect was being observed was provided by the excellent agreement between observed and calculated values of the critical concentration. The equation for calculating the critical concentration (c_{crit}) was shown to be

$$c_{crit} = 0.0436k^3/[\eta]_B,$$

where k is a (dimensionless) proportionality constant whose value is apparently very close to unity. The constant should have substantially the same value for all the polymers used as polymer A in the systems we have studied, for all of them are flexible linear vinyl polymers. The same equation, viz. $c_{crit} = 0.0436k^3/[\eta]_B$, should therefore apply to all the systems.

The value of c_{crit}, the critical concentration, obtained from the equation is marked on each of the plots by means of an arrow; any dip or peak in the $[\eta]$–c_B curve invariably occurs at or near this point. In Table IV are listed values of the product of the observed critical concentration and the intrinsic viscosity of polymer B. The essential constancy of this product is strong evidence for the validity of our assumptions. Visual evidence of

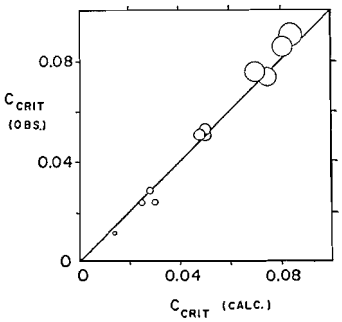

FIG. 6. Plot of observed vs. calculated critical concentrations.

the good agreement between calculated and observed values is afforded in Fig. 6, in which c_{crit}(observed) is plotted against c_{crit}(calculated) for all systems in which a discontinuity has been observed. The agreement would be perfect if the points fell on the 45° line; it is not perfect, but it is surprisingly good.

EXPERIMENTAL

The apparatus and experimental methods were those used previously (1). The intrinsic viscosities of the various polymers used are given in Table V.

THE SYNTHESIS OF ω-DEOXY-ω-*S*-ETHYL-POLYOLS[1]

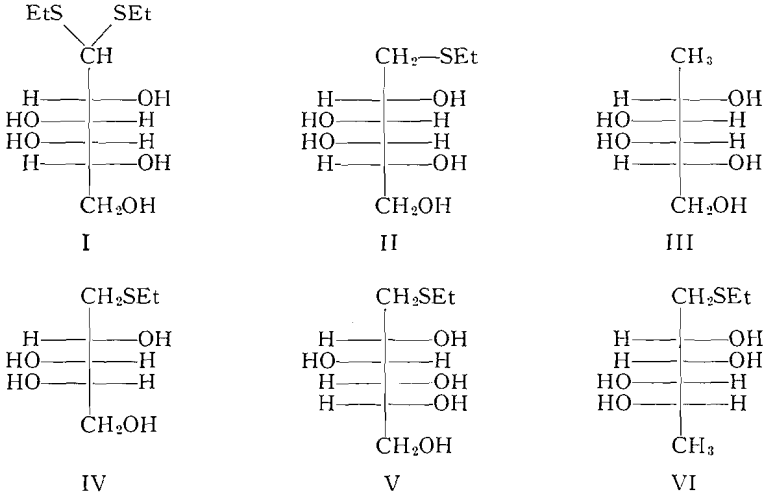
J. K. N. JONES AND D. L. MITCHELL[2]

ABSTRACT

Treatment of an aldose diethyl thioacetal with a limited amount of aged Raney nickel catalyst resulted in the reductive cleavage of one thioethyl group. 1-Deoxy-1-*S*-ethyl derivatives of D-galactitol, L-arabitol, L-rhamnitol, and D-glucitol have thus been synthesized and their structures proved. 1-Deoxy-1-*S*-ethyl-L-galactitol has been prepared by the borohydride reduction of 6-deoxy-6-*S*-ethyl-D-galactose.

INTRODUCTION

Reductive desulphurization of aldose thioacetals (1, 2, 3, 4, 5, 6) and aldose thioacetal acetates (1, 7) using an excess of Raney nickel catalyst provides a simple method of preparing 1-deoxy sugar alcohols. In a review, Fletcher and Richtmyer (8) questioned the value of using as high catalyst ratios as have been reported in the literature. They tabulate examples of ratios from 9:1 to 15:1 (grams of Raney nickel catalyst to grams of thioacetal derivative). Generally, the yield of 1-deoxy-polyol or 1-deoxy-polyol acetate varied inversely with the catalyst ratio. The decrease in yield was probably due to adsorption of product on the catalyst. We found that when a catalyst with a low hydrogen content (e.g. W-2 catalyst) was used, and a low catalyst ratio was chosen (*ca.* 5 : 1), a mixture of three compounds resulted. When D-galactose diethyl thioacetal was thus treated, paper chromatographic examination of the product indicated the presence of a fast-moving compound, D-galactose diethyl thioacetal; a slow-moving compound, 1-deoxy-D-galactitol (L-fucitol); and a second sulphur-containing compound (II) which was between these two compounds on the chromatogram. A catalyst ratio was determined, by means of trial experiments in which compound II was the main product of the reaction. In this reaction one thioethyl group of the aldose diethyl thioacetal (I) was replaced by a hydrogen atom to give the monothioethyl derivative (II). Compound II on reductive desulphurization gave 1-deoxy-D-galactitol (L-fucitol) (III).



[1]*Manuscript received September 9, 1957.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.
[2]*Present address: Department of Organic Chemistry, University of Bristol, Bristol 8, England.*

The diethyl thioacetals of D-galactose, L-arabinose, D-glucose, and L-rhamnose were also partially desulphurized, and respectively yielded 1-deoxy-1-*S*-ethyl-(D-galactitol) (II), -(L-arabitol) (IV), -(D-glucitol) (V), and -(L-rhamnitol) (VI). Crystalline acetates of compounds II, IV, and V were also prepared. The yields were not appreciably reduced when large scale experiments were carried out. This result corresponded with the observations of Richtmyer and co-workers (2, 3, 4, 5, 6). Complete reductive desulphurization of compounds II, IV, V, and VI yielded the known ω-deoxy sugar alcohols, which are 1-deoxy-D-galactitol (L-fucitol), 1-deoxy-L-arabitol (L-lyxomethylitol), 1-deoxy-D-glucitol (L-gulomethylitol), and 1,6-dideoxy-L-mannitol respectively.

ω-Deoxy-ω-*S*-alkyl polyols can also be synthesized by the reduction of the corresponding aldose (9). In this manner 6-deoxy-6-*S*-ethyl-D-galactose (6-deoxy-6-thioethyl-D-galactose) (10) was reduced with potassium borohydride to 1-deoxy-1-*S*-ethyl-L-galactitol (6-deoxy-6-*S*-ethyl-D-galactitol). This compound had about the same melting point and magnitude of optical rotation (but in the opposite direction) as the D-isomer. The D- and L-isomers had identical rates of movement on paper chromatograms. The racemate melted at about 10° C. lower than the isomers.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (*ca.* 15 mm.) at a bath temperature of 50° C. or less. Melting points were uncorrected and optical rotations were determined in water unless otherwise stated. Paper chromatography was carried out by the descending method (11) on Whatman No. 1 filter paper using the following solvent systems (v: v): (*a*) ethyl acetate – acetic acid – water (9: 2: 2), (*b*) ethyl acetate – acetic acid – formic acid – water (18: 3: 1: 4), (*c*) *n*-butanol–ethanol–water (3: 1: 1), (*d*) *n*-butanol–pyridine–water (10 : 3 : 3). Non-reducing compounds were detected on paper chromatograms with a silver nitrate spray reagent (12). The rate of movement of the compound on paper chromatograms is quoted relative to that of the solvent front (R_f value) or relative to that of rhamnose (R_{Rh} value).

A standard method of preparing Raney nickel catalyst W-2 (13) was followed exactly. It was stored in ethanol at 0–5° C. This catalyst will be referred to as catalyst (*a*) in these experiments. A catalyst of slightly lower hydrogen content was obtained from the Aldrich Chemical Company.* It was washed free from traces of alkali and was stored in ethanol at 0–5° C. This catalyst will be referred to as catalyst (*b*). The activity of catalysts (*a*) and (*b*) did not change appreciably over a storage period of 4 months.

Preliminary Experiments

Weighed samples (*ca.* 0.5 g.) of D-galactose diethyl thioacetal (14) were dissolved in 75% *iso*propanol (50 ml.). A range of catalyst ratios was chosen (*ca.* 3 : 1 to 8 : 1) and the appropriate volume of Raney nickel catalyst (*a*) was added to the flasks. The mixture was boiled under reflux for 2 hours and cooled. The solutions were filtered from the catalyst and examined by paper chromatography. The catalyst ratio that produced the maximum amount of component with a rate of movement between galactose diethyl thioacetal and fucitol was used in subsequent experiments. Catalyst ratios are expressed in liters of settled volume of nickel per mole of aldose thioacetal.

Preparation of 1-Deoxy-1-S-ethyl-D-galactitol

(i) D-Galactose diethyl thioacetal (3.73 g., 0.013 mole) and Raney nickel catalyst (*a*)

**Aldrich Chemical Co., Inc., Milwaukee 12, Wisconsin.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

(settled volume 30 ml. equivalent to 2.3 liters/mole) in 75% *iso*propanol (200 ml.) were shaken in a hydrogen atmosphere (pressure *ca.* 800 mm.) for 2 hours at 60° C. and then boiled under reflux on the water bath (100° C.) for an additional 3 hours. The filtered solution was concentrated to a crystalline mass, which was recrystallized from methanol and acetone (5 : 1) to give 1.24 g. (57.5%) of product melting at 151–153° C. (The catalyst was lost accidentally before it could be washed.) The rate of movement on a paper chromatogram ((*a*) R_f 0.47, R_{Rh} 1.70; (*b*) R_f 0.52, R_{Rh} 1.29) was intermediate between galactose diethyl thioacetal and fucitol, and the compound on treatment with silver nitrate spray reagent gave an intense spot which appeared immediately, whereas the spot due to fucitol appeared slowly. The product on recrystallization from methanol gave a chromatographically pure product that had m.p. 149–151° C. and $[\alpha]_D^{25°}$ −9°±2° (*c*, 0.95). Anal. Calc. for $C_8H_{18}O_5S$: C, 42.6; H, 8.1; S, 14.2. Found: C, 42.5; H, 8.1; S, 14.0.

(ii) *Large scale experiment.*—D-Galactose diethyl thioacetal (11.0 g., 0.038 mole) and Raney nickel catalyst (*a*) (83.5 ml. settled volume equivalent to 2.2. liters/mole) in 75% *iso*propanol (1 liter) were boiled under reflux on the water bath (100° C.) for 3 hours. The solution was decanted from the catalyst, which was washed twice with ethanol and separated by centrifugation. The catalyst was digested with ethanol (3 times with 300 ml.) and then with water (2 times with 200 ml.), and the combined washings and decanted solution were filtered through a pad of Celite and evaporated to dryness. Recrystallization from methanol and acetone (5 : 1) gave 5.80 g. (67%) of product in three crops of crystals, m.p. 148–149° C. Duplicate readings gave $[\alpha]_D^{21°}$ −8.2° (*c*, 2.24); $[\alpha]_D^{24°}$ −8.9° (*c*, 2.33).

*1-Deoxy-1-S-ethyl-*D*-galactitol Pentaacetate*

1-Deoxy-1-*S*-ethyl-D-galactitol (88 mg.) in pyridine (1 ml.) was acetylated for 24 hours with acetic anhydride (1 ml.). The product crystallized when it was poured into a slurry of chipped ice and water, and it was collected by filtration. It was dissolved in hot methanol, and the solution was purified with a little charcoal and filtered through a pad of Celite. The filtrate was warmed and an equal volume of hot water was added. After cooling, the crystals in the form of flakes were collected by filtration and washed with cold water. Yield: 117 mg. (60%), m.p. 150.5–151.0° C. $[\alpha]_D^{22°}$ 8°±1° (*c*, 1.1, chloroform). Anal. Calc. for $C_{18}H_{24}O_{10}S$: C, 49.5; H, 6.5; S, 7.3. Found: C, 49.8; H, 6.7; S, 7.1.

*Conversion of 1-Deoxy-1-S-ethyl-*D*-galactitol to* L*-Fucitol*

1-Deoxy-1-*S*-ethyl-D-galactitol (120 mg.) was dissolved in 70% ethanol (10 ml.) containing Raney nickel W-2 catalyst (3 ml. settled volume) and the suspension was boiled under reflux on the water bath (100° C.) for 3 hours. The catalyst was removed by filtration through a pad of Celite, and the filtrate was concentrated to a crystalline mass. The product moved as a single spot on paper chromatograms developed in solvents (*a*), (*b*), (*c*), and (*d*) and had a rate of movement identical with that of L-fucitol prepared by the borohydride reduction of L-fucose. The following R_f and R_{Rh} values were obtained: R_f 0.37, R_{Rh} 1.12 (*a*); R_f 0.39, R_{Rh} 1.07 (*b*); R_f 0.31, R_{Rh} 1.00 (*c*); R_f 0.30, R_{Rh} 0.93 (*d*). Recrystallization from ethanol (3 ml.) gave 33.4 mg. (38%) of fine needles melting at 156.0–156.5° C. The mixed melting point with an authentic specimen was 156.0–156.5° C.

*1-Deoxy-1-S-ethyl-*L*-arabitol*

(i) L-Arabinose diethyl thioacetal (1.50 g., 0.008 mole) (15, 16) and freshly prepared Raney nickel catalyst (*a*) (settled volume 12 ml., 1.5 liters/mole) in 75% *iso*propanol (80 ml.) were boiled under reflux on the water bath (100° C.) for 3 hours. The cooled solution was decanted and the catalyst was washed with ethanol and separated by centrifugation. The catalyst was then digested with ethanol (2×100 ml.) and the combined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

For personal use only.

washings and decanted solution were filtered through a pad of Celite and evaporated to dryness. The crystalline mass was examined by paper chromatography, which indicated the presence of two compounds. The main constituent had a rate of movement of R_f 0.61, R_{Rh} 1.79 (*a*) and the second component had a rate of movement of R_f 0.43, R_{Rh} 1.27 (*a*). The ratio of the two components was visually estimated to be 20 : 1. The crude product was dissolved in hot acetone (40 ml.), filtered, and chilled in the refrigerator. The crystals were collected by filtration and the mother liquors were concentrated to yield a second crop. Yield: 0.71 g. (68%), m.p. 118.5–119.5° C., $[\alpha]_D^{22°}$ −12°±1° (*c*, 2.59). Anal. Calc. for $C_7H_{16}O_4S$: C, 42.8; H, 8.2; S, 16.3. Found: C, 43.1; H, 8.5; S, 16.1.

(ii) L-Arabinose diethyl thioacetal (19.0 g., 0.074 mole) and 75% *iso*propanol (3 liters) were stirred mechanically with aged Raney nickel catalyst of a low hydrogen content (settled volume 250 ml., 3.3 liters/mole) and boiled under reflux on the water bath (100° C.) for 3.5–4 hours. The cooled solution was decanted and the catalyst was treated in the manner described above. Examination of the product by paper chromatography revealed only a single spot (R_f 0.69, R_{Rh} 1.83 (*a*)). The product was recrystallized from acetone–ethanol (3 : 1) to give a total yield of 8.43 g. (58%) in four crops, m.p. 119–120° C., $[\alpha]_D^{26°}$ −12°±1° (*c*, 1.75). Recrystallization from *iso*propanol gave fine needles, m.p. 118.5–119.5° C. When tested in high concentration, a trace of L-lyxomethylitol was revealed on the chromatogram and this impurity was removed by repeated recrystallizations from *iso*propanol, but the melting point remained unchanged (118.5–119.5° C.).

*1-Deoxy-1-S-ethyl-*L*-arabitol Tetraacetate*

The tetraacetate was prepared in the manner previously described for the acetylation of 1-deoxy-1-*S*-ethyl-D-galactitol. Recrystallization from ethanol and water (3 : 1) gave white plates (40%) melting at 58.0–58.5° C., $[\alpha]_D^{26°}$ −35°±1° (*c*, 1.64, chloroform). Anal. Calc. for $C_{15}H_{24}O_8S$: C, 49.4; H, 6.6; S, 8.8. Found: C, 49.5; H, 6.5; S, 8.9.

*1-Deoxy-*L*-arabitol* (L-*Lyxomethylitol*)

1-Deoxy-L-arabitol (7) was prepared in 70% yield by the desulphurization of 1-deoxy-1-*S*-ethyl-L-arabitol in the same fashion as is described for the desulphurization of L-fucitol. The product (0.19 g.) was recrystallized from ethyl acetate (40 ml.), m.p. 128–129° C., $[\alpha]_D^{27°}$ −1.8° (*c*. 1.70), (lit. m.p. 129–131° C., $[\alpha]_D^{30°}$ −1.46° (water) (9)). 1-Deoxy-D-arabitol has a reported m.p. 129–131° C. and a $[\alpha]_D^{20°}$ +0.7° (6).

*1-Deoxy-1-S-ethyl-*D*-glucitol*

D-Glucose diethyl thioacetal (15) (5.0 g., 0.017 mole) in 75% *iso*propanol (600 ml.) was boiled under reflux with aged Raney nickel catalyst (*b*) (50 ml. settled volume, 2.9 liters/mole) in exactly the same manner as is described for the preparation of 1-deoxy-1-*S*-ethyl-D-galactitol in experiment (ii). The crude product, 1.94 g. (51%), contained a trace of 1-deoxy-D-glucitol (paper chromatography), and was recrystallized four times from *iso*propanol. The pure compound had a rate of movement on a paper chromatogram of R_f 0.59, R_{Rh} 1.70 (*a*); R_f 0.61, R_{Rh} 1.53 (*b*); R_f 0.52, R_{Rh} 1.61 (*c*); R_f 0.53, R_{Rh} 1.48 (*d*); a m.p. 107.5–108° C.; and $[\alpha]_D^{26°}$ −29°±1° (*c*, 1.85). Anal. Calc. for $C_8H_{18}O_5S$: C, 42.7; H, 8.1; S, 14.2. Found: C, 42.9; H, 8.2; S, 14.0.

When the experiment was repeated on a larger scale (D-glucose diethyl thioacetal, 23.6 g., Raney nickel catalyst (*b*), 215 ml. settled volume, and *iso*propanol, 3 liters) in the manner previously described for the preparation of 1-deoxy-1-*S*-ethyl-L-arabitol, part (ii), a yield of 9.87 g. (49%) of crude product was obtained. Repeated recrystallizations from *iso*propanol gave 6.9. g. (34%) of pure compound, m.p. 107.5–108° C., $[\alpha]_D^{24°}$ −30° (*c*, 1.89).

*1-Deoxy-1-S-ethyl-*D*-glucitol Pentaacetate*

The pentaacetate was prepared in the manner previously described and was crystallized from methanol and water (1:1) in a 59% yield, m.p. 82° C., $[\alpha]_D^{26°}$ 5°±1° (*c*, 1.1, chloroform). Anal. Calc. for $C_{18}H_{28}O_{10}S$: C, 49.5; H, 6.5; S, 7.4. Found: C, 49.7; H, 6.5; S, 7.4.

*1-Deoxy-*D*-glucitol Pentaacetate*

Reductive desulphurization of 1-deoxy-1-*S*-ethyl-D-glucitol in ethanol with an excess of Raney nickel catalyst (*a*) in the usual manner gave a non-crystalline product which appeared to be chromatographically pure (R_f 0.60, R_{Rh} 1.52 (*a*); R_f 0.28, R_{Rh} 0.95 (*c*); R_f 0.29, R_{Rh} 0.88 (*d*)). It was therefore acetylated and the pentaacetate was recrystallized from ethanol, m.p. 105.5–107° C., $[\alpha]_D^{26°}$ 21°±1° (*c*, 1.26, methanol) (lit. m.p. 105–106° C., $[\alpha]_D^{21°}$ 21° (methanol) (7, 17)).

*1-Deoxy-1-S-ethyl-*L*-rhamnitol*

L-Rhamnose diethyl thioacetal (15) (4.0 g., 0.015 mole) was dissolved in 75% *iso*propanol (600 ml.) and was boiled under reflux with Raney nickel catalyst (*a*) (33 ml. settled volume equivalent to 2.2 liters/mole) for 4 hours. The crude product (1.0 g. (32%)), m.p. 118–119.5° C., was isolated in the usual way. This compound was readily soluble in water, ethanol, and *iso*propanol but it could be recrystallized from a small volume of ethyl acetate. Repeated recrystallizations from ethyl acetate gave flat plates melting at 120.5–121° C. and with $[\alpha]_D^{26°}$ −21.2° (*c*, 1.36). The rates of movement on paper chromatograms were R_f 0.76 (*a*) and R_f 0.73 (*b*). Anal. Calc. for $C_8H_{18}O_4S$: C, 45.7; H, 8.6; S, 15.2. Found: C, 46.1; H, 8.9; S, 15.1.

Reductive desulphurization of this compound in the usual way gave 1,6-dideoxy-L-mannitol. Recrystallization from a small volume of ethyl acetate gave clusters of crystals melting at 146–147° C. and with $[\alpha]_D^{24°}$ 23° (*c*, 1.02) (lit. m.p. 145–146° C., $[\alpha]_D^{20°}$ 22.8° (3)).

*1-Deoxy-1-S-ethyl-*L*-galactitol*

The preparation of 6-deoxy-6-*S*-ethyl-D-galactose described by Baker (10) was followed except that 1,2;3,4-di*iso*propylidene-6-*O*-methanesulphonyl-D-galactose (18) was used as the starting compound. 1,2;3,4-Di*iso*propylidene-6-deoxy-6-*S*-ethyl-D-galactose, $[\alpha]_D^{29°}$ 1.4765, $[\alpha]_D^{26°}$ −85.8° (*c*. 5.90, chloroform), was obtained in 92% yield after purification by high vacuum distillation. The reported constants are: $[\alpha]_D^{24°}$ 1.4795, $[\alpha]_D^{22°}$ −85.7° (chloroform) (10). Mild acid hydrolysis gave a reducing sirup that moved as a single spot on a paper chromatogram (R_f 0.53, R_{Rh} 1.35 (*b*)) (*p*-anisidine spray reagent).

A solution of this sirup (2.6 g. in 25 ml. of water) was added dropwise to a stirred solution of potassium borohydride (0.85 g. in 20 ml. of water). After 2 hours a test portion was neutralized with acetic acid and it gave a negative test with Fehling's solution. The solution was acidified with acetic acid, then percolated through a column of IR-120 (H form) ion exchange resin. The solution and washings were filtered and concentrated to dryness. After six codistillations with methanol, the residue was dissolved in a solution of methanol–acetone (5:1)(15 ml.). Crystals (1.0 g. (39%)) were deposited when the solution was chilled to −20° C. A second recrystallization from methanol–acetone gave a chromatographically pure compound which had a rate of movement on a paper chromatogram identical with that of 1-deoxy-1-*S*-ethyl-D-galactitol in solvents (*a*), (*b*), and (*c*), m.p. 151–153° C., $[\alpha]_D^{24°}$ 8.6 (*c*, 4.18). The racemate melted at 141.5–142.0° C. Anal. Calc. for $C_8H_{18}O_5S$: C, 42.6; H, 8.1; S, 14.2. Found: C, 42.8; H, 8.1; S, 13.9.

The pentaacetate was prepared in 57% yield in the usual way. Recrystallization from methanol–water (5:1) gave flakes melting at 151.0–151.5° C., $[\alpha]_D^{24°}$ −9°±1° (*c*, 1.31

THE RELATION BETWEEN THE SULPHATE AND NITROGEN CONTENT OF UNSTABILIZED CELLULOSE NITRATE[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] AND BRIAN T. NEWBOLD[3]

ABSTRACT

The sulphate and nitrogen contents of cellulose nitrates prepared from mixed acids containing different amounts of sulphuric acid were compared. The sulphate content showed a tendency to decrease with increasing nitrogen, for instance it was 1.96% for 10.54% and 0.44% for 13.31%. Similar results were obtained with a series of wood cellulose nitrates, for instance 2.40% for 11.01% and 0.91% for 12.47%. With practically the same amount of sulphuric acid in the mixed acid, cellulose nitrates were prepared and the sulphate and nitrogen contents were compared. For unstabilized cotton cellulose nitrates, the sulphate content decreased steadily with increasing nitrogen content. Similar results were obtained with wood cellulose nitrates.

INTRODUCTION

In a recent publication (1) the degree of nitration of cotton linters and wood cellulose was determined when the same mixed acid was used. The sulphate content of the unstabilized cellulose nitrates obtained was shown to be dependent upon the sulphuric acid content of the mixed acid.

Miles (4) has stated that the total sulphate content of cellulose nitrate tends to increase with decreasing nitrogen content. The object of the present work was to determine the relation between the total sulphate and nitrogen contents of both cotton and wood unstabilized cellulose nitrates.

EXPERIMENTAL

Cellulose Nitrate

The procedure for the nitration of cotton linters and wood cellulose was given in a recent publication (2). The methods used to analyze the mixed acids and to determine the sulphate and nitrogen contents of the unstabilized cellulose nitrates were also described in previous papers (1, 3).

RESULTS AND DISCUSSION

In general the total sulphate content of unstabilized cellulose nitrate depends upon several factors, namely, the composition of the mixed acid used to nitrate the cellulose, the nitration conditions, the degree of washing, and the nitrogen content of the cellulose nitrate. The sulphate content has been shown to increase when the proportion of sulphuric acid in the mixed acid increased (1).

In the present work, the sulphate and nitrogen contents of unstabilized cotton and wood cellulose nitrates were determined by good precision methods (1) and compared. The nitrogen contents of the cellulose nitrates varied from 13.3 to 7.7% for cotton, and 13.0 to 7.3% for wood cellulose nitrate.

The sulphate and nitrogen contents of cotton cellulose nitrates prepared from mixed acids containing different amounts of sulphuric acid are compared in Table I. The sulphate content showed a tendency to decrease with increasing nitrogen, for instance

14	70.35	0.47	13.21	14	65.00	0.93	11.91
15	65.66	0.44	13.31	15	65.66	0.91	12.47

it was 1.96% for 10.54% and 0.44% for 13.31%, but no definite curve can be drawn. Similar results were obtained with a series of wood cellulose nitrates, as shown also in Table I, for instance 2.40% for 11.01% and 0.91% for 12.47%.

The nitrogen contents of the cellulose nitrates given in Table I varied from 13.3% to 10.5%, which is the range for cellulose nitrates used in industry. In the present work, cellulose nitrates containing less than 10.0% nitrogen did not give satisfactory results because they were either swollen or gelatinized to such an extent that it was not possible to attain a reproducible degree of washing.

The nitration conditions and the degree of washing with water for the preparation of the two types of cellulose nitrates mentioned in Table I were very similar; therefore any effects on sulphate content due to the latter can be discounted. The fact that no precise curve could be drawn to show the relation between the sulphate and nitrogen contents of the cellulose nitrates prepared from various mixed acids was thought to be due to the effects of the proportion of sulphuric acid in the mixed acid and that of the nitrogen in the cellulose nitrate. Since it has been shown that the sulphuric acid content of the mixed acid has a profound effect upon the sulphate content (1), it was essential

to remove this factor before determining the sulphate–nitrogen relation. Accordingly, cellulose nitrates were prepared using mixed acids containing an almost constant amount of sulphuric acid, and their sulphate and nitrogen contents were compared. The results for cotton and wood cellulose nitrates are given in Table II and Fig. 1.

For unstabilized cotton cellulose nitrates, the sulphate content decreased steadily with increasing nitrogen content. Furthermore, similar results were obtained for wood cellulose nitrates.

A CONTRIBUTION TO THE CHEMISTRY OF UNSTABILIZED CELLULOSE NITRATE[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] AND BRIAN T. NEWBOLD[3]

ABSTRACT

Cotton linters and wood cellulose were nitrated in parallel experiments with a series of mixed acids and the products examined for nitrogen and sulphate content. A higher degree of nitration was obtained with the cotton cellulose, and the sulphate content of the nitrated cotton increased steadily with increasing concentration of sulphuric acid in the nitration medium while the sulphate content of the wood cellulose passed through a maximum value which depended on the degree of nitration. The sulphate content of the cotton cellulose nitrates was higher than that of the wood cellulose nitrates when the nitrations were performed under similar conditions.

INTRODUCTION

The sulphate content of crude, but well washed, cellulose nitrate prepared from mixed acid varies from about 0.2 to 3.0%, expressed as sulphuric acid, according to the composition of the nitric–sulphuric acid mixture. The total sulphate and the proportion of sulphate ester tend to increase with decreasing nitrogen content (2, 4).

The object of the present work was to compare the degree of nitration of cotton linters and wood cellulose obtained when the composition of the mixed acid used was the same, and to establish the relation between the sulphate content of unstabilized cellulose nitrate and the sulphuric acid content of the mixed acid.

EXPERIMENTAL

Cellulose Nitrate

Cotton linters and wood cellulose were nitrated with mixed acids, using the method given in a previous publication (2). The mixed acids were analyzed by standard methods. The total sulphate content in the cellulose nitrates was determined as barium sulphate (3). The nitrogen content was obtained by the Devarda method.

RESULTS AND DISCUSSION

Degree of Nitration

Many nitrations of cotton linters and wood cellulose were carried out using a variety of mixed acids, in order to determine the relation between mixed acid constitution and nitrogen content. Miles (4) states that "the degree of nitration possible in any mixed acid is chiefly a function of acid composition". In the present work, the results obtained were in accord with this statement. The range of mixed acids varied from 65.0 to 73.6% for the sulphuric acid, from 9.0 to 25.5% for the nitric acid, and from 8.4 to 20.4% for the water. The composition of the mixed acids and the corresponding nitrogen contents for the cotton cellulose nitrates together with a few results reported by Miles and Milbourn for ramie fiber cellulose nitrates are given in Table I.

Miles and Milbourn (5) nitrated ramie fiber with a wide range of mixed acids, and expressed their results for the relation between "composition and degree of nitration" in the form of a triangular chart. The results obtained for the nitration of cotton linters

in the present work are given in Fig. 1, which is a portion of the triangular chart used by Miles (4), but drawn on a larger scale. Miles's constant nitrogen lines are shown by broken lines and the results of the present work are plotted as individual points over the nitrogen range 9.0 to 13.3%.

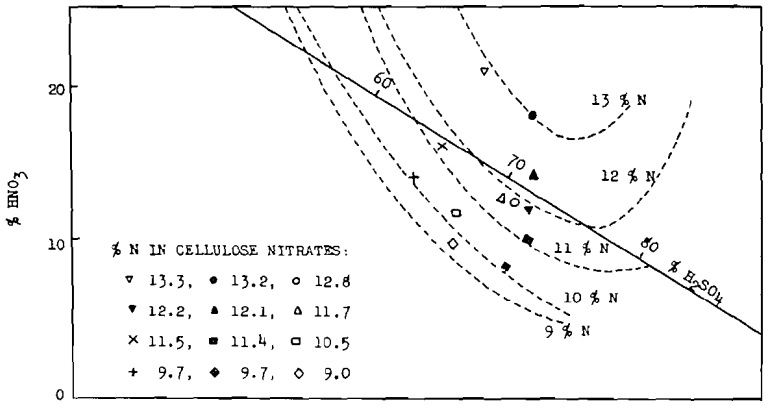

FIG. 1. Mixed acid chart.

Part of the difference in the nitrogen content of cellulose nitrate prepared from ramie fiber and from cotton linters with the same nitric–sulphuric acid, as shown in Table I, experiments 16 and 17, can be attributed to structural differences in the fibers employed. In two experiments, the cellulose nitrate dissolved, a phenomenon encountered by Miles and Milbourn (5).

In order to assess the experimental error involved in attempts to prepare identical cellulose nitrates from the same nitric–sulphuric acid, several duplicate experiments were carried out and the nitrogen determined on each sample. The results are shown in Table II. The mean difference in the nitrogen content of the duplicates was 0.08%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

TABLE II

NITROGEN CONTENTS IN CELLULOSE NITRATES PREPARED BY DUPLICATE NITRATIONS

Expt. No.	Cotton cellulose nitrate, %N		Wood cellulose nitrate, %N	
	Original	Duplicate	Original	Duplicate
1	12.1	11.9	11.7	11.8
2	11.7	11.6	11.4	11.4
3	11.4	11.4	10.8	10.8
4	8.9	9.0	8.5	8.4

and the standard deviation was 0.07. The confidence limits for the difference calculated by the method of Dean and Dixon (1) were 0.08%±0.08, 95% confidence. This difference for duplicates is significantly less than the difference in nitrogen content, 0.4%, found between ramie and cotton cellulose nitrate prepared from the same mixed acid (Table I, expts. 16 and 17).

Further evidence for varying degrees of nitration of different fibers nitrated with the same mixed acid is shown in Table III. A series of mixed acids were used to nitrate

TABLE III

NITROGEN CONTENTS OF CELLULOSE NITRATES

Expt. No.	Cotton cellulose nitrate, %N	Wood cellulose nitrate, %N
1	13.3	12.8
2	13.2	12.8
3	12.8	12.0
4	12.2	11.7
5	12.1	11.9
6	11.7	10.9
7	11.5	10.8
8	11.4	11.0
9	10.5	9.9
10	10.2	10.0
11	9.7	9.7
12	9.4	9.3
13	9.0	8.4
14	8.9	8.5

cotton linters and wood cellulose. The cotton cellulose nitrate almost invariably had a greater nitrogen content than the corresponding wood cellulose. The average difference was 0.4% and the standard deviation was 0.29. The confidence limits for the difference were 0.46%±0.17, 95% confidence.

Assuming the same conditions for nitration, it appears that the percentage of nitrogen obtained from the same mixed acid varies with the nature of the fibers as follows:

ramie, 9.4; cotton linters, 9.0; wood cellulose, 8.4.

Cotton cellulose was nitrated to a higher degree than wood cellulose when the same conditions were employed. The sulphate content of both was dependent upon the composition of the mixed acid. The sulphate content of wood cellulose nitrate was almost always

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

higher than that of cotton cellulose nitrate. The different behavior exhibited by cotton and wood cellulose during nitration could be attributed to the different structures. These results agree with the experience of Schur and McMurtrie (6), who found that cotton linters, when nitrated with mixed acid containing 26.0% nitric acid, yielded cellulose nitrate of higher nitrogen content, under the conditions of nitration employed, than did most of the wood pulp samples used. These authors concluded that the behavior of the wood pulps during nitration depended partly on the gross physical form and partly on differences in the physical characteristics of the fibers undergoing nitration.

Sulphate Content

In order to establish the relation between the sulphuric acid content of the mixed acid and the total sulphate content of the cellulose nitrates, many experiments were carried out with cotton linters and wood cellulose, using mixed acids containing amounts of sulphuric acid varying from 65.0 to 73.3%. The sulphate contents of the cellulose nitrates are given in Table IV.

TABLE IV

SULPHURIC ACID IN MIXED ACID AND TOTAL SULPHATE IN CELLULOSE NITRATES

Expt. No.	%H_2SO_4 in mixed acid	Cotton cellulose nitrate		Wood cellulose nitrate	
		%H_2SO_4	%N	%H_2SO_4	%N
1	65.0	1.54	9.7	2.17	9.7
2	68.3	1.86	10.5	2.36	9.9
3	73.3	2.30	11.0	2.40	11.0
4	65.7	0.79	11.5	1.13	10.8
5	70.7	1.53	11.7	1.46	10.9
6	65.0	0.63	12.1	0.93	11.9
7	72.8	2.26	12.2	2.12	12.0
8	71.3	1.13	12.8	2.09	12.0
9	70.4	0.47	13.2	1.30	12.8
10	65.7	0.44	13.3	0.91	12.5

It was found that the sulphate content of wood cellulose nitrate was almost always higher than that of cotton cellulose nitrate, when products prepared from the same mixed acid and containing about the same amount of nitrogen were compared. The mean difference was 0.38% and the standard deviation was 0.29. The confidence limits for the difference were 0.38%±0.21, 95% confidence.

To test the reproducibility of the sulphate determinations, several duplicate experiments were performed and typical results are given in Table V. The mean difference

TABLE V

SULPHATE DETERMINATIONS ON COTTON CELLULOSE NITRATES PREPARED BY DUPLICATE NITRATIONS

Expt. No.	%H_2SO_4 in mixed acid	Total sulphate, %H_2SO_4		Nitrogen, %	
		Original	Duplicate	Original	Duplicate
1	68.3	1.91	1.86	10.8	10.5
2	70.1	1.76	1.62	8.9	8.9
3	70.7	1.53	1.55	11.7	11.6
4	71.3	1.13	1.17	12.0	11.8
5	65.4	1.00	0.89	11.4	11.4
6	65.3	0.69	0.58	11.9	12.1

in the duplicate sulphate contents was 0.09% and the standard deviation was 0.05. The confidence limits for the difference were 0.09%±0.05, 95% confidence. Similar results were obtained from sulphate analyses of wood cellulose nitrates.

The relation between the sulphuric acid content of the mixed acid and the sulphate content of the cellulose nitrates is shown in Figs. 2 and 3. In Fig. 2, three curves are given for cotton cellulose nitrates of average nitrogen content of 9.4, 11.5, and 12.4%. The sulphate content increases with increasing concentration of sulphuric acid.

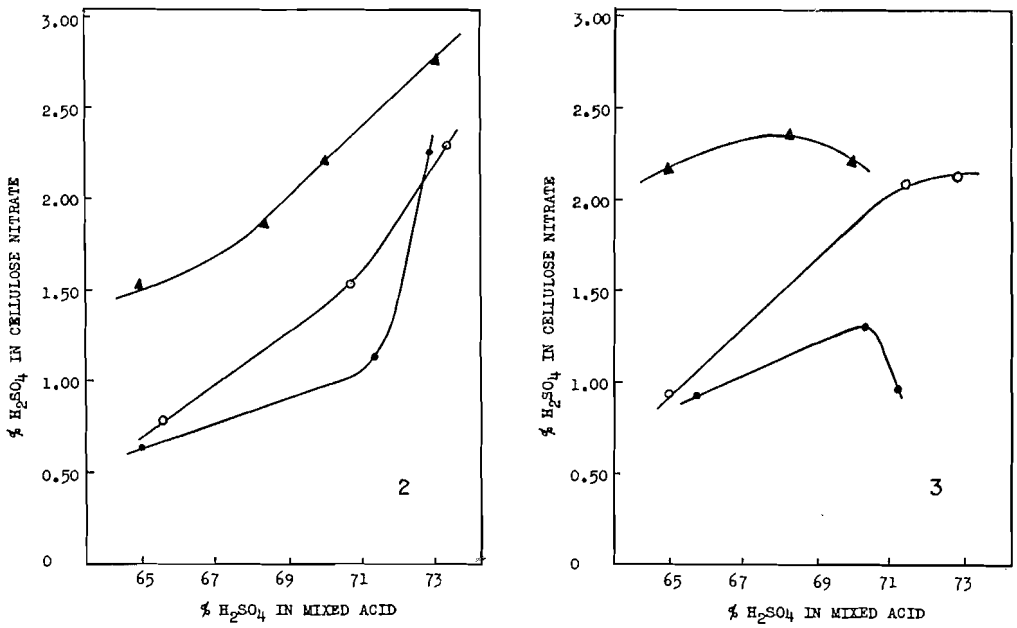

FIG. 2. Relation between $\%H_2SO_4$ in mixed acid and the sulphate content of cotton cellulose nitrates. Av. %N in cellulose nitrate: ● 12.4%, ○ 11.5%, ▲ 9.4%.

FIG. 3. Relation between $\%H_2SO_4$ in mixed acid and the sulphate content of wood cellulose nitrates. Av. %N in cellulose nitrate: ● 12.8%, ○ 11.9%, ▲ 9.4%.

The curves for wood cellulose nitrates (Fig. 3) possess a maximum indicating the optimum concentration of sulphuric acid for the highest sulphate content. For instance, 70.3% sulphuric acid was the optimum concentration for 1.30% sulphate in a wood cellulose nitrate containing 12.8% nitrogen.

Conclusion

The nitrogen and sulphate contents of both cotton and wood cellulose nitrates are shown to be intimately related. The sulphate content of the cellulose nitrates depends upon the formation of sulphate ester, which will be discussed in a forthcoming publication.

AMMONOLYSIS OF 1,2-EPOXYCYCLOHEXANE AND *TRANS*-2-BROMOCYCLOHEXANOL[1]

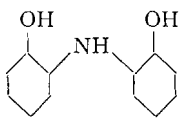
L. R. HAWKINS AND R. A. B. BANNARD

ABSTRACT

Optimum conditions for the preparation of *trans*-2-aminocyclohexanol by ammonolysis of 1,2-epoxycyclohexane or *trans*-2-bromocyclohexanol are realized by use of a 20-fold excess of aqueous alcoholic ammonia at 100°. Under these conditions formation of secondary amines is minimized. Lower ammonia–reactant ratios, or the use of absolute methanolic ammonia or aqueous ammonia, lead to lower yields of primary amine and higher yields of secondary amines. 1,2-Epoxycyclohexane has been isolated from the interaction of *trans*-2-bromocyclohexanol with aqueous ammonia. The oxide reacts more rapidly with aqueous alcoholic ammonia than the bromohydrin and the rate of conversion of the latter to amine is thus controlled by the rate of conversion of bromohydrin to oxide.

INTRODUCTION

Winstein and Henderson (31) have emphasized that reactions involving *trans*-1,2-halohydrins under basic conditions can proceed via the corresponding oxide as intermediate. If such is the case, approximately equal yields of primary amine should be obtainable from either reactant, and the preferred starting material for preparation of 1,2-aminocyclanols would be the halohydrin rather than the oxide, a synthetic step thereby being eliminated. For the synthesis of a 1,2-aminocyclanol, practical considerations demand that attention be given to the possible intervention of side reactions. Mousseron and Granger (16), for example, found in a number of instances that ammonolysis of alicyclic epoxides or 1,2-chlorohydrins led to formation of considerable quantities of secondary amines together with the desired primary amine. Brunel (4) prepared *trans*-2-aminocyclohexanol by heating 1,2-epoxycyclohexane with a sixfold excess of aqueous ethanolic ammonia at 110–115°. When a twofold excess of ammonia was used, however, the main products were two diastereoisomeric bis-2-hydroxycyclohexylamines (I) of m.p. 114° and 153°, subsequently shown by Mousseron and Granger (16) to be *dl* and *meso* forms respectively.



I

Godchot and Mousseron (9), however, studying the same reaction, obtained cyclohexadiene as by-product. Osterberg and Kendall (17) obtained a 61% yield of *trans*-2-aminocyclohexanol by heating *trans*-2-chlorocyclohexanol at 100° with an unspecified excess of aqueous alcoholic ammonia, and reported that omission of the alcohol resulted in formation of secondary and tertiary amines as the main products. They failed, however, to characterize these substances. Wilson and Read (32) studied the same reaction at room temperature, and did not note formation of by-products. Our purpose was to determine whether the halohydrin is the preferred starting material and to establish experimental conditions leading to maximum yield of primary amine, since we required

certain more complex aminocyclanols in connection with other studies to be described later.

The ammonolysis of 1,2-epoxycyclohexane and *trans*-2-bromocyclohexanol with aqueous alcoholic, aqueous, and absolute methanolic ammonia has been studied at 100° and at room temperature. The influence of these and other variables, such as molar ratio of ammonia to reactant and time of contact, on the yield of primary and secondary amines has been determined.

RESULTS AND DISCUSSION

From Table I it is clear that, within the limits of the variables examined, optimum conditions for conversion of 1,2-epoxycyclohexane and *trans*-2-bromocyclohexanol to

§13.6% of mixed secondary amines was not further purified.

trans-2-aminocyclohexanol are realized by ammonolysis for 1 hour at 100° with aqueous ethanolic ammonia in which the ammonia–reactant ratio is 20:1. Under these conditions the oxide and bromohydrin furnish the primary amine in 85% and 75% yield respectively and formation of secondary amines is limited to 3.5% (runs 1 and 3). In spite of the slightly higher yield of *trans*-2-aminocyclohexanol obtained by the one-step ammonolysis of the bromohydrin (75% vs. 68%), the two-step method, involving prior preparation of the oxide, is preferred because of greater ease of isolation of the product. Prolonging the time of heating has no significant effect on the yield of amines (runs 2 and 4). Use of only a fivefold excess of ammonia, however, causes a marked drop in the yield of primary amine and a corresponding increase in yield of secondary amines (runs 5–8). This result follows from the Law of Mass Action.

The effect of temperature on yield and rate of reaction is illustrated by comparing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

the results of runs 9 to 14 at room temperature with runs 1 to 8 at 100°. It is evident that ammonolysis is much slower at room temperature, as would be expected. However, the results described here for the oxide contrast with Brunel's observation (4) that 1,2-epoxycyclohexane requires several weeks to react with aqueous alcoholic ammonia at room temperature. At room temperature the bromohydrin reacts more slowly than the oxide at both high and low ammonia–reactant ratios. It is thus clear that in the case of bromohydrin, the rate of formation of the intermediate oxide (see below) at room temperature becomes the governing factor.

Aqueous ammonia is a less satisfactory medium for ammonolysis of 1,2-epoxycyclohexane or *trans*-2-bromocyclohexanol than aqueous alcoholic ammonia (runs 15, 16, and 18), presumably because two-phase systems are formed and there is an increased tendency toward formation of 1,2-cyclohexanediol as by-product (4, 20). The especially poor yield from the bromohydrin is to be expected because the intermediate oxide is readily soluble in the bromohydrin. The result reported in run 18 contrasts with Osterberg and Kendall's claim (17) that ammonolysis of *trans*-2-chlorocyclohexanol with aqueous ammonia produces secondary and tertiary amines as the main products. We did not obtain tertiary amines under any of the conditions studied, in agreement with Brunel's (4) results on ammonolysis of 1,2-epoxycyclohexane. Normally, ammonolysis of a 1,2-epoxide or halohydrin in aqueous solution leads to formation of primary, secondary, and tertiary amine together with quarternary ammonium salt (19), but in the present case formation of the last two may be prevented by steric factors. Brunel's (4) observation that treatment of the oxide with a twofold excess of ammonia produces the diastereoisomeric secondary amines as major product has been verified (run 17). Ammonolysis with anhydrous methanolic ammonia causes the yield of primary amine to fall approximately 30% from maximum. This result was not unexpected since water exerts a catalytic effect on the ammonolysis reaction (6, 3, 22) and, moreover, reaction of 1,2-epoxides or 1,2-halohydrins with alcohols under basic conditions leads to formation of glycol monoethers (4, 13, 14). We did not attempt to isolate glycol or glycol monoethers from the ammonolyses but these compounds would undoubtedly be present in small amounts in the distillate collected prior to sublimation of the primary amine.

The reaction of ammonia or amines with 1,2-epoxides in aqueous solution is considered to proceed by an S_N2 mechanism (31, p. 27; 12; 23; 7). The stereochemical course of the reaction of 1,2-epoxycyclohexane with ammonia (15) and the fact that the reaction rate increases (runs 9 and 13) when the concentration of nucleophile is increased (12, p. 321) are in agreement with such a mechanism.

Ammonolysis of *trans*-2-bromocyclohexanol proceeds with over-all retention of stereochemical configuration, and this suggests that 1,2-epoxycyclohexane is an intermediate (27; 30; 31, pp. 11 and 27). The conversion of 1,2-halohydrin to oxide in the presence of a strong base is rapid and almost quantitative (31, p. 8) but there does not appear to be any definite evidence for formation of oxide in the presence of a weak base such as ammonia, other than the kinetic data of Smith and Nilsson (23). On the other hand Elderfield *et al.* (8) and Petrov and Lagucheva (18) have published data which indicate that amination of 1-chloropentanol-2 with diethylamine or ethylene chlorohydrin with 2,5-dichloroaniline does not proceed via an intermediate oxide stage. Therefore, although oxide can intervene (31), this is not always the case and proof must be sought in each instance. In the present study, we treated *trans*-2-bromocyclohexanol with 28% aqueous ammonia at room temperature, obtained 1,2-epoxycyclohexane and ammonium bromide in 38.8% and 41.8% yield respectively, and recovered 43.3% of the bromohydrin. This is the first time to our knowledge than an oxide has actually been isolated from inter-

action of a halohydrin and ammonia. This observation, together with the fact that the rate of formation of amine from oxide is greater than from bromohydrin at both high and low ammonia–reactant ratios (runs 9 to 14), leads to the conclusion that the oxide is an intermediate in ammonolysis of *trans*-2-bromocyclohexanol.

The bis-2-hydroxycyclohexylamine of m.p. 126° was reported by Brunel (4) to have m.p. 114°, and it presumably contained a trace of the higher melting diastereoisomer. *meso*-Bis-2-hydroxycyclohexylamine hydrochloride was reported (4) to have m.p. 264°, whereas the *dl*-isomer exhibited a double melting point, the first at 192° and the second at 264°. Brunel (4) suggested that the *dl*-isomer was converted to the *meso*-isomer above its first melting point, melting again at 264°. We have found *dl*-bis-2-hydroxycyclohexylamine to possess a single melting point, 194–195°, and conclude that Brunel's suggestion regarding interconversion of the isomers is incorrect. The hydrobromides of *meso*- and *dl*-bis-2-hydroxycyclohexylamine were prepared and have m.p. 257–258° and 180–182° respectively.

Recently, Guss and Rosenthal (10) reported the preparation of *trans*-2-bromocyclohexanol by bromination of cyclohexene with *N*-bromosuccinimide. We used their method and found that the liquid product frequently darkens rapidly either during distillation or on storage. Similar observations regarding the rapid discoloration of *trans*-2-bromocyclohexanol have been made independently by Schmidt, Schumacher, and Asmus (21), Bedos (1), and Hunter and Marriott (11), all of whom used different methods of preparation. Swarts' observation (25) that *trans*-2-bromocyclohexanol is a solid of m.p. 27° seems to have been overlooked by subsequent workers (10, 26, 28, 29). Guss and Rosenthal's (10) procedure was modified by using a 5 mole % excess of olefin over bromoimide, and *trans*-2-bromocyclohexanol was obtained in 89% yield as a colorless solid of m.p. 27°, after purification by recrystallization from heptane rather than distillation. This product does not discolor on standing in contact with light and air. The colorless solid, if distilled *in vacuo*, discolors much more slowly than preparations made by Guss and Rosenthal's method. This observation suggests that *trans*-2-bromocyclohexanol decomposes slightly on distillation (cf. Swarts (25)) and that the excess of olefin used in our method of preparation is beneficial, possibly in preventing the presence of excess hypobromous acid, which could either cause slight oxidation of the product or lead to formation of *trans*-1,2-dibromocyclohexane as observed by Coffey (5). The latter substance is difficult to obtain in a colorless condition because it undergoes oxidation readily in the presence of air (24). During several ammonolysis experiments in which discolored *trans*-2-bromocyclohexanol was used, explosions occurred. Explosions were not experienced when colorless bromohydrin was used. Boon (2) found the reaction of alkylene dibromides with certain amines to be very exothermic during the initial stage, and it is possible that a trace of *trans*-1,2-dibromocyclohexane present in the bromohydrin is responsible for the observed explosions.

EXPERIMENTAL

All melting points are uncorrected. Microanalyses are by Micro-Tech Labs., Skokie, Ill., and C. E. Reynolds of these Laboratories.

trans-2-Bromocyclohexanol

Guss and Rosenthal's (10) procedure was modified as follows. Cyclohexene (86.2 g., 1.05 moles), water (400 ml.), and N-bromosuccinimide (178 g., 1.00 mole) were placed in a 1-liter three-necked flask equipped with a "trubore" stirrer and thermometer. The mixture was stirred mechanically until the N-bromosuccinimide dissolved and a colorless heavy layer of bromohydrin separated (15 minutes), during which time the

temperature rose to 75°. The two-phase system was allowed to cool to room temperature, the bromohydrin layer was separated, and the aqueous phase extracted with ether (2×100 ml.). The extracts and bromohydrin were combined and the ether removed *in vacuo*. The residue was diluted with heptane (1 liter) and kept at 4° overnight. The precipitated succinimide was removed and the filtrate was allowed to stand overnight at −20°. The colorless crystals of *trans*-2-bromocyclohexanol which separated were collected by suction filtration and washed with ice-cold heptane. Concentration of the mother liquor gave further crops. Yield, 160 g. (89.0%), m.p. 27°. Swarts (25) reports m.p. 27.5°. Calc. for $C_6H_{11}OBr$: C, 40.24; H, 6.19; Br, 44.63%. Found: C, 40.20; H, 6.10; Br, 44.58%. *trans*-2-Bromocyclohexanol prepared as described above has remained colorless for more than 4 months on storage in clear bottles not protected from daylight.

Ammonolysis of trans-2-Bromocyclohexanol

The bromohydrin was treated with aqueous, aqueous ethanolic, or absolute methanolic ammonia in glass or stainless steel pressure vessels at room temperature or 100° for varying lengths of time. Experimental conditions required for maximum yield of *trans*-2-aminocyclohexanol are as follows. *trans*-2-Bromocyclohexanol (35.8 g., 0.200 mole) was heated for 1 hour at 100° with an aqueous ethanolic ammonia solution prepared from 28% aqueous ammonia (270 ml., 4.00 moles) and absolute ethanol (120 ml.). The pale yellow solution was evaporated to dryness *in vacuo* at room temperature. The residual solid was treated with a boiling solution of sodium hydroxide (8.0 g.) in absolute ethanol (100 ml.) for 20 minutes with stirring. The insoluble salt was collected and washed with anhydrous ether (50 ml.). The combined filtrate and washings were evaporated to dryness *in vacuo* at room temperature, and the primary amine (17.6 g., 76.4%) was obtained as a colorless sublimate, m.p. 67–68°, by heating the residue at 80–100° at 1 mm. (McCasland *et al.* (15) report m.p. 68°). *trans*-2-Aminocyclohexanol is hygroscopic and carbonates rapidly. Complete separation of primary amine from the mixture of secondary amines and inorganic salt is not effected and the residue still possesses the characteristic piperidine-like odor of the primary amine. The water-insoluble *meso*-bis-2-hydroxycyclohexylamine (m.p. 154°) was isolated by filtration after the residue from the sublimation was treated with boiling water (100 ml.) and allowed to cool. The *dl*-secondary amine (m.p. 126°) was isolated by evaporation of the filtrate to dryness. The experiment under consideration yielded only 0.36 g. (1.7%) of a mixture of the two secondary amines, m.p. 114–116°. Calc. for $C_{12}H_{23}NO_2$: C, 67.56; H, 10.86%. Found: C, 68.00; H, 11.10%.

1,2-Epoxycyclohexane from Ammonolysis of trans-2-Bromocyclohexanol

trans-2-Bromocyclohexanol (35.8 g., 0.200 mole) was stirred at room temperature for 6 hours in a stoppered flask with 28% aqueous ammonia (20 ml., 0.297 mole). The lower layer was decanted and the aqueous layer extracted with ether (3×10 ml.) and combined with the non-aqueous layer. The ether solution was dried and distilled, yielding 7.6 g. (38.8%) of cyclohexene oxide, b.p. 130°, n_D^{25} 1.4497, and 15.5 g. (43.3%) of *trans*-2-bromocyclohexanol, b.p. 50–52° at 1.5 mm., n_D^{25} 1.5185. Evaporation of the aqueous solution to dryness yielded 8.2 g. (41.8%) of ammonium bromide which contained only a trace of *trans*-2-aminocyclohexanol as revealed by paper chromatography using *n*-butanol – acetic acid – water (25:6:25) as developer and bromcresol green as detector.

1,2-Epoxycyclohexane

1,2-Epoxycyclohexane was prepared in 80% yield from *trans*-2-bromocyclohexanol by the method of Guss and Rosenthal (10), b.p. 130°, n_D^{25} 1.4498.

Ammonolysis of 1,2-Epoxycyclohexane

1,2-Epoxycyclohexane was ammonolyzed with aqueous, aqueous alcoholic, or absolute methanolic ammonia in glass or stainless steel pressure vessels at room temperature or 100° for varying lengths of time. Experimental conditions which produce maximum yield of *trans*-2-aminocyclohexanol are as follows. 1,2-Epoxycyclohexane (19.6 g., 0.200 mole) was heated for 1 hour at 100° with aqueous ethanolic ammonia solution as described for *trans*-2-bromocyclohexanol. The pale yellow solution was evaporated to dryness *in vacuo* at room temperature. The residue was heated at 80–100° at 1 mm. and *trans*-2-aminocyclohexanol (19.9 g., 86.5%) was obtained as a colorless sublimate, m.p. 67–68°. The two secondary amines were recovered by the method described under ammonolysis of *trans*-2-bromocyclohexanol. More complete recovery and separation of the amines was effected because the process is uncomplicated by the presence of inorganic salt. The *meso*-secondary amine (m.p. 154°) was obtained in 2.0% yield and the *dl*-isomer (m.p. 126°) in 1.5% yield.

trans-2-Aminocyclohexanol Hydrochloride

trans-2-Aminocyclohexanol (23.0 g., 0.200 mole) was dissolved in hot anhydrous benzene (250 ml.) and hydrogen chloride gas was passed into the solution until precipitation was complete. The colorless hydrochloride was collected, washed with anhydrous ether (2×100 ml.), and recrystallized from absolute ethanol (180 ml.), yielding 26.5 g. (87.2%) of colorless *trans*-2-aminocyclohexanol hydrochloride as clusters of fine prisms, m.p. 180–181°. McCasland *et al.* (15) report m.p. 176–177°.

trans-2-Aminocyclohexanol Hydrobromide

trans-2-Aminocyclohexanol (2.88 g., 0.025 mole) was dissolved in anhydrous ether and treated with hydrogen bromide gas as described above. The salt was collected, washed with anhydrous ether, and recrystallized from absolute ethanol (20 ml.), yielding 4.28 g. (92.2%) of fine colorless clusters of needles, m.p. 191–192°. Osterberg and Kendall (17) report m.p. 191°.

trans-2-Acetamidocyclohexanol

trans-2-Aminocyclohexanol (1.00 g., 0.0878 mole) was dissolved in acetic anhydride (5.0 ml.) and a very exothermic reaction occurred. Water (3.0 ml.) was added and the mixture was evaporated to dryness *in vacuo*. The amide was collected and washed with cold anhydrous ether. Yield 1.14 g. (82.4%), m.p. 126–127°. McCasland *et al.* (15) report m.p. 126–127°. Calc. for $C_8H_{15}O_2N$: C, 61.12; H, 9.62; N, 8.91%. Found: C, 61.22, 61.36; H, 9.55, 9.55; N, 8.98, 8.82%.

meso-Bis-2-hydroxycyclohexylamine

This substance had m.p. 145–150° when first obtained from the ammonolysis reactions. Recrystallization from benzene (17 ml./g.) gave colorless platelets, m.p. 154°. Brunel (4) reports m.p. 153°.

meso-Bis-2-hydroxycyclohexylamine Hydrochloride

meso-Bis-2-hydroxycyclohexylamine (1.07 g., 0.005 mole) was dissolved in anhydrous ether (250 ml.) and treated with hydrogen chloride gas as described above. The precipitate was collected, washed with anhydrous ether (3×25 ml.), and recrystallized from absolute ethanol (100 ml.), yielding 1.14 g. (91.2%) of *meso*-bis-2-hydroxycyclohexylamine hydrochloride, m.p. 270–271°, as colorless clusters of prisms. Calc. for $C_{12}H_{24}NO_2Cl$: N, 5.61; Cl, 14.19%. Found: N, 5.68, 5.79; Cl, 14.50, 14.56%. Brunel (4) reports m.p. 264°. This substance sublimes below its melting point.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

meso-Bis-2-hydroxycyclohexylamine Hydrobromide

The hydrobromide was prepared in the same manner as the hydrochloride and recrystallized from absolute ethanol (70 ml.), yielding 1.89 g. (95.5%) of fine colorless needles, m.p. 257–258°. Calc. for $C_{12}H_{24}NO_2Br$: N, 4.76; Br, 27.16%. Found: N, 4.85, 4.91; Br, 27.05, 26.75%.

dl-Bis-2-hydroxycyclohexylamine

This substance usually had m.p. 114–116° when obtained from the ammonolysis reactions. Recrystallization from ethanol–ether or benzene gave colorless needles, m.p. 126°. Brunel (4) previously reported m.p. 114° for this substance. Calc. for $C_{12}H_{23}NO_2$: C, 67.56; H, 10.87; N, 6.57%. Found: C, 67.76; H, 11.20; N, 6.39%. Recrystallization did not effect recovery of all the lower melting isomer in a pure condition. A small portion always remained contaminated with the higher-melting isomer. Such residues usually melted over a 1° range within the region 110–118° and analyzed satisfactorily for secondary amine.

dl-Bis-2-hydroxycyclohexylamine Hydrochloride

dl-Bis-2-hydroxycyclohexylamine (200 mg., 0.000935 mole) was dissolved in anhydrous ether (40 ml.) and the solution treated with hydrogen chloride gas. The precipitate was collected and washed with anhydrous ether (2×10 ml.) yielding 213 mg. (91.0%) of colorless substance, m.p. 193–194°. Calc. for $C_{12}H_{24}NO_2Cl$: N, 5.61; Cl, 14.19%. Found: N, 5.45, 5.59; Cl, 14.34, 14.46%. The double melting point phenomenon previously reported by Brunel (4) for this substance was not observed.

dl-Bis-2-hydroxycyclohexylamine Hydrobromide

dl-Bis-2-hydroxycyclohexylamine (2.00 g., 0.00935 mole) was dissolved in ethanol–ether and treated with hydrogen bromide gas as above. The salt was collected and recrystallized from ethanol–ether yielding 2.1 g. (76.1%) of colorless needles, m.p. 180–182°. Calc. for $C_{12}H_{24}O_2NBr$: C, 48.98; H, 8.22; N, 4.76; Br, 27.16%. Found: C, 48.93, 48.99; H, 8.07, 8.37; N, 5.04, 5.00; Br, 27.10, 27.00%.

CONFORMATIONAL EFFECTS AND THE INFLUENCE OF PRESSURE ON REACTION RATES[1]

E. WHALLEY

ABSTRACT

It has been suggested that the pressure coefficient of the rate constant of some reactions may be influenced by the formation of intermolecular or intramolecular conformations prior to reaction. This has been examined theoretically and the relevant experimental evidence has been discussed. No examples of an effect in which the conformations are at equilibrium are known with certainty, but the effect of pressure on termination in the polymerization of styrene appears to be an example of a conformational effect when the conformations are not at equilibrium.

The pressure coefficient of the rate constant for the isomerization of citraldehyde to 3,8-carvomenthenediol is not consistent with a unimolecular slow step, but it is consistent with either a bimolecular or a termolecular slow step. It is pointed out that the pressure coefficient of rate constants may be very useful in determining the molecularity of some reactions.

1. INTRODUCTION

According to the theory of absolute reaction rates (4) the rate constant k for a chemical reaction in dilute solution which goes via an activated complex is given by

$$k = \kappa(kT/h)\exp(-\Delta F^{\ddagger}/RT), \qquad [1.1]$$

where κ is the transmission coefficient, k is Boltzmann's constant, h is Planck's constant, and $\Delta F^{\ddagger}$ is the partial free energy of activation in the solution under discussion. The pressure coefficient of k is obtained by taking logarithms of equation [1.1], differentiating with respect to pressure, and using the identity

$$\partial F/\partial p = V,$$

where V is the molar volume. One finds

$$d \ln k/dp = -\Delta V^{\ddagger}/RT + d \ln \kappa/dp, \qquad [1.2]$$

where $\Delta V^{\ddagger}$ is the partial volume of activation. If $\ln \kappa$ is effectively independent of pressure—and no other assumption is fruitful at present—equation [1.2] reduces to the well-known equation

$$d \ln k/dp = -\Delta V^{\ddagger}/RT. \qquad [1.3]$$

This derivation has of course been given many times; it is included to emphasize that the variation of $\ln \kappa$ with pressure is quite unknown and introduces an uncertainty into all discussions of the pressure coefficient of reaction rate constants in terms of the activated state theory.

There are some reactions which either can or must occur in at least two stages, the first stage of which is the formation of an intermolecular or intramolecular conformation which is favorable to the reaction. For example, the reaction

$$\mathrm{A} + \mathrm{B} \rightarrow \text{products} \qquad (1.1)$$

may need or be helped by the formation of a conformation A′ of A thus

$$\mathrm{A} \rightarrow \mathrm{A}', \qquad (1.2)$$

$$\mathrm{A}' + \mathrm{B} \rightarrow \text{products}, \qquad (1.3)$$

[1]*Manuscript received September 26, 1957.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 4552.

where the products of reactions (1.1) and (1.3) are identical. The term conformational effects is used in this paper to denote the effects of the conformation A′. It has been suggested several times (2, 5, 11), though without detailed examination, that the acceleration of some reactions by pressure is due to the increase in concentration with pressure of a favorable conformation. This is a very interesting suggestion and it deserves quantitative investigation, not least because the pressure coefficient of reaction rate constants can be very valuable in elucidating reaction mechanisms, and it is important to know all that may influence the pressure coefficient. The purpose of this paper is to discuss the pressure coefficients of the rate constants of reactions in which a conformational effect may occur, and in particular to examine the effect of the conformational change (1.2). The theory is discussed in Section 2 and the experimental evidence in Section 3.

2. THEORY OF CONFORMATIONAL EFFECTS

We consider the simple reaction

$$\mathrm{A} + \mathrm{B} \rightarrow \text{products}, \tag{2.1}$$

with a rate constant k_1, and assume either that it can go in one step as above or that A can take up an intramolecular or intermolecular conformation A′ which can also react with B to give the same activated state and same products as reaction (2.1). Thus the reactions

$$\mathrm{A} \rightarrow \mathrm{A}', \tag{2.2}$$

$$\mathrm{A}' \rightarrow \mathrm{A}, \tag{2.3}$$

$$\mathrm{A}' + \mathrm{B} \rightarrow \text{products}, \tag{2.4}$$

with rate constants k_2, k_3, and k_4 respectively, are also possible. We note that

$$[2.1] \qquad k_2/k_3 = K_2,$$

where K_2 is the equilibrium constant for the formation of A′, the standard state being such that the molar extensive properties are equal to the partial molar properties in the (dilute) solution under discussion. We assume that reactions (2.1) and (2.4) give the same activated complexes; if they do not, then two different reactions occur simultaneously and the analysis of the effect of pressure must take account of this. Hence the partial volumes of activation of (2.1) and (2.4), $\Delta V_1^{\ddagger}$ and $\Delta V_4^{\ddagger}$ respectively, are related to the partial volume change ΔV_2 of reaction (2.2) thus

$$[2.2] \qquad \Delta V_1^{\ddagger} = \Delta V_2 + \Delta V_4^{\ddagger}.$$

Also

$$[2.3] \qquad d \ln K_2/dp = -\Delta V_2/RT.$$

We have chosen a simple bimolecular reaction for consideration and assume that A can take up only two conformations; if the reaction is of different molecularity, or if it occurs in a number of steps, and if there are many conformations of A each with its different rate constant for reaction with B, simple modifications of the treatment will lead to results similar to those below.

The rate constant usually measured is k, where

$$\begin{aligned} \text{rate of reaction} &= k(c_{\mathrm{A}}+c_{\mathrm{A}'})c_{\mathrm{B}} \\ &= kc_{\mathrm{A}}c_{\mathrm{B}}(1+c_{\mathrm{A}'}/c_{\mathrm{A}}), \end{aligned} \qquad [2.4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

and c_A, $c_{A'}$, and c_B represent the concentrations of A, A′, and B. By considering reactions (2.1)–(2.4) the rate of reaction is given by

$$\text{rate of reaction} = k_1c_Ac_B+k_4c_{A'}c_B$$

$$= k_1c_Ac_B\{1+(k_4/k_1)(c_{A'}/c_A)\}. \quad [2.5]$$

By equating [2.4] and [2.5] we have

$$k = k_1\{1+(k_4/k_1)(c_{A'}/c_A)\}/\{1+(c_{A'}/c_A)\}. \quad [2.6]$$

It is convenient to let $c_{A'}/c_A$ be the fraction α of its equilibrium value K_2, so that

$$c_{A'}/c_A = \alpha K_2. \quad [2.7]$$

If $c_{A'}$ is the same as if it were independent of time a simple kinetic analysis shows that

$$\alpha = (1+c_Bk_4/k_3)^{-1}. \quad [2.8]$$

By taking logarithms of [2.6], differentiating, inserting [2.7], using equation [1.3] for k_1 and k_4, and using [2.2], which is equivalent to

$$d\ln(K_2k_4/k_1)/dp = 0, \quad [2.9]$$

we find

$$\frac{d\ln k}{dp} = \frac{d\ln k_1}{dp} + \frac{\alpha K_2k_4/k_1}{1+\alpha K_2k_4/k_1}\frac{d\ln\alpha}{dp} - \frac{d\ln(1+\alpha K_2)}{dp}. \quad [2.10]$$

This is a rather complicated equation but it simplifies quite considerably under some extreme conditions as follows.

(*a*) If A and A′ are always at equilibrium with one another, $\alpha = 1$ and [2.10] becomes

$$d\ln k/dp = d\ln k_1/dp - d\ln(1+K_2)/dp. \quad [2.11]$$

There is therefore a conformational effect contained in the second term of [2.11]. The direction of the effect is at first sight unexpected. If A′ is favored by pressure, K_2 is increased by pressure and consequently $d\ln(1+K_2)/dp$ is positive. The effect of this term in equation [2.11] is therefore to reduce or to make more negative $d\ln k/dp$. The effect of a conformation favored by pressure is therefore to reduce the pressure coefficient below that which would otherwise occur. A conformational effect of this kind, in which the conformations are at equilibrium with one another, cannot therefore be invoked to explain an apparently anomalously large pressure coefficient of k unless it is assumed that the conformations are disfavored by pressure.

If the concentration of A′ is small so that $K_2 \ll 1$, equation [2.11] becomes

$$d\ln k/dp = d\ln k_1/dp - dK_2/dp$$

$$= -\Delta V_1^{\ddagger}/RT+K_2\Delta V_2/RT. \quad [2.12]$$

The conformational effect, though present, is small unless

$$|\Delta V_2/\Delta V_1^{\ddagger}| \gg 1.$$

If the concentration of A is small so that $K_2 \gg 1$, equation [2.11] becomes

$$d\ln k/dp = d\ln k_1/dp - d\ln K_2/dp - dK_2^{-1}/dp$$

$$= -\Delta V_4^{\ddagger}/RT+(1/K_2)\Delta V_2/RT, \quad [2.13]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

where we have used equation [2.2]. Again the conformational effect is very small unless $|\Delta V_2/\Delta V_4^{\ddagger}| \gg 1$.

Even when K_2 is at its most effective value the effect will usually be rather small because

$$d \ln(1+K_2)/dp < d \ln K_2/dp = -\Delta V_2/RT;$$

since ΔV_2 is the difference in volume between two orientations, either mutual or intramolecular, of the molecules it will usually be less than the volume of melting, which is rarely more than a few cm.^{3} mole $^{-1}$ except perhaps for very large molecules. It will consequently not be easy to distinguish it from the volume of activation, though a conformational effect probably occurs frequently since a reaction between two molecules, of which at least one is not spherically symmetrical, necessitates some prior orientation which may occur with a change of volume. No certain examples are known at present, as we shall show in Section 3.

(*b*) If A and A′ are always at equilibrium and $k_1 = 0$, the reaction will not go unless a particular conformation is first formed, and it is formed at equilibrium. Then equation [2.6] becomes, when differentiated and with the substitutions as above,

$$\begin{aligned} d \ln k/dp &= d \ln k_4/dp + d \ln K_2/dp - d \ln(1+K_2)/dp \\ &= -\Delta V_1^{\ddagger}/RT - d \ln(1+K_2)/dp. \end{aligned}$$

This is identical with equation [2.11], so the discussion which follows that equation applies to this. Even when the conformation is necessary for the reaction to go, the effect of the conformation on the pressure coefficient will usually be rather small if the conformations are present at equilibrium.

(*c*) If the reaction will not go unless a particular conformation is first formed, and the rate of formation of the conformation is the rate determining step, then

[2.14] $$k_1 = 0, \qquad k_4 \gg k_3,$$

and so

$$\alpha \sim (k_3/k_4)c_B \ll 1.$$

An example of this appears to be the diffusion into proximity of the live ends of polymer chains in the termination step in the polymerization of styrene (see Section 3). Inserting [2.14] in [2.6], differentiating, and making the usual substitutions, we find

$$k = k_2/c_B,$$

which could be obtained directly much more easily. The pressure coefficient of k is very nearly that of k_2. For this example the conformational effect may be quite large.

3. EXPERIMENTAL EVIDENCE FOR CONFORMATIONAL EFFECTS

In this section the experimental evidence for the occurrence of the conformational effects which we are discussing is reviewed.

The first suggestion that conformational effects alter the pressure coefficient of chemical reactions was made by Conant and Peterson (2) to explain the qualitative observation that aliphatic aldehydes and isoprene could be polymerized to products of high molecular weight by subjecting them to pressures of several kilobars, but no reaction took place under the same conditions at normal pressure. In their own words, "the accelerating effect of great pressures is due to the orientation of the molecules of the isoprene or the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

aldehyde into a more compact bundle in which longer reaction chains would be propagated". It was realized by Conant (3) in an earlier paper that aliphatic aldehydes do not polymerize at ordinary temperatures and pressures because the chemical equilibrium between monomer and polymer is well on the side of the monomer; under pressures of several kilobars the free energy of polymerization is altered, because of the large contraction which occurs in polymerization, enough to shift the equilibrium to the side of the polymer. This is shown by the fact that the polymer depolymerizes to monomer at atmospheric pressure. Any conformational effect on the rate is secondary to the equilibrium effect, and cannot at present be distinguished from it.

The effect of pressure on the polymerization of isoprene is probably similar to its effect on the polymerization of styrene, which has recently been investigated in some detail by Nicholson and Norrish (8). The rate constants for both the propagation and termination steps are altered by pressure, but for quite different reasons. The rate constant for the propagation step,

$$M_n^{\cdot} + M \rightarrow M_{n+1}^{\cdot},$$

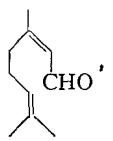
where $M_n^{\cdot}$ is a free radical n-mer and M is the monomer, is increased by pressure by an amount which corresponds to an apparent volume of activation of -13.4 cm.^{3} mole^{-1} (12). This is an altogether reasonable value, being about 60% of the total decrease in volume of the propagation step (10, 12), and it is not necessary to invoke conformational effects to explain it.

The rate constant for the termination step,

$$M_n^{\cdot} + M_m^{\cdot} \rightarrow M_{n+m},$$

is reduced by increasing pressure and it was shown (8) that this is probably caused by a reduction, consequent on the decrease in diffusion coefficients with increasing pressure, in the rate at which the live polymer ends can diffuse to one another. This then is an example of a conformational effect of the kind discussed in Section 2(*c*), in which the necessary conformation is the juxtaposition of two live polymer ends and the rate of formation of this conformation is the rate of reaction. The effect of pressure on the polymerization of isoprene is probably caused in part by a combination of these two effects, with the second one perhaps predominant. Hence a conformational effect probably occurs, but of a type quite different from that envisaged by Conant and Peterson.

The pressure coefficient of the rate of isomerization of citraldehyde to 3,8-carvomenthenediol (5) corresponds to a volume of activation of -24.5 cm.^{3} mole^{-1} at atmospheric pressure. This was not explicable by the mechanism proposed by Price and Dickman (9) and consequently conformational effects were invoked. In order to cyclize, citraldehyde,



must undoubtedly take up a conformation in which the 1 and 6 carbon atoms are very close. The conformations are almost certainly in equilibrium with one another because the energy differences between them will be smaller than the activation energy for cyclization, which is 12.5 kcal. mole^{-1} (5). The arguments of Section 2(*b*) apply and show that a conformation which is favored by pressure would tend to reduce the apparent volume of activation. It is possible that conformations in which the 1 and 6 carbon atoms are

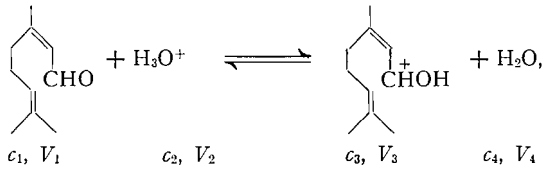
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

close together may be disfavored by pressure, and so contribute a little negatively to the apparent volume of activation. This is unlikely to be more than a few cm.^{3} mole^{-1} and is probably much less than this because the equilibrium constant for the formation of the cyclic conformation is probably much less than unity because of the relatively high steric hindrance in this conformation. The observed volume of activation cannot be explained as the result of conformational effects, and another explanation must be sought; it is shown in Section 4 that a slight change in mechanism is enough.

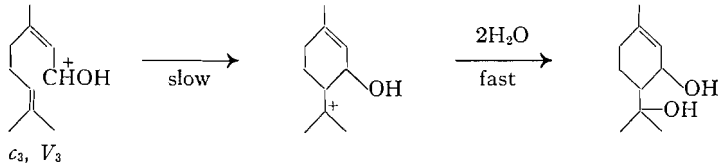
We conclude therefore that the only reaction in which conformational effects influence the pressure coefficient of the rate constant by an appreciable amount is the termination step in the polymerization of styrene. Pressure acts by reducing the rate at which the live polymer ends diffuse into juxtaposition.

4. THE EFFECT OF PRESSURE ON THE RATE OF ISOMERIZATION OF CITRALDEHYDE

Citraldehyde isomerizes in the presence of aqueous acid to 3,8-carvomenthenediol, and Price and Dickman (9) have proposed that the slow step is the unimolecular cyclization of the conjugate acid of citraldehyde as follows:



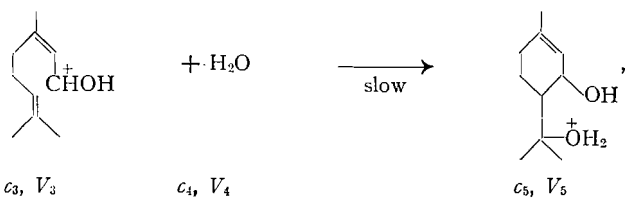
(4.1)



(4.2)

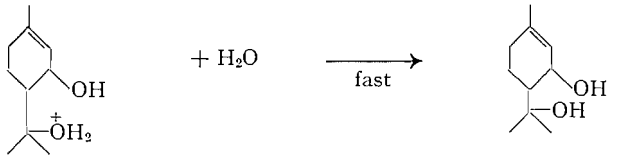
the concentrations and standard molar volumes are written under compounds for which they are required. The effect of pressure on the rate constant was investigated by Harris and Weale (5). They found an unexpectedly high pressure coefficient of ln k, 24.5 cm.^{3} mole^{-1}/RT at 25.2° C. and 1 atm., and this is not consistent with the above mechanism. The arguments are summarized thus: the volume change in reaction (4.1) will be rather small; the volume change in the slow step of reaction (4.2) should be very roughly 10 cm.^{3} mole^{-1} since this is about the volume lost in converting a van der Waals to a C–C valence interaction and the volume of activation will be smaller than this; the change of volume of the solvent during the reactions will be small. Consequently it is not possible to explain the measured volume of activation by a simple unimolecular slow step. Harris and Weale (5) suggested that an unspecified conformational effect was responsible. I have shown in the preceding section that this is unlikely to be correct.

There are two other likely mechanisms by which the conjugate acid of citraldehyde might be cyclized, a bimolecular reaction and a termolecular reaction, as follows:

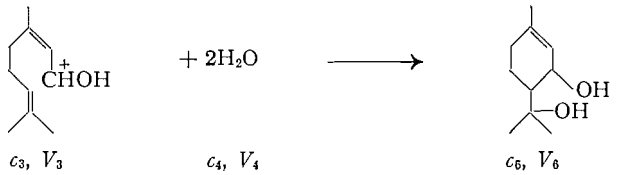


(4.3)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.



and



It will be shown below that both the bimolecular and the termolecular mechanisms are consistent with the measured pressure coefficient. It is less easy to distinguish between the two multimolecular mechanisms than to distinguish between these and the unimolecular mechanism. It is indeed possible that there is no formal distinction; reaction (4.4) may be so fast that the proton may leave the activated complex or may leave later depending upon the availability of a water molecule suitably oriented to accept it.

The measured rate constant k is defined by

[4.1] $$\text{rate of cyclization} = k(c_1+c_3)c_2.$$

If the reaction goes via reactions (4.3) and (4.4), then

[4.2] $$\text{rate of cyclization} = K_1k_3c_1c_2,$$

where K_1 is the equilibrium constant of reaction (4.1) and k_3 the rate constant of reaction (4.3). From equations [4.1] and [4.2] we find

[4.3] $$k = K_1k_3/(1+c_3/c_1), \quad \text{bimolecular.}$$

If the reaction goes via reaction (4.5), then

[4.4] $$\text{rate of cyclization} = K_1k_5c_1c_2c_4,$$

and from [4.1] and [4.4] we find

[4.5] $$k = K_1k_5c_4/(1+c_3/c_1), \quad \text{termolecular.}$$

In order to reduce repetition we discuss equation [4.5] in detail and later state the results of considering in a similar manner the bimolecular equation [4.3].

Taking logarithms of [4.5] and differentiating with respect to pressure, we obtain

[4.6] $$d\ln k/dp = d\ln K_1/dp + d\ln k_5/dp + d\ln c_4/dp - d\ln(1+c_3/c_1)/dp.$$

Now

[4.7] $$d\ln K_1/dp = -\Delta V_1/RT, \qquad d\ln k_5/dp = -\Delta V_5^{\ddagger}/RT,$$

where ΔV_1 is the partial volume change of reaction (4.1) and $\Delta V_5^{\ddagger}$ the partial volume of activation of reaction (4.5). K_1 is probably very small, so

[4.8] $$d\ln(1+c_3/c_1)/dp = 0 \quad \text{very nearly.}$$

The value of $d\ln c_4/dp$ depends upon the compressibility of the solution; assuming that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

it is the same as that of the pure solvent (44.1% w/w ethanol in water) and using the measurements of Moesveld (7) we find

[4.9] $$d \ln c_4/dp = -49\times10^{-6} \text{ atm.}^{-1} \quad \text{at } p = 0.$$

From [4.6]–[4.9] we obtain

[4.10] $$d \ln k/dp = -(\Delta V_1+\Delta V_5^{\ddagger}+1.2 \text{ cm.}^3 \text{ mole}^{-1})/RT \quad \text{at } p = 0.$$

Let ΔV_5^* be the change in partial volume between the activated complex of reaction (4.5) and the final products and ΔV_5 be the change in partial volume of reaction (4.5) so that

[4.11] $$\Delta V_5 = \Delta V_5^{\ddagger}+\Delta V_5^*.$$

Now

$$\Delta V_1 = V_3+V_4-V_1-V_2,$$

and

$$\Delta V_5 = V_6+V_2-V_3-2V_4,$$

so by addition

[4.12] $$\Delta V_1+\Delta V_5 = V_6-V_1-V_4, = \Delta V,$$

where ΔV is the partial volume change of the whole reaction. From equations [4.10], [4.11], and [4.12] we have

[4.13] $$d \ln k/dp = -(\Delta V-\Delta V_5^*+1.2 \text{ cm.}^3 \text{ mole}^{-1})/RT.$$

The density of citraldehyde at 20° C. is 0.887 g. cm.$^{-3}$ (6) and hence

$$V_1 = 171 \text{ cm.}^3 \text{ mole}^{-1}$$

if the solution is perfect. Also

$$V_4 = 18 \text{ cm.}^3 \text{ mole}^{-1}.$$

The density of 3,8-carvomenthenediol has not, apparently, been recorded but if we assume that it is the same as that of the 6,8-diol, 1.13 g. cm.$^{-3}$ (1), we find

$$V_6 = 168 \text{ cm.}^3 \text{ mole}^{-1}.$$

Hence

$$\Delta V = -21 \text{ cm.}^3 \text{ mole}^{-1},$$

and

$$d \ln k/dp = (\Delta V_5^*+19.8 \text{ cm.}^3 \text{ mole}^{-1})/RT.$$

Experimentally $d \ln k/dp = 24.5$ cm.^{3} mole$^{-1}/RT$ at zero pressure; hence

$$\Delta V_5^* = 4.7 \text{ cm.}^3 \text{ mole}^{-1} \quad \text{at } p = 0.$$

If the termolecular mechanism is correct the final products of reaction (4.5), the 3,8-diol and H_3O^+, have a slightly higher volume than the activated complex. The value of ΔV_5^* may be somewhat in error because partial molar volumes differ from molar volumes, and the molar volume of 3,8-carvomenthenediol will differ from that of 6,8-carvomenthenediol. However, it seems safe to conclude that if reaction (4.5) is correct, the bond lengths in the activated state are close to those in the products.

If the bimolecular mechanism is correct, a similar treatment of equation [4.3] results in

$$\Delta V_4+\Delta V_3^* = 3.5 \text{ cm.}^3 \text{ mole}^{-1},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

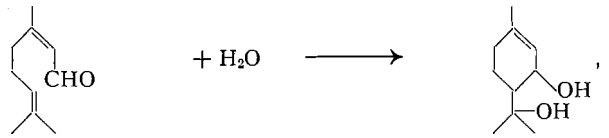
where ΔV_4 is the partial volume change of reaction (4.4) and ΔV_3^* is the difference in partial volume between the products and the activated complex of reaction (4.3). ΔV_4 is probably close to zero and the remarks of the preceding paragraph apply here also; if reactions (4.3)and (4.4) are correct the bond lengths in the activated state are close to those in the products.

We may note in passing that the pressure coefficient for the complete reaction is independent of the pressure coefficient of K_1. This is shown by the absence of ΔV_1 from equation [4.13] and its counterpart in the bimolecular mechanism and is due to the fact that because K_1 is small a change of ΔV_1 is exactly balanced by an equal and opposite change of ΔV_3 or ΔV_5.

The apparent volume of activation decreases rapidly with pressure from -24.5 cm.^{3} mole^{-1} at 1 atm. and 25.2° C. to -1.3 cm.^{3} mole^{-1} at 5000 atm. and the same temperature (5). If the reaction is termolecular, then by differentiating [4.13] with respect to pressure we obtain

$$[4.14] \qquad d^2\ln k/dp^2 = -(1/RT)(d\,\Delta V/dp - d\,\Delta V_5^*/dp + d^2 \ln c_4/dp^2).$$

It seems unlikely that ΔV_5^* will change much with pressure because it is already small, and $d^2\ln c_4/dp^2$ is negligible, so the major part of $d^2\ln k/dp^2$ is $d\,\Delta V/dp$. ΔV is the volume change of the reaction



and $d\,\Delta V/dp$ depends upon the difference in compressibilities of the reactants and products. The reactants will be much more compressible than the products because two van der Waals interactions in the reactants, the intramolecular interaction between carbon atoms 1 and 6 and the intermolecular interaction between the water and the aldehyde, are converted into valence interactions which are much less compressible. Consequently $-\Delta V$ will decrease fairly rapidly with pressure, in agreement with the kinetic results. Very similar arguments hold if the slow step is bimolecular.

We conclude therefore that the kinetics of the isomerization of citraldehyde at 1 atm. together with the effect of pressure on the rate constant show that the elementary steps of the reaction are (4.1), and (4.3) and (4.4), or (4.1) and (4.5) in which the rate-controlling step is either bimolecular or termolecular. The unimolecular step (4.2) is excluded. It is likely that in the activated complex the bond lengths are close to those in the products. We note also that the effect of pressure on reaction rates may help to determine in other similar reactions whether or not the solvent is incorporated into the activated complex.

SUMMARY

1. The effect of a change of intermolecular or intramolecular conformation prior to reaction on the pressure coefficient of a reaction rate constant has been examined theoretically and the pertinent experimental evidence has been discussed.

2. If the conformations involved are at thermodynamic equilibrium with one another and if one conformation is present in much higher concentrations than the others, no effect will occur. If the concentrations of the conformations involved are of the same order of magnitude, an effect is present but it will usually be rather small.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

3. If the conformations are far from equilibrium and a particular conformation is necessary for reaction to occur, the rate of formation of the necessary conformation is rate controlling and a well-defined conformational effect may occur.

4. The experimental evidence for the existence of conformational effects is reviewed and it is concluded that the only authentic example is that on the termination rate constant in the polymerization of styrene, which falls into class 3 above.

5. The apparent volume of activation for the cyclization of citraldehyde to 3,8-carvomenthenediol can be explained if the slow step is either bimolecular or termolecular but not if it is unimolecular. The bond lengths in the activated complex are close to those in the products. It is pointed out that the molecularity of other reactions may be determinable by measuring volumes of activation.

THE PREPARATION OF AMINES AND HYDRAZO COMPOUNDS USING HYDRAZINE AND PALLADIZED CHARCOAL[1]

P. M. G. BAVIN[2]

ABSTRACT

The reduction of nitro compounds to amines by ethanolic hydrazine and palladized charcoal probably proceeds through the nitroso and hydroxylamine derivatives. This reagent is shown to be useful for the reduction of azo to hydrazo compounds.

The reduction of nitro compounds to amines using ethanolic hydrazine and Raney nickel (2, 3) or palladized charcoal (10, 24) as catalyst offers many advantages over classical reducing agents. In particular, the catalyzed hydrazine reductions are very rapid and give high yields of easily isolable amines without the use of special apparatus.

The earlier work showed that hydrazine–palladium was useful for the preparation of aniline, the toluidines, phenylenediamines, *p*-aminobenzoic acid, and aminofluorescein (24), and the amino derivatives of polynuclear hydrocarbons (10). The present work, most of which is summarized in Table I in the Experimental section, extends the usefulness of the method and points out some limitations.

The reduction of 2,2′-dinitrodiphenyl proceeded erratically, the products obtained depending on the activity of the catalyst. A highly active palladium-on-charcoal catalyst gave 2,2′-diaminodiphenyl in good yield, but a less active one gave a mixture of the diamine with benz-[*c*]-cinnoline. The latter compound could be obtained pure in 92% yield using Raney nickel of low activity[3] as catalyst.

Ortho- and *p*-chloronitrobenzene and *p*-nitrophenylacetonitrile did not give pure amines. 2,5-Dichloronitrobenzene gave, very rapidly, an excellent yield of β-(2,5-dichlorophenyl)-hydroxylamine and, more slowly, 2,5-dichloroaniline. 2-Chloro-5-nitroterephthalic acid (11) and 2-fluoro-5-nitrotoluene gave good yields of the amines.

The reduction of nitrobenzene, which has been reviewed by Sidgwick (25), is known to proceed through nitrosobenzene and β-phenylhydroxylamine to aniline, much of our knowledge being due to Haber (17) and Brand (4, 5, 6). Goldschmidt showed (13, 14, 15, 16) that the relative rates of reduction were in the order nitrosobenzene > β-phenylhydroxylamine > nitrobenzene, explaining the difficulty encountered in isolating nitrosobenzene as a reduction product except under rigorously controlled conditions. In alkaline media nitrosobenzene and β-phenylhydroxylamine condense to form azoxybenzene, giving rise to another series of reduction products.

The hydrazine–palladium reagent reduces nitro- and nitroso-benzene and β-phenylhydroxylamine to aniline, but azo- and azoxy-benzene are reduced to hydrazobenzene.[4] These facts suggest that the reduction of nitro compounds to amines by this reagent proceeds through monomeric compounds, as shown below in route I. The isolation of

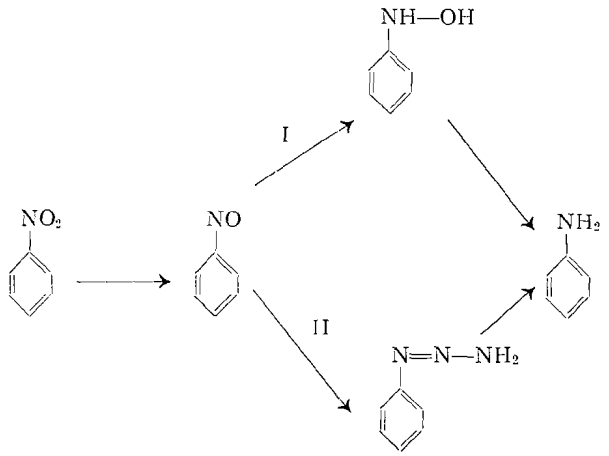
[3]*The Raney nickel catalyst was W1 (1, 8), which had been stored for several months at 0° under absolute methanol.*
[4]*It is interesting to note that fermenting yeast will reduce nitro- and nitroso-benzene and β-phenylhydroxylamine but not azo- or azoxy-benzene, to aniline (23).*

β-(2,5-dichlorophenyl)-hydroxylamine as a reduction product of 2,5-dichloronitrobenzene lends strong support to this mechanism.



An alternative mechanism is shown, route II, based on the known easy condensation of nitrosobenzene with many amines and phenylhydrazine. Hydrazine was found to react rapidly with nitrosobenzene but the red oil obtained appeared to be stable to hydrazine–palladium, making route II improbable.

The reduction of azobenzene to hydrazobenzene by hydrazine–palladium is a considerable improvement on the usual zinc – alcoholic potash method. An excess of hydrazine is advantageous since it appears to protect the hydrazobenzene during crystallization. Hydrazo-*o*-diphenyl was also prepared in good yield, and the method may prove to be generally useful for the preparation of hydrazo compounds.

EXPERIMENTAL

Melting points are uncorrected. The active palladium-on-charcoal catalyst was 10%, supplied by Baker and Co., Newark, New Jersey; the less active catalyst was an old sample.

The reductions were carried out essentially as described by Pietra (24). Most of the results are presented in Table I. Wherever possible the identity of a product was confirmed by taking the melting point of a mixture with an authentic sample, and by taking the infrared spectrum. Many of the amines were acetylated to aid isolation.

o-Chloronitrobenzene did not give a pure product. *p*-Chloronitrobenzene gave, after several crystallizations from benzene, impure *p*-chloroacetanilide (27%), m.p. 171–175° (lit. m.p. 178° (19)).

β-(2,5-Dichlorophenyl)-hydroxylamine

Hydrazine hydrate (4 ml.) was added to a suspension of 2,5-dichloronitrobenzene (5 g.) and active 10% palladium-on-charcoal (0.1 g.) in ethanol (100 ml.). The vigorous exothermic reaction was over in 2 minutes, as shown by a pronounced slackening in the rate of nitrogen evolution. After the catalyst was removed by filtration, the solution was poured into ice water (500 ml.). A white solid separated and was collected, washed, and dried by suction. The yield was almost quantitative.

Recrystallization was achieved by dissolving the product in hot benzene (100 ml.),

6,6′-Dimethyl-2,2′-dinitrodiphenyl	6,6′-Dimethyl-2,2′-diaminodiphenyl	63[6]	133–135	136 (19)

[1] *Yield and melting point refer to crude dried product unless otherwise indicated.*
[2] *Crystallized from ethanol containing hydrazine.*
[3] *Melting point with decomposition and dependent on the rate of heating.*
[4] *Characterized by condensation with phenanthraquinone to give 1,2;3,4;5,6-tribenzphenazine, yellow prisms from xylene, m.p. 272–273° (lit. m.p. 273° (21)).*
[5] *Using a catalyst of low activity, a mixture of the diamine with benz-[c]-cinnoline, m.p. 155–156°, was obtained.*
[6] *The low yield is probably due to the use of only 0.1 g. of nitro compound.*
[7] *Raney nickel has been used as the catalyst for this reduction, a yield of 100% being claimed (22).*

adding a little anhydrous magnesium sulphate to remove traces of water, and decanting off the supernatant solution. Addition of hot heptane gave, on cooling, long white needles, m.p. 95–96° with decomposition to a black tar. The melting point depended on both the rate of heating and the crystal size, powdered samples having m.p. 93–94° (lit. m.p. 93° (9)). The melting point was not depressed when the product was mixed with an authentic sample, prepared by Lapworth's general method (18). The identity was confirmed by oxidation to 2,5-dichloronitrosobenzene, m.p. 99–100° (lit. m.p. 101° (9)), and by comparison of infrared spectra. Sharp peaks at 3600 and 3340 cm.$^{-1}$ in the spectra of dilute chloroform solutions were probably O—H and N—H stretching bands since the spectrum of β-phenylhydroxylamine was identical in that region.

Recrystallized β-(2,5-dichlorophenyl)-hydroxylamine is stable at 0° but heating a benzene solution on the steam bath for a few minutes causes extensive decomposition to a brown tar.

When the reduction was carried out for 24 hours, 2,5-dichloroaniline was obtained, m.p. and mixed m.p. 49–50° (lit. m.p. 50° (9)).

Benz-[c]-cinnoline

2,2′-Dinitrodiphenyl was reduced using the general method described by Balcom and Furst (2). After the catalyst was removed by filtration, the filtrate was concentrated to give, on cooling, benz-[c]-cinnoline as yellow prisms, m.p. 155–156° (lit. m.p. 156° (19)). The yield was consistently greater than 90% when a weakly active Raney nickel catalyst was used.

Benz-[c]-cinnoline picrate crystallized from benzene as dark yellow prisms, m.p. 194–195° (lit. m.p. 194° (19)).

NOTE ADDED IN PROOF

Since this paper was accepted for publication, two more articles have become available (26, 27) which deal with some uses of hydrazine as a reducing agent in the presence of metal catalysts.

TRIARYLMETHANE COMPOUNDS AS REDOX INDICATORS IN THE SCHOENEMANN REACTION

III. THE DYES AND THEIR SPECTRA[1]

G. A. Grant, R. Blanchfield, and D. Morison Smith

ABSTRACT

A series of triarylmethane dyes were made by varying the substituents in the thiophene ring of the dye [4-(*p*-dimethylamino-α-2-thienylbenzylidene)-2,5-cyclohexadiene-1-ylidene]-dimethylammonium chloride. The spectra of the zinc salts of these dyes were shown to be similar to that of the dye formed in the Schoenemann reaction when the parent triarylmethane compound was used as an indicator. Neither of the absorption bands occurring in the 475 mμ or 625 mμ regions is affected by pH or buffer salts in the pH range 2.4 to 6.4 but both bands are hypsochromically shifted when the pH is lowered to 0.5. The substitution of 5-nitro and 5-acetamido groups in the thiophene ring results in the largest bathochromic and hypsochromic shifts respectively. Interpretation of the effect of substitution and pH was attempted employing existing theories on the relation between color and constitution.

INTRODUCTION

The preceding papers in this series (4, 14) described the preparation and use of some triarylmethane compounds as indicators in the Schoenemann reaction with a view to improving the method for detecting the phosphonofluoridate type of anticholinesterase compounds. As the success of the method depended greatly on the color of the dye produced it was of interest to ascertain the effect of various substituents attached to the thiophene ring on the spectra of the dyes. The effect of the replacement of the benzene nucleus by thiophene and a number of 5-substituted thiophene nuclei on triarylmethane dyes has been reported by Mason and Nord (11, 12). However, the present investigation enlarges on the previous studies by including a number of new mono- and di-substituted thienyl derivatives. The effect of pH on the spectra is also reported.

It was of interest to check the assumption that the oxidized compound produced in the Schoenemann reaction was the same as that of an authentic dye cation. Therefore spectral comparisons have been made of a number of zinc chloride salts of prepared dyes with the dyes formed in the Schoenemann reaction.

EXPERIMENTAL

Preparation of Dyes

The preparation and purification of the triarylmethane compounds from which the dyes were made have been described previously (4).

The zinc chloride salts of the dyes were prepared from the corresponding triarylmethane compounds according to the procedure of Mason and Nord (11) except that identical molar concentrations of the solutions were always used in an attempt to produce salts of the same composition. The method of Davies and Hodgson (2) was investigated but was not found to be superior to the method outlined by Mason and Nord (11) or Levi (7).

Briefly, the leuco compounds (0.04 mole) were dissolved in 2 *N* HCl (80 ml.) and the solutions were diluted with 800 ml. of water. Freshly prepared lead dioxide (0.04 mole) was added with stirring and cooling. After 2 hours sodium sulphate (0.05 mole) was

[1]*Manuscript received July 24, 1957.*
Contribution from Defence Research Board, Defence Research Chemical Laboratories, Ottawa, Ontario. Issued as D.R.C.L. Report 135C. Presented at the Annual Conference of the Chemical Institute of Canada at Vancouver in June, 1957.

added and the solution filtered. To 400 ml. of solution were added saturated zinc chloride solution (0.03 mole) and saturated brine solution (800 ml.). The precipitated dye was filtered off and the dye crystals were washed with ice water. The average yields were approximately 80%. An exception to the above procedure was the case of the dye with a nitro group in the 5-position in the thiophene ring. This leuco compound could not be made satisfactorily by the usual condensation of the nitrothiophenealdehyde with dimethylaniline (11). However, removal of the excess dimethylaniline and the oxidation of the reaction mixture by the above procedure gave the dye salt. The nitrothiophenealdehyde mentioned above was prepared from thiophenealdehyde by nitration of the aldehyde diacetate and subsequent hydrolysis according to the procedure of Patrick and Emerson (13).

The composition of some of these dyes is given in Table I.

Spectral Measurements

On the basis of the analysis of the dyes, solutions of a definite molarity were made up in distilled water or in the appropriate Clark and Lubs buffer and the spectra were determined on a Beckman Model DU Spectrophotometer between 320 and 700 mμ. Spectra were also taken of known dyes, e.g. malachite green, for comparison purposes. Absorption spectra of the dyes produced in the Schoenemann reaction were obtained employing a test procedure as outlined previously (4). The spectra were scanned from 320 to 700 mμ in 20 mμ steps 10 minutes after the addition of all the reagents.

RESULTS AND DISCUSSION

Composition of Dyes

The analyses for the dye salts given in Table I showed that the zinc chloride salts as prepared do not have a definite composition. Mason and Nord (11) on the basis of nitrogen analyses suggested a formula with 2 moles of zinc chloride and 3 moles of water.

Spectra of Dyes Formed in the Schoenemann Reaction

A comparison was made between the spectra of the dye solutions obtained in the Schoenemann reaction and the spectra of the corresponding solutions of the zinc chloride salts of the dyes. Fig. 1 is an example of this comparison for the 4,5-dimethylthienylidene dye. Along with similar plots obtained for other compounds this supports the assumption that I is the dye formula responsible for the color in the Schoenemann reaction.

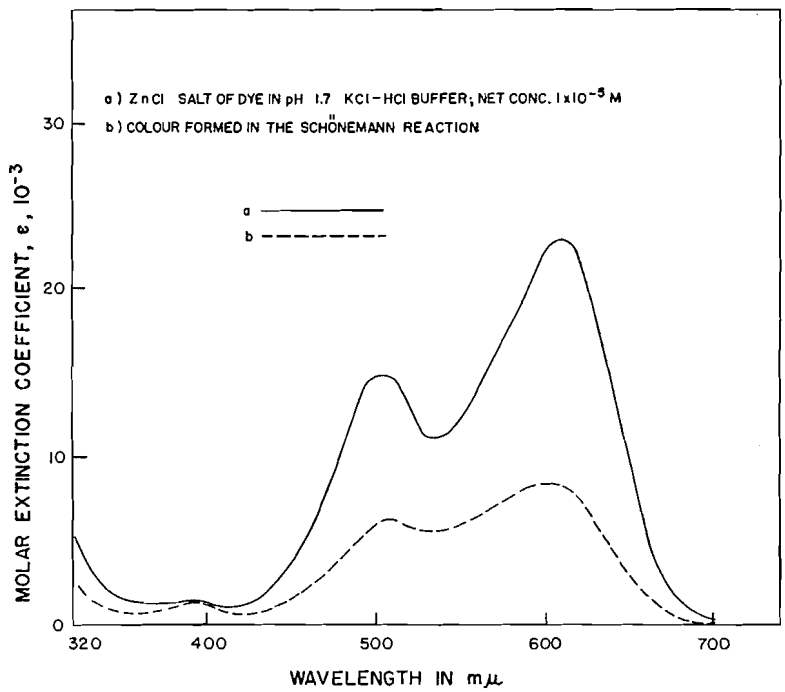

FIG. 1. Comparison of color formed in Schoenemann reaction with that of a solution of zinc chloride salt of the 4,5-dimethylthienyl substituted dye.

Effect of pH on Dye Spectra

Although a pH of approximately 2.2 or lower is necessary for the formation of the dye from the leuco compound, the pH for optimum color intensity may occur at a different pH. However, only under acid conditions would the results be of significance in the Schoenemann reaction, because the dyes are rapidly destroyed by alkaline peroxide, an excess of which is always present in this reaction.

The effect of pH was investigated over the range 0.5 to 6.4 in buffered solution. The results are reported in Table II. Neither the y band nor the x band is affected by pH or buffer salts in the pH range 2.4 to 6.4, but both bands are hypsochromically shifted for all the compounds studied except the 3-methyl and 5-acetamido derivatives when the pH is lowered to 0.5. At pH 0.5 the absorption intensity of some of the dyes decreased, and it was thought that decomposition might be taking place. The system was found to be only partially reversible, for although on the addition of alkali the color reappeared the original absorption bands were not entirely restored in intensity. All the dyes studied showed the same reversible reaction except the 3-methyl substituted compound which gave an irreversible bathochromic shift from 469 to 474 mμ when the pH was dropped from 1.60 to 0.5. Fig. 2 illustrates this decrease in intensity and shift in the absorption

curve of the 3-methyl compound when the pH value is decreased from 6.4 to 0.5. At pH 1.6 an inflection appears in the absorption curve at 555 mμ, which becomes a distinct band when the pH value is lowered to 0.5.

From pH 2.54 to 6.45 dyes with alkyl substitution in the 5-position absorb similarly to those with 3-methyl substitution, while from pH 1.6 to 2.54 they are markedly different. The appearance of the band at 540 mμ at pH 0.5 was more pronounced in the case of 5-substitution (e.g., 5-methylthienyl, Fig. 3), than with 3-substitution. The dialkyl substituted dyes responded to pH change in a similar manner to the unsubstituted and monosubstituted compounds.

The examination of the effect of pH on triarylmethane dyes containing a thienyl or substituted thienyl group showed that they were behaving as acid–base indicators similar to crystal violet. Adams and Rosenstein (1) examined the color changes of crystal violet in acid solution and showed that the absorption spectra corresponded to successive addition of positive charge to the cation. However, it is of interest to compare spectra obtained in the present investigation with those of the triphenylmethane dyes because of the difference in resonance structure between thienyl and phenyl groups. The hetero-sulphur atom in the thienyl group changes the electronic distribution and makes it impossible for the thienyl group to contribute quinoidal resonance hybrids as postulated for other triphenylmethane dyes.

In the case of crystal violet, the addition of a proton to one dimethylamino group results in the loss of the contribution of that dimethylaminophenyl group to the resonance of the molecule. The electron cloud is then redistributed between the other two dimethyl-anilino groups and the absorption spectrum becomes similar to that of malachite green.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

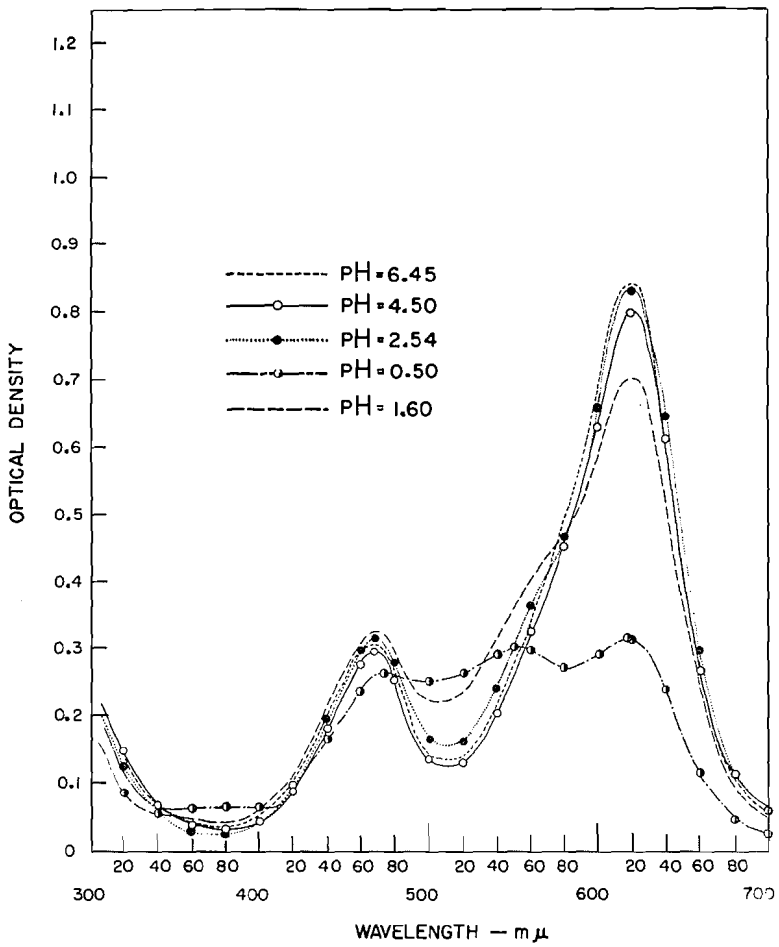

FIG. 2. Spectra at various acidities for 3-methylthienyl substituted dye.

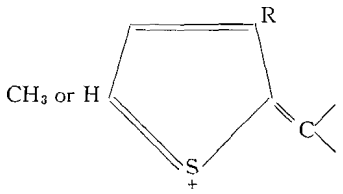
In the case of thiophene malachite green a proton attack on one of the dimethylaminophenyl groups would substantially change the picture since the electron cloud would either be concentrated in the remaining dimethylaminophenyl group or shared between it and the 2-thienyl group. However, when the 2-thienyl group is unsubstituted or substituted only in the 3-position the resonance form showing a continuous conjugated system has a high probability.



II

This structure is less likely to be subject to a proton attachment but the S=C bond may be attacked and split. This in part may account for some of the decomposition of the unsubstituted and 3-methyl substituted dyes at the lower pH. In all cases that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

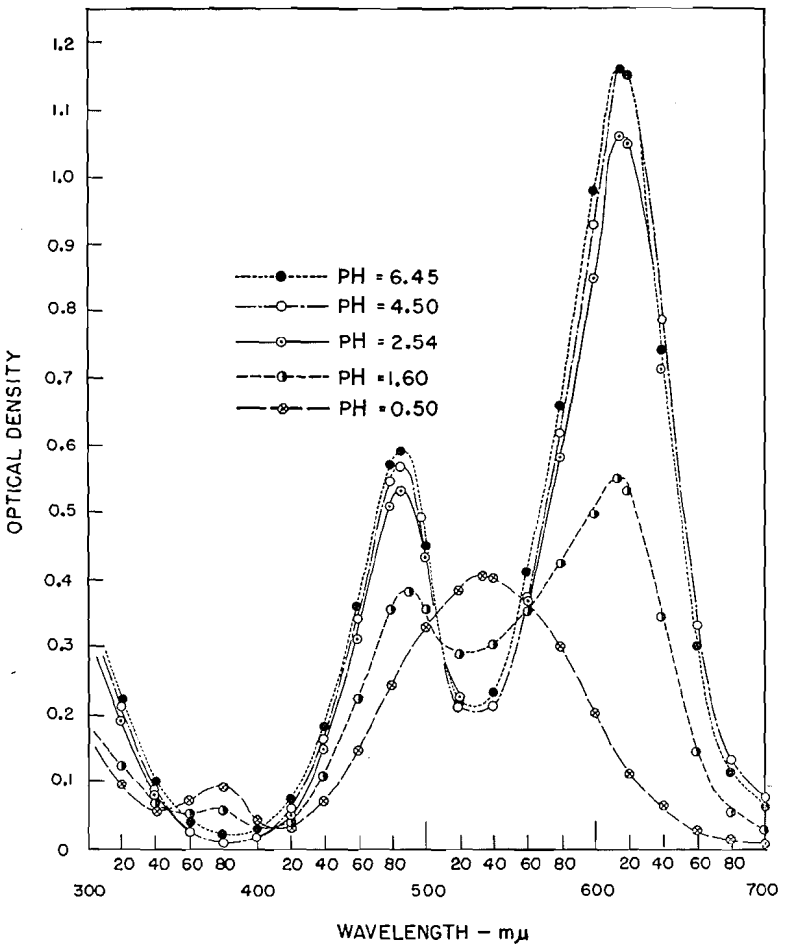

FIG. 3. Spectra at various acidities for 5-methylthienyl substituted dye.

were studied, except that of the 3-methyl-2-thienyl dye, a proton attack caused a general hypsochromic shift. The resonance hybrid of the 3-methyl substituted thienyl dye is therefore different from that obtained by disubstitution in the 4,5-positions or monosubstitution in the 5-position. That there is no shift with a proton attack on the 3-methyl substituted dye may be explained by the fact that when a methyl group is substituted in the 3-position of the thiophene ring, a larger proportion of the resonance hybrid is in the conjugated form (Formula II).

Effect of Substitution

Because of the variable composition of the zinc chloride salts the values of extinction coefficients are not reported. The wavelengths of the absorption maxima are comparable since it has been shown that the salt forming Lewis acid has little or no effect on wavelength maxima of the dye spectra (10).

For those dyes which are the same as those made previously (11, 12), the spectra and wavelength shifts obtained in this study in aqueous solution exhibit the same tendencies but are not identical in magnitude to those obtained by Mason and Nord in acetic acid solutions (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

The relation between color and chemical constitution has been explored by Lewis (9), Knott (6), and Dewar (3). According to Lewis (9) the change from the single x absorption band of crystal violet to the x and y absorption bands of malachite green indicates the introduction of the second mode of electronic oscillation involving the unsubstituted phenyl ring. The wavelength of the x absorption of malachite green is higher than that of crystal violet because, in the malachite green case, the positive charge is distributed mainly between the two dimethylaniline rings, whereas it is distributed between three equivalent rings in the crystal violet case (8). In this degenerate case the x and y bands coincide. It would seem that the wavelength difference between the x and y bands could be used as a measure of the degree of participation of the resonance forms of the aryl portion in the aryl bis(dimethylaniline) dyes. That is, it would indicate qualitatively how close they were to the crystal violet case when there is equal participation of all three groups attached to the central carbon atom, and as well might provide a way of ranking substituted aryl rings according to their positive nature when involved in this kind of attachment. These differences are given in Table III.

**Taken in distilled water solution.*

Table III also includes a comparison of the wavelengths of the x and y bands of some of the triarylmethane dyes. Substitution in the 5-position, with nitro, halo, or phenyl groups, produces bathochromic shifts while alkyl or acetamido substitution produces a hypsochromic shift in the x band. The largest bathochromic and hypsochromic shifts (37 and 23 mμ respectively) result from 5-nitro and 5-acetamido substitution. The effect of substitution on y band absorption is also appreciable. Substitution of a phenyl or nitro group in the 5-position results in hypsochromic shifts of 7 and 9 mμ respectively while substitution of alkyl, acetamido, halogen groups or both alkyl and halogen groups produced bathochromic shifts.

Mason and Nord (12) reported that the hypsochromic influence exerted on the x band increased with the size of the alkyl group. The total shift was 3 mμ when the group size was increased from methyl to propyl. Our data indicate that 5-propyl thiophene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

malachite green absorbs at a shorter wavelength than the 5-methyl and 5-ethyl compounds. However, there is no strong evidence to indicate that the magnitude of the hypsochromic shift increases significantly with the size of the alkyl group.

It was reported (12) that substitution of the electronegative chlorine and bromine atoms in the 2-position of the thiophene ring causes bathochromic shifts of the x and y bands. Larger bathochromic shifts of the x band were reported for the chloro compound than for the bromo compound, while the reverse was true for the y bands. The present investigation confirms that bathochromic shifts occur for the x and y bands. However, no difference in the magnitude of the shifts was noted when the less electronegative bromine atom was substituted for a chlorine atom.

It is also of interest to note that if both electron attracting and donating groups are substituted in the thiophene nucleus no appreciable shift occurs. When a methyl group is placed in the 4-position and a bromine atom in the 5-position, it is evident from the absence of wavelength shift that most of the electrons attracted by the halogen are obtained at the expense of the methyl group in the 4-position. Thus the net electronic distribution approaches that of the unsubstituted 2-thienyl nucleus.

The new members of the series are the 4,5-dialkyl, and acetamido-, nitro-, and phenyl-substituted thiophene dyes. The spectra of the 4,5-dialkyl dyes show an enhancement of the effects observed for the 5-monoalkyl dyes. These compounds possess more resonance forms with a positive charge in the thiophene ring. The 5-acetamidothienyl dye approaches most closely to the situation in crystal violet where all rings are equivalent, thus indicating possible participation of positively charged nitrogen in the amide group in the resonance of the dye. In the case of 5-nitrothienyl dye the difference between x and y peaks is much greater because the electron-attracting nitro group makes the thiophene ring system even less positive than usual. A similar effect is observed with the 5-phenylthienyl dye where the charge is dissipated over two aromatic rings, although the effect is less pronounced than in the nitro compound, because the phenyl ring, in itself, is only slightly more negative than the thiophene ring ($\lambda_x - \lambda_y = 189$ mμ for malachite green vs. 160 mμ for the thiophene analogue). With respect to this difference in x and y peaks, "furan malachite green" appears to be quite similar to the thiophene derivative. The effect of a para-methyl group in the phenyl ring (8) is about the same as the effect of a 5-methyl group in the thiophene ring, that is, $\lambda_x - \lambda_y$ is decreased by 30 mμ.

In summary, it may be noted that the leuco compounds effective as indicators in the Schoenemann reaction (14) have a wavelength difference between the absorption maxima of 110 to 150 mμ, and the order of their effectiveness increases as the wavelength difference decreases. It may also be noted that this order of substituents given in Table III corresponds to the order to be expected for Hammett's σ constants, going from negative to positive values (5), allowing for the difference to be expected between the phenyl and thienyl ring systems.

THE PHOTOCHEMICAL OXIDATION OF ALDEHYDES IN THE GASEOUS PHASE

PART I. THE KINETICS OF THE PHOTOCHEMICAL OXIDATION OF ACETALDEHYDE[1]

C. A. McDowell and L. K. Sharples

ABSTRACT

The photochemical oxidation of acetaldehyde has been studied in the gaseous phase at 20° C. and a wavelength of 3130 Å. It has been established that when the pressure of oxygen is between 0.5 mm. and 150 mm. the reaction obeys the kinetic law:

$$-d[CH_3CHO]/dt = (k_3/k_6^{\frac{1}{2}})(\phi_2 I_a)^{\frac{1}{2}}[CH_3CHO],$$

where k_3 is the velocity constant for the propagating reaction [3]:

$$CH_3CO_3 + CH_3CHO = CH_3CO_3H + CH_3CO, \qquad [3]$$

k_6 is the velocity constant for the terminating reaction [6]:

$$2CH_3CO_3 = (CH_3CO)_2O_2 + O_2, \qquad [6]$$

and $\phi_2 I_a$ is the rate of initiation of the photooxidation, i.e. the rate of formation of acetyl radicals, which are thought to be produced in one or both of the following ways:

$$(a) \quad CH_3CHO \overset{h\nu}{\underset{3130\text{ Å}}{=}} CH_3 + CHO,$$

$$\left.\begin{matrix} CH_3 \\ CHO \end{matrix}\right\} + O_2 = R,$$

$$R + CH_3CHO \overset{\phi_2 I_a}{=} RH + CH_3CO;$$

$$(b) \quad CH_3CHO \overset{h\nu}{\underset{3130\text{ Å}}{=}} CH_3CHO^*,$$

$$CH_3CHO^* + O_2 = CH_3CO + HO_2.$$

INTRODUCTION

Considerable progress has been made during the past decade in our knowledge of the mechanisms of the oxidation of hydrocarbons and related compounds. It has been well established that aldehydes are produced early in all hydrocarbon combustion reactions (15). Evidence has been produced which indicates that the decomposition of primary products such as peroxide radicals leads to the production of these aldehydes. It has also been shown that various aldehydes are capable of eliminating the induction periods which are observed in certain slow oxidation reactions (2, 15). Thus evidence has accumulated showing that the main course of the combustion of many hydrocarbons is largely controlled by the way aldehydes react with oxygen. In many cases it is evident that the hydrocarbon acts as a precursor of aldehyde and the combustion is largely that of the aldehyde formed early in the reaction between the hydrocarbon and oxygen (19).

It is, therefore, of considerable importance that the mechanism of the reactions between aldehydes and oxygen be thoroughly understood. There is general agreement as to the main features of the mechanism of the thermal oxidation of acetaldehyde (9, 13), and doubtless a similar mechanism is applicable to the cases of the oxidation of higher aldehydes though there have been rather few detailed studies of these latter reactions

[1]*Manuscript received July 22, 1957.*
Contribution from the Department of Inorganic and Physical Chemistry, University of Liverpool, Liverpool 7, England, and the Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada.

(9, 17). It is, for example, generally accepted that the thermal oxidation of acetaldehyde is a chain reaction in which the acetyl radical (CH_3CO) and the peracetic radical (CH_3CO_3) play important parts. There are, however, certain details of the reactions of these radicals which have not been elucidated.

It was the aim of the work here described to discover the mechanism of the photochemical oxidation of acetaldehyde, for it is obvious that this is a very direct way to investigate the reactions of the acetyl and peracetic radicals. Furthermore, as will be seen later in Part III of this series, it is desirable to know the absolute values of the velocity constants for the propagating and terminating steps in the oxidation chain involving the acetyl and peracetic radicals, and photochemical techniques present a ready means of evaluating these constants.

The photochemical oxidation of acetaldehyde in the gaseous phase was first studied by Bowen and Tietz (6) using a flow method. It was later investigated briefly by Carruthers and Norrish (8). Bowen and Teitz found that the rate of the reaction at about 20° C. was independent of the oxygen concentration and directly proportional to the aldehyde concentration. It was also found that the rate was proportional to the square root of the light intensity. A brief investigation was also carried out later by Mignolet (14) and some preliminary studies were more recently reported briefly by McDowell and Farmer (13). The present study, which covers much of the earlier work of McDowell and Farmer, was preliminary to that reported in Part III, in which is described the determination of the absolute values of the velocity constants for the propagating and terminating steps in the photooxidation of acetaldehyde.

EXPERIMENTAL

The acetaldehyde and oxygen were prepared by the methods described previously (13). The same photochemical apparatus was used except that a "Mazda" high pressure mercury arc was used as a light source. This was supplied with power from a d.c. generator, which was driven by an a-c. synchronous motor. Calibrated fine mesh wire gauzes were used to vary the intensity of the illumination. The rate of the reaction was determined by measuring the amount of peracetic acid produced in a known time, the analytical method being that previously described (13). To obtain reproducible results it was necessary to evacuate and bake the reaction vessel at above 200° C. for more than 4 hours between runs. These precautions made it possible to obtain results reproducible to $\pm 7\%$, and any thermal or induced thermal reaction was kept to a minimum. For experiments up to $\frac{1}{2}$ hour in duration the reaction rate was accurately proportional to time.

RESULTS

The main product of the photooxidation of acetaldehyde is peracetic acid and the rate of the reaction was determined by measuring the amount of this compound formed in a given time on illuminating the reaction vessel with light of wavelength 3130 Å.

Dependence of Rate of Reaction on Acetaldehyde Concentration

The dependence of the rate of the reaction, $d[CH_3CO_3H]/dt$, on the concentration of acetaldehyde was measured at a fixed light intensity for mixtures containing 5 mm. pressure of oxygen at 20° C.; the results are given in Table I and shown graphically in Fig. 1, where we have plotted the logarithm of the corrected rate against the logarithm of the concentration of acetaldehyde. The straight line shown in Fig. 1 has a slope of 0.98. Thus it is apparent that the rate of formation of peracetic acid in the photooxidation of acetal-

Dependence of the Rate of Reaction on the Intensity of Illumination

In Table III are given the rates of reaction observed for a mixture of 150 mm. Hg of acetaldehyde and 5 mm. Hg of oxygen at 20° C. and for different intensities of the incident radiation. In column three of this table is shown the value of the ratio "rate/square root of intensity absorbed". These data show clearly that the rate of formation of peracetic acid in this photooxidation is proportional to $I_a^{\frac{1}{2}}$. This conclusion is also demonstrated by Fig. 2, where the logarithm of the rate of reaction has been plotted against the logarithm of the absorbed intensity. The slope of the dotted line is 0.55 and that of the continuous line 0.51. It is important to note that in the experimental data listed in Table II the light intensity has been varied over a 73-fold range.

TABLE III

DEPENDENCE OF THE RATE OF THE PHOTOOXIDATION OF ACETALDEHYDE ON THE INTENSITY OF THE ILLUMINATION

All data refer to a mixture containing 150 mm. Hg of acetaldehyde and 5 mm. Hg of oxygen at 20° C.

I_a, percentage	Rate, mole $l.^{-1}$ $sec.^{-1} \times 10^9$	Rate/$I_a^{\frac{1}{2}}$
0.086	2.7	9.2
0.185	4.4	10.2
0.40	5.4	8.6
0.58	7.4	9.7
0.62	7.8	9.9
0.83	8.6	9.5
1.74	15.6	11.8
2.74	18.8	11.4
3.82	27.4	14.0
3.94	27.1	13.7
6.21	33.6	13.5

Over-all Activation Energy

It was difficult to obtain an extremely accurate value for the over-all activation energy for this reaction because above 30° C. there intervenes a troublesome thermal reaction. A value for the activation energy was, however, obtained by taking a mean of seven experiments carried out at 20° C. and a mean of a similar number carried out at 30° C. These data are set out in Table IV and there is also given the value for the activation energy E calculated from the equation $E = [RT_1T_2/(T_1 - T_2)] \ln(R_1/R_2)$, where R_1 and R_2 are relative rates of the reaction at temperatures T_1 and T_2.

TABLE IV

ACTIVATION ENERGY FOR THE PHOTOOXIDATION OF ACETALDEHYDE

Data refer to a mixture of 150 mm. Hg of acetaldehyde and 5 mm. Hg of oxygen and a light intensity of 2.05% of the total intensity

Rate at 293° K.	30.6 ± 0.7	Arbitrary units, mean of seven experiments
Rate at 303° K.	45.7 ± 1.8	
E	7.16 ± 1.0	kcal. $mole^{-1}$

DISCUSSION

The above experimental results show that the photochemical oxidation of acetaldehyde at 20° C. is governed by the kinetic equation:

$$d[CH_3CO_3H]/dt = K\, I_a^{\frac{1}{2}}[CH_3CHO].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

There has been considerable discussion as to the nature of the primary process which occurs when acetaldehyde absorbs a quantum of radiation. Steacie (16) gives a detailed discussion of the relevant facts. Suffice it to say that Volman *et al.* (18) have shown that free radicals are produced in the direct photolysis of acetaldehyde at a wavelength of 3130 Å. There has been considerable controversy as to the primary quantum efficiencies of the two processes [1*a*] and [1*b*]:

$$CH_3CHO + h\nu = \begin{cases} \longrightarrow CH_3 + HCO, & [1a] \\ \longrightarrow CH_4 + CO. & [1b] \end{cases}$$

Early work (2, 3, 10) led to the view that at 3130 Å and moderate temperatures reaction [1*a*] predominated but the quantum yield was low. More recent studies by Calvert, Pitts, and Thompson (7) have shown that at low light intensities of 3130 Å radiation and at temperatures in excess of 250° C. the sum of all the primary efficiencies of free radical formation at 3130 Å is equal to 0.8. This conclusion is based on careful measurements of the quantum efficiencies for the formation of hydrogen at different temperatures. In this connection it is interesting to note that Lossing (12) has shown recently that in the mercury (Hg $^3P_1$) photosensitized decomposition of acetaldehyde at 55° C. the primary step is at least 95% to form methyl and formyl radicals.

The work of Leermakers (11) on the low temperature photolysis of acetaldehyde gave a quantum yield of 0.2 to 0.3. This could represent either a molecular rearrangement or a free radical non-chain reaction. Blacet and Volman's (4) results, however, indicate that at 3130 Å the primary process is entirely a free radical one.

In the case of acetaldehyde mixed with oxygen there is no reason a priori for assuming that entirely the same process or processes will occur as those which take place when pure acetaldehyde absorbs a quantum of radiation of wavelength 3130 Å. In view of the difficulties in understanding the results obtained by the photolysis of acetaldehyde in the presence of iodine (2, 3, 10), it would be unwise to assume that the presence of oxygen in the acetaldehyde would not give rise to some difficulties of interpretation.

It is to be expected that on the absorption of radiation of wavelength 3130 Å, acetaldehyde will be excited to several different states. One or more of these may dissociate to yield free radicals as in reaction [1*a*]. Energy transfer processes will probably occur from the other states; fluorescence may also occur; and by collisions with other acetaldehyde molecules some of those in excited states will be quenched. In the presence of oxygen some of these excited states may also be preferentially quenched.

The work reported in this paper does demonstrate, however, that a photolytic oxidation of acetaldehyde at a wavelength of 3130 Å does occur at 20° C. We shall, therefore, assume that this photochemical oxidation is initiated by one, or both, of the following processes:

(*a*) By the absorption of a quantum of radiation of wavelength 3130 Å the acetaldehyde, even in the presence of oxygen, undergoes the primary process [1*a*],

$$CH_3CHO \underset{3130\,\text{Å}}{\overset{h\nu}{=}} CH_3 + CHO. \qquad [1a]$$

The two radicals produced can then react with oxygen as indicated in equation [1*d*],

$$\left.\begin{matrix} CH_3 \\ CHO \end{matrix}\right\} + O_2 = R. \qquad [1d]$$

It is assumed that the radical R can then abstract a hydrogen atom from acetaldehyde to form an acetyl radical which is regarded as being the chain initiator in the thermal oxidation of acetaldehyde (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

(*b*) The absorption of a quantum of radiation of wavelength 3130 Å can lead to excited states of acetaldehyde which may not dissociate to form radicals by reaction [1*a*]. Nevertheless, though it is possible that in the presence of oxygen some or all of these excited states may be quenched, it is at least likely that the excited acetaldehyde molecules may react with oxygen to yield free radicals which can start the oxidation chain. There is no reason why, for example, one or more of these excited states of acetaldehyde, here denoted in [1*c*] simply by CH_3CHO^*, may not react with oxygen by a process [1*f*] analogous to that thought (13) to be the mode of initiation of the thermal oxidation between ground state acetaldehyde molecules and oxygen:

$$CH_3CHO \overset{h\nu}{\underset{3130\ \text{Å}}{=}} CH_3CHO^*, \qquad [1c]$$

$$CH_3CHO^* + O_2 = CH_3CO + HO_2. \qquad [1f]$$

Reaction [1*f*] would, of course, be expected to occur at a much lower temperature than that at which the corresponding reaction between ground state acetaldehyde molecules and oxygen has a reasonable rate.

Whatever the means whereby acetyl radicals are produced following the initial absorption of radiation at 3130 Å by the acetaldehyde this radical is regarded as being the initiator of the oxidation chain and we may then write the following mechanism for the photooxidation of acetaldehyde at 3130 Å and at low temperatures (20–40° C.):

$$CH_3CHO \overset{h\nu}{\underset{3130\ \text{Å}}{=}} CH_3 + CHO \qquad [1a]$$

$$CH_3CHO \overset{h\nu}{\underset{3130\ \text{Å}}{=}} CH_3CHO^* \qquad [1c]$$

$$\left.\begin{aligned} CH_3 + O_2 &= \\ CHO + O_2 &= \end{aligned}\right\} R \qquad [1d]$$

$$\left.\begin{aligned} R + CH_3CHO &= RH + CH_3CO \\ CH_3CHO^* + O_2 &= CH_3CO + HO_2 \end{aligned}\right\} \phi_2 I_a \qquad \begin{matrix}[1e]\\[1f]\end{matrix}$$

$$CH_3CO + O_2 = CH_3CO_3 \qquad [2]$$

$$CH_3CO_3 + CH_3CHO = CH_3CO_3H + CH_3CO \qquad [3]$$

$$2CH_3CO = (CH_3CO)_2 \qquad [4]$$

$$CH_3CO + CH_3CO_3 = (CH_3CO)_2O_2 \qquad [5]$$

$$2CH_3CO_3 = (CH_3CO)_2O_2 + O_2 \qquad [6]$$

Since it has been shown that the rate of the photochemical oxidation is proportional to $I_a^{\frac{1}{2}}$, and independent of the oxygen pressure, it is probable that reaction [2] is rather fast and it is also likely that at the oxygen pressures used reactions [4] and [5] are negligible compared with reaction [6].

The application of the stationary state hypothesis to the above reaction mechanism leads to the equation

$$\frac{d[CH_3CO_3H]}{dt} = \frac{k_3(\phi_2 I_a)^{\frac{1}{2}}[CH_3CHO]}{(k_4\beta^2 + k_5\beta + k_6)^{\frac{1}{2}}},$$

where $\beta = k_3[CH_3CHO]/k_2[O_2]$. When $\beta \ll 1$, as is likely to be the case in our experiments (see above), this equation reduces to

$$d[CH_3CO_3H]/dt = (k_3/k_6^{\frac{1}{2}})(\phi_2 I_a^{\frac{1}{2}})[CH_3CHO]. \qquad [A]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

This equation is in agreement with the experimental results reported above and it, therefore, follows that the proposed mechanism is a satisfactory one. It is, of course, similar to that shown to govern the rates of oxidation of olefins and other organic compounds in solution (5) and for aldehyde oxidations in the gas phase (9, 13).

Equation [A] and our results are in accord with the view that the main terminating step in the oxidation is the interaction of two peracetic radicals (CH_3CO_3). Thus it follows from [A] that the over-all activation energy for the photo-oxidation is $E = E_3 - \frac{1}{2}E_6$. It is in general thought that reaction [6] requires little or no activation energy. If this is so, then the value which we have obtained for the activation energy, namely, 7.16 ± 1.0 kilocalories mole^{-1} refers to E_3. It is interesting to compare this with the value of 7.5 ± 0.3 kilocalories mole^{-1} (19) for the activation energy of the corresponding reaction for the methyl radicals, namely:

$$CH_3 + CH_3CHO = CH_4 + CH_3CHO.$$

ACKNOWLEDGMENT

Most of the experimental work described in this paper was carried out in the Department of Inorganic and Physical Chemistry, University of Liverpool, and we wish to thank Professor C. E. H. Bawn, C.B.E., F.R.S., for laboratory facilities and for his interest in the work.

THE PHOTOCHEMICAL OXIDATION OF ALDEHYDES IN THE GASEOUS PHASE

PART II. THE KINETICS OF THE PHOTOCHEMICAL OXIDATION OF PROPIONALDEHYDE[1]

C. A. McDowell and L. K. Sharples

ABSTRACT

The photochemical oxidation of propionaldehyde has been studied in the gaseous phase at 23° C. and a wavelength of 3130 Å. With pressures of oxygen varying from 0.3 mm. to 100 mm. Hg it has been established that the reaction obeys the same kinetic law as that found for the corresponding reaction with acetaldehyde, namely:

$$d[C_2H_5CO_3H]/dt = (k_3/k_6^{\frac{1}{2}})\ (\phi_2 I_a)^{\frac{1}{2}}[C_2H_5CHO],$$

where k_3 is the velocity constant for the propagating reaction [3]:

$$C_2H_5CO_3 + C_2H_5CHO = C_2H_5CO_3H + CH_3CO \qquad [3]$$

and k_6 is the velocity constant for the terminating reaction [6]:

$$2C_2H_5CO_3 = (C_2H_5CO)_2O_2 + O_2. \qquad [6]$$

$\phi_2 I_a$ is the rate of initiation and it is regarded as being a composite quantity representing the rate of formation of propionyl radicals, which are thought to be the initiators of the oxidation chain. The propionyl radicals are thought to be formed by two processes: (*a*) from the subsequent reactions of free radicals produced in the primary free radical process which occurs when propionaldehyde absorbs a quantum of radiation at 3130 Å, and (*b*) from the subsequent reactions, with oxygen, of excited states of propionaldehyde, which are also thought to be formed by the absorption of light of wavelength 3130 Å.

INTRODUCTION

Following the study of the photooxidation of acetaldehyde (Part I) reported in the preceding paper, it seemed desirable to study other higher aldehydes. It is important to know if the derived mechanism was of general application. It was also necessary to establish this mechanism for several aldehydes, for one of our main aims was to determine the absolute values for the propagating and terminating steps in the oxidation chain. A knowledge of the velocity constant for these oxygen-containing radicals is most important if the general features of the rates of combustion processes of hydrocarbons and other organic compounds are to be understood. Such results would also add to our available information of the factors influencing the interactions of large radicals in the gaseous phase.

Few studies have been made of the kinetics of the oxidation of aldehydes higher than acetaldehyde. Steacie *et al.* (8) investigated the gas phase thermal oxidation of propionaldehyde and showed that its kinetics were similar to those found for acetaldehyde. More recently a similar investigation (4) has largely substantiated the earlier work. Both of these studies were carried out at temperatures between 100° and 200° C. and the rates were determined by measuring pressure–time curves. It was found that the main product was perpropionic acid. Blacet and Volman (2) reported a study of the photooxidation of crotonaldehyde, but their results were not detailed enough to yield much information about the mechanism and kinetics of the reaction.

EXPERIMENTAL

Eastman-Kodak white label propionaldehyde was dried three times over anhydrous $CaSO_4$ and distilled, at a reflux ratio of 20: 1, through an efficient column in an atmosphere

[1]*Manuscript received July 22, 1957.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada.

of cylinder "purified" grade nitrogen. A fraction boiling at 47.9° C., comprising half of the sample, was collected. This sample was redistilled and finally bulb-to-bulb distilled 10 times on the vacuum line, each time a middle fraction being taken.

Oxygen was prepared by heating A.R. grade potassium permanganate. A trap plugged with glass wool and immersed in liquid oxygen was interposed between the oxygen reservoir and the potassium permanganate.

A sample of ethanol from a freshly opened can of "absolute" was dried over anhydrous magnesium sulphate and bulb-to-bulb distilled on the vacuum line. A sample of A.R. isopropyl alcohol was similarly purified.

A sample of A.R. acetone was dried over anhydrous potassium carbonate, refluxed with potassium permanganate, and bulb-to-bulb distilled on the vacuum line.

The apparatus was a conventional high vacuum system utilizing stopcocks lubricated with Apiezon L grease. A cylindrical quartz reaction vessel (volume 76 ml., 4 ml. of which was dead space) having optically flat ends was housed in a block aluminum furnace, the temperature of which could be readily adjusted and accurately maintained. The gases were metered into the vessel using either a calibrated, sensitive spiral gauge, or, for lower pressures, the same gauge in conjunction with a calibrated expansion volume. The reaction products were trapped in a series of cold traps, which could be plugged with glass wool, the last of which was removable to facilitate analysis of the normally liquid reaction products. A copper oxide furnace was incorporated to analyze for CO and H_2, and means was incorporated for measuring small quantities of gas, and for collecting small samples of gaseous products for analysis by mass spectrometry.

A water-cooled, General Electric AH6 mercury arc, housed in a small, water-cooled box with a 3 mm. diameter hole in one side, gave a "point" source of illumination. The input voltage to the 1000 volt transformer for the arc was stabilized at 100 volts by a Sorensen a-c. voltage regulator. The arc had a short-term stability within 5%. Liquid filters were used to isolate a fairly narrow wavelength band in the 3200 Å region. Neutral density filters made by evaporating aluminum on quartz plates were used to vary the intensity incident upon the reaction vessel. Quartz lenses were arranged so that light from the "point" source was collimated through a 5 mm. diameter hole and then into a 50 mm. diameter, very nearly parallel, beam which uniformly filled the reaction vessel. The intensity of the radiation was monitored by an electronic photometer unit utilizing a QVA39 quartz photocell as a light detector. The linearity of the response of this unit was checked occasionally and found to be good.

Perpropionic acid was estimated by the ferrous thiocyanate method, a Bausch and Lomb "Spectronic 20" absorptiometer being used to assess the intensity of the color developed by the various concentrations of peroxide. The absorptiometer was calibrated using a solution of perpropionic acid, the actual strength of which was determined iodometrically by the method of Sully (9).

The light intensity was estimated by measuring the amount of CO formed when gaseous acetone was illuminated under identical conditions to those prevailing during runs, at temperatures from 100° to 120° C. for a given length of time. The quantum yield of CO formation was found to be very nearly constant over the region 100–120° C. In calculating the intensity of our source, the quantum yield of CO from acetone was taken as being 1 (7). The estimated intensity may be in error owing to the fact that an unknown, but presumably appreciable, fraction of the light used was in the 3130–3300 Å region of the spectrum (owing to lack of sharpness of the filters and the continuous background delivered by the arc) and the precise CO quantum yield in this region is not known.

RESULTS

Initial runs showed that the main product of the reaction was perpropionic acid, with a quantum yield proportional to the square root of the absorbed intensity, $I_a^{\frac{1}{2}}$, and of the order of 50 for a medium intensity. The oxygen uptake was found to be equal to the perpropionic acid formation within experimental error. A complete analysis of the products was not carried out, but CO_2 and CO were formed in approximately equal amounts with a quantum yield of the order of 1. A very small quantity of ethane was formed, but the quantum yield was not estimated.

The reaction rate was estimated by measuring the amount of peracid formed in a given time. In all runs, except those for the determination of CO_2 and CO formation and O_2 uptake, the reaction was confined to $<0.5\%$ conversion of aldehyde.

There was found to be no measurable thermal reaction at all in a range from 20° to 40° C. and the absence of this was frequently checked. However, after about 70 runs, quite suddenly an appreciable thermal reaction became apparent and built up to a rate which was about 2% of the photochemical rate. This was only appreciable because the reactants were allowed to mix for 1 hour prior to photolysis. When the cell was removed, cleaned, and replaced, no thermal reaction took place.

No cell aging effect was noticed and runs were generally reproducible within $\pm 7\%$. A colorless, transparent polymeric substance of unknown composition was gradually deposited upon the cell walls. On being heated to 300° C. the polymer did not simply decompose and evaporate, but charred. When propionaldehyde is photolyzed, a certain amount of polymerization does take place (6); hence the polymer on the wall may be polypropionaldehyde with physically absorbed reaction products, or a polyoxypolymer formed by reaction of polypropionaldehyde with perpropionyl radicals.

Dependence of Rate of Reaction on Time

The rate of reaction remained constant up to a conversion of 0.7% of the aldehyde during a 10 minute run, indicating that there was no induction period or photochemical growth effect and no autocatalysis. See Fig. 1.

Later on in this study the apparent rate for certain runs of $<0.5\%$ conversion, but of longer duration than usual, was lower than had been anticipated. This was due to the slow decomposition or removal of perpropionic acid, and the rate of this reaction was therefore investigated.

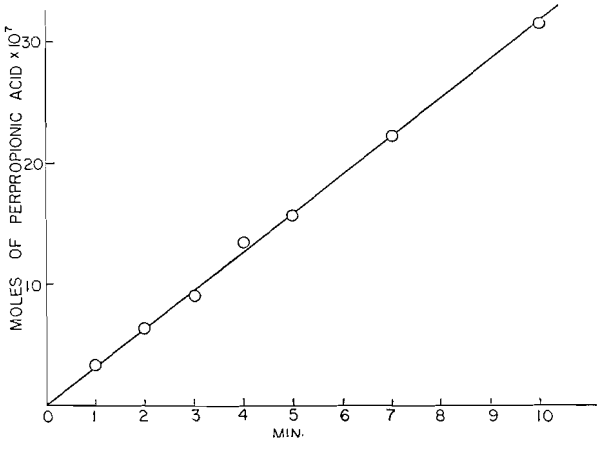

FIG. 1. Dependence of rate of photochemical oxidation of propionaldehyde on time.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Effect of Decomposition of Perpropionic Acid on Rate

The rate of peracid decomposition was not very reproducible, but it was found to be proportional to the concentration of the peracid within experimental error and roughly proportional to the reciprocal of the aldehyde pressure. It was initially thought that removal of peracid may have been due to the reaction

$$C_2H_5CO_3H + C_2H_5CHO = 2C_2H_5COOH$$

either homogeneously or at the wall, but this was obviated by the 1/[aldehyde] dependence of the rate. The rate is too slow for diffusion to be the rate-controlling step. A possible explanation is that the peracid is removed by physical absorption at the wall and the aldehyde deactivates absorption sites.

In a system where peracid is formed at a constant rate and is removed at a rate proportional to [peracid], then if P is the amount of peracid measured after t seconds, and P_1 is the amount of peracid that would have been formed in t seconds if the peracid was not being removed at all, then $P/P_1 = 1-e^{-k_p t}/k_p t$ where k_p is the rate constant of the removal step; hence the ratio of the measured rate of formation of peracid to the real rate of formation is a function of time only for a given k_p. The values of k_p were calculated for 100 mm. Hg and 35 mm. Hg of aldehyde, and the ratios P/P_1 were calculated for various times. The results are shown in Table I. The results are probably correct within $\pm 20\%$.

TABLE I

EFFECT OF TIME ON RATIO OF OBSERVED RATE TO ACTUAL RATE

Time, min.	k_p, sec.$^{-1}$	P/P_1
1	0.0011	1.00
10	0.0011	0.97
30	0.0011	0.91
60	0.0011	0.80
1	0.0023	0.99
10	0.0023	0.92
30	0.0023	0.79
60	0.0023	0.68

It is seen that the error, due to removal of peracid, in the measured rate for a 10 minute run with 100 mm. aldehyde, is about 2%; hence the only runs in this study which require correction in this respect are runs 53, 54, and 60.

Dependence of Rate of Reaction on Intensity of Absorbed Radiation

The dependence of the rate of oxidation on the light intensity was studied over a 10,000-fold range of absorbed intensity for a mixture of 100 mm. Hg of propionaldehyde and 3 mm. of O_2. It was found that over a range of I_a from 10^{-10} to 2.5×10^{-6} einstein l.$^{-1}$ sec.$^{-1}$ the rate was accurately proportional to $I_a^{\frac{1}{2}}$, but at $I_a < 10^{-10}$ einstein l.$^{-1}$ sec.$^{-1}$ this $I_a^{\frac{1}{2}}$ dependence falls off. The results are shown in Fig. 2 and Table II.

Dependence of Rate of Reaction on Pressure of Propionaldehyde

The dependence of the rate on the aldehyde pressure was studied by maintaining the oxygen pressure at 3 mm. Hg and varying the aldehyde pressure from 10 to 200 mm. Hg. As the aldehyde pressure was varied, the absorbed intensity also varied, so all these runs were carried out in the intensity region where rate is accurately proportional to $I_a^{\frac{1}{2}}$, and the tabulated results are corrected to 100% absorption of a given constant intensity (Table III). The plot of rate against aldehyde pressure was a straight line passing through

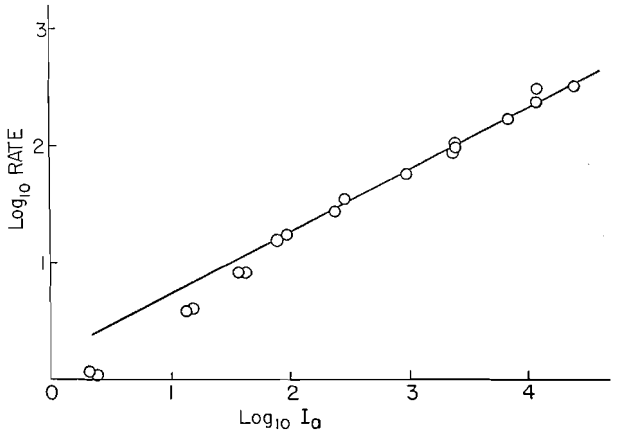

FIG. 2. Dependence of rate of photochemical oxidation of propionaldehyde on intensity of absorbed radiation.

49	1.18×10^{4}	1.86×10^{2}
50	2.29×10^{3}	8.00×10

the origin, Fig. 3, but the apparent rates for low aldehyde pressure runs fall well below the straight line. This is probably due to the peracid removal step mentioned earlier, and if a correction is applied, these points fit more closely to the line.

Dependence of the Rate of Reaction on Pressure of Oxygen

The rate of oxidation was found to be independent of oxygen pressure over a range of 0.3–100 mm. Hg, in a system in which the aldehyde pressure and I_a were maintained constant. The results are shown in Table IV.

Over-all Activation Energy

In Table V are given the values of the over-all rate of the reaction at observed different temperatures for a mixture containing 3 mm. of oxygen and 5.87×10^{-3} mole $l.^{-1}$ of

propionaldehyde. These experiments were performed using a value of I_a of 1.11×10^{-9} einstein $l.^{-1}$ $sec.^{-1}$.

These data have been plotted in Fig. 4. From these data we have calculated by the method of least squares that the activation energy for the photooxidation of propionaldehyde is 6.75 ($\pm$0.5) kilocalories $mole^{-1}$.

DISCUSSION

The above experimental results indicate that the gas-phase photooxidation of propionaldehyde at about 23° C. is a chain process and the initial stage is governed by the kinetic equation

$$d[C_2H_5CO_3H]/dt = kI_a^{\frac{1}{2}}[C_2H_5CHO]^1[O_2]^0.$$

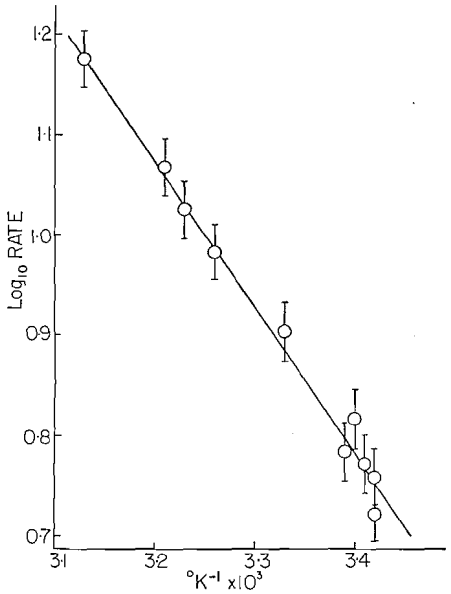

FIG. 4. Activation energy curve for the photochemical oxidation of propionaldehyde.

At low intensities this expression ceases to apply because the $I_a^{\frac{1}{2}}$ dependence falls off. Also in later stages of the oxidation, removal of the peracid becomes a significant part of the process. The $I_a^{\frac{1}{2}}$ dependence is undoubtedly due to a radical initiation process which is proportional to I_a and a chain termination process which is bimolecular. Deviation from $I_a^{\frac{1}{2}}$ dependence at low intensities indicates that the termination process is no longer solely bimolecular, but that a first-order termination starts to become important. Such a first order termination could be at the wall; which is inherently feasible, because the concentration of radicals at low I_a is small, and hence the bimolecular termination would be similarly small, thus giving radicals more chance to reach the wall.

The too low rates observed for runs at low aldehyde concentration may be due entirely to the removal of peracid at the wall, but even when a correction is applied, these rates are still somewhat low. There are two possible explanations which could account for this. At low concentrations of aldehyde and consequent low absorbed intensities, the rate of initiation of chain propagating radicals may have an aldehyde pressure dependence if there is a possible fate of the radical R other than reacting with aldehyde to yield C_2H_5CO. The radical R could react at the wall, and if it did, the wall reaction would be favored by low aldehyde pressure and low intensity, and hence under these conditions the rate would be reduced. The other possible explanation is that at low aldehyde pressure and low intensity, first-order termination of propagating radicals at the wall may become appreciable, thus reducing the observed rate.

The photolysis of propionaldehyde at a wavelength of 3130 Å has been studied by several workers (3, 5, 6). A recent detailed investigation has been made by Blacet and Pitts (1). These authors conclude that there are four separate primary processes involved:

$$C_2H_5CHO + h\nu = \begin{cases} \longrightarrow C_2H_5 + CHO & \text{(i)} \\ \longrightarrow C_2H_6 + CO & \text{(ii)} \\ \longrightarrow C_2H_4 + HCHO & \text{(iii)} \\ \longrightarrow CH_3 + CH_2CHO & \text{(iv)} \end{cases}$$

From this work it is apparent that the ratio of the primary process (ii) to primary process (i) at 3130 Å is 0.046. This result and most of the conclusions of Blacet and Pitts are based on experiments performed on mixtures of propionaldehyde and iodine. There have been some doubts expressed (see preceding paper, Part I) about the validity of some of the deductions regarding free radical mechanisms based on the use of iodine "to fix" the radical. It is to be expected that at 3130 Å propionaldehyde will form several excited states, and only some of these may dissociate to form free radicals. Further, the presence of iodine will undoubtedly quench some of these excited states of propionaldehyde by energy transfer processes (see Part I).

Our view is that it is best to regard the photolysis of propionaldehyde–oxygen mixtures as following the same processes as suggested in Part I for the case of acetaldehyde–oxygen mixtures. Namely, that the primary process (i) will undoubtedly occur, but that excited states of propionaldehyde will be formed. Some of these will undoubtedly be quenched by the oxygen, but some may react with oxygen molecules to form free radicals which should be capable of initiating the propionaldehyde oxidation chain. Thus we think that the photochemical oxidation of propionaldehyde, since it evidently obeys the same kinetic law as that of acetaldehyde as shown by our experiments, should also follow the same mechanism.

It is, therefore, assumed that the photochemical oxidation of propionaldehyde is initiated by one, or both, of the following processes:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

(1) By the absorption of a quantum of radiation of wavelength 3130 Å, the primary process (i) occurs even in the presence of oxygen,

$$C_2H_5CHO \underset{3130\,Å}{\overset{h\nu}{=}} C_2H_5 + CHO. \qquad [1a]$$

These two radicals can then react with oxygen as follows:

$$\left.\begin{matrix} C_2H_5 \\ CHO \end{matrix}\right\} + O_2 = R. \qquad [1d]$$

The radical R can then abstract a hydrogen atom from propionaldehyde to form a propionyl radical, C_2H_5CO, which is regarded as being the initiation of the oxidation chain (4).

(2) Besides primary process (i) occurring, it is possible that excited states are also formed when propionaldehyde absorbs radiation of wavelength 3130 Å (equation [1*c*]). One or more of these excited states may react with oxygen molecules to form propionyl radicals as indicated in equation [1*f*] where in both [1*c*] and [1*f*] the excited states of propionaldehyde are denoted simply as $C_2H_5CHO^*$:

$$C_2H_5CHO \underset{3130\,Å}{\overset{h\nu}{=}} C_2H_5CHO^*, \qquad [1c]$$

$$C_2H_5CHO^* + O_2 = C_2H_5CO + HO_2. \qquad [1f]$$

The succeeding steps in the mechanism of the photooxidation of propionaldehyde at low temperatures are regarded as being analogous to those shown (Part I) to lead, on the application of the stationary state hypothesis, to a satisfactory explanation of the kinetics of the photochemical oxidation of acetaldehyde:†

$$C_2H_5CO + O_2 = C_2H_5CO_3 \qquad [2]$$

$$C_2H_5CO_3 + C_2H_2CHO = C_2H_5CO_3H + C_2H_5CO \qquad [3]$$

$$2C_2H_5CO = (C_2H_5CO)_2 \qquad [4]$$

$$C_2H_5CO_3 + C_2H_5CO = (C_2H_5CO)_2O_2 \qquad [5]$$

$$2C_2H_5CO_3 = (C_2H_5CO)_2O_2 + O_2 \qquad [6]$$

The application of the stationary state treatment to the above mechanism leads to the equation [A], when it is assumed (see Part I) that $k_3[C_2H_5CHO]/k_2[O_2] \ll 1$, which is likely to be the case in our experiments,

$$d[C_2H_5CO_3H]/dt = (k_3/k_6^{\frac{1}{2}})(\phi_2 I_a)^{\frac{1}{2}}[C_2H_5CHO]. \qquad [A]$$

Equation [A] agrees with the experimentally determined kinetic equation for the photochemical oxidation of propionaldehyde.

It follows from the above results and equation [A] that the over-all activation energy $E = E_3 - \frac{1}{2}E_6$. E_6, which is the activation energy for the mutual interaction of perpropionic radicals, is likely to be zero. Thus the value which we obtained for the over-all activation energy, namely 6.75 ($\pm$0.5) kilocalories mole.$^{-1}$, must equal E_3. There are no reliable values for the reaction analogous to [3] but involving the ethyl radical. Comparison of the value of E_3 for the abstraction of a hydrogen atom from propionaldehyde by

†*From the data given in the following paper (Part III) we calculate* $\phi \simeq 1.6$. *Blacet and Pitts (1) found* $\phi_{C_2H_5I}$ *and* ϕ_{HI} *in their experiments on propionaldehyde–iodine mixtures to be* $\simeq 0.45$. *Since we regard both the* C_2H_5 *and* HCO *radicals as being capable of reacting with oxygen to form a radical which can abstract a hydrogen atom from propionaldehyde to form a propionyl radical it follows that the portion of the quantum yield* ϕ_2 *which arises from the reaction of excited states of propionaldehyde [1f] is approximately* $1.6 - 0.9 = 0.7$.

the perpropionic radical with those found for the corresponding metathetical reactions with methyl (7.5 ± 0.3 kilocalories mole^{-1}) and peracetic (7.16 ± 1.0 kilocalories mole^{-1}) radical shows that it is a realistic value.

THE PHOTOCHEMICAL OXIDATION OF ALDEHYDES IN THE GASEOUS PHASE

PART III. THE ABSOLUTE VALUES OF THE VELOCITY CONSTANTS FOR THE PROPAGATING AND TERMINATING STEPS IN THE PHOTOCHEMICAL OXIDATION OF ACETALDEHYDE AND PROPIONALDEHYDE[1]

C. A. McDowell and L. K. Sharples

ABSTRACT

It has been established (Parts I and II) that the photochemical oxidation of acetaldehyde and propionaldehyde obeys the kinetic expression

$$d[RCO_3H]/dt = (k_3/k_6^{\frac{1}{2}})(\phi_2 I_a)^{\frac{1}{2}}[RCHO],$$

where RCHO represents the aldehyde and RCO_3H the corresponding peracid. k_3 is the velocity constant for the propagating reaction, and k_6 that for the terminating reaction involving the mutual interaction of two RCO_3 radicals. $\phi_2 I_a$ represents the rate of initiation of the photooxidation.

Alcohols have been found to retard the photooxidation and it has been shown that the retarded reaction obeys the kinetic expression:

$$d[RCO_3H]/dt = R_i\{1+k_3[RCHO]/k_7[ROH]\}.$$

It has thus been possible to determine the rates of initiation $R_i = \phi_2 I_a$ for each of the photooxidations. Application of the rotating sector technique has enabled the lifetime of the oxidation chains to be measured. These data together with the information given in Parts I and II have been used to calculate the absolute values for the velocity constants for the propagating and terminating reactions, k_3 and k_6:

$$RCO_3 + RCHO \overset{k_3}{=} RCO_3H + RCO, \qquad [3]$$

$$2RCO_3 \overset{k_6}{=} (RCO)_2O_2 + O_2, \qquad [6]$$

in the gas-phase photooxidations of acetaldehyde and propionaldehyde.

The values of the respective velocity constants are: acetaldehyde at 20°, $k_3 = 8.05(\pm 2.04) \times 10^3$ l. mole^{-1} sec.$^{-1}$, $k_6 = 8.93(\pm 4.20) \times 10^{10}$ l. mole^{-1} sec.$^{-1}$; propionaldehyde at 22°, $k_3 = 4.35(\pm 0.9) \times 10^4$ l. mole^{-1} sec.$^{-1}$, $k_6 = 2.69(\pm 1.35) \times 10^{10}$ l. mole^{-1} sec.$^{-1}$. These values for the velocity constants for the "recombination" reactions of the peracetic and perpropionic radicals indicate that for these radicals reaction [6] is very efficient.

INTRODUCTION

The study of the combustion of hydrocarbons and related compounds has now reached a point where the main features of the over-all kinetics are apparent. It remains, however, to discover the details of the mechanisms of many of the radical reactions which control the over-all processes. It is also desirable to determine the absolute values for the velocity constants for the various radical reactions known to proceed during combustion processes.

The determination of the absolute values of the velocity constants for many radical reactions in oxidation processes has been retarded because of the need to develop sufficiently accurate experimental methods. This has been especially the case for gaseous-phase reactions. In the case of the liquid-phase oxidation of aldehydes (5), olefins (2), and some other compounds (11), it has been possible to apply photochemical techniques to determine the absolute values for the velocity constants for the propagating and terminating steps in the oxidation chains.

[1]*Manuscript received July 22, 1957.*
Contribution from the Department of Inorganic and Physical Chemistry, University of Liverpool, Liverpool 7, England, and the Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada.

In the preceding papers, Parts I and II, we have elucidated the mechanisms of the photochemical oxidations of acetaldehyde and propionaldehyde. Both of these oxidation reactions have been shown to obey the kinetic expression:

$$d[RCO_3H]/dt = (k_3/k_6^{\frac{1}{2}})(\phi_2 I_a)^{\frac{1}{2}}[RCHO], \qquad [A]$$

in which RCO_3H represents the peracid which is the main product of the oxidation, k_3 is the velocity constant for the propagating reaction [3]:

$$RCO_3 + RCHO \overset{k_3}{=} RCO_3H + RCO, \qquad [3]$$

k_6 is the velocity constant for the interaction of two RCO_3 radicals in the terminating reaction [6]:

$$2RCO_3 \overset{k_6}{=} (RCO)_2O_2 + O_2, \qquad [6]$$

and $\phi_2 I_a = R_i$ is the rate of initiation of the photochemical oxidation at 3130 Å, the wavelength of the radiation used. Equation [A] is of the same general form as that found to be obeyed by the liquid-phase oxidation of aldehydes (5) and olefins (2), and so the application of the rotating sector technique in the present cases should enable us to determine the absolute value of the velocity constants for the reactions [3] and [6].

EXPERIMENTAL

The acetaldehyde and propionaldehyde were purified as described in Parts I and II. The alcohols were carefully purified by repeated distillations.

The photochemical apparatus was essentially the same as that employed previously. Two different sectors were used. One had two apertures of $\pi/2$ and the other had two of $\pi/4$. The former was used for the experiments with acetaldehyde and the latter in those with propionaldehyde. The light beam was focused at the sector plane so that at the point of interruption the time taken by the edge of the sector to scan the beam was less than 1/30th of the light period. Oscillographic studies showed that the light pulse was quite square. At low speeds the rotation of the sector was timed using a stop watch. An accurate gear enabled the intermediate speeds to be measured. High rotational speeds were measured accurately on a cathode ray oscillograph.

RESULTS

In a chain reaction obeying the kinetic expression [A] in which steady state conditions are quickly established (see Part I), the velocity constant for the termination step, k_6, is given by the equation

$$k_6 = 1/\tau^2 R_i, \qquad [B]$$

where R_i is the rate of initiation and τ is the lifetime of the kinetic chain. This quantity τ may in the case of the oxidation of acetaldehyde be expressed as:

$$\tau = \frac{\text{concentration of peracetic radicals}}{\text{rate of removal of peracetic radicals}}$$

with a similar expression for the lifetime of the kinetic chain in the oxidation of propionaldehyde. Thus it is seen that if R_i and τ can be determined, then the absolute value of the velocity constant, k_6, can be calculated from equation [B]. The ratio $k_3/k_6^{\frac{1}{2}}$ is readily obtainable from equation [A] once the rate of initiation $\phi_2 I_a$ is known; hence once k_6 has been determined, k_3, the absolute value of the velocity constant for the propagating step in the oxidation chain, may also be calculated.

Determination of the Rate of Initiation $R_i = \phi_2 I_a$

It is known that the oxidation of aldehydes is retarded by alcohols (3, 7) and the mechanism of this process is fairly well established. It is thought that when an alcohol, ROH, is added to a mixture of aldehyde and oxygen the ensuing retarding effect is caused by the reaction:

$$RCO_3 + ROH = RCO_3H + R'OH. \qquad [7]$$

The radical R'OH may react with a similar radical by addition or disproportionation reactions to form stable products faster than it can abstract a hydrogen atom from an aldehyde molecule. Thus the chain length of the oxidation is shortened and the reaction is retarded.

The mechanism for the retarded photochemical oxidation of acetaldehyde and propionaldehyde would then be written as:

$$RCHO \underset{3130\ Å}{\overset{h\nu}{=}} R + CHO$$

$$RCHO \underset{3130\ Å}{\overset{h\nu}{=}} RCHO^*$$

$$\left.\begin{matrix} R \\ CHO \end{matrix}\right\} + O_2 = R$$

$$\left.\begin{matrix} R + RCHO = RH + RCO \\ RCHO^* + O_2 = HO_2 + RCO \end{matrix}\right\} \phi_2 I_a$$

$$RCO + O_2 = RCO_3 \qquad [2]$$

$$RCO_3 + RCHO = RCO_3H + RCO \qquad [3]$$

$$RCO_3 + ROH = RCO_3H + R'OH \qquad [7]$$

$$2RCO_3 = (RCO)_2O_2 + O_2 \qquad [6]$$

When stationary state kinetics are applied to this mechanism the following expression results if it is assumed that $k_7[ROH][RCO_3] > k_6[RCO_3]^2$:

$$d[RCO_3H]/dt = R_i\{1+k_3[RCHO]/k_7[ROH]\}. \qquad [C]$$

In equation [C] we have written $R_i = \phi_2 I_a$. This expression implies that if the alcohol-retarded oxidation obeys the mechanism given, the rate of the retarded reaction at a constant concentration of alcohol should be directly proportional to the intensity of illumination. Furthermore, at a constant intensity of illumination the rate of the retarded oxidation is required to be directly proportional to the reciprocal of the concentration of the retarding alcohol. Thus a graph of the rate of the retarded reaction against $[ROH]^{-1}$ should be a straight line with slope $k_3[RCHO]/k_7$ and an intercept equal to the rate of initiation $\phi_2 I_a$.

Dependence of Rate of Retarded Reaction on Intensity

In Table I are given the results of experiments carried out at 20° C. on a mixture of 150 mm. Hg pressure of acetaldehyde, 5 mm. Hg pressure of oxygen, a constant concentration of ethanol (30 mm. Hg pressure), and varying intensity of illumination.

These data have been plotted in Fig. 1 and it is seen that the required dependence of the rate of retarded reaction on the intensity of illumination is found, thus substantiating the above mechanism for the retarded reaction.

Dependence of Rate of Reaction on Concentration of Retarder

In Table II are given the results of experiments carried out at 20° C. with a mixture of 150 mm. Hg pressure of acetaldehyde, 5 mm. Hg of oxygen, a constant intensity of

illumination, and varying concentrations of ethanol. These data are shown graphically in Fig. 2, where the rate of the ethanol-retarded reaction is plotted against the reciprocal of the concentration of the ethanol. The linear relation at higher alcohol concentrations confirms the deductions from equation [C]. The intercept of the straight line in Fig. 2 on the rate axis gives the rate of initiation at the intensity used in these experiments as 1.12×10^{-9} mole $l.^{-1}$ $sec.^{-1}$.

Experiments were carried out to see if equation [C] was also obeyed by the alcohol-retarded photochemical oxidation of propionaldehyde. In Table III are given the results

TABLE III

DEPENDENCE OF RATE OF ETHANOL AND ISOPROPANOL RETARDED OXIDATION OF PROPIONALDEHYDE ON CONCENTRATION OF ALCOHOL

All data refer to mixtures containing 100 mm. Hg pressure of propionaldehyde, 3 mm. Hg of oxygen at 22° C., and a value of I_a of 1.12×10^{-9} einstein $l.^{-1}$ $sec.^{-1}$

Run No.	Alcohol	Alcohol pressure, mm.	Rate, mole $l.^{-1}$ $sec.^{-1}$ $\times10^9$

of experiments carried out at 22° C. with a mixture of 100 mm. Hg pressure of propionaldehyde, 3 mm. Hg of oxygen, and varying concentrations of ethanol and isopropanol. These experiments were all performed with a light absorption of 1.12×10^{-9} einstein $l.^{-1}$ $sec.^{-1}$. The data in Table III are plotted in Fig. 3, where the rate of the alcohol-retarded reaction is again plotted against the reciprocal of the concentration of the alcohol. It is evident from the straight lines obtained that equation [C] is obeyed by the reaction. Further, it is obvious that isopropanol is a much more efficient retarder than is ethanol.

To obtain an accurate value for the rate of initiation in the case of the oxidation of propionaldehyde a series of experiments were carried out at a somewhat higher value of I_a. These results are recorded in Table IV. The data there refer to a mixture of 100 mm. Hg of propionaldehyde and 3 mm. Hg of oxygen at 22° C. The value of I_a was 1.16×10^{-8} einstein $l.^{-1}$ $sec.^{-1}$. The data are plotted in Fig. 4. The intercept of the straight line in Fig. 4 was calculated by the method of least squares using weighted means to be 1.98×10^{-8} mole $l.^{-1}$ $sec.^{-1}$, which is of course the value of the rate of initiation $\phi_2 I_a$. This value is probably correct to $\pm10\%$.

The results quoted in the above paragraphs leave little doubt that the mechanisms proposed for the alcohol-retarded photooxidation of acetaldehyde and propionaldehyde are correct. This in turn is evidence in favor of the correctness of the proposed mechanisms for the over-all photooxidations of acetaldehyde and propionaldehyde.

Measurement of the Chain Lifetimes

To measure the lifetimes of the chains in the photooxidation of acetaldehyde and propionaldehyde the usual (6) photochemical sector technique was employed. It was

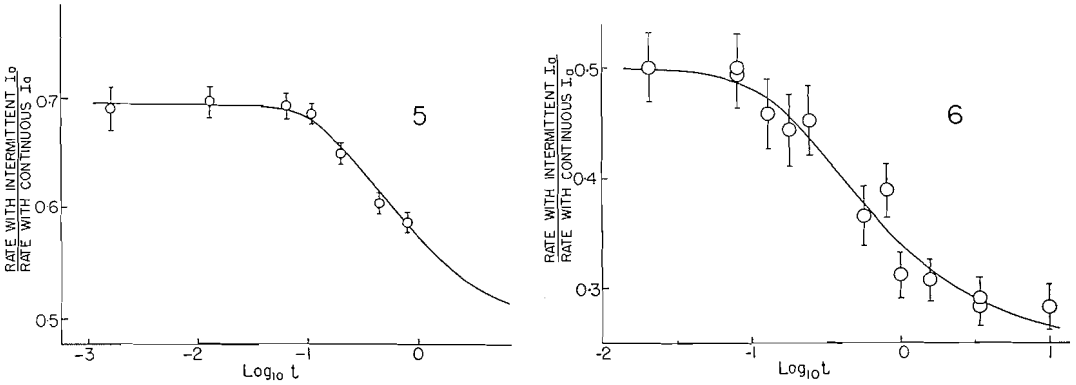

FIG. 5. Rotating sector experiment in the photochemical oxidation of acetaldehyde. Determination of the lifetime of the oxidation chain.

FIG. 6. Rotating sector experiments in the photochemical oxidation of propionaldehyde. Determination of the lifetime of the oxidation chain.

ments before and after the "intermittent" rate experiment. These data are given in Table V for the acetaldehyde oxidation, and in Table VI for the propionaldehyde.

Following the usual procedure a graph of $\log_{10}t$ against γ was plotted. Fig. 5 refers to the case of the acetaldehyde oxidation and Fig. 6 to the oxidation of propionaldehyde. In the former case a $\pi/2$ sector was used so the values of γ range from 0.5 to 0.7. In the case of the propionaldehyde oxidation a $\pi/4$ sector was used and here γ varies from 0.25 to 0.5.

Using the relevant mathematical equations given by Dickinson (6), a theoretical curve of γ against $\log_{10}b$, where $b = t/\tau$, was fitted to the experimental points. It was then possible to determine τ in each case. For the photochemical oxidation of acetaldehyde at 20° C. the data in Fig. 5 give the lifetime of the chain, τ, as 0.10 second. The data in Fig. 6 give a value of 0.14 second for the lifetime of the chain, τ, in the photochemical oxidation of propionaldehyde. These values could be in error by ± 0.05 second.

ABSOLUTE VALUES FOR THE VELOCITY CONSTANTS k_3 AND k_6 IN THE PHOTOCHEMICAL OXIDATION OF ACETALDEHYDE AND PROPIONALDEHYDE

Acetaldehyde

Using the above experimentally determined values for $R_i = \phi_2 I_a$, and τ, it is possible to calculate the absolute value of the velocity constant for the terminating reaction [6], i.e. k_6, from equations [A] and [B]. The values of 1.12×10^{-9} mole l.$^{-1}$ sec.$^{-1}$ for the rate of initiation ($= \phi_2 I_a$) and 0.10 second for τ obtained from the experiments with acetaldehyde lead to the following values for k_3 and k_6 at 20° C. in the photochemical oxidation of acetaldehyde:

$$k_3 = 8.05(\pm 2.40)\times10^3 \text{ l. mole}^{-1} \text{ sec.}^{-1},$$

$$k_6 = 8.93(\pm 4.20)\times10^{10} \text{ l. mole}^{-1} \text{ sec.}^{-1}.$$

Propionaldehyde

Our experiments lead to the values of 1.90×10^{-9} mole l.$^{-1}$ sec.$^{-1}$ for the rate of initiation ($= \phi_2 I_a$) at the light intensity of 1.12×10^{-9} einstein l.$^{-1}$ sec.$^{-1}$ used in the sector experiments, and 0.14 second for τ for the photochemical oxidation of propionaldehyde.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

The substitution of these data in equations [A] and [B] leads to the following values for k_3 and k_6 at 22° C. for this reaction:

$$k_3 = 4.35(\pm 0.91)\times 10^4 \text{ l. mole}^{-1} \text{ sec.}^{-1},$$

$$k_6 = 2.69(\pm 1.35)\times 10^{10} \text{ l. mole}^{-1} \text{ sec.}^{-1}.$$

DISCUSSION

It is of considerable interest to compare these values for the velocity constants for the propagating (k_3) and terminating (k_6) steps involving peroxidic radicals derived from acetaldehyde and propionaldehyde with those for other radicals. It seems appropriate to compare the value for the velocity constant for the propagating step in the photochemical oxidation of acetaldehyde, i.e. equation [3]:

$$CH_3CO_3 + CH_3CHO \overset{k_3}{=} CH_3CO_3H + CH_3CO, \qquad [3]$$

for which we obtained the value of 8.05 $(\pm 2.40)\times 10^3$ l. mole^{-1} sec.$^{-1}$ at 20° C., with the velocity constant for the reaction [8] of the methyl radical:

$$CH_3 + CH_3CHO \overset{k_8}{=} CH_4 + CH_3CO. \qquad [8]$$

From Volman and Brinton's experiments (14) we calculate the value of 2.7×10^3 l. mole^{-1} sec.$^{-1}$ for k_3 in reaction [8] at 20° C. These data indicate that at equal concentration reaction [3] is more rapid. This must be attributed to the higher reactivity of the peracetic radical over the methyl radical. The absolute values for the velocity constant for the terminating reactions, k_6, in the photooxidation of acetaldehyde and propionaldehyde, namely $8.93(\pm 4.2)\times 10^{10}$ l. mole^{-1} sec.$^{-1}$ at 20° (acetaldehyde) and $2.89(\pm 1.35)\times 10^{10}$ l. mole^{-1} sec.$^{-1}$ at 22° C. (propionaldehyde), may be compared with the values of 2.2×10^{10} l. mole^{-1} sec.$^{-1}$ for the recombination of methyl radicals (12), and about 2.0×10^{10} l. mole^{-1} sec.$^{-1}$ (9, 4, 13) for the recombination of ethyl radicals (at 20° C.). These data indicate that the peracetic radicals "recombine" (see below) more rapidly than do methyl or ethyl radicals, and that perpropionic radicals "recombine" at about the same rate as do the hydrocarbon radicals.

It is instructive to compare the collision efficiencies for the mutual interaction of the methyl, ethyl, peracetic, and perpropionic radicals. To do this it is necessary to have the absolute values for the velocity constants for the recombination reactions and also to know the collision numbers of the radicals. It is further necessary to know if the recombination reactions require any activation energy. In nearly all the investigations of the recombination of methyl (10), trifluoromethyl (1), and ethyl radicals (4, 9, 13) there has been but little reliable evidence to show whether or not these reactions do require an activation energy. In the study of the recombination of methyl radicals by mass spectrometry (8) it has been claimed that there is a net activation energy of -1.5 kilocalories mole^{-1} and this was attributed to a third-body effect. Shepp and Kutschke (13) have recently claimed that their studies on the recombination of ethyl radicals indicate an activation energy for this process of 2.0 ± 1 kilocalories mole^{-1}. Such small activation energies as these are difficult to establish unambiguously and as the assumption that the recombination reactions require but little or zero activation energy introduces little error into our discussion, we shall therefore adopt this commonly-made assumption.

For personal use only.

Using Shepp's (12) recalculated value for the velocity constant for the recombination of methyl radicals and the value of 3.5 Å for the collision diameter one obtained a value of about 0.3 for the collision efficiency at 125° C. In the case of trifluoromethyl radicals Ayscough (1) used a collision diameter of 4 Å and calculated a value of 0.16 for the collision efficiency of these radicals at 127° C. These values are comparable with those of 0.12 for the collision efficiency of the recombination of two ethyl radicals found by Shepp and Kutschke (13), and 0.15 for the same process obtained by Bradley, Melville, and Robb (4). We have used a value of 5.4 Å for the collision diameters of both the peracetic and perpropionic radicals—this value seemed to be the most reasonable one as judged from Courtauld models of the radicals. This leads to a collision efficiency for the mutual interaction of the peracetic radicals of 0.8 and a value of 0.29 for the collision efficiency for the mutual interaction of two perpropionic radicals. These values suggest that the mutual interactions of these peroxidic radicals are somewhat more efficient than those of comparable hydrocarbon radicals.

Chemistry of the Recombination Reaction of Peroxide Radicals

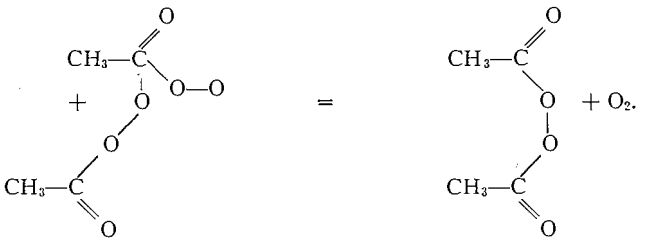
The data described in the above paragraphs show that the "recombination" reactions of peracetic and perpropionic radicals are relatively efficient. It will be recalled that the recombination or terminating step in the photooxidations is the process:

$$2RCO_3 = (RCO)_2O_2 + O_2. \qquad [6]$$

It is not easy to see why this process should be so very efficient, for it is evident from our data that one in every two collisions is effective in the case of the peracetic radical and one in every three or four is effective in the case of the perpropionic radicals. One might have thought that a rather special orientation would have been necessary before two radicals with structures like the peracetic or the perpropionic ones could have reacted.

The chemistry of process [6] is not clear. It could be that when the two peroxide radicals interact the oxygen molecule which is formed is produced by the elimination of an oxygen atom from each of the interacting radicals. This would probably be a rather complicated process and entropy considerations make us believe that it is not the mechanism of process [6].

A more likely mechanism is that the oxygen molecule which is eliminated comes wholly from one of the interacting radicals. This could be understood if the mechanism were as shown below:



Here it is assumed that the peroxide oxygen atoms of one radical attack the second radical at the acyl carbon atom causing the attacked radical to lose two oxygen atoms to form an oxygen molecule. It is thought that the use of isotopically enriched oxygen may enable the chemistry of this process to be elucidated and we are planning to carry out such experiments.

ULTRAVIOLET IRRADIATION OF PYRIMIDINE DERIVATIVES
II. NOTE ON THE SYNTHESIS OF THE PRODUCT OF REVERSIBLE PHOTOLYSIS OF URACIL*

A. M. MOORE

Solutions of uracil, when irradiated with ultraviolet light (2537 Å), undergo photolysis to yield a product that lacks the absorption band (max. 2590 Å) typical of uracil but which regenerates uracil on treatment with acid (4). Several derivatives of uracil, such as uridine, uridylic acid (4, 5), and 1,3-dimethyluracil (2), exhibit a similar "reversible" photolysis.

Using 1,3-dimethyluracil as a model, Moore and Thomson (3) showed that the product of irradiation is 1,3-dimethyl-6-hydroxy-hydrouracil, resulting from the addition of a molecule of water to the 5,6 double bond. This compound has also been synthesized by reduction of 5,5-dibromo-1,3-dimethyl-6-hydroxy-hydrouracil (3) and of the 5-monobromo compound (6).

The analogous derivative of uracil has now been synthesized and compared with the "reversible" product of ultraviolet irradiation of uracil.

5,5-Dibromo-6-hydroxy-hydrouracil (I) (m.p. 136°) synthesized by the method of Wheeler and Johnson (7) was reduced with zinc dust and acetic acid (pH 4–5) using the same technique as that used for the reduction of 1,3-dimethyl-5,5-dibromo-6-hydroxy-hydrouracil (3). The product of reduction was then compared chromatographically and spectroscopically with the product of irradiation of uracil. Although the latter has not been isolated in the pure state it can readily be separated on paper chromatograms, the position of the "reversible" product on the developed chromatogram being found by exposing a test strip to HCl vapor to promote conversion of the product to uracil, which is then easily located by the ultraviolet print method of Markham and Smith (1) (Fig. 1).

Accordingly, the product of reduction was chromatographed on paper in parallel with the product of irradiation using four different solvent systems. The observed R_f values are given in Table I.

In Fig. 2 are plotted the respective relative changes in optical density that occurred when a photolyzed solution of uracil and the product of reduction of the dibromo com-

AN ALTERNATIVE SYNTHESIS OF 2-*O*-METHYL-D-XYLOSE

W. D. S. BOWERING AND T. E. TIMELL

In studying the structure of a xylan the need arose for 2-*O*- and 3-*O*-methyl-D-xylose as reference compounds. The latter was synthesized from 1,2-*O*-isopropylidene-D-xylofuranose (1) and it was preferable to prepare the former from the same starting material if possible. Such a procedure would also obviate the necessity of using the acid-labile methyl 3,5-*O*-isopropylidene-α,β-D-xylofuranoside as described in a previous synthesis of 2-*O*-methyl-D-xylose (2).

1,2-*O*-Isopropylidene-D-xylofuranose was benzylated to give the corresponding 3,5-di-*O*-benzyl derivative, which was converted to methyl 3,5-di-*O*-benzyl-α,β-D-xylofuranoside by methanolysis. Methylation (3) of this compound yielded the 2-*O*-methyl derivative, which was then reductively debenzylated to methyl 2-*O*-methyl-α,β-D-xylofuranoside. Hydrolysis of this compound gave crystalline 2-*O*-methyl-D-xylose.

EXPERIMENTAL

*3,5-Di-O-benzyl-1,2-O-isopropylidene-*D*-xylofuranose*

1,2-*O*-Isopropylidene-D-xylofuranose, $[\alpha]_D^{21}$ −19.2° (*c*, 2.1 in water), (46.4 g.) (1) was treated with benzyl chloride (230 ml.) and powdered potassium hydroxide (57 g.) at 100° C. for 5 hours. The solution was poured into water and the sirupy material obtained on concentration was extracted with boiling ethanol. Evaporation yielded a sirup (103.2 g.) which could not be induced to crystallize, $[\alpha]_D^{22}$ +9.2° (*c*, 2.5 in ethanol). Anal.: Calc. for $C_{22}H_{26}O_5$: C, 71.3%; H, 7.1%. Found: C, 72.3%; H, 7.5%.

*Methyl 3,5-Di-O-benzyl-α,β-*D*-xylofuranoside*

A portion of the above sirup (40.0 g.) was boiled under reflux with anhydrous methanol (200 ml.) containing 1.5% hydrogen chloride. Neutralization (silver carbonate) and evaporation yielded a sirup, $[\alpha]_D^{22}$ +17.6° (*c*, 5.3 in ethanol), (37.5 g., 100.8%). Anal.: Calc. for $C_{20}H_{24}O_5$: OCH_3, 9.0%. Found: OCH_3, 8.8%.

*Methyl 3,5-Di-O-benzyl-2-O-methyl-α,β-*D*-xylofuranoside*

The above sirupy compound (37.0 g.) was dissolved in a mixture of dimethyl formamide (54 ml.) and methyl iodide (20.4 ml.). Silver oxide (20.4 g.) was added in small portions over a period of 1 hour and the mixture was shaken for 24 hours. The methylated material was recovered (3) to yield a sirup, $[\alpha]_D^{22}$ +23.7° (*c*, 3.2 in ethanol), (33.3 g., 86.5%). Anal.: Calc. for $C_{21}H_{26}O_5$: C, 70.4%; H, 7.3%; OCH_3, 17.3%. Found: C, 71.5%; H, 8.1%; OCH_3, 17.6%. An infrared spectrum of the material indicated the presence of only a trace of hydroxyl groups.

*Methyl 2-O-Methyl-α,β-*D*-xylofuranoside*

The above sirup (33.0 g.) was reductively debenzylated (4). The aqueous solution obtained was passed through a column of Amberlite IRC 50 exchange resin and the eluate was concentrated and extracted with ethanol to yield a sirup, $[\alpha]_D^{22}$ +35.4° (*c*, 2.9 in ethanol), (22.1 g.).

*2-O-Methyl-*D*-xylose*

The above material (22.0 g.) was hydrolyzed with 0.5 *N* sulphuric acid (150 ml.) by boiling under reflux for 14 hours. After neutralization with barium hydroxide and filtration through Celite, concentration of the filtrate gave a sirup (7.5 g.). Examination by paper chromatography using a system of methyl ethyl ketone – ethanol – water (20:5:2) indicated the presence of 2-*O*-methyl-D-xylose and a trace of xylose.

The crude material was added to the top of a column containing cocoanut charcoal and was eluted with 2% ethanol until the eluate gave a negative Molisch test. Evaporation yielded a white, crystalline compound, which was recrystallized from ethanol, m.p. 132–133° C. (corrected), $[\alpha]_D^{21}$ +35.1° (*c*, 3.5 in water), (3.1 g., 15.3%). Anal.: Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 18.9%.

THE INFRARED AND RAMAN SPECTRUM OF DIMETHOXYMETHANE

J. K. WILMSHURST*

Infrared spectra of solutions of dimethoxymethane ($CH_3OCH_2OCH_3$) in CCl_4 and CS_2 have been obtained over the 3–7 μ and 7–33 μ regions respectively (Fig. 1) using a Perkin-Elmer model 112S double pass spectrometer equipped with LiF, CaF_2, NaCl, and CsBr optics. The infrared spectrum of the vapor has also been obtained around 3 μ and from 6.5 to 33 μ (Fig. 2). Although the Raman spectrum of the liquid had been recorded previously (4) a better resolved spectrum was obtained here (Fig. 3) using a White grating Raman spectrometer (7) with photoelectric recording.† Depolarization

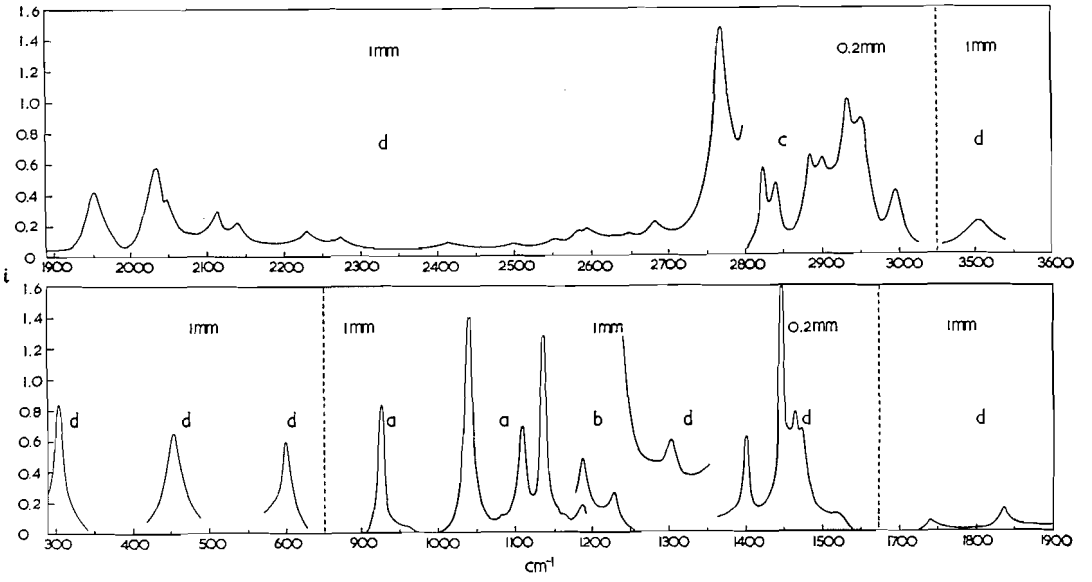

FIG. 1. The infrared spectrum of a solution of dimethoxymethane in CCl_4 (3600–1400 cm.$^{-1}$) and in CS_2 (1400–300 cm.$^{-1}$). The cell length is as shown and the concentrations (in volume) are a = 1:400, b = 1:150, c = 1:25, d = 2:25.

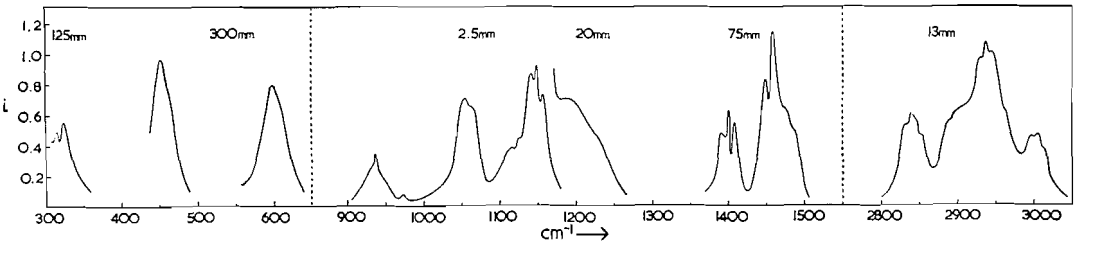

FIG. 2. The infrared spectrum of dimethoxymethane vapor in a 10-cm. cell at the pressure shown.

ratios were measured by the method of Edsall and Wilson (2) and corrected for convergence error by the method of Rank and Kagarise (6).

From dipole moment studies (5) it has been concluded that the molecule has point symmetry C_2, the two O—CH_3 bonds making angles of ~60° with the OCO plane. Electron diffraction data (1) support this model. Thus, of the 33 fundamental vibrations, 17 should be symmetric (type *a*) and 16 antisymmetric (type *b*) with respect to rotation about the symmetry axis. Calculation of the moments of inertia of the molecule* shows that it is an approximate symmetric top, the Gerhard and Dennison (3) parameter being $\beta = 2.17$. Thus, two types of bands are expected: perpendicular-type bands having a prominent *Q* branch with weaker unresolved *P* and *R* branches, and parallel-type bands having three nearly equal maxima with *PR* separation of ~17 cm.$^{-1}$. The vapor band contours observed (Fig. 2) can be seen to be essentially consistent with this, the average *PR* separation of the parallel bands being 16 cm.$^{-1}$, in agreement with the previously proposed configuration (5) for the molecule.

The type *a* modes should give rise to polarized bands in the Raman and perpendicular-type bands in the infrared, while the type *b* modes should give rise to depolarized Raman bands and either parallel or perpendicular type bands in the infrared, depending on whether the change of dipole moment is parallel to the minor axis, 0*x*, or to the major axis, 0*y* (Fig. 4). Since the two methyl groups are sufficiently far apart, the internal vibrations of one group should be independent of those of the other and, thus, the six *a*-type internal modes should have the same frequency as the corresponding six *b*-type modes. With this in mind the vibrational assignment is fairly straightforward.

**The moments of inertia were calculated (assuming* $r_{CO} = 1.44$ *Å,* $r_{CH} = 1.09$ *Å,* $\angle COC = 104°$*, and all other angles tetrahedral) to be:* $I_x = 75.6$*,* $I_y = 245.2$*, and* $I_z = 230.5 \times 10^{-40}$ *g. cm.*^{2}*, where z is the symmetry axis of the molecule and x and y axes are as shown in Fig. 4.*

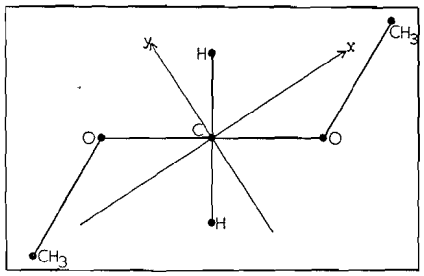

FIG. 4. Projection of the dimethoxymethane molecule on a plane perpendicular to the symmetry axis.

The polarized bands at 2996 and 2935 cm.$^{-1}$, having corresponding parallel-type infrared bands, are taken as the superimposed *a*- and *b*-type asymmetrical and symmetrical methyl stretchings respectively. The polarized band at 2956 cm.$^{-1}$ is taken as the remaining superimposed *a*- and *b*-type asymmetrical methyl stretching mode. Of the pair of intense polarized bands at 2826 and 2841 cm.$^{-1}$, the former is assigned to the symmetrical CH_2 stretching mode while the latter is assigned as 2×1436 cm.$^{-1}$, the high intensity arising from Fermi resonance with the fundamental. The asymmetrical CH_2 stretching mode is not obvious but is assigned to the infrared band at 2997 cm.$^{-1}$ coincident with the *a*- and *b*-type methyl asymmetric stretching mode.

The infrared bands at 1473 and 1465 cm.$^{-1}$ are assigned to the two superimposed *a*- and *b*-type asymmetrical methyl bending modes, while the parallel-type band at 1458 cm.$^{-1}$ is taken as the superimposed *a*- and *b*-type symmetrical methyl bending mode. The polarized band at $\sim$1436 cm.$^{-1}$ is taken as the symmetrical methylene deformation mode while the parallel-type infrared, depolarized Raman band at 1400 cm.$^{-1}$ is assigned to the methylene wagging mode. The Raman band at 1310 cm.$^{-1}$, though depolarized, is assigned to the methylene twisting vibration. From electronegativity considerations (8), the four methyl rocking modes would be expected to occur around 1150–1240 cm.$^{-1}$ and the four infrared bands observed in this region are assigned accordingly.

The intense parallel-type infrared band at 1148 cm.$^{-1}$ is assigned to the OCO asymmetric stretching mode, and the perpendicular-type infrared band at 937 cm.$^{-1}$ corresponding to a medium intensity polarized Raman band to the symmetric OCO stretching mode. The strong polarized Raman band at 912 cm.$^{-1}$, having no infrared counterpart, is taken as the symmetric CH_3—O stretching mode. From the geometry of the molecule, this latter vibration can be seen to give rise to only a small change in dipole moment and, hence, only a weak infrared band would be expected, in contrast to the stronger infrared band expected from the OCO symmetrical stretching mode at 937 cm.$^{-1}$. Of the two strong infrared bands at 1110 and 1042 cm.$^{-1}$, the former, though it appears to have a possible parallel-type band contour, is taken as the methylene rocking mode from electronegativity considerations (9), while the latter has a hybrid-type contour and is taken as the asymmetrical O—CH_3 stretching mode. The smaller difference in frequency between the two OCH_3 stretching vibrations, as compared with the difference between the two OCO stretching modes, is consistent with the expected smaller coupling constant between the two OCH_3 bonds.

The polarized band at 325 cm.$^{-1}$ is assigned to the type *a* COC bending mode, and the depolarized band at 602 cm.$^{-1}$, corresponding to a perpendicular-type infrared band, to the type *b* COC bending mode. The perpendicular-type band at 454 cm.$^{-1}$ is taken as the type *a* OCO bending mode. The four torsional vibrations would be expected to have low frequencies (<300 cm.$^{-1}$) and were not observed.

DETERMINATION OF SULPHATE ACID ESTER IN UNSTABILIZED CELLULOSE NITRATE BY THE HYDROLYSIS METHOD[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] AND BRIAN T. NEWBOLD[3]

ABSTRACT

The method of determining sulphate acid ester in unstabilized cellulose nitrates by hydrolysis in acetone/water solution was evaluated. The precision of duplicate determinations for cotton and wood cellulose nitrates containing about 100% sulphate ester was −0.1 to +5.9% and +0.4 to +9.2%, respectively. With cellulose nitrates containing 69–43% and 69–47% sulphate ester, it was +1.8 to +13.4% and +0.4 to +21.0%. The sulphate acid ester content of both unstabilized cotton and wood cellulose nitrates increased with decreasing nitrogen content.

INTRODUCTION

The sulphate acid ester content of cellulose acetate sulphate was estimated by ion exchange methods (5) and more recently by titration in acetone/water solution before and after hydrolysis (2). In a previous paper (3), methods were described for the determination of the sulphate ester content of unstabilized cellulose nitrates.

One of the objects of the present work was to evaluate the hydrolysis method of determining the sulphate acid ester content of unstabilized cotton and wood cellulose nitrates with a view to establishing the reproducibility of the results. The other aim was to determine the relation between the sulphate acid ester content and the nitrogen content of cotton and wood cellulose nitrates.

EXPERIMENTAL

Cellulose Nitrate

The nitrations of cotton linters and wood cellulose were performed according to the method mentioned in a recent paper (4) and the sulphate and nitrogen contents were determined by procedures previously described (3, 5).

Hydrolysis of Sulphate Ester Groups in Unstabilized Cellulose Nitrate

The sulphate acid ester content of cellulose nitrate was determined by the method given in a recent paper (3), except that in the present work the seventh aliquot removed for titration with 0.01 *N* potassium hydroxide was 50 ml. instead of 100 ml.

Zero Hydrolysis of Sulphate Ester Groups in Unstabilized Cellulose Nitrate

A moist sample (3–4 g.) of the cellulose nitrate was dissolved in 90% acetone/water solution (700 ml.) to prevent hydrolysis and the acidity was determined on aliquots (100 ml.) by titration with 0.01 *N* potassium hydroxide using a Macbeth pH meter.

Evaluation of the pH Meter Titration Method of Determining Acidity

In a series of experiments, various quantities (5–50 ml.) of 0.1 *N* sulphuric acid were added to 700 ml. samples of acetone/water solution and the acidity was determined on 100 ml. aliquots by titration with 0.01 *N* potassium hydroxide and was measured on a Macbeth pH meter. The average of four determinations on each acetone/water/sulphuric acid aliquot was compared to the theoretical acidity. The mean difference from the theoretical value was −4.5%. The standard deviation was 2.8 and the 95% confidence limits were −4.5% ±6.3, as calculated by the Dean and Dixon method (1).

Determination of Sulphate Ester in Cellulose Nitrates Prepared by Duplicate Nitrations

The sulphate acid ester contents of unstabilized cotton and wood cellulose nitrates prepared by duplicate nitrations were determined using the hydrolysis method.

The precision of the ester determinations for cotton cellulose nitrate containing about 100% ester was expressed as follows: the mean difference was 11.0%, the standard deviation 6.0, and the 95% confidence limits were 11.0% ±8.8. For wood cellulose nitrate containing about 100% sulphate ester, the mean difference was 8.0%, the standard deviation 8.7, and the 95% confidence limits were 8.0% ±12.8.

RESULTS AND DISCUSSION

Evaluation of the Hydrolysis Method of Determining Sulphate Acid Ester

In the present work the sulphate acid ester, RSO_4H, contents of a wide range of cotton and wood cellulose nitrates (containing about 7 to 13% nitrogen) were determined by titration in acetone/water solution before and after hydrolysis. Determination of the ester by this method depends on the supposition that hydrolysis of the ester is completed after 24 hours and therefore the 24-hour titer value should give the total sulphate content of the cellulose nitrate. The gravimetric and 24-hour titrimetric sulphates of a series of cotton and wood unstabilized cellulose nitrates are compared in Table I.

TABLE I

COMPARISON OF GRAVIMETRIC AND TITRIMETRIC SULPHATE PERCENTAGES IN CELLULOSE NITRATES

Expt. No.	% H_2SO_4 in cellulose nitrates			
	Cotton		Wood	
	Gravimetric	Titrimetric	Gravimetric	Titrimetric
1	2.38	2.28	2.36	2.41
2	2.26	2.02	2.17	2.15
3	1.54	1.54	2.13	2.18
4	1.23	1.22	2.12	1.95
5	1.13	1.00	2.02	1.96
6	1.00	0.93	2.01	1.90
7	0.95	0.94	1.34	1.26
8	0.95	0.88	1.33	1.36
9	0.89	0.98	1.30	1.32
10	0.85	0.89	1.23	1.26
11	0.69	0.75	1.04	1.05
12	0.63	0.70	0.93	1.01
13	0.47	0.52	0.91	0.92

There is good agreement between the gravimetric and titrimetric sulphates. The differences are shown statistically in Table II, and the confidence limits for the differences were calculated by the method of Dean and Dixon (1). These results provide evidence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

that hydrolysis of the sulphate acid ester was complete after 24 hours. Comparison of 24-hour and 48-hour titrimetric sulphate values, given in Table II, showed that hydrolysis continued slowly, and that the 48-hour titrimetric sulphate was always higher than the gravimetric sulphate, for instance, for cotton cellulose nitrate, about 5%. Therefore the 24-hour titrimetric sulphate was the best indication that hydrolysis of the sulphate acid ester was complete and this value was used for the ester determinations. The precision of 24- and 48-hour titrimetric sulphate determinations on duplicate samples of cellulose nitrates is shown in Table II.

TABLE II

PRECISION OF TITRIMETRIC TOTAL SULPHATE DETERMINATIONS ON CELLULOSE NITRATES

Samples		Difference, %	Standard deviation	95% Confidence limits
Nature	Time, hr.			
Cotton	24*	+0.2	8.2	+0.2 ±4.9
Wood	24*	−0.1	4.3	−0.1 ±2.6
Cotton	24 and 48	+5.2	2.5	−5.2 ±1.5
Wood	24 and 48	+4.8	4.1	−4.8 ±2.4
Cotton	24	4.0	1.6	4.0 ±1.6
Cotton	48	4.5	1.8	4.5 ±1.8
Wood	24	3.2	2.6	3.2 ±2.6
Wood	48	4.0	4.2	4.0 ±4.2

**Compared to gravimetric sulphate.*

The titration value before hydrolysis of the sulphate acid ester had started was originally determined from a rate of hydrolysis curve by extrapolation to zero time. However, more recently, experiments have been performed with 90% acetone/water solution which effectively stopped hydrolysis of the sulphate acid ester. Determinations of the ester using the zero hydrolysis titer obtained by the latter method have shown that the original zero hydrolysis figure obtained from the rate of hydrolysis curve was always too high. Thus an error of from 8 to 65% for cotton and 7 to 50% for wood cellulose nitrate was introduced into the ester determinations. The error was less when determinations were made on low ester content cellulose nitrates; thus it appears that the rate of hydrolysis when the ester is present in small amount is slower than that when a considerable amount of ester is present. It is evident that the initial hydrolysis of the sulphate acid ester, RSO_4H, is extremely rapid.

The above discussion shows that it is possible to obtain good measures of acidity for samples of cellulose nitrate in which there is no hydrolysis and others in which there is 100% hydrolysis of the sulphate acid ester; therefore the latter can be determined.

It was essential to determine the errors in the method and to establish the reproducibility of the results. The hydrolysis experiments were always performed on duplicate samples and the average results used for sulphate acid ester calculations. The precision of sulphate acid ester determinations on duplicate samples of cotton and wood cellulose nitrates containing about 100% ester is shown in Table III. It is seen that good precision can be obtained. An indication of the experimental error involved in the pH meter titration method for determining the acidity in cellulose nitrate was obtained by means of a series of acidity determinations on sulphuric acid solutions. The 95% confidence limits for the difference between the experimental and theoretical acidity were −4.5% ±6.3. Therefore in view of the latter error, the precision of the ester determinations mentioned above was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

TABLE III

PRECISION OF SULPHATE ACID ESTER DETERMINATIONS ON DUPLICATE SAMPLES OF CELLULOSE NITRATES

Samples		Difference, %	Standard deviation	95% Confidence limits
Nature	Ester, %			
Cotton	100	2.9	3.0	2.9 ±3.0
Wood	100	4.8	4.4	4.8 ±4.4
Cotton	69–43	7.6	5.8	7.6 ±5.8
Wood	69–47	10.7	10.3	10.7 ±10.3

good. However, these determinations were made on cellulose nitrates containing close to the maximum amount of sulphate acid ester and therefore the precision obtained was the best possible.

It was expected that the precision of ester determinations would decrease when cellulose nitrates containing less than 70% sulphate acid ester were used. This was the case, as shown in Table III. The precision of ester determinations on cotton cellulose nitrate was better than that for those on wood cellulose nitrate. The precision of sulphate acid ester determinations on very low ester content cellulose nitrates was poor; for instance, for a cotton cellulose nitrate containing 22% sulphate acid ester the difference between duplicate determinations rose to 59%. This fact was not surprising in view of the low sulphate content, 0.47%, of the cellulose nitrate and the fact that the difference in the pH meter titration was −7.4% for the titers obtained.

Several cotton and wood cellulose nitrates were prepared by duplicate nitrations and their sulphate acid ester contents were determined. Typical nitration conditions and ester contents for wood cellulose nitrates are shown in Table IV and the precision of the ester determinations is given in the experimental part. As expected, the precision decreased for both cotton and wood cellulose nitrates.

TABLE IV

DETERMINATIONS OF SULPHATE ACID ESTER IN WOOD CELLULOSE NITRATES PREPARED BY DUPLICATE NITRATIONS

Expt. No.	Temperature, ° C.				Nitrogen, %	Ester, % of total sulphate
	Mixed acid		Drowning water			
	Initial	Maximum	Initial	Maximum		
1	26.0	29.5	25.0	43.0	11.4	81
	23.0	28.0	24.5	56.0	11.4	98
2	23.0	27.1	24.0	43.0	11.7	97
	20.0	23.4	21.0	45.0	11.8	96
3	25.0	29.0	26.0	42.5	10.8	104
	23.0	25.8	24.0	41.0	10.8	97
4	22.0	24.3	21.5	41.5	10.6	94
	20.8	24.1	20.4	40.0	10.7	99

By the hydrolysis method, sulphate acid ester can be determined on duplicate samples of cotton and wood cellulose nitrates containing about 100% sulphate acid ester, with a precision of −0.1 to +5.9% and +0.4 to +9.2%, respectively. When determinations are made on cotton cellulose nitrates containing 69–43% sulphate acid ester, the precision is +1.8 to +13.4%, and for wood cellulose nitrates containing 69–47% sulphate acid ester, +0.4 to +21.0%.

Relation between Sulphate Acid Ester and Nitrogen Content

Kullgren (6) using ion exchange studies showed that 12.57% *N* cellulose nitrate contained about three times as much sulphate acid ester as 13.05% *N* cellulose nitrate. Miles (7) reported that the proportion of sulphate ester tended to increase with decreasing nitrogen content, and Gagnon *et al.* (3) recently provided some evidence in support of the latter contention.

In the present work, the sulphate acid ester contents of a variety of unstabilized cotton and wood cellulose nitrates were determined and compared to the nitrogen contents of the cellulose nitrates. The results are shown in Fig. 1.

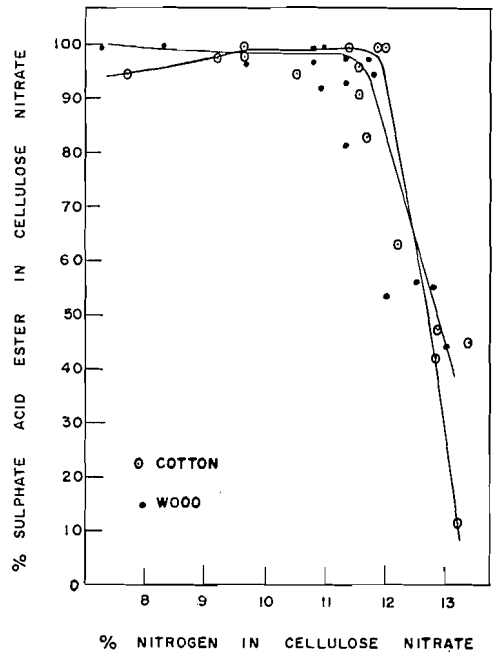

FIG. 1. Relation between sulphate acid ester and nitrogen contents of cellulose nitrate.

It is seen that for cotton cellulose nitrates containing less than 12.2% nitrogen, the sulphate acid ester content is about 100%, but for higher nitrogen contents the sulphate acid ester content rapidly decreases. Similar results were obtained for wood cellulose nitrates.

The sulphate acid ester content of both cotton and wood cellulose nitrate definitely increases with decreasing nitrogen content. This fact is very important evidence for the existence of a sulphate acid ester in unstabilized cellulose nitrate.

THE REACTION OF CARBON DISULPHIDE WITH ALUMINA[1]

A. G. PINKUS AND J. S. KIM

ABSTRACT

The absorption spectrum in aqueous solution of the yellow substance formed by the reaction of carbon disulphide and alumina exhibits absorption maxima at 398 and 325 mμ. This yellow color is not due to sodium disulphide as previously proposed since the latter substance showed an entirely different spectrum with shoulders at about 360–375 mμ and 290–300 mμ. The presence of *both* water and sodium hydroxide in the alumina is necessary for the formation of the yellow color in confirmation of previous work. A study of the gain in weight of the alumina with time of contact with carbon disulphide showed that this reaction begins to level off after about 24 hours. A minimum value for the heat evolved for the alumina – carbon disulphide system was determined as 8.6 cal. per g. of alumina reacting with an excess of carbon disulphide.

INTRODUCTION

In connection with another problem, spectroscopically pure carbon disulphide was needed. A simple method of purifying many solvents is by passing them through a column of some adsorbent. For example, spectroscopically pure cyclohexane can be obtained by passing it through a column of silica gel (7, 18*a*) or alumina (19) (after shaking with a nitrating mixture), and peroxides can be removed from ethyl ether, butyl ether, or dioxane by passing through a column containing activated aluminum oxide (4, 18*b*, *c*). There are other examples making use of silica gel (18*b*). When we passed carbon disulphide through a column of activated alumina, it was observed that the entire column turned a yellow color. That this was not due to the removal of impurities from the carbon disulphide was indicated by the fact that passing the same effluent successively through several more alumina columns gave the same result. In view of the widespread use of alumina in chromatography and the use of carbon disulphide as a chromatographic solvent (1, 11) it appeared to be of importance to study this phenomenon. It is stated that the reaction of carbon disulphide with alumina at elevated temperatures produces aluminum sulphide and carbon dioxide (5). At 200° to 500° carbon disulphide reacts with water over activated alumina to produce hydrogen sulphide and carbon dioxide in 98% conversions (2) whereas under milder conditions it is reported that carbonyl sulphide (COS) is formed (16). The formation of a yellow color during the adsorption of carbon disulphide vapors by alumina gel at room temperature was first noted by Perry (15). A thorough study of the action of gaseous carbon disulphide on alumina led to the conclusion on the basis of chemical tests that the yellow color was due to sodium disulphide which was produced by the reaction of carbon disulphide with sodium hydroxide adsorbed on the alumina (13). Since the yellow color was not removed by the usual solvents for sulphur, it was concluded that no free sulphur was present. The reaction products were explained according to the following summarized equations [1]–[6]:

$$[1] \quad CS_2 + 2H_2O \rightarrow CO_2 + 2H_2S,$$

$$[2] \quad CS_2 + H_2O \rightarrow COS + H_2S,$$

$$[3] \quad COS + H_2O \rightarrow CO_2 + H_2S,$$

$$[4] \quad COS \rightarrow CO + S,$$

$$[5] \quad NaOH + H_2S \rightarrow NaHS + H_2O,$$

$$[6] \quad 2NaHS + S \rightarrow Na_2S_2 + H_2S.$$

The presence of sodium in the yellow aqueous extract was shown by microchemical tests and in the alumina by spectroscopic means. The presence of sodium hydroxide in the alumina (in equation [5]) was inferred by showing that alumina which had been washed with water (until the aqueous extracts showed the absence of sodium) and reactivated at 400° did not form a yellow color with carbon disulphide. The alumina had been previously saturated with carbon disulphide. In another paper (14) a quantitative study of the same reaction showed that the amount of hydrogen sulphide produced and the intensity of the yellow color qualitatively paralleled the amount of water present, there being an optimum amount (about 8%) below or above which the amount of hydrogen sulphide produced decreased. In our work we made further studies toward a characterization of the reaction of alumina with *liquid* carbon disulphide. We have used absorption spectra to check the conclusion (13) that the yellow color was due to sodium disulphide. Besides various miscellaneous observations, we have made initial studies on the rate by studying the gain in weight of the alumina and also have done some preliminary calorimetric determinations.

EXPERIMENTAL

Purification and Preparation of Materials

ACS grade carbon disulphide was purified by two methods: (*a*) a previously published procedure (18*d*, 20) and (*b*) a simple distillation. No observable differences in results were noted in using these two samples of solvent. Water used in making up solutions was redistilled from potassium permanganate in a nitrogen atmosphere and had a pH of 6.85 to 6.90. Sulphur was purified by recrystallization from redistilled ACS grade carbon disulphide and also by a previously published method (3). No apparent differences in results were detected for these two samples of sulphur. Sodium disulphide was prepared by stirring or shaking ACS analytical grade sodium sulphide ($Na_2S.9H_2O$) with the calculated weight of sulphur for about 5 hours and then adding dilute aqueous sodium hydroxide (or distilled water) in small portions with stirring or shaking until all of the solid dissolved. This solution was then diluted up to the desired concentration (approx. 0.0018 *M* for the curve reported). Sodium hydroxide was used in order to repress hydrolysis.

Several commercial grades of alumina were used in this work; however, most of the experiments were done using the same grade in order to have a better basis for comparison. Where a related series of experiments were carried out, samples from the same batch were used. The basic character of the alumina was demonstrated by the following experiments in which the pH of aqueous washings was determined. In a typical determination, a 1.000 g. sample of alumina was stirred with 50 ml. of distilled water (pH 7.00) for 1 hour. The alumina was allowed to settle, the supernatant decanted, and its pH determined by means of a Beckman glass-electrode line-operated pH meter Model H 2. The pH meter was checked at a pH of 7.0 by means of Clark and Lubs buffer mixture (10). Repeated washings with further 50 ml. portions of water showed a rapid decrease in pH from the initial value of 7.42 and then a leveling off to a pH close to 7.0. The data are plotted in Fig. 1. A quantitative estimate of the amount of base in the alumina (calculated as NaOH) was determined by titration of the washings with 0.005 *N* HCl using methyl red indicator. An asymptote was reached at about 11 washings. The total amount of NaOH calculated was 0.40%. The approximate water content of the alumina used in most of the experiments as determined by ignition to constant weight was $12.6 \pm 0.9\%$ (average of several determinations). A constant weight was attained after about 24 hours of heating.

Dilutions of the yellow reaction product from the alumina – carbon disulphide reaction

were made by using water saturated with carbon disulphide. Carbon disulphide saturated water was used rather than distilled water alone for two reasons. Since the yellow color was found to disappear when attempts were made to remove the excess carbon disulphide from the alumina *in vacuo*, it was thought that the use of carbon disulphide saturated water would tend to repress this decolorization. Secondly, in order to observe the character of the absorption band at the lower wave lengths, it was found desirable to compensate for the excess carbon disulphide by using the saturated solution of carbon disulphide in the blank absorption cell. The carbon disulphide saturated water was freshly prepared each time just before using. It was found that when distilled water alone was used a more rapid decolorization of the solution occurred.

Various shades of color ranging from yellow to orange were obtained by the reaction of carbon disulphide with the various grades of alumina. Some of the columns themselves showed the same range of colors in different parts of the column. However, the spectra of the aqueous extracts from the various types of alumina showed remarkably similar shapes and absorption band positions. The absorption spectra for the aqueous extract of the yellow reaction product and for sodium disulphide are shown in Fig. 2. In order to show that the use of dilute sodium hydroxide in making up the solutions of sodium disulphide (to repress hydrolysis) did not greatly affect the character of the absorption curve, a curve is also shown for a solution prepared with distilled water alone. (The two are at different concentrations and are not directly comparable as to absorption intensity.)

It was of importance to investigate the possibility that different products might be formed by the reaction of alumina and carbon disulphide depending on the time of contact. In a series of experiments, it was definitely shown that the same absorption spectra were obtained regardless of the time of contact from up to 6 hours down to 1 minute contact before shaking with water and filtering. The amount of the yellow substance produced in general increased with time of contact. In order to check the possibility that the yellow

substance formed from carbon disulphide vapor and alumina (13) might be different than when liquid carbon disulphide was used, we have also run the spectrum of the aqueous extract. The same absorption peaks were obtained.

Absorption Spectra

Absorption spectra were determined with a DK–1 Beckman spectrophotometer using matched glass-stoppered 1 cm. quartz cells. A tungsten lamp was the light source for the part of the spectra above 325 mμ and a hydrogen lamp below 375 mμ. (The overlapping parts of the spectra matched in each case.) A photomultiplier detector was used with both lamps. Absorbance (A) was calculated (6, 21) by means of the ratio $A = \log(I_0/I)$, where I_0 is the intensity of the incident light and I the intensity of the transmitted light, both in % transmission. Wavelengths were checked by comparison of accurate values reported (17) for benzene vapor. These were about 0.1 mμ higher than the reported values.

Calorimetric Studies

The evolution of heat during the passage of carbon disulphide down the column was also noted. It was hoped that a determination of the heat of reaction would aid in the elucidation of the nature of the reaction. A few preliminary calorimetric determinations were made on this reaction following a described method (8). The calorimetric constant was determined by using the reaction of standard solutions of sodium hydroxide and hydrochloric acid. In a typical run, 250 ml. (assumed to be in excess) of carbon disulphide was introduced into the Dewar flask and allowed to come to equilibrium. Then 40.00 g. of alumina was added and the mixture stirred (by using a glass stirrer or a teflon-coated stirring bar) and readings of temperature with time were taken using a Beckman differential thermometer. Since the increase in temperature was not complete even at the end of 18 hours, this indicated a slow approach to equilibrium. Since a more elaborate apparatus would be needed to determine the heat of reaction for such a long reaction period, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

discontinued these experiments at this point. On the basis of the data obtained in the longest experiment, we have calculated (9) a minimum value for the heat of reaction[2] of 8.6 cal./g. of alumina reacting with an excess of carbon disulphide (based on specific heats for alumina and carbon disulphide as deduced from the International Critical Tables).

Rate Studies

It was found that on standing the yellow color would disappear from the alumina. This decolorization would also take place when the sample was placed in a desiccator and evacuated using a water pump. This decolorization was shown not to be dependent on the presence of water since it also occurred when the sample was protected during evacuation by means of calcium chloride. Furthermore, it was shown that the alumina gained in weight even though the yellow color had disappeared. This indicated a decomposition of the yellow substance into a gaseous product which was removed leaving a non-volatile colorless product. Since this observation appeared to be an important lead in the elucidation of the nature of the yellow substance, we studied this reaction by determining the gain in weight of the alumina with time during its reaction with carbon disulphide.

In a typical experiment 0.250 g. of alumina was stirred with 25 ml. of carbon disulphide by means of a teflon-enclosed magnetic stirrer, the mixture being kept in a water bath maintained at 30°±1°. At specified times, the carbon disulphide was decanted and the alumina placed in a desiccator, which was evacuated by means of a water pump. The desiccator was protected from the water pump by means of calcium chloride. The evacuation was carried out until the weight approached a constant value (usually about 24 hours). For the next point, the decanted carbon disulphide was again added to the same alumina and the procedure repeated. The data are plotted in Fig. 3. The yellow color would disappear in about 15 minutes for experiments having a short contact time to about 6 hours for the longer times. The maximum gain in weight of the alumina in our

[2]*The referee has suggested that this probably represents a heat of wetting which varies with the activation of the alumina and the amount of water in the carbon disulphide if not anhydrous. Another possibility suggested by the referee is that it may include heat of adsorption, which is often observed with many materials. The referee has kindly furnished the following references dealing with this: J. L. Culbertson and L. L. Winter, J. Am. Chem. Soc.* **59**, *308 (1937), report a value of 6.7 cal./g. for the heat of wetting of carbon disulphide on silica gel. A. B. Lamb and E. N. Ohl, J. Am. Chem. Soc.* **57**, *2154 (1935), give values for the heat of adsorption of carbon disulphide on various substances. Bartell in Coll. Symposium Mon. VII gives 31 cal./g. for the heat of wetting of carbon disulphide on charcoal and silica gel. We have found a further reference in which heat of wetting values ranging from 2.7 to 4.7 cal./g. adsorbent are listed for various hydrocarbons on alumina: A. S. Russell, W. H. Gitzen, J. W. Newsome, R. W. Ricker, V. M. Stowe, H. C. Stumpf, J. R. Wall, and P. Wallace, Alumina properties (Technical Paper No. 10 (Revised), Aluminum Company of America, Pittsburgh, Pa., 1956), p. 42.*

The authors feel, however, that the heat of reaction contributes to a large extent to the total heat measured. In support of this, the following points can be made: (a) When carbon disulphide is passed through a column of alumina, sufficient heat is produced to make the column very noticeably warm to the touch. (b) Since we have found no such noticeable heat produced in our experiments with silica gel (see below), we conclude that the heat of wetting produced in this case is insufficient to make the column warm to the touch. (c) Since carbon disulphide dried over phosphorus pentoxide produces this noticeable heat effect, this excludes the possibility of water in the carbon disulphide. (d) Since wetting and adsorption are physical processes it would be expected that the heats of wetting and adsorption would be produced very rapidly. In our experiments we note that heat was still being produced at the end of 18 hours. This would indicate a slow exothermic chemical reaction taking place in addition. (e) Since this point was brought to our attention by the referee, we have conducted the following additional experiment. When alumina was washed free of alkali and reactivated by heating, a heat effect (to the touch) was no longer produced when carbon disulphide was passed through a column of this alumina. (It was also noted that no yellow color was produced.)

In summary we believe that in addition to the heats of wetting and adsorption, the heat of reaction contributed to a large extent to the total heat produced. Actually we have pointed out that our value is a minimum value since the reaction was still incomplete after 18 hours. Furthermore, it is probable that heat was lost during the time of measurement since our apparatus was not designed for a long period of measurement, as we have pointed out. It should be possible to obtain an estimate for the heat of reaction by measuring the heat of wetting (and adsorption) for alumina washed free of alkali and dried and subtracting this value from the total heat obtained for the alumina before washing. (This assumes that the heats of wetting and adsorption are nearly the same for the two alumina samples.) Since we do not have the equipment necessary to obtain the latter data accurately, however, we are not planning any further work along these lines. We thank the referee for bringing these points to our attention.

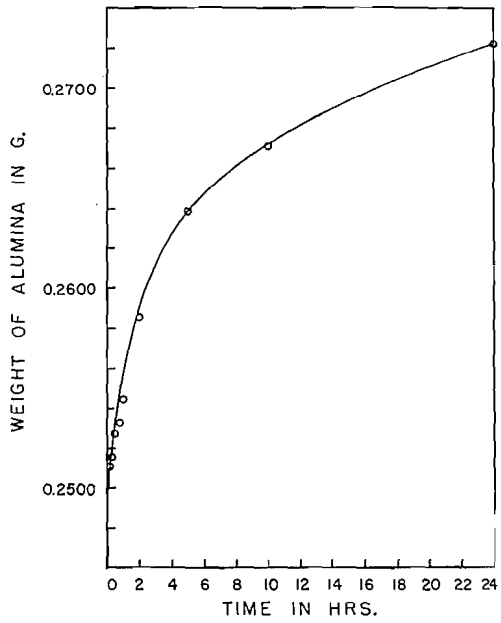

FIG. 3. Gain in weight of alumina on stirring with CS_2 for varying amounts of time using the same CS_2 each time.

experiments was 0.0045 g./0.2500 g. of alumina or 0.1800 g./10 g. of alumina. The saturation value reported by Perry (15) for the *adsorption* of carbon disulphide on alumina gel was 2.96 g./10 g. of alumina. It should be pointed out that in his work he was measuring the increase due to the yellow reaction product plus *adsorbed* carbon disulphide whereas in our work we are measuring mainly the *colorless reaction product*.

Miscellaneous Experiments and Observations

(*a*) When alumina which had been washed with water and dried was shaken with carbon disulphide, no yellow color was formed. This result confirms the previous observations (13). However, after a longer period of contact, the alumina turned a light brown color. This color, however, was not soluble in water, in contrast to the previously mentioned yellow substance, and thus appears to be a different substance. (*b*) When alumina (previously ignited to constant weight) was treated with dry carbon disulphide, no color formed even after they had been in contact for 1 week. This is in accord with the findings of Munro and McCubbin (14), who found that the catalytic activity of their alumina gel decreased to zero at zero water content of the gel. (*c*) The odor of hydrogen sulphide was quite evident from the reaction of alumina and carbon disulphide in agreement with the previous observations (13). (*d*) Silica gel did not form a yellow color with carbon disulphide, and no noticeable heat effect (to the touch) was noted when carbon disulphide was passed through a column of silica gel.

RESULTS AND DISCUSSION

The absorption spectrum for the yellow product of the reaction between alumina and carbon disulphide is shown in Fig. 2 and shows two maxima at 398 and 325 mμ. The curves for sodium disulphide (shown in the same figure) show two shoulders: 360–375 mμ and 290–300 mμ. To our knowledge the absorption spectrum of sodium disulphide below 400

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

For personal use only.

mμ has not been previously reported. Recently the curves for potassium disulphide and other polysulphides were reported (12) *above* 400 mμ. However no structure is evident in this region. It is interesting that hydrolysis causes only minor differences in the spectra of the two. We have also noted that the shoulders broaden with dilution for both the basic and water solutions. For example, when the basic solution was diluted to about 0.0006 *M* the shoulder extended from about 360 to 380 mμ. In either case it is evident that these spectra differ markedly from the spectrum of the yellow reaction product from alumina and carbon disulphide. In deference to Munro and McCubbin, it should be pointed out that absorption spectra were not generally available at that time. Evidently the yellow substance must respond to the same chemical tests as sodium disulphide. This observation may be helpful in the elucidation of the nature of this substance.

It is clear from our results and those of Munro and McCubbin that *both* water and sodium hydroxide must be necessarily present in the alumina for the formation of the yellow color. Any mechanism to explain the formation of the yellow color must take these facts into account.

The studies on the gain in weight of the alumina show that equilibrium is approached after more than 24 hours of reaction. This indicates the approximate amount of time needed for a calorimetric study.

We are continuing a study of other possible compounds as the cause of the yellow color in question.

ACKNOWLEDGMENTS

The authors express their appreciation to the Texas Gulf Sulphur Co. for a research fellowship to J. S. K. under which part of this work was done and to the Aluminum Company of America for samples of activated alumina.

BLOCK AND GRAFT POLYMERS

I. GRAFT POLYMERS FROM ACRYLAMIDE AND ACRYLONITRILE[1]

M. L. MILLER

ABSTRACT

Graft polymers of acrylonitrile and acrylamide with from 1 to 20 grafts have been prepared by chain transfer to polymer and by photolysis of a copolymer containing a few per cent of α-chloroacrylonitrile. The intrinsic viscosities and softening points have been measured and the dependence of these properties on the number of grafts observed.

I. INTRODUCTION

The properties of homopolymers and, to an even greater extent, those of copolymers can be changed by changing the arrangement of the monomer units in the polymer molecule. This opens up the possibility of preparing polymers with new and improved properties from old monomers and old combinations of monomers.

There are at least three ways in which monomer units A and B can be arranged in a copolymer. These three types of copolymers, random, graft, and block, are illustrated by the schematic diagrams shown below.

...AABABBBABAA...	...AAAAAAAAAA...	...AAAAABBBBBBAA...
	B B	
Random	B B	Block
	B B	
	⋮ ⋮	
	Graft	

It was the object of this series of investigations to prepare block and graft polymers with known lengths and numbers of blocks and grafts and to use these polymers to study the effect of different arrangements of monomer units on some representative physical properties. The monomer pairs chosen for this work were acrylonitrile and acrylamide and acrylic acid and acrylamide. The work falls into two parts, the preparation of the polymers and the study of their properties. This paper describes the preparation and study of graft polymers. The following paper will treat block polymers.

II. EXPERIMENTAL PREPARATION OF GRAFT POLYMERS

Two methods were used to prepare graft copolymers. These methods were: (1) chain transfer to polymer, and (2) photolysis of polymers containing a small amount of copolymerized alpha-chloroacrylonitrile.

Preparation of Graft Copolymers by Chain Transfer to Polymer

In the preparation of graft copolymers by chain transfer, the backbone polymer was dissolved in 65–70% sodium perchlorate, the second monomer added, and the grafting carried out at 55° C. with a persulphate–bisulphite catalyst. Either polyacrylonitrile or polyacrylamide could be used as the backbone polymer.

Sodium perchlorate solution was used as a solvent because it dissolves the graft copolymer and both homopolymers. Furthermore, this solvent is not a chain transfer medium

[1]*Manuscript received August 15, 1957.*
Contribution from the Stamford Laboratories, Research Division, American Cyanamid Company, Stamford, Connecticut. Presented in part before the Seventh Canadian High Polymer Forum, Sarnia, Ontario, Canada, November 8–9, 1956.

and it does not compete with the grafting reaction. A further advantage is the fact that sodium perchlorate, unlike other possible solvent salts, is not attacked by the oxidizing agent in the catalyst.

A typical preparation was as follows: 999 g. of $NaClO_4$ was dissolved in 560 g. of oxygen-free water. Eleven grams of polyacrylonitrile (molecular weight 175,000) and 33 g. of acrylamide were dissolved in this solution and the polymerization carried out at 55° C. under a blanket of CO_2 for 4 hours. 0.28 mole of ammonium persulphate and 0.07 mole of sodium metabisulphite were used as catalyst. The yield was: 20.5 g. graft polymer (containing 50 mole % acrylonitrile and 50 mole % acrylamide), 6 g. of polyacrylamide (recovered from water-solubles after dialysis to remove salts), and no dimethylformamide-soluble polymer.

By this method, polymers with as much as 50 mole per cent of the grafted monomer and with from 1 to 6.5 grafts per molecule were obtained. This method suffered from the disadvantage that excessive amounts of catalyst were required. Nevertheless, a supplementary experiment showed that the backbone polymer, when treated as in a grafting experiment but in the absence of a second monomer, suffered little or no reduction in intrinsic viscosity.

Photolysis of Copolymers of Alpha-Chloroacrylonitrile

The second and preferred method for making graft copolymers was a modification of the method used by M. H. Jones and associates (6, 7, 8). These workers brominated polystyrene to the extent of a few per cent and then photolyzed the partly brominated polystyrene in the presence of methyl methacrylate to make a graft copolymer. In our experiments, we have used for backbone polyacrylonitrile or polyacrylamide which has been copolymerized with one to three mole per cent of alpha-chloroacrylonitrile. Alpha-chloroacrylonitrile is convenient for this purpose because the copolymer containing 1–3% chloroacrylonitrile is stable to storage under ordinary laboratory conditions and to solution in and precipitation from such solvents as concentrated salt solutions and ethylene carbonate. It is less stable in dimethylformamide, but can be handled in this solvent if neutral and if the temperature is kept low. In spite of the relative stability, the presence of the nitrile on the same carbon as the chlorine acts somewhat like a second halogen and sensitizes the copolymer to photolysis (9).

The copolymers of α-chloroacrylonitrile and acrylonitrile were prepared by the following recipe:

76 cc. redistilled methanol
242 cc. oxygen-free water
5.75 cc. catalyst A (17.3 g. ammonium persulphate in 240 cc. water)
2.55 cc. catalyst B (7.68 g. sodium metabisulphite in 240 cc. water)
1.60 cc. catalyst C (0.45 g. $FeCl_3.6H_2O$ in 100 cc. water)
30 cc. acrylonitrile
1.25 cc. α-chloroacrylonitrile (b.p. 87.5–88° C. uncorr., $n_D^{25} = 1.4257$)
200 mg. sodium lauryl sulphate

The mixture was cooled to −10° to −14° C. before monomer or catalyst was added. The mixture was kept at −10° to −14° C. under a blanket of CO_2 for 120 hours. Yield 100%, molecular weight about 50,000.

In a grafting experiment, the polymer containing α-chloroacrylonitrile was dissolved in 66–70% sodium perchlorate or 50% NaSCN, the second monomer added, and the solution photolyzed for 2–4 hours at 25° to 35° C. in a quartz tube under a G.E. Sun Lamp.

An illustrative experiment used:

0.50 g. polyacrylonitrile (molecular weight 200,000, 1.5% α-chloroacrylonitrile)
50 g. of 70% $NaClO_4$ solution
2 g. acrylamide

Yield: 0.3 g. graft polymer (40 mole % acrylonitrile, 60 mole % acrylamide)
0.0 g. polyacrylonitrile
0.023 g. polyacrylamide (molecular weight 84,000)

Isolation and Characterization of Graft Polymers

After the grafting reaction was completed, the reaction mixture, whether prepared by the first or second procedure, was poured into methanol. The precipitate was extracted alternately and repeatedly with hot water and hot dimethylformamide.

Three or four extractions with each solvent were required. In each extraction, the polymer was intimately dispersed in the extracting medium. During this extraction, some polymer stuck to the glassware or was decanted with solvent. These losses resulted in a lowered over-all recovery of backbone polymer.

The graft polymer was insoluble in both dimethylformamide and water. The dimethylformamide extract contained any free polyacrylonitrile that was present. This extract was concentrated and methanol added to precipitate the polymer. The water extract contained any free polyacrylamide that was present. The water extract was concentrated, dialyzed to remove salt, and freeze-dried. In general, none of the backbone polymer was recovered ungrafted, but there was usually a relatively large amount of the homopolymer of the composition used to make the grafts. The composition of all polymers was determined by infrared examination of thin films. Films of copolymers were cast from dimethylsulphoxide and those of homopolymers from water or dimethylformamide. After evaporation of the solvent, the films were washed three times in boiling methanol and dried 16 hours at 117° C. under vacuum. A preliminary experiment showed that this treatment reduced the solvent content to less than ½%.

Because the object was to prepare graft polymers with well-defined structures, the initial backbone polymers had to be unbranched. For this reason, backbone polymers were prepared by polymerization at 0° C. Since polyacrylonitrile (11) and polyacrylamide (4) have very little branching when prepared at 50° C., polymers prepared at zero degrees can be considered essentially unbranched.

Fractions of these unbranched polymers were used as backbones. Fractions of polyacrylonitrile were prepared by precipitation from dimethylformamide by a mixture of ether and heptane (5) and fractions of polyacrylamide were prepared by precipitation from water by dioxane.

The molecular weight of polyacrylonitrile was estimated from intrinsic viscosity measured in dimethylformamide at 30° C. and calibrated against light scattering data (2, 11). The molecular weight of polyacrylamide was estimated from intrinsic viscosity measured in water at 30° C. and calibrated against molecular weights obtained by light scattering (1) and by sedimentation (13).

The chlorine-containing polymer was sensitive to degradation when attempts were made to fractionate it by the methods used with polyacrylonitrile. Therefore, it was dissolved, at 0° C., in neutral dimethylformamide to give a 1.0% solution. An equal volume of 40% ethanol was added and the clear solution fractionated by spinning in a preparative ultracentrifuge with an iced rotor at 78,000g.

The graft polymers, although insoluble in water and dimethylformamide, dissolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

readily in dimethylsulphoxide and in concentrated salt solutions. This showed that they were not cross-linked. The polymers gave optically clear films and optically clear concentrated solutions that did not show a two-phase structure when examined visually or by phase contrast microscopy. These facts are evidence that the polymers are graft polymers and not mixtures of homopolymers.

Since none of the backbone polymer was recovered ungrafted, it is evident that all of the polymer initially present has been incorporated in the graft polymer. Therefore, the molecular weight of the backbone in the graft polymer is the same as that of the dead polymer used. On this basis, the molecular weight of the graft polymer was computed from the molecular weight of the backbone polymer and the composition of the graft polymer. If we make the assumption that the molecular weight of the chains that did not become attached is the same as that of the chains that grafted on, then we can calculate the average number of grafts on the backbone chain. This assumption is reasonable and is supported by experiment (8, 10). The graft polymers shown in Table I have been characterized in this way.

TABLE I

SUMMARY OF GRAFT COPOLYMERS

Backbone polymer	Mole % acrylonitrile in graft polymer	Molecular weight of:		Number of branches	Softening point, ° C.
		Graft polymer	Branches		
Polyacrylamide	15–20	185,000	3,800	6.7	162

III. PROPERTIES OF GRAFT POLYMERS

Intrinsic Viscosity

Intrinsic viscosities were measured in 50% (by weight) aqueous sodium thiocyanate solution at 30° C. This is a solvent for graft copolymers and both homopolymers. Ostwald viscometers with flow times for the blank from 67.5 to 289.4 seconds were used. A kinetic energy correction was applied. Tests for the viscosity slope constant k' (3) were run on the graft polymers that had 2.7 and 6.3 grafts per molecule. Solutions were made up by weight and diluted by weight and the charge was weighed into the viscometer. There was no evidence for a dependence of k' on the number of grafts.

For graft polymers, linear random copolymers, and for polyacrylonitrile k' was 0.34 ± 0.02.

Table II summarizes the viscosity data. This table lists the intrinsic viscosity of the backbone polymer, of the graft polymer, and the intrinsic viscosity calculated for a hypothetical mixture of homopolymers each having the same molecular weight as the graft polymer. It will be noted that in every preparation the intrinsic viscosity of the graft polymer is greater than that of the backbone polymer. This must be true if the preparation has been carried out correctly.

In all but the first sample, the intrinsic viscosity of the graft polymer is less than that calculated for an ideal mixture of homopolymers of the same molecular weight. This is to

TABLE II

INTRINSIC VISCOSITY OF GRAFT POLYMERS IN 50% SODIUM THIOCYANATE AT 30° C.

Number of branches	Intrinsic viscosity, dl./g.		
		Graft polymer	
	Backbone	Observed	Observed/computed
1	1.35	5.1	1.13
1–1.5	1.10	1.30	0.95
2.7	0.85	1.50	0.63
4.8	2.10	4.3	0.63
6.3	2.00	3.3	0.73
6.7	1.00	1.60	0.68
21	2.10	5.6	0.58

be expected because of the branched structure. It is also to be expected that, as the number of grafts increases, the ratio of observed to computed viscosity will decrease. The last column in the table shows that this is only roughly true.

Softening Points

Softening points were measured as sticking points using a calibrated Parr melting point bar in an atmosphere of dry nitrogen. They were reproducible to ±7° C. The tests were made on films 5 to 10 mils thick that were cast from dimethylsulphoxide. After being dried in a forced draft oven at 110° C., the films were washed in boiling methanol and in boiling acetone and dried in vacuum at 117° C. for 16 hours. After this treatment, the films retained less than ½% of solvent. The films were boiled in acetone and vacuum dried another 16 hours before testing. The observed softening points are shown in Table I. Fig. 1 plots the difference between the observed softening points and a line joining the

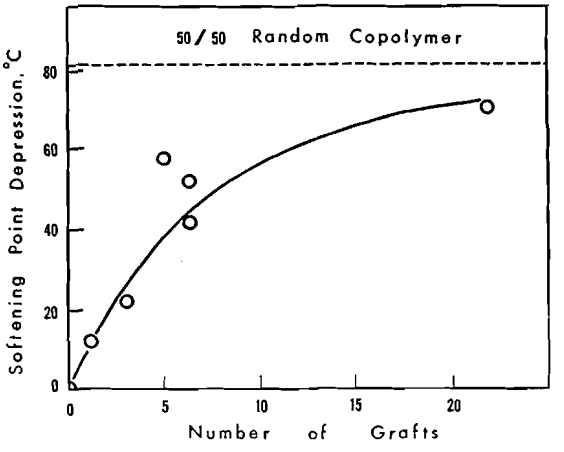

FIG. 1. Dependence of softening point depression on number of grafts.

softening points of the two homopolymers (12) against the number of grafts. Polymer 4 (Table I), for which the number of grafts is subject to some doubt, has been omitted from the figure. As the number of grafts increases, the softening point decreases and approaches, as a limit, the softening point of the 50/50 random copolymer.

BLOCK AND GRAFT POLYMERS

II. BLOCK POLYMERS FROM ACRYLAMIDE AND ACRYLONITRILE AND ACRYLAMIDE AND ACRYLIC ACID[1]

M. L. MILLER

ABSTRACT

Block polymers of acrylamide and acrylonitrile and of acrylamide and acrylic acid have been prepared by photolysis of polymers with end groups that contained bromine. The intrinsic viscosities and softening points of these polymers have been measured and compared with the viscosities and softening points of random copolymers having the same composition and molecular weight.

I. INTRODUCTION

The preceding paper describes the preparation and study of graft polymers of acrylamide and acrylonitrile. This paper is concerned with block polymers of acrylamide–acrylonitrile and acrylamide – acrylic acid.

II. PREPARATION OF POLYMERS

Development of Method

Block polymers were made by a modification of the method devised by Dunn, Stead, and Melville (2). This method uses a polymer with end groups containing bromine to sensitize the photopolymerization of a second monomer. Conditions necessary to make the initial blocks of polyacrylonitrile and the block polymer were worked out on the basis of the following preliminary experiment.

In this experiment, acrylonitrile and mixtures containing equal volumes of acrylonitrile and bromoform or dibromomethane or monobromoethane were sealed in Pyrex tubes. These tubes were partly immersed in ice water and exposed to the light from a G.E. sun lamp, screened by 5 mm. of window glass for 3 hours. The glass was removed and irradiation continued for 3 hours more. The results, shown in Table I, indicate that one bromine

atom is split off from the bromoform with the glass screen in place, but not from the compounds containing only one or two bromine atoms on a single carbon. With the glass removed, bromine is split off from a carbon loaded with two bromines after ½ hour exposure. A bromine atom on a carbon loaded with a single bromine is not touched before

the blank, containing acrylonitrile alone, starts to polymerize. These are the conditions needed to prepare block polymers.

Preparation of Block Polymers from Acrylonitrile and Acrylamide

The initial blocks of polyacrylonitrile were made as follows. Acrylonitrile and bromoform were mixed in the proportions 25 cc. acrylonitrile to 15 cc. of bromoform. The mixture was sealed in 12 mm. i.d. Pyrex tubes containing approximately 10 cc. each. The tubes were placed in an ice bath with 5 mm. of ordinary window glass $2\frac{1}{2}$ inches above them and a G.E. sun lamp $3\frac{1}{2}$ inches above the glass. The tubes were irradiated in 15-minute exposures (with cooling and mixing between exposures) for a total of 3 hours' exposure. The tubes were opened and the contents poured into methanol. The polymer was washed with methanol three times, then with acetone, and air dried. The molecular weight was estimated from the intrinsic viscosity in dimethylformamide at 30° C. (1, 3). Two preparations by this method had molecular weights of 135,000 and 265,000.

A typical recipe for adding the polyacrylamide block was as follows. Two grams of the polyacrylonitrile (prepared as above) was dissolved in 235 cc. of 50% (by weight) sodium thiocyanate solution (prepared and kept free from oxygen by flushing and blanketing with CO_2). Three grams of acrylamide was added and the solution sealed in Pyrex tubes and exposed to the light from an unscreened sun lamp at 30–50° C. The product was worked up as described for graft polymers (4). Even though the ratio of acrylamide to polyacrylonitrile was varied within relatively wide limits, 2/1, 2/3, 2/5, 2/6, the product always had about the same composition as determined by infrared, i.e., 60 mole per cent nitrile and 40% amide. This is due, apparently, to the fact that the same solvent treatment was used for isolating the product. In one experiment, a small amount of a second block polymer containing 35 mole per cent nitrile and 65 mole per cent amide was isolated as a less soluble portion of the water solubles. Less than a third as much of this was obtained as of the main product. Little or none of the initial polyacrylonitrile block was recovered.

Preparation of Block Polymers from Acrylic Acid and Acrylamide

Blocks of polyacrylic acid were made by essentially the same method as was used for making blocks of polyacrylonitrile. Mixtures of acrylic acid and bromoform (in some experiments diluted with benzene) were irradiated as above but for only $\frac{3}{4}$ to $1\frac{1}{2}$ hours. The contents of the tubes became solid but were entirely soluble in water. After irradiation was finished the tubes were opened and the contents washed into benzene, centrifuged, and rewashed with benzene several times to remove bromoform and monomer. The polymer was dissolved in water and freeze-dried. Its molecular weight was estimated from the intrinsic viscosity measured in dioxane (5). This procedure gave polymers with molecular weights ranging from 145,000 to 540,000.

The polyacrylamide block was added to this polyacrylic acid block by the method previously used to add acrylamide to polyacrylonitrile. In an illustrative preparation, approximately $\frac{2}{3}$ of a gram of the undried or freeze-dried polyacrylic acid with end groups which contained bromine was dissolved in 100 cc. of oxygen-free water under a blanket of carbon dioxide. Two grams of acrylamide was added and the solution was sealed in tubes and irradiated by an unscreened sun lamp. Irradiation was carried out at 25° to 35° C. for 2 hours. The contents of the tubes were poured into 500 cc. of dioxane and extracted twice with hot dioxane. The flow sheet, Fig. 1, shows the work-up of the product. The over-all recovery of initial polyacid was about 40% and the ungrafted acid was 25% of the starting polyacid block.

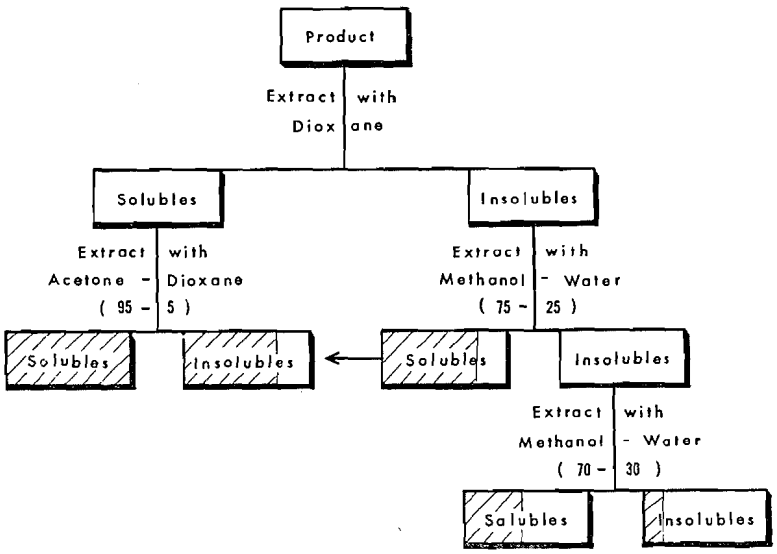

FIG. 1. Separation of block polymers of acrylic acid and acrylamide from reaction mixture. Shaded areas represent per cent of fraction that is acrylic acid.

Discussion of Preparation

In the first step, irradiation caused the photodecomposition of the bromoform,

$$\underset{}{CHBr_3} + h\nu \rightarrow \underset{(1)}{CHBr_2^{\bullet}} + \underset{(2)}{Br^{\bullet}}$$

Each of these radicals, (1) and (2), can initiate polymerization to give polymeric radicals (3) and (4):

$$\underset{(3)}{CHBr_2\text{----}^{\bullet}} \text{ and } \underset{(4)}{Br\text{----}^{\bullet}}$$

These four types of radicals can terminate by combination with one another, by disproportionation, or by chain transfer to solvent or to monomer. Although initially there are approximately equal numbers of moles of acrylonitrile and bromoform, the amount of acrylonitrile decreases very rapidly as polymerization proceeds. Thus, it is reasonable to assume that, for the bulk of the reaction, termination is by chain transfer to solvent. This mode of termination would produce two types of polymer molecules (*a*) and (*b*), i.e.,

$$CHBr_2\text{----}^{\bullet} + CHBr_3 \rightarrow \underset{(a)}{CHBr_2\text{----}Br} + CHBr_2^{\bullet}$$

$$Br\text{----}^{\bullet} + CHBr_3 \rightarrow \underset{(b)}{Br\text{----}Br} + CHBr_2^{\bullet}$$

This process would also result in the liberation of a free radical which could, in turn, initiate other chains so that the reaction could, and probably does, become autocatalytic. Molecules of type (*b*) will be unaffected by further irradiation and will be isolated as unchanged polyacrylonitrile in the work-up of the product. Molecules of type (*a*), when photolyzed, will add on acrylamide to form block polymer. These polyradicals could terminate by (1) combination with one another, (2) combination with $Br^{\bullet}$, or (3) disproportionation. Except where termination is by combination of radicals, all block polymers will consist of two blocks:

$$Br\text{----}CHBr\text{----}X$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Here X is either Br or double bond. If there is a significant amount of combination of radicals of type (*b*) with one another, there will be polymer molecules made up of three blocks. More complex molecules are possible, but they are less probable.

III. RESULTS

Block Polymers Containing Acrylonitrile and Acrylamide

Table II summarizes the block polymers of acrylonitrile and acrylamide that have been prepared. Column 1 gives the mole per cent of nitrile, measured by infrared; column 2 the molecular weight of the block polymer as computed from the molecular weight of the initial block and the composition of the polymer; columns 3 and 4 give the intrinsic viscosity in 50% sodium thiocyanate as measured and as computed for a hypothetical mixture of homopolymers each having the same total molecular weight as the block polymer. It is seen that, except in one instance where the molecular weight is very high, the computed viscosity is in good agreement with the observed.

TABLE II

BLOCK POLYMERS FROM ACRYLONITRILE AND ACRYLAMIDE

Mole % of acrylonitrile	Molecular weight $\times 10^{-3}$	Intrinsic viscosity in 50% NaSCN at 30° C., dl./g.	
		Observed	Computed
66	196	—	
63	360	—	
60	257	2.15	2.19
62	250	2.25	2.22
60	500	—	
35	935	—

50	620	5.2	4.0

Block Polymers Containing Acrylic Acid and Acrylamide

Table III describes two block polymers of acrylamide and acrylic acid. The molecular weight of these polymers was estimated in two ways, both of which are approximations.

In the first method the polymers were hydrolyzed until the hydrolysis stopped. The viscosity of this hydrolysis product was measured in 1 *N* NaOH and the corresponding molecular weights read from a plot of molecular weight vs. viscosity for random copolymers of the same acid contents.

TABLE III

INTRINSIC VISCOSITIES OF BLOCK POLYMERS FROM ACRYLIC ACID AND ACRYLAMIDE

Fraction No.	Acid	Molecular weight ($\times 10^{-3}$) by:		Intrinsic viscosity, dl./g.		
		Hydrolysis	Computation	Observed	Computed	Of random polymer
2	75	310	366	1.60	1.55	2.30
3	45	637	610	2.50	2.45	3.80

In the second method the molecular weight was computed from the composition of the copolymer on the assumption that the initial block of acrylic acid has not been fractionated by the processing of the mixture containing the graft polymer. The agreement of the molecular weights by the two methods is good. Columns 3 and 4 in Table III compare

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

the intrinsic viscosities measured in 1 *N* sodium nitrate, after neutralization, and the intrinsic viscosities computed for a hypothetical mixture of homopolymers each having the same molecular weight as the block polymer. The agreement between the observed and computed values is good.

This agreement between observed and computed viscosities for block polymers (with two or three blocks) is to be contrasted with the intrinsic viscosity of linear random copolymers. In general it is not possible to estimate the intrinsic viscosity of a linear random copolymer from measurements of the viscosity of homopolymers made from the two comonomers that were used to prepare the random polymer.

This unpredictability is illustrated by the data in column 7 of Table III which gives the intrinsic viscosity of linear random copolymers of acrylic acid and acrylamide that have the same composition and molecular weight as the block polymers. These viscosities are far greater than the computed viscosities or the viscosities of the block copolymers.

IV. PROPERTIES OF BLOCK POLYMERS

General

The properties of random copolymers from two monomers usually pass through a maximum or a minimum as the composition is changed from 100% of one comonomer to 100% of the other. If, however, the copolymer contains one long graft or, better yet, two or three long blocks the value of a given property should be very close to the value computed for a hypothetical mixture of two homopolymers each having a molecular weight equal to that of the block polymer as a whole. Preceding measurements have shown that this is true for intrinsic viscosity. It is of interest to examine the validity of this mixture rule for block copolymers with some other properties. This has been done for softening points of acrylonitrile–acrylamide copolymers and for acid dissociation constants for acrylic acid – acrylamide copolymers. The work on dissociation constants will form the subject of the third paper in this series.

Softening Points

Softening points of the copolymers of acrylamide and acrylonitrile were measured as

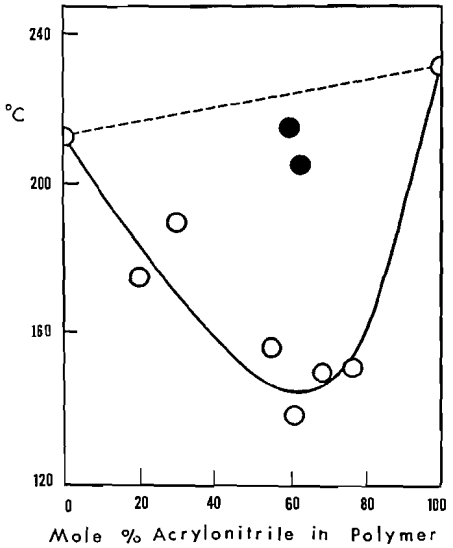

FIG. 2. Softening point of random and block copolymers of acrylamide and acrylonitrile; ○—random copolymers, ●—block copolymers.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12

sticking points of films using a calibrated Parr melting point bar in an atmosphere of dry nitrogen. The measurements were reproducible to ±7° C. They are to be regarded as empirical values useful for comparison. The tests were made on films 5 to 10 mils thick that were cast from dimethylsulphoxide. After being dried in a forced draft oven at 110° C., the films were washed in boiling methanol and in boiling acetone and vacuum dried at 117° C. for 16 hours. After repetition of this treatment, the films retained less than ½% of solvent. Fig. 2 plots the softening point of random copolymers of acrylonitrile and acrylamide against mole per cent of acrylonitrile. Open circles designate random copolymers and filled circles block polymers. It is seen that the softening point of random copolymers falls off very sharply as the composition is changed from 100% of one comonomer to 100% of the other. For block polymers, the softening points are very close to a line joining the softening points of the two homopolymers.

CONCLUSIONS

These experiments have shown that the softening points and intrinsic viscosities of block polymers having two or three long blocks can be computed from the corresponding properties of the homopolymers. This can be done also as a first approximation for graft polymers with only one graft (4). As the number of grafts increases, the deviations from the expected values become greater as a result of the branched structure and the increased heterogeneity.

ACKNOWLEDGMENTS

It is a pleasure to thank Miss C. A. Ederle, Mr. R. M. McGrath, and Mr. R. Polistina for assistance with the experimental work and Miss E. C. Eberling for the infrared analyses.

A MODIFICATION OF THE DIRECT CURRENT CONDUCTANCE METHOD[1]

G. D. GRAHAM AND O. MAASS

ABSTRACT

A modification in the employment of the direct current method of measuring conductivities is described. The main objective is that pure metallic probe and current carrying electrodes can be used, thus making it possible to investigate the conductivity of solutions such as hydrogen peroxide, aqua regia, etc. This necessitates a choice of electrodes which are inert to such solutions. An electrometer having an infinite resistance so as to avoid any polarization at the probes, in this case the quadrant electrometer, is described in its use as a null instrument. An accuracy as high as or greater than that of the alternating current method could be obtained. Furthermore, this method entails greater equipment economy and simplicity in apparatus required.

INTRODUCTION

In the measurement of electrolytic conductivity in water and other solvents, two main methods have been used, the alternating current method, the more common one, in which polarization is compensated for depending on frequency, capacity, and inductance, and the direct current method in which the so-called probe electrodes (as will be explained later on) bring in experimental hazards. It has been shown by Gordon (5) and co-workers that the direct current method with the experimental setup he devised will give the same accuracy in measurements that the alternating current method gives. Previous to Gordon, a number of other workers (1, 2, 3, 8) had used the direct current method, and since Gordon's publication others have substantiated his find, among them Schiff (4), Lim (7), and Ives (6).

In planning a number of investigations of electrolytic conductivity of certain systems, hydrogen peroxide solutions, so-called aqua regia solutions, and in general to make use of the direct current method, it was thought that it would be desirable to have pure metallic probe electrodes and current carrying electrodes all made of the same pure metal. For hydrogen peroxide solutions, electrodes of pure tin, which does not cause any decomposition of hydrogen peroxide, are the best to use. For aqua regia, tungsten electrodes are the best and also for every purpose in which conductivities are measured; the nature of the material of the electrodes would not diminish the accuracy of the results obtained by using the direct current method. Furthermore, the direct current method, as used by others and with certain simplifications described below, makes it possible to determine accurate conductivity data over the range of conductivities from pure solvents to highly conducting solutions without the financial expenditures for instrumentation involved in the alternating current method.

EXPERIMENTAL

As indicated above, in the direct current method, polarization of the probe electrodes has to be minimized. In this, a great deal depends on the nature of the instrument used to measure the ratio of the voltages of the electrolytic cell and the metallic resistance in series with it. If the voltage measuring instrument is to be used as an absolute one, a potentiometer will give accurate measurements but this entails having the probe electrodes of such a nature that no variable polarization will occur during the course

of the measurement. The choice of an electrometer which has an infinite resistance will have a determining advantage, as no polarization of the probe electrodes can occur owing to the infinite resistance of this electrometer. The employment of the obsolescent quadrant electrometer, which was used as a first choice of this type of instrument, is described in some detail. There the four metallic electrodes can be used.

Before going on to a detailed description of this electrometer it might be well to discuss the probe metallic electrodes. As indicated, tin electrodes were considered to be of considerable interest. When these were made by molding pure tin metal in wooden molds they were found to show an insignificant difference of potential when immersed in an aqueous solution of an electrolyte; small as this potential was it also showed no measurable variation with time and concentration of electrolyte. This potential difference, as will be elaborated on later, did not affect experimental observations. With platinum electrodes made out of foil or wire this difference in potential between two such electrodes immersed in a solution of an electrolyte was measurably large (0.1 volt), and was variable to the extent of 0.01 volt under certain experimental conditions; as the over-all voltage on the electrometer was 20 volts, the variation of 0.01 volt meant the accuracy would only be 1 part in 2000. However, if instead of platinum electrodes, platinum black electrodes are used, the difference of potential between two such electrodes in a solution containing an electrolyte is very much less, and therefore any variation in the accuracy attained is diminished. The same concept applies to any other electrodes that are used inasmuch as the probe electrodes must be made as uniform as possible, physically and chemically. Sample data for tin and platinum black electrodes are given after the description of the use of the quadrant electrometer as the measuring instrument in the direct current method.

The quadrant electrometer was originally designed as an instrument for the direct measurement of voltages and it must be kept in mind that in this work the quadrant electrometer is used as a null instrument comparing equal voltages. It then becomes an instrument giving a very high degree of precision, with which an accuracy of 1 in 10,000 can be obtained under our experimental conditions when the over-all voltage measured is 20 volts, which can be considerably enhanced with higher voltages. In using the quadrant electrometer to attain such accuracy it is important that measurements be made quickly to avoid drift owing to external electrostatic charge environment and to avoid any hysteresis effect in the suspension of the electrometer should it be subjected to sudden major changes. To countervene these effects a setup was arranged in such a way that the voltage on the electrometer was maintained continuously, except for the fractional second interval in which a double pole switch was manipulated so that small changes in the metallic resistance could be made. These only affected slightly the needle position as reflected on the scale, and were made to bring the null point register of the cell and the resistance box together.

Now for a detailed description of the experimental outlay. Referring to Fig. 1, the resistance R_1 is adjusted until it equals the cell resistance and the electrometer reading does not change when the alternating switch D is placed across the probe electrodes A,A of the cell or the resistance R_1.

An image from a Leeds and Northrup galvanometer lamp was focused on the electrometer, which was set up on a Julius suspension. The image was in turn projected onto a scale calibrated in millimeters placed 4 meters from the electrometer. A telescope was focused on this image making possible a detection of 1 part in 10,000 when a 45-volt dry cell was used in the circuit giving approximately 20 volts across the electrometer.

The electrolytic cell was placed in a water bath, the temperature of which was con-

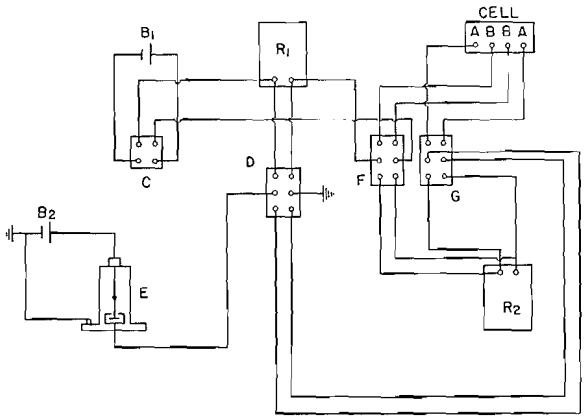

FIG. 1.

trolled to 1/100° C., and the electrodes A,A and B,B were connected. The current flowing from dry cell B_1 through switch C and resistance R_1 passes through the cell. The measurements are then made by alternating switch D from the cell side (probe electrodes A,A) to the resistance R_1 side, and then obtaining a null position on the scale by varying resistance R_1.

The simplest way of maintaining the voltage on the electrometer, and thus maintaining the image on the screen, would be to have a continuous passage of the current through the circuit including the cell. With time, electrolysis would take place owing to this continuous passage of current, although it is greatly reduced by the design of the cell (shown later). To eliminate this, switches F and G are employed, which are double pole, double throw switches connected together and reversed simultaneously. Resistance R_2 is adjusted to the cell resistance and when switches F and G are reversed the current by-passes the cell through resistance R_2. By this means the current passes through the cell only during the time when measurements are being made, which is of the order of less than 1 minute. The voltage is maintained at any time on the electrometer within the fractional second of alternating switches F and G. This makes the quadrant electrometer, with all its disposition to take up vagrant electrostatic voltages, a null instrument of the high degree of accuracy outlined above.

When the sensitivity of the electrometer is arranged to measure a variation of 1 part in 10,000, it is important that no variation in voltage occurs in the circuit during the time required for making measurements. During this time interval it was proved that the voltage of the dry cell remained constant. There remains the question of any inherent voltage between the probe electrodes, which would not affect the measurements, if it remained constant; and as was pointed out previously between tin electrodes prepared as described and between platinum black electrodes, such voltages are insignificant, and therefore no variation could be expected or was found.

Two platinum, tin, or tungsten probe electrodes when freshly cut exhibited a difference of potential in an electrolytic solution and were variable with time and external conditions; where such probes are used the accuracy of conductivity measurements may be reduced to 1 part in 500 under extreme conditions. Platinum electrodes can also be molded and would probably be as effective as molded tin. With tungsten this cannot be done, but still for most purposes where the nature of the electrolyte requires tungsten (aqua regia solutions) a sufficient degree of accuracy for the purpose of the measurements can be obtained.

CELL

In Fig. 2 the design of the cell is shown. A,A are the probe electrodes and B,B are the current carrying electrodes, all of which are made of pure tin as previously described, or of platinum black (not shown in the diagram). In this arrangement advantage is taken of the work of Ives (6) to ensure that the physical position of the probe electrodes will not affect the cell constant. The bulbs C,C below the current carrying electrodes are to ensure that any slight change in concentration due to electrolysis around the current carrying electrodes would not permeate into the main body of the cell where the conductivity is being measured. In this connection it may be recorded that it was found that over a period of 5 minutes during which a continuous current was passed through the cell, no measurable changes in resistance due to such electrolysis were found to occur. This time factor is very much below that which is involved in making our measurements.

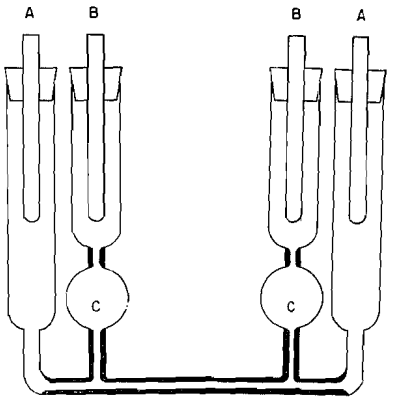

FIG. 2.

PREPARATION OF SOLUTIONS

Three solutions, 0.1, 0.05, and 0.01 *N* in potassium chloride, were made up by volume using reagent grade potassium chloride and taking all the experimental precautions which are normally taken to ensure the accuracy of the concentration. Corrections for temperature and volume showed that the solutions used had actual concentrations of 0.09990, 0.049950, and 0.009990 *N* potassium chloride. The data for aqueous potassium chloride conductivity have been well established by Shedlovsky (9) and the cell constants were calculated in the usual way using these data.

RESULTS

When the quadrant electrometer system, as outlined above, was used to measure a known metallic resistance in place of the electrolytic cell, an absolute accuracy of 1 part in 10,000 was obtained over a considerable range of resistance. The test consisted of having someone set the resistance box (replacing the cell) at a definite resistance and then having the observer make a measurement. At first, some difficulty was encountered in attaining this degree of accuracy when the electrolytic cell (replacing the metallic resistance) was measured. However, when the probe electrodes were conditioned as described, the same degree of accuracy was attained as in the measurement of the metallic resistance. It now remains to tabulate a sample set of experimental observations, which

confirm the claim that the particular experimental procedure involving probe and current carrying electrodes made of any desired material will give results to a high degree of accuracy.

In Table I are given the data which have been corrected for the conductivity of the solvent (water). This was measured conveniently by the direct current method employing a cell having a very much lower cell constant than the one used in this work. This was accomplished by using a glass tube between the probe electrodes 50 times larger in diameter than the one illustrated in Fig. 2, which was 2-millimeter capillary tubing.

It can be seen that with tin electrodes an accuracy of 1 part in 7000 and with platinum black electrodes of 1 part in 5000 was attained.

DISCUSSION

The authors believe that an even higher degree of accuracy by the method described can be obtained if more accurate measurements are made of the conductivity of the solvent. This conductivity depends on the time that the electrolytic solution used as a standard is in contact with glass containers. A teflon cell can and has been used in certain experiments, and it is considered that if the standards are made up in teflon containers it will be possible to get reproducible results to even better than 1 part in 10,000. Taking the 0.09990 and the 0.049950 *N* solutions as in Table I, it is seen that a very high degree of relative accuracy is attained.

The accuracy required by the investigator is dependent on the fact that an accurate determination of the solvent conductivity will be of greater importance when solutions of 0.009990 *N* are used.

Instead of using a quadrant electrometer, which embodies the requirement of having an infinite resistance, a more simple device can be used. This consists of a charged metallic fiber subject to displacement between two electrodes leading to alternately the probe electrodes and the metallic resistance in series. The first electrometer of this nature showed it was possible to make null measurements giving an accuracy of 1 part in 1000. It is considered that this accuracy can be considerably enhanced by changing the dimensions involved in this instrument, and a study of this is underway.

THE PHOTOLYSIS OF METHYL CYANIDE AT 1849 Å[1]

D. E. McElcheran,[2] M. H. J. Wijnen,[3] and E. W. R. Steacie

ABSTRACT

The photolysis of MeCN has been investigated under a considerable range of conditions and a mechanism proposed which accounts satisfactorily for the products found, viz. H_2, HCN, C_2N_2, CH_4, C_2H_6, C_2H_5CN. Two primary processes occur

$$CH_3CN \rightarrow H + CH_2CN$$
$$CH_3CN \rightarrow CH_3 + CN$$

of which the former is apparently the more important. HCN is formed predominantly by an H atom abstraction of the CN group which is believed to occur through addition to the unsaturated bond with the formation of an unstable imine radical. This and similar intermediates formed by other radicals are proposed to account for several anomalies found in the photochemistry of nitriles.

A brief investigation of the photolysis of carbonyl cyanide is reported.

INTRODUCTION

The photochemistry of the nitriles has received very little attention, undoubtedly because the nitriles are generally transparent well into the Schumann region. Certainly no direct photolysis of a nitrile has been reported previously in the literature beyond a simple spectrographic investigation of MeCN and EtCN by Terenin and Neujmin (1), who established the presence of excited CN radicals in the far ultraviolet photolysis of these molecules and concluded that excitation is followed by dissociation of the carbon–carbon bond. The possibility of a system of CN reactions parallel to those of CH_3 in which HCN and C_2N_2 would be formed in an analogous manner to the well-known methane- and ethane-forming reactions of CH_3 was of considerable interest when we undertook the present work. In view of the unsaturated nature of the CN group this conjecture was quite unjustified and the reaction proved to be considerably more complex and unusual.

EXPERIMENTAL

The ultraviolet absorption of MeCN lies entirely within the Schumann region. The 1849 Å mercury resonance line roughly coincides with the long-wave edge of a band which occurs between 1600 Å and 1800 Å (Platt and Klevens (2)). Although this marginal absorption is unfortunately weak, the mercury arc conveniently compensates by providing a relatively intense light source. The decisive advantage of the mercury arc, however, proved to be the reasonably high transparency of fused quartz to 1849 Å, which allowed the use of a conventional quartz cell; this is an important consideration because of the accumulation of polymer in the MeCN photolysis. The only effective method of removing this obscuring deposit was by heating the cell to red heat in the presence of oxygen.

The use of the 6^1P_1 mercury resonance line, of course, necessitates the complete absence of mercury vapor from the reaction cell, and a mercury-free system employing an oil

diffusion pump backed by a previously unused Welsh Duoseal pump was provided for the reagents and cell. The problem of transferring the reaction products to the analysis train, a separate mercury-containing vacuum system, was solved very satisfactorily by bridging the two lines with a small single-stage diffusion pump operating continuously with stable, inert Dow 703 silicone oil. The effectiveness of this arrangement in preventing back-diffusion of mercury vapor and the subsequent contamination of the reaction system was variously proved. At regular intervals both ethane and MeCN were illuminated with the 2537 Å resonance line using a Corning 7910 filter to cut off 1849 Å; at no time during the investigation was the mercury-photosensitized production of H_2 detected even after an illumination period of several days. The efficiency of the transfer diffusion pump in preventing back-diffusion was exhibited more directly, perhaps, by the complete lack of absorption of 1849 Å in the evacuated cell when the bridge section between the cell and the mercury system was opened. It should be emphasized that such drastic measures are necessary if a mercury-free system is to be obtained. The conventional use of gold foil as a mercury trap is almost totally ineffective. It is our experience that if mercury vapor has ever entered a vacuum system it can never be completely removed.

The reaction cell was the usual cylindrical quartz vessel, 15 cm. long and 252 cc. volume, mounted centrally in a split aluminum block furnace and attached to the vacuum line through a quartz–pyrex graded seal. A low pressure mercury arc, shaped into a flat spiral of somewhat greater diameter than the cell, was sealed into one end of the furnace with a solid plug of asbestos so that maximum intensity could be obtained by operating in a stream of nitrogen (to avoid absorption by oxygen). For this purpose, liquid nitrogen was boiled at a controlled rate from a 3-liter Dewar flask by an immersion heater. The cool gas was introduced into the furnace from behind the lamp, cooling it and incidentally helping to balance the temperature gradient caused by the lamp. The 1849 Å intensity is increased in this way by as much as a factor of 10, perhaps partly because of the efficiency peak of this type of lamp at about 55° C. Collimation was impracticable and for optimum operating conditions the lamp was spaced about 5 cm. from the cell window. The cell temperature, controlled through a 10-amp. Variac auto transformer operating from a Sorensen voltage stabilizer, was uniform to within 2° and stable to ±2° over long periods of time. Cell pressures were measured by a null point quartz spiral manometer with a mercury manometer reference accurate to ±0.5 mm.

The analytical line consisted of mercury cutoffs throughout with the exception of the bridge connection from the reaction cell which was isolated by a stopcock and led directly into a U-trap, which in practice was cooled with liquid nitrogen whenever the bridge stopcock was open, although it was shown that the oil diffusion pump was effective by itself in preventing mercury from diffusing into the mercury-free line. Two Leroy stills and a solid nitrogen trap followed the U-trap to effect fractional distillation of the products, which were pumped into the gas burette by a small two-stage mercury diffusion pump. The burette, which was stopcock-free, could be evacuated through cutoffs by either of two Töpler pumps, one for cycling the products through hot CuO and the other for filling sample tubes for mass spectrometric analysis. The CuO was maintained at 570° C. in a fused silica U-tube in order to oxidize methane to CO_2. At this temperature the methane oxidation rate was very slow, taking 12 hours to effect completion, while hydrogen was almost instantaneously oxidized with negligible attack on methane. This procedure permitted the convenient analysis of a mixture of H_2, CH_4, and N_2 with high accuracy as proved by standard mixtures. Dead space was kept to a minimum by using capillary tubing for the U-trap and connecting tubing. Higher CuO temperatures must be avoided to prevent O_2 production.

Methyl cyanide was treated with KOH to remove traces of HCN, distilled into the mercury-free line through P_2O_5, the middle third being preserved in a stopcocked reservoir, and thoroughly outgassed. A clean mass spectrum was obtained, but as a further precaution a sample of the MeCN was fractionated from a Leroy still into three samples which were compared on the mass spectrometer; no significant difference in the three spectra was observed.

The runs were carried out with maximum light intensity rather than constant absorbed intensity, since the intensity was generally so low that illumination periods ranged from 4 to 20 hours. Even in the longest runs less than 5% conversion of MeCN occurred. The gaseous products were identified by the mass spectrometer as HCN, C_2H_5CN, H_2, C_2N_2, CH_4, and C_2H_6 with traces of C_2H_2, C_2H_4, and C_3H_8. Of other possible products, N_2 and NH_3 were specifically sought but never detected within our range of conditions.

The products were separated by low temperature fractionation into three distinct fractions:

(1) H_2 and CH_4 were collected as the volatile fraction at $-210°$ C. and subsequently analyzed by CuO at 570° C. at which temperature H_2 was oxidized and determined by difference in a single pass. CH_4 was determined as CO_2 after 12 hours in contact with CuO as a check against the presence of N_2. The CO_2 invariably reproduced the CH_4 measurement to within 0.5%; N_2 was not observed.

(2) C_2H_6 containing only traces of C_2H_4 was usually checked by the mass spectrometer.

(3) HCN and C_2N_2 were collected together for mass spectrometric analysis by distillation from the first Leroy still at a bottom temperature of $-80°$ C. through the second Leroy still at $-100°$ C. To ensure complete collection, distillation was continued well into the MeCN fraction. C_2H_5CN was always evident on the mass spectrum as it came over with the MeCN. Although it was shown to be a major product, approximately 80% of HCN concentration, satisfactory separation was not practical.

The results of a series of runs over a pressure range of 26 mm. to 300 mm. and temperatures from 55° C. to 300° C. are expressed as rates of formation in Table I.

In addition to the gaseous products some unidentified solid remained on the cell walls, except at the highest temperatures, in sufficient quantity to decrease the light intensity by as much as 20% by the end of the run. It proved necessary to burn the polymer from the cell walls by introducing air or oxygen after each run and this prevented the use of a more efficient assembly of combined lamp and cell. Furthermore it restricted experiments to a normal quartz cell and made it impracticable to use thin sucked-in windows, thus preventing investigation at shorter wavelengths.

The CO_2 formed by total combustion of the solid residue was found to be roughly equal to twice the HCN formed in the reaction; incidentally, no observable pressure change occurred during any of the runs; hence it appears likely that the solid product is largely dinitrile. Certainly little polymerization of MeCN takes place.

Accurate quantum yields were virtually impossible to obtain since I_{ab} is almost immeasurable and the incident intensity is unstable over long periods. However, using N_2O as an actinometer, ΦHCN was shown to be of the order of unity. Intensity studies suffered similarly in crudity, yet the most reliable results obtained (Fig. 1) show clearly that

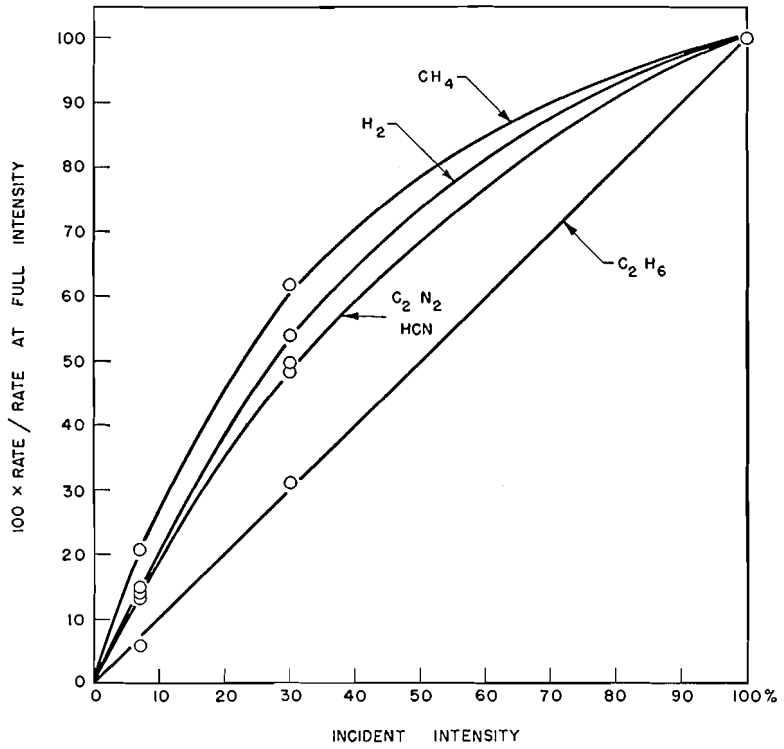

FIG. 1. Effect of intensity on formation of products.

$R_{C_2H_6}$ varies linearly with I_{ab}, in a quite different manner from the behavior of R_{HCN}, $R_{C_2N_2}$, R_{CH_4}, and R_{H_2} which are more nearly proportional to $\sqrt{I_{ab}}$. (The incident intensity is used in Fig. 1. In view of the weak absorption, however, it is strictly proportional to the absorbed intensity.)

Some experiments were made to investigate the part played by H atoms in the MeCN photolysis. H_2S and D_2S were photolyzed in the presence of MeCN using the 2537 Å region of a Hanovia S500 lamp. The mercury photosensitized decomposition of H_2 and D_2 in the presence of MeCN was also carried out in an auxiliary cell on the mercury system using the 2537 Å resonance line isolated from 1849 Å by a Corning 7910 filter. Incidentally, little direct photosensitized decomposition of MeCN occurs although the quenching cross-section is comparable to that of H_2. In both cases, all the products of the direct photolysis were found with the significant exception of C_2N_2. A material balance showed that $R_{HCN} = (R_{CH_4} + 2R_{C_2H_6})$ to within 5%, which can be accounted for only by a reaction such as

$$H + CH_3CN \rightarrow HCN + CH_3,$$

a conclusion reached also by Forst and Winkler (3).

DISCUSSION

At 1849 Å two primary processes are energetically possible:

$$CH_3CN \rightarrow CH_3 + CN,$$
$$CH_3CN \rightarrow H + CH_2CN.$$

From the nature of the products it is evident that all four radicals are involved in the reaction mechanism. Only CH_2CN would normally be expected to arise from secondary reactions as a result of H abstraction from the parent molecule; however in the present system CH_3 radicals have been proved to be liberated by an H atom attack on MeCN to form HCN.

$$H + CH_3CN \begin{cases} \nearrow H_2 + CH_2CN \\ \searrow HCN + CH_3 \end{cases}$$

On the other hand neither H atoms nor CN radicals are accounted for by secondary reactions and must be primary species. The absence of C_2N_2 in the H atom sensitization of MeCN precludes the third possibility of H atom interactions:

$$H + CH_3CN \not\rightarrow CH_4 + CN.$$

Theoretically this type of reaction is most unfavorable, since it involves the attack of a highly shielded atom and although it has been recently invoked in the reaction

$$CH_3 + CH_3COCF_3 \rightarrow C_2H_6 + COCF_3$$

(Ref. (4)), our observations are consistent with the current view. The 'abstraction' of the CN group on the other hand almost certainly results from the addition of an H atom to the group with its easily accessible π-bonds, to form an unstable imine radical. Bentley and Wijnen (5) observed a similar reaction with CH_3 radicals and in the present work there is positive evidence of the formation of C_2N_2 by 'abstraction'. It is therefore evident that the reaction is not limited to H atom attack but is of more general occurrence:

$$R + MeCN \begin{cases} \nearrow RCN + CH_3 \\ \searrow RH + CH_2CN \end{cases}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

Both primary processes are important in the photolysis of MeCN, although the evidence favors the predominance of a C—H split. It is impossible to arrive at a unique mechanism on the basis of the information available, but the following mechanism appears reasonable and is in general agreement with the facts:

$$CH_3CN \xrightarrow{\phi' I_{ab}} H + CH_2CN$$

$$CH_3CN \xrightarrow{\phi'' I_{ab}} CH_3 + CN$$

$$H + CH_3CN \rightarrow HCN + CH_3 \quad [1]$$

$$H + CH_3CN \rightarrow H_2 + CH_2CN \quad [2]$$

$$CN + CH_3CN \rightarrow C_2N_2 + CH_3 \quad [3]$$

$$CN + CH_3CN \rightarrow HCN + CH_2CN \quad [4]$$

$$CH_3 + CH_3CN \rightarrow CH_4 + CH_2CN \quad [5]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [6]$$

$$CN + CN + M? \rightarrow C_2N_2 + M? \quad [7]$$

$$CH_3 + CH_2CN \rightarrow C_2H_5CN \quad [8]$$

$$CH_3 + R \rightarrow CH_4 + M \quad [9]$$

$$CH_2CN + CH_3CN \rightarrow CNCH_2CN + CH_3 \quad [10]$$

$$CN + CH_2CN \rightarrow CNCH_2CN \quad [11]$$

$$CH_2CN + CH_2CN \rightarrow CNCH_2CH_2CN \quad [12]$$

Direct evidence for reaction [1] was obtained in the H- and D-atom investigations, as previously mentioned, and we infer from the temperature independence of the ratio R_{H_2}/R_{HCN} (Table I) that the activation energy is very close to that of reaction [2]. It can only be assumed that reactions [3] and [4] are similar in this respect also. The evidence for reaction [3] is somewhat less direct; however, it is apparent that C_2N_2 production does not kinetically parallel that of C_2H_6. The intensity dependence of $R_{C_2N_2}$ is quite different from the linear relationship of $R_{C_2H_6}$ (see Fig. 1) and is more characteristic of abstraction reactions. Furthermore, C_2N_2 production increases with higher temperatures in direct contrast to C_2H_6 production, a fact that can be explained only by a competition between a high temperature reaction [3] and a low temperature combination reaction [7] in the formation of C_2N_2.

The removal of the CN group in reactions [1] and [3] is almost certainly not a true abstraction reaction. Only the π-bonds of the nitrile group are open to radical attack resulting in an unstable excited addition complex which can either split off the CH_3 group or back-dissociate.

$$R + CH_3CN \rightleftarrows \begin{matrix} R \\ \diagdown \\ C{=}N \\ \diagup \\ H_3C \end{matrix} \rightarrow CH_3 + RCN$$

When R is H or CN the forward reaction is exothermic by 10 kcal. and 8 kcal., respectively.

The addition product intermediate, which is an imine radical, apparently has a short lifetime, since no stable imine end product has been detected. It may, however, be a source of methane by reaction [9]. It is evident from the results in Table I that reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

[5] and [6] do not completely describe the methane–ethane relationship. There is a small but real influence of pressure on the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$[MeCN] (Fig. 2) which does not appear in the photosensitization of MeCN with acetone-d_6 carried out by Wijnen (6). The Arrhenius plot of Wijnen's results gives a linear slope of 10 kcal. for the abstraction of H from MeCN. In the direct photolysis a 10-kcal. slope is found only at high temperatures while at 55° C. it has tailed off to only 4 kcal. (Fig. 3). There is some parallel here to the photosensitization of HCN with acetone-d_6 by Eaton and Wijnen (7), in which an abnormally low activation energy was found for H abstraction. Apparently the same intermediate is formed by the addition of CH_3 to HCN as obtains with H and CH_3CN, which must take part in the methane reaction. Since this radical does not break down to form CH_4 and a CN radical, it must act by providing a readily abstractible hydrogen. Further evidence of a radical–radical methane step such as reaction [9] is the marked intensity dependence of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$[MeCN] (Table I) at 55° C. which does not occur at higher temperature.

C_2H_5CN was identified as a product by the mass spectrometer and can be accounted for only by reaction [8], which is analogous to the $C_2H_5COCH_3$-producing reaction in the photolysis of acetone. Reactions [11] and [12] in the absence of direct identification are included in the mechanism as reasonable analogues of the acetone photolysis and of

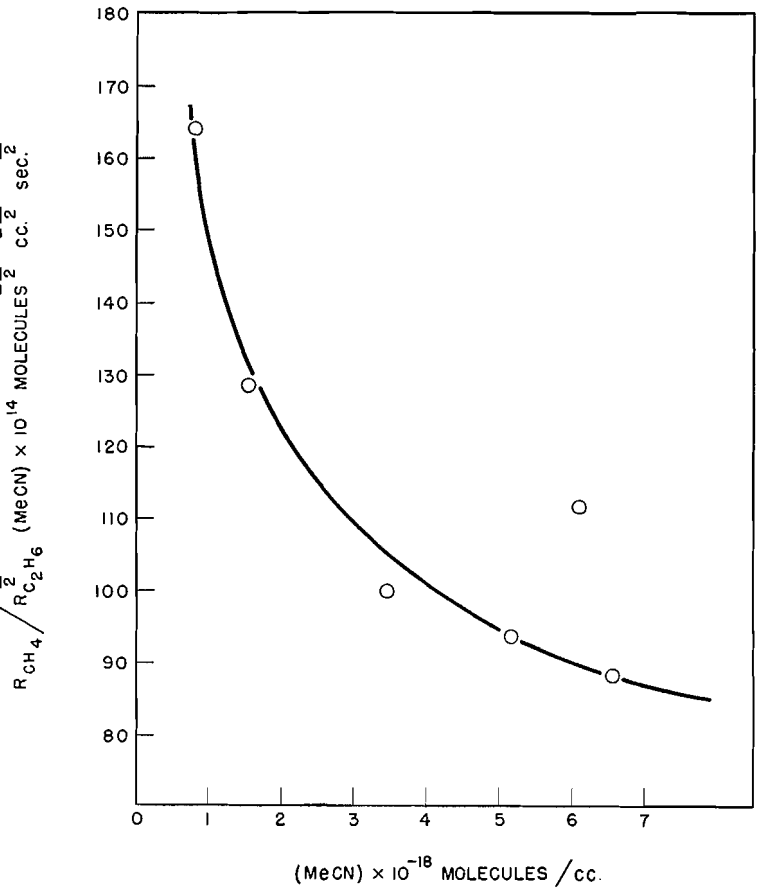

FIG. 2. Effect of pressure on production of methane and ethane. Temperature ~456° K.

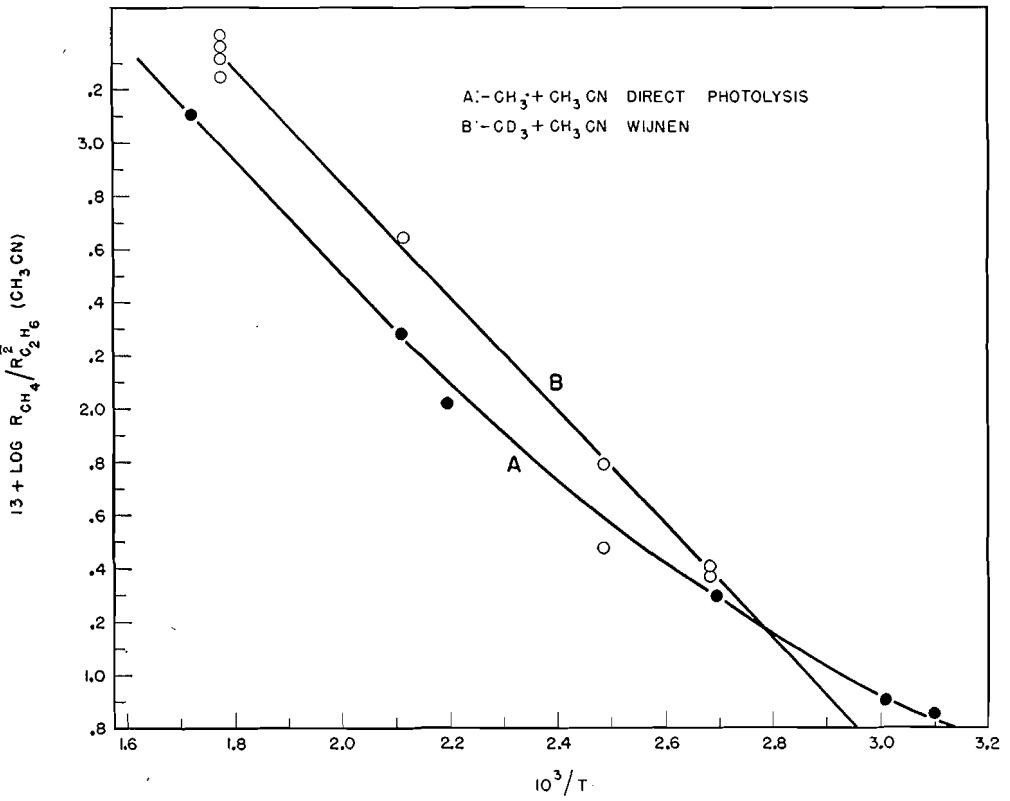

FIG. 3. Arrhenius plot for the reaction of methyl radicals with methyl cyanide.

reaction [8]. However, there is some evidence that much of the deposit on the cell walls is dinitrile. The absence of the deposit in high temperature runs is deemed significant in view of the boiling points of the two nitriles, which are of the order of 250° C. Reaction [10] has been retained for symmetry although it is unlikely to be extensive since the two carbon–carbon bonds in the intermediate would be very similar in strength.

We believe it is of interest to report on some experiments with CNCOCN, which has a similar absorption spectrum to that of acetone and which was available through the kindness of Dr. Leitch of this laboratory. It was an obvious choice as a possible source of CN radicals which would have been very useful in the present investigation. However, there are serious difficulties which render CNCOCN useless as a photosensitizing agent. Very extensive polymerization occurs in photolysis which apparently starts homogeneously since the illuminated volume of the cell becomes almost immediately filled with a fine suspension of particles. Furthermore, CNCOCN apparently undergoes a molecular reaction with water to form 1 mole of CO_2 and 2 moles of HCN. This effect appeared to be virtually inescapable as considerable care had been taken to outgas the vacuum system. C_2N_2 and CO were certainly products of the reaction. However, in view of the difficulties just mentioned, nothing can be stated regarding a mechanism.

The authors are greatly indebted to Dr. K. O. Kutschke for much helpful advice and criticism.

THE LIMITING EQUIVALENT CONDUCTANCES OF AMMONIUM CHLORIDE, AMMONIUM BROMIDE, AND AMMONIUM NITRATE AT 35.00° C.[1]

A. N. CAMPBELL AND E. BOCK[2]

ABSTRACT

The limiting equivalent conductances of ammonium chloride, ammonium bromide, and ammonium nitrate as well as the limiting ionic conductances of the ammonium and nitrate ions were determined at 35° C. with a probable error of 0.05%. The values found were $\Lambda_{0_{NH_4Cl}}$ 180.97 mhos, $\Lambda_{0_{NH_4Br}}$ 182.73 mhos, $\Lambda_{0_{NH_4NO_3}}$ 174.21 mhos, $\lambda_{0_{NH_4^+}}$ 88.73 mhos, and $\lambda_{0_{NO_3^-}}$ 85.48 mhos. These values were obtained by the application of the Shedlovsky method of extrapolation to equivalent conductance data, which had been corrected for the hydrolysis of the ammonium ion.

Observed equivalent conductances of aqueous solutions of ammonium nitrate at 35° C., in the concentration range from 0.0002 *N* to 10 *N*, have been compared with those calculated by means of the Wishaw–Stokes and Falkenhagen–Leist equations. The Wishaw–Stokes equation was found to give better agreement with experiment than the Falkenhagen–Leist equation.

In order to apply the conductance equations of Wishaw and Stokes (1) and of Falkenhagen and Leist (2) to conductance data obtained in this laboratory for ammonium nitrate at 35° C., it is necessary to know Λ_0, the limiting conductance of ammonium nitrate at this temperature, and we therefore undertook to determine it. At the same time, we thought it would be interesting to determine the limiting conductances of the individual ions, viz. NH_4^+ and NO_3^-. This information results at once from the limiting conductance of the salt, if the transference numbers are known. Since, however, no experimental values of the transference numbers of the ions of ammonium nitrate are given in the literature (for 35° C.), we approached the problem by making experimental determinations of the limiting conductances of ammonium bromide and of ammonium chloride. Since the conductances of bromide and of chloride ions are known accurately at 35° C., it was possible to obtain the conductance of ammonium ion and of nitrate ion.

EXPERIMENTAL TECHNIQUE

The technique of measurement of conductance in very dilute solutions has been worked out in great detail, over the years, and it is to be found in works of reference. Nevertheless, some reference to the methods used by us is necessary, if only to prove that the necessary precautions were taken.

A. Purity of Materials

1. Salts

Fisher certified reagents were used; they were recrystallized twice from conductance water, dried at 90° C., and kept over sulphuric acid until needed. The potassium chloride used for cell constants was, in addition, ignited before use. Objection has been made to fusing the potassium chloride on the ground that a minute trace of hydrogen chloride may be expelled from the moist salt, leaving the residue alkaline, but direct testing showed that this did not happen with us.

2. Conductance Water

A good quality distilled water was passed through an Amberlite MB-3 ion exchange column. When the effluent water was exposed to the air, its specific conductance increased,

[1]*Manuscript received September 25, 1957.*
Contribution from the Chemistry Department of the University of Manitoba, Winnipeg, Manitoba.
[2]*Holder of the Comminco Fellowship of the Consolidated Mining and Smelting Company of Canada, to whom we are also indebted for a grant for the expenses of the research.*

rapidly at first and then more slowly, as the water became saturated with carbon dioxide from the air. The final value obtained, for the so-called "equilibrium water" (usually about 1×10^{-6} mhos), was the one used when applying the solvent correction to the observed specific conductances of the solutions, since the solutions were prepared and all measurements made in contact with the atmosphere.

B. Conductance Measurements

1. The Bridge

A Leeds and Northrup Campbell–Shakelton bridge was used, for which the makers claim an accuracy of 0.05%. A tuned telephone headpiece in series with a two-stage resistance-coupled amplifier served as detector; high sensitivity with low power input was thus obtained.

2. The Conductance Cells

Three cells were used, all of the design recommended by Jones and Bollinger (3). The electrodes were lightly platinized. The cell constants varied from 0.55032 to 46.1383.

3. Preparation of Solutions

(*a*) *Concentrations from 0.1 M to 0.005 M.*—A quantity of salt (never less than 2 g.) was weighed to 1/10 mg. The salt was transferred to a pyrex flask of 1-liter capacity, water added to give approximately the desired concentration, and the weight of the solution determined to the nearest 5 mg. All weighings were reduced to vacuum. The density was then determined.

(*b*) *Concentrations from 0.005 M to 0.0005 M.*—Twenty to fifty grams (weighed to 0.1 mg.) of a more concentrated solution were diluted with approximately 1600 g. water. The resulting solution was weighed to the nearest 5 mg., and the normality calculated from the known amounts of salt and water. It was not necessary to know the density at these concentrations, since the density of the solutions is not appreciably different from that of water.

4. Measurement of Equivalent Conductance

The cells were allowed to remain in the thermostat for $\frac{1}{2}$ hour after filling, before commencing the measurements. Readings of conductance were then taken at 5-minute intervals for another $\frac{1}{2}$ hour. For solutions stronger than 0.001 *M*, no change in conductance with time was observed, but with solutions more dilute than 0.001 *M*, as well as with conductance water, a slow but steady increase of conductance with time was observed. For the most dilute solutions the change amounted to 0.02% and for water to 0.1%.

In order to correct for the increase of conductance with time, conductance readings were plotted against time and the curve extrapolated to zero time. The extrapolated value was taken as the "true" conductance of the solution. That this procedure was sound is borne out by the fact that conductance measurements of solutions having identical concentrations showed agreement to better than 0.01%. Moreover, no less than seven determinations of the conductances of potassium chloride solutions, ranging in concentration from 0.001 *M* to 0.0005 *M*, were made and the results compared with those obtained by Gordon (4). The comparison was effected by calculating Λ_0 from the following empirical equation proposed by Gordon, using experimental concentration and conductance data:

$$\Lambda_0 = \Lambda_0' - Bc + Dc \log c. \qquad [1]$$

In all seven instances the values of Λ_0 did not differ from that reported by Gordon by more than 0.04%. In view of the fact that Gordon used a fundamentally different method of measurement (direct current method) and that equation [1] is claimed to represent conductance data to within 0.02 to 0.03%, the agreement obtained is quite satisfactory.

For personal use only.

5. Thermostat

The thermostat was oil-filled and controlled to 0.002° C. Temperature was read on a Beckmann thermometer, which was calibrated periodically against a platinum resistance thermometer.

EXPERIMENTAL RESULTS

The main experimental results are summarized in Table I. The table contains the specific and equivalent conductances and densities of aqueous solutions of ammonium nitrate, of ammonium chloride, and of ammonium bromide at 35.00° C.

DISCUSSION OF RESULTS

Any attempt at direct determination of degree of accuracy, as apart from reproducibility, is exceedingly laborious and, in the end, the figure arrived at is always somewhat doubtful. We thought it better, therefore, to estimate our accuracy by comparing our results for the limiting conductances of potassium chloride at 25° C. and at 35° C., and for ammonium chloride at 25° C., with the values reported in the literature. These salts were chosen because their limiting conductances have been determined by highly reputable workers, who claim an experimental accuracy of 0.01%.

For the limiting conductance of potassium chloride at 25° C., Shedlovsky (5) reports a value of 149.85 mhos. Our determination gave 149.90 mhos; the discrepancy is 0.05 mhos or 0.03%. Gordon (4) obtained 180.42 mhos for potassium chloride at 35° C.; we obtained (for the limiting conductance) 180.45 mhos, a difference of 0.03 mhos or 0.02%. Finally, Longsworth (6) quotes a Λ_0 value of 149.90 mhos for ammonium chloride at 25° C. We found 149.93 mhos, a difference of 0.02%. It seems, therefore, that we may reasonably claim an accuracy of at least 0.05% in our experimental work. This claim is further supported by the fact that the difference between the limiting conductances of ammonium bromide and ammonium chloride, as determined by us, is equal, within 0.03%, to the difference between the literature values of the limiting conductances of the bromide and chloride ions.

For the determination of Λ_0, the plot of Λ against $\sqrt{c}$ proposed by Kohlrausch (7) is one of the best methods. The main difficulty in applying this method lies in the fact that the conductances of extremely dilute solutions are required (from 0.002 N to 0.0001 N) and these are difficult to measure accurately. An alternative method for the evaluation of Λ_0 was suggested by Shedlovsky (5). If the function $\Lambda_0' = (\Lambda+\alpha\sqrt{c})/(1-\beta\sqrt{c})$, where α and β are the Debye–Hückel constants, is plotted against c, the concentration, a straight line is obtained. The correct value of Λ_0 is then derived by extrapolating to zero concentration. Some exceptions to the Shedlovsky rule, however, have been observed. Thus, the function Λ_0' for the alkali nitrates and iodates and silver nitrate passes through a minimum at a concentration of about 0.005 N; this vitiates the use of the function for the determination of Λ_0 for these salts and the Kohlrausch method must be employed. The chief advantage of the Shedlovsky method lies in its applicability to a far wider concentration range than the Kohlrausch method. Whereas the latter is limited to an upper concentration of 0.002 N, the former holds up to 0.1 N. Thus, not only does the Shedlovsky method provide a wider working range but it also enhances the accuracy of determination of Λ_0, since measurements at higher concentrations are less subject to error than those at lower concentrations.

The three salts investigated (ammonium bromide, ammonium chloride, and ammonium nitrate) are hydrolyzed in aqueous solution. It was therefore necessary to apply a so-called hydrolysis correction to the experimentally determined equivalent conductances. Since the essence of the hydrolysis of ammonium ion is the replacement of ammonium ions by hydrogen ions, the conductance of the solution is increased and the increase will be the more significant the more dilute the solution. There may be some difference of opinion as to what constitutes the limiting equivalent conductance of a hydrolyzable salt but we define it as the limiting equivalent conductance derived from equivalent conductance measurements which have been corrected for hydrolysis.

The hydrolysis correction may be determined by two different methods. One method, which has been employed by McInnes and Shedlovsky (8) in their determination of the limiting conductance of the acetate ion, consists in measuring the conductance and pH

of a buffered solution. The second method, used in this work, consists in calculating x, the degree of hydrolysis, from the known value of the hydrolysis constant, i.e.,

$$x = -K_h/2c + \sqrt{[(K_h^2/4c^2)+(K_h/c)]}, \quad [2]$$

where K_h is the hydrolysis constant and c the stoichiometric concentration of the salt before hydrolysis. From x, the "true" conductance of the solution may be calculated as follows: the conductance of 1 g-equiv. of a hydrolyzed salt is made up of the conductance of $(1-x)$ equivalents of unhydrolyzed salt and x equivalents of free acid, i.e.,

$$\Lambda = (1-x)\Lambda_{corr} + x\Lambda_{0_{HA}}. \quad [3]$$

In this equation, Λ is the observed equivalent conductance of the solution, Λ_{corr} is the "true" equivalent conductance of the unhydrolyzed salt, and $\Lambda_{0_{HA}}$ is the equivalent conductance of the free acid in the salt solution. From equation [3] the "true" equivalent conductance of the unhydrolyzed salt follows as

$$\Lambda_{corr} = (\Lambda - x\Lambda_{0_{HA}})/(1-x). \quad [4]$$

$\Lambda_{0_{HA}}$ is assumed to be equal to the limiting conductance of the free acid.

The value of K_h, the hydrolysis constant, was calculated by means of the following formula, due to Bates and Pinching (9):

$$-\log K_h = A_1/T - A_2 + A_3T. \quad [5]$$

From the given values of the constants A_1, A_2, and A_3 and by inserting the appropriate value of T, viz. 308.16° K., the value of K_h for ammonium ion at 35.00° C. was found to be 1.012×10^{-9}. The values of Λ_0 for hydrochloric and hydrobromic acids were obtained from the literature (10, 11), while that of nitric acid was obtained by adding the limiting conductance of the nitrate ion, as determined by us, to the value of the limiting conductance of the hydrogen ion.

In Table II are summarized the degrees of hydrolysis and the observed and corrected equivalent conductances for the aqueous solutions of the three salts investigated. Also incorporated in this table are the values of the Shedlovsky function Λ_0' derived from the observed and from the corrected equivalent conductances.

The limiting conductances, Λ_0, of the three salts were determined by using both methods of extrapolation described above, and employing observed and corrected equivalent conductances in each case. It was observed that the function Λ_0' obtained from uncorrected equivalent conductance data passed through a minimum but, when corrected equivalent conductances were used, the minimum disappeared. It is our opinion that the increase in Λ_0' with increase in dilution observed in the low concentration region when uncorrected values are used is (in these cases) a direct consequence of hydrolysis. We also believe that the Shedlovsky method for the evaluation of Λ_0 is applicable to all three salts investigated, provided the hydrolysis effect is taken into account.

The values of the limiting equivalent conductances for the three salts at 35° C., derived from the application of the Shedlovsky extrapolation method to the corrected equivalent conductances, as well as the mean deviation of the function Λ_0' from the straight line obtained by the method of least squares, are summarized in Table III.

Application of the Kohlrausch method to observed and corrected equivalent conductances resulted in a straight plot in every case. The mean deviations from the straight line obtained by the method of least squares and the respective limiting conductances at 35° C. are summarized in Table IV. It will be observed that Λ_0 (uncorrected) is appreciably greater than Λ_0 (corrected) and this is undoubtedly due to hydrolysis.

TABLE IV

LIMITING EQUIVALENT CONDUCTANCES DERIVED BY THE KOHLRAUSCH METHOD

Salt	Mean deviation		Λ_0, mhos	
	Corr.	Uncorr.	Corr.	Uncorr.
Ammonium chloride	0.04%	0.04%	180.86	181.47
Ammonium bromide	0.03%	0.03%	182.57	183.34
Ammonium nitrate	0.02%	0.02%	173.99	174.73

A comparison of the corrected Λ_0's obtained by the two methods of extrapolation shows that the Λ_0 determinations by the Kohlrausch method are in all cases smaller than those by the Shedlovsky method. This discrepancy, amounting to about 0.1%, we believe to be due to a partial "over-correction" of the conductances in the very dilute region. Since the Kohlrausch method depends solely on conductance measurements made in the dilute region it is to be expected that Λ_0 derived by this method will be more affected by "over-correction" and therefore will be somewhat lower than the Λ_0 derived by the Shedlovsky method, which applies to a much wider concentration range. We believe that the over-correction has resulted from the use of too large a solvent correction for the measured specific conductances of the more dilute solutions. The magnitude of the solvent correction is determined by measuring the conductance of the solvent. The solvent used in this research was water saturated with carbon dioxide under its partial pressure in the laboratory atmosphere. The increase in conductance imparted to the water is due to the ionization of dissolved carbon dioxide:

$$CO_2 + H_2O \rightleftarrows H^+ + HCO_3^-.$$

The equation indicates that the ionization (and therefore the conductance of the carbon dioxide) is repressed by hydrogen ions. In dilute solutions, however, hydrogen ions are produced by hydrolysis. Therefore the ionization of the dissolved carbon dioxide is less in the salt solutions than in pure solvent and hence the magnitude of the solvent correction should be less for these solutions than that determined by measuring the conductance of the pure solvent. Since, however, it was impossible to ascertain quantitatively the extent of the decrease in the magnitude of the solvent correction, the full solvent correction had to be applied.

The limiting equivalent conductance of the ammonium ion at 35.00° C. was determined to be 88.73 mhos ±0.05 mho. This represents the average of the two values obtained by subtracting the limiting conductances of the bromide and chloride ions, as determined by Gordon (4), from the limiting conductances of ammonium bromide and ammonium chloride respectively. The limiting conductance of the nitrate ion was then obtained from the limiting conductance of ammonium nitrate. The value thus obtained for nitrate ion at 35.00° C. was 85.48 mhos ±0.05 mho.

It is customary, in the work proceeding from this laboratory, to compare experimental results with the conductances calculated by the equations of Falkenhagen and Leist (2) and of Wishaw and Stokes (1), viz.:

$$\Lambda = \Lambda_0 - \frac{e^2}{3DkT} \cdot \frac{\kappa\Lambda_0}{1+\kappa a} \cdot \frac{q}{(1+\sqrt{q})(1+\kappa a\sqrt{q})} - \frac{\eta e^2 1000\ \kappa}{3\pi c 9(1+\kappa a)10^{11}} \quad \text{(Falkenhagen and Leist)},$$

where the symbols have their usual significance and $q = \frac{1}{2}$, and

$$\Lambda = \left(\Lambda_0 - \frac{B_2\sqrt{c}}{1+B\mathring{a}\sqrt{c}}\right)\left(1 - \frac{B_1\sqrt{c}}{1+B\mathring{a}\sqrt{c}} \times F\right) \text{ (Wishaw and Stokes)},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

where $B_1 = 8.20\times10^5/(DT)^{3/2}$, $B_2 = 82.5/\eta(DT)^{\frac{1}{2}}$, $B\mathring{a}\sqrt{c} = 50.29\mathring{a}\sqrt{c}/(DT)^{\frac{1}{2}}$,

and $$F = (\exp 0.2929\, B\mathring{a}\sqrt{c}-1)/0.2929\, B\mathring{a}\sqrt{c}.$$

The conductances of concentrated solutions of ammonium nitrate at 35.00° C. have been determined by Campbell, Gray, and Kartzmark (12) and the results compared with the results of the Wishaw–Stokes equation in a separate paper (13), but, at that time, they were unacquainted with the Falkenhagen–Leist equation and with the true value of Λ_0 for ammonium nitrate at 35.00° C. We have now recalculated with the Wishaw–Stokes equation, using the true value of Λ_0, and also we have calculated using the Falkenhagen–Leist equation. Results are given in Table V. The Wishaw–Stokes equation was found to give better agreement with experiment than the Falkenhagen–Leist equations. Moreover, the assumed value of 3.0 Å for å, the distance of closest approach of the ions,

is more reasonable than the 2.3 Å required by the Falkenhagen–Leist equation. Spectroscopic indications (14) that the oxygen atoms in the nitrate ion are coplanar with the nitrogen atom and surround the latter at the corners of an equilateral triangle are well supported by electron diffraction data (15). It is, therefore, not unreasonable to suppose that the distance of closest approach of the ammonium and nitrate ions is somewhat smaller (e.g. 3.0 Å) than the value of 4.0 to 6.0 Å usually encountered with ions known to be spherical, e.g., Li^+, K^+. Even, however, if the nitrate ion is assumed to have spherical shape, the distance of 3.0 Å is still less than the sum of the crystallographic radii of the ammonium ion (1.48 Å) and the calculated radius of the nitrate ion (1.34 Å).

(−)-HOMOSTACHYDRINE, A NEW ALKALOID ISOLATED FROM THE SEEDS OF MEDICAGO SATIVA L. GRIMM[1]

GERHARD WIEHLER[2] AND LÉO MARION

ABSTRACT

The seeds of *Medicago sativa* (alfalfa) have previously been shown to contain other bases besides stachydrine. One of these bases has now been isolated and found to be a homologue of stachydrine for which the name homostachydrine is suggested. (−)-Homostachydrine is shown to be identical with the (−)-methyl betaine of pipecolic acid. The synthetic racemate of the betaine of pipecolic acid has similar properties to homostachydrine, and their infrared spectra and X-ray powder diagrams are identical.

In the course of a recent study of the biogenesis of stachydrine in *Medicago sativa* L. Grimm (alfalfa), Leete, Marion, and Spenser (1) observed the presence of three unknown bases. Paper chromatography has now revealed that one of these unknown bases accompanies stachydrine through all stages of its isolation from the plant. Chromatography of the reineckates of stachydrine and this unknown base over alumina or of the bases themselves on ion-exchange resins failed to effect any separation. This behavior indicates that the new base is probably closely related to stachydrine. In the course of further experiments on the biogenesis of stachydrine, it became obvious that neither Steenbock (2), who first showed the presence of stachydrine in alfalfa, nor any of the later investigators (3) were dealing with pure stachydrine, but with a mixture.

Since our biogenetic studies with alfalfa involved feeding substances labelled with C^{14} to the growing plant and resulted in the formation of radioactive stachydrine (4), it was deemed necessary to separate the unknown base from the stachydrine and to study its structure.

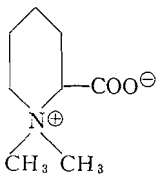
Originally it had been assumed that the unknown base might be betonicine or turicine (1), but this assumption had to be abandoned, since neither of these methyl betaines of hydroxyproline[3] produced a purple spot with Dragendorff's reagent on a paper chromatogram, whereas the unknown base did, and since a hydroxyl base should separate readily from stachydrine on an alumina column.

The unknown base was more abundant in the seeds than in the leaves of alfalfa, and therefore a mixture of the unknown base and stachydrine was isolated from the seeds by a slight modification of the known procedure (1). The crystalline colorless mixture of the hydrochlorides of the bases (m.p. 212–214° decomp.) dissolved in Munier's Bc 20 solvent[4] (5) was chromatographed on a column of cellulose powder and eluted with the same solvent. In this solvent system the unknown base showed a higher R_F value than stachydrine and was eluted first. The first fractions of the eluate yielded the analytically pure hydrochloride of the new base (m.p. 216–217° decomp.) while the following fractions contained a mixture of the hydrochlorides of the new base and stachydrine. The new base hydrochloride yielded analytical figures corresponding to the empirical formula $C_8H_{15}O_2N.HCl$, which is that of a homologue of stachydrine hydrochloride ($C_7H_{13}O_2N.HCl$), and it is proposed to designate it homostachydrine.

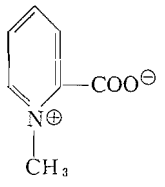
[1]*Manuscript received October 25, 1957.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4580.
[2]*National Research Council of Canada Postdoctoral Fellow 1956–1957.*
[3]*Samples of betonicine and turicine were given to us by Dr. B. Witkop, National Institute of Health, Bethesda, Maryland, to whom we are most grateful.*
[4]*Consists of a mixture of n-butanol, concentrated hydrochloric acid, and water, in the proportions of 100 ml.: 20 ml.: 39 ml. respectively.*

The specific optical rotation of homostachydrine hydrochloride in absolute ethanol was $[\alpha]_D$ $-13.3°$ while that of pure stachydrine hydrochloride in the same solvent was $[\alpha]_D$ $-22.2°$. Stachydrine isolated from *Galeopsis grandiflora* Lam. (6) and *Citrus aurantium* Amar. (6) appears, from the rotations reported for the hydrochloride, to have been pure since these were in agreement with the rotation of synthetic (−)-stachydrine hydrochloride (7). Steenbock (2), who first isolated stachydrine from alfalfa, reports $[\alpha]_D$ $-20.7°$ in water, which is appreciably lower than the rotation of synthetic (−)-stachydrine hydrochloride ($[\alpha]_D$ $-26.7°$ in water) (7). Since stachydrine isolated from alfalfa is always contaminated with homostachydrine, the low rotation reported by Steenbock was probably not due to racemization as he thought, but to the lower rotation of the homostachydrine, which must have been present because his method of isolation would not have separated the two bases.

Although there existed many possible structures for a homologue of stachydrine, it was thought that one of the most likely structures of homostachydrine would be that of the methyl betaine of pipecolic acid (I). Because of the small quantity of homostachydrine available no degradative experiments were tried, but a synthetic specimen of the



I



II

methyl betaine of pipecolic acid was prepared. Following the procedure of Patchett and Witkop (8) for the preparation of betonicine and turicine, the silver salt of (±)-pipecolic acid was converted to the betaine I by treatment with methyl iodide.

The synthetic (±)-betaine hydrochloride, m.p. 210–211° (decomp.), had the same properties as homostachydrine. On a paper chromatogram it showed the same red-purple spot with Dragendorff's reagent and, within the limits of error, the same R_F value. The infrared spectrum and the X-ray diffraction powder diagram of the synthetic racemate hydrochloride were identical in every respect with those of (−)-homostachydrine hydrochloride. There can be no doubt, therefore, that (−)-homostachydrine is identical with the (−)-methyl betaine of pipecolic acid (I). Attempted resolution of the synthetic racemate with *d*- and *l*-tartaric acids and with *d*-camphorsulphonic acid was unsuccessful.

Although this is the first reported occurrence of homostachydrine, pipecolic acid has been found recently in different plants (9). It has been shown that biogenetically pipecolic acid arises from lysine (10, 11, 12). The occurrence of lysine in alfalfa has been reported (3), and it can be presumed to be the precursor of homostachydrine.

Hoppe-Seyler, who first isolated homarine II from the tissues of *Arca noae* (13), mentions the possibility that it might be formed from lysine. He also assumes that ornithine is the precursor of stachydrine and since the latter occurs with homarine in *Arca noae* (13, 14), he concludes that the two bases are likely synthesized by parallel routes. Since from recent work, however, the pyridine ring does not seem to arise from lysine (15), although this amino acid is the precursor of the piperidine ring (15), it appears most improbable that lysine could be the precursor of homarine.

EXPERIMENTAL

All the melting points determined by us are corrected. The infrared absorption spectra were measured in nujol mulls on a Perkin-Elmer double beam spectrometer model 21B.

Isolation of the Mixture of Stachydrine and Homostachydrine

Air-dried alfalfa seeds (1 kg.) were ground in a Wiley mill and boiled with 70% ethanol (2 l.) for 3 hours. The mixture was filtered and the solid residue extracted twice more by boiling with 70% ethanol (1.5 l.) for 3 to 4 hours. The yellowish-brown filtrates were combined, diluted with water to a volume of 7 l., and treated with lead acetate in the usual way to remove the proteins.

The lead-free filtrate was evaporated to a brown residue (*ca.* 100 ml.), which was boiled with two successive 300-ml. portions of absolute ethanol. The combined alcoholic extract was filtered and evaporated to a brown viscous sirup. This sirup was boiled with two successive 200-ml. portions of absolute ethanol, and the combined ethanolic solutions evaporated to dryness. The residue thus obtained was dissolved in water (150 ml.) and the solution adjusted to pH 8 with dilute ammonia. A 5% reinecke salt solution in methanol was added and the mixture stored in a refrigerator for 16 hours. The precipitate was filtered off, 100 ml. of the reinecke salt solution added to the choline-free filtrate (16), and the liquor acidified with concentrated hydrochloric acid (50 ml.). A pink crystalline precipitate formed immediately, and after 30 minutes it was filtered with suction and washed with *n*-propanol, the yield of crude reineckate being 4.14 g. This crude reineckate was dissolved in acetone (200 ml.), the solution was filtered to remove some insoluble impurity and evaporated to dryness. The residue (3.87 g.) left after evaporation was dissolved in acetone (250 ml.) and the reineckate converted to the chlorides of the bases by the usual method (17) of treatment with aqueous solutions of silver sulphate (1.56 g.) and barium chloride (1.22 g.). The final filtrate obtained was evaporated to dryness. A crystalline residue resulted, which was extracted with hot absolute ethanol (25 ml.), filtered, and the filtrate evaporated to dryness. This process was repeated twice. The final filtrate was evaporated to dryness, the residue (1.28 g.) was dissolved in water (20 ml.), and the betaines precipitated with mercuric chloride (in 20% hydrochloric acid solution). The mercuric salt complex was filtered with suction, washed with the reagent solution, and decomposed with hydrogen sulphide. After filtration, the solution was evaporated to dryness *in vacuo* leaving a residue of 1.13 g. of crystalline colorless base hydrochlorides. These were dissolved in absolute ethanol (15 ml.) and precipitated by the addition of acetone (200 ml.) and ether (300 ml.). The filtered dry precipitate (0.63 g.) consisted of the pure mixture of stachydrine and homostachydrine hydrochlorides, m.p. 212–214° (decomp.).

A paper chromatogram on Whatman No. 1 paper ascending in Munier's Bc 20 solvent (5) showed two red-purple spots after spraying with a modified Dragendorff's reagent (18), R_F 0.48 (stachydrine) and R_F 0.57 (homostachydrine). The specific optical rotation of the mixture is $[\alpha]_D^{26}$ −15.5° (*c*, 1.55 in absolute ethanol).

Separation of Homostachydrine from Stachydrine

"Whatman Standard Grade" ash-free cellulose powder (200 g.) was packed dry into a column, 34 mm. by 530 mm. (19). The column was moistened with Munier's Bc 20 solvent, and a solution of 8-hydroxyquinoline (1.0 g.) in the same solvent (40 ml.) was percolated through the column. It was washed with the solvent for 48 hours, after which it was free of 8-hydroxyquinoline (no color with ferric chloride).

A methanolic solution of 500 mg. of the homostachydrine–stachydrine hydrochlorides was mixed with 10 g. of cellulose powder and dried *in vacuo*. The mixture was then ground in a mortar and conditioned by being kept for some time in an atmosphere of Munier's Bc 20 solvent. In order to indicate the position of the moving solvent front a few drops of a solution of "Orange II" (sodium salt of *p*-(2-hydroxy)-naphthylazo)-benzenesulphonic acid) were added to the top of the column. The conditioned cellulose powder containing the bases was then introduced on top of the wet cellulose column, packed carefully, and moistened with the solvent. The chromatogram was developed by passing Munier's Bc 20 solvent through the column at a rate of flow of 12 ml. per hour. The "Orange II" band reached the outlet of the column after 19 hours, and fractions of 4 ml. were collected by means of an automatic fraction collector. Altogether, 62 fractions were taken, and every fraction was tested by spotting a small amount of the eluate on a filter and spraying with Dragendorff's reagent.

Fraction 38 and all the following ones showed red-purple spots, and chromatography on Whatman No. 1 paper indicated that fractions 38–54 contained homostachydrine exclusively while the later fractions contained both homostachydrine and stachydrine. Fractions 20–54 were pooled and evaporated *in vacuo* to a volume of a few milliliters, water was added, and the evaporation *in vacuo* repeated. The residual yellow liquid was filtered and treated with mercuric chloride as already described above. The homostachydrine hydrochloride obtained after this treatment was crystallized twice from ethanol–ether. It consisted of colorless microprisms, wt. 61 mg., m.p. 216–217° (decomp.), $[\alpha]_D^{26}$ −13.3° (*c*, 1.43 in absolute ethanol). Found: C, 49.61; H, 8.33; N, 7.23; Cl, 18.31. Calc. for $C_8H_{16}O_2NCl$: C, 49.37; H, 8.21; N, 7.45; Cl, 18.29%.

The solubility of homostachydrine hydrochloride is very similar to that of stachydrine hydrochloride. Both salts are readily soluble in water and alcohol, slightly soluble in acetone, and insoluble in ether, petroleum ether, and carbon tetrachloride.

Synthesis of (±)-*Methylbetaine of Pipecolic Acid*

α-Picoline (50 g.) was oxidized with potassium permanganate (20) to α-picolinic acid, which was isolated as the hydrochloride (34 g.), m.p. 213–216° (decomp.). The α-picolinic acid hydrochloride in water was hydrogenated over platinum oxide catalyst as described by Stevens and Ellman (21). The crystalline product, after recrystallization from alcohol–benzene and methanol–acetone, consisted of 19.27 g. of pure (±)-pipecolic acid hydrochloride, m.p. 259–262° (decomp.). (±)-Pipecolic acid hydrochloride (2.58 g., 0.0156 mole) was dissolved in water (6 ml.) and, according to the procedure of Patchett and Witkop (8), silver oxide (6.95 g., 0.03 mole) was added to the solution. After 4 hours, water (4 ml.) was removed by distillation *in vacuo* and methanol (50 ml.) and methyl iodide (3.8 ml., 0.061 mole) were added to the residual mixture, which was warmed gently for a few minutes and then kept at room temperature for 1 hour. Another 3.8 ml. of methyl iodide was added, the mixture refluxed for 2.5 hours, and the precipitate filtered and washed with methanol. The combined filtrate and washings were evaporated *in vacuo* leaving the free base as an hygroscopic oil which was dissolved in absolute ethanol (50 ml.). Hydrogen chloride was passed through the solution, which was subsequently evaporated *in vacuo*. The crystalline residue was dissolved in absolute ethanol, the solution treated with charcoal and filtered, and the filtrate mixed with acetone. (±)-Pipecolic acid methylbetaine hydrochloride crystallized out (1.30 g., 0.0067 mole; yield, 43%), m.p. 208–209° (decomp.). A second crystallization from alcohol–acetone yielded 0.90 g. of the pure hydrochloride, m.p. 210–211° (decomp.). Found: C, 49.71; H, 8.44; N, 7.21. Calc. for $C_8H_{16}O_2NCl$: C, 49.61; H, 8.33; N, 7.23%.

For personal use only.

A chromatogram on Whatman No. 1 paper developed with Munier's Bc 20 solvent showed a red-purple spot (R_F 0.56–0.58) after a spray with Dragendorff's reagent. Under the same conditions (−)-homostachydrine hydrochloride showed a red-purple spot at the same R_F value. The infrared absorption spectra in nujol mulls of both the synthetic hydrochloride and (−)-homostachydrine hydrochloride were identical in every respect, and showed a strong carbonyl absorption band at 1705 cm.$^{-1}$. The X-ray powder patterns were also identical.

ACKNOWLEDGMENTS

We wish to express our gratitude to Dr. Maria Przybylska for preparing the X-ray powder diagrams and Dr. R. Norman Jones and Mr. R. Lauzon for the infrared absorption spectra.

THE PHOTOLYSIS OF AZOETHANE[1]

H. CERFONTAIN[2] AND K. O. KUTSCHKE

ABSTRACT

The photolysis of azoethane at λ 3660 Å has been reinvestigated. The quantum yield of nitrogen formation was found to be dependent on the azoethane pressure and the temperature, indicating collisional deactivation of excited azoethane molecules.

The results confirm the mechanism proposed by Ausloos and Steacie (1). For the activation energy of the addition reaction $C_2H_5+C_2H_5N_2C_2H_5$ a value of 6.0±0.3 kcal./mole has been obtained, assuming a negligible activation energy for the combination reaction of two ethyl radicals.

INTRODUCTION

The formation of nitrogen in the photooxidation of azoethane (2) was found to be greater than expected and dependent on the pressures of azoethane and oxygen, as well as on the temperature.

Weininger and Rice (3) have studied the primary process in the photolysis of azoethane and showed that the quantum yield of nitrogen formation was dependent on the azoethane pressure in a manner which is explicable in terms of an activated molecule intermediate. In their study they made the implicit assumption that the quantum yield was independent of temperature. On the other hand, Durham and Steacie (4) found the quantum yield of nitrogen formation in the photolysis of azoisopropane to be temperature dependent. This suggested that a reinvestigation of the primary process in the photolysis of azoethane would be required in order to be certain of temperature effects for the photooxidation studies.

EXPERIMENTAL

Azoethane was obtained from Merck and Company. It was distilled several times and stored behind a mercury cutoff in a blackened tube. The reaction cell, with a volume of 180 ml., was completely filled with a parallel beam of light. The total reaction cell system, including a cold finger, a magnetically driven stirrer, and connecting tubing, had a volume of 282 ml. The analytical section consisted of a solid nitrogen trap, two Ward stills, a McLeod gauge, a diffusion pump, and a combined Toepler pump and gas burette. The photolysis products were separated as follows: Nitrogen was removed at solid nitrogen temperature; C_2 hydrocarbons were separated at −165° C. and analyzed mass spectrometrically. Butane was removed at −125° C.

A Hanovia S 500 medium pressure mercury arc was used as a light source, together with a Corning filter 5860 which limited the effective radiation to the 3660 Å group of lines. Absorption measurements were made with a photocell coupled to a sensitive galvanometer. At low azoethane concentrations (<0.001 mole/l.) the absorption measurements suffered from lack of precision. In this case the light absorption was calculated from the extinction coefficient, which was estimated from the experiments at higher concentration. For the highest concentration used, about 75% of the light was absorbed. Quantum yield measurements were carried out using a potassium ferrioxalate actinometer (5, 6) according to the procedure modified by Baxendale (5). The experiments were done at room temperature in subdued light. The radiation was completely absorbed by the actinometer. For these conditions, Hatchard and Parker (6) report a quantum yield of 1.21 for the actinometer at λ 3660 Å.

RESULTS AND DISCUSSION

Primary Processes

The light intensity was measured by placing the actinometer cell before and after the reaction cell. In the first position the intensity was found to be 1.64×10^{16} and 1.70×10^{16} quanta/second; in the second position 1.16×10^{16} and 1.00×10^{16} quanta/second. This observed difference appreciably exceeds that accounted for by simple reflections only. Assuming identical absorption and scattering by the front and rear windows of the reaction cell to be the only cause of light loss, a transparency factor $\alpha = 0.85$† per window was calculated from these data. Corrections for this and for first-order reflections from quartz–gas and pyrex–gas interfaces were made for all measurements, applying the general argument of Farkas and Melville (8) to our optical system. The data for the dependence of the nitrogen formation on temperature and azoethane concentration are given in Table I. The molar extinction coefficient E was calculated

from $\ln I/I_0 = -Ecd$. Fig. 1 shows the relation between the quantum yield of nitrogen formation, temperature, and pressure. The accuracy of the actinometer measurements is ±10%. This means that the uncertainty in the $1/\phi$ scale is ±10%. It should be recognized, however, that the uncertainty in the $1/\phi$ values relative to each other is much less than this.

The mechanism proposed by Weininger and Rice (3) represents the results satisfactorily:

$$A + h\nu \rightarrow A^*, \quad [1]$$

$$A^* \rightarrow N_2 + 2C_2H_5, \quad [2]$$

$$A + A^* \rightarrow 2A, \quad [3]$$

†*This* α *corresponds to* $1-A$ *of Hunt and Hill* (7).

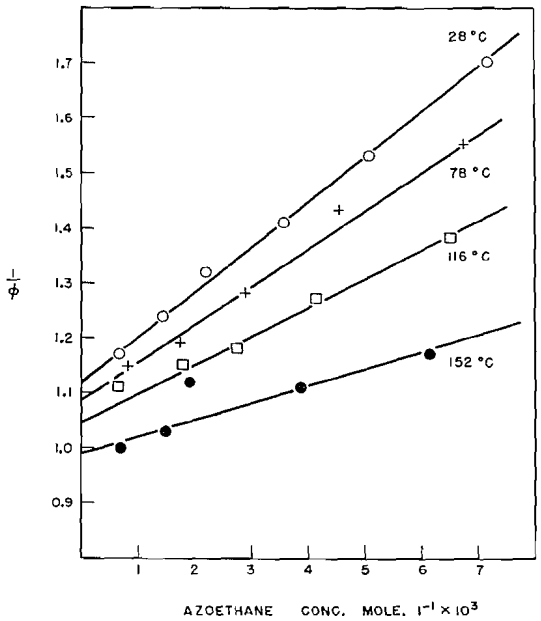

FIG. 1. Effect of pressure on reciprocal quantum yield of nitrogen formation from azoethane.

where A* represents an excited azoethane molecule. From a steady state treatment of the excited azoethane molecules, the following relation may be deduced:

$$1/\phi = 1+(k_3/k_2)\,|A|, \qquad [4]$$

where ϕ represents the quantum yield of nitrogen formation and $|A|$ the azoethane concentration.

It follows from relation [4] that a plot of $1/\phi$ against $|A|$ should be linear at each temperature with an intercept of unity, in close agreement with the experiments. By determining the slopes of these lines, values for k_3/k_2 at each temperature were derived.

The rate constant for deactivation k_3 was calculated from collision theory assuming zero activation energy and a steric factor of unity. A value of 7.0 Å was assumed for the kinetic collision diameters of normal and excited azoethane molecules. As shown in Table II, k_2 is temperature dependent. An Arrhenius plot (Fig. 2) shows the activation energy E_2 to be 2.1±0.4 kcal./mole.

TABLE II

VALUES OF RATE CONSTANTS

Temp., ° C.	k_3, molec.$^{-1}$ cm.^{3} second^{-1} $\times 10^{10}$	k_3/k_2, molec.$^{-1}$ cm.^{3} $\times 10^{19}$	k_2, second^{-1} $\times 10^{-9}$
28	2.96	1.35	2.19
78	3.20	1.13	2.84
116	3.37	0.88	3.84
152	3.52	0.515	6.8

The following observations indicate that the mechanism mentioned above is oversimplified:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

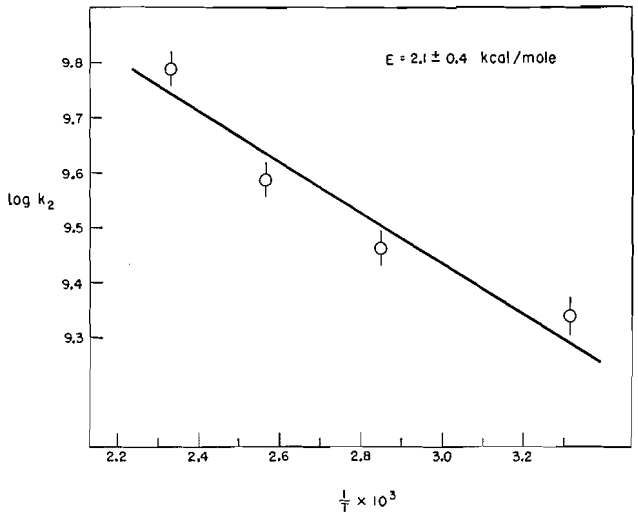

FIG. 2. Arrhenius plot of k_2.

(*a*) At higher temperatures nitrogen is formed not only by the primary process, but also by thermal decomposition of the $C_2H_4N_2C_2H_5$ radical (1),

$$C_2H_4N_2C_2H_5 \rightarrow C_2H_4 + N_2 + C_2H_5. \qquad [15]$$

An estimate of the amount of nitrogen produced by reaction [15] was made as follows: The amount of ethylene formed by disproportionation was calculated from the amount of butane, using a value of 0.12 for the ratio of disproportionation to combination of ethyl radicals (see below, *Secondary Processes*). The deviation of this amount from the total amount of ethylene formed was assumed to be due to reaction [15] only and is consequently equal to the amount of nitrogen formed by this reaction. The percentage of nitrogen formed under our experimental conditions by reaction [15] is 0.8% of the total amount at 107° C. and 2% at 152° C. This effect is very small, even at the highest temperatures employed; hence it can be neglected for the calculation of k_2.

(*b*) The intercepts of the reciprocal quantum yields of nitrogen show a small increase with a decrease in temperature.

(*c*) The curvature of the Arrhenius plot for k_2 probably exceeds experimental error.

(*d*) A fluorescence spectrogram did not indicate any fluorescence.

All these facts might well be explained by a diffusion controlled deactivation reaction of excited molecules at the wall of the reaction cell,

$$A^* + \text{wall} \rightarrow A. \qquad [5]$$

As the rate of disappearance of A* varies exponentially with temperature and the rate of diffusion varies with the square root of the temperature, an increasing deviation from unity for the reciprocal quantum yield at zero pressure may be expected with decreasing temperature. The rate of disappearance of excited molecules for wall deactivation is given by $k|A^*|/|A|$. From a steady state treatment for excited azoethane molecules one can derive

$$1/\phi = 1+(k_3/k_2)|A|+(k/k_2)|A|. \qquad [6]$$

Applying this equation, a corrected value for E_2 was calculated and found to be 2.4 ± 0.4 kcal./mole.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

An alternative explanation might involve the $C_2H_5N_2$ radical, which might recombine with ethyl or decompose:

$$C_2H_5N_2C_2H_5 + h\nu \rightarrow C_2H_5N_2 + C_2H_5, \quad [7]$$

$$C_2H_5N_2 \rightarrow C_2H_5 + N_2, \quad [8]$$

$$C_2H_5N_2 + C_2H_5 \rightarrow C_2H_5N_2C_2H_5. \quad [9]$$

The stability of the $C_2H_5N_2$ radical is expected to be greatest at low temperatures, and this results in a maximum decrease in quantum yield for the nitrogen formation at these temperatures. The quantum yield of nitrogen formation should be intensity dependent in the temperature range in which the lifetime of the $C_2H_5N_2$ radical is comparable to the time between collisions of C_2H_5 and $C_2H_5N_2$ radicals. The observed quantum yield, however, (Table III) is independent of the light intensity. It may therefore be concluded that the lifetime of $C_2H_5N_2$ is short compared to the time between collisions. Reaction [9] can therefore be excluded.

TABLE III

EFFECT OF LIGHT INTENSITY ON QUANTUM YIELD AT 28° C.

Azoethane conc., mole $l.^{-1} \times 10^3$	I_a, quanta $second^{-1}$ $\times 10^{-16}$	R_{N_2}, molec. $second^{-1}$ $\times 10^{-16}$	$1/\phi$
0.75	0.242	0.215	1.12
0.75	0.0246	0.0212	1.16
0.75	0.00286	0.00248	1.15

Internal conversion of the excited azoethane molecule to another electronic state which is incapable of dissociation (9) might be considered as a third explanation,

$$A^* \rightarrow A. \quad [10]$$

From a steady state treatment of excited azoethane molecules it follows that

$$1/\phi = 1 + k_{10}/k_2 + (k_3/k_2)|A|. \quad [11]$$

The value of k_2 increases with increasing temperature (Table II) and if k_{10} is less temperature dependent, the intercept of the plot of $1/\phi$ against $|A|$ may be expected to decrease with increasing temperature, and to approach unity, as is, in fact, the case. Collisional deactivation has been observed in the photolysis of azoisopropane (4). For azomethane (10) the quantum yield of decomposition was found to be unity, independent of temperature and pressure. The difference in collisional deactivation for the three homologous azoalkanes is illustrated in Fig. 3. It is generally accepted (3) that, although the primary excitation in photochemical decompositions is mainly electronic, the mechanism of decomposition involves its transfer to vibrational energy and the accumulation of this energy in a particular bond. Hence the reasonable observation is made that collisional deactivation is negligible in the photolysis of azomethane, but is of considerable importance in the photolysis of the higher homologues because of their larger number of degrees of vibrational freedom.

Secondary Processes

The results of the photolysis are shown in Table IV. To avoid side reactions the

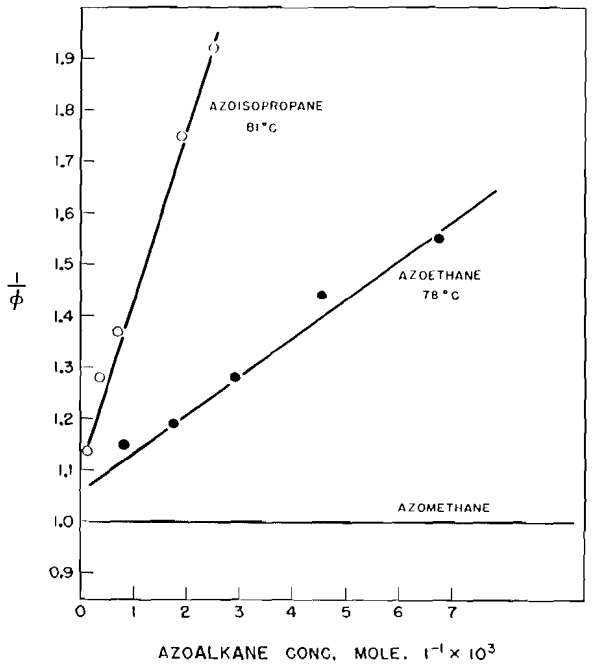

FIG. 3. Effect of pressure on reciprocal quantum yield of nitrogen formation from the lower azoalkanes.

conversion was kept below 3%. Ausloos and Steacie (1) explained their results in the photolysis of azoethane by means of the following mechanism:

$$C_2H_5N_2C_2H_5 + h\nu \rightarrow C_2H_5N_2C_2H_5^*, \quad [1]$$

$$C_2H_5N_2C_2H_5^* \rightarrow N_2 + 2C_2H_5, \quad [2]$$

$$2C_2H_5 \rightarrow C_4H_{10}, \quad [12]$$

$$2C_2H_5 \rightarrow C_2H_4 + C_2H_6, \quad [13]$$

$$C_2H_5 + C_2H_5N_2C_2H_5 \rightarrow C_2H_6 + C_2H_4N_2C_2H_5, \quad [14]$$

$$C_2H_4N_2C_2H_5 \rightarrow C_2H_4 + N_2 + C_2H_5, \quad [15]$$

$$C_2H_5 + C_2H_4N_2C_2H_5 \rightarrow C_4H_5N_2C_2H_5, \quad [16]$$

$$2C_2H_4N_2C_2H_5 \rightarrow (C_2H_4N_2C_2H_5)_2. \quad [17]$$

Assuming ethylene, ethane, and butane to be formed only by reactions [12], [13], and [14], the following relations should be obeyed:

$$\frac{R_{C_2H_4}}{R_{C_4H_{10}}} = \frac{k_{13}}{k_{12}}, \quad [18]$$

$$\frac{R_{C_2H_6} - R_{C_2H_4}}{R_{C_4H_{10}}} = \frac{k_{14}[A]}{k_{12}^{1/2} R_{C_4H_{10}}^{1/2}}, \quad [19]$$

$$\frac{R_{C_2H_6} + R_{C_2H_4}}{R_{C_4H_{10}}} = 2\frac{k_{13}}{k_{12}} + \frac{k_{14}[A]}{k_{12}^{1/2} R_{C_4H_{10}}^{1/2}}. \quad [20]$$

The ratio $R_{C_2H_4}/R_{C_4H_{10}}$ is found to be constant with a value of 0.12 ± 0.01 in the temperature range 27–118° C. This means that $E_{13} - E_{12} = 0$ (cf. Shepp and Kutschke (11)). At higher temperatures an increase in the ethylene to butane ratio is observed owing to thermal decomposition of $C_2H_4N_2C_2H_5$. In Fig. 4, $(R_{C_2H_6} + R_{C_2H_4})/R_{C_4H_{10}}$ and $(R_{C_2H_6}$

$-R_{C_2H_4})/R_{C_4H_{10}}$ are plotted against $|A|/R_{C_4H_{10}}{}^{1/2}$ for runs at 28° C. According to relation [20] the intercept of this curve with the ordinate should be equal to $2k_{13}/k_{12}$. A value of $k_{13}/k_{12} = 0.12\pm0.01$ was obtained. Values of $k_{14}/k_{12}{}^{1/2}$ were calculated from relation [19]. By plotting log $k_{14}/k_{12}{}^{1/2}$ against $1/T$ (Fig. 5) a value of $E_{14}-\frac{1}{2}E_{12} = 8.0\pm0.2$ kcal./mole was obtained. This value is higher than that reported by Ausloos and Steacie, who estimated $E_{14}-\frac{1}{2}E_{12} = 7.5\pm0.1$ kcal./mole. This low value, as well as the curvature they observed in the Arrhenius plot below 70° C., may well be explained by a small impurity in their azoethane sample.

Some high (~20%) conversion experiments were done in order to accumulate significant quantities of heavier products for possible mass spectrometric identification; the fraction remaining after butane and higher products were removed was submitted for analysis. After subtraction of the contributions due to unreacted azoethane a large number of peaks remained between masses 28 and 150. In particular the presence of major peaks at masses 114 and 144, together with peaks corresponding to plausible fragments, suggested that ethyl butyl diimide and tetraethyl hydrazine are amongst the products. In addition, peaks at masses 56, 55, and 42, possibly corresponding to the ions $C_2H_4N_2{}^+$, $C_2H_3N_2{}^+$, and $C_2H_4N^+$ or $CH_2N_2{}^+$ respectively, suggested the presence of diazoethane. These ions might also arise as fragments in the spectrum of ethyl butyl diimide, however, and in the absence of pure standards the identification can be considered tentative only. Should diazoethane be a product, reaction [15*a*] could be suggested as a source. This is similar to the reaction thought to lead to methyl ketene in the photolysis of diethyl ketone (12),

$$C_2H_5N_2C_2H_4 \rightarrow C_2H_5 + CH_3CHN_2. \qquad [15a]$$

Since diazoethane is transparent at λ 3660 Å (13) no photolysis is expected even under conditions of high conversion.

The material balance $(R_{C_2H_6}+R_{C_4H_{10}})/R_{N_2}$ should be equal to unity if only reactions [2], [12], [13], [14], [15], and [16] are involved and should be greater than unity if reaction [15*a*] or [17] occurs as well. As can be seen from Table IV a value smaller than unity was observed, showing a decrease with increase in temperature. Since tetraethyl hydrazine is probably among the products, the following addition reactions between ethyl radicals and azoethane may be suggested:

$$C_2H_5—N{=}N—C_2H_5 + C_2H_5 \rightarrow (C_2H_5)_2N—N—C_2H_5, \qquad [21]$$

$$(C_2H_5)_2N—N—C_2H_5 + C_2H_5 \rightarrow (C_2H_5)_2N—N(C_2H_5)_2. \qquad [22]$$

The rate of formation of tetraethyl hydrazine will be equal to $R_{T.E.H.} = R_{N_2}-R_{C_4H_{10}}$ $-R_{C_2H_6}$ subject to the following assumptions:

(*a*) Reaction [21] is the rate determining step in the formation of tetraethyl hydrazine.

(*b*) Reaction [15], [15*a*], and [17] may be neglected, i.e., for every molecule of ethane formed by abstraction, a molecule of ethyl butyl diimide is formed. As pointed out before, the number of $C_2H_5N_2C_2H_4$ radicals disappearing by reaction [15] is small.

The following relation may be deduced on this basis:

$$k_{21}/k_{12}{}^{1/2} = R_{T.E.H.}/R_{C_4H_{10}}{}^{1/2}|A|. \qquad [23]$$

By plotting log $k_{21}/k_{12}{}^{1/2}$ against $1/T$ (Fig. 6) a value of $E_{21}-\frac{1}{2}E_{12} = 6.0\pm0.3$ kcal./mole was obtained. A large scatter in $R_{T.E.H.}$ and log $k_{21}/k_{12}{}^{1/2}$ may be expected at low temperatures since the material balance approaches unity under these conditions. The present value of $E_{21}-\frac{1}{2}E_{12}$ is in agreement with the activation energies for other reactions of the addition of radicals to double bonds (10, 14, 15).

TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS

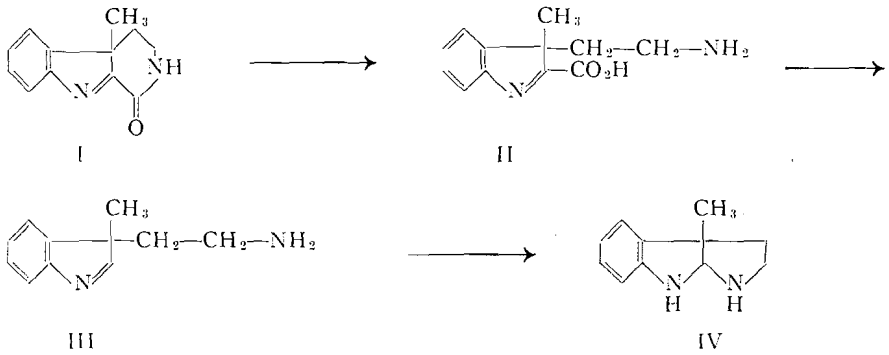
PART IV. ATTEMPTED SYNTHESIS OF THE PHYSOSTIGMINE RING SYSTEM[1,2]

R. A. ABRAMOVITCH[3]

ABSTRACT

4-Methylpiperid-2,3-dione-3-phenylhydrazone failed to undergo ring closure under Fischer-cyclization conditions but rearranged to a more stable form of the phenylhydrazone. *Cis–trans* isomerism is suggested for the two forms.

In Parts II and III (1, 2) a relatively general method of preparing tryptamines was developed which involved the hydrolysis of 1,2,3,4-tetrahydro-1-oxo-β-carbolines to tryptamine-2-carboxylic acids, followed by decarboxylation. It occurred to us that if the tryptamine-2-carboxylic acid had a 3-methyl substituent (II) decarboxylation of this indolenine carboxylic acid would give rise to an amine (III) which should cyclize readily to give the tricyclic system (IV) present in physostigmine.



I II III IV

To this end, ethyl malonate was condensed with allyl cyanide to give diethyl (2-cyano-1-methyl)ethylmalonate (V). Allyl cyanide rearranges in the presence of alkali to crotononitrile, and it is this which undergoes the Michael addition (3). Similar reactions involving the addition of fluorene (4) and 9-monosubstituted fluorenes (5) to crotononitrile following the allylic rearrangement have been reported. The nitrile (V) was catalytically reduced under pressure to give 3-ethoxycarbonyl-4-methyl-2-oxopiperidine (VI), which was hydrolyzed to the corresponding acid. This was not isolated but its solution was treated with benzenediazonium chloride at pH 4, when it underwent the Japp–Klingemann reaction giving the phenylhydrazone (VII). The conditions of the Japp–Klingemann reaction were found, as in previous cases (1, 2), to be critical because at lower or higher pH's considerable tar formation took place.

Cyclization of the phenylhydrazone (VII) to the indolenine (I) could not be effected. Under mild conditions which effect the cyclization of unsubstituted piperidone phenylhydrazones (e.g. boiling with 90% acetic acid) VII was unchanged. If more powerful reagents were used for prolonged periods only tar formation took place. With boron trifluoride in acetic acid, or with zinc chloride, the phenylhydrazone (VII) rearranged to a

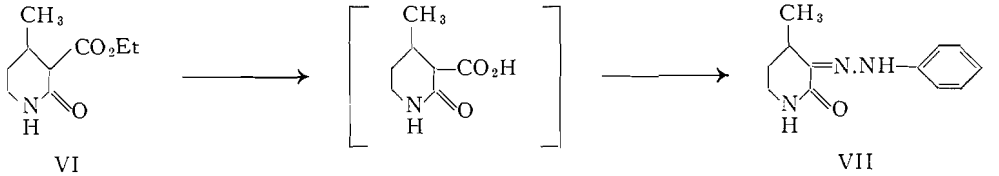
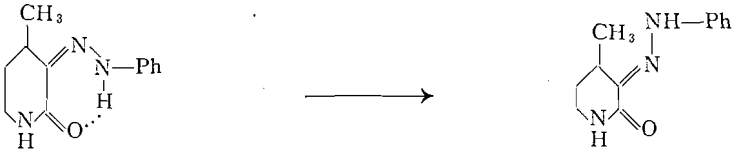
V



VI VII

more stable form which resisted all attempts to effect cyclization. This rearrangement of a phenylhydrazone to a more stable form, instead of undergoing cyclization, is not unique; Snyder and Smith (6) found that ethyl 4-cyano-2-oxobutyrate 2-phenylhydrazone was isomerized to a more stable form but could not be induced to cyclize. The failure of our phenylhydrazone to cyclize is somewhat surprising since Millson and Robinson (7) were able to prepare the tetrahydro-9,11-dimethylcarbazoles from the 2-methyl*cyclo*hexanone *N*-methoxyphenyl-*N*-methylhydrazones, so that possible hindrance arising from the conformation of the methyl-group does not seem to be the cause.

It seems probable that the isomerism of these hydrazones is geometrical. Recently, we have obtained evidence for the existence of such geometrical isomerism with the phenylhydrazones of pyruvamide and methyl pyruvate (8), and it had previously been observed with acetaldehyde phenylhydrazone (9) and pyruvic acid 2,4-dinitrophenylhydrazone (10). Consideration of the positions of the amide-carbonyl absorption bands in the infrared spectra of the isomeric phenylhydrazones studied here suggests that the more stable form (B) has the *anti*-configuration while the form (A) obtained from the Japp-Klingemann reaction has the *syn*-configuration.



A B

The difference in the amide C=O frequencies is not, however, as large as in the other cases previously studied so that the assignments are only tentative. The *syn*-form, which has the possibility of being intramolecularly hydrogen bonded, should exhibit a lower ν_{CO} (1658 cm.$^{-1}$ in this case) than the *anti*-structure (1669 cm.$^{-1}$), where this possibility does not exist.

In view of the failure to effect cyclization at this stage the piperidone (VII) was hydrolyzed to the amino acid. This route, however, offers no advantage over well-established approaches to the physostygmine ring system and was, therefore, not pursued further.

EXPERIMENTAL

M.p.'s and b.p.'s are uncorrected. Infrared spectra were measured on a Grubb-Parsons model S4 double-beam instrument with sodium chloride optics.

Diethyl (2-Cyano-1-methyl)ethylmalonate

Ethyl malonate (16 g.) was added to a cold solution of sodium (0.5 g.) in ethanol (20 ml.). To this solution was added dropwise with stirring a solution of allyl cyanide (4 g.) in absolute ethanol (10 ml.), the temperature being maintained below 35°. The solution was kept at room temperature overnight, treated with acetic acid (1.3 g.), and the alcohol evaporated under reduced pressure. The residue was extracted with ether and the extract dried ($MgSO_4$) and evaporated, eventually *in vacuo* at 130° (water pump). The residue was distilled under reduced pressure giving the colorless ester (11.7 g.), b.p. 180° at 16 mm., 119° at 0.4 mm. Calc. for $C_{11}H_{17}O_4N$: C, 58.2; H, 7.5; N, 6.2. Found: C, 58.4; H, 7.7; N, 6.55. I.R. spectrum (liquid film) (main bands only): C≡N, 2283 cm.$^{-1}$ (w); $(CO_2Et)_2$, 1742 (s), 1730 cm.$^{-1}$ (s).

3-Ethoxycarbonyl-4-methyl-2-oxopiperidine

The above malonate (30 g.) in commercial absolute ethanol (120 ml.) was hydrogenated in the presence of Raney nickel (1 g.) at 80° and 100 atm. until hydrogen uptake was complete (*ca.* 3–4 hours). The filtered solution was evaporated, eventually under reduced pressure, on the water bath, and the cooled residue treated with light petroleum (b.p. 60–80°). Crystallization occurred immediately. The product (24 g.) was filtered, washed with cold light petroleum, and recrystallized from that solvent containing a few drops of benzene, giving colorless plates, m.p. 83–84°. Calc. for $C_9H_{15}O_3N$: C, 58.4; H, 8.2. Found: C, 58.6; H, 8.1.

4-Methylpiperid-2,3-dione-3-phenylhydrazone (A)

3-Ethoxycarbonyl-4-methyl-2-oxopiperidine (1.85 g.) in water (20 ml.) containing potassium hydroxide (0.6 g.) was kept at room temperature for 18 hours. The solution was cooled in ice and treated, with stirring, with a partially neutralized solution (30 ml.) of benzenediazonium chloride prepared from aniline (0.97 g.) and sodium nitrite (0.55 g.), and the pH of the mixture immediately adjusted to *ca.* 4 by addition of glacial acetic acid. Ammonium chloride (4 g.) was added and stirring was continued, the temperature of the solution being slowly allowed to reach room temperature. After 10 hours the solid which had separated was filtered, washed with water, and recrystallized from dilute alcohol giving the phenylhydrazone (A), m.p. 141–142°. Calc. for $C_{12}H_{15}ON_3$: C, 66.3; H, 7.0. Found: C, 66.0; H, 7.0. I.R. spectrum (Nujol mull): NH, 3185 cm.$^{-1}$ (broad); CO (amide), 1658 cm.$^{-1}$ (s); C_6H_5- 751, 702 cm.$^{-1}$ (s). The picrate separated from a small volume of alcohol as dark red needles, m.p. 105–106°.

Attempted Fisher Cyclization of the Phenylhydrazone (A)

(*a*) The phenylhydrazone (0.5 g.) in glacial acetic acid (2 ml.) was treated with a 45% ethereal solution (0.36 g.) of boron trifluoride. The solution turned red and the solid complex separated. The suspension was slowly heated to 60°, when the solid went into solution, and this was then boiled for 2 minutes, poured into cold water, and the acid neutralized with an excess of saturated aqueous sodium carbonate solution. The crude yellow product which separated was insoluble in boiling water and only sparingly soluble in boiling ethanol, but readily soluble in hot dilute ethanol, from which it was recrystallized, giving colorless flat needles (0.19 g.) of the phenylhydrazone (B), m.p. 207–208°. Calc. for $C_{12}H_{15}ON_3$: C, 66.3; H, 7.0; N, 19.3. Found: C, 66.1; H, 6.75; N, 18.8. I.R. spectrum (Nujol mull): NH 3226 cm.$^{-1}$; CO (amide) 1669 cm.$^{-1}$ (s); C_6H_5- 754, 692 cm.$^{-1}$ (s). The picrate separated from a small volume of ethanol as yellow needles, m.p. 139–140°. The filtrate from the recrystallization of the crude product was evaporated to a small volume giving crystals of the starting phenylhydrazone (A) (0.22 g.), m.p. 136–138°, undepressed on admixture with an authentic sample, m.p. 141–142°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

If the acetic acid solution was boiled for ½ hour instead of 1 minute only a dark brown gum was obtained which could not be purified. Boiling the phenylhydrazone (A) with an absolute ethanolic solution of dry hydrogen chloride for 1 minute led to recovery of starting material, whereas heating it with polyphosphoric acid led to tar formation.

(*b*) The phenylhydrazone (A) (0.5 g.) and anhydrous zinc chloride (2.5 g.) were heated to 170° (oil bath) and kept at that temperature for 1 hour. The cooled mass was treated with water and then with an excess of 15% aqueous sodium hydroxide, the residue was filtered, washed repeatedly with water, and extracted with boiling 70% ethanol. The filtered extract was evaporated down till crystallization occurred, giving the crude phenylhydrazone (B) (0.31 g.), m.p. 199–200°, raised to 207–208° on recrystallization from dilute ethanol. The I.R. spectrum was identical with that of the product obtained as under (*a*).

Alkaline Hydrolysis of Phenylhydrazone (*A*)

The hydrazone (0.5 g.) was boiled under reflux for 10 hours with a solution of potassium hydroxide (1.1 g.) in 60% ethanol (12 ml.). The alcohol was partially evaporated and replaced by water, the hot solution filtered, made just acid with glacial acetic acid, and kept overnight, when the impure amino acid, contaminated with silica, had separated. Recrystallization from a small volume of 90% ethanol gave colorless crystals (0.2 g.) of 5-amino-3-methyl-2-oxopentanoic acid 2-phenylhydrazone, m.p. 172–173° (effervescence). Calc. for $C_{12}H_{17}O_2N_3$: C, 61.3; H, 7.2. Found: C, 61.1; H, 7.3.

DEOXYMERCURATION[1]

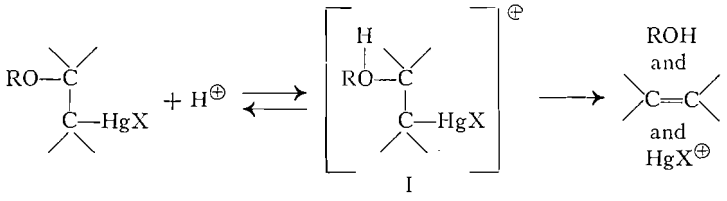
O. W. Berg, W. P. Lay, A. Rodgman, and G. F Wright

ABSTRACT

The conversion of several stereoisomeric oxymercurials to alkenes (deoxymercuration) has been studied with hydrogen chloride in anhydrous and near-anhydrous methanol. In each instance the addition of water decreases the second-order rate. In benzene the addition of water to the anhydrous system first accelerates and then decreases the reaction rate. These results have been interpreted in support of molecular rather than ionic participation by hydrogen chloride. Since molecular participation requires the ↑↑ arrangement of alkoxy and chloromercuri groups for easy reaction it follows that oxymercuration also follows a molecular and not a "mercurinium ion" mechanism in the normal reaction.

The decomposition of 2-oxyorganomercuric salts to mercuric salts and alkenes has been called deoxymercuration (11). It is a much milder reaction than is the scission of simple alkylmercuric salts, some of which resist prolonged heating with strong acids. This difference must be due to the vicinal oxygen linkage. Several opinions have been expressed about the manner in which this oxygen assists the scission of the carbon–mercury link. It will be seen that these opinions are closely related to the ideas of oxymercurial formation. For this reason a decision about the manner in which deoxymercuration occurs ought to specify the mechanism of oxymercuration.

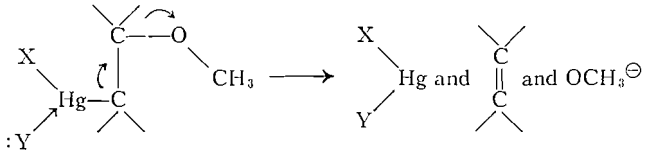
According to Whitmore (20) deoxymercuration is induced by formation of an oxonium salt, I, which then decomposes into an alcohol, an alkene, and a mercuric monocation (where X is an acid substituent bound covalently).



I

According to this mechanism the rate of deoxymercuration ought to be dependent on the strength of the acid used in the reaction. This dependence on acid strength has been confirmed by experiment (11).

According to another, more recent, opinion the reaction is of the "E_2 elimination" type (22) in which an anion is presumed to coordinate with the mercurial (II) to force the

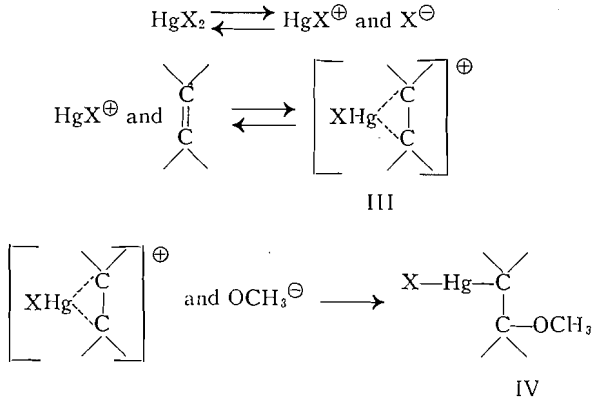


II

indicated electronic displacement. Presumably the experimental basis for this scheme lies in the early work of Sand and Breest (15) and a recent reconsideration of it (14). However these experiments were inconclusive. Moreover it has been shown (11) that deoxymercuration by hydrogen chloride in methanol is insensitive to addition of sodium chloride or mercuric chloride. Actually no factual proof of the E_2 scheme exists.

[1]*Manuscript received August 7, 1957.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

The scheme may have been revived for several reasons. First it is essentially the reversal of a popular mechanism for oxymercuration (9). These authors propose that a mercuric monocation coordinates with an alkene to give an "alkanemercurinium" ion, III, which reacts with an alkoxide ion to yield the oxymercurial, IV.



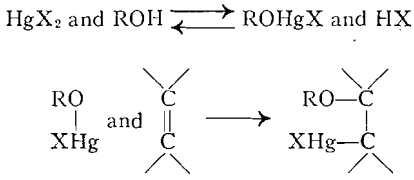
III

IV

Secondly, it may be noted that the final reaction of this series involves an inversion (postulated also for the deoxymercuration) from which a *trans* (↑↓) oxymercurial would be formed. The mechanism received strong support from an X-ray diffraction study (4) in which α-2-methoxycyclohexylmercuric chloride was assigned the ↑↓ configuration. However, it is now realized that this X-ray diffraction study is non-definitive because the ring constellation cannot be discerned adequately in the presence of several heavy atoms. If, instead of the orthodox "crown" ring, the "flexible" cyclohexane ring (8, 7) is assumed, the location of the ring substituents may be a consequence of the ring deformation rather than of substituent configuration. Attempts to refine the structures so as to locate the ring carbon atoms more concisely than in the original study have proved to be fruitless.

However, the inversion mechanism does account satisfactorily for the experimental observation that in certain circumstances the deoxymercuration is stereospecific. When the single diastereomeric oxymercurial produced from a single geoisomer is treated with concentrated hydrochloric acid the single geoisomer is regenerated without contamination (24). Inspection of the postulated mercurinium ion shows that it will be involved stereospecifically in oxymercuration, as also will the E_2 reaction specified for deoxymercuration. Moreover, the conformation required for the inversion reactions should be more favorable in one diastereomer than in another, and in many instances this difference in reactivity is observed. Thus it remains only to demonstrate that the ionic species significant to these mechanisms actually are available in the reacting systems.

There is evidence against the direct participation of ionic species in the oxymercuration of alkenes. According to these studies (12) the reacting species is a basic mercuric salt which undergoes a four-center addition to the alkene.

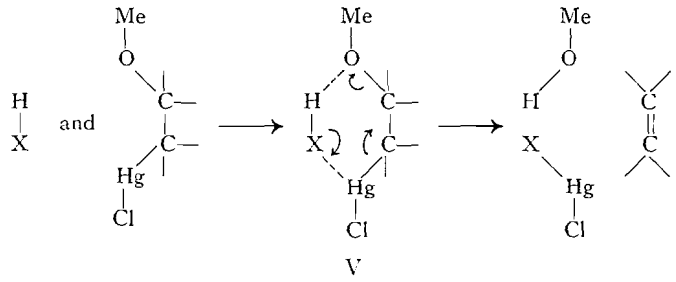


It may be seen that this mechanism also satisfies the experimental requirement of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

second-order stereospecific reaction but it differs from the ionic inversion mechanism because it involves direct (↑↑) addition rather than ↑↓ addition.

This mechanism, essentially molecular* rather than ionic, has its counterpart in deoxymercuration, where a molecule of hydrochloric acid (X = Cl) is thought to coordinate with the alkene to form a six-atom "quasi-cyclic" intermediate, V. In V the



V

electronic redistribution causes scission to the products. It may be seen that these explanations that are based on direct rather than inverse addition also imply stereospecificity, either of product or of reaction rate. Actually the direct (↑↑) explanation fits better the oxymercuration of stilbene and isostilbene and the deoxymercuration of the corresponding two diastereomeric methoxymercurials than does the inverse mechanism (23). However, one essential difference in the two mechanisms involves ion participation in one but not in the other. This criterion has been evaluated in the present report.

The deoxymercurations described above have involved hydrochloric acid. To some, this might seem to involve high ion concentration although it is evident to the experimenter, by the presence of hydrogen chloride in the gas phase above these deoxymercuration systems, that molecular hydrogen chloride must be present. Moreover, the deoxymercurating agents do not need to be strong acids. For example, α-2-methoxycyclohexylmercuric chloride reacts rapidly in methanol with isopropylmercaptan. Although the K_A of this mercaptan in water is probably smaller than that of acetic acid (toward which the mercurial is reasonably stable at 25°) the precipitation of chloromercuric isopropylmercaptide is immediate. Steric convenience ought to be involved, and this effect is typified by a quasi-cyclic intermediate like IV in which HX would be isopropylmercaptan.

It is convenient to deoxymercurate in a solution consisting of methanol and concentrated hydrochloric acid but this stereospecific system may contain ionic as well as molecular species. As the water content of the system is decreased, the extent of ionization ought to become minimal. Therefore it is of interest to measure the rate of deoxymercuration in anhydrous and near-anhydrous methanol and this has been done by use of the colorimetric analysis for reacting systems of oxymercurials (3, 12).

The deoxymercurations of α-2-methoxycyclohexylmercuric halides by the appropriate halogen acids are recorded in Table I. In anhydrous methanol the reaction is second-order and very rapid but the rate is decreased markedly by the addition of a few per cent of water. Comparison of the rate constants shows that the deoxymercuration is relatively insensitive to the halide involved in the reaction although the order of reactivity is roughly paralleled by the dipole moments of the three halides in dioxane solution (2). The β-2-methoxycyclohexylmercuric chloride, which should be sterically unfavorable toward deoxymercuration, does indeed react with hydrogen chloride in anhydrous methanol at

*This term is applied to a substance which acts as a stereochemical unit and therefore will include the category of "ion-pair".

least 100 times slower than the α-diastereomer even when the concentration is increased 15-fold. However, this slow rate is decreased at least 10-fold by addition of 1% of water.

TABLE I

DEOXYMERCURATION OF α-2-METHOXYCYCLOHEXYLMERCURIC HALIDES (RHgX, 1.0×10^{-3} MOLE/LITER) BY HYDROGEN HALIDES, HX, IN 96:4 METHANOL–WATER OR METHANOL AT 25°

**Rate constants for bromides and iodides are calculated from early stages of the reaction; the rate decays slightly in later stages.*

A similar effect is observed during the deoxymercuration of either of the diastereomeric 2-methoxy-1,2-diphenylethylmercuric chlorides. The β-diastereomer (derived from *trans*-stilbene) in anhydrous methanol follows rapid second-order kinetics (k = 2.1 liters mole^{-1} sec.$^{-1}$) and is 80% complete within an hour. Fig. 1 shows that this rate, determined by analysis after 45 minutes of reaction time, is decreased according to the amount of water present in the methanol. The α-diastereomer (derived from *cis*-stilbene) is deoxymercurated more slowly, and it is necessary to use methanol solutions four times as strong as those 0.001 molar in mercurial and in hydrogen chloride which were used for the reaction with the β-diastereomer. Fig. 2 shows that the deoxymercuration rate of the α-diastereomer also decreases with increasing amounts of water in the methanol. It may be of interest that the rate is essentially constant when more than 6% of water is present. This

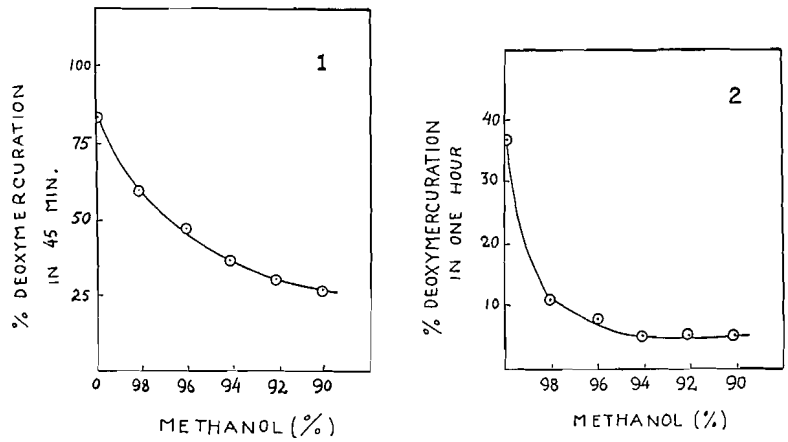

FIG. 1. Effect of water on the amount of deoxymercuration of β-1-chloromercuri-2-methoxy-1,2-diphenylethane during 45 minutes at 25°. [HCl] = [mercurial] = 0.001 mole/liter.

level is about the same as that reported for the minimum in limiting equivalent conductance for hydrogen chloride in aqueous methanol (16).

The following set of equations describe the chemistry which thus far has been reported here:

$$MeOH + HX \rightleftharpoons MeOH_2^{\oplus} + X^{\ominus} \quad [1]$$

$$MeOH_2^{\oplus} + MeO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX \rightleftharpoons MeO\overset{H}{\uparrow}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX^{\oplus} + MeOH \quad [2]$$

$$MeO\overset{H}{\uparrow}CH_2CH_2HgX^{\oplus} \rightarrow MeOH + \overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}} + HgX^{\oplus} \quad [3]$$

$$H_2O + HX \rightleftharpoons H_3O^{\oplus} + X^{\ominus} \quad [4]$$

$$MeOH_2^{\oplus} + H_2O \rightleftharpoons H_3O^{\oplus} + MeOH \quad [5]$$

$$H_3O^{\oplus} + MeO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX \rightarrow MeO\overset{H}{\uparrow}{-}C{-}C{-}HgX^{\oplus} + H_2O \quad [6]$$

$$HX + MeO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX \rightleftharpoons MeO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX \quad (\text{with } H{-}X \text{ bridging}) \quad [7]$$

$$MeO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgX \rightarrow MeOH + \overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}{-} + HgX_2 \quad (\text{with } H{-}X \text{ bridging}) \quad [8]$$

Among these, equations [1], [2], [3], [7], and [8] represent reactions in anhydrous media, while [4], [5], and [6] represent reactions in which water is present. Since the addition of water decreases the rates of deoxymercuration by hydrogen chloride that are described in the report, it is doubtful that equation [6] is significant to these reactions. On the other hand the diminution of molecular hydrogen chloride by increasing amounts of water according to equation [4] would account for the decreasing rate of deoxymercuration in this circumstance if equations [7] and [8] are valid. The expectation conforms with the observation of Shedlovsky and Kay (16) that the ionization of hydrogen chloride seems to decrease as the alcohol content of methanol–water systems increases.

The numerical data of this latter paper (16) indicate that 10^{-3} molar solution should contain slightly more than 1 mole per cent of molecular or ion-pair hydrogen chloride. Reaction according to the equations [7] and [8] is thus plausible. However, the experimental results may also be explained in terms of equations [1], [2], and [3], assuming that the concentration of methoxonium ion is reduced by addition of water according to equation [5]. Actually the paucity of information respecting the true composition of the methanol – hydrogen chloride system makes a choice between the two mechanisms relatively meaningless except insofar as the results may be compared with those in a solvent of lower dielectric constant.

We have chosen to use benzene for this comparison. For our studies in this solvent we have considered the following additional equations:

$$2HX \rightleftharpoons (HX)_2 \quad [9]$$

$$C_6H_5 + HX \rightleftharpoons C_6H_7^{\oplus} + X^{\ominus} \quad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

$$C_6H_7^{\oplus} + MeO-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-HgX \rightleftharpoons MeO\overset{H}{\uparrow}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-HgX^{\oplus} + C_6H_6 \qquad [11]$$

It is evident from equations [1]–[11] inclusive that the use of benzene includes the complication that methanol is released as one of the products. Partly for this reason the kinetic data are not very reproducible and only the first stages of the reaction give useful data. The rate constants calculated from these data may be expected to be in error on the low rather than on the high side because of inadvertent admission of water vapor, even though atmospheric contamination was avoided vigorously.

According to electrical polarization studies (17) with hydrogen halides in benzene there seems to be no evidence for the phenyl cation. If it exists at all the concentration must be extremely low. Deoxymercuration in benzene via the phenyl cation ought therefore to be inordinately slow. Moreover, an initially slow rate ought to be enhanced if the reaction proceeds by an ionic mechanism because of methanol which appears as a product. Actually the rate constant for deoxymercuration of α-2-methoxycyclohexylmercuric chloride in anhydrous benzene (described below) is greater than that in anhydrous methanol; also there is no indication of autocatalysis.

The reaction of α-2-methoxycyclohexylmercuric chloride in anhydrous benzene is too fast for convenience, and solutions not stronger than 2.0×10^{-4} molar in mercurial and hydrogen chloride must be used in order to follow the reaction kinetically. Because of analytical difficulties prior to the actual colorimetric reading and because of hygroscopicity the numerical value of the second-order rate constant (5.6 liters mole^{-1} sec.$^{-1}$ at this low concentration is uncertain. However a comparison of this slope (*A*, Fig. 3) with *B* (2.2 liters mole^{-1} sec.$^{-1}$) and *C* (1.6 liters moles^{-1} sec.$^{-1}$) in which approximately 3×10^{-3} mole liter^{-1} of water is included with the benzene shows that this deoxymercuration is strongly inhibited by water.

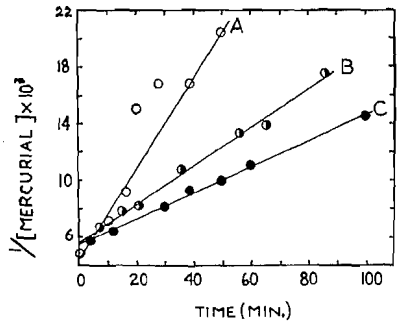

FIG. 3. Second-order rate constants (25°), deoxymercuration in benzene, anhydrous (○) or containing about 3×10^{-3} mole/liter water (◑, ●).

According to this behavior deoxymercuration in benzene does not involve freely-mobile ions which can enter into second-order rate processes. On the other hand, the alternative to a free ionic agent is not simple. Perhaps it should not be expected to be simple. The enhanced electric moment of hydrogen chloride in benzene over the moment in the gaseous state indicates association of the halide with the solvent (17), and self-association together with the solvent is not rigorously excluded. Indeed Beckmann and Lockemann in their classical study (1) show that hydrogen chloride seems to associate in anhydrous benzene and that the extent of association (1.75–2.79) decreases (to 1.16) as very small amounts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

of water are added progressively. Therefore evidence for equation [9] exists and seems to be involved in deoxymercuration studies with the two 2-methoxy-1,2-diphenylethylmercuric chloride diastereomers.

The β-diastereomer of 2-methoxy-1,2-diphenylethylmercuric chloride reacts more slowly with hydrogen chloride in benzene than does α-methoxycyclohexylmercuric chloride, so solutions $1.5–2.0\times10^{-3}$ molar in the stilbene mercurial and in hydrogen chloride may be used. Although this deoxymercuration is thus easier to study in respect of water content it is, unfortunately, subject to strong catalytic acceleration by mercurous chloride. Since this β-mercurial tends spontaneously (especially in light) to decompose into mercurous chloride, and also because of the catalytic effect of liberated methanol, the reactions may be studied only qualitatively. Fig. 4 shows that the rate is decreased by

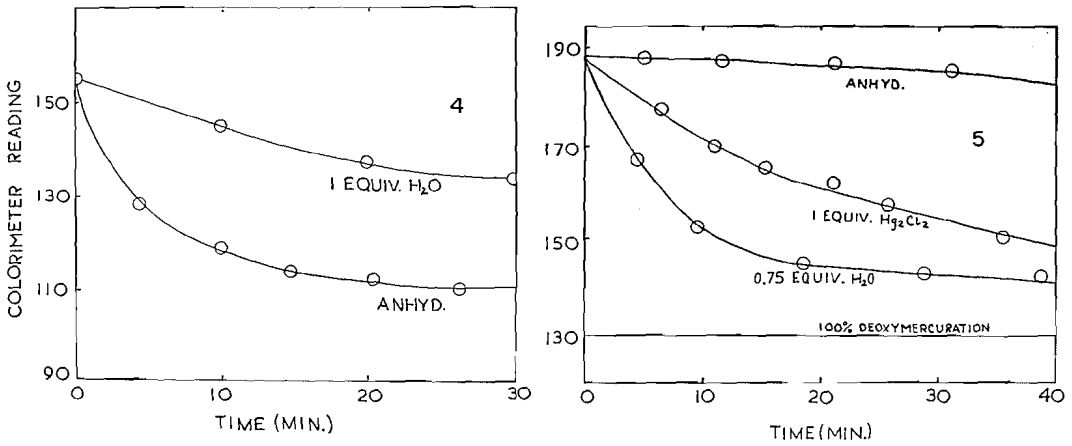

FIG. 4. Deoxymercuration of β-2-methoxy-1,2-diphenylethylmercuric chloride 2×10^{-3} molar at 25° by hydrogen chloride 2×10^{-3} molar.

FIG. 5. Deoxymercuration at 25° of β-2-methoxy-1,2-diphenylethylmercuric chloride 2.0×10^{-3} molar in benzene.

addition to the anhydrous system (2×10^{-3} molar in mercurial and acid) of a molar excess of water. On the other hand the addition of less than a molar equivalent of water to the anhydrous system causes an increase in rate. The latter behavior is shown in Fig. 5. This diagram includes also an example of the accelerating effect of mercurous chloride, which we shall not now attempt to explain. However, with respect to water it seems reasonable to suggest that the enhancement of rate by addition of 0.75 equivalent involves the reversal according to equation [9] of the association observed by Beckmann and Lockemann, while the decreased rate with one or more equivalents of water is caused by loss of molecular hydrogen chloride because of ionization according to equation [4].

The effect of water in benzene has also been studied in the deoxymercuration of α-2-methoxy-1,2-diphenylethylmercuric chloride by hydrogen chloride. In this instance the analytical method is a manometric one depending on diminution of the vapor pressure of hydrogen chloride as it is consumed in the reaction. The record (Fig. 6) of an experiment in anhydrous benzene versus a benzene solution containing less than one molar equivalent of water shows its accelerating effect to be similar to that observed for the β-diastereomer. Not shown is a curve demonstrating that mercurous chloride also accelerates the deoxymercuration of the α-diastereomer.

In summary it would seem that if deoxymercuration is faster in benzene than in methanol, if common ion effects are not found in the latter medium, and if the retarding

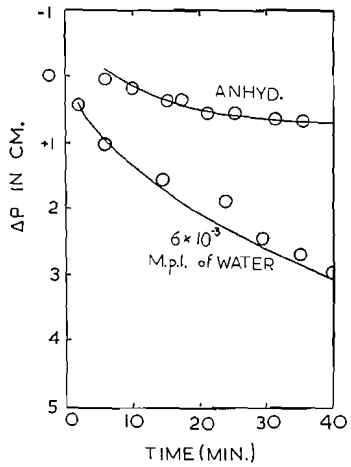

FIG. 6. Manometric analysis, deoxymercuration at 25° of α-2-methoxy-1,2-diphenylethylmercuric chloride 0.01 molar by hydrogen chloride 0.01 molar.

effect of water is comparable in both media, then the improbability of an ionic mechanism in benzene renders improbable an ionic mechanism for all of these stereospecific deoxymercurations. However, it remains to prove that the reaction in benzene is as stereospecific as it is in methanol. This similarity has now been established by isolation of *cis*-stilbene uncontaminated by the *trans* isomer when α-2-methoxy-1,2-diphenylethylmercuric chloride is treated with one equivalent of hydrogen chloride in benzene.

It should be noted that the non-ionic deoxymercuration is specified only for the stereospecific reactions. Actually we have succeeded in producing a few per cent of *trans*-stilbene from the α-diastereomer by treatment with a 1:1 mixture of concentrated hydrochloric acid in methanol. Of course we cannot attribute the slight non-stereospecificity to an ionic deoxymercuration because *cis*-stilbene might have been the initial product which then was isomerized by the acidic medium. But also the non-stereospecificity may be due to the ionic reaction specified by Whitmore.

Such an ionic reaction may also apply to the very slow deoxymercurations of some β-oxymercurials in which the configuration is unfavorable to a quasi-cyclic transition state. Likewise it may apply to deoxymercurations by acids other than the hydrogen halides. But it does not apply to the deoxymercuration which has the same stereospecific behavior as does the corresponding oxymercuration. Both of these processes seem to involve molecular reactants. Therefore both should require *cis* (↑↑) configuration in the mercurial. It follows that the "inversion" mechanism is not adequate to describe either oxymercuration or deoxymercuration, in respect of alkenes such as are considered in this report.

EXPERIMENTAL*

α-2-Isopropoxycyclohexylmercuric Chloride

To a solution of 3.18 g. (0.01 mole) of mercuric acetate in 30 ml. of propanol-2 was added 0.90 g. (0.011 mole) of cyclohexene. After 3 hours, filtration into 25 ml. of 5% aqueous sodium chloride at 0° C. precipitated 3.05 g. (80%) of the isopropoxymercurial, m.p. 90.5–91.5° C. Crystallization from absolute ethanol (20 ml./g.) raised the melting point to 94.8–95.5° C. Calc. for $C_9H_{17}ClHgO$: C, 28.7; H, 4.52; Hg, 53.2. Found: C, 28.4; H, 4.68; Hg, 52.2.

Deoxymercuration Using Benzoyl Chloride

A. With α-2-Methoxy-1,2-diphenylethylmercuric Chloride

To 1.12 g. (0.0025 mole) of this mercurial in 15 ml. of ethanol-free anhydrous chloroform was added 0.29 ml. (0.0025 mole) of freshly distilled benzoyl chloride, b.p. 197° C. After 96 hours, 0.66 g. (97%) of mercuric chloride was filtered off. Vacuum evaporation of the filtrate left 0.80 g. of oil with the odor of methyl benzoate. It was refluxed with 20 ml. of 10% aqueous sodium hydroxide for 270 minutes, then steam-distilled. Etherous extraction (45 ml.) of the distillate removed 0.42 g. of *cis*-stilbene (89%), m.p. 3.5–6.0° C. This geoisomer (0.0022 mole) was characterized by treatment with 0.70 g. (0.0022 mole) of mercuric acetate in 15 ml. of anhydrous methanol for 5 hours, followed by filtration into 25 ml. of 10% aqueous sodium chloride. A mixture melting point of the precipitate (0.85 g., 70%, m.p. 142.5–143.5° C.) with α-methoxydiphenylethylmercuric chloride was not lowered.

B. With β-2-Methoxy-1,2-diphenylethylmercuric Chloride

To 2.24 g. (0.005 mole) of this mercurial in 25 ml. of ethanol-free chloroform was added 0.58 ml. (0.005 ml.) of freshly-distilled benzoyl chloride, b.p. 197° C. After 1 day 1.34 g. (98%) of mercuric chloride was filtered off. Vacuum evaporation of the filtrate left a semisolid oil (1.55 g.). This was crystallized from 8 ml. of ethanol, 0.71 g. (79%) of *trans*-stilbene, m.p. 122.5–124° C., authenticated by mixture melting point.

C. With α-2-Methoxycyclohexylmercuric Chloride

To 3.49 g. (0.01 mole) of this mercurial in 25 ml. of ethanol-free chloroform was added 1.40 g. (0.01 mole) of freshly-distilled benzoyl chloride. After 18 hours, 2.58 g. (95%) of mercuric chloride was filtered off. Vacuum evaporation of the solvent left an oil which was extracted with water. The oil, 1.35 g. (99%), was then distilled at 196–198° C. This methyl benzoate (1.10 g., 81%) was characterized by saponification; acidification precipitated 0.78 g. (87%) of benzoic acid, authenticated by mixture melting point.

The use of benzoyl chloride rather than gaseous hydrogen chloride is a convenient variation for stereospecific deoxymercuration. However, there is evidence (by Mr. Paul Chu) that the reaction is not a simple one; indeed it is catalyzed by mercuric chloride, which may be present in trace amounts in the chloromercurials. In relation to the catalytic action it is of interest that the solubility of mercuric chloride in chloroform is enhanced by the presence of an organochloromercurial which is dissolved in the chloroform.

Deoxymercuration Using Hydrogen Chloride with α-2-Methoxy-1,2-diphenylethylmercuric Chloride

A. In Anhydrous Benzene

To 4.47 g. (0.01 mole) of mercurial in a 250-ml. distilling flask was added 60 ml. of a 0.195 *N* (0.012 mole) solution of hydrogen chloride in benzene during 3 minutes. Mercuric chloride was deposited during this addition; evidently reaction is rapid. After 7 minutes more the solvent was vacuum-evaporated with swirling at 25° C. In a short time the solvent was gone and the residue was quickly treated with excess of 10% aqueous alkali. The *cis*-stilbene was taken up by five washings with ether. The extract, dried by potassium carbonate, was evaporated, 1.62 g., and distilled, b.p. 140–142° C. (14 mm.), n_D^{20} 1.6217, 1.51 g. (84%), leaving no *trans*-stilbene.

B. In Aqueous Methanol

The same amount of mercurial was stirred 12 hours at 25° C. in 90 ml. of methanol plus 90 ml. of concentrated hydrochloric acid. The system, containing oil droplets, was diluted to 700 ml. with water and thrice extracted with 90-ml. lots of ether. The extract, dried by calcium chloride, was vacuum-evaporated, and the residue chromatographed from commercial hexane on a 12 cm. by 0.8 cm. alumina column (activated at 450° C.). After 90 ml. of eluate the column was extruded, the *trans*-stilbene located by permanganate streak, and removed from the zone by ether. Evaporation left 10 mg. of *trans*-stilbene, m.m.p. 120–122° C., authenticated by mixture melting point. The column eluate yielded 1.37 g. of *cis*-stilbene, which was reconverted to the α-mercurial, crude m.p. 143–144° C.

Chloromercuric Isopropylmercaptide

To a solution of 2.85 g. (0.008 mole) of α-2-methoxycyclohexylmercuric chloride in 60 ml. of methanol was added 0.99 g. (0.013 mole) of isopropylmercaptan. A voluminous white precipitate formed immediately. It was filtered off, washed with methanol (30 ml.), and then with ether (60 ml.), 3.11 g. (100%) of infusible chloromercuric isopropylmercaptide. Calc. for C_3H_7ClHgS: C, 11.6; H, 2.25. Found: C, 12.1; H, 2.41.

Identical results were obtained with ethylmercaptan. This compound was regenerated by acidification of the infusible precipitate with hydrochloric acid.

Kinetic Measurements

These were carried out at 25.0°±0.1°C.

A. Reagents

The methanol was purified under nitrogen by Lund and Bjerrum's method (10) to be peroxide-free ($TiCl_3$) and aldehyde-free (Schiff reagent). The benzene, purified by refluxing and distillation from sodium under nitrogen, was anhydrous and peroxide-free according to test with sodium benzophenone ketyl. The hydrogen chloride and hydrogen bromide were dried by passage through concentrated sulphuric acid and then through anhydrous aluminum chloride. The diphenylthiocarbazone (dithizone) was purified by the method of Winkler (21, 18).

B. The Apparatus Used for Anhydrous Reactions

The essential pieces of apparatus are shown as the storage burette in Fig. 7 and the reaction flask in Fig. 8. The storage burette, after thorough drying in a nitrogen stream, is filled with 160 ml. of benzene in the tubular absorber (195×20 mm. with fritted glass disperser) and the spherical chamber (68 mm. diameter) above it to a level just below the inlet from the top stopcock. Then hydrogen chloride is passed in through the horizontally-projecting conical joint by distillation (using a dry-ice bath as a source of heat) from a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

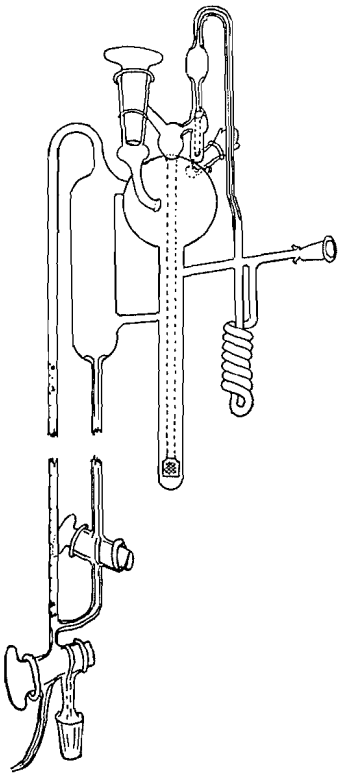

FIG. 7. The storage burette for hydrogen chloride in benzene or methanol.

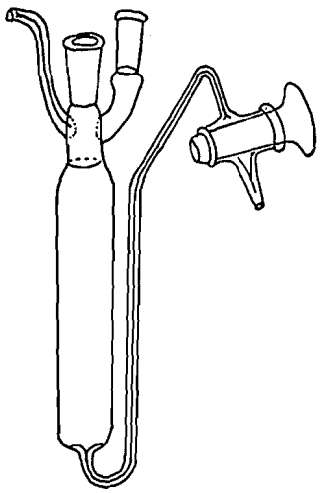

FIG. 8. The deoxymercuration vessel for kinetic studies.

trap in which the acid has been condensed by use of liquid air. When the top stopcock is closed and the three-way stopcock at the bottom of the burette is open hydrogen chloride will pass through the benzene. Finally after 30 minutes sufficient acid has been absorbed. The inlet spiral is immersed in a liquid air bath while the source of hydrogen chloride is

removed, the three-way stopcock having been closed. The latter is now reopened while a stream of dry nitrogen is passed through the horizontal inlet tube (the top stopcock being open) in order to sweep excess hydrogen chloride away from the area above the benzene solution. Then, all stopcocks being closed, the apparatus is tilted to transfer 100 ml. of the benzene solution into the storage reservoir (155×38 mm.) whence it may be standardized in the 10 ml. microburette by sample withdrawal from the plain outlet at the three-way stopcock. During all these operations the vents from the apparatus are protected from moisture by means of connections with U-tubes immersed in liquid air. All interchangeable joints are graphite-lubricated.

The reaction flask (Fig. 8) is constructed with an attachment joint to the burette, a second joint through which the solid mercurial sample is introduced by tipping from a hollow interchangeable stopper at the appropriate time, a dry-gas inlet tube and a capillary stopcock-closed outlet tube from the bottom. With these attachments the vessel does not need to be removed from the thermostat during reaction, the samples being withdrawn by rubber bulb inlet pressure which forces them out via the capillary stopcock into a cup. A definite aliquot is then withdrawn by pipette from the cup. The subsequent colorimetric procedure has been described previously (3, 12). Further detail is available in Mr. Berg's M. A. thesis.

C. The Manometric Apparatus

A differential manometer of the Warburg (19) type was modified by addition of an interconnecting stopcock between the reaction side and the compensator side in order to equilibrate the gas phase before the sample tube containing solid mercurial was inverted into the benzene – hydrogen chloride solution. Transferral of this solution to reaction and compensator flask from its preparative source (essentially the burette and reaction flask described above) was accomplished through serum caps via a hypodermic syringe.

D. Effect of Water in Methanol on Deoxymercuration

Into each of six 10 ml. volumetric flasks containing either 0, 0.2, 0.4, 0.6, 0.8, or 1.0 ml. of water was added 0.52 ml. of anhydrous methanol which was 0.0194 *N* in hydrogen chloride. Then 2 ml. of 0.005 *M* of mercurial in anhydrous methanol was added and the flask was filled quickly to volume with methanol. After brief shaking the flask was held at 20° for 5 minutes, then 1 ml. was rapidly diluted to 100 ml. with water. Ten milliliters of the diluate was thrice extracted at once by 5 ml. portions of chloroform, then 5 ml. of the aqueous layer was analyzed colorimetrically. The percentages of deoxymercuration of β-1-chloromercuri-2-methoxy-1,2-diphenylethane with increasing additions of water were 83.6, 59.5, 46.3, 36.7, 30.1, and 27.2. The corresponding percentages for the α diastereomer were 36.7, 10.7, 7.7, 5.2, 5.2, 5.2.

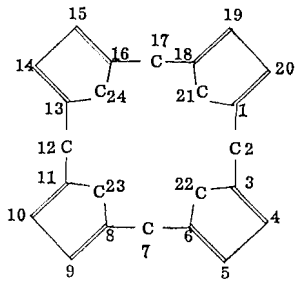
SYNTHESIS OF PORPHYRINOGEN-LIKE COMPOUNDS (MIXED QUATERENES)[1]

WILLIAM H. BROWN[2] AND WARREN N. FRENCH[3]

ABSTRACT

Three porphyrinogen-like compounds, or mixed quaterenes, have been synthesized. One quaterene contains a pyrrole and three furan residues while the others contain two pyrrole and two furan residues. The chief reaction in the preparation of these mixed quaterenes involves the condensation of a dimethylcarbinol of furan at the α-position on a furan or pyrrole ring. Several previously unknown compounds of pyrrole and furan have been prepared as necessary intermediates.

The mode of condensation of furan with acetone in the presence of hydrochloric acid has recently been investigated by Ackman, Brown, and Wright (1). They found that the end product is a cyclic compound consisting of four residues each of furan and acetone after intermolecular elimination of four molecules of water. For this compound, m.p. 243°, Ackman, Brown, and Wright (1) devised the trivial name "octamethyl-tetroxaquaterene" in which "quaterene" denotes a closed system of four cyclopentadiene nuclei linked through the 1- and 4-positions by methylene bridges.



QUATERENE NUCLEUS

Similar results have been obtained in the pyrrole series in the search for compounds having porphyrinogen-like structures. In 1886, Baeyer (2) discovered the first condensation leading to such a compound; viz., the condensation of pyrrole with acetone in the presence of hydrochloric acid. The structure of the substance, m.p. 296°, was investigated by Dennstedt and Zimmerman (3) and later by Chelintzev and Tronov (4). The compound is designated as octamethyl-porphyrinogen, or 2,2,7,7,12,12,17,17-octamethyl-21,22,23,24-tetrazaquaterene in the vernacular.

We have now succeeded in preparing mixed quaterenes containing both furan and pyrrole residues. One quaterene contains one pyrrole and three furan residues (X) while two others each contain two pyrrole and two furan residues (XI, XII). The third member of the series, containing three pyrrole and one furan residue, was not obtained

[1]*Manuscript received October 30, 1957.*

by the methods reported in this communication. The chief reaction in the preparation of these mixed quaterenes involves the condensation of a substituted furylcarbinol at the α-position on a furan or pyrrole ring.

This type of condensation has previously been demonstrated by Ackman, Brown, and Wright (1), who prepared 2,2-difurylpropane from dimethylfurylcarbinol and furan, and by Brown and Sawatzky (5), who similarly prepared difurylmethane and 1,1-difurylethane.

Since the reactions of pyrrole are, in general, similar to those of furan, it was proposed that dimethylfurylcarbinol (II) would condense with pyrrole to give an analogous product. This was indeed found to be the case. In addition to obtaining the expected

For personal use only.

2-furyl-2-pyrrylpropane (III), a second product, thought to be 2,5-*bis*(dimethylfurfuryl)-pyrrole (IV), was isolated. Increasing the ratio of pyrrole : dimethylfurylcarbinol from 1.1 : 1.0 to 1.5 : 1.0 increases the yield of 2-furyl-2-pyrrylpropane from 20 to 40%.

Treatment of 2-furyl-2-pyrrylpropane (III) with acetone in the presence of hydrochloric acid gives 2,2,7,7,12,12,17,17-octamethyl-21,23-diaza-22,24-dioxaquaterene (XI), m.p. 230.5°. The reaction might be expected to give rise to two products, the symmetrical quaterene (XI) and the unsymmetrical quaterene (XII), but only one was isolated. Actually, the melting point of the crude product differs only a few degrees from that of the purified product. The high purity of the crude product also suggests that III reacts as a unit and not by reversion to its constituent parts. A mixture of products, which would be expected if III decomposed, is not apparent. Furthermore, it has been shown that the product formed by the condensation of III with acetone is the symmetrical quaterene (XI), since the same compound is formed by the condensation of 2,5-diisopropylolfuran (IX) with pyrrole. The unsymmetrical quaterene (XII), also containing two furan and two pyrrole residues, is formed by the condensation of 2,2-*bis*(5-isopropylolfuryl) propane (VII) with 2,2-dipyrrylpropane (VIII).

Although the condensation of pyrrole with acetone has been previously investigated, the progenitor of the reaction, 2,2-dipyrrylpropane (VIII), has not been reported. It was found that when the mole ratio of pyrrole to acetone is 2 : 1, a small amount of 2,2-dipyrrylpropane is formed, along with a greater amount of tetrazaquaterene. When the reaction is allowed to proceed slowly with a pyrrole : acetone ratio of 4 : 1, 2,2-dipyrrylpropane is obtained in about 21% yield.

The preparation of the other intermediate, 2,2-*bis*(5-isopropylolfuryl)propane (VII), utilized in the formation of 2,2,7,7,12,12,17,17-octamethyl-21,22-diaza-23,24-dioxaquaterene (XII), m.p. 260°, involved the synthesis of several previously unknown compounds. Acetylation of 2,2-difurylpropane (V) with acetic anhydride gives two products, depending on the conditions of the reaction. Under mild catalysis, such as with iodine, or when the reaction is stopped before completion under more vigorous catalysis, such as with boron trifluoride, the monoacetylated product, 2-furyl-2-(5-acetylfuryl)propane, is obtained. By allowing the reaction to proceed to completion when boron trifluoride is the catalyst, only the diacetylated product, 2,2-*bis*(5-acetylfuryl)propane (VI), results. The identity of each was established by preparing the semicarbazone; analysis for nitrogen indicated the presence of the mono- and di-acetylated compounds. Treatment of 2,2-*bis*(5-acetylfuryl)propane (VI) with methylmagnesium iodide, followed by hydrolysis, results in the expected di-tertiary alcohol (VII), which subsequently gives XII by condensation with 2,2-dipyrrylpropane (VIII).

The third mixed quaterene, 2,2,7,7,12,12,17,17-octamethyl-21-aza-22,23,24-trioxaquaterene (X), m.p. 223°, is obtained in about 13% yield from the condensation of 2,2-*bis*(5-isopropylolfuryl)furan (VII) with 2-furyl-2-pyrrylpropane (III). The preparation of X was also attempted by treating 2,5-*bis*(dimethylfurfuryl)pyrrole (IV) with 2,5-diisopropylolfuran (IX) in the presence of hydrochloric acid. However, only resinous products resulted. Similarly, Ackman, Brown, and Wright (1) obtained only resinous products by treating 2,5-*bis*(dimethylfurfuryl)furan with 2,5-diisopropylolfuran.

During the course of the investigation, several characteristics of the condensations leading to mixed quaterenes were observed. In general, it was found that the dimethylcarbinol of furan condenses with a furan nucleus to give a product in low yield (14%). However, the dimethylcarbinol of furan reacts quite readily with a pyrrole nucleus to form a product in good yield (69%). This points up the greater reactivity of pyrrole

α-hydrogen over furan α-hydrogen. It was also found that dimethylfurylcarbinol does not condense with thiophene under the conditions employed. A variety of products are formed, none of which contains a thiophene residue. Apparently, the furylcarbinol condenses with itself to form several indefinite products rather than condensing with thiophene. In view of these observations, it would appear possible to prepare other mixed quaterenes by the condensation of a substituted carbinol of thiophene with a furan or pyrrole nucleus.

EXPERIMENTAL

All melting points have been corrected against reliable standards. Molecular weights were determined by the Rast method.

Acetylfuran (I)

The compound was prepared by the method of Heid and Levine (6) involving the acetylation of furan with acetic anhydride using a boron trifluoride catalyst (B & A Code 1471).

Dimethylfurylcarbinol (II)

The method used for the preparation of the compound was that of Reichstein, Zschokke, Gehring, and Rona (7) involving the treatment of acetylfuran with methyl Grignard reagent.

2-Furyl-2-pyrrylpropane (III)

A solution of 30 g. (0.45 mole) of pyrrole in 30 ml. of commercial absolute ethanol was placed in a 125 ml. Grignard-type flask equipped with stirrer and dropping funnel and cooled to 0° in an ice-bath. Ten milliliters of 37% hydrochloric acid solution was added slowly while the solution was being stirred. To the resulting colorless solution, 48.7 g. (0.39 mole) of dimethylfurylcarbinol was added dropwise over a period of 15 minutes. The mixture turned yellow at first, then a dark green. The ice-bath was removed and the mixture stirred for 2 hours at room temperature. The addition of 100 ml. of water resulted in the formation of two liquid phases. The lower amber organic phase was separated from the upper aqueous phase, washed until neutral with 10% sodium carbonate solution, then dried over anhydrous magnesium sulphate. The excess pyrrole was removed under diminished pressure and the residual oil fractionally distilled.

The first fraction, a colorless fluorescent oil, distilled at 96–98° (2–3 mm.) and weighed 13.6 g. (20%); η_D^{20} 1.5330, d_4^{20} 1.056. Anal. Calc. for $C_{11}H_{13}NO$: N, 8.00; Mol. wt., 175. Found: N, 8.00; Mol. wt., 182.

2,5-Bis(dimethylfurfuryl)pyrrole (IV)

A second fraction from the preceding distillation, a light yellow oil, boiled at 154–156° (3 mm.) and weighed 17.1 g. (31%); η_D^{20} 1.5286, d_4^{20} 1.052. Anal. Calc. for $C_{18}H_{21}NO_2$: N, 4.94; Mol. wt., 283. Found: N, 5.00; Mol. wt., 290.

2,2-Bis(5-acetylfuryl)propane (VI)

A solution of 20 g. (0.114 mole) of 2,2-difurylpropane (V) and 24.5 g. (0.228 mole) of 95% acetic anhydride in a 125 ml. Grignard-type flask equipped with stirrer and thermometer was cooled to 0° in an ice-bath. While the solution was being stirred vigorously, 2 ml. of boron trifluoride etherate (B & A Code 1471) was added all at once. The color of the solution changed to cherry red, then to dark purple, and the temperature slowly rose to 30° and then fell. When the ice-bath was removed, the temperature slowly rose to 70°. Stirring was continued until the reaction mixture cooled to room temperature,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

then 50 ml. of water was added and stirring continued for 30 minutes. The upper aqueous phase was separated from the lower organic phase and the former extracted with three 15-ml. portions of chloroform. The chloroform extracts and the lower organic phase were combined and washed with 50 ml. of 10% sodium carbonate, 50 ml. of water, and dried over anhydrous magnesium sulphate. The chloroform was flashed off and the residue distilled under diminished pressure. The product, a viscous light yellow oil, weighed 15 g. (51%) and distilled at 178–182° (2–3 mm.). On cooling in the refrigerator, the material formed a thick gel but did not crystallize.

The disemicarbazone derivative of this compound, m.p. 235° (with decomposition), was prepared in the usual manner. Anal. Calc. for $C_{17}H_{22}N_6O_4$: N, 22.4. Found: N, 22.4.

2-Furyl-2-(5-acetylfuryl)propane

A solution of 20 g. (0.114 mole) of 2,2-difurylpropane and 28.2 g. (0.262 mole) of 95% acetic anhydride was cooled to 0° by means of an ice-bath and treated with 2 ml. of boron trifluoride etherate (B & A Code 1471). The temperature of the reaction mixture rose to 34°, then fell. Stirring was continued for 30 minutes with the ice-bath still in place. After being worked up as described before, the product was fractionally distilled. The first fraction, a colorless oil which crystallized in the receiver, distilled at 123–126° (2 mm.) and weighed 5.5 g. (25%). Crystallization from an ethanol–water solution gave shiny flat plates, m.p. 84.0–84.5°. Calc. for $C_{13}H_{14}O_3$: Mol. wt., 218. Found: 210.

The semicarbazone, which was prepared in the usual manner, had a melting point of 186.5°. Anal. Calc. for $C_{14}H_{17}N_3O_3$: N, 15.3. Found: N, 15.6.

2,2-Bis(5-isopropylolfuryl)propane (VII)

An ethereal solution of 0.123 mole of methylmagnesium iodide was prepared. The solution of the Grignard reagent was cooled in an ice-bath and while it was being stirred vigorously, 15 g. (0.0577 mole) of 2,2-*bis*(5-acetylfuryl)propane was added dropwise to it over a period of 30 minutes. Stirring was continued for 2 hours at room temperature. The mixture was then poured over 150 g. of chipped ice to decompose the yellow complex. The aqueous layer was saturated with sodium carbonate and the ether decanted. After extraction with ether, the combined ether extracts were dried over anhydrous potassium carbonate. Most of the ether was removed by distillation, the remainder by passing a current of air over the cold solution. The residue was a sticky yellow solid, which was dissolved in hot hexane; the resulting solution was cooled and partially evaporated by means of a current of air. A white crystalline solid formed on the walls of the flask. After the process had been repeated three times, a total of 6.0 g. (36%) of white crystals was obtained, m.p. 91–92°.

This product was not amenable to purification for analysis by ordinary crystallization procedures since it readily decomposes with formation of an oil. The compound is assumed to be the di-tertiary alcohol based on its mode of formation and subsequent reactions. A molecular weight determination on the crude product gave a value of 308, which is in agreement with the theoretical value of 298 based on the molecular formula $C_{17}H_{24}O_4$.

2,2-Dipyrrylpropane (VIII)

A solution of 67 g. (1 mole) of pyrrole and 20 ml. of commercial absolute ethanol in a 125 ml. Grignard-type flask equipped with stirrer, dropping funnel, and thermometer was cooled to 0° in an ice-bath. While the solution was being stirred, 3 ml. of 37% hydrochloric acid solution was slowly added, followed by 14.5 g. (0.25 mole) of acetone, which was added dropwise over a period of 25 minutes. The temperature was kept at 10° throughout the addition. Stirring was continued for 2 hours during which time the

solution turned yellowish-green in color. The solution was poured into 100 ml. of water and the resulting mixture neutralized with solid sodium carbonate. The upper organic phase was removed, washed with water, and dried over anhydrous magnesium sulphate. The excess pyrrole was removed under diminished pressure and the residual oil fractionally distilled from a Claisen flask to give 13.5 g. (31%) of a light yellow oil (b.p. 146–153°, 8 mm.), which partially solidified on cooling. Fractional distillation through a column as described by Bower and Cook (8) gave 9.2 g. (21%) of a colorless fluorescent oil (b.p. 125–126°, 3 mm.), which solidified in the receiver, m.p. 59°. Crystallization from petroleum ether gave rhomboid crystals but did not change the melting point. Anal. Calc. for $C_{11}H_{14}N_2$: N, 16.1; Mol. wt., 174. Found: N, 16.3; Mol. wt., 184.

2,2,7,7,12,12,17,17-Octamethyl-21-aza-22,23,24-trioxaquaterene (*X*)

A solution of 0.50 g. (0.00172 mole) of 2,2-*bis*(5-isopropylolfuryl) propane (VII) and 0.30 g. (0.00172 mole) of 2-furyl-2-pyrrylpropane (III) in 5 ml. of absolute ethanol was cooled in an ice-bath. While the solution was being agitated, 0.4 ml. of 37% hydrochloric acid solution was added dropwise. A greenish-yellow color developed immediately, which soon changed to orange and then to dark brown. Solid material started to form in 15 minutes. After the solution was left for 15 hours, a sticky solid was removed by filtration. Crystallization from absolute ethanol gave 0.10 g. (13.5%) of light yellow needles, m.p. 217–220°. A second crystallization gave fine white needles, m.p. 223°. Yields are lower when the above reaction is carried out on a larger scale. Anal. Calc. for $C_{28}H_{33}NO_3$: N, 3.26; Mol. wt., 431. Found: N, 3.24; Mol. wt., 450.

2,2,7,7,12,12,17,17-Octamethyl-21,22-diaza-23,24-dioxaquaterene (*XII*)

A solution of 0.522 g. (0.003 mole) of 2,2-dipyrrylpropane (VIII) and 0.875 g. (0.003 mole) of 2,2-*bis*(5-isopropylolfuryl)propane (VII) in 10 ml. of absolute ethanol was cooled in an ice-bath. To this solution was added 0.15 ml. of 37% hydrochloric acid solution. A solid began to form immediately. After 3 hours, the solid was removed by filtration and washed with ethanol to give 0.89 g. (69%) of light gray needles, m.p. 255–257° (with darkening). Crystallization from benzene (15 ml./g.) gave 0.51 g. of white needles, m.p. 260° (with darkening). Anal. Calc. for $C_{28}H_{34}N_2O_2$: N, 6.50; Mol. wt., 431. Found: N, 6.58; Mol. wt., 440.

2,2,7,7,12,12,17,17-Octamethyl-21,23-diaza-22,24-dioxaquaterene (*XI*)

(*a*) *From 2-Furyl-2-pyrrylpropane and Acetone*

A solution of 2.0 g. (0.011 mole) of 2-furyl-2-pyrrylpropane (III) and 3.0 g. (0.052 mole) of acetone in 10 ml. of absolute ethanol was cooled in an ice-bath. While the solution was being swirled, 37% hydrochloric acid solution was added dropwise. The solution became orange in color, then a deep cherry red. After 2 ml. of acid had been added, an oil began to separate. The mixture was heated to 50° during which time the oil dissolved and crystals started to form. After it was left for 30 minutes, the mixture was filtered. The residue was washed with 95% ethanol until the color had been removed (about 5 ml.) leaving 0.36 g. (15%) of fine white needles, m.p. 227.5–228.5°. Crystallization from an acetone–water solution, including treatment with charcoal, gave shiny white needles, m.p. 230.5°. Anal. Calc. for $C_{28}H_{34}N_2O_2$: C, 78.1; H, 7.96; N, 6.51; Mol. wt., 431. Found: C, 78.0; H, 7.83; N, 6.73; Mol. wt., 424.

(*b*) *From 2,5-Diisopropylolfuran and Pyrrole*

The method of Ackman, Brown, and Wright (1) was used for the preparation of 2,5-diisopropylolfuran (IX) from diethyl 2,5-furandicarboxylate which had been previously prepared by the dehydration of mucic acid and esterification of the product. A

solution of 0.55 g. (0.003 mole) of 2,5-diisopropylolfuran and 0.20 g. (0.003 mole) of pyrrole in 10 ml. of absolute ethanol was cooled in an ice-bath. Then, while it was being agitated, 0.3 ml. of 37% hydrochloric acid solution was added. A white crystalline solid began to form immediately. The solution was colorless at first, then became a deep red. After 4 hours, the mixture was filtered and the residue washed with 5 ml. of 95% ethanol to give 0.090 g. (14%) of white needles, m.p. 228–229°. Crystallization from absolute ethanol (100 ml./g.) gave shiny white needles, m.p. 230.5°. A mixture melting point of this compound with that obtained in (*a*) showed no depression.

ACKNOWLEDGMENTS

We are grateful for financial assistance from the National Research Council of Canada for one of us (W.N.F.). The Du Pont Company of Canada has been most helpful by supplying generous quantities of furan and pyrrole.

SYNTHESIS OF GUANIDINE FROM UREA, AMMONIUM BENZENESULPHONATE, AND AMMONIUM SULPHAMATE[1]

JEAN L. BOIVIN AND MEUDE TREMBLAY

ABSTRACT

Guanidine benzenesulphonate has been obtained in yields exceeding 70% by heating urea, ammonium sulphamate, and ammonium benzenesulphonate in respective molar ratios of 1:1:0.75. The effects of temperature, proportion of reactants, and reaction time were studied batchwise. Then the process was operated on a continuous basis in a four-flask cascade reactor at temperatures between 240° and 260° C.

INTRODUCTION

The fusion of urea with ammonium sulphamate gives rise to guanidine sulphamate in relatively low yield, and even a large excess of ammonium sulphamate does not effect the transformation in yields higher than 80% (3). Moreover, the fusion is hampered by the formation of ammonium sulphate coming out of the melt at high temperature. The presence of this insoluble salt in the fusion mixture makes a continuous process impossible.

A search has been made for a guanidine salt which would be stable up to 300° C. in the fused state and could be readily transformed into either guanidine nitrate or nitroguanidine. Sulphonic acids appeared to be suitable since they are stable and, unlike sulphamic acid, are not readily hydrolyzed. Guanidine benzenesulphonate melts at 212° C. and can be fused at 300° C. without decomposition or appearance of melamine (2). Moreover, guanidine benzenesulphonate is less soluble in water than guanidine nitrate and can be crystallized from it.

Guanidine benzenesulphonate can be obtained by the reaction between urea, ammonium sulphamate, and ammonium benzenesulphonate. The fusion of urea and ammonium sulphamate gives cyanamide and ammonium sulphate (1); cyanamide then reacts with ammonium benzenesulphonate to yield guanidine benzenesulphonate according to the following equations:

$$NH_2SO_3NH_4 + NH_2CONH_2 \rightarrow NH_2CN + (NH_4)_2SO_4,$$
$$NH_2CN + NH_4SO_3C_6H_5 \rightarrow NH_2C(NH)NH_2.HSO_3C_6H_5.$$

A study of the effect of temperature, molar ratio of reactants, and reaction time was made batchwise by heating the mixture in a flask, and on a continuous basis in a four-flask cascade reactor. It was observed that the addition of ammonium sulphate to the urea – ammonium benzenesulphonate – ammonium sulphamate mixture did not appreciably change the fluidity of the melt at the synthesis temperature, because of its relative solubility in the fused mixture. The crude guanidine benzenesulphonate thus formed was isolated by crystallization from water and melted at 212° C. A mixed melting point determination with an authentic sample was not depressed.

EXPERIMENTAL AND RESULTS

Preparation of Guanidine Benzenesulphonate

Batch Process

The preliminary experiments were directed to the study of the effect of temperature, molar ratio of reactants, and time of the reaction on the yield. The reaction was carried

[1]*Manuscript received October 23, 1957.*
Contribution from Canadian Armament Research and Development Establishment, Valcartier, Quebec.

out in a three-necked flask equipped with a stirrer, a thermometer, and gas inlet. Heating was accomplished by means of a heating mantle. The mixture of ammonium sulphamate, ammonium benzenesulphonate, and urea melted at about 100° C., and at 180–200° C. an exothermic reaction took place with evolution of gases and the formation of a sublimate. The melt was heated to the desired temperature for a period of 15 to 90 minutes. The liquid was then poured into a beaker, allowed to cool, dissolved in water, and diluted to 500 cc. in a volumetric flask. The solution was analyzed for guanidine with a solution saturated with ammonium picrate and guanidine picrate.

Effect of reaction temperature.—Table I shows the results obtained at different temperatures. The maximum yield of guanidine benzenesulphonate was obtained at 240° C. after a 1-hour period of heating.

TABLE I

EFFECT OF TEMPERATURE

Urea: 15 g. (0.25 mole); ammonium sulphamate: 28.5 g. (0.25 mole); ammonium benzenesulphonate: 57.4 g. (0.25 mole)

Temp., ° C.	Time, min.	Yield from urea, %	Temp., ° C.	Time, min.	Yield from urea, %
290	30	27.0	300	60	16.0

220	"	43.0	240	"	60.0
			230	"	55.4
			220	"	53.5

Effect of molar ratio of reactants.—Results are summarized in Table II. Yields increased with excess of urea, but much decomposition occurred giving rise to a material insoluble in water. Yields increased also with the amount of ammonium sulphamate and remained practically constant as the proportion of benzenesulphonate was increased.

TABLE II

EFFECT OF MOLAR RATIO OF REACTANTS

Effect of reaction time.—The results are shown in Table III. At low temperature (240° C.) yields were practically the same, but a 30-minute period of heating was sufficient. With longer heating times some solid separated from the melt and impaired the stirring. Higher temperatures (260° C.) required shorter times.

TABLE III

Continuous Process

The main object of this work was to produce guanidine benzenesulphonate on a continuous basis. A cascade reactor consisting of four 500-ml. flasks was built in such a way that molten material overflows from flask 1 to flask 4 by gravity. A stream of anhydrous ammonia was introduced at the bottom of each flask to stir the molten solid while the flasks were heated by mantles.

Runs were made by adding urea, ammonium sulphamate, and ammonium benzenesulphonate in respective molar ratios of 1:1:0.9. These molar ratios were considered to be the optimum proportions to give maximum melt fluidity. The reduced molar ratio of ammonium benzenesulphonate was sufficient to form the salt of the guanidine produced in the reaction. The residence time in the reaction flasks varied from 15 to 120 minutes at the rates of feed of 20 to 5 grams per minute respectively. The mixture was first added manually at a constant rate of 5 to 15 grams per minute. Attempts were made to introduce the same mixture by means of a screw feeder to obtain a constant rate of addition but this mixture absorbed water rapidly and became tacky, causing plugging of the screw feeder. It was found that the mixture became hygroscopic owing to the presence of urea. Two screw feeders were then used to introduce respectively urea and the mixture of ammonium sulphamate and ammonium benzenesulphonate. With this arrangement two 8-hour runs were made successfully using 10 pounds of mixture each.

The mixture was melted at 160–170° C. in the first flask and allowed to overflow to the second flask where the temperature reached 250–260° C. The reaction in the second flask was exothermic with evolution of ammonia. The liquid flowed through two more flasks to complete the reaction and was finally collected in a beaker where it solidified. After solidification, a weighed sample was dissolved in the minimum of water and analyzed for guanidine. The guanidine benzenesulphonate was also crystallized, weighed, and its purity determined. Yields of about 60 to 80% were obtained depending on the rate of feed. The results given in Table IV show that the yields obtained by adding the mixture at a constant rate from 10 to 15 grams per minute were 66 to 71% by crystallization, the product obtained being about 97% pure.

15	20	53.4–90.0	

Using two screw feeders.
†A mixed melting point with an authentic sample of guanidine benzenesulphonate (m.p. 212° C.) was not depressed.

RECOVERY OF UNREACTED AMMONIUM SULPHAMATE

To make the synthesis more attractive, the unreacted ammonium sulphamate should be recovered. The melt obtained from the continuous reactor was dissolved in water and fractionally crystallized. Results given in Table V show that guanidine benzenesulphonate crystallized first, then on further concentration ammonium sulphate was obtained, and finally ammonium sulphamate. The separation is not very clear-cut and a more practical procedure is required to reclaim the ammonium sulphamate on a production scale.

TABLE V

5	100	76.3	54.4	20.6	0.0

DISCUSSION

The results obtained by the fusion of urea, ammonium sulphamate, and ammonium benzenesulphonate are promising. The fusion stage is sufficiently exothermic to preclude any use of external heating and the conversion of urea into guanidine is high using a stoichiometric ratio of reactants. It has been shown that the proportion of ammonium benzenesulphonate could be reduced below the stoichiometric amount with equally good results.

The use of ammonium benzenesulphonate stabilizes the guanidine formed and prevents its transformation into melamine; this stabilizing effect could otherwise be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

accomplished by the use of a large excess of ammonium sulphamate. The presence of ammonium benzenesulphonate in the fusion mixture also increases the fluidity of the melt and prevents the separation of ammonium sulphate.

The presence of guanidine as its benzenesulphonate salt makes possible a continuous process which has been demonstrated in a laboratory system. Guanidine benzenesulphonate was separated easily from the salts present in the fusion mixture. However, the high stability of this salt made difficult its transformation into guanidine nitrate directly by means of ammonium nitrate or nitric acid.

This fusion has the advantage of being made at atmospheric pressure. A reactor will be easily constructed from conventional materials. No difficult heat transfer problem will arise since the reaction is self-sustaining.

THE PHOTOLYSIS OF ALKYL ESTERS[1,2]

P. AUSLOOS[3]

ABSTRACT

An attempt has been made to determine the primary processes in the gas and liquid phase photolysis of simple alkyl esters.

The liquid phase photolysis of methyl, ethyl, *n*-propyl, and *n*-butyl formate has been briefly investigated. Besides the dissociation processes, two intramolecular rearrangements were found to occur:

$$\begin{aligned} HCOOR + h\nu &= CO + HOR, && I \\ &= HCOOH + \text{alkene}. && II \end{aligned}$$

Process I takes place with approximately the same yield for all the formates studied. Process II occurs only when there is a β-hydrogen in the alkyl group.

An investigation of the gas and liquid phase photochemical decomposition of esters other than formates showed the existence of the following primary processes:

$$\begin{aligned} XCOOY + h\nu &= XCOOH + \text{alkene}, && VI \\ &= CH_3COOY + \text{alkene}, && VII \\ &= XCO + OY, && X \\ &= X + COOY. && XI \end{aligned}$$

Processes VI and VII require β- and γ-hydrogens, respectively, in the Y and X alkyl groups.

It was found that processes I and X occur mostly at short wavelength, while the other processes take place at long wavelengths as well.

EXPERIMENTAL

The liquids were irradiated in a quartz cell of 5 cm. diameter and 0.1 cm. depth. The cell was closed with a break seal which made it possible to attach the cell to the analysis system after each run.

Spectra taken with a Cary spectrophotometer indicated that for a 0.1 cm. path length 100% of the useful radiation was absorbed. Absorption occurred only below 2400 Å. Experiments with a Corning filter 9863, cutting off radiation below 2250 Å, reduced the rates of formation of the products by a factor of approximately 20. Absorption spectra of formates diluted with ethanol showed a maximum around 2150 Å, while the extinction coefficients were appreciably higher than those of ketones and aldehydes.

Irradiation was carried out in a quartz Dewar filled with distilled water. For a few low temperature runs, however, 3-methyl pentane was used.

The gas phase experiments were performed with a cylindrical quartz cell (5 cm. diameter, 10 cm. long) which was completely filled with a nearly parallel light beam. The low temperature runs were performed in a brass cylinder thermostat with double quartz windows. Ethyl alcohol was used as a cooling medium.

Two Hanovia (16A-13) SH type medium pressure lamps were used in the course of this work. Because a slight change in wavelength distribution changes the relative rates of formation of the products, the number of each run is preceded by a letter *a* or *b* depending on which lamp was used. Except when stated otherwise, the incident intensity was kept constant for all the runs with lamp *a*. This allows comparison of the rates of

formation of the products from one table to another. All rates are given in cc./min. 10^{+4}. No absolute quantum yields were determined.

The analysis procedure was the same as described earlier (2).

The esters were obtained from Eastman Kodak Co. (White Label). Ethyl formate, methyl acetate, and methyl propionate were fractionated in a 10 plate column before distillation in the vacuum line. The other compounds were distilled and degassed in vacuum.

PART I. THE PHOTOCHEMICAL DECOMPOSITION OF FORMATES

Results

The results of runs performed in the liquid phase at constant incident intensity and varying temperatures are given in Table I.

TABLE I

LIQUID PHOTOLYSIS OF FORMATES

	*a*12	85	98.0	12.0	169	108	116

It can be seen that the rates of formation of hydrogen and of carbon monoxide change very little with temperature for each compound taken separately and show only slight variations from one compound to another.

Formates with a β-hydrogen in the alkyl groups have under these experimental conditions an alkene as most important product. The rates of formation of these alkenes vary only slightly with temperature, but, unlike the rates of formation of carbon monoxide, change considerably from one compound to another.

The only other products analyzed for were carbon dioxide and the hydrocarbons: methane, ethane, propane, butane, formed respectively in the photolysis of methyl, ethyl, propyl, butyl formate.

The results indicate that the rate of formation of carbon dioxide is roughly equal to that of the corresponding hydrocarbon. They both increase appreciably with increase in temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

The rates of formation of the recombination products ethane and butane, formed in the photolysis of methyl and ethyl formate, respectively, are not given in Table I because these products were always present in amounts too small to be measured accurately. The amount of ethane formed in experiments 1 and 2 was less than 1% of the carbon dioxide fraction. No attempt was made to determine the rates of formation of hexane and octane in the photolysis of propyl and butyl formate.

The results of a few more liquid phase experiments on ethyl formate are included in Table II. Runs 13, 14, and 15 were performed in order to obtain a rough idea of the effect on the products of a variation in the wavelength distribution. The temperature was

**3-Methyl pentane bath.*
†Corning filter 9863.
§Iodine added 0.035 cm.

kept constant. Run 14 was done with a 3-methyl pentane bath which absorbed most of the radiation below 2150 Å. In order to cut off radiation below 2250 Å, a Corning filter 9863 was used in run 15. It follows from these experiments that a change in the wavelength distribution appreciably affects the ratio C_2H_4/CO. The rates of formation of carbon monoxide and hydrogen decrease appreciably as compared to the rate of formation of ethylene when only the longer wavelengths are absorbed by ethyl formate.

Runs 16 and 17 were done with the same experimental setup and at the same intensity as experiment 14. From the results of these experiments it follows that the rates of formation of carbon monoxide and hydrogen are practically independent of temperature, while the rate of formation of ethylene decreases with decrease in temperature. Runs 3, 4, and 5 of Table I lead to the same observation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

In the same table results are presented of runs where only the intensity has been varied. It can be seen that the carbon monoxide, hydrogen, and ethylene yields as well as the ratio C_2H_4/CO change only slightly, while the carbon dioxide and ethane yields increase markedly with diminishing intensities.

The results of the gas phase runs given in Table II indicate that addition of iodine does not affect the rate of formation of ethylene to any appreciable extent, while the rates of formation of methane, propane, and butane were reduced to negligible amounts. Increase of the temperature increases the rate of formation of the products with the exception of ethylene.

Discussion

The results of Tables I and II indicate that the following intramolecular process occurs:

$$HCOOR + h\nu = HOR + CO. \qquad I$$

The independence with respect to temperature variation of the rate of formation of carbon monoxide over a temperature range from $-80°$ to 13° C. and over a large intensity range is good evidence for the occurrence of this process. The small increase of the hydrogen and carbon monoxide yields at high temperatures and low intensities may be attributed to a thermal decomposition of formyl radicals. The fact that the less stable acetyl radicals formed in the liquid phase photolysis of methyl and ethyl acetate decompose only to a small extent agrees with the proposition that at low temperatures carbon monoxide is formed mostly by process I.

Formates with a β-hydrogen may also decompose by process II:

$$HCOOR + h\nu = HCOOH + \text{alkene}. \qquad II$$

The following facts may be cited as evidence in favor of process II:

(*a*) the independence of the ethylene yield in the liquid phase photolysis of ethyl formate over a considerable intensity range,

(*b*) the only slight variation of the rate of formation of the alkenes with temperature,

(*c*) the rate of formation of ethylene which in the gas phase photolysis of ethyl formate is unchanged upon addition of iodine.

It may be mentioned that pyrolysis studies (5) of several formates by the toluene carrier technique showed that formates with a β-hydrogen decompose by a molecular elimination process analogous to process II. Acetic anhydride may be cited as another example of the same type where photolysis (1) and pyrolysis (8) produce ketene and acetic acid in a direct process.

The ethyl formate results show that process I occurs mostly at wavelengths shorter than are required for process II. This indicates that processes I and II probably occur from different electronic levels.

Besides the intramolecular processes one or more of the following dissociative steps has to occur:

$$HCOOR + h\nu = HCO + OR, \qquad III$$

$$= H + COOR, \qquad IV$$

$$= HCOO + R. \qquad V$$

From our results little can be said about the occurrence of these processes. Analogy with the liquid phase photolysis of the acetates and propionates favors processes III and IV.

Recent studies (6) on the gas phase photolysis of acetone in the presence of methyl formate have shown that methyl radicals only abstract the hydrogen atom from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

acyl group. One carbon dioxide molecule was found for every hydrogen abstracted. In agreement with this, the pronounced increase of the rate of formation of carbon dioxide and the corresponding hydrogen with increase in temperature and diminishing intensities can be explained by the following chain propagating steps:

$$R + HCOOR = RH + COOR,$$

$$COOR = CO_2 + R.$$

The initiator may be any of the radicals formed in processes III, IV, and V.

Considering the primary processes mentioned above, hydrogen can at low temperatures only be produced by a reaction of the hydrogen atoms formed in process IV with other radicals present in the system or with formate molecules. It is perhaps surprising that the ratio H_2/CO is approximately the same for all runs done with the same lamp and at the same wavelength distribution.

It may be pointed out that at these wavelengths, hydrogen atoms cannot be formed by a primary process in which a hydrogen atom is split off from the alkyl group. This is substantiated by the fact that no hydrogen was found in the gas or liquid phase photolysis of the esters to be discussed later in this paper.

The methane and propane formed in the gas phase photolysis of ethyl formate indicate that even at room temperature the ethoxy radicals decompose to an appreciable extent into a methyl radical and formaldehyde.

PART II. THE PHOTOLYSIS OF ESTERS OTHER THAN FORMATES

Results

Liquid Phase

The results of the liquid phase photolysis of a few simple alkyl esters at varying temperatures and intensities have been summarized in Table III.

Only the volatile products have been determined quantitatively. In a few runs however some of the products were present in amounts too small to be measured with any accuracy. Except when stated otherwise, the incident intensity was the same as for the experiments given in Table I. For the runs where the intensity has been changed, the incident intensity is given relative to the constant intensity experiments. All the rates are expressed in cc./min. $\times 10^4$.

A few general features are as follows:

(*a*) Ethyl acetate and ethyl propionate give ethylene as an important product. The ethylene quantum yields are virtually not affected by a change in intensity.

(*b*) Propylene is the main volatile product in the photolysis of isopropyl and *n*-propyl acetate.

(*c*) In the photolysis of methyl *n*-butyrate a considerable amount of ethylene has been found.

(*d*) Some ethylene is also formed in the photolysis of methyl propionate. However, the rate of formation is only 10% of the rate of ethylene production in the photolysis of ethyl propionate.

(*e*) For most of these compounds a change in temperature produces a slight variation in the yields of the alkenes.

(*f*) All esters have carbon monoxide and carbon dioxide as products. The rates of formation of both compounds increase with temperature. The acetates produce less carbon monoxide, carbon dioxide, and hydrocarbons than the propionates and the butyrates.

(*g*) In the photolysis of methyl and ethyl propionate, the rates of formation of carbon dioxide, methane, and ethane approach constant values at high temperatures. A decrease in intensity results in an increase of the yields of these three products. The results of the methyl propionate experiments indicate that at low intensities the rates of formation of carbon dioxide and methane are equal, while at high intensities the rate of formation of methane is somewhat less than that of carbon dioxide.

(*h*) Ethers were found to be present in the liquid phase photolysis of all the esters but their rates of formation were too small to be measured with any accuracy.

Gas Phase

Table IV represents the results of a few gas phase experiments. The incident intensity

was kept the same for all experiments done with mercury arc *a*. Except for runs 69, 76, and 77, the incident intensity has been kept constant for the runs performed with lamp *b*.

It can be seen that at high temperatures and for unfiltered light, carbon monoxide is the main product for all the esters studied. Under these experimental conditions CO/CO_2 was found to be larger than 3. However, a Corning filter 9863 used in the photolysis of ethyl propionate and methyl *n*-butyrate brings this ratio close to unity, while the C_2H_4/CO_2 ratio stays practically unchanged.

The results indicate that the rates of formation of carbon monoxide and carbon dioxide decrease appreciably with decrease in temperature. In the photolysis of ethyl acetate C_2H_4/CO_2 increases gradually with diminishing temperature. At $-23°$ C. ethylene accounts for about 70% of the volatile products.

Addition of iodine to ethyl acetate and ethyl propionate causes only a slight decrease of the ethylene yield, while all the other hydrocarbons are reduced to trace amounts. In the photolysis of the methyl propionate – iodine mixture, the ethylene yield amounted to about 10% of the ethylene yield found in the photolysis of ethyl acetate and ethyl propionate. No other hydrocarbons were formed.

Except for the iodine mixtures, ethers were found in all runs but were not determined quantitatively.

Discussion

The results given in Tables III and IV indicate that the following intramolecular processes occur:

$$XCOOY + h\nu = XCOOH + \text{alkene}, \qquad \text{VI}$$

$$= CH_3COOY + \text{alkene}. \qquad \text{VII}$$

Y and X represent alkyl groups with respectively β- and γ-hydrogens.

In favor of process VI the following facts may be mentioned:

(*a*) At low temperatures ethylene is practically the only volatile product formed in both the gas and liquid phase photolysis of ethyl acetate. The other esters with a β-hydrogen in the alkoxy group have an alkene as major product. There is only slight variation with temperature of the rate of formation of the alkenes in the photolysis of these esters.

(*b*) In the liquid phase photolysis of ethyl acetate and ethyl propionate, the ethylene yields are independent of intensity.

(*c*) In the photolysis of the ethyl propionate – iodine mixture, ethylene is a major product. The decrease of the ethylene yield is probably due to the elimination of the following disproportionation reactions:

$$C_2H_5 + C_2H_5 = C_2H_4 + C_2H_6, \qquad [1]$$

$$C_2H_5 + C_2H_5O = C_2H_4 + C_2H_5OH. \qquad [2]$$

The existence of process VII is substantiated by the presence of ethylene as an important product in both the gas and liquid phase photolysis of methyl *n*-butyrate. This process is analogous to the intramolecular rearrangement which was found to occur in the photolysis of ketones and aldehydes with γ-hydrogens in the alkyl groups (7).

The small ethylene and propylene yields in the liquid phase photolysis of methyl propionate and methyl *n*-butyrate indicate that process VIII does not occur to any appreciable extent,

$$XCOOY + h\nu = HCOOY + \text{alkene}. \qquad \text{VIII}$$

Also, a considerable fraction of the ethylene and propylene may be expected to be formed in disproportionation reactions between ethyl radicals and other radicals present.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

However, the small amount of ethylene found in the gas phase photolysis of the methyl propionate – iodine mixture seems to indicate that process VIII might occur to some extent. In analogy with this, recent work (4) on the gas phase photolysis of propionaldehyde and *n*-butyraldehyde showed that at 2380 and 1870 Å, these two compounds decompose to some extent into formaldehyde and the corresponding alkene. It should be pointed out, however, that the iodine runs given in Table IV were performed with unfiltered light. This may have led to the formation of ethylene by a disproportionation between ethyl radicals and iodine atoms.

The low carbon monoxide yields in the low temperature gas and liquid phase photolysis of the acetates, the very small ether yields in the liquid phase photolysis of all the compounds studied, and the absence of ethers in the iodine experiments indicate that process IX does not occur,

$$XCOOY + h\nu = XOY + CO. \qquad IX$$

Dissociation Processes

The following primary processes will be considered briefly:

$$XCOOY + h\nu = XCO + OY, \qquad X$$
$$= X + COOY, \qquad XI$$
$$= XCOO + Y. \qquad XII$$

The fact that for unfiltered light, carbon monoxide is the main product in the high temperature gas phase photolysis of all the esters indicates that under these experimental conditions process X is the most important one. It can be seen that the carbon monoxide yield for the high temperature gas phase runs is practically the same for all compounds and does not show any appreciable variation with temperature.

The decrease of the rate of formation of carbon monoxide with diminishing temperatures in both gas and liquid phase photolysis proves that only a small fraction of the XCO radicals decompose by the excess energy carried over from the primary process. In the iodine runs the CO yields are fairly high. However, it is possible that at these low iodine pressures a fraction of the XCO radicals decompose before reacting with iodine.

It is not possible to decide from the gas phase runs if the CO_2 comes from the decomposition of COOY, XCOO, or from both radicals:

$$COOY = CO_2 + Y, \qquad a$$
$$XCOO = CO_2 + X. \qquad b$$

Both radicals are considered to be fairly unstable at room temperature. However, at low temperatures the CO_2 yield decreases appreciably in both the gas and liquid phase photolysis. Although no conclusive evidence can be given, the following facts indicate that reaction *b* and consequently process XI is the most likely one to occur:

1. The rates of formation of methane and carbon dioxide in the liquid phase photolysis of methyl propionate are equal at low intensities and at all temperatures. Recombination of methyl radicals with other radicals present in the system explains the somewhat lower methane yields in the high intensity runs. The results of the liquid phase photolysis of methyl *n*-butyrate lead to the same conclusion.

2. At low temperatures $(C_2H_6+2\,C_4H_{10}+C_3H_8)/(CO+CO_2)$ is much larger than unity in the liquid phase photolysis of methyl propionate, while $C_3H_8 > (CO_2+CO)$ in the photolysis of methyl *n*-butyrate. This proves that there are COOY radicals formed which react with other species instead of decomposing.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/04/12
For personal use only.

However, the fact that the carbon dioxide yields are considerably lower for the acetates than for the propionates and butyrates remains unexplained. On the assumption that the CH_3CO_2 radicals are more stable than the $C_2H_5CO_2$ or $C_3H_7CO_2$ radicals, this observation would rather tend to favor process XII.

Cutting off short wavelengths in the gas phase photolysis of ethyl propionate and methyl *n*-butyrate reduces considerably the carbon monoxide yield as compared to the ethylene and carbon dioxide yields. This proves that process X occurs at shorter wavelengths than processes VI, VII, and XI.

After subtracting the amounts of ethylene formed in reaction [1], values of 0.66, 0.64, and 0.63 can be obtained for the ratio C_2H_4/CO_2 in the gas phase ethyl propionate runs *a*75, *b*76, and *b*77. The ethyl propionate – iodine run indicates that the contribution of reaction [2] is small. In the gas phase photolysis of methyl *n*-butyrate, values of 0.304 and 0.303 were obtained for the ratio C_2H_4/CO_2 in experiments *b*68 and *b*69. From the independence of the C_2H_4/CO_2 rates with change in wavelength, it may be concluded that processes VI and XI on the one side, and processes VII and XI on the other side, probably result from the same electronic level.

It can be seen that the value for the C_2H_4/CO_2 ratio in the liquid phase photolysis of ethyl propionate at 90° C. and low intensity, under which conditions the CO_2 yield attained a constant value, does not differ very much from the one found in the gas phase photolysis of this compound.

Summarizing the results, it may be concluded that processes I and X take place at short wavelengths, while the other intramolecular and dissociation processes occur at long wavelengths as well. In a later publication (3) it will be shown that addition of certain solvents leaves processes I and X unaffected, while the others are strongly suppressed.

ACKNOWLEDGMENTS

TREATMENT OF EXPERIMENTAL DATA IN THE STUDY OF CHELATION[1]

G. F. Atkinson and W. A. E. McBryde

ABSTRACT

Calculation from experimental formation constants of the various species of metal chelates that predominate for a given system under different experimental conditions is facilitated by the use of a digital computer. A convenient graphical representation of the results obtained in this way is proposed. From the plotted data one may select conditions for a photometric analytical procedure that will ensure the exclusive formation of a single chelate species. The changes in species that accompany changes in pH for some systems introduce a variable and appreciable contribution to the ionic strength of the solution, the magnitude of which may be estimated from the results of the foregoing calculation.

USE OF A DIGITAL COMPUTER

Many methods of attacking the problem of the stoichiometry and stability of metal chelate complexes have been reported in the literature (1, 2, 3, 4, 5). These give rise to sets of values for

p = number of ligand groups attached,
K = formation constant(s),

at particular values of

r = molar ratio of reagent to metal,
$[M]_T$ = metal concentration put in.

The choice of experimental conditions by each investigator often seems rather arbitrary.

Clearly, it is advantageous for the analytical chemist to survey the behavior of a chelate system over a range of pH and r, rather than to devise an empirical procedure closely based on the conditions of the original study. Not only may it be possible to economize on the consumption of frequently expensive reagents, but also it may be possible to arrive at an estimate of the precision needed in reproducing conditions (buffering, etc.) in successive determinations. Unfortunately, because of the number of equilibria involved in forming chelate complexes in aqueous solutions, the determination of the probable solution constituents involves exceedingly tedious calculations, and is seldom undertaken.

We have sought to reduce the labor of calculation by making use of the University of Toronto's electronic digital computer "FERUT".

The chelate system selected was iron(III) plus tiron (4,5-dihydroxybenzene-1,3-disulphonic acid). We shall employ the abbreviated formula H_4Bz for tiron, following Schwarzenbach (6). This system presents more than usual complexity for computation because of the presence in acidic solutions of both protonated and unprotonated 1:1 complexes (6). It was further felt to be an appropriate choice since K values determined for $r = 3$ and for $r = 6.4$ are in fair agreement with each other (7). Schwarzenbach's values for K were used for the calculation.

The Equations

Iron(III) is distributed according to

$$[1] \qquad [Fe]_T = [Fe_0]+[FeBz]+[FeBz_2]+[FeBz_3]+[FeHBz],$$

where $[Fe]_T$ = stoichiometric concentration of iron put in,
Fe_0 = all species not involving tiron,
Bz = "tironate" ion, $C_6H_2(SO_3)_2O_2^{-4}$.

[1]*Manuscript received October 17, 1957.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

Tiron is distributed among the four species with iron as above, and also among Bz, HBz, and H_2Bz. So when iron is not present

$$[2] \qquad [T]_T = [T_F] = [Bz]+[HBz]+[H_2Bz]$$

and when iron is present

$$[3] \qquad \begin{aligned}[T]_T &= [T_F]+[T_C] \\ &= [Bz]+[HBz]+[H_2Bz]+[FeBz]+2[FeBz_2]+3[FeBz_3]+[FeHBz],\end{aligned}$$

where $[T]_T$ = stoichiometric concentration of tiron put in,
T_F = tiron not in species with iron,
T_C = tiron in species with iron.

Using the expressions defined by Schwarzenbach and Willi (6) for the equilibrium constants, we may set up the following equations:

$$[4] \qquad [Bz]/[T]_T = 1/(1+K_1[H]+K_1K_2[H]^2) \equiv \alpha,$$

$$[5] \qquad [HBz]/[T]_T = (1-\alpha)/(1+K_1[H]) \equiv \beta,$$

$$[6] \qquad [H_2Bz]/[T]_T = 1-(\alpha+\beta),$$

$$[7] \qquad \begin{aligned}[Fe_0]/[Fe]_T &= 1/(1+K_3[Bz]+\alpha^2K_3K_4[Bz]^2+\alpha^3K_3K_4K_5[Bz]^3+K_7[Bz]) \\ &\equiv C_0,\end{aligned}$$

$$[8] \qquad \begin{aligned}[FeBz]/[Fe]_T &= (1-C_0)/(1+\alpha K_4[Bz]+\alpha^2K_4K_5[Bz]^2+K_6[H]) \\ &\equiv C_1,\end{aligned}$$

$$[9] \qquad \begin{aligned}[FeBz_2]/[Fe]_T &= \{1-(C_0+C_1)\}/\{1+\alpha K_5[Bz]+K_6[H]/\alpha K_4[Bz]\} \\ &\equiv C_2,\end{aligned}$$

$$[10] \qquad [FeBz_3]/[Fe]_T = \{1-(C_0+C_1+C_2)\}/\{1+K_6[H]/\alpha^2K_4K_5[Bz]^2\} \equiv C_3,$$

$$[11] \qquad [FeHBz]/[Fe]_T = 1-(C_0+C_1+C_2+C_3) \equiv C_4.$$

The Calculations

The computer program was devised to evaluate these equations systematically at regularly spaced values of [Bz], pH, and $[Fe]_T$. Sets of values having $r<1$, and having $[T]_T>0.5$ molar were automatically discarded, thus limiting the output of results to a useful range. Output was presented as shown for each case:

[Bz]	pH	$[Fe]_T$		
$[T_F]$	$[T_C]$	$[T]_T$	$[T_C]/[T]_T$	
C_0	C_1	C_2	C_3	C_4

It should be pointed out that the application of this technique to all systems consisting of equivalent sets of complex species requires the writing of only one program for the computer, the various K values being supplied as number input in each application of the program. Furthermore it is apparent from the equations that minor modifications will enable the many *tris*-complex systems in which only three species are recognized (MR, MR_2, and MR_3) to be handled by the program.

PRESENTATION OF COMPUTED RESULTS

Various graphical methods of displaying the computed results are possible.

In dealing with the effect of pH on polybasic acids, the fraction of acid present in each ionic or molecular species is often plotted against pH (see, e.g., 8). Curves of this type for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

several values of r are shown in Fig. 1. Their greatest usefulness is in the interpretation of experiments in which a property having a characteristic value for each species (e.g. optical absorption) is measured over a range of pH.

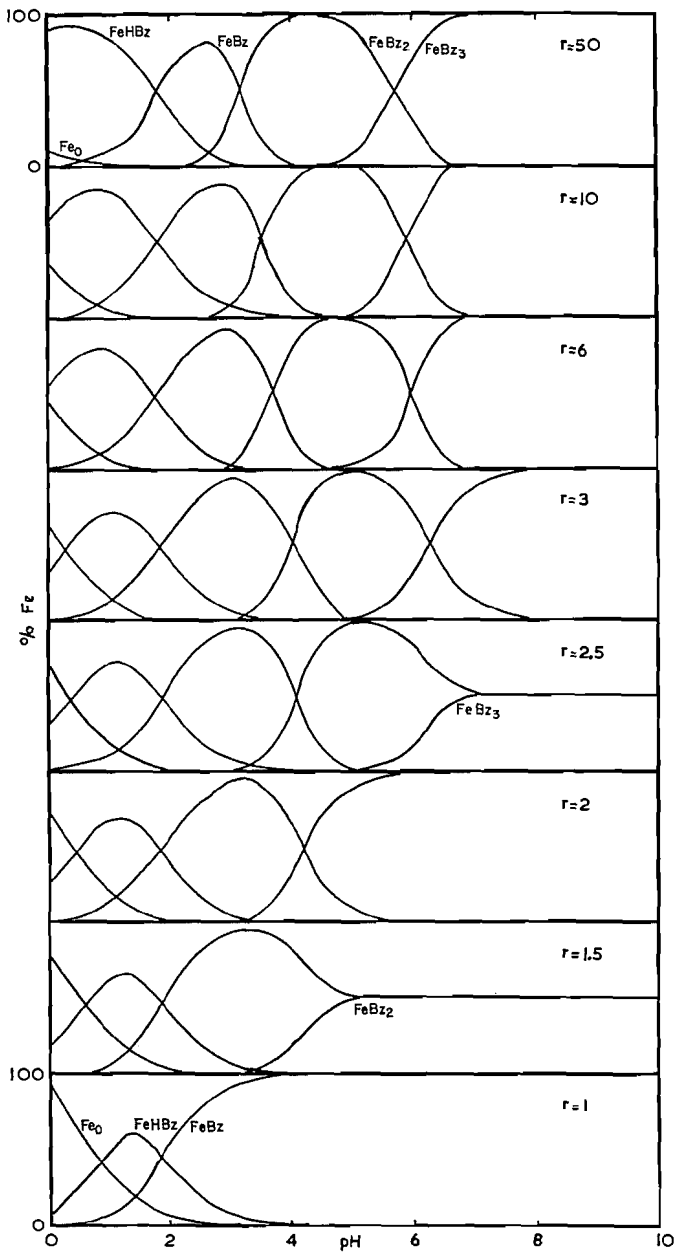

FIG. 1. Distribution of species according to pH.

Ågren (1), having drawn such diagrams with non-overlapping regions, proposes that the abscissae be made pH − pRH rather than pH, to permit the representation of conditions at more than one concentration of chelating agent.

We propose that such data may to advantage be represented as in Fig. 2(*a*), which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

shows a contour map of fractions of species, plotted on axes of pH and log r. The region of greatest occurrence of each species is designated by the formula; and contours showing the percentage distribution of iron among the several species are also drawn. In Fig. 2(*b*), on the same axes, are shown areas in which stated proportions of reagent are present as species with iron. Used together, such diagrams indicate the regions of greatest interest for the development of analytical procedures, and suggest the necessary precision of pH adjustment, etc., in such procedures.

It is not difficult from such a diagram to see why different authors have differently described the color of iron(III)–tiron solutions in the vicinity of pH 4. The maintenance of constant pH by buffering does not assure the presence of a single species, changes in solution composition occurring also with variation of r, and of ionic strength. It may be added that, as far as the authors have been able to determine, the species FeBz and FeHBz have identical absorption spectra, but in order to produce these species in equivalent concentrations from solutions possessing the same content of iron(III) it has been necessary to provide solutions of equal ionic strength.

The figures reproduced here are simplified by the plotting of very few contour lines in the interest of facile reproduction, but any desired smaller interval could be selected. If this is done, it is less confusing to plot the curves for each species on a separate diagram.

These diagrams, while providing a potentially useful analysis of the solution constituents in the iron(III)–tiron system, must be applied with some restraint. For one thing, in the calculations upon which they are based it has been assumed that values of K taken from experiments in which $r = 3$ are valid for all values of r. In principle this assumption should be permissible, but it must be recalled that Freiser and co-workers have shown for *o*-aminophenol and for dimethylglyoxime that values of the apparent stability constants for certain metallic derivatives are *not* completely independent of values of r (9, 10). We therefore feel that, lacking evidence on this score, our values in the range $r > 10$ should be regarded with less confidence than those in the range $r < 10$. Care must also be taken to confine application of the data within limits for which the postulated reactions are valid. Thus, to select $r = 5$, pH = 9, for the determination of iron as its 3 : 1 tiron complex may introduce difficulty because of air-oxidation of the reagent, in which case equation [3] is no longer valid.

Strictly speaking, precise knowledge of the distribution of ferric iron among several species in solution requires that account be taken also of the formation of complex ions with any other anions in solution, particularly of any buffer present, and of hydrolysis of the metallic ion. For the latter one might incorporate the data of Hedström (11) or of Milburn and Vosburgh (12) into the calculation. As far as making allowance for other species in solution is concerned, several difficulties arise: data for interaction of ferric iron with acetate or phthalate are apparently not available (13), but even if they were the manner of using them would be complicated by the probability of formation of mixed complexes with tiron; there would then have to be as many calculations of the distribution of species as there are buffer systems selected. The data of Fig. 2 are applicable to systems including other anions only if the assumption is made that the stability constants of species formed by ferric iron with the latter are very small compared with the formation constants of the tironate species. Furthermore, since Schwarzenbach measured the formation constants upon which our calculations are based in 0.1 M chloride solutions, any use of the results of the calculations for solutions of other concentrations of chloride requires the further assumption that the reaction of ferric iron with chloride is only slight compared to that with tiron. In this connection it may be recalled that Foley and Anderson described the effect of changing the buffering constituents on the formation of ferric

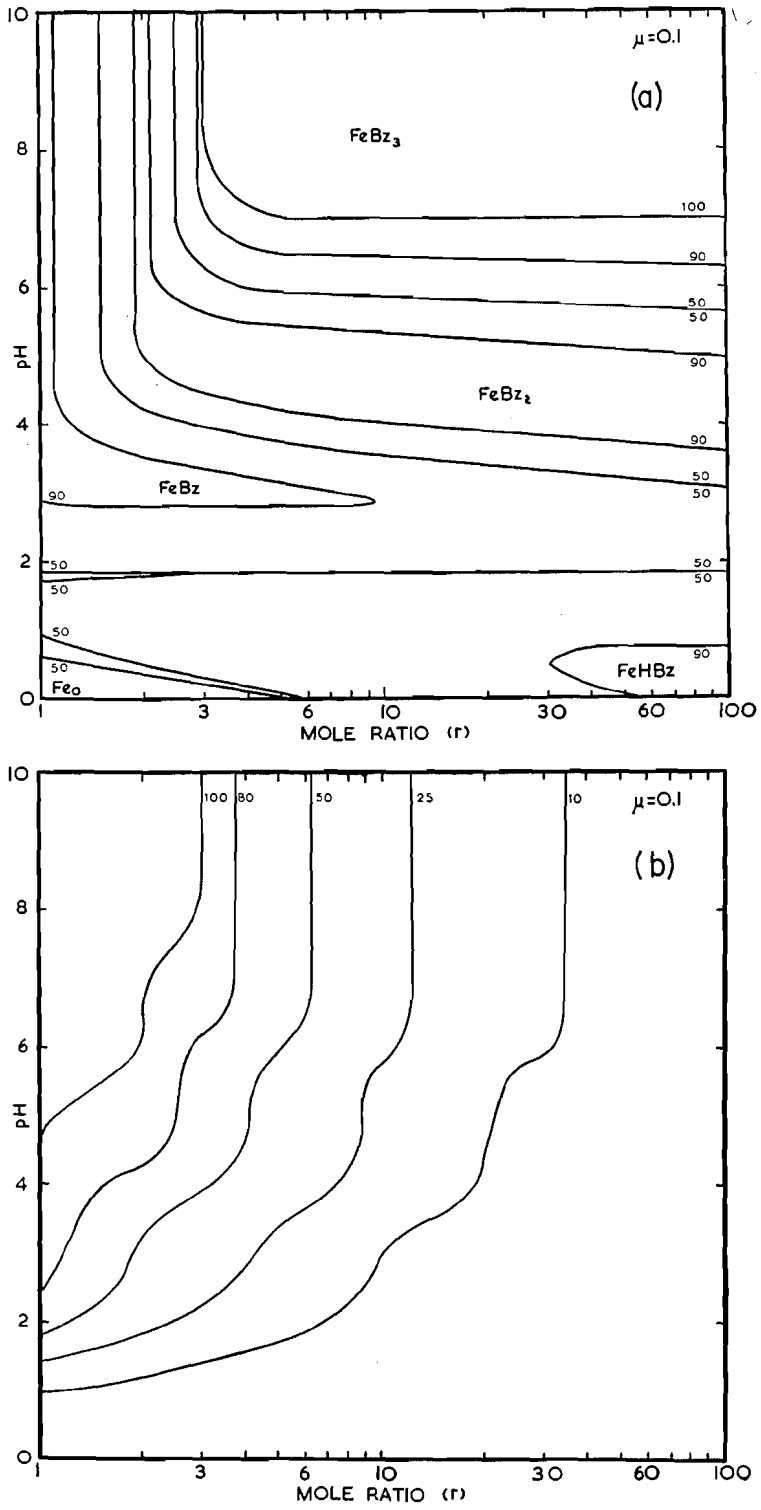

FIG. 2. Distribution of species according to pH and r; (a) percentage of iron present in stated forms, (b) percentage of tiron bound to iron.

sulphosalicylate complexes (14). However, the interpretation of these results by these authors has not been borne out by the more complete investigations of Ågren (1) or Vareille (15).

EFFECT OF CHANGES IN pH ON IONIC STRENGTH

The authors are currently investigating the effect of changes in ionic strength upon the apparent equilibrium constants for this system, and consequently upon the distribution of metal among the various species. We have already observed in spectrophotometric measurements that this effect is considerable at low pH(16).

For our experiments it would be desirable to be able to work at values of the ionic strength low enough to deny to us the convenience of adding gross amounts of indifferent electrolyte, and thereby the need arises to know rather accurately the contributions to ionic strength of all species in solution. It is apparent that the large contribution of the highly charged chelate species (in this system) will vary markedly with pH. In a similar context Olson and Simonson (17) have shown that the effects of maintaining "constant concentration of inert electrolyte" and "constant ionic strength" are not the same when the species present are changing.

By means of Fig. 2 we have computed the total contribution of species arising from ferric perchlorate and tiron for values of $r = 3$, 10, and 30. These results, plotted as log μ against pH, are shown in Fig. 3.

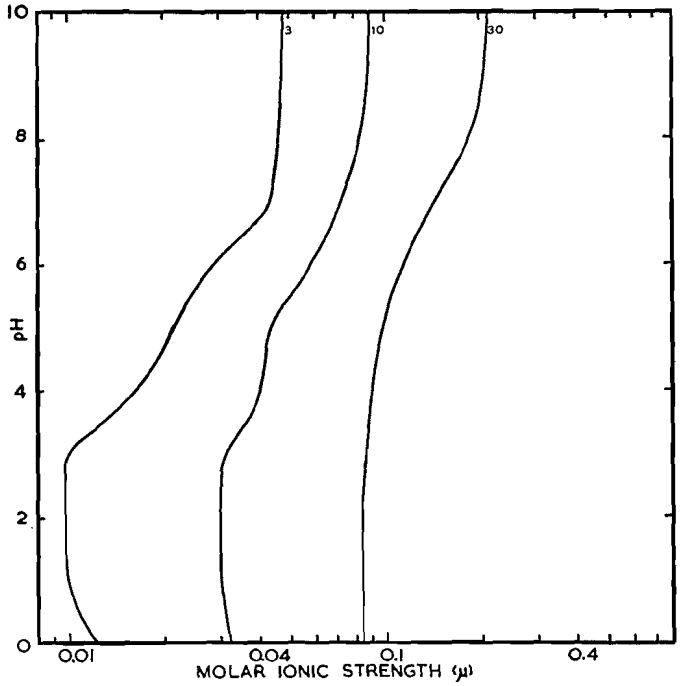

FIG. 3. Contribution to ionic strength of species from $Fe(ClO_4)_3$ and tiron. Determinant variable of curves: r.

It may be noted that Schwarzenbach's values for K were determined with $[Fe]_T = 1.11\times10^{-3}$ M, $r = 3$, and a solution of nominal ionic strength 0.1 M by addition of potassium chloride. It appears from our calculations that to this value must be added a

For personal use only.

contribution from the several complex species amounting to as much as one-half of the nominal value, depending on pH. It follows that only in solutions of moderately high concentration of indifferent electrolyte (cf. Ågren (1)) will the ionic strength be relatively "constant" throughout the range of pH corresponding to the formation of the different complexes in this system.

ACKNOWLEDGMENT

THE LIQUID PHASE PHOTOLYSIS OF DIETHYL KETONE AND METHYL ETHYL KETONE[1,2]

P. AUSLOOS[3]

ABSTRACT

The liquid phase photolysis of diethyl ketone has been studied in the temperature range from −35° to 95° C. The CO quantum yield at 95° C. was found to be close to unity. At 28° C. decrease in intensity and addition of heptane led to a substantial increase of the CO and the ethane yields.

The methyl ethyl ketone liquid phase photolysis at temperatures between 5° and 75° C. led to the same observations. Arrhenius plots of $R_E/R_B^{1/2}[K]$ gave for both compounds a value of 5 kcal./ mole.

Gas phase studies in the temperature range of 0° to 60° C. confirmed the low CO quantum yield reported previously and showed evidence for disproportionation and recombination reactions between ethyl and propionyl radicals.

EXPERIMENTAL

Eastman Kodak Company methyl ethyl ketone and diethyl ketone (white label) were distilled through 10 theoretical plates with rejection of large head and tail fractions. Air was removed by bulb-to-bulb distillation in the vacuum line.

Gas phase experiments were performed with a Hanovia (16A-13) SH type medium pressure lamp. The cylindrical quartz cell (5 cm. diameter, 10 cm. long) was completely filled with a nearly parallel light beam.

The liquids were irradiated in a quartz cell of 5 cm. diameter and 0.05 cm. depth. The cell was provided with two outlets, one of which was sealed after filling, while the other was closed by a break seal which made it possible to attach the cell to the analysis system after each experiment. Between runs the cell was washed out with diethyl ketone and dried at about 150° C. The irradiation was carried out in a thermostat consisting of a brass cylinder with evacuated double walls and double quartz windows. For experiments above room temperature an electric immersion heater was brought into distilled water, while for the low temperature experiments the thermostat was filled with methanol cooled by dry ice. In this way it was possible to maintain the temperature constant within half a degree.

At 3130 Å about 98% of the incident radiation is absorbed by the undiluted ketone. In order to compensate for this sharp absorption decrease throughout the cell, two Hanovia lamps were placed opposite each other with the cell fixed in the center of the nearly parallel light beam.

Except for experiments 1 and 2 Corning filters (9-53) were used to cut off wavelengths below 2800 Å. The incident intensity was varied by means of copper gratings.

After irradiation of the liquid the cell was attached to the analysis system, consisting of three traps and one modified Ward still. The CO–CH_4 fraction was removed at solid nitrogen temperature and was analyzed by combustion over hot CuO. The C_2H_6–C_2H_4 fraction was taken off at −160° C. C_2H_4 was determined by hydrogenation over a Ni

catalyst (16). The C_4H_{10} fraction was separated at about $-120°$ C. In view of the high C_2H_6/C_4H_{10} ratio, which in some experiments was higher than 100, great care was taken that no ethane was left over from the previous distillation.

RESULTS

Gas Phase

Table I represents the data of experiments performed at approximately constant diethyl ketone concentration. Runs 1 and 2 were done with an unfiltered light beam and at constant intensity. The other runs were performed with a Corning filter 9-53 and constant incident light intensity.

**Iodine added.*

It can be seen that in both series of experiments the rates of formation of all the products decrease with temperature. In the last column M.B. stands for the material balance $[\frac{1}{2}(C_2H_4+C_2H_6)+C_4H_{10}]/CO$. This ratio increases appreciably with decrease in temperature.

Liquid Phase

All experiments given in Tables II and IV and runs 36, 39, 40, 44, 45 of Table V were conducted at the same incident intensity.

Table II shows the results of experiments done in a temperature range from $-35°$

to 94° C. It can be seen that the rates of formation of carbon monoxide and ethane both increase with temperature. At higher temperatures they approach constant values.

A rough measure of the quantum yield was obtained by comparing the rate of formation of carbon monoxide from the gas phase photolysis of diethyl ketone at 95° C. with the rate of formation from the liquid phase photolysis at the same temperature. The measurements were done with Corning filter 9-53 and cells of respectively 5 and 0.05 cm. depth. On the assumption that the quantum yield for CO in the vapor phase was unity, it was found that approximately 8×10^{16} quanta per second were absorbed by the liquid. This led to $\phi(CO) \sim 0.87$ at 95° C.

The rates of formation of ethylene and butane show a pronounced increase with temperature up to 28° C. followed by a gradual decrease.

In the same table are included the results of one acetone liquid phase experiment, performed at 28° C. and under the same experimental conditions as the previous runs. Comparison with the diethyl ketone results leads to a CO quantum yield roughly equal to 2×10^{-3}. This figure is somewhat higher than previous estimates (11, 15).

In Table III the results of experiments carried out at 5°, 28°, and 84° C. and at various intensities are shown. I_{rel} represents the incident intensity relative to the highest intensity run. Values of $R_{C_2H_6}/I_{rel}$ given in the last column show an increase with decrease in intensity. It can be seen from the data that this trend is even more pronounced for R_{CO}/I_{rel}. These results indicate clearly that the CO and ethane yields increase with diminishing intensity. However, this increase is much smaller at 84° C. where the quantum yield is already close to unity.

Octane.

In Table V are given the results of the liquid phase photochemical decomposition of methyl ethyl ketone. The experiments were done in the temperature range from 5° to 70° C. and at varying intensities. The rates of formation of carbon monoxide, methane, ethylene, ethane, and butane have been measured. Although propane was present, it could not be determined with any accuracy because it was present in an amount less than 1% of the ethane fraction.

45	1	8	70	7.00	7.60	1.01	59.2	0.56	24.8

Comparison of the runs at constant intensity at varying temperatures shows that the rates of formation of carbon monoxide, methane, and ethane increase with temperature. However, the increase of the rate of formation of ethane is less pronounced at higher temperatures, where it reaches a value close to one half the value found in the liquid phase photolysis of diethyl ketone under the same experimental conditions.

The ratios C_2H_4/C_4H_{10} do not differ very much from those found in the diethyl ketone photolysis. The rates of formation of ethane and butane both go through a maximum around 28° C. Decrease of intensity leads to a substantial decrease in the CO, C_2H_4, and C_4H_{10} yields, while the C_2H_6 yields increase slightly.

DISCUSSION

Diethyl Ketone

(*a*) *Gas Phase*

The gas phase photolysis of diethyl ketone has been extensively investigated in the past (8, 9, 10, 13).

In the course of this work a few runs were performed at low temperatures in order to obtain additional information about the primary process and reactions involving the propionyl radical.

The results given in Table I indicate that at relatively high intensities, the quantum yield of the CO production drops appreciably at temperatures below 60° C. A value of 0.23 can be estimated for the CO quantum yield at 0° C., if at 60° C. the quantum yield is assumed to be 1. These results are in agreement with earlier work (13), where at 25° C. and comparable intensities a value of 0.6 was found for the quantum yield of the CO formation.

The low CO quantum yield suggests as main primary process:

$$C_2H_5COC_2H_5 + h\nu = C_2H_5CO + C_2H_5, \qquad \text{I}$$

in which the propionyl radical may eventually decompose by excess energy carried over from the primary process or by thermal reaction:

$$C_2H_5CO = C_2H_5 + CO. \qquad [1]$$

Assuming that no collisional deactivation of the excited diethyl ketone molecules occurs, run 7 as well as recent work on the photooxidation of diethyl ketone (12) suggests that at most 5% of the propionyl radicals decompose as a result of the primary process.

Besides decomposing, the propionyl radical may react with other species. Several combination and disproportionation reactions involving the propionyl radical may occur:

$$C_2H_5CO + C_2H_5 = C_2H_5COC_2H_5, \qquad [2]$$
$$= C_2H_6 + CH_3CH{=}CO, \qquad [3]$$
$$= C_2H_4 + C_2H_5CHO; \qquad [4]$$
$$C_2H_5CO + C_2H_5CO = C_2H_5COCOC_2H_5, \qquad [5]$$
$$= C_2H_5CHO + CH_3CH{=}CO; \qquad [6]$$
$$C_2H_5CO + C_2H_5COC_2H_4 = C_2H_5COC_2H_4COC_2H_5, \qquad [7]$$
$$= C_2H_5CHO + C_2H_5COCH{=}CH_2, \qquad [8]$$
$$= CH_3CH{=}CO + C_2H_5COC_2H_5. \qquad [9]$$

The increase of the C_2H_4/C_4H_{10} and C_2H_6/C_4H_{10} ratios with diminishing temperatures may be considered as good evidence for the occurrence of the reactions [3] and [4], while the fact that $(C_4H_{10}+\frac{1}{2}C_2H_4+\frac{1}{2}C_2H_6)/CO$ becomes larger than unity at low temperatures substantiates reaction [5] and perhaps also reaction [6]. Although there is no direct evidence for reactions [7], [8], and [9], it is quite likely, in view of their exothermicity, that these reactions occur.

Ethyl radicals disappear mainly by reactions [2], [3], [4], or by one of the following reactions:

$$C_2H_5 + C_2H_5COC_2H_5 = C_2H_6 + C_2H_5COC_2H_4; \qquad [10]$$
$$C_2H_5 + C_2H_5 = C_4H_{10}, \qquad [11]$$
$$= C_2H_4 + C_2H_6; \qquad [12]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

$$C_2H_5 + C_2H_5COC_2H_4 = C_2H_5COC_4H_9, \quad [13]$$
$$= C_2H_4 + C_2H_5COC_2H_5, \quad [14]$$
$$= C_2H_6 + C_2H_5COCH{=}CH_2. \quad [15]$$

Gas phase studies led to a value of 0.12 ± 0.01 for k_{12}/k_{11} (2, 8, 13), while $E_{10} - \frac{1}{2}E_{11}$ was found to vary from 7.5 to 9 kcal./mole depending on the temperature range (3, 8, 13).

At the temperatures used in this work the pentanonyl radical does not decompose to any appreciable extent and will eventually disappear by a radical reaction such as [7], [8], [9], [13], [14], [15] or by one of the following reactions:

$$C_2H_5COC_2H_4 + C_2H_5COC_2H_4 = C_2H_5COC_2H_5 + C_2H_5COCH{=}CH_2, \quad [16]$$
$$= (C_2H_5COC_2H_4)_2. \quad [17]$$

(*b*) *Liquid Phase*

Primary process

From the results given in Table II it follows that the carbon monoxide and ethane yields approach constant values at high temperatures, which correspond to a primary quantum yield close to unity.

The fact that at room temperature the carbon monoxide yield increases appreciably with diminishing intensity and increasing dilution may be considered as evidence for a competition between reaction [1] and the radical reactions involving the propionyl radical. It is likely that infinite dilution at these temperatures may lead to a primary quantum yield equal to one.

The quantum yield determination at 95° C. is not accurate enough to decide whether any primary or secondary diffusive recombination occurs. If any recombination takes place between original partners, disproportionation ought to occur as well. From the results given in Table I, a rough estimate of 0.02 can be obtained for the ratio of the rate of the disproportionation reaction [4] to the rate of the recombination reaction [2].† From this estimate and from the amount of ethylene formed in the lowest intensity runs (Table III), it follows that under these conditions less than 20% of the ethyl radicals recombine with propionyl radicals. In view of the fact that ethylene may also be formed in several other reactions, recombination between original partners may be considered negligible.

Recent work (15) on the liquid phase photolysis of mixtures of light and heavy acetone showed that deactivation is a more likely explanation for the low quantum yield than primary or secondary diffusive recombination. In earlier work (7) diacetone alcohol was determined in the liquid phase photolysis of undiluted acetone. It was also found that addition of hydrocarbons led to a decrease of the quantum yield of the volatile products (15) and the formation of an alcohol (6, 11). These results indicate that, besides dissociation and normal deactivation by collision, the following processes involving excited acetone molecules have to be considered:

$$CH_3COCH_3^* + CH_3COCH_3 = (CH_3)_2COHCH_2COCH_3, \quad a$$
$$CH_3COCH_3^* + RH = (CH_3)_2COHR. \quad b$$

When RH is a hydrocarbon like hexane or heptane, process *b* is faster than *a*. It may be mentioned that processes of type *b* have also been found to occur in the liquid phase photolysis of esters (1).

†*In order to obtain this value the assumption was made that the* CO *quantum yield was one at 60° C., and a value of 0.12 was used for the ratio of the rate of reaction [12] to the rate of reaction [11].*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The fact that at 28° C. addition of normal heptane to diethyl ketone increases the quantum yield of the volatile products to a value close to unity indicates that at these temperatures the process analogous to process *b* does not occur. A shorter lifetime of the excited diethyl ketone molecules may explain the difference in quantum yield between the liquid phase photolysis of acetone and diethyl ketone.

In analogy with the acetone photolysis, where a decrease of the quantum yield with temperature was found in both gas (14) and liquid (15) phase, it is quite possible that the low quantum yield at temperatures below 28° C. (Table II) is partly due to deactivating processes.

It has been suggested previously (5) that, in view of the relatively high ethylene yield, the following primary process occurs:

$$C_2H_5COC_2H_5 + h\nu = C_2H_5CHO + C_2H_4.$$

The fact, however, that the ethylene yield drops appreciably with intensity means that this compound is formed mainly in a radical–radical reaction. The iodine experiments (run 7) and the lowest intensity run of Table III indicate that the quantum yield of this process has to be lower than 5×10^{-3}.

Secondary reactions

Although their relative importance may change, the same secondary reactions can be expected to occur in both gas and liquid phase photolysis. In order to explain the liquid phase results, it has to be visualized that, owing to the higher ketone concentration, alkyl radicals will react mostly with diethyl ketone itself. Consequently, reactions of the ethyl radical with other radicals will be of less importance. Indeed, it can be seen from the data of Tables II and III that ethane is the main product. The fact that at higher temperatures the amount of CO formed is about half the amount of ethane proves that at these temperatures practically all of the propionyl radicals are decomposed.

As mentioned before, the decrease of the rate of formation of ethylene and butane with intensity points to the formation of these products in a radical–radical reaction. The data of Table II show that both compounds go through maxima around 28° C. This can be explained by a competition between an increase of the ethyl radical concentration caused by a substantial increase of the quantum yield up to 28° C. and the increase in rate of the hydrogen abstraction reaction [4] which tends to decrease the stationary radical concentration.

The C_2H_4/C_4H_{10} ratio is under all conditions considerably higher than the value of 0.12 generally accepted for k_{11}/k_{12}. Because no third body is required for processes [11] and [12] (8), the ratio for the two rate constants should be the same in both gas and liquid phase. It is probable that the excess ethylene is formed in a radical–radical reaction such as [4] and [14]. Reaction [4] may be expected to be of importance at low temperatures, while reaction [14] will occur mainly in the high temperature region.

If ethane and butane are produced only by reactions [10] and [11], the following relationship exists:

$$R_E/R_B^{1/2}[K] = k_{10}/k_{11}^{1/2} = A_{10}/A_{11}^{1/2}e^{-(E_{10}-\frac{1}{2}E_{11})/RT};$$

[K], R_E, and R_B represent respectively the concentration of diethyl ketone and the rates of formation of ethane and butane.

If this relation holds, $R_E/R_B^{1/2}$ should be independent of the absorbed intensity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The results given in Table III indicate that this ratio varies only slightly over a considerable intensity range. From this it may be concluded that ethane and butane are formed in normal kinetic processes.

In Fig. 1, log $R_E/R_B^{1/2}[K]$ calculated from the data of Table II has been plotted as a function of $1/T$. It can be seen that a good straight line is obtained which corresponds to an activation energy of 5 kcal./mole. This value may be ascribed to the activation difference $E_{10}-\frac{1}{2}E_{11}$. Gas phase studies in a temperature range from 25° to 150° C. lead to a value of 7.5 kcal./mole. The lower value obtained in the liquid phase photolysis may at least be partly due to the fact that, in a liquid, recombination of radicals may require an activation energy. In order to account for the difference between the gas and liquid phase photolysis results, a value of 5 kcal./mole has to be ascribed to the activation energy of the diffusion process.

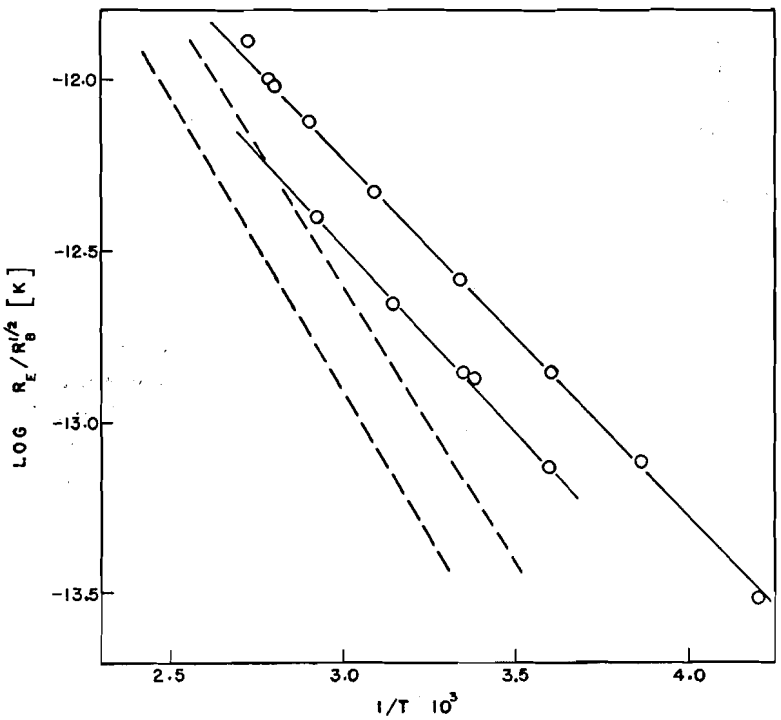

FIG. 1. Plot of log $R_E/R_B^{\frac{1}{2}}[K]$ against $1/T$ for the photolysis of diethyl ketone and methyl ethyl ketone:
——— liquid phase photolysis: upper curve—diethyl ketone,
lower curve—methyl ethyl ketone;
— — — gas phase photolysis: upper curve—diethyl ketone,
lower curve—methyl ethyl ketone.

In the above treatment, the ethane formed by reactions [3], [12], and [15] has not been taken into account. The low amount of butane formed shows reaction [12] to be unimportant. Assuming that reactions [14] and [15] on one side and [3] and [4] on the other side have comparable rates, it can be deduced from the low ethylene yield that the amount of ethane formed by reactions [3] and [15] is small compared to the amount formed by the abstraction reaction [10].

Addition of *n*-heptane and *n*-octane to diethyl ketone leads to a substantial decrease

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

of the ratio $R_E/R_B^{1/2}$. Increasing dilution apparently leads to a limiting constant value for this ratio which is about 22% of the one found for the undiluted diethyl ketone. These results point to an appreciably lower rate for the abstraction of a hydrogen atom from heptane and octane than from diethyl ketone itself. In agreement with this, a few gas phase photolysis experiments of equal diethyl ketone heptane mixtures at 95° C. (1) indicated that at least 80% of the ethyl radicals abstract a hydrogen atom from the diethyl ketone molecules.

Methyl Ethyl Ketone

Primary Process

Gas phase studies (17) have shown that two primary processes have to be considered:

$$CH_3COC_2H_5 + h\nu = CH_3CO + C_2H_5, \qquad \text{II}$$

$$= CH_3 + C_2H_5CO. \qquad \text{III}$$

At 3130 Å process II was found to occur about 10 times more often than process III.

The data given in Table V show that at higher temperatures, the methane and CO yields are approximately equal and appreciably lower than the ethane yields. From this it follows that in the liquid phase photolysis too, process II is the most important. The fact that at higher temperatures the ethane yield is approaching a constant value, which is approximately half that obtained in the liquid phase photolysis of diethyl ketone, indicates that in this temperature range the primary quantum yield is approximately the same for both compounds.

As in the liquid phase photolysis of diethyl ketone, the ethane yield increases slightly with decrease in intensity. From this it may be concluded that the low ethane yield at the lower temperatures is at least partly due to the disappearance of the ethyl radicals by normal radical recombination processes. However at low temperatures, diminishing intensities led to a decrease in the carbon monoxide and methane yields; this is contradictory to what was found in the liquid phase photolysis of diethyl ketone. It may be pointed out that liquid phase photolysis studies of several compounds where acetyl radicals are formed in the primary process led to the same observation (1). At high temperatures where normal thermal decomposition of acetyl radicals becomes important, an increase of the CO yield with decrease in intensity was found for all the compounds studied. Although no conclusive interpretation can be given, it is likely that at low temperatures CO and methane result from a radical–radical process.

The decrease in ethylene yield with diminishing intensity indicates that, as in the diethyl ketone photolysis, ethylene is produced mainly in a radical–radical process, instead of being formed in a primary process.

Secondary Reactions

Essentially the same reactions may be expected to occur as those described in an earlier paper on the gas phase photochemical decomposition of methyl ethyl ketone (4).

Only the following two reactions will be considered:

$$C_2H_5 + CH_3COC_2H_5 = C_2H_6 + CH_6COC_2H_4, \qquad [18]$$

$$C_2H_5 + C_2H_5 = C_4H_{10}. \qquad [11]$$

Then

$$R_E/R_B^{1/2}[K] = k_{18}/k_{11}^{1/2} = A_{18}/A_{11}^{1/2}e^{-(E_{18}-\frac{1}{2}E_{11})/RT}.$$

The data of Table V indicate that the ratio $R_E/R_B^{1/2}$ is practically independent of intensity, which substantiates the above relationship.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

In Fig. 1, log $R_E/R_B^{1/2}$[K] has been plotted against $1/T$. It can be seen that this Arrhenius curve corresponds to an activation energy which is about the same as the one found for diethyl ketone. The two plots are separated by approximately 0.3 logarithmic units. The dashed lines which represent the gas phase results for the hydrogen abstraction reaction from diethyl ketone (3) and methyl ethyl ketone (4) show clearly that these plots are also approximately parallel and show the same separation as the liquid phase Arrhenius curves. These results can be explained by assuming that mainly secondary hydrogen atoms are abstracted from the ketones.

As mentioned earlier, the lower values found for the activation energy differences $E_{12}-\frac{1}{2}E_{11}$ and $E_{18}-\frac{1}{2}E_{11}$ in the liquid phase experiments may be due to the fact that diffusion of radicals in a liquid requires an activation energy. However, solvation of the reactants and activated complexes may also influence the rate of the abstraction and recombination reactions.

ACKNOWLEDGMENTS

The author wishes to thank Professors W. A. Noyes, Jr. and C. Ouellet for advice and encouragement. He also wishes to express his appreciation to the National Research Council of Canada for a University Postdoctorate Fellowship under the tenure of which part of this work was carried out.

THE HEMICELLULOSE OF WHITE ELM (ULMUS AMERICANA)

I. IDENTIFICATION OF 2-O-(4-O-METHYL-D-GLUCOPYRANOSYLURONIC ACID)-D-XYLOPYRANOSE[1]

J. K. GILLHAM AND T. E. TIMELL

ABSTRACT

Alkaline extraction of wood meal from white elm (*Ulmus americana*) has yielded a hemicellulose which on hydrolysis gave a sugar mixture containing xylose together with traces of galactose, glucose, mannose, and rhamnose in addition to two monouronic acids and one aldobiouronic acid. The latter was identified as 2-*O*-(4-*O*-methyl-D-glucopyranosyluronic acid)-D-xylopyranose.

This series of investigations deals with the constitution and properties of the hemicellulose portion of white elm wood. The present paper is concerned with the structure of an aldobiouronic acid obtained on partial hydrolysis of the latter.

RESULTS AND DISCUSSION

Alkaline extraction of wood meal from white elm gave a hemicellulose in a yield of 16.5%, or slightly higher than the methyl glucurono-xylan content of the wood, 15.4% (1). Hydrolysis of the crude hemicellulose yielded a sugar mixture containing six sugar acids and xylose as well as traces of galactose, glucose, mannose, and rhamnose. The acids were separated from the neutral sugars by the use of an anion exchange resin and were then resolved on a column containing the same resin by eluting with dilute acetic acid. Three main fractions were obtained, corresponding on the paper chromatogram to an aldobiouronic acid, a monouronic acid, and a methyl monouronic acid, respectively.

The methoxyl content and the equivalent weight of the aldobiouronic acid as well as chromatographic evidence suggested that it was a methoxyuronic acid linked to a pentose. A portion of the acid was converted to the methyl ester methyl glycoside, reduced with lithium aluminum hydride, and hydrolyzed. Examination on the paper chromatogram indicated the presence of 4-*O*-methyl-D-glucose and D-xylose; the latter crystallized and the former was identified through its crystalline osazone (2, 3).

The aldobiouronic acid was completely methylated and the methyl ester methyl glycoside was reduced and hydrolyzed. The two methylated sugars obtained were separated and identified through their crystalline aniline derivatives as 3,4-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose, respectively (4, 5). The methylated aldobiouronic acid was accordingly methyl 2-*O*-(2,3,4-tri-*O*-methyl-D-glucopyranosyluronic acid)-3,4-di-*O*-methyl-D-xylopyranoside methyl ester. This conclusion was further corroborated by the fact that it gave the same infrared spectrum as a compound with this structure, previously isolated from white birch wood (6). The aldobiouronic acid was therefore 2-*O*-(4-*O*-methyl-D-glucopyranosyluronic acid)-D-xylopyranose. Confirmation of this structure was obtained from lead tetraacetate oxidation, which produced 1.2 moles of formaldehyde per mole of acid (7), a result to be expected only from a 1,2-linked disaccharide (8, 9).

The synthesis of one or both of the existing anomers of this compound is presently being attempted (10) to determine the nature of the glycosidic linkage. The high positive rotation of the compound (+110°) as well as earlier evidence (11) indicate that it is probably of the α-type.

[1]*Manuscript received October 31, 1957.*
Contribution from McGill University and Pulp and Paper Research Institute of Canada, Montreal, Quebec.

The aldobiouronic acid isolated here is identical with that obtained on partial hydrolysis of a number of other hardwood hemicelluloses, including those from trembling aspen (12), American beech (13), European beech (14), and white birch (6). It has also been tentatively identified in the hydrolyzate of hemicelluloses from Finnish birch (15), yellow birch (16), and *Eucalyptus regnans* (17).

EXPERIMENTAL

All specific rotations are equilibrium values and melting points are corrected. Evaporations were carried out *in vacuo* at 40° C.

Paper Chromatography

Solvents used for separating the sugars were (A) ethyl acetate: acetic acid: water (9: 2: 2), (B) 1-butanol: pyridine : water (10: 3: 3), and (C) 1-butanol: ethanol: water (40: 11: 19). Separations were carried out on Whatman No. 1 filter paper by the descending technique. The spray reagent was *o*-aminodiphenyl (18).

Isolation of the Hemicellulose

Extractive-free white elm wood meal (500 g., 40–60 mesh) was extracted in a nitrogen atmosphere with 4 liters of 24% (w/w) aqueous potassium hydroxide by shaking for 2 hours at room temperature. The extract was separated from the alpha-cellulose by filtration through sintered glass and was poured slowly with stirring into a mixture of glacial acetic acid (1.5 liter) and anhydrous ethanol (12 liters), cooled to −16° C. The precipitated hemicellulose was collected on a centrifuge at −20° C., was washed five times each in succession with 80% aqueous ethanol, anhydrous ethanol, and petroleum ether (b.p. 30–60° C.), and was finally dried *in vacuo* at room temperature over calcium chloride for 1 week. The yield was 82.5 g., corresponding to 16.5% of the original wood.

Acid hydrolysis and subsequent examination by paper chromatography (solvents A and B) indicated the presence of six sugar acids and xylose in addition to traces of galactose, glucose, mannose, and rhamnose.

Separation of Sugar Acids

Hemicellulose (75 g.) was partially hydrolyzed with sulphuric acid (19). After neutralization with barium carbonate and filtration through Celite, the sugar acids were adsorbed on a column of Dowex 1-4X anion exchange resin (carbonate form). Neutral sugars were removed by washing with water, after which the sugar acids were eluted with *N* sulphuric acid. The latter was removed with barium carbonate, barium ions were eliminated by treatment with Amberlite IR 120 exchange resin, and the solution was concentrated to a sirup (10 g.).

A portion of the material (7 g.) was added to the top of a column (160×5 cm.) containing Dowex 1-4X exchange resin (acetate form) and the sugar mixture was resolved by eluting with *N* acetic acid. Analysis of the fractions collected (18) indicated the presence of six sugar acids, one of which (2.5 g.) was chromatographically identical with an aldobiouronic acid previously obtained from white birch wood (6). Two others corresponded in position and color reactions to galacturonic or glucuronic acid (5–10 mg.) and 4-*O*-methyl-D-glucuronic acid (500 mg.). Anal. Calc. for $C_{12}H_{20}O_{11}$ (aldobiouronic acid): OCH_3, 9.1%; equiv. wt., 340. Found: OCH_3, 8.8%; equiv. wt. 369. $[\alpha]_D^{20}$ +110° (*c*, 2.2 in water).

Reduction and Hydrolysis of the Aldobiouronic Acid

The aldobiouronic acid (975 mg.) was converted to its methyl ester methyl glycoside by refluxing with 2% methanolic hydrogen chloride (50 ml.) for 8 hours. Neutralization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

with silver carbonate and evaporation yielded a sirup which was dissolved in tetrahydrofuran (50 ml.) and reduced with a solution of lithium aluminum hydride (1.2 g.) in 75 ml. of the same solvent (20). Hydrolysis of the neutral disaccharide with *N* sulphuric acid, neutralization with barium carbonate, and concentration yielded a sirup which showed two spots of equal intensity on the paper chromatogram with solvent B, corresponding in color reaction and position to xylose and 4-*O*-methyl-D-glucose.

Identification of Hydrolysis Products

The sugar mixture was added to the top of a column (1.5×15 cm.) containing coconut charcoal. Elution with 2% and 10% aqueous ethanol yielded D-xylose (322 mg.) and 4-*O*-methyl-D-glucose (395 mg.), respectively. The xylose crystallized and had m.p. and mixed m.p. 144.5° C., $[\alpha]_D^{20}$ +18° (*c*, 3.2 in water). The 4-*O*-methyl-D-glucose was converted to its osazone derivative (2), m.p. and mixed m.p. 157° C. It was distinguished from 4-*O*-methyl-D-mannose by treatment with hydrogen bromide (21), after which glucose was the only sugar detectable on the paper chromatogram. Anal. Calc. for $C_7H_{14}O_6$: OCH_3, 16.0%. Found: OCH_3, 15.8%.

Methylation of the Aldobiouronic Acid

The aldobiouronic acid (826 mg.) was dissolved in water (10 ml.), dimethyl sulphate (10 ml.) was added, and then dropwise over a 12-hour period 30% (w/w) aqueous sodium hydroxide (30 ml.). Two further methylations were carried out with powdered sodium hydroxide (18 g.) and dimethyl sulphate (25 ml.). The material was recovered in the usual way by extraction with chloroform and was then methylated four times with methyl iodide (20 ml.) and silver oxide (6 g.) to yield a clear sirup (439 mg.). The infrared spectrum of the latter indicated the absence of any free hydroxyl groups and was identical with the spectrum of methyl 2-*O*-(2,3,4-tri-*O*-methyl-D-glucopyranosyluronic acid)-3,4-di-*O*-methyl-D-xylopyranose, previously obtained from white birch wood (6).

Reduction and Hydrolysis of the Methylated Aldobiouronic Acid

The sirup was dissolved in anhydrous ether and reduced with lithium aluminum hydride in the same solvent. The reduced material was subjected to methanolysis and was then hydrolyzed with 0.5 *N* hydrochloric acid (25 ml.) for 10 hours. The acid was removed with silver carbonate and the solution was deionized with Amberlite IR 120 and Dowex 1-4X (acetate form) exchange resins. Examination by paper chromatography revealed the presence of two components, corresponding to 2,3,4-tri-*O*-methyl-D-glucose and 3,4-di-*O*-methyl-D-xylose.

Identification of 2,3,4-Tri-O-methyl-D-glucose and 3,4-Di-O-methyl-D-xylose

The sugar mixture was resolved on a charcoal column (1.5×15 cm.) by eluting with 20% aqueous ethanol to yield chromatographically pure sirups of a tri-*O*-methyl glucose (180 mg.) and a di-*O*-methyl xylose (169 mg.) Anal. Calc. for $C_9H_{18}O_6$: OCH_3, 41.9%. Found: OCH_3, 41.5%. $[\alpha]_D^{20}$ +78° (*c*, 3.5 in water). The tri-*O*-methyl glucose was converted to the aniline derivative, 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 144° C. Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 34.3%. $[\alpha]_D^{20}$ +20.3° (*c*, 2.2 in water). The 3,4-di-*O*-methyl-*N*-phenyl-D-xylosylamine had m.p. 115–116.5° C. after recrystallization from ethyl acetate.

Oxidation of the Aldobiouronic Acid with Lead Tetraacetate

The oxidation of the aldobiouronic acid was carried out by the method of Perlin (7, 8) in the presence of potassium acetate. The formaldehyde was determined by the dimedon method, the crystalline precipitate having a m.p. of 188.5° C. (22).

COEXISTENCE PHENOMENA IN THE CRITICAL REGION

V. THE GRAVITY EFFECT IN THE BINARY LIQUID SYSTEM ANILINE-CYCLOHEXANE FROM LIGHT SCATTERING[1]

F. E. MURRAY[2] AND S. G. MASON

ABSTRACT

Transmittance measurements were used to investigate vertical concentration gradients, at temperatures slightly above the critical, in a binary liquid system. The gradients, which are predicted theoretically, did not begin to form during time intervals of several hours. It was found that a theoretical relation between transmittance and concentration gradient did not apply, even qualitatively, to the results obtained. The significance of these observations is discussed.

INTRODUCTION

In previous publications (3, 4), the authors reported large vertical gradients in density near the liquid–vapor critical point in one-component systems. These gradients, due to gravitational compression, were anticipated owing to the large compressibility of a fluid in the critical region.

The case of vertical concentration gradients in a binary liquid system, at temperatures slightly above the critical, forms an analogue which is not so obvious. It was, however, shown by Yvon (9) that such concentration gradients are predicted theoretically. Since Rice and Rowden (6) reported a flat apex on the coexistence curve for aniline–cyclohexane, it was of interest to see if this flat top could be ascribed to concentration gradients by analogy to the gravity effect in one-component systems (3, 4, 7, 8).

The critical solution point for a binary liquid system is defined by the conditions

$$[1] \qquad (\partial\mu_1/\partial c_1)_{T,P} = (\partial^2\mu_1/\partial c_1^2)_{T,P} = 0,$$

where μ_1 and c_1 are respectively the chemical potential and mole fraction of component 1 in the solution.

For the variation of concentration with height in a binary liquid mixture, Yvon (9) obtained an expression which may be simplified to the form

$$[2] \qquad (\partial c_1/\partial x)_T = G(x)/(\partial\mu_1/\partial c_1)_{T,P},$$

where x is distance measured positive downward and $G(x)$ is a finite function of x. From Equation [2], Yvon concluded that when the solution approaches the critical state, i.e. when $(\partial\mu_1/\partial c_1)_{T,P} \to 0$, $(\partial c_1/\partial x)_T$ becomes very large.

It was considered that the light-scattering coefficient, which is highly sensitive in the critical region, might be used to reveal experimentally the composition gradients. Following the work of Einstein (1), the turbidity in a binary liquid system is given by the expression

$$\tau = B\bar{V}_1 c_2 (\partial\epsilon/\partial c_2)^2/(\partial\mu_1/\partial c_1)_{T,P}, \quad [3]$$

where B is a constant at any temperature and wave length of the incident light, $\bar{V}_1$ is the partial molar volume of component 1, ϵ is the optical dielectric constant of the fluid. By combining Equations [2] and [3] the variation of concentration with height becomes

$$(\partial c_1/\partial x)_T = B'G(x)\tau. \quad [4]$$

B' is a constant for any given concentration, temperature, and wave length of the incident light. Equation [4] is analogous to the relationship between turbidity and density gradient in a one-component system near the gas/liquid critical point.

Equation [2] predicts large vertical gradients in concentration when $(\partial\mu_1/\partial c_1)_{T,P}$ becomes very small at temperatures slightly above the critical. Equation [4] predicts that the magnitude of these gradients, at any height in the fluid column, will be directly proportional to the turbidity.

The following symbols are used to denote measured quantities:

T = temperature in degrees centigrade,
T_f = the value of T at which visible droplets form when the fluid is cooled slowly,
T_c = the highest value of T_f observed,
$\Delta T = (T - T_c)$,
V_1 = the volume fraction of aniline in the binary mixture,
I_0 = the intensity of the incident light,
I = the intensity of the transmitted light,
$\tau = 2.30 \log I_0/I$.

EXPERIMENTAL

Apparatus

The essential details of the apparatus have already been described (3, 4). In the present experiments, only the methods of filling and changing the composition of the fluid were altered.

To facilitate changing the composition of the system, the device illustrated in Fig. 1 was attached to the valve V_2 (the connection between V_2 and the bomb is illustrated in Fig. 1*a* of Reference 3). In Fig. 1, the double line denotes glass tubing and the single line metal; the open side of the valve V_5 was attached to a vacuum system. With the pinch-clamp y open and the tubing from the mercury surface to V_2 filled with cyclohexane, liquid could be forced into the bomb by opening valve V_2.

Procedures

The cyclohexane was purified by distillation from silica gel. Merck's reagent grade aniline was dried for 5 days over KOH and then fractionated. The sample fraction was collected in a glass bulb, which was sealed to valve V_2 (Fig. 1) with a Kovar glass-to-metal seal.

The aniline sample was degassed under vacuum and then forced, by mild heating, into the evacuated bomb under its own vapor pressure. The initial amount of cyclohexane was introduced in the same manner until the volume fraction of aniline was

For personal use only.

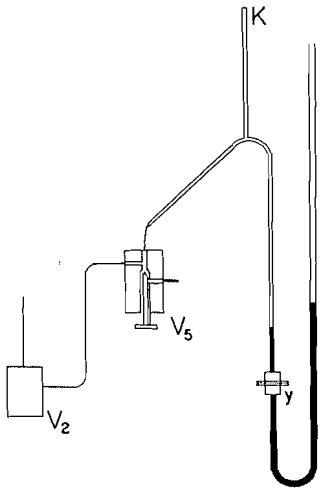

FIG. 1. Auxiliary filling system used for adding cyclohexane to the system aniline–cyclohexane.

0.416. With this initial filling, the liquid column in the bomb was about 30 cm. long.

The composition of the binary mixture was changed by allowing cyclohexane to enter the bomb by opening valve V_2 (Fig. 1). This was possible since the vapor pressure in the bomb was about 150 mm. of mercury, while the cyclohexane in the filling device was at atmospheric pressure. Volume fractions were obtained by measuring the length of the fluid column in the bomb. This procedure, which assumed no volume change on mixing, was considered sufficiently accurate for the purposes of this experiment.

RESULTS

Coexistence Curve

The curve bounding the region of two discrete phases (lower diagram, Fig. 2) was obtained by observing the first formation of visible droplets when the liquid mixture

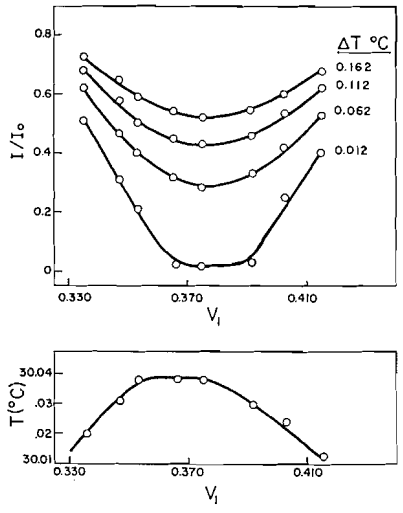

FIG. 2. The variation of optical transmittance with volume fraction of aniline at a number of temperatures above T_c (upper diagram). The coexistence curve for aniline–cyclohexane at the vapor pressure of the fluid system (lower diagram).

was cooled very slowly. The observed value of T_c was $30.04 \pm 0.02°$ C., which is slightly higher than the value 29.63° C. reported by Rice and Rowden (6). T_c was observed at three values of V_1; however, the apex of the curve could be drawn either flat or rounded within the limits of experimental error.

At T_f, the appearance of droplets occurred uniformly throughout the length (approximately 30 cm.) of the fluid column. The initial fog of condensation did not form at a particular level in the bomb, as was observed in one-component systems (3, 4, 8). This indicates that a vertical concentration gradient did not exist.

The Variation of Transmittance with Volume Fraction

The upper diagram in Fig. 2 shows the variation of optical transmittance (I/I_0) with volume fraction of aniline. The almost flat portion at the minimum of the curve at $\Delta T = 0.012°$ C. is probably due to insensitivity of measurements at this very low value of the transmittance. At all other values of ΔT, the transmittance–composition isothermals are smooth curves which pass through a minimum at a value of V_1 at which the phase volumes are equal at T_c. These isothermals are of the same form as those obtained by Zimm (10) for the binary liquid system perfluoromethylcyclohexane – carbon tetrachloride.

The Variation of Transmittance with Height

No vertical gradients in transmittance formed over periods of several hours after cessation of stirring at any value of V_1 and at various temperatures down to $\Delta T = 0.012°$ C. Since, at constant temperature, transmittance varies with composition as shown in Fig. 2 (upper diagram), it follows that no concentration gradients were formed. This was unexpected.

No extensive time-lag phenomena were observed in the binary liquid system such as were found in one-component systems near the critical point (5). When the binary liquid column, above T_c, was stirred, prestirring values of the optical transmission were re-established within 5 minutes after cessation of stirring. This time was of the order required for establishment of thermal equilibrium after the fluid had been heated by the viscous work of stirring.

The Variation of Turbidity with Temperature

Fig. 3 shows the variation of the inverse of the turbidity τ with temperature at positive values of ΔT. Results obtained for the one-component systems ethylene and xenon (4) are included for comparison.

The higher turbidities observed for the aniline–cyclohexane system show a linear dependence of τ^{-1} on ΔT right down to $\Delta T = 0$. Zimm (10) reported a similar dependence of turbidity on temperature for the system perfluoromethylcyclohexane – carbon tetrachloride.

The Effect of Radiant Energy

The action of the polychromatic light beam in passing through the fluid column caused no noticeable effect on the turbidity of one-component systems. Above T_c, in the aniline–cyclohexane mixture, the light beam caused the turbidity to slowly decrease. After about 10 minutes at a fixed level, a relatively clear path through the turbid fluid was visible at the point where the light beam had been; on moving the light source, this region of relative transparency disappeared within several minutes. The phenomenon was very pronounced at small values of ΔT. This type of behavior seems to

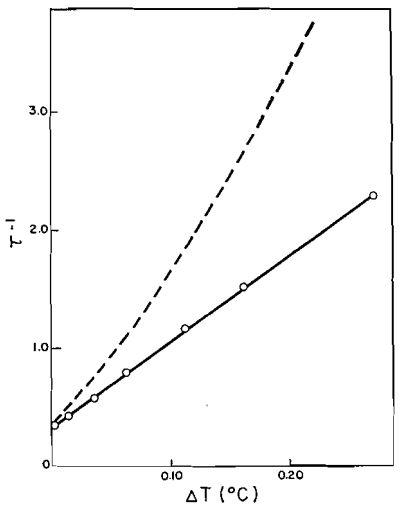

FIG. 3. Variation of the inverse of the turbidity with ΔT at the critical composition in the system aniline–cyclohexane (solid line). The broken line shows the results obtained for ethylene and xenon under similar conditions.

correspond to that observed in disperse systems, which is called "photophoresis" (2). To minimize the effect of this phenomenon on the transmission measurements, observations were recorded immediately after moving the light source. This effect is worthy of further investigation.

DISCUSSION

Since no concentration gradients are formed in the system aniline–cyclohexane at temperatures slightly above T_c, it seems that the flat apex observed by Rice and Rowden (6) on the coexistence curve for aniline–cyclohexane could not be caused by the effect of gravity. This is in contrast to the behavior in one-component systems where the flat-topped coexistence curve, observed by several authors, can be explained in terms of density gradients (4, 7, 8).

Failure to observe the gradients predicted by Equations [2], [3], and [4] may indicate that the theoretical homophase model, used in the derivation of these equations, is inadequate to describe conditions in the region of the critical solution point. Previous observations (5) indicated that molecular clusters, formed at temperatures slightly above T_c in one-component systems, have appreciable lifetimes and it may be more realistic in both cases to treat the clusters as droplets of another phase.

It must be realized that, at temperatures slightly below the classically-defined critical temperature, the difference in density and the interfacial tension between the two phases become so small that a dispersion of the two phases could be extremely stable. It may well be that the temperature T_c, now accepted as the critical temperature, is in reality the minimum temperature at which the two existing phases, of critical composition, will form a stable dispersion of minute droplets when the difference in density and the interfacial tension between the two phases have reached a very low value.

The classically-defined critical temperature, at which the difference in density and the interfacial tension between the two phases actually become zero, would be somewhat higher and could not be detected visually. It would, in fact, be extremely difficult to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

detect the temperature corresponding to the classically-defined critical point owing to the continuous nature of the transition. In view of the above considerations, it may be better to refer to the temperature T_c, presently accepted as the critical temperature, as the "critical dispersion temperature".

PHOTOOXIDATION OF KETONES IN AN O^{18} ENRICHED ENVIRONMENT[1]

J. R. DUNN[2] AND K. O. KUTSCHKE

ABSTRACT

A technique is described in which the origins of the products of photooxidation of ketones can be obtained in respect to whether they arise from the carbonyl or the alkyl groups of the ketone molecule. This is accomplished with the use of reactant molecular oxygen which has been enriched in the O^{18} isotope. Application of this to the photooxidation of acetone indicates that a large fraction of the carbon dioxide contains the carbonyl group of the ketone and that acetyl radicals play an important role in the oxidation to temperatures at least as high as 175° C. Propionyl radicals are much less stable, and, in the photooxidation of diethyl ketone, their reactions, other than decomposition, appear to be negligible at quite low temperatures. Some comment is made on the mechanisms of these photooxidations.

In the course of recent work on the photooxidation of azomethane it was observed that relatively small amounts of the oxides of carbon were produced (1). In particular, it has been suggested (1) that, under the conditions used in these experiments, methyl radicals are not oxidized to carbon dioxide to any large extent and that the greater amounts of the dioxide found in the photooxidation of acetone (2) must have arisen from an oxidation of the carbonyl group. Such an oxidation might occur, for example, by reactions of acetyl radicals (3) or acetonyl radicals (1) with oxygen. This disagrees with the work of Christie (4), who observed that essentially all of the carbon dioxide was radioactive when produced in the photooxidation of $C^{14}H_3COC^{14}H_3$. In view of this contradiction and of the impure acetone sample used by Christie (some unidentified material which led to unexpectedly large yields of carbon dioxide (4)), it was thought worth while to check the result by an independent method.

If oxygen enriched in O^{18} is used in these experiments, any carbon dioxide containing the methyl carbon atom will show the same O^{18} enrichment as does the reactant oxygen. Conversely, if the carbonyl group is the source of the dioxide and if it is assumed that the carbonyl group survives the reaction without rupture of the C—O carbonyl linkage, the carbon dioxide produced will show only one-half the enrichment of the reactant oxygen. By a similar argument, carbon monoxide which arises from the carbonyl group, for example by the decomposition of acetyl radicals, will possess the natural isotopic composition, while that which is formed from the terminal carbon atom will be enriched to the same extent as is the reactant oxygen. Similar considerations show that formaldehyde that arises from the carbonyl group will have the natural abundance of O^{18}, while that arising from methyl radical oxidation will be enriched.

The carbon monoxide observations also aid in the investigation of the primary products of ketone photolysis. It seems well established that methyl and acetyl radicals are the first radicals produced from the excited acetone molecule formed by light absorption at ~3130 Å (5). Acetyl radicals so formed are energy rich, and a certain fraction of them are thought to decompose before experiencing any significant number of collisions. The remainder react as acetyl radicals, the predominant reaction being decomposition into carbon monoxide and a methyl radical presumably by a quasi-unimolecular process (6), so that

[1]*Manuscript received October 29, 1957.*

Φ_{CO} is temperature dependent. General confirmation of this is found in the observations made here, which indicate that the extent of decomposition of the acetyl radical varies with temperature at a given oxygen pressure.

An analogous argument may be made in the case of diethyl ketone photooxidation in which the primary process is thought to differ only in degree from that in acetone (7). Substantiation for such a view may be deduced from the data presented here.

Only preliminary results appear here; more detailed investigations are reported in forthcoming publications from these laboratories. Since this work was completed, the results of Taylor and Blacet (8) appeared; these authors presented a similar treatment of biacetyl photooxidation.

EXPERIMENTAL

Experimental procedures were similar to those used previously in these laboratories (1) with a few exceptions. The reaction cell together with a magnetically driven stirrer was housed in a thermostatted air oven. A few centimeters of 8 mm. tubing were external to the oven and connected via glass float-valves to a mercury cutoff, leading to the storage and analytical systems, and to a small Toepler pump which served to "dose" oxygen into the reaction system as required to maintain the oxygen pressure constant to within some 10–15%. The system appeared to prevent the polymerization of formaldehyde during exposure since reproducible recoveries from the LeRoy still (9) were achieved for this product. The carbon monoxide – oxygen fraction, removed at −196° C., was slowly introduced into a vessel containing a fresh surface of yellow phosphorus. With sufficiently slow introduction negligible oxidation occurred; blank experiments showed no exchange during this procedure. Carbon monoxide recovered was submitted for mass spectrometric analysis. The carbon dioxide fraction, separated at −160° C., was submitted for mass analysis with no further treatment; small amounts of formaldehyde were always present. The bulk of the formaldehyde was recovered with prolonged pumping at −130° C. and submitted for isotopic analysis. Higher-boiling compounds were not investigated in the work reported here.

Analogous procedures were used with diethyl ketone; formaldehyde was absent but acetaldehyde was a major product. Some C_2 hydrocarbon was also found.

Acetone and diethyl ketone were good quality commercial products, carefully dried and outgassed. Oxygen was obtained from the slow electrolysis, *in vacuo*, of about 1 cm.^{3} of outgassed, enriched water (from Dr. L. C. Leitch of these laboratories) using a drop of sulphuric acid as an electrolyte. The oxygen was led over platinized asbestos at 300° C., and then through several liquid nitrogen traps to storage. Mass spectrometric analysis yielded a 34/32 ratio 2.90×10^{-2} (natural 0.34×10^{-2}) indicating that 2.8% of the oxygen molecules contained an atom of O^{18}. The same procedure was followed with water stated to contain 10.17% O^{18} (Dajac Laboratories); analysis of the oxygen gave 9.59 atom % O^{18}. Only a few experiments, not reported here, were made with the more highly enriched oxygen; they were in essential agreement with the results reported.

RESULTS AND DISCUSSION

With conditions of acetone and oxygen pressures, absorbed light intensity, and temperature similar to those used by earlier workers (2, 4, 10), over-all quantum yields for the production of the oxides of carbon and for the consumption of oxygen were in excellent agreement. However, the fraction of the total carbon monoxide produced which contains the carbonyl group, x_1, varies with temperature and oxygen pressure as shown in Table I.

The trend, aside from one experiment at 175° C., indicates that even at these temperatures acetyl radical lifetime is sufficiently long to allow a reaction with oxygen which apparently does not produce carbon monoxide. This is in agreement with the observations of McDowell and Thomas (11), who observed that acetyl radicals reacted with oxygen, rather than decomposed, as high as 200° C.

Only a small fraction $(1-x_2)$ of the carbon dioxide ever arises from the methyl group (Table I). It is felt that this conclusion is more reliable than that reached by Christie (4) in view of the uncertainty, mentioned earlier, in the latter work. Moreover, it agrees with the observation that, in the absence of carbonyl groups in the substrate molecule, carbon dioxide is a minor product of methyl radical oxidation (1).

Attempts were made to determine the origin of the formaldehyde product by observing the 32/30 ratio in its mass spectrum. The results were inconclusive, however, since the 32 residual varied in an unpredictable manner whenever formaldehyde was present in the sample chamber.

Some experiments were done on the diethyl ketone photooxidation; the data are included in Table I. Absolute values of quantum yields were again in essential agreement with those of other workers (12, 13). Two experiments at room temperature yielded negligible amounts of carbon monoxide (other workers found $\Phi_{CO} \sim 0.1$ for similar conditions); the carbon dioxide from the room temperature experiments all contained the carbonyl group. The higher values for x_1 from diethyl ketone as compared to those from acetone at the same temperature and oxygen pressure presumably reflect the greater ease with which propionyl radicals decompose. Carbon dioxide could arise in part by mechanisms analogous to those suggested earlier for acetone, but at the higher temperatures a mechanism must exist which produces carbon dioxide from the ethyl group of the ketone. This conclusion is in harmony with the carbon-14 tracer data obtained by Finkelstein and Noyes (12). It is to be noted that the mechanism proposed by Jolley (13) does not take this fact into consideration. The origin of the acetaldehyde found here (x_3 is that fraction of the aldehyde which contains the carbonyl group of the ketone—see Table I)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

cannot be explained simply. The present result disagrees with the conclusion of Finkelstein and Noyes (12), who found that essentially all the acetaldehyde arose from ethyl radical oxidation. No explanation can be offered for this disagreement. The possibility of exchange between acetaldehyde and reactant oxygen (mostly O^{16}) cannot be ruled out on the basis of present data.*

Much more data are obviously required before a consistent mechanism can be written for either of these photooxidations; tracer experiments are of particular importance. It is felt that the technique outlined here presents a means whereby such data may be obtained relatively simply since the enriched oxygen is readily prepared.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for the interest expressed throughout this work, and Mrs. June Garlick and Mrs. Frances Kutschke for the mass spectrometric analyses.

RADIOCHEMICAL ANALYSIS FOR LONG-LIVED FISSION PRODUCTS IN ENVIRONMENTAL MATERIALS[1]

W. F. MERRITT

ABSTRACT

A method is described whereby radiochemical analysis for the long-lived fission products Ru^{106}, Sr^{90}, Cs^{137}, and Ce^{144} may be performed on the same sample of soil, water, or biological material. Carriers are added and the material is fused at 550° C. with KOH, KNO_3, and K_2CO_3. Ruthenium and cesium are extracted with water, strontium and cerium remaining in the melt. Ruthenium is extracted into carbon tetrachloride as ruthenium tetroxide, cesium is absorbed on Duolite C-3 cation-exchange resin from alkaline solution, strontium and cerium are extracted from the melt with acid, cerium is precipitated as the hydroxide and strontium as the carbonate. The elements are precipitated, weighed, and counted according to standard procedures.

INTRODUCTION

Low-level radioactive wastes produced at Chalk River are disposed of from seepage pits in a carefully selected disposal area. In addition, sewage and other liquid effluent streams entering the Ottawa river may contain small but measurable quantities of radioactive material. It is necessary, therefore, to monitor the drainage basin of the disposal area and the Ottawa river below the plant site for any undesirable escape of radioactivity.

The movement of activity in the disposal area is followed by drilling wells and taking soil samples, by sampling the drainage water, and by taking specimens of vegetation and animals from the surrounding area. Activity in the river is monitored by continuous sampling of the project effluents and by taking samples of bottom muds, fish, clams, aquatic plants, etc. at regular intervals. The radioactive isotopes present and important from the public health point of view are the long-lived, high-yield fission products Sr^{90}, Ru^{106}, Cs^{137}, and Ce^{144}. Since Sr^{90} is readily absorbed into the body, is fixed in the bone, and has a long half-life and energetic radiation, it is considered the most hazardous of these radioisotopes.

An analytical method was desirable which could be applied to a wide variety of natural materials and which would detect very low concentrations of the isotopes listed above in the presence of substances occurring commonly in nature.

Analytical methods for these isotopes have been described by Coryell and Sugarman (1), by Meinke (2), and by Kleinberg (3). Crouch and Cook (4) have published an excellent detailed method of separation of a large number of radioisotopes. Kahn (5) has given detailed methods for the analysis of several isotopes adsorbed on soil using acid leaching for preliminary separation from the soil. However, we have found that, in particular, Cs^{137} could not be leached quantitatively from the typical sandy soil found at Chalk River. It has been shown (6) that the cesium ions are fixed in the interlayer positions of the layer silicate minerals, and thus it is necessary to destroy the silicate structure to release them.

Standard methods for decomposing silicates are of two general classes. The first involves heating with hydrofluoric and perchloric acid so that the silicon is volatilized as the tetrafluoride. In the second the material is fused with an alkali hydroxide, carbonate,

or peroxide. If the first method is used, ruthenium will be volatilized. In the second, the large amount of alkali added will interfere with standard cesium separations. Therefore, a different approach to the cesium analysis was needed.

Miller and Kline (7) first reported the ability of phenolic methylene–sulphonic-type cation-exchange resins to adsorb cesium from highly alkaline solutions. Ring (8) has adapted this method for separating cesium from large quantities of sodium. The method described here makes use of the ability of Duolite C-3* resin to effect a clean separation of as little as a milligram of cesium from gram quantities of potassium after alkali fusion.

PROCEDURES

Preparation of Samples

Water samples were evaporated to a few milliliters. Organic materials were wet ashed with nitric acid and hydrogen peroxide. Soil samples were ground to a fine powder with a mortar and pestle. Suitable quantities of material, determined by rough counting, were weighed or transferred into nickel crucibles, and standardized carrier solutions amounting to 20 mg. of strontium, cerium, and cesium and 10 mg. of ruthenium added by pipette. The mix was neutralized with dilute potassium hydroxide and dried under an infrared lamp. A fusion mixture of 2:1:1 by weight of potassium hydroxide, nitrate, and carbonate was added to the crucible to about 5–10 times the weight of the sample. The material was fused in a muffle at 550° C. for 2 hours, with the contents being swirled at 15-minute intervals. In this fusion the hydroxide and carbonate attack the silicate structure, and the nitrate oxidizes the ruthenium present to a soluble ruthenate. The melt was allowed to cool, and was leached twice with 10 ml. of water. The ruthenate and the cesium dissolve while the strontium and cerium remain in the melt as the insoluble carbonate and hydroxide.

Ruthenium

Potassium periodate (0.25 g.) was added to the solution to oxidize the ruthenate to ruthenium tetroxide. Zirconium, if present, will precipitate at this stage and can be removed by centrifuging. The solution was neutralized to a pH of 7 with 9 *M* sulphuric acid. Ten milliliters of redistilled carbon tetrachloride was added, and solvent extraction was started using an automatic "spitzer". The pH was reduced to 4 during the extraction by the dropwise addition of acid. Occasionally two extractions were necessary. The layers were separated and the ruthenium was stripped from the carbon tetrachloride with 6 *N* hydrochloric acid. The ruthenium was reduced to the metal with powdered magnesium as described by Kleinberg (3).

Cesium

The aqueous layer from the ruthenium solvent extraction was treated with saturated lithium hydroxide and the resulting precipitate of lithium carbonate was removed by centrifuging. A column of Duolite C-3, 60–100 mesh, 12×50 mm., was prepared in the lithium form by washing with 100 ml. of 0.5 *N* lithium hydroxide followed by 50 ml. of water. The sample solution was poured through the column and washed with 50 ml. of water. The column was then treated with 125 ml. of 0.5 *N* lithium hydroxide to elute the potassium. After a 50-ml. water wash, the lithium was eluted with 125 ml. of 0.2 *N* hydrochloric acid. The cesium was stripped off in 50 ml. of 6 *N* hydrochloric acid. Flow rates throughout were held to 2–3 ml./min.

The cesium solution was evaporated to 0.5 ml., made up to 3 ml. with water, and the cesium was precipitated with 2 ml. of 5% chloroplatinic acid.

Cerium

The solids from the original melt were treated with 10 ml. of 6 *N* nitric acid with heating. This solution was taken to dryness twice, with a few milliliters of concentrated nitric acid added, to dehydrate the silica. The dry mass was treated with 5 ml. of 6 *N* hydrochloric acid and two or three drops of 30% hydrogen peroxide to reduce any ceric ions to cerous, and the silica removed by centrifuging. The supernatant was diluted to 10 ml. and neutralized with ammonia gas to precipitate cerous hydroxide.

The cerium was then purified according to Kleinberg (3) by fluoride precipitation and by an oxidation–reduction cycle, oxidizing to Ce^{+4}, precipitating the cerium as ceric iodate, reducing to Ce^{+3}, and scavenging with zirconium iodate. The cerium was precipitated and weighed as the oxalate.

Strontium

After removal of the cerium as the hydroxide, strontium was precipitated by the addition of sodium carbonate. The precipitate was dissolved in 6 *N* nitric acid and the strontium was purified by two precipitations from fuming nitric acid. Calcium was removed by leaching the dried nitrate with alcohol–ether solution. Barium, if present, was removed by precipitation from alcoholic hydrochloric acid. The strontium salt was dissolved in water, scavenged with ferric hydroxide, and precipitated and weighed as the carbonate.

Counting

The precipitates were weighed and counted on standard 1-in. aluminum dishes. The counter used was a β scintillation counter, consisting of an anthracene crystal 1 in. in diameter and 10 thousandths of an inch thick, mounted on an RCA 6199 photomultiplier and covered with aluminized Mylar film. The unit was mounted in a 2-in. lead shield on a "Nuclear Chicago" model C110A* sample changer. The background of this system was 6 c.p.m., and the efficiency for $Sr^{90}+Y^{90}$ about 30%. The observed counting rates were corrected for background, for chemical yield based on added carrier, and for counter efficiency.

A typical set of results is shown in Table I.

TABLE I

TYPICAL RADIOCHEMICAL ANALYSIS OF DUPLICATE SAMPLES OF CONTAMINATED SOIL

DISCUSSION

The basic procedures described have been used in the radiochemical laboratory of the Health Physics Branch of these laboratories for several months. The methods employed standard semimicroanalytical techniques. Precipitations were carried out in 50-ml. centrifuge tubes. Filtering and ignition were not required. Junior technicians achieved 50–75% yields based on added carrier.

Modifications were introduced as required. For example, it was sometimes necessary to remove silica from the insoluble portion of the melt by fuming with hydrofluoric and perchloric acids in platinum crucibles. This system was used if an analysis for ruthenium was not required. The sample was fumed with the acids, cooled, and cesium precipitated by addition of alcohol. The precipitate was dissolved in water, made alkaline with 0.5 *N* lithium hydroxide, and scavenged with 1 mg. of iron. The solution was adsorbed and eluted from an 8×30 mm. column of Duolite C-3, using reagents in the same ratio to column volume as above. The strontium and cerium were separated, purified, and precipitated as described.

For samples with a high concentration of anions (e.g. phosphate in fish specimens) it was advantageous to absorb the cations from 0.1 *N* acid solution on a Dowex 50 cation-exchange resin, wash the anions through with water, and elute the cations with 6 *N* hydrochloric acid. If an analysis of an anionic component such as P^{32} or S^{35} was required, this was a convenient method of preliminary separation.

ACKNOWLEDGMENTS

The author would like to thank Dr. Margaret Tutt, who did preliminary work on the methods, Dr. W. G. Cross, who designed and constructed the counter, and Mr. A. J. W. Hitchman for helpful discussion of the cesium method.

SUR LA TRANSFORMATION DE LA DIHYDROHÉTÉROCONESSINE EN DIHYDROCONESSINE[1]

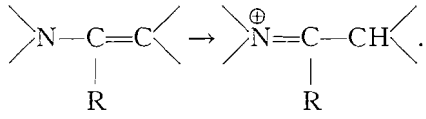
H. FAVRE ET B. MARINIER[2]

SOMMAIRE

On montre que le diperchlorate de la base résultant de la déshydrogénation de la dihydro*hétéro*conessine par l'acétate mercurique est identique à celui que l'on obtient, par ce procédé, à partir de la dihydroconessine; ce diperchlorate est réduit catalytiquement en dihydroconessine. On en conclut que la dihydro*hétéro*conessine et la dihydroconessine sont bien des épimères en position 20; la configuration du groupe méthyle dans cette position peut être déterminée par ce procédé de déshydrogénation–réhydrogénation.

La constitution de la conessine, telle que proposée par Haworth, McKenna et leurs collaborateurs (1, 2), a été confirmée par des travaux récents (3, 4, 5). Un pas décisif dans les travaux de Haworth fut l'étude du système conessine–*hétéro*conessine qui conduisit à formuler ces deux isomères comme des épimères en position 20 (2, 6).

Nous rapportons dans ce mémoire la déshydrogénation par l'acétate mercurique de la dihydroconessine (I) et de la dihydro*hétéro*conessine (II). Bien que chacune de ces bases possède un groupe méthyl-imino et un groupe diméthyl-amino capables de réagir avec l'acétate mercurique (voir (7) pour de nombreuses références bibliographiques) un seul de ces groupes semble être le siège de la réaction. En effet, lorsque 1 mole des bases I ou II est traitée par 4 moles de réactif dans les conditions opératoires habituelles (7), deux atomes d'hydrogène seulement sont éliminés (cette détermination se fait en mesurant la quantité d'acétate mercureux qui précipite). On obtient dans les deux cas une base extrêmement altérable, qui forme toutefois un diperchlorate bien cristallisé et stable. La base déshydrogénée peut être isolée sous forme solide, p.f. 100–125°; tous nos essais de purification par cristallisation n'ont conduit qu'à des huiles jaunes; nous avons cependant réussi à en obtenir un spectre infrarouge acceptable: on y décèle une bande à 1645 cm.$^{-1}$. Les diperchlorates insaturés (en provenance de I et de II) sont identiques, comme le prouvent leur pouvoir rotatoire, leur point de fusion et leur spectre infrarouge qui présente en particulier une bande à 1690 cm.$^{-1}$. Le déplacement de la bande infrarouge de 1645 à 1690 cm.$^{-1}$ par formation du diperchlorate de la base déshydrogénée est caractéristique du système

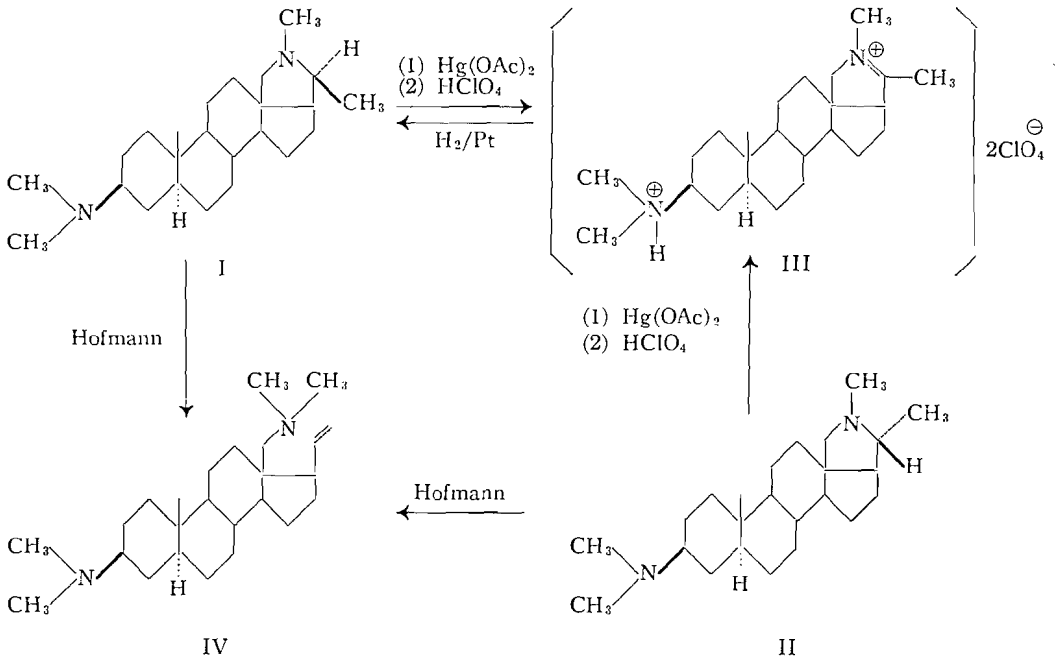


. ClO_4, quand l'amine est tertiaire (7). A la réduction catalytique (platine) le diperchlorate III (issu soit de I, soit de II) absorbe une molécule d'hydrogène et conduit spécifiquement à la dihydroconessine.

On sait, avec Haworth (2), que les bases isomères dihydroconessine (I) et dihydro*hétéro*conessine (II) se différencient uniquement par leur anneau hétérocyclique[3] et que l'ouverture de cet anneau, par dégradation selon Hofmann, supprime cette différence, comme le montre la formation de la dihydro-5,6 conessiméthine (IV) à partir de I et de II. On sait d'autre part que les bases *apo* et méthines—dont l'anneau hétérocyclique est ouvert—ont toutes une double liaison en 20–21,[4] à l'image de la base IV: ceci établit

[1]*Manuscrit reçu le 31 octobre, 1957.*
Contribution du Département de Chimie de l'Université de Montréal, Montréal, Qué.
[2]*Boursier du Conseil National de Recherches du Canada.*
[3]*Voir le travail (2) pour une discussion détaillée de ce point.*
[4]*On l'a amplement démontré (8, 9) en établissant des relations de synthèse et de dégradation entre l'apoconessine (diméthylamino-18 pregnatriène-3,5,20), la conessiméthine (bis-(diméthylamino)-3β,18 pregnadiène-5,20) et l'hydroxy-3β pregnadiène-5,20.*

indiscutablement que le carbone 17 n'est pas touché par le processus de formation de la double liaison en 20–21 et exclut l'hypothèse qui ferait de la conessine et de l'*hétéro*-conessine (par conséquent des bases I et II) des épimères en position 17. On peut donc considérer comme acquis que les bases I et II ne se distinguent ni par la position ou la configuration de leur groupe diméthylamino, ni par la configuration de leurs carbones 5 et 17.



I III IV II

La présence d'un groupement $>C=\overset{\oplus}{N}<$ dans le diperchlorate obtenu par déshydrogénation, la disparition chez ce dernier de la différence qui existe entre les bases saturées I et II et la transformation de la dihydro*hétéro*conessine en dihydroconessine ne peuvent se concevoir qu'en situant la double liaison dans l'anneau hétérocyclique et en fonction des formules I et II pour les bases saturées et de la formule III pour le diperchlorate de la base déshydrogénée. Si la déshydrogénation ne s'était pas portée sur le noyau hétérocyclique nous aurions obtenu à partir de I et de II deux produits de déshydrogénation distincts, reflétant encore la différence qui existait à l'origine entre I et II. La dihydroconessine et la dihydro*hétéro*conessine, et par suite la conessine et l'*hétéro*conessine, sont donc bien des épimères en position 20.

La grande instabilité de la base déshydrogénée, correspondant au diperchlorate III, ne nous a pas permis d'approfondir pour le moment les relations qui doivent exister entre sa liaison éthylénique et celle qui est localisée en position 17–20 chez les alcaloïdes du type de la conkurchine (10, 11). Le fait que la double liaison de la base de déshydrogénation puisse se placer en position 17–20, détruisant ainsi deux centres d'asymétrie dans l'anneau hétérocyclique, n'infirme pas la conclusion que nous tirons au sujet des structures épimères en position 20 des bases I et II, puisque ces dernières ne sont pas des épimères en position 17.

Le procédé de réduction mis en oeuvre pour passer de III à I amène en règle générale la fixation de l'hydrogène sur le côté le moins empêché de la molécule (12, 13); il est raisonnable ainsi d'admettre que le groupe méthyle se trouvera au-dessus du plan de l'anneau hétérocyclique dans le produit d'hydrogénation de III—donc dans la dihydroconessine (formule I). On rejoint de cette manière les conclusions de Černý, Lábler, et Šorm (3) et de Phillips et Johnson (4) relatives à la configuration du groupe méthyle en position 20 de la conessine.

Il convient cependant de signaler quelques différences dans le mode d'action de l'acétate mercurique sur I et sur II.

Le diperchlorate III, venant de la dihydroconessine (I), se présenta d'abord sous la forme de paillettes, p.f. 317°, puis sous la forme d'une poudre, p.f. 335–337°, lorsqu'on le cristallisa. Les spectres infrarouges de ces deux variétés sont très semblables. Cette hétérogénéité montre que la déshydrogénation qui amène en majorité la formation d'une seule double liaison s'accompagne de réactions secondaires. On peut théoriquement en retenir deux: (*a*) réaction du groupe diméthylamino en position 3; (*b*) hydroxylation sur le carbone 17, comme c'est le cas pour certaines bases tertiaires dont le carbone en β de l'azote est tertiaire, par exemple la méthyl-1 décahydroquinoléine (14); cette hydroxylation pourrait justifier la présence d'une bande —OH dans le spectre infrarouge de III. Ces réactions secondaires, quelles qu'elles soient, n'ont pu être décelées avec certitude en raison de la petite quantité de base mise en oeuvre dans nos expériences.

La déshydrogénation de la dihydro*hétéro*conessine n'engendra que le diperchlorate à point de fusion élevé; le rendement en sel brut fut de 64% seulement, comparé à 85% dans le cas de la dihydroconessine. Il est raisonnable d'attribuer ces différences à l'accessibilité plus ou moins grande de l'hydrogène en position 20 chez I et II.

PARTIE EXPÉRIMENTALE[5]

Déshydrogénation de la dihydroconessine

A 1.424 g. (0.00446 mole) d'acétate mercurique dans 12 ml. d'acide acétique aqueux à 5%, on ajoute 0.400 g. (0.00114 mole) de dihydroconessine, p.f. 109°, $[\alpha]_D^{22} = +50.4°$ ($c = 3.0$; $CHCl_3$ (2, 15)). Le mélange agité mécaniquement est chauffé au bain-marie durant $1\frac{1}{2}$ heure. L'acétate mercureux apparaît après 2 à 3 minutes de chauffage. On l'élimine par essorage: 0.512 g. (soit 88.5% de ce qui est nécessaire pour éliminer deux atomes d'hydrogène); on peut déceler dans ce précipité une petite quantité de mercure. Le filtrat est saturé avec H_2S; le précipité noir est séparé du liquide par centrifugation. La solution brunâtre est recueillie, refroidie à 0° et rendue alcaline avec NaOH 50% (2–3 ml.); un solide précipite; on ajoute de l'eau et on extrait trois fois par de l'éther. Les solutions éthérées réunies sont lavées à l'eau, séchées sur du sulfate de sodium anhydre et traitées à 0° par 0.5 ml. (jusqu'au virage bleu du Congo) d'une solution faite de volumes égaux d'acide perchlorique 70% et d'éthanol 95%. Le diperchlorate précipite et après quelques heures on le recueille par essorage: 0.527 g. (85% de la théorie), poudre blanche, p.f. 307–310° (bloc Maquenne). Après une cristallisation dans l'éthanol 95% on obtient des paillettes jaune pâle, p.f. 317° (bloc), dont le spectre infrarouge: bande forte 1694 cm.$^{-1}$, $\diagdown\overset{\oplus}{\mathrm{N}}{=}\mathrm{C}\diagup$, bande moyenne 3060 cm.$^{-1}$, $-\overset{|}{\underset{\oplus}{\mathrm{N}}}\mathrm{H}-$, et

[5]*Les points de fusion (p.f.) ne sont pas corrigés; sauf indication contraire ils ont été déterminés dans un appareil de Thiele. Les spectres infrarouges ont été déterminés à l'aide d'un spectromètre "Perkin-Elmer", modèle 112, à simple faisceau et parcours double, optique* NaCl.

bande très faible 3620 cm.$^{-1}$ (présence de —OH). Une cristallisation de ces feuillets dans l'éthanol 95% donne une poudre jaune pâle, p.f. 335–337° (bloc), $[\alpha]_D^{24} = +29.9°$ ($c = 1.0$; tétrahydrofuranne–eau: 8–2). Spectre infrarouge (nujol): bande forte 1690 cm.$^{-1}$, $\rangle\overset{\oplus}{N}{=}C\langle$, bande moyenne 3110 cm.$^{-1}$, $-\underset{\oplus}{\overset{|}{N}}H-$, et bande très faible 3620 cm.$^{-1}$ (présence de —OH). Calculé pour $C_{24}H_{40}N_2.2HClO_4$: C, 51.70; H, 7.59; N, 5.02%. Trouvé[6]: C, 51.76; H, 7.60; N, 4.95%. Le rendement en diperchlorate cristallisé est de 0.303 g. (49%).

A 0.007 g. de diperchlorate en suspension dans 1 ml. d'eau on ajoute 1 ml. de NaOH 50% et 10 ml. d'eau; on extrait trois fois avec de l'éther. Après les lavages habituels, on évapore l'éther sous vide partiel; on obtient 0.004 g. d'un solide jaune très pâle, p.f. 100–125°. Cette amine est très instable et jaunit rapidement à l'air. Spectre infrarouge (nujol): bande forte à 1645 cm.$^{-1}$, $\rangle C{=}C\langle$.

Déshydrogénation de la dihydrohétéroconessine

La dihydro*hétéro*conessine (0.404 g.), p.f. 105°, $[\alpha]_D^{22} = +17°$ ($c = 1.8$; $CHCl_3$ (2, 15)), est déshydrogénée dans les conditions décrites plus haut. L'acétate mercureux commence à précipiter au bout de 5 minutes de chauffage. Il ne contient pas de mercure lorsqu'on le recueille à la fin de la réaction: 0.546 g. (94.1% de ce qui est nécessaire pour éliminer deux atomes d'hydrogène). On obtient 0.400 g. de diperchlorate brut (64.2%) sous forme de poudre blanche; après deux cristallisations dans l'éthanol 95% on a une poudre blanche: 0.187 g. (30%), p.f. 338° (bloc; ne donne pas de dépression de point de fusion avec le diperchlorate décrit plus haut, p.f. 335–337°); $[\alpha]_D^{24} = +29.7°$ ($c = 1.0$; tétrahydrofuranne–eau: 8–2). Spectre infrarouge (nujol): bande forte 1690 cm.$^{-1}$, $\rangle\overset{\oplus}{N}{=}C\langle$, bande moyenne 3110 cm.$^{-1}$, $-\underset{\oplus}{\overset{|}{N}}H-$, et bande très faible 3640 cm.$^{-1}$ (présence de —OH).

Hydrogénation catalytique des diperchlorates

(*a*) *Diperchlorate en provenance de la dihydroconessine.*—Le diperchlorate (0.100 g.) dans 2.5 ml. d'un mélange dioxanne–eau: 8–2, est hydrogéné en présence de 15 mg. de platine hydrogéné au préalable. L'absorption d'hydrogène cesse au bout d'une heure: absorbé, 4.76 ml.; calculé pour 1 H_2, 4.48 ml., pour 756 mm. et 25°. On essore le catalyseur, dilue le filtrat avec de l'eau, rend alcalin avec NaOH 50% et extrait avec de l'éther. On isole à la manière habituelle 0.062 g. (97%) de solide jaune pâle, p.f. 103°. Ce composé brut ne donne pas de dépression de p.f. en mélange avec de la dihydroconessine, mais le mélange avec la dihydro*hétéro*conessine accuse une dépression et fond à 85° environ. Après une cristallisation dans l'acétone, on retire 0.038 g. de cristaux, p.f. 106.5°, $[\alpha]_D^{25} = +49.4°$ ($c = 3$; $CHCl_3$) et 0.010 g. de cristaux, p.f. 103.5°. Le rendement total en dihydroconessine est de 0.048 g. ou 75%.

(*b*) *Diperchlorate en provenance de la dihydrohétéroconessine.*—Ce diperchlorate (0.100 g.) absorbe la quantité théorique d'hydrogène en 55 minutes dans des conditions opératoires semblables à celles décrites sous (*a*). On obtient 0.064 g. (100%) de dihydroconessine brute, p.f. 103°, et après cristallisation dans l'acétone 0.036 g., p.f. 106.5°, $[\alpha]_D^{25} = +50°$ ($c = 3$; $CHCl_3$) et 0.018 g., p.f. 104°, soit 0.054 g. ou 84.4%. Les p.f. de mélange ont été déterminés avec la dihydroconessine (aucun abaissement) et avec la dihydro*hétéro*conessine (abaissement à 89°).

[6]*L'analyse fut effectuée par M. W. Manser, Herrliberg.*

THE CHEMISTRY OF PEAT

PART I. THE STEROLS OF PEAT MOSS (SPHAGNUM)[1]

D. A. J. IVES[2] AND A. N. O'NEILL

ABSTRACT

Peat moss (*Sphagnum*) from the surface of an Atlantic peat bog has been extracted with a mixture of benzene and ethanol. The extract has been fractionated chromatographically on alumina. A mixture of sterols has been isolated from one fraction. This mixture has been proved by oxidation experiments to consist of β-sitostanol (stigmastanol) and β-sitosterol. It constituted approximately 0.2% by weight of the dried peat moss.

INTRODUCTION

A considerable amount of work has been done on the chemical composition of peat (8), lignite (brown coal) (8), and coal (8), but relatively little on the composition of peat moss (*Sphagnum*). The latter is considered to be the main precursor of peat in the Atlantic area of Canada. This work was undertaken in an effort to remedy this defect, and also to ascertain what chemical changes occur in humification. Black and his co-workers (4) carried out an extensive analysis on a sample of peat moss from Scotland and reported the presence of β-sitosterol.

The peat moss used in our experiments was a living surface moss, from Shipigan, New Brunswick, and was essentially a mixture of *Sphagnum fuscum*, *S. capillaceum*, and *S. magellanicum* with the first two predominating. It was comparatively free of other common bog plants. The moss was dried to a moisture content of approximately 5% and ground to pass through a 20-mesh screen. Only relatively small quantities of the powder could be extracted at a time, owing to its bulk. The process used was a continuous extraction method, with a constant stream of pure solvent passing through the moss.

After evaporation of the solvent, the dark brown gum (approximately 6% of the total solids) was saponified with methanolic potassium hydroxide solution and the unsaponifiable material extracted with ether. This extract (approximately 1.5% of the total solids), after evaporation, was dissolved in light petroleum and chromatographed roughly on alumina. A small portion of the gum (approximately 3%) did not dissolve in the petrol and was kept for further investigation. The eluate from the chromatogram was divided into five fractions: materials eluted progressively by (*a*) light petroleum, (*b*) benzene, (*c*) ether, (*d*) ether containing 10% methanol, and (*e*) methanol. These fractions will be described separately. The composition of fractions (*c*) and (*d*) varied from extraction to extraction and with the grade of alumina used. The ether fraction sometimes consisted of a white, low-melting solid, and the ether–methanol fraction of a colorless crystalline solid, subsequently proved to be the sterols. In the majority of extractions, however, the components were mixed and tended to be removed from the column together in fraction (*d*) as a light yellow glass. The mixture was separated into cyclic and linear aliphatic compounds by treatment with urea with which the latter formed an insoluble complex. Decomposition of the complex yielded an alcohol which has been tentatively identified as lignoceryl alcohol by melting point, mixed melting point, and molecular weight.

The colorless crystalline material, which did not form a complex with urea, when obtained relatively pure gave a strong Liebermann–Burchard test, which indicated that it was a sterol or triterpene. The melting point was 135°–137°, but the optical rotation tended to vary from −12° to −24°. The latter depended on which fraction was taken in the chromatogram. The average value obtained was −18°. These constants were unchanged by many recrystallizations or by careful chromatographic separation into about 200 fractions. From this it was at first assumed that two sterols were present with rotations of −12° and −24°, but the infrared spectra of the two materials were identical and only differed slightly in the intensities of certain peaks. Subsequent work showed that the sterols were actually an inseparable mixture of β-sitostanol (stigmastanol) and β-sitosterol in various proportions. The infrared spectrum of the mixture indicated the presence of a secondary hydroxyl group from bands at 3584 and 1050 cm.$^{-1}$ and the presence of only one double bond from bands at 837 and 800 cm.$^{-1}$. This bond was of the type >C=CH—, and the spectrum bore a striking resemblance to that of the 5,6-double bond in cholesterol, which has bands at 839 and 800 cm.$^{-1}$. In confirmation of this the infrared spectrum of fucosterol, which has a 24,28-double bond besides the nuclear one, was markedly different from those of cholesterol and the sterols from peat moss. From this it was inferred that there was no double bond in the side chain of the sterols under investigation.

On catalytic hydrogenation the mixture gave pure β-sitostanol, identified by its melting point and rotation, and the melting points and rotations of the derived acetate and ketone. This indicated that the components of the mixture differed only in the degree or position of unsaturation. As already stated the infrared spectrum indicated a nuclear double bond and preliminary oxidation showed that this double bond was in a position to give an α,β-unsaturated ketone. There remained the possibility that some of the material had the double bond in the nucleus in a position other than the 5,6. The only remaining positions for a secondary–tertiary double bond in a six-membered ring are the 7,8-position and the 9,11-position. On attempted hydrogenation with platinum as a catalyst and in the presence of acetic acid, the 7,8-double bond will migrate to the 8,14-position (3), which is stable to hydrogenation, and requires treatment with hydrochloric acid before moving to the 14,15-position where it can be reduced (10). To date no natural sterol has been found with a 9,11-double bond. It is probable that under slightly acid conditions this bond would migrate to the 8,9-position, and attempted hydrogenation of sterols with this type of double bond will rearrange the double bond to the 8,14-position again (12, 13). Since the reduced material obtained from the hydrogenation was completely saturated, it seemed logical to assume from the above evidence that we were dealing with a mixture of β-sitostanol and β-sitosterol. This assumption has been proved correct by chemical evidence.

A further attempt to separate the mixture by chemical means failed. This involved treating the mixture with bromine and trying to recover the less soluble β-sitosterol dibromide by recrystallization. No pure crystalline dibromide was obtained however.

The composition was finally established by oxidation. The sterol mixture was oxidized with chromium trioxide in acetic acid solution. Under these conditions β-sitostanol (I) will be readily oxidized to β-sitostanone (III). β-Sitosterol, on the other hand, will form a variety of products arising from oxidation of the double bond (6). All these products will have two or more oxygen atoms, and will thus be more polar in character than β-sitostanone. In agreement, chromatography of the oxidation product first gave β-sitostanone (III), proved by melting point, rotation, and mixed melting point with an authentic specimen, followed by a series of non-crystalline oils.

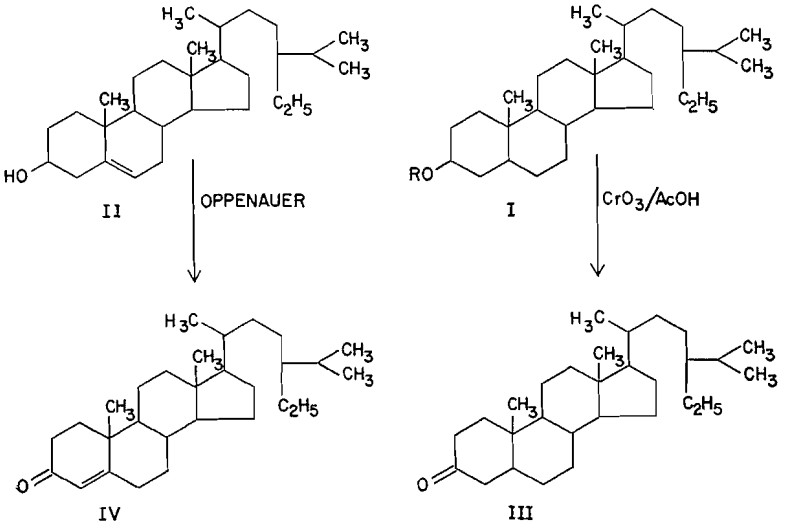
Oxidation of the sterol mixture to give β-sitostenone (IV) alone was achieved by the Oppenauer method with aluminum isopropoxide. The yield, however, was poor and some oxidation of the β-sitostanol took place (7). To parallel the above work, the mixture of sterols was oxidized in such a manner as to give both β-sitostenone and β-sitostanone. This was achieved by brominating the mixture, oxidizing the β-sitosterol dibromide and β-sitostanol in a two-phase system with chromium trioxide (9), removing the bromine from the dibromide by means of sodium iodide (11), and chromatographing the resulting mixture. Both β-sitostenone and β-sitostanone were obtained, although the former was not quite as pure as desirable. From the infrared spectrum the contaminant appeared to be β-sitostanone, and the two ketones are known to be fairly difficult to separate by chromatography (7).

The proportions of β-sitostanol and β-sitosterol present in the steroid mixture obtained can be calculated directly from the rotations of the pure sterols and the rotation of the mixture. From these figures the percentage of β-sitostanol varied from 20% to 40%, with an average value of 30%. The oxidation experiments carried out to determine the chemical composition were not accurate enough to give physical composition since the yields varied and were never 100%.



EXPERIMENTAL

All rotations were measured in a 1-dm. tube with a Rudolph polarimeter. Melting points were observed on a Kofler micro melting point apparatus and are corrected. The ultraviolet spectra were determined in ethanolic solution with a Beckman Model DU spectrophotometer. The infrared spectra were determined in carbon disulphide solution with a Baird double-beam infrared spectrophotometer model 4-55. Light petroleum refers to the fraction with boiling point 35°–60°.

Extraction of Peat Moss

The dried and ground peat moss (2.5 kg.) was loaded into a large copper percolator equipped with a pump and overflow system which permitted fresh solvent to percolate continuously through the bed. This was essentially a countercurrent extraction system. The solvent used was a mixture of benzene and ethanol (3:2, 40 liters). It was run slowly through the moss, at a rate which was controlled by a valve at the bottom of the extraction

apparatus. The extraction usually required about 12 hours. The resulting extract was concentrated to 2 liters at 50° under reduced pressure in a climbing film evaporator. Potassium hydroxide (100 g.) in methanol (500 ml.) was then added and the mixture heated under reflux for 2 hours. The mixture was diluted with water and extracted with ether, the ether extract washed and evaporated to dryness, to give the crude unsaponifiable extract. The acids were obtained by acidification of the alkali-soluble fraction followed by filtration.

Treatment of Crude Extract

The crude extract (35 g.) was dissolved in light petroleum (500 ml.). A small portion of the material which did not dissolve was removed by centrifugation for later investigation. The main bulk of the petrol solution was added to the top of a column (55×5 cm.) of alumina. The column was eluted with light petroleum (2 liters), benzene (2 liters), ether (6 liters), ether–methanol (9:1, 3 liters), and methanol (1.5 liters). The amounts of material eluted were approximately as follows: from the petrol fraction, 1 g.; benzene, 1.5 g.; ether, variable (see text, max. of 4.5 g.); ether–methanol, variable (see text, max. of 10 g.); methanol, 6–7 g.

Separation of Sterols from Crude Combined Fractions

The partly crystalline mixture (10 g.) obtained by solvent removal from the ether–methanol eluate was dissolved in light petroleum (500 ml.) and added to a mixture of urea (15 g.) made slushy with methanol. The mixture was shaken for 1 hour, and the resulting urea complex filtered off. The filtrate was again treated with a second batch of urea, but very little more material was precipitated. The petrol solution was evaporated to 250 ml., refiltered, and washed twice with distilled water to remove any remaining complex. The solution was evaporated to dryness and the product crystallized from aqueous ethanol to give a white crystalline material (4.5 g.), m.p. 135°–137°, $[\alpha]_D^{26}$ −18° (c = 1.4 in chloroform). The material complexed by the urea was recovered by treating the complex with hot water for 1 hour and extracting with benzene, washing the extract well and evaporating to dryness to give a white, waxy solid (5 g.). This was recrystallized from carbon tetrachloride, m.p. 75.5°–76.5°. It was optically inactive and a mixed melting point with lignoceryl alcohol of m.p. 74° was undepressed. Anal. Calc. for $C_{24}H_{50}O$: C, 81.27; H, 14.21; mol. wt. 354. Found: C, 81.64; H, 14.01; mol. wt. 372 (ebullioscopic in butanone), 347 (Rast). Bleyberg and Ulrich (5) report a melting point of 75.4° for lignoceryl alcohol. The alcohol was oxidized with chromic acid in acetic acid and benzene to yield an acid of melting point 81°–82°. This value is in good agreement with values reported for lignoceric acid.

Reduction of Sterols

A portion (500 mg.) of the sterol mixture obtained from the above separation was dissolved in ethyl acetate (100 ml.) and acetic acid (5 ml.). Platinum oxide (50 mg.) was added and the mixture shaken with hydrogen at a pressure of 40 p.s.i. overnight. The platinum was then filtered off and the filtrate washed free of acetic acid and evaporated to dryness. The resulting product was crystallized from aqueous ethanol to give β-sitostanol, m.p. 140°–141° (melts and resolidifies at 136°), $[\alpha]_D^{25}$ +24° (c = 1.2 in chloroform). The values recorded in the literature are m.p. 141°–142°, $[\alpha]_D$ +24° (1).

Acetylation

β-Sitostanol (100 mg.) was dissolved in pyridine (2 ml.) and acetic anhydride (3 ml.) added, and the mixture heated on the steam bath for 1 hour. The mixture was diluted with benzene, washed with dilute alkali, dilute acid, and water, and evaporated to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

dryness. The product was crystallized from chloroform–methanol to give β-sitostanol acetate, m.p. 135°–136°, $[\alpha]_D^{26}$ +15° (c = 1.0 in chloroform). The values recorded in the literature are m.p. 138°–139°, $[\alpha]_D$ +15° (1).

Oxidation

β-Sitostanol (100 mg.) was dissolved in acetic acid (10 ml.), and chromium trioxide (20 mg.) in water (1 ml.) and acetic acid (10 ml.) added. The solution was allowed to stand overnight at room temperature, then diluted with water and extracted with benzene. The benzene extract was washed free of acetic acid and evaporated to dryness. The resulting crude product was dissolved in benzene and filtered through alumina. Evaporation of the solvent yielded a material which was crystallized from chloroform–methanol to give β-sitostanone, m.p. 155°–157°, $[\alpha]_D^{26}$ = +38° (c = 1.28 in chloroform). The 2,4-dinitrophenylhydrazone made in the usual manner was yellow and had m.p. 221° (dec.). For this compound Barton (2) reports m.p. 157°, $[\alpha]_D$ +38°, and the m.p. of the yellow 2,4-dinitrophenylhydrazone 223° (dec.).

Oxidation of Sterols

The sterol mixture (1 g.) was dissolved in acetic acid (15 ml.), and chromium trioxide (60 mg.) in water (1 ml.) and acetic acid (10 ml.) added. The mixture was allowed to stand at room temperature for 1 hour, then diluted with water and extracted with benzene. The benzene extract was washed well and evaporated to dryness. The crude material was chromatographed on alumina and eluted with benzene to afford β-sitostanone (50 mg.), m.p. 156°–157°, undepressed in mixed m.p. with a genuine specimen, $[\alpha]_D^{24}$ +37° (c = 1.3 in chloroform).

Oxidation of Sterols

The sterol mixture (1 g.) was dissolved in dry acetone (15 ml.), and aluminum isopropoxide (1 g.) in dry benzene (30 ml.) added. The solution was heated under reflux overnight, then diluted with water, washed twice with 2 N sulphuric acid and water, and the benzene layer evaporated to dryness. The crude oil obtained was heated on the steam bath under reduced pressure for 1 hour, then chromatographed carefully. Elution with petrol–benzene (2:1) gave a small amount of β-sitostanone (30 mg.), identified by m.p. and mixed m.p. Elution with benzene–petrol (3:1) gave β-sitostenone (120 mg.), m.p. 87°–88°, λ_{max} = 241, ϵ_{max} = 17,000. Barton and Jones (2) give m.p. 88°, λ_{max} = 240.5, ϵ_{max} = 20,000.

Oxidation of Sterols

The sterol mixture (4 g.) was dissolved in chloroform (30 ml.) and acetic acid (30 ml.). Sodium acetate (400 mg.) in acetic acid (10 ml.) was added and the solution cooled to 0°. A solution of bromine (1.5 g.) in acetic acid (10 ml.) also cooled to 0° was then added. The resulting solution was then washed with sodium thiosulphate solution to remove the excess bromine and then with water, and then evaporated to dryness. The crude material so obtained was dissolved in benzene (50 ml.) and shaken with a solution of chromium trioxide (1.5 g.) in water (15 ml.) and acetic acid (25 ml.) for 6 hours. The benzene solution was washed thoroughly to remove acetic acid and evaporated to dryness. The crude yellow oil obtained was dissolved in acetone, and sodium iodide (7 g.) in acetone (30 ml.) added. The mixture was heated under reflux for 3 hours, diluted with benzene, and washed with sodium thiosulphate solution and water, and evaporated to dryness. Chromatography of the crude oxidation product on alumina and elution with benzene gave β-sitostanone (200 mg.), identified by m.p. and mixed m.p. Elution with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

benzene–ether (19:1) gave β-sitostenone (1.25 g.), m.p. 86°–87°, $[\alpha]_D^{25}$ +78° (c = 1.13 in chloroform), λ_{max} = 241, ϵ_{max} = 16,000. The value recorded in the literature for the rotation is $[\alpha]_D$ +85° (11).

ORGANIC DEUTERIUM COMPOUNDS

XIX. SYNTHESIS OF SOME DEUTERATED LAURIC ACIDS AND THEIR METHYL ESTERS[1]

M. Elaine Isabelle and L. C. Leitch

ABSTRACT

The synthesis of lauric acids deuterated in the carboxyl, the terminal methyl, and the α-methylene groups and in various combinations of these is described. The methyl and methyl-d_3 esters of each of the acids were also prepared.

Two further examples of homolytic halide addition to olefins are reported.

The reaction between alkyl halides and silver acetylides is described. A mechanism involving a new type of free radical is postulated.

In connection with studies by Jones and co-workers (9) on the infrared spectra of aliphatic fatty acids and their methyl esters it became necessary to prepare a number of deuterated lauric acids and methyl laurates. The series of compounds synthesized in this work are shown below.

$CH_3(CH_2)_{10}CO_2R$ (I) $\qquad$ $CH_3(CH_2)_9CD_2CO_2R$ (III)

$CD_3(CH_2)_{10}CO_2R$ $\qquad$ $CD_3(CH_2)_9CD_2CO_2R$

(R = H, D, CH_3, CD_3)

The compounds in the first group presented no particular problem. Lauric acid-d was obtained by decomposing lauroyl chloride with deuterium oxide. Methyl-d_3 laurate was obtained in excellent yield by heating silver laurate with methyl-d_3 bromide (14).

The synthesis of the key compound in the second series, lauric acid labelled on the terminal carbon atom of the chain, proved more difficult. Since methyl-d_3 iodide of high isotopic purity is now readily available, the preparation of the deuterolauric acid in question was attempted by the reactions shown below:

$$CD_3I + NaC{\equiv}C(CH_2)_8CO_2CH_3 \rightarrow CD_3C{\equiv}C(CH_2)_8CO_2CH_3 + NaI,$$

$$CD_3C{\equiv}C(CH_2)_8CO_2CH_3 \rightarrow CD_3(CH_2)_{10}CO_2CH_3.$$

In pilot experiments with methyl iodide, however, we were unable to methylate the sodium derivative of methyl 10-undecynoate in liquid ammonia. This observation is in agreement with that of Taylor and Strong (20), who found that the alkynes $CH_3(CH_2)_mC{\equiv}CH$ did not condense in sodamide – liquid ammonia with $I(CH_2)_nCl$ where $m < 10$ or $n < 3$. Attempts to alkylate by this method were therefore abandoned.

The reaction of deuterated alkyl iodides (and even bromides) with the silver salts of aliphatic acids is a very convenient reaction for the synthesis of deuterated esters (13) and was used above to prepare methyl-d_3 laurate. There was a possibility that silver acetylides would also react under suitable conditions, at least with methyl iodide, to give alkylacetylenes. Observations in the literature (6) relating to the inertness of silver acetylides to alkyl halides were ignored, and the silver derivative of methyl 10-undecynoate was heated to 75° C. for several hours with an excess of methyl iodide. It was an agreeable surprise to isolate methyl 10-dodecynoate although in only 40 to 50% yields. The new ester was identified by its infrared spectrum, which showed no absorption

[1]*Manuscript received August 26, 1957.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4610.

for acetylenic hydrogen, and by the melting point of the acid; it was evidently methyl 10-dodecynoate. A similar reaction was found to take place with ethyl iodide to give methyl 10-tridecynoate. It therefore appears that silver acetylides will react with certain alkyl halides. The synthesis is particularly valuable with labelled halides owing to the ease with which unreacted halide may be recovered.*

In order to avoid using a large excess of labelled methyl iodide an experiment was next carried out in ether as a solvent. The product isolated from the reaction was not pure methyl 10-dodecynoate; its index of refraction was low, the melting point of the 10-dodecynoic acid was also low, and the ester gave a precipitate of the silver acetylide when shaken with ammoniacal silver nitrate in alcohol. The product seemed to be a mixture of methyl 10-undecynoate and 10-dodecynoate.

Several other runs were made in ether or benzene as solvent and in one case, in the absence of methyl iodide. The results of these experiments, which show the yield of ester, its index of refraction, and the melting point of the acid obtained on hydrolysis, are given in Table I.

TABLE I

INFLUENCE OF SOLVENT ON THE YIELD AND PURITY OF THE METHYL 10-DODECYNOATE

Wt. of silver derivative (g.)	Vol. of methyl iodide (ml.)	Solvent (ml.)	Yield (ml.)	n_D^{20}	M.p. of acid (°C.)
12.7	10.0	None	4.0	1.4529	51
13.7	10.0	10 ml. ether	5.4	1.4510	47
10.0	4.0	10 ml. ether	0.5	1.4500	–
6.0	5.0	10 ml. C_6H_6	1.0	1.4480	–
6.0	5.0	None	–	1.4516	50–51
6.0	None	10 ml. ether	1.0	1.4460	42–43

The formation of methyl 10-undecynoate in the presence of ether may well take place by a free radical mechanism. According to this view the silver acetylide would produce the radical $CH_3OOC(CH_2)_8C{\equiv}\dot{C}$ mentioned in reference 11, which could then give rise to the acetylenic ester by abstraction of a hydrogen atom from the solvent or from the ester itself:

$$CH_3OOC(CH_2)_8C{\equiv}CAg \rightarrow CH_3OOC(CH_2)_8C{\equiv}\dot{C} + Ag,$$

$$CH_3OOC(CH_2)_8C{\equiv}\dot{C} + C_2H_5OC_2H_5 \rightarrow CH_3OOC(CH_2)_8C{\equiv}CH + \dot{C}_2H_4OC_2H_5.$$

The following observations are submitted as evidence in favor of this mechanism. When the silver derivative of methyl 10-undecynoate was heated alone in a sealed tube, a silver mirror was formed and a small yield of methyl 10-undecynoate was obtained. Much polymeric material was found. Moreover, when the acetylide was heated in benzene-d_6, a product was isolated which had a small band in the region of the acetylenic deuterium vibration. Waters (23) is inclined to believe that silver derivatives ought to participate readily in free radical reactions because of the weak electropositive character of silver. Also, Glockling (5) has shown that the heterogeneous decomposition of iso-1-butenyl silver gives rise to iso-1-butenyl radicals, $(CH_3)_2C{=}\dot{C}H$. On the basis of all this evidence we submit that a $CH_3OOC(CH_2)_8C{\equiv}\dot{C}$ radical is involved in the present reactions and that the formation of methyl 10-undecynoate in the presence of ether takes place by abstraction of hydrogen from the solvent or from the ester itself.

**After this work was completed Davis and Schreiber (3) reported the synthesis of acetylenic ketones by reaction of the silver derivatives of 1-hexyne and 1-octyne with acid chlorides in* CCl_4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Regarding the alkylation of the silver acetylide by methyl and ethyl iodides, one is tempted to invoke a free radical mechanism and represent the reaction by the steps shown below:

$$CH_3OOC(CH_2)_8C{\equiv}CAg \rightarrow CH_3OOC(CH_2)_8C{\equiv}\dot{C} + Ag,$$

$$CH_3I + Ag \rightarrow \dot{C}H_3 + AgI,$$

$$CH_3 + CH_3OOC(CH_2)_8C{\equiv}\dot{C} \rightarrow CH_3OOC(CH_2)_8C{\equiv}CCH_3.$$

However, the formation of methane by abstraction of hydrogen from the solvent or of ethane by dimerization, which are normal reactions of free radicals, has not been observed in these experiments.

In view of the comparative stability of the ions $R.C{\equiv}C^-$, it is possible that the alkylation takes place by a "push-pull" mechanism via the transition state shown below:

$$R.C{\equiv}C^- + CH_3I \xrightarrow{Ag^+} R.C{\equiv}C\text{- -}CH_3\text{- -}I \rightarrow R.C{\equiv}CCH_3 + AgI.$$

With methyl-d_3 iodide, methyl 10-dodecynoate deuterated on the terminal carbon atom of the chain was obtained. Reduction in an alkaline medium by the method of Schwenk *et al.* (19) gave lauric-12-d_3 acid from which methyl laurate-12-d_3 was obtained on esterification. There was no evidence of α-deuteration as judged from the infrared spectra of the acid or ester.

Lauric-12-d_3 acid was also synthesized by an alternative method. Jensen, Kharasch, and Urry have reported the peroxide induced addition of polyhalogenomethanes to olefins (7). It has now been found that addition of chloroform to methyl undecylenate gives a mediocre yield of methyl 12-trichlorolaurate. Dechlorination of the ester by means of zinc and acetic acid-*d* gave an 80% yield of methyl laurate-12-d_3. Deuterium oxide – dioxane mixtures can also be employed for the dehalogenation, and thus the necessity of preparing acetic acid-*d* can be avoided. Infrared spectra gave no evidence of α-deuteration in the acid or ester. The other members of this series of deuterated lauric acids were prepared by methods already described for lauric acid itself (7).

The third series of compounds involved the preparation of lauric acid deuterated on the α-methylene group. Interest was focused first on α-dibromolauric acid as a starting material. Textbooks on organic chemistry often make the general statement that further bromination of an α-bromo acid chloride by the Hell-Volhard method leads to the α-dibromo acid chloride. However, there are few references to these acids or their derivatives in the literature to substantiate this statement. α,α-Dibromoheptanoic acid has been reported but it was prepared from *n*-heptaldehyde diacetal (2), not from the acid. α,α-Dibromobutyric acid was supposedly formed when α-bromobutyric acid was heated with excess bromine in a sealed tube (15). Bromination of lauric acid beyond the α''-bromo stage in sealed tubes was completely unsuccessful in our hands in that inseparable mixtures of polybromobutyric acids seemed to be formed.

The required methyl ester was synthesized by making use of another peroxide induced addition to olefins. Methyl dichloroacetate was found to add readily to 1-decene to give a mediocre yield of methyl 2,2-dichlorolaurate. Dechlorination with deuterium oxide in dioxane and zinc dust gave an excellent yield of methyl laurate-2,2-d_2 (III; R=CH_3). The other members of this series were obtained as already described for the normal acid.

The final series of deuterated lauric acids and their esters (IV) were prepared from methyl laurate-12-d_3 by the following route:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

$$(CO_2C_2H_5)_2 + CD_3(CH_2)_{10}CO_2CH_3 \xrightarrow{C_2H_5OK} CD_3(CH_2)_9CH(CO_2CH_3)_2$$

$$CD_3(CH_2)_9CH(CO_2CH_3)_2 \xrightarrow{^-OD} CD_3(CH_2)_9CD(CO_2D)_2$$

$$CD_3(CH_2)_9CD(CO_2D)_2 \longrightarrow CD_3(CH_2)_9CD_2CO_2D + CO_2.$$

The reactions were first carried out with the normal ester. The Claisen condensation with methyl laurate to *n*-decyl malonic ester took place readily and the yields from there on were nearly quantitative (17, 18). Similar syntheses were then carried out with the terminally labelled ester; thus lauric acid labelled on both the α-methylene and the terminal carbon atom of the chain was obtained.

An interesting observation relative to the 1420 cm.$^{-1}$ band of fatty acids in the infrared came to light on comparison of the spectra of the acids in carbon tetrachloride solution. Jones (8) has attributed the 1420 cm.$^{-1}$ band to the scissoring vibrations of the α-methylene group in $R.CH_2CO_2CH_3$. When the spectrum of α-deuterated lauric acid was examined it still showed a band of medium intensity at 1417 cm.$^{-1}$. It seemed most unlikely that deuterium would have been lost by exchange in the α-position during hydrolysis of the ester. The band was also present but of reduced intensity in the acid after exchange with deuterium oxide. However, it was entirely absent from the spectrum of the α-deuterated acid chloride. It was likewise absent from the spectrum of methyl 2,2-dichlorolaurate and 2,2-dichlorolauroyl chloride. It was present, however, in the spectrum of lauroyl chloride and lauronitrile. The absorption in the 1420 cm.$^{-1}$ region is therefore not due solely to the α-methylene but also to the hydroxyl group. The spectrum of lauric acids labelled in the methyl group showed no absorption in the 1380 cm.$^{-1}$ region. Quantitative studies on the spectra of these acids by Jones and co-workers now in progress will be reported by them in detail elsewhere.

EXPERIMENTAL

Lauroyl Chloride

Lauric acid (1.0 g.) was warmed on the steam bath with 1 ml. of thionyl chloride (purified by distillation over quinoline and linseed oil). After 4 hours' heating, excess thionyl chloride and hydrogen chloride were pumped off. The residue was then twice distilled on the vacuum line in a Späth bulb. Yields: 0.8 ml., n_D^{20} 1.4455. Its infrared spectrum showed no absorption in the 3000–3600 cm.$^{-1}$ region and the band at 1407 cm.$^{-1}$ was reduced to one-half of its intensity in the spectrum of lauric acid where it appears at 1417 cm.$^{-1}$.

Lauric Acid-d

Lauroyl chloride was warmed on the steam bath for 1 hour with 2.0 ml. of deuterium oxide. After hydrolysis the lauric acid-*d* was extracted with pentane. After one recrystallization from pentane, 0.8 g. of acid was obtained. Since the acid still showed some absorption in the 3000–3400 cm.$^{-1}$ region in the infrared, it was exchanged by being heated with 10 ml. of deuterium oxide on the steam bath overnight. The equilibrated product was worked up as already described. There was little if any change in its spectrum by this treatment. The intensity of the band at 1417 cm.$^{-1}$ was the same as that in lauroyl chloride; part of it was masked by the absorption in the 1325–1410 cm.$^{-1}$ region. There was slight absorption in the 3000–3600 cm.$^{-1}$ region due to the presence of residual OH.

Methyl-d_3 Laurate, $CH_3(CH_2)_{10}CO_2CD_3$

Silver laurate was prepared as described in reference 12 by adding at the same rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

equivalent amounts of aqueous silver nitrate and potassium laurate to hot water, with stirring. The precipitate was filtered off, washed with water, and then acetone, and dried under vacuum in the dark.

Six grams of thoroughly dry silver laurate was placed in a tube (2 cm.×15 cm.) fitted with a ground glass joint. After the tube was constricted to facilitate sealing later, 15 ml. of anhydrous ether and 1.85 g. of methyl-d_3 bromide (13) were distilled into the tube, which was then frozen in liquid nitrogen, evacuated, and sealed. The reactants were heated to 85° C. in a rocking furnace for 20 hours.

Silver iodide was filtered off and washed with anhydrous ether. The residue, after removal of the ether, was distilled in a Späth bulb placed in an air furnace at 100° C. The yield of methyl-d_3 laurate was 3.5 g. (85.7%). It was a colorless liquid melting at + 10° C., n_D^{20} 1.4329.

For ordinary methyl laurate prepared in the same manner n_D^{20} was 1.4329.

Methyl 10-Undecynoate, $HC{\equiv}C(CH_2)_8CO_2CH_3$

10-Undecynoic acid was prepared as described in reference 10. Thirty grams of the acid were esterified with methanol and a trace of sulphuric acid under reflux for 4 hours. The ester had b.p. 69–71° at 1 mm., n_D^{20} 1.4465. Yield: 32 g.

Methyl 10-Dodecynoate, $CH_3C{\equiv}C(CH_2)_8CO_2CH_3$

The silver derivative of methyl 10-undecynoate was prepared by shaking overnight 10.0 g. of the ester with 170 ml. of ammoniacal silver nitrate solution (prepared by dissolving 8.5 g. of the salt in 100 ml. of water and adding ammonium hydroxide until the precipitate of silver oxide initially formed had just dissolved). Yield: 13.2 g. of product, m.p. 76–78° C. Calc. for $C_{12}H_{19}O_2Ag$, % Ag 35.6. Found: 35.2%.

The silver derivative (12.7 g.) was heated at 75° C. in a sealed tube overnight with 10.0 ml. of methyl iodide. The solids were filtered off in a gravity funnel and washed with ether. The residue, after removal of the ether by distillation, was distilled under vacuum from a Späth bulb in an air furnace at 85° C. Yield of product n_D^{20} 1.4529 was 4.0 ml. (45% of the theoretical).

10-Undecynoic Acid, $CH_3C{\equiv}C(CH_2)_8COOH$

The methyl ester was hydrolyzed by being heated on the steam bath for a few minutes with a slight excess of alkali in 50% ethanol–water. The solution was diluted with water and acidified at 0° C. with dilute hydrochloric acid. After one recrystallization from petroleum ether the acid melted at 51° C. Neutralization equivalent, calc. for $C_{12}H_{20}O_2$: 196; found: 198.

Methyl 10-Tridecynoate, $C_2H_5C{\equiv}C(CH_2)_8CO_2CH_3$

Eight grams of the silver derivative of methyl 10-undecynoate was heated with 4.0 ml. of ethyl iodide in a sealed tube overnight at 80° C. The reaction product was worked up and purified as described for the lower homologue. Yield: 1.2 g., n_D^{20} 1.4504.

Methyl 10-Decynoate-12-d_3, $CD_3C{\equiv}C(CH_2)_8CO_2CH_3$

The silver derivative of methyl 10-undecynoate was heated in a sealed tube with 6.7 ml. of methyl-d_3 iodide (13) overnight at 65° C. The product was isolated and purified as already described. Yield: 1.8 g. (50% of the theoretical) of ester, n_D^{20} 1.4514.

Methyl 12-Trichlorolaurate, $CCl_3(CH_2)_{10}CO_2CH_3$

A solution of 45 ml. of methyl 10-undecylenate in 75 ml. of chloroform containing 0.5 g. of dissolved dibenzoyl peroxide was heated in a pressure bottle for 4 hours at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

110° C. in an oven; a further 0.5 g. of peroxide was added at the end of this time and heating was resumed overnight or for another 12 to 15 hours. The bulk of the chloroform was removed on the steam bath and the residue was distilled in a Vigreux column under reduced pressure (0.5 mm.). After collection of the unchanged methyl undecenoate at 65° C. the boiling point rose rapidly to 128–130° C. at 0.5 mm. and the trichloroester began to distill. Yield: 12.0 ml., n_D^{20} 1.4695.

Methyl Laurate-12-d_3, $CD_3(CH_2)_{10}CO_2CH_3$

(*a*) *By reduction of 10-dodecynoic acid with Raney nickel.*—10-Dodecynoic acid (1.0 g.) was dissolved in 200 ml. of 2% sodium hydroxide in water, and Raney nickel alloy (10.0 g.) was added in small portions over a period of 1 hour while the mixture was being heated on the steam bath. The hot solution was then filtered and the filtrate was acidified with dilute hydrochloric acid. The melting point of the acid which was filtered off was 42–43° C. The acid was converted into the methyl ester by heating the silver salt with methyl bromide as described above.

(*b*) *By zinc dust – deuterium oxide dechlorination.*—To a suspension of 14.0 g. zinc dust (50% excess) in 150 ml. of anhydrous dioxane containing 30 ml. of deuterium oxide was added dropwise, with stirring, 15 g. of methyl trichlorolaurate. The reaction mixture was stirred overnight at 90° C. and under reflux for 4 hours. The reaction mixture was filtered and freed of dioxane by distillation under reduced pressure. The residue was taken up in ether and filtered from suspended solids. The filtrate was freed of ether and distilled in a Späth bulb yielding 8.2 g. (80.3% yield) of methyl laurate-12-d_3, n_D^{20} 1.4332.

The trichloro ester can also be dehalogenated with acetic acid-*d* and zinc dust with slightly higher yield but at the expense of preparing acetic acid-*d*.

Lauric-12-d_3 Acid, $CD_3(CH_2)_{10}COOH$

The acid was obtained by hydrolysis of the ester in nearly quantitative yield. Its infrared spectrum did not show the presence of a band for the CH_3 group at 1383 cm.$^{-1}$.

Lauric-12-d_3 Acid-d, $CD_3(CH_2)_{10}CO_2D$

This acid was prepared from the previous acid through the acid chloride.

Methyl-d_3 Laurate-12-d_3, $CD_3(CH_2)_{10}CO_2CD_3$

Silver laurate-12-d_3 prepared as described for the normal acid was heated with excess methyl-d_3 bromide in a sealed tube and the product was isolated as described in the case of methyl-d_3 laurate. The yield of distilled product, n_D^{20} 1.4337, was 92%.

Bromination of Lauric Acid

Attempts to brominate lauric acid under reflux in the presence of small amounts of phosphorus trichloride always resulted in the formation of α-bromolauric acid. No evidence of the presence of α-dibromolauric acid was ever found.

Brominations carried out at 140° C. in sealed tubes as described by Otto (15) likewise were unsatisfactory. Vast quantities of hydrogen bromide were evolved when the tubes were opened but the product boiled over a wide temperature range. Mixtures of dibrominated lauric acids were probably formed under these conditions. It is apparently not possible to introduce two bromine atoms in the α-position by this means.

Methyl 2,2-Dichlorolaurate, $CH_3(CH_2)_9CCl_2CO_2CH_3$

1-Decene (115 ml.), methyl dichloroacetate (177 g.), and 4.0 g. of dibenzoyl peroxide were heated for 15 hours on the steam bath. Unreacted decene and dichloroacetate ester were distilled off under 50 mm. pressure. After collection of a fraction (7.5 ml.) between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

86° and 90° C. at 0.1 mm., methyl dichlorolaurate distilled over between 92° and 94° C. at 0.1 mm., n_D^{20} 1.4594, n_D^{23} 1.4584. The yield was only 28–30% but is offset by the ease of preparation of the ester.

Methyl Laurate-2,2-d_2, $CH_3(CH_2)_9CD_2CO_2CH_3$

Acetic acid-*d* was prepared as already described from acetyl chloride and deuterium oxide (16). To the acetic acid-*d* obtained from 26 ml. of acetyl chloride was added 6 g. of zinc dust and 5 ml. of methyl 2,2-dichlorolaurate. After the mixture had been stirred at room temperature overnight the zinc had nearly all turned white. The reaction mixture was poured into ice-water and extracted with 40 ml. of pentane. The residue, after removal of the pentane by distillation, was distilled in a Späth bulb. Yield: 3–6 g. of product, n_D^{22} 1.4342.

Reduction with deuterium oxide instead of acetic acid-*d* resulted in an impure product which showed unsaturation.

Lauric-2,2-d_2 Acid, $CH_3(CH_2)_9CD_2COOH$

The ester was hydrolyzed, isolated, and purified as described for lauric-12-d_3 acid. The yield was 2.9 g.

Lauric-2,2-d_2 Acid-d

This acid was prepared from lauric-2,2-d_2 acid via the chloride.

2,2-Dichlorolauroyl Chloride, $CH_3(CH_2)_9CCl_2COCl$

Dichloroacetyl chloride was prepared as described by Brown (1). The acid chloride (180 g.), decene-1 (53 ml.), and dibenzoyl peroxide (2.0 g.) were heated on the steam bath overnight. The reaction mixture was fractionated in a short Vigreux column under 0.06 mm. pressure. Unreacted decene and dichloroacetyl chloride were collected up to 80° C. 2,2-Dichlorolauroyl chloride then distilled at 82–83° C. Yield: 6.0 ml., n_D^{20} 1.4629.

The amide was prepared by treating a sample of the chloride with ammonia and dilute ethanol. After one recrystallization from ethanol the amide melted at 62–64° C.

2,2-Dichlorolauric Acid, $CH_3(CH_2)_9CCl_2COOH$

A mixture of 1 ml. of 2,2-dichlorolauroyl chloride and 5 ml. of water was stirred overnight at room temperature and extracted with ether. The ether solution was dried over anhydrous sodium sulphate and distilled. The residue which remained was distilled in a Späth bulb. The distillate was a colorless liquid with an odor of lauric acid. Its neutralization equivalent was somewhat low.

Methyl-d_3 Laurate-2,2-d_2, $CH_3(CH_2)_9CD_2CO_2CD_3$

The silver salt was prepared as has already been described for ordinary lauric acid and lauric-12-d_3 acid. Methyl-d_3 laurate-2,2-d_2 was prepared from the silver salt and methyl-d_3 bromide as described above.

Diethyl n-Decylmalonate, $CH_3(CH_2)_9CH(CO_2C_2H_5)_2$

"Molecular" potassium (2.0 g.) was prepared in xylene dried over sodium (21), and washed three times by decantation with absolute ether. It was then covered with 40 ml. of absolute ether and anhydrous ethanol (2.8 ml., dried by distillation over magnesium ribbon) was added. The reaction mixture was heated for 4 hours under reflux. Diethyl oxalate (9.4 ml.) and methyl laurate (9.2 ml.) were added to the ice-cold suspension of potassium ethoxide in ether. After 25 hours' stirring the reaction mixture was poured into ice-water containing a little hydrochloric acid. The ether was separated, washed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

three times with water, and dried over anhydrous sodium sulphate. The ether was removed at the ordinary pressure and the residue decarboxylated by heating under vacuum at 150° C. until no further evolution of gas took place. The product began to reflux as the pressure fell to 0.5 mm. The yield of product, n_D^{20} 1.4364, b.p. 120–124° C., was 9.0 ml.

Floyd and Miller (4) report b.p. 155–158° C. at 3 mm. and n_D^{25} 1.4353 for *n*-decylmalonic ester.

n-Decylmalonic-2-d Acid-d_2, $CH_3(CH_2)_9CD(CO_2D)_2$

Sodium deuteroxide was prepared by adding 7.0 g. of clean sodium in small portions to 50 ml. of deuterium oxide stirred under an atmosphere of dry nitrogen. *n*-Decylmalonic ester was then added and the reaction mixture was stirred overnight just below the boiling point. The solution was acidified by addition of deuterium sulphate until strongly acid, and extracted with ether. On evaporation of the ether, 6.1 g. of white solid melting at 111–113° C. was obtained. According to Wallingford (22) *n*-decylmalonic acid melts at 118–119°. Recrystallization of the acid from chloroform raised its melting point to 116° C. The deuterated acid could be expected to melt at a lower temperature than the normal one (24).

Heating above its melting point converted the *n*-decylmalonic-d_2 acid-d_2 into lauric-2,2-d_2 acid-*d*.

Diethyl n-Decylmalonate-10-d_3, $CD_3(CH_2)_9CH(CO_2C_2H_5)_2$

A Claisen condensation between diethyl oxalate and methyl laurate-12-d_3 was carried out exactly as just described. From 9.3 g. of laurate ester there was obtained 9.3 ml. of malonic ester, n_D^{20} 1.4373. Hydrolysis gave 6.1 g. of acid, m.p. 111–113° C.

Lauric-2,2,12,12,12-d_5 Acid-d, $CD_3(CH_2)_9CD_2CO_2D$

This acid was obtained by decarboxylating the corresponding malonic acid in a glycerine bath at 140° C.

Methyl Laurate-2,2,12,12,12-d_5, $CD_3(CH_2)_9CD_2CO_2CH_3$

Silver laurate-2-2,12,12,12-d_5 was prepared as already described for the normal acid. It was converted into the ester by heating with methyl iodide, also as described above.

Methyl-d_3 Laurate-2,2,12,12,12-d_5, $CD_3(CH_2)_9CD_2CO_2CD_3$

This ester was prepared by the methods described above.

ACKNOWLEDGMENTS

The authors wish to thank Dr. R. N. Jones for helpful discussions and Mr. R. Lauzon for the infrared spectra of several compounds.

ELECTROLYTIC CONDUCTANCE IN HYDROGEN PEROXIDE – WATER MIXTURES

PART I. THE ALKALI CHLORIDES[1]

D. K. THOMAS[2] AND O. MAASS

ABSTRACT

The equivalent conductance of a series of alkali chlorides has been measured in water – hydrogen peroxide mixtures over the whole range of solvent composition. The measurements were made by a simple direct-current method, and the results obtained are interpreted in terms of the viscosity of the solvent.

INTRODUCTION

The close similarity in the values of certain of the physical constants for water and hydrogen peroxide has been appreciated for some time, and in some instances extensive studies of their variation in mixtures of the two compounds has been carried out (1, 2, 3, 4). In all cases these similarities have received adequate explanation in terms of the possession by both molecules of structures adapted to strong hydrogen bonding.

Mixtures of hydrogen peroxide and water have been found to display non-ideality in that

(*a*) there is a volume change on mixing (3),

(*b*) there is a finite heat of mixing (4),

(*c*) the vapor pressures of the solutions do not obey Raoult's law (5).

The direction of these departures from ideality is interpreted as indicating an enhancement of either the number or the force of the attractions between molecules upon forming the solutions.

One of the least-studied aspects of the hydrogen peroxide – water system has been that of its behavior as an ionizing medium, this possibly being due to the difficulty, until fairly recently, of obtaining concentrated hydrogen peroxide of a high degree of purity. Recently, measurements (6, 7) of the conductivities of a few acids and salts in solvents of compositions ranging from 100% water to 100% hydrogen peroxide have been made. In all cases it appears that addition of hydrogen peroxide to water brings about a marked reduction in the electrical conductance, and furthermore, a point is reached at which the conductance of an acid is lower than that of its potassium salt (7). No completely adequate explanation has been forthcoming to account for these results.

In the present work an attempt has been made to carry out a comprehensive study of the alkali chloride series in solvents of composition varying from 100% water to 98% hydrogen peroxide, with the object of

(*a*) seeing whether the conductance trends displayed in aqueous solution are maintained,

(*b*) attempting to account for the variation in conductance with solvent composition.

EXPERIMENTAL

The use of hydrogen peroxide as a solvent for conductivity work is beset with one major difficulty, namely its tendency to decompose at room temperature in the presence of only minute quantities of impurity. Even in the apparent absence of any catalyst sufficient

[1]*Manuscript received October 23, 1957.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4614.
[2]*N.R.C. Postdoctorate Fellow 1956–57.*

decomposition may occur to render a conductance measurement extremely inaccurate.

All the results subsequently quoted were obtained by the use of a very simple direct-current method, in which the potential difference between two points in the solution, as measured by a pair of probe electrodes, was balanced against that across a standard resistance placed in series with the conductivity cell. This method is identical in principle to that used for the measurement of the conductance of aqueous solutions of alkali halides by Brönsted and Nielsen (8), Gunning and Gordon (9), and more recently by Ives and Swaroopa (10), and Lim (11). In the hands of these workers this direct-current method has been shown to give results closely similar to those obtained on the same systems by the use of the alternating-current method. In fact, Gunning and Gordon found that in dilute solution the results obtained from the two methods agreed to within the apparent precision of either set of measurements.

The conductivity cells used were of Pyrex glass construction, the probe electrodes and the current-carrying electrodes being molded from pure tin. All solutions were made by weight from the pure constituents and, because of their inherent instability, were used immediately. The cell constants were determined using aqueous potassium chloride solutions of concentrations 0.01 N, 0.05 N, and 0.10 N.

A typical set of values was as follows:

(a) $c = 0.01$, $K = 361.0$;
(b) $c = 0.05$, $K = 361.4$;
(c) $c = 0.10$, $K = 361.1$.

The cells were immersed in a thermostat controlled to $\pm 0.01°$ C. during all observations, and balance between the solution and the standard resistance was obtained by varying the latter until identical readings were obtained on a Keighley model 210 electrometer.

Before proceeding with the main series of measurements a study was made of the system K_2SO_4–H_2O_2–H_2O in order that a comparison could be made between the precision of the a-c. method as used by Shanley *et al.* (6, 7) and the d-c. method used in these investigations. As will be seen from Fig. 1, both methods lead to essentially the same result over the whole range of solvent composition. At the lower concentrations a solvent correction of the form $K_{\text{solute}} = K_{\text{solution}} + K_{\text{solvent}}$, where K signifies specific conductance, was applied.

It was found that the reproducibility in all the solvents used was always as good as 1%.

MATERIALS

(*i*) *Alkali Chlorides*

The alkali chlorides, i.e. those of lithium, sodium, potassium, rubidium, and cesium, were all high-grade analytical reagents, each containing only trace quantities of other alkali metals. They were dried by prolonged heating at 120° C. and stored in a desiccator until required.

(*ii*) *Hydrogen Peroxide*

Becco Chemicals 98% hydrogen peroxide was used throughout. Solvents of lower peroxide concentration were made by dilution of the concentrated material with water of specific conductance 1.5×10^{-6} mhos, and were standardized volumetrically with potassium permanganate.

(*iii*) *Tin*

The probe electrodes and current-carrying electrodes were made from pure tin, the maximum limits of impurity being as follows: As, 0.0003%; Cu, 0.002%; Te, 0.005%; Pb, 0.010%.

RESULTS

The results obtained are presented graphically in Figs. 2–6. Except in the cases of rubidium and cesium chloride the data for aqueous solution were obtained from the literature; for these two the only available data were those due to Boltwood (12) and Bredig (13). Since these showed the curves for equivalent conductance against concentration to cross at $C^{1/2} = 0.125$ it was felt that confirmation of these results would be in order. The measurements made did, in fact, substantiate these early observations, but deviated from them slightly at low concentration to give a value of Λ_0 different by 0.5% (see Fig. 6).

In all cases a solvent correction was applied at the lowest concentrations.

DISCUSSION

Reference to the results shows that the addition of hydrogen peroxide to the system alkali chloride – hydrogen peroxide – water leads to a reduction in the equivalent conductance of the solution. This is in accord with previous observations (6, 7). The greatest changes are effected by adding H_2O_2 to solutions containing a high percentage of water, and, in fact, once the H_2O_2 concentration exceeds about 75% by weight, further addition leads to only very small changes in conductance. A curve showing the variation of equivalent conductance with the percentage of H_2O_2 for KCl solutions is reproduced in Fig. 7, and this displays a behavior typical of all the alkali chlorides.

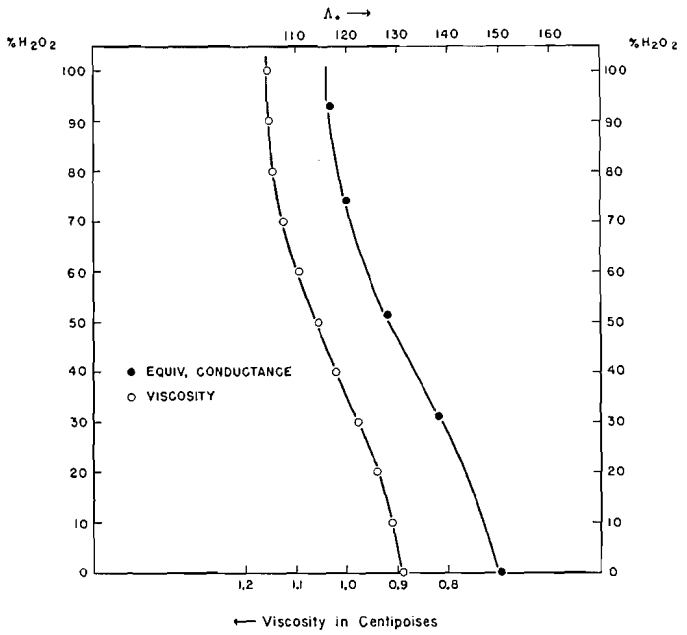

FIG. 7.

It will be seen that the sequence of conductivity values is the same as that in aqueous solution insofar as lithium chloride has the lowest value and sodium chloride the next lowest. The chlorides of potassium, rubidium, and cesium lie rather close to each other in aqueous solution, and addition of hydrogen peroxide appears to bring them even closer together until eventually, as in 98% peroxide, they are indistinguishable.

There seems little doubt that, in hydrogen peroxide as in water, the ions are solvated and that in concentrated hydrogen peroxide the relative degrees of solvation for the cations are Li > Na > K $\simeq$ Rb $\simeq$ Cs. At what particular stage the hydrogen peroxide begins to replace the water in the solvation sheath remains a matter for conjecture, but there seems good reason to suppose that, in view of its much higher dipole moment (14), there would be a tendency for this to occur. This view is supported by the work of Gorin (15), who observed a 'salting-in' of hydrogen peroxide in a number of aqueous solutions of electrolytes. Further reference to Fig. 7 shows the similarity in the variations of equivalent conductance, and of viscosity, with the percentage by weight of hydrogen peroxide in the solvent. This suggests that viscosity change is responsible for the conductance change. If that is the case, and assuming the applicability of Stokes' law to the solvated ions, the product $\Lambda_0\eta$ should be a constant. That this is indeed so may be seen by reference to Table I. The viscosity data in Table I are those of Shanley *et al.* (16).

TABLE I

Wt.% H_2O_2	Viscosity in centipoises	LiCl		NaCl		KCl		RbCl		CsCl	
		Λ_0	$\Lambda_0\eta$	Λ_0	$\Lambda_0\eta$	Λ_0	$\Lambda_0\eta$	Λ_0	$\Lambda_0\eta$	Λ_0	$\Lambda_0\eta$
0	0.00895	114.7	1.02	127.0	1.14	150.4	1.34	150.5	1.35	153.0	1.37
31	0.00970	107.8	1.05	116.6	1.13	138.0	1.33	140.0	1.36	131.2	1.27
52	0.01055	101.2	1.07	106.9	1.12	128.4	1.35	121.0	1.28	118.0	1.25
75	0.01132	99.0	1.12	102.0	1.15	117.4	1.36	117.2	1.33	108.0	1.22

CONCLUSION

The conductivity trends shown by the alkali chlorides in pure water are to a large extent maintained in hydrogen peroxide – water mixtures, and in pure hydrogen peroxide it appears that the relative degree of solvation of the alkali metal cations is Li > Na > K $\simeq$ Rb $\simeq$ Cs.

The decrease in conductance for all these salts in passing from a solvent of lower to one of higher peroxide concentration is accounted for in terms of the accompanying increase in viscosity.

ACKNOWLEDGMENTS

Thanks are due to Becco Chemicals for a gift of the hydrogen peroxide, and for valuable discussion in the early stages of the work; and to Mr. Gordon Graham for invaluable technical assistance.

A STUDY OF THE CONDUCTIVITY OF CERTAIN ACIDS AND ALKALI HALIDES IN GLYCOL AND THE INFLUENCE OF THE ADDITION OF A SECOND SOLVENT[1]

P. KIRBY[2] AND O. MAASS

ABSTRACT

The conductivities of HCl, H_2SO_4, HNO_3, and a number of their alkali metallic salts were measured in ethylene glycol. The influence of the addition of water, methanol, and hydrogen peroxide was determined. The results are discussed on the basis of well-known theories of electrolytic conductivity involving H^+ ions.

INTRODUCTION

The conductivity of various halogen acids and alkali halides in methyl and ethyl alcoholic solutions has been studied by Goldschmidt and co-workers, and although generally the results obtained were predictable on the basis of prevailing conductivity theories, anomalous results were found on the addition of small quantities of water to the acidic solutions (1).

It was found that water gave an initial diminution of conductivity until a minimum was reached after the addition of between 1 and 2 moles of water per liter. Continued addition of water then produced a steady rise in conductivity. Similar results were found later for the addition of water to solutions of strong acids in alcoholic solution by Murray-Rust and Hartley (2), and Beznan and Verhoek (3).

Goldschmidt and Aarflot (4) also studied the effect of the addition of small quantities of methyl alcohol to an ethanolic solution of HCl, but found that it "hardly affected" the conductivity.

The present investigation describes a series of similar conductivity determinations on hydrochloric acid and alkali halides in ethylene glycol. Small quantities of water were added to both the acidic and salt solutions, and the acidic solutions showed a decrease in conductivity similar to that found by Goldschmidt and Dahll (1), although the range of water content over which this diminution was observed was much wider than that found for the solutions of acids in methanol. It was also found that addition of methanol to the solutions studied gave no decrease in conductivity. The conductivity of H_2SO_4 in glycol was decreased, however, by the addition of hydrogen peroxide.

EXPERIMENTAL

The direct-current method of conductivity determination was used in this work. The apparatus consisted of a conductivity cell, 90 v. dry cell, resistance box, and reversing switch in series. In addition, the potential difference across either the probe electrodes of the conductivity cell or the resistance box of the main circuit could be placed on the needle of a modified gold-leaf electroscope, by means of a two-way switch.

The electroscope consisted of a pair of brass plates at a separation of $\frac{1}{2}$ in., with a steady 90 v. across them; a charge could then be placed onto a gold-wire needle and the displacement observed by a microscope through a transparent window.

The electroscope was used as a null-point instrument, i.e. the metallic resistance in the conductivity circuit was varied until the same displacement of the needle was given by (and hence the same potential difference existed across) both the resistance box and the probes of the conductivity cell. This instrument had the great advantage of a high resistance (air gap); hence no current was drawn from the probe electrode circuit when placed across the electroscope. This in turn means that negligible polarization occurred at the probe electrodes themselves.

The conductivity cell had a capacity of 300 cc., the cell constant being determined by using three different concentrations of potassium chloride solution (four determinations were made at each of the concentrations 0.01 *N*, 0.002 *N*, and 0.001 *N*; at each concentration the agreement was within 1%; the over-all agreement was also within 1%). Using the conductivity values of Shedlovsky (5) for potassium chloride the cell constant was found to be 2.300 ± 0.003 cm.$^{-1}$. The electrodes and probes used in the conductivity cell were all of platinum.

The ethylene glycol used was reagent-grade Eastman-Kodak material ($n_4^{22} = 1.4313$). The hydrochloric acid was anhydrous and was added as a gas. The weight added was determined by a pressure-difference technique involving the freezing out of the gaseous material into a small bulb and then the evaporation of it directly into the solution.

In the nitric acid determinations, fuming nitric acid was used ($HNO_3 = 89.5\%$), but here, as with the sulphuric acid estimations ($H_2SO_4 = 96\%$), the amount of water added with the solute is so small that its effect on the conductivity of the system can be considered negligible ($\sim 0.05\%$ of the volume of solvent taken). A 0.05 *N* solution of HNO_3 in glycol was made up and allowed to stand for 7 days. During this time 25-ml. samples were withdrawn from time to time and titrated against 0.1 *N* sodium hydroxide solution. The titer was found to remain steady throughout the seven days. A similar result was obtained when 5% aqueous glycol was used as the solvent.

It was shown, therefore, that no reaction occurs between HNO_3 and ethylene glycol during the course of the conductivity determinations, which are of the duration of 45 minutes.

Hydrochloric acid was also found to give no chemical reaction with glycol by the same method.

EXPERIMENTAL RESULTS

The experimental work carried out can be divided into two sections: one, the determination of limiting values of conductivities of certain acids and salts in ethylene glycol; the other, the effect of addition of small quantities of a second solvent on the conductivity of various solutions in ethylene glycol.

As a preliminary to this work, the conductivity of ethylene glycol itself was determined and was found to be 1.28×10^{-7} cm.$^{-1}$. (Previous value recorded (6) is 2.4×10^{-7} cm.$^{-1}$.)

The authors' value was used as a solvent correction in the determination of Λ_0 for HNO_3, KNO_3, and $NaNO_3$. The values of Λ_0 to be derived by extrapolation to zero concentration of the conductivity values are determined from Table I.

The corrected values of Λ_0 found at 25° C. for these compounds are recorded in Table II. Owing to extrapolation, the accuracy of Λ_0 is a good deal less than the 1% claimed for the experimental determination, but should be within 3%.

In Table II the values for Λ_0 are given for glycol solutions. Also, for comparison, those in water (5), methanol (6), and ethanol (6) are given in Table II. It is interesting to

TABLE I

THE VARIATION OF Λ_c (CM.$^{-1}$) WITH $\sqrt{c}$ (G-MOL./LITER)$^{\frac{1}{2}}$

HNO_3		KNO_3		$NaNO_3$	
$\sqrt{c}$	Λ_c	$\sqrt{c}$	Λ_c	$\sqrt{c}$	Λ_c
0.0183	28.4	0.0104	9.43	0.0151	7.49
0.0272	27.8	0.0201	9.27	0.0279	7.35
0.0368	27.0	0.0307	8.95	0.0438	7.29
0.0538	25.7	0.0425	8.80	0.0539	7.23
0.100	22.2	0.0540	8.73	0.0642	7.19
		0.0635	8.54		

note that the conductivities of the salts are much lower compared with nitric acid in glycol than is the case in either methanol or ethanol. Glycol, in fact, gives a relationship similar to that given by water.

TABLE II

CORRECTED VALUE OF Λ_0

Comp.	Glycol	Water	MeOH	EtOH
HNO_3	29.8	421	203	88
$NaNO_3$	7.6	121	107	47
KNO_3	9.6	145	115	50

The remaining results can best be illustrated by means of Figs. 1–6; in all these figures specific conductivity has been plotted against concentration, as it was considered that this best illustrated the effects under examination.

Fig. 1 shows the effect of the addition of water to solutions of hydrochloric acid in ethylene glycol and Fig. 2 is derived from this to illustrate the effect over the range of

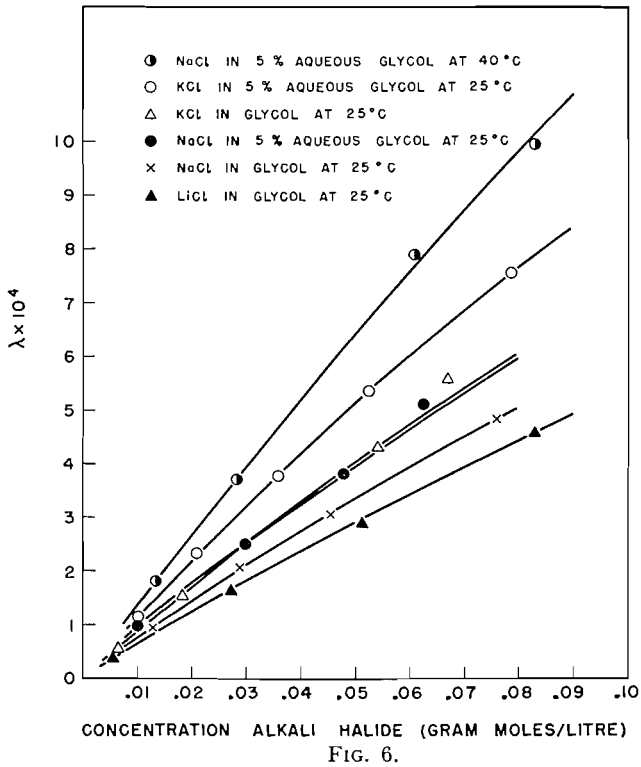

FIG. 6.

water content 0–10 g-mol./liter for a solution containing 0.05 g-mol. HCl/liter. Also in Fig. 2 is shown the curve obtained by Goldschmidt (1) for the addition of water to a solution of 0.05 g-mol. HBr/liter in ethanol. It was found that the diminution effect was much more gradual in glycol and also was evident over a much greater range of water content, although the over-all fall in conductivity was similar in either case.

Fig. 3 illustrates the effect of the addition of methanol to a glycolic HCl solution. It can be seen that an increase in conductivity was found roughly proportional to the amount of methanol added.

Fig. 4 shows the resultant conductivities for the addition of water, 98% hydrogen peroxide, and methanol to a glycolic solution of sulphuric acid. Both water and hydrogen peroxide produce a reduction of conductivity but that produced by hydrogen peroxide is less than that of water. Again, a steady increase was found on addition of methanol.

Fig. 5 deals with the temperature coefficients of hydrochloric acid both in glycol and in 5% aqueous glycol. A temperature coefficient of 2% per ° C. increase was found for the glycol solution over the range of temperature covered (25°–40°), whereas that of the 5% aqueous glycol solution was 2.3% per ° C. over the same temperature range.

Fig. 6 gives the conductivity values found for the alkali metal chlorides again in both glycol and 5% aqueous glycol at 25° C. The order of conductivity was $K^+ > Na^+ > Li^+$. The curve for NaCl in 5% aqueous glycol at 40° C. is also shown. Sodium chloride was found to have a temperature coefficient of 2.4% per ° C. between 25° and 40° C. in 5% aqueous glycol.

DISCUSSION OF RESULTS

Previous workers on the diminution of the conductivity of solutions of hydrochloric acid in organic solvents by the addition of water have always taken as a basis of their

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

interpretation of these results the greater stability of the H_3O^+ ion than that of the corresponding ROH_2^+ ion (1, 9, 11), which results in a certain degree of fixing of the proton, causing it to be less available as a charge carrier in slightly aqueous solutions of acids than it is in the solution of an acid in the pure solvent.

More recently a survey of the subject has been made by Conway, Bockris, and Linton (10), who suggest that the addition of water molecules to a proton-containing alcoholic solution presents an alternative route for the protons through the solution. The protons may now go to the H_2O molecules and a study of the equilibrium constants for the changes

$$H_3O^+ + ROH \rightleftharpoons ROH_2^+ + H_2O,$$

where R = Me, Et, or *n*-Pr, indicates that as soon as a trace of water is present nearly all the protons form H_3O^+ ions, and that the reverse process is improbable since it would require an increase in free energy.

When a trace of water is added to a solution of an acid in an alcoholic solution, not only are the protons mainly incorporated into the H_3O^+ ions, but so are the added water molecules. Thus proton exchanges between H_3O^+ and H_2O molecules will be infrequent owing to the smaller number of H_2O molecules present. The H_3O^+ ion rather than being involved in the transfer of protons along a chain of water molecules, as is present in aqueous solutions, will tend to remain as an independent ion, and it could be predicted that it should behave like the similarly sized K^+ ion.

To examine this prediction KCl and HCl were each studied in 0.05 g-mol./liter solution at 25° C., in a solvent of ethylene glycol containing 2.8 g-mol. water/liter, and the conductivity values were as follows:

Solvent	HCl	KCl
Aq. glycol	13.2	10.2
Water (7)	415.8	143.5
Glycol	21.2	8.1

The values for water and glycol are also given where the conductivity values are far more divergent. Further evidence for the presence of free H_3O^+ ions in solutions of acids in ethylene glycol containing small quantities of water was obtained by studying the temperature coefficients. A conductance mechanism involving proton transfer along a chain of glycol molecules should be far less sensitive to temperature than is a conductance caused by the movement of ions, since in the former case any acceleration caused by exciting the particles will be offset by the breakdown of the chain, whereas in the latter case the particles will move more quickly.

Conductivity determinations were carried out for hydrochloric acid and sodium chloride in 5% aqueous glycol at 25° C. and 40° C. and the temperature coefficients were determined.

The values are given in Table III together with those found for HCl in both glycol and water. It was found that the temperature coefficient for the conductivity of HCl was greater in 5% aqueous glycol than in either glycol itself or water; also the temperature coefficient in 5% aqueous glycol was similar to that found for NaCl in the same solvent.

Figure 2 illustrates that the decrease in conductivity found in proton-containing glycolic solutions occurred over a much larger range of water content than that found for solutions of acids in ethanol. This is no doubt a viscosity effect. In the more viscous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

TABLE III

	Solvent	$\Lambda_{0.5}$ 25°	$\Lambda_{0.5}$ 40°	% dec./° C.
NaCl	5% aq. glycol	8.0	12.7	2.4
HCl	5% aq. glycol	13.2	20.1	2.3
HCl	Glycol	21.2	28.6	1.8
		25°	35°	
HCl	Water	399.09 (7)	460 (12)	1.3

glycol solution the chance of a collision between an H_3O^+ ion and a free water molecule will be much less than that in alcohol as the velocity of both particles will be reduced. Hence a minimum conductivity value is found for a 0.05 *N* solution of HBr in ethanol at 0.7 g-mol. water/liter, whereas a 0.05 *N* solution of HCl in ethylene glycol has 3.5 g-mol./liter water for a minimum conductivity.

In the runs where methyl alcohol was added to glycolic hydrochloric acid solution no decrease in conductivity was obtained. In fact, the addition seemed to produce a steady increase in conductivity dependent upon the amount of alcohol added. On the basis of previous theory this would indicate that the protons in a methanol – ethylene glycol mixture can attach themselves equally well to either type of molecule and the proton exchange mechanism is not affected.

It is interesting to note, however, that addition of hydrogen peroxide does give a decrease in conductivity. This was a considerably smaller effect than that given by water but does indicate the comparative stability of the $H_3O_2^+$ ion.

With regard to the conductivity of the alkali halides in both glycol and 5% aqueous glycol solution the order of conductivity $K^+ > Na^+ > Li^+$ is found. Thus it would seem reasonable to suppose that in both solvents solvation occurs, as the size of the unsolvate ions is in the opposite direction.

Addition of water to the alkali halide solutions in glycol gives also a steady increase in conductivity.

CONCLUSIONS

A study of the conductivity of various acids and alkali halides in solutions of glycol and aqueous glycol has shown that the behavior of these solutions supports the present theories of the diminution of conductivity caused by the addition of small amounts of water to alcoholic solution.

It was also shown that a similar, although smaller, effect was also produced by the addition of small amounts of hydrogen peroxide to acidic solutions in glycol. In the case of addition of methyl alcohol, no diminution in conductivity was observed and it was considered that this was due to the instability of the OH_2^+ ion.

To recapitulate, it is accepted that the relatively large conductivity of acids in aqueous solution is due to the formation of an H_3O^+ ion, where the proton, without any significant change in energy, can pass from one water molecule to another. While this movement from water molecule to water molecule does not involve any great change in energy, it is still recognized that the proton is always held as an H_3O^+ ion by a water molecule.

The high conductivity of acids in aliphatic alcohols is explained in a similar way, but the proton is not held so firmly in the ROH_2^+ ion. The addition of water to a solution of this type may actually decrease the conductivity because the water molecule capturing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

the proton is not apt to pass it on to organic molecules as easily. It is thus taken out of circulation except insofar as it acts as a free ion. With the continued addition of water the opportunity of the proton to pass from water molecule to water molecule increases with the result that the conductivity eventually will again increase.

ACKNOWLEDGMENT

To Mr. G. Graham the authors wish to record their indebtedness for the valuable technical assistance given during the course of this research.

NITRIMINO-(1H)PYRIDINIUM AND NITRIMINO-(3H)THIAZOLIUM INNER SALTS

THE STRUCTURE OF SOME NITRIMINES IN THE LIGHT OF INFRARED STUDY[1]

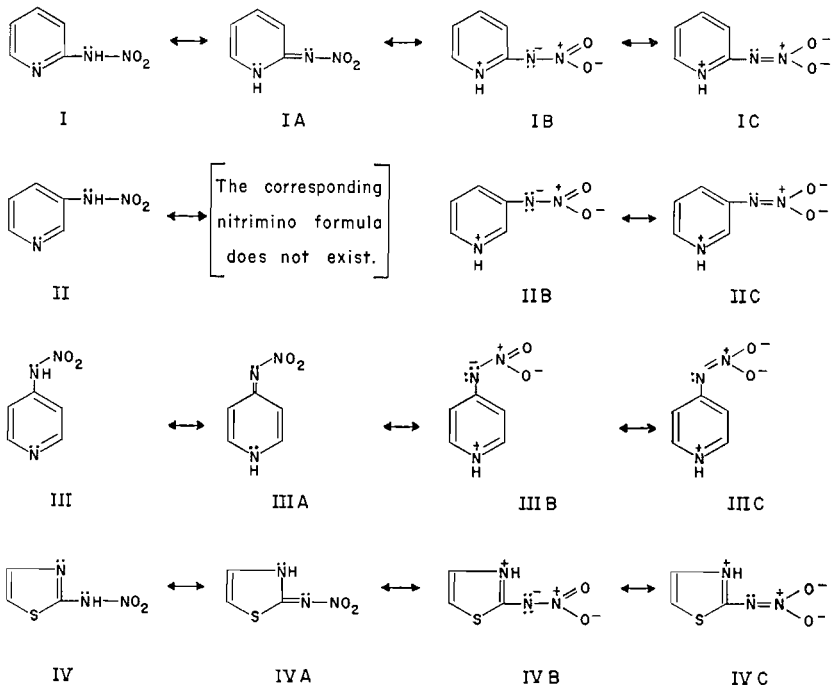
ALFRED TAURINS

ABSTRACT

Compounds previously known as nitraminopyridines and 2-nitraminothiazoles are formulated as nitrimino-(1H)pyridinium and 2-nitrimino-(3H)thiazolium inner salts on the basis of the infrared study. In the solid state, the three isomer nitriminopyridines do not exhibit any infrared absorption of the —NH group in the region 3400–3200 cm.$^{-1}$ but show a wide band at lower frequencies in the region 2880–2550 cm.$^{-1}$. 2-Nitriminothiazole shows only a wide band between 3140 and 2270 cm.$^{-1}$. These shifts of absorption bands can be correlated with structures derived from the classical nitrimino tautomeric forms in which the resonance effect stabilizes (1H)pyridinium and (3H)thiazolium cations, and a nitrimino group carrying a negative charge. *n*-Butylnitramine, a non-resonating compound, absorbs strongly at 3300 cm.$^{-1}$, indicating that nitramino groups are not associated.

INTRODUCTION

The nitration product of 2-aminopyridine reacts in two tautomeric forms, 2-nitramino- (I) and 2-nitrimino-pyridine (IA), as was postulated by Tschitschibabin and Menschikow and proved by methylation with dimethyl sulphate in alkaline medium (1), or with diazomethane in ether solution (2). A similar tautomerism can be predicted for 4-nitraminopyridine (III and IIIA) (3). However, 3-nitraminopyridine (II) cannot assume

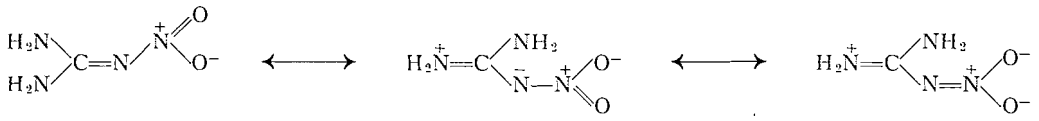


[1]*Manuscript received October 3, 1957.*
Contribution from the Department of Chemistry, McGill University, Montreal, Que. The financial support for this work was supplied by the Defence Research Board under D.R.B. Grant No. 9530-06, Project D46-95-30-06, and the National Research Council, Ottawa, Canada.

the nitrimine structure because the corresponding 3-pyridone structure is impossible (4). Also, 2-nitraminothiazole (IV) (5, 6) could exhibit a similar tautomerism to form the nitrimine (IVA).

The purpose of the present work was to study the infrared absorption spectra of the solid nitrimines of pyridine and thiazole series in order to establish the correlation between the structure and spectra. The results of the infrared study could give additional information on the structure of these substances in the crystal state. It is obvious that the structure of the solid nitrimines could differ from that established in solutions. It was expected beforehand that the presence of the heterocyclic ring in the nitrimines could greatly influence the positions of the absorption bands of the NH and NO_2 groups compared with the spectra of aliphatic nitramines. The anticipation was mainly based on facts established by several workers, that the change of a trivalent nitrogen atom to a substituted ammonium cation causes certain shifts in the infrared absorption bands (*vide infra*) (7, 8, 9, 10, 11, 12). A similar shift could be expected in the spectra of nitrimino- pyridines and -thiazoles. The nitrimino tautomeric forms IA to IVA possess resonance hybrid structures, as has been postulated by Taurins and Viron (2) for I and IA, and the most important resonance structures of the nitrimines could arise by the electron shift from the heterocyclic ring nitrogen to the nitrimino group creating a positive charge on the ring nitrogen atom. There are no resonance structures of the nitramino tautomeric form of I to IV having a positive charge on the pyridine ring nitrogen.

It is well established that resonance is present also in other compounds containing nitrimino groups and basic nitrogen atoms. On the basis of the study of electronic spectra McKay, Picard, and Brunet (13) concluded that nitroguanidine existed as a resonance hybrid of several contributing structures:



This was confirmed by Bryden, Burkardt, Hughes, and Danouhe (14) by the determination of the crystal structure of nitroguanidine. The equality of the three carbon–nitrogen distances (1.34–1.35 Å) indicated that the second structure contributes predominantly.

Resonance hybrid structures have also been considered for the anion of the monoacid salt of 5-nitraminotetrazole by Lieber, Sherman, and Pantikin (15).

Some of the papers dealing with the shift of the infrared absorption bands are mentioned here briefly. It has been found that amines and their salts absorb differently in the infrared high-frequency region (7). Heacock and Marion (8) have investigated a number of secondary amines and their salts. They found that the spectra of the salts contain several absorption bands which are absent from the spectra of the amines. The new bands in the region 1620 to 1560 cm.$^{-1}$ are characteristic of secondary amine salts, and they arise by $\overset{+}{N}H_2$ deformation vibrations. In the spectra of tertiary amine salts, the stretching vibrations of the $\overset{+}{N}$—H group are displaced towards lower frequencies. Lord and Merrifield (9) have reported that in the spectrum of pyridine hydrochloride the $\overset{+}{N}$—H stretching band at 2450 cm.$^{-1}$ is broad and structureless and that this band is accompanied by absorption maxima at 1980 and 2090 cm.$^{-1}$.

α-Amino acids, which exist in the form of dipolar ions, do not exhibit any bands in the region 3400–3300 cm.$^{-1}$ (with the exception of isovalin) (10) which could be expected

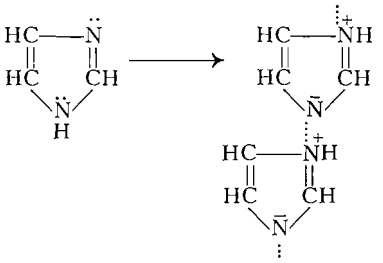
For personal use only.

if the amino group were free. Instead, a wide and structureless band occurs between 3030 and 2546 cm.$^{-1}$, which is given by C—H and $\overset{+}{N}H_3$ stretching vibrations. In most of the spectra of α-amino acids, there is also a band at 2128 cm.$^{-1}$ present which arises by the $—\overset{+}{N}H_3$ stretching vibrations only.

From the study of the infrared spectra of myosmine and nicotine, and their mono- and di-hydrochlorides, Witkop (11) showed that it is possible to distinguish the type of substituted nitrogen cations. The substituted ammonium group  showed the absorption at 2440–2350 cm.$^{-1}$, and the immonium group  at 2095–1980 cm.$^{-1}$.

The absence of the infrared absorption at 3300 cm.$^{-1}$ by imidazole in the solid state and in concentrated solutions led Otting (12) to an explanation that, in imidazole, protons are transferred from the NH groups to the tertiary nitrogen atoms giving rise to positively and negatively charged nitrogen atoms which become associated by ionic charges:



In dilute chloroform solutions, the association of imidazole is broken and the spectrum shows a maximum at 3450 cm.$^{-1}$ characteristic of the free N—H group of imidazole.

EXPERIMENTAL

The infrared spectra of nitramines were recorded with a Perkin-Elmer Model 21 double beam spectrophotometer. The settings of the instrument were as follows: resolution 927, gain 5, speed 5, response 1, suppression 0. The spectrum of *n*-butylnitramine was taken in a 0.025 mm. NaCl cell. The solid nitramino-pyridines and -thiazoles were investigated in potassium bromide pellets. The substance (1 mg.) and potassium bromide (0.4 g.) were mixed and ground by vibrating in a 1 ml. glass-stoppered tube with four steel balls for 3 minutes in a Perkin-Elmer magnetic vibrator. The pellets were pressed in a Perkin-Elmer die for 2 minutes by applying a pressure of 20,000 lb./sq. in. *n*-Butylnitramine was prepared by Mr. C. C. Bombardieri; and 2-, 3-, and 4-nitriminopyridine, and 2-nitrimino- and 4-methyl- and 4,5-dimethyl-2-nitrimino-thiazoles were made by Mr. S. Kasman. The results have been summarized in Tables I, II, and III.

RESULTS AND DISCUSSION

Region 3800–2000 cm.$^{-1}$

The infrared spectrum of the liquid *n*-butylnitramine was compared with the spectra of 2-, 3-, and 4-nitriminopyridines and 2-nitriminothiazole in the region 3800–2000

cm.$^{-1}$. The inclusion of *n*-butylnitramine in the infrared study was essential in answering the question whether the shift of —N—H absorption bands in this region arises by the association of the —N—H group with oxygen of the nitro group, or by the resonance effect. Since there is no resonance between the *n*-butyl group and nitramino group in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

n-butylnitramine, the association of the —N—H group could be the only determining factor in shifting the absorption band from 3300 cm.$^{-1}$ to lower frequencies. The examination of the spectrum of *n*-butylnitramine shows that the absorption band of the N—H bonds has not been shifted but occurs at the expected position of 3300 cm.$^{-1}$. Consequently, there is no association in the liquid *n*-butylnitramine to such extent that it could influence the absorption of —N—H groups.

The analysis of the infrared spectra of the solid 2-, 3-, and 4-nitriminopyridines indicates clearly that there are no absorption bands in the region 3400–3200 cm.$^{-1}$ which could arise if the N—H group was present either in the nitramino (I to III), or nitrimino (IA to IIIA) structures. Instead of these bands, the three nitriminopyridines give wide bands between 2880 and 2550 cm.$^{-1}$. 2-Nitriminothiazole shows only a wide band between 3140 and 2270 cm.$^{-1}$, thus excluding structures IV and IVA.

These data indicate that the structures of nitriminopyridines and 2-nitriminothiazoles do not correspond to the classical formulae I to IV and IA to IVA assigned by Tschitschibabin. Since there is a very small probability that the solid heterocyclic nitrimines are associated by —N—H groups, it must be concluded that the shift of the infrared absorption bands of pyridine and thiazole nitrimines arises from the structures formed by the resonance effect. The resonance in these compounds allows the formation of pyridinium and thiazolium betaines possessing a positively charged nitrogen of the heterocyclic rings, and a negative charge located on the nitrimino group (structures IB to IVB and IC to IVC). Although nitrimino-pyridines and -thiazoles can conveniently be described as hybrids of several contributing structures, including also the IA to IVA, the infrared spectroscopic evidence points out that the structures IB to IVB and IC to IVC predominate. Accordingly, we propose to name the nitrimines of pyridine and thiazole series *nitrimino-(1H)pyridinium and nitrimino-(3H) thiazolium hydroxides, betaines (or inner salts)*. For example, the substance previously called 2-nitraminopyridine must be named 2-nitrimino-(1H)pyridinium hydroxide, betaine; the substance previously described as 4,5-dimethyl-2-nitraminothiazole must be designated 4,5-dimethyl-2-nitrimino-(3H)-thiazolium hydroxide, betaine.

The physical properties of these compounds are in good agreement with their dipolar structure. Contrary to aliphatic nitramines, which retain their old names, the heterocyclic nitrimino-(1H)pyridinium and -(3H)thiazolium hydroxides, betaines are only weakly acidic. They are insoluble in non-polar organic solvents and they possess relatively high decomposition points, without melting.

Region 1650–1235 cm.$^{-1}$, n-Butylnitramine

The infrared spectrum of *n*-butylnitramine has a very strong band at 1580 cm.$^{-1}$ which is given by the asymmetric vibrations of the nitro group. The symmetric stretching vibrations of this group produce a strong wide band at 1325 cm.$^{-1}$ accompanied by weaker bands at 1270 and 1235 cm.$^{-1}$. A band of high intensity at 1406 cm.$^{-1}$ arises by merging the absorption bands of the nitro and the methyl groups with the result of widening and intensifying of the band. There is no doubt that electronically the nitro group in *n*-butylnitramine is very similar to the nitro group in ordinary nitro compounds and therefore exhibits almost the same absorption maxima (16).

Region 1650–1375 cm.$^{-1}$, Nitrimino-(1H)pyridinium Betaines

In each of the infrared spectra of the three isomer monoaminopyridines (17), the first band in the region 1636 to 1400 cm.$^{-1}$ is shifted as much as 10 to 20 cm.$^{-1}$ towards lower frequencies, compared with the spectrum of liquid pyridine (18) which gives bands at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

1636, 1584, 1485, and 1439 cm.$^{-1}$. The shift is even greater in the spectra of methylpyridines (18), the absorption beginning in the region 1604–1590 cm.$^{-1}$. Nitrimino-(1H)pyridinium betaines absorb at 1630 cm.$^{-1}$ and this band is followed by a number of peaks of high intensity in the region 1630–1375 cm.$^{-1}$ (Table I). It is obvious that the stretching vibrations of the double bonds of the pyridine ring and nitrimino group are close to each other and the final effect is the increasing of the band intensities. The nitrimino group shows its greatest effect on the bands at 1512–1543 cm.$^{-1}$ and 1478–1375 cm.$^{-1}$. It is also possible that the absorption frequency of the $\overset{+}{N}$—H group coincides with that of the pyridine ring at 1620 cm.$^{-1}$. Therefore, a very precise assignment of the band frequency to the nitrimino group is rather difficult.

Region 1000–650 cm.$^{-1}$, Nitrimino-(1H)pyridinium Betaines

In the spectra of the 2-, 3-, and 4-nitrimino-(1H)pyridinium betaines, there are bands at 672, 670, and 650 cm.$^{-1}$ respectively, which are absent in the spectra of pyridine, 2-, 3-, and 4-methylpyridines (18), and 2-aminopyridine (17). Therefore, these three bands must be considered as characteristic to the nitrimino group and can be assigned to the out-of-plane vibrations of this group. With the same type of vibrations probably are associated the strong bands at 880, 877, and 885 cm.$^{-1}$ occurring in the spectra of the three nitrimino-(1H)pyridinium betaines (Table I). This assignment is based on the observation that these bands are absent in the spectra of 2-amino- (17), 2-amino-3-methyl- (19), and 2-amino-5-methyl-pyridines (19) and they are weak in pyridine and in the three methylpyridines.

2-Nitrimino- and 4-nitrimino-(1H)pyridinium betaines possess characteristic bands at 940 and 932 cm.$^{-1}$ respectively, which are absent in the spectra of 2-, 3-, and 4-methyl-(18), 2-amino- (17), 2-amino-3-methyl- and 2-amino-5-methyl-pyridines (19).

Region 1650–1250 cm.$^{-1}$, 2-Nitrimino-(3H)thiazolium Betaines

The infrared spectrum of thiazole (20) possesses six strong absorption maxima between 1615 and 1200 cm.$^{-1}$, and in the spectrum of 2-nitrimino-(3H)thiazolium betaine there are eight bands (Table II) which are wider and more intense than the bands given by thiazole in the same region. The band at 1525 cm.$^{-1}$ exhibited by 2-nitrimino-(3H)-thiazolium betaine is characteristic of the ring vibrations of substituted thiazoles; for example, methylthiazoles (20) show absorption between 1505 and 1530 cm.$^{-1}$, and 2-aminothiazole (21) has a band at 1520 cm.$^{-1}$. The intense band at 1567 cm.$^{-1}$ given by nitrimino-(3H)thiazolium betaine must be assigned to the nitrimino group because it is wide and intense. The nitro groups of C-nitro compounds and of the nitramino group in *n*-butylnitramine absorb at the same frequency.

The skeletal vibrations of the substituted thiazole ring give bands also in the region 1210–1240 cm.$^{-1}$ and 1290–1340 cm.$^{-1}$. In the spectrum of 2-nitrimino-(3H)thiazolium betaine the corresponding bands of the thiazole ring are at 1247 cm.$^{-1}$. Some other bands at 1257, 1285, and 1320 cm.$^{-1}$ originate by the vibrations of the nitrimino group and thiazole ring. They are wide and of high intensity, similarly to the bands observed in the pyridine series.

LYCOPODIUM ALKALOIDS

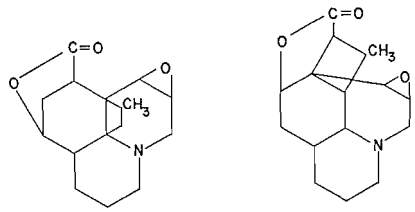
VI. REACTIONS OF THE DIPHENYL DERIVATIVE OF DESOXODIHYDROANNOTININE[1]

E. E. BETTS[2] AND DAVID B. MACLEAN

ABSTRACT

Desoxodihydroannotinine reacted with phenyl lithium to yield a diphenyl derivative, $C_{28}H_{35}O_2N$ (III). This compound yielded a ketone, $C_{28}H_{33}O_2N$ (V), upon oxidation by the Oppenauer procedure and a dihydroxyketone, $C_{28}H_{33}O_3N$ (VI), upon oxidation with chromic acid. A ketone VIII, epimeric with V, was obtained by treatment of III with potassium tertiary butoxide in cyclohexanone. Both V and VIII underwent elimination of their diphenyl carbinol groups upon treatment with potassium tertiary butoxide to yield an unsaturated ketone, $C_{15}H_{21}ON$ (IX), and benzohydrol. These reactions are discussed in relation to the recently proposed structures for the parent alkaloid, annotinine.

Annotinine, $C_{16}H_{21}O_3N$, the major alkaloid of *Lycopodium annotinum*, was first isolated by Manske and Marion (1). In a later paper they established the presence of a lactone ring and an ether ring in the molecule (2). The size of the ether ring and its relationship to the nitrogen atom were demonstrated by MacLean and Prime (3) while Wiesner *et al.* were able to relate the lactone ring to the other functions in the molecule (4). Several total structures for the alkaloid have been proposed in the past by Wiesner *et al.* (4, 5, 6) on the basis of dehydrogenation experiments on annotinine and its derivatives. In their latest publication (7) they have established the detailed structure of ring B (formula A) and have suggested that formula A adequately explains the reactions of annotinine.



Martin-Smith, Greenhalgh, and Marion (8) have also proposed a structure for annotinine which is represented in formula B. Arguments were advanced that their structure explained the dehydrogenation reactions of annotinine equally as well as previous structures of Wiesner's. However, the seven-membered nature of ring A is not consistent with the work of Betts and MacLean (9). Nor is the structure of ring B consistent with the latest work of Wiesner *et al.* (7), nor with the results of the present study.*

Annotinine (I) was converted to desoxodihydroannotinine† (II) by the method of Manske and Marion (2). This compound has the same ring structure as annotinine but lacks the epoxide function (9). It reacted readily with phenyl lithium to yield diphenyldesoxodihydroannotinine, $C_{28}H_{35}O_2N$ (III). This compound dehydrated readily with

Formula B has since been withdrawn by Marion and Przybylska (Can. J. Chem.* **35, *1075 (1957)), who have shown by an X-ray investigation that annotinine has structure A.*
†*This compound has been previously called saturated lactone A, but the present name seems more descriptive and less ambiguous in the present context.*

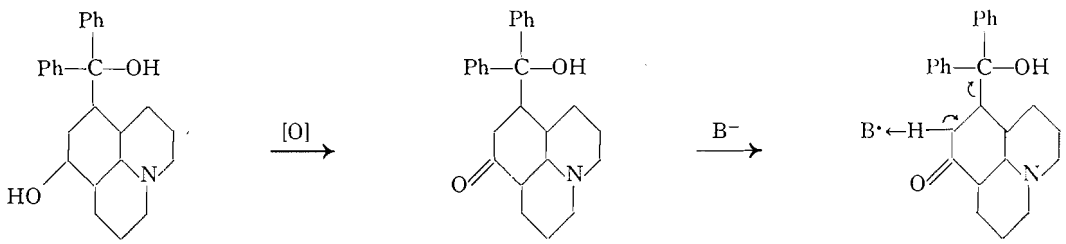
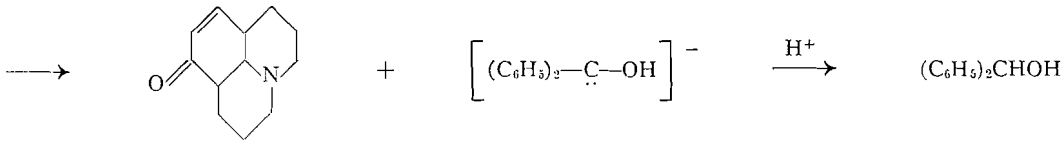
boiling, aqueous hydrochloric acid to yield the anhydro derivative, $C_{28}H_{33}ON$ (IV), which has an ultraviolet spectrum characteristic of a 1,1-diphenylethylene despite the fact that the compound would not absorb hydrogen at low pressures nor oxidize with ease. Oxidation of III with aluminum isopropoxide in the presence of cyclohexanone yielded the hydroxyketone, $C_{28}H_{33}O_2N$ (V), while oxidation with chromic acid in acetic acid yielded a dihydroxyketone, $C_{28}H_{33}O_3N$ (VI), also obtainable by the chromic acid oxidation of V. The new hydroxyl function in VI is probably tertiary in character; otherwise it would have been expected to oxidize in the medium. The activated positions in the molecule at which an hydroxyl group could be introduced are alpha to the carbonyl function to yield an α-hydroxyketone, or alpha to the nitrogen to yield a carbinolamine. Tests for a carbinolamine function were negative. Anhydronium salts of VI were not formed, the methiodide of VI was normal in character, and hydride reduction of VI or its hydrochloride yielded a trihydroxy compound, $C_{28}H_{35}O_3N$ (VII). Neither VI nor VII reacted with periodic acid, but VI reacted with lead tetraacetate with consumption of 3 moles of the reagent. The products of this reaction have not yet been characterized but are presently under study. The tetraacetate reaction, because of its complexity, cannot be considered evidence for an α-hydroxyketone structure in VI. However, the carbonyl absorption in the infrared of V and VI lies at 1700 cm.$^{-1}$ and 1720 cm.$^{-1}$, respectively. This shift implies a close structural relationship between the two groups in which the hydroxyl function is alpha and axial to the carbonyl function. Furthermore it has been shown in a similar series of reactions on diphenylannotinine (10) that the introduction of the new hydroxyl function is dependent on the presence of the carbonyl group. The evidence, therefore, points to an α-hydroxyketone structure for VI.

We also examined the oxidation of III with potassium tertiary butoxide and cyclohexanone. When this reaction was carried out in refluxing benzene, a ketone, $C_{28}H_{33}O_2N$ (VIII), was isolated; in refluxing toluene the reaction proceeded to yield a conjugated ketone, $C_{15}H_{21}ON$ (IX), identified through its hydrochloride and hydrobromide salts. Both V and VIII were also converted to IX by treatment with potassium tertiary butoxide in refluxing toluene.

The formation of IX directly from III or from V or VIII requires the elimination of the diphenyl carbinol group and it has been shown that it was eliminated as benzohydrol. When V was heated with potassium tertiary butoxide in an atmosphere of oxygen-free nitrogen, a quantitative recovery of benzohydrol was realized. In the presence of air some of the benzohydrol was converted to benzophenone, which was isolated as its 2,4-dinitrophenylhydrazone. In the reaction of III with potassium tertiary butoxide and cyclohexanone the presence of benzophenone was indicated in the non-basic fraction through its carbonyl absorption in the infrared at 1660 cm.$^{-1}$.

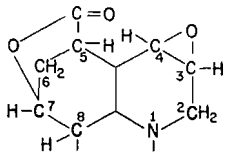
This reaction is very likely a reverse Michael reaction and can be depicted according to the sequence below:





The formation of ketone VIII in the presence of potassium tertiary butoxide and ketone V in the presence of aluminum isopropoxide might suggest a more deep-seated difference between the two isomers than that of simple epimers. However, ketone V was partially converted into ketone VIII by prolonged refluxing with sodium ethoxide, a reagent which would not be expected to bring about other changes in the system. The more rapid transformation induced by potassium tertiary butoxide is likely related to its greater basic strength and greater ionic character. The two ketones V and VIII behave differently toward chromic acid in glacial acetic acid. It was pointed out previously that V was readily converted to VI by this oxidant. However, VIII was recovered unchanged upon similar treatment. This difference in behavior toward chromic acid is probably dependent on the conformation of the tertiary hydrogen in the two compounds.

The ultraviolet spectrum of IX has a peak at 2280 Å, log $\epsilon = 3.85$, which is characteristic of an α,β-unsaturated ketone with a single β-alkyl substituent (11). Thus, position "6" (formula A) must be a methylene group. The isomeric ketones V and VIII can be epimeric only at position "8" while compound VI will carry its hydroxyl function at the same position. The detailed structure of annotinine can therefore be extended to that represented by the partial formula below, which is in complete accord with the recent work of Wiesner *et al.* (7).



EXPERIMENTAL

Diphenyldesoxodihydroannotinine

A solution of phenyl lithium in 150 ml. ether was prepared from 4 g. of lithium and 40 g. of bromobenzene and treated with 6 g. of desoxodihydroannotinine (prepared from annotinine by the method of Manske and Marion (2)) dissolved in 100 ml. of ether. After addition was complete the mixture was refluxed for 2 hours, cooled, and decomposed in ice – hydrochloric acid. Some insoluble hydrochloride separated at this point. The ether layer was separated and washed with dilute hydrochloric acid. The acid washings and original aqueous portion were combined, made alkaline with ammonia, and extracted four times with ether. The ether extracts were dried and concentrated to yield a residue which deposited 3.5 g. of crystalline product from an acetone solution. The mother liquors were treated with concentrated hydrochloric acid to yield a crystalline hydrochloride. The total recovery as base and as hydrochloride represented a yield of 75–80%.

The base was recrystallized from acetone to yield a product which melted at 218°–220° C. Calc. for $C_{28}H_{35}O_2N$: C, 80.57; H, 8.39%. Found: C, 80.39, 80.65; H, 8.75, 8.81%.

The ultraviolet spectrum in ethanol had λ_{max} 2580 Å, log $\epsilon = 2.8$. The infrared spectrum showed hydroxyl absorption at 3600 cm.$^{-1}$ and 3150 cm.$^{-1}$ (broad) and weak phenyl absorption at 1590 cm.$^{-1}$. $[\alpha]_D^{21} = -106°$ (c, 1% in chloroform).

Dehydration of Diphenyldesoxodihydroannotinine

A solution of 0.150 g. of diphenyldesoxodihydroannotinine in 2.5 ml. of concentrated hydrochloric acid and 7.5 ml. of methanol was refluxed for 2 hours, and then evaporated to dryness. Addition of acetone yielded a crystalline hydrochloride which after recrystallization from methanol–acetone melted at 295° C. with decomposition. Calc. for $C_{28}H_{33}ON.HCl$: C, 77.15; H, 7.83; N, 3.21%. Found: C, 76.45, 76.41; H, 8.21, 7.76; N, 3.13, 3.26%.

The hydrochloride was converted to the free base by suspension in aqueous ammonia and extraction with ether. The dried ether extracts yielded a residue on evaporation, which after recrystallization from methanol melted at 189°–190° C. Calc. for $C_{28}H_{33}ON$: C, 84.21; H, 8.27; N, 3.50%. Found: C, 83.67, 83.84; H, 8.59, 8.61; N, 3.70%.

The infrared spectrum (chloroform) had hydroxyl absorption at 3630 cm.$^{-1}$ and phenyl absorption at 1600 cm.$^{-1}$ and conjugated phenyl at 1580 cm.$^{-1}$. The ultraviolet absorption spectrum had strong but broad absorption in the region 2200–2800 Å, $\log \epsilon = 3.6$–4.0. No definite band was detectable.

When this base was treated with hydrogen at 50 p.s.i.g. for 12 hours over Adam's catalyst, it failed to take up hydrogen and was recovered unchanged. It was also resistant to the action of potassium permanganate in acetone.

Oxidation of Diphenyldesoxodihydroannotinine with Aluminum Isopropoxide and Cyclohexanone

A solution of 1.2 g. of aluminum isopropoxide in 30 cc. of dry toluene was treated with 0.5 g. of compound III and 1.5 cc. of cyclohexanone. The reaction mixture was refluxed 1 hour and 15 minutes, cooled and poured on ice. The toluene layer was separated and the aqueous layer was further extracted three times with ether. The toluene and ether extracts were combined and washed four times with 10% hydrochloric acid. The acid washings were made alkaline with ammonium hydroxide and extracted with ether. The ether extracts were dried with anhydrous sodium sulphate and taken to dryness. The residue crystallized on addition of ether. The product (0.350 g.), after two recrystallizations from ether, melted sharply at 201° C. A mixed melting point with the ketone isolated from the oxidation using potassium tertiary butoxide was depressed 10°. Calc. for $C_{28}H_{33}O_2N$: C, 80.97; H, 7.95; N, 3.37%. Found: C, 80.98, 81.08; H, 7.74, 7.73; N, 3.25%.

The infrared spectrum (nujol) had phenyl absorption at 1595 cm.$^{-1}$, carbonyl absorption at 1700 cm.$^{-1}$, and a band in the hydroxyl region at 3500 cm.$^{-1}$. $[\alpha]_D^{21} = +100.7$ (c, 1% in chloroform).

Chromic Acid Oxidation of $C_{28}H_{33}O_2N$ (*V*)

A sample of compound V (0.108 g.) was dissolved in 5 cc. glacial acetic acid, the solution was warmed to 50°–60°, and excess CrO_3 in water added. After 10 minutes the excess CrO_3 was destroyed with methanol and the resulting green solution was taken to dryness under reduced pressure. Water was added to the residue, the mixture was made alkaline with ammonium hydroxide and extracted four times with ether. The combined ether extracts were dried with sodium sulphate and the ether removed. The residue (0.086 g.) was taken up in methanol and acidified with hydrochloric acid. The hydrochloride of the reaction product, after recrystallization from methanol, melted at 273°. A mixed melting point with the hydrochloride of VI was not depressed. (Yield, 50%.) The infrared spectrum was similar to that of compound VI described below.

Oxidation of Diphenyldesoxodihydroannotinine with Chromic Acid

A solution of 1.0 g. of compound III in 20 ml. of glacial acetic acid was warmed to 50°–60° and treated with concentrated aqueous solution of chromic acid in water until the dichromate color was persistent. The excess oxidizing agent was destroyed with methanol and the solution was taken to dryness under reduced pressure. The residue was taken up in water, made basic with ammonia, and exhaustively extracted with ether. The ether extracts were dried and evaporated. The residue was taken up in methanol and acidified with hydrochloric acid, whereupon the hydrochloride separated in crystalline form. Recrystallization from methanol yielded a compound which melted at 276° C. Calc. for $C_{28}H_{33}O_3N.HCl.H_2O$: C, 69.20; H, 7.48; N, 2.88%. Found: C, 69.11, 69.10; H, 7.74, 7.84; N, 2.98, 2.86%.

The infrared spectrum (nujol) had absorption at 1595 cm.$^{-1}$ (phenyl), 1720 cm.$^{-1}$ (carbonyl), and broad absorption in the region 3350–3420 cm.$^{-1}$. The ultraviolet spectrum had λ_{max} at 2600 Å, log $\epsilon = 2.69$.

The base was regenerated from the hydrochloride by treatment with aqueous ammonia and extraction with ether. It was recrystallized from methanol to yield a product which melted at 208° C. Calc. for $C_{28}H_{33}O_3N$: C, 77.94; H, 7.65; N, 3.25; act. H (2), 0.46%. Found: C, 77.94, 78.09; H, 7.81, 7.77; N, 3.65; act. H, 0.47, 0.53%.

The infrared spectrum (nujol) showed phenyl absorption at 1590 cm.$^{-1}$, carbonyl absorption at 1720 cm.$^{-1}$ (shoulder at 1728 cm.$^{-1}$), and hydroxyl absorption at 3450 cm.$^{-1}$ and 3500–3550 cm.$^{-1}$. The ultraviolet spectrum had λ_{max} at 2600 Å, log $\epsilon = 2.9$. $[\alpha]_D^{21} = +43.0$ (c, 1% in chloroform).

Compound VI (0.20 g.) was treated with 3 ml. of methyl iodide and the mixture allowed to stand at room temperature for 2 days. The crystalline solid which had separated (0.05 g.) was recrystallized from acetone and melted at 245° C. Calc. for $C_{28}H_{33}O_3N.CH_3I$: C, 60.71; H, 6.32; N, 2.44%. Found: C, 60.80, 60.67; H, 6.62, 6.38; N, 2.91%.

The infrared spectrum had phenyl absorption at 1600 cm.$^{-1}$, carbonyl absorption at 1720 cm.$^{-1}$, and a double peak in the hydroxyl region at 3250 cm.$^{-1}$ and 3430 cm.$^{-1}$.

Reduction of $C_{28}H_{33}O_3N$ *(VI) with Lithium Aluminum Hydride*

A solution of 0.4 g. of $C_{28}H_{33}O_3N$ in 40 ml. of anhydrous ether was added slowly to a solution of 1.0 g. of lithium aluminum hydride in 30 ml. of anhydrous ether. The reduction mixture was refluxed for 2.5 hours when the excess hydride was destroyed with wet ether followed by addition of a few milliliters of water. The ether solution was separated and evaporated to dryness to yield 0.34 g. of residue. The residue was dissolved in acetone and acidified with hydrochloric acid. The crystalline hydrochloride, obtained upon evaporation of the acetone, was recrystallized twice from methanol (m.p. 272° C.). The base was regenerated from the hydrochloride by extraction with ether from an aqueous ammoniacal solution. It was recrystallized twice from ether and melted at 209°. Calc. for $C_{28}H_{35}O_3N$: C, 77.56; H, 8.13%. Found: C, 77.71, 77.59; H, 8.14, 8.18%.

The infrared spectrum showed absorption at 1595 cm.$^{-1}$ (phenyl) and at 3620 cm.$^{-1}$ (slight) and 3430 cm.$^{-1}$ (broad) in the hydroxyl region.

Treatment of the hydrochloride of VI by the same procedure yielded the same product.

Reaction of $C_{28}H_{33}O_3N$ *(VI) with Lead Tetraacetate*

Compound VI (179 mg.), dissolved in 40 ml. of glacial acetic acid, was added to a mixture of 50 ml. of 0.1 N lead tetraacetate in glacial acetic acid. To this mixture 5 ml.

of water was added and the volume was made up to 100 ml. by the addition of glacial acetic acid. A blank was prepared in the same manner omitting only the sample. Aliquots of 10 ml. were withdrawn at intervals, added to 15 ml. of buffer solution containing 5 g. potassium iodide and 125 g. of potassium acetate in 250 ml. of solution. The liberated iodine was titrated with 0.02 *N* sodium thiosulphate. After about 30 hours 3 moles of reagent per mole of compound VI had been consumed, whereupon the reaction virtually ceased.

Oxidation of Diphenyldesoxodihydroannotinine with Cyclohexanone and Potassium Tertiary Butoxide

A solution of 0.2 g. of III in 20 ml. of toluene was treated with 1 ml. of cyclohexanone and 0.28 g. of freshly prepared potassium tertiary butoxide for 1 hour under reflux. The mixture was decomposed in ice water, the toluene layer separated, and the aqueous layer extracted three times with ether. The toluene and ether extracts were combined and extracted several times with 10% hydrochloric acid. The acid washings were made alkaline with ammonia and extracted with ether. The dried ether extracts yielded 0.1 g. of basic material which was dissolved in acetone and treated with concentrated hydrochloric acid. A crystalline hydrochloride separated, which after recrystallization from acetone melted at 261°–262° C. Calc. for $C_{15}H_{21}ON.HCl$: C, 67.26; H, 8.28; N, 5.27%. Found: C, 67.61, 67.62; H, 8.49, 8.77; N, 5.80, 5.80%.

The hydrobromide was prepared by a similar procedure and recrystallized from acetone–methanol. It melted at 267°–268° C. Calc. for $C_{15}H_{21}ON.HBr$: C, 57.68; H, 7.10%. Found: C, 57.54, 57.54; H, 6.89, 6.90%.

The ultraviolet spectrum of the hydrochloride showed weak absorption at 3180 Å (carbonyl) and had maximum absorption at 2280 Å, $\log \epsilon = 3.85$ (conjugated carbonyl). The infrared spectrum had peaks at 1680 cm.$^{-1}$ (conjugated carbonyl) and 1625 cm.$^{-1}$ unsaturation.

The ether–toluene mixture was examined for non-basic material. Evaporation yielded an oily residue which was mostly cyclohexanone. Examination of the infrared spectrum revealed the presence of a strong carbonyl band at 1660 cm.$^{-1}$, which corresponded to that of benzophenone, as well as the cyclohexanone carbonyl absorption at 1710 cm.$^{-1}$.

In another experiment carried out in refluxing benzene for 15 minutes, only a trace of conjugated ketone was obtained. There was isolated instead another compound which crystallized from ether and melted at 223° C. (Yield, 25%.) Calc. for $C_{28}H_{33}O_2N$: C, 80.93; H, 8.00; N, 3.30%. Found: C, 80.83, 80.67; H, 8.02, 8.03; N, 3.12%.

The infrared spectrum of this material had absorption at 1595 cm.$^{-1}$ (phenyl), 1710 cm.$^{-1}$ (carbonyl), and 3420 cm.$^{-1}$ (hydroxyl). The ultraviolet spectrum was similar to that of the starting material, $\lambda_{max} = 2580$ Å, $\log \epsilon = 2.75$. $[\alpha]_D^{21} = -60.2°$ (*c*, 1% in chloroform).

The mother liquors remaining after the separation of the above compound yielded a residue which melted over a wide range and was probably a mixture of V and VIII.

Treatment of $C_{28}H_{33}O_2N$ (*V*) *with Potassium Tertiary Butoxide in Toluene*

Compound V (0.33 g.) was dissolved in 30 ml. of dry toluene, 0.45 g. of freshly prepared potassium tertiary butoxide was added, and the mixture was refluxed for 30 minutes under an atmosphere of oxygen-free nitrogen. The reaction mixture was worked up for recovery of the conjugated ketone as described in the previous experiment. The non-basic material remaining in the toluene–ether layer was recovered by evaporation of the solvent under vacuum. The residue (0.148 g.) had an infrared spectrum identical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

to authentic benzohydrol. It was recrystallized from petroleum ether and melted at 70° C. either alone or in admixture with an authentic sample of benzohydrol.

The basic material yielded a hydrochloride identical to the hydrochloride of the conjugated ketone.

When the reaction was carried out in air rather than nitrogen, the non-basic fraction was a mixture of benzohydrol and benzophenone. The latter was identified by conversion to its 2,4-dinitrophenylhydrazone.

Attempted Oxidation of VIII with Chromic Acid in Acetic Acid

About 40 mg. of VIII was dissolved in acetic acid and treated with a solution of CrO_3 in H_2O at 50°–60° for 10 minutes. After the excess CrO_3 was destroyed with methanol, the solution was taken to dryness under reduced pressure. The residue was taken up in water, the mixture was made alkaline and extracted with ether. Concentration of the dried ether extracts yielded the starting material.

Treatment of V with Sodium Ethoxide

Compound V (0.13 g.) was refluxed overnight in a dilute solution of sodium ethoxide in ethanol. The solution was evaporated to dryness, water was added, and the mixture was extracted with ether. The dried ether extracts were concentrated and seeded with a crystal of compound VIII. After 2 hours the crystalline needles (20 mg.) were separated from the solution by filtration. They melted at 220° C. and did not depress the melting point of VIII. The residual material obtained from the mother liquors melted over a wide range and was likely a mixture of V and VIII.

D-APIOSE[1]

P. A. J. GORIN AND A. S. PERLIN

ABSTRACT

Naturally-occurring apiose is shown by synthesis to be the D-isomer in the open-chain form. In this synthesis 3-*O*-benzyl-D-fructose is cyanohydrated and the resulting heptonic lactones are reduced to 3-*O*-benzyl-2-*C*-(hydroxymethyl)-D-*arabo*-hexitol. The latter is oxidized with lead tetraacetate affording 2-*O*-benzyl-3-*C*-(hydroxymethyl)-D-*glycero*-tetrose which, on debenzylation, gives 3-*C*-(hydroxymethyl)-D-*glycero*-tetrose (D-apiose).

INTRODUCTION

Apiose was first isolated by Vongerichten (1), who recognized it as a component sugar of the parsley flavone glycoside, apiin. The sugar has since been found in still other glycosides present in parsley (2, 3, 4, 5) and more recently in *Posidonia australis* (6) and in the rubber plant, *Hevea brasiliensis* (7). The researches of Vongerichten and later work by Schmidt (8), which have been reviewed by Hudson (9), established that apiose is a branched-chain pentose whose structure is represented by I. The synthesis of DL-apiose (10) provides additional confirmation of this structure. In the open-chain form the compound possesses only one asymmetric center, at carbon atom 2, for which the D-configuration has been assigned (8) by application of the salt–acid (11, 12) and phenylhydrazide and amide (12, 13) rules to the derived apionic acid and its derivatives. The present study furnishes an alternative proof for the configuration at C-2 through synthesis of D-apiose, which is found to be identical with the naturally-occurring sugar.

A ready synthetic pathway to D-apiose was suggested by the preparation of 4-*C*-(hydroxymethyl)-D-*threo*-pentose[2] (II) by Woods and Neish (14). It was apparent that D-apiose could be obtained by a one-step descent of the sugar series. However, attempts to achieve this by the Weerman degradation (15) or by partial lead tetraacetate oxidation (16) resulted in the production of only trace amounts of the desired product.

An alternative synthetic pathway, starting with 3-*O*-benzyl-D-fructose (III), was more successful. 1,2;4,5-Di-*O*-*iso*propylidene-D-fructose (17) was benzylated to give 3-*O*-benzyl-1,2;4,5-di-*O*-*iso*propylidene-D-fructose. The acetone groups were removed by acid hydrolysis, affording sirupy 3-*O*-benzyl-D-fructose (III), which was characterized by formation of 3-*O*-benzyl-D-glucose phenylosazone (18) on treatment with phenylhydrazine acetate. The 3-*O*-benzyl-D-fructose was cyanohydrated, the nitrile was hydrolyzed under alkaline conditions, and the product was acidified, yielding a mixture of the corresponding *O*-benzyl-α- and -β-D-fructoheptonic lactones (e.g., IV); the β-isomer was isolated as the crystalline γ-lactone. Reduction of the mixture with sodium borohydride (19, 20) gave the sirupy alcohol, 3-*O*-benzyl-2-*C*-(hydroxymethyl)-D-*arabo*-hexitol (V). The structure of V was confirmed by its conversion, on catalytic hydrogenolysis with palladium oxide followed by acetylation, to the known hepta-*O*-acetyl-2-*C*-(hydroxymethyl)-D-*arabo*-hexitol ("D-fructoheptitol" heptaacetate (21)).

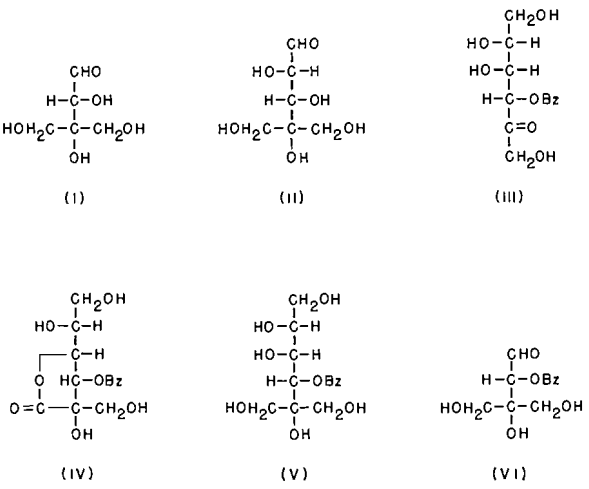
The alcohol (V) rapidly consumed approximately 2 moles of oxidant when treated with lead tetraacetate in acetic acid or aqueous periodate, but a moderately rapid over-oxidation followed, which was more pronounced with the latter reagent. Consumption of 2 moles of oxidant was expected to correspond to cleavage of the 1,2,3-triol of V affording 2-*O*-benzyl-3-*C*-(hydroxymethyl)-D-*glycero*-tetrose (2-*O*-benzyl-D-apiose) (VI), in preference to attack at the tertiary hydroxyl group (22). Accordingly, V was oxidized



with 2 moles of lead tetraacetate in acetic acid and the product was treated with methanolic hydrogen chloride to promote formation of the methyl glycosides. The latter were debenzylated with hydrogen – palladium oxide and the product hydrolyzed with aqueous acid. The final material was found by paper chromatography to contain three components present in approximately equal proportions, the central component corresponding in its rate of travel to D-apiose (I). Presence of the faster- and slower-moving components suggests that over- and under-oxidation occur in addition to the desired reaction on treatment of IV with lead tetraacetate.

The product corresponding to D-apiose was separated as a sirup from the mixture by column chromatography on cellulose (23). Its rate of travel on a paper chromatogram was identical with that of authentic D-apiose isolated from parsley. Detected on the chromatogram with the aniline oxalate spray (24) the natural and synthetic sugars each gave a faint yellow-brown spot which exhibited a strong yellow fluorescence under ultraviolet light, a characteristic of tetroses (25). The identity of the two compounds was demonstrated further by the fact that they gave identical infrared absorption spectra and 2,5-dichlorophenylosazones (6). The specific rotation of the synthetic specimen was $[\alpha]_D$ +6.4°, which is in good agreement with the values of $[\alpha]_D$ +3.8° found by Vongerichten and Müller (26) and $[\alpha]_D$ +5.8° found by Schmidt (8) for D-apiose obtained by regeneration from the 1-benzyl-1-phenylhydrazone.

Since the configuration of carbon atom 2 of synthetic D-apiose, originally carbon atom 3 of D-fructose, is known, the present results confirm Schmidt's assignment of the D-configuration to naturally-occurring apiose.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 paper using *n*-butanol–ethanol–water (40: 11: 19, v/v) as solvent. Chromatograms were developed with aniline

oxalate (24) and ammoniacal silver nitrate (27) sprays. The distance travelled by compounds on chromatograms (R_{Rh}) was measured relative to the distance travelled by L-rhamnose. Evaporations were carried out *in vacuo* at 40° C.

3-O-Benzyl-1,2;4,5-di-O-isopropylidene-D-fructose

1,2;4,5-Di-*O-iso*propylidene-D-fructose (17) (45 g.) was dissolved in a mixture of benzyl chloride (75 ml.) and xylene (50 ml.). The solution was agitated vigorously with an Ultra-Turrax stirrer (28) and powdered potassium hydroxide (180 g.) was added during a period of 0.5 hour, the reaction temperature being maintained at 85°–95° C. during this time and for an additional 1.5 hours' reaction period. The mixture was cooled, washed with water three times, and concentrated. Water was added to the resulting sirup and the suspension heated on the steam bath at 1 mm., more water was added, and the evaporation repeated. The residue was taken up in acetone, filtered through a bed of filter-cel, and concentrated, yielding a yellow, viscous sirup; n_D^{24} 1.5080. Weight 59.0 g. After distillation (135°–155° C. at 0.05 mm.) the product was colorless and had n_D^{24} 1.5033, $[\alpha]_D^{25}$ −95.0° (*c*, 4.6, ethanol). Calculated for $C_{19}H_{26}O_6$: C, 65.12%; H, 7.48%. Found: C, 65.00%; H, 7.43%.

3-O-Benzyl-D-fructose

3-*O*-Benzyl-1,2;4,5-di-*O-iso*propylidene-D-fructose (55 g.), dissolved in 50% acetic acid (200 ml.), was heated on a steam bath for 18 hours. After evaporation of the solvent, the product was found (infrared absorption) still to contain some *iso*propylidene groups and was therefore treated on a steam bath for 2 hours with 0.1 *N* sulphuric acid. The hydrolyzate was neutralized with barium carbonate and the solution filtered and concentrated, affording a pale yellow amorphous solid $[\alpha]_D^{25}$ −24.9° (*c*, 4.1, water). Weight 30.4 g. On a paper chromatogram the product gave a single spot (R_{Rh} 2.4) detected by silver nitrate. Calculated for $C_{13}H_{18}O_6$: C, 57.77%; H, 6.71%. Found: C, 57.78%; H, 6.81%.

As expected for a 3-substituted ketose, the compound consumed lead tetraacetate slowly (29).

3-O-Benzyl-D-fructose-(D-glucose)-phenylosazone

3-*O*-Benzyl-D-fructose (400 mg.) was dissolved in water (10 ml.) containing acetic acid (1.5 ml.) and phenylhydrazine (1 ml.). The solution was kept at 50° C. for 18 hours and the red-brown mass which formed was taken up in methanol. On addition of water, crystals were deposited and these were recrystallized from aqueous ethanol and then benzene. The light-yellow product (37 mg.) had m.p. 151°–152° C. Calculated for $C_{25}H_{28}O_4N_4$: C, 66.94%; H, 6.29%. Found: C, 67.14%; H, 6.20%. (Melting point of 3-*O*-benzyl-D-glucose-phenylosazone 149°–150° C. (18).)

3-O-Benzyl-2-C-hydroxymethyl-D-glucono- and -D-mannono-γ-lactones (3-O-Benzyl-α- and -β-D-fructoheptonic lactones)

In preliminary tests, cyanohydration of 3-*O*-benzyl-D-fructose with aqueous sodium cyanide at pH 9.3 was approximately 95% complete within 40 hours' reaction time, as measured by evolution of ammonia after alkaline hydrolysis. Accordingly, 3-*O*-benzyl-D-fructose (14.7 g.) in water (25 ml.) was added to a solution (200 ml.) of sodium cyanide (4.1 g.) buffered to pH 9.3 with acetic acid. The pH of the solution rose rapidly to pH 9.8 and more acetic acid was added, further additions of the acid being required during the first 5 hours' reaction time to maintain the pH at 9.3. After 48 hours at room temperature, the reaction mixture was diluted with water (200 ml.) and then concentrated, water was added again and evaporated, the procedure being repeated three times, with the last evaporation at 70° C. to promote complete hydrolysis of the nitrile. The sirup obtained

was dissolved in water, treated with Amberlite IR-120, and the hydrocyanic and acetic acids released were removed upon evaporation. After the residue was heated at 100° C. *in vacuo* over phosphorus pentoxide for 4 hours, a pale yellow amorphous solid was obtained. Weight 11.1 g. The infrared absorption spectrum of the product showed a predominance of the γ-lactone form to be present (strong absorption band at 1770 cm.$^{-1}$ (30)). The product (46.5 mg.), in water, consumed 0.26 ml. of 0.1 *N* sodium hydroxide by direct titration to a stable end point. Excess of the alkali was added, the solution heated, and back-titrated with acid. The total alkali consumed was 1.57 ml. (required, 1.55 ml.), indicating that approximately 85% of the material existed as the γ-lactone.

*3-O-Benzyl-2-C-hydroxymethyl-*D*-mannono-γ-lactone (3-O-Benzyl-β-*D*-fructoheptonic lactone)*

Partial crystallization of the lactone mixture occurred after several months. The sirup was taken up in ethyl acetate and the crystals were filtered off and recrystallized from ethyl acetate. Weight, 120 mg. from 500 mg. of the mixture. Melting point 150.5°–152.0° C., $[\alpha]_D^{27}$ +45.5° (*c*, 1.2, alcohol). Calculated for $C_{14}H_{18}O_7$: C, 56.38%; H, 6.08%. Found: C, 56.16%; H, 6.05%. The compound absorbed strongly in the infrared region at 1770 cm.$^{-1}$, which, together with the stability exhibited to alkaline hydrolysis, showed the presence of a γ-lactone structure (30). The non-crystalline fraction showed $[\alpha]_D^{27}$ +89.3° (*c*, 1.6, alcohol).

The crystalline lactone was treated with one equivalent of hot sodium hydroxide solution; the resulting sodium salt showed $[\alpha]_D^{27}$ +11.6° (*c*, 1.4). This value was altered to $[\alpha]_D^{27}$ +15.4° (*c*, 1.3) by liberation of the free acid through addition of one equivalent of hydrochloric acid. Likewise, the salt and acid prepared from the non-crystalline material had $[\alpha]_D^{27}$ −1.1° (*c*, 1.9) and $[\alpha]_D^{27}$ −5.7° (*c*, 1.7), respectively. These data are in close agreement with the results obtained (31) by application of the salt–acid rule (11, 12) to α- and β-D-fructoheptonic lactones, and indicate that the crystalline lactone is the β-(*mannono*)-isomer.

*3-O-Benzyl-2-C-(hydroxymethyl)-*D*-arabo-hexitol*

The crude mixture of *O*-benzyl-D-fructoheptonic lactones (7.5 g.) in water (15 ml.) was added slowly to a solution of sodium borohydride (1.5 g.) in water (25 ml.) (19). After 2 hours, excess of acetic acid was added, the solution passed through a column of Amberlite IR-120, and the solvent evaporated. The resulting sirup was taken up in methanol, the methanol was evaporated, and this procedure repeated five times to ensure removal of boric acid. The product contained some free acid and lactone (infrared spectrum). Accordingly the material was neutralized in methanol with ethereal diazomethane, again treated with sodium borohydride, and the product was worked up as described above. A small quantity of acid and lactone still present was removed by dissolving the product in excess hot 0.05 *N* sodium hydroxide and then treating with a mixed-bed resin of Amberlite IR-120 and IR-4B. (Reduction of the lactone was more efficient when, in a separate run, the reaction was carried out in cold methanol in the presence of sodium methoxide (20).) The final product was a colorless glass which gave a single spot (R_{Rh} 1.9) on a paper chromatogram using the ammoniacal silver nitrate spray, and was shown by its infrared spectrum to contain neither carboxyl nor lactone groups; $[\alpha]_D^{25}$ +13.7° (*c*, 2.9, water). Weight 3.0 g. Calculated for $C_{14}H_{22}O_7$: C, 55.62%; H, 7.34%. Found: C, 55.66%; H, 7.34%.

*2-C-(Hydroxymethyl)-*D*-arabo-hexitol* ("D-*Fructoheptitol*")

The *O*-benzyl heptitol was dissolved in ethanol (20 ml.) and treated at ambient temperature and pressure with hydrogen in the presence of palladium black catalyst (0.10 g.).

Approximately 1 mole of hydrogen was taken up in 2 hours' reaction time; ultraviolet absorption analysis then showed complete absence of the benzyl group. Removal of the catalyst and evaporation of the solvent afforded a sirupy product having the same R_{Rh} (0.53) on a paper chromatogram as authentic "D-fructoheptitol" (21), and an infrared absorption spectrum indistinguishable from that of the latter compound. The material was acetylated with hot acetic anhydride – sodium acetate. The sirupy acetate formed gave an infrared absorption spectrum which, except for the added presence of a weak hydroxyl band, was indistinguishable from that of "D-fructoheptitol" heptaacetate (21), and had the same specific rotation; $[\alpha]_D^{25}$ +31.0° (*c*, 6.0, chloroform) (authentic material has $[\alpha]_D^{24}$ +31.6° (21)). The product crystallized with difficulty, however, and after repeated recrystallization from ethanol–water the acetate (10 mg.) melted at 63°–67° C., undepressed by admixture with an authentic specimen (69°–70° C.). The X-ray diffraction pattern of the compound was indistinguishable from that of "D-fructoheptitol" heptaacetate. Calculated for $C_{21}H_{30}O_{14}$: C, 49.80%; H, 5.97%; acetyl, 60.8%. Found: C, 50.15%; H, 6.35%; acetyl, 60.5%.

Glycol-Cleavage Oxidations of 3-O-Benzyl-2-C-(hydroxymethyl)-D-arabo-hexitol

Oxidation of the *O*-benzyl polyol was examined using excess lead tetraacetate in acetic acid and excess sodium metaperiodate in water. At intervals, aliquots were removed from each reaction mixture and the consumption of oxidant was measured: lead tetraacetate (moles per mole)—1.85 (10 minutes), 2.20 (25 minutes), 2.55 (40 minutes); periodate (moles per mole)—2.45 (5 minutes), 2.60 (15 minutes), 2.77 (25 minutes).

3-*C*-(*Hydroxymethyl*)-D-*glycero-tetrose* (D-*Apiose*)

3-*O*-Benzyl-2-*C*-(hydroxymethyl)-D-*arabo*-hexitol (1.5 g.) was dissolved in acetic acid (20 ml.) and lead tetraacetate (4.2 g., 1.9 molar equivalents) in acetic acid (140 ml.) was added. After the oxidant has been consumed, oxalic acid (0.8 g.) in acetic acid (8.0 ml.) was added with stirring, the precipitate was filtered off, and the solvent evaporated. The sirup was extracted with ethyl acetate and the extract concentrated yielding a sirup (1.0 g.) which was treated under reflux with methanolic hydrogen chloride (0.5%, 20 ml.) for 2 hours and at room temperature for 18 hours. Acid was removed with silver carbonate and the methanolic filtrate evaporated yielding a sirup (0.88 g.) non-reducing to Fehling's solution. The product was catalytically debenzylated as described above, and then hydrolyzed with 0.3 *N* sulphuric acid for 1 hour at 95° C. The hydrolyzate was neutralized with Dowex-1 resin (bicarbonate form) and concentrated. The resulting sirup (0.40 g.), which was found by paper chromatography to contain three components (R_{Rh} 1.3, 0.9, and 0.5, respectively), was chromatographed on a cellulose column (23) using *n*-butanol half-saturated with water. The fraction corresponding to D-apiose (R_{Rh} 0.9) was collected, filtered through a Seitz bacterial filter, and concentrated. The residue was taken up in water, and the solution filtered through charcoal and concentrated giving a clear colorless sirup (94 mg.); $[\alpha]_D^{25}$ +6.4° (*c*, 1.0, water). The infrared absorption spectrum was identical with that of D-apiose isolated from parsley. Treated with 2,5-dichlorophenylhydrazine according to the procedure of Bell *et al.* (6), the product (50 mg.) gave an osazone which after two recrystallizations from aqueous ethanol (weight 47 mg.) had m.p. 194°–195.5° C. (corr.) (Bell *et al.* (6) report m.p. 188.5°–190.5° C. for D-apiose-2,5-dichlorophenylosazone). The X-ray diffraction pattern of the osazone was identical with that of the 2,5-dichlorophenylosazone prepared from D-apiose isolated according to the procedure of Vongerichten (1) from parsley. Calculated for $C_{17}H_{16}O_3N_4Cl_4$: C, 43.80%; H, 3.46%. Found: C, 44.04%; H, 3.43%.

SYNTHESIS OF SOME HEXANEDIOLS[1]

E. VON RUDLOFF

ABSTRACT

A general method for the preparation of 1,3-, 1,4-, and 1,5-hexanediols is described. The synthesis involves the preparation of a corresponding ketohexanoate, which is reduced to the diol with lithium aluminum hydride. Countercurrent distribution was found useful in the purification of small amounts of intermediates and end products. 1,2-, 1,6-, and 2,5-hexanediols were also prepared by known procedures. The infrared spectra of these diols have been recorded and their *p*-nitrobenzoates were prepared.

The analysis of mixtures of polyols obtained in the hydrogenolysis of methyl glucoside (1) required small amounts of various hexanediols for identification purposes. This paper describes a convenient method for preparing 3-, 4-, and 5-ketohexanoates, from which the 1,3-, 1,4-, and 1,5-hexanediols were obtained in 75–85% yield by lithium aluminum hydride reduction (2). It also describes the preparation of 1,2-, 1,6-, and 2,5-hexanediols by known procedures, and the preparation and characteristics of the *p*-nitrobenzoates. The infrared spectra of all of these hexanediols are recorded.

Hexanediols have been prepared by a variety of methods, none of which appeared to be generally applicable, and most suffered from the disadvantage that the starting materials were not readily available. Also, different types of crystalline derivatives were reported, making characterization by comparison difficult. No reference to the infrared spectra of these hexanediols could be found, although Kuhn (3) discusses the effect of hydrogen bonding on the infrared absorption band of the hydroxyl groups in 1,6-hexanediol.

The direct synthesis of hexanediols by general methods, such as the Grignard synthesis (4), did not appear feasible. A useful approach to their preparation appeared to be the synthesis of the corresponding keto- or hydroxy-acid (or ester), the latter being reduced readily to the hexanediol. When the synthesis of 4- and 5-ketohexanoic acids was attempted on a 10th molar scale by the methods of Winterfeld and Rönsberg (5), Yoho and Levine (6), and Perlin and Purves (7) only very low yields of rather impure keto-acids were obtained. Purification by fractional distillation on this scale proved unsatisfactory. The method of Cason *et al.* (8) for the preparation of keto-esters (III) was then modified according to Perlin and Purves and satisfactory results were obtained when the difficulties of purification of 5 to 10 g. reaction products had been overcome. The synthesis involves the preparation of a given carboxy acyl chloride (I), via the semi-ester of the dicarboxylic acid, which was reacted with the appropriate dialkyl cadmium (II). The latter was prepared in isopropyl ether (7) from the Grignard intermediate.

$$\underset{\text{I}}{2R'O_2C.(CH_2)_n.COCl} + \underset{\text{II}}{CdR_2} \longrightarrow \underset{\text{III}}{2R'O_2C.(CH_2)_n.\overset{\overset{O}{\|}}{C}.R} + CdCl_2$$

Provided the semi-ester was pure, the keto-ester was obtained in a satisfactory state of purity on fractional distillation. When the semi-ester was isolated impure (e.g. monoethyl malonate), neither the ketohexanoate nor the hexanediol could be purified satisfactorily

Can. J. Chem. Vol. 36 (1958)

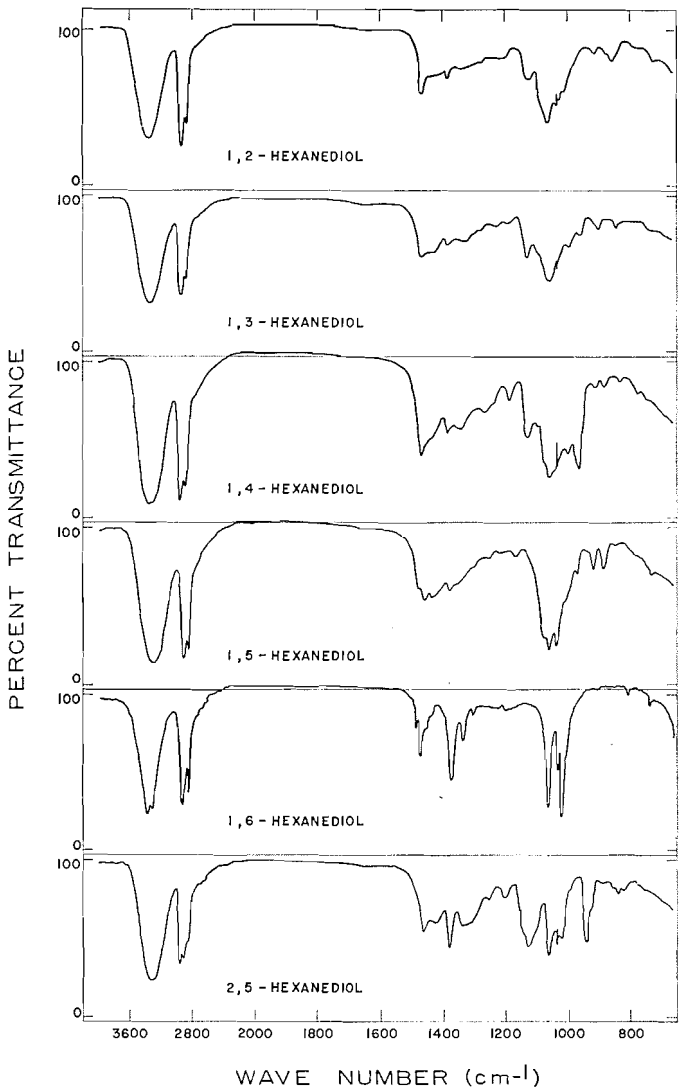

FIG. 1. Infrared spectra of hexanediols.

by fractional distillation. However, purification was possible by using countercurrent distribution. The distribution pattern of the keto-esters could not be obtained by weight analysis because of high solvent volatility. The impure keto-esters, therefore, were reduced and the reaction product was then fractionated and analyzed by countercurrent distribution, using weight analysis to obtain the distribution pattern. This analysis showed that the contaminant was the diol corresponding to the dicarboxylic acid component, indicating that the di-ester must have been present in the reaction mixture.

Reduction of the keto-esters with lithium aluminum hydride proceeded smoothly, and a good recovery of the products was obtained by salting out and extracting with ether containing 5–10% acetone. The use of methylal as solvent (9), as used in the reduction of adipic acid to 1,6-hexanediol, also gave satisfactory results. Catalytic reduction, as in the conversion of ethyl 5-ketohexanoate to 1,5-hexanediol in 85% yield by Hill and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

Adkins (10), may sometimes be advantageous since the reaction can be carried out in ethanol or dioxane and larger quantities can be readily handled. The over-all yields of 1,5-, 1,4-, and 1,3-hexanediols were about 50%, 45%, and 30% respectively (based on the weight of semi-ester).

1,2-Hexanediol was prepared in about 45% over-all yield by α-bromination of caproic acid (11), hydrolysis to α-hydroxycaproic acid (12), and reduction with lithium aluminum hydride. Lithium aluminum hydride reduction of adipic acid (9) and acetonyl acetone gave 1,6- and 2,5-hexanediol, respectively, in better than 80% yield. 2,5-Hexanediol was also prepared in about 95% yield by catalytic hydrogenation of acetonyl acetone, using ethanol as solvent and copper chromium oxide as catalyst (10, 13).

Previously, it was found that hexanediols give a better yield of the *p*-nitrobenzoate than of the 3,5-dinitrobenzoate (1). Since the *p*-nitrobenzoates of hexanediols are crystalline compounds with high melting points, these were prepared as suitable derivatives. The 1,3-isomer was dimorphous, a phenomenon which was also observed with the *p*-nitrobenzoate of 1,3-propanediol.

The infrared spectra of the individual hexanediols (see Fig. 1), except those of 1,2- and 1,3-hexanediol, differ sufficiently from each other to allow identification. No significant differences were found in the spectra of the *p*-nitrobenzoates.

EXPERIMENTAL

All melting points are corrected and were measured with a Leitz heating stage microscope. The infrared spectra were recorded with a Perkin Elmer model 21 spectrometer equipped with a sodium chloride prism. Liquid compounds were mounted by the suspended film technique and solids by the potassium bromide disk technique (14). Countercurrent distribution was carried out with a 100 tube modified E.C. Apparatus Co. fractionator having 40 ml. tube capacity (20 ml. upper and 20 ml. lower phase). *p*-Nitrobenzoates were prepared by the Schotten–Baumann reaction, using pyridine as base and solvent (15), and they were recrystallized from ethyl acetate – petrol and 2-butanone–petrol (b.p. 64°–66° C.).

Semi-esters of Dicarboxylic Acids

Succinic anhydride and glutaric anhydride were prepared by refluxing the dicarboxylic acids with excess acetic anhydride (16). The anhydrides were then converted to the monomethyl esters by the method of Ruggli and Maeder (17), e.g. succinic anhydride, 25 g. (0.25 mole), was refluxed with absolute methanol, 20 ml., for ½ to 1 hour. The excess methanol was removed by evaporation in a rotary evaporator and the residue cooled to about 5° C., when it solidified. The crude material was recrystallized three times from ether to give monomethyl succinate, 29 g. (88% of theory), m.p. 58° C. Monomethyl glutarate was obtained similarly in about 80% yield and was purified by fractional distillation, b.p. 153°–155° C. at 10–11 mm.

Monoethyl malonate was prepared by saponification of the diethyl ester with the theoretical amount of potassium hydroxide (18). Diethyl malonate, 50 g. (0.31 mole), in 200 ml. absolute ethanol was added slowly to a solution of potassium hydroxide, 17.5 g. (0.31 mole), in 200 ml. absolute ethanol. The mixture was allowed to stand at room temperature until it was neutral. It was then heated and filtered hot. The potassium salt crystallized rapidly and after crystallization was complete it was filtered off, washed twice with cold ethanol and once with ether. The crystalline product was dissolved in a minimum of water and acidified in the cold with concentrated hydrochloric acid. On

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

standing, a little malonic acid crystallized, which was filtered off. The aqueous solution was then extracted repeatedly with ether. The ethereal extracts were washed once with water and then dried over anhydrous sodium sulphate. When the dried ethereal solution was reduced to a small volume, more malonic acid crystallized. The residue from evaporation of the filtered ethereal solution was fractionally distilled *in vacuo*, to give 29 g. monoethyl malonate (about 70% of theory), b.p. 131°–133° C. at 11–12 mm.

Synthesis of Ketohexanoates

The following is a typical example of the procedure adopted for the preparation of methyl or ethyl 3-, 4-, and 5-ketohexanoate.

To monomethyl succinate, 13.2 g. (0.10 mole), was added thionyl chloride (reagent grade), 15 g. (0.125 mole), and the mixture was left at room temperature under a reflux condenser equipped with a calcium chloride tube. After the evolution of gas had subsided, the solution was heated at 40°–45° C. for 3 to 6 hours and was left at room temperature for a further 16 hours. Excess thionyl chloride was then removed on a rotary evaporator at 15 mm. and 40°–45° C. (17). The residual acid chloride was dissolved without further purification in 25 ml. dry, peroxide-free isopropyl ether and added dropwise with stirring to a cooled mixture of the dialkyl cadmium. The latter mixture was prepared by reacting magnesium, 3.6 g. (0.15 g. atom), in isopropyl ether (7), 60–65 ml., with dry ethyl bromide, 17.4 g. (0.16 mole), in 25 ml. isopropyl ether in the normal Grignard manner, and adding to the cooled solution with vigorous stirring anhydrous cadmium chloride (dried in a vacuum oven at 70° C. for 18 to 24 hours), 14.7 g. (0.08 mole), in one portion.

After addition of the acid chloride was complete, the mixture was refluxed with stirring for 3 to 4 hours and was left at room temperature for 16 hours, and was then poured into excess ice and 10% sulphuric acid. The aqueous layer was separated and extracted three times with an equal volume of ether. The ethereal extracts were added to the isopropyl ether layer and the combined solution was washed once with 5% sodium bicarbonate solution, twice with water, and dried over anhydrous sodium sulphate. On evaporation of the ether a light brown liquid was obtained. It was distilled *in vacuo* and the fraction of b.p. 75°–78° C. at 11–12 mm. was collected. The yield of impure methyl 4-ketohexanoate was 9 g. (63% of theory).

Attempts to purify the keto-esters thus obtained by fractional distillation were unsuccessful, presumably because of the small amounts available. Countercurrent distribution, using 40 to 70% ethanol and petrol b.p. 64°–66° C. as solvent pair, gave a satisfactory separation, but about one-half of the keto-esters was lost on evaporation of the solvents. In this manner methyl 5-ketohexanoate, b.p. 100°–101° C. at 11–12 mm., was obtained in 20–25% over-all yield. Calc. for $C_7H_{12}O_3$: C, 58.31; H, 8.39%; saponification equivalent 144.17. Found: C, 58.17; H, 8.45%; saponification equivalent 145.

Reduction to Hexanediols

A solution of impure methyl 4-ketohexanoate, 4.3 g. (0.03 mole), in dry ether, 50 ml., was added dropwise with stirring to a suspension of lithium aluminum hydride, 1.9 g. (0.05 mole), in dry ether, 100 ml., which had been refluxed previously for $\frac{1}{2}$ to 1 hour. The usual precautions against moisture were taken. The mixture was refluxed for $\frac{1}{2}$ to 1 hour after addition of the ester, and, after cooling, ice water was added dropwise until excess lithium aluminum hydride had reacted. To the cold mixture was added cold 10% sulphuric acid, 10–20 ml., and after the mixture had cleared, it was saturated with potassium carbonate. The ether layer was withdrawn after adding 10 to 15 ml. acetone. The aqueous layer was then extracted exhaustively with ether containing 5–10% acetone. The ethereal

For personal use only.

extracts were dried first over anhydrous potassium carbonate and then over anhydrous sodium sulphate. On evaporation of the ether, impure 1,4-hexanediol, 2.8 g. (80% of theory), was obtained. The mixture, 1.87 g., was fractionated by countercurrent distribution, using 2-butanone–water as solvent pair and 70 transfers. The distribution pattern was obtained by evaporating every second tube and weighing the residue in 20-ml. porcelain crucibles. Tubes 9–26 contained a viscous liquid, 0.45 g., which had an infrared spectrum identical to that of 1,4-butanediol. Calc. for $C_4H_{10}O_2$: C, 53.23; H, 11.49%. Found: C, 53.31, H, 11.19%. The *p*-nitrobenzoate, m.p. 175°–176° C., was undepressed in a mixture with an authentic specimen (m.p. 175°–176° C.). Tubes 28–40 contained 1,4-hexanediol, 1.25 g. The analytical data for this, as well as all the other hexanediols and their *p*-nitrobenzoates, are summarized in Table I.

TABLE I

[1]Levene and Haller (19): b.p. 110°–131° C. at 6 mm. (dinaphthylurethan m.p. 172°–174° C.).
[2]Glacet (20): b.p. 123°–123.4° C. at 13 mm., n_D^{22} 1.4461 (diphenylurethan m.p. 99.3° C.).
[3]Glacet (20): b.p. 127.5°–127.7° C. at 13 mm., $n_D^{16.3}$ 1.4530 (diphenylurethan m.p. 71° C.).
[4]Hill and Adkins (10): b.p. 89°–91° C. at 0.5 mm.
[5]Haworth and Perkin (21): b.p. 152° C. at 17 mm.; m.p. 42° C.
[6]Heyns and Woyrsch (22): m.p. 120° C.
[7]Duden and Lemme (23): b.p. 120°–122° C. at 12 mm.; n_D^{20} 1.4475.

In the same manner 1,5-hexanediol and 1,3-hexanediol were obtained in about 50% and 30% over-all yield respectively. In addition to 1,3-hexanediol, a considerable amount of 1,3-propanediol, *p*-nitrobenzoate, m.p. 109°–111° C. and 117°–118.5° C., mixed m.p. with an authentic specimen 111°–112° C. and 117°–118.5° C., was isolated.

Lithium aluminum hydride reduction of α-hydroxycaproic acid, adipic acid (9), and 2,5-hexanedione (acetonyl acetone) gave 1,2-, 1,6-, and 2,5-hexanediol respectively in 75–85% yield. α-Hydroxycaproic acid, m.p. 60°–62.5° C., was prepared in about 60% over-all yield by α-brominating caproic acid (11) and hydrolyzing the α-bromocaproic acid with aqueous potassium carbonate (12). Adipic acid, m.p. 151°–153° C., and 2,5-hexanediol, b.p. 192°–194° C., were obtained commercially. 2,5-Hexanediol was also prepared in better than 90% yield by hydrogenation over copper chromium oxide according to the method of Hill and Adkins (10).

ACKNOWLEDGMENTS

The author wishes to express his thanks to Mr. J. A. Baignee for the microanalyses, to Miss A. Epp and Mr. G. Rennie for recording the infrared spectra, to Mr. M. Granat for technical assistance, and to Dr. A. S. Perlin for advice and discussions.

THE COMPOUND $CaO.Ti_2O_3$[1]

NORMAN F. H. BRIGHT,[2] JOHN F. ROWLAND,[2] AND JOSEPH G. WURM[3]

ABSTRACT

By electrolyzing baths of molten $CaCl_2$ containing perovskite ($CaO.TiO_2$), a compound within the ternary Ca–Ti–O system, namely $CaO.Ti_2O_3$, has been obtained. The compound has been identified by chemical analysis, and its crystallographic data have been determined by X-ray means. Attempts to synthesize the compound apart from the electrolytic cell have, so far, failed.

INTRODUCTION

The only publications of work dealing with compounds within the ternary system Ca–Ti–O in which the titanium is in any state of valency other than the tetravalent are those of Bertaut and Blum (1, 2). In their work, the crystallography of a compound, to which is assigned the formula $CaTi_2O_4$, is described. The system CaO–TiO_2 has been studied by von Wartenberg, Reusch, and Saran (3), and their work did not indicate the existence of any compound between $CaO.TiO_2$ and TiO_2, but merely of a eutectic having a melting point of approximately 1450° C.; further, there was no indication in their work of any compound containing a lower proportion of oxygen.

In the course of work on the electrochemistry of the production of titanium, a material was encountered which forms the subject of this paper. The material was examined by chemical, X-ray diffraction, and spectrographic means and has been shown to be $CaTi_2O_4$ (or $CaO.Ti_2O_3$); some of its properties have been determined. This work was done independently and without the knowledge of the work of Bertaut and Blum. Their work was entirely crystallographic, whereas, as mentioned above, the present work includes chemical data.

EXPERIMENTAL

(*a*) *Preparation of the Compound*

When a bath composed of 300 g. of calcium chloride and containing 60 g. of calcium titanate, $CaO.TiO_2$, which is slightly soluble in the molten chloride, was electrolyzed under an inert atmosphere for 70 minutes at a current of 14 amp. at 850° C. and allowed to cool, some black, lustrous, well-formed crystals were observed close to the cathode.

(*b*) *Chemical Examination of the Compound*

Examination of the crystals under a low-power microscope showed them to be prismatic in form and very well developed. No difficulty was experienced in selecting suitable specimens for detailed X-ray crystallographic examination.

The examination of the material by semiquantitative spectrographic analysis showed that Ca and Ti were the only detectable major metallic constituents.

About 60 mg. of the material was available for chemical analysis, and the determinations shown in Table I were made.

The methods used for analysis were as follows:

Calcium.—Determined with a Perkin–Elmer flame photometer at 6200 Å, after

TABLE I

Element	% by weight
Ca	20.3±0.2
Ti	47.0±0.1 (all trivalent)
Fe	1.05±0.05 (mean of two determinations)
C	0.07±0.02
F	None detectable

removal of iron and titanium as "cupferrides", aluminum as 8-hydroxyquinolate, and after removal of excess organic reagents.

Iron.—Determined in the chloroform solution of the "cupferride" by colorimetric means with *o*-phenanthroline, using a Coleman MK.14 spectrophotometer at $\lambda = 500\ \mu\mu$.

Titanium.—Determined in the chloroform solution of the "cupferride" by colorimetric means with hydrogen peroxide, using a Coleman MK.14 spectrophotometer at $\lambda = 410\ \mu\mu$. This gives the total titanium. The trivalent titanium was determined by dissolving the sample in aqueous sulphuric acid, and titrating against standard ferric alum, all under an argon atmosphere.

Carbon.—Determined by a standard combustion procedure.

Fluorine.—HF steam-distilled off at 135°–140° C. from an aqueous perchloric acid suspension of the sample. Fluoride estimated amperometrically at pH = 7.0 using thorium nitrate solution previously standardized against NaF.

The unestimated material, approximately 31.6%, is presumably oxygen since no major constituent other than calcium and titanium was detectable spectrographically.

An X-ray powder diffraction pattern of the crushed material was taken using CoK_α radiation and a 57.3 mm. diameter Debye-Scherrer camera. The pattern was well defined, but could not be identified by reference to either the A.S.T.M. Card Index of X-Ray Diffraction Patterns or any other source of data available to the authors.

The material showed slight signs of ferromagnetism, and certain weak lines in the X-ray diffraction pattern could be interpreted as being due to the presence of a small amount of metallic iron. It was considered, therefore, that the iron in the above chemical analysis is probably due to the presence of a small quantity of free metallic iron and that the main compound is essentially a calcium–titanium–oxygen compound. On this basis, the observed and theoretical compositions and atomic ratios of the relevant compounds are as follows:

	Ca	Ti	O
Observed	20.3±0.2%	47.0±0.1%	31.6±0.3% (by difference)
Atomic ratios	1.000	1.937±0.015	3.900±0.075
Calculated for $CaTi_2O_4$	20.1%	47.9%	32.0%
Calculated for $CaTi_2O_5$	18.6%	44.4%	37.0%

It thus seems reasonable to conclude that the compound represented by our data is, in fact, $CaO.Ti_2O_3$. It must, however, be borne in mind that the above chemical analyses were made on very small quantities of material and, in any case, the analytical procedures were not simple.

The limits of error quoted in Table I are merely those of the final stage of each estimation; with the very small quantities of material available for investigation there was no

20	1.632	1.632	511	10	1.305	1.310	412

ready means of assessing the errors of the various stages of separation involved in these analyses; hence it is possible that the estimations, considered as a whole, may be subject to somewhat larger errors than those quoted. This being the case, a molecular formula of $CaO.2TiO_2$ (i.e., $CaTi_2O_5$) is regarded as very unlikely but not entirely impossible. Such a formula would be analogous to that of magnesium dititanate, $MgO.2TiO_2$, which is a well-established compound. This supposition is, however, in conflict with the work of von Wartenberg *et al.* (3).

Several attempts were made to synthesize both $CaO.Ti_2O_3$ and $CaO.2TiO_2$ by sintering suitable mixtures of the constituent oxides at high temperature under appropriate atmospheric conditions. In neither case was any success achieved, and all the results obtained confirmed the work of von Wartenberg *et al.*

In general, however, it may be said that the chemical evidence supports the formula $CaO.Ti_2O_3$ for the material which forms the subject of the present study, rather than the formula $CaO.2TiO_2$.

(c) Crystallographic Studies of the Compound

The following morphological data were obtained as the average of observations on two well-formed crystals, using a standard two-circle optical goniometer:

Crystal class: orthorhombic.

Axial ratio: $a:b:c = 0.916:1:0.308$.

The single crystal X-ray work included rotation photographs, zero-layer and first-layer Weissenberg photographs, and cone-axis, zero-level, and first-level precession photographs. The Weissenberg photographs were made using CoK_α radiation, with rotation about the prismatic axis, and the precession photographs were made using MoK_α radiation, with the prismatic axis as the dial axis. The cell edges were determined from these photographs; from the systematic extinctions, the space group was obtained. The results of these examinations are given in Table II.

The space group quoted is the same as for the mineral pseudobrookite, $Fe_2O_3.TiO_2$ (i.e. $TiFe_2O_5$), and for the isomorphous compound magnesium dititanate, $MgO.2TiO_2$ (i.e. $MgTi_2O_5$), referred to earlier.

The powder diffraction pattern was indexed according to our cell dimensions, as shown in Table III, and the agreement between the observed and calculated spacings is quite good; also, the axial ratios determined by optical goniometry agree well with those determined by X-ray diffraction.

DISCUSSION OF RESULTS

It has thus been possible to describe the crystallography of this compound, to which is assigned the formula $CaO.Ti_2O_3$, in a reasonably complete fashion, and to provide a chemical analysis of sufficient accuracy to indicate the molecular formula with virtual certainty, even though it was not found possible to synthesize it apart from the electrolytic method in which it was first prepared. In the work of Bertaut and Blum, the material was obtained by the electrolysis of TiO_2 in molten $CaCl_2$. Their formula is based entirely on X-ray crystallographic evidence. There is good agreement between their X-ray results and those obtained in the course of the present work. The formula, $CaTi_2O_4$, quoted by them is also in good accord with our chemical data. The fact that the titanium is in the trivalent condition, as shown by the chemical analysis, indicates that this compound is best represented by the formula $CaO.Ti_2O_3$. Thus, the present work gives additional data on the electrolytic conditions of preparation of this compound and on its chemical composition, while providing good confirmation of the X-ray crystallographic work of Bertaut and Blum.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Miss E. M. Penner, Mr. L. G. Ripley, and Mr. R. C. McAdam, of the Chemical Laboratory of the Mines Branch, Ottawa, for performing the chemical analyses referred to in this publication.

AMINO ACIDS

IV. THE REACTION OF GLYCINE AND β-ALANINE WITH CARBON DISULPHIDE[1]

E. J. TARLTON AND A. F. MCKAY

ABSTRACT

Glycine and β-alanine on condensation with carbon disulphide gave the corresponding 1,3-di-(carboxyalkyl) thioureas. 1,3-Di-(carboxymethyl) thiourea is rearranged to 2-thio-3-(carboxymethyl) hydantoin by warming with hydrochloric acid solution or heating above its melting point. Evidence is presented for the reversible condensation of 2 mole equivalents of the sodium salt of 2-thio-3-(carboxymethyl) hydantoin by the elimination of water. This condensation product is obtained as well-defined pink crystals. 1,3-Di-(β-carboxyethyl) thiourea was oxidized with an alkaline solution of hydrogen peroxide or sodium hypochlorite solution to 1,3-di-(β-carboxyethyl) urea. 1,3-Di-(β-carboxyethyl) thiourea and 1,3-di-(β-carboxyethyl) urea have been cyclized by heating with *p*-toluenesulphonic acid. The products were 2-thio-3-(β-carboxyethyl) hydrouracil and 3-(β-carboxyethyl) hydrouracil respectively.

The reaction of several α-amino acids and carbon disulphide in aqueous sodium bicarbonate solution has been studied earlier by Kodama (1, 2). In most cases, he found that the only identifiable products were substituted thiohydantoins, which presumably were formed by cyclization of the intermediate 1,3-di-(carboxymethyl) thioureas. In the reaction with glycine, however, no distinct products were obtained although the copious evolution of hydrogen sulphide indicated that condensation had occurred. The reaction has now been reinvestigated in conjunction with the condensation of glycine and its homologue, β-alanine, with carbon disulphide.

Sodium glycinate and carbon disulphide were condensed in aqueous solution to yield the crude disodium salt of 1,3-di-(carboxymethyl) thiourea (I*c*). Reaction of this disodium salt with methanolic hydrogen chloride at room temperature gave 1,3-di-(carbomethoxymethyl) thiourea (I*b*) in 25% yield. The combined mother liquors on treatment with concentrated hydrochloric acid gave 2-thio-3-(carboxymethyl) hydantoin (II*a*) (m.p. 214°–215° C. dec.) in 17% yield. The latter compound was identified by analysis and by desulphurization with aqueous chloroacetic acid, to the known 3-(carboxymethyl) hydantoin (III*a*) and methyl ester of 3-(carboxymethyl) hydantoin (III*b*) (3). The methyl ester of 2-thio-3-(carboxymethyl) hydantoin (II*b*) melted at 113°–114° C.

Careful saponification of the dimethyl ester (I*b*) gave 1,3-di-(carboxymethyl) thiourea (I*a*) which melted at 164°–165° C. with loss of 1 mole of water and resolidified to form 2-thio-3-(carboxymethyl) hydantoin which then melted at 214°–215° C. with decomposition. 1,3-Di-(carboxymethyl) thiourea was previously reported (4) as melting at 170° C. with decomposition. In concurrence with previous work (4, 5) this thiourea diacid (I*a*), its dimethyl ester (I*b*), and disodium salt (I*c*) all cyclize in acid solution to give 2-thio-3-(carboxymethyl) hydantoin. As a preparative method, the reaction mixture of crude disodium 1,3-di-(carboxymethyl) thiourea (I*c*) on brief treatment with concentrated hydrochloric acid gave the thiohydantoin (II*a*) in 48% yield.

When the condensation of sodium glycinate and carbon disulphide was conducted in the usual manner and the reaction mixture was acidified at room temperature to a pH of 2 with hydrochloric acid, no precipitation of product occurred. However, the solution yielded an orange-colored product (V)[2] melting at 287°–290° C. with decomposition. A 23% yield of 2-thio-3-(carboxymethyl) hydantoin (II*a*) was obtained from the mother liquors. In another experiment, the high melting condensation product (V) appeared in 31% yield on acidification of the reaction mixture with 2.2 moles of hydrochloric acid, followed by subsequent evaporation and extraction. In this case, the residue from the mother liquors gave on methylation 2-thio-3-(carbomethoxymethyl) hydantoin (II*b*) in 7% yield. The colored condensation product (V) proved to contain chemically bound sodium but it gave a negative halogen test. Potentiometric titration of the compound in aqueous solution with standard alkali showed it to be an acid with a primary pK_a of 3.4 and a neutralization equivalent of 373, which agrees with the acid equivalent (374.31) of the empirical formula $C_{10}H_8N_4O_5S_2Na_2$. Attempts to methylate this product with methanolic hydrogen chloride gave 2-thio-3-(carbomethoxymethyl) hydantoin (II*b*) in 81% yield. Brief treatment of the condensation product (V) with concentrated hydrochloric acid gave an 84% yield of 2-thio-3-(carboxymethyl) hydantoin (II*a*), while desulphurization with aqueous chloroacetic acid followed by methylation gave 3-(carbomethoxymethyl) hydantoin (III*b*) in 25% yield. Other attempted alkylation experiments with benzyl chloride or dimethyl sulphate in the presence of aqueous base led to the isolation of 2-thio-3-(carboxymethyl) hydantoin (II*a*) and not to a derivative of the condensation product (V). Empirically, these observations indicate the condensation product (V) to be the result of an easily reversible condensation of 2 moles of the sodium salt of 2-thio-3-(carboxymethyl) hydantoin with the elimination of 1 mole of water in such a way as to leave a titratable acid function in the product. Potentiometric titration data on 2-thio-3-(carboxymethyl) hydantoin (II*a*) and the colored condensation product add additional evidence to this hypothesis.

The titration of 2-thio-3-(carboxymethyl) hydantoin (II*a*) (Fig. 1, curve A) with 0.1 *N* sodium hydroxide solution gave a typical titration curve for an acid (pK_a 3.2) with an observed neutralization equivalent of 173 (calculated, 174). At the neutralization point (n_1) the color of the solution changed from yellow to red-orange. The solution was then back-titrated with standard hydrochloric acid (Fig. 1, curve B). Again, at the neutralization point (n_2), a color change of red-orange to orange occurred. Curves A and B do not coincide and it will be observed that if the amount of sodium hydroxide solution (0 to n_1) required to neutralize 2-thio-3-(carboxymethyl) hydantoin (II*a*) is 1 mole, then the difference between n_1 and n_2 is 0.5 mole. This can be explained by consideration of the following reaction sequence:

[2]*This product is referred to hereafter as condensation product.*

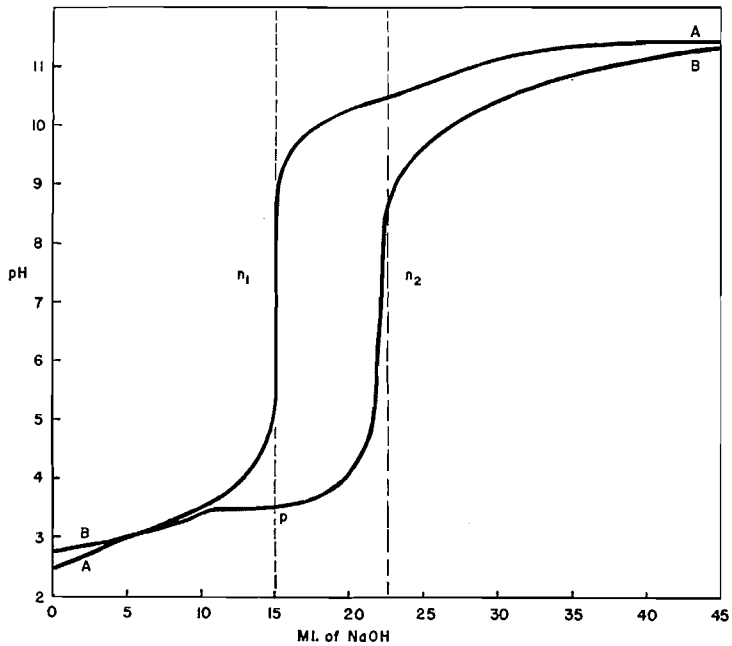

FIG. 1. Titration (*A*) and back-titration (*B*) of 2-thio-3-(carboxymethyl) hydantoin (II*a*) in aqueous solution.

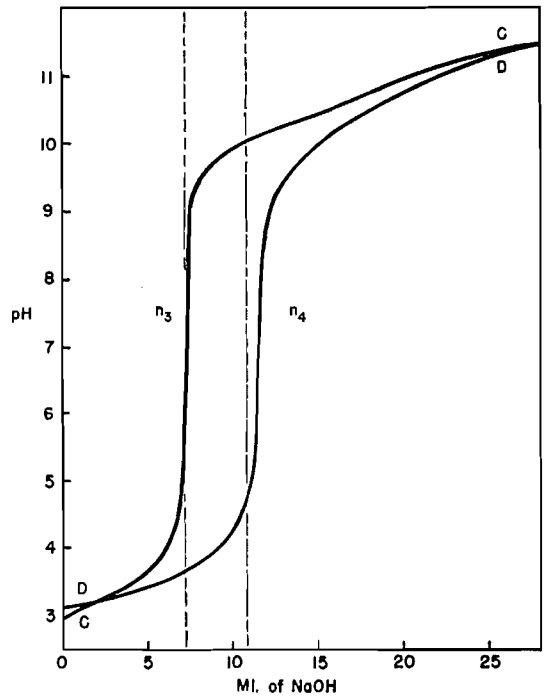

FIG. 2. Titration (*C*) and back-titration (*D*) of condensation product (V) in aqueous solution.

Following curve A, the conversion of 2-thio-3-(carboxymethyl) hydantoin (II*a*) into its monosodium salt (IV) is complete at n_1; at n_1, IV undergoes self-condensation with elimination of water to give the condensation product (V), which is in turn neutralized to give VI. The neutralization of V to VI requires 1 mole of base per mole of condensation product or *one-half the amount of base required to neutralize IIa originally*. On the back-titration curve B, the conversion of VI to V begins at n_2 and should be complete at p. The validity of this interpretation rests on the isolation of the condensation product (V) from the solution used in the titration and back-titration of II*a*. Experimentally, this method gave an 80% conversion of II*a* into V. The analytical values obtained for the condensation products prepared by the two methods agreed within experimental error. However, in both cases the values obtained for hydrogen were higher than the value calculated for the empirical formula $C_{10}H_8N_4O_5S_2Na_2$.

The titration and back-titration of the condensation product (V) gave the same result (Fig. 2). Again, the difference between the two curves (C and D) at n_3 and n_4 represents approximately one-half the amount of base required to reach n_3. In analogy with the titration experiments on 2-thio-3-(carboxymethyl) hydantoin (II*a*), it appears that the condensation process has again occurred.

Although there is not sufficient evidence to formulate the structure of the condensation product (V) with its two combined sodium atoms, the data suggest that the product has a free carboxyl group and that the sodium atoms are bound as salts of an enolic structure. Furthermore, the structure of the initial condensation product (V) must be such that the same mode of self-condensation can be repeated.

The condensation of sodium β-alaninate and carbon disulphide proceeded normally. The product, 1,3-di-(β-carboxymethyl) thiourea (VII*a*), proved to be very water soluble and hence was isolated in the form of its dimethyl ester (VII*b*) in 56% yield. Saponification of the diester (VII*b*) in aqueous base readily gave the diacid (VII*a*). This thiourea–diacid (VII*a*) was oxidized with 4 moles of aqueous sodium hypochlorite or hydrogen peroxide in the presence of 4 moles of base to 1,3-di-(β-carboxyethyl) urea (VIII).

There are numerous examples in the literature of the cyclization of β-thioureido and β-ureido alanines to hydrouracil and its derivatives. This was accomplished by the cyclizing action of acetic anhydride, hydrochloric acid, or simply heat (6, 7, 8, 9, 10, 11) on the β-ureido alanines, while others (12, 13, 14) found that the corresponding esters undergo ring closure in the presence of sodium alkoxides. When 1,3-di-(β-carboxyethyl) thiourea (VII*a*) was heated with *p*-toluenesulphonic acid at 160°–175° C., 2-thio-3-(β-carboxyethyl) hydrouracil (IX) was obtained in 85% yield. In accordance with observations on other hydrouracil derivatives (7, 15) this process was easily reversed by the action of warm aqueous base on IX. Similarly, the action of hydrochloric acid or acetic anhydride on 1,3-di-(β-carboxyethyl) urea (VIII) gave 3-(β-carboxyethyl) hydrouracil (X).

As a preparative method, the 2-thio-3-(β-carboxyethyl) hydrouracil (IX) can be prepared in 46% yield from the crude 1,3-di-(β-carboxyethyl) thiourea (VII*a*) by cyclization with *p*-toluenesulphonic acid. It is of interest to note that the cyclization of 1,3-di-(carboxymethyl) thiourea (I*a*) to yield 2-thio-3-(carboxymethyl) hydantoin (II*a*) is more facile than the ring closure of its homologue (VII*a*) to the thiohydrouracil (IX). This is demonstrated by the behavior of the two compounds on fusion. As noted above, 1,3-di-(carboxymethyl) thiourea (I*a*) loses water readily at its melting point while VII*a* remains unchanged under these conditions.

During the investigation of the cyclization of 1,3-di-(β-carboxyethyl) thiourea (VII*a*) with acetic anhydride under reflux, desulphurization as well as cyclization occurred. The product, 3-(β-carboxyethyl) hydrouracil (X), was obtained in 26% yield. To our knowledge, the desulphurization of a thiohydrouracil with acetic anhydride has not been observed previously.

EXPERIMENTAL[3]

1,3-Di-(carboxymethyl) Thiourea and 2-Thio-3-(carboxymethyl) Hydantoin

A stirred mixture of glycine (20 g., 0.26 mole), carbon disulphide (10.2 g., 0.13 mole), and water (20 ml.) was treated dropwise with a solution of sodium hydroxide (10.68 g., 0.26 mole) in water (27 ml.) over a period of 15 minutes. After the initial heat effect had abated additional carbon disulphide (2 g.) was added and the solution was held at the reflux temperature of carbon disulphide for 30 minutes. The excess carbon disulphide was evaporated and the remaining solution was refluxed for 7 hours. During this latter heating stage copious evolution of hydrogen sulphide occurred. The solution was cooled, filtered, and divided into two equal portions.

One portion of the solution was evaporated to dryness *in vacuo* on the steam bath and the residual viscous red oil was dried *in vacuo* over potassium hydroxide pellets. This residue was treated with 10% methanolic hydrogen chloride solution (100 ml.) at room temperature. A pale yellow solution containing some insoluble crystals of sodium chloride was obtained. Methylation was allowed to proceed at room temperature overnight. The filtered solution was evaporated to dryness *in vacuo* and the residue was dissolved in

[3]*All melting points are uncorrected. Microanalyses were performed by Micro Tech Laboratories, Skokie, Illinois.*

chloroform. The chloroform solution was extracted with water, dried, and then evaporated to dryness. The residue on treatment with benzene gave 3.7 g. (25%) of crude crystalline 1,3-di-(carbomethoxymethyl) thiourea (m.p. 97°–98° C.). Several crystallizations from benzene–hexane solution gave colorless platelets melting at 99°–100° C. Anal. Calc. for $C_7H_{12}N_2O_4S$: C, 38.17; H, 5.49; N, 12.72; S, 14.56%. Found: C, 38.59; H, 5.61; N, 12.81; S, 14.10%.

Part of the 1,3-di-(carbomethoxymethyl) thiourea (0.5 g., 0.002 mole) in a solution of sodium hydroxide (0.3 g., 0.007 mole) in water (7 ml.) was heated on a steam bath for 30 minutes. The solution was cooled to 0° C. and acidified with cold concentrated hydrochloric acid solution. The crystals (m.p. 157°–158° C.; resolidifies and remelts with decomposition at 214°–215° C.) were recovered by filtration, yield 0.38 g. (89%). This material was purified by solution in cold methanol and precipitation with benzene. The pure sample gave a double melting point of 164°–165° C. and 214°–215° C. with decomposition. Anal. Calc. for $C_5H_8N_2O_4S$: C, 31.25; H, 4.20; N, 14.58; S, 16.69%. Found: C, 31.49; H, 4.23; N, 14.43; S, 16.61%.

The mother liquors and washings from the preparation of 1,3-di-(carbomethoxymethyl) thiourea were combined and evaporated to dryness. The residue in concentrated hydrochloric acid solution (35 ml.) was warmed on a steam bath for 20 minutes. When the solution was cooled, 2-thio-3-(carboxymethyl) hydantoin (m.p. 210°–212° C. with decomposition) separated as pale yellow crystals, yield 2 g. (17%). Recrystallization from methanol–benzene solution raised the melting point to 214°–215° C. with decomposition. The melting points reported in the literature are 212° C. with decomposition (4) and 210°–212° C. (5). Anal. Calc. for $C_5H_6N_2O_3S$: C, 34.47; H, 3.47; N, 16.09; S, 18.41%. Found: C, 34.55; H, 3.54; N, 16.10; S, 18.21%.

A solution of 2-thio-3-(carboxymethyl) hydantoin (0.5 g., 0.003 mole) in 10% methanolic hydrogen chloride solution (10 ml.) was allowed to stand at room temperature overnight. The solvent was removed *in vacuo* at room temperature and the crystalline residue was crystallized from benzene (3 ml.) to yield 0.49 g. (91%) of 2-thio-3-(carbomethoxymethyl) hydantoin melting at 112°–113° C. One crystallization from benzene–hexane solution raised the melting point to a constant value of 113°–114° C. Anal. Calc. for $C_6H_8N_2O_3S$: C, 38.29; H, 4.28; N, 14.89; S, 17.04%. Found: C, 38.51; H, 4.37; N, 14.46; S, 16.74%.

The methyl ester of 2-thio-3-(carboxymethyl) hydantoin on hydrolysis with either 6% potassium hydroxide solution or 37% hydrochloric acid solution gave a 72% yield of 2-thio-3-(carboxymethyl) hydantoin (m.p. 214°–215° C. with decomposition). The product was identified by a mixture melting point determination with an authentic sample of 2-thio-3-(carboxymethyl) hydantoin.

The second portion of solution from the original reaction was acidified to a pH of 2 with concentrated hydrochloric acid solution. This solution was evaporated to dryness *in vacuo* and the residue was dried *in vacuo* over potassium hydroxide pellets. The dried residue was extracted with boiling methanol (2×100 ml.) and the insoluble inorganic salts were removed by filtration. After the methanolic filtrate was taken to dryness, the residue was crystallized from water (15 ml.). Orange-red crystals of condensation product (m.p. 270°–275° C. with decomposition) were obtained, yield 2.9 g. (24%). One crystallization from water (7 ml.) together with treatment with Nuchar raised the melting point to 287°–290° C. with decomposition. The product gave a negative halogen test and it gave a neutralization equivalent of 373 on titration with 0.1 *N* sodium hydroxide solution. Anal. Calc. for $C_{10}H_8N_4O_5S_2Na_2$ (mol. wt. 374.31): C, 32.09; H, 2.15; N, 14.97%. Found: C, 32.50; H, 3.13; N, 15.11; Ash, 17.53%.

The mother liquors from the condensation product were evaporated to dryness and the residue was heated with 37% hydrochloric acid solution (25 ml.) for 1 hour on the steam bath. The solution was cooled and a crystalline precipitate of 2-thio-3-(carboxymethyl) hydantoin (m.p. 210°–212° C. with decomposition) was obtained, yield 2.6 g. (23%). This product was identified by a mixed melting point determination with a known sample of 2-thio-3-(carboxymethyl) hydantoin (m.p. 214°–215° C. with decomposition).

In another experiment, after the stage of the condensation reaction, the reaction mixture was acidified with 1.1 mole of hydrochloric acid per mole of sodium hydroxide originally used. The colored condensation product (m.p. 285°–290° C. with decomposition) was obtained in 32% yield. The dry residue from the mother liquors was methylated with 10% methanolic hydrogen chloride to yield 7% of the methyl ester of 2-thio-3-(carboxymethyl) hydantoin (m.p. 112°–113° C.). This product gave no depression in melting point on admixture with an authentic sample of 2-thio-3-(carbomethoxymethyl) hydantoin (m.p. 113°–114° C.).

Direct Preparation of 2-Thio-3-(carboxymethyl) Hydantoin

A mixture of glycine (150 g., 2 moles), carbon disulphide (76 g., 1 mole), and sodium hydroxide (80 g., 2 moles) in water (350 ml.) was condensed in the above-described manner. After complete reaction, the solution was filtered and evaporated to dryness. The residue in concentrated hydrochloric acid solution (500 ml.) was heated on a steam bath for 45 minutes. The yellow solid which separated was collected and dried to give 84 g. (49%) of 2-thio-3-(carboxymethyl) hydantoin (m.p. 214°–215° C. with decomposition). This product was identified by a mixture melting point determination.

3-(Carboxymethyl) Hydantoin

2-Thio-3-(carboxymethyl) hydantoin (1.3 g., 0.007 mole) was converted into 3-(carboxymethyl) hydantoin (m.p. 183°–191° C.) in 37% yield by heating with chloroacetic acid under the conditions described by Johnson and Renfrew (5). Two crystallizations from ethanol–hexane solution raised the melting point to 197°–198° C. The melting points reported in the literature are 190°–191° C. (5), 195°–196° C. (16), and 199°–201° C. (17). Anal. Calc. for $C_5H_6N_2O_4$: C, 37.98; H, 3.83; N, 17.72%. Found: C, 38.28; H, 3.94; N, 17.95%.

A solution of 3-(carboxymethyl) hydantoin (0.1 g., 0.0006 mole) in 10% methanolic hydrogen chloride solution (8 ml.) was allowed to stand overnight. The solvent was removed *in vacuo* and the residue was crystallized from benzene–hexane solution to give 91 mg. (84%) of the methyl ester of 3-(carboxymethyl) hydantoin melting at 88°–89° C. One crystallization from acetone–hexane solution raised the melting point to 90°–91° C. The previously (3) reported melting point is 91° C.

Chemistry of the Condensation Product

(*a*) *Conversion into 2-Thio-3-(carboxymethyl) Hydantoin*

The condensation product (0.5 g., 0.0013 mole) in 37% hydrochloric acid solution (4 ml.) was heated at 100° C. for 7 minutes. The mixture was cooled and the precipitate of 2-thio-3-(carboxymethyl) hydantoin (m.p. 212°–213° C. with decomposition) was removed by filtration, yield 0.39 g. (84%). One crystallization from glacial acetic acid raised the melting point to 214°–215° C. with decomposition. This product was identified by a mixture melting point determination with a known sample of 2-thio-3-(carboxymethyl) hydantoin.

(*b*) *Conversion into 2-Thio-3-(carbomethoxymethyl) Hydantoin*

A solution of the condensation product (0.5 g., 0.0013 mole) in 10% methanolic hydrogen chloride solution (10 ml.) was allowed to stand at room temperature overnight. The solvent was removed *in vacuo* and the residue was extracted with chloroform. The chloroform extract was washed with water, dried, and evaporated to dryness. The crystalline residue was crystallized from benzene, yield 0.4 g. (81%). It melted at 112°–113.5° C. alone and on admixture with a known sample of 2-thio-3-(carbomethoxymethyl) hydantoin (m.p. 113°–114° C.).

(*c*) *Conversion into 3-(Carbomethoxymethyl) Hydantoin*

An aqueous solution (2 ml.) of the condensation product (0.5 g., 0.0013 mole) and chloroacetic acid (0.5 g., 0.005 mole) was refluxed for 1 hour. The solution was taken to dryness *in vacuo* and the residue was methylated with 10% methanolic hydrogen chloride solution (15 ml.) at room temperature overnight. The solvent was removed *in vacuo* and the residual oil was dissolved in chloroform. The chloroform solution was washed with 5% sodium bicarbonate solution and water. It was dried and the chloroform evaporated. The residue was crystallized from benzene–hexane solution (3 ml.) to give 116 mg. (25%) of 3-(carbomethoxymethyl) hydantoin melting at 89°–90° C. A sample crystallized from acetone–hexane solution melted at 90°–91° C. alone and on admixture with a known sample of 3-(carbomethoxymethyl) hydantoin.

(*d*) *Condensation Product from 2-Thio-3-(carboxymethyl) Hydantoin*

A solution of 2-thio-3-(carboxymethyl) hydantoin (5.0 g., 0.0287 mole) in water (100 ml.) was titrated with 0.1 *N* sodium hydroxide solution. After each addition of base, the pH of the solution was determined by means of a Beckman Model G pH meter equipped with external glass and calomel electrodes. At the neutralization point (288 ml. of 0.1 *N* NaOH, 0.0288 mole), the color of the solution changed from pale yellow to red. After addition of an equal amount of base, the solution was back-titrated with 118 ml. of 0.244 *N* hydrochloric acid (0.0288 mole). Again, a color change from red to orange at the equivalence point was observed when approximately half of the hydrochloric acid solution had been added. The solution was evaporated *in vacuo* until crystals began to appear. These were collected and dried to give 1.28 g. (m.p. 287°–292° C. with decomposition). A second crop (3.02 g., m.p. 270°–285° C. with decomposition) was obtained on further concentration of the mother liquor to give a total crude yield of 80%. Recrystallization of the product from water (10 ml.) together with Nuchar treatment gave orange-red crystals (2.04 g., m.p. 287°–291° C. with decomposition) which gave no depression in melting point on admixture with the condensation product (above). It gave a neutralization equivalent of 378 on titration with 0.1 *N* sodium hydroxide solution. Anal. Calc. for $C_{10}H_8N_4O_5S_2Na_2$: C, 32.09; H, 2.15; N, 14.97%. Found: C, 32.61; H, 3.36; N, 15.55; Ash, 17.47%.

(*e*) *Titration Experiments*

The titration curves (Fig. 1 and 2) were obtained by titration of aqueous solutions (1 g./100 ml.) of 2-thio-3-(carboxymethyl) hydantoin and the condensation product with 0.1 *N* sodium hydroxide solution and back-titration with standardized hydrochloric acid solution. The pH of the solution was determined by means of a Beckman Model G pH meter equipped with external glass and calomel electrodes.

1,3-Di-(β-carboxyethyl) Thiourea

A mechanically stirred mixture of β-alanine (15 g., 0.16 mole), carbon disulphide (6.4 g., 0.08 mole), and water (10 ml.) was treated dropwise with a solution of sodium

hydroxide (6.7 g., 0.17 mole) in water (17 ml.) over a period of 5 minutes. The temperature gradually rose to 30° C. and in 30 minutes all of the carbon disulphide had been consumed in the reaction. Additional carbon disulphide (2 g.) was added and the solution was heated at the reflux temperature for 30 minutes. The excess carbon disulphide was removed by distillation and the clear solution was refluxed for 7 hours. It was cooled and then filtered to remove a small amount of insoluble material. The filtrate was acidified to pH 2 with 10% hydrochloric acid solution and then evaporated to dryness *in vacuo*. The residue was extracted with hot methanol to remove the inorganic salts. The dry residue from the methanolic extract was treated with 5% methanolic hydrogen chloride solution (50 ml.) and allowed to stand at room temperature overnight. The residue from evaporation of the methanolic solution was dissolved in chloroform and the chloroform solution was washed with 5% hydrochloric acid solution, 5% sodium bicarbonate solution, and water. The dried chloroform solution was evaporated to dryness *in vacuo* and the residue was crystallized from cold benzene (60 ml.), yield 11.6 g. (56%). The melting point was raised from 69°–73° C. to 73°–74° C. by one crystallization from methanol–water solution, yield 10.4 g. Anal. Calc. for $C_9H_{16}N_2O_4S$: C, 43.53; H, 6.50; N, 11.28; S, 12.92%. Found: C, 43.93; H, 6.65; N, 11.10; S, 12.65%.

The dimethyl ester of 1,3-di-(β-carboxyethyl) thiourea (5.5 g., 0.02 mole) in a solution of potassium hydroxide (3.7 g.) in water (65 ml.) was heated on a steam bath for 45 minutes. The solution was cooled, acidified to pH 2 with 10% sulphuric acid solution, and then evaporated to dryness. The residue was extracted with acetone (2×100 ml.). After the acetone was evaporated from the combined extracts, the residue was crystallized from acetone–chloroform solution. This procedure gave 4.5 g. (93%) of 1,3-di-(β-carboxyethyl) thiourea melting at 137°–139° C. A further crystallization from the same solvent pair raised the melting point to 138°–139° C. Anal. Calc. for $C_7H_{12}N_2O_4S$: C, 38.18; H, 5.50; N, 12.73; S, 14.56%. Found: C, 38.18; H, 5.66; N, 12.45; S, 14.68%.

1,3-Di-(β-carboxyethyl) Urea

Method A

A solution of 1,3-di-(β-carboxyethyl) thiourea (1.4 g., 0.006 mole) and sodium hydroxide (1.1 g., 0.028 mole) in water (10 ml.) was treated at 20°–25° C. with 32 ml. (0.028 mole) of 0.891 *M* sodium hypochlorite solution. The addition was complete in 5 minutes and the oxidation was allowed to proceed at room temperature overnight. A small amount of insoluble sulphur was removed by filtration, and the filtrate was acidified with 10% hydrochloric acid to pH 2. It was evaporated *in vacuo* on the steam bath to a volume of 20 ml. or until white crystals began to appear. The solution was cooled and the crystals were collected, washed, and dried, yield 1.07 g. (80%). The melting point was raised from 183°–185° C. to 185°–185.5° C. by crystallization from methanol. Anal. Calc. for $C_7H_{12}N_2O_5$: C, 41.17; H, 5.93; N, 13.72%. Found: C, 41.17; H, 5.98; N, 13.68%.

Method B

A mixture of the dimethyl ester of 1,3-di-(β-carboxyethyl) thiourea (10 g., 0.04 mole) and sodium hydroxide (6.4 g., 0.16 mole) in water (70 ml.) was dissolved by slight warming on a steam bath. The solution was cooled and treated with 7.9 *M* hydrogen peroxide solution (20.4 ml., 0.16 mole) at 15°–20° C. The oxidation was allowed to proceed at room temperature overnight, after which the pH of the solution was adjusted to 2 with 37% hydrochloric acid solution. This solution was concentrated *in vacuo* until crystals began to appear. The crystals (m.p. 183°–185° C.) were removed by filtration and dried, yield 7.1 g. (86%). These crystals did not depress the melting point of 1,3-di-(β-carboxyethyl) urea (m.p. 185°–185.5° C.) prepared by Method A.

2-Thio-3-(β-carboxyethyl) Hydrouracil

β-Alanine (75 g., 0.8 mole) and carbon disulphide (35 g., 0.46 mole) in a solution of sodium hydroxide (33.7 g., 0.8 mole) in water (135 ml.) were condensed in the usual manner by refluxing for 7 hours. This solution was cooled, acidified to a pH of 2 with concentrated hydrochloric acid, and evaporated to dryness. The residue was extracted with hot methanol and the methanol extract was taken to dryness *in vacuo*. The residual oil was heated with *p*-toluenesulphonic acid monohydrate (8 g.) at 160°–175° C. *in vacuo* (15 mm.) for 30 minutes. This melt on crystallization from water (200 ml.) gave 38.8 g. (46%) of 2-thio-3-(β-carboxyethyl) hydrouracil (m.p. 163.5°–164.5° C.). Crystallization from acetone–water solution raised the melting point to 166°–167° C. Anal. Calc. for $C_7H_{10}N_2O_3S$: C, 41.57; H, 4.98; N, 13.86; S, 15.86%. Found: C, 41.80; H, 4.89; N, 14.00; S, 15.90%.

In another experiment a mixture of 1,3-di-(β-carboxyethyl) thiourea (0.5 g., 0.002 mole) and *p*-toluenesulphonic acid monohydrate (0.05 g., 0.0003 mole) was heated at 160°–175° C. for 10 minutes. The melt was cooled and crystallized from water (4 ml.) to give 0.4 g. (85%) of 2-thio-3-(β-carboxyethyl) hydrouracil melting at 166°–167° C.

2-Thio-3-(β-carboxyethyl) hydrouracil (0.5 g., 0.002 mole) was heated on a steam bath for 35 minutes in a solution of 85% potassium hydroxide (0.48 g., 0.007 mole) in water (8 ml.). This solution on acidification to pH 2 and evaporation to a small volume gave 1,3-di-(β-carboxyethyl) thiourea (m.p. 137°–138° C.) in 75% (0.41 g.) yield. The product was identified by a mixture melting point determination.

3-(β-Carboxyethyl) Hydrouracil

Method A

A mixture of 1,3-di-(β-carboxyethyl) urea (1 g., 0.005 mole) and acetic anhydride (10 ml.) was refluxed for 15 minutes. The solution was cooled, diluted with 100 ml. of water, and the excess acetic anhydride allowed to hydrolyze. Evaporation of the aqueous solution *in vacuo* on the steam bath gave a crystalline residue. The residue was crystallized from ethanol–benzene solution (10 ml.) to yield 0.59 g. of product. Concentration of the mother liquors gave another 0.1 g. of crystalline product. The total yield of 3-(β-carboxyethyl) hydrouracil (m.p. 178°–184° C.) was 76%. One crystallization raised the melting point to 183°–184° C. A sample of this compound mixed with the starting material, 1,3-di-(β-carboxyethyl) urea (m.p. 185°–185.5° C.), gave a depressed melting point. Anal. Calc. for $C_7H_{10}N_2O_4$: C, 45.16; H, 5.41; N, 15.05%. Found: C, 45.50; H, 5.48; N, 15.23%.

Method B

A solution of 1,3-di-(β-carboxyethyl) urea (0.5 g., 0.0025 mole) in 37% hydrochloric acid solution (3 ml.) was evaporated to dryness in an open beaker on a steam bath. This procedure was repeated twice and the final dry residue was extracted with hot acetone (25 ml.). After the solvent was removed by evaporation, the residue was crystallized from acetone–chloroform solution. The crystals melted at 172°–175° C., yield 0.38 g. (83%). One crystallization from methanol–benzene solution raised the melting point to 181°–182° C. A mixture melting point determination with a known sample of 3-(β-carboxyethyl) hydrouracil gave no depression.

Method C

1,3-Di-(β-carboxyethyl) thiourea (0.27 g., 0.001 mole) in acetic anhydride (5 ml.) was refluxed for 30 minutes. The solution was cooled, poured into ice-water (25 ml.), and the excess acetic anhydride was allowed to hydrolyze at room temperature. The oil remaining after evaporation of the solution was crystallized from acetone–chloroform solution. The

crude crystalline product (m.p. 179°–181° C.) was obtained in 26% (0.059 g.) yield. After two recrystallizations from the same solvent pair it melted at 183°–184° C. alone and on admixture with a known sample of 3-(β-carboxyethyl) hydrouracil (m.p. 183°–184° C.).

PHOTOCONDUCTIVITY AND ABSORPTION AND FLUORESCENCE SPECTRA OF 9,10-DICHLOROANTHRACENE[1]

E. Bock,[2] J. Ferguson,[3] and W. G. Schneider

ABSTRACT

The spectral response, voltage, light intensity, and temperature dependences of the photocurrent generated in crystals of 9,10-dichloroanthracene have been studied as well as the absorption and fluorescence spectra. The magnitude of the measured photocurrent was 10^2–10^3 times larger than that observed in anthracene under similar conditions. The spectral response of the photocurrent in the surface cell arrangement was found to depend on the direction of the incident light relative to the electrodes. Above a certain value of the applied voltage the photocurrent was found to be ohmic. The photocurrent increased as the 0.7 or 0.8 power of the light intensity depending on whether the light was incident on the same side or opposite sides of the crystal face containing the electrodes. When the crystal was cooled the photocurrent passed through a maximum between 20° and 0° C.

The absorption edge of crystalline 9,10-dichloroanthracene as well as the absorption spectrum in chloroform solution were determined. When the crystals were cooled the fluorescence spectrum was observed to shift to longer wavelengths and the intensity increased between two and three times.

INTRODUCTION

Compton and Waddington (1) observed that anthracene crystals treated with either NO_2 or Cl_2 gas showed marked and permanent changes in the photoconduction. They attributed the changes to the formation of complexes between the anthracene and the gases. In the case of Cl_2 there is the possibility of the formation of 9,10-dichloroanthracene under the conditions of their experiments, and it was therefore decided to investigate the photoconduction of this substance in the pure crystalline state. Furthermore, 9,10-dichloroanthracene is an interesting compound in its own right since the presence of the heavy atoms should facilitate internal conversion from singlet to triplet states. The fact that the photocurrents observed were 10^2–10^3 times those usually encountered in anthracene under similar conditions suggests that this mechanism may have some importance, although it is of course not necessarily the determining factor giving rise to the enhanced photoconduction in the present case.

EXPERIMENTAL

Reagent grade 9,10-dichloroanthracene, obtained from Eastman Organic Chemicals, was purified by chromatography through alumina and was then recrystallized from light petroleum.

The crystals were grown from carbon tetrachloride solution as this solvent was found to produce the best crystals. Typical dimensions were: 1×0.2 cm. and $50\pm20\ \mu$ thick. Attempts at growing crystals by sublimation resulted in very thin needles, too fragile for handling.

X-Ray measurements showed the crystals to belong to the orthorhombic system and it was established that most, if not all, of the crystals were multiple twins. The most-developed plane was the (010) face, which is also the twinning plane. The electrodes (colloidal suspension of graphite in alcohol) were both placed on this (010) face with a separation of between 0.6 and 0.8 mm. Electrodes were considered "good" only when

there was no apparent space charge associated with the photocurrent. The photocurrents were measured with a Keithley micromicroammeter and were of the order 10^{-7} to 10^{-11} amp. Since it was observed that air increased the photocurrent, all measurements were carried out in an inert atmosphere of argon. The temperature dependence of the photocurrent was measured with an almost identical arrangement to that of Kommandeur, Korinek, and Schneider (2). The absorption and fluorescence measurements were obtained with a semiautomatic Beckman DU spectrometer.

RESULTS AND DISCUSSION

A. Photoconduction

I. Photocurrent–Wavelength Relation

Fig. 1 shows that the spectral dependence for a surface cell is sensitive to the direction of the incident light. When the electrodes are carefully placed only on one (010) face of the crystal the spectral dependence with the light incident normal to this face is different to the case when the light is incident normal to the opposite (010) face of the crystal. Anthracene sublimation flakes have also been observed to show a variation of the spectral dependence with a surface cell arrangement when the direction of the incident light is changed (3), and this behavior, hitherto unnoticed, may well be quite general and should be looked for in all surface cell measurements.

Fig. 1 also shows the absorption edge of a typical crystal in polarized light. Spectral dependences were determined with polarized light but the differences between the two polarizations are not great and the curves in Fig. 1 are therefore for unpolarized light.

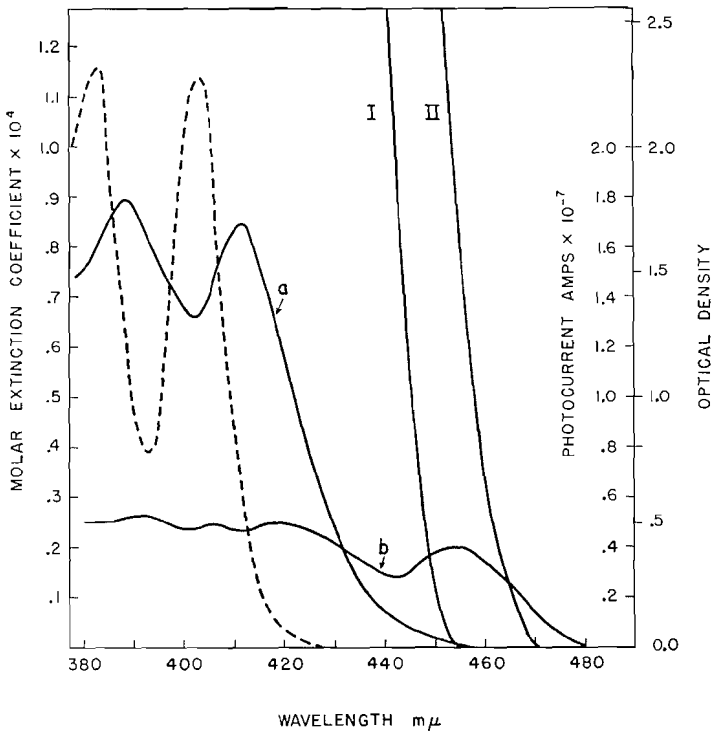

FIG. 1. Broken curve, molar extinction coefficient in $CHCl_3$. *a*, photocurrent with front face illuminated; *b*, photocurrent with back face illuminated. I and II, optical density of crystal: I, light polarized parallel to *c* axis; II, light polarized parallel to *a* axis.

When the light is incident normal to the face on which the electrodes are placed the photocurrent response curve shows two maxima, at 3875 and 4135 Å. Essentially the same spectral dependence was obtained with a total of six crystals. If the spectral dependence is compared with the absorption edge it will be seen that the maximum photocurrent is obtained only at wavelengths well below those corresponding to absorption edge optical densities of 2.0 (99% light absorbed), i.e., at 4415 and 4530 Å. However, if the light is incident on the opposite (010) face of the crystal a marked change is found in the spectral dependence. Only one peak is observed, at 4525 Å, and the response at lower wavelengths is relatively uniform. The peak appears slightly displaced to the long-wavelength side of the absorption edge. Unfortunately the crystals were far too thick to permit the determination of the complete absorption spectrum, and lacking this we cannot say whether there is any relation between the spectral dependence and the absorption spectrum for either of the two arrangements. It is however only in the *latter* arrangement, with the back crystal face illuminated, that the photocurrent reaches a maximum in the vicinity of the absorption edge.

II. Photocurrent – Light Intensity Relation

The photocurrent was found to be proportional to the 0.7 power of the light intensity when the light was incident normal to the face with the electrodes. With the light incident normal to the opposite face the relation involved the 0.8 power of the light intensity. This behavior was found over the whole spectral region from 3800 to 4700 Å, and typical results are shown in Fig. 2.

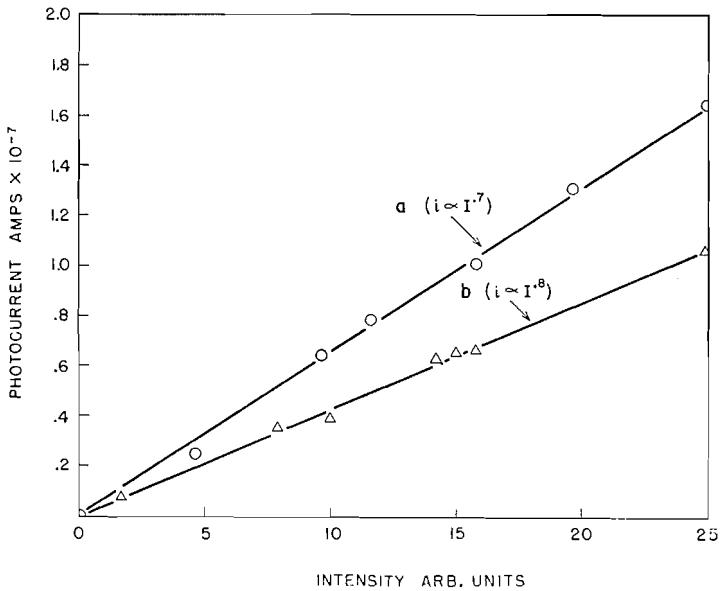

FIG. 2. Light intensity – photocurrent relation: *a*, front face illuminated; *b*, back face illuminated.

The increase of the photocurrent as a fractional power of the light intensity means that the carrier lifetime is shortened when the light intensity is increased (4), presumably by some recombination process.

III. Photocurrent–Voltage Relation

The voltage dependence was determined over the spectral region 3800 to 4700 Å. It was found to increase slowly (see Fig. 3) at low field strengths up to a value, different

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

for each crystal, of about 350 ± 100 v./cm.; above this point the photocurrent increased linearly with applied voltage. This behavior, which was similar when either the front or back crystal face was illuminated, was observed with all crystals measured. No saturation or deviation from linearity was found for the highest field strengths used, about 5000 v./cm.

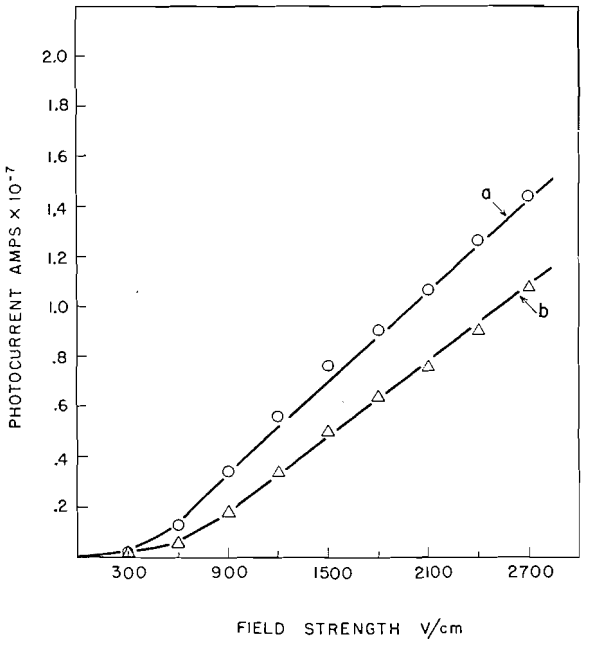

FIG. 3. Voltage–photocurrent relation: *a*, front face illuminated; *b*, back face illuminated.

IV. Photocurrent–Temperature Relation

Kommandeur, Korinek, and Schneider (2) studied the temperature dependence of the photocurrents from a number of organic crystals and they found that the photocurrents decrease exponentially with decreasing temperature. However, when 9,10-dichloroanthracene was cooled the photocurrent was observed to pass through a maximum between 20° and 0° C. On further cooling the photocurrent decreased, but as the crystals are very sensitive to thermal shock this could not be followed accurately. A similar behavior, but at higher temperature, was found by Drefahl and Henkel (5) with 4,4′-diphenylstilbene. This behavior may be related to the increase in the fluorescence efficiency that was found when the crystals were cooled (see below). This observation then supports a growing body of evidence that any process which quenches the electronic excitation energy of a crystal, whether it be energy transfer to an impurity or thermal-induced lattice quenching, leads to a decrease of the photocurrent.

B. Absorption and Fluorescence

As mentioned above in connection with the spectral dependence, all of the crystals were far too thick to penetrate the absorption band so only the absorption edge could be measured. From Fig. 1 it can be seen that this edge is at much longer wavelengths than the absorption band in solution so that intermolecular interactions are considerable.

The number of molecules in the unit cell is uncertain but from what is known about the crystal structure it seems likely that the molecules are stacked with the molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

planes more nearly parallel to the *ab* crystal plane than any other. In addition, the short axis of the anthracene framework lies most likely closer to the *b* crystal axis than the other two. These considerations are in agreement with visual observations of the polarization of the fluorescence emitted normal to the (010) and (100) faces at room temperature, if the molecular transition is polarized along the short molecular axis. These observations are that normal to the (100) plane the fluorescence is strongly polarized parallel to the *b* crystal axis, while normal to the (010) plane the fluorescence is greater along the *a* crystal axis than along the *c*, but the ratio is not as high as in the former case.

The fluorescence spectra reported here were taken normal to the (010) face as this is the most developed. The striking feature of the fluorescence spectrum is that at room temperature the origin lies well inside the absorption edge. This is found only when the fluorescence is observed from the face which is irradiated. When the crystal is cooled the fluorescence spectrum is shifted to longer wavelengths and the relative intensities of individual bands is altered, but the total intensity of emission is increased. These changes are shown in Fig. 4, which records the *a* polarized component (the *c* component is similar

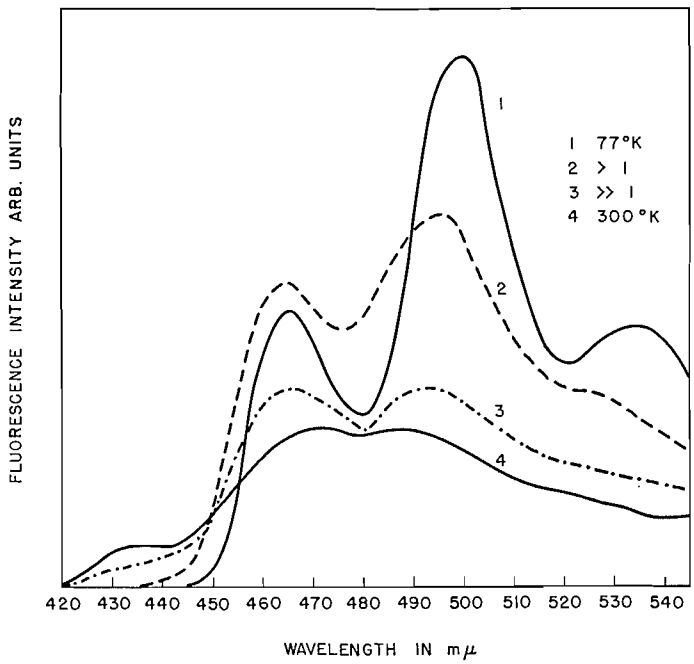

FIG. 4. Fluorescence spectrum at various temperatures: (1) 77° K., (2) >77° K., (3) ≫77° K., (4) room temp. ~290° K.

but weaker by a factor between 3 and 4) at room temperature, 77° K., and two intermediate temperatures. These spectra were all taken without moving the sample or the optical arrangement. All of the crystals examined showed the same fluorescence spectrum at 77° K. and measurements with two crystals at 4° K. produced very little further sharpening of the bands.

We are greatly indebted to Dr. M. Przybylska for crystallographic examinations of 9,10-dichloroanthracene.

THE CHANGE OF PHOTOCONDUCTION AND SEMICONDUCTION IN AROMATIC HYDROCARBONS ON MELTING[1]

J. KOMMANDEUR,[2] G. J. KORINEK,[3] AND W. G. SCHNEIDER

ABSTRACT

The variation of the photocurrent and dark current on melting naphthalene and biphenyl was studied. A large increase in the value of the photocurrent was observed. This change is very similar to that of the dark current. It is concluded that the increased mobilities of the charge carriers in the melt are mainly responsible for the change in both cases. The existence of photoconduction in the non-crystalline state is discussed.

INTRODUCTION

The investigation of various aspects of the photoconductivity of aromatic hydrocarbons has been reported from this laboratory (1, 2, 3). The present communication deals with the changes of the photo- and semi-conduction connected with the transition from crystal to melt.

It was observed earlier by Riehl (4) and Rabinowitch (5) that the semiconductivity of anthracene, paraffin, and naphthalene increases by a factor up to 10^3–10^4 on melting. The change is largest with pure material and single crystals and is less with the increasing amount of impurities or in polycrystalline material. This may explain why some of the earlier investigators (6) did not observe this change.

The large increase in semiconductivity of anthracene, paraffin, and naphthalene on melting is similar to that of ionic conductors. The observed ratio of σ_L, the conductivity of the liquid, to σ_S, that of the solid, is anywhere between 10 and 10^5. This change in conductivity is associated in ionic substances with the large increase in the number of lattice flaws on melting and with the fact that the expansion in volume on fusion reduces the activation energy for migration of the ions.

In contrast with ionic conductors, in metals there is a decrease in conductivity on melting, this being the result of increased scattering of electrons in the molten metal owing to the greater disorder of the atoms.

It was of interest to study the influence of melting on photoconduction, the result of which could possibly contribute to the elucidation of its mechanism. Naphthalene and diphenyl were the substances studied. Both photoconduct, are obtainable as single crystals, and have reasonably low melting points. This condition is of great importance because the semiconduction increases much faster with temperature than the photoconduction and the higher the melting point the greater is the dark current, which may completely mask any change in photocurrent.

EXPERIMENTAL

Naphthalene and biphenyl used were purified by chromatography through alumina and subsequent recrystallization from petroleum ether. The purification was carried out in the dark.

Single crystals were used exclusively. They were grown for us by Dr. F. R. Lipsett in a Bridgman furnace (7). Only those sections of the crystals which were free of flaws were used.

APCO-15 (colloidal graphite in alcohol, supplied by APCO Industries Limited) and silver paste (Hanovia Mfg. Co.) electrodes were used first. Both these electrodes proved unsatisfactory because during the melting they contaminated the melt and increased the semiconductivity by several orders of magnitude. The only arrangement which proved feasible was to carefully melt the crystal at its edges; the melt wetted the platinum electrodes and established the contact.

Because of the known effect of gases on photoconduction all measurements were done on outgassed single crystals in vacuum ($\sim 10^{-5}$ mm. Hg).

The measurements were carried out in a properly shielded glass silica cell (see Fig. 1). The cell was designed in such a way that the field strength was practically the same for

single crystals and the melt. Measurements were taken in the direction of increasing temperature and at temperatures ranging from 290° to 373° K., which include the melting point. The procedure could of course not be reversed, since once the single crystal was melted, subsequent cooling results in a polycrystalline mass.

The cell was mounted on a brass carriage which could at any time be removed or submerged in the water bath. This mounting provided the greatest stability and avoidance of vibrations.

The currents were measured with a Keithley micromicroammeter as described earlier

(3). In the cases where the photocurrent was substantially smaller than the dark current, the latter was "bucked out" by applying an auxiliary e.m.f. from a battery circuit. The ultraviolet light source employed was a BTH direct-current 250 w. mercury lamp, operated from a stabilized (Nobatron) d-c. power source. A filter cutting off all wavelengths shorter than 3000 Å was used.

RESULTS

Fig. 2 shows a plot of the log of the photocurrent vs. $1/T$ for naphthalene. The plot is a fairly straight line until just below the melting point, where a curvature appears. At the melting point there is a sharp rise in the photoconduction by a factor of 10^3. The graph is very similar to Fig. 3, which depicts the dependence of the semiconductivity of naphthalene on temperature. Three crystals of naphthalene yielded results similar to those shown on Figs. 2 and 3.

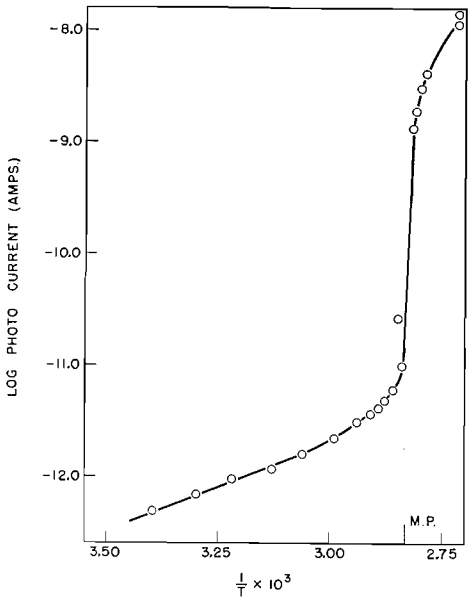

FIG. 2. Change of photocurrent of naphthalene upon melting.

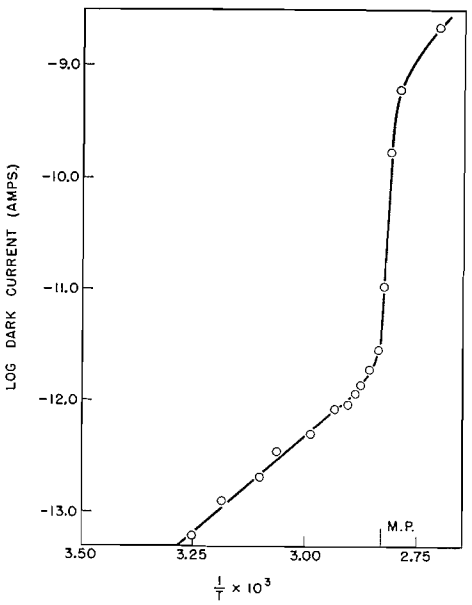

FIG. 3. Change of dark current of naphthalene upon melting.

Figs. 4 and 5 show the dependence of photo- and semi-conduction on temperature for diphenyl. In this case the log of photocurrent vs. $1/T$ dependence is hardly linear even in the intermediate region. The curvature is more pronounced and the rise at the melting point is only about a factor of 10. The logarithm of the dark current vs. the inverse temperature yields a good straight line nearly to the melting point and then a sharp increase by a factor of 10^2. A similar behavior was observed on two other crystals of biphenyl. From the slopes of the dark current vs. $1/T$ plots from room temperature until just below the melting point activation energies were determined from the relation $i = i_0 e^{-E/RT}$. Their average values are 16.5 ± 1.0 kcal. for naphthalene and 16.7 ± 0.7 kcal. for biphenyl. The value for naphthalene is close to that found by Riehl (4). The temperature dependence of the semiconduction of biphenyl has not been reported previously.

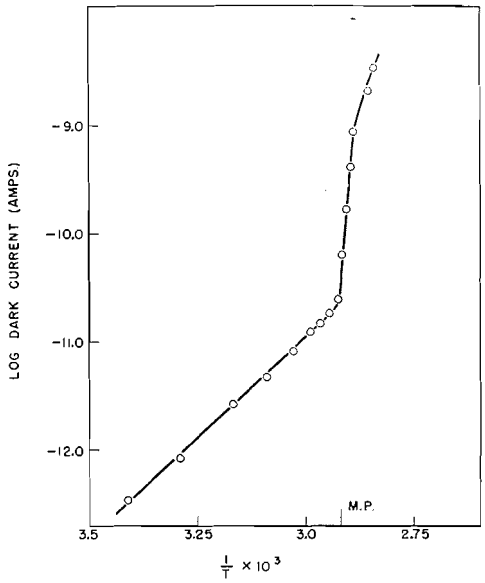

FIG. 5. Change of dark current of diphenyl upon melting.

DISCUSSION

As far as our understanding of the process of melting in the aromatic hydrocarbons goes, we can say that the melting is connected with some increase of positional disorder as evidenced, for example, by the increase in free volume. The fractional increase can be expressed as $f = (V_L - V_S)/V_S$, where V_L is the volume of melt per molecule at the melting point and V_S is the volume of solid per molecule at the melting point. It is of interest to note these values for naphthalene, biphenyl, and anthracene (8), which are: naphthalene, 16.7%; biphenyl, 12.4%; anthracene, 14.1%.

According to Riehl (9), the photoconduction of the solid at the melting point can be expressed by the equation $i_{solid} = CveFe^{-E/RT}$, where C is the concentration of the charge carriers, v the mobility, e the electronic charge, and F the applied field, and similarly in the melt $i_{melt} = C'v'eFe^{-E'/RT}$, where the symbols have the same meaning as above except that they apply to the melt.

Then in the case of naphthalene

$$\frac{i_{melt}}{i_{solid}} = 10^3 = \frac{C'v'eF}{CveF}\frac{e^{-E'/RT}}{e^{-E/RT}}.$$

The quantities which can change are C, v, and E.

The activation energy for the photoconductivity even in the crystal is very low, 2 kcal. (3), and was postulated to be connected with the transport process of the charge carriers through the crystal. Even if the value of the activation energy on going from crystal to the melt decreases to one-quarter of its value, it still cannot explain the large increase in photocurrent. Moreover, all the currents are seen to level off at higher temperatures, so there is no major permanent decrease in the activation energies. Riehl (9) showed that the activation energy for semiconduction undergoes no major change in going from the solid to the melt. Any increase in the activation energy of photoconduction will therefore also be limited. Thus $E \approx E'$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The similarity of the changes of the photocurrent on melting with those of the dark current suggests that in both cases the pronounced change at the melting point has a common underlying cause. It is rather unlikely that the number of charge carriers would be changed by a very similar magnitude on melting irrespective of their being produced thermally as in semiconduction or optically as in photoconduction. Therefore $C = C'$. On the other hand, if on melting the transport of the charge carriers is facilitated, then it would be quite natural to expect a similar change in semiconduction and photoconduction on melting because for the transport process the way the charge carriers have been produced is of secondary importance. Thus $v' \gg v$.

The change in photocurrent as measured would involve any contribution to conductivity by movement of the molecular ions themselves which should be easier in the melt than in the solid. Nevertheless, this contribution should be rather small because (1) of the large size of molecular ions themselves (10); (2) at the melting point and at temperatures not too much above the melting point the melt is composed of clusters rather than of single molecules (8); (3) the activation energy for diffusion and migration of molecular ions should be substantially higher than that of electrons or positive holes.

We can conclude that even if there is a small contribution to the photocurrent in the melt due to the purely ionic conduction and due to the lowering of the activation energy of the charge carrier transport, the main contribution to the large increase of the photo- and semi-conductivity on melting must come from the change in the mobility of the charge carriers.

A further conclusion is that the photoconduction in aromatic hydrocarbons is not limited to the crystalline state. The existence of the photoconduction in the melt, as shown in this paper for naphthalene and biphenyl and also observed for stilbene by Henkel (11), and in a dispersion of anthracene in solid paraffin (down to concentration 2% by weight) (12) shows that an ordered arrangement of molecules in the lattice is not a necessary condition for photoconduction.

THE SYSTEM LITHIUM NITRATE – ETHANOL – WATER AND ITS COMPONENT BINARY SYSTEMS[1]

A. N. CAMPBELL AND R. A. BAILEY[2]

ABSTRACT

The system lithium nitrate – water has been investigated by thermal analysis and by X-ray powder diffraction studies. No trace of the hemihydrate reported by Donnan and Burt was found. The X-ray powder diffraction pattern of $LiNO_3.3H_2O$ has been obtained.

The equilibrium diagram of the system ethanol–water shows an inflection at −30° C., corresponding to 40 weight per cent ethanol. This is almost certainly a true peritectic point. The formula of the hydrate formed (if there is one) is uncertain but it may be $C_2H_5OH.5H_2O$.

The system lithium nitrate – ethanol could only be studied in dilute solution (of lithium nitrate) and at temperatures near room temperature, because of high viscosity and extreme supercooling. No evidence for the existence of a solid alcoholate has been obtained.

The system lithium nitrate – ethanol – water has been investigated in the form of a series of pseudobinary systems containing water and alcohol in fixed ratios. No solid alcoholate of lithium nitrate has been found in solutions containing less than 50 weight per cent ethanol. The investigation could not be pushed beyond this alcohol content because of high viscosity and supercooling.

INTRODUCTION

This study was undertaken as a result of work on the conductance of lithium nitrate in a mixed solvent of water and ethanol (1). We think that, as the alcohol content of such a solvent is increased, the solvation of the lithium ion must change, either progressively or suddenly, from a water solvation to an alcohol solvation, with consequent increase in the effective diameter of the lithium ion. We hoped to support this view by the isolation of a solid crystalline alcoholate of lithium nitrate, analogous to the water compound $LiNO_3.3H_2O$, but it appears, as a result of the work here described, that such an alcoholate does not exist, or at least that it cannot be isolated. Despite the failure of the original aim of this work, much interesting information has resulted, particularly that relating to the important system ethanol–water.

The system lithium nitrate – ethanol – water involves the three binary systems lithium nitrate – water, ethanol–water, and lithium nitrate – ethanol. The latter system has not previously been investigated but the first two have been the subjects of several researches.

The system $LiNO_3$–H_2O was first studied in detail by Donnan and Burt (2). They reported the existence of a congruently melting trihydrate and of a hemihydrate, which decomposed into anhydrous salt and solution at 61.1° C. Campbell and Kartzmark (3) repeated the dilatometric experiments of Donnan and Burt but were unable to find any evidence for the existence of the supposed hemihydrate; neither did hemihydrate appear in their isothermal study at 25° C.

The system ethanol–water has attracted the attention of many workers but much uncertainty has always surrounded it. This system is well known for its anomalous physical behavior, and the large deviations from ideality shown by its physical properties have often been put forward as evidence of compound formation. Maxima, minima, and discontinuities on curves of various physical properties versus concentration have led to the attribution of various formulae to supposed hydrates. A bibliography of the such physical properties as density, change in volume on mixing, and viscosity, as a function of composition of the homogeneous system, it cannot be accepted as evidence

in favor of compound formation. Anomalous physical properties can only indicate that interaction is taking place; they cannot give quantitative information about the nature of such interaction.

The soundest method of dealing with such problems is that of the phase rule and this has been applied as thermal analysis by several workers. The first systematic freezing-point determinations were carried out by Pictet (8) and by Pickering (9) but they were only interested in the point of first crystallization. Pushin and Glagoleva (10) made the first comprehensive thermal analysis and they concluded that no compounds are formed; they suggest, however, that solid solutions of ice in ethanol exist up to nearly 15 mole per cent water. Supercooling is a difficulty which has beset all investigators and this is particularly extensive in the region around 80 mole per cent ethanol.

Tarassenkov (11) repeated the thermal analysis measurements up to 75 weight per cent ethanol. He obtained an inflection on the freezing-point curve which he interpreted as evidence for the existence of a solid hydrate but he failed to obtain a peritectic halt on any cooling curve. The inflection fell at about 42 weight per cent ethanol and at $-33°$ C.

Shalberov and co-workers (12) have studied ethanol in solutions of concentration up to 53 mole per cent, as well as the ternary system ethanol – water – lithium chloride. In both systems they found a point of inflection which, for ethanol and water, fell at 34 weight per cent ethanol. Again, no peritectic halt was obtained. They suggest that the supposed hydrate has the formula $C_2H_5OH.5H_2O$.

Ross (13) determined the freezing points of a number of ethanol–water mixtures. He also obtained an inflection on the freezing-point curve at $-30°$ C. and 42 weight per cent ethanol.

The strongest indication of compound formation in the system ethanol–water is the occurrence of the point of inflection or break in the freezing-point curve but even this, without the presence of a peritectic halt on the cooling curve, cannot be accepted as truly significant unless there is further evidence that a second solid phase separates beyond this point. If this is a true peritectic point, the failure to obtain a peritectic halt is difficult to explain but the reason may lie in the persistent supercooling of alcohol–water mixtures: the peritectic halt may be hidden by the metastability of the system.

Studies of liquid ethanol at low temperatures throw some light on the physical anomalies and metastability of the system ethanol–water. Concentrated alcohol solutions supercool readily and eventually form a rigid glass near $-190°$ C. Prietzschk (14) studied the X-ray scattering at $-150°$ C. and at $-75°$ C. of liquid ethanol. From Fourier analysis he derived a radial intensity distribution curve of the pattern and from this he was able to deduce an average distribution of atoms. The structure thus determined is applicable to cold absolute alcohol and to cold alcohol containing a few per cent of water, and may be expected to give a qualitative indication of the interactions in any alcohol solution. At $-150°$ C., every oxygen atom is linked to two others, presumably by hydrogen bonding. We thus have a structure where the oxygen atoms are linked through hydrogen to form zigzag chains, the C_2H_5 groups lying at right angles to this chain. (Fig. 1 is a plane projection of such a three-dimensional chain.)

Harvey's investigation (15) of ethanol at $-75°$ C. gave the same result as that of Prietzschk. The number of nearest neighbors of each oxygen atom is found to be only older work (4, 5, 6, 7) is given but since all such work consists in the investigation of 1.2 at this temperature. This shows that the hydrogen bonding is becoming less as the temperature increases, but it is still quite appreciable at $-75°$ C.

Perfectly dry ethanol is readily crystallized but the addition of small amounts of water

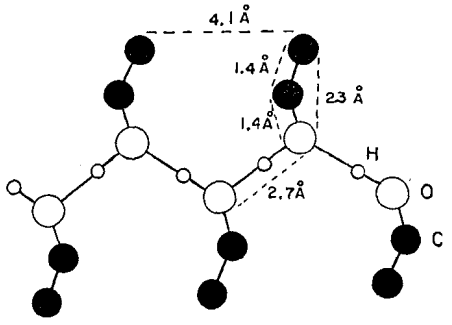

FIG. 1. Structure of absolute alcohol.

renders crystallization extremely difficult. Furthermore, at a given temperature the viscosity is sharply increased by small amounts of water, and the lower the temperature the less water is required for an increase of the same degree. Bernal and Fowler (16) have shown that at low temperatures the oxygen atom of a water molecule can be surrounded by four others, linked to it by hydrogen bonds. It is evident that the oxygen atom of water might equally well be surrounded by four oxygen atoms of ethanol. Therefore, in an alcoholic solution of low water content, we might expect that each water molecule could form the point of linkage of four alcohol chains, if the temperature were low enough. At higher temperatures dissociation would be greater and perhaps only three, or two, alcohol chains would be attached to water. Fig. 2 is a planar diagram

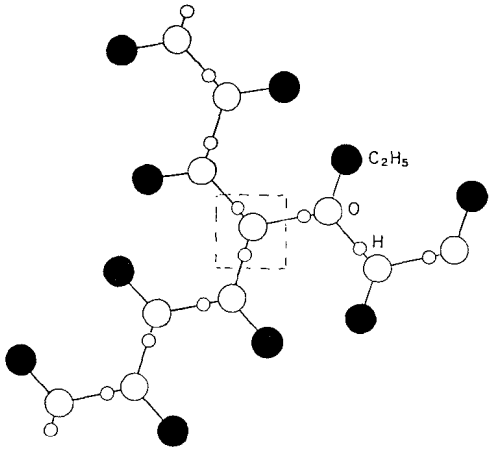

FIG. 2. Structure of "wet" alcohol.

of three ethanol chains linked to a water molecule. Prietzschk has used the viscosity data of Tammann and Hesse (17) to calculate the average length of the alcohol chains linked by water at $-130°$ C.; he finds that there are about 25 molecules of ethanol for each molecule of water, that is, each ethanol chain is six or eight molecules long, depending on whether four or three chains are linked by each water molecule at this temperature.

It is evident that there is a fundamental difference between absolute alcohol and "wet" alcohol, at low temperatures. Pure alcohol is linked only in the form of linear chains but, when water is present, an irregular three-dimensional network is formed which is analogous to the structure in silicate glasses. The lack of the three-dimensional linking in pure ethanol accounts for the comparative ease with which the material is crystallized.

Prietzschk found the powder pattern of solid ethanol to be extremely simple, consisting only of a very broad, intense line, flanked very closely on each side by a sharper but weaker line. Wahl (18) concluded that the crystals of ethanol belong to one of the low symmetry classes but he was unable to obtain further definite information.

As to the ternary system ethanol – water – lithium nitrate, there exists only the isothermal investigation of Campbell and Kartzmark (3) at 25° C., who found no evidence of compound formation between lithium nitrate and ethanol.

EXPERIMENTAL

Purity of Materials

The lithium nitrate was Fisher "Certified Reagent" and it was used without further purification. Water was removed by fusing at least twice. Grinding and transferring were done in a dry-box.

The ethanol used, when absolute alcohol was not required, was purified by distillation through a Podbelniak-type column; the middle third was the only fraction retained. Absolute ethanol was prepared from commercial material by prolonged refluxing with quicklime, followed by treatment of the distillate with magnesium according to the method described by Fieser (19). Absolute alcohol was transferred only in the dry-box. The dryness of the absolute alcohol was constantly tested with aluminum ethoxide by the method of Henle (20), and the density of each new batch was determined.

Methods of Analysis

Lithium nitrate was determined by evaporation to dryness, fusing the residue and weighing. The fusion was repeated at least once, since lithium nitrate is hygroscopic. An accuracy of about 0.1% could be obtained. The ethanol content of a mixture was determined by distilling and determining the density of the distillate.

Apparatus for Thermal Analysis

Glass cells equipped with stirrers and closed from the atmosphere were used. Temperatures were measured with copper–constantan thermocouples, whose e.m.f.'s were recorded by a Brown recording potentiometer. Double or triple copper–constantan junctions were used to increase the sensitivity to the maximum consistent with the range of the recorder. The couples were calibrated from the freezing points of purified, redistilled mercury (f.p. = −38.87° C.), of "spectro" grade carbon tetrachloride (f.p. = −22.8° C.), of reagent grade toluene (f.p. = −95.0° C.), and of "spectro" grade diethyl ether (f.p. = −116.7° C.). Calibration above 0° C. was done by comparison with a previously calibrated mercury-in-glass thermometer reading to 0.1° C.

Both types of freezing-point cell are illustrated in Fig. 3; they differed only in the method of stirring. Both consisted of an inner glass tube containing the solution and surrounded by an outer jacket which could be evacuated as required to reduce the rate of cooling. A well for the thermocouple extended into the solution near the stirrer. The first type of cell (3*a*) was stirred electromagnetically. The second type of cell (3*b*) was used when the viscosity prevented the weaker magnetic stirring of the former type from being effective; most low-temperature work was done in the latter type. Either dry-ice–acetone or liquid nitrogen was used as the cooling agent.

X-Ray Technique

A high-temperature camera of the Buerger type (21) was available and we succeeded in modifying this to take pictures at low temperatures (down to −120° C.). The manner of the modification, and particularly the method of cooling, may be of interest to others; details can be obtained from this laboratory.

EXPERIMENTAL PROCEDURE

The System Lithium Nitrate – Water

This system was submitted to thermal analysis. Since the results showed no indication of the existence of the peritectic point reported by Donnan and Burt (2), and since the work of Campbell and Kartzmark (3) had indicated that the hemihydrate did not exist, X-ray diffraction work was done as an additional check. Diffraction pictures of anhydrous lithium nitrate were taken at room temperature, at 45°, and at 100° C. A second picture was taken at the latter temperature, after prolonged heating, in case any phase transformation occurred slowly. A mixture of lithium nitrate and water was then made up to have a composition corresponding closely to that of the supposed hemihydrate. After this mixture had been maintained at 45° C. for some time, an X-ray diffraction photograph was taken of it.

No diffraction pattern for $LiNO_3.3H_2O$ is listed in the A.S.T.M. index of diffraction patterns, so this compound was photographed at room temperature. For all pictures, copper K_α radiation was used. The standard camera had a diameter of 57.3 mm.

The System Ethanol–Water

In the thermal analysis, little supercooling was encountered in dilute solutions, but as the alcohol content was increased, the supercooling also increased until, beyond 75 weight per cent ethanol, it became extremely difficult to obtain a freezing point at all. Little difficulty from supercooling was encountered with absolute ethanol, but as water was added supercooling increased rapidly.

To investigate the solid phase separating, X-ray diffraction photographs were taken of frozen solutions. Photographs were taken first of ice at temperatures from −20° to −80° C., as a basis of comparison. A series of pictures was also taken of solutions

For personal use only.

containing less than 40 weight per cent ethanol, at various temperatures, particularly above the suspected peritectic temperature of −30° C. If any new phase were to appear, it was expected that it would do so beyond 40 weight per cent ethanol and photographs were taken in this region at a series of temperatures and compositions. The composition was not taken beyond 65% ethanol, since the mixture often refused to crystallize beyond this point, nor was the temperature taken below −100° C. All these pictures were taken with copper K_α radiation and an exposure time of about 1.5 hours. Diffraction pictures were also taken of absolute ethanol, both with copper and with iron radiation, at temperatures between −120° and −130° C.

The System Lithium Nitrate – Ethanol

The thermal analysis of this system could not be carried very far because all solutions were very viscous and supercooled extensively; freezing points could only be determined in solutions containing less than about 6% salt. The solubility curve was therefore determined at 50°, 30°, 20°, 0°, and −21° C. The temperature could not be carried lower than this because the extreme viscosity made sampling impossible. During a determination, sampling was made on successive days, but no change in concentration was found. At low temperatures, the mixture was chilled before stirring to prevent possible supersaturation.

The Ternary System Lithium Nitrate – Ethanol – Water

The first approach to the ternary system involved an attempt to follow the eutectic troughs inward from the lithium nitrate – water edge of the diagram but the high viscosity of the solution made sampling impossible. As an alternative a study was undertaken of a number of pseudobinary systems in each of which the ratio of alcohol to water was kept constant and the concentration of lithium nitrate varied. The freezing points of such pseudobinary systems lie on a straight line radiating from the lithium nitrate apex and cutting the ethanol–water edge at the composition of the solution used as solvent. Only the point of first crystallization may be used since, in general, the crystallization path of the solution does not lie along the line of the pseudobinary "cut". Therefore, the pseudobinary eutectic temperatures can be found accurately only if the original solution has the composition of the eutectic. Since it was not considered worth while for the purpose of this investigation to prepare mixtures having the exact pseudobinary eutectic composition, the eutectic halt of a solution near this point was used. When the solid separating is the anhydrous salt, however, the crystallization path does follow the line of the pseudobinary "cut", and true eutectic temperatures can then be obtained. The same applies to peritectic halts, under the same conditions.

Systems having a fixed lithium nitrate – water ratio can be treated in the same way. Accordingly, the freezing points of systems consisting of the hydrate, $LiNO_3.3H_2O$, to which increasing amounts of ethanol were added, were investigated. This system behaves as a true binary system between the compounds $LiNO_3.3H_2O$ and C_2H_5OH, as long as the trihydrate is the stable solid separating.

EXPERIMENTAL RESULTS

The experimental results are contained in Tables I to XIV. The headings are self-explanatory.

DISCUSSION OF RESULTS

The System Lithium Nitrate – Water

The results, as listed in Table I and shown graphically in Fig. 4, are not in complete

66.4	70.0	27.9	"
66.9	75.6	27.9	"

agreement with those of Donnan and Burt (2). The ice–trihydrate eutectic lies at −22.9° C. and 24.5 weight per cent lithium nitrate; this is at both a lower temperature and a lower concentration than reported by Donnan and Burt (−17.8° C., 33 weight per cent lithium nitrate). The values for the higher eutectic, 27.9° C. and 61.5 weight per cent lithium nitrate, are also different from those previously accepted (29.6° C., 59 weight per cent $LiNO_3$). Here, trihydrate is in equilibrium with anhydrous lithium nitrate (and solution) and not with hemihydrate, as the previous study had supposed. The melting point of lithium nitrate trihydrate was found to be 29.6° C.

All the X-ray pictures taken on anhydrous lithium nitrate between room temperature and 100° C. were identical, showing that only one phase of anhydrous salt exists between these temperature limits. A mixture of lithium nitrate and water, corresponding in composition to the supposed hemihydrate, gave only the pattern of anhydrous salt (above 27.9° C.). This evidence, together with the observations of Campbell and Kartzmark (3), refutes the claim that a hemihydrate exists.

The X-ray powder diffraction pattern for $LiNO_3.3H_2O$ is listed in Table II. Relative intensities were estimated visually, the strongest line being assigned an intensity of 10. The trihydrate pattern has many lines in common with the anhydrous salt.

The System Ethanol–Water

The results of thermal analysis are listed in Table III and the equilibrium diagram is shown in Fig. 5. It was found that supercooling increased with ethanol content and became extremely persistent beyond 75 weight per cent ethanol, where it was impossible to detect an initial freezing point although eutectic halts could be obtained with solutions up to the eutectic composition. On the alcohol side of the eutectic, supercooling and viscosity increased with increasing water content but reasonably good freezing points could be observed up to the eutectic point. No eutectic halts were obtained in this region and this may be an indication that the solid solution formation reported by Pushin (10) does indeed exist.

Formation of solid solution is most common between substances having similar crystal structure, although this is by no means a necessary condition. Ice crystallizes in the hexagonal system but, although the structure of the ethanol molecule is known, nothing is known about the crystal structure of solid alcohol; the direct observations of Wahl

(18) indicate that solid ethanol has a very unsymmetrical form. This may easily be so, if the crystal is made up from the irregular chains of ethanol molecules which Prietzschk (14) has shown to be present in the cold liquid. It would then be possible for water to enter such a crystal lattice as part of an alcohol chain, or even as the point of linkage of two or more chains, since Prietzschk shows that such linkage certainly occurs in the "wet" liquid. Formation of solid solutions of ice in ethanol may thus be accounted for without the assumption of similar crystal structures.

The freezing-point curve shows the inflection previously found by Tarassenkov (11) and by Shalberov *et al.* (12) but no peritectic halt was ever observed. The inflection occurs at −30° C. and 39.5 weight per cent ethanol. We find the eutectic to lie at −124.1° C. and about 93.0 weight per cent ethanol, whereas Pushin and Glagoleva (10) reported the values −118° C. and 93.5 weight per cent ethanol, for this point. The freezing point of absolute ethanol was found to be −114.4° C., agreeing within the experimental error with the generally accepted value of −114.6° C.

The results of X-ray diffraction studies at low temperatures are collected in Tables IV, V, and VI, which list the spacings and intensities of the lines from diffraction photographs of ice, of dilute ethanol solutions (i.e. solutions containing less than 30% by weight of ethanol), and of more concentrated ethanol solutions, respectively. The pictures in all cases showed much background darkening and the lines were quite broad, since it

was necessary to use wide capillaries to prevent separation of the liquid column on cooling, so that no great accuracy in the measurements of the spacings could be obtained. Although the nominal diameter of the camera was 57.3 mm., the fact that the ice pattern, the mean of four pictures, has spacings consistently larger than those listed in the A.S.T.M. index and determined by Dennison (22) and by Barnes (23) indicates either that the camera is slightly smaller than the figure given above or that shrinkage of the film occurred. No attempt was made to calibrate the camera, since only comparative results were desired and, in any case, the discrepancy is not large. Neither the strong line of spacing $d = 3.67$ Å nor the weaker line at $d = 3.44$ Å could be found but a strong line was observed at $d = 3.55$ Å and this is probably equivalent to the two missing lines. A very weak line at $d = 4.14$ Å, which does not appear in the literature tabulation, also occurred.

The diffraction patterns of dilute alcohol solutions taken under such conditions that no compound could be formed (i.e., at temperatures above that of the point of inflection) were not good. The lines were quitè diffuse, largely owing to unfrozen liquid in the tests. The results agree fairly well with the literature tabulation for ice, although an additional line at $d = 3.76$ Å appeared in three cases and many of the weaker lines were absent.

The pattern given by solutions containing more than 40% by weight ethanol is listed in Table VI. A total of 10 pictures containing distinguishable lines were used. These pictures were little better than those taken in dilute solutions and the lines were particularly broad, since in general wider capillaries were required for such solutions. Few lines were obtained; only three appeared at all consistently. Of these, the first, at $d = 3.61$ Å, lies close to the position of a strong line in the ice pattern. Since this line is both weak and diffuse, there is the possibility that it is due to ice deposited on the outside of the capillary, from moisture present in the camera at the beginning of the run, but it is difficult to see how enough ice could be deposited in this way to give an observable line; it is probably a true line from the specimen. The other two lines, both strong and both nearly always present, are quite far removed from any ice lines. This is particularly true of that falling at $d = 2.97$ Å. The other line falls at $d = 3.32$ Å. These two lines were predominant on the diffraction patterns of solutions of alcohol exceeding 40 weight per cent ethanol and taken at temperatures between −35° C. and −90° C. The temperature was never taken as low as the freezing point of ethanol, so the lines cannot be due to solid alcohol. Moreover, they do not appear on any picture of ice at any temperature, or of more dilute solutions of alcohol at temperatures above −30° C. They can only be explained by the formation of a new solid phase separating from solution. They indicate that an incongruently melting hydrate of ethanol may be formed and that therefore the point of inflection on the freezing curve is a true peritectic point.

A few solutions of roughly the expected composition of the hydrate, $C_2H_5OH.5H_2O$, were made up and photographed at temperatures well below the supposed peritectic temperature. These pictures showed only the ice pattern, whereas, if a compound is formed, lines from it also should be present. This behavior can only be explained if the system cools metastably past the peritectic temperature, the reaction "ice + solution → compound" failing to take place. The absence of a peritectic halt on the cooling curve can be explained in the same way. The spacings measured from these diffraction patterns are not highly accurate and any picture alone would be of doubtful value because of the broad lines and the generally dark background. As a group, however, the results are consistent, and errors in the spacings listed are not great enough to invalidate the general conclusion.

The question of the composition of this hypothetical hydrate of ethanol cannot be answered with certainty. The position of the point of inflection corresponds to an alcohol: water ratio of 3.98, but the compound must contain more water than this. Although the formula $C_2H_5OH.4H_2O$ is possible, it is unlikely, since this composition is so close to the composition of the peritectic point. Perhaps the most probable formula is that proposed by Shalberov (12), viz. $C_2H_5OH.5H_2O$.

The diffraction photographs of absolute ethanol resulted only in a single broad line of strong intensity at $d = 3.89$ Å. This is the result of two pictures, one taken with copper, the other with iron, radiation. The latter was used in the hope that it would result in the resolution of the single line into the closely spaced triplet observed by Prietzschk (14), but it did not. The position of the single line was similar to that of the triplet in the photograph published by Prietzschk but, unfortunately, he does not indicate any spacings.

The System Lithium Nitrate – Ethanol

The results obtained by thermal analysis are shown in Table VII. Only quite dilute solutions could be frozen, the supercooling increasing with lithium nitrate content. No eutectic halt could be detected. Solubility measurements are summarized in Table VIII.

A plot of freezing point and solubility data, as in Fig. 6, shows that, in order that the two curves may intersect without compound formation, the eutectic point must lie unusually far into the diagram. For systems involving substances whose melting points are so dissimilar as are those of ethanol and lithium nitrate, it is seldom that the eutectic lies more than a short distance from the axis of the lower-melting compound. It is therefore quite possible that an alcoholate of lithium nitrate may exist in the solid state.

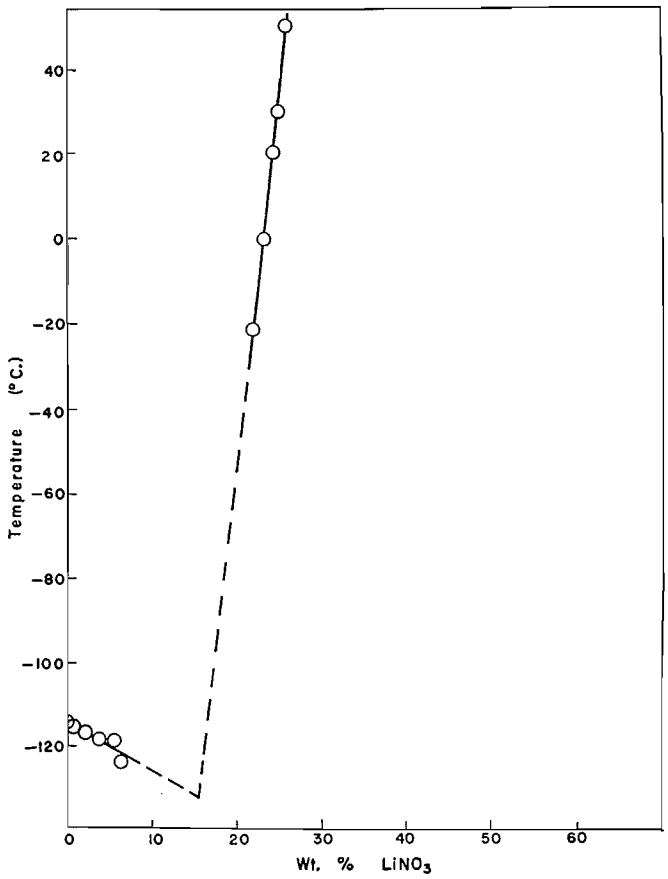

FIG. 6. The system $LiNO_3$–C_2H_5OH.

The very great viscosity of alcoholic lithium nitrate solutions at low temperatures indicates some sort of interaction between ethanol and lithium nitrate. It is very probable that the strongly electropositive lithium ion and the electronegative oxygen of the alcohol will exhibit strong electrostatic attraction, just as do lithium ion and water. Since at low temperatures the ethanol molecules are linked in chains, the lithium ions could be solvated by a number of these chains and they would, in effect, form the points of linkage of them.

The System Lithium Nitrate – Ethanol – Water

Five pseudobinary "cuts" in which lithium nitrate was dissolved in solvents of fixed ethanol: water ratio were made through the ternary system. The solvents were 27.2,

42.0, 49.7, 66.4, and 78.2 weight per cent ethanol. Tables IX to XIII give the thermal analysis data, while Figs. 7 to 11 show the freezing-point curves which were obtained. It was found that supercooling increased with alcohol content except when anhydrous lithium nitrate was the solid phase, when it was nearly negligible even in solutions containing considerable quantities of alcohol. Supercooling was especially pronounced with solutions in 78.2% ethanol, and freezing points below −20° C. could not be obtained.

The system lithium nitrate trihydrate – ethanol is shown in Fig. 12 and the thermal analysis data are given in Table XIV. Some of the points are taken from the freezing-point curves of the other pseudobinary systems.

Figs. 13 and 14 show the ternary system as a whole, so far as we have been able to determine it. In Fig. 13, a series of isothermal solubility lines are depicted. These were obtained from the various pseudobinary "cuts" by reading off the compositions corresponding to each temperature. Isothermals at 25°, 20°, 15°, 10°, 0°, −15°, −35°, and

−60° C. are shown, as well as the line in the ice region at −20° C. In Fig. 14, only the eutectic and peritectic troughs are shown. Again, the composition data were obtained from the pseudobinary cuts.

Some uncertain indications, not described here, have been obtained of the existence of a ternary compound (incongruently melting), such as $LiNO_3.2C_2H_5OH.H_2O$, but the evidence is extremely inconclusive.

It is reasonably certain that no alcoholate of lithium nitrate crystallizes from solutions of less than 50 weight per cent ethanol, but in more concentrated alcohol solutions the nature of the solid phase is uncertain. When the solvent contained more than 80% ethanol, pronounced supercooling made experimental study impossible.

THE CONDENSATION OF FURAN WITH CARBONYL COMPOUNDS[1]

WILLIAM H. BROWN AND WARREN N. FRENCH[2]

ABSTRACT

A homologous series of substituted quaterenes has been synthesized by the condensation of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] with keto acids and their esters. Substituted quaterenes containing chlorine have also been prepared. Only one out of the theoretically possible four geometrical isomeric quaterenes which could arise from the condensation of furan with butanone has been isolated. In all instances where more than one geometrical isomeric quaterene would be theoretically possible, only one has been isolated. Two new dinitro compounds have been prepared by the nitration of 2,2-difurylbutane and 3,3-difurylpentane.

Recently, Ackman, Brown, and Wright (1) reported the formation of difurylalkanes by the condensation of furan with the corresponding methyl ketone in the presence of hydrochloric acid. Brown and Sawatzky (2) and Beals and Brown (3) have extended the series to include the condensation of furan with aldehydes, chlorinated aldehydes and ketones, keto acids, and 3-pentanone.

The difurylalkane, 2,2-difurylpropane, has been isolated from the reaction mixture of furan with acetone. Subsequent reaction between two molecules of 2,2-difurylpropane and two molecules of acetone with the elimination of two molecules of water leads to the formation of a cyclic compound (II; R, R_1, R_2, R_3 = Me) composed of four residues each of furan and acetone. This cyclic compound has been assigned the trivial name "octamethyl-tetroxaquaterene". "Quaterene" denotes a closed system composed of four methylene-bridged 1,4-disubstituted cyclopentadienes (1). Another product of the condensation of furan with acetone is 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] (I; R, R_1, R_2 = Me), which condenses with one molecule of acetone to form the same octamethyl-tetroxaquaterene.

In the present investigation, two quaterenes containing chlorine were synthesized. Treatment of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] [I; R, R_1, R_2 = Me) with chloroacetone in the presence of hydrochloric acid gives the expected 2-chloromethyl-2,7,7,12,12,17,17-heptamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1, R_2 = Me; R_3 = CH_2Cl). The other quaterene containing chlorine, 2,12-*bis*(chloromethyl)-2,7,7,12,17,17-hexamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1 = Me; R_2, R_3 = CH_2Cl), is formed by the condensation of 2,2-difurylpropane with chloroacetone. While two geometric isomers (*cis* and *trans*) of the latter quaterene are possible, only one was found. A compound having the same structure would also be expected as a result of the condensation of 2,2-difuryl-1-chloropropane with acetone. This possibility has been previously investigated (4). No reaction was observed.

The presence of halogen in the carbonyl compound appears to inhibit the above condensations since lower yields of the condensation product are obtained when chloroacetone is used in place of acetone. Chlorinated aldehydes and ketones containing two or more chlorine atoms, such as *sym*dichloroacetone, do not undergo complete condensation with I (R, R_1, R_2 = Me) to form quaterenes. The reaction probably proceeds to the carbinol stage but further condensation is prevented by the negative chlorine atoms. Carbinol formation has been demonstrated by Willard and Hamilton (5). They found that furan condenses with chloral to form 1-furyl-2,2,2-trichloroethanol.

Other substituted quaterenes are formed by the condensation of keto acids or their esters with 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] (I; R, R_1, R_2 = Me). Thus pyruvic acid, methyl and ethyl acetoacetate, levulinic acid, and methyl levulinate react with I (R, R_1, R_2 = Me) to give the corresponding substituted tetroxaquaterenes. Since the condensations were all carried out using absolute alcohols as the reaction solvent and hydrogen chloride as the condensing agent, esterified products resulted: viz., methyl and ethyl esters. Transesterification can also occur during the reaction since the condensation of I (R, R_1, R_2 = Me) with methyl levulinate results in the formation of the corresponding ethyl ester with ethanol as the reaction solvent. The products are listed in Table I. Each

ethyl ester condensation product was hydrolyzed to the corresponding free acid and then treated with diazomethane to give the methyl ester. The same methyl ester is formed by the condensation of I (R, R_1, R_2 = Me) with a keto acid or methyl ester in methanol.

Inspection of Table I shows that the carboxyl group exerts a deactivating influence on the condensation when in proximity to the carbonyl group. Thus pyruvic acid gives a lower yield than levulinic acid under similar conditions. Yields are also lower when methanol rather than ethanol is the reaction solvent, probably owing to greater furan ring fission by methanolic hydrogen chloride than by ethanolic hydrogen chloride.

Ackman, Brown, and Wright (1) have also investigated the condensations of furan with butanone, methyl *n*-propyl ketone, methyl isobutyl ketone, and methyl *n*-amyl ketone. In each case, only one out of the possible four geometric isomers of the tetroxaquaterene has been isolated. One would expect to find more than one geometric isomer since the condensation of 2,2-difurylbutane with acetone yields the two expected geometric isomers (*cis* and *trans*) in the ratio of about 8 to 1 (1). A search for other isomers was considered to be important because of the alternative paths of formation of a tetroxaquaterene by the condensation of either I or a difurylalkane with the parent ketone.

In the present investigation, a search for additional isomeric tetroxaquaterenes was made in the reaction mixture resulting from the condensation of furan with butanone. The progenitor of the reaction, 2,2-difurylbutane, has previously been isolated (1). It condenses with butanone to form only one geometric isomer of 2,7,12,17-tetraethyl-2,7,12,17-tetramethyl-21,22,23,24-tetroxaquaterene (II; R = Me; R_1, R_2, R_3 = Et). A third product, thought to be 2,5-*bis*(ethylmethylfurfuryl)furan (III), has now been isolated from the condensation of furan with butanone. It is not a direct intermediate in the formation of the tetroxaquaterene. A fourth compound which was obtained by us is 2,2-butylidene-*bis*[5-(ethylmethylfurfuryl)furan] (I; R = Me; R_1, R_2 = Et) which condenses with butanone to yield a single tetroxaquaterene identical with the one formed from 2,2-difurylbutane and butanone. No additional isomeric tetroxaquaterenes were found in the original reaction mixture.

An inspection of the formula of I (R = Me; R_1, R_2 = Et) shows that it could exist as three diastereomers, one of which should be resolvable. Similarly, III could exist as two diastereomers, one of which should be resolvable. However, only one form of each was isolated by fractional distillation of the reaction products. Attempts to form derivatives of I (R = Me; R_1, R_2 = Et) and III having a functional group suitable for resolution purposes were unsuccessful. Nitration, aminomethylation, and acetylation reactions all gave resinous products while the condensation of I (R = Me; R_1, R_2 = Et) with keto acids gave products in insufficient yield for resolution.

The absence of possible geometric isomers of substituted quaterenes has also been noted in the pyrrole series. Chelintzev and Tronov (6) have reported that only two of the four theoretically possible isomers are obtained from the condensation of pyrrole with butanone. One geometric isomer was found to be in preponderance.

The existence of only one isomeric form of the quaterene from furan and butanone implies that the condensation is strongly influenced by steric factors which compel the reaction to proceed in such a manner as to form only one geometric isomer.

Two new dinitro compounds, 2,2-*bis*(5-nitrofuryl)butane and 3,3-*bis*(5-nitrofuryl)-pentane, have been prepared from the corresponding difurylalkanes using a nitration procedure typical for furans. The other member of the series, 2,2-*bis*(5-nitrofuryl)propane, has been previously reported (1). The data for these compounds are recorded in Table II.

Although the nitration of 1,1-difurylethane appears to proceed normally, the products are quite unstable.

TABLE II

NITRATION PRODUCTS OF DIFURYLALKANES

Compound nitrated	% yield	Melting point	Molecular formula	Analysis, % N	
				Calc.	Found
1,1-Difurylethane		No product isolated			
2,2-Difurylpropane (1)	57	135.0–135.5	$C_{11}H_{10}N_2O_6$	10.53	10.33
2,2-Difurylbutane	59	84.0–84.5	$C_{12}H_{12}N_2O_6$	10.00	9.40
3,3-Difurylpentane	67	120.0–120.5	$C_{13}H_{14}N_2O_6$	9.52	9.10

EXPERIMENTAL

All melting points have been corrected against reliable standards. Molecular weights were determined by the Rast method. A typical preparative method for the substituted quaterenes listed in Table I is given for the condensation of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] (I; R, R_1, R_2 = Me) with levulinic acid and its methyl ester. The other substituted quaterenes in Table I may be obtained by a similar procedure using acetoacetic esters or pyruvic acid. The nitrated difurylalkanes were prepared by the method of Ackman, Brown, and Wright (1).

2-Chloromethyl-2,7,7,12,12,17,17-heptamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1, R_2 = Me; R_3 = CH_2Cl)

A solution of 0.4 g. (0.001 mole) of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] (I; R, R_1, R_2 = Me) and 0.93 g. (0.01 mole) of chloroacetone in 5 ml. of commercial absolute ethanol was saturated with anhydrous hydrogen chloride gas. The solution turned deep red and crystals began to form immediately. The solid was filtered off and washed with 5 ml. of ethanol to give 0.26 g. (56%) of crude product, m.p. 214°–216°. Crystallization from an ethanol–benzene mixture gave 0.20 g. (43%) of white needles, m.p. 219.5°–220.0°. Anal. Calc. for $C_{28}H_{31}ClO_4$: Cl, 7.60; mol. wt., 467. Found: Cl, 7.80; mol. wt., 475.

2,12-Bis(chloromethyl)-2,7,7,12,17,17-hexamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1 = Me; R_2, R_3 = CH_2Cl)

A solution of 1.76 g. (0.01 mole) of 2,2-difurylpropane and 0.93 g. (0.01 mole) of chloroacetone in 10 ml. of absolute ethanol was saturated with anhydrous hydrogen chloride gas. The solution turned a deep red and solid material began forming in 2 hours. After 2 days, a sticky yellow material was filtered off and successively leached with 10-ml. portions of boiling ethanol. The first leaching contained 0.26 g. of sticky yellow material, and the following seven a total of 0.29 g. (11.5%) of white needles. Crystals from the second extract had a m.p. of 201.0°–203.5°, while those from the seventh had a m.p. of 211.0°–211.5°. The crystalline products were combined and crystallized from a 1:1 ethanol:benzene mixture (20 ml./g.) to give 0.15 g. (6.0%) of white needles, m.p. 211.0°–211.5°. Anal. Calc. for $C_{28}H_{30}Cl_2O_4$: Cl, 14.1; mol. wt., 501. Found: Cl, 14.0; mol. wt., 498.

2-Carbethoxyethyl-2,7,7,12,12,17,17-heptamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1, R_2 = Me; R_3 = $CH_2CH_2COOC_2H_5$)

A solution of 1.0 g. (0.00025 mole) of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] (I; R, R_1, R_2 = Me) and 0.58 g. (0.005 mole) of levulinic acid in 10 ml. of absolute ethanol was saturated with anhydrous hydrogen chloride gas. The solution became deep red and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

cloudy within 3 minutes. After 20 hours, the mixture was filtered to give 0.93 g. of a yellow solid. Crystallization from ethanol gave 0.77 g. (63%) of light yellow crystals, m.p. 146.0°–147.5°. A second crystallization, including treatment with charcoal, resulted in 0.49 g. (40%) of white needles, m.p. 153°. Anal. Calc. for $C_{32}H_{38}O_6$: OC_2H_5, 8.69; mol. wt., 519. Found; OC_2H_5, 8.87; mol. wt., 517.

2-Carboxyethyl-2,7,7,12,12,17,17-heptamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1, R_2 = Me; R_3 = CH_2CH_2COOH)

A solution of 0.25 g. (0.00048 mole) of the ethyl ester obtained as above in 20 ml. of *N*/1 solution of ethanolic potassium hydroxide was refluxed for 2 hours. After acidifying with glacial acetic acid, water was added until the saturation point was reached. On cooling, the resulting solid was removed by filtration and crystallized from benzene to give 0.11 g. (45%) of white needles, m.p. 225.5°–226.0°.

2-Carbomethoxyethyl-2,7,7,12,12,17,17-heptamethyl-21,22,23,24-tetroxaquaterene (II; R, R_1, R_2 = Me; R_3 = $CH_2CH_2COOCH_3$)

(*a*) *From 2,2-isopropylidenebis[5-(dimethylfurfuryl)furan] and levulinic acid in methanol.*—A solution of 0.4 g. (0.001 mole) of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] and 0.58 g. (0.005 mole) of levulinic acid in 5 ml. of absolute methanol was saturated with hydrogen chloride gas. The solution slowly turned deep red with the formation of a yellow oil. Solid material began forming after 30 minutes. After 22 hours, a light yellow solid was removed by filtration. Crystallization from methanol, including treatment with charcoal, gave 0.17 g. (34%) of white needles, m.p. 157.5°. Anal. Calc. for $C_{31}H_{36}O_6$: OCH_3, 6.15. Found: OCH_3, 6.13.

(*b*) *From treatment of the acid* (II; R, R_1, R_2 = Me; R_3 = CH_2CH_2COOH) *with diazomethane.*—A solution of 0.10 g. of the acid obtained as above in ether was treated with an ethereal solution of diazomethane to give a product with a melting point of 157.5°. A mixture melting point with the methyl ester obtained in (*a*) showed no depression.

(*c*) *From 2,2-isopropylidenebis[5-(dimethylfurfuryl)furan] and methyl levulinate in methanol.*—Treatment of a solution of 0.4 g. (0.001 mole) of 2,2-isopropylidene*bis*[5-(dimethylfurfuryl)furan] and 0.65 g. (0.005 mole) of methyl levulinate in 5 ml. of absolute methanol with anhydrous hydrogen chloride gas resulted in 0.17 g. (34%) of crude product, m.p. 155.5°–156.5°. Crystallization from methanol (35 ml./g.) gave 0.09 g. (18%) of white needles, m.p. 157.7°. A mixture melting point with the compound obtained in (*a*) showed no depression. When the above reaction (*c*) was carried out using ethanol as a solvent, the ethyl ester condensation product was obtained in 47% yield.

2,2-Difurylbutane

In a three-necked 2-liter flask, fitted with reflux condenser, mechanical stirrer, and dropping funnel, were placed 340 g. (5.0 moles) of furan, 150 ml. of commercial absolute ethanol, and 100 ml. of 37% hydrochloric acid solution. To this mixture was added dropwise, while stirring, 180 g. (2.5 moles) of butanone. The addition of butanone was complete after 60 minutes, during which time no heat was evolved and the reaction mixture had taken on a reddish tinge. When stirring was discontinued after 190 hours, the mixture separated into two phases. The lower dark orange organic phase was separated from the upper pink aqueous phase and washed with 5% sodium bicarbonate solution until neutral. It was then dried over anhydrous magnesium sulphate. After the excess furan and butanone were flashed off, the residual oil was fractionally distilled under reduced pressure.

The first fraction, a colorless oil, boiled at 64°–66° (1 mm.), and weighed 71 g. (15%).

2,5-Bis(ethylmethylfurfuryl)furan (III)

A second fraction from the preceding distillation was a pale yellowish-green oil boiling at 143°–145° (1 mm.). It weighed 168 g. (43%), η_D^{20} 1.5094, d_4^{20} 1.045. Anal. Calc. for $C_{20}H_{24}O_3$: C, 76.9; H, 7.74; mol. wt., 312. Found: C, 76.6; H, 7.54; mol. wt., 327.

2,2-Butylidenebis[5-(ethylmethylfurfuryl)furan] (I; R = Me; R_1, R_2 = Et)

A third fraction from the preceding distillation, a viscous, fluorescent, yellow oil, boiled at 205°–210° (1 mm.). It weighed 82.8 g. (23%), η_D^{20} 1.5173, d_4^{20} 1.046. Anal. Calc. for $C_{28}H_{34}O_4$: C, 77.4; H, 7.89; mol. wt., 435. Found: C, 77.0; H, 7.79; mol. wt., 400.

2,7,12,17-Tetraethyl-2,7,12,17-tetramethyl-21,22,23,24-tetroxaquaterene (II; R = Me; R_1, R_2, R_3 = Et)

(*a*) *From 2,2-difurylbutane and butanone.*—The method of Ackman, Brown, and Wright (1) was used. A solution of 1.0 g. (0.0052 mole) of 2,2-difurylbutane and 3.0 g. (0.042 mole) of butanone in 10 ml. of absolute ethanol was saturated with anhydrous hydrogen chloride gas. Purification of the resulting solid resulted in 0.335 g. (27%) of white needles, m.p. 174°.

(*b*) *From 2,2-butylidenebis[5-(ethylmethylfurfuryl)furan] and butanone.*—A solution of 1.1 g. (0.025 mole) of I (R = Me; R_1, R_2 = Et) and 1.9 g. (0.025 mole) of butanone in 10 ml. of absolute ethanol was saturated with anhydrous chloride gas. The solution turned a deep cherry red and crystals began to form. On cooling, the mixture was filtered and the residue washed with 5 ml. of 95% ethanol to give 1.06 g. (87%) of light yellow needles, m.p. 169°–170°. Crystallization from absolute ethanol gave 0.78 g. (65%) of shiny white needles, m.p. 174°. A mixture melting point of this compound with the one obtained in (*a*) showed no depression.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the National Research Council for financial assistance to one of us (W.N.F.).

We are indebted to the du Pont Company of Canada for generous supplies of furan.

THE MOLECULAR WEIGHT OF POLYVINYL ACETATE[1]

A. F. Sirianni, R. Tremblay,[2] and I. E. Puddington

ABSTRACT

The molecular weights of a series of unfractionated polyvinyl acetates of low degrees of polymerization have been measured by determining the lowering of the vapor pressure of their solutions. An approximate molecular-weight range of 5000–40,000 was examined. While most of the determinations were made in benzene solutions at 55° C., other solvents and temperatures were used. Anomalous results were obtained with one sample of fractionated material.

INTRODUCTION

A method for the determination of the molecular weights of chemical compounds based on measurements of the difference in vapor pressure between solutions of these compounds and the pure solvents has already been described (1). The previous publications dealt with the behavior of substances of known chemical constitution having molecular weights below about 1000 when examined in a variety of solvents and concentrations and over a range of temperatures.

The present communication describes results obtained with a series of commercial vinyl acetate polymers of comparatively low degree of polymerization. The individual samples, designated as Gelva 1.5, 2.5, 2.61, 7, 10, and 15, were obtained through the courtesy of Shawinigan Chemicals Ltd. The range of molecular weight covered by the series is approximately 5000 to 40,000. A single sample of fractionated polyvinyl acetate recovered from a solution was also examined.

APPARATUS AND EXPERIMENTAL

The apparatus and experimental technique have been described elsewhere (1). Molecular-weight determinations were usually carried out in benzene solution at 55° C. In some instances, however, other temperatures were used and a few determinations were made in acetone, methanol, and ethanol.

About 1 to 8 mg. of the dried polymer was weighed from the bulk sample into a 4 mm. i.d. pyrex tube and anchored to the bottom of the sample holder with a drop of distilled solvent. The occasional sample of polymer was prepared in powder form by freeze-drying its benzene solution. No difference in behavior during subsequent operations was found with samples prepared in this manner, however, and the simpler procedure was generally used. A metal stirrer about 1.5 cm. in length enclosed in a glass sheath was inserted into the tube containing the sample. The sample holder was sealed to the apparatus and the pressure reduced to about 10^{-5} mm. Hg. The apparatus was then flushed out with solvent vapor and re-evacuated. Solutions of various concentrations were prepared by condensing different amounts of solvent on the polymer sample. In this way a number of concentrations could be examined without opening the apparatus to the atmosphere. Differential vapor pressure measurements were normally begun after the solution had stood overnight with stirring. The reproducibility of these measurements was usually within 1%. The null point of the instrument was checked at the end of a series of measurements. Two or three different amounts of solute were used to obtain the entire concentration range studied.

RESULTS

The variation of apparent molecular weight as a function of solution concentration for a series of Gelvas in benzene at 55° C. is shown in Fig. 1. The values for the molecular weight recorded here were calculated from Raoult's law. In addition to the determinations made in benzene, results obtained with Gelva 10 in absolute ethanol at 55° C., with Gelva 1.5 in acetone and in methanol at 20° C., and with Gelva 10 and Gelva 2.5 in benzene at 42.5° C. are shown in Fig. 2. In each case good agreement was obtained when the molecular-weight values were extrapolated to zero solute concentration.

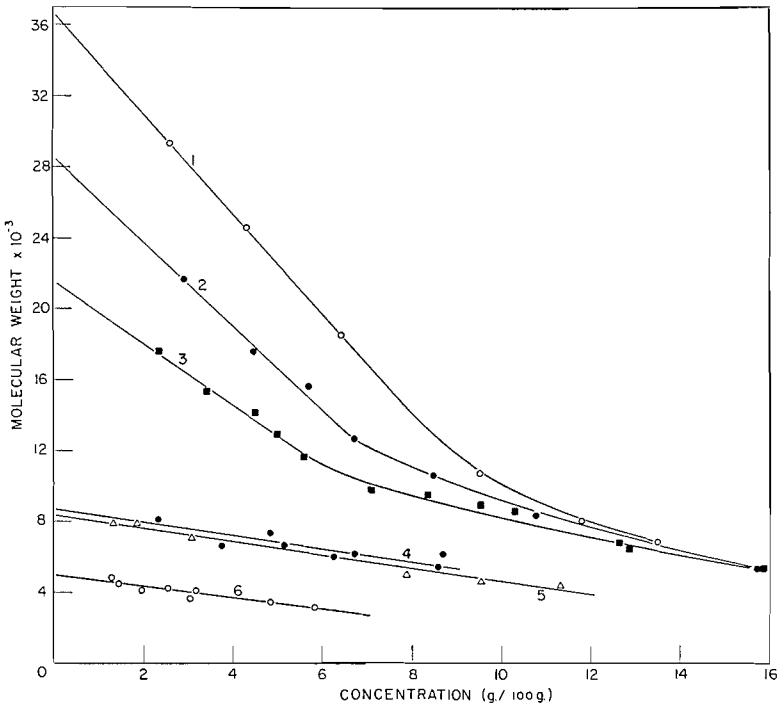

FIG. 1. Apparent molecular weight versus concentration of a series of Gelvas in benzene at 55° C. Curve 1, Gelva 15; Curve 2, Gelva 10; Curve 3, Gelva 7; Curve 4, Gelva 2.61; Curve 5, Gelva 2.5; Curve 6, Gelva 1.5.

It is evident that in most cases the apparent molecular weight is not a linear function of concentration. This is particularly obvious where the extrapolated molecular weight is in excess of 10,000. However, a straight line can be fitted reasonably well at lower concentrations, and where the molecular weight is below 10,000 the relation is quite linear up to 12% concentration.

In contrast to its behavior in benzene and in acetone, the measured molecular weight of Gelva 1.5 in absolute methanol appears to be independent of concentration over the range examined.

The behavior of the system Gelva 10 – ethanol is of considerable interest. The first determinations after fresh samples of solute were used produced a graph that was similar to that obtained with Gelva 1.5 in methanol. Subsequent determinations where the solvent was replaced by fresh ethanol gave a series of points where the molecular weight varies considerably with concentration. The extrapolated values in each case were virtually identical, however.

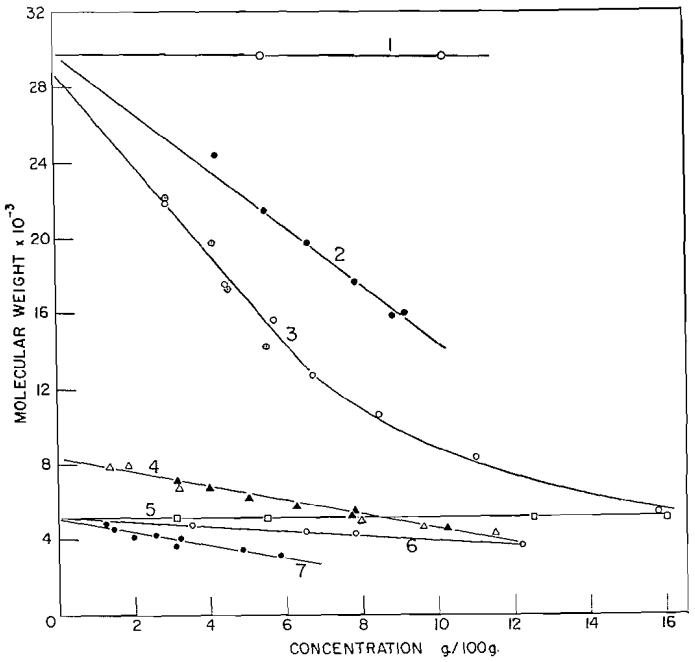

FIG. 2. Apparent molecular weight versus concentration of some Gelvas in different solvents and at various temperatures. Curve 1, Gelva 10, first determination in ethanol at 55° C.; Curve 2, Gelva 10, normal determination in ethanol at 55° C.; Curve 3, open circles, Gelva 10 in benzene at 55° C., and starred circles, at 42.5° C.; Curve 4, open triangles, Gelva 2.5 in benzene at 55° C., filled triangles, in benzene at 42.5° C., Curve 5, Gelva 1.5 in methanol at 20° C.; Curve 6, Gelva 1.5 in acetone at 20° C.; Curve 7, Gelva 1.5 in benzene at 20° C.

Since methanol is not a good solvent for polyvinyl acetate, the low degree of solute–solvent interaction may cause the solution of Gelva 1.5 to behave in the "ideal" fashion indicated. The similar behavior of fresh samples of Gelva 10 in ethanol might be ascribed to a trace of residual water in the resin which reduces solute–solvent interaction in the original solutions. If this were indeed the case, the water should be removed in subsequent operations and a higher solute–solvent interaction would be expected in succeeding solutions where the same sample of solute is used with fresh solvent.

In view of the departures of the apparent molecular weight vs. concentration curve from linearity in Fig. 1, it seemed of interest to apply an alternative method of presenting the vapor pressure data. The equation used, applicable over a wider range of concentrations provided μ_1 remains constant, is based on the theoretical equation developed by Huggins (2, 3) and by Flory (4, 5)

$$\phi \equiv (\ln a_1 - \ln V_1)/V_2 - 1 = -\bar{V}_1/\bar{V}_2 + \mu_1 V_2,$$

where

V_1, V_2 = volume fractions of components,
$\bar{V}_1$, $\bar{V}_2$ = partial molar volumes of components,
$\bar{V}_1 \simeq M_1/d_1$,
$\bar{V}_2 \simeq M_2/d_2$,
and a_1 = activity of the solvent;

M_1 and d_1, M_2 and d_2 are the molecular weight and density of the solvent and solute respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

A plot of ϕ vs. V_2 for the various polymers is shown in Fig. 3. In this case reasonably linear relations were found over the concentration range examined. The slopes of these graphs give the constant μ_1 directly and the molecular weight can be calculated from the intercept.

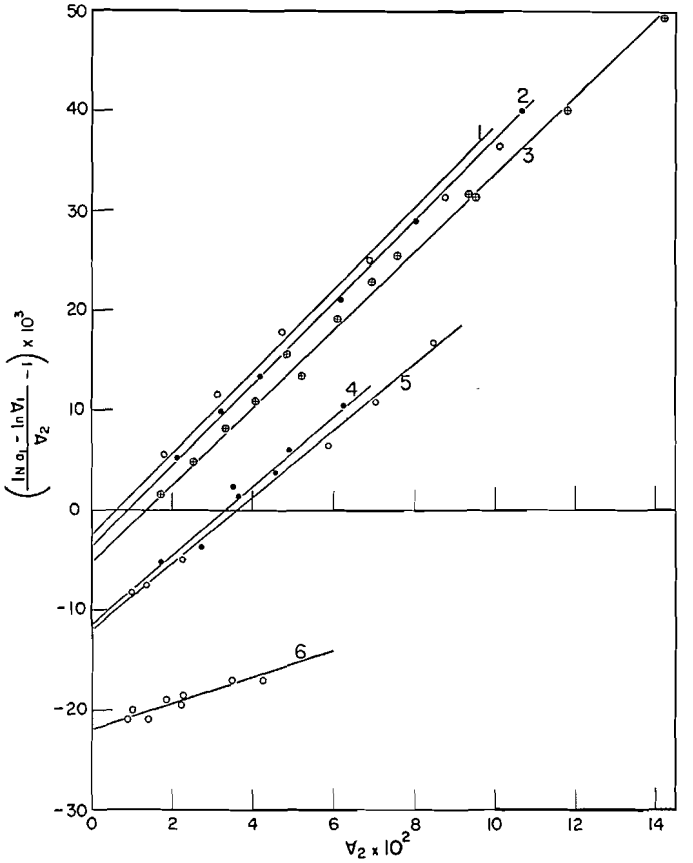

FIG. 3. Variation of $(\ln a_1 - \ln V_1)/V_2 - 1$ vs. V_2 for a series of Gelvas in benzene at 55° C. Curve 1, Gelva 15; Curve 2, Gelva 10; Curve 3, Gelva 7; Curve 4, Gelva 2.61; Curve 5, Gelva 2.5; Curve 6, Gelva 1.5.

The number-average molecular weight and the values of μ_1 for the series of Gelvas in benzene at 55° C. are given in Table I. Allowance for the non-ideal behavior of the solvent vapor has been made in calculating the concentration of the solutions. This correction amounted to about 2% on the molecular weight at infinite dilution.

TABLE I

MOLECULAR WEIGHTS OF POLYVINYL ACETATE IN BENZENE AT 55° C.

		Huggins' equation	
Gelva No.	M, Raoult's law	M	μ_1
1.5	5,100	4,960	0.134
2.5	8,500	9,010	0.333
2.61	9,000	9,560	0.347
7	22,000	21,800	0.387
10	28,600	30,300	0.401
15	36,700	45,400	0.402

In calculating the solution concentration, it was assumed that the volumes of solute and solvent are additive (6). The density of polyvinyl acetate was taken as 1.17 g./ml. for all of the fractions (7). The error involved by the change of density with molecular weight should not exceed 1%. The density of Gelva 0.9 at 20° C. has been reported as 1.159 g./ml. (8).

In addition to the work on the unfractionated polymers, several molecular-weight determinations were carried out on a sample of fractionated polyvinyl acetate made available to us through the kindness of Prof. M. Rinfret of the University of Montreal. When determined by a viscometric technique this sample had a weight-average molecular weight of 29,000. The polymer was recovered, after it had been stored for 6 months as an ethylene dichloride solution, by evaporation of the solvent under reduced pressure. It was then dissolved in benzene, filtered, and evaporated to a small volume. This concentrated solution was frozen and the solute was finally isolated as a fluffy brownish solid by subliming off the benzene.

Molecular weights were determined in ethanol and in benzene at 55° C. Two extra points were obtained in benzene solution at 65° C. The results, shown in Fig. 4, were calculated from Raoult's law.

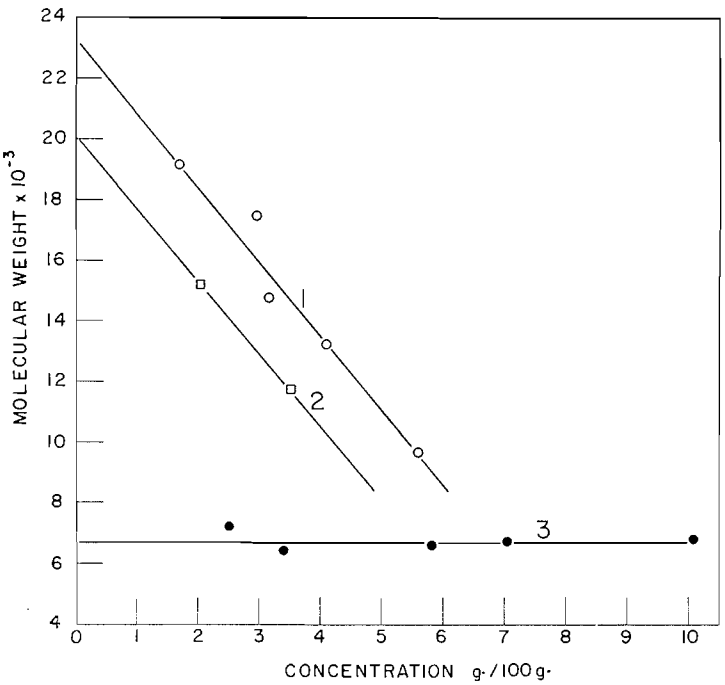

FIG. 4. Variation of apparent molecular weight versus concentration of a recovered fraction of polyvinyl acetate in benzene and in ethanol. Curve 1, in benzene at 55° C.; Curve 2, in benzene at 65° C.; Curve 3, in ethanol at 55° C.

The values obtained in ethanol solution were independent of concentration over the range used and were lower than expected. In benzene, although the molecular weight decreased as the temperature was raised from 55° C. to 65° C., the extrapolated value at both temperatures was much higher than in alcohol. While the reason for this difference is not obvious, it appears that the polymer may have become degraded during the long period of solution in the ethylene dichloride. The apparent difference in molecular weight in the polar and non-polar solvents might be ascribed to association of the solute

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

in the latter if any hydrolysis had occurred in the degraded polymer. Association phenomena have been observed (9, 10) with solutions of polymers containing a few hydroxyl groups in non-polar solvents and our results suggest the possibility of similar behavior. It may be added, however, that with unfractionated Gelva 10 and Gelva 2.5 there was virtually no difference in molecular weight when determinations were made in benzene at 42.5° C. and at 55° C.

DISCUSSION

The values of μ_1 are seen to decrease with decreasing molecular weight of the polymers in the series used. While this is sometimes attributed to solute impurities (3), the phenomenon has been observed for a series of polystyrene fractions in different solvents (11). Flory (12) suggested that μ_1 should be slightly dependent on molecular weight. The possibility that the variation of μ_1 with molecular weight is caused by chain branching (13) in the commercial samples (14) should not be excluded.

The values of the number-average molecular weights obtained using Raoult's law agree reasonably well with those found with Huggins' equation (2, 3) in spite of the fact that the values estimated by the latter method are very sensitive to slight changes in the slope of the curve and that rather long and possibly uncertain extrapolations were required using Raoult's law. This probably accounts for the difference found in Table I when the values obtained by the two procedures are compared.

The vapor-pressure data may also be presented as corrected π/c vs. C plots. These have not been included however, since this relationship is linear over the concentration range examined for the three polymers of the group with the lowest molecular weights only.

It is difficult to check the vapor-pressure method by calibration with known compounds of similar molecular weight since for the samples used reliable values for the degrees of polymerization are not readily available. A molecular weight of 61,000 was reported for Gelva 15 by Robertson, McIntosh, and Grummitt (15). This value was obtained by osmotic-pressure measurements on a commercial sample that had been dissolved in acetone, filtered, and precipitated in water. Since only that portion of the polymer that gathered around the glass stirrer was recovered, this treatment may have resulted in the loss of some low-molecular-weight material, and the value of 37,000 for Gelva 15 obtained in this work is perhaps not unreasonable. The distribution curves for Gelva 15 and Gelva 2.5 obtained by Blease and Tuckett (16) lend support to the molecular-weight values found here.

In favor of the vapor-pressure method, it may be pointed out that good agreement was generally obtained for the same material with different solvents and very satisfactory results were produced with pure compounds having molecular weights below 1000. Its most obvious advantage over osmotic-pressure methods, particularly where the molecular weights of the solute involved are low, is in avoiding semipermeable membranes. Its applicability over a wide temperature range is also an attractive feature.

METHYLATION OF SUGAR MERCAPTALS

I. INTRODUCTION AND D-GLUCOSE DIETHYL MERCAPTAL[1]

G. G. S. DUTTON AND K. YATES

ABSTRACT

The methylation of the diethyl mercaptals of D-glucose, D-mannose, D-galactose, and L-arabinose in methyl iodide has been re-examined. The apparent lack of reactivity of the last three has been shown to be due to their insolubility in methyl iodide since appreciable methylation occurs in tetrahydrofuran. The case of D-glucose diethyl mercaptal has been examined in some detail and although polysubstitution occurs on reaction with methyl iodide in tetrahydrofuran the only monomethyl derivative formed is the 2-*O*-methyl ether. Preliminary work suggests that this is not the case with D-mannose mercaptal.

The reactions of sugar mercaptals are of particular interest in that the sugar molecule is acyclic, thus exposing an extra hydroxyl group which in the more common glycoside structure is involved in ring formation. It was reported in 1934 by Lieser and Leckzyck (1) that D-glucose diethyl mercaptal could be selectively methylated by the use of methyl iodide and silver oxide at 0° C. to give exclusively 2-*O*-methyl-D-glucose diethyl mercaptal in 52% yield. This reaction affords an easy route to 2-*O*-methyl-D-glucose and has been used by other workers (2). It was also reported by Lieser and Leckzyck that the mercaptals of D-galactose, L-arabinose, D-xylose, and L-rhamnose failed to yield methylated products when treated similarly.

It seemed to us that there was no a priori reason why other mercaptals should not react like the glucose compound. We have, therefore, re-examined this reaction to determine its generality and with the hope that it might furnish a convenient route to other partly methylated sugars such as are needed when carrying out structural studies by the methylation technique. Apart from the practical significance of such a reaction the nature of the monomethyl sugars obtained has considerable theoretical interest with respect to a study of the relative reactivity of the hydroxyl groups in an acyclic sugar derivative.

The early literature on relative reactivities of hydroxyl groups in carbohydrates has been reviewed (3) but the great majority of the examples refer to cyclic sugar structures. In 1952 there appeared a paper (4) showing that hexitols adopt a planar zigzag form resulting in selectivity in certain reactions, and it is reasonable to suppose that in some respects the acyclic mercaptals may be compared to the polyols. More recently Zinner (5, 6) has shown that in partial esterification of sugar mercaptals the terminal or primary hydroxyl group is the most reactive.

The present paper describes the qualitative paper-chromatographic examination of the products obtained on methylating the diethyl mercaptals of D-galactose, D-mannose, D-glucose, and L-arabinose. The results of a larger-scale methylation of D-glucose diethyl mercaptal and the quantitative separation of the products by column chromatography are also given.

In the initial experiments small amounts of the above mercaptals were methylated by the method of Lieser and Leckzyck (1). Upon separation of the products from excess methyl iodide and silver oxide, sirups were obtained. The sirup from the reaction of

[1]*Manuscript received November 4, 1957.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada. Presented in part at the 40th Annual C.I.C. Conference at Vancouver, B.C., June 3–5, 1957, and at the Northwest A.C.S. Regional Meeting at Spokane, Wash., June 13–14, 1957.

D-glucose diethyl mercaptal crystallized spontaneously to give a 46% yield of 2-*O*-methyl-D-glucose diethyl mercaptal, the others failing to yield any crystalline material except unchanged mercaptal. The mother liquor from the 2-*O*-methyl-D-glucose mercaptal and the remaining three sirups were investigated by paper partition chromatography. On development of the chromatogram with iodine vapor (7), the presence of several components was indicated as shown in Table I, indicating qualitatively that the

KEY.—O = *orange*, Y = *yellow*, I = *intense*, F = *faint*.

reaction is more general than had been supposed. The presence of a further amount of 2-*O*-methyl-D-glucose diethyl mercaptal in the mother liquor suggested that, if desired, the yield of this product could be increased to 52% as given by the earlier workers (1). It can be seen from Table I that the reaction in each case gave products of two types; those having a high R_f value corresponded to methylated and unchanged mercaptals, while those having slower R_f's are presumably more polar compounds whose constitution is at present unknown. The latter compounds are referred to subsequently as the "slow fraction". It can, however, be stated that in these slow-moving compounds the mercaptal group has not been removed completely since they gave no spot for reducing sugar with *p*-anisidine hydrochloride (8). It is also apparent that these compounds are probably carbohydrate in nature since their R_f values varied from sugar to sugar, but on hydrolysis with acid, however, they did not regenerate the parent sugars. It was observed that the most intense of these slow spots can be produced by reacting the mercaptal with methyl iodide in the absence of silver oxide.

From the distribution and concentration of the products in Table I it appears that the reaction has been most extensive in the case of D-glucose since no unchanged mercaptal was detected. Somewhat less reaction occurs in the case of D-galactose and only a small amount in the cases of the other two mercaptals. Owing to the high R_f values of the mercaptals and consequent low degree of chromatographic separation, the products were hydrolyzed and reinvestigated by paper chromatography as the free sugars thus produced. These results are shown in Table II. From a comparison with the characteristic R_f values of known compounds it appears that the first components (from the origin) correspond to unsubstituted sugars, the second to their monomethyl derivatives, and the remainder to more highly substituted sugars. From this it can be seen that some monomethylation has occurred in each case, which is in apparent disagreement with the earlier statement that the reaction failed for sugar mercaptals other than those of D-glucose (1). Since the amount of methylation which has apparently taken place in

the case of the D-mannose and L-arabinose mercaptals is very slight and considerable polymethylation has occurred with D-galactose mercaptal, it is not surprising that no crystalline methyl derivative was isolated (1).

During this preliminary work it was observed that there were considerable differences in the solubilities of the various mercaptals in methyl iodide. Under the conditions used it was found that the extent of methylation corresponded approximately to the degree of solubility of the particular mercaptal being reacted. D-Glucose diethyl mercaptal was found to be the most soluble of the four and its unusual reactivity appears in part to be due to the fortuitous choice of methyl iodide as a reaction solvent. Large amounts of D-mannose and L-arabinose mercaptals were found undissolved at the end of the reaction.

In order to eliminate this solubility effect it was decided to use an inert reaction solvent in which all four mercaptals had comparable solubilities and to compare the reaction of each again on a more equal basis. The most suitable of the common organic solvents which are inert to methylation was found to be tetrahydrofuran. The presence of a large amount of inert solvent necessitated the use of increased amounts of methyl iodide and silver oxide. In order to determine whether changing the original reaction temperature of 0° C. had any critical effect on the nature of the products three parallel reactions were carried out on each mercaptal at 3°, 22°, and 50° C. In the case of all four mercaptals no significant difference could be detected either in the distribution or in the intensity of the components when the reaction mixtures were examined by paper chromatography. The results of a typical methylation in tetrahydrofuran are shown in Table III. It was noted that the same "slow" products were present and the extent

of methylation appeared more comparable in each case. The unusual reactivity of D-glucose diethyl mercaptal was not now so marked since unreacted mercaptal was shown to be present. In order to investigate the nature of the methylated mercaptals these were hydrolyzed and examined as the free sugars. These results are shown in Table IV, from which it is apparent that some monomethylation has taken place in all cases and that D-glucose mercaptal no longer yields exclusively monomethyl products. From these preliminary experiments it was concluded that if the methylation was carried out in a solvent it was generally applicable to the four mercaptals used and that the peculiar selectivity of the D-glucose mercaptal was no longer apparent.

In the light of the above results it was decided to repeat the methylation of D-glucose diethyl mercaptal on a larger scale to permit separation and identification of the reaction products. We were particularly concerned with the identification of the monomethyl fraction in order to determine if monomethylation still occurred preferentially at the 2-position. For this reason no attempt has been made at the present time to identify more highly methylated derivatives.

A large-scale methylation of D-glucose diethyl mercaptal was carried out in tetrahydrofuran at 22° C. After removal of the solvent and excess reagents the sirupy reaction product was separated on a cellulose column into two fractions: the "fast" fraction containing methylated and unreacted mercaptals and the "slow" fraction containing the unidentified products. The "fast" fraction was then hydrolyzed and the mixture of free sugars separated by chromatography on a cellulose–hydrocellulose column (9). The results of this separation are shown in Table V and the monomethyl fraction was

shown to be one component by paper chromatography and the constancy of optical rotation throughout the fraction. This fraction crystallized spontaneously and failed to depress the melting point of an authentic sample of 2-*O*-methyl-D-glucose on admixture with it. It was further characterized by the preparation of the characteristic *p*-toluidide derivative. It was thus shown that although polymethylation occurs when D-glucose diethyl mercaptal is reacted with methyl iodide in a solvent it is only the 2-monomethyl ether that is formed, thus demonstrating the superior reactivity of the 2-position.

When a large-scale methylation of D-mannose diethyl mercaptal was carried out under identical conditions two principal monomethyl derivatives were produced and these appeared to be the 5-*O*- and 6-*O*-methyl-D-mannoses. In the case of L-arabinose mercaptal, under these conditions mainly di- and tri-methylation occurred. These results and those on D-galactose mercaptal will be reported more fully at a later date.

EXPERIMENTAL

All melting points were taken by means of a Leitz electrically heated melting-point block and are corrected. All evaporations were done *in vacuo* at 40° C. Duolite A_4 anion-exchange resin is a product of Chemical Process Co., Redwood City, California.

Preparation of Diethyl Mercaptals

The four mercaptals were prepared by the method of Fischer (10) and had melting points and rotations in agreement with those given. The rotations of D-mannose diethyl mercaptal and of L-arabinose diethyl mercaptal do not appear to have been previously recorded and were found to be $[\alpha]_D^{20} = 0°$ (*c*, 0.77 in pyridine) and $-5°$ (*c*, 1.78 in pyridine).

Methylation of Mercaptals in Methyl Iodide (1)

D-Glucose diethyl mercaptal (0.94 g.) was shaken with freshly prepared silver oxide (1.5 g.) and methyl iodide (10 ml.) for 21 hours at 0° C. under anhydrous conditions. The mixture was allowed to attain room temperature (1 hour) and filtered. The residue was extracted successively with boiling chloroform, acetone, and methanol. The filtrate and extracts were combined and evaporated to a sirup, which was dissolved in a small amount of methanol. On standing, this solution deposited crystals (0.46 g.) of 2-*O*-methyl-D-glucose diethyl mercaptal, m.p. 154°–155° C. Lit. m.p. 155°–156° C. (1). Anal.: Calc. for $C_{11}H_{24}O_5S_2$: $-OCH_3 = 10.37\%$. Found: $-OCH_3 = 10.99\%$. Yield 46%.

The diethyl mercaptals of D-mannose, D-galactose, and L-arabinose were also methylated by the above procedure but the sirups obtained failed to yield any crystalline product.

Chromatographic Investigation of the Reaction Products

Chromatograms of the four reaction products above were run on Whatman No. 1 paper, using *n*-butanol–ethanol–water (40:10:50). Detection of the chromatograms with iodine vapor (5) showed the components whose R_x values are given in Table I. Duplicate chromatograms were sprayed with *p*-anisidine hydrochloride but failed to detect any reducing sugars (8).

Effect of Individual Reagents

Two samples of D-glucose diethyl mercaptal (10 mg.) were dissolved in carbon tetrachloride (5 ml.) and shaken for 21 hours at 0° C. with methyl iodide and silver oxide respectively. After they were filtered, the solutions were chromatographed with standards and detected as before. Mercaptal plus methyl iodide: three products of $R_x = 0.21, 0.35$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(intense), and 0.94 (unchanged mercaptal). Mercaptal plus silver oxide: one product of $R_x = 0.95$ (unchanged mercaptal).

Hydrolysis of Reaction Products

The sirups resulting from methylation of the four mercaptals were dissolved in 20% aqueous ethanol containing 5% hydrogen chloride. The solution was heated to reflux, a stream of nitrogen being bubbled through continuously. When chromatography of the solutions failed to detect any unchanged mercaptals (5 to 6 hours), they were passed through a column of Duolite A-4 anion-exchange resin and concentrated by evaporation. The four hydrolyzates were chromatographed on paper as before and detected with *p*-anisidine hydrochloride, the results being shown in Table II.

Methylation of Mercaptals in Tetrahydrofuran

The mercaptal (0.3 g.) was dissolved in dry peroxide-free tetrahydrofuran (20 ml.). After silver oxide (1 g.) and methyl iodide (10 ml.) were added, the whole was shaken vigorously for 22 hours. Three parallel experiments were carried out on each mercaptal at 3°, 22°, and 50° C. The products were then extracted as before, no crystalline materials being obtained. Paper chromatography of the sirups as before yielded results shown in Table III. After hydrolysis and chromatography of the free sugars the results shown in Table IV were obtained.

Large-Scale Methylation of D-*Glucose Diethyl Mercaptal*

Silver oxide (6.7 g.) and methyl iodide (67 ml.) were added to a solution of D-glucose diethyl mercaptal (2.0 g.) in purified tetrahydrofuran (100 ml.). The vessel was flushed with nitrogen, sealed, and shaken at room temperature for 22 hours. After extraction of the products there was obtained an amber sirup (2.07 g.). Paper chromatography of this sirup using methyl ethyl ketone – water azeotrope gave essentially the same results as shown in Table III. Part of the sirup (1.96 g.) was placed on a cellulose column (2.8 cm. diam. by 40 cm.) and developed with the same solvent. Fractions were collected at 1-hour intervals for 8 hours. (The time for the solvent front to pass down the column was 4 hours as judged by the addition of Sudan IV dye.) Two fractions were then collected at 2-hour intervals and the remaining material was removed by developing for a further 80 hours without any attempt at fractionation. Paper chromatographic examination of the first eight fractions in methyl ethyl ketone – water and detection with iodine vapor showed that fractions 2–5 contained all of the mercaptalated products with only slight traces of the "slow" fraction. When these fractions were combined and the solvent evaporated there was obtained a sirup (0.88 g.) designated as mercaptal fraction. The higher fractions were discarded.

The mercaptal fraction was hydrolyzed as before and yielded a sirup (0.425 g.). Duplicate chromatograms of the sirup were run in methyl ethyl ketone – water. One chromatogram was exposed to iodine vapor and the other sprayed with *p*-anisidine hydrochloride. The former showed no glucose mercaptal, indicating that hydrolysis was complete. The latter showed four components with R_f's 0.014, 0.06, 0.21, and 0.47, corresponding to the characteristic ranges of glucose and mono-, di-, and tri-methyl glucoses respectively.

A portion of the sirup (0.406 g.) in the minimum amount of methyl ethyl ketone was placed on a column (2.8×42 cm.) of cellulose–hydrocellulose (1:1) and developed with methyl ethyl ketone – water azeotrope. Fractions were collected at 30-minute intervals at a flow rate of 40 ml. per hour. After 300 fractions had been collected no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

further carbohydrate material could be detected (Molisch). The results of this fractionation are shown in Table V.

All the fractions were found to be chromatographically pure except for some overlap between dimethyl glucose fractions A and B. By evaporation of the solvent from a few tubes from the beginning, middle, and end of the monomethyl fraction it was shown to have a constant rotation throughout. This monomethyl fraction yielded spontaneously, a crystalline product melting at 153°–157° C. After recrystallization, admixture with an authentic sample of 2-*O*-methyl-D-glucose gave a melting point of 154°–158° C. (2). The *p*-toluidide was prepared in poor yield by the method of Smith (11), m.p. 144°–146° C. Lit. m.p. 150°–151° C. (12).

It will be noted from Table V that the methoxyl analysis of the separate fractions is in some cases much lower than is demanded by theory. This is attributed to the difficulty of purifying small amounts of sirup from inert material from the column (cellulose?). The main significance of the methoxyl analyses was to indicate that the other components were not monomethyl glucoses.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to the Research Corporation for financial support and to the National Research Council for the award of a bursary (K.Y.) and a summer research associateship (G.G.S.D.).

THE THERMODYNAMICS OF MUTAROTATION OF SOME SUGARS

I. MEASUREMENT OF THE HEAT OF MUTAROTATION BY MICROCALORIMETRY[1]

M. A. KABAYAMA, D. PATTERSON, AND L. PICHE

ABSTRACT

The heats of mutarotation of D-glucose, D-xylose, lactose, maltose, and cellobiose have been determined using a microcalorimeter of the Tian-Calvet type. Part I of this paper describes the experimental work and the results obtained. Discussion of these results is reserved for Part II.

INTRODUCTION

Since the discovery of the phenomenon of mutarotation, much work has been done to elucidate the kinetics and mechanism of the reaction as well as to study the stability of the various forms postulated. Some attempt has also been made to determine the heats of mutarotation of the sugars from the temperature dependence of the equilibrium constants for the mutarotations (1). The only direct measurement of a heat of mutarotation has been performed by Sturtevant (2, 3) for D-glucose using an adiabatic calorimeter. It seemed desirable, however, to have values for other sugars, particularly for those undergoing an opposing first-order mutarotation, in order to make a comparison of the appropriate thermodynamic quantities.

MATERIALS

The sugars studied were all of reagent grade purity, and were obtained as almost pure α or β anomers by slow recrystallization from slightly supersaturated aqueous or alcoholic solutions according to the method of Hudson and Dale (4).

The "purity", i.e. the percentage of α or β anomer in the "α" or "β" sugar, may be determined polarimetrically using known optical rotations. These experiments were performed at 0° C. Isbell and Pigman (5) have determined the optical rotations at 0° C. for both anomers of D-glucose and lactose and for α-D-xylose and β-maltose. They have also obtained a value at this temperature for β-cellobiose (6). The optical rotations at 20° C. for the other anomers required have been obtained by Hudson and Yanovsky (7) using an indirect method requiring the separation of only one of the anomers of the sugar. Their values have been used to find the "purity" of the sugars at 0° C. Since the "purities" of the sugars, save for cellobiose, were nearly 100%, this introduces a negligible uncertainty. In the case of cellobiose, the "purity" was sufficiently far from 100% to warrant a polarimetric run at a higher temperature.

The water used in all experiments was ordinary distilled water, saturated with CO_2, and of pH approximately 5.5. Since the rate of mutarotation of D-glucose is constant (8) between pH 2 and 7, buffering of the solution (8, 9) was deemed unnecessary for a determination of the heats of mutarotation.

EXPERIMENTAL

The Tian-Calvet microcalorimeter has been described in various publications (10, 11, 12), but an outline of its more relevant characteristics will be given here. Although arranged differentially, it consists essentially of a cell in which the reaction takes place

[1]*Manuscript received November 12, 1957.*
Contribution from the Department of Chemistry, University of Montreal, Montreal, Que.

and a block whose temperature remains constant. The temperature difference between the cell and the block is detected by a set of thermocouples and galvanometer and recorded by a photopen on a chart.

However, the heat evolved by the reaction only in part raises the temperature of the cell producing the deflection recorded on the chart. The rest of the heat is conducted down the thermocouples to the block. Nevertheless, the rate of evolution of heat is related to the deflection and the time rate of change of the deflection by the following equation:

$$W(t) = \frac{p}{g}\delta + \frac{\mu}{g}\frac{d\delta}{dt}. \qquad [1]$$

Here $W(t)$ is the rate of evolution of heat in joules/second, p is the rate of thermal conduction of heat down the thermocouples per degree temperature difference between the cell and the block, δ is the deflection on the chart in cm., g is the sensitivity of the thermocouples, galvanometer, and photopen in cm. deflection per deg. temperature difference between cell and block.

Equation [1] may be expressed as:

$$W(t) = \frac{p}{g}\Delta, \qquad [2]$$

where

$$\Delta = \delta + \frac{\mu}{p}\frac{d\delta}{dt} \qquad [3]$$

and is a "corrected" deflection related to $W(t)$ by a constant, p/g.

In the present case, the large heat of solution of the sugar had to be separated from the much smaller heat of mutarotation. This was effected by determining the evolution of heat some time after the dissolution of the sugar when the heat was due to the mutarotation alone; by extrapolation to zero time, the whole heat of mutarotation was determined. Thus, using [3], Δ was obtained graphically from the curve of the deflection δ against time commencing some 30 minutes after dissolution of the sugar. The mutarotations studied are all single first-order opposing reactions; a curve of log Δ against time was extrapolated back to zero time in an appropriate fashion, and the intercept of log Δ on the axis $t = 0$ gave the log of the total heat evolved by the mutarotation. Since the "purity" of the sample was slightly less than 100%, a correction to 100% purity was then made.

Prior to the experiment, the sugar was held in a special holder (Fig. 1) within the stainless steel reaction cell of the microcalorimeter. The holder was designed to give a low heat effect on opening. After the tension of the spring (not shown) was released, the bracket was lowered via the control wire. The hook in the center engaged the shaft to suspend the holder so that the water was allowed to circulate through the top and bottom of the cylinder to dissolve the sugar. The endothermic heat of solution was compensated by evolution of heat from a resistor within the cell in order to allow the microcalorimeter to be put as quickly as possible onto its maximum sensitivity. This was required for following the evolution of the small heat of mutarotation.

The heat of mutarotation of a sugar possessing a fast rate constant, D-lyxose, and a check on the value of D-xylose, was obtained by the so-called "ballistic" method. Dissolution of a sugar gives an immediate "ballistic" deflection on the chart which quickly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

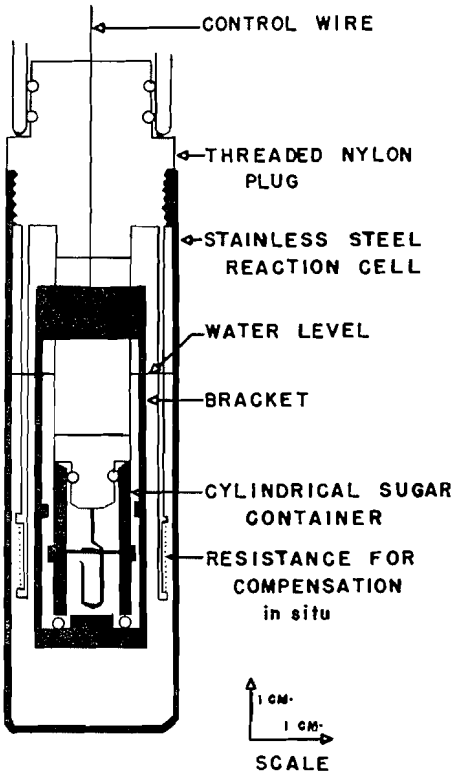

FIG. 1. Reaction cell and sugar container.

reaches a maximum and then slowly falls off. This peak deflection is almost entirely due to the heat of solution and is proportional to it. By measuring the height of the peak for the dissolution of KNO_3, whose heat of solution is well known, the instrument may be calibrated. Thus the heat of solution of the sugar may be determined. Measurement of the total area under the curve of deflection vs. time gives the heat of solution plus the heat of mutarotation. By subtracting the heat of solution, the heat of mutarotation may be obtained separately. Owing to the small size of the difference, the precision of this method is not high.

RESULTS

A typical curve of deflection vs. time as recorded on the chart is displayed in Fig. 2, with the curve of Δ against time as found by using equation [2]. A plot of $1+\log \Delta$ against time is shown in Fig. 3 with an extrapolation to zero time.

The second column of Table I shows the heat of mutarotation found for the various sugars on the basis of total conversion of the sugar from the α to the β anomer. The precision attained in the calorimetric determinations is indicated by the second number in this column. In the fourth column, the percentage β in the equilibrium mixture is found, these values (except for a small correction) having been drawn from the references cited above (5, 6, 7), which are valid at 20° C. The correction is necessary because of the temperature difference, and has been made using the Gibbs–Helmholtz equation and the experimentally determined heats of mutarotation. By the use of well-known thermodynamic relations, values of ΔF and ΔS may be found, and these are given in columns five and six. Fig. 4 presents a plot of ΔH vs. ΔS.

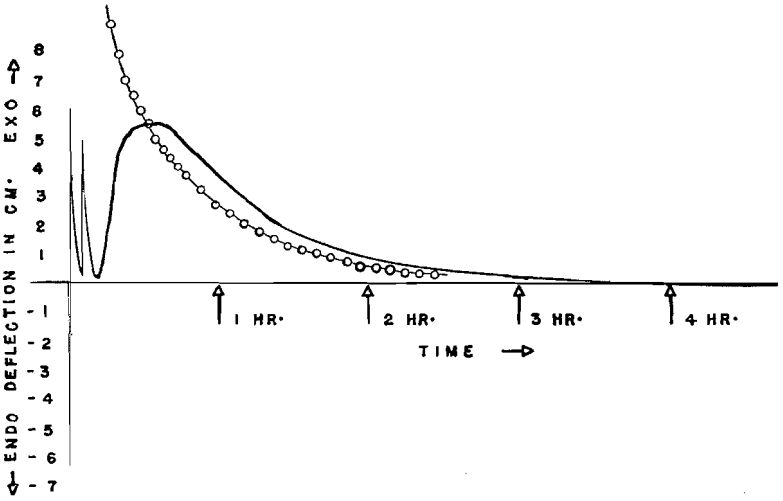

FIG. 2.

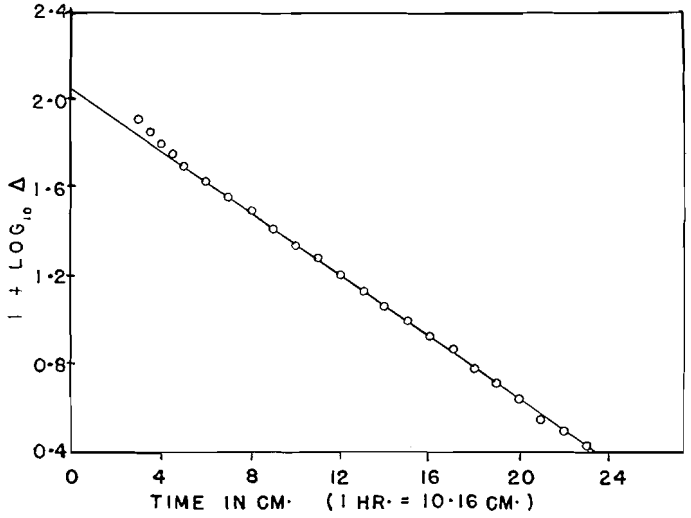

FIG. 3.

TABLE I

Sugar	ΔH, cal./deg.-mole, precision in %	Starting form	% β at 24.8° C.	ΔF, cal./mole	ΔS, e.u.	k_1+k_2, min.$^{-1}$, precision in %
D-Xylose	−535 ±3.9	α	65.5	−379	−0.52	0.038 ±10
Cellobiose	−438 ±2.0	β	64.4	−352	−0.29	0.0053 ± 2
D-Glucose	−270 ±1.4	α	63.6	−327	+0.19	0.0112 ± 4
Lactose.H_2O	−270 ±1.4	α	62.3	−297	+0.08	0.0070 ± 7
Maltose.H_2O	−126 ±7.3	β	63.9	−335	+0.70	0.0090 ±11

The accuracy of the work, as distinct from the precision, is more difficult to assess. For D-glucose and lactose, since the initial rotations of both anomers of the sugars have been determined accurately by Isbell and Pigman (5, 6), the percentage composition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

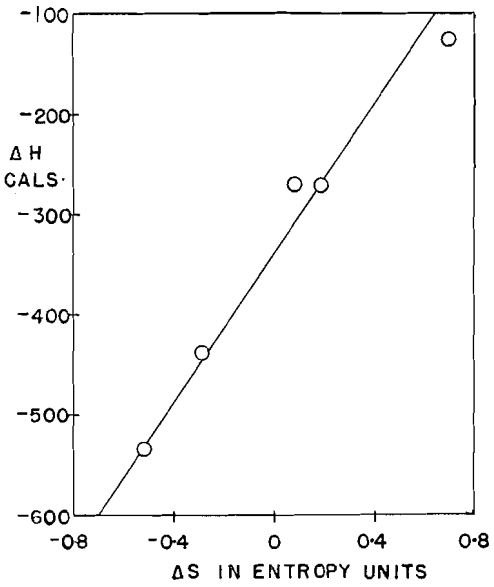

FIG. 4.

of the equilibrium solution is also known, so that the error in the values of the thermodynamic quantities should be of the order of the precision found. In fact, the value of ΔH for D-glucose agrees within 3% with that obtained by Sturtevant, viz., 277.7 cal./mole. However, in the case of the three other sugars, we are forced to rely upon the approximate values of Hudson and Yanovsky for one of the initial rotations. From a discussion of the possible uncertainty in these values, we conclude that in the case of maltose, the following limits are not unreasonable: for ΔH, $\pm 4\%$, ΔF, $\pm 10\%$, and for ΔS, $\pm 20\%$. The large relative error in the last value is due to the small value of ΔS. This introduces an uncertainty in the absolute value of 0.1 e.u. For D-xylose and cellobiose, these limits would be less.

The "ballistic" method gave a value of the heat of mutarotation of D-xylose equal to -460 cal./mole, which provides only a rough check of the value in Table I since the precision of the "ballistic" method is estimated to be $\pm 28\%$. The value obtained for D-xylose was $+312$ cal./mole with a similar precision. The positive value of ΔH is no doubt due to the axial hydrogen on $C_{(2)}$ which renders the β anomer energetically unfavored; ΔF for the mutarotation is now positive and the equilibrium composition of the sugar is 24.8% β at 25° C.

It is also possible to obtain the rate constant of the mutarotation from the slope of log $W(t)$ plotted against the time, hence from the slope of the straight line in Fig. 2. The values of k_1+k_2, the rate constant of the reaction, are shown in the last column of Table I, with the variation which was found for a series of four to seven experimental runs. The rather large variation found here seems also to occur amongst values in the literature. Isbell and Pigman (6) point out that the mutarotation is sensitive to the presence of certain metals, and it is possible that in our case, the reaction was catalyzed to some extent by brass which might have shown through the rhodium plating of the holder for the sugar. Since, however, we are interested in the heat of mutarotation between equilibrium states, any change in the rate of the reaction should not affect the thermodynamic values obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The values of k_1+k_2 found by Isbell and Pigman (6) at 0° C. and 20° C. have been extrapolated to yield the following values at 24.8° C.: D-glucose, 0.0102 min.$^{-1}$; lactose.H_2O, 0.0076 min.$^{-1}$; D-xylose, 0.0381 min.$^{-1}$; maltose.H_2O, 0.0086 min.$^{-1}$. The agreement is thus seen to be satisfactory in view of the variations found.

DISCUSSION

We may note that the value of ΔH obtained for D-glucose agrees reasonably well with that obtained by Sturtevant (6), namely -278 cal./mole at 25° C.

Apart from D-lyxose, the sugars studied are identical in the neighborhood of the anomeric carbon. It is therefore surprising to find the large range of values for ΔH and ΔS shown in Table I. This is particularly so since ΔF is nearly constant for these sugars; this latter fact is reflected in the straight line obtained in Fig. 4.

A detailed discussion of these results is presented in Part II of this paper.

ACKNOWLEDGMENTS

The work described above was performed under a National Research Council research grant. Furthermore, one of us (M.A.K.) held an N.R.C. studentship during most of the period of this research and another (D.P.) was a Summer Research Associate during part of this time. We are most grateful for this financial assistance and should like to thank the National Research Council.

The award of a bursary (to M.A.K. during the early part of the research) from the Office of Scientific Research of the Province of Quebec is gratefully acknowledged.

We should also like to thank Prof. M. Rinfret for guiding us in the use of the microcalorimeter and for many helpful suggestions. We are greatly indebted to Mr. C.-E. Pion for his skilled technical assistance.

THE THERMODYNAMICS OF MUTAROTATION OF SOME SUGARS

II. THEORETICAL CONSIDERATIONS[1]

M. A. KABAYAMA AND D. PATTERSON

ABSTRACT

An interpretation of ΔH and ΔS for the mutarotation of D-glucose, D-xylose, maltose, lactose, and cellobiose is given in terms of changes in the hydration of the reducing hydroxyl group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

INTRODUCTION

In this part of the paper we shall attempt to give an interpretation of the experimental results shown in Table I and Fig. 4 of Part I.* We shall first consider the conformations of the sugars used in Part I and note that in all of them the neighboring groups of the reducing carbon are identical.

There is a large body of evidence for strong hydrogen bonding between the sugar hydroxyl groups and adjacent water molecules in aqueous solution. On the basis of the known conformations of the sugars and of the structure of water it is possible to come to tentative conclusions about the packing of the water molecules about the sugar molecule, and to predict that an equatorial hydroxyl group will be more strongly hydrated than an axial group. We also find that the reducing hydroxyl of the sugars of Part I is bonded to the adjacent water molecule in the same manner, with only slight variations in bond length.

The large value of ΔS for mutarotation of the various sugars can be associated with changes in the frequency of torsional oscillation of this reducing hydroxyl group about the $C_{(1)}$—O axis. On the basis of a simple model of the hydrogen bond between the group and the water molecule, the order of magnitude of this frequency can be calculated and shown to be low enough to give a large contribution to the entropy.

Using the hydrogen bond model, the order of magnitude of the variation of ΔS and ΔH amongst the sugars is calculated, and the slope of ΔH vs. ΔS in Fig. 4 of Part I can be estimated theoretically.

Finally ΔF for the mutarotation of the sugars can be viewed in the light of the free energies of interaction between adjacent hydroxyl groups in the cyclitols which have been the subject of thermodynamic study by Angyal and McHugh (1). Because the pyranose ring contains an oxygen atom, whereas the cyclitol ring does not, a difference exists between group interactions in the two cases.

CONFORMATIONS OF THE SUGARS

Reeves (2) has shown that of the two chair and six boat conformations possible for the hexopyranoses the chair conformations are normally preferred. More recent work in Reeves' laboratory (3, 4) has indicated the possibility of a boat conformation in some of the pyranoses, the tendency of hydroxyl groups to take up equatorial positions apparently overcoming the normal stereochemical preference for the chair conformation.

[1]*Manuscript received November 12, 1957.*

**Preceding paper.*

D-Glucose and D-xylose, however, retain the normal C1 conformation shown for β-glucose in Fig. 1. This conformation has been confirmed by X-ray diffraction evidence for cellulose (5) and methyl β-D-xyloside (6, quoted in 5).

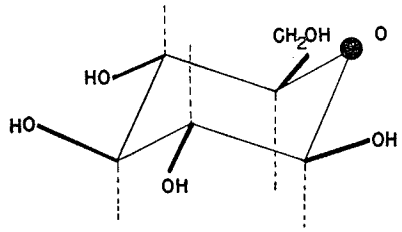

FIG. 1. The conformation of the β-D-glucose molecule.

In the disaccharides, there is no reason to suppose that the β-D-(1→4)-linked glucose residues of cellobiose are not both in the conformation found for solid cellulose. In the case of lactose, 4-*O*-(β-D-galactopyranosyl)-D-glucose, there is some evidence from X-ray diffraction work on the solid (7) that the galactose residue is distorted from the C1 conformation because of the axial OH on $C_{(4)}$ to produce a flatter molecule than would otherwise be the case. Reeves and Blouin (4) also suggest that the axial hydroxyl in galactose tends to become more equatorial distorting the C1 conformation.

The presence of a boat conformation in maltose and amylose seems to be indicated (3). Haworth (8) originally predicted that the α-D-(1→4)-linked glucose residues of amylose would lie in a boat conformation. Reeves has shown that they take up either of two boat conformations which put the α-D-(1→4) linkages in equatorial positions. Maltose, however, does not seem to have the same extent of boat conformation. Here the only steric requirement is that the 1-hydroxyl on the glycosidic residue and the 4-hydroxyl on the reducing residue be in equatorial positions to make the 1→4 linkage equatorial. This requirement is satisfied if the glycosidic residue is in a boat conformation (actually, most likely the B1), leaving the reducing glucose residue in the C1 conformation. This structure is in accord with the resemblance of the mutarotation thermodynamics of maltose to that of the other sugars shown in Fig. 4 of Part I. Such would not be the case were the reducing residue in maltose also in a boat conformation.

SOLVATION OF THE SUGARS

(*a*) *Evidence for Hydration*

Thermodynamic studies of glucose and sucrose in aqueous solution (9) show that they must be extensively hydrated, presumably by hydrogen bonding between the hydroxyl groups and the water molecules. Evidence from the intrinsic viscosities of aqueous solutions of D-glucose and sucrose shows that the van der Waals volume of these molecules is increased by a factor of about two by hydration (10).

The distances between adjacent hydroxyl groups in the pyranose ring are almost identical with those in the 1,2-cyclohexanediols. There, intramolecular hydrogen bonds can exist when the molecules are in CCl_4 solution (11), and result in decreases of the hydroxyl stretching frequency equal to 32 $cm.^{-1}$ when both hydroxyls are equatorial, and equal to 39 $cm.^{-1}$ when one is equatorial and the other axial. It is apparent from the smallness of these shifts that the intramolecular bonds are very weak. It is therefore highly probable that in aqueous solution, the sugar hydroxyls are directed outwards to oxygen atoms of adjacent water molecules, thus destroying the intramolecular hydrogen bonding between hydroxyls.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

If, however, intramolecular hydrogen bonding is preserved by sugar molecules in solution, the hydroxyl stretching-frequency shift should be of the order of that observed for the 1,2-cyclohexanediols in CCl_4. On the other hand, if the hydroxyls form strong hydrogen bonds with the water oxygens, frequency shifts of several hundred cm.$^{-1}$ might be expected.

Some infrared spectroscopic observations seem pertinent to this subject, and they also give evidence of intermolecular association between sugar molecules. A Perkin-Elmer model 112 spectrometer with a NaCl prism was used to obtain spectra of a 0.1 *M* solution of α-D-glucose in pyridine and of 0.1 *M*, 0.01 *M*, and 0.002 *M* solutions of α-D-xylose in pyridine. The hydroxyl stretching-frequency band of α-D-glucose had a peak about 3250 cm.$^{-1}$ compared with the free hydroxyl value of about 3625 cm.$^{-1}$. With increasing dilution, the peak of the band for D-xylose moved from about 3300 cm.$^{-1}$ to about 3400 cm.$^{-1}$, presumably showing the effect of an association between the sugar molecules.

Since the mutarotation experiments were performed with concentrations of the order of 0.2 *M*, we must conclude that some intermolecular interaction occurred. The same may be said of the experiments of Sturtevant (12), who used concentrations of 0.15–0.3 *M* D-glucose. At low concentrations when intermolecular association was greatly reduced, the hydroxyl stretching frequency still seems too low (~3400 cm.$^{-1}$) for it to be due to intramolecularly bonded hydroxyl groups. It appears that hydroxyl groups of the sugar molecules form hydrogen bonds with the ring nitrogens of the pyridine molecules, rather than remaining intramolecularly bonded. Similarly, in water, the relatively weak intramolecular hydrogen bonds are in all probability replaced by strong bonds with the oxygen atoms of surrounding water molecules.

(*b*) *The Water Structure*

In water, the oxygen atom of each molecule is tetrahedrally coordinated by means of hydrogen bonds to the oxygen atoms of adjacent water molecules, the water structure thus resembling the SiO_2 structure. Bernal and Fowler (13) proposed the rather open tridymite SiO_2 structure for ice, and the closer-packed but still four-coordinated quartz SiO_2 structure for water at normal temperatures. X-Ray diffraction work by Morgan and Warren (14) has shown that the assumption of a quartz structure for water must be modified slightly. Recently, Pople (15) proposed a continuation of the tridymite ice structure with increasing bending of the hydrogen bonds and a movement of molecules into formerly unoccupied regions of the open ice structure.

Fig. 2(*a*) shows a plane of oxygen atoms of water molecules in the tridymite structure (16), as viewed along the hexagonal axis, each hydrogen bond between adjacent oxygen atoms containing a hydrogen atom which is not shown. The hexagons are skew and are all in the chair conformation. The atoms of the plane are repeated directly above and below those shown, but the chairs are rotated through 60°, so that atoms below the median plane of the chair are now above, and vice versa. In Fig. 2(*a*), the atoms marked ▽ and △ are joined by straight hydrogen bonds to the atoms directly above and below, respectively. In the adjacent planes above and below, the corresponding atoms would be marked △ and ▽ with the convention referred to above. The tridymite structure appears in Fig. 2(*b*) as seen from the side.

(*c*) *Hydration of the Monosaccharides*

In discussing hydration of the sugar molecules, we shall take the tridymite structure as a model for water, thus neglecting bending of the hydrogen bonds and the accompanying molecular disorder. The dimension marked on Fig. 2(*a*) for the O—O distance (2.90 Å) was found by Morgan and Warren (14) for water just above 0° C.

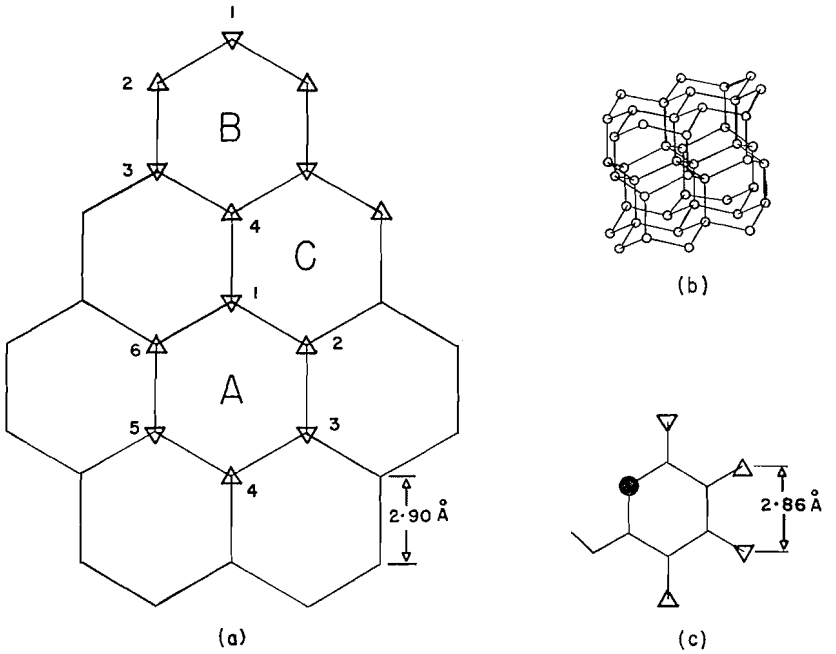

FIG. 2. (*a*) A plane of the tridymite structure in water showing direction of H bonds. (*b*) The tridymite structure. (*c*) The D-glucose molecule showing direction of possible perpendicular H bonds.

Fig. 2(*c*) shows the β-D-glucose molecule from above. The triangles mark the oxygens of hydroxyl groups on $C_{(1)}$ to $C_{(4)}$. Assuming the chair form of Fig. 1 for the β-D-glucose ring, one finds that the hydrogens of these hydroxyl groups may be placed directly above (▽) or directly below (△) the oxygens, and are thus capable of forming hydrogen bonds in these directions in a manner similar to that of the oxygen atoms in the water structure. Furthermore, the distance between adjacent oxygens of the D-glucose hydroxyls (2.86 Å) is almost identical with that between adjacent oxygens in water (2.90 Å).

It is thus apparent that the D-glucose molecule can replace a chair conformation of water oxygens in Fig. 2(*a*), e.g. the hexagon A. The oxygens on $C_{(1)}$ to $C_{(4)}$ replace oxygens marked 1 to 4 forming strong hydrogen bonds with water oxygens in planes above and below; the only distortion involved is the replacement of a hexagon of side 2.90 Å by one of side 2.86 Å. It may be seen from a model that the primary hydroxyl group on $C_{(6)}$ may form a bent hydrogen bond with an adjacent oxygen of a water molecule in the same plane as the sugar molecule. Finally, the "lone-pair" orbitals of the ring oxygen found near position 6 lie in the direction of the hydrogen atom on the adjacent oxygen in the same plane.

There is a second mode of hydration which might also occur. This involves bonding of the equatorial hydroxyls to adjacent water molecule oxygens in the same plane rather than in planes above and below. In order to do this, the molecule must be flattened as if a conformational inversion were taking place.

It seems difficult to choose between these two modes of hydration for equatorial hydroxyl groups. The energy necessary to flatten the ring would seem to favor the first mode of hydration. There seems, however, to be some evidence (17) that the glucose ring consists of five carbon atoms more or less in a plane, with an oxygen atom out of the plane, rather than the skew hexagon of the cyclohexane ring. In this case, the second mode of hydration would probably be favored.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

On the other hand, if we have an axial hydroxyl, inspection of a model shows that hydrogen bonding may take place only with the oxygens of water molecules adjacent to the sugar and in the same plane. A considerably bent H bond is the result, and at the same time a partial inversion of the conformation must take place; because of the bent bond, we conclude that the hydration of an axial hydroxyl group is considerably less than that of an equatorial hydroxyl of a chair conformation. This is in conformity with the preference (as found by Reeves) of the sugars to assume those conformations having equatorial hydroxyls.

The hydration of D-xylose should take place in essentially the same manner as that outlined above for D-glucose.

(*d*) *Solvation of the Disaccharides*

The structure of the cellobiose molecule in the solid is shown from above in Fig. 3(*a*), and is identical with that of any two adjacent units of the cellulose chain (17). The C—O—C valence bond angle of the glycosidic linkage lies in the plane perpendicular to that of the paper so that the linkage appears straight. Haworth (8) originally proposed the structure of Fig. 3(*b*) as the unit of the cellulose chain. The C—O—C valence angle now lies in the plane of the paper and one residue has rotated 60° from position B to C. (In Fig. 3(*a*) appropriate bond distances are foreshortened to allow for the C—O—C valence angle.) It is interesting to note that the over-all lengths of these two different conformations are the same, viz. 10.3 Å. The triangles again show the relative directions of the hydrogen bonds, which can be directed in perpendicular directions.

A consideration of steric interferences in atomic models has led Hermans and his collaborators (18) to propose the cellobiose molecule of Fig. 3(*b*) as a unit of the cellulose chain. More recently, X-ray diffraction work (19) suggests this unit for the cellulose II (mercerized cellulose) chain while the unit of Fig. 3(*a*) is retained for cellulose I (native cellulose).

There are two reasons for supposing that, when the cellobiose molecule is in aqueous solution, the structure of Fig. 3(*a*) may transform itself into that of Fig. 3(*b*). Firstly, in order to fit the two D-glucose residues into the water lattice in the extended form, we

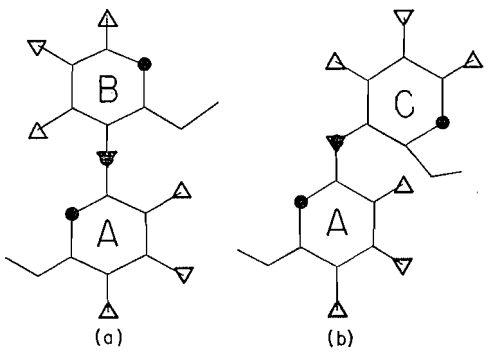

FIG. 3. Two conformations of the cellobiose molecule.

must identify the residues with the two hexagons of Fig. 2(*a*) marked A and B. In A, oxygens on $C_{(2)}$ to $C_{(4)}$ fall on points 2 to 4, and in B, oxygens on $C_{(1)}$ to $C_{(3)}$ fall on points 1 to 3. However, as shown by the positions of the triangles, the hydroxyls in D-glucose residue B cannot form hydrogen bonds in the directions required by hexagon B of the water lattice. The second point is that the over-all length of hexagons A and B in the water lattice is ~12.2 Å, whereas the corresponding cellobiose length is 10.3 Å;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

this discrepancy would appear to be rather large and would result in greatly decreased hydration.

In the structure of Fig. 3(*b*), however, both residues will fit into the water lattice. Having rotated the residue B through 60° to position C, the hydrogen bonds now fit with those of hexagon C in the water lattice. Furthermore, the dimensions are such as to allow the molecule to take the place of the two adjacent hexagons A and C in the water structure without undue distortion.

As a result of these considerations, it seems likely that the cellobiose molecule takes up Haworth's Fig. 3(*b*) conformation in aqueous solution rather than retaining the conformation followed by the solid (Fig. 3(*a*)).

Presumably the same point of view will hold good for lactose. As previously mentioned, there is some evidence of distortion of the C1 galactose conformation owing to the axial 4-hydroxyl, possibly to increase hydration. This might also exist in the galactose residue in lactose.

The structure of maltose in solution may be deduced from that of amylose in solution. Haworth (8) originally proposed a conformation for amylose analogous to that which he suggested for cellulose. It is capable of forming spiral structures (20) whose dimensions have been verified by X-ray diffraction measurements on the amylose–iodine complex (21). Fig. 4 shows two units of the chain. The residue to the right must be considered to be in a boat conformation. While the dimensions of the molecule are appropriate for fitting it into the water structure, consideration of the model shows that, owing to the boat conformation, at least one of the hydrogen bonds formed by the right-hand residue must be somewhat bent. One might therefore expect that hydration of maltose would be less than that of other sugars.

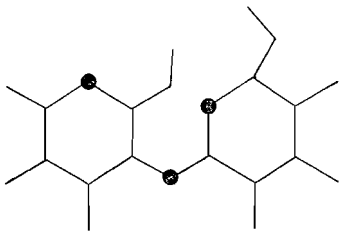

FIG. 4. The structure of the maltose molecule in solution.

As a result of the foregoing discussion of hydration, it seems likely that the packing of water molecules about the reducing hydroxyls will be much the same in D-glucose, D-xylose, cellobiose, lactose, and maltose. We have already noted the similarity of the conformations of these sugars. It thus appears that the differences in the thermodynamics of mutarotation presented in Part I must be due to rather small perturbations in the neighborhoods of the reducing carbons of these sugars.

THERMODYNAMICS OF MUTAROTATION

The negative ΔH for mutarotation of the sugars in Table I of Part I is in accord with the greater hydration for equatorial hydroxyl groups than for axial groups. Some of the values of ΔS are positive while others are negative; most would seem to be rather large as has been pointed out in Part I. Furthermore, the variation in ΔS amongst the sugars studied seems extremely large since the nearest neighbors of the reducing carbon are the same throughout, the conformations of the reducing residue being the same, in spite of small distortions of the molecules induced by the hydration. We shall first

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

develop a model to show that the large ΔS values are reasonable, and then use the model to discuss the relation between ΔH and ΔS manifested in Fig. 4 of Part I.

(a) The Magnitude of the Entropy Change

The entropy of a single vibrational mode is given (22) by

$$[1] \qquad S = k\left[\frac{x}{e^x-1} - \ln(1-e^{-x})\right], \qquad x = h\nu/kT,$$

where ν is the vibrational frequency,
k is Boltzmann's constant, and
h is Planck's constant.

ΔS for the mutarotation is thus given by a summation of terms as in [1] if the change of vibrational frequencies upon mutarotation is known. It seems natural to suppose ΔS to result from the changing of frequency in a relatively small number of modes per molecule. For instance, Barker, Bourne, Stacey, and Whiffen (23) have demonstrated the existence of small characteristic differences between the spectra of α and β anomers of D-pyranoses in the region of 730–960 cm.$^{-1}$. Consideration of [1] shows, however, that the contribution of a vibrational mode to the entropy diminishes with increasing frequency so that frequency changes in the above region produce a negligible contribution to the entropy change. The largest change of frequency mentioned by Barker and collaborators produces a change of about 0.032 e.u. One must therefore seek the basis of the large ΔS values in a low-frequency vibrational mode, which is thus likely to be associated with a torsional oscillation rather than a bond bending vibration. The torsional oscillation of the OH group about the $C_{(1)}$—O bond would seem to be an attractive possibility. The torsional oscillation of the free hydroxyl in CH_3OH vapor (24) was found to have a mean frequency of 225 cm.$^{-1}$. With the formation of the hydrogen bond in the liquid phase of CH_3OH, the hydroxyl oscillation gives a very wide band centering about 650 cm.$^{-1}$ (25). In the case of a sugar hydroxyl hydrogen-bonded to a water molecule, the shift in the hydroxyl stretching frequency is rather less ($\sim$200 cm.$^{-1}$) than in the case of the hydroxyl in polymeric liquid methanol (301 cm.$^{-1}$(11)).

It is therefore reasonable to suppose a smaller energy for the hydrogen bond in the D-glucose hydration case than in liquid methanol. Hence one might expect an OH torsional frequency between 225 cm.$^{-1}$ and 650 cm.$^{-1}$, and thus of the order of magnitude required to give the ΔS values found. (A torsional frequency of 400 cm.$^{-1}$ gives a contribution to the entropy, following [1], of $\sim$1 e.u.)

(b) Model of the Hydrogen Bond

The following simple model of the hydrogen bond between the reducing hydroxyl and an adjacent water oxygen atom may be used to determine the order of magnitude of the hydroxyl's frequency of torsional oscillation. We assume electrostatic forces between point charges of magnitude $-q$ and $+q$ at the O and H of the reducing hydroxyl group and a charge $-2q$ at the O of the adjacent water molecule, as shown in Fig. 5. For the simple calculation which follows, we neglect the effect of $C_{(1)}$ and the ring on

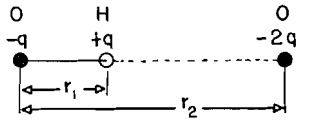

FIG. 5. Simple model of the hydrogen bond.

For personal use only.

the charges of the hydroxyl oxygen and hydrogen. A repulsive Born–Mayer interaction also exists between the hydroxyl H and the water oxygen. This adds a term A/r^n to the energy. Verwey (26) in his simplified treatment of the hydrogen bond in water takes $n = 12$. Allowing the hydroxyl group to make small oscillations through an angle ϕ about an axis through its oxygen and perpendicular to the O—H direction, we find the torsional force constant:

$$g = [\partial^2 E/\partial\phi^2]_{\phi=0},$$

where E is the energy of the system. In this way,

$$[2] \qquad g = \frac{2q^2 r_1 r_2}{(r_2-r_1)^3}\left[1-\left\{\frac{An}{2(r_2-r_1)q^2}\right\}^{n-1}\right].$$

$(An/2q^2)^{n-1}$ has the dimensions of a (length)$^{n-1}$, or R^{n-1}. R has the physical significance of being the distance between the hydrogen and the water oxygen at which the repulsive force between these two atoms balances the attractive force. Then [2] becomes

$$[3] \qquad g = \frac{2q^2 r_1 r_2}{(r_2-r_1)^3}\left[1-\left\{\frac{R}{(r_2-r_1)}\right\}^{n-1}\right],$$

and the frequency is given by

$$\frac{1}{\lambda} = \frac{1}{2\pi c}\sqrt{\frac{g}{I}},$$

where I is the moment of inertia of the hydroxyl group about its axis of rotation. The energy of the hydrogen bond may be written as:

$$[4] \qquad E = -2q^2\left[\frac{1}{(r_2-r_1)}\left\{1-\left(\frac{1}{n}\right)\left(\frac{R}{r_2-r_1}\right)^{n-1}\right\}-\frac{1}{r_2}\right].$$

We take $q = 1.51\times10^{-10}$ e.s.u., chosen to give a dipole moment of 1.86 D. to the water molecule,

$$r_1 = 0.96 \text{ Å},$$
$$r_2 = 2.90 \text{ Å},$$
$$I = 1.236\times10^{-40} \text{ g-cm.}^2 \text{ (Ref. 24)}.$$

From the relation of ΔH to ΔS (Fig. 4, Part I), it will be found that $[R/(r_2-r_1)]^{n-1} \sim 0.7$. Using these values in [3], g becomes 5.63×10^{-13} ergs and the frequency of torsional oscillation of the OH group is 360 cm.$^{-1}$, which seems very reasonable when compared with the OH torsional frequency of methanol. The energy of the hydrogen bond between the hydroxyl group and the oxygen atom of the adjacent water molecule is ~9.7 kcal./mole, which must be considered rather high. The effect of $C_{(1)}$ would be to raise the negative charge of the hydroxyl oxygen above that assigned to it here, and therefore to lower the energy of the hydrogen bond. A more detailed calculation does not appear warranted, however, since only orders of magnitude are sought.

THE RELATION BETWEEN ΔH AND ΔS

We shall assume that ΔH and ΔS change from sugar to sugar in Fig. 4 of Part I by reason of slight perturbations in the surroundings of the reducing hydroxyl which change the length of the hydrogen bond between the hydroxyl and the adjacent water molecule. This in turn is manifested in small changes in the enthalpy and entropy of either or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

both of the α and β anomers, causing a variation of ΔH and ΔS between the sugars. Furthermore, we shall use the simple model of the hydrogen bond developed above for both anomers of the sugars. Thus, supposing slight changes $\Delta r_2'$ and $\Delta r_2''$ in the lengths of the hydrogen bonds in the α and β anomers respectively, the changes in ΔH and ΔS are given by:

$$\delta\,\Delta H \simeq \left(\frac{\partial E}{\partial r_2}\right)(\Delta r_2'' - \Delta r_2') \equiv \frac{\partial E}{\partial r_2}\,\Delta r_2,$$

$$\delta\,\Delta S \simeq \left(\frac{\partial S}{\partial r_2}\right)(\Delta r_2'' - \Delta r_2') \equiv \frac{\partial S}{\partial r_2}\,\Delta r_2.$$

Here E and S are given by expressions [4] and [1] respectively. Thus,

$$[5] \qquad \delta\,\Delta H = \frac{2q^2}{(r_2-r_1)^2}\left[1-\left(\frac{R}{r_2-r_1}\right)^{n-1}-\left(\frac{r_2-r_1}{r_2}\right)^2\right]\Delta r_2$$

and

$$[6] \qquad \frac{\delta\,\Delta S}{R} = -\frac{x^2e^x}{(e^x-1)^2}\,\frac{1}{2g}\,\frac{\partial g}{\partial r_2}\,\Delta r_2.$$

In [6], using [3], and deriving g with respect to r_2, we have

$$[7] \qquad \frac{\delta\,\Delta S}{R} = -\frac{x^2e^x}{2(e^x-1)^2}\left[\frac{1}{r_2}\left\{1-\frac{3r_2}{r_2-r_1}\right\}+\frac{[(n-1)/(r_2-r_1)][R/(r_2-r_1)]^{n-1}}{1-[R/(r_2-r_1)]^{n-1}}\right]\Delta r_2.$$

Using the previously given values of the various quantities and with $[R/(r_2-r_1)]^{n-1} = 0.7$, we find $\Delta H = -2790 r_2$ cal./mole with r_2 in Å. Thus, a change of 0.1 Å produces 279 cal./mole change in ΔH. Correspondingly, $\delta\,\Delta S/R = -4.76\ \Delta r_2$ where r_2 is in Å. For $\Delta r_2 = 0.1$ Å, $\delta\,\Delta S = 0.946$ e.u. Furthermore, the slope of the line in Fig. 4 of Part I is given by

$$\mathscr{E}^* = \frac{\delta\,\Delta H}{\delta\,\Delta S/R} = 580 \text{ cal./mole.}$$

Although this figure is lower than the experimental value of 741 cal./mole, the agreement must be considered satisfactory considering the simplicity of the model. The value of $\mathscr{E}^*$ is not sensitive to the choice of $[R/(r_2-r_1)]^{n-1}$. When $[R/(r_2-r_1)]^{n-1} = 0.45$, the electrostatic attraction H . . . . . $O_{(2)}$ balances the $O_{(1)}$—$O_{(2)}$ electrostatic repulsion plus the Born–Mayer repulsion. Here $\delta\,\Delta H = 0$, and $\mathscr{E}^* = 0$. With our choice of $[R/(r_2-r_1)]^{n-1}$, we are assuming that the OH and the water oxygen are pushed slightly nearer together than this equilibrium distance.

STERIC INTERACTIONS IN THE PYRANOSE RING

Finally a word must be said about the steric interactions in the pyranose ring. Eliel and Lukach (27) have recently obtained a value for the free energy change for $OH_a \rightarrow OH_e$, and have made a comparison with other values available in the literature. There is a rather wide spread of these values, and the authors suggest a possible effect of the solvent used. Of the values mentioned, probably only that found by Angyal and McHugh (1) is relevant here, since although cyclitols rather than pyranoses were studied, their experiments were carried out in aqueous solution.

We notice that for all of the sugars in Table I of Part I, $\Delta F \sim 0.33$ kcal./mole. In each of these sugars the reducing residue is in the C1 conformation, and the change from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

the α to the β anomer breaks two OH_a: H_a interactions and replaces an OH_e: OH_e interaction by an OH_e: OH_a interaction within the molecule. To a first approximation, these last two interactions may be taken as equal. At the same time, an axial group has become equatorial, changing the hydration energy of the molecule in aqueous solution. Thus, the total change of free energy may be written:

$$E - A - 2(OH_a: H_a) = 0.33 \text{ kcal./mole},$$

where E is the hydration free energy of an equatorial OH,
A is the hydration free energy of an axial OH,
OH_a: H_a is the free energy for formation of an OH_a: H_a interaction.

Thus OH_a: $H_a + \frac{1}{2}(A-E) = 0.17$ kcal./mole.

Angyal and McHugh have not taken account of hydration of the cyclitol hydroxyls explicitly. Nevertheless, of one allows for this effect, it is found that their interaction free-energy OH_a: H_a becomes OH_a: $H_a + \frac{1}{2}(A-E) = 0.45$ kcal./mole.

Thus a discrepancy exists between the two values. A tentative explanation may be advanced.

In the pyranose ring, the ring oxygen has four unpaired electrons located in two "lone-pair" orbitals on the upper side of the ring oxygen in Fig. 1. These would repel the corresponding "lone-pair" orbitals of the $C_{(1)}$ hydroxyl, and one might expect that the α anomer would be preferred to the β anomer. Such an effect has been mentioned by Edward (28). The size of the effect obviously depends on the orientation of the hydroxyl group in the α and β anomers, and hence on the manner of hydration. Two possible modes of hydration of the OH in the β anomer were considered above. It is interesting to note that the effect hardly exists for one mode of hydration, that where the hydroxyl forms a hydrogen bond with the plane of water molecules above the plane of the sugar molecule. With the other mode of hydration, that in which the hydrogen bond is directed to a water molecule in the same plane as the sugar molecule, the effect would be important Here, the lone-pair orbitals of the ring oxygen and the hydroxyl oxygen are considerably closer together in the β anomer than in the α anomer.

We may note also that the other interaction free-energies of the OH groups in the cyclitols as found by Angyal and McHugh are an indication of hydration of the cyclitols.

The interactions OH_a : OH_a and OH_e: OH_e† are found to have free energies of formation of 1.9 kcal./mole and 0.35 kcal./mole (13) respectively. In the cyclohexanediols in CCl_4, however, Kuhn finds intramolecular hydrogen bonding between pairs of OH groups and particularly in the OH_a: OH_a case. If this intramolecular hydrogen bonding were to exist for the cyclitols in aqueous solution, one would expect negative free-energies. On the other hand, hydrogen bonding of the hydroxyls to water molecules would break the intramoleculr hydrogen, turning the hydrogens of the hydroxyls outward. This would allow the "lone-pair" orbitals of the hydroxyl oxygens to interact and thus contribute towards a positive ΔF.

It may be further shown that if hydration is allowed for, we have OH_a: $OH_a + (A-E)$ = 1.9 kcal./mole,

$$OH_e: OH_e = 0.35 \text{ kcal./mole}.$$

Thus, in the case of interaction between two axial hydroxyls the essentially positive

†*Angyal and McHugh do not differentiate between* OH_e : OH_e *and* OH_a : OH_e. *However, they appear to have actually found* ΔF *for* OH_e : OH_e *interactions, the other type of interaction cancelling out of the calculation.*

term $(A-E)$ also contributes to the high positive values for the total interaction free-energy.

ACKNOWLEDGMENTS

We wish to thank Dr. C. Sandorfy of this department, who very kindly obtained the infrared spectra referred to in the paper. We are grateful to Dr. H. Favre of this department for many interesting discussions of stereochemical problems and to Dr. R. U. Lemieux for a helpful discussion of this work. Finally, we would like to acknowledge the generous financial assistance of the National Research Council for which we are extremely grateful. One of us (M.A.K.) was the recipient of an N.R.C. studentship while doing this research, and the other (D.P.) was a Summer Research Associate for part of the time.

SOME ANOMALOUS ELECTRICAL POLARIZATIONS[1]

PETER PODLESCHKA, LISELOTTE WESTLAND, AND GEORGE F WRIGHT

ABSTRACT

Dielectric-constant determinations of a series of solids previously reported to have high atom polarizations have not confirmed earlier opinions. Moreover, when it has been practicable to determine the change in polarization with respect to temperature, the relationship is not invariant. This variation may be, and in some instances should be, interpreted as evidence for orientation polarization. However, all such assignments cannot be certain until the change in solid dielectric constant with respect to temperature has been studied.

INTRODUCTION

This report is a continuation of recent (1) work showing that many electrical polarizations formerly attributed entirely to distortion polarization seem instead to have a component of orientation polarization in an applied field of about 1 electrostatic volt at 500 kc. These reassignments were based on dielectric constants of thin pellets pressed to maximum density from randomly oriented powders and were confirmed by determinations of the dielectric constants in benzene solutions at several temperatures. The present results, shown in Table I, also have previously been assigned abnormally high atom polarizations in lieu of orientation polarizations. These assignments seem to have been made in deference to current organic chemical theory or by analogy with another substance of the same class. It is evident from the data of Table I that the earlier opinions require revision. Each item will be discussed in order of appearance in the table.

TABLE I

DIELECTRIC CONSTANTS OF SOME SOLIDS AND SOLUTIONS IN BENZENE

Substance	d^{20}	ϵ, solid	Solution						
			Temp., °C.	$\Delta\epsilon/\Delta\omega$	$\Delta V/\Delta\omega$	P_T, cc.	P_{e+a}, cc.	P_e,* cc.	μ, D.
p,p'-Dicyanobiphenyl	1.267	3.244					68.9	61.1	
Tetramethylcyclobutanedione	1.167	2.406				47–48*	38.3	37.7	0.8*

Quoted from pertinent literature (4, 5).
†*These pellets contain 2% of Koroseal.*

p,p'-Dicyanobiphenyl

In our earlier publication we doubted that the total polarization of 4,4'-dinitrobiphenyl in benzene could be due to electronic plus atomic polarization alone, because our distortion-polarization determination was only 0.8 cc. more than a reasonable value for electronic polarization. Moreover, our total polarization in benzene was about 10 cc.

[1]*Manuscript received November 20, 1957.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

lower at 40° than that found by LeFevre and Vine (2) at 25°. The latter criterion of orientation polarization may be questionable because of the low solubility at 25°. For the same reason we would not rely on the total polarization value for the dicyano analogue in benzene, either as it was reported by LeFevre and Vine (at 25°) or on our own attempt to get a meaningful value at 40°. Therefore we cannot affirm that *p,p'*-dicyanobiphenyl has an orientation polarization. But we can say that the distortion polarization of 68.9 cc. which we found by capacitance measurements on the pelleted solid can account for only 68.9 − 61.1 = 7.8 cc. of atom polarization, in contrast to the larger value (35 cc.) previously assigned (3).

Tetramethylcyclobutanedione

The total polarization of this substance has been reported as 46.9 cc. in the vapor phase (4) and 48.5 cc. in benzene (5). Since the electronic-polarization value calculated from the latest bond constants (6) accounts for only 37.4 cc., our distortion polarization, determined experimentally, would include only 0.9 cc. of atom polarization. Thus there remains about 9 cc. of polarization indicative of a low orientation polarization for this supposedly rigid molecular structure.

p-Dinitrobenzene

The dielectric constant of pellets of this substance shows that the distortion polarization is 40.1 cc., or 1.6–1.9 cc. higher than the electronic polarization calculated from group refractions. This directly determined atom polarization is somewhat lower than that postulated (4) previously (8.2 cc.). In order to confirm our result we have determined the polarization in benzene solution at 20°, 30°, and 40° C. We find (Table I and Fig. 1) that the total polarization does vary appreciably with temperature, as would be expected if it included a component of orientation polarization. Although this interpretation is contrary to that of Coop and Sutton (4) the experimental work may not be in disagreement. From the curvature of the plot of total polarization versus the reciprocal of absolute temperature (Fig. 1) it might be expected that the polarization at 200°–255° C. would be close to the 46.5 cc. that Coop and Sutton observed in their vapor phase study.

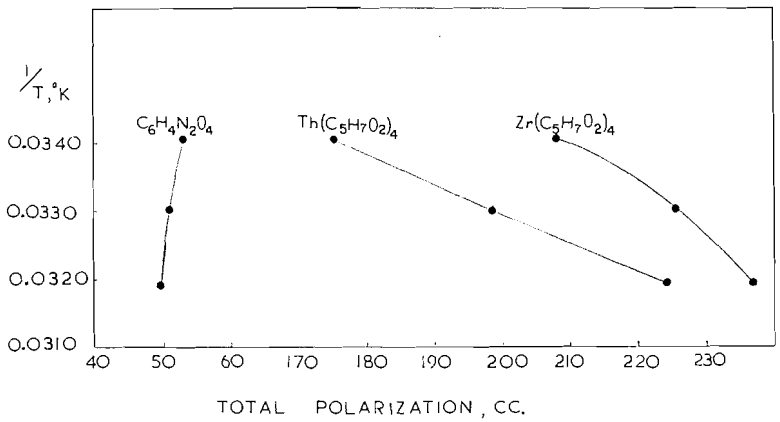

FIG. 1. Temperature coefficient of electrical polarization.

Agreement between our results and those of LeFevre and LeFevre is not as satisfactory. These workers found approximately the same polarization (46 cc.) in benzene at 25° and 45°, whereas in our apparatus (in which benzene solutions of naphthalene give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

polarizations of 46.5 cc. for the latter substance both at 20° and 40°) the polarization of *p*-dinitrobenzene in benzene varies from 53.0 to 49.7 cc. over the 20° temperature range. The only difference (aside from the method of computation) apparent to us is the higher purity (m.p. 177.5°–178°) of our sublimed dinitrobenzene over that (m.p. 171°–172°) used by the earlier workers. Of course the greater precision due to improvements in electrical circuitry since 1935 may be contributory.

At any rate our results compel us to an assignment of a small but significant moment for *p*-dinitrobenzene which varies from 0.78 debye to 0.69 debye over our 20° temperature range. Since the moment decreases with increasing temperature it is unlikely to be due to out-of-plane bending of the nitro groups because of thermal agitation in a normally planar structure.

Indeed there is evidence that *p*-dinitrobenzene is normally not completely coplanar (7, 8). These structure analyses by X-ray diffraction have designated an angle of 11° 42′ between the planes of the nitro group and the benzene ring in an otherwise symmetrical molecule, but the electron density maps do not actually confirm the postulation of a centrosymmetrical molecule. In point of fact the possibility of accumulated errors (angle error ±2%) makes the X-ray diffraction study of limited value as a criterion of the out-of-plane atom distribution, which could account for the observed temperature-dependent polarization (9).

Metal Acetonylacetates

Two of these organometallic compounds have been studied. The polarizations found for thorium acetylacetonate at 20° and 30° in benzene fall in line approximately with the polarization in this solvent observed previously at 25° (10). The trend in our polarization data at 20°, 30°, and 40° is in disagreement with the previously determined vapor phase measurement, but observable decomposition (4) renders the latter observations unreliable. Of interest is the large temperature coefficient (Table I and Fig. 1) which we have observed in benzene solution. This evidence for appreciable orientation polarization (1.18–2.00 debyes from 20° to 40°) is confirmed by a separate determination of the dielectric constant of randomly distributed solid thorium acetylacetonate. Comparison of P_{e+a} (145.7 cc.) derived by this method with the P_e (127.5 cc.) calculated from refractive indices of benzene solutions (7) shows an atom polarization (P_A = 18.2 cc.) not very different from that reported for beryllium acetylacetonate (P_A = 21.2 cc.). The latter substance is the only one of the metal chelates with which a temperature–polarization study has previously been made, and the data showed that it had no permanent dipole moment (7).

Comparisons like these above are unsatisfactory in the case of zirconium tetraacetylacetonate. From the dielectric constant of the randomly oriented solid a distortion polarization (P_{e+a} = 136.0 cc.) has been calculated which is only 12.5 cc. greater than the electronic polarization calculated by Finn, Hampson, and Sutton (10). However, we are reluctant to compare any of our data for zirconium acetylacetonate with theirs. One cannot tell from the report by these authors whether their sample was pure. Neither melting point, density, nor analysis is mentioned so it is uncertain whether their sample was completely anhydrous. We have found the melting point (11) to be an unreliable criterion, but analysis for carbon, hydrogen, and water shows that our sample is pure within the limits of precision for these determinations.

The purity of our sample is important because our total solute polarizations of zirconium acetylacetonate (Table I) at 20° and 30° are both higher than that reported

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(7) at 25°. Reference to Fig. 1 shows that the polarization increases markedly with increasing temperature. The line drawn through these polarization values differs from that for the thorium analogue because it is curved. This curvature might suggest a limiting temperature at which polarization is invariant.

One may be inclined to interpret these temperature-variable polarizations entirely in terms of dipole moment, but at present there is no justification for this simple interpretation. It seemed reasonable to us when we designated the temperature-dependent polarization of ferric acetylacetonate entirely in terms of dipole moment (1) because it decreased as temperature increased. Of course the opposite effect for thorium and zirconium acetylacetonates does not exclude the possiblity that these substances have dipole moments which increase because of less intramolecular hindrance at higher temperatures. In short the thorium and zirconium acetylacetonates might resemble a sterically hindered compound like 1,2-dichloroethane (3, p. 281). But also temperature-variation of atom polarization might occur as it does in substances like barium titanate (12). Such behavior would not be unexpected in these metal chelates, the molecular character of which need not entirely obliterate some salt-like properties.

It might have been expected that we would test the latter postulation by examination of the dielectric constants of the solids at different temperatures. Unfortunately we have not yet been able to devise a proper instrument for this purpose. An ultimate decision concerning the temperature-variable polarizations of thorium and zirconium acetylacetonates must await the successful construction of such apparatus.

The authors wish to thank P. Cooper, W. Boos, and M. Malaiyandi for experimental aid. The investigation could not have been made without generous financial support by the National Research Council of Canada. Mr. C. C. Meredith has given valuable advice.

EXPERIMENTAL*

Purification of Materials

The solvents used for dielectric-constant studies were purified and maintained as was described previously (1). Dicyanobiphenyl, prepared according to Ferris and Turner (13), was obtained in 70% yield, m.p. 185°–220°. After crystallization from pyridine, acetic acid, pyridine, and dioxane (m.p. 228°–232°, 39% of crude) the substance was sublimed at 180°–190° (20 mm., m.p. 232°–235°) and then crystallized (Darco) from ethanol (75 ml. per g.) to melt at 236°–237.5°. Tetramethylcyclobutanedione, synthesized from isobutyroyl chloride and triethylamine (14), was purified by repeated crystallization from benzene and finally by sublimation at 95° (750 mm.) during 4 days, repeated until a melting point of 114°–114.4° was attained. Dinitrobenzene (E.K. White Label) was sublimed repeatedly at 150°–160° (750 mm.) until it melted at 177.5°–178°. Thorium acetylacetonate (15) was crystallized from ethanol, m.p. 171°, when inserted at 155° (6° per min.). Titration with Karl Fischer reagent showed that not more than 0.15 $\pm$0.05% of water could be present.

Many crystallizations of the decahydrate of zirconium acetylacetonate (16) were required in order to remove the water. The crystallization temperature should not exceed 40°. Titration of the dehydrated form (m.p. 190°–191°) with Karl Fischer reagent showed that not more than 0.3$\pm$0.05% of water could be present. The sample used for dielectric constant determination was dried at 40° (20 mm.) for 24 hours before use. The density at 20° was found to be 1.415. According to combustion analysis the percentage of hydrogen in this sample is 5.68% as compared with 5.78% expected in $C_{20}H_{28}O_8Zr$.

Melting points have been corrected against reliable standards: Can. J. Technology, **34, 89 (1956).*

FIG. 3. Dielectric constants (*F*, *D*, *E*) and specific volumes (*V*, *U*, *W*) respectively for *p*-dinitrobenzene, thorium acetylacetone, and zirconium acetylacetonate in benzene at 30°.

FIG. 4. Dielectric constants (*A*, *B*, *C*) and specific volumes (*Q*, *P*, *S*) respectively for *p*-dinitrobenzene, thorium acetylacetonate, and zirconium acetylacetonate at 40°.

Density of Solids

These densities were determined by the air-displacement method described previously (17). The density determination of tetramethylcyclobutanedione was subject to error because of the significant vapor pressure of this substance. This error was evaluated and corrected after a series of analyses with samples varying in weight from 0.3 to 1.0 g.

Dielectric-Constant Measurements

The procedures and equipment described previously (1, 18) were used. A modification of the method for determination of ϵ for solids (17) involved a test capacitor built from a mild steel annulus 2.5 in. I.D. and 4 in. O.D. by 1 in. thick which was diametrically drilled for a Shardlow micrometer head at the top and a polystyrene-insulated "anvil" rigidly connected at the bottom to the ungrounded side of the VFO resonant circuit. Although this capacitor was very good for measurements at room temperature it was unsatisfactory at higher temperatures because of mechanical distortion, despite a prior normalization of the annular ring at liquid air temperatures.

The measurements in benzene solutions are shown in Figs. 2, 3, and 4. It may be seen that the dielectric constants and specific volumes are closely convergent at 20° (for benzene alone $\epsilon = 2.284$ and $\bar{V} = 1.1380$) and at 30° (for benzene alone $\epsilon = 2.263$ and $\bar{V} = 1.1525$) but at 40° (for benzene alone $\epsilon = 2.241$ and $\bar{V} = 1.1675$) two batches of benzene were used. The lack of convergence at 40° actually is less serious than is apparent. In each experiment the extrapolation to the dielectric constant and the specific volume at zero concentration is within 0.0003 and 0.0001 respectively of the values for the pure solvent (1). The differences actually are due to variations in the residual capacity following disassembly of the test capacitor. At any rate the values for the most critical of these determinations (that of the *p*-dinitrobenzene) are very close to the dielectric

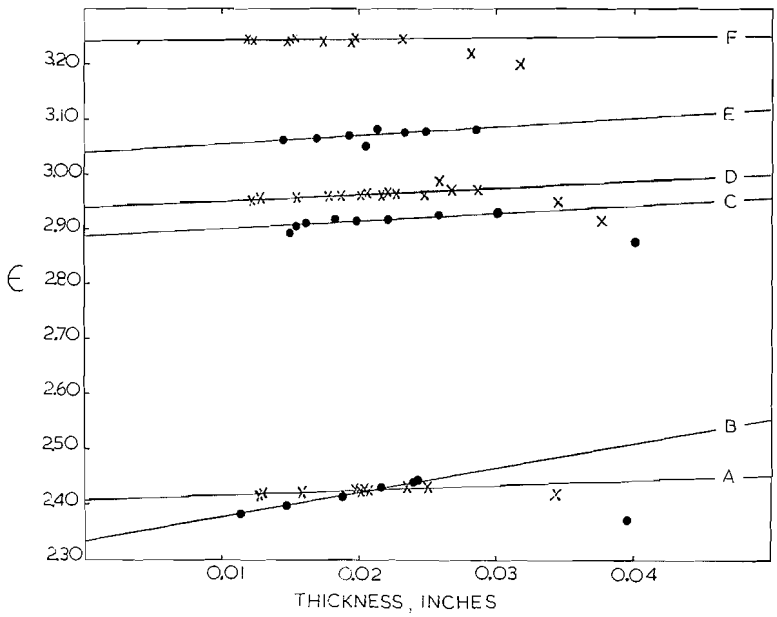

FIG. 5. Dielectric constants of solid:

constant (2.2410) and the specific volume (1.1675) found for the pure solvent immediately after reassembly of the cell.

The dielectric constants of the solids, shown in Fig. 5, have been determined by use of gold amalgam. Included are data for the polyvinyl chloride sold under the trade name Koroseal. It is necessary to use 2% of this binder for satisfactory pelleting of some substances, such as the metal acetylacetonates marked † in Table I. In these instances a correction has been made by adding algebraically 2% of the difference between the dielectric constant of Koroseal and the mixture to the dielectric constant of the mixture.

It may be seen in Fig. 5 that the pellets of greatest thickness usually show dielectric constants lower than those falling on an extrapolatable line. It has been found by the flotation method that these pellets are less dense than those of lesser thickness. Since all pellets have been pressed at 12,000 lb. dead load, which is close to the yield-point of our dies, it is evident that thin pellets must be used for this method of determining distortion polarization.

THE SYNTHESIS OF CRYPTOPLEURINE AND RELATED PHENANTHROQUINOLIZIDINES[1]

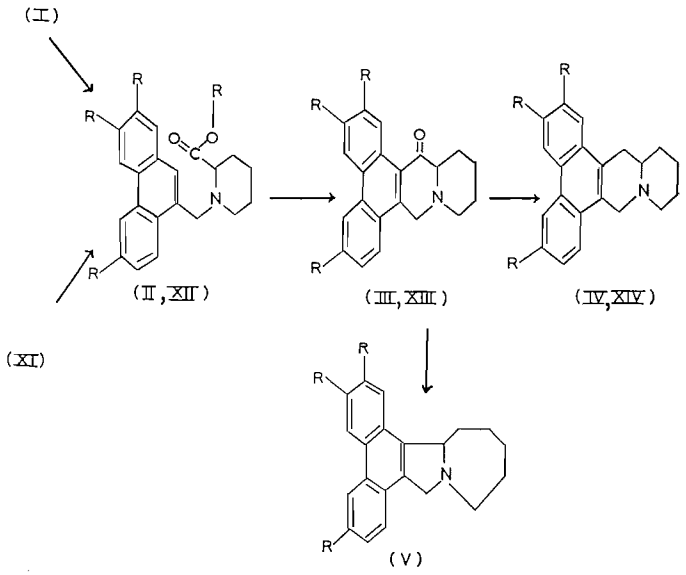
P. MARCHINI[2] AND B. BELLEAU

ABSTRACT

The synthesis of the alkaloid cryptopleurine has been accomplished by a sequence involving as the key step the cyclization of amino acid XII. It was established that the approach is applicable to the synthesis of simpler phenanthroquinolizidines such as IV. The biogenesis of the alkaloid is briefly discussed.

INTRODUCTION

The structure of the unusual alkaloid cryptopleurine (1) was deduced by Fridrichsons and Mathieson (2) by an X-ray investigation and its chemistry examined by Gellert (3). The remarkable physiological properties of this alkaloid have been described by de La Lande (1). Recently Bradsher and Berger (4) reported on a synthesis of cryptopleurine through the application of the general method already developed by Bradsher and Beavers (5, 6) for the synthesis of polycondensed quinolizines. In an independent investigation which was completed at the time Bradsher's report appeared, we accomplished the synthesis of cryptopleurine by a different route involving a series of well-characterized intermediates. Our approach differs from that of Bradsher's in that only reduced quinolizines are involved as intermediates (Chart I).



II, III, IV, V, R = H.
XII, XIII, XIV, R = CH_3O—.

CHART I.

In a model experiment, the synthesis of the phenanthroquinolizidone III was attempted through cyclization of the amino acid II, which was readily obtained from 9-chloromethylphenanthrene and methyl pipecolate followed by acid hydrolysis; this amino acid (II)

[1]*Manuscript received November 14, 1957.*
Contribution from the Department of Biochemistry, School of Medicine, Laval University, Quebec, Que.
[2]*Postdoctorate Fellow of the National Research Council of Canada (1956–1958).*

was heated to 100° in polyphosphoric acid whereupon smooth ring closure to the desired amino ketone (III) occurred in 50% yield. Optimum conditions for this conversion were studied and are given in the experimental section. Evidence for structure III is based on elemental analysis, the infrared absorption spectrum which includes a strong band at 1664 cm.$^{-1}$ characteristic of an aromatic ketone, and the ultraviolet spectrum (curve B, Fig. 1) which shows the characteristic secondary peak of 9-phenanthryl ketones at 320 mμ (7,8). Reduction of the ketone (III) by the Huang-Minlon (9) procedure afforded

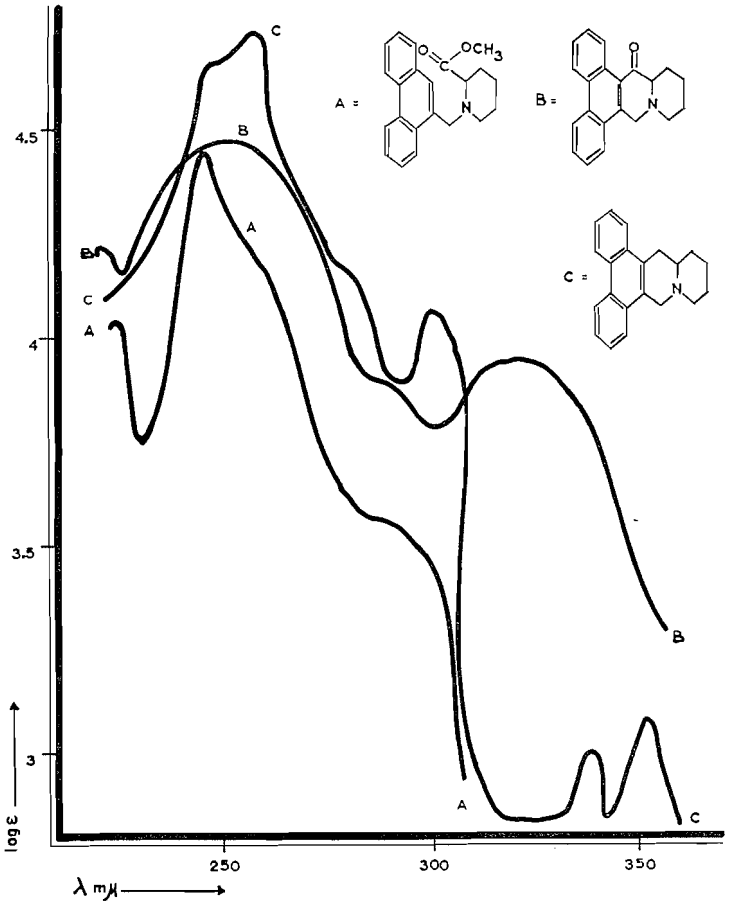


FIG. 1.

the desired phenanthroquinolizidine (IV) in high yield. Its ultraviolet absorption spectrum (curve C, Fig. 1) shows only the characteristic absorption bands of the phenanthrene nucleus, as expected. It is pertinent to note that Clemmensen reduction of the ketone (III) also produced a crystalline base in high yield of identical composition, but different from the one obtained by Wolff-Kishner reduction. Structure V is assigned to this product on the basis of the previous observations of Leonard and Wildman (10) on the reductive rearrangement of 1-quinolizidones.

With these results on hand, the synthesis of cryptopleurine itself could be considered, and a sequence of reactions also adopted by Bradsher (4) for the preparation of 9-bromomethyl-2,3,6-trimethoxyphenanthrene was carried out. Details of this synthesis are given in the experimental section and differ from Bradsher's synthesis in that only the

For personal use only.

pure crystalline 9-chloromethyl derivative was used as a key intermediate. Reaction of the latter with methyl pipecolate followed by hydrolysis gave the amino acid (XII), which underwent smooth ring closure to 1-cryptopleurinone (XIII) when heated in polyphosphoric acid. The ultraviolet spectrum of the latter was recorded and as can be seen in Fig. 2 (curve E), the principal maxima exhibit a bathochromic shift with respect to the phenanthrene series and although the spectrum is similar to the one reported for

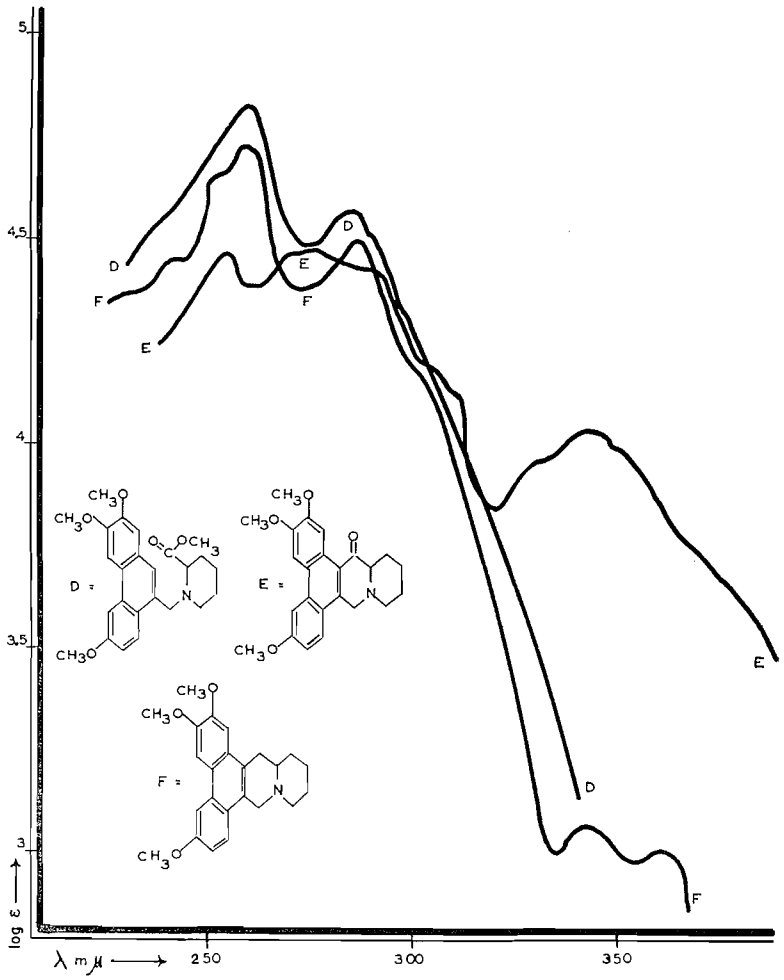

FIG. 2.

cryptopleurine, the peak at 345 mμ is of much greater intensity. Wolff-Kishner reduction of this ketone (XIII) gave rise to a mixture of phenolic compounds from which after treatment with diazomethane a small amount of crystalline material was obtained. The identity of the latter with cryptopleurine was ascertained by mixed melting point determination and by comparison of the infrared spectrum with an authentic specimen kindly provided by Dr. Bradsher. It should be noted that the spectrum was virtually superimposable on that of cryptopleurine except for the presence of a low-intensity band at 1700 cm.$^{-1}$ which is absent in the authentic specimen. It is most probable that this minor difference can be attributed to the presence of trace amounts of unchanged starting material in our sample or to deterioration of the latter on storage. The instability of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

cryptopleurine has been commented upon before by Gellert (3). The small amount of material available precluded further purification or the preparation of the stable methiodide.

Additional proof of the identity of our material with cryptopleurine was obtained by comparison of the respective ultraviolet spectra, which proved to be identical in every respect (curve F, Fig. 2).

In view of Bradsher's recent report (4), no effort was made to improve the yield at the final stage of reduction although there can be little doubt that other procedures could be more successful.

The structure of cryptopleurine being of a novel type, it is of interest to attempt uncovering its biogenetical links with other classes of alkaloids. Robinson (11) suggested that the alkaloid originates from two tyrosine and one lysine unit. However, no mechanism was offered in support of this idea and we would like to suggest the scheme outlined in Chart II.

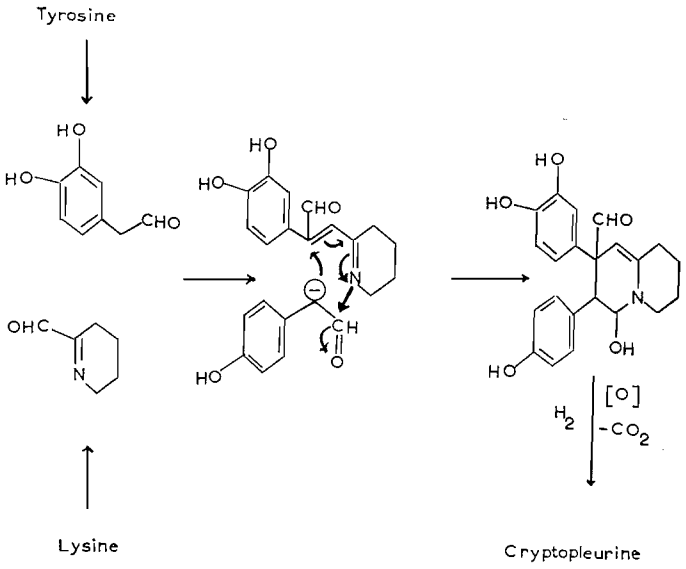

CHART II.

EXPERIMENTAL*

The spectra were determined with a Beckman spectrophotometer, Model DU, in 95% ethanol. Melting points are uncorrected and were obtained with a hot-stage microscope.

The pipecolic acid methyl ester was prepared by esterification of picolinic acid followed by hydrogenation in the presence of platinum oxide according to the procedure described by Tilford and co-workers (12).

The chloromethylphenanthrene was obtained by chloromethylation of phenanthrene as reported by Badger and co-workers (13).

Methyl N-(9-Phenanthrylmethyl)-pipecolate (1)

To a solution of 7 g. of methyl pipecolate in 150 ml. of methyl alcohol, containing 1.4 g. of potassium carbonate (freshly fused), 8.6 g. of 9-chloromethylphenanthrene was added at once. The mixture was then heated at 60°–70° and stirred for 12 hours. The suspension was evaporated almost to dryness and poured into water, and then extracted

**Microanalyses by Midwest Microlaboratories Inc., Indianapolis, Indiana, and Messrs. B. Girard and B. Mercier of our laboratories.*

For personal use only.

with ether. The ethereal solution was washed with water, dried with sodium sulphate, and evaporated to a small volume. Treatment with dry hydrogen chloride gave a precipitate which after crystallization from acetone–ethyl acetate weighed 5 g., m.p. 177°–178°. λ_{max}: 255, 260, 289 mμ; log ε: 4.45, 4.40, 3.98 (curve A, Fig. 1). Calc. for $C_{22}H_{23}NO_2$. $HCl.H_2O$: C, 68.21; H, 6.70; N, 3.61. Found: C, 68.60; H, 6,92; N, 4.07.

Hydrolysis to the amino acid was accomplished by refluxing 5.5 g. of the ester (1) for 2 hours in 100 ml. of concentrated hydrochloric acid. After evaporation to half volume and cooling, 5.3 g. of crystalline material (II) was collected, m.p. 195°–200°. Calc. for $C_{21}H_{21}NO_2.HCl$: N, 3.9. Found: N, 3.8.

Phenanthro-(9,10;2,3)-1-quinolizidone (III)

To a solution of 10 g. of phosphorus pentoxide in 10 g. of sirupy phosphoric acid, 3 g. of the acid II was added at once. The mixture was heated to 100° for 6 hours with rapid stirring. After cooling the mixture was poured into ice-water, made alkaline with 50% sodium hydroxide solution, and extracted with chloroform.

The chloroform solution was washed with water, dried, and evaporated. The residue (III), weighing 1.4 g., crystallized from chloroform–methanol in light yellow prisms, m.p. 168°–169°. Calc. for $C_{21}H_{19}NO$: C, 83.74; H, 6.38; N, 4.64. Found: C, 83.46; H, 6.43; N, 4.62. The infrared spectrum showed (nujol mull) a strong band at 1664 $cm.^{-1}$. λ_{max}: 250, 260, 285, 320 mμ; log ε: 4.47, 4.42, 3.95, 3.95 (see Fig. 1, curve B).

Phenanthro-(9,10;2,3)-quinolizidine (IV)

To a solution of 0.6 g. of potassium hydroxide in 7 ml. ethylene glycol and 1 ml. hydrazine hydrate 0.5 g. of the ketone III was added. After refluxing for 1 hour (9), water was distilled, and distillation continued until the temperature of the vapors reached 195°; the mixture was then heated to 200° for 6 hours. The mixture was poured into water and extracted with ether. After evaporation of the solvent, the solid material was dissolved in hot ethanol and allowed to stand overnight: 0.3 g. of white needles was obtained, m.p. 169°–170° (sublimes at 155°). Calc. for $C_{21}H_{21}N$: C, 87.82; H, 7.31; N, 4.87. Found: C, 87.68; H, 7.52; N, 4.76. λ_{max}: 255, 260, 289, 330, 353 mμ; log ε: 4.48, 4.42, 3.90, 3.03, 3.07 (see Fig. 1, curve C).

3,4-Phenanthro-1-azabicyclo[0,3,5]decane (V)

To a refluxing solution of 0.4 g. of ketone III in 50 ml. of hydrochloric acid and water (3:1), 2.5 g. of zinc amalgam was added in small portions over a period of 4 hours. Every hour, 5 ml. of concentrated hydrochloric acid was added. After cooling, the solution was made alkaline and extracted with chloroform. The chloroform solution was evaporated and the residue dissolved in benzene. After filtration through a small column of basic alumina, the solution was evaporated to dryness. The solid material so obtained by crystallization from methanol gave 0.25 g. of white needles melting at 164°. Calc. for $C_{21}H_{21}N$: C, 87.82; H, 7.31; N, 4.87. Found: C, 87.46; H, 8.19; N, 5.05.

6-Nitro-3,4,4'-trimethoxy-α-phenylcinnamic Acid (VI)

Upon heating under reflux for 24 hours 58 g. of 6-nitroveratraldehyde (14) with 60 g. of homoanisic acid (15) in 300 ml. of acetic anhydride containing 5 g. of potassium acetate, 50 g. of crude product was obtained. After several crystallizations from acetic acid the m.p. was constant at 183°–184° (reported 185°–186°) (yield 38 g.).

2,3,6-Trimethoxyphenanthrene-9-carboxylic Acid (VII)

The preceding compound (37 g.) was dissolved in 112 ml. of 14% aqueous ammonia, and the resulting solution added at once to a hot solution of 228 g. of ferrous sulphate in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

1 l. of 14% aqueous ammonia; the temperature was then maintained at 90° for a further 30 minutes. After cooling, careful neutralization of the mixture gave 30 g. of the corresponding amino acid. After several crystallizations from dilute ethanol, 25 g. of silky yellow crystals were obtained, m.p. 203°–204° (reported 206°–207°). Calc. for $C_{18}H_{19}NO_5$: N, 4.25%. Found: N, 4.23%.

This amino acid (23 g.) was suspended in 1400 ml. of water followed by the addition of 100 ml. of concentrated hydrochloric acid and 400 ml. dioxane. The mixture was cooled to 3°–5° and a solution of 9 g. of sodium nitrite in 100 ml. of water was added dropwise over a period of 2 hours, the temperature being kept below 5°. The clear, dark brown solution was then stirred for an additional 90 minutes.

After this time, 20 g. of activated copper bronze was added and stirring continued at room temperature for 24 hours. Evaporation *in vacuo* to half volume gave an amorphous precipitate which was collected by filtration and dissolved in chloroform. Evaporation of the solvent and crystallization of the residue from acetic acid afforded 12 g. of white crystalline material, m.p. 219°–220° (reported 222°). λ_{max}: 260, 280, 285 mμ; log ϵ: 4.58, 4.36, 4.33.

2,3,6-Trimethoxyphenanthrene-9-carboxylic Acid Methyl Ester (VIII)

The preceding acid (11.5 g.) (VIII) was heated under reflux for 2 hours in 250 ml. of methanol containing 15 ml. of sulphuric acid. The solution was then poured on ice and extracted with chloroform. Evaporation *in vacuo* left 10 g. of crude solid material. Chromatography on neutral alumina afforded in the petroleum ether eluate 5.4 g. of white crystals which crystallized from ethyl acetate – isopropyl alcohol, m.p. 156°–157°.* Calc. for $C_{19}H_{18}O_5$: C, 66.87; H, 5.52. Found: C, 66.76; H, 5.43. Extraction of the alumina with hot methanol gave 2 g. of white crystalline material, m.p. 85°–86°, which was not examined further.

2,3,6-Trimethoxy-9-phenanthrenemethanol (IX)

A solution of 5 g. of VIII in tetrahydrofuran was added dropwise with cooling to a suspension of 2.5 g. of lithium aluminum hydride in 100 ml. of ether. The mixture was then heated under reflux for 90 minutes, the excess of hydride decomposed with ethyl acetate, and the mixture poured into water and extracted with chloroform–ether. Evaporation of the solvent gave 4.5 g. of white solid mass. Crystallization from ethanol gave 4 g. of white silky needles, m.p. 186° (reported 185°–187°).

2,3,6-Trimethoxy-9-chloromethylphenanthrene (X)

To a solution of 3.7 g. of IX in 170 ml. of anhydrous chloroform containing 2.2 ml. of pyridine was added dropwise 2.96 ml. of thionyl chloride at ice temperature. The reaction was brought to completion by heating at 40°–60° while stirring for 60 minutes. The mixture was then poured on ice, and the chloroform layer separated, washed with dilute bicarbonate solution, then with water, and dried. The residue obtained by evaporation of the solvent was crystallized from benzene and weighed 3.45 g., m.p. 150°–151°. Calc. for $C_{18}H_{17}O_3Cl$: C, 68.35; H, 5.35; Cl, 11.08. Found: C, 68.11; H, 5.56; Cl, 11.30.

Methyl 2,3,6-Trimethoxy-N-9-phenanthrylmethyl-pipecolate (XI)

A mixture of 3 g. of X and 6 g. of methyl pipecolate as free base† in 100 ml. of anhydrous toluene was heated under reflux with stirring for 20 hours.

The residue obtained after evaporation of the solvent was poured into water and the

**The ethyl ester of III prepared in an analogous way was crystallized from ethanol and melted at 137° (reported 136.5°–137°).*

†The base was prepared by treatment of the hydrochloride with sodium methoxide at room temperature for 12 hours and vacuum distillation, b.p. 88°/16 mm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

pH adjusted to 9 with alkali followed by extraction with chloroform. After it was washed with water, the solution was dried and evaporated to dryness to yield a solid which was dissolved in a small volume of ether. Treatment of this solution with dry hydrogen chloride gave a precipitate which crystallized from acetone – ethyl acetate. The weight of the hydrochloride was 4.7 g., m.p. 165°–167°. λ_{max}: 250, 260, 285 mμ; log ε: 4.67, 4.80, 4.55 (see Fig. 2, curve D). Calc. for $C_{25}H_{29}O_5N.HCl.\frac{1}{2}H_2O$: C, 64.10; H, 6.41; N, 3.00. Found: C, 63.49; H, 6.84; N, 3.03.

2,3,6-Trimethoxyphenanthro-(9,10;2,3)-1-quinolizidone (XIII)

The above ester (XI) was hydrolyzed by heating for 90 minutes in 80 ml. of hydrochloric acid. After cooling a microcrystalline material was collected and dried, and without further purification, 2.4 g. of this amino acid (XII) was added to a mixture of 10 g. of phosphorus pentoxide and 10 g. of phosphoric acid and the solution heated for $3\frac{1}{2}$ hours. After cooling, the violet mixture was slowly poured on ice, and after 50% potassium hydroxide solution had been added to pH 9, the mixture was extracted with chloroform.

The solution was washed with water, dried, and evaporated *in vacuo* under nitrogen to give 1 g. of a slightly yellow solid which crystallized from acetone–methanol as yellow prisms, m.p. 154.5°–155°. λ_{max}: 255, 270, 290, 310, 345 mμ; log ε: 4.42, 4.51, 4.40, 4.02, 4.01 (see Fig. 2, curve E). Calc. for $C_{24}H_{25}O_4N$: C, 73.66; H, 6.39. Found: C, 73.87; H, 6.84.

2,3,6-Trimethoxyphenanthro-(9,10;2,3)-quinolizidine (XIV)

The reduction of 0.45 g. of XIII was effected as described above in the case of IV except that the reaction was carried out under nitrogen. The crude reaction product was chromatographed on basic alumina but no pure substance could be obtained from the various eluates. A ferric chloride test was strongly positive for all of the main fractions; a 0.25 g. portion of the brown waxy material was therefore treated in methanol–ether with a large excess of diazomethane and allowed to stand overnight.

Evaporation of the solvent *in vacuo* gave an oil which was dissolved in ether and extracted with dilute hydrochloric acid. Neutralization of the acidic solution gave a precipitate which was extracted with ether. After evaporation of the solvent, the residue was dissolved in a small volume of acetone and allowed to stand at −10°. The solution slowly deposited 5 mg. of light yellow needles which after several recrystallizations had m.p. 199°–201° (reported 197°–198° (3), 199°–200° (4)). Mixture with an authentic specimen of cryptopleurine gave no depression of the melting point. λ_{max}: 258, 286, 345, 358 mμ; log ε, 4.70, 4.47, 3.12, 2.97.

The infrared spectrum was recorded with a Baird double-beam instrument using the KBr pellet technique. The spectrum was identical to that of cryptopleurine except for the presence of a low-intensity band at 1700 $cm.^{-1}$.

ACKNOWLEDGMENTS

We express our gratitude to Dr. C. K. Bradsher for supplying an authentic specimen of cryptopleurine and to Dr. H. Hooper of Bristol Laboratories Inc. for the infrared determinations. We also express our thanks to the National Research Council of Canada for a fellowship to one of us (P.M.) and for financial assistance.

NOTES

THE REDUCTION OF SOME HALOGENATED COMPOUNDS BY CHROMOUS CHLORIDE

F. A. L. Anet and Elaine Isabelle

Reduction of annotinine chlorohydrin by chromous chloride gave two compounds (1, 2), (*a*) "hydroxylactone" and (*b*) "unsaturated lactone A", neither of which was the "normal" reduction product which would be formed by replacement of chlorine by hydrogen. Anet and Marion (2) suggested that these two compounds were formed by 1,2-elimination, analogous to the reduction of *vic*-dibromides to alkenes (3), and involving a chlorine atom and a β-nitrogen atom in the case of the "hydroxylactone", and a chlorine atom and a β-hydroxyl group in the case of the "unsaturated lactone A".

In order to obtain analogies for the reduction of annotinine chlorohydrin, whose structure is now firmly established (4, 5), we have studied the chromous chloride reduction of some simple β-halogenated alcohols and amines. 2-Chloroethanol was not reduced under the conditions used. 2-Bromoethanol was reduced slowly and gave 20% ethylene, isolated as the dibromide, but a considerable amount of starting product was hydrolyzed. 2-Bromoethylamine was reduced to a mixture of ethylamine, ammonia, and ethylene. In this case the "normal" reduction product, formed by simple replacement of halogen by hydrogen, was a reaction product, whereas the "normal" reduction product of annotinine chlorohydrin has not been observed. Nevertheless, the same type of reduction was found in the simple model compounds as occurred in annotinine chlorohydrin.

EXPERIMENTAL

Preparation of Aqueous Chromous Chloride Solution

Chromic chloride hexahydrate (100 g.) was dissolved in 15% hydrochloric acid (600 ml.) and reduced with amalgamated mossy zinc (100 g.) under an atmosphere of nitrogen. An apparatus of the type suggested by Lingane and Pecsok (6) was used for the reduction and storage of the reagent.

Reduction of 2-Chloroethanol

2-Chloroethanol (0.1 mole) was treated with chromous chloride solution (0.2 mole) under an atmosphere of nitrogen. The reaction mixture was heated under reflux for 3 hours and all escaping vapors were passed through an all-glass system to a series of bromine traps. During this time there was no evidence of any evolution of gas and no visible loss of blue color in the chromous solution. The bromine in the traps on being worked up yielded no trace of ethylene bromide, and distillation of the reaction mixture yielded no ethanol.

Reduction of 2-Bromoethanol

2-Bromoethanol (0.05 mole) was reduced with chromous chloride solution (*ca.* 0.1 mole). The mixture was heated under reflux in an atmosphere of nitrogen for 3 hours during the last half-hour of which a slow stream of nitrogen was allowed to pass through the system to entrain any ethylene produced and carry it to the bromide absorption traps. A trap containing water was placed before the bromide traps to scrub out any ethanol entrained.

The dibromide collected was washed with water and sodium carbonate solution until colorless. The dibromide layer was separated, the washings extracted with ether, and the combined extract, after being dried over calcium chloride, yielded on distillation 2.1 g. of pure ethylene dibromide (22% yield).

A Schotten–Baumann reaction modified (7) to detect small quantities of ethanol in aqueous solution failed to produce any ethanol derivative either from the water trap or from the initial distillate of the reaction mixture.

Control on Hydrolysis of 2-Bromoethanol

2-Bromoethanol (5 g.) was heated under reflux with 15% hydrochloric acid (30 ml.) for 3 hours. The mixture was salted out with sodium chloride and extracted five times with small quantities of ether. The ether extracts were combined, dried over magnesium sulphate, and evaporated, leaving slightly less than 1 g. of residual oil.

Reduction of 2-Bromoethylamine Hydrobromide

2-Bromoethylamine hydrobromide (0.05 mole) was reduced under nitrogen with chromous chloride solution (0.1 mole) by heating under reflux for 3 hours. The ethylene evolved was converted to the dibromide as described above, yield 4.6 g. (49%).

The residue was rendered alkaline with sodium hydroxide and steam-distilled into a dilute hydrochloric acid solution. The acidic solution was evaporated to dryness, yielding 3.49 g. of white solid. By fractional crystallization from ethanol the ammonium chloride was separated from ethylamine hydrochloride, m.p. 96°–98°, which did not depress the melting point of a known sample of ethylamine hydrochloride, and formed a benzoyl derivative, m.p. 70° (lit. m.p. 71° (8)). The ammonium chloride was estimated to comprise approximately 60% of the mixture, the ethylamine hydrochloride 40%.

have been measured by gas–liquid partition chromatography (GLPC). The results are recorded in the accompanying table. Few references to the separation of organic sulphur compounds by GLPC have so far appeared in the literature (1, 2, 3).

EXPERIMENTAL

The samples were eluted with nitrogen from glass columns containing tricresyl phosphate supported on Johns-Manville C-22 firebrick in the ratio 2:5 w/w. Particle sizes were 35–80 mesh for columns up to 12 ft. in length and 35–60 mesh for 18-ft. columns. The injection system consisted of a heated chamber at the column head; inside the chamber were two disks of 60-mesh stainless-steel gauze from which the liquid was flashed on to the column packing after having been introduced in the usual manner by a syringe through a self-sealing rubber cap. Flow rates were in the range 25–40 ml./min. with 1 atmosphere pressure at the column head and pressures down to 5 mm. Hg at the outlet. A thermal conductivity gauge served as monitor for the effluent stream; both the detector and reference elements were placed at the column outlet with liquid nitrogen traps interposed between the two. The traps were designed to fit directly onto a mass spectrometer. In this manner the mass spectra of separate eluate fractions could be determined.

The standard liquids indicated in Table I were benzene (B), toluene (T), and ethyl-

VOLUME 36 APRIL 1958 NUMBER 4

SYNTHESIS OF 4-AMINOBUTYRIC ACID AND 2,4-DIAMINOBUTYRIC ACID FROM BUTYROLACTONE[1,2]

GUY TALBOT, ROGER GAUDRY, AND LOUIS BERLINGUET

ABSTRACT

The ring opening of γ-butyrolactone with 1 mole of potassium phthalimide and the hydrolysis of the intermediate product gave 4-aminobutyric acid with an excellent yield. The condensation of 1 mole of potassium phthalimide with 2-bromo-4-butyrolactone gave a 2-phthalimidolactone which can also be opened by treatment with a second molecule of potassium phthalimide. This diphthalimido acid when hydrolyzed gave, with an excellent yield, 2,4-diaminobutyric acid dihydrochloride.

INTRODUCTION

4-Aminobutyric acid has long been considered as a metabolic by-product of bacteria and yeast (1, 2, 3, 4). Recently it has been isolated from proteins (5), from plants (6), and from brain tissues (7). Now we know that it is a catabolic product of glutamic acid (8, 9) and that the reaction is reversible (10).

Several methods are available for its synthesis, which are classified in four groups:

(*a*) Oxidation of piperylurethan or sparteine (11, 12).

(*b*) Condensation of potassium phthalimide or of potassium cyanide with halogenated intermediates (13, 14, 15, 16).

(*c*) Reduction of succinimide or 3-cyanopropionic acid or succinonitrile (17, 18, 19, 20, 21, 22).

(*d*) Chemical or enzymatic degradation of glutamic acid or glutarimide (23, 24, 25, 26).

Even then, the abundant supply of 4-aminobutyric acid is somewhat limited because of the nonavailability of the starting products and the four or five steps required for the synthesis.

Since γ-butyrolactone is readily available, a new synthesis starting from the lactone was considered. Bornstein and his collaborators (27) and Paris, Gaudry, and Berlinguet (28) have clearly shown that phthalide can be opened by potassium phthalimide and γ-butyrolactone can be opened by potassium cyanide.

The γ-butyrolactone ring was opened with a 73% yield by reaction with potassium phthalimide in boiling dimethylformamide.

The intermediate compound was then hydrolyzed with hydrochloric acid and the free amino acid was obtained and characterized after the usual treatment with silver car-

bonate. The yield of 4-aminobutyric acid was 68%. It was also identified by paper chromatography. The R_f values in phenol–water and pyridine–water systems are respectively 0.76 and 0.19.

Another interesting amino acid, namely 2,4-diaminobutyric acid, was synthesized using a somewhat similar pathway from γ-butyrolactone.

This naturally occurring diamino acid has been found recently in several antibiotic polypeptides (29, 30, 31, 32). The known methods of synthesis are classified in three main groups:

(*a*) Synthesis involving a phthalimido aldehyde (33).
(*b*) Synthesis involving the Hofmann degradation of glutamic acid (34, 35, 36, 37, 38) or the Curtius and Schmidt reactions (39, 40, 41).
(*c*) Synthesis from ethyl acrylate and diazomethane (42).

The last method is by far the best even if it makes use of diazomethane and high-pressure hydrogenation.

Since Livak and his collaborators (43) have brominated very easily γ-butyrolactone, this halogenated lactone was treated with one molecule of potassium phthalimide in boiling dimethylformamide. The 2-phthalimidobutyrolactone thus obtained was opened by treatment with a second molecule of potassium phthalimide.

The total yield of 3,4-diphthalimidobutyric acid from the bromolactone was 73%. This insoluble intermediate when hydrolyzed with concentrated hydrochloric acid gave an 80% yield of the 2,4-diaminobutyric acid dihydrochloride. The over-all yield from the bromolactone was nearly 60%.

The diamino acid was characterized by paper chromatography and paper electrophoresis. R_f values in phenol–water and pyridine–water systems were respectively 0.16 and 0.04. Being a diamino acid, it migrated toward the cathode in a buffer solution of pH 8.6.

EXPERIMENTAL[3]

4-Phthalimidobutyric Acid

Potassium phthalimide (18.5 g., 0.1 mole) was added to 4-butyrolactone (10.0 g., 0.116 mole) in 50 ml. of dimethylformamide. After it was boiled for 12 hours, the mixture was poured onto ice to which had been added 30 ml. of glacial acetic acid. The solid obtained was filtered and recrystallized from water and ethanol. Yield: 17.1 g. (73%), m.p. 117°–118° (Lit. m.p. 117°–118° (44)). Anal. Calc. for $C_{12}H_{11}O_4N$: N, 6.01. Found: N, 6.09.

4-Aminobutyric Acid

4-Phthalimidobutyric acid (5.0 g., 0.021 mole) was dissolved in 100 ml. of dilute hydrochloric acid (1:1). The solution was refluxed during 5 hours, after which it was cooled. The phthalic acid was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue consisted of 4-aminobutyric acid hydrochloride, which was very hygroscopic. It was treated as usual with silver carbonate, hydrogen sulphide, and charcoal. Yield: 1.5 g. (68%), m.p. 195°–196° (Lit. m.p. 196° (12)). Anal. Calc. for $C_4H_9O_2N$: N, 13.57. Found: N, 13.33.

2-Phthalimido-4-butyrolactone

Potassium phthalimide (55 g., 0.297 mole) was added to a solution of 150 ml. of dimethylformamide and 2-bromo-4-butyrolactone (43) (50 g., 0.303 mole). The well-mixed solution was heated at 100° during 12 hours, after which it was poured onto ice.

[3]*Melting points are uncorrected.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The precipitate was collected by filtration and it was recrystallized from acetone–water. Yield: 59 g. (86%), m.p. 160°–162°. Anal. Calc. for $C_{12}H_9O_4N$: N, 6.06. Found: N, 6.15.

By acid hydrolysis, the hydrochloride of 2-amino-4-butyrolactone was obtained. It gave a yellow color when treated with ninhydrin and its R_f value in a water–pyridine system was 0.75.

2,4-Diphthalimidobutyric Acid

Potassium phthalimide (10.0 g., 0.054 mole) was added to a solution of 30 ml. of dimethylformamide and 2-phthalimido-4-butyrolactone (11.56 g., 0.05 mole). The solution was heated to reflux during 7 hours. It was then poured onto ice to which 20 ml. of glacial acetic acid had been added. The precipitate was collected by filtration. Yield: 16.0 g. (85%). It can be recrystallized from acetic acid. M.p. 177°–179°. Anal. Calc. for $C_{20}H_{14}O_6N_2$: N, 7.40. Found: N, 7.27.

2,4-Diaminobutyric Acid Dihydrochloride

2,4-Diphthalimidobutyric acid (2.0 g.) was suspended in 50 ml. of dilute hydrochloric acid (1:1). The mixture was refluxed during 12 hours, after which it was cooled. The phthalic acid was collected by filtration, and the filtrate was evaporated to dryness *in vacuo*. The residue was recrystallized from a mixture of hydrochloric acid and glacial acetic acid. Yield: 0.8 g. (79%), m.p. 206° (Lit. m.p. 202°–205° (45)). Anal. Calc. for $C_4H_{10}O_2N_2.2HCl$: Cl, 37.1; N, 14.65. Found: Cl, 36.9; N, 14.50.

ARSENATES OF THE TRANSITION METALS

THE ARSENATES OF COBALT AND NICKEL[1]

J. B. TAYLOR[2] AND R. D. HEYDING

ABSTRACT

Complex oxides occurring in the systems CoO/As_2O_5 and NiO/As_2O_5 have been studied using Debye–Sherrer diagrams. The compounds were prepared either by high-temperature reaction of the oxides and subsequent pyrolysis of the products or by aqueous precipitation of arsenates followed by thermal dehydration.

The existence of compounds having metal oxide to arsenic pentoxide ratios of 1:1, 2:1, and 3:1 has been clearly demonstrated and the thermal stabilities of each *in vacuo* and in air have been studied. Corresponding compounds in the cobalt and nickel series are isostructural and unit-cell dimensions have been determined. The compounds with a 2:1 ratio could not be isolated readily although their existence is indisputable and tentative figures for the unit-cell dimensions have been obtained.

Another compound, probably with a metal oxide to arsenic pentoxide ratio of 6:1, has been observed during the pyrolysis of the 3:1 compounds. Apparently the cobalt and nickel compounds are isostructural and represent the only phase existing between the 3:1 compounds and the metal oxides.

INTRODUCTION

Continuing an investigation into the chemistry of cobalt speiss and its behavior on roasting in air we have sought to prepare and examine the so-called arsenates of cobalt and nickel which occur in the composition range between $M^{II}O.As_2O_5$ and $M^{II}O$. Previous compounds reported were in many cases hydrates and have been called meta-, pyro-, and ortho-arsenates in the usual manner. We prefer to regard the compounds which we have studied as complex oxides and accordingly will refer to them in terms of their metal oxide to arsenic pentoxide ratios.

Both cobalt and nickel occur naturally as arsenates in the form of erythrite and annabergite respectively. These compounds are of the type $3M^{II}O.As_2O_5.8H_2O$ and have been classified crystallographically as monoclinic (space group $C2/m$), having unit-cell dimensions of $a = 10.056$ Å, $b = 13.340$ Å, $c = 4.730$ Å, $\beta = 102°0'$ for the cobalt compound, and $a = 10.015$ Å, $b = 13.284$ Å, $c = 4.698$ Å, $\beta = 102°14'$ for the nickel compound (1). The structures undoubtedly contain arsenic tetrahedrally co-ordinated with oxygen (2). These compounds have been prepared synthetically together with numerous other hydrated arsenates. The latter were of little interest as far as the present work was concerned since their structures have not been established. In general it may be said that these arsenates have metal oxide to arsenic pentoxide ratios of 0.5 : 1, 1 : 1, 2 : 1, 2.5 : 1, 3 : 1, 4 : 1, and 5 : 1. They were usually prepared by one of two methods: either the reaction of metal, metal oxide, or carbonate with acid at atmospheric or high pressure (3); or the precipitation of the arsenate by addition of metal ion to arsenate ion (4).

Anhydrous complex oxides of nickel have been prepared by Guérin and Masson (5) by dehydration of a hydrated arsenate, $NiO.2As_2O_5.5H_2O$, at an elevated temperature under vacuum. They report that the product $NiO.2As_2O_5$ can be pyrolyzed *in vacuo* to give $NiO.As_2O_5$, $2NiO.As_2O_5$, and $3NiO.As_2O_5$ at 550°, 650°, and 750° C. respectively.

An alternative method of making the complex oxides involves high-temperature reaction of the metal oxide $M^{II}O$ with As_2O_5 mixed in the desired proportions. Thus

$CoO.As_2O_5$ and the isomorphous calcium, strontium, cadmium, mercury, and lead compounds have been prepared (6) as well as $CoO.Sb_2O_5$, $NiO.Sb_2O_5$ (7), and several trivalent antimony and arsenic compounds (8). The so-called 'cobalt meta-arsenate' $CoO.As_2O_5$ is reported to be hexagonal (6) (space group $P312$) with unit-cell dimensions: $a = 4.766$ Å, $c = 4.493$ Å. The structure is well established, being the same as $PbO.Sb_2O_5$ (9), and contains arsenic in octahedral co-ordination with oxygen, which appears to be an exception to the generally accepted fourfold co-ordination of arsenic. Comparison of this type of structure with that of $FePO_4$ (10) reveals a considerable difference between phosphorus and arsenic in the compounds as the structural chemistry of the former is based on PO_4 tetrahedra and is probably best compared with the SiO_4 tetrahedra in silicates.

Some crystallographic data have been reported for the 1:1 pentavalent antimony compounds of iron, cobalt, and nickel (7) and these have been found to be isostructural, with a trirutile structure $P4/mnm$. The cell dimensions of the cobalt compound are: $a = 4.64$ Å, $c = 9.25$ Å and of the nickel analogue: $a = 4.63$ Å, $c = 9.18$ Å.

MATERIALS

The arsenic pentoxide used was Mallinckrodt 'A.R.' containing 0.05% trivalent arsenic and 0.02% lead.

The nickel oxide, cobalt oxide, and cobalt sponge were obtained from Johnson, Matthey & Co. The nickel oxide contained 5 p.p.m. of iron and no cobalt. The cobalt oxide contained 2 p.p.m. of iron and was sold as Co_3O_4 but analyzed $CoO_{1.103}$. The cobalt sponge which was finally used in the preparation of cobalt monoxide contained 5 p.p.m. of iron and no nickel.

Cobalt Oxide, CoO

The CoO was prepared by thermal decomposition of the basic carbonate under vacuum as this method proved more rapid than ignition of the Johnson, Matthey oxide. Cobalt sponge was dissolved in hot 6:1 nitric acid and from this solution the basic carbonate was precipitated by addition of potassium bicarbonate solution. The carbonate was decomposed to CoO by ignition in a continuously pumped vacuum system at 1040° C. for about 2 hours. The product was analyzed for cobalt and its X-ray powder diagram compared with standards.

ANALYSIS FOR COBALT, NICKEL, AND ARSENIC

Nickel was analyzed using the dimethyl glyoxime reagent and weighing as $NiC_8H_{14}O_4N_4$ after drying at 110° C. The most satisfactory method for cobalt analysis was reduction in hydrogen at 950° C. Arsenic was determined by precipitation as silver arsenate and subsequent titration of the silver with thiocyanate. Samples which contained nickel and arsenic or cobalt and arsenic in admixture were first treated to obtain a separation of the components, and the resulting solutions estimated as above. The arsenate hydrates could be dissolved in dilute nitric acid and the metal separated by slow addition of dilute sodium hydroxide solution. Samples of the complex oxides were insoluble in mineral acids and were fused with Na_2CO_3/KNO_3 (2:1) fusion mixture. The soluble arsenate was then readily leached out and the residue containing the metal taken up by a pyrosulphate fusion.

EXPERIMENTAL

To investigate the formation of compounds of the type $xM^{II}O.As_2O_5$ by direct reaction of the oxides at a high temperature a series of nickel oxide – arsenic pentoxide mixtures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

with values of x from 1 to 3 were made and sealed under vacuum in quartz ampoules. Other mixtures were also prepared containing cobalt monoxide and arsenic pentoxide in 1 : 1 admixture. The ampoules were heated in furnaces carefully maintained at 500° C., 650° C., and 800° C. for periods of up to 9 days. In all cases attack of the quartz by the As_2O_5 took place and in the samples at 800° C. this weakened the quartz to the point that several of the ampoules exploded. Reaction between the oxides occurred in all cases, resulting in a yellow or green product in the nickel experiments and a purple product for the cobalt compounds.

Several cobalt monoxide – arsenic pentoxide 1 : 1 mixtures were made taking great care to exclude as much moisture as possible. The arsenic pentoxide for this series of experiments was dried at 400° C. for 30 hours under vacuum and all operations prior to sealing the ampoules were performed in a dry box. After heating for 5 days at 460° C. no reaction had occurred between the oxides although at 800° C. some reaction was observed. The results suggest that the reaction may be partly or wholly hydrothermal and probably depends for its success on the small amount of water retained by the arsenic pentoxide when precautions to exclude it are omitted.

The complex oxides resulting from these reactions were pyrolyzed by heating in porcelain boats in quartz tube furnaces capable of being evacuated or flushed with an air stream. The progress of the thermal decomposition and loss of arsenic was followed by observing the weight loss on the sample and removing portions from time to time for X-ray analysis. Chemical analyses were also performed on some of the products.

The powder diagrams were taken in 11.46 cm. Norelco cameras with CuK_α and CoK_α radiation for the nickel and cobalt complexes respectively.

RESULTS AND DISCUSSION

$M^{II}O.As_2O_5$ *Compounds*

These were well-defined compounds formed by high-temperature oxide reactions. The cobalt compound was obtained by heating a 1 : 1 cobalt monoxide – arsenic pentoxide mixture in a quartz tube at 500° C. for 3 days and was a bright purple color. The powder diffraction pattern agrees with that obtained by Magnéli (6) and could be indexed as hexagonal with unit-cell dimensions of $a = 4.773$ Å, $c = 4.494$ Å (Table I).

Powder diagrams of the $NiO.As_2O_5$ prepared by direct reaction of the oxides at 500° C. for 10 days showed several lines which did not appear in the $CoO.As_2O_5$ pattern. However, these lines decreased gradually in intensity on heating so that after 6 hours at 700° C. under vacuum they were completely absent. It was possible to index the pattern as hexagonal with unit-cell dimensions of $a = 4.759$ Å, $c = 4.431$ Å. The diffraction patterns and density data are recorded in Table II.

The two compounds are clearly isostructural and have the $PbO.Sb_2O_5$ structure (9) previously assigned to $CoO.As_2O_5$ by Magnéli.

$2M^{II}O.As_2O_5$ *Compounds*

Reactions between cobalt or nickel oxide and arsenic pentoxide in 2 : 1 and 3 : 1 ratios at 800° C. produced mainly $M^{II}O.As_2O_5$ but the diffraction patterns showed some lines which were later attributed to the $2M^{II}O.As_2O_5$ compounds. The amount of information obtainable from these patterns was limited by contamination of the sample resulting mainly from the severe attack of the quartz by the arsenic pentoxide at the high temperature.

Vacuum pyrolysis experiments on $NiO.As_2O_5$ produced no new phase after 12 hours at 710° C. with removal, grinding, and sampling at intervals of 2 hours. A further heating

for 5 hours at 760° C. gave a material which on X-ray powder analysis showed a series of new lines together with some NiO and $NiO.As_2O_5$. A plot of per cent loss of weight against time of pyrolysis showed no inflection at the 2 : 1 composition under these conditions. By repeating the pyrolysis at a temperature of 720° C. the necessary weight loss was achieved in 230 hours but again it was impossible to reach equilibrium conditions. Powder photographs in this composition range were ill-defined at best. Pyrolysis in air gave the same decomposition products at about 920° C. but no better diffraction patterns were obtained. The material approximating in composition to $2NiO.As_2O_5$ had an ocher-yellow color as compared with the yellow-green of the 1 : 1 compound.

Similar experiments on the pyrolysis of $CoO.As_2O_5$ gave comparable results with a rather poorly defined dark purple 2 : 1 compound after 40 hours' heating at 736° C. under vacuum.

By careful selection of lines in the powder diagrams and elimination of lines from other phases identified in the system it is possible to suggest an orthorhombic symmetry for $2CoO.As_2O_5$ and $2NiO.As_2O_5$ having unit-cell dimensions of $a = 8.16$ Å, $b = 8.56$ Å, $c = 9.16$ Å for the cobalt compound, and $a = 8.12$ Å, $b = 8.52$ Å, $c = 9.29$ Å for the nickel compound. Interplanar spacings, indices, and observed intensities of the powder diagrams are recorded in Table III.

The 2 : 1 compounds are not isostructural with $2PbO.Sb_2O_5$, which has the cubic pyrochlore form $a = 10.3$ Å (11), or with $2CaO.Sb_2O_5$, which has an orthorhombic weberite structure, $a = 7.28$ Å, $b = 7.44$ Å, $c = 10.18$ Å.

The results of these experiments do not entirely agree with those of Guérin and Masson

(5), who claimed that $NiO.As_2O_5$ decomposes *in vacuo* at 650° C. to give $2NiO.As_2O_5$ as a single phase. However, no attempt was made to substantiate their claim by published X-ray data and it may be that they also had a mixture in the 2 : 1 composition range.

$3M^{II}O.As_2O_5$ *Compounds*

Continuing the pyrolysis by increasing the temperature, compounds appeared in both systems corresponding to a metal oxide to arsenic pentoxide ratio of 3 : 1. At 750° C. this phase is perfectly stable in contrast to the behavior of the 2 : 1 compounds.

As an alternative approach to the preparation of these compounds the hydrates $3CoO.As_2O_5.8H_2O$ (erythrite) and $3NiO.As_2O_5.8H_2O$ (annabergite) were prepared and dehydrated. These minerals were synthesized by addition of $Na_2H.AsO_4.7H_2O$ solution to hot nickel nitrate or cobalt chloride solution using 0.1 weight per cent solutions in the preparation of the cobalt compound and 5% solutions for the nickel compound.[3] Powder photographs of the synthetic minerals were in excellent agreement with those of erythrite and annabergite.

On dehydration in an open crucible at 800° C. these hydrates yielded compounds having the same powder diagrams as those obtained from pyrolysis of the 1 : 1 compounds. The diffraction patterns could be indexed as orthorhombic with a = 5.775 Å, b = 8.498 Å,

[3]*The very small crystallites obtained from the more concentrated nickel solution were developed by digestion in water at 100° C. for 1 week. It may be remarked that regardless of the relative concentrations of nickel and arsenate ion in solution only annabergite was precipitated. Similarly the residue obtained by digestion of varying quantities of basic nickel carbonate with arsenic acid exhibited only the diffraction pattern of annabergite although analyses indicated nickel to arsenic ratios of from 3:2 to 6:2. The amorphous nickel compound (probably the hydroxide) retained in these residues could not be removed by chemical means. On pyrolysis at 500° C., however, a face-centered cubic pattern appeared on the Debye–Sherrer diagrams. The unit-cell dimension of this compound (approximately 4.13 Å) was less than that of* NiO *(4.177 Å). That this pattern was directly associated with the amorphous nickel compound admixed with the annabergite was shown by the increase in intensity with increasing excess nickel content. This cubic compound was converted to* NiO *on pyrolysis at 800° C., when* $3NiO.As_2O_5$ *lines also appeared resulting from the decomposition of the annabergite. We were unable to obtain this cubic pattern by any other means.*

$c = 10.85$ Å for $3CoO.As_2O_5$, and $a = 5.693$ Å, $b = 8.30$ Å, $c = 11.04$ Å for $3NiO.As_2O_5$.

Powder diffraction data and results of density measurements are given in Tables IV and V.

In agreement with Guérin and Masson we found that $3NiO.As_2O_5$ cannot be hydrated to give annabergite even under 10 atm. pressure of water vapor.

$6M^{II}O.As_2O_5$ *Compounds*

The 3 : 1 compounds decompose under vacuum at about 850° C. to give the metal oxides but it was observed that an intermediate phase appeared in both the cobalt and nickel systems. The intermediate compounds were best prepared by pyrolysis in an air stream at 1000° C. The nickel compound was a bright green as compared with the dull green of $3NiO.As_2O_5$, and the cobalt compound a dark gray color in contrast to the dark powder blue of the $3CoO.As_2O_5$. Both gave good powder diffraction patterns. As a result of observations on weight losses during their formation and determinations of nickel and arsenic percentages it was concluded that these materials had a composition corresponding to $6M^{II}O.As_2O_5$. Results of analyses on two independently prepared samples of $6NiO.As_2O_5$ are given in Table VI. Although the figures do not appear to be very accurate allowance must be made for contamination by other compounds, which were just visible on the diffraction patterns.

It was at first considered possible to index the powder diagrams on the basis of hexagonal symmetry, the nickel compound having unit-cell dimensions of $a = 10.48$ Å, $c =$

12.03 Å. However, the cobalt powder diagram contained a rather broad intense line that was resolved into a doublet by annealing the sample at 800° C. in an evacuated quartz tube for 5 days. These lines could not be indexed in the hexagonal system.

In view of the isostructural nature of the other nickel and cobalt arsenates in the series it seems reasonable to assume that the 6 : 1 complexes are also structurally similar, and on the basis of this assumption the hexagonal symmetry assigned to the nickel complex has been discarded. However, the diffraction patterns of both compounds can be indexed by assuming orthorhombic cells, for which it is found that the reflections giving rise to the strong doublet in the cobalt compound overlap in the nickel compound producing a rather broad line. Observed intensities, interplanar spacings, and indices for these two compounds are recorded in Tables VII and VIII.

SUMMARY

This study of the complex oxides occurring in the CoO/As_2O_5 and NiO/As_2O_5 systems has established the compounds $M^{II}O.As_2O_5$, $2M^{II}O.As_2O_5$, $3M^{II}O.As_2O_5$, and $6M^{II}O.As_2O_5$ as the only ones existing in the composition range $M^{II}O.As_2O_5$ to $M^{II}O$.

The 1 : 1 compounds are hexagonal and the 2 : 1, 3 : 1, and 6 : 1 compounds have been tentatively assigned orthorhombic symmetry. It is interesting to note that the unit-cell volumes of the 1 : 1 and 2 : 1 complexes are just less than those calculated for a close-packed oxygen-ion system (assuming $z = 6$ for the 2 : 1 compounds). The observed unit-cell volumes for the 3 : 1 and 6 : 1 compounds are greater than those required by a close-packed oxygen-ion array.

Both cobalt and nickel compounds exhibit similar thermal stabilities in that corresponding compounds in each system were observed to be stable over the same temperature range. *In vacuo* the 1 : 1 compounds decompose at 720° C. to give 3 : 1 compounds but an intermediate structure occurs in the composition range about 2 : 1. The 3 : 1 compounds decompose to give the 6 : 1 structure at 850° C., and at 850° to 875° C. the metal oxides are formed. In air at atmospheric pressure these decompositions are observed about 150° C. higher and even at 1000° C. the 6 : 1 complexes are stable. From this it would appear that the primary process in the decomposition of the arsenates is ejection of oxygen from the lattice.

PHOTOCONDUCTIVITY OF SOME POLYNUCLEAR AROMATIC HYDROCARBONS[1]

J. KOMMANDEUR,[2] G. J. KORINEK,[3] AND W. G. SCHNEIDER

ABSTRACT

The spectral response, voltage dependence, and intensity dependence of the surface photocurrent in naphthalene, terphenyl, pyrene, stilbene, and azulene have been measured. Pyrene and naphthalene have a high sensitivity for photoconduction at the long-wavelength edge of the optical absorption spectrum. In the spectral response of pyrene three peaks appear at 4475 Å, 4275 Å, and 4100 Å. It is suggested that these peaks are due to weak optical absorptions to energy levels which are highly efficient in promoting conduction. It is possible that a similar effect occurs in naphthalene, where maximum photoconductivity coincides with a weak absorption reported by McClure and Schnepp. Azulene only shows photoconductivity at wavelengths corresponding to absorption to the second singlet state.

INTRODUCTION

Recently a substantial amount of work has been devoted to the photoconductive properties of anthracene and tetracene (1, 2, 3, 4). Intensity, voltage, and spectral dependence as well as rise time, decay time, and temperature dependence of the photocurrent have been investigated thoroughly. More recently Lyons and Morris (5) published a note on the spectral dependences of a number of other polycyclic hydrocarbons. As the photocurrents were extremely low, they had to restrict themselves to measurements at wavelengths where a mercury arc provided a high enough intensity, i.e. to the wavelengths of the major mercury lines. In our laboratory the temperature dependence of the photocurrent in a number of compounds has been studied (6). Recently Lyons and Morris (7) reported experiments in which they used the qualitative resemblance of the spectral response of the photocurrent to the absorption spectrum to draw conclusions about the polarization ratio and thus about the assignments of this spectrum. In our measurements of the temperature dependence of the photocurrent we observed that some compounds photoconduct at wavelengths considerably longer than those within the region of the absorption spectrum. This was the case particularly for thicker crystals. With the aid of a 1000 w. xenon lamp as a strong ultraviolet source, it was decided to try to obtain a continuous spectral response for some of the compounds studied by Lyons and Morris and for some other ones that appeared to be of interest. The results of these measurements, and particularly those for pyrene which has been studied more extensively, are given in the present paper.

EXPERIMENTAL

Naphthalene, stilbene, and terphenyl single crystals were obtained from the Harshaw Chemical Company. A number of crystals of naphthalene for comparison were kindly grown for us by Dr. F. R. Lipsett in a Bridgeman furnace (8). No dependence on the source of the crystals was found. Azulene and pyrene crystals were measured as sublimation flakes. Thicker pyrene crystals were grown from a solution of pyrene in petroleum ether.

The light of a 1000 w. XBO 1001 (Osram) xenon lamp was passed through a Farrand 300 U.V. monochromator. The image of the exit slit of this monochromator was focused onto the specimen by means of a quartz achromat. A plane-parallel quartz plate placed in the light beam between achromat and crystal reflected part of the light onto a G.E. 935 vacuum photocell. Thus the current through the photocell is proportional to the intensity of the light incident on the crystal at any specific wavelength. The crystals were mounted on a quartz or teflon disk. Aquadag or silver paste contacts were painted round the ends of the crystal. All of the crystal and at least part of the contacts were illuminated. The teflon or quartz disks were mounted in a cell essentially the same as the one described by Chynoweth and Schneider (10), in which all insulation had been replaced by scrupulously cleaned teflon so as to prevent any spurious dark currents. From the cell went an insulated straight, rigid, and shielded lead to the input terminal of a Keithley 200 B micromicroammeter. The whole assembly was mounted on a board which slid on an optical rail and could also be adjusted in the two remaining directions; the monochromator was held in a fixed position on the same rail. With this setup currents down to about 5×10^{-14} amp. could be measured reproducibly within 2–3%.

The wavelength knob of the monochromator could be driven by a motor with gear assembly while the output of the micromicroammeter was recorded by a Varian G-10 recorder. At the beginning of each series of experiments the photoconduction assembly was replaced by a Moll thermopile (Kipp, Holland). This allowed calibration of the photocell. During a run readings of the current were continuously taken so as to allow subsequent correction for equal intensity input.

Intensity dependences were determined by placing neutral density filters between the monochromator and the deflecting quartz plate. The actual transmitted intensities could thus be read on the galvanometer of the photocell. The linearity of the photocell was checked with the thermopile and found satisfactory.

Voltage dependences were obtained by means of a 300 v. battery with a decade shunt of selected 1 meg resistances. All points for voltage and intensity dependence were taken at random.

In some pyrene crystals it was of interest to determine the absorption edge and the photoconductivity response. For these experiments the crystals were mounted on a quartz disk. The response curve was determined first and then without disturbing the crystal on the quartz disk the absorption edge was measured. These measurements were carried out in a Carey recording spectrograph. As only very small crystals were available, a condenser system was used to focus the beam from the exit slit of the Carey onto the crystal specimen. An image of the pinhole behind the crystal was focused on the entrance window of the photomultiplier. The objective lens of the condenser system was made adjustable so as to allow proper focusing outside the spectrophotometer. Lenses and specimen holder were mounted on a base which was made to fit onto the cell holder plate of the spectrophotometer compartment. For each spectrum a blank was run by removing the crystal from over the pinhole. Accurate positioning of the crystal could be carried out by looking through the objective lens, thus using it as a magnifying glass. By adjusting the slitwidths of the apparatus care was taken to ensure that about the same beamwidth was obtained in measuring spectra and spectral response curves.

RESULTS

All voltage and intensity dependences were found to be linear within the experimental error. For very low photocurrents sometimes a slight departure from the linearity of

the intensity dependence could be observed. Allowing more time between the measurements usually made any deviations disappear. Such departures from linearity could be super- or sub-linear and could never be reproduced from crystal to crystal.

The spectral dependences are given in Fig. 1. They are all corrected to an incident light intensity of about 20 μw./cm.^{2} The average beamwidth with which these curves have been measured was about 30 Å. Intensity considerations did not allow us to use polarized light in these experiments.

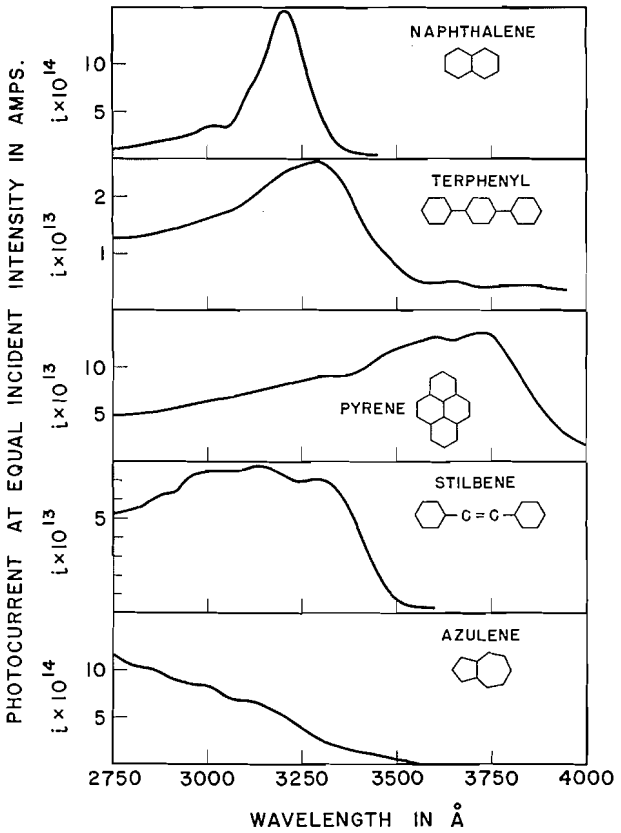

FIG. 1. Spectral response of the surface photocurrents in naphthalene, terphenyl, pyrene, stilbene, and azulene.

A feature of the spectral dependence of some of these compounds is their high sensitivity at the absorption edge. In this respect the present curves are in partial disagreement with those given by Lyons and Morris (5). However, light on the long-wavelength side of the absorption spectrum will be more strongly absorbed in the thicker crystals used in this work, and therefore lead to a higher photocurrent at these wavelengths.

The case of pyrene is most interesting, as even on the relatively thin sublimation flakes a structure in the spectral response could be observed beyond the region of the absorption spectrum of the crystal, which has its first peak at 3750 Å (11). It was therefore decided to investigate this material more closely, especially because the absorption edge lies in a spectral region where still an appreciable light intensity can be obtained without sacrificing too much resolution. It will be clear from Fig. 2 that the spectral response curves vary with the thickness of the crystals. At the long-wavelength edge of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12

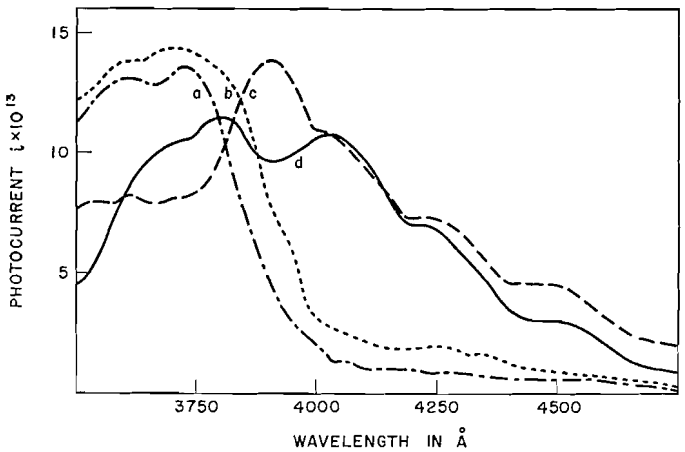

FIG. 2. Spectral response of the photocurrent of pyrene crystals of various thicknesses: (*a*) thickness 5 μ; (*b*) thickness 20 μ; (*c*) thickness 0.63 mm.; (*d*) sandwich-cell thickness 1.57 mm.

the absorption spectrum light will be absorbed throughout the crystal and contributions of deeper layers may be expected. Therefore the photocurrent at the absorption edge of the crystal will be favored with respect to the photocurrent at shorter wavelengths when the thickness of the crystals is increased. Curves *a* and *b* of Fig. 2 are for a thin (about 5 μ) and a thicker (20 μ) sublimation flake respectively. It is seen that the currents at wavelengths outside the absorption region are very low. Curve *c* applies to a crystal 0.63 mm. thick. The long-wavelength side of the curve is now very appreciable. Curve *d* is for a sandwich cell (4) of thickness 1.57 mm. with silvered contacts. Here also the long wavelengths make a greater contribution to the photocurrent. Contrary to anthracene, the bulk current in pyrene is of about the same magnitude as the surface current. A number of peaks appear at the long-wavelength side of the spectral response curves. One of these peaks is apparent. Although the curves have been calculated for an equal incident energy of 20 μw./cm.^{2} at all wavelengths, all this energy is not absorbed by the crystal. At longer wavelengths the major part is transmitted and absorbed by the black background. For this reason the absorption edges of the crystals were directly measured. Because the intensity dependence is linear the photocurrent is directly proportional to the amount of light absorbed:

$$i = \phi(I_e - I) = \phi I_0(1 - 10^{-D})$$

where i is the photocurrent, I_0 the incident intensity, I the transmitted intensity, D the optical density, and ϕ a proportionality factor we can call the "efficiency". Then:

$$\phi = (1/I_0)[i/(1 - 10^{-D})].$$

A plot of $i/(1-10^{-D})$ at constant incident intensity versus the wavelength will give a measure of the relative efficiency of the absorbed light in producing the photocurrent.

At wavelengths longer than 4100 Å no change in the absorption of a crystal could be detected. Owing to the large amount of scattered and reflected light in these thick crystals it is impossible to obtain an actual optical density at these wavelengths. As it would seem impossible for the crystal to photoconduct without the absorption of light it must be supposed that the crystals have a small but finite optical density as far out of the absorption region as 4750 Å. Fig. 3 gives a plot of $i/(1-10^{-D})$ at constant intensity

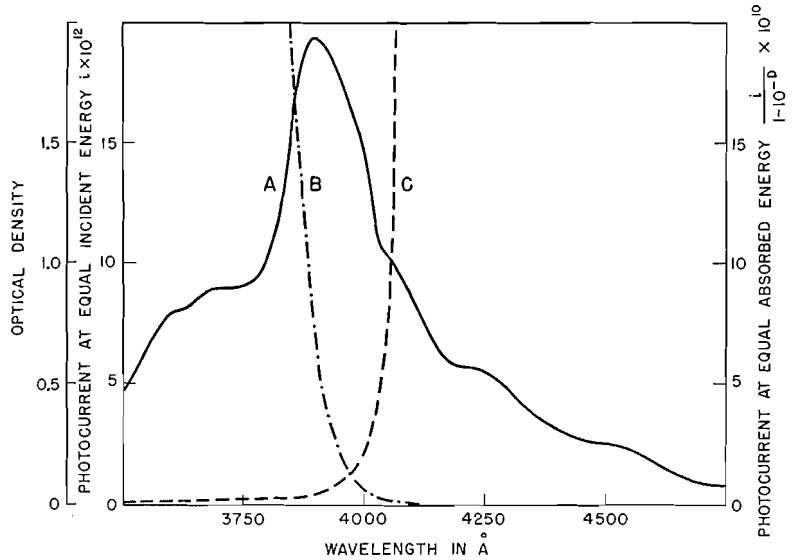

FIG. 3. Curve A shows the photocurrent as corrected for equal absorbed energy (scale at left). Curve B is the optical absorption edge (scale at left). Curve C gives the efficiency of the light in promoting photoconduction, i.e. the photocurrent corrected for equal absorbed energy (scale at right).

for a crystal with a very high apparent peak at 3900 Å. It will be seen that this peak is lost when the correction is applied. It will also be noted that light on the long-wavelength side of the absorption spectrum is very efficient in producing photoconduction. At the long-wavelength side of the response curve three peaks are observed: at 4475 Å, 4725 Å, and 4100 Å. Similar curves were obtained for a number of other crystals and within 25 Å the peak values all agree.

The fact that the 3900 Å peak is apparent could also be shown in another way. Comparison of Fig. 2 and Fig. 3 will show that its position and its magnitude changes with the thickness of the crystal. To rule out any peculiarities of the crystal, the following experiment was carried out. A crystal was mounted on a quartz disk and the spectral response curve determined with the quartz disk mounted against a black background. Then a layer of silver was evaporated on the back of the quartz plate without taking the crystal off, so as to create a mirror reflecting transmitted light and the spectral response curve was again determined. As is clear from Fig. 4 the apparent peak shifted from 3900 Å to 3950 Å.

A similar effect is observed with a background of white teflon. As the spectral response curves for the other compounds are all given for crystals on a white background it should be borne in mind that the long-wavelength side of the spectral dependence may be somewhat exaggerated.

It is of interest to note that in all materials except azulene photoconduction was detected at wavelengths where the optical absorption is negligible compared to its peak value. Stray light being ruled out by the use of suitable filters in the light beam, photoconduction was shown to take place in these materials as far out as 8000 Å, the limit of our instrument. No structure, except as mentioned for pyrene, could be observed, only a steady fall in sensitivity.

At the short-wavelength side of the spectral response curve some structure was always found. Although the accuracy at these wavelengths is rather poor owing to the low

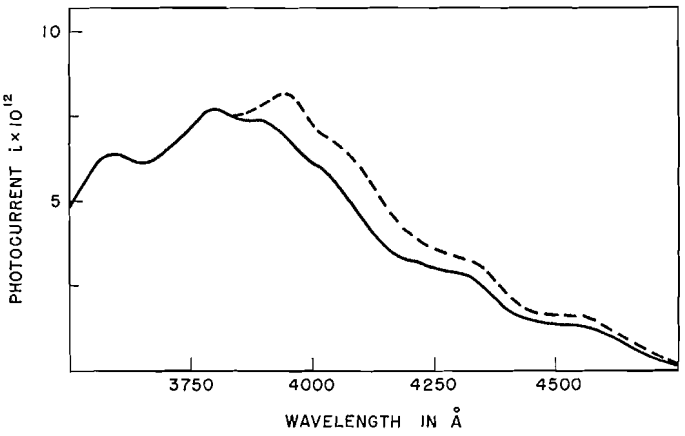

FIG. 4. Change of the spectral response of the surface photocurrent of a pyrene crystal with the reflective properties of the background. Solid curve: spectral response with a non-reflective background. Dotted curve: with a highly reflective background.

intensity of the incident light, peaks were usually observed at about 3600 Å and 3700 Å in pyrene.

In the course of obtaining absorption spectra for the pyrene crystals used in this work, it was observed that a weak absorption was present at the long-wavelength side of the absorption spectrum as given by Ferguson and Schneider (11). They observed the first main absorption band at 3750 Å. On crystals about 0.1 mm. thick, a shoulder on the main absorption was present with its center at 3832 Å.

DISCUSSION

From our results it appears that in pyrene and naphthalene light at the long-wavelength edge of the crystal absorption spectrum is very efficient in producing photoconduction. In naphthalene the peak of photoconduction appears at 3220 Å, where McClure and Schnepp (12) report a relatively weak absorption. However, in pyrene our measurements show peaks in photoconduction where there is no detectable absorption at all, even in crystals about 2 mm. thick.

There seem to be two possible explanations for this phenomenon. The first that comes to mind is the presence of an impurity. It is well known that commercial pyrene has a yellow color, and that this color persists after chromatographic purification through alumina (9). Chromatography through silica gel, however, yields completely colorless pyrene. After the first observations of the long-wavelength photoconduction, the chromatography through silica gel was repeated, but this did not change the appearance of the spectral response curve. Assuming an extinction coefficient of 10^4 for the impurity, to escape optical detection in a 1 mm. thick crystal, the concentration would have to be lower than 10^{-5} molar. If that impurity is then responsible for the photoconduction it must have a very high quantum yield. No organic photoconductors have been reported so far to possess this property. Moreover Carswell and Lyons (13) studied the influence of the addition of tetracene to anthracene on the photoconduction of anthracene. At the concentrations used (10^{-4} molar) no photoconduction by direct excitation of the tetracene could be observed. These considerations make it rather unlikely that an impurity can be held responsible for the observed effect.

We will therefore examine the other possibility, i.e. the photoconduction observed at the long-wavelength edge of the absorption spectrum is intrinsic and takes place by

For personal use only.

direct excitation of the pyrene. Northrop and Simpson (14) have proposed levels of partly ionic character lying between the triplet and the singlet state. Terenin (15) introduced the concept of shared triplet levels, which would lie at the same energies. Lyons (16) considered the levels arising from the fact that an electron would be bound to a neutral molecule with the resulting hole on its neighbors. He thus concludes that there are a series of "ionized levels with bound electrons". For anthracene he calculated these levels to lie at energies lower and higher than the energy of the first singlet state. Murrell (17) pointed out that charge-transfer states too might be considered in this respect. All these levels have been suggested to be responsible for the electrical conduction in organic materials.

Ferguson and Schneider (11) report that the fluorescence of crystalline pyrene has its origin far below the first singlet state and propose to explain this by a charge-transfer process which would be facilitated by the close proximity of the pyrene molecules in the crystal. Contrary to naphthalene and anthracene, the molecules in the pyrene crystal lattice occur in pairs. Lyons (16) suggests that the absorption at 3339 Å as found in naphthalene (12) might be a direct observation of a transition to an ionized state.

At present it is still rather difficult to choose between the various mechanisms of photoconduction proposed by the different authors. Much more experimental work is needed to elucidate the exact nature of the transitions that can apparently take place between the ground state and some excited species with an energy lower than the singlet state. From the present work, however, the following conclusions can be drawn for crystalline pyrene:

A finite absorption exists between 4750 Å and the optically measured long-wavelength limit of the ultraviolet absorption spectrum. In this absorption, peaks appear at 4475 Å, 4275 Å, and 4100 Å. The transitions that take place in this region lead to states that are highly active in producing conduction, as is clear from the efficiency plot in Fig. 3. The peaks are at wavelengths between the absorption limit and the wavelengths of the fluorescent light as found by Ferguson and Schneider (11).

Similar conclusions can probably be drawn for naphthalene, where McClure and Schnepp (12) and various other workers reported weak absorptions in the region of maximum photoconductivity, as reported in this work.

For stilbene and terphenyl the crystal spectra so far are not available. The case of azulene is interesting because in first approximation the photoconductive response appears to coincide with the absorption to the second singlet state as measured by Sidman and McClure (18) in a solid solution of naphthalene. No photoconduction was found in the region of the absorption to the first singlet state. It is of interest to note that Beer and Longuet-Higgins (19) as well as Viswanath and Kasha (20) found that azulene does not fluoresce when it is irradiated in its first absorption band, but that it does fluoresce when irradiated in the second absorption band. Apparently the same mechanism that inhibits fluorescence also inhibits photoconduction.

The observation of photoconduction at longer wavelengths than the absorption spectrum may be useful to solve the problem of the apparent discrepancy between the thermal and optical activation energy. Pick and Wissman (21) showed that the thermal activation energy for naphthalene semiconduction in a high vacuum is 3.7 ev. This agrees well with the optical threshold energy as found in this work for naphthalene: 3400 Å $\approx$ 3.65 ev. Inokuchi (2) found for pyrene bulk currents, where gas effects will be limited, 2.4 ev., while the optical threshold appears to be at 4750 Å $\approx$ 2.61 ev. The threshold has been taken as the wavelength where the photoconductive sensitivity is approximately one hundredth of its peak value in crystals of about 1 mm. thickness. In view of the extended

For personal use only.

long-wavelength tail, however, the concept threshold becomes rather vague, and in this respect Northrop and Simpson's idea (14) of a large number of levels, of which the higher ones contribute more to the conduction than the lower ones, becomes attractive.

ACKNOWLEDGMENTS

The authors are indebted to Dr. L. E. Lyons for the opportunity of reading his manuscript before its publication. Thanks are due to Dr. J. N. Murrell with whom we had some interesting discussions.

SOME NEW FLUORIDE COMPLEXES OF TRIVALENT TITANIUM[1]

NORMAN F. H. BRIGHT[2] AND JOSEPH G. WURM[3]

ABSTRACT

Three new complex fluorides of trivalent titanium have been isolated from the products of electrolysis, under an inert atmosphere, of molten baths of KCl, NaCl, or mixtures of KCl and NaCl, containing either K_2TiF_6 or Na_2TiF_6. Electrolytic baths containing a mixture of KCl and NaCl with either K_2TiF_6 or Na_2TiF_6 yielded a violet-colored, face-centered cubic compound identified as K_2NaTiF_6, which was virtually insoluble in water and amenable to electrostatic separation from the metallic titanium also produced in the electrolysis. Baths containing molten mixtures of K_2TiF_6 and KCl gave a pale violet compound K_3TiF_6, which was slightly soluble in water. Baths containing Na_2TiF_6 and NaCl gave a deep violet-colored compound Na_3TiF_6 which was almost insoluble in water. The compounds K_3TiF_6 and Na_3TiF_6 have structures which approximate to cubic. The compounds K_2NaTiF_6 and Na_3TiF_6 are more stable to atmospheric oxidation than is K_3TiF_6. X-Ray diffraction patterns have been recorded for these compounds and some of their physical and chemical properties determined.

1. INTRODUCTION

The mechanism of titanium production by the electrolysis of fused alkali halide baths containing complex titanium salts of the type Na_2TiF_6 or K_2TiF_6 has recently been discussed by Wurm, Gravel, and Potvin (1). In the course of their work, certain products were obtained which yielded X-ray diffraction patterns corresponding to no previously published data. A preliminary notice of the isolation of the compounds giving rise to these patterns appeared in the above-mentioned publication. The present paper represents an amplification of this information and gives details of the X-ray and other data obtained on three new complex titanium fluorides which were isolated from the electrolytic products.

2. EXPERIMENTAL PROCEDURES

The alkali titanofluorides, having the formula M_2TiF_6, based on tetravalent titanium, are readily soluble in molten alkali chlorides in the temperature range 650° C. to 850° C., depending upon the particular compounds involved.

The electrolytic baths contained, at the start of the electrolysis, 20 to 30% of either Na_2TiF_6 or K_2TiF_6 in solution in a molten mixture of NaCl and KCl, having approximately the eutectic composition of 55% KCl, by weight. In certain later electrolyses, solutions of Na_2TiF_6 in NaCl and of K_2TiF_6 in KCl were used to yield products in which only one type of alkali ion was present in each case.

When these molten baths were subjected to electrolysis under an argon atmosphere, using a water-cooled stainless-steel cathode and a graphite crucible containing the melt as anode, the products of the electrolysis, examined after they had cooled and solidified, showed the following phenomena:

(*a*) Surrounding the cathode was a spherical core or "nut", composed of dendritic metallic titanium crystals embedded in a salt of deep violet color.

(*b*) Around the outside of this "nut" was the solidified salt bath, having a pale violet color.

[1]*Manuscript received November 1, 1957.*
Contribution from the Mineral Dressing and Process Metallurgy Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, and the Faculté des Sciences, Université Laval, Québec. Published with the permission of the Director, Mines Branch, Ottawa.

[3]*Faculté des Sciences, Université Laval, Québec.*

The cathodic "nut" was crushed and separated into its constituents by electrostatic means, yielding the titanium metal and the violet salt substantially free from each other. The crystalline salts were examined by the standard procedures of X-ray diffraction analysis, using CoK_α radiation and 57.3 mm. diameter Debye–Scherrer powder cameras. Occasionally, for greater precision in measuring line spacings, a 114.6 mm. diameter camera was used.

The solidified melt surrounding the "nut" was examined similarly, both directly as obtained and also after it was leached with boiling distilled water in the proportion of 2 g. of crushed melt to 25 ml. of water to dissolve the alkali chlorides and concentrate the remaining materials which carry the violet color. Residues of deep violet color, almost insoluble in water, were obtained by this leaching. These residues were analyzed chemically for sodium, potassium, total and trivalent titanium, chloride, and fluoride. Certain reference materials, used for preparing X-ray patterns in attempts to identify the unknown substances, were also analyzed chemically; these included the pure starting titanofluorides, Na_2TiF_6 and K_2TiF_6, and sodium titanate. All the chemical analyses referred to in this paper were done in the Chemical Laboratory of the Division of Mineral Dressing and Process Metallurgy, Mines Branch, Ottawa.

A résumé of the analytical procedures used is as follows:

Potassium and sodium.—Fluorine removed by evaporation of the sample with dilute sulphuric acid three times; titanium removed by hydrolysis of aqueous solution of product; potassium and sodium determined with a Perkin-Elmer flame photometer.

Fluorine.—HF steam-distilled off at 135°–140° C. from an aqueous perchloric acid solution of the sample. Fluorine determined amperometrically at pH = 7.0 using thorium nitrate solution previously standardized against NaF.

Chlorine.—Determined by potentiometric titration with 0.05 N $AgNO_3$ of a sulphuric/nitric acid solution of the sample. Less than one drop of reagent was required for a 0.2 g. sample, in those cases where chlorine was not expected to be present.

Titanium (total).—Residue from fluorine distillation reduced with zinc amalgam and titrated with ferric alum.

Titanium (trivalent).—Sample dissolved in aqueous sulphuric acid and titrated with ferric alum, all under an argon atmosphere. Alternatively, sample dissolved in ferric alum solution, and the reduced iron (equivalent to the trivalent titanium) titrated with standard potassium dichromate.

3. EXPERIMENTAL RESULTS

A comparison of the X-ray diffraction patterns of a considerable group of electrolytic products, using either Na_2TiF_6 or K_2TiF_6 as the starting material, in solution in mixed NaCl–KCl, showed that the principal products in all the solidified melt samples were sodium and potassium chlorides, each containing some of the other in solid solution. However, of greater interest was a group of weaker diffractions which was the same regardless of the initial material used. The violet materials, obtained as residues after the alkali chlorides were leached out, gave this same group of diffractions but in much greater strength. The same pattern was obtained from the violet material obtained from the cathodic "nut". In some of the leached products, no other pattern was detectable, and thus, presumably, the material giving rise to this set of diffractions was reasonably pure in these particular products.

The chemical analyses of the insoluble residues resulting from the water leaching of the electrolytic fusion products using K_2TiF_6 or Na_2TiF_6 with the mixed alkali chlorides are given in Table I. The two analyses obviously correspond to the same substance.

It can be seen from these analyses that the molecular formula for either material is very close to K_2NaTiF_6. The theoretical figures for this compound are also given in Table I.

From the chemical data alone, however, the material could equally well be a mixture of K_3TiF_6 and Na_3TiF_6 in the proportion of approximately 2 : 1. It therefore remained to determine whether this material (to which has been assigned the formula K_2NaTiF_6) is, in fact, a discrete compound in its own right, or merely one particular composition in a solid-solution series K_3TiF_6–Na_3TiF_6, should such a series exist. The fact that the same composition was obtained using either K_2TiF_6 or Na_2TiF_6 in molten NaCl–KCl as the starting material strongly supports the view that a single compound was present, rather than merely one particular composition in a solid-solution series. If it were a member of a solid-solution series, one might expect to obtain different compositions in the two cases. The matter was resolved with reasonable certainty by studying the products of electrolyses in which either K^+ or Na^+ ions were the sole alkali ions present.

The material obtained from the electrolysis of Na_2TiF_6 in NaCl was a deep violet in color, virtually insoluble in water, and gave the analysis given in Table II. This analysis corresponds very closely to Na_3TiF_6, and the titanium is all in the trivalent state, in accordance with the color of the material.

TABLE II

Element	% by weight	Theoretical for Na_3TiF_6
K	None detectable	Nil

Ti (total)	20.2±0.25	20.74
Ti (trivalent)	20.2±0.5	20.74
F	49.7+0.25	49.38
Cl	0.034	Nil

The preparation of the corresponding potassium compound was more troublesome, since the material obtained by leaching out the KCl was readily oxidized in air. By evaporation of the water under an argon atmosphere, however, a product was obtained which contained either some unchanged or regenerated K_2TiF_6, a trace of residual KCl, and a compound of pale violet color, slightly soluble in water. In the analysis of this material, the chloride present was used as a measure of the KCl, the tetravalent titanium (i.e. total titanium minus trivalent titanium) used as a measure of the K_2TiF_6 present, and the remainder of the composition calculated accordingly. The results of this analysis are given in Table III.

The molecular formula of the compound calculated on this basis is $K_{2.997}TiF_{5.994}$,

i.e. K_3TiF_6, and the composition of the product then works out at K_3TiF_6, 90.9%; K_2TiF_6, 8.4%; KCl, 0.34%.

When this product was examined by microscope, a very small amount of KCl was visible. Approximately 10% of colorless needle-shaped crystals were observed, having one refractive index $\omega = 1.475$ and the other (ϵ) slightly lower; this is in accord with the known optical properties of K_2TiF_6. The remaining material, about 90%, had a refractive index of approx. 1.406 and was slightly anisotropic. These proportions are in excellent accord with the above chemical analyses.

The material to which the formula K_2NaTiF_6 has been assigned was strictly isotropic optically and had a refractive index of 1.408. The compounds Na_3TiF_6 and K_3TiF_6 were both slightly birefringent, Na_3TiF_6 having refractive indices of $\omega = 1.387$ and $\epsilon = 1.382$, and K_3TiF_6 having refractive indices of $\omega = 1.406$ and $\epsilon =$ slightly lower than 1.406.

The mixed potassium–sodium material gave a face-centered cubic pattern based on a

cell edge of 8.3669 Å. The *d*-spacings observed, together with the indices of the various reflections and the calculated *d*-spacings using the above cell edge, are given in Table IV.

The X-ray spacings for the compound Na_3TiF_6 are given in Table V. It can be shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

that the main diffractions conform approximately to a cubic arrangement but that some distortion either of cell edge or of angle has occurred to cause a departure from the true cubic structure. The crystallography was not studied further because no single crystals of this compound of sufficient size were obtained.

Similarly, the compound K_3TiF_6 gave the X-ray diffraction data shown in Table VI. These data also indicate a slight distortion from a cubic structure, though probably not in the same way as for Na_3TiF_6. Again the crystallography has not been studied further.

4. DISCUSSION

The question to be decided is whether the material to which has been assigned the formula K_2NaTiF_6 should properly be regarded as a compound in its own right, or whether it is merely one particular member in a solid-solution series of which the end members are the compounds Na_3TiF_6 and K_3TiF_6, if such a solid-solution series in fact exists.

It has been shown that both end members are slightly anisotropic optically, whereas the material containing both potassium and sodium is strictly isotropic. This is strong, though not conclusive, evidence that K_2NaTiF_6 is a definite compound, since certain cases are known in which an optically isotropic member of a solid-solution series exists where neither end member is isotropic. A notable example of this exceptional optical behavior is in the melilite solid-solution series (2); here the end members, akermanite $2CaO.MgO.2SiO_2$ (3) and gehlenite $2CaO.Al_2O_3.SiO_2$ (4), are both anisotropic but an intermediate composition of approximately 65% akermanite: 35% gehlenite is isotropic.

If this behavior were applicable in the present instance, then the refractive index of the mixed sodium–potassium material would have to lie between the values given by the two end members, Na_3TiF_6 and K_3TiF_6. This is not the case, however, as the refractive index of K_2NaTiF_6 is 1.408 whereas the values for K_3TiF_6 are 1.406 and slightly below 1.406, and the values for Na_3TiF_6 are 1.387 and 1.382. In a solid-solution series, it is normal for the refractive index of an intermediate member to approximate to the value obtained by a linear interpolation between the values for the end members. In this case the intermediate material gives a value lying outside the range of values given by the end members; hence this is not analogous to the melilite behavior. This strongly suggests that the material K_2NaTiF_6 is to be considered as a compound and not as a member of a solid-solution series.

This optical evidence is further supported by the X-ray diffraction data, which show that the pattern given by K_2NaTiF_6 can be completely indexed according to a cubic unit cell; by contrast, neither K_3TiF_6 nor Na_3TiF_6 possesses a cubic structure, although both are close to it. Thus, the fact that neither the potassium nor the sodium compound is cubic, whereas the mixed potassium–sodium material is strictly so, is a cogent argument in favor of regarding K_2NaTiF_6 as a true compound. It may be mentioned by way of contrast that in the case of the melilites, referred to above, all members of the series, including the isotropic member, have a tetragonal structure with a c/a ratio in the range 0.6 to 0.7.

The above arguments support the validity of the contention that K_2NaTiF_6 is a definite compound in its own right. The strongest evidence, however, lies in the fact that the same composition is obtained regardless of whether K_2TiF_6 or Na_2TiF_6 is used as the starting material with the NaCl/KCl eutectic in the electrolytic preparation.

There are, thus, the following arguments in favor of the K_2NaTiF_6 being a definite compound:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

(*a*) Its isotropic optical behavior, as contrasted with those of K_3TiF_6 and Na_3TiF_6.

(*b*) The value of its refractive index as compared with those of K_3TiF_6 and Na_3TiF_6.

(*c*) Its cubic X-ray pattern.

(*d*) The constancy of its chemical composition, irrespective of starting material.

Additional unequivocal evidence could have been provided by conducting liquidus determinations across the system K_3TiF_6–K_2NaTiF_6–Na_3TiF_6, when, if K_2NaTiF_6 were a true compound, a peak in the liquidus curve would have been obtained at that composition. It would also have been of interest to attempt to prepare the mixed potassium–sodium material from an appropriate mixture of the pure potassium and sodium compounds. However, the small quantities of material available precluded these two lines of investigation from being followed.

It is of interest to note that an exactly analogous series of compounds is known in the complex aluminofluorides, viz. K_3AlF_6, K_2NaAlF_6, and Na_3AlF_6; in this series, the mixed potassium–sodium compound is cubic and neither the sodium nor the potassium compound alone is cubic. Thus, K_3AlF_6 (potassium cryolite) is tetragonal with $c_0 = 8.468$ Å and $a_0 = 5.944$ Å (5); K_2NaAlF_6 (elpasolite) is cubic with $a_0 = 8.109$ Å (6); and Na_3AlF_6 (cryolite) is monoclinic (almost orthorhombic, and not far removed from tetragonal) with $a_0 = 7.80$ Å, $b_0 = 5.61$ Å, $c_0 = 5.46$ Å, and $\beta = 90°11'$ (7).

In addition, many other six-coordinated complexes of transitional elements containing two different alkali elements crystallize in the cubic system. The corresponding compounds containing one alkali element only in many cases either do not exist, or are not very stable, or do not crystallize in the cubic system. This behavior is due to the greater ease of packing three alkali ions of two different sizes (two larger, and one smaller) than of packing three ions of equal size.

The three compounds described in this paper are examples of new complexes in which the titanium is present in the trivalent state. Various compounds have been described in a more or less complete manner from a chemical viewpoint, in which the titanium in the trivalent condition was the starting material, and which were supposed still to contain the titanium in that state. In no case, however, was there any specific analysis for trivalent titanium in the product, but merely for total titanium content. Also, no crystallographic data (either optical or X-ray) have been provided for such compounds. These earlier publications included the following:

(*a*) Work by Piccini (8) in which compounds designated as $(NH_4)_3TiF_6$, K_2TiF_5, and $(NH_4)_2TiF_5$ were produced by the electrolytic reduction of fluotitanates in an aqueous solution of either NH_4F or KF. These compounds were in no case obtained in the pure state.

(*b*) Work by Petersen (9) in which $(NH_4)_3TiF_6$ was obtained by the cadmium reduction of aqueous K_2TiF_6 in warm hydrochloric acid solution with subsequent addition of NH_4F.

(*c*) Work by Stähler and his co-workers (10, 11) in which hydrated complexes of titanium trihalides were produced; these workers also prepared hydrated trivalent sulphates, oxalates, acetates, formates, and thiocyanates. In all cases the titanium was considered as forming part of a coordination complex.

(*d*) Work by Schumb and Sundström (12) in which ammine complexes of titanium di- and tri-chlorides were prepared.

In a recent patent (13), complexes containing divalent and trivalent titanium are claimed, but they were not isolated nor identified precisely.

For personal use only.

Thus, in the present work, three new compounds have been described which are complexes containing trivalent titanium. They have been characterized by chemical analysis, optical data, and X-ray crystallographic study.

ACKNOWLEDGMENTS

The authors wish to express their thanks to members of the Mines Branch staff, especially to Miss E. M. Penner, Mr. L. G. Ripley, and Mr. R. C. McAdam for the difficult and painstaking chemical analyses done in connection with this work, and to Mr. Richard H. Lake for valuable assistance with the X-ray diffraction work.

MOLECULAR REARRANGEMENTS IN THE REACTIONS OF OXYGEN ATOMS WITH OLEFINS[1]

R. J. CVETANOVIĆ

ABSTRACT

Reactions of oxygen atoms with propylene, butene-1, *iso*-butene, *cis*-butene-2, *trans*-butene-2, *cis*-pentene-2, and tetramethyl ethylene have been studied at room temperature and at pressures between 50 and 600 mm. The following generalizations can be made. The oxygen atom adds predominantly to the "less-substituted" carbon atom of the olefinic double bond to form a short-lived biradical which rapidly rearranges into isomeric epoxy and carbonyl compounds. Rearrangements involve migration of radicals (including H atoms) from the carbon atom to which oxygen is attached to the other carbon atom of the original double bond. Partly inhibited rotation around the original double bond also takes place. Migration of H atoms is exclusively internal. Migration of larger radicals, such as CH_3, is only partly internal: a large fraction of these radicals become completely detached from the rest of the molecule and the particular carbonyl compound is produced both by radical combination and by internal migration. The fragmentation resulting from the splitting off of a migrating radical is pressure independent. The final addition products formed are "hot" as a result of high heats of reaction and undergo decomposition if the excess energy is not removed by collisions. This second type of fragmentation is, therefore, pressure dependent. It is very extensive in the case of ethylene and appears to be completely suppressed in the investigated pressure range in the case of more complex olefins (possessing a greater number of degrees of freedom) such as butenes and higher homologues. Propylene exhibits an intermediate behavior. For orientation of addition of oxygen atoms a carbon atom of an olefinic double bond to which CH_3 is attached is "less substituted" than a corresponding carbon atom to which C_2H_5 is attached.

INTRODUCTION

In a previous publication (1) some preliminary results of a study of the reactions of oxygen atoms with a number of butenes have been briefly reported. This investigation has two distinct objectives: (1) to establish the general mechanism and the type of products formed, and (2) to obtain information on the rates of these reactions. In the present paper the first of the two aspects of the investigation is presented in detail and is extended to some further olefins studied in the meantime.

This work is a part of a more extensive study of the reactions of oxygen atoms with different organic compounds. The reactions with ethylene (2) and acetaldehyde (3) have already been described, while the results obtained with some other types of compounds will be published at a later date. Oxygen atoms are generated by mercury-photosensitized decomposition of nitrous oxide (4) and are probably in their ground, triplet $O(^3P)$, state. The amount of nitrogen formed gives a direct quantitative measure of the oxygen atoms generated and serves as an internal actinometer.

EXPERIMENTAL

A conventional-type high-vacuum apparatus was used. It incorporated a cylindrical silica reaction cell, 5 cm. in diameter and 10 cm. long, an all-glass circulating pump supported on teflon bearings, a LeRoy still (5), and a constant volume burette with a copper oxide tube and outlets for sampling tubes connected with it. Two low-pressure mercury lamps were placed one at each end of the reaction cell and were used singly or simultaneously as the source of mercury resonance radiation.

For the analysis of products use was made of the LeRoy still (for a preliminary separation into fractions), the copper oxide tube in conjunction with the constant-volume

burette (for the analysis of the non-condensables), gas–liquid chromatography (GLC), infrared and mass spectroscopy. An attempt was made, whenever possible, to verify the qualitative identification of the products by directly comparing the GLC relative elution times (6) and the infrared and mass spectra for the unknown product (after separation on GLC) and for a standard sample of the corresponding compound. In one or two cases a standard sample was not available and the identification was based on the comparison of the mass and infrared spectra with the existing literature data. In the early stages of the investigation, before the type of products formed was established, relative elution times were determined for a number of different C_4H_8O isomers and, thus, several possibilities were readily ruled out. A 10 ft. column of dinonyl phthalate on glass spheres (passing 270 mesh) was used, and the GLC apparatus differed from the one previously described (7) in that the low pressure (*ca.* 30 mm.) at the outlet of the column was maintained constant by inserting a suitable *internal* capillary in the lead to the high-vacuum pump and not by an external leak. A better stability was obtained in this manner and a gradual deterioration in the performance of the high-vacuum pump was prevented. The inlet pressure was maintained at 14 p.s.i. and the column temperature varied from 25° to 110° C. depending on the volatility of the products.

Best available grades of reactants were used after thorough degassing and bulb-to-bulb distillation *in vacuo*. N.B.S. samples of *cis*-pentene-2 and 3-methylheptane were kindly supplied by the Stanford Research Institute. *cis*-C_4D_8-2 was prepared by Dr. L. C. Leitch of these laboratories. Molecular oxygen was produced by heating reagent grade $KMnO_4$.

In the experiments carried out a large excess of nitrous oxide was used (100 to 600 mm. N_2O and usually only a few millimeters of the olefin). The ratio of the over-all quenching efficiency of an olefin and nitrous oxide is about 2 (8). The quantum yield of decomposition of nitrous oxide, however, is quite high (3) while that of olefins is as a rule very low, especially at the high total pressures used (9). Experimental conditions, therefore, could be readily adjusted so as to eliminate complications from direct quenching decompositions of olefins. By not extending the reactions to too high conversions, secondary reactions involving the products could also be avoided. Actually no trends in the rates of formation of the products per oxygen atom consumed were observed, except at very high conversions, after most of the olefin was consumed.

RESULTS

Experiments carried out with a number of hydrocarbons have shown that in general three types of reactions may be expected between the ground-state oxygen atoms and olefins: (1) addition of atoms to the olefin to form addition products, (2) fragmentation of the initially produced addition products, and (3) hydrogen abstraction.

Hydrogen Abstraction

At room temperature at least, and with the olefins studied so far, no evidence was found of any direct hydrogen abstraction by oxygen atoms. This finding is in agreement with the observed much higher rates of addition of oxygen atoms to the olefinic double bond relative to the hydrogen abstraction from paraffins. Thus, for example, the addition of oxygen atoms to *cis*-pentene-2 was found to be 43 times faster than the reaction of oxygen atoms with 3-methylheptane. It is conceivable, however, that with certain olefins a small amount of direct hydrogen abstraction takes place even at room temperature and that at elevated temperatures the abstraction reaction might become quite important.

Reaction of Oxygen Atoms with Propylene

In the reactions reported in the present communication the observed addition compounds, isomeric epoxides and carbonyl compounds, are the major reaction products, although a certain amount of fragmentation occurs as well. In this respect propylene exhibits a behavior intermediate between that of ethylene on one side and higher alkenes on the other. In the case of ethylene (2) extensive fragmentation takes place (CO yield ≈ 0.5). At best very little ethylene oxide is formed, and while the remainder of the oxygen is recovered mainly in the form of aldehydes at least a large fraction of these results from free-radical reactions. There is, however, an indication of a pressure effect, although this is quite small: there is a slight increase in the yields of aldehyde and ethylene oxide and a decrease in CO with increasing pressure. In contrast to this, in the case of higher olefins, taking as an example butene-1, large amounts of α-butene oxide and *n*-butyraldehyde are formed by direct addition of oxygen atoms and subsequent molecular rearrangement, their yields are pressure independent between 100 and 600 mm. within the experimental error, and there is relatively little fragmentation. The main trends observed in the case of propylene are shown in Fig. 1. At higher pressures

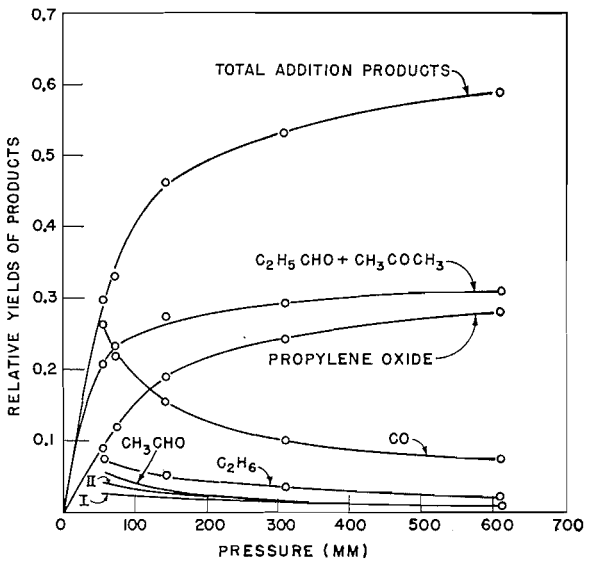

FIG. 1. Products observed in the room-temperature reaction of oxygen atoms with propylene at various total pressures. Curve I gives the yields of H_2 and also those of C_2H_4. Curve II gives the yields of CH_4. (For H_2, C_2H_4, CH_4, and CH_3CHO experimental points are not shown because of the mutual proximity and partial overlapping of the curves.)

increasing amounts of propylene oxide and propionaldehyde are formed and the character of the reaction approaches the one exhibited by butene-1, while at lower pressures fragmentation becomes more important and the reaction in many respects resembles that of ethylene. The pronounced pressure effect in the case of propylene is of particular interest and will be further discussed in the following section. With the chromatographic column used acetone could not be resolved from propionaldehyde, and total peak areas for the two compounds are plotted in Fig. 1. Infrared and mass spectra indicated large predominance and perhaps exclusive formation of the aldehyde. One separation was carried out on a 50 ft. tricresyl phosphate on firebrick column (120°) on which the two compounds completely resolved, and the ratio of the peak area of the aldehyde to that of acetone was about 9:1.

Formation of Addition Products

The addition products formed in the different reactions studied are summarized in Table I. The fractions of the addition products given in the table are based on GLC peak areas, taking the sum of the peak areas of all the addition products observed as unity. In some cases, as, for example, *cis*-β-butene oxide and *iso*-butanal as well as for *cis*-β-pentene oxide and 2-methylbutanal, the peaks partially overlapped and were approximately resolved graphically to obtain the individual peak areas. The last column in Table I gives the sum of the peak areas of all the fragmentation products observed by GLC analysis as a fraction of the total peak area of all the products (both addition and fragmentation). No attempt was made to identify the very small amounts of these fragmentation products in the cases where they were observed. In the case of butene-1 they seemed to consist largely of acetaldehyde and propionaldehyde.

TABLE I

PRODUCTS OBSERVED BY GLC ANALYSIS

(After removal of the unconsumed reactants and of any products of the same or greater volatility)

Reactant	Addition products[a]				Fragmentation products[b]
	Epoxides		Carbonyl compounds

[a] *The fractions are calculated from GLC peak areas taking the total area of all* addition *products as unity.*

[b] *The fractions are calculated from the total GLC peak area of the observed compounds other than the addition products taking the total peak area of* all *the products observed as unity.*

[c] *Extrapolated values for infinite pressure.*

[d] *Predominantly propanal (about 90%).*

[e] *Predominantly methyl-n-propyl ketone; some diethylketone is probably also formed (a small peak of the same elution time is observed; infrared and mass spectra, however, indicate a very low upper limit and perhaps absence of diethylketone).*

Formation of a restricted number of principal products in these reactions, mutually isomeric and of a molecular weight equal to that of the olefin used plus an oxygen atom, suggested strongly a direct addition of the atoms followed mainly by a molecular rearrangement rather than a free-radical process. This was substantiated by experiments in which two olefins were used simultaneously. In these experiments no new products were found but only those observed with the same two olefins when used singly, and their respective amounts were approximately proportional to the concentrations of the olefins used. Further information on the nature of these processes was obtained by studying the effect of additions of molecular oxygen.

Effect of Additions of Molecular Oxygen

Several experiments were carried out with *iso*-butene, butene-1, *cis*-butene-2, and tetramethyl ethylene in the presence of molecular oxygen. Initial pressures of 500 mm. N_2O, 7 to 15 mm. olefin, and 3 to 30 mm. O_2 were used.

In the case of *iso*-butene and butene-1 there was no or at best very little inhibition of the formation of the addition products even when the partial pressure of molecular oxygen was relatively quite high. The yields of aldehydes appeared to be slightly lowered and smaller amounts of some new products were also formed. In the case of *iso*-butene the latter amounted roughly to about 20% of the total product and probably were *tert*-butanol and acetone, although the identification was not certain. These two compounds were not found in the mercury-photosensitized reaction of *iso*-butene (60 mm.) in the presence of small amounts of O_2 but in the absence of N_2O. No attempt was made to study in detail these products or the mode of their formation.

In experiments with *cis*-butene-2 it was found that after a small amount of quenching by oxygen itself was taken into account approximately, the yields of *cis*- and *trans*-β-butene oxide and of methylethyl ketone were, within the analytical error, unaffected by the presence of molecular oxygen. On the other hand, the yield of ethane (produced normally in this reaction in small amounts, as discussed later) was rapidly suppressed and that of *iso*-butanal was reduced to about 20 to 25% of its value in the absence of oxygen and then remained independent of further oxygen additions. Simultaneously, appreciable amounts of methanol began to be formed. The effect of additions of O_2 on the composition of liquid products is shown in Table II. These results indicate that a large fraction of *iso*-butanal is formed by radical combination but that, nevertheless, a certain amount is produced by internal migration of CH_3 radicals. Similarly, one experiment with tetramethyl ethylene in the presence of about 40 mm. of O_2 showed a substantial reduction but not complete suppression of pinacolone while the yield of the epoxide appeared to be unaffected.

TABLE II

THE EFFECT OF MOLECULAR OXYGEN ON LIQUID PRODUCTS IN THE REACTION OF O ATOMS WITH *cis*-BUTENE-2 (500 mm. N_2O, 7 mm. *cis*-C_4H_8-2; irradiation time 30 min. Fractions of the sum of the observed GLC peak areas are given.)

Run	pO_2, mm.	*trans*-β-C_4H_8O	*cis*-β-C_4H_8O	$CH_3COC_2H_5$	*iso*-C_3H_7CHO	CH_3OH

267	41.7	0.26	0.23	0.27	0.052	0.19

Effects of Irradiation Time and of Pressure

Effects of time of irradiation and of the total pressure were checked with butene-1 and *cis*-butene-2 and, in a less systematic manner, with some of the other olefins used. Within the experimental error the rates of product formation were found to be independent of irradiation time up to relatively high conversions. The results of experiments with constant small amount of *cis*-butene-2 (about 5 mm.) and nitrous oxide varying from 80 to 600 mm. are given in Table III. There was at best only a very slight decline at low pressures in the yields per oxygen atom consumed of the addition products, and their ratios remained constant (in these experiments total peak areas of *iso*-butanal plus *cis*-β-butene oxide were measured). The yield of C_2H_6 showed a slight decline at first;

there was, however, a tendency for leveling off rather than for complete suppression of this product at still higher pressures. The nitrous oxide technique is not suitable for the study of these processes at quite low pressures because of the increasing importance of secondary phenomena. In the pressure range 50 to 600 mm. the ratio of the two major products from butene-1, α-butene oxide and *n*-butanal, remained constant—their absolute yields per oxygen atom consumed appeared also to be constant although a very slight pressure dependence might have been masked by a small random run-to-run variation in GLC response. With the other olefins occasional experiments with variable pressures did not show any significant pressure effects. Of the minor products, carbon monoxide seemed to show generally a slight pressure dependence; thus, with butene-1 its yield per oxygen atom consumed decreased from about 0.06 at a total pressure of 50 mm. to 0.03 at 600 mm.

The Extent of Fragmentation

The very small amounts of fragmentation products detected by GLC analysis (Table I) were thought at first (1) to indicate that fragmentation occurred only to the extent of a few per cent. Actually, it proved difficult to establish accurately the extent of fragmentation. A number of GLC calibrations showed that the observed addition products accounted only for about 70 to 80% of the oxygen atoms consumed and in some cases even less. The quantitative aspect of this result, however, is not entirely satisfactory. Apart from the likelihood that some hydrogen abstraction may occur, there is no certainty that all the addition products formed are quantitatively recovered, in spite of all the precautions. Also, it is somewhat difficult to obtain accurate GLC calibrations with the very small amounts involved, especially so with some of the substances formed in these reactions. An attempt was, therefore, also made to estimate the extent of fragmentation from the amount of other fragmentation products detectable.

The fragmentation products more volatile than nitrous oxide were separated on the LeRoy still into the non-condensables and the "C_2" fraction and then further analyzed. The results are given in Table IV and refer to experiments in which 300 mm. N_2O and small amounts of the olefin were used. No systematic analysis could be made for products of similar volatility to that of N_2O, such as C_3H_8, C_3H_6, etc. In some cases, infrared spectra were taken of the N_2O fraction and no additional peaks were observed; minor amounts of any substances present need not have been detected in this manner. Similarly, in the GLC analysis, minor amounts of substances eluting with the original olefin or of those much less volatile than the major products observed could have escaped detection.

[a]*Mass spectrometer analyses of the* C_2H_6 *fraction indicated at best only trace amounts of* C_2H_4.

The appreciable amounts of ethane formed in some cases, as shown in Table IV, indicate that at least in some of the studied reactions the fragmentation is not negligible even when appreciable pressure effects are absent. With *cis*-butene-2, for example, an experiment in which a mixture of *cis*-C_4H_8-2 and a smaller amount of *cis*-C_4D_8-2 was used no C_2D_6 was formed but only CH_3CD_3 and C_2H_6. Ethane is, therefore, formed by combination of free methyl radicals. The results obtained in the presence of O_2 also showed that ethane and a large fraction of *iso*-butanal were formed by combination of free radicals, as already pointed out. On the basis of these results, the extent of fragmentation into free radicals at higher pressures can be estimated at about 30 to 35% (based on the consumption of oxygen atoms) for *cis*-butene-2 and in the case of tetramethyl ethylene probably as much as 60%. Such large fragmentation at higher pressures appears to take place when rearrangements which follow the addition of oxygen atoms involve migration of methyl radicals, but not (or at best only to a small extent) when H atoms migrate. It is significant that even when large fragmentation of this kind occurs the greater part of the free radicals recombine to form the same compound as produced by direct internal migration. Thus it would seem that the fragmentation involves entirely (or predominantly) only the splitting off of the migrating radicals.

DISCUSSION

On the basis of the comparison of the addition products formed with butene-1, *cis*-butene-2, and *iso*-butene, the mechanism of addition of oxygen atoms to a CC double bond in alkenes was generalized in the preliminary communication (1) in the form of two rules. In view of the additional information available, these rules can now be amplified. The consistency of the results obtained in all the reactions of alkenes with oxygen atoms studied so far indicates that the addition products formed can in general be explained and predicted by assuming that: (1) an oxygen atom adds to one carbon atom of the double bond to form a biradical and this addition takes place in the case of unsymmetrical alkenes predominantly at the less-substituted carbon atom, and (2) the triplet thus formed degrades to the ground-state compounds in two ways: (*a*) by forming the corresponding epoxides without any internal rearrangement except a partially restricted rotation about the original double bond, and (*b*) by forming carbonyl compounds through migration of a particle (either a hydrogen atom or a radical) attached to the carbon atom carrying the oxygen atom to the other carbon atom of the original double bond. Migrating radicals may in the course of this process become to a smaller or greater extent detached from the molecule, as will be discussed later.

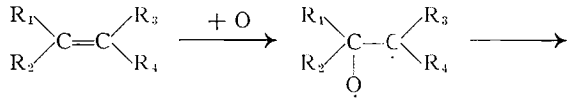
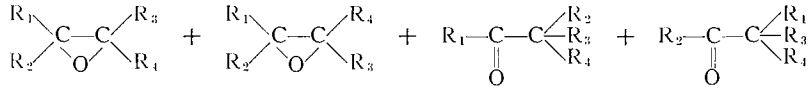
The following scheme for the reaction of oxygen atoms with a generalized olefin (A) illustrates the above rules. R_1, R_2, R_3, and R_4 are alkyl radicals or hydrogen atoms. The first C atom of the double bond is assumed to be "less substituted".



A B



I II III IV

Each of the compounds I to IV is produced in substantial quantities: these four compounds are the main and may be the exclusive addition products formed. (Compounds III and IV will be identical if $R_1 = R_2$, and similarly I and II if either $R_1 = R_2$ or $R_3 = R_4$.) It is possible also that some addition of oxygen atoms may take place at the "more-substituted" carbon atom, in which case minor quantities of carbonyl compounds V and VI will also be formed. In all the cases studied so far, addition to the "more-substituted" carbon atom has been of minor importance inasmuch as it occurred at all.

V VI

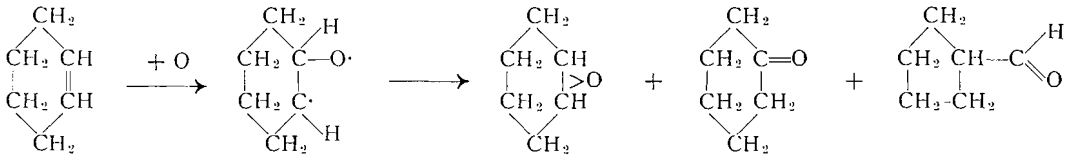
This reaction scheme has been illustrated in the preliminary communication (1) by the example of *cis*-butene-2, a symmetrical olefin. The predicted and observed addition products in this case are *cis*- and *trans*-2,3-epoxybutane, methylethyl ketone (formed through migration of an H atom) and *iso*-butanal (formed through migration of a CH_3 radical). The same products are to be expected and have been observed with *trans*-butene-2. In the case of *iso*-butene the main addition products are *iso*-butene oxide and *iso*-butanal and, therefore, oxygen atoms add predominantly to the "less-substituted" carbon atoms of the double bond. Addition to the "more-substituted" carbon atom of the double bond would require formation of some methylethyl ketone as well; some methylethyl ketone appears to be formed but its amount is extremely small. In the case of butene-1, small amounts of methylethyl ketone besides the main addition products, 1,2-epoxybutane and *n*-butanal, indicate that minor addition to the *more*-substituted carbon atom of the double bond might be also taking place. The same is true for propylene where small amounts of acetone seem to be formed, besides the expected main addition products, propylene oxide and propanal. With tetramethyl ethylene the addition products are tetramethyl ethylene oxide and pinacolone, as expected.

The case of *cis*-pentene-2 is of particular interest since it shows that in terms of the above rules the carbon atom to which the methyl radical is attached is "*less* substituted" than the other carbon atom of the double bond to which an ethyl radical is attached. Addition of an oxygen atom to the former would lead to the formation of methyl-*n*-propyl ketone besides 2-methylbutanal and the two isomeric epoxides, *cis*- and *trans*-2,3-epoxypentane, while the addition to the latter would result in diethylketone and the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

aldehyde and epoxides. Methyl-*n*-propyl ketone is definitely the predominant ketone formed although, perhaps, small amounts of diethylketone are formed as well.

Cycloölefins represent an interesting special case. For cyclohexene, for example, the same reaction scheme would require the formation of the following compounds:



C VII VIII IX

In addition to cyclohexene oxide (VII), two carbonyl compounds would be expected to be formed: cyclohexanone (VIII) through migration of an H atom and cyclopentyl formaldehyde (IX) through migration of the "radical" attached to the carbon atom to which oxygen is attached in the biradical (C). These compounds are actually formed and no other products have been detected.*

There are indications that the intermediate biradical (B) is very short-lived. This is suggested by the difference in the ratios of *cis*- and *trans*-2,3-epoxybutane formed in the reactions of oxygen atoms with *cis*- and *trans*-butene-2, respectively. The lack of appreciable effects of the presence of molecular oxygen on the amounts of the addition products formed also supports this conclusion. It appears, therefore, that the initially formed biradical isomerizes extremely rapidly into the final addition compounds. Since these reactions, however, are very exothermic, the addition compounds carry a large excess of energy when formed (carbonyl compounds about 115 kcal./mole and epoxides probably about 90 kcal./mole). The probability of decomposition of these compounds before dissipation of the excess energy can take place will depend largely on their complexity (the number of "degrees of freedom"). The simplest olefin, ethylene, appears to undergo almost exclusive decomposition on reacting with oxygen atoms. Propylene exhibits a pronounced collisional stabilization of the addition products formed (Fig. 1), while pressure effects appear to be absent with higher alkenes in the investigated pressure range. There is, however, a certain amount of decomposition even when no pressure effects are observed, which suggests that there is an intrinsic probability of a certain fraction of the initially formed biradical undergoing fragmentation. In view of the extremely short life of the biradical, it is not surprising that this fragmentation process is pressure independent.

The nature of the two types of fragmentation processes occurring in the reactions of oxygen atoms with olefins should now be briefly discussed. The pressure-dependent fragmentation, as observed in the case of propylene (and previously with ethylene), is characterized by the formation of products which could be expected from thermal decomposition of the major addition products and is consistent with the assumption that these are initially formed in an energy-rich state. The excess energy is in most cases readily removed by collisions in the gas phase. An inspection of the data given in Tables II and IV shows that the initial act (or part of the initial act) of the pressure-independent decomposition is probably the splitting off of a radical attached to the same carbon atom to which oxygen initially adds. In other words, the same particles which migrate in the rearrangement processes may become detached from the molecule.

**Details of the experiments performed with cyclohexene and cyclopentene will be published elsewhere.*

Thus, ethane is formed only in those cases where CH_3 is a migrating particle and then a great part of the resulting product is inhibited by the additions of O_2. The remaining fraction of the molecule would probably dimerize and the amount of the dimer formed should be comparable with that of ethane. Such dimers are likely to be of too low volatility to be readily detectable by the analytical techniques employed. Their formation could explain the low material balances observed. The pressure-independent fragmentation in the case of butene-2 appears, therefore, to be similar to the pressure-independent decomposition induced in 2,3-epoxybutane by mercury photosensitization (10). It is not certain whether migrating H atoms split off to a small extent. Thus, in the case of *iso*-butene, in spite of considerable effort no products other than the addition products already described could be isolated and identified. Any free H atoms which might be produced by splitting off from the initially formed biradical would readily add to excess *iso*-butene and the tertiary butyl radicals formed would be largely converted to compounds of low volatility.

The data in Fig. 1 for the propylene reaction can be treated kinetically. Thus, a plot of the reciprocal rates of the production of propanal (plus small amounts of acetone) against reciprocal pressure gives a straight line (Fig. 2), indicating a single-stage collisional

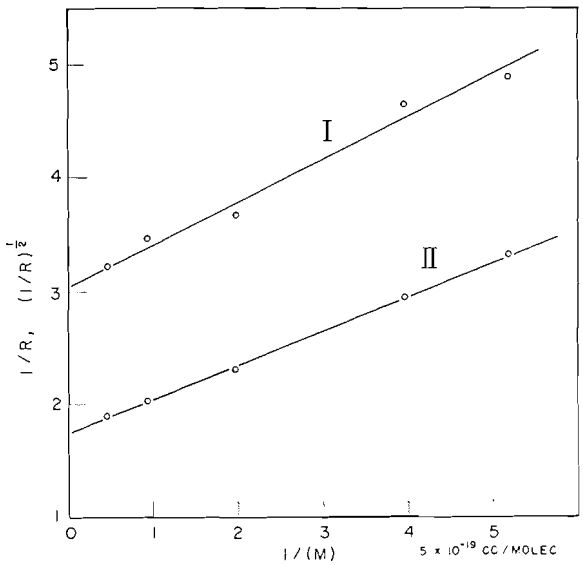

FIG. 2. I. Plot of the reciprocal relative rate $(1/R)$ of formation of propanal + acetone against the reciprocal concentration of reactants. II. Plot of the square root of the relative rate of formation of propylene oxide $(1/R)^{\frac{1}{2}}$ against the reciprocal concentration of reactants.

deactivation. A similar plot for propylene oxide shows a distinct curvature; a plot of the square root of the reciprocal rate against reciprocal pressure, on the other hand, is a straight line. Such a relationship should be expected for a two-stage collisional deactivation with decomposition occurring at both stages provided the lifetimes of the two forms are approximately equal. The following reaction scheme for the propylene reaction is probably, with minor modifications, representative of the general reaction scheme for the reactions of oxygen atoms with olefins, provided it is realized that with increasing number of degrees of freedom the energy-rich molecules formed become longer lived and the pressure-dependent fragmentation becomes less important under otherwise comparable conditions.

$$C_3H_6 + O \rightarrow CH_3 \cdot \underset{\diagdown O \diagup}{CH}—CH_2O. \quad \begin{matrix} \nearrow \\ \rightarrow \\ \searrow \end{matrix} \quad \begin{matrix} C_2H_5CHO^* \\ CH_3CH—CH_2^{**} \\ \diagdown O \diagup \end{matrix} \qquad [1] \; [2]$$

$$\text{decomposition} \qquad [3]$$

$$C_2H_5CHO^* \rightarrow \text{decomposition} \qquad [1a]$$

$$C_2H_5CHO^* + M \rightarrow C_2H_5CHO + M \qquad [1b]$$

$$CH_3CH—CH_2^{**} \rightarrow \text{decomposition} \qquad [2a]$$
$\diagdown O \diagup$

$$CH_3CH—CH_2^{**} + M \rightarrow CH_3CH—CH_2^{*} + M \qquad [2b]$$
$\diagdown O \diagup$ $\diagdown O \diagup$

$$CH_3CH—CH_2^{*} \rightarrow \text{decomposition} \qquad [2c]$$
$\diagdown O \diagup$

$$CH_3CH—CH_2^{*} + M \rightarrow CH_3CH—CH_2 + M \qquad [2d]$$
$\diagdown O \diagup$ $\diagdown O \diagup$

If, as assumed, $k_{2a}/k_{2b} = k_{2c}/k_{2d}$, the steady-state treatment leads to the relationships

$$1/R_{1b} = (1/\alpha_1)(1+k_{1a}/k_{1b}(M))$$

and

$$(1/R_{2d})^{\frac{1}{2}} = [1/(\alpha_2)]^{\frac{1}{2}}(1+k_{2a}/k_{2b}(M)),$$

where R_{1b} and R_{2d} are the rates of production of propanal and propene oxide per oxygen atom consumed, and α_1 and α_2 are the fractions of O atoms consumed in reactions (1) and (2) respectively. Taking approximately $k_{1b} = k_{2b} = k_{2d} = 10^{-10}$ cc./molec. sec., the plots in Fig. 2 indicate that the lifetimes of the energy-rich molecules $C_2H_5CHO^*$, $CH_3 \cdot \underset{\diagdown O \diagup}{CH}—CH_2^{**}$, and $CH_3 \cdot \underset{\diagdown O \diagup}{CH}—CH_2^{*}$ are between 10^{-8} and 10^{-9} second. It ought to be stressed, however, that the good straight-line plots in Fig. 2 are considerably better than should be expected in view of the likely experimental errors, and their quantitative implications should be taken with some reserve. Reaction (3) in the above scheme represents the pressure-independent fragmentation process.

The chemical reactions of oxygen atoms with olefins and the molecular rearrangements following the initial addition of the atoms exhibit certain regularities which have to be considered in the light of hyperconjugation and inductive effects. These regularities embrace: (1) systematic variation of reaction rates with the structure of the olefin, (2) specificity with respect to the position of addition of the atoms, and (3) nature of internal rearrangements which take place. These effects can best be discussed simultaneously and it is, therefore, convenient to defer their discussion until further results of the present investigations are published, particularly the relative rate constants of these reactions.

Oxygen atoms produced by the technique employed in the present study are probably in their ground, $O(^3P)$ state. This conclusion is valid provided the spin conservation rule is obeyed in the mercury-photosensitized decomposition of nitrous oxide. In this connection it is of interest that investigations now carried out in this laboratory (11) show that the course of the reaction of butene-1 with $O(^3P)$ atoms produced by photolysis of NO_2 is the same as observed in the present work.

STUDIES OF THE MECHANISM OF THE FORMATION AND DECOMPOSITION OF THE MOLECULAR COMPLEX BETWEEN SOLID UREA AND *n*-OCTANE VAPOR[1]

H. G. McAdie[2] and G. B. Frost

ABSTRACT

The formation and decomposition of the molecular complex between solid urea and *n*-octane vapor, in the presence and absence of initiators, has been studied by a variety of techniques. Suggestions are made for the possible mechanism of this heterophase reaction incorporating known structural and thermodynamic data.

INTRODUCTION

It has been known for some time that when straight-chain hydrocarbon molecules are added to a concentrated solution of urea in a suitable solvent, crystallization of the urea molecules occurs in such a way that each hydrocarbon molecule becomes imprisoned in a canal formed by a hexagonal lattice of urea molecules, as contrasted with the normal tetragonal lattice of urea.

Schlenk (1) has reported that a slow formation of such molecular-inclusion complexes (frequently referred to as adducts) occurs on the mere contact of finely divided tetragonal urea crystals with certain pure liquid *n*-paraffins. Calderbank and Nikolov (2) have presented evidence that complex formation under these conditions is observable only when the particle size is less than a certain critical value.

Very little information is available regarding the formation of molecular complexes between solid (tetragonal) urea and *n*-paraffin vapor. Schlenk (1) noted that such a process could occur in air saturated with *n*-paraffin vapor if the *n*-paraffin possessed a relatively low boiling point. This type of reaction is of interest not only from the standpoint of the mechanism of complex formation under these conditions, but also since, in a more general way, it is an example of the type of heterophase reaction

$$\text{solid I} + \text{gas} \rightarrow \text{solid II}$$

for which a good deal of information is available regarding the crystallographic and energetic factors involved, and for which the changes occur in a readily accessible temperature range.

McAdie and Frost (3) attempted to carry out the process

$$\text{urea (tetragonal)} + n\text{-octane (vapor)} \rightarrow \text{complex (hexagonal)}$$

by exposing small urea crystals to *n*-octane vapor at close to its saturation vapor pressure at 25° C. for long periods of time, and were unable to observe any reaction. They found, however, that an uptake of the hydrocarbon occurred rapidly in the presence of water vapor; that if the products, so formed, were decomposed under vacuum, addition of *n*-octane then occurred rapidly in the absence of water vapor; and that cycles of decomposition and absorption of *n*-octane could then be carried out. The purpose of this paper is to report the results of some experiments which were designed to investigate these findings more extensively, and to consider the results in the light of the structural and thermodynamic data available. The experiments involve measurements of the rate of

formation of the complex under various conditions in the presence and absence of water vapor, the identification of the lattice types by X-ray diffraction, the determination of changes in surface area, the effect of temperature, and other factors.

EXPERIMENTAL METHODS

Rate Studies

The apparatus is shown schematically in Fig. 1. Liquid *n*-octane was contained in a reservoir, R, the pressure of *n*-octane vapor being controlled by means of a jacket surrounding the reservoir through which water at any desired temperature could be

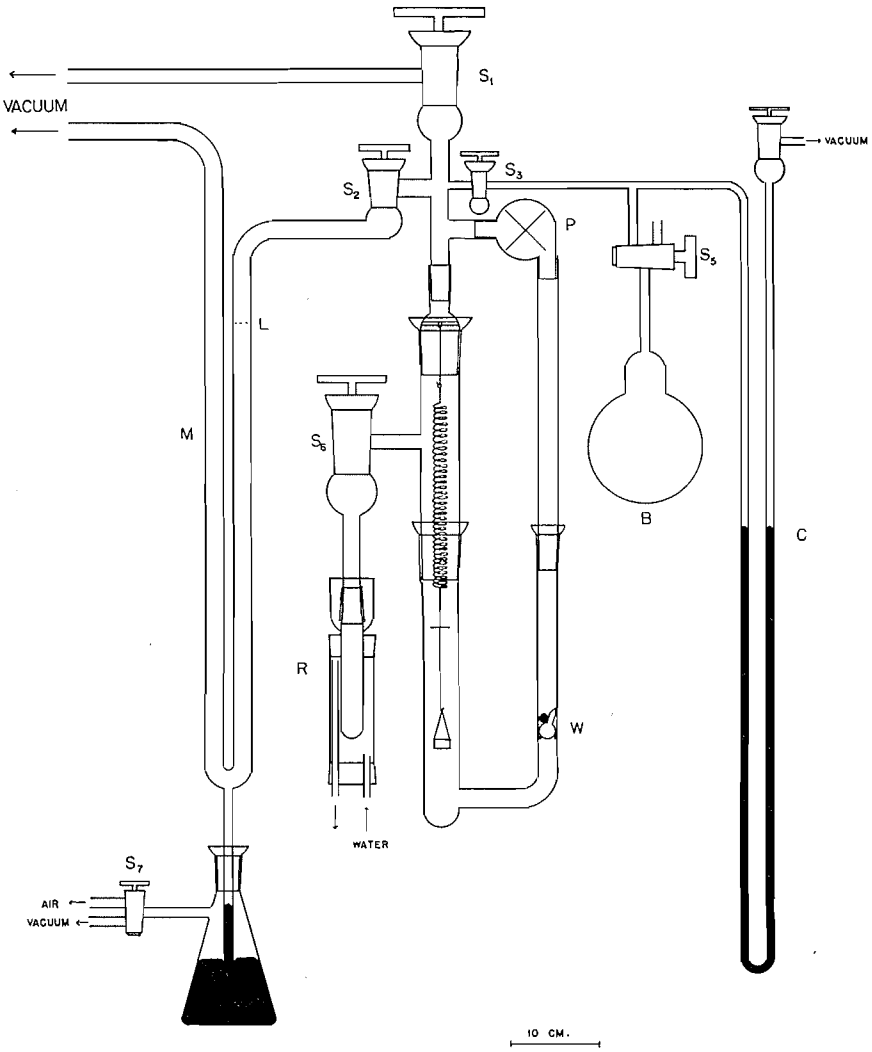

FIG. 1. Apparatus for rate studies.

rapidly circulated. Water vapor was introduced into the system by breaking a small bulb, W, containing the requisite amount of pure liquid water. The total volume of the reaction system to mark L on manometer M was found by application of the gas law in the usual way, making use of bulb B, which was of known volume, and manometer C.

For personal use only.

To ensure mixing of the two vapors, a magnetically driven circulating pump, P, was provided. The entire apparatus was contained in a thermostatically controlled cabinet.

Reagent grade urea was recrystallized, dried, and screened, the "through 60 mesh on 80 mesh" portion being used. About 40 mg. of this material was weighed into a small copper gauze basket and suspended from a quartz spiral microbalance of sensitivity 2.006 mg. per mm. extension. The previously filled water bulb, together with a small steel ball for breaking, was placed in position. About 5 cc. of liquid *n*-octane was placed in reservoir R, with the constant-temperature jacket removed, frozen by means of liquid air, and repeatedly outgassed in the usual manner. Stopcock S_6 was then closed and the water jacket placed in position. The *n*-octane was brought to constant temperature by circulating water through the jacket. The cabinet was closed and brought to temperature.

After the urea was evacuated for 2 hours, the length of the spiral was measured to ± 0.01 mm. with a rigidly mounted twin telescope cathetometer and S_1 closed. The gas circulating pump, P, was started and S_6 opened to admit *n*-octane vapor to the system. The water bulb was broken and zero time for the reaction taken at this point. This was generally 1 to 2 minutes after the admission of the *n*-octane vapor.

Readings of spiral length, pressure on manometer M, and *n*-octane reservoir and cabinet temperatures were recorded at various intervals. The reaction was timed with an ordinary stopwatch.

When the reaction had proceeded to constant weight, S_6 was closed, S_1 opened, and the decomposition, under a pressure of 10^{-5} mm. Hg, allowed to proceed. S_6 was then carefully opened with S_1 still open and about 2 cc. of liquid *n*-octane evaporated in order to ensure removal of water vapor from the *n*-octane reservoir. S_6 was then closed and the system thoroughly evacuated. *n*-Octane was admitted to the system as described and the formation reaction in the presence of *n*-octane vapor only allowed to proceed. Subsequent decomposition and formation procedures were carried out in an identical manner.

X-Ray Diffraction Studies

Characterization, by X-ray diffraction, of the products formed during repeated formation and decomposition reactions was made by means of the apparatus shown in Fig. 2, in which the bulb below the stopcock S_3 contained water and that below S_2 contained liquid *n*-octane. This arrangement ensured adequate mixing of the vapors. A series of segments of urea were loaded into the long capillary tube, T, made of Corning 707-DG lead-free glass. After outgassing of the reactants, and evacuation of the urea for 24 hours, S_1 was closed and S_2 opened. When the equilibrium vapor pressure of *n*-octane was reached, as indicated by the manometer M, S_3 was opened until sufficient water vapor had been admitted. S_3 was then closed and reaction allowed to proceed. After 24 hours' exposure, one segment of urea was sealed off out of the center of the capillary and the X-ray diffraction pattern determined using copper K_α radiation. A central segment was chosen, so that if reaction were found to have occurred in this region, it was reasonable to assume that other segments of urea, through which the vapors had to pass before reacting with the segment in question, had reacted also. After exposure to vacuum for 24 hours at 25° C., with S_2 closed, a second segment was sealed off and its diffraction pattern determined. A similar procedure was followed after re-exposure to *n*-octane vapor only, for 24 hours, and also after re-evacuation for 24 hours.

The diffraction patterns obtained were compared with those obtained from tetragonal urea and from several known urea–*n*-paraffin complexes prepared from solution.

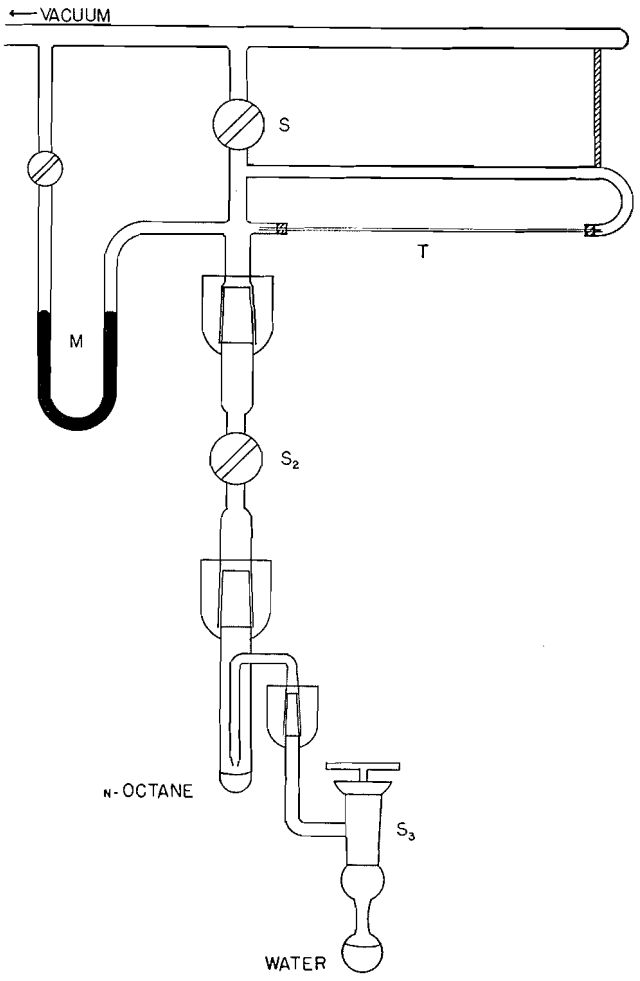

FIG. 2. Apparatus for X-ray studies.

Surface-Area Measurements

Measurements of the changes in surface area resulting from successive formation and decomposition reactions were obtained by argon adsorption at liquid-nitrogen temperatures in the usual volumetric manner. The adsorbent was contained in the annular space between two concentric cylinders of 100-mesh copper gauze. Following determination of the isotherm for urea of the particle size used in the rate experiments, the system was evacuated for 24 hours and subjected to *n*-octane and water vapors, the gas mixture being formed in an assembly similar to that shown in Fig. 2. The partial pressure of water vapor was 12.0 mm. and that of *n*-octane was 13.1 mm. The mixture was allowed to remain in contact with the urea for 5 days to ensure complete reaction. The system was then evacuated for 24 hours at room temperature (Residue I) and a second isotherm determined. The sample was exposed for 5 days to *n*-octane vapor only at its saturation pressure, the system evacuated for 24 hours (Residue II), and a third isotherm determined.

Photomicrography

Changes in the appearance of urea crystals during complex formation were followed by photomicrographic observation. Urea crystals were placed on a small glass plate ground smooth on both sides, the underside of which was painted with optical black to reduce reflections. The plate was contained in a glass tube connected to an assembly similar to that shown in Fig. 2, by means of which the urea crystals could be exposed to *n*-octane vapor and water vapor at known pressures. A small hole was blown out directly over the position of the plate, the edges ground, and a small clear glass plate cemented in position. The usual microscope and camera assembly were provided.

After evacuation of the urea for 2 hours, and outgassing of the *n*-octane and water reservoirs, the urea was photographed and exposed to a mixture of vapors. Photographs were then taken at regular intervals until the reaction was completed, as determined from earlier rate studies under identical conditions. Vacuum was then applied and the crystals photographed while undergoing decomposition.

RESULTS

Preliminary Rate Determinations

The results of a series of formation and decomposition reactions are shown in Fig. 3. These curves differ from those previously reported (3) in that diffusion effects were substantially eliminated by the gas circulating pump shown in Fig. 1. A sample of 0.0364 g. urea was exposed, at 25° C., to a mixture of *n*-octane and water vapor, the partial pressures being 13.1 mm. and 10.0 mm., respectively. An increase in weight was observed, the weight becoming constant in about 7 hours. The amount of *n*-octane taken

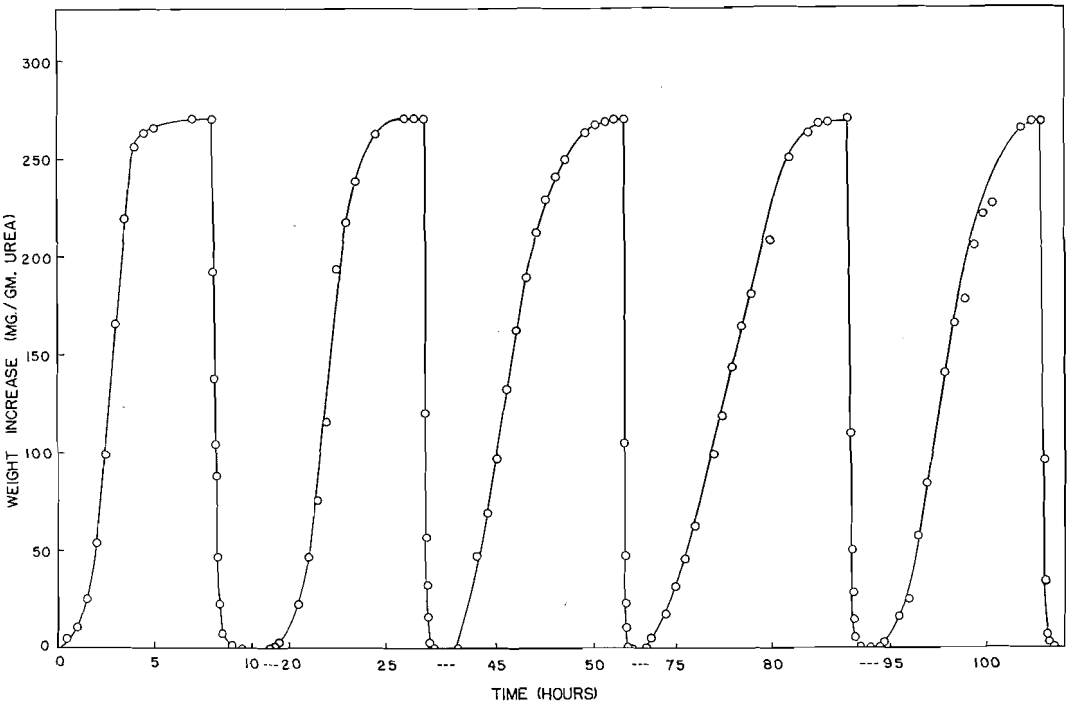

FIG. 3. Experimental results of successive formation and decomposition reactions.

For personal use only.

up was found to be 272.3 mg. per g. urea. From the crystal structure data reported by Smith (4), the composition of the urea–*n*-octane complex is 272.7 mg. *n*-octane per g. urea. A marked swelling in the crystal mass was noted.

The system was evacuated, a rapid loss in weight being observed but no visible change in the volume of the crystal mass. The sample was next exposed to *n*-octane vapor only at 13.1 mm. pressure and an uptake of *n*-octane was observed, constant weight being attained at the same composition as before. Further decomposition and formation reactions were then carried out, no further change in the volume of the crystal mass being visible.

It is apparent that, although tetragonal urea of the particle size used is unreactive to *n*-octane vapor initially, absorption of the hydrocarbon does occur in the presence of water vapor, and that if the hydrocarbon is removed by evacuation, the residual urea is reactive to hydrocarbon and the presence of water vapor is unnecessary. The constancy of composition in successive formation reactions, and the agreement of these values with those reported by Smith (4), suggest that water is not retained in the complex in measurable amounts. From this it appears that the function of water vapor is merely to initiate the reaction.

The formation curves are all of the type characteristic of growth processes, an initial, gradual increase in rate being followed by a linear portion, this being followed in turn by a decline in rate as the reaction nears completion. No long induction periods were observed. The rate of formation, as indicated by the linear slopes of the formation curves, decreases with the number of times the reaction is carried out. It appears that the reaction proceeds to completion and is not impeded by formation of a surface layer of complex. The very rapid decomposition of the complex when subjected to vacuum, and the absence of induction periods under these conditions, are also of interest.

No change in spiral extension was observed when urea was exposed for long periods of time to water vapor only, at pressures comparable to that used in the foregoing experiment. Adsorption of water vapor at such pressures is, therefore, too small to be detected by the quartz spiral used. When the urea, so exposed to water vapor, was subjected to vacuum and then exposed to *n*-octane vapor, no reaction was observed. It is clear, therefore, that the urea crystals cannot be activated for complex formation by prior exposure to water vapor followed by evacuation, but that the reaction is initiated by water vapor in the presence of the hydrocarbon vapor.

X-Ray Diffraction Studies

The marked differences between the X-ray diffraction patterns of tetragonal urea and urea in the hexagonal complex lattice enabled the two lattices to be readily distinguished. Schlenk (1) has reported the similarity between the X-ray diffraction patterns of urea complexes of a given homologous series of reactant molecules. A number of urea–*n*-paraffin complexes, prepared from solution, confirmed this fact by giving identical diffraction patterns. All these patterns agreed with those obtained from the reaction products formed from tetragonal urea in the presence of *n*-octane vapor, with or without the presence of water vapor, thus confirming the presence of the hexagonal complex lattice. The diffraction patterns of the decomposition products formed by evacuation of the urea–*n*-octane complex conformed to that of tetragonal urea.

It is clear from these results that the complex is formed during exposure of urea to *n*-octane and water vapors, that on evacuation the lattice reverts to the tetragonal form, and that on subsequent exposure to *n*-octane vapor only, the complex is again formed, the lattice becoming hexagonal.

Surface-Area Measurements

The argon surface areas, calculated from Hüttig plots obtained from each isotherm, gave the following results:

Adsorbent	Area ($m.^2 g.^{-1}$)
Urea crystals	0.13
Residue I	1.76
Residue II	1.56

These values were found to be reproducible to about 10% although the absolute values given are not very significant in view of the relatively small areas involved. However, the 14-fold increase in the surface area of Residue I (obtained from formation of the complex in the presence of water vapor and subsequent decomposition) over that of the pure urea sample is of interest, as is the decrease in the area of Residue II (obtained by formation of the complex from Residue I in the presence of *n*-octane vapor only, and subsequent decomposition).

With successive formation and decomposition reactions, the decrease in surface area is attended by a corresponding decrease in the rate of reaction, as indicated by the slopes of the linear portions of the formation curves shown in Fig. 3. The ratio of the rates of complex formation with Residue I and Residue II is 1.32. The ratio of the corresponding surface areas is 1.13. The correlation is of interest bearing in mind the somewhat elaborate nature of the experiments and the sources of error attending them.

Photomicrography

Upon exposing urea crystals (following evacuation) to mixtures of *n*-octane vapor (about 13 mm.) and water vapor (about 16 mm.) the following observations were made:

(*a*) The reaction starts at random points, which are usually marked by the development of a slight protuberance of somewhat fuzzy appearance. The reaction spreads at first slowly and then quite rapidly through the crystal from these points.

(*b*) The time required for the initiation of the reaction is greater in some crystals than in others. The size of the crystal does not appear to be a significant factor.

(*c*) As the formation of the complex proceeds, the opaque appearance observed at the initiation of the reaction develops through the entire crystal.

(*d*) Essentially the same outward shapes of the original single crystals are retained during reaction, but some over-all expansion occurs, and the surfaces become very irregular and less clearly defined.

(*e*) No further visible change in shape or appearance occurs on evacuation, or on re-exposure to *n*-octane vapor only, although, as has been pointed out, X-ray diffraction shows that the hexagonal lattice is formed during reaction and reverts to tetragonal on evacuation.

Under the conditions of pressure employed, the reaction was complete in about 2 hours.

Effect of Water-Vapor Pressure on the Initial Formation Reaction

To determine the effect of water-vapor pressure on the rate of the initial formation of the complex, a number of experiments were performed at 25° C., using the apparatus shown in Fig. 1, at a pressure of 13.1 mm. *n*-octane. The pressures of water vapor ranged from 7.1 mm. to 16.3 mm.

A group of typical curves obtained are shown in Fig. 4. With decreasing pressure of water vapor, induction periods of increasing duration are observed, as well as decreasing slope of the linear portions of these curves. Rates, as estimated from these slopes, are

plotted against the water-vapor pressure in Fig. 5. It will be seen that this rate is linearly dependent on the water-vapor pressure over the range of experiments. Extrapolation to zero rate suggests that a limiting pressure of 4.8 mm. of water vapor is required to initiate the complex formation reaction under these conditions. Separate experiments have shown that the reaction does not proceed at a measurable rate below this value.

The experiments at different pressures of water vapor were carried out using separate samples of urea. The composition of the end products obtained at water-vapor pressures of 11.2 mm. and 8.7 mm. is slightly higher than those shown in Fig. 3. These differences are probably due to errors inherent in the experimental method. The composition of the end product obtained at 16.3 mm. is significantly higher and may be due to adsorption of water vapor at this pressure, which is close to that of a saturated solution of urea in water.

Effect of n-Octane Pressure on the Initial Formation Reaction

A group of curves obtained at a constant water-vapor pressure of 11.5 mm., 25° C., and several *n*-octane pressures is shown in Fig. 6. The curves show the same features as those in Fig. 4, the slopes decreasing and the induction periods lengthening with decreasing *n*-octane pressure. Rates, as estimated from these slopes, are plotted against *n*-octane pressure in Fig. 7. This curve suggests that the reaction will not proceed below 7.2 mm. *n*-octane with the crystals of urea used in these experiments and in the presence of 11.5 mm. of water vapor at 25° C. A gradual leveling off in rate is observed as the *n*-octane pressure approaches the saturation pressure of 14.0 mm. at 25° C.

Effect of Temperature on the Initial Formation Reaction

A series of experiments were carried out at a constant *n*-octane pressure (9.8 mm.), a

constant water-vapor pressure (11.5 mm.), and different reaction temperatures. Weight increase versus time curves at 20.9° C., 22.4° C., and 25.0° C. are shown in Fig. 8. It will be seen that with increasing temperature over this range the induction periods lengthen markedly and the slopes of the linear portions of the curves decrease.

The dependence of rate, calculated from these slopes, on temperature is shown in Fig. 9. This indicates that under the particular experimental conditions employed, no reaction should be observed in finite time above 28.7° C. However, other conditions could conceivably alter this value.

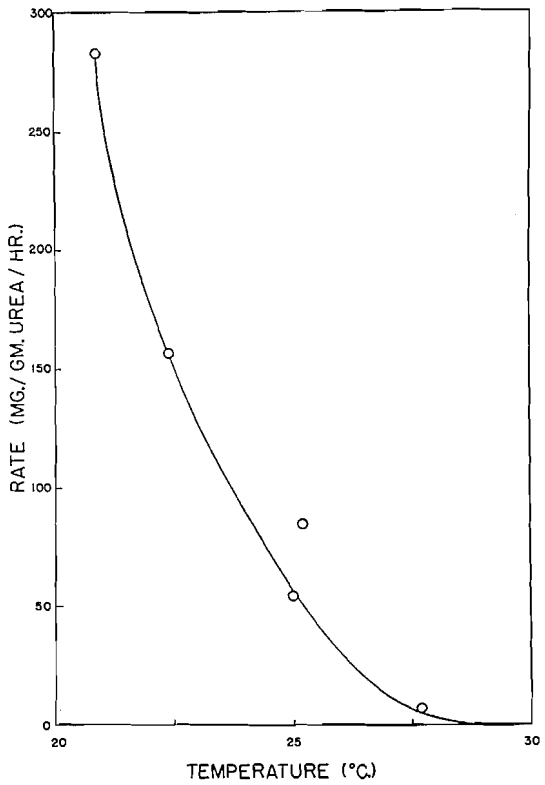

FIG. 9. Dependence of rate of initial formation reaction on temperature.

Effect of Temperature on the Second Formation Reaction

The effect of temperature on complex formation between *n*-octane vapor and the residue from a complex, previously formed in the presence of water vapor and decomposed, is shown in Fig. 10. Although the data are limited, it is significant that clearly marked induction periods are absent. However, the slopes of the linear portions of these curves decrease with temperature as in the case of the initial formation reaction.

Other Initiators

In view of the effect of water vapor in initiating the reaction between urea and *n*-octane vapor, a brief search was made for other compounds which might act in a similar manner. Two classes of compounds were considered, (*a*) those which were good solvents for urea, e.g. methanol and ethanol, and (*b*) those which are known to be highly polar e.g. nitromethane, ethylenediamine, and ammonia.

A small amount of urea, contained in a copper gauze basket, was exposed to *n*-octane vapor and the vapor of the particular compound being studied in an apparatus similar to that shown in Fig. 2. Swelling of the urea was taken as evidence of reaction, and X-ray diffraction patterns of the product were obtained as confirmation.

For personal use only.

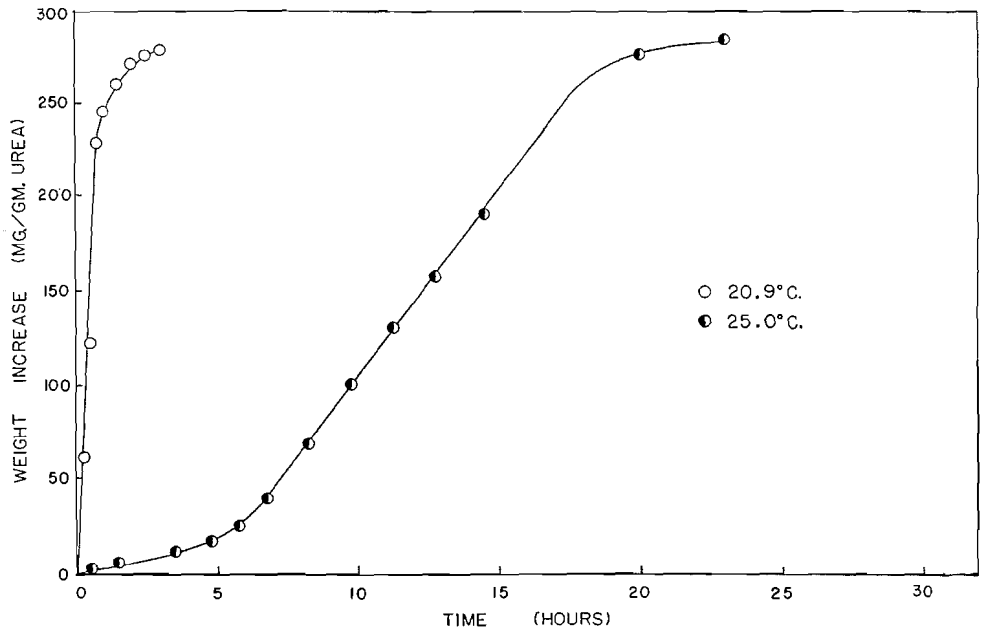

FIG. 10. Weight increase curves for the second formation reaction at constant *n*-octane pressure and varying temperature.

With methanol vapor at a pressure of about 12 mm., complex formation appeared complete after 12 hours. With ethanol vapor, at about 14 mm., about 48 hours were required. No reaction was evident with *n*-propanol vapor (10 mm.) after 1 week.

Reaction occurred in the presence of 12 mm. nitromethane vapor after about 80 hours, while with ethylenediamine at its saturation vapor pressure at room temperature, a slight swelling was observed after 5 days. No effect was found with ammonia.

In all cases, except with *n*-propanol and ammonia, X-ray diffraction patterns confirmed the presence of the hexagonal complex lattice.

DISCUSSION

Structural Factors

On the basis of X-ray (5, 6), infrared absorption (7), nuclear magnetic resonance (8, 9), and neutron-diffraction (10) data, the urea molecule may be said to possess an entirely planar structure.

The most careful determinations, by X-ray diffraction, of the crystal structures of tetragonal urea, and of urea in the hexagonal complex, have been carried out by Vaughan and Donohue (6) and by Smith (4), respectively. In the hexagonal complex, Smith (4) has shown that the molal ratio of urea to hydrocarbon is a linear function of the number of carbon atoms, n, in the hydrocarbon chain and is equal to $0.6848(n-1)+2.181$. Thus, 6.975 moles of urea are associated with 1 mole of *n*-octane in the urea–*n*-octane complex. Smith has also suggested that the configuration of the hydrocarbon molecules in the complex is very similar to that in the pure solid. Consideration of the crystal structure of these complexes shows that the hydrocarbon chains lie parallel to one another in the extended zigzag configuration.

Comparison of the tetragonal and hexagonal lattices of urea shows that the changes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

in arrangement of the planar urea molecules occurring in the transition from the tetragonal to the hexagonal lattice involve the shortening of two N—H...O hydrogen bonds per urea molecule from a bond length of 2.99 Å to one of 2.93 Å. The two other N—H...O bonds per molecule of urea remain unchanged at a length of 3.04 Å. Data have recently been published on the heat of formation of N—H...O hydrogen bonds in various substances, obtained by subtracting the van der Waals energy from the total lattice energy as given by the heat of sublimation. Suzuki, Onishi, Koide, and Seki (11) suggest that the energies of N—H...O bonds will be greater in compounds where the ratio of the number of protons to the number of proton acceptors is unity, than in those compounds where it is greater than two. Examples of this latter class of compounds are urea, oxamide, and acetamide. From the data of Suzuki *et al.* (11) and the reported lengths of N—H...O bonds in oxamide (12), the heat of shortening of the N—H...O bond may be estimated to be 0.065 kcal. for a change of 0.01 Å. Thus, in the transition of urea from the tetragonal to hexagonal lattice, where two N—H...O bonds shorten by 0.06 Å each, the change in bond energy will be 0.78 kcal. mole^{-1} urea.

It has been suggested (4) that the van der Waals forces in tetragonal urea are less than normal because of the relatively open structure, while those in the complex appear to be normal. Because tetragonal urea possesses this relatively open structure, it would appear that in the tetragonal to hexagonal lattice transition there is a relaxation of the N—H...O hydrogen bond length to a state approaching the normal equilibrium distance, and not a compression of the bond to less than this distance. The process, therefore, should be exothermic, i.e. ΔH of shortening $= -0.78$ kcal. mole^{-1} urea for the tetragonal to hexagonal lattice transition.

Thermodynamic Considerations

Redlich, Gable, Dunlop, and Millar (13) have determined the equilibrium constants of a number of complex-forming reactions between urea and liquid hydrocarbons. The value of the equilibrium constant, K, corresponding to the standard free-energy change for the process

$$\text{complex (hexagonal)} \rightarrow \text{urea (tetragonal)} + \text{hydrocarbon (liquid)}$$

is p/p_0, where p is the equilibrium pressure when the coexistent phases are complex, tetragonal urea, and hydrocarbon vapor, and p_0 is the vapor pressure of the pure liquid hydrocarbon. These workers reported, in graphic form, values of $\log p/p_0$ for several hydrocarbons at various values of $1/T°$ K., the relations being found to be linear.

By interpolation from their data, and using the known values of the vapor pressure of liquid *n*-octane at various temperatures (14), values of the standard free-energy change corresponding to the change in state

$$\text{urea (tetragonal)} + n\text{-octane (vapor)} \rightarrow \text{complex (hexagonal)}$$

have been calculated, and are given in Table I.

It is seen that this reaction, under standard conditions, becomes decreasingly spontaneous with temperature increase. From the data of Table I, there is obtained: $\Delta H°$ (over the temperature range) $= -20430$ cal. mole^{-1} *n*-octane; $\Delta S°_{298° \text{ K.}} = -58.07$ cal. deg.$^{-1}$ mole^{-1} *n*-octane. The process, therefore, is markedly exothermic, the enthalpy change being opposed by a large entropy factor. Also, it may readily be calculated that at 25° C. the complex will tend to form spontaneously at *n*-octane vapor pressures above approximately 4.0 mm.

Using the above data and the molal heats of vaporization and fusion of *n*-octane

308.16	−0.3092	23.54	0.0152	−2560
313.16	−0.1928	31.11	0.0263	−2270

(9915 cal. mole^{-1} and 4957 cal. mole^{-1}, respectively (14)), it is found that for the process:

urea (tetragonal) + *n*-octane (solid) → complex (hexagonal)

$\Delta H°_{298} = -5560$ cal. mole^{-1} *n*-octane. However, it has been pointed out that 6.975 moles of urea are associated with 1 mole of *n*-octane in the complex; hence $\Delta H°_{298} = -800$ cal. mole^{-1} urea. This value agrees with the lattice energy change due to shortening of N—H...O bonds discussed earlier. Similar calculations for the complexes of *n*-decane, *n*-dodecane, and *n*-hexadecane give $\Delta H°_{298}$ values of −748, −750, and −720 cal. mole^{-1} urea, respectively.

This agreement suggests that the spontaneous energy liberation on complex formation is almost entirely due to the shortening of the N—H...O hydrogen bonds. In other words, the process of complex formation from tetragonal urea and *n*-octane vapor is energetically accounted for by this hydrogen-bond shortening along with the heat of solidification of gaseous *n*-octane. The configuration of the hydrocarbon molecules in the complex is similar to that in the pure solid hydrocarbon, and it appears, therefore, that any changes in the van der Waals forces between hydrocarbon chains lying parallel to one another in the solid state, and those lying parallel to one another in the hexagonal urea lattice, are not energetically significant. The process of complex formation appears, then, to involve a competition between the energetically favorable arrangement of planar urea molecules in a hexagonal lattice around the hydrocarbon molecule and a reversion to the more probable tetragonal configuration.

The Effect of Water Vapor

The foregoing experiments have shown that although complex formation is energetically favorable, actually no reaction is observed when small urea crystals are exposed to *n*-octane vapor only, at close to its saturation vapor pressure at 25° C. However, complex formation occurs in the presence of water vapor and if the complex so formed is decomposed under vacuum, addition of *n*-octane then occurs rapidly and cycles of decomposition and formation may be carried out.

The function of water vapor would appear to be the freeing of separate urea molecules from their positions in the tetragonal lattice. The lattice structure of urea suggests that on adsorption of water vapor on the crystal surface two types of hydrogen bonds may be formed, depending on the disposition of the urea molecules at the surface of the crystal, namely, N—H...O bonds between NH_2 groups and the oxygen of water, and O—H...O bonds between the C=O groups and the O—H of water. Since the O—H...O

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

bond is one of higher energy, the molecular field in the region of the adsorption interface will be disturbed, resulting in the weakening of the N—H...O bonds in the lattice itself. Severance of urea molecules may then occur under molecular forces comparable to those involved in the solution of urea in water. This severance may occur more readily at lattice imperfections. In the presence of hydrocarbon chains, which may be imagined as crystallization nuclei, the planar urea molecules so severed will "crystallize" in a hexagonal pattern around the hydrocarbon with the energetically favorable shortening of N—H...O bonds. Since water does not enter into the composition of the complex, it must be freed from the urea molecules in this process. As the interface spreads into the tetragonal crystal, the heat liberated by the exothermic reaction will aid in freeing an increasing number of urea molecules from their tetragonal environment. Photomicrographs have shown that the reaction proceeds from isolated points on the crystals, as would be expected if lattice imperfections are favorable points for nucleation.

The presence of a limiting pressure of water vapor below which the reaction is not observed suggests that a definite (although very small) amount of water must be adsorbed at the reaction sites in order to nucleate the process, that is to provide centers from which the exothermic reaction may proceed through the crystal. In this nucleation process the presence of both water and *n*-octane vapor is necessary. The curves of Fig. 4 and Fig. 6 show that the nucleation periods progressively shorten with increase in water-vapor pressure at a constant pressure of *n*-octane, or with increase in *n*-octane pressure at a constant pressure of water vapor. The rate of uptake of *n*-octane following nucleation increases with the pressure of water vapor (Fig. 4) or with the pressure of *n*-octane vapor (Fig. 6). These rates will depend upon the extent of nucleation, and possibly upon the rate of diffusion of *n*-octane and of water vapor into the reaction zone as the reaction interface spreads into the original crystal. From the data presented, it is not possible to separate these factors for quantitative discussion.

The Decomposition of the Complex under Vacuum

When the complex is formed in the presence of water vapor, a marked increase in the volume of the entire crystal aggregate is observed. Microscopic examination reveals also an over-all increase in the size of each individual crystalline unit, which might be expected since the volume of the hexagonal unit cell is greater than that of the tetragonal. Furthermore, the surfaces become very irregular, and the appearance becomes opaque.

When the complex is subjected to vacuum, rapid decomposition occurs, the lattice reverting to the tetragonal arrangement. It is interesting to note that this process occurs without induction periods (Fig. 3). This process may be analogous to the sublimation of a solid hydrocarbon, since essentially the same configuration exists for the hydrocarbon chain in the lattice of the complex as for such chains in the solid state (4). However, since the formation of the complex appears to involve a competition between the energetically favorable formation of the hexagonal lattice around the hydrocarbon mandrel, and a reversion to the more probable tetragonal configuration, a lowering of the density of hydrocarbon molecules below the equilibrium value would result in the collapse of the hexagonal lattice without the occurrence of a preliminary escape of the hydrocarbon molecules from the hexagonal canals. Regardless, however, of the mechanism involved, rapid reversion to the tetragonal form occurs. This should be attended by a decrease in volume. However, this does not occur. Photomicrographs show that the external size and appearance of the decomposed crystal is not significantly different from the complex crystal, although the surface may be more highly pitted. The surface area (1.76 $m.^2 g.^{-1}$) is about 14-fold that of the original urea crystals. This increase would be readily accounted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

for by the observed irregularity of surface. It appears possible, therefore, that during the initial reaction a honeycomb structure of hydrocarbon molecules each surrounded by a hexagonal cage develops at the reaction interface and spreads through the entire crystal. The tendency toward lattice contraction upon reversion to the tetragonal form would set up severe strains causing some areas of the crystal to buckle. Alternatively, however, the development of an opaque appearance during the initial reaction may indicate that each of the relatively large crystals of tetragonal urea breaks down into a mosaic of microcrystals which together retain essentially the same outward shape as the original single crystal. On removal of the *n*-octane, the small crystals revert to the tetragonal form with individual contraction, but with little obvious change in what was the original crystal. The X-ray diffraction lines obtained after successive formation and decomposition reactions are more clearly defined than those obtained for the original urea crystals, which suggests that such microcrystals are formed. However, diffraction lines may be obtained for microcrystals as small as 100 Å in dimensions. On this view, the surface area should be very much greater than the value obtained. It is possible that the adsorbing gas measures only the external surface of the mosaic and not that of the individual crystals, which may lie very close together.

The Reaction in the Absence of Water Vapor

It is significant that the curves of Fig. 3 and those of Fig. 10 in comparison with those of Fig. 8 show that once the complex has been formed in the presence of water vapor and then decomposed, further formations occur without clearly marked induction periods. It follows that the tetragonal material formed by decomposition of the complex can reform the hexagonal complex without extensive nucleation. If decomposition of the complex results in lattice strain and buckling, such centers might well be points of attack where separate urea molecules would become separated for complex formation. On the other hand if a mosaic of microcrystals were formed, it is possible that a few of these are much smaller than 100 Å in size, and possibly of the order of a few unit cells. At such centers the molecular process of formation of the hexagonal lattice and reversion to the tetragonal can be readily visualized.

As the complex is formed and decomposed repeatedly, there will result a gradual ordering in the repacking of the urea molecules into the tetragonal lattice. This process has been shown to be attended by a decrease in surface area, and a corresponding decrease in rate. The correlation between rate and surface area may be simply due to the fact that there is a corresponding decrease in lattice imperfections or in extremely small and reactive microcrystals. However, the over-all reaction is exothermic and if this heat is a factor in energizing the urea molecules in the tetragonal lattice for complex formation it is obvious that the rate will increase as this heat can be utilized by a greater available surface.

Comment

Some preliminary experiments have been made on the adsorption of water vapor on urea crystals. These indicate the existence of a very small but definite adsorption, and of a monolayer formation in the region of water-vapor pressure (about 4 mm.) where nucleation is just observed. Further experiments are in progress from which it is hoped that accurate adsorption isotherms of water vapor and *n*-octane vapor on urea, and heats of adsorption, can be calculated. When the results of this and other work are available, it is hoped that it will be possible to assess the foregoing possible mechanisms in a more quantitative way, and to relate the effects of other initiators to those obtained with water vapor.

A NEW SPOT TEST FOR NITRATE ION[1]

B. B. COLDWELL AND S. R. MCLEAN

ABSTRACT

Under the influence of short ultraviolet radiation, diphenylamine and nitrate salts react to produce a yellow-colored product. The reaction appears specific and makes it possible to detect 1 μg. of nitrate ion in 0.01 ml. of solution.

INTRODUCTION

The well-known diphenylamine and brucine tests for nitrate (1), while sensitive, are lacking in specificity. Other oxidizing agents, such as chlorates and nitrites, give the same color reaction as nitrate (1, 2). In both tests the reagent is dissolved in concentrated sulphuric acid and this prevents their use for the detection of nitrate on substrates which might be charred by the strong acid, e.g. on paper chromatograms.

This paper describes a simple, specific, and relatively sensitive test for nitrate ion which does not require concentrated acid.

METHOD

The acidity of the test solution is adjusted with dilute sodium hydroxide or hydrochloric acid so that the pH lies between 3 and 10. A convenient volume (0.05 ml. to 0.01 ml.) is transferred with a pipette to a circle of No. 30 Whatman filter paper. The spot is allowed to dry at room temperature (or with gentle warming). The same volume of reagent (1% solution of reagent grade diphenylamine in absolute or 95% ethanol or methanol) is then spotted on either side of the test solution so that the areas covered by the reagent partially overlap the area occupied by the test solution. Alternatively, the reagent may be sprayed over the area of the test solution. After the solvent has evaporated, the filter paper is exposed to short-wavelength ultraviolet light for 2 to 5 minutes. If nitrate is present, the areas of the paper covered by both reagent and test solutions will show pale to bright yellow in daylight against the faint brown color of the area occupied by the reagent alone.

The *limit of identification* of the method was 1 μg. of nitrate ion and the *dilution limit* was 1:10,000.

While the *limit of identification* was found to be 1 μg., this quantity can be built up on the filter paper by successive application of more dilute solutions. Thus, nitrate was detected in a solution containing 0.2 μg. of the anion in 0.01 ml., by making five applications of this volume to the filter paper and allowing the spot to dry between the applications.

EXPERIMENTAL RESULTS

Interference of Cations and Anions

Preliminary tests established that the yellow color was given by all colorless solutions of nitrate salts. No cation interferences were observed. The test is unsatisfactory with highly colored solutions because the yellow color is usually obscure in these cases, e.g. with solutions containing relatively large amounts of iron, cobalt, copper, and cerium salts. Aqueous solutions of the following sodium or potassium salts gave no color with

5 μg. of nitrate ion can definitely be detected in the presence of 3 to 10 times this quantity of interfering ion. None of the compounds tested reacted with diphenylamine to give a color similar to that given by nitrates. Iodates and bromates gave a gray color, vanadates and peroxides a brown color, and mineral acids produced various shades of blue or green depending on the concentration. Nitrate was detected without difficulty in solutions made 0.1 *N* with respect to hydrobromic, molybdic, orthophosphoric, ortho- and hypo-phosphorous, hydrochloric, and sulphuric acids, in solutions containing penta- and tri-oxides of arsenic, and in sodium sulphide solutions. Thallous, stannous, and manganous ions did not interfere. If the solution was acidic, the yellow spot produced by the diphenylamine–nitrate reaction usually turned blue after several hours.

Effect of Other Factors

The ultraviolet light source used in these experiments was a Hanovia analytic model quartz lamp with type "L" burner,[2] which transmits radiations from 1849 Å into the visible spectrum. Test samples were prepared and exposed to the radiations passing the following filters:

Filter	Description*	Result
SC 5026	Range 3300–3900, maximum at 3600 Å	15 min. exposure—no yellow color
SC 5023	Range 3150–4100, maximum at 3660 Å	15 min. exposure—no yellow color
SC 5028 with SC 5025	Range 2300–4200, maximum at 3200 Å	2 min. exposure—yellow color

**Taken from transmission curves supplied by the manufacturer.*

Apparently, short-wave ultraviolet radiations are required to initiate the reaction between diphenylamine and nitrate resulting in the formation of a yellow product.

No yellow product was visible when the reaction was carried out on glass or porcelain plates. However, positive results were obtained when the reaction took place on glass wool, filter paper, or asbestos mats. Apparently the substrate is not involved in the reaction but may hinder or enhance visual detection of the yellow color. No characteristic colored product was observed when diphenylamine was replaced by diphenylbenzidine, diphenylnitrosamine, diphenylthiocarbazone, 1,3-diphenylguanidine, dipicrylamine, or brucine. α-Naphthylamine gave a yellow-orange to brown-colored product against a lilac-colored background.

Study of Yellow Substance

In the hope of characterizing the yellow-colored reaction products, large sheets of filter paper were soaked in aqueous 1% sodium nitrate solution, air-dried, and then treated with the diphenylamine reagent, air-dried, and exposed to ultraviolet light for approximately 5 minutes. Another lot of paper was treated with the reagent only and similarly exposed. In daylight, the latter had a very faint yellowish-brown tint compared to the bright yellow color of the nitrate-treated paper. Both lots of paper were extracted with ether. Drierite was added to each extract and after several days with intermittent shaking, the extracts were filtered and the filtrates concentrated to about 50 ml. The remaining ether was allowed to evaporate at room temperature and the residues were recrystallized from petroleum ether.

Microscopic examination of the products showed that the extract from the nitrate-treated paper consisted of crystals ranging in color from white through yellow to orange (product A), while the material extracted from paper treated only with diphenylamine consisted mostly of white and pale-yellow-colored crystals (product B). The melting point ranges of A, B, and diphenylamine were 49.9°–51.0° C.; 50.5°–51.5° C., and 52.5°–52.9° C., respectively. A minute orange-colored crystal from product A melted below 40° C. (All melting points are uncorrected.) Attempts to separate the yellow-colored material in product A from the rest of the mixture, by chromatographic methods, were unsuccessful.

The ultraviolet and infrared spectra of pure diphenylamine and products A and B were identical. At 397 mμ, A exhibited an absorption maximum, B gave some absorption but no pronounced maxima, while diphenylamine did not absorb (see Fig. 1).

The results suggest that diphenylamine undergoes a photochemical reaction when

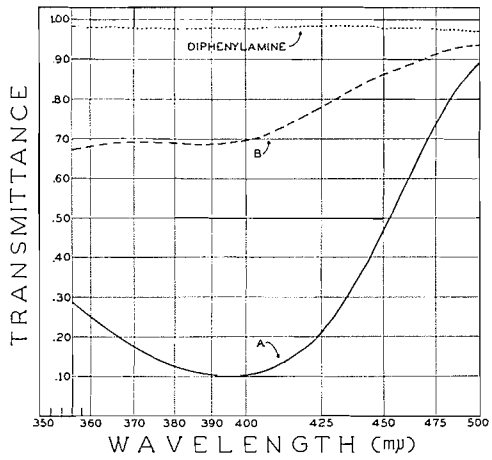

FIG. 1.

activated by short ultraviolet radiation to yield a yellow-colored product. Nitrate ions probably catalyze the reaction. The investigation is continuing.

SUMMARY

A new spot test for nitrate ion is described. The identification is based on the yellow-colored product formed when diphenylamine and nitrate, spotted on filter paper, are exposed to short-wave ultraviolet radiations. The yellow color is probably due to products formed during the photochemical reaction. The reaction appears specific and relatively sensitive, making it possible to detect 1 μg. of NO_3^- in 0.01 ml. of solution.

ACKNOWLEDGMENT

The authors are indebted to Mr. R. Lauzon for recording the infrared spectra.

STRUCTURE AND PROPERTIES OF CYCLIC COMPOUNDS

XI. DISSOCIATION CONSTANTS OF THE CYANOHYDRINS OF SOME METHYLCYCLOHEXANONES[1,2]

OWEN H. WHEELER[3] AND JACOB Z. ZABICKY[4]

ABSTRACT

The dissociation constants of the cyanohydrins of a series of methylcyclohexanones have been measured. The polymethylcyclohexanone cyanohydrins show increasing instability on substitution owing to the effects of "axial crowding". The cyanohydrins of 3- and 4-methylcyclohexanone were found to be more stable than that of cyclohexanone and to explain this a new concept of "equatorial interference" is introduced.

The measurement of the dissociation constants of cyanohydrins has proved a useful method for studying the reactivities of aldehydes and ketones and has been used much (1, 2, 3, 4, 5).

As part of a general study of the effect of substitution on the reactivity of ring compounds we wished to investigate the influence of methyl groups, in various positions in the ring, on the reactivity of cyclohexanone. Accordingly, a series of methylcyclohexanones were prepared and the dissociation constants of their cyanohydrins measured (see Table I).

TABLE I

DISSOCIATION CONSTANTS OF THE CYANOHYDRINS

Cyclopentanone	149[a]	210[b]	205 ±6[c]	34.8[d]
Cyclohexanone	9.2	10	5.91±0.11	1.0
2-Methylcyclohexanone	5.9	—	10.7 ±0.3	1.8
3-Methylcyclohexanone	30	—	5.5 ±0.1	0.93
4-Methylcyclohexanone	12.7	—	3.15±0.05	0.53
2,2-Dimethylcyclohexanone	—	—	9.2 ±0.3	1.6
cis-3,5-Dimethylcyclohexanone	—	—	25.7 ±0.7	4.4
3,3-Dimethylcyclohexanone	—	—	176 ±4	30
3,3,5-Trimethylcyclohexanone	—	—	224 ±6	38
3,3,5,5-Tetramethylcyclohexanone	—	—	4690 ±120	800
Menthone	796	1300	313 ±11	53

[d]*Ratio of dissociation constants to cyclohexanone cyanohydrin = 1.0.*

The cyanohydrin reaction has been shown to be reversible and to involve a base-catalyzed nucleophilic attack of cyanide ion on the carbon atom of the carbonyl group (6). The reaction involves a change in co-ordination number from 3 to 4 and Brown (7) has discussed such reactions in relation to the reactivity of simple cycloalkanones. Thus cyclopentanone is relatively unreactive in the cyanohydrin reaction (see Table I) since addition to the keto group gives a sterically crowded structure. However, cyclohexanone is much more reactive since a change to co-ordination number 4 relieves the angle strain in the ketone and also the small steric interference between the ketone group and the

adjacent hydrogen atoms (8). From the results in Table I it can be seen that the effect of placing methyl groups in the ring of cyclohexanone is to greatly reduce the stability of the cyanohydrins, except in the case of 3- and 4-methylcyclohexanone where there is a small but appreciable increase in stability.

Considering first the four dimethylcyclohexanones, the dissociation constant of 3,3-dimethylcyclohexanone cyanohydrin is much greater than either that of cyclohexanone or that of *cis*-3,5-dimethylcyclohexanone cyanohydrin. In the former case one of the methyl group must be in an axial position (9) and in the same axial direction as either a bulky cyano or a hydroxyl group. With the two large groups in this position there is considerable crowding in the cyanohydrin and consequently this readily dissociates to the ketone. This "axial crowding" effect of two bulky groups in the same axial direction is absent in *cis*-3,5-dimethylcyclohexanone cyanohydrin since both methyl groups lie in the equatorial plane (10). In the case of 2,2-dimethylcyclohexanone cyanohydrin one of the methyl groups will be in an axial position but in a direction opposite to the cyano group, and hence little "axial crowding" effect will be operative. However, the inductive effect of the methyl groups will place a partial negative charge on the carbonyl carbon atom and this will decrease the reactivity of the ketone (5) and increase the dissociation constant of the cyanohydrin. In menthone (2-isopropyl-5-methylcyclohexanone) the combined electronic and steric effects of the isopropyl group will make the cyanohydrin more unstable.

The cyanohydrin of 3,3,5-trimethylcyclohexanone is slightly less stable than that of 3,3-dimethylcyclohexanone since the extra methyl group will be in an equatorial position and exert only a small additional effect. However, in the case of 3,3,5,5-tetramethylcyclohexanone two methyl groups will be in an axial position and both in the same axial direction as the cyano (or hydroxyl) group. Consequently, there is a large "axial crowding" effect in the cyanohydrin, which is very unstable. The ratio of the stabilities of the cyanohydrins of cyclohexanone and cyclopentanone is 35:1 and the stabilities of most of the methylcyclohexanone cyanohydrins are within this range. However, in the cases of 3,3,5-tri- and 3,3,5,5-tetra-methylcyclohexanone the differences produced by the steric effects are equal to or greater than those which result from a difference in ring size.

Numerous examples exist in the literature of the instability of groups in an axial position (9) but few have demonstrated directly the presence of an "axial crowding" effect. Recently Corey and co-workers (11) have shown that while the preferred configuration of α-halogenocyclohexanones is with the halogen atoms axial, in the case of α-halogeno-4,4-dimethylcyclohexanones the halogen atoms are equatorial owing to crowding with the axial methyl group on carbon atom 4.

In the case of the monomethylcyclohexanones the 2-isomer will be subjected to the inductive effect of the methyl group, which will deactivate the ketone grouping and decrease the extent of cyanohydrin formation (5). The slightly increased reactivity of 2,2-dimethylcyclohexanone with respect to 2-methylcyclohexanone may be due to the fact that 2-methylcyclohexanone is free to assume both a methyl axial and an equatorial configuration (12) and the methyl group will have little steric effect on the ketone itself, whereas in 2,2-dimethylcyclohexanone one of the methyl groups will interfere with the ketone grouping (13) and this will favor the formation of the less-hindered staggered cyanohydrin. The cyanohydrins of both 3- and 4-methylcylcohexanone have dissociation constants which are smaller than that of cyclohexanone. The differences are not large, but are significant and suggest the operation of some other effect.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

The large internal angle of the carbonyl group in cyclohexanone produces a twisting of the ring, and ring atoms 2 and 6 are pushed outwards and ring atom 4 turned inwards to the equatorial plane of the ring (8, 13). This brings the atoms on the equatorial bonds at positions 3 and 5 nearer to the equatorial bond of atom 4 and the axial bonds of atoms 2 and 6. This results in a general strain in the ring which is relieved when the co-ordination number of the carbonyl carbon atom is changed from 3 to 4 (7, 14) as in cyanohydrin formation. A substituent on carbon atom 4 will increase this strain relative to cyclohexanone itself and thus 4-methylcyclohexanone should be more reactive since the additional strain is relieved when the cyanohydrin is formed. In the case of 3-methylcyclohexanone the axial hydrogen atoms at positions 2 and 6 have some freedom of movement towards the carbonyl group and the effect will be less marked. The effect for which the term "equatorial interference" is suggested has not previously been noted. However, Brown, Fletcher, and Johannesen (14) found that in the hydrolysis of methyl-substituted 1-methyl-1-chlorocyclohexanes the order was 2-methyl > 3-methyl > 4-methyl, the reverse to that observed in the present work, and this would be expected since the reverse process of a change in co-ordination number from 4 to 3 is being measured. This distortion effect would be expected to be transferred into a second ring, and cholestan-3-one and coprostan-3-one have been found (15) to be slightly more reactive than cyclohexanone.

A quantitative comparison of the various non-bonded interactions must consider these effects in both the ketone and the cyanohydrin. Considering *cis*-3,5-dimethylcyclohexanone and 3,3,5-trimethylcyclohexanone and their cyanohydrins, interactions between the axial methyl groups and the axial hydrogen atoms will be present in both the ketones and their cyanohydrins. The principal factor contributing to the large difference between the dissociation constants of these cyanohydrins will be one non-bonded interaction between an axial methyl group and the axial cyano (or hydroxyl) group in the trimethyl ketone. The ratio of the two dissociation constants (8.7:1) gives a value of 1.3 kcal. (calculated from $\Delta F = -RT \ln(K_1/K_2)$ at 25.0°) for the free energy of interaction. Similarly the principal destabilizing effect contributing to the difference in stability of the cyanohydrins of *cis*-3,5-dimethyl- and 3,3,5,5-tetramethyl-cyclohexanone is two "non-bonded" axial interactions of methyl and cyano (or hydroxyl) groups, and the ratio of their dissociation constants (182:1) gives 1.55 kcal. for the mean interaction energy. The energy change on moving a methyl group from an axial to an equatorial position has been estimated to be about −1.8 kcal. (at 25°) (10) and found, from equilibration experiments on *cis*- and *trans*-dimethylcyclohexanes, to be about −1.5 kcal. (16). These are measurements of the repulsion energy between a methyl group in an axial position and the two hydrogen atoms in the same axial direction. Thus the individual methyl hydrogen interaction energy is about 0.8 kcal. From a study of the boric acid complexes of cyclohexanediols (17) the oxygen–oxygen axial–axial interaction energy is 1.9 kcal. The present results are thus reasonable in comparison with these other measurements.

The "equatorial interference" effect is much less than the "axial crowding" effect and in the case of 4-methylcyclohexanone increases the free energy with respect to cyclohexanone by −0.4 kcal. (ratio of dissociation constants 0.53:1). Small distortions resulting from "equatorial interference" will occur in the polymethylcyclohexanones but the effect is submerged by the much greater effects of "axial crowding". Nevertheless equatorial interactions cannot be ignored in any complete study of the influence of groups on ring reactivity, and further work is being carried out to test the hypothesis.

EXPERIMENTAL

Ketones

The ketones were initially fractionated and semicarbazones prepared from fractions of constant refractive index. The semicarbazones were recrystallized from ethanol or aqueous ethanol to constant melting point and the ketones liberated by steam distillation with phthalic anhydride (18). The regenerated ketones were carefully fractionated and middle cuts used for the equilibrium studies. The physical constants are given in Table II.

Cyclopentanone, cyclohexanone, and 3- and 4-methylcyclohexanone were commercial samples (Eastman-Kodak white label grade).

2-Methylcyclohexanone and menthone were prepared by oxidation of the corresponding alcohols (19) and 2,2-dimethylcyclohexanone by methylation of 2-methylcyclohexanone (20).

cis-3,5-Dimethylcyclohexanone was obtained by hydrogenation of 3,5-dimethylcyclohexenone (21, 22) in ethanol over 5% palladium–charcoal and 3,3,5-trimethylcyclohexanone similarly from isophorone.

3,3-Dimethylcyclohexanone resulted from oxidation of 3,3-dimethylcyclohexanol (23) and 3,3,5,5-tetramethylcyclohexanone from a 1,4-addition of methylmagnesium iodide to isophorone (24).

Cyanohydrins

The solvent, 95% ethanol, was prepared by mixing 4 l. of lime-dried ethanol with 160 ml. of distilled water and had d_{25}^{25} 0.8020, d_4^{25} 0.7996.

Anhydrous hydrogen cyanide was prepared from sodium cyanide and 50% sulphuric acid (25) and dissolved in the above ethanol to give a *ca.* 0.1 *N* solution.

Aliquots of the pure ketone (0.015–0.15 g.) were dissolved in the 95% ethanol in a 50 ml. graduated flask and the hydrogen cyanide solution (10–20 ml.) added and 1 ml.

of a 2% solution of tri-*n*-propylamine in 95% ethanol. The solutions were allowed to reach equilibrium during 20–24 hours in a constant-temperature bath maintained at 25.0° ±0.2°. Samples (four of 10 ml.) were withdrawn and added to an excess of 0.1 *N* aqueous silver nitrate containing 0.5% nitric acid and the excess determined with standard 0.1 *N* potassium thiocyanate using ferric alum as indicator. All the determinations were carried out three to five times and the results, together with their mean standard deviations, are given in Table I.

The present results, obtained with highly purified specimens of ketones, differ from previous results obtained with ketones which have only been distilled.

HYDROGENOLYSIS OF CARBOHYDRATES

IV. 1,2-*O*-*ISO*PROPYLIDENE-D-GLUCOFURANOSE[1]

P. A. J. GORIN AND A. S. PERLIN

ABSTRACT

1,2-*O*-*Iso*propylidene-D-glucofuranose was treated with hydrogen at 180° C. and 2900 p.s.i. using copper chromium oxide catalyst and dioxane as solvent. The major isolated products were a hexanediol (2.4%), a mixture of hexanetriols (6.5%), a hexanetetrol (4.3%), and an *iso*propylidene-aldohexose (4.2%) which differed from the starting material. The latter product yielded L-idose on hydrolysis, showing clearly that isomerization of carbon 5 of monoacetone-D-glucose occurs under the reaction conditions used.

The diol and the major components of the triol mixture were found to possess a 1,2-glycol group which was derived mainly from the 5,6-glycol group of the original monoacetone-D-glucose. Thus, hydrogenolysis of 1,2-*O*-*iso*propylidene-D-glucofuranose-1-C^{14} afforded the 1,2-hexanediol and mixed triols containing only about 30% of the total specific activity in carbon 1. The tetrol was shown to be 1,2,5,6-hexanetetrol. The results suggest that the carbon–oxygen bonds at carbons 5 and 6 of *iso*propylidene-D-glucose are least prone to hydrogenolysis and that those at carbons 3 and 4 are most readily cleaved.

When methyl glycosides are subjected to hydrogenolysis in the presence of copper chromium oxide catalyst one of the major reactions involves reductive cleavage of the carbon–oxygen bond at the anomeric center with formation of an anhydro derivative (1, 2, 3). Thus methyl-β-L-arabopyranoside is attacked primarily at carbon–oxygen bonds 1, and 2 or 4, giving a mixture of 1,5-anhydro-2- and -4-deoxypentitols (*cis*- and *trans*-pyran-2,3-diols) (1). Likewise, methyl-α-D-glucopyranoside yields mainly a mixture of 1,5-anhydrodeoxyhexitols (2, 3). Sugar derivatives other than glycosides are now being examined to evaluate the stability of various substituent groups to hydrogenolysis, one objective being the possible discovery of resistant-blocking groups or of substituents easily cleaved, which may facilitate the preparation of deoxy sugars. The present paper concerns the hydrogenolysis of one of these derivatives, 1,2-*O*-*iso*propylidene-D-glucofuranose.

Under reaction conditions slightly milder than used earlier for the methyl glycosides, i.e., at about 180° C., at hydrogen pressures of 2000–3000 p.s.i., and with dioxane as solvent, the *iso*propylidene group was found to be more stable than a glycosidic methoxyl group, over half of the starting material remaining unchanged; no reaction occurred at 150° C., and at 250° C. extensive hydrogenolysis was evident. Among the reaction products obtained at 180° C. a sugar other than D-glucose was detected after hydrolytic removal of the *iso*propylidene groups. This sugar was isolated in 4.2% yield by cellulose-column chromatography (4) as a levorotatory sirup ($[\alpha]_D$ −10°) which formed a crystalline 1-benzyl-1-phenylhydrazone. The rate of movement of the sugar on a paper chromatogram (R_F = xylose) suggested that the compound might be deoxy-hexose. However, treatment of the sugar with 1.5 moles of lead tetraacetate in acetic acid and hydrolysis of the resulting formate esters gave two products which were indistinguishable from xylose and threose on a paper chromatogram. Since under the same conditions D-glucose gives D-arabinose and D-erythrose (5), it was evident that the configuration of the

Issued as N.R.C. No. 4651 and Paper No. 251 on the Uses of Plant Products.

hydroxyl group at carbon 5 of the D-glucose had been altered during the hydrogenation reaction. The sugar was shown, in fact, to be L-idose, for on treatment with phenylhydrazine acetate it yielded L-idose phenylosazone (L-sorbosazone) and on reduction followed by acetylation it gave L-iditol hexaacetate (6).

The conversion of D-glucose into L-idose affords a clear demonstration of a sugar isomerization promoted by catalytic hydrogenation conditions. Taken together with the recent finding (3) that dihydro-D-altral is formed from methyl-α-D-glucopyranoside and the observation (7) that under similar conditions D-xylose, D-ribose, and D- and L-lyxose are obtainable from methyl-β-L-arabopyranoside, the present results suggest that extensive isomerization may occur during hydrogenolysis reactions. Cyclic alcohols are known to isomerize in the presence of Raney nickel or platinum catalysts and hydrogen (8). It has been postulated that an intermediate ketone is formed in this reaction so that the over-all reaction represents a dehydrogenation followed by hydrogenation. A similar mechanism may be operative also in the current isomerizations of carbohydrates but, as yet, no evidence is forthcoming to support such a possibility. An apparent isomerization has recently been encountered in the catalytic hydrogenation of hexahydroxybenzene for preparation of inositols (9).

In addition to *iso*propylidene-L-idose, the hydrogenolysis of 1,2-*O*-*iso*propylidene-D-glucofuranose gave a mixture of hexanepolyols, comprising a diol, at least two triols, and a tetrol, in yields of 2.4%, 6.5%, and 4.3%, respectively, based on the weight of starting material. The tetrol, which was readily isolated from an aqueous solution after extraction of the other reaction products into chloroform, was crystalline and yielded a crystalline tetraacetate. When treated with periodate it consumed 2 moles of oxidant and liberated 2 moles of formaldehyde, but gave neither formic acid nor acetaldehyde. These properties served to characterize the tetrol as 1,2,5,6-hexanetetrol (3,4-dideoxyhexitol).

The diol and triol fractions, obtained from the chloroform extract, were separated by cellulose column chromatography. The diol, which yielded a crystalline bis-*p*-nitrobenzoate, was shown to be 1,2-hexanediol for it consumed 1 mole of periodate with production of 1 mole of formaldehyde. The sirupy triol fraction consumed almost 1 mole of oxidant and yielded close to 1 mole of formaldehyde, establishing the presence of a 1,2-diol group as a main structural feature of the triols present. Periodic acid oxidation of the triols followed by reduction with sodium borohydride (10) yielded a mixture of alcohols which could not be completely resolved into pure components via the derived *p*-nitrobenzoates. One apparently pure tris-*p*-nitrobenzoate was obtained in low yield on recrystallization from ethyl acetate. The resistance of its parent triol to periodate oxidation indicates either a 1,3,5- or a 1,3,6-hexanetriol structure, making this minor component the only hydrogenolysis product isolated which is not reconcilable with Adkins' β-hydrogenation rule (11). Because of the possibility that isomerization had occurred during formation of the various polyols, the configuration of the secondary hydroxyls cannot be assigned with certainty by reference to the parent compound, D-glucose.

The 1,2-glycol group of the diol and triols was derived principally from the 5,6-glycol group of the original D-glucose derivative. This was shown by hydrogenolysis of 1,2-*O*-*iso*propylidene-D-glucofuranose-1-C^{14}. The labelled diol and triols obtained from the latter compound were oxidized with periodate yielding formaldehyde (isolated as the dimedon derivative), which accounted for only 24% and 35%, respectively, of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

specific activity of the acetone-glucose-1-C^{14}. Further, when the diol was oxidized with the permanganate–periodate reagent (12), it yielded *n*-valeric acid possessing an activity which corresponded to 73% of that of the starting material; likewise, the mixture of pentanediols derived from the hexanetriol-C^{14} fraction by sodium periodate oxidation followed by sodium borohydride reduction accounted for 70% of the total activity. About three-quarters of the 1,2-glycol groups of the diol and triol originate from carbons 5 and 6 of the D-glucose and the remainder from carbons 1 and 2, implying that at least two different mechanisms operate in the hydrogenolysis of the *iso*propylidene group, one involving cleavage of ketal carbon–oxygen bonds, the other, of alcohol or the hemiacetal carbon–oxygen bonds.

It appears unlikely that the polyols are formed as a result of hydrolysis of the *iso*propylidene group (although the solvent was not rigorously dried, and water is a product of the reaction). This is suggested by hydrogenolysis control runs using hexitols (13), presumably the first products formed if the acetone group is hydrolyzed off, in which the variety of products was much greater than found in the present instance. The formation of these polyols is taken, rather, as an indication of the relative stability to hydrogenolysis of the various carbon–oxygen bonds in 1,2-*O*-*iso*propylidene-D-glucose. Accordingly, the bonds at carbons 3 and 4 are by far the least stable, while those at carbons 5 and 6 are most resistant to reductive cleavage. These relative stabilities may be altered substantially, however, by modification of the *iso*propylidene-D-glucose molecule. For example, the corresponding 3-*O*-methyl- and 6-deoxy-derivatives are unaffected by treatment under the same reaction conditions (13). Still other substituents at different positions may induce greater susceptibility to hydrogenolysis. The utilization of variations of this kind, it is anticipated, should extend the usefulness of catalytic hydrogenation in the synthesis of carbohydrate derivatives.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper using *n*-butanol–ethanol–water (40:11:19 v/v) as solvent. Spray reagents used were *p*-anisidine hydrochloride in butanol (14), aniline oxalate (15), and ammoniacal silver nitrate (16). Melting points are uncorrected. Evaporations were carried out under reduced pressure. Optical rotations were measured at 27° C.

Radioactive samples were combusted and the specific activity of the carbon dioxide liberated was measured by the procedure of Buchanan and Nakao (17).

Hydrogenolysis of 1,2-O-Isopropylidene-D-glucofuranose-1-C^{14}

The *iso*propylidene-D-glucose-1-C^{14} (22.5 g.; 6.84 mμc./mM.) in dioxane (400 ml.) was hydrogenated at 2000–2900 p.s.i. for 6 hours at 180° C. using copper chromium oxide (6.0 g.) as catalyst. Removal of the catalyst and solvent left a colorless sirup, an aqueous solution of which was continuously extracted with chloroform.

1,2,5,6-Hexanetetrol

The aqueous solution which had been extracted with chloroform was evaporated, giving a sirup (2.0 g.) which crystallized from methanol–acetone. Two recrystallizations from the same solvent mixture gave a hexanetetrol (0.66 g.), m.p. 95°–97° C. and $[\alpha]_D$ 0° (*c*, 1.5, saturated borax) (1 dm. tube). Calculated for $C_6H_{14}O_4$: C, 47.98%; H, 9.40%. Found: C, 47.75%; H, 9.42%. The periodate equivalent, measured by the arsenite method (18), was 80 (calculated value, 75) and the formaldehyde equivalent, measured by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

chromotropic acid method (19), was 63 (calculated value, 75). No formic acid (20) or acetaldehyde (21) was formed.

Acetylated by the hot sodium acetate method the tetrol gave a tetraacetate which, after two recrystallizations from acetone – light petroleum (b.p. 60°–80° C.), had m.p. 76°–77° C. and $[\alpha]_D$ 0° (*c*, 5.5, $CHCl_3$) (1 dm. tube). Calculated for $C_{14}H_{22}O_8$: C, 52.82%; H, 6.97%. Found: C, 52.85%; H, 7.30%.

1,2-Hexanediol

The chloroform extract (above) was evaporated to a sirup, which was dissolved in hot ethyl acetate (100 ml.). On cooling, unchanged 1,2-*O*-*iso*propylidene-D-glucofuranose was deposited and the filtered mother liquor was evaporated to a sirup (6.2 g.). The latter was dissolved in 0.1 *N* sulphuric acid (50 cc.) and hydrolyzed at 100° C. for 1 hour. The acid was neutralized ($BaCO_3$), and the solution filtered and evaporated to give a sirup. Paper chromatographic examination indicated a mixture with R_F's corresponding to glucose and a deoxy-hexose (*p*-anisidine hydrochloride spray) and also a triol together with smaller amounts of diol (ammoniacal silver nitrate spray).

The mixture was fractionated on a cellulose column. Benzene–ethanol–water (500:50:1 v/v) eluted the diol, which was obtained as a mobile sirup, $[\alpha]_D$ −12° (*c*, 2.0, saturated borax), distilling at 160°–170° C. (air bath) at 1 mm., and having a specific activity of 9.28 mμc./mM. (calc. 10.2 mμc./mM.). Yield 290 mg. Calculated for $C_6H_{14}O_2$: C, 60.98%; H, 11.94%. Found: C, 60.40%; H, 12.14%. It had a periodate equivalent of 124 and a formaldehyde equivalent of 104. Calculated periodate and formaldehyde equivalents, 118. The product had an infrared spectrum identical with that of an authentic specimen (22).

The diol (67 mg.) was converted to the bis-*p*-nitrobenzoate, which after two recrystallizations from ethanol had m.p. 91°–93° C. Yield 67 mg. Racemic 1,2-hexanediol bis-*p*-nitrobenzoate has m.p. 101.5°–102.5° C. (22); the lower melting point of the current material may be due to the presence of mixed D- and L-forms or of one isomer, the diol being optically active. Calculated for $C_{20}H_{20}O_8N_2$: C, 57.69%; H, 4.84%. Found: C, 57.40%; H, 4.79%.

The diol (59 mg.) was oxidized with periodic acid (0.21 g.) in water (10 ml.), and the solution was then distilled into a solution of dimedon (0.50 g.) in 50 ml. of 0.15 *M* phosphate buffer of pH 7.0. The formaldehyde dimedon which formed was filtered off and twice recrystallized from ethanol; yield 21 mg., m.p. 190°–191° C., specific activity 0.78 mμc./mM., corresponding to an activity of 13.3 mμc./mM. for C-1. Calculated for $C_{17}H_{24}O_4$: C, 69.83%; H, 8.27%. Found: C, 70.05%; H, 8.31%.

The diol (75 mg.) was oxidized for 4 hours with a solution (150 ml.) containing potassium permanganate (14 mg.), sodium periodate (580 mg.), and potassium carbonate (183 mg.) (12), excess reagent being destroyed with sodium bisulphite and 0.1 *N* sulphuric acid. The clear solution was extracted continuously with ether and the resulting extract was neutralized with dilute sodium hydroxide and then evaporated to dryness. The residue was dissolved in water (1 ml.), ethanol (10 ml.) added, followed by *p*-bromophenacyl bromide (180 mg.). After being refluxed for 1 hour, the solution was evaporated to dryness and the product was recrystallized three times from aqueous ethanol. The product had m.p. 71° C., undepressed on admixture with *n*-valeric acid *p*-bromophenacyl ester, and a specific activity of 3.13 mμc./mM. corresponding to an activity of 40.5 mμc./mM. for C-1. Calculated for $C_{13}H_{15}O_3Br$: Br, 26.7%. Found: Br, 26.2%.

For personal use only.

Hexanetriol Fraction

The triol fraction (0.89 g.) was eluted from the cellulose column by *n*-butanol; it had $[\alpha]_D$ −3° (*c*, 1.6, saturated borax) and a specific activity of 9.50 mμc./mM. (Calc. 10.2 mμc./mM.). Oxidation of the material with periodic acid indicated a periodate equivalent of 143 and a formaldehyde equivalent of 140.

The triol (224 mg.) was oxidized in water (10 ml.) containing periodic acid (500 mg.). After 15 minutes a slurry of barium carbonate was added to remove excess iodate and periodate and the solution was filtered. The filtrate was treated with sodium borohydride (200 mg.) and after 15 minutes the solution was acidified with dilute sulphuric acid, then continuously extracted with ether, and the extract was evaporated repeatedly with methanol to remove boric acid. A sirupy product (143 mg.) was obtained and a 55 mg. portion was converted to its *p*-nitrobenzoate by the same method as described previously. Two fractions were obtained after several fractional crystallizations from ethyl acetate and ethyl acetate – light petroleum (b.p. 50°–60° C.). The major portion (33 mg.) had m.p. 153°–156° C. (an authentic specimen of 1,5-pentanediol bis-*p*-nitrobenzoate prepared in the same way had m.p. 101°–103° C.) and an infrared spectrum similar to that of 1,5-pentanediol bis-*p*-nitrobenzoate. Calculated for $C_{19}H_{18}O_8N_2$: C, 56.71%; H, 4.51%. Found: C, 57.17%; H, 4.72%. The specific activity of the bis-*p*-nitrobenzoate was 2.11 mμc./mM. On the basis of the infrared spectrum and periodate oxidation data, the product possibly comprises a mixture of 1,5-pentanediol bis-*p*-nitrobenzoate and an impurity, thus indicating a 1,2,6-structure for the parent hexanetriol. The minor *p*-nitrobenzoate component (5 mg.) had m.p. 171°–173° C. and a tris-*p*-nitrobenzoate structure was indicated by the carbon and hydrogen microanalyses. Calculated for $C_{27}H_{23}O_{12}N_3$: C, 55.77%; H, 3.99%. Found: C, 55.49%; H, 3.93%.

L-*Idose*

Elution of the cellulose column with *n*-butanol one-quarter saturated with water gave a reducing sugar as a sirup (0.94 g.) with $[\alpha]_D$ −10° (*c*, 0.8, water). The sugar was oxidized with lead tetraacetate in acetic acid (5). After 2, 5, 10, and 30 minutes 2.02, 2.08, 2.12, and 2.14 moles/mole of reagent were consumed respectively. Oxidation of the sugar with 1.5 moles/mole of reagent gave a mixture, which, after removal of inorganic material from the solution and hydrolysis of the resulting formate esters, was indistinguishable from xylose and threose on a paper chromatogram.

The sugar (0.35 g.) was heated for 4 hours at 100° C. in an aqueous solution (20 ml.) containing phenylhydrazine (0.89 ml.) and acetic acid (1 ml.). On cooling, yellow crystals were deposited and were filtered off and recrystallized twice from methanol–benzene. The product (0.16 g.) had m.p. 170°–172° C. and $[\alpha]_D$ −13.8° (*c*, 1.0, pyridine–ethanol (1:1 v/v)) and was indistinguishable from L-sorbose phenylosazone (23) by its X-ray diffraction pattern and mixed melting point. Calculated for $C_{18}H_{22}O_4N_4$: C, 60.32%; H, 6.19%. Found: C, 60.51%; H, 6.09%.

The aldose (98 mg.) was refluxed for 15 minutes in a water (10 ml.) – ethanol (5 ml.) mixture containing 1-benzyl-1-phenylhydrazine hydrochloride (110 mg.). The solution was evaporated to a sirup which crystallized. Three recrystallizations from benzene – ethyl acetate afforded L-idose 1-benzyl-1-phenylhydrazone (104 mg.) having m.p. 113°–115° C. and $[\alpha]_D$ −19° (*c*, 1.2, ethanol). Calculated for $C_{19}H_{24}O_5N_2$: C, 63.32%; H, 6.71%. Found: C, 62.94%; H, 6.79%.

The aldose (140 mg.) was dissolved in a solution of sodium borohydride (100 mg.) in water (10 ml.). After 3 hours excess reagent was destroyed with acetic acid and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

solution then treated with Amberlite IR-120. The solution was evaporated to dryness and excess boric acid was removed by repeated evaporations of the product in methanol; yield, 126 mg., of which 104 mg. was acetylated at 100° C. in a mixture of acetic anhydride (2 ml.) and sodium acetate (0.2 g.) for 1 hour. The acetate crystallized from ethanol, and recrystallization from the same solvent gave a product (95 mg.) having m.p. 123°–124° C. and $[\alpha]_D$ −23° (*c*, 1.1, chloroform). An X-ray diffraction pattern and mixed melting point showed that the compound was L-iditol hexaacetate (6). Calculated for $C_{18}H_{26}O_{12}$: C, 49.77%; H, 6.03%. Found: C, 50.01%; H, 5.99%.

ACKNOWLEDGMENTS

The authors are grateful to the following for their assistance: Mr. J. A. Baignée for microanalyses, Mr. J. W. L. C. Christ for technical assistance, Mr. J. Dyck and Dr. A. C. Neish for specific activity estimations, Mr. T. M. Mallard for X-ray diffraction measurements, and Mr. G. B. Rennie for preparation of infrared spectra. Dr. A. C. Neish kindly supplied a sample of L-iditol hexaacetate.

ÉTARD REACTION

I. ITS SCOPE AND LIMITATION WITH SUBSTITUTED TOLUENES[1]

OWEN H. WHEELER[2]

ABSTRACT

The scope and limitations of the Étard oxidation of substituted toluenes to substituted benzaldehydes by chromyl chloride have been studied. The conditions of the reaction were investigated and an improved method of performing it was developed.

INTRODUCTION

Though the chromyl chloride oxidation of toluenes to benzaldehydes was discovered by Étard in 1877 (1, 2) the reaction has been little used and no systematic study has been made of its potentialities. In connection with other work it was necessary to prepare a series of substituted benzaldehydes and this method seemed the most general and convenient. Accordingly a study of its scope and limitations for the conversion of substituted toluenes to substituted benzaldehydes was carried out.

The procedure used is to add a solution of chromyl chloride to a stirred solution of the toluene. The solvents usually used are carbon tetrachloride (3, 4, 5), carbon disulphide (6, 7, 8, 9), and chloroform. Carbon disulphide has the disadvantage of a low boiling point. The chloroform must be free from preservative alcohol and also was found to give troublesome emulsions during working up. In preliminary experiments the yields were little different with each solvent and carbon tetrachloride was therefore chosen as the general solvent for the study.

A complex is formed as intermediate in the reaction and this must be hydrolyzed under reducing conditions to prevent oxidation of the benzaldehyde to a benzoic acid. Saturated aqueous sodium sulphite (3) was the most convenient, but the aqueous solution must be well cooled and stirred during addition to prevent overoxidation. It has been recommended (3) that the complex be isolated by filtration and decomposed separately. This gives a purer product, since the complex contains no unreacted toluene, but the decomposition was found to be less easily controlled than when carried out with the complex suspended in the original solvent.

During the exothermic addition of chromyl chloride to the toluene, the initial dark red color of the solution becomes dark brown to black as the complex is slowly precipitated. These observations suggest that the initial step is the formation of a π- or σ-complex between the aromatic and chromyl chloride, which is followed by the formation of the true solid complex. (Spectroscopic evidence has been obtained for the rapid formation of a soluble complex (10).) It has been the usual practice to allow the reaction mixture to stand for a period of a few days (3, 11) to several weeks (4, 8) to allow complete separation of the complex. However, if sufficient time is allowed for formation of the physical complex, it should be possible to accelerate the second step of formation of the solid complex without harm to the aromatic nucleus, by heating the reaction mixture. This has been found to be the case and the reaction time can be considerably reduced by allowing the mixture to stand a short time and then refluxing it for several hours. Reaction times of 2 to 12 hours only are then required and this makes the reaction

[1]*Manuscript received December 16, 1957.*
Contribution from the Instituto de Quimica, Universidad Nacional Autonoma de Mexico, Mexico, 20, D.F.
[2]*Present address: Department of Chemistry, Dalhousie University, Halifax, N.S.*

a very convenient one. If the reaction mixture is not initially cooled, or is heated too soon after the chromyl chloride is added, a vigorous or explosive reaction can occur.

To study the scope of the reaction with various toluenes the addition was carried out as usual and the mixture allowed to stand overnight. The product was isolated in the normal way and the aldehyde content estimated gravimetrically with 2,4-dinitrophenylhydrazine reagent. In the preparative experiments the mixture was refluxed for several hours before decomposition. The optimum conditions of reaction were generally not determined though enough data (Table I) were collected to predict them. In the case of *p*-iodotoluene the most suitable conditions are reported.

[f]*Solid m.p. 211°–214°. p-Cyanobenzoic acid has m.p. 219°, Ref. 23.*

The three isomeric xylenes (I–III) all give tolualdehydes with oxidation of only one methyl group, as previously observed (3, 11), since the complex precipitates and further reaction is prevented. The yields and conversions are little different for all three. For the series *p*-fluoro-, *p*-chloro-, *p*-bromo-, and *p*-iodo-toluene (IV, VII, VIII, XI, XV, XVI, XVII) the yields decrease progressively for reaction at room temperature. Good conversions are obtained for *p*-chlorotoluene by refluxing for 4 hours (IX), whereas *p*-bromotoluene requires 6 hours (XII), and *p*-iodotoluene requires some 10 hours (XVIII, XIX). In these cases the yields of recovered product are all good (>80%) and the aromatic nucleus is not destroyed by prolonged refluxing. In the case of the ortho-halogenated toluenes the increasing size of the halogeno atom for the series chlorine, bromine, and iodine results in a considerably decreasing ease of oxidation (V, VI, X, XIII, XIV). Good

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

conversions can be obtained in the case of *o*-chloro- (V, VI) and *o*-bromo-toluene (X) by refluxing, but *o*-iodotoluene (XIII) is only oxidized very slowly, and prolonged reaction (XIV) tends to destroy the entire molecule.

p-Nitrotoluene is only slowly oxidized (XXI) and the ortho-isomer less so (XX). This must be due to the deactivating effect of a nitro group on an aromatic ring (12).

Of the other substituted toluenes investigated (XXII–XXVII), none of them gave any useful yield of a substituted benzaldehyde. Very little methoxytoluene (XXII) was recovered from its reaction with chromyl chloride. The major product was an undistillable polymer, and the chromyl chloride, which is a strong Lewis acid, must have caused polymerization. However, in the case of *p*-cresol (XXIII) and *p*-thiocresol (XXIV), though no aldehyde was formed, increased quantities of starting material could be recovered.

In the oxidation of *p*-chloromethyltoluene only some 30% of product could be obtained, but this analyzed for 10% of aldehyde. The 2,4-dinitrophenylhydrazone seemed to be that of *p*-chloromethylbenzaldehyde, since it had a higher melting point than that of *p*-tolualdehyde, the other possible product, suggesting that the methyl and not the chloromethyl group had been attacked.

p-Toluonitrile (XXVI, XXVII) was largely destroyed by reaction with chromyl chloride but a small amount of *p*-cyanobenzoic acid could be isolated.

In many cases the Étard reaction provides a simple and convenient one-step method of converting a toluene to a benzaldehyde. This gives better yields than the corresponding oxidations with manganese dioxide (3, 13) in sulphuric acid or electrolytically (3), and is simpler than the two-stage conversions of side-chain bromination and hydrolysis (14) and of oxidation with chromium trioxide in acetic anhydride followed by hydrolysis of the resulting diacetate (15).

EXPERIMENTAL

Chromyl Chloride

Chromyl chloride was a gift from the Mutual Chemical Division of the Allied Chemical Corporation, and was used as received.

Toluenes

Most of these were commercial samples, which were distilled before use. Some were made by a Sandmeyer reaction from the appropriate toluidines (16, 17).

p-Methoxytoluene

p-Cresol (21.6 g.) was dissolved in water (100 ml.) containing sodium hydroxide (8.3 g.). The mixture was cooled to 10° C. and methyl sulphate (27.0 g.) was added dropwise with stirring over 1/2 hour (18). The mixture was heated under reflux for 2 hours, cooled, diluted with water, and then extracted with ether. Isolation of the product gave 19.5 g. (80%), b.p. 163°–165° at 580 mm., n_D^{21} 1.5112 (lit. b.p. 175°–177° (19)).

p-Chloromethyltoluene

A mixture of toluene (70 g.), paraformaldehyde (6 g.), and pulverized zinc chloride (6 g.) was heated to 60°, and a stream of gaseous hydrogen chloride passed in (20) for 20 minutes. The product (25 g.) had b.p. 88°–90° at 18 mm.

Oxidations with Chromyl Chloride

In a typical experiment the toluene (1/10–1/5 mole) was dissolved in carbon tetrachloride (5–6 volumes). Chromyl chloride (0.21–0.42 mole) in an equal volume of carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

tetrachloride was added slowly over 1 hour with stirring and external cooling in a bath of cold water so that the temperature never rose above 35°. Stirring was continued for another 2 hours and the mixture was then either allowed to stand at room temperature or refluxed with stirring for a number of hours. If the reaction is *not initially cooled* or if stirring is discontinued too soon, a *violent or explosive reaction* may take place. The reaction mixture was decomposed by pouring onto a stirred mixture of ice and saturated aqueous sodium sulphite solution. The use of insufficient ice or stirring may lead to overheating and overoxidation of the benzaldehyde to the benzoic acid. The organic layer was separated and the aqueous layer extracted several times with carbon tetrachloride. Extraction is sometimes made difficult by the precipitation of basic chromium salts, and these can best be removed by adding diluted (1:1) hydrochloric acid. The products were isolated by distillation and their content of benzaldehydes determined by treating a portion with 2,4-dinitrophenylhydrazine sulphate dissolved in aqueous methanol. The precipitates formed on warming were washed with water and cold methanol and dried at 100° before they were weighed.

p-Iodobenzaldehyde

A solution of *p*-iodotoluene (43.6 g., 0.2 mole) in carbon tetrachloride (150 ml.) was placed in a three-necked flask, immersed in ice-cold water. Chromyl chloride (65.2 g., 0.42 mole) in carbon tetrachloride (150 ml.) was allowed to run in dropwise, with good stirring, during 1 hour. The mixture was stirred at room temperature for a further 1 hour, and then heated slowly to reflux during another 1 hour. The mixture was stirred while refluxing for a further 20 hours. The cooled reaction mixture was poured slowly with vigorous stirring by hand onto sodium sulphite (60 g.) dissolved in water (300 ml.) containing ice (300 g.). Diluted (1:1) hydrochloric acid (100 ml.) was added to dissolve the basic chromium salts, and the organic layer separated and the aqueous layer extracted three times with portions of carbon tetrachloride. The combined organic solution was washed with water and dried. The residue left when the solvent was removed was distilled, giving the product, b.p. 145°–150° at 25 mm., m.p. 55°–65° (27.0–30.0 g., 58–64%). A forerun, b.p. 125°–130° at 25 mm. (3.5–5.0 g.) was largely unchanged *p*-iodotoluene. The *p*-iodobenzaldehyde can be recrystallized from aqueous ethanol to m.p. 75° (lit. m.p. 77°–78° (21)).

SLURRY TITRATIONS OF UNSTABILIZED CELLULOSE NITRATE[1]

PAUL E. GAGNON, KARL F. KEIRSTEAD,[2] AND BRIAN T. NEWBOLD

ABSTRACT

Slurry titrations were performed on unstabilized cotton and wood cellulose nitrates. The results for total sulphate were compared with those from gravimetric, 24-hour, and zero hydrolysis methods. The agreement was best in the case of wood cellulose nitrates. The ester sulphate contents obtained were also compared with those from 24-hour and zero hydrolysis. The agreement was again best in the case of wood cellulose nitrates. It was shown that slurry titration for the determination of sulphate acid ester could be used for wood cellulose nitrates containing not less than 100% sulphate ester, the error being −2.7 to −11.9%. For cotton cellulose nitrates, the results were not satisfactory.

INTRODUCTION

Unstabilized cellulose acetate and cellulose nitrate contain a small amount of sulphate. It has been established by Malm *et al.* (1) that the sulphate in unstabilized cellulose acetate is in the form of a sulphate acid ester, RSO_4H. The form of the sulphate content of unstabilized cellulose nitrate has for many years been a subject of discussion.

In 1942, Kullgren (2) produced some evidence for the presence of a hemiester form, RSO_4H, by means of ion-exchange studies. A few years later, support for the existence of a sulphate ester was obtained by Reeve and Giddens (3), who studied the mechanism of stabilization of cellulose nitrate by ammonia. Later, Miles (4) summarized the work done on the determination of sulphate ester in cellulose nitrate by means of titration in acetone solution. Gagnon *et al.* (5) have shown that the sulphate ester in unstabilized cellulose nitrate can be determined by titration in water, or by analysis for calcium after ion exchange, or hydrolysis in acetone/water, or determination of sulphate after treatment with 50% alcohol.

Recently, the hydrolysis method for determining the sulphate acid ester was carefully studied (6). The object of the present work was to evaluate the slurry titration of unstabilized cellulose nitrate in water and to investigate the possibility of using this type of titration for determining the sulphate acid ester content of unstabilized cellulose nitrate.

EXPERIMENTAL

Cellulose Nitrate

The preparation of the unstabilized cotton and wood cellulose nitrates was described in a previous paper (7). The sulphate content of the cellulose nitrates was determined as barium sulphate, (8), and the nitrogen by the Devarda method. In the present work, the nitrogen contents of the unstabilized cotton and wood cellulose nitrates varied from 12.1 to 7.7% and from 11.8 to 7.3%, respectively.

Slurry Titration of Unstabilized Cellulose Nitrate

The unstabilized cellulose nitrates were washed continuously with distilled water as previously described (8) and then dried to about 50% water content by centrifuging (5). Duplicate samples of moist cellulose nitrate (about 2 g. dry weight for cotton and 3 g. for wood cellulose nitrate) were placed in a beaker and distilled water (200 ml.)

[1]*Manuscript received November 14, 1957.*

was added. The mixture was well stirred and the acidity determined by titration with 0.01 *N* potassium hydroxide using a Macbeth pH meter. Hydrolysis of the cellulose nitrate was minimized by completing the titration within 20 minutes.

In later experiments, the unstabilized cellulose nitrate obtained after centrifuging was ground with sand, so that the slurry titration could be completed within 10 minutes. "Ottawa sand"* (Standard, code 2170, 30 g.) was placed in a mortar and moist cellulose nitrate (3–5 g.) and distilled water (15–25 ml.) were added. The mixture was ground vigorously with a pestle for 10 minutes. The contents of the mortar were transferred to a beaker, the pestle and mortar washed with distilled water, and the combined washings added to the mixture in the beaker. The volume of solution was then made up to 200 ml. The change in the pH of the solution due to the presence of the sand was negligible. The mixture was well stirred and the acidity determined as before.

RESULTS AND DISCUSSION

Determination by Slurry Titration of the Total Sulphate Content of Cellulose Nitrate

Titration of unstabilized cellulose nitrate in the form of a slurry in water, when performed before hydrolysis of the nitrate begins, provides a measure of the total sulphate content. Unstabilized cellulose nitrate is thought to contain a sulphate acid ester, RSO_4H, free sulphuric acid, and possibly a very small amount of a neutral ester, R_2SO_4. The slurry titration gives the acidity due to these constituents.

In the present work, the slurry titer, expressed as milliliters 0.01 *N* potassium hydroxide, was converted to milliliters per gram of cellulose nitrate. The proportion of the slurry titer value due to sulphate acid ester can be calculated using the sulphate acid ester content obtained by the hydrolysis method (6). The portion of the slurry titer due to sulphate acid ester can be converted to sulphate, expressed as % H_2SO_4, by using 98 as the equivalent weight of the ester. An example serves to illustrate the calculations involved. For instance, a cotton cellulose nitrate was shown to contain 96% sulphate acid ester by the hydrolysis method (6). The slurry titer expressed as ml./g. was 8.90. Therefore the proportion of the latter value due to ester was 8.54 ml./g., i.e. $8.54 \times 0.01 \times 98 = 8.36$ mg. H_2SO_4 per gram of nitrocellulose, which was equivalent to 0.84% H_2SO_4. Assuming that the amount of neutral ester is negligible, the remainder of the slurry titer value, 0.36 ml./g., represents free sulphuric acid. Conversion of the latter value, using 49 as the equivalent weight, gives 0.02% H_2SO_4. Therefore the total sulphate content was 0.86% H_2SO_4. The gravimetric and slurry titration total sulphate contents of a series of cotton and wood cellulose nitrates are compared in Table I. The differences are shown statistically in Table II, together with the confidence limits for the differences, calculated by the method of Dean and Dixon (9). The precision of slurry titration total sulphates is given in Table III. The coefficients of variation by differences between duplicate results (10) for cotton and wood cellulose nitrates were 1.5 and 2.5, respectively. The slurry titration results show best agreement with the gravimetric values in the case of wood cellulose nitrates.

In cases where there was 100% sulphate acid ester present in the cellulose nitrate, the total sulphate content and the sulphate due to sulphate acid ester had the same value because of the absence of free sulphuric acid. Thus the total slurry titer represented the sulphate content due to sulphate acid ester and, using 98 only as the equivalent weight, could be converted to sulphate. For example, a wood cellulose nitrate was shown to contain 100% sulphate acid ester by the hydrolysis method (6). The slurry titer,

For personal use only.

expressed as ml./g., was 14.10, which was equivalent to 1.38% H_2SO_4. Four examples of slurry titration total sulphate values for cellulose nitrates containing 100% sulphate acid ester are given in Table I.

**100% ester content.*

The total sulphate values obtained from the 24-hour hydrolysis and slurry titers are compared in Table I. The differences are shown statistically in Table II. The coefficients of variation for cotton and wood cellulose nitrates were 2.8 and 1.0, and the Rank-correlation coefficients (11) +0.80 and +0.97, respectively. It is evident that there is good agreement between the sulphate values, especially in the case of wood cellulose nitrates.

TABLE II

DIFFERENCES BETWEEN TOTAL SULPHATES DETERMINED BY SLURRY TITRATION AND THOSE DETERMINED BY OTHER METHODS

Wood	95% Confidence limits	−3.2±5.4	5.6±3.1	5.1±3.3

Comparison of Slurry Titration and Zero Hydrolysis Total Sulphates

It has been shown recently (6) that cellulose nitrate can be titrated in 90% acetone/water solution with no hydrolysis of the sulphate acid ester occurring. Therefore zero hydrolysis and slurry titers should give the same results, expressed as milliliters 0.01 *N* potassium hydroxide per gram of cellulose nitrate. Results obtained by zero hydrolysis and slurry titrations for cotton and wood cellulose nitrates were compared. For instance,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

for a wood cellulose nitrate the zero hydrolysis titer expressed as ml./g. was 14.51 and the slurry titer 14.13 ml./g. In general, there was good agreement between results, especially for wood cellulose nitrates.

The zero hydrolysis titers can be converted to total sulphate values by using sulphate acid ester contents obtained by the hydrolysis method (6) and the appropriate equivalent weights as mentioned for the slurry titration results. Total sulphate contents determined by zero hydrolysis and slurry titrations for cotton and wood cellulose nitrates are compared in Table I. The differences are shown in Table II. The coefficients of variation for cotton and wood cellulose nitrates were 6.1 and 3.2 and the Rank-correlation coefficients were +0.70 and +0.92, respectively. The precision of zero hydrolysis sulphate values is given in Table III. The Rank-correlation coefficients for cotton and wood cellulose nitrates were +0.99 and 0, respectively. It is evident that there was good agreement between zero hydrolysis and slurry titration results.

TABLE III

PRECISION OF TOTAL SULPHATE DETERMINATIONS ON DUPLICATE SAMPLES OF CELLULOSE NITRATES

		Methods	
Samples	Differences	Slurry	Zero hydrol.
Cotton	Mean difference, %	3.9	4.6
Wood	Mean difference, %	2.4	1.6
Cotton	Standard deviation	2.7	3.3
Wood	Standard deviation	4.4	1.3
Cotton	95% Confidence limits	3.9±1.9	4.6±3.3
Wood	95% Confidence limits	2.4±3.1	1.6±1.3

Total sulphates were calculated from zero hydrolysis titers of cellulose nitrates prepared by duplicate nitrations. The precision of the sulphate determinations decreased as expected. For cotton cellulose nitrate the mean difference was 11.3%, the standard deviation 12.5, and the 95% confidence limits were 11.3% ±4.8, and for wood cellulose nitrate the corresponding values were 11.1%, 7.0, and 11.1% ±8.4. Total sulphates were also calculated from slurry titers of samples prepared by duplicate nitrations but were not reproducible.

Comparison of Slurry Titration with 24-Hour Hydrolysis and Zero Hydrolysis Ester Sulphates

Ester sulphate values as determined by the hydrolysis method (6) can be compared with those calculated from slurry titration. Twenty-four hour hydrolysis and slurry titration ester sulphates are compared in Table IV. The differences are shown in Table V. The coefficients of variation for cotton and wood cellulose nitrates were 6.7 and 1.7, respectively. The precision of slurry titration ester sulphates is given in Table VI. The coefficients of variation for cotton and wood cellulose nitrates were 1.4 and 2.6 respectively.

Further comparison can be made between zero hydrolysis and slurry titration ester sulphates as shown for cotton and wood cellulose nitrates in Table IV. The differences are given in Table V. There is agreement but the best results were obtained with wood cellulose nitrates. The precision of the zero hydrolysis ester sulphates is mentioned in Table VI. It decreases markedly for results obtained from samples prepared by duplicate nitrations. For cotton cellulose nitrates, the mean difference was 15.2%, the standard deviation 9.2, and the 95% confidence limits were 15.2% ±10.9. The corresponding values for wood cellulose nitrates were 12.2%, 5.2, and 12.2% ±6.2.

In general, the slurry titration results are better if obtained from wood instead of cotton cellulose nitrates. It seems that the physical form of the cellulose nitrate plays an important part in the degree of success with slurry titrations. Wood cellulose nitrate could be finely divided whereas the cotton cellulose nitrate fibers retained their thickness even after they were ground and stirred rapidly in water. The zero hydrolysis titer can be looked upon as a more reliable measure of acidity than the slurry titer, because titration of cellulose nitrate in 90% acetone/water solution presents less difficulty than a slurry titration in water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 200.7.193.243 on 09/04/12
For personal use only.

When ester contents of cellulose nitrates determined by the hydrolysis method (6) are used to calculate total sulphate and ester sulphate values from slurry titration, the latter values compare favorably with those obtained directly by the hydrolysis method. Furthermore, slurry titration results are similar to those obtained from zero hydrolysis titrations. The fact that both slurry and zero hydrolysis results compare satisfactorily with those obtained by 24-hour hydrolysis is good evidence that the latter method is reliable.

Slurry Titration as a Method of Determining Sulphate Acid Ester in Cellulose Nitrate

Slurry titration should provide a direct method of determining sulphate acid ester in unstabilized cellulose nitrate when the sulphate content is solely in the form of sulphate acid ester. This is the case for unstabilized cellulose acetate (1), but not for unstabilized cellulose nitrate, which frequently contains some sulphate in the form of free sulphuric acid.
