The material was heated with sodium iodide in acetone as described for 2,4-*O*-benzylidene-di-*O*-tosyl-D-xylose dimethyl acetal. After 2 hours in the boiling water bath no sodium toluene-*p*-sulphonate was produced.

2,4-O-Benzylidene-xylitol (XI)

3,5-Di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose diethyl dithioacetal (IV) (5.15 g) was dissolved in a solution of acetone (4 parts) plus water (1 part) (80 ml). Cadmium carbonate (12 g) was added to the solution, which was stirred vigorously while a solution of mercuric chloride (12.3 g) in acetone (40 ml) was added portionwise at room temperature. After the addition (3 hours) stirring was continued for a further 15 hours at room temperature and the mixture was then boiled under reflux (40 minutes). The product was worked up as described for 2,4-*O*-benzylidene-3,5-di-*O*-acetyl-D-xylose dimethyl acetal, a clear syrup (3.7 g) being obtained.

The above crude 3,5-di-*O*-acetyl-2,4-*O*-benzylidene-aldehydo-D-xylose (3.0 g) was dissolved in 50% aqueous methanol (100 ml) and to the cooled solution was added an excess (2.2 g) of sodium borohydride. The solution was left at room temperature (3 hours) after which excess sodium borohydride was destroyed with glacial acetic acid. The solution was deionized by passage through a column of Amberlite IR-400 (OH) resin and the acidic eluate was shaken with Amberlite IR-120 (H) resin in the cold. The neutral solution was evaporated to dryness and boric acid was removed as methyl borate by codistillation with methanol (4×40 ml). A residue remained (1.05 g, 46% over-all yield) which crystallized on standing and was recrystallized from water. It had a melting point of 142–143° C and showed no optical rotation. Literature (16) gives a melting point of 143–144° C. The material formed a crystalline triacetate which had a melting point of 94–95° C and showed no optical rotation. Literature (16) gives a melting point of 94–95° C.

2,4:3,5-Di-O-benzylidene-D-xylose Dimethyl Acetal (XIII)

2,4:3,5-Di-*O*-benzylidene-D-xylose diethyl dithioacetal (5 g) was demercaptalated using mercuric chloride and cadmium carbonate in dry methanol as described for 3,5-di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose diethyl dithioacetal (IV). The product was extracted in the same way yielding a white crystalline residue (3.1 g, 72%) which was recrystallized from chloroform/light petroleum. It had a melting point of 210–211° C and $[\alpha]_D$ −9° (*c*, 2.2, chloroform).

Di-*O*-benzylidene-D-xylose dimethyl acetal was also prepared as described by Breddy and Jones (17) by allowing D-xylose to react with methanol and benzaldehyde in the presence of hydrochloric acid. The white crystalline product was recrystallized from chloroform/light petroleum and had a melting point of 210–211° C undepressed by admixture with 2,4:3,5-di-*O*-benzylidene-D-xylose dimethyl acetal and $[\alpha]_D$ −9° (*c*, 2.25, chloroform). Literature (17) gives a melting point of 211° C and $[\alpha]_D$ −9° (*c*, 1.2, chloroform). The infrared spectrum of this material and that of 2,4:3,5-di-*O*-benzylidene-D-xylose dimethyl acetal were identical.

STEREOCHEMICAL STUDIES

I. CONFIGURATIONS OF SOME 4-AZACHOLESTANES[1]

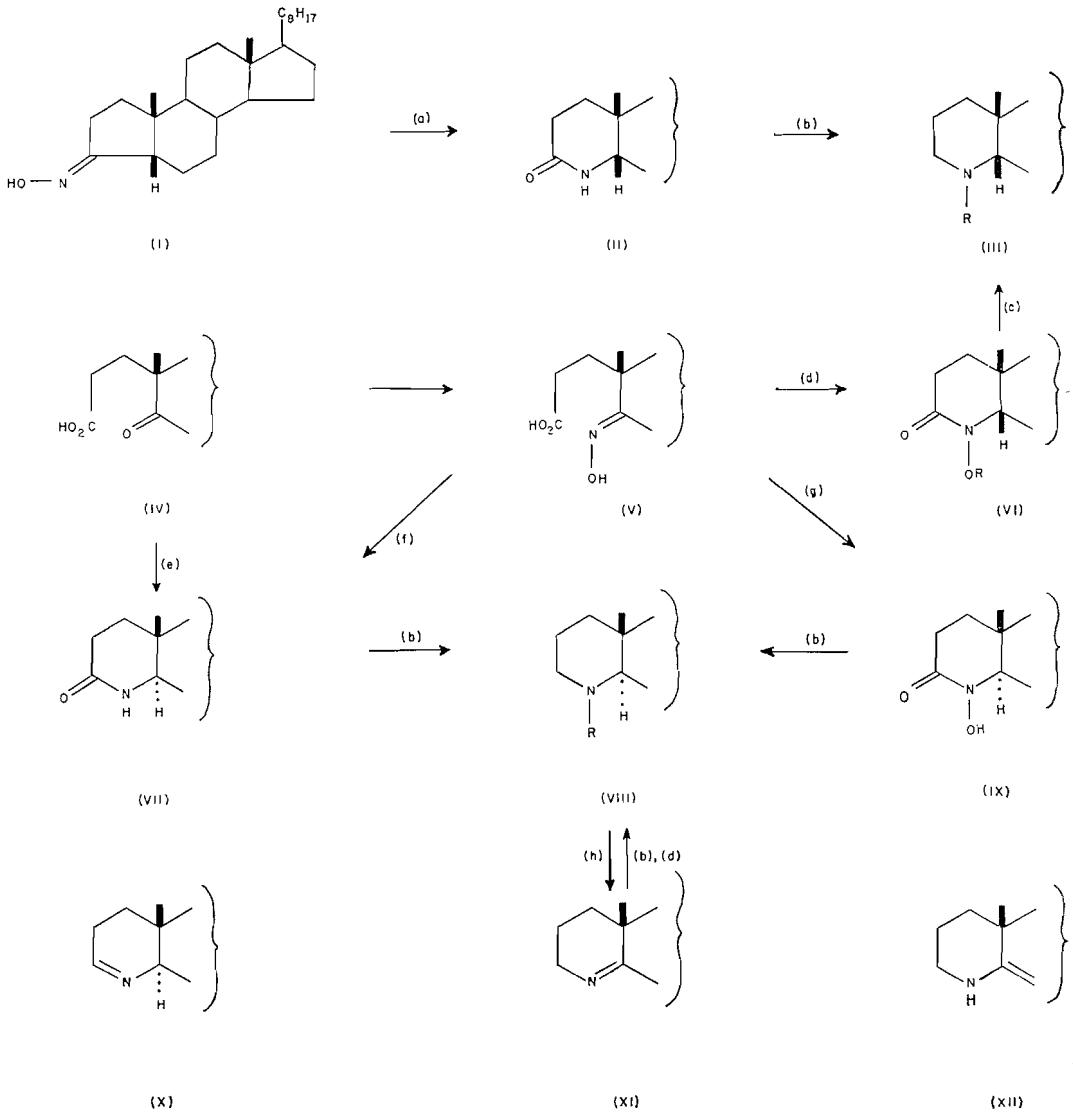
J. T. Edward and Peter F. Morand[2]

ABSTRACT

The Beckmann rearrangement of the oxime of A-nor-5β-cholestan-3-one gave 4-aza-5β-cholestan-3-one; the isomeric lactam obtained by the reduction of the oxime of 5-oxo-3,5-seco-A-norcholestan-3-oic acid with sodium in alcohol must consequently be 4-aza-5α-cholestan-3-one. Other methods of reducing the oximino acid afforded hydroxamic acids. 4-Aza-5α- and 4-aza-5β-cholestane were obtained by reduction of the appropriate lactam or hydroxamic acid.

For stereochemical studies we required 4-aza-5α-cholestane (VIII, R = H) and 4-aza-5β-cholestane (III, R = H), and hence the 5α- (VII) and 5β-lactam (II).

Bolt (1) obtained a lactam of this structure, but of undetermined configuration at the 5-position, by reduction of the oxime (V) of Windaus' keto acid (IV) (2) with sodium in ethanol. We have repeated Bolt's work and have obtained a lactam having properties agreeing closely with those reported. This lactam would be expected, from previous experience of reductions by sodium in alcohol (3, 4), to have a trans fusion of rings A and B, as shown in the structure VII. This stereochemistry is also suggested by the direct preparation of the lactam from the keto acid (IV) by the Leuckart reaction, which is known to be sensitive to steric effects (5, 6) and which with 5α-cholestan-3-one gives β-amino derivatives (7).



The structure (VII) for Bolt's lactam has now been proved by preparing the isomeric cis-fused lactam (II) by the Beckmann rearrangement of the oxime (I) of Windaus' norketone (8, 9). The configuration of the migrating center is known to be retained in the Beckmann rearrangement (10), and the migration of the 5- rather than 3-carbon atom would be expected from analogy with a similar reaction in the cholanic acid series (11). Evidence confirming this expectation is given below.

The lactams (VII and II) afforded 4-aza-5α- (VIII, R = H) and 4-aza-5β-cholestane (III, R = H) respectively on reduction with lithium aluminum hydride. The latter azasteroid could be obtained only as an oil but gave a crystalline perchlorate.

Bolt (12) claimed that hydrogenation over platinum of the oximino acid (V) gave the same lactam (VII) as did reduction with sodium in ethanol (1), together with a smaller amount of an amino acid. In our hands catalytic reduction has given as sole product a hydroxamic acid, shown to have the cis-fused structure (VI, R = H) by its further reduction with tin in hydrochloric acid to 4-aza-5β-cholestane (III, R = H). This reaction establishes also the 4-aza structure for the lactam (II) obtained by the Beckmann rearrangement. The isomeric trans-fused hydroxamic acid (IX, R = H) was obtained by reduction of the oximino acid (V) with zinc in acetic acid; its structure was established by its conversion to 4-aza-5α-cholestane (VIII, R = H) with lithium aluminum hydride. The differing stereochemical effects of the reducing agents in giving the isomeric hydroxamic acids are as expected (3).

While the infrared absorption frequencies of the carbonyl group in hydroxamic acids (13, 14) are generally lower than in the corresponding amides, the differences are considerably greater for the six-membered (VI, R = H, and IX) than for five-membered

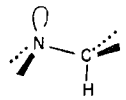
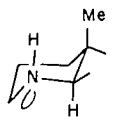
REAGENTS: (*a*) *p*-Acetamidobenzenesulphonyl chloride, (*b*) $LiAlH_4$, (*c*) Sn in HCl, (*d*) H_2/Pt, (*e*) HCO_2NH_4, (*f*) Na in ethanol, (*g*) Zn in AcOH, (*h*) $Hg(OAc)_2$.

cyclic compounds (15). The very low values for the former compounds (1623 and 1630 cm^{-1}) may be due to the more effective intramolecular hydrogen bonding possible between the carbonyl and hydroxyl groups. Some support for this view comes from the higher frequencies of the derivatives (VI, R = PhCO (1677 cm^{-1}) and VI, R = Me, (1658 cm^{-1})).



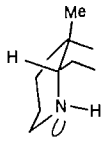
Oxidation of 4-aza-5α-cholestane (VIII, R = H) with mercuric acetate afforded 4-azacholest-4-ene (XI). The alternative structures X and XII, considered less likely from the course of oxidation of analogous compounds (16), were eliminated by the absence of absorption bands in the regions 3030–3040 cm^{-1} and 800–970 cm^{-1}, characteristic of =C—H stretching vibrations and out-of-plane deformation vibrations (17),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.



and by the absence of an absorption maximum which could be assigned to an N—H stretching vibration.

Reduction of 4-azacholest-4-ene with lithium aluminum hydride gave back 4-aza-5α-cholestane. The same product was obtained by catalytic hydrogenation which might, by analogy with the hydrogenation of cholest-4-ene in neutral solution (8), have been expected to give the 5β compound.



From a study of the infrared spectra of about 50 nitrogenous bases, Bohlmann (18) has suggested that the structural unit XIII, in which the tertiary hydrogen and the orbital containing the unshared electrons of the nitrogen are coplanar and trans, gives rise to an absorption band in the frequency region 2700–2800 cm^{-1}. The absence of absorption in this region by 4-aza-5α- and 4-aza-5β-cholestane may be interpreted as evidence for the conformations XIV and XV of these compounds. Such conformations

(XIII)

(XIV)

(XV)

for piperidines have been postulated by Barton and Cookson (19), who consider the space-filling requirements of the orbital containing the unshared electron pair to be greater than those of the hydrogen atom; and recently these conformations have been supported by measurements of molar Kerr constants (20). On these grounds one would expect the stable conformations of the N-methyl compounds (III and VIII, R = Me) to contain the structural unit XIII, since the space-filling characteristics of the methyl group will certainly be greater than those of the pair of unshared electrons. N-Methyl-4-aza-5α-cholestane (VIII, R = Me) and N-methyl-4-aza-5β-cholestane (III, R = Me) were prepared by heating the secondary amines (VIII and III, R = H) with formaldehyde and formic acid, and each showed an absorption band of medium intensity at 2775 cm^{-1} which disappeared when the perchlorate was formed. However, N-methyl amines generally show a peak in this region of the spectrum (21) which disappears on salt formation (22). Recently McKenna and Tulley (J. Chem. Soc. 945 (1960)) have described the preparation of the compounds III, R = Me, and VIII, R = Me, the former by a route differing from ours. On the basis of the products given by the Hofmann degradation of these compounds, they assign them the configurations assigned on other grounds in this paper.

EXPERIMENTAL

Where not otherwise specified, Merck acid-washed alumina was used for chromatography. Infrared spectra were obtained on a Perkin–Elmer Model 21 spectrophotometer; in listing the frequencies of absorption bands, the intensities are designated w (weak), m (medium), s (strong), sh (shoulder). Microanalyses were carried out by W. Manser (Zurich) and A. Bernhardt (Mülheim, Germany).

A-Nor-5-β-cholestan-3-one

3,4-Seco-5β-cholestane-3,4-dioic acid (2.60 g) (23), covered with 12 ml of acetic anhydride, was gradually heated, over a period of 30 minutes, to remove most of the

acetic anhydride by distillation at atmospheric pressure. The temperature was then raised and the fraction distilling at 260°–274° C/4 mm was collected as a pale yellow oil. An ether solution of the oil was washed with alkali and then water, dried (sodium sulphate), and concentrated. The residue dissolved partially in warm methanol, from which crystals (0.57 g), m.p. 72°–73° C, separated on cooling. The residue from the mother liquors was taken up in pentane and chromatographed on alumina. Elution with pentane containing increasing amounts of benzene gave, on concentration, a further crop (1.00 g), m.p. 72°–73° C. Recrystallization of the combined crops from methanol afforded 1.35 g (60% yield) of A-nor-5β-cholestan-3-one, m.p. 73°–74° C, $[\alpha]_D^{24}$ +122° (*c*, 1.995 in chloroform) (lit. m.p. 73°–74° C (8), $[\alpha]_D$ +105° (chloroform) (24)).

A-Nor-5β-cholestan-3-one Oxime (I)

A mixture of A-nor-5β-cholestan-3-one (0.60 g), hydroxylamine hydrochloride (0.5 g), and anhydrous sodium acetate (0.6 g) in 75% aqueous ethanol (50 ml) was refluxed for 4 hours. The precipitate obtained on dilution with water was crystallized from methanol to give rosettes of the *oxime* (0.55 g), m.p. 123°–124° C, $[\alpha]_D^{24}$ +81.7° (*c*, 0.416 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3630 m, 3290 m, 3170 sh, 2940 s, 2860 sh, 1617 w, 1465 s, 1440 m, 1425 sh, 1377 m, 1364 w, 1342 w, 1319 w, 1304 w, 949 m, 919 m, 888 m. Calc. for $C_{22}H_{45}ON$: C, 80.55; H, 11.71; N, 3.62%. Found: C, 80.57; H, 11.80; N, 3.62%.

4-Aza-5β-cholestan-3-one (II)

A solution of A-nor-5β-cholestan-3-one oxime (0.50 g) and *p*-acetylaminobenzenesulphonyl chloride (0.25 g) in absolute pyridine (13 ml) was allowed to stand for 2 days (cf. 25). The solution was then diluted with water and acidified with dilute sulphuric acid. The pale brown solid (0.49 g) thus obtained contained lactam (strong infrared band at 1660 cm^{-1}) and oxime (bands at 949, 919, and 888 cm^{-1}), and melted at 119–135° C. After several recrystallizations from methanol, the material (258 mg) was chromatographed on alumina (6 g, activity I). Elution with ether–acetone and acetone removed starting material (173 mg). Further elution with ethanol:acetone (1:2, 100 ml) afforded impure 4-aza-5β-cholestan-3-one (59 mg), purified by repeated recrystallization from methanol to give the lactam (19 mg), m.p. 151–155° with decomposition (bath preheated to 140° C), $[\alpha]_D^{24}$ +68.2° (*c*, 0.909 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3410 w, 3205 w, 3080 w, 2940 s, 2870 sh, 1660 s, 1460 m, 1443 m, 1408 w, 1377 m, 1355 w, 1303 m, 920 w. Calc. for $C_{26}H_{45}ON$: C, 80.55; H, 11.71; N, 3.62%. Found: C, 80.40; H, 11.57; N, 3.58%.

N-*Hydroxy-4-aza-5β-cholestan-3-one* (VI, R = H)

The oxime of 5-oxo-3,5-A-norcholestan-3-oic acid (2.20 g), prepared according to Windaus (2), was dissolved in acetic acid (125 ml) and hydrogenated in a Parr apparatus for 4.5 hours in the presence of platinum oxide (0.50 g). After removal of the platinum, the solution was concentrated at reduced pressure to give a brownish residue. Recrystallization of this material from methanol gave a first crop (1.30 g) of white crystals of N-hydroxy-4-aza-5β-cholestan-3-one; a second crop (0.35 g) was obtained from the mother liquors. After two more crystallizations, the melting point was 122°–124° C, $[\alpha]_D^{24}$ +31.8° (*c*, 1.949 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3240 w, 2940 s, 2870 sh, 1623 s, 1465 m, 1443 sh, 1430 sh, 1388 m, 1360 sh, 1328 w, 1314 sh, 1299 m, 1165 w, 1140 w, 1095 w. With chloroform as solvent, the carbonyl absorption occurred at 1607 cm^{-1}. In both carbon tetrachloride and chloroform the carbonyl frequency was not changed by dilution of the solution. The compound gave a reddish-purple color in alcoholic ferric chloride

solution. When the compound was dried at 65°/0.1 mm, it analyzed as a monohydrate. Calc. for $C_{26}H_{47}O_2N$: C, 74.07; H, 11.23; N, 3.32%. Found: C, 74.25, 74.14; H, 11.13, 11.14; N, 3.33%. When dried at 110°/0.1 mm for 4 hours the water of crystallization was lost. Calc. for $C_{26}H_{45}ON$: C, 77.40; H, 11.24; N, 3.47%. Found: C, 77.33; H, 11.28; N, 3.55, 3.48%.

N-*Benzoyloxy-4-aza-5β-cholestan-3-one* (VI, R = PhCO)

A solution of N-hydroxy-4-aza-5β-cholestan-3-one (200 mg) and benzoyl chloride (1.5 ml) in absolute pyridine (3.0 ml) was refluxed for 1 hour. After the reaction mixture was cooled, it was diluted with ether and washed with aqueous sodium bicarbonate and then with water. After it had been dried (magnesium sulphate) and concentrated the ether produced a yellow oil which was chromatographed on alumina (5 g, Woelm, activity II–III). Elution with benzene–ether (1:1, 50 ml; 1:3, 50 ml) gave 40 mg of crystalline material, which, after one recrystallization from ligroin–benzene, had a melting point of 209°–212° C, $[\alpha]_D^{24}$ −6.4° (*c*, 0.621 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3420 w, 3220 w, 3080 w, 2940 s, 2870 sh, 1720 s, 1677 s, 1565 m, 1450 m, 1443 sh, 1425 sh, 1377 m, 1357 w, 1330 w, 1312 m, 1265 s, 1174 m, 1110 s, 1093 sh, 1065 m, 1025 m, 902 w. Calc. for $C_{33}H_{49}O_3N$: C, 78.06; H, 9.73; N, 2.76%. Found: C, 77.55; H, 9.66; N, 3.10%.

N-*Methoxy-4-aza-5β-cholestan-3-one* (VI, R = Me)

A mixture of N-hydroxy-4-aza-5β-cholestan-3-one (475 mg), methyl iodide (0.35 ml), and 7% aqueous potassium hydroxide (2.0 ml) in ethanol (10 ml) was refluxed for 4.5 hours. The alcohol was removed under reduced pressure, the mixture was diluted with aqueous 10% potassium hydroxide, and extracted several times with ether. The ether extract, worked up in the usual way, gave a white solid (278 mg). Part of the substance (95 mg) was chromatographed over alumina (3.0 g, Woelm, activity II). Elution with benzene–hexane (4:1, 20 ml) and benzene (80 ml) gave crystalline material (70 mg), m.p. 106°–108° C. One recrystallization from aqueous methanol gave plates, m.p. 114°–115° C, $\nu_{max}^{CCl_4}$ in cm^{-1}: 2945 s, 2870 sh, 1688 sh, 1658 s, 1470 m, 1445 m, 1385 m, 1333 w, 1295 m, 1245 w, 1220 w, 1097 w, 1051 m, 955 w, 955 w, 909 w, 892 w, 850 w. Calc. for $C_{27}H_{48}O_2N$: C, 77.46; H, 11.55; N, 3.35%. Found: C, 77.69; H, 11.43; N, 3.40%.

4-Aza-5β-cholestane (III, R = H)

(a) By the Reduction of 4-Aza-5β-cholestan-3-one

A mixture of lithium aluminum hydride (0.30 g) and 4-aza-5β-cholestan-3-one (309 mg) in dioxane (35 ml) was refluxed for 40 hours. The mixture was then treated with water, and extracted four times with chloroform. The extracts were dried over magnesium sulphate and evaporated to give 4-aza-5β-cholestane as an uncrystallizable oil, $[\alpha]_D^{33}$ +22.1° (*c*, 1.808 in chloroform), ν_{max}^{film} in cm^{-1}: 3305 w, 2940 s, 2870 sh, 2800 sh, 2730 sh, 2620 sh, 1467 s, 1445 s, 1382 s, 1337 w, 1312 m, 1254 w, 1234 w, 1214 w, 1169 w, 1128 m, 1108 sh, 1067 w, 1030 w, 988 w, 968 w, 931 w, 884 w, 860 w, 837 w, 806 w, 777 w, 724 w. The *perchlorate* was precipitated by adding a few drops of 70% perchloric acid to 4-aza-5β-cholestane (50 mg) in methanol (5 ml). Crystallized from methanol, it had a melting point of 203–206° C, $[\alpha]_D^{33}$ +21.4° (*c*, 2.049 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3190 sh, 3100 m, 2950 s, 2870 sh, 1590 w, 1467 m, 1455 sh, 1430 w, 1407 w, 1381 m, 1366 sh, 1336 w, 1309 w, 1287 w, 1125 s, 1090 s, 918 w, 903 sh, 856 w. Calc. for $C_{26}H_{48}O_4NCl$: C, 65.85; H, 10.20; N, 2.95%. Found: C, 65.70; H, 10.29; N, 2.99%.

(b) By the Reduction of N-*Hydroxy-4-aza-5β-cholestan-3-one*

A mixture of granulated tin (3.0 g) and N-hydroxy-4-aza-5β-cholestan-3-one (307 mg)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

in ethanol (9 ml) and concentrated hydrochloric acid (3 ml) was refluxed on the steam bath for 7 hours. Every hour a further 1 ml of hydrochloric acid was added, as well as enough ethanol to keep the organic material in solution. The solution was decanted from tin and diluted with water, giving 4-aza-5β-cholestane hydrochloride (295 mg), obtained after two recrystallizations from acetone as short needles which darkened at 237° and melted at 256°–265° C (bath preheated to 230° C). Calc. for $C_{26}H_{48}NCl$: C, 76.14; H, 11.80%. Found: C, 75.92; H, 11.76%.

The free base, obtained in the usual way as an uncrystallizable oil, $[\alpha]_D^{33}$ +24.2 (*c*, 0.910 in chloroform), was converted by treatment with 70% perchloric acid to a crystalline perchlorate, which, after one recrystallization from methanol, had a melting point of 201°–205° C, $[\alpha]_D^{33}$ +19.7° (*c*, 1.521 in chloroform). This compound was shown by mixed melting point and by its infrared spectrum to be identical with the perchlorate obtained by reduction of 4-aza-5β-cholestan-3-one.

N-*Methyl-4-aza-5β-cholestane* (III, R = Me)

A mixture of 4-aza-5β-cholestane (97 mg), 40% formaldehyde solution (1.0 ml), and 99% formic acid (1.0 ml) was heated on the steam bath for 3 hours. After the mixture was cooled, it was diluted with water and made basic with ammonium hydroxide. Extraction with ether and working up in the usual way gave a colorless uncrystallizable syrup (90 mg), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 s, 2870 sh, 2775 m, 2715 sh, 2620 w, 1465 s, 1445 s, 1376 s, 1263 w, 1236 w, 1215 w, 1200 w, 1187 w, 1173 w, 1143 w, 1112 w, 1090 w, 1073 w, 1025 sh, 1014 m, 978 w, 960 w, 930 w, 877 w, 833 w. The *perchlorate* had a melting point of 246°–251° C; in its infrared spectrum the absorption band at 2775 cm^{-1} had disappeared and bands at 1100 and 1052 cm^{-1} (perchlorate anion) had appeared. Calc. for $C_{27}H_{50}O_4NCl$: C, 66.40; H, 10.32; N, 2.87%. Found: C, 66.60; H, 10.39; N, 3.04%.

4-Aza-5α-cholestan-3-one (VII)

Ammonium formate (2.5 g) was distilled from a 25-ml conical flask until a temperature of 165° C was reached in the flask. 5-Oxo-3,5-seco-A-norcholestan-3-oic acid (1.70 g) suspended in nitrobenzene (10 ml) was introduced into the flask and the temperature of the resulting mixture was kept at 180°–200° C for 24 hours (cf. 26). After the reaction mixture was cooled, it was washed with water. The water-insoluble liquid was refluxed for 2 hours in 6 *N* hydrochloric acid (8 ml) and ethanol (7 ml). After the removal of nitrobenzene and ethanol by steam distillation, the aqueous solution was extracted with ether. The ether solution was washed with dilute sodium carbonate and with water, dried over sodium sulphate, and evaporated to dryness. The residue, after one recrystallization from methanol, weighed 1.27 g, m.p. 240°–251° C. Several recrystallizations from methanol raised the melting point to 250°–252° C with decomposition (bath preheated to 240° C), $[\alpha]_D^{22}$ +45° (*c*, 1.585 in chloroform), (lit. m.p. 252°–253° C, $[\alpha]_D$ +44 (in pyridine) (1)). The melting point and infrared spectrum of this compound were identical with those of authentic 4-aza-5α-cholestan-3-one obtained by the reduction of the oxime of 5-oxo-3,5-seco-A-norcholestan-3-oic acid (V) with sodium and alcohol (1); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3422 w, 3210 w, 3070 w, 2940 s, 2870 sh, 1662 s, 1467 s, 1444 sh, 1404 m, 1383 m, 1358 m, 1306 m, 1223 w, 1162 w, 1132 w. Calc. for $C_{26}H_{45}ON$: N, 3.62%. Found: N, 3.70%.

N-*Hydroxy-4-aza-5α-cholestan-3-one* (IX)

The oxime of 5-oxo-3,5-seco-A-norcholestan-3-oic acid (0.64 g) and zinc dust (1.09 g) in acetic acid (20 ml) were heated to 90–95° C for 1 hour. The zinc was then removed

by filtration, and the filtrate diluted with water to yield N-hydroxy-4-aza-5α-cholestan-3-one as a fluffy white solid (0.59 g, m.p. 140°–153° C). Repeated recrystallizations from ethyl acetate and then from methanol raised the melting point to 185°–187° C with decomposition (bath preheated to 150° C), $[\alpha]_D^{28}$ −49.5° (*c*, 1.98 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3260 w, 2940 s, 2870 sh, 1677 sh, 1630 s, 1487 s, 1461 s, 1448 sh, 1428 w, 1395 s, 1380 s, 1328 w, 1315 w, 1306 m, 1267 w, 1223 s, 1187 w, 1138 w, 1072 w, 940 m, 925 w, 887 w, 860 w. Calc. for $C_{26}H_{45}O_2N$: C, 77.40; H, 11.24; N, 3.47%. Found: C, 77.23; H, 10.99; N, 3.39%. In methanolic ferric chloride the compound gave a reddish-purple color.

4-Aza-5α-cholestane (VIII, R = H)

(a) By the Reduction of 4-Aza-5α-cholestan-3-one

A mixture of 4-aza-5α-cholestan-3-one (509 mg) and lithium aluminum hydride (0.50 g) in dioxane (75 ml) was refluxed for 40 hours. Isolation of the product in the usual way gave a solid, melting at 114°–115° C, after two recrystallizations from acetone (lit. m.p. 116°–117° C (1)), $[\alpha]_D$ +36° (chloroform), ν_{max}^{KBr} in cm^{-1}: 3270 w, 2940 s, 2870 sh, 1470 s, 1445 s, 1384 s, 1368 sh, 1210 w, 1173 w, 1128 m, 1116 sh, 1077 w, 946 w, 933 m, 905 w, 889 w, 867 w, 858 w, 840 w. Calc. for $C_{26}H_{47}N$: C, 83.56; H, 12.68; N, 3.75%. Found: C, 83.44; H, 12.69; N, 3.71%.

The *perchlorate*, crystallized from methanol, had a melting point of 224°–225° C, $[\alpha]_D^{33}$ +21.1 (*c*, 2.36 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3190 sh, 3100 m, 2950 s, 2870 sh, 1590 w, 1467 m, 1450 m, 1392 sh, 1383 w, 1377 sh, 1366 sh, 1330 w, 1307 w, 1125 s, 1090 s, 918 w. Calc. for $C_{26}H_{48}O_4NCl$: C, 65.85; H, 10.20; N, 2.95%. Found: C, 65.67; H, 10.14; N, 2.72%.

(b) By the Reduction of N-Hydroxy-4-aza-5α-cholestan-3-one

A mixture of N-hydroxy-4-aza-5α-cholestan-3-one (121 mg) and lithium aluminum hydride (0.30 g) in dry ether (50 ml) was refluxed for 12 hours. Then water (0.60 ml) and 10% aqueous sodium hydroxide (0.48 ml) were added, and the mixture stirred for 10 minutes. The inorganic salts were removed by filtration, and the filtrate was evaporated to dryness. The brown syrupy residue (93 mg) had an infrared spectrum which showed no carbonyl peak. When treated with 70% perchloric acid it gave a salt, m.p. 222°–224° C, which was shown by its infrared spectrum and by a mixed melting point to be identical with the perchlorate of 4-aza-5α-cholestane obtained from 4-aza-5α-cholestan-3-one.

N-*Methyl-4-aza-5α-cholestane* (VIII, R = Me)

4-Aza-5α-cholestane (95 mg) was treated with 99% formic acid (1.0 ml) and 40% formaldehyde solution (1.0 ml) under the conditions described for preparing N-methyl-4-aza-5β-cholestane. The product (77 mg) after two crystallizations from methanol had a melting point of 63°–64° C (lit. m.p. 61°–62° C (12)), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2950 s, 2870 sh, 2775 m, 2715 sh, 2620 w, 1465 s, 1445 s, 1378 m, 1365 sh, 1328 w, 1179 m, 1160 m, 1107 m, 1068 w, 1022 m, 1000 sh, 970 sh. Calc. for $C_{27}H_{49}N$: C, 83.64; H, 12.74%. Found: C, 83.82; H, 12.97%.

The *perchlorate* melted at 231°–235° C, and had no absorption band at 2775 cm^{-1}. Calc. for $C_{27}H_{50}O_4NCl$: C, 66.40; H, 10.32; N, 2.87%. Found: C, 66.18; H, 10.24; N, 2.93%.

N-*p-Nitrobenzoyl-4-aza-5α-cholestane*

A solution of 4-aza-5α-cholestane (330 mg) and *p*-nitrobenzoyl chloride (0.25 g) in dry benzene (15 ml) was refluxed for 1.5 hours. After the solution was cooled, it was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

washed with dilute sodium carbonate, dilute hydrochloric acid, and water, dried over sodium sulphate, and evaporated to dryness. Crystallization of the residue from methanol gave 180 mg of substance melting at 232°–238° C; after several recrystallizations the melting point rose to 243°–245° C (decomp.), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 s, 2865 sh, 1647 s, 1600 m, 1520 w, 1465 m, 1434 s, 1382 sh, 1363 sh, 1346 s, 1308 m, 1287 m, 1175 w, 1140 w, 1117 w, 1103 w, 1010 w, 945 w, 927 w, 856 w, 848 w. Calc. for $C_{33}H_{51}O_3N_2$: C, 75.67; H, 9.82; N, 5.32%. Found: C, 75.55; H, 9.72; N, 5.32%.

4-Azacholest-4-ene (XI)

A solution of 4-aza-5α-cholestane (0.51 g) and mercuric acetate (1.78 g) in 5% aqueous acetic acid (10 ml) was heated on the steam bath for 2 hours. After the solution was cooled, mercurous acetate was removed by filtration. The filtrate was saturated with hydrogen sulphide, centrifuged, and the supernatant liquid made strongly basic with aqueous 40% sodium hydroxide solution. The solid which precipitated was taken up in ether and the ether solution washed with water and dried (magnesium sulphate). Evaporation of the ether left a semisolid residue (0.33 g) which was dissolved in methanol (5 ml) and treated with a few drops of 70% perchloric acid. The *perchlorate* precipitated, and after one recrystallization from methanol had a melting point of 212°–213° C, ν_{max}^{KBr} in cm^{-1}: 3240 w, 3120 w, 2950 s, 2870 sh, 1680 s, 1468 s, 1455 sh, 1382 m, 1367 sh, 1335 w, 1283 w, 1213 w, 1105 s, 1080 s, 927 w. In carbon tetrachloride the C=N absorption occurred at 1677 cm^{-1}. Calc. for $C_{26}H_{26}O_4NCl$: C, 66.15; H, 9.82; N, 2.97; Cl, 7.51%. Found: C, 65.93; H, 9.68; N, 2.97; Cl, 7.34%.

The *free base* obtained from the perchlorate had a melting point of 101°–102° C after two crystallizations from acetone, $\nu_{max}^{CCl_4}$ in cm^{-1}: 2945 s, 2870 sh, 2800 sh, 2720 sh, 1649 s, 1467 s, 1445 s, 1383 m, 1377 sh, 1366 m, 1328 w, 1320 w, 1305 w, 1166 w, 1127 m, 1075 w, 1054 w, 1027 w, 954 w, 928 w, 854 w. In potassium bromide pellet also, no absorption occurred in the region 3100–3450 cm^{-1}. Calc. for $C_{26}H_{45}N$: C, 84.04; H, 12.21; N, 3.77%. Found: C, 83.78; H, 12.18; N, 3.79%.

Reduction of 4-Aza-cholest-4-ene Perchlorate

(a) With Lithium Aluminum Hydride

A slurry of 4-azacholest-4-ene perchlorate (30 mg) and lithium aluminum hydride (0.10 g) in anhydrous ether (8 ml) was refluxed with stirring for 4.5 hours, after which the excess of lithium aluminum hydride was destroyed with 30% aqueous sodium hydroxide. The aqueous solution was extracted three times with ether, and the combined ether extracts dried and concentrated to give a brownish solid (21 mg). The perchlorate of this material melted at 222°–224° C and was shown by mixed melting point and infrared spectrum to be identical with 4-aza-5α-cholestane perchlorate.

(b) By Catalytic Hydrogenation

A solution of 4-azacholest-4-ene perchlorate (92 mg) in ethanol was hydrogenated at atmospheric pressure in the presence of platinum oxide (35 mg). The calculated amount of hydrogen was taken up in 8 minutes. Removal of the catalyst by filtration, and basification and concentration of the filtrate gave a white solid, crystallizing from acetone as needles, m.p. 113°–114° C. The compound was shown by mixed melting point and infrared spectrum to be 4-aza-5α-cholestane.

ACKNOWLEDGMENTS

The authors are grateful to Dr. A. Taurins for help in obtaining infrared spectra and to the National Research Council for generous financial support.

STEREOCHEMICAL STUDIES

II. CONFIGURATIONS OF SOME 4-OXACHOLESTANES[1]

J. T. EDWARD AND PETER F. MORAND[2]

ABSTRACT

The oxidation of A-nor-5β-cholestan-3-one with peracids gave 4-oxa-5β-cholestan-3-one. This was identical with one of the two lactones produced by the reduction of Windaus' keto acid; the other lactone must be 4-oxa-5α-cholestan-3-one. The two lactones were reduced by lithium aluminum hydride to diols, which were cyclized to 4-oxa-5α- and -5β-cholestane.

Turner (1) obtained by catalytic reduction of Windaus' keto acid (I) (2) two lactones, m.p. 109.5°–110° C and 116°–116.5° C, the former in larger amount. He tentatively assigned to these compounds the structures V and VI, respectively, because of their optical rotations and because hydrogenation of 4-oxacholest-5-en-3-one, which should be expected to give VI, gave the higher melting isomer.

Further evidence for these structures comes from a consideration of their molecular rotations (3) including the differences between the molecular rotations of the lactones and of the amides (II or III, R = NH_2) or hydrazides (II or III, R = $NHNH_2$), which are, as shown in Table I, in the directions predicted by the Klyne–Hudson "lactone rule"

TABLE I

[a]In 95% ethanol. [b]In chloroform.

(3). Finally, unequivocal proof comes from the Baeyer–Villiger oxidation of Windaus norketone (IV), which is known to have the cis ring juncture shown (4). With peracetic acid this affords the lactone with the lower melting point. The Baeyer–Villiger reaction proceeds with retention of configuration of migrating optically active groups (5, 6) and almost always, as in the present case, involves the migration of the more alkylated of the two carbon atoms flanking the carbonyl group (7, 8).

A notable exception to the latter generalization is afforded by the oxidation of camphor, carried out by Baeyer and Villiger themselves (9). In reinvestigating this reaction, Sauers (10) found that in acetic acid camphor is oxidized by peracetic acid to the expected lactone (XI) (82% yield) but in the presence of concentrated sulphuric acid is oxidized to campholide (XII) (30% yield), although some of the isomeric lactone (XI) also may be formed but destroyed in the strongly acidic solution. Sauers explained the formation of campholide by a mechanism involving a protonated form of the Criegee intermediate (11, 12). In the destruction of this intermediate the electronic effects which favor the migration of the more heavily alkylated carbon atom become less important than they are in the destruction of the neutral Criegee intermediate. Conformational and

For personal use only.

other effects may then become relatively more important. It had already been argued by Murray *et al.* (13) that conformational effects favor the formation of campholide since the transition state leading to it has a chair conformation, while the transition state leading to the lactone (XI) has a boat conformation.

Serious doubt is cast on this argument by the fact that A-nor-5β-cholestan-3-one (IV) even in the presence of sulphuric acid is oxidized to 4-oxa-5β-cholestan-3-one (V = XV). The line of reasoning developed by Murray *et al.* (13) would indicate that in this reaction the protonated form of the Criegee intermediate (XIV) would have a greater tendency to rearrange to give 3-oxa-5β-cholestan-4-one (XIII): indeed, the conformational effects favoring XIII over XV would appear to be greater than those favoring XII over XI.

XIII XIV XV (=V)

We have found the most convenient method of preparing the trans lactone (VI) to be the reduction of Windaus' keto acid (I) with sodium borohydride, but the yield of pure product (35%) is not great. Bolt (14) obtained this lactone by carrying out the reduction with sodium in alcohol, but his reported yield of 75% is based on the crude product; we obtained a satisfactory product, m.p. 115°–116° C, in only 34% yield. Reduction with sodium in isopropanol (15) gave a slightly higher yield (41%). Reduction with aluminum isopropoxide in isopropanol gave an oily product shown by infrared spectroscopy to contain both cis and trans lactones.

Reduction of the lactones (V and VI) with lithium aluminum hydride gave the diols (VII and VIII), from which the 4-oxacholestanes (IX and X) were obtained by treatment with benzenesulphonyl chloride and pyridine or lutidine (16). As expected, the 4-oxacholestane having the trans fusion of rings A and B had a higher melting point than the cis compound; however, the trans 4-oxa- and 4-aza-cholestanes had higher molecular rotations than the cis compounds, unlike their carbocyclic analogue (Table II). Replacing the carbon atom at position 4 by oxygen had a much greater effect on optical rotation than replacing it by nitrogen; this may be due to the greater alteration in molecular shape caused by substitution by the smaller oxygen atom, since the polarizabilities of the two atoms are not greatly different (17).

EXPERIMENTAL

4-Oxa-5β-cholestan-3-one (V)

A solution of peracetic acid (20) in glacial acetic acid (4.0 ml containing 0.46 g of peracetic acid) (21) and *p*-toluenesulphonic acid (0.02g) were added to A-nor-5β-cholestan-3-one (0.20 g) dissolved in 2.0 ml of glacial acetic acid. The solution was left in the dark for 24 hours at 35° C. Dilution with water precipitated a product which, after one recrystallization from dilute methanol, yielded 0.17 g (90% of the theoretical) of transparent plates, m.p. 90°–99° C. Repeated recrystallizations from dilute methanol raised the melting point to 107°–107.5° C, $[\alpha]_D^{24}$ +18.6° (*c*, 6.129 in chloroform) (lit., m.p. 109.5°–110° C, $[\alpha]_D$ +18.3° (1)). The infrared spectrum of this compound was identical with that of an authentic sample of 4-oxa-5β-cholestan-3-one obtained by catalytic hydrogenation of 5-oxo-3,5-seco-A-norcholestan-3-oic acid (1), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 (s), 2870 (sh), 1738 (s), 1470 (s), 1432 (sh), 1425 (sh), 1384 (m), 1367 (m), 1345 (m), 1325 (sh), 1235 (w), 1198 (m), 1173 (w), 1156 (m), 1113 (w), 1095 (w), 1075 (w), 1040 (s), 1016 (sh) (s = strong; m = medium; w = weak band; sh = shoulder). Calc. for $C_{26}H_{44}O_2$: C, 80.38; H, 11.41%. Found: C, 80.24; H, 11.24%.

In another experiment, a solution of the norketone (205 mg) in glacial acetic acid (2 ml) and concentrated sulphuric acid (0.75 ml) was treated with a solution of peracetic acid in glacial acetic acid (0.75 ml 40%). The solution was left in the dark at 27° for 5 days, and then worked up as before. The product crystallized once from aqueous ethanol gave plates (55 mg), m.p. 85°–95°; after several recrystallizations the melting point was raised to 107°–108° C, and the product was shown by mixed melting point and infrared spectrum to be 4-oxa-5β-cholestan-3-one. No other crystalline product could be isolated from the mother liquors.

4-Oxa-5α-cholestan-3-one (VI)

5-Oxo-3,5-seco-A-norcholestan-3-oic acid (2.5 g) (1) was dissolved in 30 ml of 0.8 *N* sodium hydroxide and 7.5 ml of ethanol. Sodium borohydride (0.29 g) was added over a period of 10 minutes and the mixture was heated under reflux for 1.5 hours. The excess sodium borohydride was destroyed with acetic acid and the acidified reaction mixture was refluxed for 10 minutes longer to bring about complete lactonization of the hydroxy acid. After the precipitated product was filtered, several recrystallizations from petroleum ether (b.p. 66°–75° C) yielded 0.90 g of 4-oxa-5α-cholestan-3-one, m.p. 114°–115° C, $[\alpha]_D^{24}$ +80.0° (*c*, 1.526 in chloroform) (lit., m.p. 116°–116.5° C, $[\alpha]_D$ +80.5° (1)), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 (s), 2870 (sh), 1740 (s), 1467 (m), 1448 (sh), 1392 (sh), 1383 (w), 1372 (sh), 1342 (w), 1186 (m), 1130 (w), 1077 (m), 1047 (s). The residue from the mother liquors (0.96 g) was dissolved in benzene and chromatographed on alumina (24 g). Elution with benzene (90 ml) and benzene–acetone (19:1, 175 ml) gave 0.46 g of material with melting range 78°–106° C. Several recrystallizations from dilute methanol yielded 4-oxa-5β-cholestan-3-one (0.11 g), m.p. 107°–107.5° C, $[\alpha]_D^{24}$ +18.1°.

5β-Hydroxy-3,5-seco-A-norcholestan-3-amide (III, R = NH_2)

A solution of 4-oxa-5α-cholestan-3-one (VI) (0.13 g) in methanol saturated with ammonia deposited plates (0.12 g) of 5β-hydroxy-3,5-seco-A-norcholestan-3-amide, which after recrystallizing from methanol had a melting point of 149°–155° C (in a bath preheated to 135° C), $[\alpha]_D^{23}$ +30.5° (*c*, 0.918 in 95% ethanol). Calc. for $C_{26}H_{47}O_2N$: C, 76.98; H, 11.68; N, 3.45%. Found: C, 76.41; H, 11.33; N, 3.10%. The compound decomposed at its melting point (which was unsharp and dependent on the rate of heating) to regenerate the lactone (VI), identified by melting point, mixed melting point, and infrared spectrum.

5α-Hydroxy-3,5-seco-A-norcholestan-3-amide (II, R = NH_2)

Prepared in the same manner from the cis lactone (V), the amide melted at 153°–159° C (bath preheated to 135° C), $[\alpha]_D^{23}$ +22.6° (*c*, 1.06 in 95% ethanol). Calc. for $C_{26}H_{47}O_2N$: N, 3.45%. Found: N, 3.21%.

5β-Hydroxy-3,5-seco-A-norcholestan-3-hydrazide (III, R = $NHNH_2$)

A solution of 4-oxa-5α-cholestan-3-one (0.25 g) and 95% hydrazine (0.25 ml) in methanol (5 ml) after 15 hours deposited needles of the hydrazide, m.p. 168°–170° C (bath preheated to 160° C), $[\alpha]_D^{24}$ +38.4° (*c*, 2.70 in chloroform). Calc. for $C_{26}H_{48}O_2N_2$: C, 74.25; H, 11.50; N, 6.66%. Found: C, 74.27; H, 11.56; N, 6.75%.

5α-Hydroxy-3,5-seco-A-norcholestan-3-hydrazide (III, R = $NHNH_2$)

Prepared in the same way from the cis lactone (V), the hydrazide melted at 178°–181° C (bath preheated to 160° C), $[\alpha]_D^{24}$ +22.0° (*c*, 0.910 in chloroform). Calc. for $C_{26}H_{48}O_2N_2$: C, 74.25; H, 11.50; N, 6.66%. Found: C, 74.02; H, 11.56; N, 6.63%.

3,5-Seco-A-norcholestan-3,5α-diol (VII)

A solution of 4-oxa-5β-cholestan-3-one (454 mg) in ether (10 ml) was added to a solution of lithium aluminum hydride (376 mg) in ether (25 ml) in 10 minutes with stirring. The mixture was refluxed for 2.5 hours, and then water (1.0 ml) and 10% aqueous sodium hydroxide (0.8 ml) were added dropwise with continued stirring. The precipitated inorganic salts were removed by filtration. Concentration of the ether filtrate and washings gave white flakes (396 mg), m.p. 121°–127° C, raised by several recrystallizations from aqueous methanol to a melting point of 130°–131° C, $[\alpha]_D^{28}$ +45.7 (*c*, 0.656 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3655 (w), 3360 (m), 2940 (s), 2870 (sh), 1468 (m), 1445 (m), 1380 (m), 1368 (sh), 1112 (w), 1053 (m), 1032 (sh), 995 (w), 960 (w), 929 (w), 917 (w). Calc. for $C_{26}H_{48}O_2$: C, 79.50; H, 12.32%. Found: C, 79.20; H, 12.14%.

4-Oxa-5β-cholestane (IX)

Benzene sulphonyl chloride (0.09 ml) was added over a period of 5 minutes to a refluxing solution of 3,5-seco-A-norcholestan-3,5α-diol (232 mg) in 2,6-lutidine (0.21 ml). The mixture was cooled, diluted with water (15 ml), and extracted with ether. Removal of the ether left a brownish semisolid residue (210 mg), which in petroleum ether (b.p. 35–60°, 100 ml) was passed through an alumina column (5.0 g, Woelm, activity III) to give waxy crystals (107 mg), m.p. 39–46°. Rechromatography on alumina (3.5 g, Woelm, activity I), followed by crystallization from methanol gave rosettes of white needles, m.p. 51°–52° C, $[\alpha]_D^{27}$ +3.8° (*c*, 2.10 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 (s), 2860 (sh), 2720 (w), 1466 (s), 1443 (s), 1377 (s), 1365 (sh), 1356 (sh), 1340 (w), 1328 (w), 1250 (w), 1204 (w), 1193 (w), 1165 (w), 1155 (w), 1113 (sh), 1098 (s), 1086 (s), 1067 (sh), 1026 (m), 982 (w), 958 (w), 937 (sh), 932 (w), 905 (w), 880 (m), 857 (w). Calc. for $C_{26}H_{46}O$: C, 83.36; H, 12.37%. Found: C, 83.23; H, 12.25%.

3,5-Seco-A-norcholestan-3,5β-diol (VIII)

A mixture of 4-oxa-5α-cholestan-3-one (0.50 g) and lithium aluminum hydride (0.06 g) in tetrahydrofuran (50 ml) was stirred for 4 hours at room temperature, and then treated with water (50 ml) and 1 *N* sulphuric acid (5.0 ml). Extraction with ether followed by removal of the ether gave a gelatinous material (0.39 g), m.p. 128°–131° C. One recrystallization from methanol raised the melting point to 134°–135° C, $[\alpha]_D^{18}$ +25.3° (*c*, 1.61 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 3655 (w), 3395 (m), 2940 (s), 2870 (sh), 1467 (m), 1446 (m), 1383 (m), 1366 (sh), 1338 (w), 1082 (w), 1051 (m), 1025 (m), 1000 (sh), 950 (w), 925 (w), 905 (w). Calc. for $C_{26}H_{48}O_2$: C, 79.50; H, 12.32%. Found: C, 79.38; H, 12.62%.

4-Oxa-5α-cholestane (X)

Benzene sulphonyl chloride (0.19 ml) was added over 5 minutes to a refluxing solution of 3,5-seco-A-norcholestan-3,5β-diol (0.51 g) in absolute pyridine (0.45 ml). The solution was refluxed for another 5 minutes, cooled, diluted with water (50 ml), and extracted with ether. The ether extracts were washed with dilute sulphuric acid and then with water, dried (Na_2SO_4), and concentrated to give a crude brownish product (0.33 g). After several recrystallizations from methanol this had a melting point of 89°–90° C, $[\alpha]_D^{23}$ +42.3° (*c*, 1.33 in chloroform), $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 (s), 2860 (sh), 2720 (w), 1465 (s), 1445 (s), 1383 (s), 1377 (sh), 1367 (sh), 1267 (w), 1193 (w), 1169 (w), 1154 (w), 1122 (m), 1101 (s), 1086 (s), 1040 (m), 1027 (w), 978 (w), 954 (w), 928 (m), 909 (w), 876 (w), 854 (w). Calc. for $C_{26}H_{48}O$: C, 83.36; H, 12.37%. Found: C, 82.96; H, 12.29%.

CO-ORDINATION COMPLEXES OF TITANIUM (IV) HALIDES

1. PREPARATION AND INFRARED SPECTRA OF THE COMPLEXES OF TITANIUM (IV) HALIDES WITH N,N-DIMETHYL AND N,N-DIPHENYL FORMAMIDE[1]

JACQUES ARCHAMBAULT[2] AND ROLAND RIVEST

ABSTRACT

Co-ordination complexes of titanium (IV) halides with N,N-dimethyl formamide and N,N-diphenyl formamide have been prepared and their infrared spectra have been measured. In all these complexes, there is a metal-to-oxygen bond as evidenced in the infrared spectra by a negative shift of the carbonyl stretching frequency and a positive shift of the CN stretching frequency. The relative values of these shifts and the ease of decomposition observed for these complexes indicate that their stability decreases with decreasing the electronegativity of the halide bonded to titanium (IV).

In the complexes of N,N-diphenyl formamide, the effect of the conjugated phenyl groups has been observed. In these complexes the decrease of double-bond character of the carbonyl group and the increase of double-bond character of the CN group, resulting from the metal-to-oxygen co-ordination bond, are quite larger than in the complexes of N,N-dimethyl formamide.

INTRODUCTION

When a Lewis acid, as an example MX_4, is a covalent molecule, its behavior is analogous to that of a metallic ion M^{+4} of which the co-ordination sphere is partially filled. The acidity of the molecule depends upon the tendency of the ion to complete its co-ordination sphere. The nature of the negative ion X^- affects the acidity of the central metallic ion. If X^- increases in size and decreases in electronegativity, it will be more polarized by the central ion and will decrease the affinity of this ion for an additional electron pair.

In the case of the halides of titanium (IV), the equation of Hannay and Smith (1) and the electronegativity scale of Pauling (2) indicate a bonding predominantly ionic for titanium tetrafluoride and predominantly covalent for the other three halides. The acidity of these covalent halides decreases from the chloride to the iodide, the partial ionic character of the latter being less than 20%.

In a previous paper (3) the formation of complexes of titanium tetrachloride with formamide and N,N-dimethyl formamide was explained by a co-ordination through the oxygen of the amide. In order to see how the difference in covalent character between the tetrahalides of titanium would influence the co-ordination of amides to titanium (IV), we have extended our investigation to titanium tetrabromide and titanium tetraiodide.

If a donor molecule contains some electrons related to the donor atom by a conjugated system, some type of interactions between these electrons and the donor atom should be noticeable when the latter is used in co-ordination. We have then prepared the complexes of N,N-diphenyl formamide and we have observed that the electrons of the phenyl groups have a strong influence on the co-ordination bond.

EXPERIMENTAL

Materials and Manipulations

Reagent grade titanium tetrachloride was purified by the method of Gilchrist (4), redistilled, and the medium fraction was used for our experiments. Titanium tetrabromide, supplied by E. D. Mackay, New York, has been distilled under reduced pressure.

[1]*Manuscript received March 28, 1960.*
Contribution from the Department of Chemistry, University of Montreal, Montreal, Que.
[2]*Fellow of the Office Provincial des Recherches Scientifiques de la Province de Québec. Present address: Department of Chemistry, University of Florida, Gainesville, Florida.*

The medium fraction, distilling at 100° C under 10 mm Hg, had the following composition: Ti, 13.04%; Br, 85.80%. The calculated values for pure $TiBr_4$ are: Ti, 13.03%; Br, 86.97%.

Titanium tetraiodide of E. D. Mackay Co., New York, was contaminated by free iodine. The material was first heated at 100° C under vacuum to sublimate the iodine. It was then distilled at 170–175° C under 2 mm Hg. The medium fraction had the following composition: Ti, 8.71%; I, 90.1%. The calculated value for pure TiI_4 are Ti, 8.62%; I, 91.38%.

Reagent grade of N,N-dimethyl formamide has been redistilled and the medium fraction used for our experiments was kept over dry sodium sulphate.

Reagent grade of N,N-diphenyl formamide was dried under vacuum and kept in a desiccator containing phosphorus pentoxide.

The solvents used for our experiments were anhydrous. Their water content, checked by the Karl Fischer method, was only a few parts per million.

The water-sensitive complexes were prepared and handled in a dry box continuously flushed with dry nitrogen. The dry box was provided with electricity and vacuum so that all the operations could be performed in an atmosphere of very low humidity content. Under these experimental conditions, there is always a certain amount of hydrolysis of the halide, as the results of elementary analyses indicate.

The methods of analysis for chlorine, titanium, carbon, and hydrogen were described previously (3). Bromine and iodine determinations were made by the volumetric method of Volhard. Nitrogen was determined by the Kjeldahl method or by the micro-Dumas method as specified by a "k" or a "d" in each case.

The setup used for the preparation of complexes from solutions of the reactants was identical with the one used in previous experiments (3). For the preparation of the iodide complex, solid TiI_4 was added to the amide solution.

The spectroscopic measurements were carried out on a Perkin–Elmer infrared spectrophotometer, model 21, using a sodium chloride prism. The spectra of the complexes were determined in solutions of suitable solvents.

The System $TiCl_4$, $2HCON(C_6H_5)_2$

Twenty-five milliliters of an 8.5% solution of titanium tetrachloride in carbon tetrachloride was added dropwise to 45 ml of a 13% solution of N,N-diphenyl formamide in the same solvent. There was no precipitation at the beginning, but precipitation occurred when 80% of the titanium tetrachloride was added, leading to an orange-yellow powder, melting at 119–121° C. The powder was washed many times with pure carbon tetrachloride on a fritted glass filter, and then dried *in vacuo*. This powder is very slightly soluble in carbon tetrachloride, but is soluble in aromatic hydrocarbons and in halogen derivatives of aliphatic hydrocarbons. The analysis of this adduct led to the following results.

	% Ti	% Cl	% N	% C	% H	Ti/Cl
Calc. for $TiCl_4 . 2HCON—(C_6H_5)_2$	8.20	24.28	4.8	53.45	3.80	1/4.00
Found	8.05	22.39	4.7d	54.74	3.73	1/3.76

The System $TiBr_4$—$HCON(C_6H_5)_2$

Fifteen milliliters of a 13% solution of diphenyl formamide in carbon tetrachloride was added dropwise to 20 ml of a 10% solution of titanium tetrabromide in the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

solvent. The adduct obtained was a red oil. By evaporation of the solvent the compound became a solid of resinous appearance. It was washed many times with normal hexane and dried *in vacuo*. The final compound was a red powder which decomposed at 60–65° C. The elementary analysis gave the following results.

	% Ti	% Br	% N	% C	% H	Ti/Br
Calc. for $TiBr_4.2HCON(C_6H_5)_2$	6.29	41.95	3.67	40.97	2.91	1/4.00
Found	6.91	40.40	3.3d	36.21	3.02	1/3.50

The System $TiBr_4.2HCON(CH_3)_2$

Thirty milliliters of a 20% solution of $TiBr_4$ in carbon tetrachloride was added dropwise to 30 ml of a 10% solution of the amide. A red oil was obtained at the beginning of the reaction and after agitation for many hours a red solid precipitated. Its melting point was 178–181° C. The elementary analyses led to the following results.

	% Ti	% Br	% N	% C	% H	Ti/Br
Calc. for $TiBr_4.2HCON(CH_3)_2$	9.32	62.22	5.45	14.03	2.75	1/4.00
Found	9.32	60.3	5.04k 5.73d	14.03	3.76	1/3.87

The System TiI_4—HCON—$(CH_3)_2$

Powdered titanium tetraiodide was added by small quantities to a solution of the amide in carbon tetrachloride. A deep brown solution was first observed and precipitation occurred. The brown powder so obtained was washed with carbon tetrachloride to remove the excess of amide. The powder was extremely unstable even in the absence of moisture. It melted at room temperature, becoming like a paste after a few days.

Two series of experiments were performed between the iodide and the solutions of the amide where the ratio of titanium tetraiodide to the amide was 1 to 3 and 1 to 4,2 respectively. In a third experiment, the iodide was added to a 10-fold excess of the pure amide, without solvent. In each experiment, the appearance of the compound obtained was the same but the analytical results were quite different.

	% Ti	% I^-	% T_2	Ti/I total
Expt. 1, found	5.76	56.8±0.5	1.5	1/3.9
Expt. 2, found	5.28	59.9±0.5	2.1	1/4.2
Calc. for $TiI_4.4HCON(CH_3)_2$	5.65	59.7	0	1/4.00
Expt. 3, found	4.21	42.	2.5	1/4
Calc. for $TiI_4.8HCON(CH_3)_2$	4.2	44.5	0	1/4

These analytical data are not necessarily indicating a higher co-ordination number for Ti(IV) but might be the result of a solvation effect of the complex $TiI_4.2HCON(CH_3)_2$ with the pure amide.

In a previous paper (5), we have demonstrated the existence of a compound of the following composition $TiCl_3OC_4H_9.6C_4H_9OH$. Fowles (6) also reported the formation of complexes of titanium halides with ammonia where the molecular formula was $TiX_4.8NH_3$. As explained by this author, it is very unlikely that the co-ordination number of titanium (IV) is higher than six but it is more probable that the extra molecules of

For personal use only.

ligands are held in a secondary sphere of influence rather like the ammoniates formed by cobaltammine-type ion (7). The presence of free iodine in these compounds could be related to the formation of trivalent titanium. Fowles (8) has proposed that mechanism to explain the formation of iodine in the thermal decomposition of $TiI_4.6NH_3$.

Infrared Spectra and Structure Discussion

The Complexes of N,N-*Dimethyl Formamide*

The absorption maxima observed for the complexes of the titanium halides with N,N-dimethyl formamide are listed in Table I and illustrated in Fig. 1. The carbonyl

stretching frequency is shown to be lowered by 37, 34, and 27 cm^{-1} in the spectra of the chloride, of the bromide, and of the iodide complex respectively. Another band tentatively assigned to the C—N stretching vibration is shifted to higher frequencies by about the same value. As it was explained in a previous paper (3), no data are available concerning the assignment of the infrared absorption bands of N,N-dimethyl formamide. According to the following skeleton,

some authors consider the C—N vibrations in disubstitute amides as being confused with the C=O stretching band at about 1650 cm^{-1}. Mizushima and others (9) assigned the absorption bands at 1160 and 1040 cm^{-1} of N-methyl acetamide to the C—N and C′—N vibrations respectively. More recently, De Graff and Sutherland (10) proposed that a band at 956 cm^{-1} of N-methyl acetamide be assigned to C′—N stretching vibration. It seemed reasonable to us that a positive frequency shift of the band located at 1093 cm^{-1} when the amide co-ordinates to Ti(IV) was an argument in favor of its assignment to the C—N stretching vibration. The frequency shifts of the carbonyl band and of the C—N band are an indication of co-ordination through the oxygen atom. The shifts observed seem to decrease from the chloride complex to the iodide complex. If the magnitude of the shift can be related to the stability of the co-ordinated bond, the observed trend is in good agreement with the temperature of decomposition, which are 220–225° C for the chloride complex, 178–181° C for the bromide complex, and room

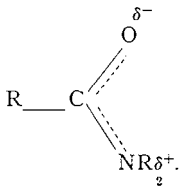
temperature for the iodide complex. This behavior is also in agreement with the decreasing electronegativities and increasing steric hindrance of the halogens from chlorine to iodine.

It is noticeable that the infrared spectrum of the iodide complex showed the carbonyl frequency and the CN frequency of the free amide. This is an indication of the presence of some unco-ordinated amide associated with the complex.



The shifts of the carbonyl frequencies in the spectra of these complexes are quite smaller than those observed for other similar complexes. We prepared the complex $TiCl_4.2CH_3COCH_3$ and observed a shift of 47 cm^{-1} when the spectrum was measured in methylene chloride solution. The small shifts observed with amide complexes can be explained by the fact that, in amides, one is dealing with a conjugated system.

1305 w	1373 s	1373 s	CN vibrations
1304 w			
1137 w			

A carbonyl frequency shift of 66 cm^{-1} was measured in the spectra of the halide complexes. Furthermore, a very broad band with four maxima at 1344, 1305, 1304, and 1260 cm^{-1}, which is in the region usually assigned to the CN stretching vibrations, is replaced in the complexes by a narrow band at 1373 cm^{-1}. If one takes 1310 cm^{-1} as the center of the broad band, a positive shift of about 60 cm^{-1} is calculated for the CN vibrations. These shifts are twice as large as those observed in the spectra of similar complexes of N,N-dimethyl formamide. The proximity of the phenyl groups on the nitrogen of the amide seems to increase the basic character of the carbonyl. This is evidenced not only by the increase of the shifts but also by the perturbations of the aromatic ring vibrations.

Susz (11) has mentioned that, for the complexes of benzophenone and acetophenone with Lewis acids, coupling of the carbonyl and phenyl vibrations appears to be appreciable, the phenyl band at 1580 cm^{-1} being considerably enhanced. An increased resonance involving electrons of the carbonyl and the phenyl groups would likely account for this behavior. The electronic pull of a Lewis acid has the same effect as the presence on the

aromatic ring of a nucleophilic parasubstituent. The spectra of N,N-diphenyl formamide complexes exhibit a similar coupling of the carbonyl band with a reinforced phenyl band, appearing at 1580–1582 cm^{-1} instead of 1602 cm^{-1} in the pure amide. In this case, the aromatic ring is not adjacent to the carbonyl, but the electron delocalization induced by the Lewis acid is likely to be transmitted through the conjugated N—C—O skeleton. This statement is further supported by Randall (12) and Bellamy (13), who consider the appearance of a band at 1580 cm^{-1} as an indication of a conjugated phenyl.

ACKNOWLEDGMENTS

The authors are indebted to the National Research Council of Canada for its financial assistance (R. R.) and to l'Office de Recherches Scientifiques de la Province de Québec, for a fellowship to one of us (J. A.). They are also grateful to Prof. Camille Sandorfy for very useful discussions on the infrared spectra measured.

RÉSUMÉ

On a préparé des complexes de coordination des halogénures de titane (IV) avec la N,N-diméthyl formamide et la N,N-diphenyl formamide. Les spectres infrarouges comparés des amides pures et des complexes nous ont permis de prouver que l'effet bathochrome de la fréquence carbonyle est fonction de l'halogène lié au titane (IV) et aussi de la nature des substituants sur l'azote de la molécule de l'amide. Tous les composés préparés sont expliqués en supposant que la coordination au titane se fait par l'oxygène de l'amide.

THE ABSTRACTION OF HYDROGEN ATOMS FROM AMINES AND RELATED COMPOUNDS[1]

R. K. BRINTON

ABSTRACT

The reaction of methyl radicals with a group of amines and amine-like compounds has been investigated in the temperature range 125° to 157° C. The abstraction activation energies of hydrogen atoms from these compounds, the corresponding pre-exponential factors, and the actual reaction rates indicate that the N—H hydrogen atoms are more labile than the C—H atoms in these compounds.

INTRODUCTION

The abstraction of hydrogen atoms by methyl radicals from various compounds has been studied in detail by Trotman-Dickenson and Steacie (1). In the case of those compounds with hydrogen atoms attached only to the carbon atom skeleton, they were able to correlate the abstraction activation energies, pre-exponential factors, and actual rates of reaction with the structure of the molecules. Compounds such as amines and alcohols having hydrogen atoms attached to nitrogen or oxygen as well as carbon atoms were found more difficult to evaluate, and they made no attempt to assess the effect of structural factors or the relative importance of the N—H and O—H hydrogen as compared with the C—H hydrogen in the over-all contribution to methane formation.

A little more information on this problem was furnished by the work of Brinton and Volman (2), who reported the activation energy for the methyl radical abstraction of hydrogen from ethylenimine to be 4.8 kcal/mole, a value much lower than any C—H type abstraction found by Trotman-Dickenson and Steacie. Brinton and Volman felt that these data indicated a greater lability of N—H hydrogen than C—H hydrogen in this compound. However, their tacit assumption that the N—H hydrogen was the active species in the abstraction was not founded on any experimental evidence.

Recently Kozak and Gesser (3) investigated the photolysis of triethylamine. In the course of the study they determined the activation energies of methane formation in the reaction of methyl radicals with trimethylamine, triethylamine, and diethylamine by a technique similar to that of Trotman-Dickenson and Steacie. The values obtained, 8.0, 5.3, and 5.7 kcal/mole respectively, led them to conclude that the hydrogen attached to carbon was being abstracted in all of these compounds, and that this was probably the case for ethylenimine also.

Confirmation of Kozak and Gesser's mechanism is to be found in the course of a number of condensations between the α-carbon of an amine and a 1-olefin occurring in the liquid phase (4). These reactions are induced by peroxides or light so a radical process may be inferred, and it is probable that an abstraction similar to that postulated by Kozak and Gesser is responsible for the type of products found.

The present study was initiated in an attempt to clarify the kinetics of the reaction of methyl radicals with amines. It was hoped that if a clear difference between the ease of hydrogen abstraction from carbon and nitrogen atoms does indeed exist, sufficient data could be obtained so predictions could be unequivocally made concerning the course of the abstraction reactions for amine-type compounds.

EXPERIMENTAL

The apparatus and experimental technique have been described previously (5). In the present study the methane and ethane fractions were separated at −215° (solid nitrogen) and −185° (liquid oxygen). Mass spectrometric analyses were made of both fractions. The −185° fraction was in all cases more than 99% ethane. The −215° fraction was 70–99% methane, depending on the sample size. Very small samples (<1 μ mole) contained appreciable amounts of nitrogen produced from the residual air left in the rather large (3 liters) reaction system.

Di-*t*-butyl peroxide was kindly supplied by the Shell Development Co.; it was purified by bulb-to-bulb distillation *in vacuo*. A center fraction was used in the pyrolysis experiments.

Methylamine and ethylamine were generated from the hydrochloride salts with saturated KOH solution. The amines were dried over KOH pellets, degassed, and distilled *in vacuo*.

Dimethylamine, diethylamine, and diisopropylamine were Eastman White Label products. They were used without further purification except for the degassing procedure.

t-Butyl ethylenimine was supplied by Dr. Albert Bottini (6).

t-Butyl acetaldimine was prepared according to the method of Hurwitz (7) from *t*-butylamine and acetaldehyde. The fraction of boiling range 78.0–78.1° (uncorr.) from a 20-plate helice column was collected for the pyrolyses.

The acetaldazine sample used was that employed in previously described work from this laboratory (8).

The pyrolyses were carried out at two temperatures: 156.73° C at which a 4-minute reaction period was used, and 124.82° where 2 to 4 hours were required for sufficient reaction. The DTBP concentration was about the same in all experiments, 4.6×10^{-7} mole cm^{-3} (ca. 11 mm). The pressure of the added compound was adjusted, insofar as it was possible, to produce comparable and significant amounts of methane and ethane so that the analyses of these gases were of good precision. Approximately 3.5% of the DTBP was decomposed at 156.73° and from 2 to 4% at 124.82°. In most trials the percentage of the added compound reacting was from 0.3 to 2%. In two experiments (dimethylamine and diethylamine at 124.82°) the percentage reacted was about 6%. The average concentration of the added compound was used in all calculations.

RESULTS AND DISCUSSION

The pyrolysis of DTBP has been frequently used as a source of methyl radicals in this laboratory (2, 5, 9, 10, 11). The important reactions are:

$$(CH_3)_3COOC(CH_3)_3 \xrightarrow{k_1} 2(CH_3)_3CO \qquad [1]$$

$$(CH_3)_3CO \xrightarrow{k_2} CH_3COCH_3 + CH_3 \qquad [2]$$

$$2CH_3 \xrightarrow{k_3} C_2H_6 \qquad [3]$$

$$CH_3 + (CH_3)_3COOC(CH_3)_3 \xrightarrow{k_4} CH_4 + (CH_3)_3COO(CH_3)_2CH_2 \qquad [4]$$

If another hydrogen-containing source, RH, is present additional methane is formed by the process

$$CH_3 + RH \xrightarrow{k_5} CH_4 + R. \qquad [5]$$

In the present study the total rate of CH_4 production, $R_{CH_4}^{total}$, the summation of [5] and [4], was corrected for the CH_4 formed by [4] in order to evaluate the rate of CH_4 formed in process [5] only, R_{CH_4}. This correction was made by the following formula:

$$R_{CH_4} = R_{CH_4}^{total} - R_{CH_4}^{DTBP}[R_{C_2H_6}/R_{C_2H_6}^{DTBP}]^{1/2}.$$

Here $R_{CH_4}^{DTBP}$ and $R_{C_2H_6}^{DTBP}$ are the rates of CH_4 and C_2H_6 production in a pyrolysis containing only DTBP. The quantity $R_{C_2H_6}$ is the rate of C_2H_6 production in a pyrolysis containing RH as an additive. As the concentration of DTBP was about identical in all trials, the ratio of rates of methane formation by process [4] of any two pyrolyses would be expected to be equal to the half power of the ratio of the corresponding rates of ethane formation in the same two experiments. In most of the experiments the correction calculated from $R_{CH_4}^{DTBP}$ was relatively small, 3–15% of the $R_{total}^{CH_4}$. However, the *t*-butyl acetaldimine reacted so slowly that the corrections in these pyrolyses were approximately equal to the methane formed by the hydrogen abstraction from acetaldimine itself.

The values of $R_{CH_4}/R_{C_2H_6}^{1/2}$ [M] = $k_5/k_3^{1/2}$ have been calculated for the listed concentration, [M], of various amine and amine-like additives. These quantities as well as the activation energies, E_5, and the log A_5 are listed in Table I. Gomer and Kistiakowsky's (12) values of $E_3 = 0$ and $A_3 = 4.5\times10^{13}$ for the combination of methyl radicals were used to calculate the individual E_5 and log A_5 in the table. For most compounds, determinations were made at two temperatures only. The previous studies with ethylenimine (2) showed the Arrhenius plot to be a straight line at least over the rather limited temperature range imposed by the use of DTBP as a methyl radical source. Pyrolyses using dimethylamine and diethylamine were made at 138.6° C as well as for the two temperatures shown in Table I. The values of $k_5/k_3^{1/2}$, 12.05 and 15.31 respectively, gave good straight lines in the Arrhenius plots of these two compounds.

The data of Table I give strong indication that the N—H hydrogen is active in the formation of methane in the methyl radical abstraction process rather than the hydrogen on the carbon alpha to the nitrogen. This evidence is most easily demonstrated by considering certain groups of Table I separately.

TABLE I

The reaction of methyl radicals with amines and related compounds

	124.8° C		156.73° C			
Reactant (M)	[M]×10⁷	$R_{CH_4}/R_{C_2H_6}^{1/2}$[M]	[M]×10⁷	$R_{CH_4}/R_{C_2H_6}^{1/2}$[M]	E_5, kcal	log A_5
Methylamine	2.73	0.944	2.73	1.92	7.6	10.9

t-Butyl ethylenimine	8.38	0.14	10.78	0.26	6.6[b]	9.6[b]
t-Butyl acetaldimine	8.62	1.09	10.66	2.26	7.8	11.1
Acetaldazine	5.89	2.26	5.33	3.99	6.1	10.5

NOTE: All rates and concentrations are expressed in units of moles, cm³, and sec.

[a]Data on ethylenimine are from ref. 2.

[b]These calculated values are of low accuracy because of the very low R_{CH_4} and the relatively large correction, $R_{CH_4}^{DTBP}$, used in the R_{CH_4} calculation.

1. Dimethylamine (DMA), *Diethylamine* (DEA), *and Diisopropylamine* (DIA)

These compounds, all secondary amines, have quite different structures of the two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

aliphatic side chains. All six of the aliphatic group hydrogens of DMA are on primary carbons, four of the 10 hydrogens of DEA are on secondary carbons, and two of the 14 hydrogens of DIA are on tertiary carbons. Table I indicates that all three of these compounds have very similar abstraction activation energies, E_5, and pre-exponential factors A_5. Trotman-Dickenson and Steacie (1) and Trotman-Dickenson (13) found the analogous reactions in hydrocarbon systems to be quite sensitive to the type of carbon containing the abstractable hydrogen. If the side-chain hydrogens were being abstracted from the amines, it would be expected that the three amines being considered would show a similar trend, say to the analogous series ethane, *n*-butane, and 2,3-dimethyl butane, which have respectively the abstraction energies 10.4, 8.3, and 6.9 kcal/mole (1). In addition, if DMA is assumed to have six abstractable hydrogen atoms (primary), DEA four (secondary), and DIA two (tertiary) the actual values of $R_{CH_4}/R_{C_2H_6}$ [M] at 124.8° per "active" hydrogen are in the ratios of 1:1.9:3.0. The corresponding ratios for ethane, *n*-butane, and 2,3-dimethyl butane found by Trotman-Dickenson and Steacie (1) are 1:7.5:51.7 at 182° C. Thus neither the abstraction activation energies nor the rates of abstraction indicate that the side-chain hydrogens of the amines are participating in the abstraction process. It must be inferred rather that the amine hydrogen is active in the reaction and the similarity of activation energy, pre-exponential factors, and the actual rates of abstraction may be attributed to their being secondary amines.

2. Ethylenimine and t-Butyl Ethylenimine

The abstraction activation energy for ethylenimine given previously (2) is considerably lower than others reported for H-atom abstraction by methyl radical from organic compounds. In this former investigation it was assumed that the N—H bond was the active participant in the reaction. It is proposed in the present study to test the validity of such a mechanism by reacting the methyl radicals with *t*-butyl ethylenimine wherein the N—H hydrogen has been replaced by the *t*-butyl group. Table I shows the rate of abstraction from the *t*-butyl ethylenimine to be less than 10% of the analogous reaction from ethylenimine itself at 124.8°. Inasmuch as the ring hydrogens are available to an equal degree from both these compounds, a strong argument can be made to eliminate these H atoms as sources of methane production and to establish the N—H hydrogen as the principal reactant with the methyl radicals. The activation energy and pre-exponential factor for *t*-butyl ethylenimine are shown bracketed in Table I. The very low rate of methane production for this compound at both experimental temperatures introduces considerable error into these calculated quantities. They should be considered as approximations only and no significance can be attributed to their values relative to the values of the corresponding constants for ethylenimine.

3. t-Butyl Acetaldimine and Acetaldazine

t-Butyl acetaldimine $(CH_3)_3C—N{=}CH—CH_3$ and acetaldazine $CH_3CH{=}N—N{=}CHCH_3$ have been included to show the behavior of compounds which do not have N—H hydrogens available. Again it is not certain which hydrogen is entering into reaction, those of the terminal CH_3 group or the H atoms on the carbon of N=C bond. However, it is quite significant that the rate at 124.8° for the acetaldazine abstraction is almost exactly twice that for *t*-butyl acetaldimine. Two hydrogens on the C=N carbon and six hydrogens on CH_3 groups are available in acetaldazine, and one hydrogen on C=N carbon and 12 hydrogens on CH_3 groups are contained on the *t*-butyl acetaldimine. Thus the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

abstraction rates of the two compounds are compatible with the interpretation that the C═N carbon atom furnishes the hydrogen for the abstraction although the evidence is not extensive enough to justify a definite conclusion.

4. Methylamine and Ethylamine

The data in Table I for these two compounds do not furnish further confirmation for the thesis that the N—H hydrogen is active in the abstraction process. On the other hand the evidence is not necessarily contradictory. The similarity in the abstraction activation energies does tend to support the idea of N—H hydrogen abstraction but it is not clear why the abstraction rate at 124.8° for ethylamine is about three times that of methylamine.

The conclusions reached in the preceding discussion as well as some of the experimentally determined data differ markedly from those of Kozak and Gesser's study (3). Their conclusion that low and similar abstraction energies for triethylamine and diethylamine probably indicate a labile C—H rather than N—H hydrogen is reasonable on basis of this evidence alone. However, their value for the abstraction constant of diethylamine ($\log A = 10.9$,* $E = 5.7$) is somewhat different from that shown in Table I ($\log A = 11.8$, $E = 7.2$). Reasons for this difference are speculative as the experimental methods used in both investigations have proved to be reliable in a large number of previously tested cases. It should be pointed out that the data of Trotman-Dickenson (13) for methylamine ($\log A = 11.3$, $E = 8.4$) and dimethylamine ($\log A = 11.3$, $E = 7.2$) are in good agreement with the corresponding quantities shown in Table I, and in addition their value for trimethylamine ($\log A = 11.8$, $E = 8.8$) agrees reasonably well with Kozak and Gesser's result ($\log A = 12.6$, $E = 8.0$) for this same compound. Thus all three studies show conformity between at least some compounds that were mutually tested.

A possible clue to the wide difference in abstraction activation energies for diethylamine between the present study and Kozak and Gesser's work may be seen in their Arrhenius plots for diethylamine and triethylamine. In both curves there is a pronounced falling off in the values of $k_{abs}/k_{comb}^{1/2}$ at the higher temperature. Their explanation for this curvature, the growing importance of the reaction,

$$CH_3 + (C_2H_5)_2NH \rightarrow C_2H_5NHCH_2 + C_2H_6, \qquad [6]$$

as temperature is increased is compatible with the experimental evidence. However, their assumption that the straight lines drawn through the limited low-temperature points truly represent the behavior of reaction [5] only is open to considerable doubt. It seems reasonable that the effect of reaction [6] is active to a degree, at least, over the whole temperature range and that the slopes of the Arrhenius lines should be somewhat steeper, thereby yielding higher activation energies for triethylamine and diethylamine. Whether both curves would be affected in a similar fashion is not predictable, but it is not unlikely that the relative magnitude of the two activation energies might shift so that different conclusions could be drawn concerning the role of the various hydrogens in the abstraction process.

The argument in the previous paragraph would apply equally as well to the present study if reaction [6] were taking place even to a limited extent in the lower temperature range. As the total rate of ethane production would then be the sum of processes [3] and

*The values calculated by Kozak and Gesser for this corresponding quantity for diethylamine, $A_{19}/A_8^{1/2} = 9\times10^{-5}$ is in error. The value should be 1.4×10^{-8} molecule$^{-1/2}$ cm$^{3/2}$ sec$^{-1/2}$. Similarly their value of $A_{11}/A_8^{1/2}$ for triethylamine shown as 3×10^{-5} should be 6.8×10^{-9}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[6], the error made by using the total $R_{C_2H_6}$ in place of $R_{C_2H_6}$ by [3] would depend on the relative rates of the two ethane-producing reactions. It can be shown that

$$\frac{R_{CH_4}}{R_{C_2H_6}^{1/2}[M]} = \frac{k_5}{k_3^{1/2}}\left[1+\frac{k_6[M]}{k_3[CH_3]}\right]^{-1/2}.$$

Thus the effect of process [6] on the value determined for $k_5/k_3^{1/2}$ will be minimized by low concentrations of additive, [M], as well as high methyl radical concentrations, $[CH_3]$.

It is significant that there is appreciable difference between the magnitude of both these variables in the two studies under comparison. The diethylamine concentrations used by Kozak and Gesser in their photolyses (12.4×10^{-7} to 16.9×10^{-7} mole cm^{-3}) were about 10 times those used in the DTBP pyrolyses. Clearly in this case the effect of the additive term in the above expression will be only about 1/10th as great for this study as for Kozak and Gesser's work.

The consequence of using an appreciably higher methyl radical steady-state concentration at 156.7° in the peroxide work than in the photolyses is not so easily evaluated. In the present work on diethylamine $R_{C_2H_6}$ is approximately 3.0×10^{-12} and 115×10^{-12} mole cm^{-3} sec^{-1} at 124.8° and 156.7° respectively. The lower temperature rate is about comparable to that of Kozak and Gesser's 123° experiment (2.5×10^{-12}), but the higher temperature rate is about 50 times the rate of their 155° photolysis (2.1×10^{-12}). From the above expression it may be seen that for a constant [M] the activation energy measured by the change in $R_{CH_4}/R_{C_2H_6}^{1/2}$ [M] as a function of temperature will be exactly that of E_5 if $k_6/[CH_3]$ is maintained constant over the range of temperature variation. Kozak and Gesser's Arrhenius curves for diethylamine and triethylamine indicate that E_6 is considerably higher than E_5, perhaps of the order of 15 kcal/mole, and therefore $k_6(156.7°)/k_6(124.8°) \cong 4$. In order for $k_6/[CH_3]$ to maintain its constancy the ratio $R_{C_2H_6}(156.7°)/R_{C_2H_6}(124.8°)$ must be of the order of 16. If this estimate of E_6 is valid and if $R_{C_2H_6}^{1/2}$ may be taken as being proportional to $[CH_3]$, the experimental technique of Kozak and Gesser in which $[CH_3]$ was about constant would yield a value somewhat too small for E_5 while that of the present work would give too large an activation energy. The magnitude of the error of course depends on the size of the additive term within the bracketed expression of the above formula. Determination of the absolute magnitude of the effect of [6] on ethane formation and thus on the value of E_5 is perhaps possible by a detailed study of diethylamine variation at constant temperature in the case of the DTBP pyrolyses. In a like manner investigation of the effect of intensity and diethylamine variation at constant temperature for the photolyses of Kozak and Gesser should produce similar information.

ACKNOWLEDGMENTS

The author wishes to thank the National Science Foundation for financial assistance in carrying out this study. He is also indebted to Dr. Amos Newton and Mr. Aldo Sciamanna of the Lawrence Radiation Laboratory, University of California, Berkeley, California, for some of the mass spectrometric analyses.

INTERACTION OF TWO PARALLEL PLATES IN A BINARY ASYMMETRICAL ELECTROLYTE

I. UNIVALENT COAGULATING ION[1]

S. LEVINE[2] AND G. M. BELL[3]

ABSTRACT

The interaction of two charged plate-like parallel colloidal particles immersed in a binary asymmetrical electrolyte of valency type $1-m$, where the coagulating ion is univalent, is considered. Applying the Derjaguin–Verwey–Overbeek theory of colloid stability, it is assumed that the plate surface potential is independent of the plate separation. The Stern modification in the absence of specific adsorption of the coagulating ion is also considered. It is demonstrated that as the valency m of the non-coagulating ion increases, the concentration of the coagulating ion at flocculation increases somewhat, but not to the extent predicted by Ostwald's activity coefficient rule. Application of the Stern theory reduces this trend and may even produce a decrease, with increasing m, in the coagulating ion concentration, particularly for a 1–2 electrolyte.

1. INTRODUCTION

According to the Schulze–Hardy rule, the concentration of a binary electrolyte required to flocculate a hydrophobic sol depends mainly on the valency of the ion whose charge is opposite in sign to that on the particles and only slightly on the valency of the ion with a charge of the same sign as that on the particles. The stability theory of Derjaguin and Landau (1) and Verwey and Overbeek (2) reproduces approximately the experimental dependence of the limiting concentration for coagulation on the valency of the flocculating (oppositely charged) ion. However, no systematic theoretical investigation of the corresponding (secondary) dependence on the valency of the like-charged ion has been made and it is the purpose of this paper to determine the relationship which is derived from the above theory for the case of a univalent flocculating ion. According to Ostwald and his collaborators (3), the coagulation concentrations for a number of hydrophobic sols are described approximately by Ostwald's empirical rule, which states that the electrolyte in the dispersion medium flocculates at the same value for the coefficient of activity of the dominating (coagulating) counter-ion. If the Debye–Huckel theory of strong electrolytes at dilute concentrations is applied to a binary electrolyte whose ion types 1 and 2 have densities n_1^0 and n_2^0 and valencies z_1 and z_2 respectively, then Ostwald's rule states that for a given colloidal system, the activity coefficient f_1 of the coagulating ion (which is assumed to be of type 1) is given by

$$[1.1] \qquad \frac{1}{\sqrt{m}} \log f_1 = -z_1^2 \left[\frac{\pi e^6}{(\epsilon k T)^3} \frac{(n_1^0 z_1^2 + n_2^0 z_2^2)}{m} \right]^{\frac{1}{2}} = \text{constant},$$

where e is the electronic charge, ϵ the dielectric constant of the electrolyte medium, k Boltzmann's constant, T the absolute temperature, and m the number of ions of type 1 in a molecule. For a univalent coagulating ion

$$[1.2] \qquad m = -(z_2/z_1) = n_1^0/n_2^0,$$

making use of the condition of electrical neutrality

$$n_1^0 z_1 + n_2^0 z_2 = 0. \qquad [1.3]$$

The factor $1/\sqrt{m}$ in [1.1] does not occur in the theory of electrolytes so that Ostwald does not employ the usual definition of activity coefficient. The introduction of this factor in colloids emphasizes the significance of the coagulating ion concentration. It follows from Ostwald's rule that for an electrolyte series of valency types $z_1 - z_2$ where $z_1 = 1$ and z_2 takes the values $-1, -2, -3, \ldots$, the quantity $n_1^0(1+m)/m$ should be a constant at the flocculating electrolyte concentration. Various objections, however, have been made to Ostwald's activity coefficient rule. Weiser (4) has commented on the wide spread in the experimental results over which Ostwald averaged and Weiser and Milligan (5) have demonstrated its limited applicability. Tezak and his school (6, 7) maintain that most of the activity coefficients compiled by Ostwald refer to concentrated sols, whereas a physical meaning to the activity coefficient of the flocculating ion can only be given for small sol concentrations. In view of the different premises on which the current theory of colloid stability is based, the Ostwald rule is inadequate theoretically and should be regarded as an empirical result.

In this paper, the interaction of two parallel plate-like particles immersed in a large volume of a binary electrolyte will be examined. It is assumed that the plates are negatively charged, the coagulating cation is univalent ($z_1 = 1$), and the valency z_2 of the anion may have the values $-1, -2, -3, -4$, or $-\infty$. Following Verwey and Overbeek (2), the charge on the plates is supposed to be due to potential-determining ions whose concentration in the dispersion medium is negligible and the binary flocculating electrolyte is indifferent, i.e. there is no specific adsorption of the cation on the plate surface. This means that the potential at the plates is constant, independent of plate separation and of both the nature and concentration of the coagulating electrolyte. Extensive work on the interaction of two parallel plates in a binary symmetrical electrolyte have been carried out by a number of authors (1, 2, 8). The corresponding problem in a 1–2 electrolyte has been treated by Levine and Suddaby (9) and related work on the solution of the Poisson–Boltzmann equation in electrolyte mixtures containing ions of valencies 1 to 4 has been published by Wood and Robinson (10, 11, 12). Electrolyte mixtures of univalent and divalent ions have also been investigated by Glazman and his collaborators (13, 14). Provided the electrolyte in the dispersion medium contains only univalent and divalent ions, it is possible to express the interaction energy of the electric double layers of the plates in terms of elliptic integrals which are tabulated. However, with electrolytes containing higher valency ions, this interaction is obtained in terms of hyperelliptic integrals which are not tabulated. We shall avoid the use of such integrals by expanding the expression for the interaction energy in the form of a series which converges rapidly provided the plate separation is not too large and the surface potential not too small. This will permit the determination of the conditions for flocculation. The investigations of the various authors mentioned above are all based on the Gouy–Chapman theory, in which the diffuse layer is assumed to extend right up to the plate walls. However, we shall also consider the modification (due to Stern) which corrects for the finite size of the ions in the absence of specific adsorption.

By an obvious change in the sign of the surface potential the formulae derived in this paper can be applied to a $m-1$ valency electrolyte, in which the coagulating ion has the valency m. This will be considered in a later paper.

2. GENERAL EXPRESSION FOR INTERACTION ENERGY

Let $2h$ be the separation of the plates and x the distance measured from the median plane. If the linear dimensions of the plates are large compared with both h and the so-called thickness of the diffuse layers, then the electrostatic potential ψ at any position x will be a function of x only. It is assumed that the potential $\psi = \psi(x)$ satisfies the classical Poisson–Boltzmann equation throughout the range $-h < x < h$ of the overlapping diffuse layers in the region between the plates. This equation reads

$$[2.1] \qquad \frac{d^2\psi}{dx^2} = -\frac{4\pi e}{\epsilon}[n_1^0 z_1 \exp(-\beta z_1 e\psi) + n_2^0 z_2 \exp(-\beta z_2 e\psi)],$$

where $\beta = 1/kT$. The potential at the median plane will be $\psi_m = \psi(0) < 0$ and that at each plate $\psi_0 = \psi(h) < \psi_m$, the potential zero being taken in the interior of the electrolyte dispersion medium. The classical electrostatic energy per unit area of the two plates is given by

$$[2.2] \qquad E_e(h) = \frac{\epsilon}{4\pi}\int_0^h \left(\frac{d\psi}{dx}\right)^2 dx.$$

The ideal (osmotic) pressure due to the thermal motion of the ions at any x in the diffuse layers where the local ion densities are n_1 and n_2 and the corresponding pressure in the electrolyte interior are respectively,

$$[2.3] \qquad \Pi = kT(n_1 + n_2) \quad \text{and} \quad \Pi_0 = kT(n_1^0 + n_2^0).$$

Also the surface charge density on each plate is

$$[2.4] \qquad \sigma = \frac{\epsilon}{4\pi}\left(\frac{d\psi}{dx}\right)_{x=h}.$$

There are a number of completely equivalent expressions for the free energy to be associated with the electric double layers of the two plates. Thus, per unit area of plates, this energy can be written as

$$[2.5] \qquad F(h) = -2\int_0^{\psi_0} \sigma d\Psi = -E_e(h) - 2\int_0^h (\Pi - \Pi_0)dx.$$

These forms include the so-called electrical and chemical contributions to the free energy and were first used by Verwey and Overbeek (2); a general derivation has been given by Levine (15). In the first integral in [2.5] it is imagined that the surface charge density σ varies from 0 to its full (actual) value σ_0 and the surface potential is Ψ which is a function $\Psi(\sigma)$ of σ; thus $\psi_0 = \Psi(\sigma_0)$. The corresponding double layer force of repulsion per unit area (the electric double layer pressure) can be expressed in the forms

$$[2.6] \qquad p_e(h) = -\frac{1}{2}\left(\frac{\partial F}{\partial h}\right)_{\psi_0} = kT(n_1^{(m)} + n_2^{(m)} - n_1^{(0)} - n_2^{(0)}),$$

where the derivative with respect to h is taken at constant plate potential ψ_0 and $n_1^{(m)}$ and $n_2^{(m)}$ are the ion densities at the median plane $x = 0$. The first form was derived by Verwey and Overbeek (2) and the second independently by Frumkin and Gorodetskaja (16) and by Langmuir (17). A first integral of the Poisson–Boltzmann equation [2.1] is

$$[2.7] \qquad \frac{d\psi}{dx} = -\left[\left(\frac{8\pi kT}{\epsilon}\right)\sum_{i=1}^{2} n_i^0 \{\exp(-\beta z_i e\psi) - \exp(-\beta z_i e\psi_m)\}\right]^{\frac{1}{2}}$$

for $x > 0$, remembering that the above derivative is negative when the plates are negatively charged. This may also be expressed as

$$\Pi - \Pi_0 - \frac{\epsilon}{8\pi}\left(\frac{d\psi}{dx}\right)^2 = p_e(h), \qquad [2.8]$$

where the left-hand side refers to any point x in the diffuse layers. It follows from [2.5] and [2.8] that

$$F(h) = -2E_e(h) - 2hp_e(h). \qquad [2.9]$$

In addition to the double layer repulsion the van der Waals attraction between the plates must be considered. If the thickness of the plates is large compared with h, the energy of attraction per unit area takes the particularly simple form (1, 2)

$$W(h) = -A/48\pi h^2, \qquad [2.10]$$

where the constant A depends upon the material of the plates and of the dispersion medium in which the plates are immersed. The resultant interaction energy per unit area of the two plates is

$$U(h) = F(h) + W(h) - F(\infty). \qquad [2.11]$$

Following Derjaguin and Landau (1) and Verwey and Overbeek (2) we shall use the following conditions to define the transition from the stable to unstable sol (i.e. the critical flocculating relations)

$$U(h) = 0, \qquad [\partial U(h)/\partial h]_{\psi_0} = 0. \qquad [2.12]$$

The second condition in [2.12] may be expressed as

$$p_e(h) = A/48\pi h^3. \qquad [2.13]$$

Making use of [2.10] and [2.13], the first relation in [2.12] can be put in the form

$$2E_e(h) + 3hp_e(h) + F(\infty) = 0. \qquad [2.14]$$

3. GENERAL FORM OF COAGULATION CONDITIONS

It is convenient to introduce a Debye–Huckel parameter K for the positive ions only, defined by

$$K^2 = 8\pi n_1^0 z_1^2 e^2/\epsilon kT, \qquad [3.1]$$

and also the quantities

$$\xi = \exp(\beta z_1 e\psi_m) < 1, \qquad u = \xi \exp(-\beta z_1 e\psi) > 1 \qquad [3.2]$$

and

$$f(u, \xi, m) = \left[\exp(-\beta z_1 e\psi) - \exp(-\beta z_1 e\psi_m) + \frac{1}{m}\left\{\exp(-\beta z_2 e\psi) - \exp(-\beta z_2 e\psi_m)\right\}\right]^{\frac{1}{2}} = \xi^{-\frac{1}{2}}\left[u - 1 + \frac{1}{m}\xi^{m+1}(u^{-m} - 1)\right]^{\frac{1}{2}}. \qquad [3.3]$$

Then [2.7] becomes

$$\frac{d\psi}{dx} = -\left(\frac{8\pi n_1^0 kT}{\epsilon}\right)^{\frac{1}{2}} f(u, \xi, m), \qquad [3.4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

so that the formula [2.2] for the electrostatic energy reads

$$[3.5] \qquad E_e(h) = \frac{\epsilon}{4\pi}\int_{\psi_m}^{\psi_0}\frac{d\psi}{dx}d\psi = \frac{2n_1^0kT}{K}\int_1^{u_0}\frac{f(u,\xi,m)}{u}du,$$

where $u_0 = \xi\exp(-\beta z_1 e\psi_0)$. Also the double layer pressure [2.6] is

$$[3.6] \qquad p_e(h) = n_1^0kT\left(\frac{1}{m}\xi^m+\xi^{-1}-\frac{m+1}{m}\right),$$

and from [3.4]

$$[3.7] \qquad Kh = K\int_{\psi_m}^{\psi_0}\frac{dx}{d\psi}d\psi = \int_1^{u_0}\frac{du}{uf(u,\xi,m)},$$

which, indeed, becomes the solution of the Poisson–Boltzmann equation if h and u_0 are replaced by x and u respectively.

When $h = \infty$, $\psi_m = 0$ and therefore $\xi = 1$. To calculate $F(\infty)$ we apply the first relation in [2.5] to unit area of both sides of a single plate immersed in an infinite volume of the electrolyte. The surface charge density at a single plate surface, whose potential is Ψ, is given by

$$[3.8] \qquad \sigma(\infty) = \frac{\epsilon}{4\pi}\lim_{h\to\infty}\frac{d\psi}{dx} = -\left(\frac{n_1^0kT\epsilon}{2\pi}\right)^{\frac{1}{2}}f(v,1,m),$$

where $v = \exp(-\beta z_1 e\Psi)$. Noting that the surface potential ψ_0 is independent of h, it follows that

$$[3.9] \qquad F(\infty) = -2\int_0^{\psi_0}\sigma(\infty)d\Psi = -\frac{8n_1^0kT}{K}J(\psi_0,m),$$

$$[3.10] \qquad J(\psi_0,m) = -\frac{1}{2}\frac{z_1e}{kT}\int_0^{\psi_0}f(v,1,m)d\psi = \frac{1}{2}\int_1^{v_0}\frac{f(v,1,m)}{v}dv,$$

where $v_0 = \exp(-\beta z_1 e\psi_0)$.

Substituting [3.5], [3.6], [3.7], and [3.9] into the coagulation criterion [2.14] and dividing through by $8n_1^0kT/K$ this criterion appears in the form

$$[3.11] \qquad \frac{1}{2}\int_1^{u_0}\frac{f(u,\xi,m)}{u}du+\frac{3}{8}\left(\frac{1}{m}\xi^m+\xi^{-1}-\frac{m+1}{m}\right)\int_1^{u_0}\frac{du}{uf(u,\xi,m)}-J(\psi_0,m) = 0,$$

which, indeed, applies to any binary electrolyte. It is immediately obvious that the electrolyte concentration variable has been eliminated from [3.11] and that for given ψ_0 and m the value of ξ at which coagulation occurs is obtained. Once [3.11] has been solved for ξ, equation [3.7] then gives Kh and the critical value of K can be obtained from [2.13] and [3.6], from which we derive

$$[3.12] \qquad K = \frac{6\epsilon}{A}\left(\frac{kT}{z_1e}\right)^2(Kh)^3\left[\frac{1}{m}\xi^m+\xi^{-1}-\frac{m+1}{m}\right].$$

Certain points about the behavior of the left-hand side of [3.11], as a function of ξ, appear on considering the left-hand side of [2.14], which is the same expression multiplied by $8n_1^0kT/K$. As a preliminary we observe that if $\xi = 1$ (which means $h = \infty$), the integral in [3.5] becomes identical with $2J(\psi_0,m)$. This shows that $F(\infty) = -2E_e(\infty)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and also, using [2.9], that $\lim_{h\to\infty} hp_e(h) = 0$. Hence, the right-hand side of [2.14] vanishes at $h = \infty$ and so $\xi = 1$ is a solution of [3.11]. Now

$$[3.13] \quad 2E_e(h)+3hp_e(h)+F(\infty) = hp_e(h)-F(h)+F(\infty) = hp_e(h)-2\int_h^\infty p_e(h)dh,$$

making use of [2.9] and the first relation in [2.6]. For large h this quantity is positive since it can be shown (see Levine and Suddaby (8)) that $p_e(h)$ diminishes exponentially with h as h increases. At $h = 0$, it is equal to $F(\infty)$ since both $F(h)$ and $hp_e(h)$ vanish. (The charge density σ vanishes at $h = 0$ if the surface potential ψ_0 is constant.) But $F(\infty)$ is negative and so the expression [3.13] must have a second zero for some finite h. As h increases from 0 to ∞, ξ increases from u_0^{-1} to 1. It follows that there is (at least) one root of [3.11] where $\xi < 1$ (see Fig. 1). This is the required solution of [3.12].

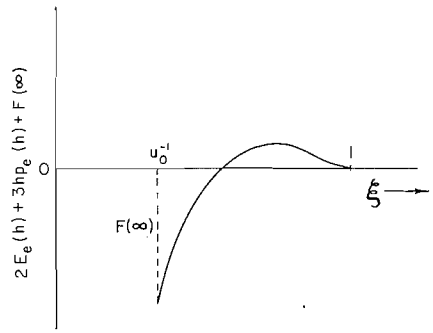

FIG. 1.

4. DETERMINATION OF $F(\infty)$

The expression [3.10] for $J(\psi_0, m)$ can be obtained in closed form for $m = 1, 2, 3, 4$, and ∞. It is helpful to take out a factor $(v-1)v^{-m/2}$ from $f(v, 1, m)$ and then [3.10] becomes

$$[4.1] \quad J(\psi_0, m) = \frac{1}{2}\int_1^{v_0} \frac{(v-1)}{v^{m/2+1}}\left\{v^{m-1}+\frac{(m-1)}{m}v^{m-2}+\ \ldots\ +\frac{2v}{m}+\frac{1}{m}\right\}^{\frac{1}{2}} dv,$$

which is integrated as follows for the above values of m.

(i) $m = 1$

$$[4.2] \quad J(\psi_0, 1) = \frac{1}{2}\int_1^{v_0} \frac{(v-1)}{v^{3/2}}dv = v_0^{\frac{1}{2}}+v_0^{-\frac{1}{2}}-2.$$

(ii) $m = 2$

$$[4.3] \quad J(\psi_0, 2) = \frac{1}{2}\int_1^{v_0} \frac{(v-1)}{v^{\frac{3}{2}}}(v+\tfrac{1}{2})^{\frac{1}{2}}dv = \frac{1}{2\sqrt{2}}\left\{\frac{(2v_0+1)^{3/2}}{v_0}-3\sqrt{3}\right\}.$$

(iii) $m = 3$

$$[4.4] \quad J(\psi_0, 3) = \frac{1}{2}\int_1^{v_0} \frac{(v-1)}{v^3}(v^3+\tfrac{2}{3}v^2+\tfrac{1}{3}v)^{\frac{1}{2}}dv$$

$$= \frac{1}{3}\left\{\frac{(v_0^3+\frac{2}{3}v_0^2+\frac{1}{3}v_0)^{\frac{1}{2}}}{v_0^{\frac{2}{3}}}-\sqrt{2}\right\}+\frac{1}{2}\int_1^{v_0}\frac{(v+\frac{1}{9}v^{-1})dv}{(v^3+\frac{2}{3}v^2+\frac{1}{3}v^3)^{\frac{1}{2}}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The integrand contains the square root of a cubic in the denominator and so the integral can be expressed in terms of elliptic integrals. By making the substitution

$$cn(t, k) = \frac{v\sqrt{3}-1}{v\sqrt{3}-1}, \qquad k^2 = \frac{\sqrt{3}-1}{2\sqrt{3}},$$

where k is the parameter of the Jacobian elliptic function $cn(t, k)$ (see Byrd and Friedman (18)), integration can be performed. If we put

$$\cos\phi_0 = \frac{v_0\sqrt{3}-1}{v_0\sqrt{3}+1}, \qquad \cos\phi_1 = \frac{\sqrt{3}-1}{\sqrt{3}+1},$$

then it follows that

$$[4.5] \qquad \frac{1}{2}\int_1^{v_0} \frac{(v+\frac{1}{9}v^{-1})dv}{(v^3+\frac{2}{3}v^2+\frac{1}{3}v)^{\frac{1}{2}}} = \frac{2}{3^{5/4}}\left[2E(\phi, k)-F(\phi, k)+\frac{(1+2\cos\phi)(1-k^2\sin^2\phi)^{\frac{1}{2}}}{\sin\phi}\right]_{\phi_1}^{\phi_0}.$$

Here $F(\phi, k)$ and $E(\phi, k)$ are elliptic integrals of the first and second kinds respectively. Substitution of [4.5] into [4.4] gives the required value of $J(\psi_0, 3)$.

(iv) $m = 4$

$$[4.6] \qquad J(\psi_0, 4) = \frac{1}{2}\int_1^{v_0}\frac{(v-1)}{v^3}(v^3+\tfrac{3}{4}v^2+\tfrac{1}{2}v+\tfrac{1}{4})^{\frac{1}{2}}dv$$

$$= -\frac{1}{4}\left[\left\{\frac{(v_0-1)}{v_0^2}(v_0^3+\tfrac{3}{4}v_0^2+\tfrac{1}{2}v_0+\tfrac{1}{4})^{\frac{1}{2}}\right\}+\frac{5}{8}\int_1^{v_0}\frac{vdv}{(v^3+\frac{3}{4}v^2+\frac{1}{2}v+\frac{1}{4})^{\frac{1}{2}}}\right].$$

The integration may be performed by elliptic substitution as in the case $m = 3$. If the elliptic parameter k equals 0.905943 while

$$\cos\phi_0 = \frac{v_0-0.226242}{v_0+1.437902}, \qquad \cos\phi_1 = \frac{1-0.226242}{1+1.437902} = 0.317387,$$

it turns out that

$$[4.7] \qquad \frac{5}{8}\int_1^{v_0}\frac{vdv}{(v^3+\frac{3}{4}v^2+\frac{1}{2}v+\frac{1}{4})^{\frac{1}{2}}} = 1.140225\left[E(\phi, k)-0.135951F(\phi, k)+\frac{(1+\cos\phi)(1-k^2\sin^2\phi)^{\frac{1}{2}}}{\sin\phi}\right]_{\phi_1}^{\phi_0}.$$

Substitution of [4.7] into [4.6] yields $J(\psi_0, 4)$.

For higher values of m the integrals will be of the hyperelliptic type, which in general are not tabulated. For $m = 5$ and $m = 6$, for instance, the integrands will involve the square root of a quintic. It is possible to express $J(\psi_0, m)$ as a series, which will be indicated in the following section, but no calculations for $m = 5$ or 6 will be made in this paper.

(v) $m = \infty$

$$[4.8] \qquad J(\psi_0, \infty) = \frac{1}{2}\int_1^{v_0}\frac{(v-1)^{\frac{1}{2}}}{v}dv = (v_0-1)^{\frac{1}{2}}-\tan^{-1}(v_0-1)^{\frac{1}{2}}.$$

In Table I, values of $J(\psi_0, m)$ are given for the two values $\beta z_1 e\psi_0 = -2$ and -4, corresponding to $\psi_0 = 50$ and -100 mv respectively at room temperature, when $z_1 = 1$.

5. CALCULATION OF COAGULATION VALUES OF ELECTROLYTE

In order to determine the critical value of ξ it is necessary to evaluate the two integrals in [3.11] which come from the equations [3.5] and [3.7] for $E_e(h)$ and Kh respectively. If the substitution $u = 1+y^2$ is made, then

$$[5.1] \qquad \frac{1}{2}\int_1^{u_0}\frac{f(u,\xi,m)}{u}du = \xi^{-\frac{1}{2}}\int_0^{y_0}\frac{y^2}{(1+y^2)}\left[1-\frac{1}{m}\xi^{m+1}\frac{[1-(1+y^2)^{-m}]}{y^2}\right]^{\frac{1}{2}}dy$$

where $u_0 = 1+y_0^2$. Now it is seen from [3.2] that provided the potential at the median plane ψ_m is appreciable, then ξ will be significantly smaller than unity particularly if h is not too large and the surface potential ψ_0 large enough. Since

$$\frac{\xi^{m+1}}{m}\cdot\frac{(1-u^{-m})}{(u-1)} = \frac{\xi^{m+1}}{m}u^{-m}(1+u+\ldots+u^{m-1}) < \xi^{m+1},$$

this suggests that if $\xi < 1$ the integrand in [5.1] be expanded in powers of ξ^{m+1}. The series for the symmetrical case $m = 1$ will be the most slowly converging and we shall retain four terms in this case, namely,

$$[5.2] \qquad \frac{1}{2}\int_1^{u_0}\frac{f(u,\xi,1)}{u}du = \xi^{-\frac{1}{2}}[\tan\theta-\theta-\tfrac{1}{2}\xi^2(\theta-I_2)-\tfrac{1}{8}\xi^4(I_2-I_4)-\tfrac{1}{16}\xi^6(I_4-I_6)+\ldots],$$

where it is convenient to introduce

$$[5.3] \qquad y_0 = \tan\theta, \qquad \xi = u_0/v_0 = \sec^2\theta/v_0,$$

and

$$[5.4] \qquad I_n = \int_0^{y_0}\frac{dy}{(1+y^2)^{n/2+1}} = \int_0^{\theta}\cos^n\alpha d\alpha.$$

This is readily evaluated from the relations

$$[5.5] \qquad I_2 = \tfrac{1}{2}(\theta+\sin\theta\cos\theta), \qquad I_n = \frac{(n-1)}{n}I_{n-2}+\frac{1}{n}\sin\theta\cos^{(n-1)}\theta.$$

Retaining three terms for $m = 2$,

$$[5.6] \qquad \frac{1}{2}\int_1^{u_0}\frac{f(u,\xi,2)}{u}du = \xi^{-\frac{1}{2}}[\tan\theta-\theta-\tfrac{1}{4}\xi^3(\theta-I_4)-\tfrac{1}{32}\xi^6(I_2+I_4-I_6-I_8)+\ldots].$$

For $m \geqslant 3$, it is sufficient to retain only two terms, i.e.

$$[5.7] \qquad \frac{1}{2}\int_1^{u_0}\frac{f(u,\xi,m)}{u}du = \xi^{-\frac{1}{2}}\left[\tan\theta-\theta-\frac{1}{2m}\xi^{m+1}(\theta-I_{2m})+\ldots\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The integral in [3.7] may be similarly approximated. Thus

$$[5.8]\qquad \int_1^{u_0}\frac{du}{uf(u,\xi,m)} = 2\xi^{\frac{1}{2}}\int_0^{y_0}\frac{1}{(1+y^2)}\left[1-\frac{1}{m}\xi^{m+1}\frac{[1-(1+y^2)^{-m}]}{y^2}\right]^{-\frac{1}{2}}dy,$$

and expanding again, in powers of ξ^{m+1},

$$[5.9]\qquad \int_1^{u_0}\frac{du}{uf(u,\xi,1)} = 2\xi^{\frac{1}{2}}(\theta+\tfrac{1}{2}\xi^2 I_2+\tfrac{3}{8}\xi^4 I_4+\tfrac{5}{16}\xi^6 I_6+\ldots),$$

$$[5.10]\qquad \int_1^{u_0}\frac{du}{uf(u,\xi,2)} = 2\xi^{\frac{1}{2}}\{\theta+\tfrac{1}{4}\xi^3(I_2+I_4)+\tfrac{3}{32}\xi^6(I_4+2I_6+I_8)+\ldots\},$$

and for $m \geqslant 3$

$$[5.11]\qquad \int_1^{u_0}\frac{du}{uf(u,\xi,m)} = 2\xi^{\frac{1}{2}}\left\{\theta+\frac{1}{2m}\xi^{m+1}(I_2+I_4+\ldots+I_{2m})+\ldots\right\}.$$

If the first two terms are retained in the expansions of [5.1] and [5.8] in powers of ξ^{m+1}, it follows that [3.11] simplifies to

$$[5.12]\quad \xi^{-\frac{1}{2}}\left[\tan\theta-\theta\left\{\frac{1}{4}+\frac{3}{4}\left(1+\frac{1}{m}\right)\xi\right\}\right]$$
$$+\frac{1}{2m}\xi^{m+\frac{1}{2}}\left[\frac{\theta}{2}+I_{2m}+\frac{3}{4}\left\{1-\left(1+\frac{1}{m}\right)\xi+\frac{1}{m}\xi^{m+1}\right\}(I_2+I_4+\ldots+I_{2m})\right]+\ldots = J(\psi_0,m),$$

where ξ is defined in [5.3], and we may also write

$$1-\left(1+\frac{1}{m}\right)\xi+\frac{1}{m}\xi^{m+1} = (1-\xi)^2\left[1+\frac{(m-1)}{m}\xi+\frac{(m-2)}{m}\xi^2+\ldots+\frac{1}{m}\xi^{m-1}\right].$$

The higher terms in the expansion, required for $m = 1$ and $m = 2$, are readily obtained from the relevant equations above. It is convenient to solve for θ rather than for ξ.

The cases $m \gg 1$ and $\xi \ll 1$ are of particular interest. The equation [5.12] becomes, very nearly,

$$[5.13]\qquad \xi^{-\frac{1}{2}}\left[\tan\theta-\theta\left\{\frac{1}{4}+\frac{3}{4}\left(1+\frac{1}{m}\right)\xi\right\}\right] = J(\psi_0,m)$$

and also [3.7] simplifies to

$$[5.14]\qquad Kh = 2\xi^{\frac{1}{2}}\theta = 2\xi^{\frac{1}{2}}\tan^{-1}[\xi\exp(-\beta z_1 e\psi_0)-1]^{\frac{1}{2}},$$

which can also be written in the form

$$[5.15]\qquad \psi_0-\psi_m = \frac{2kT}{z_1 e}\log\cos\left(\tfrac{1}{2}Kh\xi^{-\frac{1}{2}}\right).$$

This result was first given by Langmuir (17) and represents the limiting case where the potential ψ is very large at all positions in the diffuse layers of the two plates. The concentration of anions is so small compared with that of the cations that we may omit the term in n_2^0 in the Poisson–Boltzmann equation [2.1], which consequently has as solution equation [5.15]. This omission of the term in n_2^0 implies that either $m \gg 1$ or $\xi \ll 1$. If $-\psi_0$ is put equal to infinity, then it follows from [5.15] that

$$[5.16]\qquad \cos\left(\tfrac{1}{2}Kh\xi^{-\frac{1}{2}}\right) = 0 \quad \text{or} \quad \xi = (hK/\pi)^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and so the pressure between the plates becomes

$$[5.17] \qquad p_e(h) = kTn_1^0\left(\frac{1}{\xi}-1\right) \approx \frac{\pi\epsilon}{8}\left(\frac{kT}{z_1e}\right)^2\frac{1}{h^2}$$

if $\xi \ll 1$. Since [5.14] can also be written as

$$[5.18] \qquad \xi\cos^2(\tfrac{1}{2}hK\xi^{-\frac{1}{2}}) = \exp(\beta z_1e\psi_0),$$

we see that to this approximation (applicable when h is small and ψ_0 is large), at a specified separation $2h$ the electrical force is expressed as a function of the surface potential ψ_0 and concentration n_1^0 of coagulation counter-ions only. This is the "zero-order" theory, which states that if ψ_0 is assumed independent of h, then the flocculating concentration depends only on the concentration of the ions oppositely charged to the plates and is independent of the concentration or nature of the ions carrying a charge of the same sign as the plates.

The equation [5.12] for θ, and therefore for ξ, has been solved numerically for $m = 1$, 2, 3, 4, and ∞. Substitution into [3.7] then yields Kh and hence, from [3.12], the quantity $(AK/6\epsilon)(z_1e/kT)^2$ can be determined. This provides a measure of the concentration n_1^0 of the coagulating univalent ions. The results are given in Table II.

TABLE II

	$\psi_0 = -50$ mv					$\psi_0 = -100$ mv				
m	1	2	3	4	∞	1	2	3	4	∞
θ	0.885	0.872	0.865	0.864	0.880	1.23	1.23	1.23	1.24	1.26
ξ	0.338	0.327	0.322	0.321	0.334	0.168	0.166	0.168	0.170	0.190
Kh	1.08	1.01	0.98	0.98	1.02	1.02	1.01	1.01	1.02	1.09
$(KA/6\epsilon)\ (z_1e/kT)^2$	1.62	1.66	1.71	1.76	2.10	4.21	4.61	4.77	4.90	5.58
$(K_m/K_1)^2$	1	1.05	1.10	1.17	1.67	1	1.20	1.28	1.35	1.76
$2m/(1+m)$	1	1.33	1.50	1.60	2	1	1.33	1.50	1.60	2

According to the Derjaguin–Verwey–Overbeek theory, in which the Gouy–Chapman theory of the diffuse layer is applied for all distances from the particle wall and the surface potential ψ_0 is assumed independent of separation, the critical coagulating value of K and therefore of n_1^0 increases with the valency m of the non-flocculating ion. Denoting the value of K for the electrolyte type $1-m$ by K_m, the ratio $(K_m/K_1)^2$, which equals the corresponding ratio of the flocculating ion concentrations, is given in Table II. Ostwald's rule states that for a given sol $n_1^0(1+m)/m$ is a constant and therefore K is proportional to $\{m/(1+m)\}^{\frac{1}{2}}$; this yields $(K_m/K_1)^2 = 2m/(1+m)$, which is also given in the table. It is seen that Ostwald's rule is not verified by the Derjaguin–Verwey–Overbeek theory in the particular case of a $1-m$ binary electrolyte in which the flocculating ion is univalent, although the difference is not large.

It is possible to obtain a good approximation to the free energy $F(\infty)$ for a single plate when m is large ($\geqslant 4$ say) by employing the expansion [5.7]. Thus $F(\infty)$ is given by [3.9] where, from [3.10] and [5.7],

$$[5.19] \qquad J(\psi_0, m) = \tan\theta_0 - \theta_0 - \frac{1}{2m}\{\theta_0 - I_{2m}(\theta_0)\} + \ldots,$$

where $\sec^2\theta_0 = v_0 = \exp(-\beta z_1e\psi_0)$. The two terms on the right are calculated for $m = 3$ and 4 and $\psi_0 = -50$ and -100 mv in Table I. The first term on the right is identical with [4.8] and gives the exact result for $m = \infty$.

6. APPLICATION OF STERN MODEL IN THE ABSENCE OF SPECIFIC ADSORPTION

Only one of the two modifications which Stern introduced in the Gouy–Chapman theory will be considered here, namely, the effect of the finite ion size, which is sufficient when specific adsorption of ions on the plate surface is absent. It is assumed that there is a layer of water molecules at the wall which is free of ions, the thickness d, say, of this layer being the minimum distance of approach of the ions of the coagulating electrolyte. Experimental evidence (19, 20, 21) indicates that the water in this inner region of thickness d is partially oriented even in the absence of any charge on the surface and as a result of this partial dielectric saturation, the effective dielectric constant of this inner region, which will be denoted by ϵ_1, is found to be much less than that of bulk water. If $\Psi = \Psi(\sigma)$ is the potential at the colloidal wall, $x = h$ when the plate charge density is σ, and $\Psi_d = \Psi_d(\sigma)$ that at the other boundary, $x = h-d$ of the inner region (Fig. 2) then we may assume the relation

$$\Psi - \Psi_d = \frac{4\pi d\sigma}{\epsilon_1} + \chi_d, \qquad [6.1]$$

where χ_d is the potential drop due to the dipole orientation in the absence of surface charge σ; this contributes to the so-called Lange χ-potential. It will be shown in a later paper that ϵ_1 should be interpreted as a differential rather than an integral dielectric constant. The limit of the diffuse layer is now assumed to be situated at $x = h-d$ instead of $x = h$, as in the Gouy–Chapman theory.

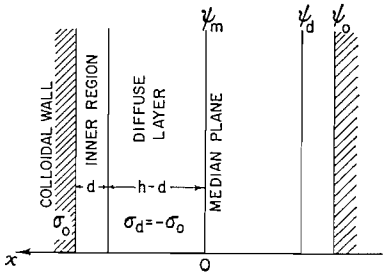

FIG. 2.

To determine the free energy for the above model of the electric double layers, it is necessary to discuss the origin of the first equation in [2.5]. The free energy consists of two terms, an 'electrical' part $F_e(h)$ given by

$$F_e(h) = 2\int_0^{\sigma_0} \Psi d\sigma \qquad [6.2]$$

and a chemical part F_c, which takes the form

$$F_c = 2C\sigma_0, \qquad [6.3]$$

where C is a constant, when the potential-determining ions responsible for the surface charge form part of the particle lattice. Since $F(h)$ must be a minimum with respect to transfer of potential-determining ions from the electrolyte dispersion medium to the plates,

$$\frac{dF(h)}{d\sigma_0} = \frac{d}{d\sigma_0}\Big[F_e(h) + F_c\Big] = 0, \qquad [6.4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

or, since $\psi_0 = \Psi(\sigma_0)$,

$$\psi_0 + C = 0. \qquad [6.5]$$

Integrating by parts

$$F(h) = F_e(h) + F_c = 2(\psi_0 + C)\sigma_0 - 2\int_0^{\psi_0} \sigma d\Psi = -2\int_0^{\psi_0} \sigma d\Psi. \qquad [6.6]$$

Substituting [6.1] we obtain

$$F(h) = -2\int_0^{\psi_d} \sigma d\Psi_d - \frac{4\pi d\sigma_0^2}{\epsilon_1}, \qquad [6.7]$$

where $\psi_d = \Psi_d(\sigma_0)$ is the potential at the limit of the diffuse layer $x = h - d$ when the plate is fully charged. The last result was given by Mackor (22). Levine (23) considered the more general case where the inner region contains an adsorbed layer of counter-ions and his formula reduces to [6.6] in the case of no specific adsorption.

The charge density σ is equal in magnitude and opposite in sign to the charge σ_d, say, contained in a column of the diffuse layer of unit cross section and situated between the planes $x = 0$ and $x = h - d$. It follows that, apart from the constant factor d/ϵ_1, the energy expression [6.7] depends solely on the charge distribution in the diffuse layer, and this is also true of the formula in [2.5]. Furthermore, the double layer repulsion per unit area can be written as

$$p_e(h') = -\frac{1}{2}\left[\frac{\partial F_e(h)}{\partial h}\right]_{\sigma_0} = \left[-\frac{\partial}{\partial h}\int_0^{\sigma_0} \Psi_d d\sigma\right]_{\sigma_0}, \qquad [6.8]$$

where $h' = h - d$, and [6.1] is substituted into [6.2]. The proof of the first relation in [6.8] has been given by Verwey and Overbeek (2), Levine (24), and Bell and Levine (25). Since $\sigma = -\sigma_d$, this means that the force per unit area also depends on the charge distribution in the diffuse layer only and thus is given by the last expression in [2.6]. Indeed it has already been stressed (26, 27) that the latter force formula, which is expressed in terms of the ion densities at the median plane, is always valid, being independent of the particular conditions at the particle surface, *provided* the median plane is embedded in the diffuse layers and the Gouy–Chapman equations can be applied to the diffuse layer. It follows that the first term on the right of [6.7] may be equated to the expression [2.9] if h is replaced by $h' = h - d$ and ψ_0 by ψ_d, and so

$$F(h) = -2E_e(h') - 2h'p_e(h') - \frac{4\pi d\sigma_0^2}{\epsilon_1}. \qquad [6.9]$$

The van der Waals attraction will take a different form from [2.10] since the inner region of water not only has a different dielectric constant but is probably in a state of considerable electrostriction. It is convenient to write the van der Waals energy in the form

$$W(h') = -\frac{A}{48\pi h'^2} + A'F_w(h'), \qquad [6.10]$$

where the second term is the correction due to the difference between the materials of the inner region and the colloidal plates. Certainly for large separations the first term on the right will be the dominant one and in view of the mathematical complexities

it seems sufficient for the present purposes to neglect the second term. In this case, the two stability conditions [2.12] become

$$[6.11] \qquad p_e(h') = \frac{A}{48\pi h'^3}, \qquad 2E_e(h')+3h'p_e(h')+F'(\infty)+\frac{4\pi d\sigma_0^2}{\epsilon_1} = 0,$$

where $F'(\infty)$ is the free energy per unit area of a single plate.

It is convenient to introduce

$$[6.12] \qquad v_d = \exp(-\beta z_1 e\psi_d), \qquad u_d = \xi v_d, \qquad v_d(\infty) = \exp\{-\beta z_1 e\psi_d(\infty)\},$$

where ξ is already defined in [3.2], and noting that ψ_d varies with separation $2h$, its value at infinite separation is denoted by $\psi_d(\infty)$. Then $E_e(h')$ is given by [3.5] and similarly Kh' by [3.7], provided the upper limit of integration u_0 on the right-hand side of both equations is replaced by u_d. Also $p_e(h')$ is again given by [3.6]. If σ_0 has the value $\sigma_0(\infty)$ at infinite separation and $J(\psi_d(\infty), m)$ is defined by [3.10], when the upper limit of integration is replaced by $v_d(\infty)$, then

$$[6.13] \qquad F'(\infty) = -8n_1^0kTJ(\psi_d(\infty), m)-\frac{4\pi d\sigma_0^2(\infty)}{\epsilon_1}.$$

By [3.4] the charge density σ_0 can be written as

$$[6.14] \qquad \sigma_0 = -\left(\frac{n_1^0kT\epsilon}{2\pi}\right)^{\frac{1}{2}} f(u_d, \xi, m)$$

and the corresponding form for $\sigma_0(\infty)$ is obtained by replacing u_d by $v_d(\infty)$ and ξ by 1. Thus the second condition in [6.11] reads

$$[6.15] \qquad \frac{1}{2}\int_1^{u_d}\frac{f(u, \xi, m)}{u}du+\frac{3}{8}\left(\frac{1}{m}\xi^m+\xi^{-1}-\frac{(m+1)}{m}\right)\int_1^{u_d}\frac{du}{uf(u, \xi, m)}-J(\psi_d(\infty), m)$$
$$= \frac{Kd\epsilon}{4\epsilon_1}[f^2(v_d(\infty), 1, m)-f^2(u_d, \xi, m)]$$

after dividing through by $8n_1^0kT/K$. This relation becomes identical with [3.11] when the thickness d of the inner region tends to zero. For non-vanishing d, however, it differs from [3.11] in that the electrolyte concentration variable has not been eliminated and it is no longer possible to solve for ξ in terms of u_d without introducing the other stability condition in [6.11].

It is convenient to express the condition [6.1] as

$$[6.16] \qquad -\beta z_1 e\psi_d = \log v_d = \Phi_0-\frac{Kd\epsilon}{\epsilon_1}f(u_d, \xi, m),$$

where $\Phi_0 = \beta z_1 e(\chi_d-\psi_0)$, which is constant independent of d. If use is made of [3.3], then at $h = \infty$ (when $\xi = 1$) this relation can be put in the form

$$[6.17] \qquad \log v_d(\infty)+\frac{Kd\epsilon}{\epsilon_1}[v_d^{\frac{1}{2}}(\infty)-v_d^{-\frac{1}{2}}(\infty)]H^{\frac{1}{2}}(v_d(\infty), m) = \Phi_0$$

where

$$[6.18] \qquad H(s, m) = 1+\frac{(m-1)}{m}\cdot\frac{1}{s}+\frac{(m-2)}{m}\cdot\frac{1}{s^2}+\ldots+\frac{1}{ms^{m-1}}.$$

Thus

$$H(s,1) = 1, \qquad H(s,2) = 1+\frac{1}{2s}, \qquad H(s,3) = 1+\frac{2}{3s}+\frac{1}{3s^2},$$

$$H(s,4) = 1+\frac{3}{4s}+\frac{1}{2s^2}+\frac{1}{4s^3}, \qquad H(s,\infty) = \frac{s}{(s-1)}.$$

The equation [6.17] yields $v_d(\infty)$ (or $\psi_d(\infty)$) as a function of K. Now χ_d measures a residual potential drop in the absence of surface charge and will be assumed independent of electrolyte type (i.e. of m). Since ψ_0 also does not depend on valency type we may presume Φ_0 to be independent of m. The thickness d of the Stern layer is some mean of the two distances of nearest approach to the colloidal wall of the cation and anion, which we denote by d_I and d_{II} respectively. For simplicity, let $d_I = d_{II}$ for the 1–1 electrolyte and noting that the radius of the hydrated anion will in general increase with its hydration number let d_{II} increase with its valency m. Then it is likely that for small $m > 1$, $d > d_I$ but the following considerations suggest that as m increases d diminishes again, tending to d_I. If the hydration number is assumed proportional to m then the ratio d_{II}/d_I will be roughly proportional to $m^{1/3}$ whereas the ratio of the concentration of anions to cations at a distance $x = d_{II}$, where the potential is $\psi_{II}(<0)$ say, will be $(1/m)\exp[\beta e(m+1)\psi_{II}]$, which rapidly tends to zero with increasing m. This means that the number of anions that would be present in the region $d_I < x < d_{II}$ if they were not excluded through steric hindrance, would be so small for $m \geqslant 3$, say, that the distance d is determined by the cations only and is therefore equal to d_I. This behavior of d as a function of m will be borne in mind below.

To examine the relation [6.16] for general h we introduce $u_d = \sec^2\alpha$ and therefore $v_d = \sec^2\alpha/\xi$. Then, making use of [3.3], [6.16] can be written as

$$[6.19] \quad \log\left(\frac{\sec^2\alpha}{\xi}\right)+\frac{Kd\epsilon}{\epsilon_1}\xi^{-\frac{1}{2}}\tan\alpha\left[1-\frac{1}{m}\xi^{m+1}\cos^{2m}\alpha\{1+\sec^2\alpha+\ldots+\sec^{2(m-1)}\alpha\}\right]^{\frac{1}{2}} = \Phi_0.$$

Similarly, equation [6.15] reads:

$$[6.20] \quad \xi^{-\frac{1}{2}}\left[\tan\alpha-\alpha\left\{\frac{1}{4}+\frac{3}{4}\left(1+\frac{1}{m}\right)\xi\right\}\right]$$
$$+\frac{1}{2m}\xi^{m+\frac{1}{2}}\left[\frac{\alpha}{2}+I_{2m}+\frac{3}{4}\left\{1-\left(1+\frac{1}{m}\right)\xi+\frac{1}{m}\xi^{m+1}\right\}(I_2+I_4+\ldots+I_{2m})\right]$$
$$+\ldots-J(\psi_d(\infty),m) = \frac{Kd\epsilon}{4\epsilon_1}\left[\frac{(v_d(\infty)-1)^2}{v_d(\infty)}H(v_d(\infty),m)\right.$$
$$\left.-\xi^{-1}\tan^2\alpha\left\{1-\frac{1}{m}\xi^{m+1}\cos^{2m}\alpha(1+\sec^2\alpha+\ldots+\sec^{2(m-1)}\alpha)\right\}\right],$$

where, as in [5.12] only two terms in the expansion in powers of ξ^{m+1} have been retained on the left-hand side. In the three equations [6.17], [6.19], and [6.20], there are four unknowns α, ξ, K, and $\psi_d(\infty)$ (or $v_d(\infty)$) so that one more equation is required; this is provided by the first stability condition in [6.11]. Making use of [3.7] and [5.11], this condition is equivalent to [3.12] provided h, u_0, and θ are replaced by h', u_d, and α. The required fourth relation is therefore

$$[6.21] \quad M = C\xi^{\frac{1}{2}}\left\{1-\left(1+\frac{1}{m}\right)\xi+\frac{1}{m}\xi^{m+1}\right\}\left[\alpha+\frac{1}{2m}\xi^{2m+1}(I_2+I_4+\ldots+I_{2m})+\ldots\right]^3,$$

where

$$[6.22] \qquad M = \frac{Kd\epsilon}{\epsilon_1}, \qquad C = \frac{48d\epsilon^2}{A\epsilon_1}\left(\frac{kT}{z_1e}\right)^2,$$

and the I_n are functions of α in [6.20] and [6.21].

The simplest case is $m = \infty$. Attaching a suffix ∞ to the quantities M and C and introducing $\phi = -\beta z_1 e\psi_d(\infty) > 0$ the four equations are readily obtained, namely

$$[6.23] \qquad M_\infty = \frac{\Phi_0-\phi}{(e^\phi-1)^{\frac{1}{2}}} = \frac{\Phi_0-\log(\sec^2\alpha/\xi)}{\xi^{-\frac{1}{2}}\tan\alpha} = C_\infty\xi^{\frac{1}{2}}\alpha^3(1-\xi),$$

$$\xi^{-\frac{1}{2}}\left[\tan\alpha-\frac{\alpha}{4}(1+3\xi)\right]-J(\psi_d(\infty),\infty) = \frac{M_\infty}{4}\left[e^\phi-1-\xi^{-1}\tan^2\alpha\right].$$

For $m = 1$, attaching the suffix 1 to the quantities M and C, the corresponding equations are

$$[6.24] \qquad M_1 = \frac{\Phi_0-\phi}{2\sinh\phi/2} = \frac{\Phi_0-\log(\sec^2\alpha/\xi)}{\xi^{-\frac{1}{2}}\tan\alpha(1-\xi^3\cos^2\alpha)^{\frac{1}{2}}}$$

$$= C_1\xi^{\frac{1}{2}}(1-\xi)^2\left[\alpha+\frac{1}{2}\xi^2I_2+\frac{3}{8}\xi^4I_4+\ldots\right]^3$$

and

$$[6.25] \qquad \xi^{-\frac{1}{2}}\left[\tan\alpha-\frac{\alpha}{4}(1+6\xi)\right]+\frac{1}{2}\xi^{3/2}\left[\frac{\alpha}{2}+I_2+\frac{3}{4}(1-\xi)^2I_2\right]$$

$$+\frac{1}{8}\xi^{7/2}\left[I_4-I_2+\frac{9}{4}(1-\xi)^2I_4\right]+\ldots-J(\psi_d(\infty),1)$$

$$= \frac{M_1}{4}\left[4\sinh^2\frac{\phi}{2}-\xi^{-1}\tan^2\alpha(1-\xi^2\cos^2\alpha)\right],$$

where three terms in the expansion in the powers of $\xi^{m+1} = \xi^{3/2}$ on the left-hand side of [6.20] have been retained. For $m = 2$ we obtain

$$[6.26] \qquad M_2 = \frac{\Phi_0-\phi}{2\,(1+\frac{1}{2}e^{-\phi})^{\frac{1}{2}}\sinh\phi/2} = \frac{\Phi_0-\log(\sec^2\alpha/\xi)}{\xi^{-\frac{1}{2}}\tan\alpha[1-\frac{1}{2}\xi^3(\cos^2\alpha+\cos^4\alpha)]^{\frac{1}{2}}}$$

$$= C_2\xi^{\frac{1}{2}}(1-\xi)^2\left(1+\frac{1}{2}\xi\right)\left[\alpha+\frac{1}{4}\xi^3(I_2+I_4)+\ldots\right]^3$$

and

$$[6.27] \qquad \xi^{-\frac{1}{2}}\left[\tan\alpha-\frac{\alpha}{8}(2+9\xi)\right]+\frac{1}{4}\xi^{5/2}\left[\frac{\alpha}{2}+I_4+\frac{3}{8}(1-\xi)^2(2+\xi)(I_2+I_4)\right]+\ldots$$

$$-J(\psi_d(\infty),2) = \frac{M_2}{4}\left[4\sinh^2\frac{\phi}{2}\,(1+\tfrac{1}{2}e^{-\phi})-\xi^{-1}\tan^2\alpha\{1-\tfrac{1}{2}\xi^3(\cos^2\alpha+\cos^4\alpha)\}\right].$$

Some numerical solutions of the above equations are given in Table III for $\Phi_0 = 10$ ($|\psi_0-\chi_d| = 250$ mv). An examination of [6.17] shows that for specified Φ_0 and Kd the magnitude of the potential $\psi_d(\infty)$ diminishes with increasing m. This suggests that if

For personal use only.

the value $\phi = 2$ ($\psi_d(\infty) = -50$ mv), for example, is chosen for $m = 1$ then $\phi < 2$ for $m > 1$. The subscripts 1, 2, or ∞ have been assigned to various quantities to designate that $m = 1$, 2, or ∞ respectively. Values of ϕ have been chosen to provide a range of values for the ratio d_m/d_1, of the thicknesses of the inner region in 1–1 and 1–m electrolytes. From the definition of C in [6.22], $d_m/d_1 = C_m/C_1$ and the corresponding ratio of the coagulating ion concentrations is $(K_m/K_1)^2 = (M_m d_1/M_1 d_m)^2$. It is seen that

TABLE III

m		1	2		∞	
ϕ		2	2	1.9	1.96	1.8	1.75
M_m		3.40	3.29	3.55	3.40	3.65	3.78
α		0.917	0.920	0.870		0.864	0.857
ξ		0.310	0.305	0.285		0.293	0.302
C_m		14.9	13.4	16.9	14.9	14.8	15.7
d_m/d_1			0.90	1.14	1	0.99	1.06
$\left(\frac{K_m}{K_1}\right)^2$	Stern		1.16	0.84	1.00	1.17	1.11
	Gouy–Chapman		1.05			1.67	($\phi = 2$)
	Ostwald (any ϕ)			1.33		2	

if $d_m \geqslant d_1$ then the Stern theory yields a greater divergence from Ostwald's rule than the Gouy–Chapman theory. In view of the variation with sol concentration of the coagulating ion activity coefficient, as stressed by Weiser and Tezak, at best the Ostwald rule seems to be an empirical approximation. On the other hand, it is probable that for asymmetrical electrolytes where $m \geqslant 3$, the Poisson–Boltzmann equation, which is the basis of the Gouy–Chapman–Stern theory of the diffuse layer, is also inadequate because of the neglect, for example, of the fluctuation or self-atmosphere effect. It is well known that the limitations of the classical Debye–Huckel theory for electrolytes containing ions of high valency are largely attributed to this fluctuation term. Since the theory developed in this paper applies to very dilute sols whereas Ostwald's rule apparently holds for concentrated sols, the measure of agreement between the Gouy–Chapman–Stern theory and experiment for the valency type 1–m is not easily determined.

ACKNOWLEDGMENTS

The authors are indebted to Mr. D. F. Ferguson, University of Manchester, for assisting with the numerical computations in the tables and to Dr. I. E. Puddington, Division of Applied Chemistry, National Research Council, Ottawa, for his helpful suggestions.

THE SULPHURIC ACID SOLVENT SYSTEM

PART I. ACID–BASE REACTIONS[1]

R. H. Flowers, R. J. Gillespie, and E. A. Robinson

ABSTRACT

Acid–base reactions in the solvent sulphuric acid are discussed. Such reactions are conveniently studied by electrical conductivity measurements. A relation between the composition at which the conductivity has a minimum value and the strengths of the acid and base is derived. Values of the dissociation constants of acids and bases obtained in this way are shown to be in good agreement with values obtained by other methods.

INTRODUCTION

Sulphuric acid is an amphoteric solvent that undergoes fairly extensive autoprotolysis (1, 2).

$$2H_2SO_4 = H_3SO_4^+ + HSO_4^-$$

An acid of the sulphuric acid system may be defined as any substance that gives rise to the sulphuric acidium ion $H_3SO_4^+$. A simple monoprotic acid would ionize according to the equation

$$HA + H_2SO_4 = H_3SO_4^+ + A^-.$$

A base may be defined as any substance that gives rise to the hydrogen sulphate ion HSO_4^-. A simple monoprotic base would ionize according to the equation

$$B + H_2SO_4 = BH^+ + HSO_4^-.$$

Reaction between an acid and a base occurs according to the equation

$$H_3SO_4^+ + HSO_4^- = 2H_2SO_4,$$

which is, of course, just the reverse of the autoprotolysis reaction.

Because of the abnormally high mobilities of the $H_3SO_4^+$ and HSO_4^- ions the electrical conductivity of any solutions can be regarded, to a reasonably good approximation, as being due to these ions alone (1, 2). In acid–base reactions in which, for example, a base is added to a solution of an acid, the concentration of $H_3SO_4^+$ decreases and the concentration of HSO_4^- increases, causing the conductivity to decrease initially, pass through a minimum, and increase again. The position of minimum conductivity depends on the strengths of the acid and base and on their modes of ionization. By following the change in conductivity accompanying an acid–base reaction, information on the nature of the reaction and on the strength of the acid and base may be obtained. This paper gives a general treatment of the variation of the electrical conductivity during an acid–base reaction and some examples of the determination of acid and base strengths by this method are discussed.

THEORY

The detailed treatment of acid–base reactions is somewhat complicated by the existence of another form of self-dissociation of the solvent in addition to autoprotolysis, namely self-dehydration (1, 2), which may be summarized by the equations

$$2H_2SO_4 = H_2S_2O_7 + H_2O,$$
$$H_2S_2O_7 + H_2SO_4 = H_3SO_4^+ + HS_2O_7^-,$$
$$H_2O + H_2SO_4 = H_3O^+ + HSO_4^-.$$

[1]*Manuscript received April 6, 1960.*
Contribution from the Department of Chemistry, University College, London, W.C.1, England, and the Department of Chemistry, McMaster University, Hamilton, Ontario.

The concentrations of all the species in a solution containing an acid HA and a base B are related by the following expressions: the four equilibrium constants describing the self-dissociation of the solvent, whose values are given in Table I (3, 4),

$$K_{ap} = [H_3SO_4^+][HSO_4^-]^* \quad [1]$$

$$K_{id} = [H_3O^+][HS_2O_7^-] \quad [2]$$

$$K_{H_2S_2O_7} = [H_3SO_4^+][HS_2O_7^-]/[H_2S_2O_7] \quad [3]$$

$$K_{H_2O} = [H_3O^+][HSO_4^-]/[H_2O], \quad [4]$$

the dissociation constants of the acid and the base,

$$K_a = [H_3SO_4^+][A^-]/[HA] \quad [5]$$

$$K_b = [BH^+][HSO_4^-]/[B], \quad [6]$$

the condition for electrical neutrality,

$$[BH^+] + [H_3O^+] + [H_3SO_4^+] = [A^-] + [HS_2O_7^-] + [HSO_4^-], \quad [7]$$

and the condition that the composition of the solvent is H_2SO_4,

$$[H_3O^+] + [H_2O] = [HS_2O_7^-] + [H_2S_2O_7]. \quad [8]$$

TABLE I

Equilibrium constants for the self-dissociation reactions of sulphuric acid

	10° C	25° C
$K_{ap} = [H_3SO_4^+][HSO_4^-]$	1.7×10^{-4}	2.4×10^{-4}
$K_{id} = [H_3O^+][H_2S_2O_7^-]$	3.0×10^{-5}	4.2×10^{-5}
$K_{H_2S_2O_7} = [H_3SO_4^+][HS_2O_7^-]/[H_2S_2O_7]$	1.4×10^{-2}	1.4×10^{-2}
$K_{H_2O} = [H_3O^+][HSO_4^-]/[H_2O]$	1	1

For the special case where $H_2S_2O_7$ is the acid equation [5] is not needed and equations [7] and [8] are replaced by

$$[BH^+] + [H_3O^+] + [H_3SO_4^+] = [HS_2O_7^-] + [HSO_4^-] \quad [9]$$

and

$$m^s_{H_2S_2O_7} = [HS_2O_7^-] + [H_2S_2O_7] - [H_3O^+] - [H_2O] \quad [10]$$

where $m^s_{H_2S_2O_7}$ is the stoichiometric molal concentration of $H_2S_2O_7$.

For the special case where water is the base being neutralized equation [6] is not needed and [7] and [8] are replaced by

$$[H_3O^+] + [H_3SO_4^+] = [A^-] + [HS_2O_7^-] + [HSO_4^-] \quad [11]$$

and

$$m^s_{H_2O} = [H_3O^+] + [H_2O] - [H_2S_2O_7] - [HS_2O_7^-] \quad [12]$$

where $m^s_{H_2O}$ is the stoichiometric molal concentration of water. The concentrations of all the species for any concentrations of acid and base in an acid–base reaction may be calculated from these equations by the method that has been previously described (3).

The acids of the sulphuric acid system, e.g. tetra(hydrogensulphato) boric acid, $HB(HSO_4)_4$ (5), and disulphuric acid, $H_2S_2O_7$, are either known only in solution in sulphuric acid, or are only easily handled in solution, whereas the common bases, e.g.

**All concentrations in this paper are in molal units and* [A] *and* m_A *are both used to denote the molal concentration of the species A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

potassium sulphate, benzoic acid, and nitrobenzene, are easily obtained in the pure state and they are easily handled as such. Thus it is convenient to carry out acid–base reactions by adding the pure base to a solution of the acid. The position of minimum conductivity is then most conveniently expressed in terms of the ratio $r = n_b/n^1_a$ of the number of moles of added base, n_b, to the initial number of moles of acid n^1_a. Figures 1 and 2 show

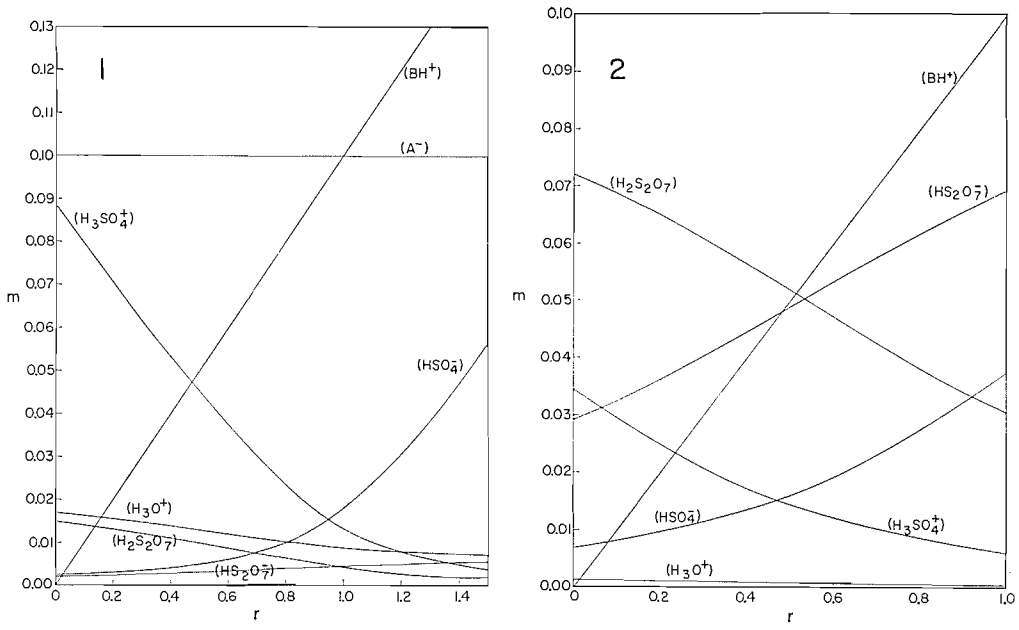

FIG. 1. Concentrations of species in a strong acid – strong base reaction at 25° ($m^i_{HA} = 0.1$).
FIG. 2. Concentrations of species in a disulphuric acid – strong base reaction at 25° ($m^i_{H_2S_2O_7} = 0.1$).

how the concentrations of all the species in reactions of the acids HA and $H_2S_2O_7$ with a strong base B vary with r for an initial concentration of acid $m^1_{H_2S_2O_7}$ or $m^1_{HA} = 0.1$.

The conductivity of the solution at any point in such a reaction is given by

$$\kappa = 10^{-3}\rho([H_3SO_4^+]\lambda_{H_3SO_4^+} + [HSO_4^-]\lambda_{HSO_4^-} + [H_3O^+]\lambda_{H_3O^+} + [HS_2O_7^-]\lambda_{HS_2O_7^-} + [BH^+]\lambda_{BH^+} + [A^-]\lambda_{A^-}) \quad [13]$$

where the λ's represent ion mobilities (molar conductances) and where it has been assumed that molar concentrations c may be replaced by $m\rho$ where m is the molal concentration and ρ the density of the solution. In view of the very small conductivities of all normally conducting ions (2) it is a reasonably good approximation to neglect their contribution to the conductivity of the solution in comparison with the relatively large contribution made by the highly conducting $H_3SO_4^+$ and HSO_4^- ions; hence we may write

$$\kappa = 10^{-3}\rho\ (\lambda_+ m_+ + \lambda_- m_-) \quad [14]$$

where λ_+ and λ_- are the mobilities, and m_+ and m_- are the molal concentrations of $H_3SO_4^+$ and HSO_4^- respectively. The mobilities of $H_3SO_4^+$ and HSO_4^- decrease with increasing concentration but at total ion concentrations of the order of $0.2m$, such as occur in the experiments described later, the variation of these mobilities with concentration is small (6) and is unlikely to be sufficiently large to appreciably affect the position of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

conductivity minimum. The ratio $\mu = \lambda_+/\lambda_-$ is, at least approximately, independent of concentration and has the value 1.45 (4). Hence we may write

$$\kappa = 10^{-3}\,\lambda_-(m_+\mu + K_{ap}/m_+). \qquad [15]$$

Since μ is constant and assuming that λ_- is also constant we have

$$\frac{\partial \kappa}{\partial m_+} = 10^{-3}\rho\lambda_-(\mu - K_{ap}/m_+^{\,2}) \qquad [16]$$

At the composition of minimum conductivity $\partial\kappa/\partial m_+ = 0$ and therefore

$$\mu - K_{ap}/(m_+)^2_{min} = 0,$$

or

$$(m_+)_{min} = \sqrt{K_{ap}/\mu}, \qquad (m_-)_{min} = \sqrt{K_{ap}\mu}. \qquad [17]$$

Substituting the values of K_{ap} given in Table I and $\mu = 1.45$ we find

$$(m_+)_{min} = 0.0132 \text{ at } 25° \quad \text{and} \quad 0.0108 \text{ at } 10°$$

$$(m_-)_{min} = 0.0182 \text{ at } 25° \quad \text{and} \quad 0.0157 \text{ at } 10°$$

Base–HA *Reactions*

Using the relation

$$[HS_2O_7^-] = \left(\frac{K_{id}\cdot K_{H_2S_2O_7}}{[H_3SO_4^+] + K_{H_2S_2O_7}}\right)^{1/2} \qquad [18]$$

which can be derived from equations [1] to [3] we obtain

$$[HS_2O_7^-]_{min} = 0.0045 \text{ at } 25° \text{ and } 0.0041 \text{ at } 10°$$

and from equation [2]

$$[H_3O^+]_{min} = 0.0088 \text{ at } 25° \text{ and } 0.0075 \text{ at } 10°.$$

Since

$$[BH^+] = m_b/(1 + [HSO_4^-]/K_b)$$

where m_b is the molality of added base B

and

$$[A^-] = m^i_a/(1 + [H_3SO_4^+]/K_a)$$

where m^i_a is the initial molality of the acid HA and if we write

$$y = [BH^+] - [A^-] = [HSO_4^-] + [HS_2O_7^-] - [H_3SO_4^+] - [H_3O^+]$$

we have

$$r_{min} = (m_b)_{min}/m^i_a = (1 + [HSO_4^-]_{min}/K_b)\{(1 + [H_3SO_4^+]_{min}/K_a)^{-1} + y/a\} \qquad [19]$$

where $a = m^i_a$.

Substituting the values given above for 25° we have

$$r_{min} = (1 + 0.018/K_b)\,\{(1 + 0.013/K_a)^{-1} + 0.0007/a\}. \qquad [20]$$

Values of r_{min} for various values of K_a and K_b are given in Table II for $a = 0.1m$.

TABLE II

Calculated values of r_{min} ("end points") for acid–base reactions

		Strong acid ($K_a = \infty$)			
K_b	∞	1.0	10^{-1}	10^{-2}	10^{-3}
r_{min}	1.01	1.02	1.19	2.82	19.1
		Strong base ($K_b = \infty$)			
K_a	∞	1.0	10^{-1}	10^{-2}	10^{-3}
r_{min}	1.01	0.98	0.89	0.44	0.08
		Disulphuric acid			
K_b	∞	1.0	10^{-1}	10^{-2}	10^{-3}
r_{min}	0.56	0.57	0.66	1.58	11.3
		Water			
K_a	∞	1.0	0.3	10^{-1}	10^{-2}
r_{min}	1.00	1.00	1.00	0.93	0.42

Base–$H_2S_2O_7$ Reactions

For reactions of $H_2S_2O_7$, $[HS_2O_7^-]_{min}$ can be calculated from the expression

$$[HS_2O_7^-] = \frac{a + \{a^2 + 4K_{id}(1 + [H_3SO_4^+]/K_{H_2S_2O_7})\}^{1/2}}{2(1 + [H_3SO_4^+]/K_{H_2S_2O_7})} \quad [21]$$

where $a = m^1_{H_2S_2O_7}$ and which can be derived from equations [2], [3], and [10]. Then $[H_3O^+]_{min}$ can be obtained from equation [2] and $[BH^+]_{min}$ from equation [9]. For $a = 0.1$, for example, we thus obtain

$$[H_3O^+]_{min} = 0.0008, \quad [HS_2O_7^-]_{min} = 0.0519, \quad \text{and } [BH^+]_{min} = 0.0561.$$

Now we have

$$r_{min} = \frac{[BH^+]_{min}}{a}\{1 + [HSO_4^-]_{min}/K_b\}. \quad [22]$$

Hence for $a = 0.1$ at 25°

$$r_{min} = 0.56\ (1+0.018/K_b). \quad [23]$$

Table II gives values of r_{min} for various illustrative values of K_b.

H_2O–*Acid Reactions*

For reactions of H_2O and an acid HA, $[H_3O^+]_{min}$ can be calculated from the expression

$$[H_3O^+]_{min} = [([A^-] + 0.0050) + \{([A^-] + 0.0050)^2 + 4K_{id}\}^{\frac{1}{2}}]/2, \quad [24]$$

which can be derived from equations [2] and [11] and the values of $[H_3SO_4^+]_{min}$ and $[HSO_4^-]_{min}$ given above, and where

$$[A^-] = a \Big/ \left(\frac{[H_3SO_4^+]_{min}}{K_a} + 1\right). \quad [25]$$

Then $[HS_2O_7^-]_{min}$ can be obtained from equation [2], $[H_2S_2O_7]$ from equation [3], and $m^s_{H_2O}$ from equation [12]. Thus, for example, for $HB(HSO_4)_4$ ($K_a = 0.3$) and $a = 0.1$ we have $[H_3O^+]_{min} = 0.1012$ and $[HSO_7^-]_{min} = [H_2S_2O_7]_{min} = 0.0004$. Hence $(m^s_{H_2O})_{min} = 0.1004$ and $r_{min} = (m^s_{H_2O})_{min}/a = 1.004$. Values of r_{min} for various values of K_a are given in Table II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

The conductivity minimum in the special case of the H_2O–$H_2S_2O_7$ reaction has been discussed in detail in an earlier paper (4).

RESULTS

$H_2S_2O_7$ – *Strong Base Reactions*

The variation in the conductivity during the reactions of the strong bases $KHSO_4$ and benzoic acid with disulphuric acid solutions of various concentrations is shown in Fig. 3.

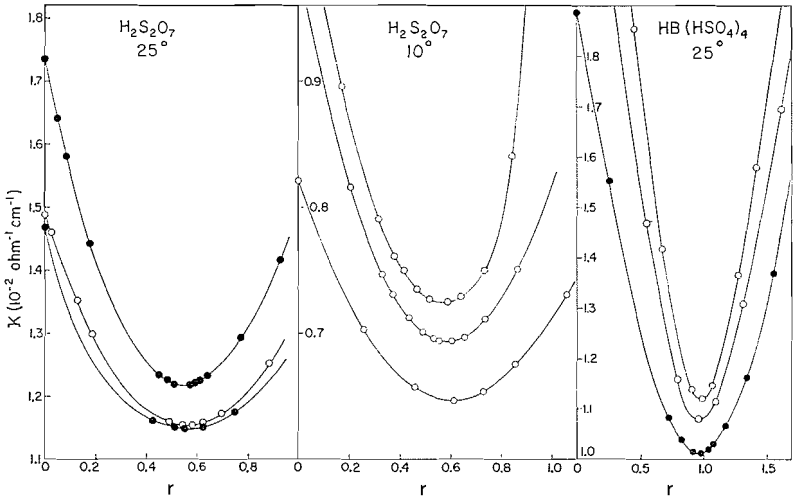

FIG. 3. Conductimetric titrations of strong bases with the acids $H_2S_2O_7$ and $HB(HSO_4)_4$. ○ $KHSO_4$, ● benzoic acid.

These experiments may be regarded as conductimetric acid–base "titrations" although the purpose of these titrations is not, as is usual, to estimate the concentration of either the solution of the acid or the base but rather to determine the dissociation constant of the acid or the base. In the present case the strengths of both the acid and the base are known so we may test the theory given above by comparing the predicted value of the "end point", i.e. the position of minimum conductivity, r_{min}, calculated from equation [23] with the observed value as is done in Table III. The agreement between observed and calculated values is excellent at 25° and good at 10°. The somewhat poorer agreement at 10° is probably due to the relatively greater contribution of the normally conducting ions to the conductivity at this temperature. This good agreement between the calculated and observed positions of the end point, r_{min}, provides support for the approximations made in the above theory and enables the equations to be used with confidence for the estimation of the strengths of weak acids and bases.

$HB(HSO_4)_4$ – *Strong Base Reactions*

The variation in the conductivity during the reactions of the strong bases $KHSO_4$ and benzoic acid with solutions of $HB(HSO_4)_4$ of various concentrations is shown in Fig. 3. The observed "end points", i.e. values of r_{min}, are given in Table III together with values for K_a calculated by means of equation [20]. The mean value, $K_a = 0.3$, is in good agreement with the value obtained from the conductivities of $HB(HSO_4)_4$ solutions (7) and

shows that $HB(HSO_4)_4$ is a moderately strong acid but is not completely ionized as had been concluded previously (5) from freezing point and conductivity measurements on solutions of boric acid in sulphuric acid which contain the electrolyte $H_3O.B(HSO_4)_4$. However, the degree of solvolysis of this electrolyte implied by $K_a = 0.3$ is too small to have been detected in these measurements.

$HB(HSO_4)_4$, $H_2S_2O_7$ – *Weak Base Reactions*

Acid – weak base reactions were studied using the acids $H_2S_2O_7$ and $HB(HSO_4)_4$ and the weak bases *o*-, *m*-, and *p*-nitrotoluenes and nitrobenzene. Of these four bases only *m*-nitrotoluene and nitrobenzene could be successfully titrated with $H_2S_2O_7$ as the other two sulphonated at an appreciable rate. All four bases were quite stable in $HB(HSO_4)_4$ solutions. This would, incidentally, seem to confirm the suggestion (8) that sulphur trioxide which is present in appreciable concentration in $H_2S_2O_7$, but not in $HB(HSO_4)_4$ solutions, is the sulphonating agent rather than $H_3SO_4^+$, which is present in both solutions in appreciable concentration. The results of some of the conductivity measurements are shown in Fig. 4 and the observed end points, i.e. values of r_{min}, are given in Table III together with the values of K_b calculated by means of equations [20] and [22]. These values of K_b are in good agreement with those obtained by other methods, which are given in Table IV for comparison. This agreement confirms the reliability of this "conductimetric titration" method of determining the strengths of weak bases in the sulphuric acid solvent system.

EXPERIMENTAL

The apparatus and general procedure for making the electrical conductivity measurements have been described elsewhere (12).

Sulphuric acid was prepared as previously described (12) and the composition was adjusted until it had the conductivity corresponding to the composition 100% H_2SO_4 ($\kappa = 0.010439$ ohm^{-1} cm^{-1}) (12). Solutions of disulphuric acid were prepared by distilling sulphur trioxide from fuming sulphuric acid into "AnalaR" sulphuric acid. Solutions of $HB(HSO_4)_4$ were prepared by adding boric acid to an oleum, whose composition was known from its conductivity, in accordance with the stoichiometric equation

$$H_3BO_3 + 3H_2S_2O_7 = HB(HSO_4)_4 + 2H_2SO_4.$$

"AnalaR" grade potassium sulphate was dried at 120°. Benzoic acid, m.p. 121 to 122° C, was recrystallized from water and dried at 100°. *p*-Nitrotoluene, recrystallized from alcohol, had a melting point of 54°. Liquid solutes were dried and redistilled: nitrobenzene, b.p. 209°, $n_D^{25} = 1.550$; *o*-nitrotoluene, b.p. 218°, $n_D^{25} = 1.543$; *m*-nitrotoluene, b.p. 228°, $n_D^{25} = 1.544$.

PROTON MAGNETIC RESONANCE SHIFTS FOR THE H_2O–SO_3 SYSTEM AND SOME ELECTROLYTE SOLUTIONS IN SULPHURIC ACID[1]

R. J. GILLESPIE[2] AND R. F. M. WHITE

ABSTRACT

Proton magnetic resonance shifts have been measured for the H_2O–SO_3 system. The results have been used to calculate the degree of ionization of water in solutions containing excess sulphuric acid. The shifts produced by a number of electrolytes in sulphuric acid have also been measured. The results are interpreted in terms of solute–solvent interactions, particularly polarization and hydrogen bonding, and are compared with the results of similar previous measurements on aqueous solutions.

INTRODUCTION

There have been two previous studies of the shift of the proton nuclear magnetic resonance in the H_2O–SO_3 system (1, 2). The present measurements on this system were undertaken as a preliminary to a more general study of the effects of both electrolytes and non-electrolytes on the proton resonance of sulphuric acid. Some differences were found between our results for the H_2O–SO_3 system and those of the earlier workers and so these results are given and discussed in some detail.

It has been found that electrolytes cause appreciable shifts in the proton resonance of water and this has been attributed to polarization and structure-breaking effects (3). Both cations and anions polarize water in such a manner that the electron density in the region of the protons is reduced and therefore resonance occurs at lower applied fields. The solvation of ions in general causes some structure-breaking in the solvent since the orientation of solvent molecules around ions is in general not the same as that in the bulk solvent and consequently a number of hydrogen bonds between the molecules in the solvation layer and those in the bulk of the solvent are broken. It has been established that generally the result of breaking hydrogen bonds is to shield the proton more effectively from the external field, thus shifting the resonance to higher applied fields (4). As ion–solvent interaction in sulphuric acid has been fairly extensively studied (5) it was of interest to see if proton shifts in sulphuric acid could be interpreted in a similar manner.

EXPERIMENTAL

The proton resonance shifts relative to pure water, $\delta = 10^6(H - H_{H_2O})/H_{H_2O}$, were measured with a Varian V4300B high-resolution spectrometer, operating at 40 Mc. Spectra were calibrated by the side-band technique using a Muirhead–Wigan L. F. Decade Oscillator. In preliminary experiments samples were sealed in 3-mm O. D. pyrex tubes, which were inserted into 5-mm O. D. tubes (2). The narrow annular space between the tubes contained distilled water which provided the reference signal. The results obtained using this type of sample tube showed a small scatter, probably due to tube imperfections. In order to reduce these effects the measurements were repeated using a different type of sample container. A small ground glass cone and socket joint was sealed to the end of a 5-mm O. D. sample tube. A reference capillary of water was sealed to the cone so that when it was inserted in the socket the capillary was centrally located in the sample tube. Scratch marks on the sample and reference tube ensured that they could

[1]*Manuscript received April 25, 1960.*
Contribution from the Department of Chemistry, University College, London, England.
[2]*Present address: Department of Chemistry, McMaster University, Hamilton, Ontario.*

always be put together in the same relative orientation. Although this technique does not completely eliminate effects due to tube imperfections any such effects will be almost constant in magnitude for all samples. Only results obtained using the second type of sample tube are reported; the results obtained from the first experiments agree with the reported results except for a somewhat greater scatter.

The diamagnetic susceptibilities of the solutions were measured by means of a Gouy balance (6). The apparatus available was designed for measurements on paramagnetic solids, and when used for diamagnetic solutions the accuracy obtainable was not better than 1%, mainly due to the small size of the sample. The measured susceptibilities and values calculated from Pascal's constants and the Wiedmann mixture law (6) indicate that the susceptibility correction (7)

$$g = (2\pi/3)\,(-0.721\times10^{-6}-\chi)\times10^{6},$$

where χ is the volume susceptibility of the solution, is almost negligible. As we give a largely qualitative interpretation of the observed shifts, susceptibility corrections have not in general been made except where stated. Sulphuric acid was prepared as previously described (8). Solutions containing small amounts of excess SO_3 or H_2O were analyzed by direct determination of their electrical conductivities (8) while those containing larger amounts of SO_3 or H_2O were analyzed by adding a known weight of the solution to a weighed amount of acid of known conductivity and measuring the change in conductivity.

RESULTS AND DISCUSSION

The Water – Sulphur Trioxide System

The results of our measurements on the H_2O–SO_3 system are given in Table I and Fig. 1.

TABLE I

Proton chemical shifts in the H_2O–SO_3 system

They agree well with Hood and Reilly's uncorrected results (2) up to about $x_{H_2SO_4} = 0.7$ but deviate from theirs at higher sulphuric acid concentrations. Although Gutowsky and Saika (1) only gave their results in graphical form they also appear to agree quite well with ours except at the highest sulphuric acid concentrations. Thus Hood and Reilly give $\delta_{H_2SO_4}$ (corrected) = −6.15 and $\delta_{H_2SO_4}$ (uncorrected) = −6.40, Gutowsky and Saika give $\delta_{H_2SO_4}$ (uncorrected) = −6.1, while we find $\delta_{H_2SO_4}$ (corrected) = −5.90 and $\delta_{H_2SO_4}$ (uncorrected) = −5.95. The earlier workers used reagent grade sulphuric acid for the

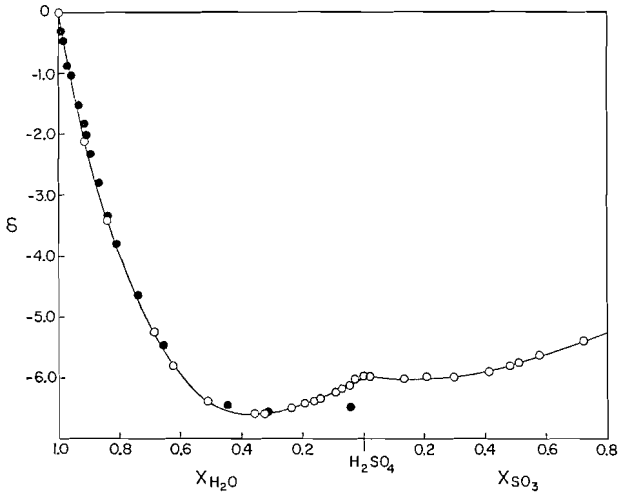

FIG. 1. Proton chemical shifts in the H_2O-SO_3 system.
○ This work; ● Hood and Reilly (2).

preparation of their solutions and determined their compositions by chemical analysis, while we have determined the composition of all our solutions by accurate conductivity measurements. It is likely that the differences in the uncorrected values of $\delta_{H_2SO_4}$ are merely a reflection of the fact that the composition of the more concentrated sulphuric acid solutions used by the earlier workers was not known with sufficient accuracy. Measurements for only two concentrations of oleum have been reported previously (1) and the same shift as for sulphuric acid was found in both cases. Our measurements on oleum solutions extend and essentially confirm these observations, showing that there is actually a very slight decrease in the shift in dilute oleum followed by a very flat minimum and a slight increase as the SO_3 concentration is increased up to and beyond the composition $H_2S_2O_7$.

Detailed analysis of the results is difficult because of the number of different species present in these solutions. We consider only the shifts in the region $x_{H_2SO_4} = 0.5$ to 1.0. Addition of water to sulphuric acid causes a shift in the proton resonance, which varies linearly with mole fraction up to approximately $x_{H_2SO_4} = 0.9$ (Figs. 1 and 3).

If we assume that the reaction that occurs when water is added to sulphuric acid can be represented simply by the equation

$$H_2O + H_2SO_4 = H_3O^+.HSO_4^-$$

then if x is the stoichiometric mole fraction of the water and α is the degree of ionization of the water the mole fractions of the species actually present in the solution are

$$N_{H_2O} = \frac{(1-\alpha)x}{1-\alpha x}, \qquad N_{H_2SO_4} = \frac{1-(1+\alpha)x}{1-\alpha x}, \qquad N_{H_3O.HSO_4} = \frac{\alpha x}{1-\alpha x}.$$

The corresponding proton fractions (i.e. the fractions of the total number of protons that are associated with any one species) are

$$p_{H_2O} = (1-\alpha)x, \qquad p_{H_2SO_4} = 1-(1+\alpha)x, \qquad p_{H_3O.HSO_4} = 2\alpha x.$$

Consequently the observed shift is given by

$$\delta = \delta_{H_2SO_4} - (1+\alpha)x\,\delta_{H_2SO_4} + 2\alpha x\,\delta_{H_3O.HSO_4}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

If the ionization of water is complete and $\alpha = 1$ then

$$\delta = \delta_{H_2SO_4} - 2x(\delta_{H_3O.HSO_4} - \delta_{H_2SO_4})$$

and we see that δ is a linear function of the mole fraction x. Experimentally this is found to be the case from $x = 0$ up to approximately $x = 0.10$. This indicates therefore that water is fully ionized over this range and by extrapolating this linear portion of the plot of δ against x to $x = 0.5$ we find $\delta_{H_3O.HSO_4} = -7.4$. At concentrations of water greater than $x = 0.10$ the curvature of the plot indicates that water is incompletely ionized. The degree of ionization α is given by

$$\alpha = \frac{\delta - \delta_{H_2SO_4}(1-x)}{x(2\delta_{H_3O.HSO_4} - \delta_{H_2SO_4})}.$$

Values of α obtained in this way are given in Table II and in Fig. 2 they are compared

with values calculated from Hood and Reilly's results (1) and with values calculated from the Raman spectral data of Young *et al.* (9). In view of the assumptions involved in both methods the agreement between our results and those of Young *et al.* seems reasonable. The agreement with Hood and Reilly's results is also satisfactory, except at their lowest water concentration.

It is difficult to separate $\delta_{H_3O.HSO_4}$ into individual values for H_3O^+ and HSO_4^- on the basis of the results for the H_2O–SO_3 system alone. Hood and Reilly attempted to do this in the following way; they obtained expressions for two quantities symbolized as s_4 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

s_5, which are functions of the shifts $\delta_{H_3O.HSO_4}$ and $\delta_{H_2SO_4}$. The quantity s_4 was determined from the measured shifts in the region $x = 0$ to 0.2 while s_5 was estimated from the measured shifts in the region $x = 0.5$ to 1.0 using the second dissociation constant of sulphuric acid obtained from e.m.f. and conductivity data and the Raman spectral measurements of Young *et al.* (9) for this region. From these values of s_4 and s_5 they obtained $\delta_{H_3O^+} = -13.1$ and hence from their results it may be calculated that $\delta_{HSO_4^-} = 10.8$. Their calculations assume that the chemical shifts of the various species in the solution are independent of the composition of the solution over the whole range from water to sulphuric acid. We believe that this assumption is not justified. Considerable difficulties arise in interpreting the shifts of metal hydrogen sulphate solutions if the value $\delta_{HSO_4^-} = 10.8$ is accepted; as is shown in the following section, a negative value is more probable. Our calculations assume that the shifts produced by H_3O^+ and HSO_4^- are constant over the composition range $x = 0$ to 0.5, which is somewhat better than Hood and Reilly's assumption but is still only an approximation.

Metal Hydrogen Sulphate Solutions

The results of the measurements of the shifts produced by a number of metal hydrogen sulphates in sulphuric acid are given in Table III and Fig. 3. If x is the stoichiometric mole fraction of the metal hydrogen sulphate the proton fraction for a univalent metal hydrogen sulphate is $p_{MHSO_4} = x/(2-x)$ and for a divalent metal hydrogen sulphate it is

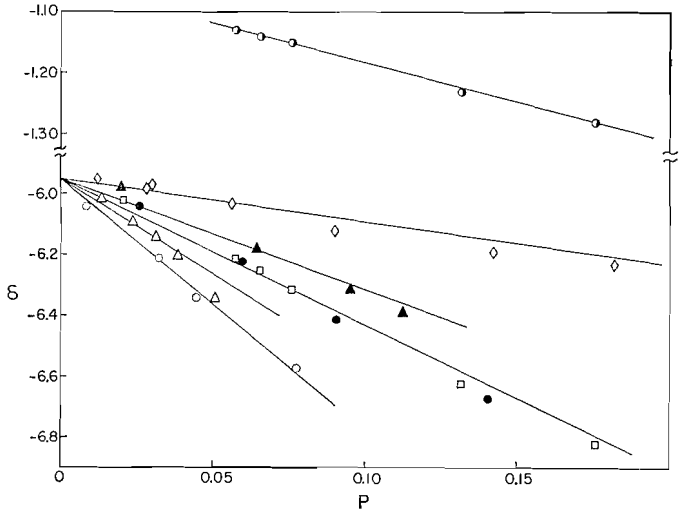

FIG. 3. Proton chemical shifts for hydrogen sulphates in sulphuric acid.
◑ HN_4; ◇ $H_3O.HSO_4$; ▲ $NaHSO_4$; ● $KHSO_4$;
□ $NH_4.HSO_4$; △ $Ba(HSO_4)_2$; ○ $TlHSO_4$.

$p_{M(HSO_4)_2} = x$. The proton shift would be expected to be the same linear function of the proton fraction p for all metal hydrogen sulphates:

$$\delta = \delta_{H_2SO_4} + p(\delta_{HSO_4^-} - \delta_{H_2SO_4}).$$

Figure 3 shows that the various metal hydrogen sulphates give linear, but nevertheless different, plots. It must be concluded that the metal ion also causes a shift in the proton resonance of the solvent in addition to that produced by the hydrogen sulphate ion. It has been found that electrolytes, even if they do not themselves contain any protons, cause appreciable shifts in the proton resonance of water (3); this has been attributed to polarization of the solvent molecules and breaking-up of the hydrogen-bonded structure of the solvent by the ions of the electrolyte. It has been shown that in aqueous solutions the polarizing effect of a cation is smaller than that of an anion of comparable size (3). This difference arises from the fact that a water molecule is oriented by a cation so that its hydrogen atoms are screened from the polarizing field by the oxygen atom. This screening effect would be considerably greater in sulphuric acid solutions because of the greater size of the sulphuric acid molecule compared with a water molecule. In sulphuric acid solutions the polarization effect of cations is therefore likely to be relatively small and the effect of cations on the proton resonance can most probably be attributed mainly to their structure-breaking effect on the solvent. The greater the extent of solvation of an ion the greater will be the number of hydrogen bonds broken and the more the resonance will shift to higher fields. Other measurements (5) have shown the extent of solvation of cations in sulphuric acid to be in the order

$$Na > NH_4 \sim K > Tl$$

and this is indeed the order of the shift of the proton resonance to high field (compared with Tl) in solutions of their hydrogen sulphates. Although the barium ion is more highly solvated than any of the univalent metal ions we have mentioned, solutions of barium di(hydrogen sulphate) give a smaller shift to high field (compared with Tl)

than solutions of sodium hydrogen sulphate. This can be attributed to the fact that at a given value of p the concentration of barium ion is only half that of a univalent metal ion and also to the fact that the dipositive charge of the barium ion will give rise to a much larger polarization effect, which may cause a significant shift of the proton resonance to low field.

Since the extent of solvation of the thallium ion is probably very small (5) it is reasonable to assume that its effect on the proton resonance is also small. An approximate value for the hydrogen sulphate ion shift may therefore be obtained by assuming that the shift produced by the thallium ion is in fact zero and that the whole of the shift observed for $TlHSO_4$ is due to the HSO_4^- ion. Hence we find $\delta_{HSO_4^-} = -13.9$. The positive value for $\delta_{HSO_4^-}$ obtained from the equations used by Hood and Reilly seems much less likely since in order to account for the observed shifts of metal hydrogen sulphates it would be necessary to attribute large low-field shifts to all metal ions, which in turn would suggest that all such metal ions produce very large polarization effects and this is rather unlikely. Moreover, if polarization of the solvent were the most important effect of the cations in these solutions it would be expected that the smallest ions would produce the greatest effects and consequently the order of the shifts of the proton resonance by different cations would be the reverse of that observed.

The large shift to low field produced by HSO_4^- is of interest. The electron density around the proton in an isolated HSO_4^- ion must be greater than that around the two protons in a sulphuric acid molecule and such an isolated HSO_4^- ion would be expected to have a proton resonance at a higher field than H_2SO_4. The shift to low field that is observed must be due to strong interaction with the solvent. Although the charge on HSO_4^- is rather dispersed it may nevertheless polarize the OH bonds of nearby sulphuric acid molecules since the hydrogen atoms will be oriented towards the HSO_4^- ion. This will cause a shift in the proton resonance of the solution to low field. The sulphuric acid molecules surrounding an HSO_4^- ion will be bound to it by hydrogen bonds and since the ion fits easily into the structure of sulphuric acid it may well cause no over-all bond-breaking but might well cause some increase in the total extent of hydrogen bonding in the solution, which would also cause a shift in the proton resonance to low field.

The shift produced by $H_3O.HSO_4$ is smaller than that of the metal hydrogen sulphates investigated and this may be attributed to the shift of H_3O^+ being smaller than that of H_2SO_4. We have that

$$\delta_{H_3O.HSO_4} = \delta_{HSO_4^-}/4 + 3\delta_{H_3O^+}/4$$

and using the values $\delta_{HSO_4^-} = -13.9$ and $\delta_{H_3O.HSO_4} = -7.4$ we find $\delta_{H_3O^+} = -5.2$. These values differ very considerably from those deduced by Hood and Reilly and they are probably only significant in systems containing excess H_2SO_4. It seems probable that the shifts produced by ions such as H_3O^+ and HSO_4^- which can hydrogen bond with the solvent change appreciably with the composition of the solvent. In order to account for the shift in the proton resonance caused by the addition of KNO_3 to HNO_3, Happe and Whittaker (10) have postulated the existence of the definite solvated species $NO_3^-.2HNO_3$ and $NO_3^-.HNO_3$ each producing its own shift and the latter gradually replacing the former with increase in the concentration of KNO_3. Similarly in predominately aqueous solutions of sulphuric acid it is very probable that the H_3O^+ ion exists in a solvated form such as $H_3O^+(H_2O)_3$ and as the concentration of acid is increased this is replaced by less hydrated complexes such as $H_3O^+(H_2O)_2$ and $H_3O^+(H_2O)$ and in strongly acid media by species such as $(H_3O^+)(H_2SO_4)_2$ (5, 11). It seems likely that the relatively

strong hydrogen-bonding in these complexes will cause each of them to have their own characteristic proton shifts. Unfortunately, if this is the case it makes any detailed analysis of this aqueous portion of the H_2O–SO_3 system almost impossible at the present time.

TABLE IV
Proton chemical shifts in HX–MX systems

Reference	HX–MX	Concn.	δ (ref. HX)
This work	H_2SO_4–$KHSO_4$	$p = 0.1$	−0.50
Gutowsky and Saika (1)	H_2O–KOH	$p = 0.1$	−1.00
Happe and Whittaker(10)	HNO_3–KNO_3	$x = 0.1$	−1.28
Unpublished (12)	HSO_3F–KSO_3F	$x = 0.1$	−1.38

Table IV shows the shifts in the proton resonance produced in different systems of the type HX–MX. All the shifts are negative, that is towards low fields, and they are all of the same magnitude. It seems reasonable to conclude that in each case X^- dissolved in HX produces a shift in the proton resonance to low field for the same reasons as given above for the HSO_4^-–H_2SO_4 system. The shifts are smallest in the cases of H_2O and H_2SO_4, which is consistent with the fact that in addition to the effects of interaction between the anions and the solvent the anions OH^- and HSO_4^- have their own intrinsic shifts, which must be to high field thus causing the over-all shift to low field to be smaller than the shift due to the anion–solvent interactions alone.

The Ammonium Ion

The proton resonance of the ammonium ion was observed as a separate peak indicating that these protons do not undergo rapid exchange with those of the solvent. The peak is a triplet due to spin–spin coupling with the nitrogen nucleus and shifts were measured from the center of this triplet which occurs on the low-field side of water and shifts to lower fields with increasing concentration (Table III and Fig. 3). This shift with increasing concentration can be plausibly attributed to an increased strength of the hydrogen bonds between the ammonium ion and the solvent as a consequence of the increasing basicity of the solvent with increasing concentration of HSO_4^-.

Acetone

Acetone produces a shift in the sulphuric acid resonance towards low field which varies linearly with mole fraction and which is of comparable magnitude to that produced by the metal hydrogen sulphates (Table III). Acetone is fully ionized (13) according to the equation

$$(CH_3)_2CO + H_2SO_4 = (CH_3)_2COH^+ + HSO_4^-$$

and if x is the mole fraction of $(CH_3)_2COH.HSO_4$ and the proton fraction is p then $p = x$. No detailed interpretation is possible at present because we cannot separate the intrinsic shift of $(CH_3)_2COH^+$ from the effect of its interaction with the solvent.

It is interesting that there is an appreciable shift in the CH_3 proton resonance to high field with increasing concentration of acetone. This could be due to a direct interaction of the CH_3 protons with the solvent, i.e. hydrogen-bonding or polarization of the C—H bond electrons by the negatively charged oxygen atoms of neighboring sulphuric acid molecules. Both these effects would lead to a shift in the proton resonance to low field with increasing concentration of hydrogen sulphate ion produced by the ionization of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the acetone. The observed shift is, however, to high field; the direct interaction of the CH_3 group with the solvent must therefore be small and the observed shift must be attributed to an indirect effect of the interaction of some other part of the molecule with the solvent. The protonated carbonyl group will be hydrogen-bonded to the solvent to an extent that will increase with the concentration of hydrogen sulphate ion and the positive charge on the oxygen atom will diminish correspondingly. This positively charged oxygen atom will polarize the C—H bond electrons of the CH_3 group and this polarization will therefore diminish with increasing concentration of hydrogen sulphate ion produced by the ionization of the acetone causing a shift in the resonance of these protons to high field.

The Fluorosulphuric Acid – Sulphuric Acid System

If the stoichiometric mole fraction of fluorosulphuric acid is x the corresponding proton fraction is $p_{HSO_3F} = x/(2-x)$. A plot of the shift of the proton resonance (Table V) against p_{HSO_3F} is linear (Fig. 4) as would be expected if there were no ionization or other interaction between the fluorosulphuric acid and the sulphuric acid. It has been found that HSO_3F is very slightly ionized in H_2SO_4 (14) but no effect of this is seen in the proton shifts.

The Chlorosulphuric Acid – Sulphuric Acid System

The proton resonance is independent of the composition of the system (Fig. 4 and Table V) and is the same as that for sulphuric acid itself. Presumably there is no ionization nor any appreciable change in hydrogen-bond strengths.

TABLE V

Proton chemical shifts in acid – sulphuric acid systems

Electrolyte	x	p	δ
$HB(HSO_4)_4$	0.037	0.122	−6.11

	0.264	0.662	−6.84
	0.420	0.901	−7.09
$HFSO_3$	0.182	0.100	−5.88
	0.287	0.168	−5.86
	0.311	0.184	−5.86
	0.639	0.470	−5.65
	0.767	0.624	−5.54
	1.000	1.000	−5.24
$HClSO_3$	0.216	0.121	−5.95
	0.417	0.263	−5.95
	0.735	0.581	−5.95
	1.000	1.000	−5.95

The Tetra(hydrogensulphato) Boric Acid – Sulphuric Acid System

Tetra(hydrogensulphato) boric acid, $HB(HSO_4)_4$, has been shown to ionize in sulphuric acid solvent as a moderately strong acid (14, 15, 16).

$$HB(HSO_4)_4 + H_2SO_4 = H_3SO_4^+ + B(HSO_4)_4^-$$

If the stoichiometric mole fraction of $HB(HSO_4)_4$ is x then the mole fractions of the species actually present in solution are

$$N_{H_3SO_4.B(HSO_4)_4} = x/(1-x) \text{ and } N_{H_2SO_4} = (1-2x)/(1-x)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

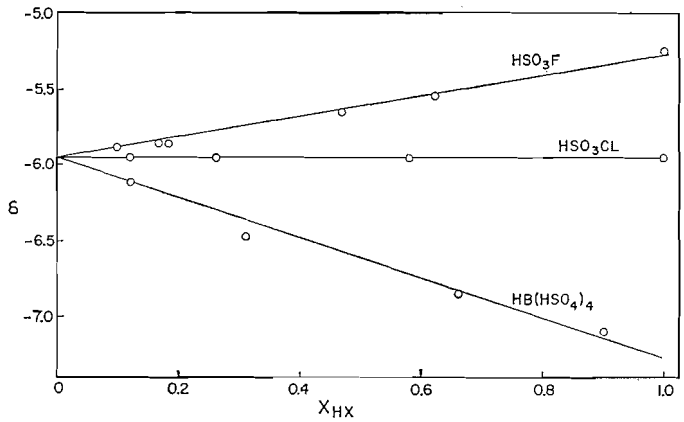

FIG. 4. Proton chemical shifts in HX – sulphuric acid systems.

and the corresponding proton fractions are

$$p_{H_3SO_4.B(HSO_4)_4} = 7x/(2+3x), \quad p_{H_2SO_4} = (2-4x)/(2+3x)$$

and the proton shift would be expected to be a linear function of $p_{H_3SO_4.B(HSO_4)_4}$:

$$\delta = \delta_{H_2SO_4} + p_{H_3SO_4.B(HSO_4)_4}\{\delta_{H_3SO_4.B(HSO_4)_4} - \delta_{H_2SO_4}\}.$$

The observed shift (Fig. 4 and Table V) is in fact a linear function of $p_{H_3SO_4.B(HSO_4)_4}$ and is smaller than that due to the metal hydrogen sulphates. There is not sufficient information on this system available at present to enable a detailed analysis of the observed shifts to be made.

THE PRESENCE OF MONOTHIOCARBONATE SUBSTITUENTS IN CELLULOSE XANTHATES[1]

D. A. ANDREWS,[2] F. G. HURTUBISE, AND H. KRÄSSIG

ABSTRACT

The presence of monothiocarbonate substituents in viscose has been demonstrated by the infrared spectra of the gases evolved during the acid hydrolysis of cellulose xanthate salts and viscose. A comparison of the results of various methods of sulphur determination and the results obtained by ultraviolet spectroscopy has been made. The results of investigations on sodium cellulose monothiocarbonate preparations support the concept of monothiocarbonate substitution.

INTRODUCTION

Sodium cellulose xanthate as normally prepared commercially from alkali cellulose and carbon disulphide is accompanied by numerous by-products. The composition of this mixture and of its solution in aqueous sodium hydroxide (viscose) changes as a result of complex hydrolytic and oxidative reactions. It is well established that the proportion of trithiocarbonate, the main by-product, increases as a result of the hydrolysis of sodium cellulose xanthate and that hydrolysis and oxidation of the trithiocarbonate lead to sulphide, perthiocarbonate, and thiosulphate (1, 2, 3, 4). The presence of other components, often suggested to account for the complex reactions, is less clearly established. Mono- and dithio-carbonate ions (5, 6) have been invoked as intermediate stages in the xanthation and side reactions, and cellulose monothiocarbonate ions can be postulated as a reaction product of monothiocarbonate ions and cellulose and as a hydrolysis product of sodium cellulose xanthate. Monothiocarbonates yield carbonyl sulphide on acid hydrolysis and the presence of this substance among the gaseous products of acidified viscose would provide substantial evidence for the existence of such derivatives.

RESULTS AND DISCUSSION

Infrared Spectra of Gases Evolved from Acidified Viscose

The presence of carbonyl sulphide in gaseous mixtures containing carbon disulphide, carbon dioxide, and hydrogen sulphide can be demonstrated by the infrared spectrum, and considerably less than 5% can be readily detected by the most sensitive band at 2030 cm^{-1} (Fig. 1).

The gaseous products of acidified viscose undoubtedly contained carbonyl sulphide (Fig. 2, Table I), and essentially the same relative proportion of carbonyl sulphide was obtained from impure viscose and from a solution of sodium cellulose xanthate purified from small anions by passage through an anion exchange column (7). This observation strongly suggests that much of the carbonyl sulphide was chemically linked to the cellulose, a conclusion supported by the observation that the viscose impurities formed from alkali and carbon disulphide gave a much smaller proportion of carbonyl sulphide than freshly prepared viscose. The relative proportion of carbonyl sulphide was smaller for a "ripened" viscose, an observation in agreement with the known fact that cellulose monothiocarbonate hydrolyzes more rapidly than cellulose xanthate (8).

These results are in agreement with those recently reported by Philipp (9), who

estimated the carbonyl sulphide evolved from viscose polarographically as ammonium monothiocarbamate. Very little reliance, however, can be placed on the quantitative data reported in this paper. Carbon disulphide, absorbed as ammonium dithiocarbamate, was found to seriously interfere in the polarographic estimations, and, under the conditions

used to minimize its absorption, only a portion of the total carbonyl sulphide was absorbed. The necessary large corrections render the method inaccurate. In addition, cadmium acetate was used to remove hydrogen sulphide from gaseous mixtures, a reagent which we found to react to some extent with carbonyl sulphide. In contrast to our observation, Herrent and Inoff (10) concluded from indirect analytical methods of somewhat doubtful validity that the proportion of monothiocarbonate increased as viscose ripened.

A quantitative assessment of the proportion of carbonyl sulphide has not been attempted. The gaseous hydrolytic products of viscose could be completely freed from the precipitated cellulose only by prolonged boiling which, in presence of acid, is said to decompose carbonyl sulphide (9). Quantitative removal of the gases in a stream of nitrogen at room temperature and subsequent absorption in alcoholic potassium hydroxide or ammonia solutions was attempted, but a quantitative recovery of the carbonyl sulphide was not possible since these reagents gave by-products, sulphide and carbonate, in addition to monothiocarbonate and monothiocarbamate, respectively.

Comparison of Results of Various Sulphur Determination Methods

Xanthates in solution are commonly estimated by oxidation to sulphate and by iodometric titration (11). Both methods are said to be quantitative for sulphides and monothiocarbonates, but we have not been able to confirm a quantitative reaction, according to equation 1, of iodine and potassium ethyl monothiocarbonate.

$$2RO{-}COS^- + I_2 \rightarrow 2I^- + RO{-}CO{-}S{-}S{-}CO{-}OR \qquad [1]$$

The presence of these substances in mixtures with xanthate, however, should be revealed by application of both methods: the assumption that sulphur is present only as xanthate would lead to higher calculated amounts of sulphur from the iodine method. In many sets of careful analyses of a variety of commercially prepared viscose samples, of which two typical examples are given (Table II, (*a*) and (*b*)), the amounts of sulphur estimated iodometrically in samples purified by ion exchange were not systematically different from those estimated as sulphate. Purified samples of potassium cellulose xanthates, however,

NOTE: All analytical data given are mean values from triplicate determinations.

showed large differences (Table II (*c*)). These samples, of higher degree of substitution, gave a much larger proportion of carbonyl sulphide on hydrolysis (Table I), and it is evident that the proportion of monothiocarbonate in commercial viscose is not sufficiently large to produce significant differences in the two analytical methods.

Ultraviolet Spectra of Various Cellulose Xanthates

In solution, absorption bands are shown by sodium cellulose xanthate at 382 and 302 mμ and by potassium ethyl xanthate at 380 and 300 mμ (12, 13). The extinction coefficients (Table III) are similar and appear to increase slightly with concentration.

The mean values for the molecular extinction coefficients of potassium ethyl xanthate and sodium cellulose xanthate in the 300–302 mμ region are 19,130 and 16,710 liters $mole^{-1}$ cm^{-1} respectively. Since monothiocarbonate does not absorb at 300 mμ, the extinction coefficient at 300 mμ of 1 mole of pure xanthate is therefore 19,130. Assuming that the lower extinction coefficient of sodium cellulose xanthate is due to the presence of monothiocarbonate, then the ratio of monothiocarbonate to xanthate groups in sodium cellulose xanthate would be

$$(19{,}130 - 16{,}710)/19{,}130 = 0.127.$$

If this value is now applied to the comparison of the percentage of sulphur estimated iodometrically and as barium sulphate the percentage of sulphur values calculated from the iodometric results should be considerably larger than those actually found (Table II). It is therefore not possible to consider the ultraviolet spectral data as conclusive evidence for the presence of monothiocarbonate substituents in the sodium cellulose xanthates investigated.

A comparison of the molecular extinction coefficients of sodium and potassium cellulose xanthate (Table IV) shows an even larger difference (e.g. 16,710 vs. 11,860). The fact that the percentage of sulphur values of potassium cellulose xanthate preparations calculated as xanthate from the iodometric method are consistently larger than those obtained by the barium sulphate method as well as the observed presence of large amounts

of carbonyl sulphide in the gases generated from the hydrolysis are indicative of the presence of monothiocarbonate substituents.

The formation of the colored by-products in purified cellulose xanthate solutions may readily be detected by a shoulder at 325 mμ; higher concentrations increase the extinction coefficient at 382 mμ and eventually produce a slight shift to longer wavelengths. These criteria are more sensitive than the detection of the trithiocarbonate absorption band at 500 mμ. The band at 382 mμ, but not that at 302 mμ, is immediately altered at a pH of between 4 and 6. The maximum is first shifted to 390 mμ and then the absorbance rapidly decreases. This observation supports previous statements (15) that the bands at 302 and 382 mμ are a result of the excitation of the C=S bond and the complete xanthate group, respectively.

Investigations on Sodium Cellulose Monothiocarbonate

Sodium cellulose monothiocarbonate was prepared at a low temperature from alkali cellulose and carbonyl sulphide, which had been carefully purified until carbon disulphide could not be detected spectroscopically. The freshly prepared white products were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

partially soluble in sodium hydroxide solution (7%), but one experiment gave a completely soluble product. About two thirds of the sulphur present was not retained by an anion exchange resin (Table V), and some carbonyl sulphide was regenerated on acid hydrolysis.

In contrast to the results obtained using sodium cellulose xanthate, the iodometrically derived sulphur values, assuming pure monothiocarbonate, are higher than those derived from barium sulphate estimations, indicating appreciable decomposition to sulphide under the conditions of the purification and estimation.

The cellulose monothiocarbonate solutions showed no spectroscopic absorption bands in the visible and ultraviolet regions at 385 and 302 mμ and cellulose xanthate was therefore absent. Only one preparation of cellulose monothiocarbonate, obtained from impure carbonyl sulphide, contained any xanthate as shown by its spectrum (cf. Fig. 3). Potassium ethyl monothiocarbonate, however, similarly prepared from carbonyl sulphide

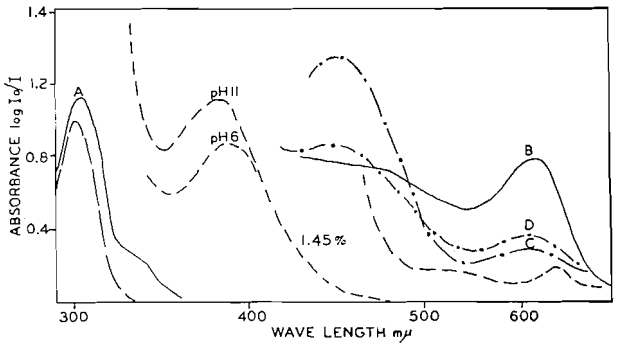

FIG. 3. Ultraviolet and visible absorption spectra of solutions of purified viscose (– – –); sodium cellulose monothiocarbonate (impure) (———): (A) in alkali, (B) acetone extract; aqueous sodium sulphide, carbon disulphide, and acetone (— · —): (C) 20 hours, (D) 26 hours.

(spectroscopically free of carbon disulphide) and potassium hydroxide in ethanol, was accompanied by detectable amounts of potassium ethyl xanthate.

In previous descriptions (14) of the reaction between alkali cellulose and carbonyl sulphide, it is stated that the product is not completely alkali soluble, but aside from some qualitative X-ray data, no analytical details are given. Philipp (8) describes the product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

as a green solid. Our products were green only when the carbonyl sulphide contained carbon disulphide. Acetone produced a more intense green or blue color, which soon faded in air, and sulphur precipitated. Such behavior is reminiscent of the oxidation of hydrosulphides, said to produce disulphides responsible for the intense color (15). Similar colors are sometimes to be seen in the mother liquors from viscose precipitated with acetone, in reaction mixtures of sodium sulphide, carbon disulphide, and acetone, and in freshly prepared viscose samples as they emerge from a column of anion exchange resin. In all cases an absorption band at about 650 mμ was observed (Fig. 3).

Infrared Spectra of Solid Samples

The infrared spectra of impure and 96% pure potassium ethyl monothiocarbonate are shown in Figs. 4A and 4C. The spectrum of the fraction containing the impurities is shown in Fig. 4B. Monothiocarbonate is characterized by important absorption bands in

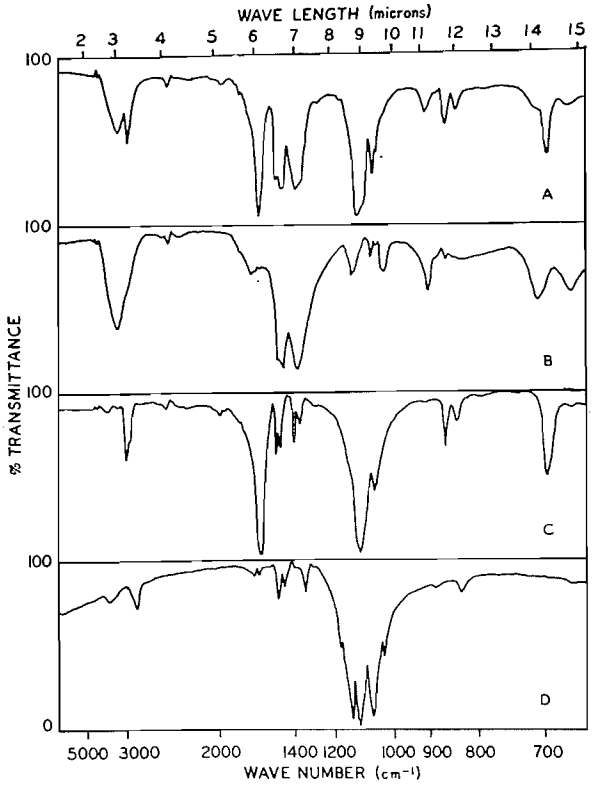

FIG. 4. Infrared spectra of potassium ethyl monothiocarbonate: (A) impure product, (B) insoluble fraction, (C) second recrystallization (96% pure). Infrared spectra of potassium ethyl xanthate (D).

the 1000–1200 cm^{-1} region, and at 1650 cm^{-1}. A less intense band occurs at 690 cm^{-1} and this is probably due to the C—S vibration. Comparison of the spectrum of potassium ethyl monothiocarbonate with that of potassium ethyl xanthate (Fig. 4D) shows that only the 1650 cm^{-1} band and to some extent the 690 cm^{-1} band can be used to detect monothiocarbonate groups in the presence of xanthate groups.

In the spectra of xanthates, intense absorption is always found in the 1060–1040 cm^{-1} region. At least two additional bands are usually found in the 1200–1100 cm^{-1} region. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

bands in the 1200–1000 cm^{-1} region are thought to be due to vibrations of the R—O—C part of the molecule.

The infrared absorption spectra of cellulose and alkali cellulose are shown in Figs. 5A and 5B. The nature of the bands in the cellulose spectrum have previously been discussed (16). The differences between the alkali cellulose spectrum and that of cellulose are mainly due to the presence of carbonate bands and to a general lowering of the cellulose bands due to changes in fine structure.

The infrared absorption spectrum of dried samples of sodium cellulose monothiocarbonate (Figs. 5C and 5D) revealed only the bands of cellulose and carbonate. Freshly

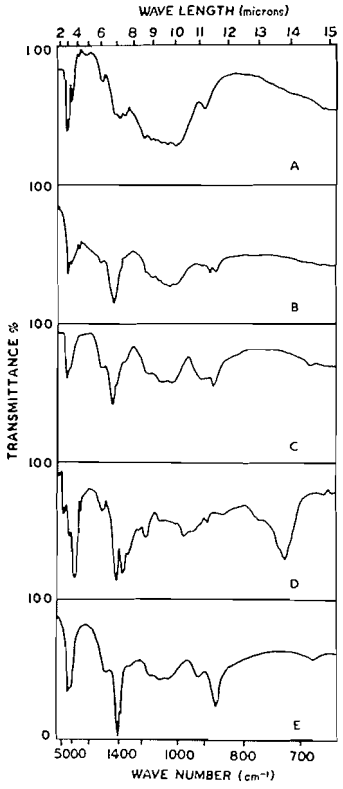

FIG. 5. Infrared spectra of cellulose (A), alkali cellulose (B), dried sodium cellulose monothiocarbonate (C, D), and freshly prepared wet sodium cellulose monothiocarbonate (E).

prepared wet samples were made into potassium bromide pellets with much difficulty (Fig. 5E). The main bands shown by this sample are those due to carbonate.

In an attempt to provide positive evidence for the presence of cellulose monothiocarbonate, the infrared spectra of potassium bromide pellets of samples of sodium cellulose xanthate precipitated from various viscose preparations (Fig. 6A) were examined as well as the corresponding S-methyl (Fig. 6B) and diethylacetamido (Fig. 6C) derivatives.

No bands analogous to those which can be ascribed to the monothiocarbonate are to be observed (Fig. 4). The degree of substitution of the cellulose monothiocarbonate samples was low, the bands are not pronounced and, as the amounts of monothiocarbonate were much less, it is not surprising that it escaped detection.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

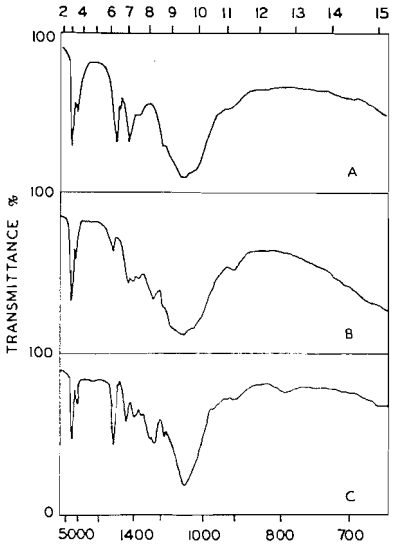

FIG. 6. Infrared spectra of cellulose xanthate precipitated from viscose (A), its S-methyl derivative (B), and its diethylacetamido derivative (C).

The precipitation of the cellulose xanthate salts by acetone or methanol at 0–5° C (17) and of the diethylacetamido derivative (18) from viscose by described methods was found to be accompanied by some loss of xanthate groups. The previous work showed no such loss. The two pronounced bands found for the sodium cellulose xanthate samples at 1563 and 1428 cm^{-1} were probably the result of impurities. Similar bands were found for some samples of the S-methyl derivative and these disappeared after successive extractions with water, acetone, and ether.

EXPERIMENTAL

Materials and Analytical Methods

Commercial samples of hydrogen sulphide (19), carbon disulphide, and carbon dioxide (20) were purified by established methods. Carbonyl sulphide was passed through sodium hydroxide solution (33%) and concentrated sulphuric acid and then liquefied by cooling with solid carbon dioxide and acetone. Two distillations through an externally cooled (−35° C) Vigreux column at a reflux ratio of about 3:1 were necessary to obtain carbonyl sulphide free of carbon disulphide. Triethylphosphine in nitrobenzene (1:10) also absorbed carbon disulphide from the impure mixture (21, 22), but some could still be detected in the infrared spectrum of the carbonyl sulphide.

Generation of Gases

One arm of a long U-tube (1 m × 2 cm diameter), separated from the other arm by a stopcock and containing the viscose (20 g), sodium cellulose xanthate or monothiocarbonate (5–10 g), was evacuated and phosphoric acid (50%) was admitted from the other arm. The heat necessary to free the gases from the cellulose was supplied externally. The reaction product of sodium hydroxide (8%, 160 ml) and carbon disulphide (25 ml) at room temperature (18 hours) was hydrolyzed similarly.

All gases were dried with phosphorus pentoxide and stored over mercury. Measured volumes in a 10-cm cell were examined in a Perkin–Elmer model 13 infrared spectrophotometer.

Preparation of Viscose

Viscose was prepared by standard commercial methods (23). All samples and solutions were kept at −5° to 0° C to minimize hydrolytic decomposition, and analyses were performed immediately after purification. Samples of viscose were allowed to "ripen" in a constant temperature bath at 8° C.

The total sulphur in viscose (10 g) diluted in sodium hydroxide solution (8%) at −5° C to 100 ml was estimated in aliquots (20 ml) by analytical method No. 2 below. The trithiocarbonate was estimated approximately from the extinction at 500 mμ of samples in 1-cm silica cells. (An extinction coefficient of 449 liters $mole^{-1}$ cm^{-1} was found using sodium trithiocarbonate solutions (16) prepared under nitrogen and estimating the trithiocarbonate content by method 1.)

Purification of Viscose

Amberlite anion exchange resin IRA 400 (8, 24) was used for purifying the viscose.

1. Viscose (100 g) was forced through the resin (200 g) by air pressure (30 lb in^{-2}) in an apparatus similar to that described by Dux (24).

2. Viscose (25 g) at 0° C was diluted with sodium hydroxide solution (8%, 250 ml) and passed through an externally cooled (−5° C) resin column (100 g, 2 cm diameter) and eluted to 1 liter. Dilution and elution with water instead of sodium hydroxide solution was found to cause a remarkable increase in elution time, particularly for cellulose xanthate of high xanthate substitution (D.S. = 0.7). The viscosity of cellulose xanthate solutions decreases with increasing alkali concentration (25).

Analytical Methods

1. Aliquots of purified viscose solution (100 ml) were oxidized by hydrogen peroxide (30%, 20 ml). After 10 minutes at room temperature, the solutions were diluted (100 ml), boiled to decompose the excess peroxide (20 minutes), cooled, made up accurately to 250 ml, and filtered. The sulphate in an aliquot (150 ml) was estimated gravimetrically as barium sulphate (26).

2. Similar aliquots were added to cooled mixtures of acetic acid (50%, 50 ml) and iodine (0.04 *M*) in potassium iodide solution (0.1 *M*, 50 ml), and excess iodine was titrated against standardized sodium thiosulphate solution (0.05 *N*) after 5 minutes.

3. The gases evolved from similar aliquots (using 150 ml of 50% phosphoric acid) were removed by a stream of nitrogen and passed through a solution of cadmium chloride (0.1 *M*) and sodium acetate (0.1 *M*) at pH = 6.8 to absorb hydrogen sulphide and subsequently through methanolic potassium hydroxide to absorb carbon disulphide (13). The sulphur was estimated either by the barium sulphate method (method 1) or by the iodometric method (method 2). Carbonyl sulphide was found to precipitate cadmium sulphide from solutions buffered at pH 4–7 with acetic acid and sodium acetate (26), and its presence invalidates the method.

4. The cellulose in aliquots (40 ml) was estimated by oxidation (27) with potassium dichromate (1 *N*) and sulphuric acid (70% in reacting solutions). Excess dichromate was titrated against ferrous ammonium sulphate using platinum and calomel electrodes.

Measurement of Ultraviolet Spectra

Aliquots were accurately diluted in sodium hydroxide solution (8%) to give a suitable range of concentrations, and the extinction for maxima at about 380 and 300 mμ was measured using 1-cm silica cells in a Beckman D.K. 2 spectrophotometer. The calculated extinction coefficient evidently depended upon the slit width which adjusts automatically at a given sensitivity.

Potassium Cellulose Xanthate

Samples of dissolving pulp (25 g) were steeped in potassium hydroxide solution (40%) at 5° C for 3 hours, filtered, and subjected to an air current for 3 hours. The alkali cellulose (35 g) and potassium hydroxide solution (100–400 ml, 40%) were stirred with carbon disulphide (400 ml) for 16–40 hours. Excess carbon disulphide was removed under vacuum (15 mm), and samples were examined as described for viscose.

Sodium Cellulose Xanthate

Viscose (50 g; S, 1.45; cellulose, 6.78%; D.S., 0.51), diluted with ice water (250 ml), was titrated with cold acetic acid (6 *M*) to pH 6–7 using glass and calomel electrodes. Cold acetone (750 ml), run in over about 10 minutes, gave a precipitate which was either centrifuged or filtered off and ground successively in a mortar with cold acetone (3×50 ml), acetone–ether mixtures (40:10, 30:20, 20:30, 10:40), and finally with anhydrous cold ether (3×50 ml). Samples for analysis (methods 1 and 4) and spectroscopic examination were dried at 20° C (0.5 mm Hg over phosphorus pentoxide). The use of methanol in place of acetone gave a more gelatinous precipitate, which was more difficult to filter or centrifuge, and which resulted in extensive xanthation of the methanol (λ_{max} = 380, 300 mμ). Dissolution of these products in cold sodium hydroxide solution formed more trithiocarbonate (λ_{max} 500 mμ; shoulder 325 mμ). Sample A, Fig. 4, found: S, 9.27; cellulose, 62.6%; D.S., 0.38.

S-*Methyl Cellulose Xanthate*

S-Methyl cellulose xanthate (cell—O—CS—SCH_3) was prepared from the precipitated sodium cellulose xanthate sample (D.S., 0.38) and methyl iodide, essentially as recently described (17). The product was washed successively with acetone, water, acetone, and solvent exchanged into ether. Sulphur in samples dried to constant weight at 20° C (0.5 mm Hg) was determined by use of a Parr bomb (28). All samples were insoluble in pyridine and lost sulphur in this solvent at 100° C (29). Sample B, Fig. 6B, found: C, 39.05; H, 5.57; S, 9.01. Calculated for D.S. of 0.26: C, 42.19; H, 5.71; S, 9.01%.

Diethylacetamido Cellulose Xanthate

Diethylacetamido cellulose xanthate (cell—O—CS—S—CH_2—$CONEt_2$) was precipitated from the same sample (D.S., 0.51) of diluted viscose neutralized to pH 6.5 as described (13), and dried to constant weight at 20° C (0.1 mm Hg). Sulphur (28) and nitrogen (30) were estimated by standard methods. This substance lost sulphur in pyridine at 100° C. Sample C, Fig. 4, found: S, 11.94; N, 2.36%; D.S., 0.47; 0.40 respectively. After reprecipitation from dimethyl sulphoxide by ether, found: S, 10.2%; D.S. 0.40.

Cellulose Dixanthate

Cellulose dixanthate (cell—O—CS—S—)$_2$, obtained in iodometric titration (method 2) of the same viscose sample, was filtered, washed with solvents (as for cellulose xanthate), and dried at 80° C (0.5 mm Hg). Sulphur (28) determinations showed loss of xanthate. Found: C, 40.73; H, 5.81; S, 9.93. Calculated for D.S. of 0.29: C, 40.64; H, 5.33; S, 9.93%.

Potassium Ethyl Xanthate

Potassium ethyl xanthate was recrystallized from acetone and dried at 80° C (0.1 mm Hg). Sulphur, determined by methods 1, 2, and 3, gave 39.3, 39.13, and 39.01% respectively (purity 98%).

For personal use only.

Potassium Ethyl Monothiocarbonate

Potassium hydroxide (6.6 g) in pure ethanol (30 ml) at −15° C absorbed less (5½ liters) than the calculated amount of pure carbonyl sulphide (11 liters) and precipitated a white solid A (10 g), which was filtered off and rapidly extracted with ethanol (50 ml) at 50° C, leaving a hygroscopic powder B (5.3 g, S 2.39%) containing much carbonate. The ethanol extract, cooled to 5° C, gave white needles C (2.6 g, S 18.54%), which on similar extraction left an insoluble powder (10 mg); cooling to 0° C gave white needles D (1 g). Found S: 21.34% C_2H_5COS; K requires S, 22.22%, purity 96%. The infrared spectra (Fig. 4) of these samples showed bicarbonate as an impurity which was not completely removed. The mother liquor showed absorption maxima at 380 and 300 mμ, which are characteristic of the ethyl xanthate.

Four similar preparations and the use of sodium hydroxide, sodium ethoxide in toluene, and potassium hydrosulphide with ethylchloroformate in ethanol gave similar mixtures. Extraction with ethanol at lower temperatures (−5 to −10° C) gave small amounts of impure products. Previous accounts of this preparation (e.g. 31) apparently resulted in a purer product. Samples of our crude reaction product A, analyzed by methods 1, 2, and 4, evidently contained sulphide as indicated by the higher iodometric results. The fact that carbonyl sulphide reacted with the cadmium reagent invalidated the gas analytical method (sulphur in sample A: by Ba_2SO_4, 10.87%; by iodometry, 11.9%; as COS^-, 9.91%; as $S^=$, 0.96%; from gas analysis: absorbed by $Cd(OAc)_2$, 1.44%; absorbed by KOH/CH_3OH = 9.12%).

Sodium Cellulose Monothiocarbonate

Alkali cellulose from cotton linters and sodium hydroxide solution was treated with liquid carbonyl sulphide at −70° C and the temperature was allowed to rise to −5° C over 18 hours. Weighed samples of the white solid were analyzed and partial solutions in 8% purified sodium hydroxide were prepared as described for viscose. Solutions in aqueous sodium hydroxide showed no absorption maxima at 382 and 302 mμ, indicating the absence of xanthate. Samples prepared by passing carbonyl sulphide gas over alkali cellulose at −15° C were green in color only when carbon disulphide was present in the carbonyl sulphide. The green color was extracted into acetone at −15° C under nitrogen, and the spectrum (Fig. 3) was examined in 1-cm silica cells; in air the color faded, and sulphur precipitated.

Diethylacetamido Cellulose Monothiocarbonate, Attempted Preparation

Sodium cellulose monothiocarbonate (10 g) in cold sodium hydroxide solution (100 ml) and N,N-diethylchloroacetamide (5 ml) were mixed and the solution was neutralized to pH 7 with cold acetic acid (6 *N*) using glass and calomel electrodes. After 2 hours, the gelatinous precipitate (3.9 g) was filtered, washed with water and solvents (13), and dried at 28° C over phosphorus pentoxide (0.1 mm Hg). The product contained neither sulphur nor nitrogen. Found: C, 40.25, 42.43; H, 6.63, 6.41. Calculated for $(C_6H_{10}O_5)_n$: C, 44.4; H, 6.22%.

Infrared Examination

Solid samples (1.5 mg) were dried at 20° C under 0.1 mm Hg pressure over phosphorus pentoxide, finely divided and made into pellets with potassium bromide (300 mg) (33). Freshly prepared cellulose monothiocarbonate samples containing appreciable quantities of water were examined as pellets and as Nujol mulls. All spectra were measured with a Perkin–Elmer model 13 infrared spectrophotometer equipped with NaCl optics and operated in double-beam mode.

NOTES

THE IDENTITY OF BAYERITE-*a* AND BAYERITE-*b*

G. YAMAGUCHI AND K. SAKAMOTO

In 1928 Fricke (1) reported the existence of two types of bayerite, $Al_2O_3.3H_2O$, which he called *a* and *b*. Both give almost identical X-ray diffraction powder patterns except that the relative intensities of some of the lines are not the same in both patterns. The most striking example is the 00.1 line, which is one of the strongest in the pattern of type *b* and is a little stronger than the 10.0 line, while in type *a* it is conspicuously weaker than the latter. Nishimura (2) has recently obtained the less common type *a* while preparing Raney nickel from a Ni–Al alloy. He has confirmed the very weak intensity of the 00.1 line and has found that it varies in relative intensity according to the conditions under which the bayerite is formed. We have repeated the preparation of type *a* by Nishimura's method and have obtained type *b* by a procedure reported elsewhere (3). Both types have now been examined by the X-ray diffraction powder method (Fig. 1), by electron microscopy (Fig. 2), and by electron microdiffraction techniques (Fig. 3). The observed *d* spacings, derived from the diffractometer charts reproduced in Fig. 1, are listed in Table I,

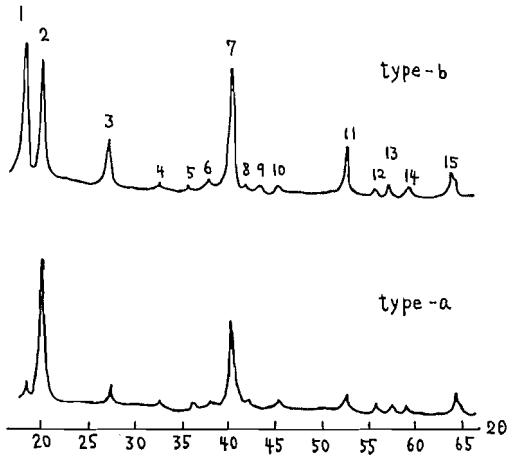

FIG. 1. X-Ray diffraction patterns of bayerite-*a* and bayerite-*b* (Cu $k\alpha_1$, filtered; Norelco-type diffractometer).

where it will be seen that, except for relative intensities, the powder patterns of type *a* and type *b* are identical. The electron micrographs (Fig. 2) show that type *a* crystallizes with a needle-like, or lath-like, habit and a tendency towards parallel growth along the direction of the needle axis, while type *b* crystallizes in thin, hexagonal plates. The structural periodicity shown in the electron microdiffraction photograph of a single crystal of type *a* (Fig. 3) was found to be 4.71 Å by comparison with an electron diffraction photograph of gold foil; this value is in good agreement with the length of the *c* axis of type *b* (a = 5.047 Å, c = 4.730 Å; S.G., $P\bar{3}1m$) reported elsewhere (4). These results indicate that bayerite-*a* and bayerite-*b* are structurally identical, that the crystals of type *a* are elongated in the direction of the *c* axis, and that the observed differences between types *a*

silicone grease was used.) The purpose of this note is to record a corrected description of 1,1-bis(4-chlorophenyl)-urea in the pure state.

This unsymmetrically substituted urea has now been obtained by a different method and characterized through conversion to known derivatives by the well-established reactions illustrated in Fig. 1.

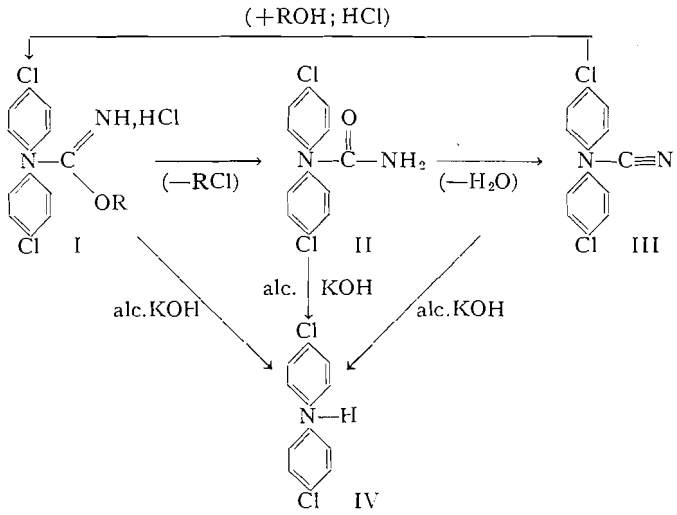

FIG. 1. The synthesis and hydrolysis of 1,1-bis(4-chlorophenyl)-urea.

Although the 3,3-diphenyl-2-alkylpseudoureas are known to undergo rearrangement and cleavage on heating to form diphenylamine and the corresponding alkyl isocyanate (2), their hydrochloride salts, when heated, retain the urea skeleton resulting in the formation of unsymmetrical diphenylurea and the corresponding alkyl chloride (3). Similar behavior of the 3,3-dialkyl-2-alkylpseudoureas was reported by McKee (4). This property has provided a convenient method for synthesis of 1,1-bis(4-chlorophenyl)-urea (II, Fig. 1). The reaction of water with the pseudourea salts, at room temperature, is observed to produce the same material, though slowly.

Evidence for the structure of II is provided by its ready dehydration to 4,4′-dichlorodiphenylcyanamide (III) using Kurzer's technique (5), as well as by its hydrolysis to 4,4′-dichlorodiphenylamine (IV) in alcoholic potassium hydroxide. Further, the infrared spectrum* of the material in the region 3600–3200 cm^{-1} is identical with that of 1,1-diphenylurea and 1,1-bis(4-methoxyphenyl)-urea, each having absorption peaks characteristic of $—NH_2$ at 3540 and 3430 cm^{-1}, as well as a strong peak at 1675 cm^{-1} typical of an amide carbonyl; a peak at 830 cm^{-1} is further indication of the paradisubstituted phenyl groups in this material.

The degradation of the 3,3-bis(4-chlorophenyl)-2-alkylpseudourea salts (I) to 4,4′-dichlorodiphenylamine may also be accomplished directly in boiling alcoholic potassium hydroxide; 4,4′-dichlorodiphenylcyanamide undergoes similar conversion (1).

*Acknowledgment is made to Mr. R. W. White of this laboratory for recording and interpreting the infrared spectra of these materials.

EXPERIMENTAL*

3,3'-Bis(4-chlorophenyl)-2-alkylpseudoureas

3,3-Bis(4-chlorophenyl)-2-alkylpseudoureas (Fig. 1, I where R = C_1 to C_{12} alkyl groups) were prepared by the alkoxide catalyzed addition of alcohols to 4,4'-dichlorodiphenylcyanamide (1, 3).

1,1-Bis(4-chlorophenyl)-urea

(a) By Thermal Decomposition of 3,3-Bis(4-chlorophenyl)-2-n-heptylpseudourea Hydrochloride

The pseudourea salt (2.0 g, 4.8 mmoles) was spread thinly over a watch glass and kept in a 90° oven until odorless and no longer water-soluble (5 days). The residue was recrystallized from methanol–water, ethanol–water, then dried *in vacuo* over calcium chloride. The yield of purified material (fine, colorless needles) was 1.0 g (75%); it gave a positive test for organic halogen, a negative test for halide, and melted at 187°–188° C. Its infrared absorption characteristics are described above. Anal. Calc. for $C_{13}H_{10}N_2OCl_2$: C, 55.53; H, 3.58%. Found: C, 55.75; H, 3.57%.

(b) By Thermal Decomposition of 3,3-Bis(4-chlorophenyl)-2-n-butylpseudourea Hydrochloride

The salt (1.17 g, 3.18 mmoles) was kept at the melting point, under vacuum (0.2 mm of mercury), on a manifold to which a cold trap was attached. After 90 minutes the crude residue weighed 0.87 g (97%) and repeated recrystallization from ethanol–water gave fine, colorless needles, m.p. 187°–188°.

The distillate in the cold trap weighed 0.265 g (90%) and had the boiling point (77°–78°) and refractive index (1.4014) of *n*-butylchloride.

(c) By the Action of Water on 3,3-Bis(4-chlorophenyl)-2-methylpseudourea Hydrochloride

An aqueous solution of the salt (0.5 g, 1.5 mmoles in 100 ml of water) was left standing in the dark at room temperature. After several days, long needle-like crystals began to grow. After 7 months the material was filtered off and recrystallized from methanol–water and ethanol–water, giving colorless needles, m.p. 187°–188°.

The three products (*a*, *b*, and *c*) were identical in chemical and physical properties.

4,4'-Dichlorodiphenylcyanamide

A solution of 0.84 g (2.98 mmoles) of 1,1-bis(4-chlorophenyl)-urea (above) in 25 ml of pyridine was treated with 1.77 g (10 mmoles) of benzenesulphonyl chloride and left standing at room temperature for 12 hours. The reaction product, after precipitation with water, filtration, and washing, was recrystallized from methanol yielding 0.58 g (73%) of long colorless needles of 4,4'-dichlorodiphenylcyanamide, m.p. 114°–115°. The material was confirmed by a mixed melting point with an authentic sample (1).

4,4'-Dichlorodiphenylamine

A 5-ml methanolic potassium hydroxide solution of 1,1-bis(4-chlorophenyl)-urea (0.12 g, 0.42 mmole) was boiled under reflux for 24 hours; some ammonia was evolved. After crystals of potassium carbonate were filtered off, the product was precipitated by adding water and recrystallized from 110° petroleum ether yielding 0.085 g (85%) of 4,4'-dichlorodiphenylamine, colorless needles, m.p. 77°–78°.

The identical product was obtained in 80–90% yield, by the same technique, starting with any of the 3,3-bis(4-chlorophenyl)-2-alkylpseudourea hydrochlorides.

**Melting points were obtained using a Fisher–Johns block and are uncorrected. Carbon and hydrogen analyses were by J. F. Alicino, Metuchen, N.J.*

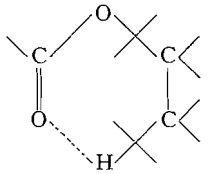
THE HYDROGEN ISOTOPE EFFECT IN THE PYROLYSIS OF ETHYL-1,1,2,2-d_4 ACETATE[1]

ARTHUR T. BLADES AND P. W. GILDERSON

ABSTRACT

The hydrogen isotope effect in the pyrolysis of ethyl-1,1,2,2-d_4 acetate has been measured in the temperature range 442–650° C. Making allowance for symmetry numbers in the formation of the ethylene products C_2D_4 and C_2D_3H, the isotope effect may be expressed as



$$k_H/k_D = 0.99e^{1145/RT}.$$

The data are interpreted as indicating a reaction co-ordinate in which a C—H bond is breaking, but contributions to the isotope effect from residual C—H and (or) incipient O—H vibrations, and from bending vibrations, must be included to explain the results satisfactorily.

INTRODUCTION

Recent studies in the pyrolysis of alkyl esters by Bailey *et al.* (1) as a preparative method for olefins have revived interest in the mechanism of this reaction. Bailey's results were characterized by the almost exclusive production of that olefin which might be described as the least-substituted ethylene, i.e. where competitive reactions were possible, the reaction followed the Hoffmann rule. This selectivity has since been shown (2) not to exist in the homogeneous reaction, the major factor influencing the ratio of products being purely statistical.

The accepted transition state for the reaction is a six-membered ring with the

β-hydrogen of the alkyl group bonded to the acyl oxygen. De Puy and Leary (3) have suggested that the reaction co-ordinate involves the simultaneous breaking of both the C—H and the C—O bonds and the development of double-bond character in the carbon–carbon bond. The alternate possibility of breaking of the C—O bond followed by the C—H bond, which they liken to an E_1 elimination, is ruled out on the basis of relative rates of pyrolysis of substituted benzyl acetates.

More recently, Maccoll (4) has suggested that this reaction may be considered to be "quasi-heterolytic", and likens the elimination to an E_2 type where the rate is primarily determined by the forming O—H bond, rather than by the breaking C—O bond. This

[1]*Manuscript received April 22, 1960.*
Contribution No. 114 from the Research Council of Alberta, Edmonton, Alberta.

suggestion has been disputed by De Puy, King, and Froemsdorf (5), who find no evidence of C—O heterolytic bond breaking, and observe a considerable hydrogen isotope effect in the pyrolysis of 1-methyl cyclohexyl-2,2,6,6-d_4 acetate, indicating the importance of the C—H bond breaking in the reaction co-ordinate. Quantitatively, this hydrogen isotope effect, 1.7 at 500° C, and 1.9 at 400° C, is interesting in that it is less than the "theoretical maxima" of 2.1 and 2.3, respectively, which they suggest is due to simultaneous O—H bond formation.

The present study of the intramolecular isotope effect in the pyrolysis of ethyl-1,1,2,2-d_4 acetate allows a more careful appraisal of the effect in a simpler compound.

EXPERIMENTAL

All pyrolyses were carried out in a conventional toluene carrier gas system as has been described previously (6). To extend the temperature range in this pyrolysis, an aluminum furnace with a glass reaction cell of about 10 times the normal volume was used for runs at 443 and 497° C. All runs were carried out at approximately two centimeters of mercury pressure where the ethyl acetate decomposition is known to be first order.

The ethylene products (C_2D_3H and C_2D_4) were separated from the reaction mixture at −80° C, and were freed from traces of toluene and ethyl acetate by passage through a trap at −160° C. The parent peaks in the mass spectrum (masses 31 and 32) were used to determine the ratio of these ethylenes. No allowance was made for sensitivity differences (7), or for possible discrimination in the source of the mass spectrometer, since these would be expected to be small and would affect only the relative frequency factors for the two modes of decomposition.

The ethyl-d_4 acetate was supplied by Merck & Co., and was 99% deuterated as indicated. Since this implies 4% of improperly deuterated ethyl acetate, the assumption was made that this consisted of 2% ethyl-1,1,2-d_3 acetate and 2% ethyl-1,2,2-d_3 acetate; a correction was applied for the production of C_2D_3H from these two impurities.

RESULTS

The relative rate data for the production of C_2D_4 and C_2D_3H are presented in Table I, and an Arrhenius plot of the data is shown in Fig. 1. The relative rate constant expression, omitting experiment 2, is

$$k_H/k_D = 0.99\, e^{1145\pm 15/RT}$$

TABLE I

Relative rate data for ethyl-1,1,2,2-d_4 acetate

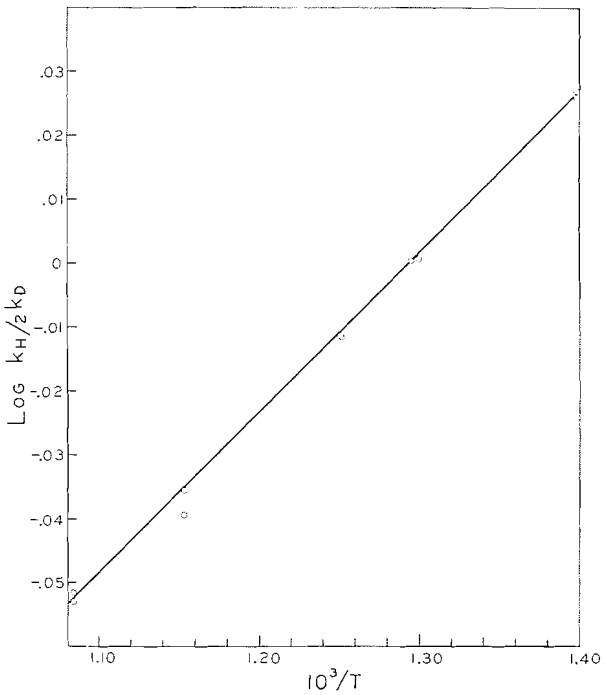

FIG. 1. Arrhenius plot for the production of C_2D_4 and C_2D_3H.

where allowance has been made for the symmetry number of two in the formation of C_2D_3H, i.e.

$$k_H/k_D = 2\,[C_2D_4/C_2D_3H]_{\text{corrected}}.$$

The correction introduced in the activation energy difference by the impurity correction was about 50 cal/mole. In view of the uncertainty in the amount and nature of the impurity, a more realistic uncertainty in the energy term would be ± 50 cal/mole.

DISCUSSION

To interpret the experimental isotope effect in terms of the mechanism of the reaction, the theoretical equation due to Bigeleisen (8) will be used,

$$k_H/k_D = \left(\frac{\mu^*_D}{\mu^*_H}\right)^{1/2} \frac{f}{f^{\ddagger}}.$$

μ^*_H, μ^*_D are the reduced masses in the reaction co-ordinate, and f and $f^{\ddagger}$ are the ratios of the partition functions of the isotopic species for the normal and activated states of the molecule. The function f is defined by the equation

$$f = \frac{s_H}{s_D} \prod_{i=1}^{3n-6} \left(\frac{\nu_D}{\nu_H}\right)_i e^{[h(\nu_H-\nu_D)_i]/2kT} \left(\frac{1-e^{-h\nu_H/kT}}{1-e^{-h\nu_D/kT}}\right)_i,$$

where s_H and s_D are symmetry numbers indicating the number of equivalent atoms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

involved in reaction and contribute nothing to the isotope effect,

ν_H and ν_D are the vibrational frequencies of the $3n - 6$ vibrational modes,

h is Planck's constant,

k is Boltzmann's constant, and

T is the absolute temperature.

$f^{\ddagger}$ is a similar function, the product being taken over the $3n - 7$ vibrational degrees of freedom in the activated complex, excluding the mode associated with the reaction co-ordinate.

For an intramolecular isotope effect, as is being considered here, $f = s_H/s_D$. The isotope effect must then arise in the reduced mass term and in the function $f^{\ddagger}$.

It has become conventional to compare experimental hydrogen isotope effects with so-called "maximum" values, obtained by assuming that the only mode making a significant contribution is the stretching mode in the breaking bond, and that residual bonding is lacking in the activated complex. The major contributions to $f^{\ddagger}$ from C—H and C—D stretching vibrations in the present molecule are from those hydrogens not directly involved in the reaction, i.e. for C—H bond break, there remain two C—D modes, and for C—D bond break, there is one C—D and one C—H mode. The net contribution to $f^{\ddagger}$ is that from one such vibrational mode; the "Arrhenius" plot for this maximum vibrational contribution, times the reduced mass term ($\sim$1.4) is shown as curve A in Fig. 2. Curve B is a best fit straight line drawn through curve A over the experimental

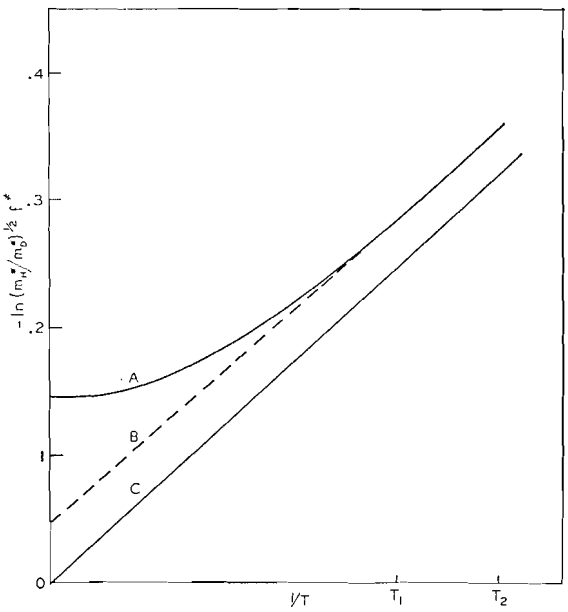

FIG. 2. Arrhenius plots: A, maximum isotope effect from reduced mass term and C—H stretching vibration; B, best fit straight line over the range T_1 to T_2; C, experimental plot extrapolated to $1/T = 0$.

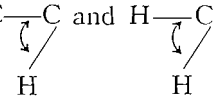

temperature range, T_1 (925° K) to T_2 (715° K). This indicates that if just this one mode is contributing to activation, then the experimental isotope effect equation should have a frequency factor ratio greater than one, and an activation energy difference of about 100 cal/mole less than the zero-point energy difference between a C—H and a C—D bond. Curve C shows the experimental equation extrapolated to $1/T = 0$. The lack of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

coincidence between curves B and C indicates that this model is not adequate to explain the experimental results.

The contribution to the isotope effect of the function $f^{\ddagger}$ due to residual carbon–hydrogen, or to incipient hydrogen–oxygen bonding, where the reacting hydrogen is considered, is shown in Fig. 3, curves A and B being as previously defined except that the reduced mass ratio is not included. Inclusion of these terms in the isotope effect equation has the effect of further increasing the discrepancy between the model and experiment.

Terms in $f^{\ddagger}$ arising from C—C and H—C bending modes give rise to the curves

A and A′ in Fig. 4, the curve A representing the effect of vibrations of the hydrogen atom involved in the reaction, and the curve A′ representing only those hydrogen atoms more or less uninfluenced by the reaction. Since vibrations involving the reacting hydrogen will have the smaller force constants, the total contribution from bending vibrations will be some curve such as A″, and over the experimental temperature range, the Arrhenius line B. Adding these terms to those derived from stretching vibrations will have a tendency to bring the theoretical isotope effect curve more into agreement with the experimental. It must be pointed out that, in view of the appreciable and opposite curvature of the plots in Figs. 3 and 4 in the experimental temperature range, it is necessary to include both of these effects to explain the remarkable linearity of the experimental Arrhenius plot.

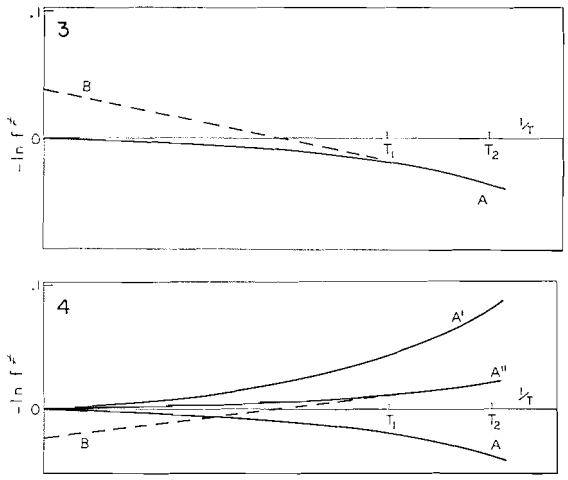

FIG. 3. Arrhenius plots: A, isotope effect from residual C—H stretching; B, best fit straight line over the range T_1 to T_2.

FIG. 4. Arrhenius plots: A, isotope effect from residual bending, A′, from other bending, A″, resultant from all bending; B, best fit straight line over the range T_1 to T_2.

These isotope effect data are then consistent with a cyclic transition state for the decomposition of alkyl esters, in which the β-hydrogen of the alkyl group is only loosely bound to either the original carbon atom, or the acyl oxygen atom, or both.

This conclusion is in complete accord with the observations of De Puy *et al.* (5) from the decomposition of 1-methyl cyclohexyl-2,2,6,6-d_4 acetate. Their conclusions are based on isotope effects being considerably below "maximum" values, i.e. 2.1 at 500° C and 2.3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

at 400° C. Since the present study indicated exactly these values for the isotope effect, it would seem that some appreciable difference in the reaction co-ordinate must exist between cyclohexyl and ethyl esters.

Some support for this view is evident in the pyrolysis of 1-methyl cyclohexyl acetate, where attention is focused on the relative rates of production of the "exo" and "endo" products, methylene cyclohexane and 1-methyl cyclohexene. The expected 60:40 ratio of these products based on the relative number of available hydrogens (which is the major determining factor with straight chain alkyl esters) is quite different from the experimental ratio of 27:73. This, and the low isotope effect, would seem to be consistent with an activated complex for the endo elimination where O—H bond formation is quite important, as suggested by De Puy *et al.*, and where the activation energy would be appreciably lower than for the exo elimination. The invariance of the product ratio over 100° C in this pyrolysis is, however, not compatible with this interpretation.

THE SECONDARY HYDROGEN ISOTOPE EFFECTS IN THE PYROLYSIS OF ETHYL-d_5 ACETATE AND ETHYL ACETATE-d_3[1]

ARTHUR T. BLADES AND P. W. GILDERSON

ABSTRACT

Rate constant expressions have been obtained for ethyl acetate and ethyl-d_5 acetate in the temperature ranges 500–603° C and 501–614° C.

$$k_{(\text{ethyl acetate})} = 3.86\times10^{12} \exp -(48{,}000\pm400/RT) \text{ sec}^{-1}$$

$$k_{(\text{ethyl-}d_5\text{ acetate})} = 4.84\times10^{12} \exp -(49{,}500\pm300/RT) \text{ sec}^{-1}$$

By measuring the relative rate of production of C_2H_4 and C_2D_4 from identical mixtures of the two esters at the temperatures 387 and 490° C, it has been possible to determine the temperature coefficient of the relative rate constant more accurately. This, coupled with the relative rate constants at 500° C derived from the above equations, gives the relative rate constant expression

$$k_H/k_D = 0.8\, e^{1515\pm35/RT}.$$

These data are compared with the intramolecular isotope effect in the decomposition of ethyl-1,1,2,2-d_4 acetate, and the differences attributed to secondary isotope effects.

The rate of decomposition of ethyl acetate-d_3 was found to be identical within experimental error with that of the normal acetate.

INTRODUCTION

In the preceding paper (1) it was shown that it was necessary to include bending vibrations and residual and (or) incipient bonding in the activated complex to explain the kinetic isotope effect data on the pyrolysis of ethyl-1,1,2,2-d_4 acetate. In that compound there is relatively little chance for contributions from secondary isotope effects. The comparison of the relative rates of pyrolysis of ethyl and ethyl-d_5 acetates provides an opportunity of evaluating the importance of these effects.

Since this is an intermolecular isotope effect rather than intramolecular as in ethyl-1,1,2,2-d_4 acetate, this pyrolysis serves as a better comparison with the previous isotope effect study on 1-methyl cyclohexyl acetate by De Puy *et al.* (2). This is especially desirable due to their finding of smaller isotope effects than in the d_4 acetate, since in the latter, the occurrence of an isotope effect does not establish that there is an isotope effect in the rate-controlling step.

It has been reported (3) that the pyrolysis of esters of different fatty acids proceed at roughly equivalent rates. It has been found, however, that although ethyl formate and acetate decompose at roughly the same rate, the acetate requires about 4 kcal/mole greater activation energy (4). Believing this to be significant information on the mechanism, an attempt has been made to study the effect of deuteration on the rate of pyrolysis of ethyl acetate-d_3.

EXPERIMENTAL

All pyrolyses were carried out using the toluene carrier gas technique as has been described previously (5). Since in both rate studies the data had relevance only when compared with normal ethyl acetate, a parallel study was carried out on this compound also. In the ethyl – ethyl-d_5 comparison, alternate runs were carried out under essentially identical conditions with each compound at various temperatures between 500–614° C.

[1]*Manuscript received April 22, 1960.*

Experiments were carried out on the ethyl acetate-d_3 at the two extremes of temperature, 502 and 592° C. The percentage decomposition in each case was determined by titration of the acetic acid produced.

Since the isotope effect studies on the ethyl-d_5 acetate gave an unsatisfactorily large error in the activation energy difference, a procedure was developed whereby this could be measured directly, although isotope effects were not measured. The procedure adopted was to mix the ethyl acetate and the ethyl-d_5 acetate as liquids, and then introduce the mixture into the toluene stream for pyrolysis. This provides a mixture of acetates whose composition over a number of experiments, if not constant, is at least changing slowly. This mixture is then decomposed by a small but known amount.

Then, if X^0_H, X^0_D are the original number of moles of the normal and deuterated compounds, and k_H and k_D are the corresponding rate constants,

$$\frac{C_2H_4}{C_2D_4} = \frac{X^0_H(1-e^{-k_H t})}{X^0_D(1-e^{-k_D t})} \approx \frac{k_H t X^0_H(1-k_H t/2)}{k_D t X^0_D(1-k_D t/2)}.$$

The approximation is adequate up to about 10% conversion, which must be known to ±.5%, i.e. 10±.5%; this accuracy is readily achieved.

Since it was unknown how constant the ratio X^0_H/X^0_D would remain over a series of runs, the system was further complicated by dividing the reactant stream such that one portion was pyrolyzed at high temperature in a small reactor to about 6% conversion, and the other at lower temperature in a 10 times larger reactor to about 1% conversion. Separate product handling systems were provided such that each experiment provided two mixtures of ethylenes.

Then

$$\frac{\left.\frac{C_2H_4}{C_2D_4}\right|_{T_1}}{\left.\frac{C_2H_4}{C_2D_4}\right|_{T_2}} \approx \frac{\left.\frac{k_H}{k_D}\right|_{T_1}}{\left.\frac{k_H}{k_D}\right|_{T_2}} \cdot \frac{(1-k_H t/2)_{T_1}}{(1-k_D t/2)_{T_1}},$$

which to a sufficient approximation may be written

$$\frac{\left.\frac{C_2H_4}{C_2D_4}\right|_{T_1}}{\left.\frac{C_2H_4}{C_2D_4}\right|_{T_2}} \approx \frac{\left.\frac{k_H}{k_D}\right|_{T_1}}{\left.\frac{k_H}{k_D}\right|_{T_2}} \left[1-\frac{(\alpha_H-\alpha_D)_{T_1}-(\alpha_H-\alpha_D)_{T_2}}{2}\right],$$

where α_H, etc. are the fractional conversions at T_1, T_2 for the H and D compounds. The temperature coefficient of the isotope effect can then be obtained by an analysis of the two ethylene mixtures and measurements of temperature and approximate conversions in the two furnaces, since

$$\frac{k_H/k_D|_{T_1}}{k_H/k_D|_{T_2}} = e^{\frac{-(E_H-E_D)}{R}\left(\frac{1}{T_1}-\frac{1}{T_2}\right)}$$

where E_H and E_D are the activation energies for the H and D compounds.

The two reactor volumes used were about 30 and 300 cc, the relative contact times being about 1:20. The ethylene ratios were determined mass spectrometrically, masses 27 and 32 being used as representative of C_2H_4 and C_2D_4 respectively. In practice, the C_2D_4 made a small contribution at mass 27; this was subtracted from mass 27 for C_2H_4 estimation. Two sets of analyses were made on each ethylene mixture at fixed sample

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pressures as it was found that the ratio of $C_2H_3^+$ to $C_2D_4^+$ varied slightly with sample pressure.

The deuterated ethyl acetates were supplied by Merck & Co., Montreal, and were 99% deuterated as indicated. A correction was applied for 3% of the impurity $CH_3COOCD_2CD_2H$ in the ethyl-d_5 acetate simultaneous pyrolysis experiments. No further purification was attempted on the deuterated compounds.

Rate constant expressions were determined by a least-squares treatment of the rate data, and errors in activation energies were obtained from the average deviation of rate constants from the least-squares line.

RESULTS

The rate data for ethyl and ethyl-d_5 acetates gave the rate constant expressions:

$$k_{(\text{ethyl acetate})} = 3.86\times10^{12}\exp(-48{,}000\pm400/RT)\ \text{sec}^{-1}, \qquad T = 500\text{–}603^\circ\text{ C}$$

and

$$k_{(\text{ethyl-}d_5\text{ acetate})} = 4.84\times10^{12}\exp(-49{,}500\pm300/RT)\ \text{sec}^{-1}, \qquad T = 501\text{–}614^\circ\text{ C}$$

the average error in k being $\pm1.5\%$ and $\pm1\%$ respectively. A plot of these data is shown in Fig. 1, along with a single rate determination for ethyl-1,1,2,2-d_4 acetate.

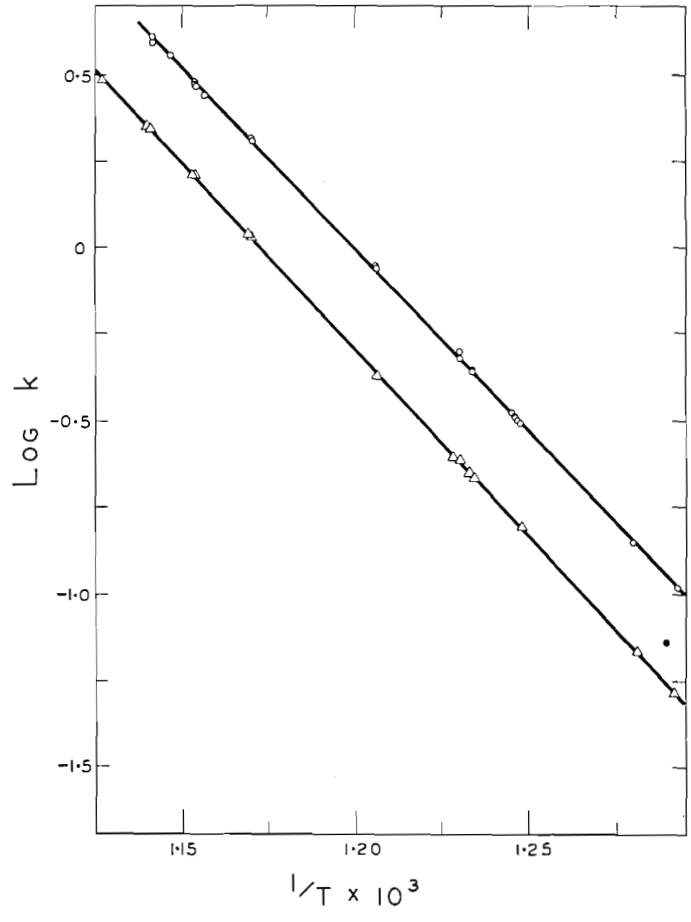

FIG. 1. Arrhenius plot for ethyl, ○, ethyl-d_5, △, and ethyl-1,1,2,2-d_4, ●, acetates.

reduced from ±700 to ±35 cal/mole. The relative rate equation $k_H/k_D = 0.8\ e^{1515\pm35/RT}$, T = 387–490° C, may then be derived, the isotope effect at 500° C being used to fix the pre-exponential factor.

Several rate constant determinations were made on the ethyl acetate-d_3 at 502 and 592° C; no isotope effect in the rate of decomposition could be observed in this temperature range within ±2%.

DISCUSSION

In the previous paper on the pyrolysis of ethyl-1,1,2,2-d_4 acetate, the isotope effect was explained on the basis of the reduced mass term and differences in the value of $f^{\ddagger}$, the value of f being determined solely by symmetry numbers. For the intermolecular isotope effect between ethyl and ethyl-d_5 acetates, the major isotope effect arises in the reduced mass term and f, terms in $f^{\ddagger}$ serving only to reduce the contributions of individual modes of vibration to f. It is therefore convenient to consider only the function f, it being understood that maximum values only are implied.

Since the activated complexes have identical structures in the ethyl-d_4, and the ethyl and the ethyl-d_5 acetate decompositions, it must be assumed that all of the modes contributing to the primary effect in the former must remain operative in the latter. The major interest in the latter centers then on the decreased frequency factor ratio (0.99 to 0.80) and on the increased activation energy difference (1145 to 1515 cal/mole). All primary effects have been accounted for in the d_4 isotope effect, so these changed constants must be a result of secondary effects.

The most obvious source of these secondary effects is in the bending vibrations at the β-carbon atom, some of which have already been considered in the d_4 compound analysis; the justification for their reconsideration is that their contribution has been increased, e.g., the $C\begin{smallmatrix}H\\ \\D\end{smallmatrix}$: $C\begin{smallmatrix}D\\ \\D\end{smallmatrix}$ comparison has become $C\begin{smallmatrix}H\\ \\H\end{smallmatrix}$: $C\begin{smallmatrix}D\\ \\D\end{smallmatrix}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

An additional, and probably important, source of secondary isotope effects could arise at the α-carbon atom if the C—O bond is breaking in the reaction co-ordinate. Both the

bending and further contributions from bending at the β-carbon atom would have the effect of reducing the frequency factor ratio, and increasing the activation energy difference over the d_4 compound, where these effects could not exist. The coincidence of this model with the observed facts instills considerable confidence not only in the present rationalization, but also in the previous analysis of the ethyl-d_4 acetate data. The suggestion of secondary isotope effects at the α-carbon atom has further interesting implications with respect to the activated complex, suggesting a concerted mechanism, wherein the β-hydrogen transfers to the acyl–oxygen atom simultaneously with the C—O bond break.

A direct comparison can be made between this intermolecular isotope effect and a similar isotope effect in the decomposition of 1-methyl cyclohexyl 2,2,6,6-d_4 acetate (2). For that molecule, De Puy *et al.* found an isotope effect of 1.7 at 500° C and 1.9 at 400° C, whereas in this study our isotope effects at the same two temperatures are 2.1 and 2.4 respectively, slightly higher, in fact, than the intramolecular effect shown by ethyl-d_4 acetate as reported in the previous paper. The inconsistency between the two intermolecular effects supports the view that the reaction co-ordinates of cyclohexyl and ethyl esters are appreciably different.

The failure to observe an isotope effect in the decomposition of ethyl acetate-d_3 lends no support to the suggestion that this methyl influences the rate through an inductive effect. Recently, however, it has been shown by Weston (6) that such an isotope effect, being due to the failure of isotopic molecules to have exactly the same potential energy surfaces, would be immeasurably small for organic reactions. The present results will serve as experimental justification of this theory, if independent evidence for this supposed inductive effect can be found.

KINETICS OF THE THERMAL DECOMPOSITION OF ETHYL PROPIONATE[1]

ARTHUR T. BLADES AND P. W. GILDERSON

ABSTRACT

The pyrolysis of ethyl propionate has been studied in the temperature range 505–602° C, yielding the Arrhenius equation

$$k = 5.2\times10^{12} \exp(-48{,}500\pm350/RT) \text{ sec}^{-1}.$$

By the copyrolysis of this compound with ethyl-d_5 acetate at 384 and 488° C, and comparison of this temperature coefficient with that for the isotopic ethyl acetates, an activation energy difference between ethyl acetate and propionate of 20±65 cal/mole was found, rather than 500 cal/mole as indicated in the individual studies. Since other evidence exists for an inductive effect in the decomposition due to the acid alkyl group, the lack of difference in activation energies is attributed to the change in effect being small and obscured by other effects.

INTRODUCTION

Studies of the kinetics of the pyrolysis of alkyl esters have indicated that the acid group forming the ester has little influence on the rate. Thus Gordon, Price, and Trotman-Dickenson (1), Rudy and Fugassi (2), and Warwick and Fugassi (3) observe about equal rates in the pyrolysis of *t*-butyl formate, acetate, and propionate; similar observations have been made in the pyrolysis of ethyl and isopropyl formates and acetates (4). More recently, Bailey and Hewitt (5) have compared a number of esters of fatty acids, chloro-acetic acid, and substituted benzoic acid, and found a correlation of rate with dissociation constant of the acid. Smith and Wetzel (6) have made other correlations, and De Puy, Bishop, and Golders (7) have noted the variability of rate between *sec*-butyl acetate and formate, and monochloro-, dichloro-, and trifluoro-acetate.

Despite the similarity of the rates for formates and acetates, a considerable difference in energy of activation has been observed between ethyl formate (44.1 kcal/mole) (4) and ethyl acetate (48.0 kcal/mole) (8). The view that this difference is the result of the inductive effect of the methyl group on the breaking of the carbon–oxygen bond gains considerable support from the above-mentioned rate data for halo-substituted acetates, where the rate is enhanced by substitution.

The present study of the decomposition of ethyl propionate was undertaken to evaluate the effect of further methyl substitution.

EXPERIMENTAL

The pyrolyses of the ethyl propionate were carried out in a conventional toluene carrier gas system as has been described previously (9), the identical apparatus being used as for the ethyl acetate pyrolysis. Rate constants were determined by titration of the propionic acid produced with 0.1 *N* sodium hydroxide solution.

In the copyrolysis of ethyl propionate and ethyl-d_5 acetate, the same technique of pyrolyzing parts of the reaction mixture simultaneously at the two temperature extremes was used as for the ethyl and ethyl-d_5 acetates (8), except that the two reactants were introduced into the toluene stream through separate capillaries; hence their proportion was not reproducible for consecutive experiments. The same procedure was adopted for mass spectrometer analysis of the ethylene, and for the correction of the data for isotopic impurities and degree of conversion.

The ethyl-d_5 acetate (Merck & Co.) was the same sample as used in the previous acetate comparison (8). The ethyl propionate was fractionally distilled and degassed before use.

RESULTS

In the separate pyrolysis of ethyl propionate, variations in contact times from 0.26 to 1.56 sec and pressures from 1.5–2.0 cm Hg showed no effect on rate constants. The Arrhenius rate equation, derived from 15 consecutive runs over the temperature range 505.2–602.4° C is

$$k = 5.2\times10^{12}\exp(-48{,}500\pm350/RT)\ \text{sec}^{-1},$$

the average error in k being $\pm1.3\%$. A plot of these data is shown in Fig. 1.

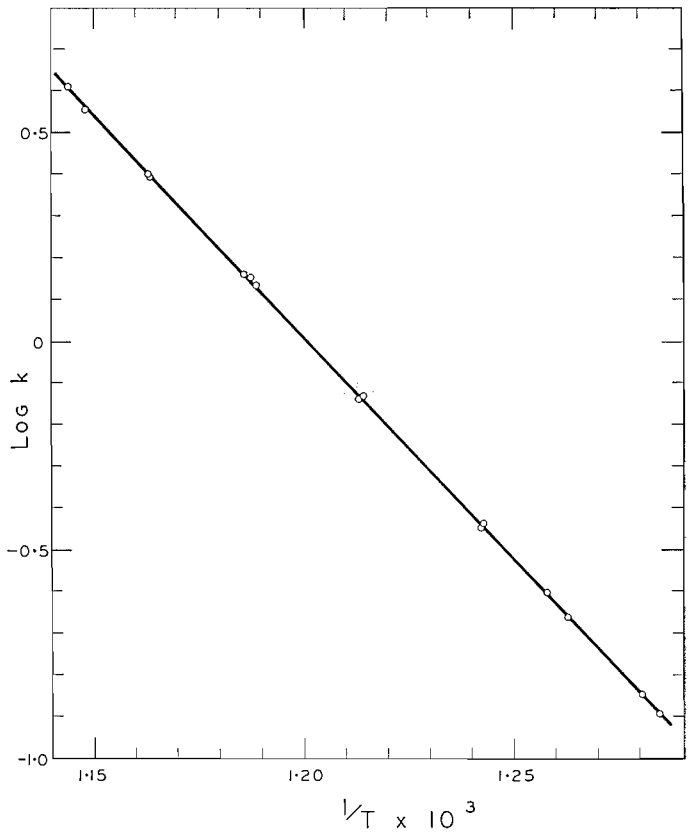

FIG. 1. Arrhenius plot for ethyl propionate.

This Arrhenius equation is to be compared with that for ethyl acetate obtained on the same apparatus,

$$k = 3.86\times10^{12}\exp(-48{,}000\pm400/RT)\ \text{sec}^{-1}.$$

In the copyrolysis experiments, only four satisfactory experiments were performed; the data for these are presented in Table I. The average value of the difference in activation energy (1495±30 cal/mole) is to be compared with the corresponding value for the

ethyl – ethyl-d_5 acetate difference (1515±35 cal/mole) (8). The indicated activation energy difference between ethyl acetate and propionate is then 20 cal/mole within limits of less than ±100 cal/mole.

DISCUSSION

The purpose of this investigation was to obtain further evidence on a supposed inductive effect of the acid alkyl group on the activation energy for the decomposition of alkyl esters. Although the individual rate constant expression determinations indicated a difference of 500 cal/mole between ethyl propionate and acetate, this was not substantiated by the comparison through the copyrolysis technique.

There is other evidence that an inductive effect is operative in these pyrolyses in that chloro- and fluoro-acetates show much greater rates of decomposition (7) and presumably lower activation energies than acetates. This is in agreement with the opposite electron-sharing character of the methyl and halo-methyl groups as is indicated in the acidity constants of the acids in Table II (10). The relatively large difference in these constants

TABLE II

Acidity constants × 10^5

Formic acid	17.7
Acetic acid	1.8

Propionic acid	1.3
n-Butyric acid	1.5

between formic and acetic acids dwarfs the difference between acetic and propionic; nevertheless, if a similar effect is operative in the ester decompositions and acid dissociations, the activation energy difference being sought here could have been expected to be several hundred calories.

A possible explanation of the negligible difference found is indicated in the increased acidity constant of *n*-butyric over propionic acid, for which there is no satisfactory

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

explanation. As suggested by Ingold (10), hyperconjugation may reduce the difference in acidity constants of acetic and propionic acids; such an effect may also be operative in the pyrolyses.

The use of the copyrolysis technique for the determination of differences in activation energy would seem to have wide applicability especially for molecular reactions where there is an interest in a homologous series. The major requirements for reactions to be successfully compared are that they shall proceed at roughly the same rate and that neither products nor reactants shall interfere with the normal course of reaction. A fairly accurate analytical method must be available for one product in each reaction, mass spectrometry seeming to be the most widely applicable, with vapor phase chromatography a possibility.

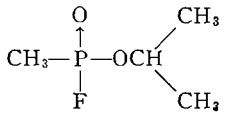
THE SYNTHESIS OF HIGHLY RADIOACTIVE ISOPROPYL METHYLPHOSPHONOFLUORIDATE (SARIN) CONTAINING P^{32} AS TRACER ELEMENT[1]



J. B. Reesor, B. J. Perry, and E. Sherlock[2]

ABSTRACT

Procedures are described for the safe processing of multicurie quantities of irradiated red phosphorus into isopropyl methylphosphonofluoridate (sarin) having a specific activity of 250 to 300 millicuries per gram. The use of costly remote-handling equipment is avoided by suitable choice of synthetic route and apparatus design.

INTRODUCTION

Several years ago, a requirement arose for radioactively tagged (P^{32}) isopropyl methylphosphonofluoridate (sarin) I, in order to study the biological effects and mode

I

of action of the so-called "nerve gases". The degree of dilution likely to be encountered in such biological studies indicated that quantities of the order of 50 grams with a specific activity of 250–300 mc/g would be required. Safe handling of multicurie sources of radiation is ordinarily achieved by placing operators behind shields and manipulating apparatus with various remote-handling devices. Such devices are complex and costly. Since the hazard depends not only upon the intensity of radiation but the duration of exposure to it, it was visualized that the greater speed of direct handling might give less actual radiation dosage than the much longer exposures to lower levels of radiation attendant on the usual remote-handling operations. The greater surety against accidents provided by direct handling was a further consideration in the synthesis of a highly toxic compound.

Accordingly a careful study of synthetic methods was carried out with a view to elimination of operations requiring long periods of attention. A time study was made of the known alternative routes of synthesis to assess the approximate radiation hazard associated with each procedure. These routes are illustrated diagrammatically in Fig. 1. The results clearly indicated that the route involving the direct conversion of phosphorus trichloride via the APC complex to methylphosphonic dichloride, followed by fluorination to methylphosphonic difluoride and preparation of sarin from the equimolecular mixture of dichloride and difluoride, was the safest practical method to use. The very high yield and purity of the agent produced by this method was a further advantage.

Investigations of this chosen route led to modifications in the chemistry and in the synthetic apparatus used which further simplified the reactions and reduced the hazards considerably. Principally, improvement was obtained in the preparation of methylphosphonic dichloride by an anhydrous procedure (1), which eliminated a filtration, and

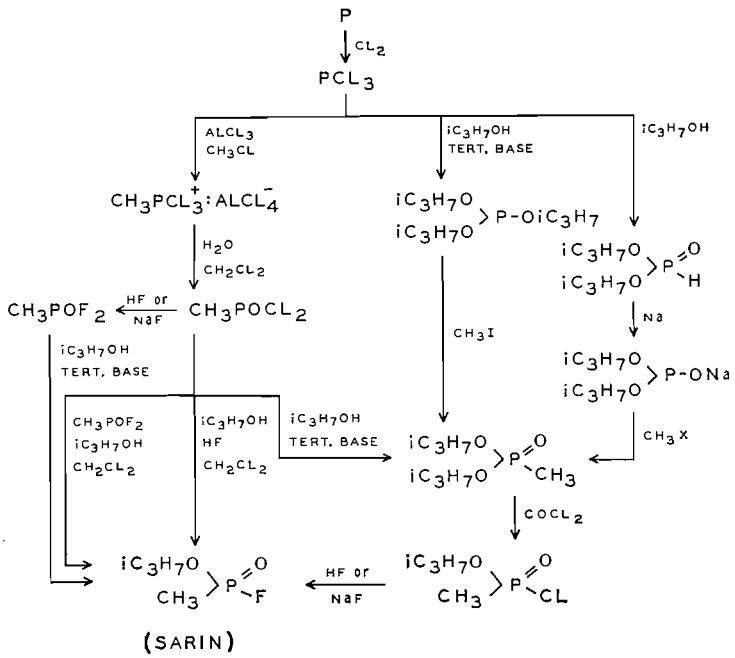

FIG. 1. Synthetic routes to sarin.

the direct conversion of methylphosphonic dichloride to sarin by the use of anhydrous hydrofluoric acid isopropyl alcohol, which eliminated a reaction and a filtration.

Our method is illustrated schematically in Fig. 2.

$$P \xrightarrow{Cl_2} PCl_3 + PCl_5 \xrightarrow{Sb} PCl_3$$

$$PCl_3 \xrightarrow[CH_3Cl]{AlCl_3} CH_3PCl_3^+.AlCl_4^-$$

$$CH_3PCl_3^+.AlCl_4^- \underset{(DEP)}{\overset{\text{diethyl phthalate}}{\rightleftharpoons}} CH_3PCl_4 + DEP.AlCl_3$$

$$CH_3PCl_4 \xrightarrow{SO_2} CH_3POCl_2 + SOCl_2$$

$$CH_3POCl_2 \xrightarrow[HF]{iC_3H_7OH} \underset{(sarin)}{CH_3PO(F)(iC_3H_7O)} + 2HCl$$

FIG. 2. Chosen synthetic route.

Over a period of approximately 5 years, 12 complete syntheses of sarin (I) containing P^{32} as tracer element have been successfully carried out. The product (I), at the desired specific activity of 250–300 mc/g, was obtained in quantity from 20 to 30 g red phosphorus of specific activity of approximately 2.2 curies/gram.

EXPERIMENTAL

Purification of Red Phosphorus

The phosphorus to be irradiated is purified in our laboratory by treatment of reagent grade material with concentrated hydrochloric acid at reflux temperature for approximately 1 hour, followed by washing with copious quantities of boiling distilled water. Repeated water washing, and decanting from the phosphorus to remove most of the "fines", give a product which is more easily handled since the inclusion of the very fine phosphorus particles sometimes results in a sintered irradiated sample. Finally the phosphorus is filtered, washed with alcohol, ether, and dried in a vacuum desiccator.

When the irradiation was carried out at Idaho Falls, Idaho, the purified red phosphorus was charged into clean, pure (Sl grade) aluminum capsules, 15 g of phosphorus per capsule, and sealed in an atmosphere of dry helium. Atomic Energy of Canada at Chalk River do their own packing, and bulk lots of purified phosphorus were sent to them in polyethylene bottles.

Transfer of Irradiated Phosphorus to the Phosphorus Trichloride Apparatus

The transfer of the irradiated phosphorus to the tared PCl_3 reaction flask is accomplished by normal "hot" radiological dry box technique under an atmosphere of dry nitrogen.

Preparation of Phosphorus Trichloride

Phosphorus trichloride is synthesized in the apparatus illustrated in Fig. 3.

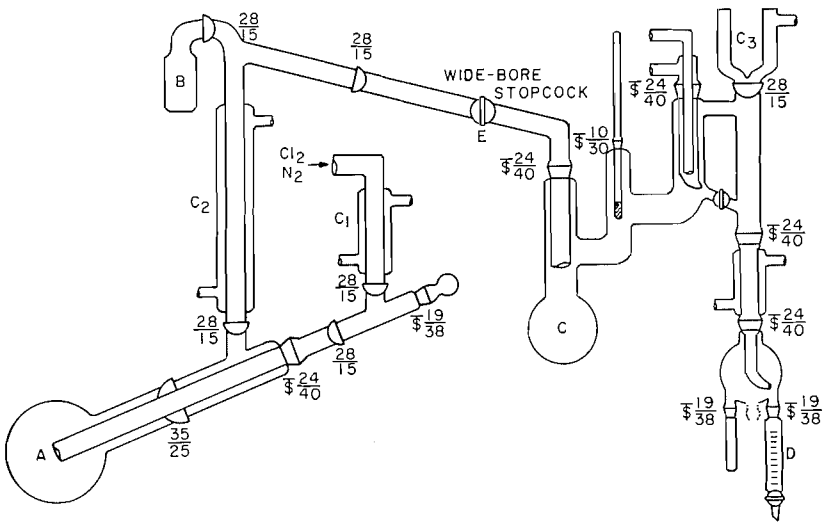

FIG. 3. PCl_3 apparatus.

Approximately 40 grams of dry boiling chips are placed in the reaction flask A, which is then evacuated and heated to dispel as much air as possible from the boiling chips. Dry nitrogen is let into the evacuated flask and the process of heating, evacuation, and admission of dry nitrogen is repeated so as to ensure that all oxygen (which would cause oxidation of the trichloride to oxychloride) is removed. The flask is then stoppered, weighed, and placed in the dry box ready for receipt of the irradiated phosphorus.

The stoppered flask is removed from the dry box after the addition of the irradiated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

phosphorus, is weighed to determine weight of phosphorus (approximately 30 grams), and coupled up to the apparatus as shown in Fig. 3.

A slow stream of dry nitrogen is passed into the apparatus through the gas inlet tube to sweep out residual traces of oxygen, and the reaction flask is heated to 110°–120° C. At this stage the slow stream of nitrogen is replaced by a metered stream (6 to 7 liters per hour) of dry chlorine gas and at the same time a jet of cool air is directed on the upper, unheated surface of the reaction flask. Reaction occurs and the phosphorus pentachloride sublimes to the cool upper surface of the flask as it is formed. After 3/4 hour, when a fairly thick crust of phosphorus pentachloride has sublimed to the cool upper surface, chlorination is stopped and a very slow stream of nitrogen (sufficient to maintain a positive pressure only) is substituted for the chlorine. The reaction flask is then rotated through 180° on its ball joint so that the phosphorus pentachloride is covered with unreacted red phosphorus. Heating, without chlorination, is continued for about 15 minutes, by which time the phosphorus pentachloride is largely reduced by the unreacted red phosphorus to phosphorus trichloride. Chlorination is recommenced and the whole procedure repeated until a 20% excess of chlorine has been introduced. Heating is continued for 1 hour or until the residual phosphorus has disappeared.

This stage is fairly easy to observe and is facilitated by the use of boiling chips. Initially glass chips were used to keep the phosphorus mobile, but it was found that they become stained a dark brown by the intense radiation which tends to obscure the end point. The white boiling chips are hardly affected by the radiation and so provide a background against which the unreacted phosphorus is readily discerned.

The mixture in the flask now consists of phosphorus trichloride and phosphorus pentachloride. The mixture is allowed to cool to room temperature. Pure granular antimony (100 g) is then added to the mixture by tipping the antimony container B, which is built onto the apparatus. Powdered antimony reacts very vigorously with phosphorus pentachloride but results in a somewhat inferior product due to the surface film of antimony oxide normally present on the surface of the antimony, giving phosphorus oxychloride as a by-product. Granular antimony reacts more slowly, and a larger excess is required: the product, however, is purer. It is found that $-20+80$ mesh antimony is most suited to the reaction as a compromise between speed and purity.

Flask C is surrounded by a dry ice – acetone mixture and the nitrogen stream increased to approximately 2 liters per hour to help sweep out the trace amounts of phosphorus pentachloride sublimed into the gas inlet tube and also to prevent phosphorus trichloride distilling too far up the inlet tube in the subsequent operations.

The reaction mixture is then slowly heated. At approximately 75° C a strongly exothermic reaction sets in and phosphorus pentachloride is reduced to phosphorus trichloride by the antimony, antimony trichloride being formed at the same time. When the initial reaction has moderated, it is normal to obtain a yellowish-brown solid precipitate in the reaction mix. Reaction is regarded as complete when the liquid layer in the reaction flask is homogeneous and it has been found that this can only be attained quickly by strongly heating the reaction mixture. The heating mantle temperature is thus slowly raised to 280°–300° C and the elevated temperature is maintained until the liquid layer becomes homogeneous. During this period of heating, the rapidly refluxing phosphorus trichloride washes the last traces of sublimed phosphorus pentachloride into the reaction flask for reduction to trichloride. At the same time some 7–9% of the trichloride, entrained by the slow stream of nitrogen, condenses out in C_3 and is collected in the receiver.

Should there still be yellow solid material in the reaction mix after heating to

280°–300° C for 1 hour, the mixture may be cooled and a further quantity of the antimony added. The initial amount added, however, is a large excess and the further addition of antimony has been required only in those cases where the phosphorus was overchlorinated to give a large quantity of the pentachloride.

When the liquid layer becomes homogeneous the heating mantle temperature is reduced to 230° C, the water removed from the condenser C_2, and the product of phosphorus trichloride distilled in a slow stream of dry nitrogen while maintaining the charge of dry ice – acetone around receiver C. Distillation is continued until white fumes of antimony trichloride are observed in the reaction flask A.

Stopcock E is closed and the crude PCl_3 redistilled from a few grams of antimony to reduce any PCl_5 which might have been sublimed from the reaction flask during the reaction. The receiver is calibrated volumetrically so that the weight of product synthesized may be calculated directly without recourse to weighing and handling the "hot" product.

Yields of pure phosphorus trichloride, based on the phosphorus used, have varied from 92–99%.

Preparation of the Aluminum Chloride:Phosphorus Trichloride:Methyl Chloride (APC) *Complex*

The apparatus devised for this synthesis is illustrated in Fig. 4. The radioactive phos-

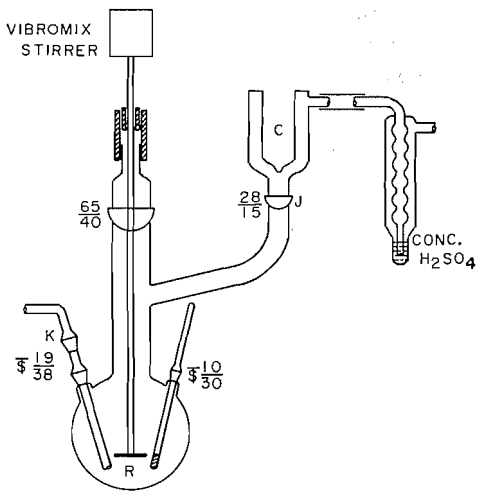

FIG. 4. APC complex apparatus.

phorus trichloride is run into the reaction flask R, which contains 1.5 molar proportions of very finely powdered anhydrous aluminum chloride. The very thick mixture is heated to 70°–75° C and agitated with a "vibrator"-type stirrer of fixed period but variable amplitude. The condenser C is charged with a dry ice – acetone mixture and a slow stream (1 to 1½ liters per hour) of dry methyl chloride is passed into the mixture as close to the point of stirring as possible. In the early stages reaction is slow, but after approximately 1 hour the mixture becomes fluid and the rate of absorption of methyl chloride increases markedly. When the mixture becomes fluid the efficiency of stirring is increased and the rate of addition of methyl chloride stepped up. On an approximate molar scale, absorption of methyl chloride is fairly rapid for approximately 2½ to 3 hours, when the mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

becomes more viscous and crystals begin to separate on the walls of the flask. At this stage the rate of addition of methyl chloride is reduced to a very slow stream (approximately 1/2 to 1 liter per hour) while heating and stirring are continued. After a further 2 hours the mixture is a semisolid mush of crystals and the reaction is virtually complete. Methyl chloride addition is stopped and heating and stirring are continued for a further hour to ensure completion of the reaction. Heating and stirring are then stopped, the dry ice – acetone is removed from the condenser, and the excess methyl chloride is allowed to boil off. Throughout the whole of the reaction the rate of methyl chloride addition must be carefully controlled so that too great a reflux return to R is not obtained, as otherwise the reaction mixture is cooled below the temperature at which the formation of complex proceeds rapidly. During the period of rapid absorption, the maximum rate of addition of methyl chloride is always used commensurate with maintaining the reaction temperature of 70°–75° C.

Preparation of Methylphosphonic Dichloride from the APC *Complex*

The apparatus used in the radioactive synthesis is illustrated in Fig. 5.

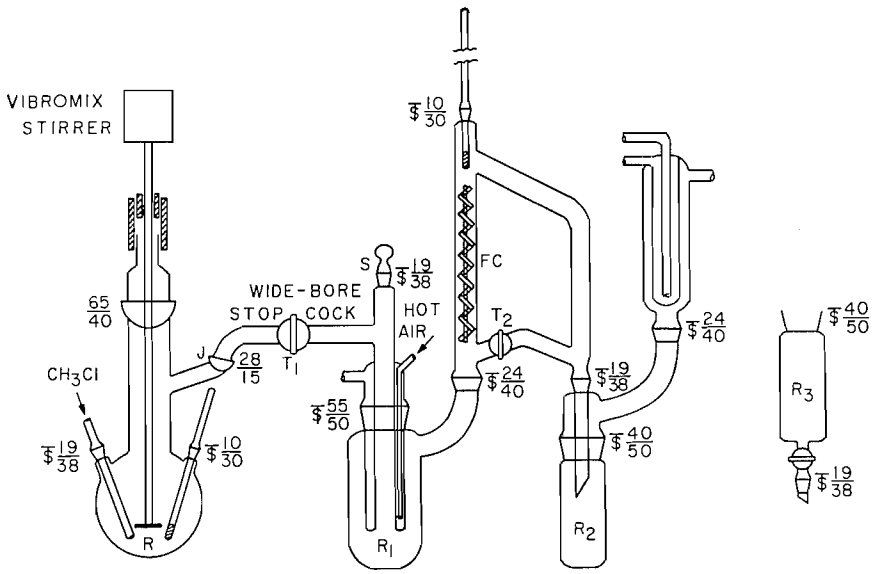

FIG. 5. Methylphosphonodichloridate apparatus.

The reaction flask in which the APC complex is prepared is also used for the breakdown of the complex and as the distillation flask for the recovery of the crude methylphosphonic dichloride. On completing the preparation of the APC complex the ball joint J (Fig. 4) is opened and 3 moles/mole complex of dry diethyl phthalate is added to the complex. The joint J is remade and stirring is begun to dissolve the complex as far as possible in the diethyl phthalate. Solution is accompanied by a pronounced rise in temperature and external water cooling should be used to prevent "hot spots" in the early stages until the solid breaks up. At this point a stream (10–12 liters/hour) of dry sulphur dioxide is passed through the stirred mixture via the inlet tube used for methyl chloride. An exothermic reaction occurs and the temperature of the reaction mixture normally rises to a maximum of approximately 50° C, and after approximately 2 hours begins to fall.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

Sulphur dioxide is passed into the stirred mixture for a further 30 minutes and the mixture is then allowed to stand for a further 1 hour to ensure completion of reaction. During the passage of the sulphur dioxide the small amount of undissolved but dispersed complex rapidly dissolves and a very fine precipitate of the diethyl phthalate : aluminum chloride complex appears.

On completion of the reaction, the joint J is opened, and the whole reaction flask and contents are transferred to the distillation unit shown in Fig. 5 and joined up via the ball joint J (Fig. 5), the reaction flask then becoming the distillation flask R of Fig. 5. The inlet joint K at the upper end of the gas inlet tube is disconnected and replaced with a capillary air bleed coupled to an air-drying train. The reaction mixture is then thoroughly degassed under water pump vacuum.

The receivers R_1 and R_2 are immersed in dry ice – acetone cooling mixture and the apparatus evacuated by a high-capacity high-vacuum pump to approximately 0.1–0.5 mm Hg. The distillation flask is then heated to 85° to 90° C, when the residual thionyl chloride and methylphosphonic dichloride distill from the diethyl phthalate into receiver R_1. During the radioactive synthesis 6 hours is allowed, after which time the distillation is considered to be complete. This crude distillation is carried out with the tap T_2 in the open position to avoid a pressure drop which might be caused by the fractionating column FC and to ensure as high a pumping speed as possible at the distillation flask. The taps T_1 and T_2 are then closed, heating is discontinued, the dry ice – acetone cooling mixtures are removed, and dry air is let into the main receiver part of the apparatus.

The receiver R_1 is then heated by a heating mantle and the thionyl chloride is fractionally distilled from the recovered mixture at atmospheric pressure via the column FC. Heating is continued until the temperature at the top of the column is approximately 150°–155° C, which indicated that methylphosphonic dichloride is about to distill. Heating is then stopped and the apparatus allowed to cool to room temperature. The stopper S is replaced by a fine capillary bleed and the receiver R_2 is removed and replaced by the receiver R_3 for methylphosphonic dichloride. The apparatus is evacuated to approximately 60 mm Hg using a water pump and R_1 is again heated to recover pure methylphosphonic dichloride by fractional distillation.

During the evacuation of the apparatus to 60 mm Hg the last traces of thionyl chloride are removed from the upper part of the column and condenser surfaces. At 60 mm Hg the methylphosphonic dichloride distills at 84°–85° C and is distilled at a sufficiently rapid rate to prevent crystallization in the cool parts of the receiver. The product receiver is weighed before and after to determine the yield.

Yields of 88–89%, based on the phosphorus trichloride, are obtained.

Preparation of Radioactive Sarin

The apparatus used in the synthesis is illustrated in Fig. 6.

The dropping funnel which forms the receiver R_3 for the collection of methylphosphonic dichloride in the previous synthesis is transferred to one neck of the three-necked reaction flask and its molten contents are run in. The funnel is washed through into the flask with 100 ml of dry methylene chloride, and the mixture, stirred by means of a magnetic stirrer, is brought to reflux. During this stage of the reaction, water is led through the jacket of the beryl-saddle-packed fractionating column F, so that it acts as a reflux condenser.

A mole/mole solution of anhydrous hydrofluoric acid in anhydrous isopropanol is then prepared. A 5% excess over the theoretical weight of this solution required to react with the methylphosphonic dichloride previously synthesized is introduced into the copper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

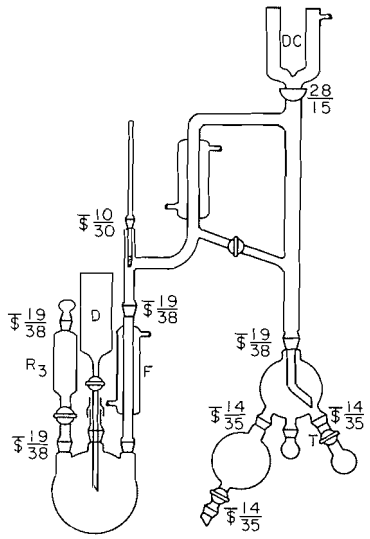

FIG. 6. Sarin apparatus.

dropping funnel D and from there run dropwise into the methylphosphonic dichloride solution at such a rate as to maintain gentle reflux without application of external heat. When addition is complete, the mixture is refluxed for 15 minutes, the water is drained from around the column F, and methylene chloride is distilled off for 15 minutes at atmospheric pressure, by which time evolution of HCl is virtually complete. The remaining methylene chloride is taken off and degassing is completed under water pump vacuum.

At this stage 10 ml of diethylaniline is added, the copper dropping funnel is replaced by a capillary bleed, and fractionation is begun at a pressure of about 10 millimeters. The condenser DC is charged with dry ice – acetone to prevent the loss of sarin which has been found to occur when distilling at this pressure. The forerun is collected in a receiver which may be shut off from the system by means of a tap T when collection is complete, thus preventing its contents from distilling back into the main fraction as distillation proceeds. This measure has been found to increase the purity of the sarin produced from 96–97% up to 99% or better. The main fraction is collected in a dropping-funnel-type receiver to facilitate subsequent dispensing of the product.

Using this method, yields of between 82 and 87% of sarin are obtained. The purity of this material has been found to be consistently better than 99%.

DISCUSSION

Safety

P^{32} is a pure β emitter and these particles are readily stopped by light weight lucite sheets. The bremsstrahlung X rays from such a source as we were handling, however, require thick, heavy metal sheets for complete protection. No laboratory with remote-handling equipment was available at Suffield but after careful consideration of the problem it was decided that the synthetic program could be undertaken using the facilities of our tracer laboratory. The laboratory consists of a main laboratory with seven in-line fumehoods each 5 ft wide and 2 ft 6 in. deep, and auxiliary observation, storage, and changing rooms. The fumehoods are of modern streamline design with all

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

service outlets inside and to the front whereas all service controls are outside. The hoods can be used singly or jointly as the size of apparatus dictates.

The bases of the fumehoods are of concrete cast in the form of a shallow sink and are lead lined; they are sufficiently robust to allow the heavy screening of local hot spots, such as reaction flasks, with lead bricks or thick sheet lead. The heavy screening of the whole apparatus was found to be impracticable and, in fact, undesirable during general distillation procedures. For general screening work, mobile screens of 1/2-in. thick Lucite (polymethyl methacrylate) faced each side with 1/16-in. steel were found to be ideal. These screens are 15 in. wide and extend the full height of the fumehood face. They run on ball races on permanent tracks along the front of the hoods, and are quickly and very easily moved to the desired screening position. Windows cut in the steel allow observations at the required height and the width of the screen allows an operator to work with his body shielded while using both hands for required manipulations in the fumehood. The steel-lined Lucite screens completely stop all β rays and reduce the bremsstrahlung X rays to approximately 15% of the unscreened value. The main face window of each hood is a vertically rising sheet of 1/2-in. Lucite and is coupled to a damper in the ventilation duct of the hood so that the draft is increased or decreased as the main window is raised or lowered respectively. With the main window completely closed each hood is positively ventilated at a low speed.

The bank of fumehoods is ventilated by a communal system powered by an 8000 cu. ft/min (at $1\frac{1}{2}$ in. static water pressure) exhaust fan. This flow is ample to allow work to proceed safely at three or four fumehoods simultaneously. Inlet air is filtered, thermostatically heated, and enters via the auxiliary rooms into the main laboratory and so to the fumehoods. This system ensures that at all times the operators work in a positive flow of clean air from the clean to the dirty parts of the laboratory.

The concept of dividing the laboratory into "clean" and "dirty" areas was vigorously enforced and easily removed coveralls and boots were worn, as were respirators at all times of transfers in order to eliminate ingestion hazards.

Monitoring of the personnel engaged in the syntheses has been carried out in three ways:

(i) by plotting the low energy X-ray dosage fields and observing the time spent by each operator at any position,

(ii) by wearing $\beta\gamma$ film badges, and

(iii) by wearing pocket dosimeters.

Probably the most important point pertaining to safety is the particular care which must be paid to the design of apparatus and choice of reaction conditions which enable the syntheses to be carried out with a minimum of handling and infrequent observation.

The five-stage synthesis is carried out in 5 days—a total of approximately 60 working hours—by three of the personnel. By dividing the hazardous tasks between the three (monitoring was continuously carried out to facilitate this), each worker receives less than 300 μr per person, the radiation dosage recommended at that time as the limit for those working continuously with radioactive materials. Since a decay period of at least 3 months is allowed to elapse between syntheses, our experience to date has indicated that complex organic syntheses involving high level sources can be carried out safely without remote handling provided adequate attention is paid to process flow and apparatus design.

Purification of Red Phosphorus

Our first irradiation of commercial red phosphorus graphically illustrated the need for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

a preliminary purification of this material. Trace quantities of sodium ion must be eliminated in order to prevent the inclusion of a high-intensity γ source in the starting material.

Preparation of Phosphorus Trichloride

$$2P + 3Cl_2 \rightarrow 2PCl_3$$
$$PCl_3 + Cl_2 \rightarrow PCl_5$$
$$2Sb + 3PCl_5 \rightarrow 3PCl_3 + 2SbCl_3$$

The method (2) of chlorinating red phosphorus to phosphorus trichloride on a large scale, although a straightforward reaction, suffers the disadvantage that an excess of phosphorus must be used to prevent the appearance of the pentachloride in the product. Saunders and Worthy (3) have developed a method for the complete conversion of small (1 g) amounts of phosphorus to the trichloride. Such a method proved impractical on the scale required at Suffield since it required careful standardization of procedures and constant supervision. To avoid waste of the active phosphorus the method of chlorination was modified and advantage was taken of the reducing properties of pure antimony to convert phosphorus pentachloride to the trichloride. The purity of the phosphorus trichloride, checked by infrared spectroscopy, is excellent. The absorption spectrum (Fig. 7) shows a very small percentage of P=O, much less than by reagent grade commercial product triply distilled in dry nitrogen.

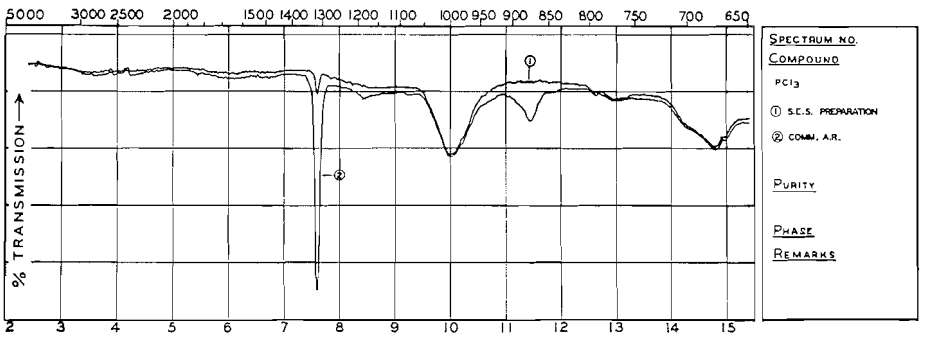

FIG. 7. Spectrum of PCl_3. (1) Synthetic product; (2) commercial product, AR grade.

Preparation of the Aluminum Chloride:Phosphorus Trichloride:Methyl Chloride (APC) *Complex*

The formation of the 1:1:1 molar aluminum chloride:phosphorus trichloride:methyl chloride (APC) complex proceeds very smoothly in pressure-type apparatus to give yields which are virtually quantitative. When the method is applied to the synthesis of radioactive APC complex, however, it has one marked disadvantage in that the solid has to be transferred from the pressure-type reaction apparatus to the reactor in which the subsequent breakdown of the complex is to be carried out. This introduces a severe radiological hazard since, of necessity, it results in external contamination of the apparatus with consequent risk of ingestion in subsequent operations. The use of the high-boiling electron-donating solvent (used in the breakdown of the APC complex) to dissolve the complex from the pressure reactor reduced, but did not eliminate, this hazard.

Fortunately, it was discovered that the formation of the APC complex at atmospheric pressure proceeds very smoothly at the temperature of refluxing phosphorus trichloride,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

and yields are very good provided that loss of the trichloride by the purging action of the methyl chloride passing through the reaction mixture is prevented, and that the reactants are vigorously agitated. The 1:1:1 molar complex can not be made satisfactorily by this method due to the high melting point of this complex, and accordingly an excess of aluminum chloride is used to give a mixture of the 1:1:1 and 2:1:1 aluminum chloride: phosphorus trichloride:methyl chloride complexes, which remain sufficiently fluid for adequate mixing at a temperature of 70°–75° C until absorption of methyl chloride is complete.

Preparation of Methylphosphonic Dichloride

The successful preparation of alkylphosphonic dichlorides was first reported by Kinnear *et al.* (4) and by Clay (5). Their method involved the hydrolysis of a refrigerated solution of the complex in methylene chloride by means of water according to the following reaction:

$$CH_3PCl_3^+.AlCl_4^- + 10H_2O \rightarrow CH_3POCl_2 + AlCl_3.9H_2O + 2HCl.$$

The temperature limits for the hydrolysis (−20° C to −30° C) are critical, and it is essential to filter off immediately the precipitate of the non-anhydrate from this very cold mixture on completion of the reaction. In the laboratory, the high cooling rate could be maintained only by the continuous addition of dry ice. Constant supervision was also required to determine the end point of the hydrolysis.

The breakdown of the complex by this method would prove to be a most difficult and radiologically dangerous part of the synthesis.

An investigation of the breakdown process was made, therefore, and resulted in a novel method, which eliminated almost entirely the excessive hazards intrinsic in the old water hydrolysis reaction scheme. The details of this process, which is completely anhydrous in its function, are reported elsewhere (1). For clarity, however, the following brief account is made.

It was found initially that a high-boiling polyether, dimethoxytetraglycol, not only exhibits excellent solvent properties but also, by complexing with the aluminum chloride itself, frees the phosphorus-containing moiety of the APC complex. The methylphosphonic tetrachloride so liberated reacts smoothly with sulphur dioxide to give thionyl chloride and methylphosphonic dichloride.

$$CH_3PCl_3^+.AlCl_4 + CH_3O(CH_2CH_2O)_4CH_3 \rightleftharpoons CH_3O(CH_2CH_2O)_4CH_3{:}AlCl_3 + CH_3PCl_4$$

$$CH_3PCl_4 + SO_2 \rightarrow CH_3POCl_2 + SOCl_2.$$

The original discovery of the role of dimethoxytetraglycol has been extended to diethyl phthalate, a more stable electron donor.

The methylphosphonic dichloride is readily recovered in excellent yields (80–85% of pure redistilled product) by vacuum distillation.

It can be seen, by comparison with the original aqueous procedure, that the new method has eliminated most of the hazardous procedures; all contaminated residues are left in the flask, no filtration is required, no refrigeration is required, no contaminated volatile gases are evolved, and observation and control are easily effected from a distance.

Preparation of Radioactive Sarin

The two-stage synthesis (reactions 3 and 4) of sarin from methylphosphonic dichloride is relatively simple to carry out and gives good yields of very pure product. The main disadvantage is the radiological hazard which results from the numerous handling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

procedures involved in preparing the equimolar di–di (methylphosphonic dichloride and methylphosphonic difluoride) mixture required for the esterification stage.

The mechanism of the di–di reaction (6) clearly indicated that it should be possible to produce sarin from methylphosphonic dichloride by direct esterification and fluorination in one stage provided that the half esterification of the dichloride is carried out in the presence of free hydrofluoric acid. The reaction was investigated using non-radioactive dichloride and was found to proceed smoothly in methylene chloride as a diluent using reaction conditions very similar to those employed in the normal di–di reaction. Distillation of the product from diethylaniline removes last traces of free acid, and the trace amount that codistills with the pure sarin stabilizes the final product. Yields of pure sarin obtained by this method are virtually the same as those by the normal di–di reaction, viz. 82–87%.

The synthesis of sarin by this one-stage process from the dichloride has the following advantages:

(*a*) The elimination of one stage decreases the time of synthesis and the radiological exposure of the operators.

(*b*) The handling procedures required in making the equimolar di–di mixture are eliminated.

(*c*) The over-all yield of sarin from dichloride is increased since the fluorination stage, which gave a 90–92% yield of difluoride, is eliminated as are small losses which were inevitable in making up the accurate equimolar di–di mixture.

The purity of the sarin prepared by the one-stage process, like that of the normal di–di reaction, is better than 99% (7) with careful fractionation.

ACKNOWLEDGMENTS

The authors wish to acknowledge their indebtedness to Drs. D. G. Coe and J. L. Ferron for their professional assistance, to Mr. W. C. Carpenter for technical assistance, to Mr. D. O'Connor for his fabrication of the glass apparatus, and to Misses B. Melanson and L. Norton for drafting.

ORGANO ARSENIC COMPOUNDS

I. N,N-DIALKYL AMIDODICHLOROARSENITES AND N-ALKYL IMIDOCHLOROARSENITES[1]

G. A. Olah and A. A. Oswald[2]

N,N-Dialkyl amidodichloroarsenites were prepared by the reaction of arsenic trichloride with aliphatic secondary amines. Arsenic trichloride and primary amines react similarly, but the N-alkyl amidodichloroarsenites formed usually lose HCl and give N-alkyl imidoarsenites on distillation.

The reaction of aromatic amines with arsenic trichloride has been studied earlier (1–6). These studies were concerned with both the addition reaction and the formation of N-aryl amidohaloarsenites. The main aim of the work reported was to ascertain the mechanism of phenarsazin syntheses.

There are two N,N-dialkyl amidodichloroarsenites described in the literature. In 1896 Michaelis and Luxembourg (7) published the synthesis of "diisobutylamino-dichloro-arsin" by adding diisobutylamine to arsenic trichloride. This method is analogous to that used for the corresponding phosphorus compounds. In 1935 Doak (8) synthesized "diethylamino dichloro arsenamide" by adding arsenic trichloride to a solution of diethylamine in *n*-heptane. When piperidine was used in the place of diethylamine, 20.95% crystalline arsenous acid tripiperidide trihydrochloride and a yellow oil (b.p. 98° C at 1 mm), supposedly piperidinodichloroarsenite, were obtained. No yields were reported for any of these compounds.

In this work the reaction of arsenic trichloride with some aliphatic secondary amines was examined.

$$AsCl_3 + 2R_2NH \rightarrow R_2NAsCl_2 + R_2NH.HCl$$

By adding 2 moles of secondary amine (dimethylamine, diethylamine, piperidine, morpholine) to every mole of arsenic trichloride (both in benzene solution), the corresponding amidodichloroarsenites were obtained in good yields as is shown in the following table:

The dimethylamido-, diethylamido-, and piperidino-dichloroarsenites are colorless liquids. The morpholidodichloroarsenite is a white, crystalline compound. All of the amidodichloroarsenites which we have prepared are decomposed by water in a violent, exothermic reaction. As a consequence of their sensitivity towards hydrolysis, the liquid compounds "fume" in contact with wet air. They cause an immediate, burning pain and later, blisters appear on contact with the skin.

No literature data were found on the reaction of monoalkyl amines with arsenic trichloride. We have studied the reaction of arsenic trichloride with some simple primary aliphatic amines under the conditions used with the secondary amines. The reaction of *tert*-butyl amine and arsenic trichloride gave a white crystalline compound, also sensitive towards hydrolysis. The analysis of the compound did not correspond to an amidodichloroarsenite, but to an imidochloroarsenite, namely N-*tert*-butyl-imidochloroarsenite. This new type of compound was formed presumably through HCl elimination from the primary amidodichloroarsenite.

$$AsCl_3 + 2\,tert\text{-}C_4H_9NH_2 \longrightarrow \begin{matrix} Cl \\ Cl \end{matrix}\!\!\diagdown\!\!\diagup As{-}NH{-}t\text{-}C_4H_9 + t\text{-}C_4H_9NH_2.HCl$$

$$\downarrow -HCl$$

$$Cl{-}As{=}N{-}t\text{-}C_4H_9$$

Michaelis and Schroeter (10) obtained a phosphorus compound with similar structure (N-phenyl imidochlorophosphite) by heating aniline hydrochloride with phosphorus trichloride. They called it benzolphosphazochloride. Arsenimides, which contain an N=As (arsazo) bond on the basis of their monomeric structural formula, were obtained by reacting aliphatic or aromatic dichloroarsines with ammonia or primary amines (12, 13). These compounds, like all compounds containing a double-bonded arsenic atom, have multiple molecular weights (12). On the basis of the freezing point depressions of their benzene solutions their molecular weights are 4 times greater than that calculated from the monomeric formula (14). In this work a twofold double molecular weight was found for the N-*t*-butyl imidochloroarsenite, which seems therefore to be present in the dimeric form. The synthesis of N-alkyl imidochloroarsenites was also effected with ethylamine and isopropylamine. However, the derivatives obtained in these cases were less stable and they decomposed slightly on vacuum distillation.

TABLE II

The raw product obtained from the reaction of cyclohexylamine and arsenic trichloride showed good analytical agreement for cyclohexyl amidodichloroarsenite, but decomposed on attempted distillation. The latter fact suggests that the imidochloroarsenites are formed from amidodichloroarsenite intermediates by losing hydrogen chloride.

EXPERIMENTAL

Owing to the sensitivity of the products towards hydrolysis, all the work was carried out with the exclusion of moisture.

N,N-*Dialkyl Amidodichloroarsenites*

To a benzene solution (200 ml) of 18.1 g (0.1 mole) arsenic trichloride a solution of 0.21 mole aliphatic secondary amine in benzene (50 ml) was added slowly while the mixture was stirred and cooled with ice. Right at the start of the addition the precipitation of amine hydrochloride began. After the addition was completed the mixture was stirred for another 10 minutes and during this time cooling was also maintained to control the exothermic reaction. To complete the reaction cooling was discontinued, but stirring was continued for another half an hour at room temperature. The reaction mixture was then filtered by suction and the precipitate washed with benzene. From the filtrate the solvent was removed by distillation at 100 mm Hg and the raw products were purified by vacuum fractionation at about 10 mm Hg to obtain the corresponding dialkyl amidodichloroarsenites, usually as colorless liquids. Some data on the compounds prepared are shown in Table I.

N-*Alkyl Imidochloroarsenites*

Arsenic trichloride (18.1 g (0.1 mole)) was reacted with 0.21 mole of the corresponding primary aliphatic amine (ethyl-, *i*-propyl-, *t*-butyl-) as described for the preparation of alkyl amidodichloroarsenites. After the reaction was completed, the solvent was removed by distillation and the remaining raw product was fractioned in vacuum. The alkyl imidochloroarsenites are colorless; if slightly decomposed they are yellow compounds. The *t*-butyl and ethyl compound solidifies after distillation. Yields, physical data, and analytical data are summarized in Table II.

N-*Cyclohexyl Amidodichloroarsenites*

The reaction between 18.1 g (0.1 mole) arsenic trichloride and 20.9 g (0.21 mole) cyclohexylamine was carried out as described. After volatile components were removed from the filtrate of the reaction mixture at 100° C/10 mm, 17.5 g pale yellow, transparent liquid was obtained. This is a 72.8% yield calculated for N-cyclohexyl amidodichloroarsenite. An attempt to distill it at 5 mm resulted in decomposition. $C_6H_{12}NAsCl_2$: molecular weight calculated, 244; found, 508. N%: calculated, 6.71; found, 6.82. Cl%: calculated, 29.06; found, 29.8.

ORGANO ARSENIC COMPOUNDS

II. N,N-DIALKYL AMIDODIFLUOROARSENITES AND N-ALKYL IMIDOFLUOROARSENITES[1]

GEORGE A. OLAH AND ALEXIS A. OSWALD[2]

ABSTRACT

The reaction of arsenic fluoride with aliphatic amines was studied. Secondary amines gave N,N-dialkyl amidodifluoroarsenites. Primary amines while reacting similarly lose HF subsequently and yield N-alkyl imidofluoroarsenites.

The reaction of aliphatic primary and secondary amines with arsenic trichloride was examined in the first part of this work (1). We report now the behavior of these amines towards arsenic trifluoride. On reacting gaseous ammonia and arsenic trifluoride, Besson (2) obtained a solid addition product, $2AsF_3.5NH_3$. Woolf and Greenwood (3) examined the complex formation of arsenic trifluoride. They found that arsenic trifluoride gives less stable complexes than boron trifluoride or antimony pentafluoride.

By adding 2 moles of a secondary amine to 1 mole of arsenic trichloride in benzene solution, N,N-dimethylamido-, N,N-diethylamido-, and piperidino-difluoroarsenites were synthesized according to the following equation:

$$AsF_3 + 2R_2NH \rightarrow R_2NAsF_2 + R_2NH.HF.$$

After the amine hydrofluoride was filtered off, the amidodifluoroarsenites were purified by vacuum distillation and obtained as colorless liquids. All these compounds have characteristic odors and are sensitive to hydrolysis.

TABLE I

Amidodifluoroarsenites
$R'R''NAsF_2$

[2]*Present address: Research Department, Imperial Oil Ltd., Sarnia, Ontario.*

they are sensitive towards hydrolysis. Their molecular weights are 2 to 4 times greater on the basis of the freezing point depressions of benzene solutions than the calculated values for the monomeric formula shown in the above equation. Consequently they are similar to the arsenimides of other type (4) and may be characterized as low molecular weight polymers.

The reaction of arsenic trifluoride with cyclohexylamine under similar conditions did not give N-cyclohexyl imidofluoroarsenite, but instead yielded N-cyclohexyl amidodifluoroarsenite. In this case the primary amine derivative did not lose hydrogen fluoride to form the corresponding imidofluoroarsenite.

*M.p. 90–91.

EXPERIMENTAL

Arsenic trifluoride was prepared according to Russel, Rundle, and Yost (5), distilled twice, and stored in a polyethylene flask. Absolute benzene and available purest anhydrous amines were used. The work was carried out with the strictest exclusion of air and moisture. The use of arsenic trifluoride (6) and the fluoroarsenite products require careful work since these arsenic compounds have both the properties of arsenic and hydrogen fluoride regarding vapor and contact effect. For molecular weight determination, the freezing point depression of benzene solutions was used.

N,N-*Dialkyl Amidodifluoroarsenites*

A solution of 0.2 mole of the secondary amine in 50 ml toluene (or benzene) was added slowly to a mixture of 13.2 g (0.1 mole) arsenic trifluoride and 150 ml toluene (or benzene) between 0 and 10° C under cooling and effective stirring. The amine hydrofluoride started to precipitate as soon as the amine addition began. After the addition of the amine was completed, the reaction mixture was kept for an additional 15 minutes below 0° C and then was allowed to come to room temperature. The stirring was continued at room temperature for about 1 hour. Then the amine hydrofluoride was filtered by suction and washed carefully with a small amount of toluene (benzene). From the clear filtrate so obtained the solvent was removed by distillation between 50 and 100 mm. This left the raw products behind as a yellow liquid. It was purified by fractionation in vacuum. In this manner the N,N-dimethylamido-, N,N-diethylamido-, and piperidino-difluoroarsenites were obtained as colorless liquids with an unpleasant smell. Yields, physical data, and analytical data of the compounds are shown in Table I.

N-*Alkyl Amidodifluoroarsenites*

Starting from 0.2 mole of the corresponding primary amine (ethyl-, *i*-propyl-, or *t*-butyl-amine) and 13.2 g (0.1 mole) arsenic trifluoride, the preparations were carried out in the same manner as that described for N,N-dialkyl amidodifluoroarsenites. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the solvent was removed by distillation, the raw product remaining was fractionated in vacuum. The N-ethyl- and N-*i*-propyl-imidofluoroarsenites were obtained as almost colorless and odorless liquids. The N-*t*-butyl imidofluoroarsenite solidified to white crystals. Physical and analytical data and the yields of the compounds prepared are shown in Table II.

N-*Cyclohexyl Amidodifluoroarsenites*

Benzene solutions of 19.8 g (0.2 mole) cyclohexylamine and 13.2 g (0.1 mole) arsenic trifluoride were reacted in the manner used with previous examples. After being filtered by suction, the cyclohexylamine hydrofluoride was washed with benzene. The filtrate containing the main product was distilled. At first benzene was distilled over and then at 95° C/9 mm N-cyclohexyl amidodifluoroarsenite, which solidified to white crystals melting at 65–66° C. Further data are shown in Table I.

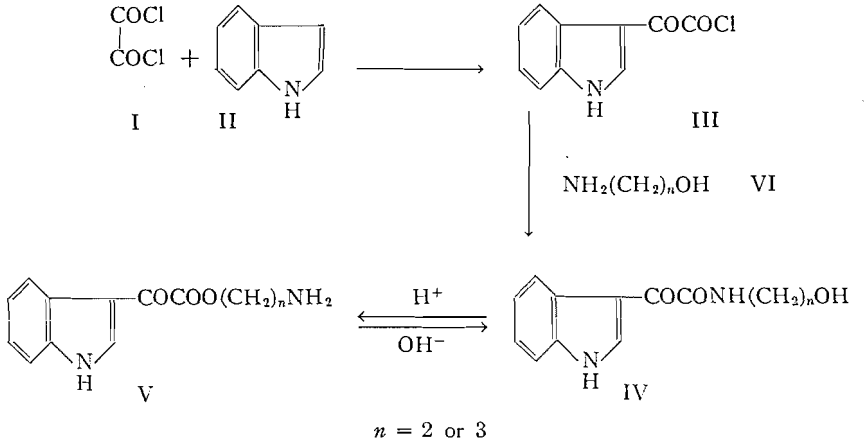
THE SYNTHESIS OF SOME INDOLYLALKYLAMINOALCOHOLS[1]



GERASSIMOS FRANGATOS, GEZA KOHAN, AND FRANCIS L. CHUBB

ABSTRACT

A series of 3-indolylalkylaminoalcohols have been obtained from the lithium aluminum hydride reduction of the amides prepared by the reaction of 3-indoleglyoxylyl chloride and 2-methyl-3-indoleglyoxylyl chloride with primary aminoalcohols. When acetone was used as solvent in the reaction of 3-indoleglyoxylyl chloride and either 2-aminoethanol or 3-aminopropanol, the solvent participated in the reaction resulting in the formation of 2,2-dimethyl-3-(3-indoleglyoxyl)oxazolidine and 2,2-dimethyl-3-(3-indoleglyoxyl)tetrahydro-1,3-oxazine respectively. When the latter two compounds were reduced by lithium aluminum hydride, both carbonyl groups were completely reduced and reductive cleavage of the oxazolidine and tetrahydro-1,3-oxazine rings occurred to form the corresponding open-chain alcohols.

It has been shown (1) that oxalyl chloride (I) reacts readily with indole (II) to form 3-indoleglyoxylyl chloride (III), which in turn reacts with amines to give the corresponding amide. Lithium aluminum hydride reduction of these amides resulted in the synthesis of a variety of substituted or unsubstituted tryptamines, except in a few cases (2, 3), where hydroxyamines were isolated from the reaction mixture, because of partial reduction of the carbonyl group to a carbinol instead of to a methylene group.

As part of a program leading to the synthesis of basic esters (4) related in structure to reserpine, the reaction of III with 2-aminoethanol and 3-aminopropanol was investigated. When III was added to a dioxane solution of a slight excess of the aminoalcohol, the corresponding amide IV was obtained in excellent yield. An excess of the aminoalcohol was necessary to prevent the rearrangement (5) of the amide to the isomeric ester V or even simultaneous formation of V. Thus when the aminoalcohols VI were added to III, the amides IV were obtained but apparently were contaminated by the isomeric esters. Lithium aluminum hydride reduction of the amides, carried out in boiling dioxane with a large excess of lithium aluminum hydride, gave the corresponding indolylalkylamines as distillable oils, listed in Table I.

When acetone was used as a solvent in the reaction of III with 2-aminoethanol and 3-aminopropanol it was found that the amides obtained were different from those obtained when dioxane was used as the solvent. Analysis and infrared spectra showed that acetone had participated in the reaction to furnish a substituted oxazolidine VII and tetrahydro-1,3-oxazine VIII respectively. The infrared spectrum of these compounds exhibited a triplet of bands in the 1020–1210 cm^{-1} region, characteristic of the oxazolidine (6) and 1,3-tetrahydrooxazine (7) rings while hydroxy group absorption was absent. Additional supporting evidence was provided by the fact that both compounds VII and VIII were obtained from the reaction of III with the preformed condensation products of acetone and either 2-aminoethanol or 3-aminopropanol. It has been shown (8, 9) that the reaction product of 2- or 3-primary aminoalcohols and aliphatic ketones is a mixture of either oxazolidine or tetrahydro-1,3-oxazine and the corresponding Schiff base in a state of mobile equilibrium. However, when a substituent other than hydrogen is attached to the nitrogen, this state of equilibrium no longer exists because the Schiff base cannot form and only the oxazolidine or tetrahydro-1,3-oxazine structure remains.

When VII and VIII were subjected to lithium aluminum hydride reduction in boiling dioxane, both carbonyl groups were completely reduced and reductive cleavage of the oxazolidine and tetrahydro-1,3-oxazine rings occurred to give the open-chain alcohols IX and X, respectively. This reductive cleavage was in agreement with earlier reports (10) on the cleavage of oxazolidines.

2-Methyl-3-indoleglyoxylyl chloride (XI) reacted with 2-aminoethanol and 3-aminopropanol in dioxane to give the corresponding amides. The latter compounds were

reduced by lithium aluminum hydride to the corresponding 2-methyl-3-indolylethyl-aminoalcohols (see Table I).

An attempt to effect the reaction of XI with 2-aminoethanol and 3-aminopropanol in acetone solution or with the preformed condensation products of acetone and 2-amino-ethanol or 3-aminopropanol only resulted in the formation of tars. Molecular models (Stuart) of the expected compounds showed that the hindrance was not purely steric.

EXPERIMENTAL*

3-Indoleglyoxylyl Chloride

The procedure of Nogradi (11) was followed for the preparation of this compound. 2-Methyl-3-indoleglyoxylyl chloride was similarly prepared.

2-(3-Indoleglyoxyl)amidoethanol

Freshly prepared 3-indoleglyoxylyl chloride (29.5 g) was suspended in 125 ml of dioxane and cooled to 15°. This suspension was added slowly with stirring to a solution of 25 ml of 2-aminoethanol in 100 ml of dioxane. During the addition and for another half hour, the reaction was kept at 12–15°. Most of the dioxane (175 ml) was distilled under reduced pressure and 150 ml of water was added to the mixture. A yellowish coarse powder precipitated, which was filtered and air-dried. Recrystallization from ethanol yielded 26 g (79%), m.p. 213°.

2-(3-Indolylethyl)aminoethanol

Nine grams of 2-(3-indoleglyoxyl)amidoethanol was dissolved in 350 ml of dry dioxane. This solution was added with mechanical stirring and under an atmosphere of dry nitrogen to a suspension of 12.5 g of pulverized lithium aluminum hydride in 230 ml of boiling dioxane. The solution was added at such a rate as to maintain refluxing of the reaction mixture without external heating. After the addition was over the heating was resumed. Great care had to be exercised during the first hour of refluxing because the reaction mixture occasionally started to foam badly. At this point heating and stirring were discontinued for a short time. After the foaming ceased the mixture was refluxed for 6 hours and cooled. The excess lithium aluminum hydride was destroyed cautiously with wet dioxane. The reaction mixture was again brought to the boiling point and filtered hot. The filter cake was washed with 50 ml of hot dioxane. The combined clear filtrates were distilled under reduced pressure and the residual oil was distilled *in vacuo*. 2-(3-Indolylethyl)aminoethanol (5.2 g, 64.5%) was obtained distilling at 205°/0.2 mm. A chloroform solution of this compound was treated with dry hydrogen chloride and the corresponding hydrochloride precipitated. It was recrystallized from a minimum amount of methanol and melted at 148°.

The amides and aminoalcohols listed in Table I (Nos. 2, 6, 9, 10, 11, 12) were prepared in the same way as 2-(3-indoleglyoxyl)amidoethanol and 2-(3-indolylethyl)aminoethanol.

2,2-Dimethyl-3-(3-indoleglyoxyl)oxazolidine

(A) Fifty grams of 2-aminoethanol was dissolved in 500 ml of acetone at 0°. To this solution a suspension of 50 g of 3-indoleglyoxylyl chloride was added slowly with stirring. The reaction mixture was cooled and stirred for an additional half hour. The yellow color of the suspension gradually faded and an oily layer separated at the bottom of the flask. The acetone was distilled under reduced pressure. The viscous residue was dissolved in

**Melting points are uncorrected. Analyses were determined by E. Thommen, Basel, Switzerland. Infrared spectra were obtained in a Perkin–Elmer 21 double-beam spectrophotometer using sodium chloride optics in potassium bromide disks.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

100 ml of boiling ethanol, treated with charcoal, and precipitated upon addition of water. 2,2-Dimethyl-3-(3-indoleglyoxyl)oxazolidine (36.5 g, 62.3%) was obtained, m.p. 208°. It exhibited a triplet absorption band in the infrared at 1104, 1131, and 1171 cm^{-1}.

(B) "2,2-Dimethyloxazolidine" was prepared according to the directions of Bergmann (9). Thirty-seven grams of freshly prepared "2,2-dimethyloxazolidine" was dissolved in 500 ml of absolute ether. To this mixture a suspension of 32 g of 3-indoleglyoxylyl chloride in 250 ml of ether was added at room temperature with stirring. After the addition was completed the reaction mixture was stirred and refluxed gently for 20 minutes. It was cooled and filtered. The crude product was washed on the filter with water and recrystallized from aqueous ethanol. Twenty-eight grams (74.5%) of 2,2-dimethyl-3-(3-indoleglyoxyl)oxazolidine was obtained melting at 208° and showing no depression of melting point upon mixing with a sample obtained according to procedure A.

2-(3-Indolylethyl)isopropylaminoethanol

The reduction of 2,2-dimethyl-3-(3-indoleglyoxyl)oxazolidine was effected by lithium aluminum hydride in boiling dioxane. The procedure already described for the synthesis of 2-(3-indolylethyl)aminoethanol was followed. It exhibited infrared absorption bands at 3538 (OH) and 3252 cm^{-1} (NH) (12).

2,2-Dimethyl-3-(3-indoleglyoxyl)tetrahydro-1,3-oxazine

This compound was obtained from the reaction of 3-indoleglyoxylyl chloride with either 3-aminopropanol in acetone solution or "2,2-dimethyltetrahydro-1,3-oxazine" (7). Similar experimental conditions to those used for the synthesis of 2,2-dimethyl-3-(3-indoleglyoxyl)oxazolidine (procedures A and B). It exhibited a triplet absorption band in the infrared at 1067, 1105, and 1148 cm^{-1}.

3-(3-Indolylethyl)isopropylaminopropanol

The lithium aluminum hydride reduction of 2,2-dimethyl-3-(3-indoleglyoxyl)tetrahydro-1,3-oxazine to 3-(3-indolylethyl)isopropylaminopropanol was effected by a procedure similar to that used for the reduction of 2-(3-indoleglyoxyl)aminoethanol.

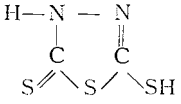
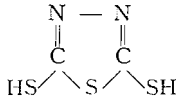
ABSORPTION SPECTRA OF 2,5-DIMERCAPTO-1,3,4-THIADIAZOLE AND ITS METHYL DERIVATIVES[1]

G. D. THORN



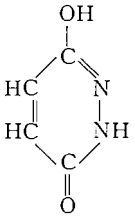
ABSTRACT

The absorption spectra of the three tautomeric forms of 2,5-dimercapto-1,3,4-thiadiazole have been determined by using the N- and S-methyl derivatives. In the ultraviolet region, a hypsochromic shift in absorption maxima is shown in the change from the dithionic to the thionic–thiolic and to the dithiolic forms. Strong bands in the infrared at 1508–1475 cm^{-1} and 1435–1415 cm^{-1} have been assigned to  and , respectively.

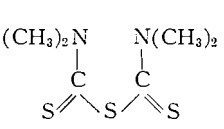


Theoretically the title compound can exist in any of three tautomeric forms (IA, IB, or IC) and thus the name 2,5-dimercapto-1,3,4-thiadiazole may be too rigid. An analogy exists in maleic hydrazide, for which the structure II has been assigned (1), and from which the various N- and (or) O-methyl derivatives have been obtained by alkylation under varied conditions. Zahradník (2) has obtained the ultraviolet absorption spectrum of dimercaptothiadiazole, and has designated the structure as being that of form IA. Sheinker *et al.* (3) believe the compound to have a mixed thionic–thiolic structure (IB).

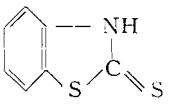
IA



IB



IC



Substitution of alkyl groups for SH or NH hydrogen in 2,5-dimercapto-1,3,4-thiadiazole forces the molecule into one of the tautomeric forms IA, IB, or IC. An investigation of the ultraviolet and infrared spectra of the various alkyl-substituted derivatives was made therefore with a view to assigning specific molecular structures to the various absorption bands of the parent compound.

II

III

IV

The dithiocarbamate grouping, as in esters of dithiocarbamic acids, or in tetramethylthiuram monosulphide (III), shows strong ultraviolet absorption bands in the regions 275–290 mμ and 245–260 mμ (both with log ϵ about 4), and weaker absorption in the region 325–360 mμ (log ϵ about 1.8) (see, for example, Janssen (4)). Zahradník (2)

[1]*Manuscript received April 25, 1960.*
Contribution No. 174, Pesticide Research Institute, Canada Department of Agriculture, University Sub P.O., London, Ontario.

observed that dimercaptothiadiazole did not follow this pattern, but instead showed strong absorption at 332 mμ (log ε 4.2, in ethanol) and a weaker absorption band at 265 mμ. This "anomalous" behavior was also seen in the spectrum of mercaptobenzothiazole (IV), and was explained on the basis of the —S—C(=S)— groups giving the ring a pseudoaromatic character. With tetramethylthiuram monosulphide (III), where the nitrogens are not joined to form a heterocyclic ring, the expected absorption maximum at 280 mμ is observed.

EXPERIMENTAL

2,5-Dimercapto- and *2-mercapto-5-methylmercapto-1,3,4-thiadiazole* (I and IV, respectively) were prepared according to Thorn and Ludwig (5).

2,5-Dimethylmercapto-1,3,4-thiadiazole (VI) was prepared by the reaction of the dimercaptothiadiazole in aqueous ethanol with stoichiometric amounts of methyl iodide and potassium hydroxide, according to Busch and Ziegele (6). Fractional distillation of the water-insoluble product gave a colorless liquid, b.p. 87–88° at 0.05 mm; $n_{23.5}^{D}$ 1.6530. Calc. for $C_4H_6N_2S_3$: S, 54.0%. Found: S, 54.1%. Busch and Ziegele (6) record a melting point of 136°, but in this laboratory a solid product was not obtained in any of several preparations.

2-Mercapto-4-methyl-1,3,4-thiadiazoline-5-thione (VII) was obtained from methylhydrazine and CS_2 according to the method of Busch and Ziegele (7). The product melted at 65–66° after crystallization from diethyl ether. Busch and Ziegele (7) record a melting point of 69°. Calc. for $C_3H_4N_2S_3$: S, 58.6%. Found: S, 58.6%.

2-Methylmercapto-4-methyl-1,3,4-thiadiazoline-5-thione (VIII) was prepared from VII according to Busch and Ziegele (7) and melted at 81–82° after crystallization from 95% ethanol. Lit. (7) gives a melting point of 88°. Calc. for $C_4H_6N_2S_3$: S, 54.0%. Found: S, 53.8%.

3,4-Dimethyl-1,3,4-thiadiazolidine-2,5-dithione (IX) was prepared by heating under reflux for 9 hours an alcohol solution of stoichiometric amounts of dimethylhydrazine dihydrochloride, potassium hydroxide, and carbon disulphide. The product was precipitated from the reaction mixture by the addition of water; yield, 50%. The melting point was 168–169°, after crystallization from 95% ethanol. Calc. for $C_4H_6N_2S_3$: S, 54.0%. Found: S, 53.7%.

Ultraviolet absorption spectra were measured in ethanol solution with the Beckman DK-1 spectrophotometer. Infrared spectra were recorded with the Perkin–Elmer Model 21 instrument with NaCl prism, in chloroform solution or KBr disk.

DISCUSSION

The various tautomeric structures for the dimercaptothiadiazole derivatives studied are given in Fig. 1, together with the ultraviolet absorption bands of these compounds. Nearly identical spectra (λ_{max} 327–335 and 260–268 mμ) are shown by compounds I, VII, and IX. This absorption thus establishes the thione structure for these compounds, as in IX the possibility of enethiolization does not exist. Forcing one of the thiocarbamoyl groups into the enethiol form as in V and VIII results in a hypsochromic shift of both absorption bands. The similarity in spectra for these latter two compounds suggests that in V the second thiocarbamoyl group is in the thione form. The fixing of both thiocarbamoyl groups into the enethiol arrangement results in a further hypsochromic shift

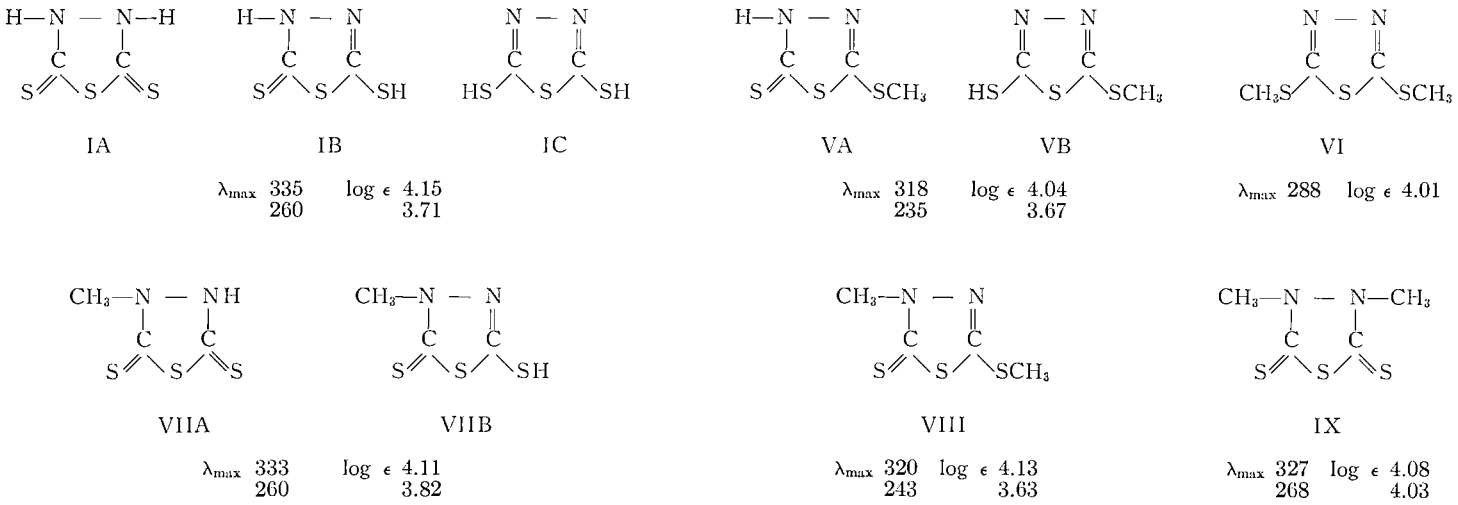

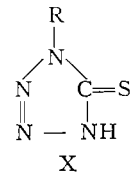

FIG. 1. Possible tautomeric forms for 2,5-dimercapto-1,3,4-thiadiazole and its methyl derivatives, and their ultraviolet absorption maxima (ethanol solution).

of the band of longer wavelength, with loss, in the region studied, of the shorter wavelength band.

Thus, on a consideration of ultraviolet absorption spectra alone, definite assignments of structure can be made. A study of the infrared absorption spectra, however, suggests that these assignments are not as categorical as given above.

The strong band in the region 1610–1470 cm^{-1} appearing in the spectra of compounds containing the $>N-C(=S)<$ group has been assigned by Randall *et al.* (8) to a ν_{CN} frequency strengthened by the ionic form $>N-\overset{+}{C}(-S^-)<$, and was termed by these authors as a "thioureide ion" band. Chatt *et al.* (9), however, have assigned this band to the contribution by the canonical form $>N^+=C(S^-)<$, in the case of dithiocarbamate esters and heavy metal complex salts, and have restricted the "thioureide ion" band to the region 1542–1480 cm^{-1}. Other workers (10, 11, 12) have concluded that this thioureide band is due to a δ_{NH} frequency. An appraisal has been made by Elmore (13) of the nature of the thioureide band. Elmore has suggested that since this band occurs with compounds having no NH group, it cannot be entirely due to a δ_{NH} vibration, although he postulated that coupling between δ_{NH} and ν_{CN} modes may occur in some instances. Lieber *et al.* (14) on the basis of the spectra of a number of 1-substituted tetrazolinethiones and 4-substituted semicarbazides have made a frequency assignment of 1555–1474 cm^{-1} for the $>N-C(=S)-$ grouping and 1395–1338 cm^{-1} for the $>C=S$ linkage. Lieber *et al.* (14) used the occurrence of these bands in 1-substituted tetrazolines (X) together with the absence of the SH band in the region 2600–2550 cm^{-1} (15) to support the thione rather than the thiol structure for these compounds.

X

Table I summarizes the important bands observed for the dimercaptothiadiazoles. In all but two of the compounds, two strong bands, at 1435–1415 cm^{-1} and 1508–1475 cm^{-1} (chloroform solution), are observed. The former is not given by compound IX, the latter not by compound VI. The above results lead us to the view that the 1508–1475 cm^{-1} is indeed assignable to the $>N-C(=S)<$ grouping, perhaps modified by resonance as suggested by Chatt *et al.* (9), and that the band at 1435–1415 cm^{-1} is associated with the $-N=C(S-)<$ grouping.

Lieber *et al.* have made a frequency assignment of 1395–1338 cm^{-1} for the C=S linkage. Mecke and Mecke (16) and Mecke *et al.* (12) had previously assigned a band of strong intensity in the region 1200–1050 cm^{-1} to the C=S grouping, and a band in the 1350–1300 cm^{-1} region to CN vibration. In the dimercaptothiadiazoles, a strong band

TABLE 1

Principal infrared bands of 2,5-dimercapto-1,3,4-thiadiazole and its methyl derivatives

Compound	Position of methyl(s)	Solvent system	Absorption bands, cm^{-1}												
I	—	Sat. $CHCl_3$	3430	3100	2590w	1508	1420	1345		1165	1127	1070			
V	S	1% $CHCl_3$	3370	3060		1487	1415	1370			1120	1055		975	
VI	S,S′	10% $CHCl_3$					1435	1395	1320	1230w	1135m	1048		973m	
VII	N	10% $CHCl_3$			2555	1485	1425	1350	1265	1230w	1130		1013m	945m	905
VIII	N,S	10% $CHCl_3$				1475	1428	1357	1265		1125	1065m	1012m	975m	907
IX	N,N′	1% $CHCl_3$				1480		1375	1285m			1097		935m	875m

is given by chloroform solution of all the compounds studied, including the S,S′-dimethyl ether (V), in the 1395–1338 cm^{-1} region assigned by Lieber *et al.* to C=S. An exception is that dimercaptothiadiazole itself does not show absorption in this region in the KBr disk. Strong bands are given also by all these compounds in Mecke's 1050–1200 cm^{-1} region. It may be mentioned that for the methyl and ethyl esters of N,N-dimethyl- and N-methyl-dithiocarbamic acid and of dithiocarbamic acid itself, a strong band is seen (17) in the region 1385–1345 cm^{-1}, but that strong absorption is shown in the 1200–1050 cm^{-1} region only by those dithiocarbamates substituted in the nitrogen, and not by ethyl or methyl dithiocarbamate. On the basis of the above, the author tends to the assignment of Lieber *et al.* of 1395–1338 cm^{-1} for C=S when forming part of the thioureide grouping, made tentative, however, by the two anomalies mentioned in the dimercaptothiadiazole compounds. The thiocarbonyl stretching frequency has been assigned recently to the region 1220–1080 cm^{-1} by Spinner (18), on the basis of unambiguous identity in such compounds as thioformaldehyde and thiocarbonyl chloride. Haszeldine and Kidd (19) previously had given the $\nu_{C=S}$ vibration as 1078 cm^{-1} for ethylene trithiocarbonate. Thus, as is pointed out by Jones *et al.* (20), the frequency for C=S is dependent on the structural environment and falls within the wide range 1400–1000 cm^{-1}.

Mention was made in the discussion on the ultraviolet absorption spectra of the dimercaptothiadiazole derivatives that the assignment of structure made was perhaps too rigorous. The infrared spectra of compounds I and VII in chloroform solution made it apparent that these compounds possess an SH group (absorption in the 2600–2550 cm^{-1} region (15)). The postulate may be advanced that in concentrated chloroform solution these two compounds are primarily in the form of structures IB and VIIB, whereas in dilute alcohol solution the dithione structures IA and VIIA are the predominant forms. For structural systems of this type it has been found that a change in medium may alter the tautomeric equilibrium position (see Spinner (20) and references quoted by him).

ACKNOWLEDGMENTS

The author is grateful for the discussions with Robert W. White on the infrared absorption spectra and expresses his thanks to Dorle Bongart for microanalyses and to Marilyn Coleman for technical assistance.

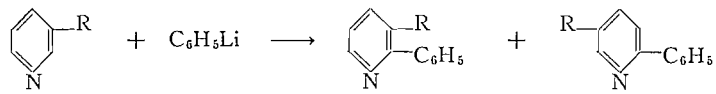
ARYLPYRIDINES



PART II. REACTION OF PHENYLLITHIUM WITH 3-METHOXY- AND 3-AMINO-PYRIDINE[1,2]

R. A. Abramovitch and A. D. Notation

ABSTRACT

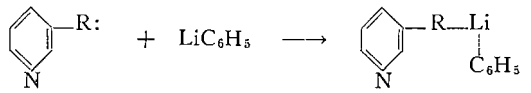
Phenyllithium has been shown to react with 3-methoxy- and 3-amino-pyridine to give exclusively 3-methoxy-2-phenylpyridine and 3-amino-2-phenylpyridine respectively. The orientation of the products has been established unambiguously. None of the 2,5-isomer was detected in either case. An explanation for this unique orientation is suggested.

In Part I of this series (1) the orientation of the entering phenyl substituent in the addition of phenyllithium to 3-picoline and to nicotine was studied. In the first case the main product was 3-methyl-2-phenylpyridine (II; R = CH_3) together with a small amount of 5-methyl-2-phenylpyridine (III; R = CH_3), the ratio of the isomers being 19:1. On the other hand phenylation of nicotine gave 2-phenyl- (II; R = -α-$C_4H_7NCH_3$) and 6-phenyl-nicotine (III; R = -α-$C_4H_7NCH_3$) in a 1:1 ratio. Evidence that the 3-substituent exerts an appreciable steric effect in the end product of the addition was

I II III

also presented. The results were interpreted to mean that addition of phenyllithium to 3-substituted pyridines occurs preferentially at the 2-position but that the 3-substituent, if sufficiently bulky, could exert a steric effect resulting in appreciable addition at the 6-position also.

The present paper gives an account of the extension of this study to 3-amino- and 3-methoxy-pyridines both of which are readily available and the products from which could serve as valuable intermediates in synthetic work. Molecular models indicate that the steric effect of a methoxyl group would be expected to be less than that of a methyl group whereas that of a primary amino group, particularly as its lithium salt, should be comparable with that of a methyl group. 3-Methoxypyridine was prepared by methylation of 3-hydroxypyridine according to Prins's procedure (2).



3-Aminopyridine (I; R = NH_2) was treated with a 3-molar excess of phenyllithium to give a 24.5% yield of product. That probably only a single isomer was present was indicated by vapor phase and by column chromatography, and that this isomer was 3-amino-2-phenylpyridine (II; R = NH_2) was shown by comparison of the base and of its picrate with authentic specimens prepared unambiguously from 3-methyl-2-phenylpyridine (3). No evidence for the presence of any 5-amino-2-phenylpyridine in the mixture could be obtained.

In a similar manner, 3-methoxypyridine reacted with phenyllithium to give a 21.2% yield of product $C_{12}H_{11}ON$. Once again this was shown chromatographically to consist

[1]*Manuscript received March 10, 1960.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*Part I: Can. J. Chem.* **38**, *761 (1960).*

of a single isomer which proved to be 3-methoxy-2-phenylpyridine. This could be established quite readily by demethylation to 3-hydroxy-2-phenylpyridine, an authentic specimen of which was obtained from the above 3-amino-2-phenylpyridine. The physical properties of the phenol corresponded also to those reported for 3-hydroxy-2-phenylpyridine (II; R = OH) by Leditschke (4). The infrared spectrum of 3-methoxy-2-phenylpyridine exhibited a band at 1584 cm^{-1} which has been shown to be characteristic of such 2,3-disubstituted pyridine derivatives (5). Once again no 5-hydroxy-2-phenylpyridine was detected in the crude reaction product.

It would seem, therefore, that in the present instance the entering phenyl group is directed *exclusively* to the 2-position. A possible explanation of this observation is that in both the examples studied here the 3-substituent has a pair of electrons which can co-ordinate with the lithium atom to form a complex such as IV in which the phenyl group would be suitably oriented for attack at the 2-position. This, together with the already established tendency for preferential addition to the 2-position (1), would account for the fact that no 6-substitution was observed. Stereospecificity in the addi-

IV

tion of phenyllithium to α-hydroxyketones has been similarly attributed to the formation of a lithium complex as an intermediate (6).

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured using a Perkin–Elmer Model 21 instrument and the vapor phase chromatographic work was carried out using a Beckman GC-2 unit with helium as the carrier gas.

Reaction of Phenyllithium with 3-Aminopyridine

Lithium (1.65 g) was finely cut and suspended in anhydrous ether (50 ml) under dry nitrogen. Bromobenzene (11.4 ml; 17 g) in anhydrous ether (20 ml) was added dropwise at such a rate as to maintain gentle reflux. When the formation of phenyllithium was complete 3-aminopyridine (4 g) in anhydrous ether (80 ml) was added over a period of 20 minutes during which time a brilliant yellow suspension was formed. The ether was distilled off and simultaneously replaced by dry toluene (100 ml) and the temperature was raised to the boiling point. The mixture was boiled under reflux with stirring for $7\frac{1}{2}$ hours during which time the color turned a dark brown. Water was carefully added to the cold suspension, the toluene layer separated, and the aqueous layer extracted repeatedly with ether. The combined ether and toluene layers were extracted with dilute hydrochloric acid, the acid extract made strongly basic with sodium hydroxide, and the product extracted with ether. The ether layer was dried (Na_2SO_4), evaporated, and the residue distilled under vacuum to give crude 3-amino-2-phenylpyridine (1.5 g). This was redistilled and obtained as a pale yellow oil, b.p. 119–121°/0.35 mm, which solidified on cooling and was recrystallized from benzene – light petroleum (b.p. 40–60°) giving colorless crystals, m.p. 62–64°. Calc. for $C_{11}H_{10}N_2$: C, 77.62; H, 5.92. Found: C, 77.90; H, 5.78. Infrared spectrum (Nujol mull) (main peaks only): 3350 (m) (br), 3220 (m) (br), 1620 (s) (br), 1585 (s), 798 (s), 743 (s), 730 (w), 695 cm^{-1} (w).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The monopicrate, on recrystallization from ethanol, had a melting point of 204–206°. Calc. for $C_{11}H_{10}N_2$, $C_6H_3O_7N_3$: C, 51.13; H, 3.28. Found: C, 51.18; H, 3.17.

A sample of crude reaction product (0.1193 g) was chromatographed on a narrow column of alumina (5 g). Elution was carried out using the following sequence of solvents: light petroleum (b.p. 40–60°), benzene – light petroleum, benzene, benzene–ether, ether, ether–methanol, and finally methanol. Only a single colorless band, exhibiting blue fluorescence under ultraviolet light was eluted, and this with benzene–ether. Different portions of the benzene–ether eluate were converted to the picrate. In each case, only 3-amino-2-phenylpyridine picrate, m.p. 204–206°, was obtained. Also, the individual fractions had identical infrared spectra. The total recovery from the column was 0.1018 g. The mixed melting point of the picrate with that of an authentic sample (3) was undepressed. Also, the infrared spectrum of the free base was identical with that of the authentic sample. Only one peak was observed on vapor phase chromatography of the crude free base under a variety of conditions.

Reaction of Phenyllithium with 3-Methoxypyridine

Phenyllithium was prepared from lithium (0.5 g) and bromobenzene (5.7 g) in anhydrous ether. 3-Methoxypyridine (4 g) in anhydrous ether (30 ml) was added dropwise over a period of 20 minutes, after which the ether was distilled off and simultaneously replaced by dry toluene (40 ml). The reaction mixture was stirred and boiled under reflux under an atmosphere of nitrogen for 7 hours, water was carefully added to the cooled suspension, and the toluene layer separated. The aqueous layer was extracted with ether, the combined ether and toluene extracts washed with dilute hydrochloric acid, and the acid solution basified and extracted with ether. The dried (Na_2SO_4) ether extract was evaporated and the residue distilled under vacuum, the fraction (1.4 g), b.p. 120–160°/0.34 mm, being collected. Redistillation gave pure 3-methoxy-2-phenylpyridine, b.p. 110–112°/0.34 mm. Calc. for $C_{12}H_{11}ON$: C, 77.81; H, 5.99. Found: C, 78.13; H, 6.43. Infrared spectrum (liquid film) (main peaks only): 1575 (s), 1265 (s) (br), 1195 (s), 1125 (s), 1015 (s), 795 (s), 735 (s), 692 cm^{-1} (s).

The picrate was recrystallized from ethanol and had a melting point of 153.5–155°. Calc. for $C_{12}H_{11}ON$, $C_6H_3O_7N_3$: C, 52.18; H, 3.41. Found: C, 52.53; H, 3.86.

The crude base was shown to consist of a single compound by column and vapor phase chromatography as described for 3-amino-2-phenylpyridine.

3-Hydroxy-2-phenylpyridine

(i) From 3-Methoxy-2-phenylpyridine

3-Methoxy-2-phenylpyridine (0.2 g) was boiled under reflux for 4 hours with 47% hydrobromic acid (3 ml). The excess hydrobromic acid was then evaporated off and the residue neutralized with 10% sodium carbonate solution and ether extracted. The dried (Na_2SO_4) ether extract was evaporated and the residue of 3-hydroxy-2-phenylpyridine recrystallized from ethanol to give colorless crystals, m.p. 206–207.5°. Leditschke (4) reported a melting point of 205° for this compound. The infrared spectrum of this product was identical with that of an authentic specimen prepared as described under (ii) below. Also, its melting point was undepressed on admixture with the authentic specimen.

(ii) From 3-Amino-2-phenylpyridine

3-Amino-2-phenylpyridine (0.4 g) was dissolved in a mixture of concentrated sulphuric acid (0.8 ml) and water (2 ml). The solution was cooled to 0–5° and diazotized with sodium nitrite (0.3 g) in water (1 ml) and after ½ hour at 0–5° the excess nitrous acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was decomposed with urea. The solution was then boiled under reflux for 1 hour after which time it gave a negative alkaline β-naphthol test. The reaction mixture was treated with solid sodium carbonate and ether extracted repeatedly. The combined ether extracts were dried (K_2CO_3) and evaporated giving crude 3-hydroxy-2-phenylpyridine (0.35 g) contaminated with some orange impurity. Recrystallization from ethanol gave the pure phenol, m.p. 206–207.5°. Infrared spectrum (Nujol mull) (main peaks only): 1573 (m), 1280 (s) (br), 1182 (s), 1115 (m), 802 (m), 735 (s), 693 cm^{-1} (m).

THE ATTACK OF CHROMITE BY SULPHURIC ACID[1]

W. J. Biermann and Menno Heinrichs

ABSTRACT

A study was made of the attack of a "low grade" chromite concentrate by sulphuric acid of various concentrations with a view toward formulating a more adequate description, or mechanism, of the process. Consideration of available evidence eliminates the possibility of hydrolysis playing an important role in the process. A qualitative mechanism consistent with the available facts is based on an initial protonic attack, followed by formation of various sulphate complexes of chromium.

INTRODUCTION

The utilization of chromites which are currently classed as "low grade", due, in great measure, to the large amount of contained iron, has been the subject of numerous investigations. These have been comprehensively collected by Udy (1) and an earlier review by Downes and Morgan (2) gives an excellent critical recount of efforts directed toward development of the North American deposits. Methods based on sulphuric acid leaching figure prominently in these reviews.

The present work started as a simple attempt to establish conditions required for the complete conversion of chromite concentrate to a soluble product by sulphuric acid digestion, preparatory to other studies. After a few experiments it became obvious that the attack of chromite by sulphuric acid was not a simple process, and the series of experiments described herein was undertaken to give some clarification to the process involved. It is, in a sense, an extension of the leaching experiments at the Mines Branch laboratories, described by Downes and Morgan. Their objective was the establishment of optimum conditions for the removal of iron by treating the chromite with insufficient acid for complete destruction of the chromite lattice. Their conclusion was that only a fixed portion of iron could be removed by leaching, and a mechanism involving hydrolysis of dissolved cations was postulated to explain this limit of beneficiation.

EXPERIMENTAL METHODS

For the rate of attack of chromite by sulphuric acid to be conveniently rapid, it is necessary that the sulphuric acid be somewhat diluted and that the temperature be maintained above the normal boiling point of the solution. A simple steel pressure vessel, sealed by a Teflon "O" ring, was found to be more convenient than the customary sealed glass tubes for containing the reactants. The reactants themselves were placed in an open glass tube, whose upper end was loosely closed by a wisp of glass wool to prevent mechanical spraying of sulphuric acid onto the inner walls of the steel container. A pressure gauge gave a rough measure of the rate of reaction; as sulphuric acid is used up the vapor pressure increases, leveling off to a constant value as the rate of reaction decreases. Experimentally, a known weight of chromite and a weighed amount of sulphuric acid of known concentration were placed in the glass vessel and digested until the constancy of the pressure reading showed that the rate of reaction had slowed down to a negligible value. The contents of the glass tube were then removed and analyzed.

After a digestion of chromite concentrate with sulphuric acid the reaction vessel contained solution, unattacked chromite, and a finely divided insoluble substance; this latter, for lack of a more definitive designation, we have called "altered chromite".

The total amount of solid residue was determined by washing with either hot water or dilute sulphuric acid, the amount of residue generally being greater when an acid was used and, under similar washing conditions, reproducible to within a few per cent. Resolution of the total solid into unattacked and altered chromite was hampered by the slow reactivity of the altered chromite. After some experimentation it was found that boiling with two molar sodium hydroxide solutions converted the altered chromite to a readily acid-soluble, gelatinous substance, permitting the isolation of the unattacked chromite by filtration. The weight of altered chromite is the difference between the total residue weight and the excess chromite. Composition of the altered chromite was obtained by analysis of the filtrate from the chromite separation.

The determination of chromium and iron was done with a standard redox titration. Sulphate was determined by precipitation and weighing as barium sulphate. Acetylacetone was added to prevent loss of sulphate by complexation with chromium (III) ions. Aluminum was determined spectrophotometrically by using alizarin red-S in the presence of calcium (3). Shapiro and Brannock (4) have shown that no interferences will result from substances present in these samples. Magnesium was titrated with standard ethylenediamminetetraacetic acid. The amounts of calcium, manganese, and titanium present were too small to have any significant effect on the conclusions reached here and hence were generally ignored.

The chromite used in these experiments was a concentrate prepared from material taken from the Bird River chromite complex and supplied through the courtesy of the Research Department of the Hudson Bay Mining and Smelting Co. This concentrate assayed 41.8% Cr_2O_3, had a chromium–iron ratio of 1.36 to 1, and the particle size was about 80 mesh.

EXPERIMENTAL RESULTS

Table I shows the weights of the three materials obtained by digestions under a variety of conditions. The amount of sulphuric acid is described in terms of "percentages of equivalence", an equivalent of sulphuric acid being calculated as the amount of sulphuric acid required to convert the concentrate completely to a mixture of normal sulphates. Concentration of sulphuric acid is described by a conventional volume ratio of concentrated sulphuric acid to water.

The data suggest that the amount of chromite unattacked by sulphuric acid is determined primarily by the amount of acid present. When the acid used is about 50% of equivalence, the unattacked chromite is generally quite close to the amount anticipated from stoichiometry, provided sufficient time is allowed for equilibrium to be established. Some silica is dissolved by the sodium hydroxide, accounting for the small apparent excess of attack. In no case was the excess attack great enough to indicate significant regeneration of sulphuric acid by hydrolysis. Figure 1 shows a relationship between the amount of unattacked chromite and the sulphuric acid concentration, most effective attack occurring in the region of equal volumes of sulphuric acid and water. A diminished rate of attack at lower concentration is anticipated in a presumably protonic attack on the chromite lattice; the falling off of rate at higher concentrations is most readily rationalized on a purely mechanical basis because, as shown in Fig. 2, the amount of "altered chromite" begins to increase rapidly at sulphuric acid concentrations higher than 1 to 1.

Selection of data for inclusion in Figs. 1 and 2 was necessary in order to compare runs which differed only in the experimental variables plotted. Examination of runs not

*The weights of products are grams per gram of chromite in the digestion charge.
†The symbol (w) after the number means that soluble products were removed with hot water; the symbol (a) means that dilute sulphuric acid was used.

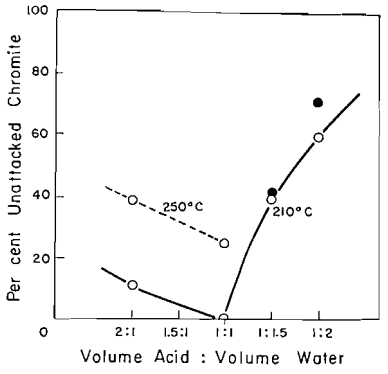

FIG. 1. Degree of attack of chromite as a function of acid concentration. The amount of acid present is 200% of equivalence and the time is 21 hours, except for blackened points which are 7.5 hours and 200° C.

included in these plots discloses no behavior contrary to the conclusions drawn from the data selected.

The dotted portion of Fig. 1 shows that the rate of attack at higher acid concentrations drops as the temperature is increased to 250° C. Comparing runs numbers 1, 2, 3, and 4 in Table I shows how this increase in temperature simultaneously brings about a marked increase in the amount of "altered chromite".

The insoluble material, which we have designated "altered chromite", is formed whenever the acid concentration is high enough to give a reasonable rate of attack on chromite. This, presumably, is the same material which the Mines Branch workers consider to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

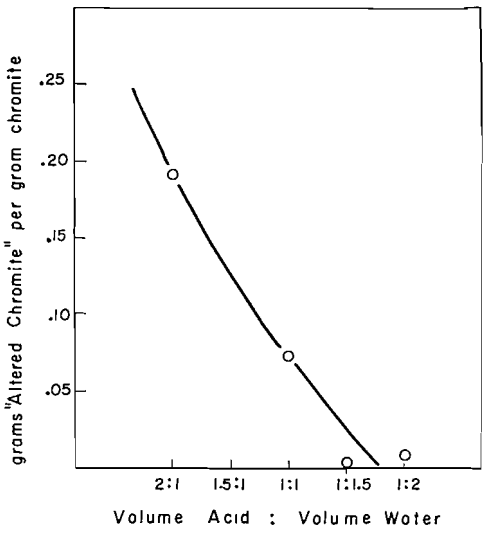

FIG. 2. Formation of "altered chromite" as a function of acid concentration. Acid is 200% of equivalence, time is 21 hours, and the temperature is 200° C.

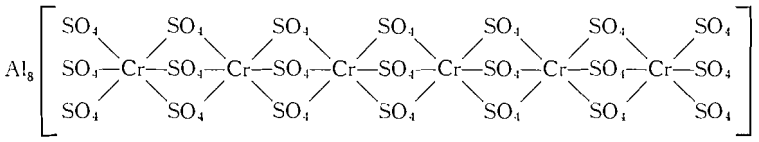
hydrolysis products of the trivalent ions, but which assumption is not consistent with their observation, substantiated in this work, that the amount of this material increases with sulphuric acid concentration. The physical and chemical properties (finely divided, grey-green, and acid-insoluble) are also suggestive that an alternate explanation is required. Chemical analyses of two representative samples of the "altered chromite" are presented in Table II, and the cation:anion ratio seems to indicate conclusively that

TABLE II

Analysis of typical "altered chromites"

From digestion No.	% Cr	Fe	Al	Mg	SO_4	Ratio equivalents, cations:anion
18a	7.25	9.56	4.39	1.82	60.0	1.12
2	10.37	6.43	2.42	1.55	68.2	.88



hydrolysis cannot be a significant factor in the formation of the insoluble material. Complete analysis of the products was not generally made, partial analysis of the products showing that the results were quite constant within a given region of acid excess. The slight excess of cation over sulphate was typical of the runs using 50% equivalence of acid. This is ascribed to hydrolysis of the product during the manipulations subsequent to digestion; during extraction of the soluble products the precipitate tended to develop a gelatinous nature, suggestive of an hydroxylation process.

The available facts are better explained on the postulate that the "altered chromite" is a mixture of the hydrogen, aluminum, magnesium, and iron (II) salts of sulphato-polychromate (III) anions. Recoura's work (5), in general confirmed by Whitney (6), substantiates the probability of this explanation, since he reports the preparation of a series of "chromium polysulphuric acids" under conditions similar to the digestion conditions, and observed most of their salts were insoluble and closely resembled the "altered chromite" in appearance. The formation and composition of such polynuclear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

complexes will be a function of ligand concentration, central ion concentration (7), and of the relative concentrations of protons and other metals which can function as cations. This is completely consistent with the observation that high sulphate concentrations favor formation of the insoluble compounds, that the percentage of sulphate in these compounds is observed to increase when excess sulphuric acid is used, and that the removal of iron and chromium (III) is lowest with concentrated sulphuric acid, which is also the most favorable condition for formation of these complexes.

To further strengthen this explanation, typical compounds of the type postulated were prepared under similar conditions. By digesting chromium (III) sulphate with sulphuric acid, in a molar ratio of 1 to 4, a water and acid-insoluble substance, whose analysis corresponded closely to $H_2[Cr_2(SO_4)_4]$, separated. On baking until sulphur trioxide fumes ceased to appear, the analysis of the solid corresponds to $H_2[Cr_4(SO_4)_7]$, agreeing in properties and chemical analysis with the product Recoura designated the "isomeric form". Digestion of an equimolar mixture of aluminum and chromium (III) sulphates with excess sulphuric acid gave precipitation of a substance corresponding in analysis to $Al_8[Cr_2(SO_4)_7]_3$. Improbable though this compound first looks, it can be assigned a provisional structure of

This is consistent with the known co-ordination chemistry of chromium (8).

DISCUSSION

The Mines Branch mechanism for the attack of chromite by sulphuric acid would seem to profit by modification to the following scheme. The initial step is a protonic attack of the chromite lattice, bringing the metallic constituents into solution in the same ratio as they occur in the lattice. Precipitation takes place in a second step. Sulphato complexes of chromium (III) are formed and, under conditions of sufficiently high concentration of chromium (III) ions and sulphate ions, these will include various anionic polynuclear species whose hydrogen or other salts are insoluble. Increasing temperature also favors formation of these polynuclear products. Attack of the chromite may become very slow after accumulation of these insoluble salts, hence the failure to complete the decomposition of the chromite in a reasonable time when excess of sulphuric acid is used.

The more obvious weaknesses of the hydrolysis theory are: first, the precipitated iron is almost completely in the form of iron (II) which is not easily hydrolyzable; second, precipitation takes place when large amounts of unused acid are present; and, third, hydrolysis cannot account for the fact that the percentage of insoluble products increases as the concentration of sulphuric acid increases.

A quantitative description of the over-all process requires considerably more knowledge of the sulphato polychromium (III) complexes, particularly equilibrium constant information, than is now available. Such information we hope will be forthcoming in part, as a result of continued work on the chemistry of chromite in this laboratory.

Metallurgically, this work makes a somewhat negative contribution to substantiating the observation that there is a limit to the amount of iron removal possible from untreated chromite by sulphuric acid leaching. A second fact, that the percentage of chromium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

convertible from chromite to insoluble polynuclear forms can be varied over a wide range by altering the concentration and temperature of the leaching acid, is an observation whose metallurgical significance cannot be assigned until the chemistry of these compounds is further explored.

QUANTITATIVE ANALYSIS OF COMBUSTION PRODUCTS BY GAS CHROMATOGRAPHY

THE OXIDATION OF A RICH *n*-PENTANE–AIR MIXTURE IN A FLOW SYSTEM[1]

S. SANDLER[2] AND J. A. BEECH[3]

ABSTRACT

A description is given of an apparatus suitable for investigations of the oxidation and decomposition reactions of volatile hydrocarbon vapors in a flow system. Most of the reaction products are analyzed quantitatively by gas chromatography in a single-stage process involving a simple column-temperature programming technique. The products of the oxidation of a rich mixture of *n*-pentane and air in an annular reactor of Vycor over a wide temperature range are shown in detailed analysis. The products, as identified by several techniques including time-of-flight mass spectrometry and infrared spectrophotometry, include C_2—C_5 mono-olefins, two di-olefins, C_1—C_4 saturated aldehydes, an unsaturated aldehyde, and 2-methyl tetrahydrofuran in addition to those usually associated with the complete oxidation of *n*-pentane.

INTRODUCTION

Earlier studies in this laboratory of the low-temperature oxidation of *n*-pentane (1, 2) indicated the need for an efficient means of analyzing the complex mixture of products so obtained. It was possible to determine the effect of certain variables on the total concentration of any particular class of components, but this information was insufficient for the determination of a reaction mechanism. The analytical difficulty is largely responsible for the lack of quantitative information concerning the effect of temperature and other variables on the mechanism of the oxidation of hydrocarbons.

One of the first attempts at a detailed analysis was that of Ubbelohde (3), who identified some of the liquid oxidation products of pentane after fractional distillation, using ultraviolet spectroscopy and chemical methods. With the development of liquid partition chromatography and polarography more of the products could be analyzed, as demonstrated by Malmberg and others (4, 5), but the experimental method was complicated and the results were of limited quantitative value.

Detailed analyses of complex mixtures of combustion products can now be effected by using the newly developed gas chromatographic techniques. Thus Yokley and Ferguson (6) were able to investigate qualitatively some of the products of the cool flame combustion of propane; Kyryacos, Menapace, and Boord (7) determined the identity of many of the components of the cool flame combustion products of *n*-hexane, and Hughes, Hurn, and Edwards (8) separated and identified oxygenated hydrocarbons in automotive engine combustion products using a three-stage unit.

Gas chromatography was used in earlier work by the authors to separate liquid oxidation products, in conjunction with Orsat analysis of the normally gaseous products. The liquid products were collected in traps surrounded by dry ice – acetone and ice–water mixtures and the condensates had to be transferred by micrometer syringe to the chromatographic column. This procedure entailed large sources of error in the handling of the samples and volatilization of some of the components. In addition, calculation of selectivities (i.e. moles of product formed/mole of fuel consumed) was tedious because it was necessary to combine the analyses of the two condensates. In addition, the calculations

involved the assumptions of uniformity of the flow rate and the furnace temperature, which were shown to be variable over the long period required for sampling.

The present development of a reproducible sampling method allowed this technique to be extended to a more detailed study of the influence of temperature on the oxidation of an *n*-pentane – air mixture.

APPARATUS

General Description

The apparatus is shown diagrammatically in Fig. 1. The required mixture of carbon-

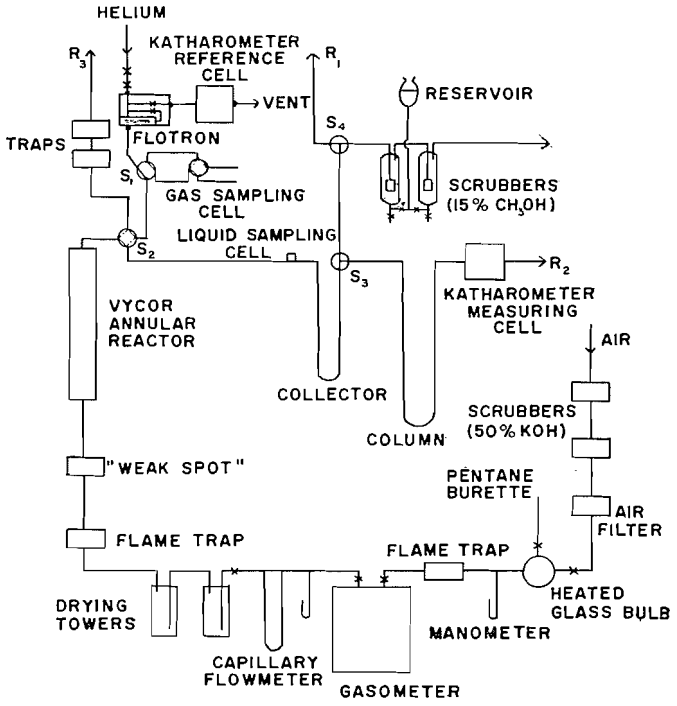

FIG. 1. Schematic diagram of apparatus.

dioxide-free air and *n*-pentane was prepared and stored in the gasometer. From this vessel it was passed at a known rate of flow through the reactor, which, for this study, was constructed of Vycor glass and was annular in form. The reactor dimensions and its positioning in a tubular furnace have already been described (2).

Until steady-state conditions were fully established so that a sample could be taken for analysis, the oxidized mixture was allowed to flow from the reactor through ice–water and dry ice – acetone cooled condenser traps to vent at the rotameter, R_3.

During this period, the eluent gas (helium) was passed through reducing valves to the Burrell "Flotron". This is a device for maintaining a reproducible volume flow and splitting the eluent stream to allow a small flow through the katharometer reference cell of the modified Burrell K1 Kromotog which was used for the analysis of the condensable oxidation products. The eluent was allowed to bypass the gas sampling cell at S_1 and pass through the collector, the column, and the katharometer measuring cell to vent at the rotameter, R_2.

Sampling for Chromatographic Analysis

In taking a condensable product sample for chromatographic analysis the flow streams

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were redirected so that helium passed through S_2 and the traps to vent at R_3 while the reactor effluent was passed during a measured time interval (usually 5 minutes) through the liquid-air-cooled collector and three-way stopcocks S_3 and S_4 to vent at rotameter R_1. The collector was a U tube with a side-arm joined to it by a three-way stopcock. It was wound with resistance tape and contained glass wool and a small amount of crushed firebrick to prevent minute crystals of condensate from being blown through it.

To complete the sampling, four-way stopcock S_2 was turned to allow eluent gas to sweep the sample remaining in the lines into the collector. Then stopcock S_3 was turned so that eluent flowed through the column. Finally, the liquid-air bath was removed and the sample in the collector was volatilized into the helium stream proceeding to the column by heating the collector for 4 minutes at about 150° C.

The uncondensed gases emerging at R_1 during the early stages of the above sampling procedure were sampled by microsyringe from the exit line leading to R_1. This sample was transferred to a homemade chromatographic unit with a Veco thermistor detector cell for analysis on an adsorption column.

The Column Material and Analysis Technique

The separation of the compounds condensed from the reactor effluent was effected on an 8-ft column packed with 25% w/w bis[2-(2-methoxyethoxy)ethyl] ether (MEEE) on 30–60 mesh C-22 firebrick. This substrate was selected as a result of a series of comparison tests using 11 different stationary phases. The operating details for these tests and a comparison of the effectiveness of these substrates for various separations are given in Table I. Subsequently it was observed that the same choice of optimum stationary phase had been made by Yokley and Ferguson (6). Chromatograms of the separations

TABLE I

Comparison of various stationary phases

Stationary phase 25% w/w on 30–60 mesh C-22 firebrick	Maximum usable temp., °C	Ethylene and carbon dioxide separation	*cis* and *trans* 2-Pentene separation	Hydrocarbon peaks	Aldehyde peaks	Water peak	Remarks

another example of the remarkable versatility of the gas–liquid chromatographic technique. Thus, the order of elution of the polar compound, acetaldehyde (peak 17), relative to the non-polar *n*-pentane (peak 9), can be radically altered, as shown, by suitable choice of stationary phase polarity.

The following very simple but quite effective system of column-temperature programming was used to obtain a reasonably efficient separation of the condensed sample in a single operation. The column temperature at the beginning and for the first 10 minutes of each analysis was 25° C. At the end of this period an electric current at a potential of 30 volts was passed through the resistance wire wound on the column. The rate of increase of temperature was such that a temperature of 60° C was attained in another 15 minutes. A fixed eluent flow rate of 100 ml per minute (25° C and 760 mm Hg), as measured at the downstream end of the chromatograph, was always maintained by the "Flotron". Hence there was little or no change in the base line due to the temperature change.

With the MEEE substrate a low initial temperature was ideal for the separation of carbon dioxide and the lower olefins. On the other hand, the gradually increasing temperatures in the following period prevented excessive peak broadening of the higher boiling components without seriously impairing their separation. The temperature finally attained allowed the analyses to be completed in less than 1 hour. A representative chromatogram obtained in this manner from a 5-minute sample of the reactor effluent taken when the maximum wall temperature was 509° C is given in Fig. 3. The excellent

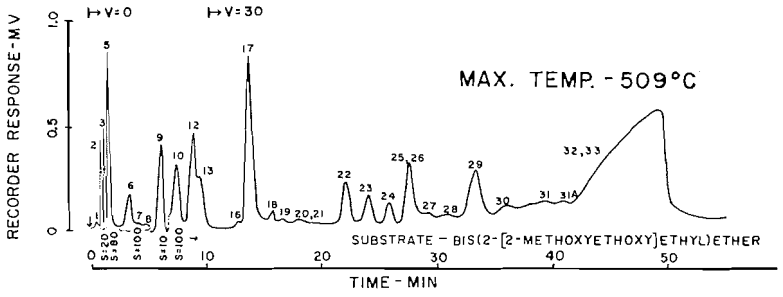

FIG. 3. Representative oxidation product chromatogram.

separation of most of the constituents and the stability of the base line despite the relatively large change in column temperature are readily apparent.

A further temperature increase to 90° C would have permitted the analysis of part of the organic acid content of the sample. However, a noticeable "bleeding" of the substrate occurs at this temperature. Hence, the analysis for the acid content was performed on a separate sample by a titration method.

The uncondensed gases were separated on a 15-ft column of 30–60 mesh 5A Linde molecular sieves. This material was dried for 6 hours in a nitrogen stream at a temperature of 300° C prior to packing. Hydrogen, oxygen, nitrogen, methane, and carbon monoxide were readily separated and all but the hydrogen were quantitatively determined on this column at a temperature of 100° C with helium flowing at 50 ml per minute. With this eluent, the sensitivity for hydrogen was about 1/20th of that for the other gases due to the similarity of its thermal conductivity to that of helium. Hence quantitative results for this gas were not obtained unless its concentration exceeded about 1% by volume of the uncondensables.

Formaldehyde Analysis

Initially, it was hoped to measure formaldehyde by gas chromatography. However, a number of experiments showed that polymerization of formaldehyde at low temperatures would require the use of a column temperature exceeding 100° C and controlled within fine limits. At these elevated temperatures a formaldehyde peak was observed. However, other oxidation products which could not be resolved interfered and a quantitative determination could not be made. In addition the substrate "bleeding" mentioned earlier became appreciable at temperatures above 100° C and the useful life of the column was thereby excessively reduced. Work on a gas chromatographic separation of formaldehyde is continuing.

The polarographic methods for formaldehyde could not be applied because of the mixture complexity and especially because of the presence of acrolein, which interferes. Hence, a chemical method of analysis was indicated. Since a large number of analyses was projected the specific reaction with chromotropic acid as recommended by West and Sen (9) was adopted rather than the precipitation and separation of derivatives.

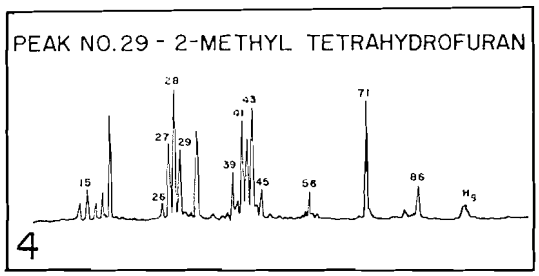
The sample was collected prior to the one for gas chromatographic analysis by a precisely similar technique. This was transferred to and absorbed in scrubbers containing 15% methyl alcohol. An aliquot of this solution was treated with chromotropic acid in sulphuric acid solution. After the mixture was heated in a boiling water bath for 5 minutes to develop the color, the color maximum at 560 mμ was read and compared with that of a similarly treated standard formaldehyde solution.

Acid Analysis

The sampling technique was modified by (*a*) condensing the sample in a dry ice – acetone cooled collector and (*b*) absorbing this sample in a scrubber containing 0.01 *N* sodium hydroxide. An aliquot of this solution was backtitrated with 0.01 *N* hydrochloric acid solution to the phenolphthalein end point. The results were calculated as formic acid.

Peroxide Analysis

Liquid air was again used for condensation and the sample was run into a scrubber containing isopropyl alcohol. An aliquot of this solution was analyzed by iodometric titration. Since the peroxide content of the effluent in the conditions of these experiments proved to be negligible, the more sensitive test of Widmaier and Mauss (10) was also applied. Again, results indicated the absence of peroxides.



PRODUCT IDENTIFICATION

The qualitative analysis of the oxidation products was effected using several techniques and is still not quite complete. The Bendix time-of-flight mass spectrometer, applied as described by Gohlke (11), successfully identified several compounds. At 100 intervals during the running of the chromatograms the column effluent was leaked into the mass spectrometer and a full mass spectrum of the compound was obtained by a very sensitive amplification and rapid-scan method. A representative spectrum which was identified as that due to 2-methyl tetrahydrofuran is shown in Fig. 4.

Our experience in the interpretation of spectra from the time-of-flight mass spectrometer leads to the following conclusions:

(*a*) Several compounds may be scanned at the same time if the chromatographic column does not have sufficient resolving power. However, by comparing scans taken at the beginning and end of a peak elution this can be detected more easily than by conventional mass spectrometer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

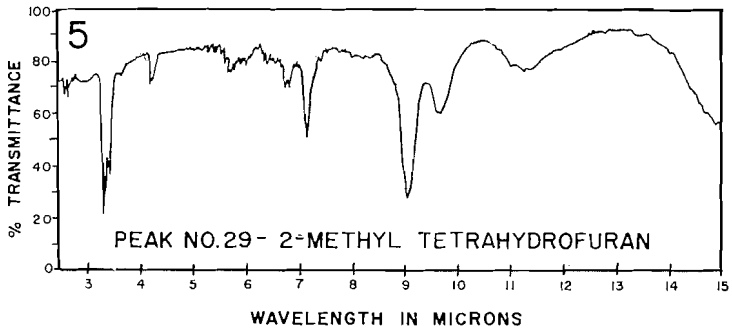


FIG. 4. Representative time-of-flight mass spectrum.
FIG. 5. Representative micro-gas-cell infrared spectrum.

(*b*) The accelerating chamber or the spectrometer lead-in is not completely swept between samples. As a result, there is a doubt as to whether any given peak is retained from a previous scan.

(*c*) With the mass scale used in our analyses, the numerical value of mass numbers greater than 80 was uncertain. We have, however, been informed that wider mass scales are now available.

(*d*) The background peaks gradually change in height when a number of scans is taken. There is therefore no way of knowing which contribution of a given mass is due to background and which to the component. This fault is also to be found, to a lesser extent, with conventional mass spectrometers.

Despite the above comments, the time-of-flight mass spectrometer has great potentialities for use in this field. The identity of most of the peaks analyzed by this means was confirmed by trapping the compound as it left the column and analyzing it by conventional mass spectrometer. For small peaks adjacent to large ones, however, the time-of-flight machine had a decided advantage.

In addition to the above analyses, the identity of seven of the peaks was confirmed by using a combination of gas chromatography and infrared spectrophotometry. Samples of the effluent from the chromatographic column were passed directly into a 600-mm path-length infrared micro-gas-cell designed by White (12). These were analyzed in a Beckman IR 4 infrared spectrophotometer equipped with a micro-optical system.

The spectrum of a representative reaction product peak, 2-methyl tetrahydrofuran, is shown in Fig. 5. It should be emphasized that the procedure described above was purposely adopted for convenience of sampling, i.e. to eliminate the troublesome sample freeze-out and transfer steps usually required. To do this, optimum spectrophotometric operating conditions were abandoned. Thus, for example, sample pressure was one atmosphere (mostly helium) rather than 50–100 mm Hg as usually recommended.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The infrared spectra thus obtained were correspondingly poorer than they might have been. Better resolution is obtained by trapping the samples in a liquid-air-cooled vessel, which may subsequently be evacuated while cool to remove helium and from which the sample may be flashed into the evacuated micro-gas-cell to the optimum pressure.

Further confirmation of the identity of any suspected component was obtained, whenever a sample of the pure compound was available, by comparison of their retention times relative to that of *n*-pentane. The compounds listed in Table II were identified by one or more of the above techniques. The relative retention times (*n*-pentane = 1) for these compounds are included in Table II. These values are the averages of from 5 to 15 determinations each, with deviations, generally, of less than $\pm 5\%$.

QUANTITATIVE EVALUATION OF RESULTS

To convert component peak areas to component concentrations, known volumes of pure compounds were analyzed under conditions similar to those used for the oxidation product mixture and calibration factors were then calculated. With eluent gas flowing through the column and the collector in a liquid-air bath, the standards were injected on to the heated connecting tube through a silicone seal in the liquid sampling cell and the eluent carried them into the collector where they were condensed. They were then transferred to the column by the technique already described. When the actual compound to be measured was not available in the pure state a similar type of compound was used as a standard. Where the peak was not positively identified the figures used for molecular weight and density in the calculation of selectivity were estimated on the basis of the suspected values. The concentrations were calculated by weight ratio. Generally areas were estimated as the product of peak height and peak width at half height. Where the base line undulated, the areas were measured by planimeter. For the water peak a piece of paper equal to the peak in area was weighed and for the earlier peaks, peak height was more convenient to measure than area.

RESULTS AND DISCUSSION

The state of the surface of the reactor is known to affect the initial rate at which oxidation occurs. The material of the reactor, together with the interrelated shape, mixture residence time, and flow configuration also affects the course of the reaction. When the reactor was first used it was found to give erratic results. Stability of the surface was rapidly obtained, however, when a little nitric acid was introduced at about 500° C and the temperature was slowly raised to 1000° C. After cooling the reactor to 500° C, a of stream helium was passed through until no chromatographic peak due to the nitric acid was obtained from a sample of the effluent.

On establishing that a fairly stable and reproducible surface could be prepared in this way, at least for the reaction of rich mixtures of pentane and air, a preliminary program was outlined for demonstrating the effectiveness of the gas chromatographic method and for obtaining new information regarding the effect of temperature on the product distribution from the reaction of one particular mixture of *n*-pentane and air. This program consisted of a series of runs at certain temperatures between 375 and 800° C with a 1.3 stoichiometric *n*-pentane – air mixture supplied to the reactor at the rate of 100 ml/minute as measured at 25° C and 1 atmosphere pressure. Product analyses were carried out on samples of the effluent from each run as outlined previously using both gas chromatographic and chemical methods.

A representative chromatogram of the oxidation products of *n*-pentane obtained from

For personal use only.

a run at a maximum reactor wall temperature of 509° C has been given in Fig. 3. By reference to Table II, which gives the key to the peak numbers, an idea of the mixture complexity and of the particular value of this method of analysis may readily be obtained. The results of calculations made from a series of such chromatograms in conjunction with those obtained from the chemical analyses are presented in Table III and Figs. 6–9.

TABLE III

Carbon balances

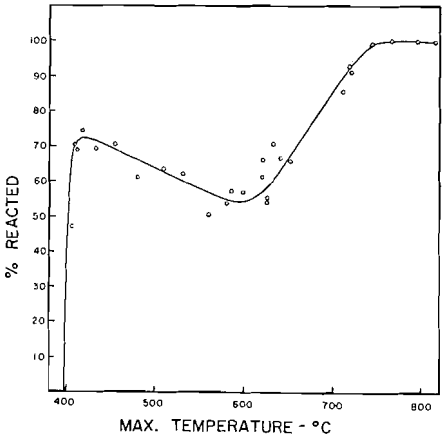

FIG. 6. The effect of temperature on the percentage of *n*-pentane reacted.

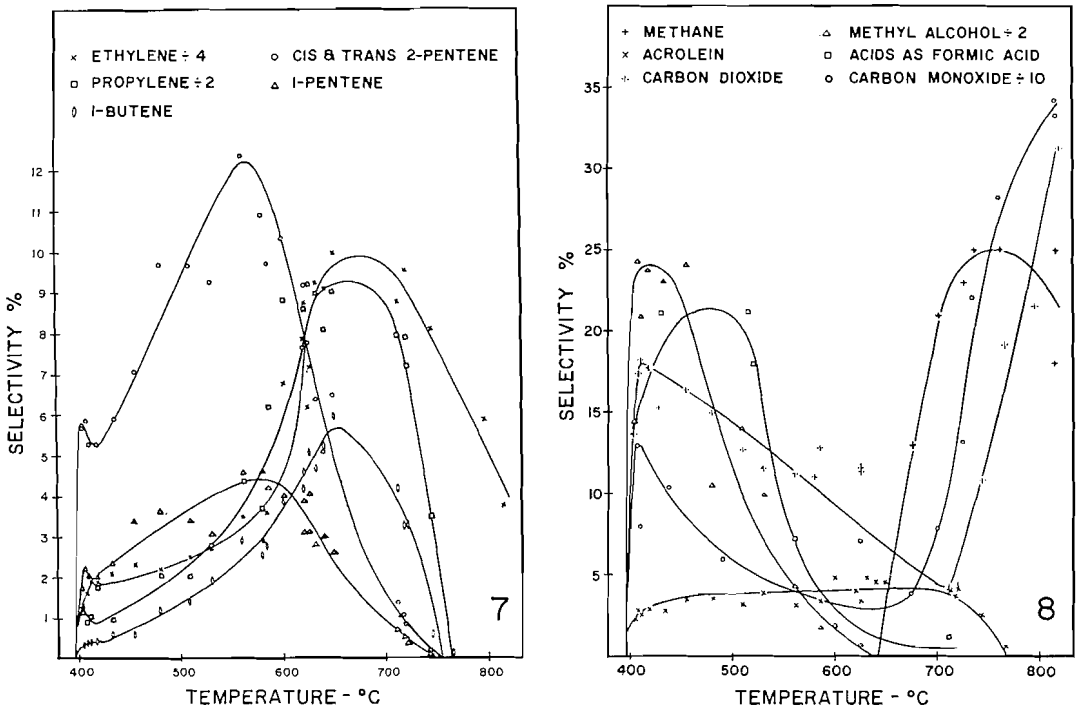
In Fig. 6 the percentage of pentane reacted is plotted against maximum reactor wall temperature. The curve for *n*-pentane reacted rises sharply to a maximum at 410° C and then falls off slowly as the temperature increases to 625° C demonstrating again the now familiar negative temperature coefficient of the reaction in these conditions. From this point the percentage of pentane reacted rises sharply to 100%. The second sharp rise in the curve occurs when the mechanism of the over-all process changes so that carbon monoxide, carbon dioxide, and water become the major oxidation products.



The variations in product distribution with reactor temperature are indicated in Figs. 7–9. Several facets of the results deserve comment.

1. The absence of peroxides is significant in view of the proved sensitivity of the methods of detection employed. However, on the basis of former studies with a reactor of high surface-to-volume ratio (2), this result was not unexpected.

2. The surprisingly high concentration of 2-methyl tetrahydrofuran in the products, which accounts for as much as 20% of the carbon content of the *n*-pentane reacted, Table III, should be noted. The conditions of high surface-to-volume ratio and nitric acid pretreatment of the surface seem to favor the formation of this product.

3. A small but quite distinct dip in the product selectivities (Figs. 7 and 9) for the olefins and oxygenated compounds other than the acids, methanol, and oxides of carbon occurs at about 420° C. This is followed by a rapid increase in product concentration to a maximum and finally by a more gradual decrease.

4. A two-stage reaction mechanism, at least, is indicated. Methane is a product of the high-temperature reaction. Its formation is not evident below about 650° C (Fig. 8). On the other hand, the rate of formation of methanol and organic acids becomes negligible at this temperature. It is interesting that the high methane concentration in the high-temperature region is not accompanied by a correspondingly high hydrogen content (the hydrogen concentration was not detectable). This is further confirmation of the view that the lower olefins are formed via an oxidation mechanism and not by simple pyrolysis of the hydrocarbon in this temperature range.

5. The rate of formation of the simple olefins, ethylene, propylene, and butylene, becomes a maximum at about 700° C and the mechanism at higher temperatures appears to involve the further oxidation of these olefins. Ethylene is the most stable in this regard. The higher olefins attain their maximum concentrations at lower temperatures (550°–600°). When the concentration of the simpler olefins has reached a maximum that of the higher olefins has become negligible.

6. Epoxides, such as ethylene and propylene oxides, which were postulated by Boord (13) and observed by Kyryacos, Menapace, and Boord (7), were not found in the present study but may have escaped detection since they come off near the large acetaldehyde peak.

7. The relatively constant acrolein concentration (Fig. 8) over the wide range of temperature between 400 and 700° C is remarkable. An explanation for this observation is not available at this time.

8. The relative preponderance of carbon monoxide over carbon dioxide in the products (Fig. 8) is consistent with the results expected from the oxidation of a rich mixture.

9. Carbon balances on the identified products of the reaction for selected temperatures from the product selectivity – temperature graphs are given in Table III. A useful and rapid means of obtaining these carbon balances has been employed here. This is the concept of a carbon selectivity of a particular product, which may be defined as the product of component percentage selectivity and the ratio of the number of carbon atoms per mole of component and reactant respectively. Considering the omission from this tabulation of the carbon in the minor and the unidentified components and in those compounds less volatile than water, these balances indicate that this method of analysis can be used to provide the detailed information required to study the kinetics and mechanism of complex reactions.

CONCLUSION

1. The purpose of this preliminary work was to develop an integrated apparatus for the investigation of an oxidation or decomposition reaction with the principal aid of the gas chromatographic technique. In this respect a method of sampling has been described which will obviate many of the difficulties associated with the transfer of gaseous or liquid samples from the reactor to the gas chromatographic apparatus and will also allow samples to be taken for the more usual chemical or physical methods of analysis. Most of the condensable products may be analyzed in a single-stage process by a simple column-temperature programming technique.

2. The use of several qualitative microanalytical methods including time-of-flight

mass spectrometry and infrared spectrophotometry for identifying the products separated by the gas chromatographic method has been described and critically evaluated.

3. Although a mechanism for the reaction studied here will not be presented until further studies involving the effects on product distribution of varying the mixture strength, residence time, and condition of the surfaces have been completed, some of the interesting features of the results have been discussed. Thus, a method of obtaining a reproducible surface has been described, variations in product distribution with temperature have been noted, and the presence of certain suspected and some unsuspected compounds in the reaction product mixture has been confirmed or determined.

ACKNOWLEDGMENTS

The research was carried out with the co-operation of Dr. R. R. McLaughlin, Dean of of the Faculty of Applied Science and Engineering, University of Toronto, and Dr. G. R. Lord, Head of the Department of Mechanical Engineering. The work was supported by the Defence Research Board of Canada in accordance with the terms of Defence Production Contract No. CD 800102. The authors are indebted to Mr. R. O. King, Director of the Combustion Research Section, for his constant advice and encouragement and to Mrs. K. Kjaer and Mrs. M. Spencer of this laboratory for their painstaking laboratory, calculation, and typing assistance. Sincere thanks are also extended to the Bendix Corporation for the time-of-flight mass spectra, to Beckman Instruments, Inc., for the micro-gas-cell infrared spectra, to Professor R. M. Farquhar, Department of Physics, University of Toronto, for the conventional mass spectra, to Mr. R. Strom of this laboratory for the gas adsorption chromatographic analyses, to the Phillips Petroleum Company for the provision of the pure hydrocarbon samples used as standards, and to the Linde Air Products Company for providing samples of their molecular sieves.

THE STRUCTURE OF MONOBROMINATED ETHYL INDOLE-3-CARBOXYLATE AND THE PREPARATION OF 7-BROMOINDOLE[1]

B. E. LEGGETTER AND R. K. BROWN

ABSTRACT

The compound reported by Majima and Kotake as ethyl 6-bromoindole-3-carboxylate, obtained from the monobromination of ethyl indole-3-carboxylate, when saponified, decarboxylated, and the product repeatedly crystallized from alcohol, actually gave a nearly equimolar mixture of 5- and 6-bromoindoles of constant melting point, 74–75°. 7-Bromoindole has been synthesized by two unambiguous routes.

INTRODUCTION

Majima and Kotake have reported the preparation of ethyl 6-bromoindole-3-carboxylate via bromination in acetic acid of ethyl indole-3-carboxylate (1). Their proof of structure rested upon the observation that dibromination, in acetic acid, of ethyl indole-3-carboxylate actually gave ethyl 5,6-dibromoindole-3-carboxylate, a fact established by the isolation of 5,6-dibromoisatin and 4,5-dibromo-2-amino-benzoic acid. Since the *mono*brominated compound gave a monobromoisatin quite different from the authentic 5-bromoisatin previously prepared by Borsche and Jacobs (2) and in view of the established structure of the dibrominated product, it was concluded that monobromination of ethyl indole-3-carboxylate had occurred at position 6. The discrepancy between the melting point of their "6-bromoisatin" (256–258°) and that of Ettinger and Friedlander's 6-bromoisatin (m.p. 263–264°) (3) was attributed to contamination of their monobromoisatin with some 5,6-dibromoisatin.

The monobrominated ethyl indole-3-carboxylate of Majima and Kotake, saponified and decarboxylated in this laboratory, gave a monobromoindole melting at 74–75° which, according to the assignment of the Japanese authors, should be 6-bromoindole. A recently reported unambiguous preparation of 6-bromoindole (4) melting at 94° casts doubt upon Majima and Kotake's structural assignment. This was further intensified by observation in this laboratory of a marked depression of the melting point of a mixture of these two bromoindoles. That the compound melting at 74–75° is neither 4- nor 5-bromoindoles is shown by comparison of their physical constants. Authentic 4-bromoindole (4) is a liquid which we found to boil at 89–92°/0.25 mm and which has a refractive index of 1.6566 at 21°, while 5-bromoindole melts at 88.5–89° (5). Furthermore, the infrared spectra of the 4-, 5-, and 6-bromoindoles failed to correspond with that obtained for the questionable bromoindole.

Since the possibility existed that the as yet unknown 7-bromoindole might actually be the compound synthesized by Majima and Kotake, its preparation was undertaken. The precursor, 7-bromoindole-2-carboxylic acid, was made by two unambiguous routes. The first method entailed the preparation of ethyl pyruvate 2-bromophenylhydrazone, which was then subjected to Fischer ring closure with polyphosphoric acid. The second method involved the conversion of 3-carboxy-2-nitrotoluene (6) to 3-bromo-2-nitrotoluene by the Hunsdiecker reaction (7). A Reissert condensation of 3-bromo-2-nitrotoluene with ethyl oxalate (5), affording optimum yields only after prolonged reaction between the ester and the nitrotoluene at room temperature, gave ethyl 3-bromo-2-nitrophenylpyruvate. This was converted to 7-bromoindole-2-carboxylic acid by the usual reductive ring closure.

[1]*Manuscript received May 6, 1960.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

The 7-bromoindole-2-carboxylic acid gave unsatisfactory decarboxylation by the usual procedures (4, 5, 8). However, a modified version of one method (8, 9), in which the acid was refluxed in synthetic quinoline for 48 hours while small amounts of copper chromite (10) were added at frequent intervals, gave a 48% yield of 7-bromoindole. This synthesis now makes available the last of the isomeric benzene ring-monobrominated indoles.

The infrared spectrum and melting point (42–43°) of 7-bromoindole showed conclusively that it was not the "6-bromoindole" derived from the "ethyl 6-bromoindole-3-carboxylate" of Majima and Kotake.

Comparison of the infrared spectra of 5- and 6-bromoindoles suggested that the unknown substance might be a mixture of the two. Accordingly, when samples containing various proportions of the two isomeric bromoindoles were prepared, it was found that a mixture of 45% of 5-bromoindole and 55% of 6-bromoindole gave a spectrum identical in every respect with that of the unknown. The bands at 1308 cm^{-1} for the 5-isomer and at 1329 cm^{-1} for the 6-isomer have nearly equal intensities and can be used as a reasonably good method for estimation of the relative amounts of these two isomers in a mixture. The two isomers can be clearly distinguished by the absorption bands shown in the following table.

Compound	Absorption bands at: (cm^{-1})						
6-Bromoindole	665 (w)	800 (s)	840 (m)	852 (w)	864 (w)	1305 (w)	1329 (s)
5-Bromoindole	664 (s)	788 (s)	Nil	Nil	864 (s)	1308 (s)	1329 (w)

NOTE: w, m, and s are respectively weak, medium, and strong.

Neither the melting point of this mixture (74–75°) nor its composition could be altered by repeated crystallization. Similar constant-melting mixtures of isomeric compounds have been recorded in the literature, a specific example being the isomeric 5- and 7-nitro-1,2,3,4-tetrahydrocarbazoles, a mixture of which crystallizes in equimolecular proportion from a variety of solvents to form a substance of constant composition and melting point (11). However, unlike the case of the tetrahydrocarbazoles, chromatography does not readily separate the 5-bromoindole from the 6-bromoindole. Since a single chromatographic operation using an alumina column did in fact achieve a partial separation, as shown by the change in the infrared spectra of the fractions, it is no doubt possible by repeated and careful chromatography to separate them completely.

We have repeated the bromination of ethyl indole-3-carboxylate as described in the literature and obtained the same results (1). Several crystallizations of the ethyl bromoindole-3-carboxylate from aqueous alcohol failed to alter the melting point of 134–137°. A sample of this substance, passed through a column of activated alumina, gave very little separation. Chromatography of the fractions obtained from this first attempt at separation also gave unsatisfactory results. However, since the melting points of the various fractions did in fact differ somewhat both in value and in range from each other it was assumed that, as for the case of the 5- and 6-bromoindoles, a separation could be achieved by painstaking care. It is to be noted that crystallization of each of these various fractions from diluted alcohol again gave the material of constant melting point of 134–137°.

Hydrolysis of the ester according to the literature (1) gave an acid which upon several crystallizations from 95% alcohol melted at 212°, a fact which had already been recorded (1). No attempt was made to separate this substance into its isomers. Our decarboxylation

For personal use only.

of this compound in quinoline at 140° afforded a compound whose analysis, following several crystallizations from alcohol, agreed with that of a monobromoindole and is now known to be a nearly equimolar mixture of 5- and 6-bromoindoles (m.p. 74–75°).

This work indicates that not only do 5-bromoindole and 6-bromoindole form a constant-melting mixture, but that their precursors, 5- and 6-bromoindole-3-carboxylic acid and the ethyl ester, do likewise. Whether the precursors are nearly equimolar mixtures is uncertain. However, if that is so, then ease of bromination of ethyl indole-3-carboxylate is approximately equal for the 5 and the 6 positions.

EXPERIMENTAL

All melting points are uncorrected. The 4-bromoindole (4), 5-bromoindole (5), and 6-bromoindole (4) were prepared according to the published procedures.

3-Bromo-2-nitrotoluene

Bromine (24 g, 0.15 mole) was added slowly to a stirred suspension of 41.5 g (0.144 mole) of silver salt of 3-methyl-2-nitrobenzoic acid in anhydrous carbon tetrachloride (350 ml) at 25°. Following the addition, the mixture was heated to reflux for 3 hours, during which time carbon dioxide was evolved. The cooled solution was freed from silver salts and the filtrate washed first with aqueous sodium bisulphite, then with aqueous sodium bicarbonate, and finally with water, and then dried over anhydrous magnesium sulphate. Removal of the sulphate and ether afforded a brown oil which, when steam distilled, yielded 18.0 g of 3-bromo-2-nitrotoluene (58%) melting at 27°, lit. m.p. 27° (12).

Potassium Enolate of Ethyl 3-Bromo-2-nitrophenylpyruvate

Potassium (2.3 g, 0.059 mole) was dissolved in anhydrous ethanol (20 ml). To this solution, diluted with 100 ml of dry ether, was added 8.7 g (0.059 mole) of diethyloxalate and the mixture was then stirred gently for 15 minutes. The addition of an ether solution of 11.0 g (0.05 mole) of 3-bromo-2-nitrotoluene produced a deep orange solution which, left at 25° for 7 days, slowly deposited the potassium salt as an orange precipitate. The solid was collected, washed thoroughly with anhydrous ether, and air-dried, yielding 12.1 g (67%) of product.

Ethyl 3-Bromo-2-nitrophenylpyruvate

When a small portion of the above potassium salt was dissolved in water, cooled to 0°, and acidified carefully with 6 *N* hydrochloric acid, a bright yellow solid precipitated. Crystallization from ethanol gave a melting point of 114–115°, which further crystallization failed to alter. Calc. for $C_{11}H_{10}BrNO_5$: C, 41.84; H, 3.17; N, 4.43. Found: C, 41.83; H, 3.19; N, 4.24.

7-Bromoindole-2-carboxylic Acid

A solution of the potassium enolate of ethyl 3-bromo-2-nitrophenylpyruvate (3.0 g, 0.009 mole) in warm 4 *N* ammonium hydroxide (100 ml) was slowly added, with stirring, to a boiling suspension of ferrous hydroxide prepared by the addition of ammonium hydroxide (6 ml, $d = 0.880$) to a boiling solution of ferrous sulphate heptahydrate (14.0 g, 0.05 mole) in 100 ml of water. The resulting reduction mixture was maintained at 90° for 30 minutes and then filtered from the ferric oxide sludge. The sludge was extracted three times with boiling 2 *N* ammonium hydroxide and the combined filtrate and extracts cooled to 25° and acidified with 6 *N* hydrochloric acid. The solid, collected by suction filtration, when crystallized once from aqueous ethanol gave 1.2 g (60%) of 7-bromoindole-2-carboxylic acid melting at 236–239°. Repeated crystallization gave an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

analytical sample of melting point 242–244°. Calc. for $C_9H_6BrNO_2$: C, 45.00; H, 2.50; N, 5.83. Found: C, 45.20; H, 2.58; N, 5.99.

7-Bromoindole

A solution of 7-bromoindole-2-carboxylic acid (2.9 g) in synthetic quinoline (20 ml) was refluxed for 48 hours, during which time small amounts of copper chromite (10) catalyst were added at frequent intervals. The cooled reaction mixture was poured into 350 ml of 1 *N* hydrochloric acid and the resulting solution extracted thrice with 150-ml portions of ether. The combined ether extracts, washed twice with 1 *N* hydrochloric acid, once with water, twice with 1 *N* ammonium hydroxide, and then with water, were dried over anhydrous magnesium sulphate. Removal of the ether yielded a yellow oil which was purified by chromatography on an alumina column, using *n*-pentane as eluant, giving 1.13 g (48%) of colorless crystals melting at 42–43°. Calc. for C_8H_6BrN: C, 48.98; H, 3.06; N, 7.14; Br, 40.81. Found: C, 49.08; H, 3.09; N, 7.13; Br, 40.42.

Ethyl Pyruvate 2-Bromophenylhydrazone

A solution containing ethyl pyruvate (15.3 g, 0.13 mole) (13), 2-bromophenylhydrazine (24.1 g, 0.13 mole) (14), and ethanol (50 ml) was refluxed for 1 hour, cooled, and poured into cold water. The precipitated yellow solid, when air-dried and crystallized for ethanol, gave 33.1 g (91%) of product melting at 44–46°. Calc. for $C_{11}H_{13}BrN_2O_2$: C, 46.32; H, 4.56; N, 9.86. Found: C, 46.36; H, 4.63; N, 9.78.

Ethyl 7-Bromoindole-2-carboxylate

A mixture of ethyl pyruvate 2-bromophenylhydrazone (33.1 g) and polyphosphoric acid* (40 g) was slowly heated. When the temperature of the mixture reached 70° a spontaneous exothermic reaction occurred raising the temperature to 150°. The reactants were kept at this temperature for 10 minutes, then cooled and poured into cold water. The ether extracts of this solution when dried with anhydrous magnesium sulphate gave a brown oil which solidified. Crystallization from ethanol yielded 14.3 g (46%) of product, m.p. 85–86°. Calc. for $C_{11}H_{10}BrNO_2$: C, 49.25; H, 3.73; N, 5.22. Found: C, 49.01; H, 3.74; N, 5.17.

When 14.3 g of ethyl 7-bromoindole-2-carboxylate was dissolved in a mixture of ethanol (200 ml) and 2.5 *N* aqueous sodium hydroxide solution (70 ml), refluxed for 2 hours, poured into cold water (1000 ml), and then acidified with 6 *N* hydrochloric acid, a solid deposited which after crystallization from ethanol afforded 7.1 g (55.5%) of product melting at 237–239°. This was found to be identical with the 7-bromoindole-2-carboxylic acid prepared above.

Decarboxylation of the Mixture of 5- and 6-Bromoindole-3-carboxylic Acids

Twelve grams of the monobromoindole-3-carboxylic acid mixture (m.p. 212°) (1) in 25 ml of quinoline was heated to 140° whereupon vigorous evolution of carbon dioxide ensued. The temperature was maintained at 140° for 2.5 hours, after which time no further evolution of carbon dioxide occurred. The reaction mixture was then poured into 300 ml of 1 *N* hydrochloric acid and a dark oil separated. The oil solidified and was collected, washed with 1 *N* hydrochloric acid, and then with water. Crystallization from aqueous alcohol yielded a product melting at 74–75°, which repeated crystallization from aqueous alcohol, skellysolve, or heptane failed to alter. Yield, 4.3 g (46%). Calc. for C_8H_6NBr: C, 49.0; H, 3.1. Found: C, 48.7; H, 2.9.

SYNTHESES OF POLYURETHANES FROM HYDROXY-TERMINATED POLYESTERS[1]

PAUL E. GAGNON, JEAN-L. BOIVIN,[2] AND GEORGE W. HOUSE[3]

ABSTRACT

Hydroxy-terminated polyesters were synthesized by treating diols with the diethyl esters of dicarboxylic acids. Ethylene, diethylene, and triethylene glycols, four polyoxyethylene glycols ranging in molecular weight from 200 to 600, 1,2-propanediol, dipropylene glycol, five polyoxypropylene glycols ranging in molecular weight from 150 to 2025, 1,3-propanediol, 1,3-butanediol, 1,4-butanediol, 2,3-butanediol, 1,5-pentanediol, 2,2′-(methylimino)diethanol, 2,2′-(ethylimino)diethanol, 2,2′-(butylimino)diethanol, and 2,2′-thiodiethanol were condensed with diethyl succinate in the absence and presence of a catalyst, and with diethyl cyanomalonate, cyanosuccinate, and α-cyanoglutarate.

Polyurethanes were obtained from the various polyesters prepared by treatment with different quantities of 2,4-tolylene diiocyanate. In general, non-elastomeric products were obtained from polyesters of monomeric glycols, while elastomeric polyurethanes with the lowest brittle points were formed from polyoxyethylene glycol 400 and 600, and polyoxypropylene glycol 750, 1025, and 2025 polyesters. Also the succinate polyurethanes, which did not contain nitrile groups, had the greatest tendency to be elastomeric and had the lowest brittle points. For the nitrile containing polyurethanes, the cyanomalonates had the lowest tendency to be elastomeric and had the highest brittle points. The cyanosuccinate and α-cyanoglutarates had about the same properties.

INTRODUCTION

Polyesters constitute an important class of synthetic polymers employed as textiles, resins, and intermediates for the preparation of polyurethanes. They can be prepared by the reactions commonly used to obtain simple esters. Hydroxy-terminated polyesters are produced by heating diols in excess with dibasic acids or esters and by continuing the heating under vacuum to yield high molecular weight polymers (1).

Polyurethanes are made by reacting polyhydroxylated compounds or polyesters with diisocyanates. They have found extensive use as rubber substitutes (2, 3, 4, 5), foams (6), coatings (7), and adhesives (8).

In the present investigation, the main object was the synthesis of polyesters and polyurethanes, some containing nitrile groups, and the comparison of their properties.

RESULTS AND DISCUSSION

Polyesters

Polyesters were prepared by the transesterification of different diols with diethyl succinate, cyanomalonate, cyanosuccinate, and α-cyanoglutarate.

$$n\text{HOROH} + n\text{EtOOR'COOEt} \rightarrow \text{H(OROOCR'CO)}_n\text{OEt} + (2n-1)\text{EtOH}$$

It was observed that the general order of reactivity of diols was thus: (*a*) the basic and therefore self-catalyzed N-substituted iminodiethanols, (*b*) the other monomeric glycols bearing two primary hydroxyl groups, (*c*) monomeric glycols bearing one or two secondary hydroxyl groups, (*d*) polymeric glycols bearing solely primary hydroxyl groups, and (*e*)

polymeric glycols bearing solely secondary hydroxyl groups. To terminate the chains by hydroxyl groups, an excess of glycol was added to the reaction mixture and heating continued.

$$H(OROOCR'CO)_nOEt + HOROH \rightarrow H(OROOCR'CO)_nOROH + EtOH$$

Then the reaction was driven towards completion and excess glycol was removed under vacuum.

Succinates

The reaction between diethyl succinate and the glycols in the absence of a catalyst proceeded only quite slowly and in most cases ethanol distilled at temperatures ranging from 155 to 215° C, and prolonged reaction times were necessary.

The molecular weights of the products, measured by hydroxyl end-group analysis, varied from 500 to 3540 but were for the most part between 800 and 2000. The values found for the polyesters of polyoxyethylene glycol 600 and polyoxypropylene glycols 425, 750, 1025, and 2025 were higher than the true molecular weight values because no excess glycol had been employed to assure the termination of polyester chains by hydroxyl groups. Furthermore, the values found for the polyesters of polyoxypropylene glycols 1025 and 2025 were certainly not high as compared to the molecular weights of the glycols themselves, indicating that very little reaction had taken place.

In order to investigate the effect of an ester interchange catalyst on the rate of the polyesterification reaction and on the molecular weight of the product, the syntheses of of the succinate polyesters were repeated in the presence of a sodium catalyst. It was observed that ethanol began to form at reaction temperatures well below those of the corresponding preparations carried out without catalyst, 70 to 90 degrees lower in most cases. Distillation was also much more rapid and complete with catalyst than without. In the case of 1,2-propanediol, for instance, without catalyst 25% of the theoretical amount of ethanol had collected after 114 hours of reaction time at 190° C, whereas with a catalyst 82% of the theoretical amount of ethanol had collected after 17 hours at the same temperature. The molecular weights of the products varied between 670 and 3620, although most lay in the region 1000 to 2000. In general, these molecular weights were higher than those of the corresponding products formed without catalyst. The viscosities of polyesters, which were of roughly the same molecular weight when prepared by either method, were higher for products prepared using catalyst than for those prepared without.

Cyanomalonates

Diethyl cyanomalonate was obtained from the reaction of the sodium derivative of ethyl cyanoacetate and ethyl chloroformate (9). The transesterification between diethyl cyanomalonate and the glycols proceeded quite rapidly, ethanol beginning to distill at reaction temperatures about the same as those in the syntheses of the corresponding succinate polyesters prepared with catalyst, and much lower than those in the syntheses of succinate polyesters prepared without catalyst. In addition, ethanol was collected more rapidly and more completely than in the syntheses of the corresponding succinate polyesters without catalyst. However, the molecular weights of the polyesters, based on hydroxyl end-group analysis and the assumption of two hydroxyl groups per molecule, were very low, below 500 in most cases. Thus it would appear that diethyl cyanomalonate, although much more reactive than diethyl succinate, gave polyesters of lower molecular weight.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The high reactivity of diethyl cyanomalonate ($pK_a = 4.76$ at 25° C) was explained by its acidity, which catalyzed the transesterification reaction with glycols. Furthermore, because of the acidity the central carbon atom of the ester was assumed to be alkylated by a glycol, with the formation of water.

$$\mathrm{HOROH + EtOOCCHCOOEt \rightarrow EtOOCC(ROH)COOEt + H_2O}$$

The resulting alkylated molecule, which possessed two ester groups and one hydroxyl group, would then undergo a series of transesterifications and alkylations. In the presence of excess glycol, polymeric cross-linked molecules containing many hydroxyl groups could build up.

The apparently low molecular weight of the cyanomalonate polyesters could thus be explained by the assumption that each molecule contained several rather than two hydroxyl groups. Because the average number of hydroxyl groups per molecule was not known, the cyanomalonate polyesters were reported as having a certain hydroxyl number rather than a certain molecular weight. The values found were above 200 for most polyesters prepared from monomeric glycols but lower for those derived from the higher molecular weight polymeric glycols and the N-substituted 2,2′-iminodiethanols. The lower hydroxyl number of polyesters of higher molecular weight polymeric glycols could be explained by the low proportion of trifunctional cyanomalonate in the polyester molecules. Also, polyesters of the N-substituted 2,2′-iminodiethanols could have low hydroxyl numbers because of salt formation between the ester and amine, which would prevent alkylations from taking place.

Cyanosuccinates

Diethyl cyanosuccinate, which was prepared by condensing the sodium derivative of ethyl cyanoacetate with ethyl chloroacetate (10), proved to be of the same order of reactivity as cyanomalonate, with respect to glycols.

α-Cyanoglutarates

Diethyl α-cyanoglutarate was synthesized by the Michael reaction between ethyl cyanoacetate and ethyl acrylate in the presence of a sodium ethoxide catalyst (11). The ester appeared to be slightly less reactive towards the glycols than was diethyl cyanosuccinate.

Polyurethanes

Polyurethanes were prepared by mixing the hydroxyl-terminated polyesters previously described with various quantities of 2,4-tolylene diisocyanate (TDI) and by allowing the mixture to cure at 100° C for 5 days in the presence of ferric acetylacetonate as a catalyst.

$$n\mathrm{HO{-}polyester{-}OH} + (n+1)\mathrm{OCNRNCO} \rightarrow \mathrm{OCNR(NHCOO{-}polyester{-}OOCNHR)_nNCO}$$

The varied consistencies of the products were classified into different categories, although completely distinct boundary lines did not exist between all of them.

It was found that, in general, more than the equivalent amount of TDI was required to cure a polyester to a solid polyurethane. It was also noted that the polyurethanes tended towards brittle solids as the amounts of TDI increased. The change from stringy to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

leathery to resinous was often observed. Also for products which were elastomeric, the elongation at break normally decreased with increasing amount of TDI and in many cases the brittle point increased, although in some cases the reverse was true.

In general, non-elastomeric products were obtained from polyesters of monomeric glycols, while elastomeric polyurethanes with the lowest brittle points were formed from polyoxyethylene glycol 400 and 600 and polyoxypropylene glycol 750, 1025, and 2025 polyesters. Also, in general, the succinate polyurethanes, which did not contain nitrile groups, had the greatest tendency to be elastomeric and had the lowest brittle points (Tables VI and VII). For the nitrile containing polyurethanes, the cyanomalonates had the lowest tendency to be elastomeric and had the highest brittle points (Table VIII). The cyanosuccinates (Table IX) and α-cyanoglutarates (Table X) had about the same properties.

EXPERIMENTAL

Polyesters

Polyesters were prepared by condensing ethylene, diethylene, and triethylene glycols, four polyoxyethylene glycols ranging in molecular weight from 200 to 600, 1,2-propanediol, dipropylene glycol, five polyoxypropylene glycols ranging in molecular weight from 150 to 2025, 1,3-propanediol, 1,3-butanediol, 1,4-butanediol, 2,3-butanediol, 1,5-pentanediol, 2,2′-(methylimino)diethanol, 2,2′-(ethylimino)diethanol, 2,2′-(butylimino)diethanol, and 2,2′-thiodiethanol with diethyl succinate in the absence and presence of a sodium catalyst and with diethyl cyanomalonate (9), cyanosuccinate (10), and α-cyanoglutarate (11).

Equimolar quantities of a glycol and diethyl ester having a combined weight of about 150 grams were placed in a 300-ml three-necked round-bottomed flask. The flask was fitted with thermometer and gas delivery tube in the side necks and Claisen head in the center neck. A vertical condenser protected by a calcium chloride tube was fitted into the side neck of the Claisen head which had a distillate take-off tap mounted at the elbow. The contents of the flask were heated to a temperature in the region of 200° C under a steady stream of nitrogen, ethanol beginning to distill off at reaction temperatures ranging from 95 to 215° C. After a heating period of from 4 to 222 hours, by which time ethanol had ceased to distill, an excess of glycol was added to the reaction mixture in most cases and heating continued for another 4 to 70 hours, at which time ethanol no longer distilled. The contents of the flask, after being allowed to cool, were slowly heated to a temperature in the region of 200° C under a vacuum less than 1 millimeter of mercury for 4 to 12 hours, until no more distillate collected.

The kinematic viscosity of polyesters was measured at 20.0° C using Ostwald–Fenske viscometers. Several determinations were carried out on each sample and the average value computed. Viscosities above 30,000 centistokes were not measured but recorded only as being greater than this value.

The average molecular weight or, in the case of the cyanomalonates, the hydroxyl number of polyesters was determined by a hydroxyl end-group analysis based on acetylation with acetic anhydride in the presence of pyridine. Duplicate determinations were carried out on each polyester and an average taken of the two values obtained.

The individual syntheses of the various polyesters are given in detail as follows: succinates prepared without catalyst, Table I; succinates prepared using sodium catalyst, Table II; cyanomalonates, Table III; cyanosuccinates, Table IV; and α-cyanoglutarates, Table V.

*1,4-Butanediol.

Polyurethanes

A polyester sample (5 or 10 g) was thoroughly mixed in an aluminum foil moisture dish (60 mm diameter, 18 mm depth) with a quantity of 2,4-tolylene diisocyanate, TDI, which was roughly equivalent. The TDI employed contained 100 mg/kg of ferric acetylacetonate as a catalyst. In four other dishes the same amount of polyester was well mixed with quantities of TDI two, three, four, and five times that used for the first sample. Highly viscous polyesters were heated sufficiently that their viscosities were reduced to a few thousand centistokes and solid polyesters melted in order to permit mixing. The moisture dishes and their contents were placed in the oven and allowed to cure for 5 days at 100° C.

The varied consistencies of polyurethane products were classified into several categories, although completely distinct boundary lines did not exist between all of them. The distinguishing features of each category were (*a*) viscous, the sample was a viscous liquid; (*b*) stringy, the sample could be drawn out into threads; (*c*) cheesy, the sample broke cleanly with little or no resistance when a stretching force was applied; (*d*) gelatinous, the sample was a sticky jelly; (*e*) elastomeric, the sample recovered its shape on deformation; (*f*) leathery, the sample was both tough and flexible; on application of a stretching force, it offered resistance but broke without stretching; and (*g*) resinous, the sample was a brittle solid.

The elongation at break of elastomeric polyurethanes was determined by measuring the increase in length which a uniform strip of sample (20 mm in length, 1–2 mm in breadth, and 2–4 mm in width) underwent before breaking when a stretching force was applied. Several determinations were made for each value calculated.

The brittle point of elastomeric polyurethanes was determined by measuring the maximum temperature at which a sample (4–5 mm in length, about 1 mm in breadth, and 1–3 mm in width), cooled in an acetone – dry ice bath, broke when a bending force was applied. Many determinations were made for each sample to establish the correct temperature. In some cases, when none of the samples formed from a particular polyester was elastomeric, the brittle point was measured on one of the samples which were either stringy, cheesy, or leathery.

The proportions of 2,4-tolylene diisocyanate and polyester employed to prepare the different polyurethanes are given together with their consistencies, elongations at break, and brittle points as follows: succinate polyurethanes from polyesters prepared without catalyst, Table VI; succinate polyurethanes from polyesters prepared using sodium catalyst, Table VII; cyanomalonate polyurethanes, Table VIII; cyanosuccinate polyurethanes, Table IX; and α-cyanoglutarate polyurethanes, Table X.

DETERMINATION OF TRACE AMOUNTS OF SILVER IN GALENA ORES[1]

E. J. Bounsall and W. A. E. McBryde[2]

ABSTRACT

An analytical method is described for the determination of microgram amounts of silver in galena ores, based on the "reversion" of silver dithizonate. Silver is separated from relatively large amounts of lead by extraction as dithizonate into chloroform from an aqueous 1:99 nitric acid solution. Separation from mercury, which is also extracted under these conditions and would, if present, interfere in the analysis, is achieved by reverting the dithizonate solution with a 5% aqueous sodium chloride solution which is also 0.015 molar in hydrochloric acid. Following dilution of this aqueous solution and adjustment of pH, silver is again extracted into chloroform as the dithizonate, and determined absorptiometrically. Analyses of a number of galena ore samples showed a precision of within 3% for a silver content ranging from 0.03 to 0.4%.

Some other methods for isolating silver from these samples, which were tried but found unsatisfactory, are discussed.

INTRODUCTION

For an accurate and precise determination of trace amounts of silver in galena ores, a quantitative chemical method of analysis is necessary. Wasserstein (1), having completed a spectrographic analysis of galena (lead sulphide) ores, reported that the sensitivity of detection for the different elements was not the same, and that the role of silver could not be accurately assessed, as its sensitivity in the spectrographic examination did not allow the estimation of even very approximate amounts of this element. Several colorimetric procedures involving extraction and determination of microgram amounts of silver by a chloroform or carbon tetrachloride solution of dithizone have been outlined by Sandell (2). The technique of reversion introduced by Irving, Risdon, and Andrew (3), and later somewhat simplified by Maynes and McBryde (4), in our opinion is an improvement over other published procedures based on the use of dithizone. It eliminates the necessity of using dithizone solutions of exactly known or constant concentration, provides for maximum sensitivity, and is of real value when amounts of interfering metals are present and a reversion agent can be found which will revert the dithizonate of the metal being determined without affecting the other metallic dithizonates.

Since the extraction of lead by dithizone requires an alkaline medium, and since silver, copper, mercury, palladium, and gold are the only metals extracted by dithizone from mineral acid solution, extraction at low pH would be expected to separate silver from the relatively large amounts of lead present in galena, and from any other but the aforementioned elements. Of the latter, gold and palladium are extremely unlikely to be in galena ores, copper is sure to be present, and mercury may possibly be (5). A reversion agent was needed which would not revert copper and mercury, but which would quantitatively revert silver, subsequent to the separation of these metals from lead.

REAGENTS AND APPARATUS

Laboratory distilled water and nitric acid were distilled in borosilicate glass stills. C.P. sulphuric acid and perchloric acid were used without further purification. The 1:99 nitric acid was prepared by dilution of 1 volume of distilled nitric acid with 99 volumes of redistilled water. The 6 *N* hydrochloric acid was prepared from C.P. concentrated

[1]*Manuscript received April 21, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada.

acid, diluted 1:1 with doubly distilled water, and then twice distilled in a borosilicate glass still, with rejection of the first 20% and last 10% of the distillate.

Chloroform

Both U.S.P. and reclaimed chloroform were purified by the procedure outlined by Biddle (6), except that the calcium oxide was filtered out before distillation in a glass still.

Dithizone and Cotton

Purification of each was carried out by the procedure described by Maynes and McBryde (4). Dithizone solutions were prepared by dissolving approximately 10 mg of the purified reagent in 1 liter of chloroform. With experience, solutions of suitable concentration were prepared, by visually estimating the color of the solution, immediately before use.

Buffer and Reversion Agent Solutions

The analytical grade reagents were dissolved in redistilled water, and the solutions shaken with dithizone in chloroform to free them of heavy metals.

Potassium Chromate Solution

A 4% (w/v) solution was prepared from reagent grade potassium chromate and redistilled water.

Standard Solutions of Metals

The composition of these solutions was based on accurately known weights of (i) dried analytical reagent grade silver nitrate; (ii) Specpure lead; (iii) Specpure copper; (iv) doubly distilled mercury. The metals were dissolved in 1:1 nitric acid, and these solutions boiled to free them of oxides of nitrogen; the silver nitrate was dissolved in, and the solutions of all the nitrates made up to, known volumes with 1:99 nitric acid. From stock solutions so prepared, standard solutions of silver, mercury, and copper, containing about 10 μg of metal (accurately known) per ml, were prepared by dilution with 1:99 nitric acid. The standard lead solution contained about 100 mg of metal (accurately known) per ml.

From time to time, checks were made on the concentration of the standard silver solution by carrying out the reversion procedure described below on a measured volume of this solution. The reversion values for these samples were compared with the standard reversion working curve which had been determined when the solution was first prepared.

Spectrophotometer and Cells

All measurements of optical density were made with a Beckman Model DU spectrophotometer set at 610 mμ, the absorption maximum of dithizone. The optical cells were cylindrical, 1 cm in path length, with Corex glass windows, and ground-glass stoppers to minimize loss of chloroform by evaporation.

Glassware

Borosilicate glassware was used throughout. It was cleaned after each use in hot nitric and sulphuric acids, rinsed thoroughly with tap water, and then washed well with doubly distilled water. Extractions were carried out in Squibb-type separatory funnels. Aliquots of standard metal solutions were measured from 5-ml class A microburettes.

EXPERIMENTAL

Reversion Procedure

A cotton pledget was inserted in the stem of a clean, dry, 125-ml separatory funnel equipped with a 7-mm delivery tube. A measured volume of the standard silver solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was transferred to the funnel, and the volume made up to 25 ml with 1:99 nitric acid. Sufficient dithizone solution was added to extract all of the silver present, and the funnel was shaken for 1 minute. When the phases separated, the dithizone–dithizonate extract was transferred to a 25-ml volumetric flask. The aqueous phase was washed twice with 8-ml portions of chloroform, and the washings were added to the volumetric flask to make the volume to 25 ml. A portion of this dithizone–dithizonate solution was added to one colorimeter cell. A second portion of approximately 5 to 7 ml was added to a 30-ml separatory funnel, and an equal volume of the reverting solution added. This funnel was shaken for 1 minute, the phases allowed to separate, and a few drops of the reverted dithizone solution allowed to flow through a fresh cotton pledget placed in the stem of the funnel. Sufficient of the reverted solution was then delivered to fill a second colorimeter cell. The spectrophotometer was set to read zero optical density for the first solution, and the apparent optical density of the reverted solution measured against this. This quantity is known as the *reversion value* of the silver solution.

Reversion Agent for Silver

The use of 6% (w/v) potassium iodide in 0.25 *N* sulphuric acid, first recommended as a reversion agent for silver (3), met with little success owing to decomposition of dithizone by free iodine. The addition of 0.1 *N* thiosulphate, suggested by Morrison and Paige (7), did not overcome this difficulty. A neutral 6% (w/v) potassium iodide solution yielded reversion values exhibiting quite poor precision, due perhaps to a solubility loss of dithizone to the neutral reverting medium. Reversions with a 6% (w/v) solution of potassium bromide in 0.1 *N* hydrochloric acid also yielded results with poor precision.

With 2.0 *N* hydrochloric acid as the reversion agent, a series of experiments on amounts of silver solution equivalent to from 5 to 50 μg of metal gave reversion values proportional to the quantity of silver taken. The average reversion value per microgram of silver was 0.0148 ± 0.0001 within a range of 0.0145 to 0.0150. Each reversion value was corrected for a blank amounting to 0.003 ± 0.001.

Test for Completeness of Extraction of Silver

Maynes and McBryde (4) suggested a convenient test for the completeness of extraction of a metal with dithizone. Applying their procedure, the molar extinction coefficient of dithizone in a chloroform solution was determined, from a solution whose composition was based on a direct weighing of dithizone, to be 3.77×10^4 liter/mole cm. The same quantity was then calculated from the reversion value obtained for a known amount of silver extracted by a known volume of dithizone solution, assuming the molar ratio of silver to dithizone in the dithizonate to be 1:1; this value was 3.94×10^4 liter/mole cm. The difference between the two values is 4%, and the sign of the difference indicates 104% recovery of silver. This difference is attributed to experimental error in the extinction coefficient obtained by direct measurement; the value obtained is somewhat lower than two other published values (4, 8), although the latter were each obtained with different instruments from that used here.

It was concluded that both the extraction of silver with dithizone and the reversion of silver using 2.0 *N* hydrochloric acid were complete; accordingly a standard reversion working curve of reversion plotted against micrograms of silver was prepared for this particular reversion agent and experimental conditions.

Extraction of Other Metals

Comparison with the standard reversion working curve showed that a slight reversion of mercury was also being obtained under the identical reversion conditions used for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

silver. In the case of copper, it was found that not even microgram amounts were extracted by dithizone from 1:99 nitric acid, and that no extraction occurred until the pH of the solution was raised by ammonia to 4.2.

Complete extraction of microgram amounts of silver occurred, and no extraction of even microgram amounts from gram quantities of lead was detected at acid concentrations as low as 1:99 nitric acid and 0.1 *N* perchloric acid. Silver was not completely extracted from solutions of perchloric acid more concentrated than 2 normal.

Separation of Silver from Copper and Mercury

In the event that extraction of silver might be required from an acidic medium from which copper was also extracted, a reversion agent was sought which would completely revert silver but not copper or mercury. Friedeberg (9) found that silver could be separated from copper and mercury by selectively decomposing silver dithizonate with a 10% sodium chloride solution which was also 0.015 *N* in hydrochloric acid. The silver was subsequently extracted from this aqueous phase after it had been diluted 10-fold with water, or had its pH raised to between 3 and 3.5, into a solution of dithizone.

To obtain complete recovery of silver by this procedure we have been obliged to modify the directions slightly. The sodium chloride concentration of this reverting solution could be lowered to 5% while the hydrochloric acid concentration was kept unchanged. Copper and mercury dithizonates were completely unreverted by this solution. It was found that the subsequent re-extraction of silver with dithizone was incomplete unless the aqueous phase was both diluted 10-fold and treated to raise its pH to 4.6. The re-extraction of silver was incomplete when the pH was below 4.6 or when the aqueous solution was less dilute regardless of the pH.

Double Reversion Procedure

The recovery of silver and its separation from copper and mercury were tested by the following procedure.

A measured volume of the standard silver solution was transferred to a clean, dry, 125-ml separatory funnel, in the stem of which was a cotton pledget, and the volume made up to 50 ml with 1:99 nitric acid. Sufficient dithizone was added to extract all of the silver present, and the funnel was shaken for 1 minute. When the phases separated, the silver dithizonate–dithizone extract was transferred to another clean, dry, 125-ml separatory funnel, in which were 3 ml of the reversion agent (5% sodium chloride, 0.015 *N* hydrochloric acid). The aqueous phase in the first funnel was washed twice with 5-ml portions of chloroform, and the washings were combined in the second funnel, which was then shaken for 1 minute. When the phases separated, the chloroform phase containing the dithizone was discarded, and the pH of the aqueous phase (containing the silver) was adjusted with sodium acetate solution (1.6 g/liter) to 4.6, and the total volume was made up to 30 ml with redistilled water. Ten milliliters of the dithizone solution was added, and the funnel was shaken for 1 minute. The rest of the procedure was exactly as outlined in the original reversion procedure described above.

This procedure was carried out on amounts of standard silver solution containing the equivalent of from 5 to 45 μg of silver. The average recovery for nine determinations corresponding to 10 μg of silver was 9.97 μg with an average deviation of 0.29 μg. The range of these values was from 9.6 to 10.7 μg after correction for the blank, which was equivalent to 0.7 μg of silver.

Determination of Silver in the Presence of Mercury, Copper, and Lead

Results, corrected for the blank, for the determination of silver, according to the

Determination of Silver in Galena Ores

The usual method employed for the dissolving of galena ores is heating with hydrochloric acid. However, since even small amounts of chloride prevent the extraction of silver with dithizone, an acid other than hydrochloric must be used. When nitric acid was employed, it was found that, regardless of the temperature (from room temperature to 200° C) or the acid concentration (from concentrated to 1:9) used, a heavy, insoluble, white precipitate of lead sulphate formed during dissolving of the ore. Concentrated perchloric acid, however, at a temperature of 120° to 135° C, was found to be completely satisfactory, with a dissolving time of approximately two hours. When lower acid concentration or lower temperatures were used, a longer time was needed for dissolving. At temperatures above 135° C, regardless of the perchloric acid concentration, a fine white precipitate formed.

Procedure

A sample of ore weighing 0.02 to 0.06 g, after being crushed to a fine powder, was transferred to a 50-ml beaker and covered with a watch glass. Two milliliters of concentrated perchloric acid was added, and the sample heated at 120° to 135° C until dissolution was complete. After the solution was cooled, the watch glass and the sides of the beaker were washed with water, and the solution was evaporated almost to dryness. Sufficient 1:99 nitric acid was added, and the solution was heated just under boiling until all the salts had dissolved. After cooling, the solution was transferred to a 125-ml separatory funnel, and the volume made up to 50 ml with rinsings of 1:99 nitric acid. The double reversion procedure with dithizone was then carried out, and the amount of silver determined by comparison with the standard reversion working curve.

Since there were no standard galena samples available with which to check the accuracy of the new procedure, and since there was no trustworthy alternative procedure of analysis, known amounts ("spikes") of silver were added to various of the ore samples immediately after dissolving, as a means of checking the subsequent analysis. An amount of silver equal to the amount added as the "spike" was then subtracted from the value determined by the analysis.

As the percentage of lead sulphide actually in the ore samples differed widely among the samples, the concentration of silver was expressed as p.p.m. lead, rather than p.p.m. ore sample. A lead analysis for each silver determination was carried out, essentially

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

according to the chromate procedure outlined by Vogel (10), on the aqueous phase containing the lead from the double reversion procedure. The accuracy and precision of the chromate method for the determination of lead were established by analyzing three 3-ml samples of standard lead solution. The results obtained were 0.4% low, with no deviation.

Galena ore samples obtained from deposits at Broken Hill, N.S.W., Australia, were kindly made available for analysis by Professor R. M. Farquhar, Geophysics Laboratory, Department of Physics, University of Toronto. The results of the analyses, corrected for the blank and "spike", are shown in Table II. The samples marked with asterisks are

*A "spike" equivalent to 10 micrograms of silver was added.

those to which a "spike" equivalent to 10 micrograms of silver was added. The results of analyses are not listed for 12 samples on which only one determination was made.

The precision of the analyses is within 0.4 to 2.8% based on the average deviation. The determinations on samples to which "spikes" of silver were added do not differ appreciably within the above-stated limits of precision from those analyzed directly.

INVESTIGATION OF OTHER WAYS OF SEPARATING SILVER FROM COPPER AND MERCURY

Extraction of Silver with Diethylammonium Diethyldithiocarbamate

Maynes (11) found that mercury, copper, and only a slight trace of silver could be extracted by a chloroform solution of diethylammonium diethyldithiocarbamate (dithiocarbamate) from aqueous solutions 5.1 N in hydrochloric acid. Subsequent dilution of the aqueous phase to 1.5 N in hydrochloric acid permitted extraction of silver. A qualitative test for silver in the remaining aqueous phase by means of dithizone revealed no silver.

It was affirmed that no silver was extracted by dithiocarbamate from solutions 5.4 N in hydrochloric acid, but that the extraction was still incomplete (50%) when the hydrochloric acid was as dilute as 0.05 N. Thus a subsequent determination of silver, after separation of copper and mercury, could not conveniently be achieved if hydrochloric acid was present. Maynes' qualitative test for silver in 1.5 N hydrochloric acid employed dithizone, but, as previously described, even small amounts of hydrochloric acid prevent formation of silver dithizonate.

According to Luke (12) silver could be extracted by dithiocarbamate from 3.6 N

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sulphuric acid. Wyatt (13) reported extraction of copper and mercury by the same reagent from 1 to 10 *N* sulphuric acid solutions. Our results for the extraction of silver by dithiocarbamate from sulphuric acid solutions of differing normality indicate that at low acid concentrations extraction is incomplete, and at high acid concentrations, at which copper and mercury are extracted, silver is as well. Thus a separation of silver from copper and mercury could not be effected.

Extraction with 1,10-Phenanthroline

This reagent forms intensely colored complex ions with iron (II) and copper (I), and the sterically hindered derivatives, 2,9-dimethylphenanthroline (neocuproine) and 2,9-dimethyl-4,7-diphenylphenanthroline (bathocuproine), in chloroform solution have been found specific for microgram amounts of copper (14, 15, 16). The greater selectivity is due presumably to steric hindrance to sixfold co-ordination. Thus, copper might possibly be separable from silver prior to the determination of the latter by the use of these reagents. However, it was found that varying amounts of silver were also extracted by a chloroform solution of 1,10-phenanthroline over the entire pH range below 7. One would expect the derivatives mentioned above to behave in a similar fashion since silver exhibits fourfold co-ordination as a maximum.

Anion Exchange Studies

Attempts with an anion exchange resin of the strongly basic type (Amberlite IRA-400) to remove chloride ion from a silver solution after its separation from mercury and copper (see page 1491) revealed that silver was also completely absorbed by the resin, indicating that silver was present in solution in some anionic form (probably $AgCl_2^-$).

ACKNOWLEDGMENTS

This investigation was made possible through generous support from the University of Toronto's Advisory Committee on Scientific Research. One author (E. J. B.) was assisted by an Eldorado Mining and Refining Geochemical Scholarship for which grateful thanks are tendered.

17α-HALOGENATED PROGESTERONES: ORALLY-ACTIVE PROGESTINS[1]

DAVID J. MARSHALL AND ROGER GAUDRY

ABSTRACT

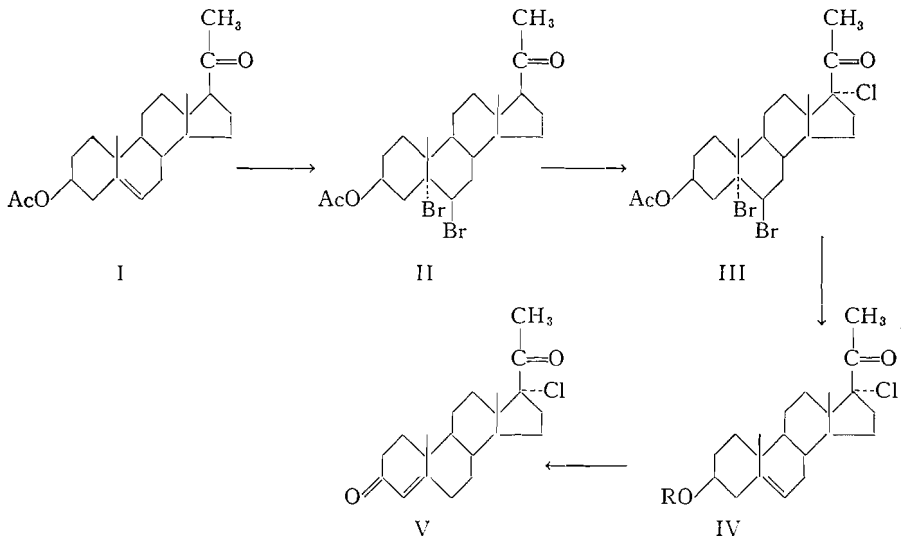
17α-Chloroprogesterone, 6α-fluoro-17α-bromoprogesterone, 1-dehydro-6α-fluoro-17α-bromoprogesterone, and 6α-chloro-17α-bromoprogesterone have been synthesized. These compounds have been found to be orally-active progestins without androgenic properties.

In recent years, considerable effort has been devoted to the search for orally-active progestational agents to substitute for the natural hormone, progesterone. The newer synthetic progestogens which have acquired prominence because of their oral activity fall into two classes: 19-norsteroids such as 19-norprogesterone (1) and 17α-ethynyl-19-nortestosterone (2) and its $\Delta^{5(10)}$-isomer (3), and derivatives of progesterone containing a 17α-acetoxy substituent (4–7).

It has been shown recently that 17α-bromoprogesterone (8) is an orally-active progestogen (9), indicating that substituents other than acetoxyl at C-17 can enhance the very weak oral activity of progesterone. It was clearly of interest to prepare other 17α-halogenated progesterones, and to determine whether modifications in structure which enhance the activity of 17α-acetoxyprogesterone, such as the introduction of a 6α-halo substituent and a Δ^1-double bond (4, 5), would have a similar effect on the comparatively weak oral activity of 17α-bromoprogesterone.

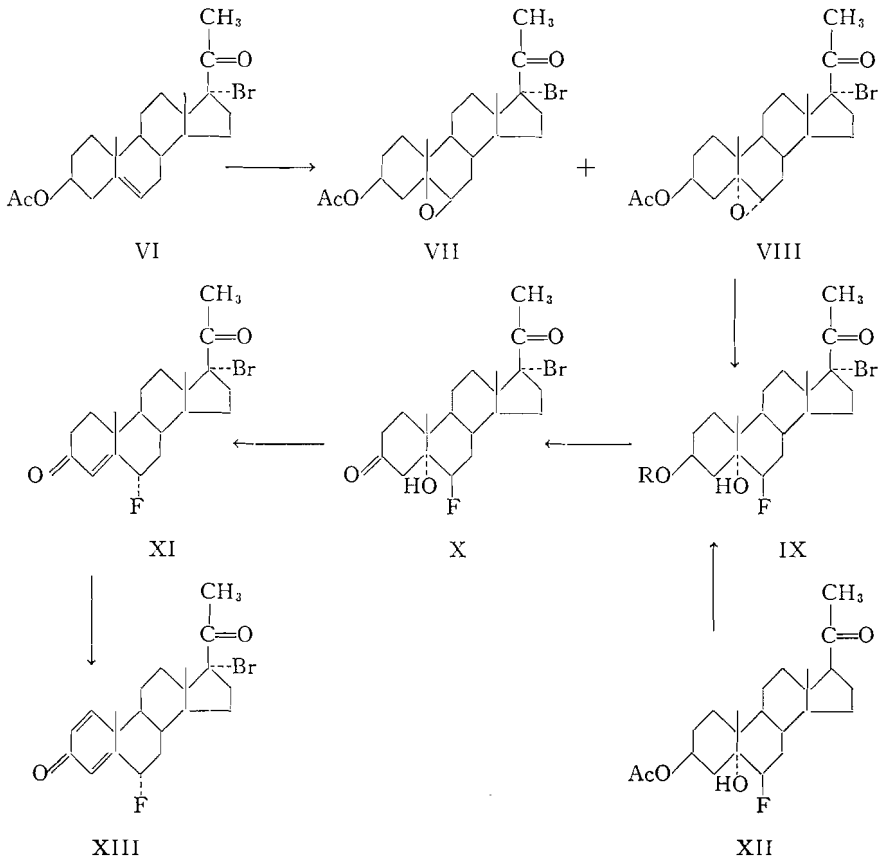
In this paper, we record the synthesis and preliminary biological evaluation of 17α-chloroprogesterone and of the 6α-fluoro-, 1-dehydro-6α-fluoro-, and 6α-chloro-derivatives of 17α-bromoprogesterone.

17α-Chloroprogesterone



Pregnenolone acetate (I) was brominated at a low temperature, and the 5,6-dibromide II was allowed to react with chlorine in acetic acid. The resulting mixture of 17- and 21-chloro derivatives (III) was treated with sodium iodide in acetone which regenerated the 5,6-double bond and replaced chlorine at C-21 with iodine. Finally, the iodine at C-21 was removed by reduction with aqueous sodium bisulphite solution (10) and 17α-chloropregnenolone acetate (IV, R = Ac) was isolated after chromatographic purification. The α-configuration of the chlorine was inferred from the general preference for "back-side" attack and from the fact that bromination of 20-ketones has been clearly shown to result in the formation of 17α-bromo derivatives (11).

Acid-catalyzed hydrolysis of IV (R = Ac) yielded 17α-chloropregnenolone (IV, R = H), which, without purification, was oxidized with chromic acid in acetone (12). The shift of the double bond into conjugation with the carbonyl group to yield 17α-chloroprogesterone (V) was completed by treatment of the crude oxidation product with oxalic acid (13).



6α-Halo-17α-bromoprogesterones[2]

17α-Bromopregnenolone acetate (VI) (8, 10) was converted to a 6-fluoro derivative by conventional means (14). Epoxidation of VI with monoperphthalic acid gave a mixture of 5β,6β- and 5α,6α-epoxides, VII and VIII. The epoxides were separated by chromatog-

[1]*Manuscript received May 9, 1960.*
Contribution from the Ayerst Research Laboratories, P.O. Box 6115, Montreal, Que.

raphy on Florisil, and the more strongly adsorbed and more levorotatory isomer was assigned the α-structure by analogy with other pairs of epimeric 5,6-epoxides (15). Cleavage of the epoxide ring of VIII with anhydrous hydrogen fluoride (14, 16) gave the

For personal use only.

5α-hydroxy-6β-fluoro derivative IX (R = Ac) in good yield. The alternative method of forming the fluorohydrin, reaction of the epoxide with boron trifluoride etherate (6, 15, 17–20), gave much less satisfactory results. The fluorohydrin acetate IX (R = Ac) was hydrolyzed with perchloric acid in methanol to the diol IX (R = H). Oxidation of the diol with sodium dichromate in acetic acid and dehydration of the resulting diketone X with anhydrous hydrogen chloride in chloroform gave 6α-fluoro-17α-bromoprogesterone (XI), λ_{max} 237 mμ, ε 17,800. The stability of XI to further treatment with acid and the value of the extinction coefficient (6β-fluoro-Δ^4-3-ketones have extinction coefficients of 10,000–13,000 (18)) served to establish that the expected inversion of C-6 had occurred, and that the fluorine was in the equatorial (6α) configuration.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The fluorohydrin IX (R = Ac) was also obtained, in good yield, by bromination of 3β-acetoxy-5α-hydroxy-6β-fluoropregnan-20-one (XII) (16, 17) with N-bromosuccinimide (21).

Dehydrogenation of XI with 2,3-dichloro-5,6-dicyanoquinone (22) yielded the 1-dehydro analogue XIII, which was also obtained, in lower yield, by reaction of XI with selenium dioxide.

For the synthesis of 6α-chloro-17α-bromoprogesterone, 17α-bromoprogesterone (XIV) was converted to the corresponding 3-monoethylene ketal XV by reaction with ethylene glycol and *p*-toluenesulphonic acid in refluxing toluene. Epoxidation of the ketal with monoperphthalic acid gave a mixture of 5β,6β- and 5α,6α-epoxides XVI and XVII, separated by chromatography on Florisil. The configurations of the epoxides were assigned on the basis of their relative behavior during chromatography and a comparison of optical rotations, since it is known (15) that in any pair of epimeric 3-ketal-5,6-epoxides, the α-epoxide is more polar toward adsorbents and is more levorotatory than the β-epimer.

Treatment of the α-epoxide XVII with anhydrous hydrogen chloride in chloroform resulted in cleavage of the epoxide linkage to form the 5α-hydroxy-6β-chloro derivative, hydrolysis of the ketal group, dehydration to the α,β-unsaturated ketone, and inversion of configuration at C-6, and 6α-chloro-17α-bromoprogesterone (XVIII) was isolated in 80% yield. The structure of XVIII was established by elemental analysis, by infrared and ultraviolet spectral data, and by the stability of the compound to acid.

In a second synthesis of XVIII, 3β-acetoxy-5α,6α-epoxypregnan-20-one (XIX) (16, 17) was allowed to react with hydrogen chloride in chloroform, and the resulting 5α-hydroxy-6β-chloro derivative XX was brominated at C-17 with N-bromosuccinimide to give XXI (R = Ac). Acid-catalyzed hydrolysis to the diol XXI (R = H), oxidation to the diketone XXII, and dehydration-inversion with hydrogen chloride then led to XVIII.

A crystalline product could not be obtained from attempted dehydrogenations of XVIII with selenium dioxide or 2,3-dichloro-5,6-dicyanoquinone.

Biological Activity

The progestational activity of the 17α-halogenated progesterones relative to progesterone (subcutaneous) and to 17α-ethynyl-19-nortestosterone (oral), as determined in the Clauberg assay, is summarized in Table I. It will be seen that chlorine has a smaller

TABLE I

Relative progestational activity (Clauberg assay)

	Subcutaneous	Oral
Progesterone	1.0	
17α-Ethynyl-19-nortestosterone		1.0
17α-Bromoprogesterone (XIV)	2.0	0.04
17α-Chloroprogesterone (V)	1.0	<0.04
6α-Fluoro-17α-bromoprogesterone (XI)	4.0	0.3
6α-Chloro-17α-bromoprogesterone (XVIII)	2.0	0.3

potentiating effect on the progestational activity than does bromine at C-17α of progesterone. But fluorine and chlorine at C-6α enhance the activity of 17α-bromoprogesterone to about the same extent as they enhance the activity of 17α-acetoxyprogesterone (6, 7). Preliminary assays indicated that the 1-dehydro derivative XIII was more active than XI.

There have been a number of reports recently that the administration of some synthetic progestins to rats (23) and to humans (24) during gestation can induce masculinization of female fetuses. For example, it has been found (23) that when pregnant rats are treated with relatively low doses of 17α-ethynyl-19-nortestosterone or 6α-methyl-17α-acetoxyprogesterone (5), serious masculinization occurs in the female offspring. It was therefore of interest to test some of the compounds made in this investigation for androgenic activity. The 17α-bromoprogesterones did not show androgenic properties in castrated male rats, nor was there any indication of masculinization in female offspring of pregnant rats which had been treated with high doses of XI or XIV.

The detailed results of the biological assays of these compounds will be published elsewhere (25).

EXPERIMENTAL

Melting points are uncorrected. Rotations were determined in chloroform solution at a concentration of about 1%, and ultraviolet spectra were taken in solution in 95% ethanol. The alumina used for chromatography was Merck chromatographic grade alumina which had been neutralized by being allowed to stand overnight in ethyl acetate and reactivated by heating *in vacuo* at 145° for 18 hours. Microanalyses were carried out in our analytical laboratory by Mr. W. J. Turnbull and associates.

17α-CHLOROPROGESTERONE

17α-Chloropregnenolone Acetate (IV, R = Ac*)*

To a stirred solution of 50.0 g of 3β-acetoxy-5-pregnen-20-one in 930 ml of chloroform cooled to −60° was added over a period of 2 hours 467 ml of a 0.3 *M* solution of bromine in carbon tetrachloride. After the solution was warmed to room temperature, the volume was reduced to about 100 ml *in vacuo* and the 5α,6β-dibromide II was precipitated by the addition of 350 ml of methanol. The yield was 60.4 g, m.p. 143–146° decomp.

To a solution of 14.0 g of II in 125 ml of acetic acid containing 0.1 ml of concentrated hydrochloric acid was added 78.4 g of a solution of chlorine in acetic acid (2.46 g chlorine per 100 g of solution) over a period of 1 hour. After 250 ml of water was added, the mixture was refrigerated overnight and the colorless solid was filtered and washed with water. Crystallization from methylene chloride – methanol yielded 10.3 g of a mixture of 17- and 21-chlorodibromides (III), m.p. 129–137° decomp. This product was dissolved in 100 ml of boiling acetone and a solution of 10 g of sodium iodide in 60 ml of acetone was added. After it was heated under reflux for 1 hour, under nitrogen, the mixture was cooled in ice and the iodine was reduced by the slow addition of 362 ml of 0.1 *N* sodium thiosulphate solution. The precipitated product was dissolved in 70 ml of ether, 10 ml of 10% sodium bisulphite solution was added, and the mixture was shaken intermittently for 30 minutes, after which no further iodine color developed on standing. The ether solution was washed with an additional portion of bisulphite solution and with water and was dried and concentrated to dryness. The resulting solid (6.8 g) could not be readily purified by crystallization.

A 1.87 g portion of this product was chromatographed on 65 g of alumina. Elution with 650 ml of benzene–petroleum ether 1:3 yielded 1.45 g of 3β-acetoxy-17α-chloro-5-pregnen-20-one (IV, R = Ac), m.p. 145–148°. Crystallization from methylene chloride – methanol gave an analytical sample, m.p. 147–149°, $[\alpha]_D$ −84.9°. Anal. Calc. for $C_{23}H_{33}ClO_3$: C, 70.30; H, 8.46; Cl, 9.02. Found: C, 70.41; H, 8.67; Cl, 9.18.

17α-Chloroprogesterone (V)

A mixture of 4.65 g of the acetate IV (R = Ac), 130 ml of methanol, and 4.65 ml of 70% perchloric acid was heated at the boiling point until the solid had dissolved and was then left at room temperature for 24 hours. Water (140 ml) precipitated 3.80 g of 17α-chloropregnenolone (IV, R = H), m.p. 120°, resolidifying and remelting at 156–161°, which was not further purified.

To a stirred solution of 3.48 g of 17α-chloropregnenolone in 140 ml of acetone cooled to 5° under nitrogen was added 2.78 ml of a chromic acid solution (26.72 g of chromium trioxide in 23 ml of sulphuric acid diluted to 100 ml with water). After the solution had been stirred for 5 minutes, 420 ml of water was added and the precipitated solid was filtered and dried (3.25 g). This product was dissolved in 43 ml of ethanol, 1.6 g of oxalic acid was added, and the solution was heated under reflux under nitrogen for 45 minutes. Water was added and the product was extracted with ether. The ether solution was washed with 5% sodium bicarbonate solution and with water, and the brown gum remaining after drying and evaporation of the solvent was adsorbed on 150 g of alumina in benzene – petroleum ether 1:1. Elution with 600 ml of benzene gave 1.14 g of colorless solid which was crystallized from aqueous methanol yielding 1.00 g of 17α-chloroprogesterone (V), m.p. 166–168°. Recrystallization from aqueous methanol gave an analytical sample, m.p. 168.5–170°, $[\alpha]_D$ +51.0°, λ_{max} 240 mμ (ε 17,900). Anal. Calc. for $C_{21}H_{29}ClO_2$: C, 72.31; H, 8.38; Cl, 10.12. Found: C, 72.63; H, 8.39; Cl, 10.31.

6α-FLUORO-17α-BROMOPROGESTERONE

Epoxidation of 17α-Bromopregnenolone Acetate

To a stirred, ice-cooled solution of 5.00 g of 3β-acetoxy-17α-bromo-5-pregnen-20-one in 75 ml of chloroform was added, over a period of 15 minutes, 102 ml of a 0.342 *M* solution of monoperphthalic acid in ether. After storage at 10° for 4 days, the mixture was filtered, and the filtrate was washed with 10% sodium bicarbonate solution and with water and dried over magnesium sulphate. The crude product obtained after evaporation of the solvent was dissolved in benzene and chromatographed on 150 g of Florisil. Two liters of benzene containing 1% ethyl acetate eluted 1.12 g of the *5β,6β-epoxide* VII, which was recrystallized from ethyl acetate, m.p. 158–160.5°, $[\alpha]_D$ −57.6°. Anal. Calc. for $C_{23}H_{33}BrO_4$: C, 60.92; H, 7.34; Br, 17.62. Found: C, 61.15; H, 7.22; Br, 17.57.

Elution of the column with 2 liters of benzene containing 5% ethyl acetate gave 2.82 g of the *5α,6α-epoxide* VIII, which, after recrystallization from ethyl acetate had a melting point of 192–193°, $[\alpha]_D$ −102.4°. Anal. Calc. for $C_{23}H_{33}BrO_4$: C, 60.92; H, 7.34; Br, 17.62. Found: C, 60.64; H, 7.12; Br, 17.31.

3β-Acetoxy-5α-hydroxy-6β-fluoro-17α-bromopregnan-20-one (IX)

A. From the Epoxide VIII

To 51.1 g of anhydrous hydrogen fluoride in a polyethylene bottle in a Dry Ice–acetone bath at −60° was added slowly, in turn, 102 g of dry tetrahydrofuran, 50 ml of chloroform, and a solution of 51.1 g of the epoxide VIII in 325 ml of chloroform. The solution was kept at −10° for 2 hours and was then poured, with stirring, into a mixture containing 200 g of potassium carbonate, 600 ml of water, ice, and 100 ml of chloroform. The chloroform solution was washed with sodium bicarbonate solution and with water, dried over magnesium sulphate, and evaporated to dryness *in vacuo*. Crystallization from methylene chloride – methanol yielded 34.7 g of the fluorohydrin IX, m.p. 170–171° decomp. The analytical sample, obtained by crystallization from the same solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixture had a melting point of 173° decomp., $[\alpha]_D$ −78.3°. Anal. Calc. for $C_{23}H_{34}BrFO_4$: C, 58.34; H, 7.24; Br, 16.88; F, 4.01. Found: C, 58.32; H, 7.26; Br, 16.85; F, 3.89.

B. From 3β-Acetoxy-5α-hydroxy-6β-fluoropregnan-20-one (XII)

A mixture of 20.0 g of the fluorohydrin XII, 15.0 g of N-bromosuccinimide, and 500 ml of carbon tetrachloride was heated under reflux on the steam bath. When the solvent was boiling vigorously, the flask was irradiated with a 250-watt infrared lamp and refluxing was continued for 10 minutes. The flask was then cooled in an ice bath, the mixture was filtered, and the filtrate was washed with dilute sodium bisulphite solution and with water. The dried (Na_2SO_4) solution was evaporated to dryness *in vacuo* and 40 ml of methanol was added to the amorphous residue. The mixture was brought rapidly to the boiling point, cooled in ice, and the crystalline product was filtered and washed with methanol. The yield of 17α-bromo derivative IX was 15.1 g, m.p. 171.5° decomp., identical (mixed m.p. and infrared spectrum) with the product obtained in *A*.

In larger runs it was found desirable to have a small amount of pyridine present to inhibit the ionic bromination which sometimes occurred. Thus, a mixture of 100 g of IX, 75 g of N-bromosuccinimide, 2.5 liters of carbon tetrachloride, 24 g of pyridine, and 6 g of benzoyl peroxide heated under reflux for 15 minutes followed by working up as above, yielded 80 g of VI, m.p. 174° decomp.[3]

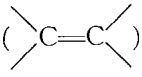
3β,5α-Dihydroxy-6β-fluoro-17α-bromopregnan-20-one (IX, R = H)

A mixture of 34.7 g of the acetate IX (R = Ac), 500 ml of methanol, and 12 ml of 70% perchloric acid was boiled until the steroid had dissolved (about 10 minutes) and was then left at room temperature for 17 hours. The solid obtained by the addition of 500 ml of water was crystallized from methanol, yielding 25.8 g of the diol IX (R = H), m.p. 174° decomp. Recrystallization from aqueous methanol gave the analytical sample, m.p. 176° decomp., $[\alpha]_D$ −65.2°. Anal. Calc. for $C_{21}H_{32}BrFO_3$: C, 58.46; H, 7.48; Br, 18.52; F, 4.40. Found: C, 58.22; H, 7.71; Br, 18.44; F, 4.56.

5α-Hydroxy-6β-fluoro-17α-bromopregnane-3,20-dione (X)

To a solution of 25.8 g of the diol IX (R = H) in 250 ml of acetic acid cooled to 15° was added with stirring a solution of 25.8 g of sodium dichromate dihydrate in 520 ml of acetic acid. After the mixture had been allowed to stand at room temperature for 16 hours, 50 ml of methanol was added, followed by 1300 ml of water. The finely divided solid was filtered and washed well with water. The wet product, which was difficult to dry, was dissolved in methylene chloride (in which it was only moderately soluble), and the solution was dried over sodium sulphate and concentrated. Crystallization from methylene chloride – methanol yielded 16.4 g of the diketone X, m.p. 174° decomp., and 2.8 g, m.p. 173° decomp. The analytical sample, m.p. 173.5–174.5° decomp., $[\alpha]_D$ −42.1°, was obtained by crystallization from *i*-propanol. Anal. Calc. for $C_{21}H_{30}BrFO_3$: C, 58.75; H, 7.04; Br, 18.61; F, 4.93. Found: C, 58.71; H, 6.91; Br, 18.90; F, 4.49.

6α-Fluoro-17α-bromoprogesterone (XI)



Anhydrous hydrogen chloride was passed for 1 hour through an ice-cooled suspension of 10.8 g of the diketone X in 200 ml of chloroform. The solid went rapidly into solution. After standing an additional hour in the ice bath, the orange solution was washed with water, 10% sodium bicarbonate solution, and again with water. Drying over sodium sulphate and evaporation of the solvent gave a solid which was crystallized from methylene chloride – methanol, yielding 6.5 g of 6α-fluoro-17α-bromo-4-pregnene-3,20-dione

[3]*We are indebted to Dr. Gordon Myers for carrying out this experiment.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(XI) as colorless needles, m.p. 173–175.5° decomp. From the mother liquors, an additional 0.5 g of product was obtained, m.p. 171–173° decomp. Recrystallization from methylene chloride – methanol yielded an analytical sample, m.p. 176–177.5° decomp., $[\alpha]_D$ +17.0°, λ_{max} 236 mμ (ε 17,800). Anal. Calc. for $C_{21}H_{28}BrFO_2$: C, 61.34; H, 6.86; Br, 19.43; F, 4.62. Found: C, 61.51; H, 7.06; Br, 19.28; F, 4.42.

1-Dehydro-6α-fluoro-17α-bromoprogesterone (XIII)

A solution of 1.00 g of XI, 0.64 g of 2,3-dichloro-5,6-dicyanoquinone (22), and 26 mg of *p*-toluenesulphonic acid in 40 ml of benzene was heated under reflux for 18 hours. The cooled mixture was filtered, and the filtrate was diluted with 20 ml of ethyl acetate and washed (initially without shaking to avoid emulsions) with 10% sodium bicarbonate solution and with water. After drying over magnesium sulphate, the solvent was removed *in vacuo*, and the solid residue was chromatographed in benzene on 10 g of Florisil. Elution with 250 ml of benzene containing 5–10% ethyl acetate yielded 656 mg of pale yellow solid. Crystallization from methylene chloride – methanol (charcoal) gave 0.51 g of XIII as colorless plates, m.p. 181–182° decomp. The analytical sample was obtained by recrystallization from acetone–hexane and melted at 181–183° decomp., $[\alpha]_D$ −20.5°, λ_{max} 241 mμ (ε 18,200), $\nu_{max}^{CS_2}$ 1711 cm^{-1} (20-ketone), 1675 cm^{-1} (3-ketone), 1637 cm^{-1} (), 904 cm^{-1}. Anal. Calc. for $C_{21}H_{26}BrFO_2$: C, 61.63; H, 6.40; Br, 19.53; F, 4.64. Found: C, 61.52; H, 6.31; Br, 19.38; F, 4.78.

6α-CHLORO-17α-BROMOPROGESTERONE

3,3-Ethylenedioxy-17α-bromo-5-pregnen-20-one (XV)

A mixture of 10.0 g of 17α-bromoprogesterone, 310 ml of toluene, 80 ml of ethylene glycol, and 0.30 g of *p*-toluenesulphonic acid was heated under reflux under a water separator for 6 hours. After it was cooled in ice, the mixture was washed with 10% sodium bicarbonate solution and with water, and the solvent was removed *in vacuo*. Crystallization from methanol containing a few drops of pyridine yielded 5.0 g of the 3-ketal XV, m.p. 128–130°. The analytical sample was obtained by crystallization from methanol, m.p. 131–132°, $[\alpha]_D$ −84.0°. The infrared spectrum (CS_2) showed a single carbonyl band at 1705 cm^{-1}. Anal. Calc. for $C_{23}H_{33}BrO_3$: C, 63.16; H, 7.60; Br, 18.27. Found: C, 63.40; H, 7.60; Br, 18.56.

Epoxidation of XV

To a solution of 2.00 g of the bromoketal XV in 40 ml of chloroform cooled to −60° was added 47 ml of a 0.192 *M* solution of monoperphthalic acid in ether over a period of 20 minutes. After it had been stirred at −60° for 2 hours, the mixture was kept overnight at 0°, washed with 5% sodium carbonate solution and with water, dried over magnesium sulphate, and the solvent was removed. The crude product was chromatographed in benzene on 60 g of Florisil. Elution with benzene containing 2% ether gave the *5β,6β-epoxide* XVI, which was crystallized from methanol, yielding 0.70 g, m.p. 119–120°. Recrystallization from methanol gave an analytical sample, m.p. 120–121°, $[\alpha]_D$ −38.4°. Anal. Calc. for $C_{23}H_{33}BrO_4$: C, 60.92; H, 7.33; Br, 17.63. Found: C, 60.69; H, 7.23; Br, 17.74.

The *5α,6α-epoxide* XVII was obtained by elution of the column with benzene containing 10% ether. Crystallization from methanol gave 0.69 g of XVII, m.p. 180–182°. The analytical sample, obtained by recrystallization from methanol, had m.p. 182–183°,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$[\alpha]_D$ −88.4°. Anal. Calc. for $C_{23}H_{33}BrO_4$: C, 60.92; H, 7.33; Br, 17.63. Found: C, 60.72; H, 7.25; Br; 17.62.

3β-Acetoxy-5α-hydroxy-6β-chloropregnan-20-one (XX)

Hydrogen chloride was passed for 1 hour through a solution of 122 g of 3β-acetoxy-5α,6α-epoxypregnan-20-one (XIX) (18, 19) in 1 liter of chloroform. After an additional hour at room temperature, the solution was washed with water, 10% sodium bicarbonate solution, and water again, and dried over sodium sulphate. Removal of the solvent and crystallization from methylene chloride – methanol yielded two crops of XVI totalling 101 g, m.p. 230–233° decomp. Recrystallization from the same solvent combination raised the m.p. to 232–234° decomp., $[\alpha]_D$ +8.1°. Anal. Calc. for $C_{23}H_{35}ClO_4$: C, 67.22; H, 8.58; Cl, 8.63. Found: C, 67.41; H, 8.49; Cl, 8.67.

3β-Acetoxy-5α-hydroxy-6β-chloro-17α-bromopregnan-20-one (XXI, R = Ac)

A suspension of 101 g of the chlorohydrin XX and 101 g of N-bromosuccinimide in 2.6 liters of carbon tetrachloride was heated to the boiling point and irradiated with two 250-watt heat lamps for 15 minutes. The mixture was then cooled in ice and filtered, and the filtrate was washed with 5% sodium bisulphite solution, 10% sodium bicarbonate solution, and water. Drying over sodium sulphate and evaporation of the solvent *in vacuo* gave a crude product, which, on crystallization from aqueous methanol, yielded 80 g of XXI (R = Ac), m.p. 188–190° decomp. The analytical sample, m.p. 190–191° decomp., $[\alpha]_D$ −66.1, was obtained by recrystallization from aqueous methanol. Anal. Calc. for $C_{23}H_{34}BrClO_4$: C, 56.39; H, 7.00. Found: C, 56.10; H, 6.92.

3β,5α-Dihydroxy-6β-chloro-17α-bromopregnan-20-one (XXI, R = H)

Eighty grams of the acetate XXI (R = Ac) was dissolved in 2 l. of methanol by warming and 50 ml of 70% perchloric acid was added. The solution was left overnight at room temperature and the product was then precipitated by the addition of 1 liter of water. The yield of diol XXI (R = H) was 54 g, m.p. 175° decomp. After recrystallization from acetone–hexane, the diol melted at 175.5° decomp., $[\alpha]_D$ −70.7°, but it did not give a satisfactory analysis. Anal. Calc. for $C_{21}H_{32}BrClO_3$: C, 56.31; H, 7.20. Found: C, 56.94; H, 7.00.

5α-Hydroxy-6β-chloro-17α-bromopregnane-3,20-dione (XXII)

To a solution of 51.5 g of diol XXI (R = H) in 515 ml of acetic acid was added a solution of 25.75 g of sodium dichromate in 515 ml of acetic acid. The mixture was left for 4 hours at room temperature, 2 liters of water was added, and the precipitated solid was filtered and washed with water. The yield of diketone XXII was 42 g, m.p. 188–190° decomp. The analytical sample, m.p. 190° decomp., $[\alpha]_D$ −62.2°, was obtained by recrystallization from *i*-propanol. Anal. Calc. for $C_{21}H_{30}BrClO_3$: C, 56.57; H, 6.78. Found: C, 56.58; H, 6.75.

6α-Chloro-17α-bromoprogesterone (XVIII)

A. From the Epoxyketal XVII

Hydrogen chloride was passed for 1 hour through a solution of 1.3 g of XVII in 30 ml of chloroform. After it had been allowed to stand an additional hour, the solution was washed with water, with 5% sodium carbonate solution, and with water again and dried over magnesium sulphate. The product obtained on evaporation of the solvent was crystallized from acetone–hexane, yielding 0.98 g of 6α-chloro-17α-bromo-4-pregnene-3,20-dione (XVIII), m.p. 156–157°. Recrystallization from the same solvent mixture gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

an analytical sample, m.p. 157–158°, $[\alpha]_D$ +6.5°, λ_{max} 237 mμ (ε 16,200). Anal. Calc. for $C_{21}H_{28}BrClO_2$: C, 58.96; H, 6.60. Found: C, 59.02; H, 6.40.

B. From the Hydroxyketone XXII

An ice-cooled suspension of 3.0 g of XXII in 75 ml of chloroform was treated with hydrogen chloride for 1 hour, and, after an additional hour, the product was isolated as in *A*. Crystallization from acetone–hexane yielded 2.3 g of XVIII, m.p. 152–153°, identical by mixed m.p. and infrared spectrum with the product obtained in *A*.

ACKNOWLEDGMENTS

We wish to acknowledge the valuable technical assistance of T. F. Muther and J. Blackwell. We are indebted to Drs. C. Revesz and C. I. Chappel for the biological data, to Mr. M. Boulerice for the ultraviolet spectra, and to Dr. G. Papineau-Couture and Mrs. J. Jachner for numerous infrared spectra.

SOME DEUTERIUM KINETIC ISOTOPE EFFECTS

II. α-DEUTERIUM EFFECTS IN THE WATER SOLVOLYSIS OF SOME ALKYL COMPOUNDS[1]

K. T. LEFFEK,[2] J. A. LLEWELLYN,[2] AND R. E. ROBERTSON

ABSTRACT

As an extension of previous work on methyl compounds, α-deuterium kinetic effects have been measured for ethyl, *n*-propyl, and isopropyl compounds. The effects can be accounted for in terms of current theory but a modification involving intramolecular van der Waals forces seems to provide a more satisfactory description of some of the processes involved in the production of the rate changes.

INTRODUCTION

When deuterium is substituted for a protium in compounds undergoing nucleophilic substitution reactions, the kinetic isotope effects (measured as the rate ratio k_H/k_D) may be greater or less than unity, i.e. deuteration may produce an increase or a decrease in rate of reaction (1). The reaction which we have studied is a simple hydrolysis in water symbolized by

$$RX + H_2O \rightarrow ROH + H^+ + X^-$$

where X, the leaving group, may be bromine, iodine, benzenesulphonate, substituted benzenesulphonate, or methanesulphonate. Earlier studies on a series of methyl compounds showed that increased reaction velocities were characteristic of the heavy analogues (2) but in this extension of that work we find effects in both directions when more complicated molecules are examined. The reaction rates were determined conductimetrically and the Guggenheim analysis (3) applied to the data to give pseudo-first order rate constants; the experimental techniques have been described in more detail elsewhere (4). Rate data are given in Table I. Several of the light analogues of the compounds examined in this investigation had already been studied and our current measurements are in excellent agreement with this data previously determined in this laboratory.

TABLE I

Deuterium isotope effect for more complicated compounds hydrolyzing in water

Compound	Solvolysis rates: Protium compound (k_1 sec^{-1})	Solvolysis rates: α-Deuterated compound (k_1 sec^{-1})	T (°C)	k_H/k_D
Ethyl *p*-toluenesulphonate	1.998×10^{-4}	1.925×10^{-4}	54.285	1.03_8
Ethyl methanesulphonate	1.957×10^{-4}	1.888×10^{-4}	60.003	1.03_7
Ethyl bromide	2.722×10^{-4}	2.769×10^{-4}	80.001	0.98_3
Ethyl iodide	1.554×10^{-4}	1.625×10^{-4}	80.000	0.96_6
Isopropyl *p*-toluenesulphonate	7.664×10^{-4}	6.757×10^{-4}	30.001	1.13_4
Isopropyl methanesulphonate	3.690×10^{-4}	3.229×10^{-4}	29.999	1.14_3
Isopropyl bromide	3.493×10^{-4}	3.269×10^{-4}	59.998	1.06_9
Isopropyl iodide	3.115×10^{-4}	2.967×10^{-4}	59.996	1.05_0
n-Propyl benzenesulphonate	2.042×10^{-4}	1.974×10^{-4}	54.192	1.03_4
n-Propyl methanesulphonate	1.370×10^{-4}	1.322×10^{-4}	60.004	1.03_6
n-Propyl bromide	1.629×10^{-4}	1.663×10^{-4}	80.009	0.98_0
n-Propyl iodide	2.230×10^{-4}	2.217×10^{-4}	90.003	1.00_6

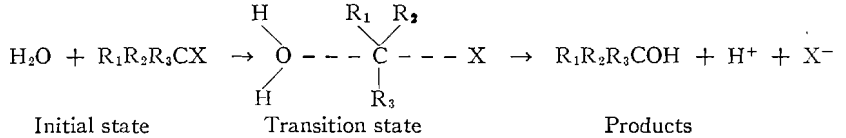
DISCUSSION



The general theory advanced for the α-deuterium effects observed with methyl compounds involved two opposing changes, both of which affected the frequencies of the fundamental modes of vibration and hence the activation energy via zero-point energy changes. It was postulated that:[3]

(A) The change in hybridization of the reacting carbon atom (sp^3 initially, sp^2 in the transition state) produced zero-point energy changes in a direction which tended to make the heavy compound react more slowly.

(B) The relative positions of entering and leaving groups will affect the ease with which the α-C—H bonds may be bent. Where crowding of the C—H bond is pronounced, fundamental modes involving C—H deformations in an important way will have higher characteristic frequencies, and the resulting zero-point changes might exceed those from factor A. In consequence the net effect would then be a more rapid reaction of the heavy compound.

If the transition state of reaction is more crowded than the initial state, then deuteration might be expected to produce an increased rate of reaction as a consequence of dominance by factor B. Such a situation would prevail where a high degree of nucleophilic assistance was required for reaction, as with the methyl halides, and the expected decrease in effect is observed as the interaction by the entering group is decreased by "better" leaving groups. As we alter the alkyl grouping by alpha methylation, nucleophilic assistance becomes less necessary and the crowding in the transition state (factor B) fades out. Eventually, factor A gives rise to an isotope effect (k_H/k_D) greater than unity. For a given alkyl group, similar changes with reversal of effect may be seen as the X group is varied.

Deutero-*n*-propyl bromide reacts more quickly than its light analogue ($k_H/k_D = 0.98_0$) whereas *n*-propyl methanesulphonate reacts more slowly when deuterated ($k_H/k_D = 1.03_6$). Again this change in the deuterium isotope effect is attributed to a more crowded transition state in the bromide reaction where nucleophilic interaction is greater than in the methanesulphonate reaction. For other alkyl groups the changes are parallel; the alpha-deuterium isotope effect increases as the transition state becomes less crowded, e.g. the rate ratios k_H/k_D for ethyl iodide, bromide, and methanesulphonate are 0.95_6, 0.98_3, and 1.03_7 respectively. In addition to these effects there is a third which is a simple consequence of the mass alteration produced by isotopic substitution. The thermodynamic properties of the molecules depend on the masses of the constituent atoms so that independently of zero-point effects there may be a "thermodynamic" isotope effect. It is difficult to state in a general way exactly what the consequences of isotope substitution will be on the contributions to the thermodynamic parameters from the various degrees of freedom. Some obvious expressions were given in an earlier paper on the methyl compounds (2), but calculations for more complicated molecules are frequently difficult and often impossible because of lack of information. Some general comments can be made, however. For reactions such as these where two molecules become partially bonded on passing to the

[3]*The suggestions concerning altered hybridization and modification of the effect by leaving group were first suggested by Streitwieser and co-workers (see ref. 8) and extended by us (ref. 2) to cover inverse isotope effects.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

transition state, then the effect of substitution with a heavier isotope on the translational contribution will always be in a direction such that k_H/k_D tends to exceed unity. For α-deuteration, a substitution close to reaction site, the center of gravity of the molecule will be brought closer to the point at which mass increase from reaction occurs, and the rotational entropy of activation will accordingly decrease, i.e. k_H/k_D tends to exceed unity. It seems reasonable to neglect changes in the vibrational contribution in this context, by comparison with the zero-point energy changes which will arise from the same source. Detailed calculations have been made in cases where it has been practical (2, 5) and the general conclusion is that the "thermodynamic" effect favors slower reaction for the heavy compound and is of a magnitude which is comparable with observed effects in some cases, but cannot account for inverse isotope effects.

Further Considerations

Interpretation in terms of factor A, the hybridization change, and B, crowding by the entering group, seemed reasonably satisfactory and led to a self-consistent scheme for the α-deuterium kinetic isotope effects. There are some aspects of factor A, however, which seem doubtful: the intermediate in an S_N1 reaction will be the carbonium ion so that the transition state will probably not have completely altered hybridization of the reacting carbon, and the more the molecule can accommodate the developing charge by internal stabilization the nearer will be the configuration to tetrahedral in the transition state (6). In an S_N2 reaction, however, the hybridization change will probably be complete in the transition state with the entering and leaving groups interacting with the p orbital and the C—H bonds sp^2 hybridized (7). Thus hybridization change will be most marked in S_N2 reactions although zero-point effects will be modified by the presence of the entering group. It seems that the hybridization change is a necessary part of the reaction but is not necessarily responsible for the decrease in zero-point sum which plays such an important part in our considerations of the α-isotope effect. The difficulty in connection with this latter point is well illustrated by Streitwieser's comment on the effect of assuming different models for the sp^2 C—H bond (8). Making the usual reservations concerning the comparison of force constants we can find (9) wide overlapping ranges of force constants for sp^2 and sp^3 bonds. Some of the confusion is undoubtedly the consequence of the application of varying force fields in the spectral analysis but some consistency does appear when similar treatments are applied; for example Table II shows an increase in stretching

TABLE II

Effect of bond type on C—H force constant (13)

System	Bond	Constant $\times 10^{-5}$ dyne/cm

CH_4	sp^3	4.79
C_2H_4	sp^2	5.1
C_2H_2	sp	5.85

force constant with increased s character in the C—H bond, which contradicts the hypothesis A set up to explain the α-deuterium isotope effect.

The bending constants appear to change in the opposite direction. Using simple valence force fields, Linnett (10) quotes the bending constants given below. In contrast, using orbital valence force fields to analyze CH_4 spectra, C—H bond bending has a

TABLE III
S.V.F.F. bending constants

System	Bending constant (erg/radian^2×10^{11})
C—C$\diagup^{H}$	0.66
C=C$\diagup^{H}$	0.60
C≡C$\diagup^{H}$	0.24

constant 1.35×10^5 dyne/cm for doubly degenerate vibrations and 0.86×10^5 dyne/cm for triply degenerate vibrations whereas a comparable figure for ethylene is 0.95×10^5 and between 1.03 and 1.09×10^5 for formaldehyde, depending on the exact dimensions of the molecule which are taken in the analysis (10, 12). Thus the evidence that a hybridization change $sp^3 \rightarrow sp^2$ does produce the proposed zero-point change appears to be inconclusive. It is possible that the decrease in frequency springs from other sources, and one in particular seems worth considering.

Examination of vibrational spectra has shown that they may be satisfactorily accounted for by including potential energy terms for non-bonded atomic interactions comparable with those for intermolecular repulsions (10, 12–16). In molecules of the type XY_3, XY_4, XY_6, non-bonded interactions must be taken into account when considering molecular distortions. CH_4 could be treated neglecting H . . . H repulsion; it was assumed negligible in treatments of C_2H_4 and HCHO with some reservations, and it was found necessary to include H . . . O and H . . . C repulsion using a function $v = a/R^{12}$. Simanouti (17–19) has also successfully analyzed the vibrational spectra of numerous XABCD compounds using valence force field plus non-bonded interatomic repulsion terms of magnitude comparable to those used by Lennard-Jones to describe rare gas interatomic forces. Encouraging results have also attended correlations of molecular geometry with simple hard-sphere potential energy functions for non-bonded intramolecular interactions (20). In the reactions that we have studied, there is a movement of the X group away from the reaction center so that a reduction in intramolecular forces between this group and the α-hydrogen atoms might be expected. The magnitude of the change will depend on the increase in the H(α)—X distance and the degree of charge separation that has occurred, but will undoubtedly produce a significant decrease in the force field that governs vibrations involving the C—H bonds. It is postulated, therefore, that the increased H(α)—X distance in the transition state produces a decrease in the zero-point sum as a consequence of reduced intramolecular van der Waals forces. This postulate is really an extension of factor B in the earlier argument and the α-isotope effect now appears to be governed largely by steric effects. Obviously it is difficult to separate this possibility from that of altered hybridization but the proposed consequences of the $sp^3 \rightarrow sp^2$ hybridization change are not evident, whereas a zero-point decrease seems inevitable when non-bonded atomic interactions are reduced.

On this basis of varying intramolecular van der Waals forces it appears that the α-isotope effect can still be interpreted as a measure of the crowding about the carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

atom which forms the reaction center. For entering and leaving groups of comparable sizes in different reactions k_H/k_D is interpreted as a measure of the extent to which bond-making and bond-breaking have occurred, with smaller ratios indicating predominance of bond-making processes and larger ratios indicating bond-breaking. Thus the alternative postulate does not materially alter the conclusions which were drawn from the observed effects but appears to offer a more satisfactory explanation of some of the changes involved in their production than does the original postulate concerning altered hybridization (8). This is not to say that the hybridization change does not occur; on the contrary it forms a very vital part of ideas on the nature of these reactions, but does say that the zero-point decrease is not an immediate and obvious consequence of the change.

EXPERIMENTAL

Ethyl-αd_2 alcohol (minimum 98% isotopic purity) supplied by Merck and Co. Ltd. was converted to ethyl-1d_2 *p*-toluenesulphonate by the method of Tipson (21). The crude product was distilled under vacuum; m.p. 30.0° C (uncorrected). A comparison of the nuclear magnetic resonance (N.M.R.) spectrum of this compound with that of an undeuterated sample indicated that the alpha carbon atom was fully deuterated.

Ethyl-αd_2 bromide and ethyl-αd_2 iodide were prepared by heating, to 50° C under a vacuum, ethyl-αd_2 *p*-toluenesulphonate with a 3-mole excess of the appropriate potassium halide in the presence of a small amount of triethylene glycol. The ethyl halide evolved was collected in a trap cooled with liquid N_2 and redistilled at reduced pressure.

Ethyl-αd_2 methanesulphonate was made by shaking, at room temperature for ca. 100 hours, an equimolar solution of ethyl-αd_2 bromide and silver methanesulphonate in acetonitrile. The precipitated silver bromide was removed by filtration and the remaining solution evaporated to dryness at reduced pressure. The residue was extracted with anhydrous ether and, after removal of the ether, the product was distilled under a vacuum. It is considered extremely unlikely that any deuterium exchange could take place during the conversion of the deuterated alkyl *p*-toluenesulphonates to the corresponding alkyl halides and methanesulphonates, for the alkyl groups which we have studied (24). The kinetic purity of the compound was verified by the straight-line kinetic plots which were obtained in all cases. With the techniques which have been developed in this laboratory this test has repeatedly proved to be more sensitive than the normal methods of analysis.

The reduction of acetone with lithium aluminum deuteride (minimum 97.4% isotopic purity) yielded isopropyl-αd alcohol. The reaction was carried out by the standard method, modified by the use of diethylene glycol diethyl ether as solvent and diethylene glycol monobutyl ether as the reagent to decompose the complex aluminum compounds (22, 23). The crude isopropyl-αd alcohol, recovered from the reaction mixture by a simple distillation, was redistilled; boiling range 83.5–85.0° C, $n_D^{22.5} = 1.3762$ (lit. $n_D^{20} = 1.3773$). The N.M.R. spectrum indicated that the alpha carbon atom was fully deuterated.

Isopropyl-αd *p*-toluenesulphonate, bromide, iodide, and methanesulphonate were prepared by a series of reactions analogous to that employed for the ethyl compounds.

n-Propyl-αd_2 bromide (minimum 98% isotopic purity) was purchased from Merck and Co. Ltd. The N.M.R. spectrum showed that the alpha carbon atom was ca. 90% deuterated. This bromide was converted into *n*-propyl-αd_2 benzenesulphonate and methanesulphonate by the silver sulphonate method as described for the ethyl compounds. The iodide was prepared from the benzenesulphonate and potassium iodide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

For each of the above preparations a parallel reaction was carried out with undeuterated compounds. The products were used to check the rate constants of the protium compounds which had been determined in the course of previous work under the same conditions. Good agreement was obtained in all cases.

ACKNOWLEDGMENTS

We are indebted to Mr. S. E. Sugamori for his skillful measurements of rate constants and would like to acknowledge discussion of synthetic methods with Dr. L. C. Leitch and the help of Dr. W. Raynes with the N.M.R. spectra.

ISOLATION AND PROPERTIES OF A GLUCOMANNAN FROM THE WOOD OF RED MAPLE (ACER RUBRUM L.)[1]

A. JABBAR MIAN AND T. E. TIMELL

ABSTRACT

A glucomannan has been isolated from the wood of red maple (*Acer rubrum* L.) in a yield corresponding to 92% of the mannose residues in this wood and with a ratio of mannose to glucose of 2:1. Partial hydrolysis of the polysaccharide yielded 4-*O*-β-D-mannopyranosyl-D-mannose, 4-*O*-β-D-mannopyranosyl-D-glucose, 4-*O*-β-D-glucopyranosyl-D-mannose, 4-*O*-β-D-glucopyranosyl-D-glucose, and *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose. The methylated glucomannan on hydrolysis gave a mixture of di-*O*-methylhexoses, 2,3,6-tri-*O*-methyl-D-mannose, 2,3,6-tri-*O*-methyl-D-glucose, and 2,3,4,6-tetra-*O*-methyl-D-glucose in a mole ratio of 7:29:13:1. The methylated polysaccharide contained 55 hexose residues per average molecule, while the corresponding value for the nitrate derivative was 67. It is concluded that the glucomannan is composed of a minimum of 70 glucose and mannose residues linked together by (1 → 4)-β-glycosidic bonds to linear molecules. The glucose residues are probably interposed between two or three contiguous mannose residues.

In the last few years, glucomannans have been isolated from the wood of many gymnosperms, where this polysaccharide constitutes the preponderant hemicellulose. Little attention has so far been directed towards the origin of the relatively few mannose residues present in the wood of the arborescent angiosperms. A glucomannan has been isolated from trembling aspen (1) and similar polysaccharides have been obtained also from red alder and from madrona (2). The isolation of a glucomannan from white birch was recently reported (3). This paper is concerned with the isolation of a glucomannan from red maple (*Acer rubrum* L.) and with the properties of this diheteroglycan.

RESULTS AND DISCUSSION

Red maple wood, containing 2.4% mannose residues, was delignified with acid chlorite (4) to give a holocellulose in a yield closely corresponding to the lignin content of the wood. The holocellulose was exhaustively extracted with 24% potassium hydroxide, which removed a pure methylglucuronoxylan. Subsequent extraction with sodium hydroxide – borate (5, 6) gave a mixture containing mannose and glucose residues in a ratio of 1.34:1 in addition to 14% of xylose. One treatment with barium hydroxide (7) removed the xylose containing polysaccharide and increased the above ratio to 1.94:1. The crude and purified products contained 95% and 92%, respectively, of the mannose residues originally present in the wood.

The pure glucomannan, $[\alpha]_D$ −31°, was a white powder, insoluble in water. When oxidized with periodate, it consumed 1.0 mole of oxidant per hexose residue. The number-average molecular weight of the nitrate derivative as determined by osmometry (8) was 18,200, corresponding to a degree of polymerization of 67. Boundary electrophoresis according to Tiselius (9) indicated that the polysaccharide was chemically homogeneous.

A portion of the glucomannan was partially hydrolyzed with aqueous formic acid to give a mixture of sugars which was resolved on a charcoal–Celite (10) column by gradient (11) elution with aqueous ethanol (12). The sugars obtained included D-mannose, 4-*O*-β-D-mannopyranosyl-D-mannose, 4-*O*-β-D-mannopyranosyl-D-glucose, 4-*O*-β-D-glucopyranosyl-D-mannose, 4-*O*-β-D-glucopyranosyl-D-glucose, and *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose. Mannobiose and glucosyl mannose

[1]*Manuscript received May 20, 1960.*
Contribution from the Pulp and Paper Research Institute of Canada and the Department of Chemistry, McGill University, Montreal, Que.

were isolated in the highest, cellobiose in the lowest, yield. Two tetraose compounds were also obtained crystalline, containing both glucose and mannose residues.

Another portion of the glucomannan was methylated to completion and subsequently hydrolyzed to a mixture of sugars which was resolved on a charcoal–Celite column. A mixture of di-*O*-methylhexoses, 2,3,6-tri-*O*-methyl-D-mannose, 2,3,6-tri-*O*-methyl-D-glucose, and 2,3,4,6-tetra-*O*-methyl-D-glucose was obtained in a mole ratio of 7:29:13:1. The tri-*O*-methylmannose was identified through its characteristic 1,4-di-*p*-nitrobenzoate derivative (13) and the tri- and tetra-*O*-methylglucoses crystallized. The methylated glucomannan contained 55 hexose residues per average molecule as estimated by osmometry.

From the above evidence a tentative structure can now be assigned to the glucomannan present in red maple wood. The large quantity of 2,3,6-tri-*O*-methylhexoses shows that the polysaccharide is composed of (1 → 4)-linked hexose residues and this conclusion is corroborated by the consumption of 1 mole of periodate per hexose residue. The negative rotation of the glucomannan suggests that the linkage is of the β-type. The isolation of 2,3,4,6-tetra-*O*-methyl-D-glucose indicates that most of the non-reducing end groups consist of glucose residues, one such end group being present per 50 anhydrohexose units. Since the average molecule contained 55 hexose residues, the glucomannan contained few, if any, branching points. The occurrence of the di-*O*-methylhexoses was probably due to demethylation during methanolysis and hydrolysis.

The above conclusions were corroborated by the nature of the oligosaccharides formed on partial hydrolysis of the glucomannan. The high yield of mannobiose and mannotriose as compared to the low yield of cellobiose suggests that few of the glucose residues were contiguous. Relatively more glucosyl mannose and more mannosyl glucose were isolated than have previously been obtained from softwood glucomannans (14–16). This is to be expected in view of the lower ratio of mannose to glucose in hardwood as compared with softwood glucomannans. Similarly, mannose has been found to form most of the non-reducing end groups in glucomannans from gymnosperms (16–21), while both the present glucomannan and a similar polysaccharide from white birch wood (22) seem to contain more glucose than mannose end groups.

The glucomannan contained approximately 70 hexose residues per average molecule. This value might not represent the molecular magnitude of the native polymer since acid chlorite was used to delignify the wood (23).

The present polysaccharide is the first representative hardwood glucomannan whose structure has been determined in detail, and direct comparison with other glucomannans of similar origin is therefore not possible. Methylation studies of the glucomannan previously isolated from aspen wood (1) indicated the presence of a (1 → 4)-linked polysaccharide with a ratio between glucose and mannose of 1:2. A glucomannan from western red alder (2) has been reported to contain glucose and mannose in a ratio of 1:1.5. For a birch glucomannan (3) this ratio was 1:1.1. Subsequent investigations of other hardwood glucomannans (24) have shown that while the ratio of mannose to glucose is close to 1.0 for birches, most other hardwoods exhibit a ratio of 1.5–2.

Glucomannans from gymnosperms usually contain approximately three times as many mannose as glucose residues. The glucomannans present in arborescent angiosperms appear to have a higher relative content of anhydroglucose units. Apart from this discrepancy, there seem to be few differences between hardwood and softwood glucomannans. Both types of polysaccharides consist of essentially linear macromolecules composed of 100–200 (1 → 4)-linked β-D-hexose residues, probably with many of the glucose residues interposed as single units between several contiguous mannose residues. Relative sugar

composition and relative abundance are therefore the only two respects in which softwood and hardwood glucomannans differ in any essential way.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated and were determined at 20° C. Melting points are corrected. Evaporations were carried out *in vacuo* at 40–50° C.

Paper Chromatography

Solvent systems used for separating sugars were (v/v): (A) ethyl acetate – acetic acid – water (9:2:2), (B) butan-1-ol–pyridine–water (10:3:3), and (C) butanone–water (89:11). Whatman No. 1 filter paper and the descending technique were used. Paper electrophoresis was carried out with Whatman No. 3 MM filter paper in 0.05 *M* borate buffer at 750 volts. The spray reagent was *o*-aminodiphenyl (25).

Wood

Logs from a freshly cut red maple were barked, chipped, and converted to sawdust. The 20–80 mesh fractions were exhaustively extracted with ethanol–benzene (1:2 v/v), extracted with cold water, and dried in the air. The following data were obtained by standard analytical procedures: cellulose (44.1%), lignin (24.0%), ash (0.2%), acetyl (3.8%), uronic anhydride (3.5%), residues of galactose (0.6%), glucose (46.6%), mannose (2.4%), arabinose (0.5%), and xylose (14.8%).

Isolation of a Crude Glucomannan

Extractive-free wood meal (1080 g) was suspended with stirring in water (18 liters) at 70–80° C. Acetic acid (120 ml) and sodium chlorite (360 g) were added every hour for a total period of 7 hours (4). The reaction mixture was cooled, and the solids were washed by decantation with tap water. They were then transferred to a filter and washed with distilled water and ethanol. The white product was dried in the air to yield 840 g of holocellulose, 76% of the wood.

The holocellulose (840 g) was shaken in an atmosphere of nitrogen with 24% (w/w) aqueous potassium hydroxide (6 liters) at room temperature for 3 hours. The alkaline extract was removed by filtration through fritted glass and the residue was washed with water. The still wet residue was extracted in the same way with 17.5% sodium hydroxide to which 4% boric acid had been added (5, 6). The alkaline extracts and washings (8 liters) were poured into ethanol (30 liters) containing glacial acetic acid (3 liters). The precipitate formed was washed on the centrifuge with 80% aqueous ethanol, ethanol, and petroleum ether (b.p. 30–60° C), yielding a white powder (40.0 g). Sugar residues in the potassium hydroxide extract were xylose and uronic acids, in the alpha-cellulose (unextracted residue) glucose and traces of xylose. The alkaline borate extract (the crude glucomannan) contained mannose and glucose in a ratio of 1.31:1 and 14% xylose residues.

Purification of the Crude Glucomannan

Crude glucomannan (40 g) was dissolved in 10% sodium hydroxide (1 liter) and 5% aqueous barium hydroxide (2 liters) was added with constant stirring over a period of 2 hours. The precipitate formed was collected by centrifuging, washed twice with water, acidified with acetic acid, and poured into ethanol (5 liters). The precipitate was recovered in the usual way (35 g, 3.3% of the wood). Mannose/glucose: 1.94. Xylose: nil. $[\alpha]_D$ $-31°$ (*c*, 1.0 in 10% sodium hydroxide).

Partial Hydrolysis of the Glucomannan

Glucomannan (9.7 g) was dissolved in 90% formic acid (50 ml). Water (50 ml) was added and the solution was heated to 95–97° C for 3 hours (14). After cooling, the clear solution was removed by decantation and the solid residue was again hydrolyzed. This treatment was repeated twice. The solutions were combined and the formic acid was removed by evaporation with water. Formate esters were hydrolyzed with 0.5 *N* sulphuric acid at 100° for 10 minutes (100 ml). After neutralization with barium carbonate, filtration through Celite, and treatment with Amberlite IR-120 exchange resin, evaporation gave a clear sirup (7.5 g). Paper chromatography (solvents A and B) indicated the presence of hexoses and hexose oligosaccharides.

Resolution of the Hydrolyzate

The partial hydrolyzate (7.5 g) was dissolved in water (50 ml) and added to the top of a Darco G-60 – Celite column (10) (6×64 cm). Gradient elution (11) was carried out with 3 liters each of the following solvents: 2% aqueous ethanol → 10% ethanol, 10% ethanol → 20% ethanol, and 20% ethanol → 40% ethanol. Fractions, 25 ml each, were collected at an average rate of two per hour and the sugar content of every third fraction was estimated by paper chromatography (solvent B).

Identification of Sugars

All sugars moved on the paper chromatogram (solvents A and B) at the same rate as authentic specimens.

(1) Monosaccharides

Following a mixture of glucose and mannose with a trace of xylose (1.45 g), pure D-mannose (1.82 g) was eluted from the column, m.p. and mixed m.p. 132° C, $[\alpha]_D$ +12.8° (*c*, 2.3 in water). The mannose phenylhydrazone had a melting point and mixed melting point of 194° C.

(2) 4-O-β-D-Mannopyranosyl-D-mannose

Hydrolysis of this compound (790 mg) gave only mannose. The mannobiose, after recrystallization from methanol, had a melting point and mixed melting point of 200–201° C, $[\alpha]_D$ −8.5° (*c*, 1.0 in water).

(3) 4-O-β-D-Mannopyranosyl-D-glucose

Hydrolysis of this fraction (193 mg) gave equal amounts of mannose and glucose. After reduction with sodium borohydride, mannose only was obtained on hydrolysis. The compound, $[\alpha]_D$ +27° (*c*, 1.5 in water), could not be induced to crystallize, nor could the derived octaacetate derivative be obtained in crystalline form.

(4) O-β-D-Mannopyranosyl-(1 → 4)-O-β-D-mannopyranosyl-(1 → 4)-D-mannose

This fraction (171 mg) readily crystallized from methanol containing some water and butan-1-ol, m.p. and mixed m.p. 230–232° C, $[\alpha]_D$ −25° (*c*, 1.3 in water). Partial hydrolysis followed by examination by paper chromatography suggested the presence of unchanged mannotriose, mannobiose, and mannose. Complete hydrolysis gave mannose.

(5) 4-O-β-D-Glucopyranosyl-D-glucose

This disaccharide (30 mg) on recrystallization from aqueous methanol had melting point and mixed melting point 226–227° C, $[\alpha]_D$ +24° (*c*, 1.0 in water). Complete hydrolysis gave only glucose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(6) 4-O-β-D-Glucopyranosyl-D-mannose

The disaccharide (663 mg) on hydrolysis gave equal amounts of glucose and mannose. The compound, when recrystallized from ethanol, had melting point and mixed melting point 137–138° C, $[\alpha]_D$ +11° → +6° (*c*, 1.0 in water).

(7) Hexotetraose Fraction

This fraction (23 mg) had a melting point of 237–238° C. Partial hydrolysis with formic acid gave glucosyl mannose, glucose, and mannose. The degree of polymerization was estimated as 4.1 (26).

(8) Hexotetraose Fraction

This compound had a melting point of 210–212° C (20 mg). Partial hydrolysis yielded a hexotriose, glucosyl mannose, glucose, and mannose. The degree of polymerization was 4.2 (26).

Methylation of the Glucomannan

Glucomannan (13 g) was dissolved in 40% (w/w) aqueous sodium hydroxide in an atmosphere of nitrogen and dimethyl sulphate (250 ml) was added dropwise over a period of 48 hours. This process was repeated three times. Solid sodium hydroxide (200 g) was added, followed by dimethyl sulphate (250 ml). This treatment was repeated six times, water being added whenever necessary for efficient stirring. The reaction mixture was neutralized with sulphuric acid to pH 4 and then heated to boiling. The precipitated polysaccharide was recovered by filtration and washed briefly with hot water. Yield, 7.5 g; OCH_3, 44.3%.

The material (7.0 g) was dissolved in dry dimethyl formamide (150 ml) (27) and treated with methyl iodide (50 ml) and silver oxide (50 g) for 48 hours at room temperature. The polysaccharide was recovered in the usual way (27) to yield 4.9 g of material. The infrared diagram indicated the absence of hydroxyl groups.

Hydrolysis of the Methylated Glucomannan and Resolution of the Hydrolyzate

Methylated glucomannan (3.5 g) was boiled under reflux with 0.7 *N* methanolic hydrogen chloride for 7 hours and subsequently with *N* hydrochloric acid for 7 hours. The solution was neutralized with silver carbonate, filtered through Celite, treated with hydrogen sulphide, again filtered through Celite, and finally evaporated to give a clear sirup (3.1 g). Paper chromatography (solvent C) indicated the presence of di-, tri-, and tetra-*O*-methylhexoses.

The hydrolyzate (3.0 g) was added to the top of a column (5×56 cm) containing a 1:1 mixture of Darco G-60 charcoal and Celite. Gradient elution was effected with 3 liters each of the following solvents: 5% aqueous ethanol → 10% ethanol, 10% ethanol → 30% ethanol, and 30% ethanol → 60% ethanol. The resolution was followed by paper chromatography (solvent C) and, for the tri-*O*-methylhexoses, by measuring the optical rotation of the fractions.

(1) Di-O-methylhexoses

This fraction (290 mg) on demethylation with hydrobromic acid (28) gave glucose and mannose on the paper chromatogram.

(2) 2,3,6-Tri-O-methyl-D-mannose

The sirup (1355 mg), $[\alpha]_D$ −12.5° (*c*, 1.2 in water), was converted to the characteristic di-*p*-nitrobenzoate derivative (13), m.p. and mixed m.p. 186–187° C after recrystallization from ethyl acetate, $[\alpha]_D$ +33° (*c*, 0.5 in chloroform).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(3) 2,3,6-Tri-O-methyl-D-glucose

This compound (640 mg), $[\alpha]_D$ +41° (*c*, 1.3 in water), could not be induced to crystallize. The 2,3,6-tri-*O*-methyl-D-glucose-1,4-di-*p*-nitrobenzoate (13) had melting point and mixed melting point 190° C, $[\alpha]_D$ −33° (*c*, 0.6 in chloroform).

2,3,4,6-Tetra-O-methyl-D-glucose

The last fraction (51 mg), on standing, crystallized. Recrystallization from hot petroleum ether gave melting point and mixed melting point 89–90° C. A portion of the original sirup on demethylation (28) yielded glucose and a trace of mannose. The fraction was thus mainly 2,3,4,6-tetra-*O*-methyl-D-glucose.

Periodate Oxidation of the Glucomannan

The glucomannan (150–200 mg) was oxidized in the dark for various lengths of time with 50.0 ml of 0.05 *M* sodium metaperiodate. Consumption of oxidant was measured by the excess arsenite method. Extrapolation to zero time indicated a consumption of periodate of 1.0 mole per hexose residue.

Determination of Number-Average Molecular Weights

The glucomannan was converted to its nitrate ester as described previously (30, 31). Osmotic pressure measurements were carried out as reported elsewhere (16, 29). The solvent for the methylated glucomannan was a 9:1 (v/v) mixture of chloroform and ethanol, and for the nitrate derivative *n*-butyl acetate. The experimental results are presented in Table I. Number-average molecular weights ($\bar{M}_n$) were calculated from the relationship $\bar{M}_n = 25{,}700/(h/w)_{w=0}$.

TABLE I

Osmometry data

Methylated glucomannan			Nitrated glucomannan

0	—	2.32	0	—	1.41

*Concentration in grams/kilogram of solution.
†Osmotic height in centimeters of solution.

Boundary Electrophoresis

The glucomannan was dissolved to a concentration of 1–2% in a buffer solution containing 7.50 g of boric acid and 4.0 g of sodium hydroxide per liter (30). The instrument was a Spinco Model H apparatus. Only one maximum was observed at various intervals of time, in addition to a stationary salt boundary.

ACKNOWLEDGMENT

The authors wish to express their gratitude to the National Research Council of Canada for financial support.

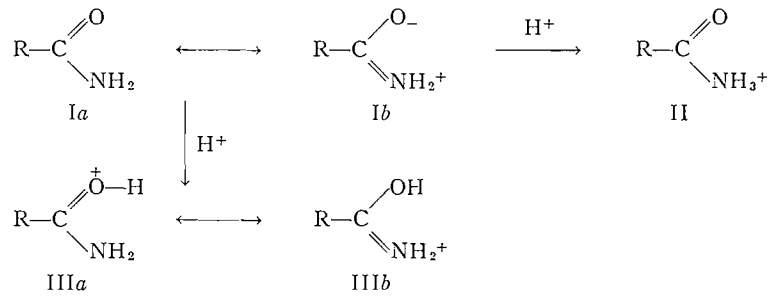
PROTONATION OF THE AMIDE GROUP

I. THE BASICITIES OF SUBSTITUTED BENZAMIDES[1]



J. T. EDWARD,[2] H. S. CHANG,[2] K. YATES,[3] AND ROSS STEWART[3]

ABSTRACT

The basicities of benzamide and of 11 meta- and para-substituted benzamides in sulphuric acid media have been determined by a spectrophotometric method. The pK_{BH^+} values of the protonated benzamides were found to be proportional to the Hammett σ constants for the substituents, unlike the pK_{BH^+} values of the protonated benzaldehydes, acetophenones, and benzoic acids, which are approximately proportional to σ^+ constants. The lack of conjugation between the protonated amide group and the ring, which is indicated by these results, is most easily interpreted in terms of N-protonation although O-protonation cannot be completely excluded. Various other aspects of the problem of N- versus O-protonation are also discussed.

INTRODUCTION

While it has been known for a long time that amides behave as moderately strong Brønsted bases in mineral acids (1), taking up one proton (2, 3), the structure of the ion formed is still debated. Two alternative sites are available for attachment of the proton, the amino nitrogen or the carbonyl oxygen. In 1931 Hantzsch (4) presented evidence for the O-protonated form (III; R = Ph) for benzamide (I; R = Ph) in concentrated

sulphuric acid, by noting the similarity of the ultraviolet absorption spectrum of this solution with that of ethyl benzimidate in acid. The protonated form of the latter compound can only have the structure Ph—C(OEt)=NH_2^+. The later work of Mizushima *et al.*, who studied the ultraviolet absorption of N-methylacetamide in acid, appeared to indicate N-protonation (5), but has not been confirmed (6).

Huisgen and Brade (7) presented arguments in favor of O-protonation based on the orders of basicities of substituted amides. However, their arguments involve several questionable assumptions and cannot be considered conclusive. Further evidence for O-protonation has come from studies of amides in neutral and in acid solution by nuclear magnetic resonance (8, 9, 10, 11, 12). In neutral solution it can be shown that there is a barrier to rotation about the C–N linkage, presumably because of its partial double bond character due to the resonance (I*a* ↔ I*b*). A barrier to rotation is found also for

amides in strong acid, as would be expected for the O-protonated form (III*a* ↔ III*b*), but not for the N-protonated form (II). However, in moderate concentrations of acid, nuclear magnetic resonance (n.m.r.) studies indicate that some N-protonation also occurs, although it has been considered that probably O-protonation predominates (11). This interpretation of the n.m.r. results has been criticized by Spinner (13), who has suggested that they are more in accord with N-protonation.

On theoretical grounds, it has been generally considered (14, 15) that the O-protonated form (III) should be preferred over the N-protonated form (II) because it preserves the resonance stabilization (III*a* ↔ III*b*) characteristic of the amide molecule itself (I*a* ↔ I*b*). Spinner, who has supported the concept of N-protonation (16), has taken the view that π electrons are not delocalized in conjugated systems (17). This idea, which will be unacceptable to many, should not be considered central to the problem. Undoubtedly, ion III possesses much more resonance energy than does ion II. The latter's total energy, however, may still be the lower of the two.

Evidence favoring N-protonation exists in the observed decreases in the N—H and increases in the C=O stretching frequencies in the infrared and Raman region (5, 16, 18, 19, 20). Particularly significant has been the evidence for an N-protonated structure for the urea cation (18), since it has been considered that for this ion the O-protonated structure is, even more than for amide conjugate acids, favored by the possibilities for resonance stabilization (15).*

It is apparent that further evidence on the structure of protonated amides is desirable. In the present paper we report the effect of meta- and para-substitution on the pK_{BH^+} of benzamide. If protonation takes place on the nitrogen, no direct resonance interaction between the charged center and the substituent is possible, and it should be expected that the pK_{BH^+} values should be proportional to σ, Hammett's constant for the substituent (22). On the other hand, if protonation takes place on the oxygen, then (as in the case of substituted acetophenones (23) and benzaldehydes (24)) direct resonance interaction is possible between the substituent and the charged carbonyl group, and one would expect pK_{BH^+} to be proportional to σ^+ (25, 26) or at least to deviate from a linear σ relation. This method has been used to show that carbonyl oxygen protonation occurs in the case of the carboxyl group since the pK_{BH^+} values are approximately proportional to σ^+ (27).

EXPERIMENTAL

Materials

N-Methyl- and N,N-dimethylbenzamide were prepared by the method of Galat and Elion (28) from benzamide and methylamine hydrochloride and from benzamide and dimethylamine hydrochloride respectively. The other amides were commercial products, or were prepared by standard methods from the acids or acid chlorides. N,N-Dimethylbenzamide was obtained as a liquid, b.p. 135°–137° C at 16 mm (lit. b.p. 132°–133° C at 15 mm (29)); its ultraviolet spectrum in water was identical with that found by Ley and Specker (30). The other amides were solids, and were recrystallized from alcohol to constant melting point, which in all cases was close to values reported in the literature. Sulphuric acid of various concentrations was prepared and standardized following methods already described (23, 24).

**The validity of the identification of the carbonyl stretching band in these salts is currently being tested with the use of oxygen-18 labelled compounds (21).*

Procedure

Absorption spectra of the benzamides in water and in various concentrations of sulphuric acid were measured at 25±0.1° according to published methods (23, 24). Solutions in water and in 59–69% acid (see Table I) were used to locate the wavelengths of

maximal absorption of the unprotonated (λ_u) and protonated (λ_l) forms respectively. Distinct maxima were obtained in all cases except for the unionized forms of *m*-chloro- (Fig. 1), *m*-bromo-, *m*-methoxy-, and N-methyl-benzamide, which showed only shoulders on the sides of more intense peaks situated in the vacuum ultraviolet region. In these cases readings of the absorption of the unionized form were taken at several wavelengths in the vicinity of the shoulder, and those wavelengths chosen to represent λ_u which resulted in the smoothest plots of $\epsilon(\lambda_l) - \epsilon(\lambda_u)$ against H_0.

2-Furamide in water had λ_{max} 253 mμ, ϵ_{max} 12,400, and in 59.0% H_2SO_4 λ_{max} 275 mμ, ϵ_{max} 14,900, and was investigated in the same way as the benzamides.

Hydrolysis of the amides was shown to be negligible in the time required for measurements by periodic checks of the measurements of absorption in the acidity range known to give maximal rates of hydrolysis (31). After several hours standing these showed variations of less than 2%.

Calculation of pK_{BH^+} Values

The pK_{BH^+} values were determined by the graphical method of Davis and Geissman (32) as used previously by Stewart and Yates (23, 24), and are listed in Table II for the benzamides; 2-furamide had a pK_{BH^+} of −2.61. *m*-Nitrobenzamide in water showed two well-defined absorption peaks (Fig. 2), and two pK_{BH^+} values were obtained depending on the wavelength chosen for $\epsilon(\lambda_u)$. In the absence of medium effects these values should be identical; the difference between them is a measure of the precision of the

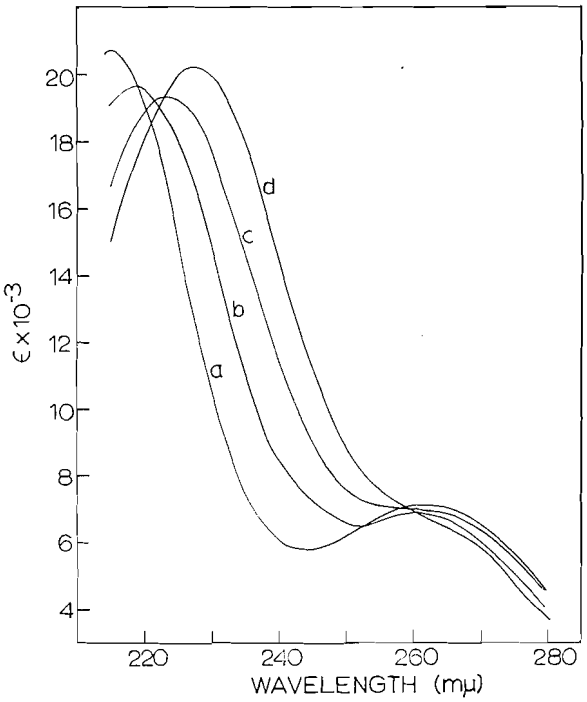

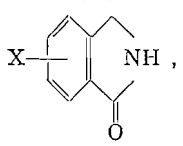

FIG. 2. Absorption spectra of *m*-nitrobenzamide in the following concentrations of aqueous sulphuric acid: *a*, 0%; *b*, 41.0%; *c*, 56.8%; *d*, 60.0%.

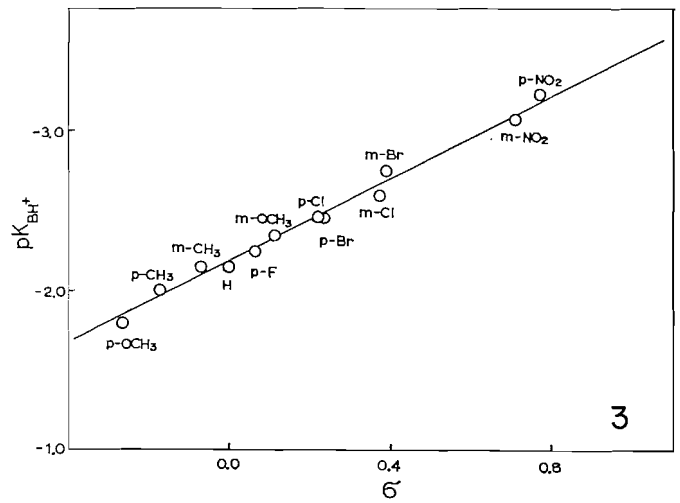
RESULTS AND DISCUSSION

The Basicities of Meta- and Para-Substituted Benzamides



In Figs. 3 and 4 the pK_{BH^+} values of the substituted benzamides are plotted against σ and σ^+ respectively (33). It can be seen that in the first case a good linear relationship is obtained ($r = 0.988$) with the usual precision (34) found for this type of ionization. The value of ρ (by the method of least squares) is 1.30. The correlation of pK_{BH^+} with σ^+ (Fig. 4) is much poorer ($r = 0.958$). The straight line has been drawn with respect to the groups *m*-methyl, *m*-bromo, and hydrogen, since the σ and σ^+ values of these groups are very close. In this case a large deviation is observed for *p*-methoxy, which is able to supply electrons by resonance to the carbonyl group. A correlation with σ^+ can only be attributed to O-protonation. A correlation with σ tells us that para substituents are not in conjugation with the protonated amide group. The most attractive explanation for this is that N-protonation has occurred. It is conceivable, however, that O-protonation has taken place and the lack of conjugation is due to lack of planarity between the ring and the protonated amide group. In other words, the extra resonance stabilization provided by the ring and its substituents might not be sufficient to cause coplanarity.*

**An attempt has been made to eliminate this possibility by examining the phthalimidine series,*

in which coplanarity is enforced. However, the precision in measuring the basicities of phthalimidine ($pK_{BH^+} = -2.1$) and its 6-nitro derivating ($pK_{BH^+} \approx -3.1$) was found to be lower than for the benzamides and further work was not considered worth while (35).

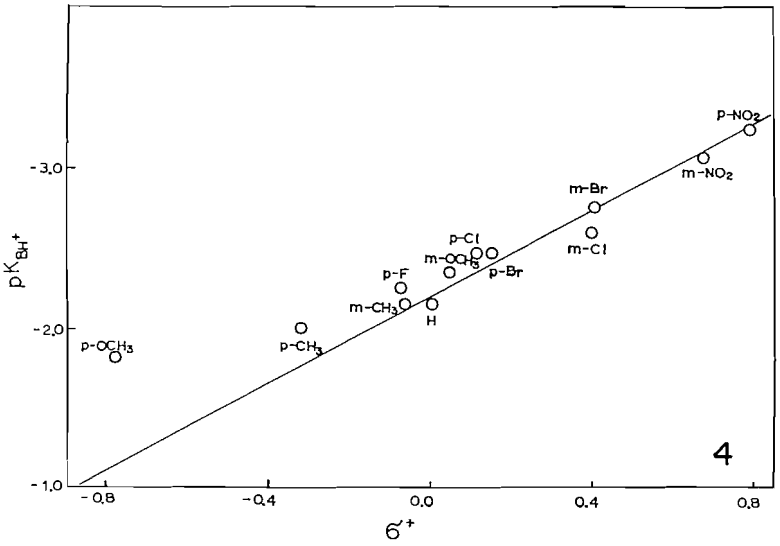

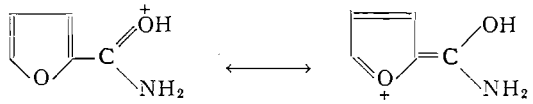

FIG. 3. pK_{BH^+} for substituted benzamides plotted against Hammett's σ constants.
FIG. 4. pK_{BH^+} for substituted benzamides plotted against Brown's σ^+ constants.

The Basicity of Furamide

Furoic acid is a stronger acid ($pK_{HA} = +3.18$) than benzoic acid ($pK_{HA} = +4.20$) (22), the net electron pull due to the inductive and resonance polar effects (36) of the furyl group evidently being greater than that of the phenyl group. This effect would be expected to make furamide a weaker base than benzamide, as is observed, if protonation takes place on the nitrogen and hence only inductive and resonance polar effects operate. In fact, we find that 2-furamide ($pK_{BH^+} = -2.61$) is a considerably weaker base than benzamide ($pK_{BH^+} = -2.15$). On the other hand, if protonation took place on the carbonyl oxygen the direct resonance interaction possible between the ring oxygen and the protonated carbonyl group (IV*a* ↔ IV*b*) would be expected to make furamide the stronger base.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

IV*a* IV*b*

It turns out, in fact, that resonance of this type is not as important as we had expected it to be. This follows from the fact that 2-furoic acid and benzoic acid, both of which, one can assume, protonate at the carbonyl oxygen (27), actually have similar basicities, −7.3 for 2-furoic acid (35) and −7.2 for benzoic acid (27). It appears that the resonance effect is only large enough to cancel approximately the inductive and resonance polar effects. Thus the support for the N-protonated form provided by the furamide basicity cannot be considered unequivocal.

Ultraviolet Spectra of Protonated Benzamides

A comparison of the spectral characteristics of protonated benzamides with those of similarly substituted unprotonated acetophenones in 44.0% sulphuric acid (Table I) shows them to be closely similar, the positions of the absorption maxima in most cases being within 2–3 mμ of each other. The similarity extends to the general shape of the absorption curves, as shown for acetophenone and protonated benzamide in Fig. 5.

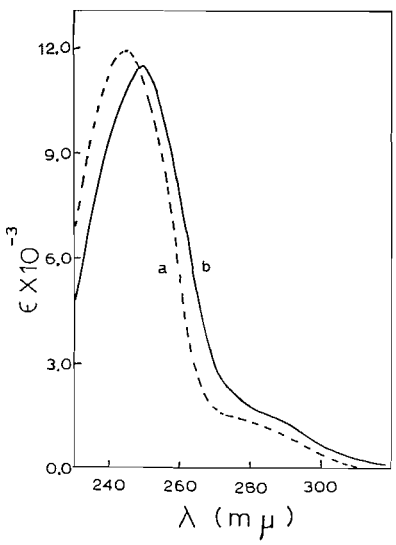

FIG. 5. Absorption spectra of benzamide in 59.3% sulphuric acid (*a*) and of acetophenone in 50% sulphuric acid (*b*). (Latter curve plotted from values from Flexser, Hammett, and Dingwall, J. Am. Chem. Soc. **57**, 2103 (1935).)

The same is true for protonated furamide (in 59.0% H_2SO_4: λ_{max} 275 mμ, ϵ_{max} 14,900), which closely resembles methyl 2-furyl ketone (in H_2O: λ_{max} 275 mμ, ϵ_{max} 13,900 (37)).

These results are to be expected for the N-protonated structures, since it has been observed that replacement of a methyl by an $-NH_3^+$ group has only a minor effect on the ultraviolet spectra of many aromatic compounds (38, 39, 40). It is evident that the absorption characteristics of protonated benzamide are equally compatible with an N- or an O-protonated structure, and are not exclusively in favor of the latter, as Hantzsch (4) assumed.

A RADIOCHEMICAL TECHNIQUE FOR STUDYING RANGE–ENERGY RELATIONSHIPS FOR HEAVY IONS OF KEV ENERGIES IN ALUMINUM[1]

J. A. DAVIES, J. FRIESEN,[2] AND J. D. MCINTYRE[3]

ABSTRACT

A rapid technique has been developed for dissolving successive thin layers of metal from the surface of an aluminum foil: viz. electrochemical oxidation at constant voltage in aqueous ammonium citrate, followed by removal of the oxide film in a phosphoric acid – chromic oxide solution. Due to the highly protective nature of the aluminum oxide film, this two-step process enables very uniform surface layers of metal as thin as 1 $\mu g/cm^2$ to be removed. The total weight of aluminum dissolved increases with the applied anodic voltage at a rate of 0.30 $\mu g\ cm^{-2}\ volt^{-1}$ (approximately 11 Å per volt) over the range 0–150 volts. The technique should be sufficiently sensitive to study the depth of penetration in aluminum of radioactive ions with kinetic energies as low as a few kiloelectron volts.

An approximate value for the range of Na^{24} recoil atoms from the Al^{27} (n,α) reaction was obtained. A more extensive application to range studies is given in the next paper.

INTRODUCTION

A great deal of attention has been devoted in recent years to studying the interaction of charged particles with matter. However, in the energy region below 1 Mev very few experimental data have been obtained on the range of heavy ions. A knowledge of the depth of penetration of ions of kev energies injected into solid materials is of interest from several points of view. It is of value in interpreting radiation damage and sputtering phenomena, and in preparing targets for nuclear research. From a theoretical viewpoint, such an investigation is of primary interest in the determination of the screened-interaction potential and of the mechanism of energy transfer in the elastic nuclear scattering of charged particles.

The current lack of experimental data may be attributed largely to the difficulties encountered in trying to measure extremely small depths of penetration. The mean range of a 45-kev Cs^{137} ion in aluminum, according to the Bohr–Nielsen theory (1), is about 5 $\mu g/cm^2$, or 180 Å. Obviously, for ions of such short range, it would be difficult, if not impossible, to prepare sufficiently thin foils for studying the depth of penetration by conventional stacked-foil techniques.

The present work was undertaken in order to develop a sufficiently sensitive and reliable technique for carrying out range studies with heavy ions in the energy region 1–100 kev. The application of this technique in determining the range of alkali-metal ions as a function of energy will be presented in subsequent papers.

One approach to the problem has been reported recently by Baulch and Duncan (2). They used a gaseous absorber to study the range of radioactive recoil atoms from certain α-decay processes, and observed the effect of pressure on the number of recoil atoms reaching a collector plate. Unfortunately, the method is restricted to those few α-emitting nuclides that have a suitable radioactive daughter. Furthermore, since the energy of the recoil atom cannot be varied, the method is not capable of extensive application.

The approach in this laboratory has been to use a solid absorber, bombard it with a monoenergetic beam of radioactive ions, and then study the depth of penetration of

ions into the target by removing successive uniform layers of target material and determining the amount of radioactivity in each. It was evident that mechanical methods would be far too coarse to remove sufficiently thin layers. Direct chemical or electrochemical etching of the surface is sensitive enough, but would almost certainly be non-uniform; corrosion phenomena are known to occur at very different rates at grain boundaries and impurity centers. Bredov and Okuneva (3) used chemical etching in an attempt to study the range of 4-kev Cs^{134} ions in germanium. They found that approximately 25% of the ions were not dissolved even after prolonged etching, and concluded that some of the ions must have penetrated several thousand angstroms into the target. However, this abnormal result could equally well be attributed to non-uniform etching of the surface.

We therefore selected a two-stage process, electrochemical formation of a uniform protective film, followed by chemical removal of the film, as the most promising possibility for further study.

It is well known that certain metals such as aluminum produce a thin highly protective oxide film when subjected to anodic oxidation in a suitable buffered electrolyte. If the oxidation is carried out at constant voltage, then within a few minutes the film thickness approaches an almost constant value. This value increases almost linearly with the applied voltage up to several hundred volts. Furthermore, according to Charlesby (4) the anodic current forming the film depends so markedly on the voltage gradient that the resulting film should be extremely uniform in thickness. Finally, Lewis and Plumb (5) have shown that a hot aqueous solution of phosphoric acid and chromium trioxide will rapidly dissolve the aluminum oxide layer without appreciably attacking the underlying aluminum metal. By using P^{32} and Cr^{51}, they demonstrated that such a treatment replaced the anodic layer with a highly protective mixed oxide film approximately 10 Å thick.

Provided the mixed oxide does not interfere with subsequent anodic oxidation, it should be possible to remove successive uniform layers of aluminum by this two-step process. However, the relationship between film thickness and applied voltage had not been determined previously below 15 volts (approximately 200 Å). It was therefore necessary to investigate film thicknesses at lower voltages in order to obtain sufficient sensitivity for the proposed range studies.

EXPERIMENTAL

Materials

The aluminum targets used throughout this work were prepared from superpure aluminum foil, 0.020-in. thick, by careful manual polishing with successively finer grades of metallurgical paper and then electropolishing for 60 minutes in a perchloric acid – acetic anhydride bath, according to the method outlined by Tegart (6). The resulting surface had a mirror-like finish; and hence surface irregularities must be considerably less than the wavelength of visible light. Immediately before use, each foil was anodized at 100 volts and then dipped in hot phosphoric acid – chromium trioxide solution to remove the resulting thick layer of aluminum oxide. This preanodizing treatment reduced the effective surface area of the foil by approximately 30% (see Fig. 2), presumably by removing submicroscopic irregularities, and gave a reproducibly flat surface.

Anodizing Step

The anodizing bath consisted of an aqueous solution of C.P. ammonium citrate (30 g per liter), maintained at $25 \pm 0.5°$ C in a 200-ml aluminum beaker which served as cathode.

The aluminum sample to be anodized was suspended in the center of the beaker by an aluminum wire, and the desired voltage provided from a bank of storage batteries. In some of the early runs, a calomel reference electrode was occasionally inserted into the bath to measure the voltage across the anodic film. However, except at the start of a run, this voltage was very close to the total applied voltage across the cell; since chloride ion is small enough to penetrate the aluminum oxide film and thereby interfere with the electrolytic process, the use of a reference electrode was discontinued in subsequent runs, and the anodic voltage was assumed to be identical with the total applied voltage.

Film-Stripping Step

Rapid dissolution of these aluminum oxide layers was accomplished by immersing the anodized aluminum samples in a hot aqueous solution of orthophosphoric acid (50 g per liter) and chromium trioxide (30 g per liter). Provided the temperature of the solution was maintained above 90° C, a 2-minute treatment completely removed even a 100-volt film.

Aluminum Analysis

The thickness of the oxide layers was determined by neutron activation analysis. Three samples of known area were cut from each anodized foil, and inserted in a nylon capsule along with an aluminum standard (approximately 100 μg Al wire). The capsule was then irradiated for 30 seconds in the pneumatic carrier (7) of NRX at a flux of 6.8×10^{13} neutrons per square centimeter per second. After irradiation the anodized aluminum was placed in the stripping solution in order to dissolve the oxide layer, and the amount of Al^{28} activity in solution determined with a well-type NaI scintillation counter. By comparing this activity with that obtained from the aluminum standard, which had been dissolved in sodium hydroxide solution to provide comparable geometry and absorption, the amount of aluminum in the oxide layer can be readily calculated. Due to the high neutron flux and rapid delivery time available, the method was sufficiently sensitive to determine 0.1 μg of aluminum. In view of the short half-life of Al^{28} (2.3 minutes), this was considered quite satisfactory.

With the exception of the films formed at zero applied voltage, a standard deviation of less than 5% was obtained. At zero voltage, the deviation was much larger (approximately 20%). This is probably due to the presence of a thin highly protective film produced on the aluminum surface by CrO_3 (5) during the preanodizing treatment. In the absence of an applied potential, this film probably continues to exert sufficient protection, even after removal from the stripping solution, to inhibit partially the subsequent oxidation process.

RESULTS AND DISCUSSION

In order to determine how rapidly the phosphoric acid – chromic oxide stripping solution dissolved an aluminum oxide barrier layer, two pieces of aluminum were anodized at 25 volts, irradiated in NRX, and then immediately immersed in stripping solution, one at 50° C, and the other at 90° C. Aliquots were removed at various times, and counted to determine the amount of aluminum that had dissolved (Table I).

A standard 2-minute treatment is evidently sufficient to remove the oxide layer completely, provided the temperature is maintained at 90° C. At the lower temperature, however, stripping was far from complete, even after 10 minutes.

In order to investigate the relationship between oxide film thickness and anodic voltage, a series of foils were anodized at different voltages from 0 to 30 volts. In each case the electrolysis was carried out at constant voltage for approximately 10 minutes.

TABLE I

Efficiency of film stripping by H_3PO_4–CrO_3 solution

Time in H_3PO_4–CrO_3 solution (minutes)	c.p.m. of Al^{28} (normalized for decay)	
	At 50° C	At 90° C
0.5	—	42,300
1.0	3,140	42,000
2.0	5,600	43,200
5.0	18,100	44,000
10.0	35,500	43,300

A typical curve of current vs. time is shown in Fig. 1, with a change of abscissa after the first 60 seconds. It is evident that the rate of film formation, which is directly related to the anodic current, falls very rapidly in the first few seconds, but gradually approaches an almost constant value. Walkenhorst (8) showed that, after 1 hour, the rate of film

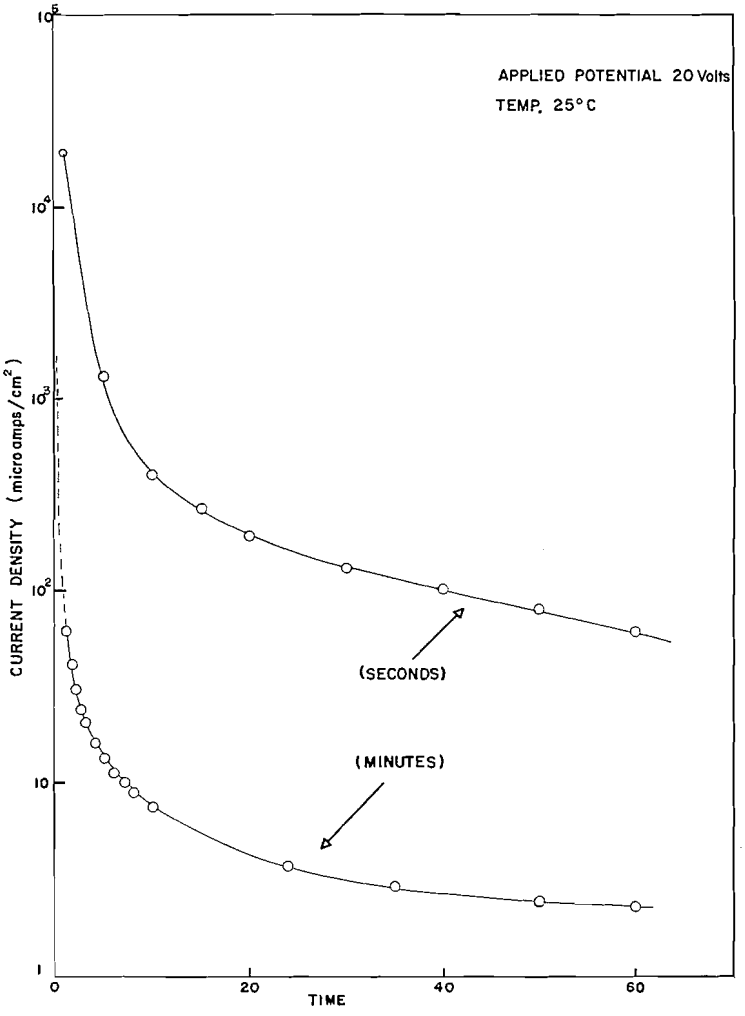

FIG. 1. Anodization of aluminum: current–time relationship.

For personal use only.

growth had decreased to less than 1% per hour. A somewhat shorter time of 10 minutes was selected as the standard anodic treatment in the present investigation, so as to permit future range studies to be carried out with fairly short-lived isotopes. Even after 10 minutes, the film formation current had usually fallen below 7 microamperes/cm^2, which is equivalent to a rate of aluminum oxidation of less than 1 Å per minute.

The effect of voltage on film thickness is illustrated in Fig. 2. Some of the foils had not

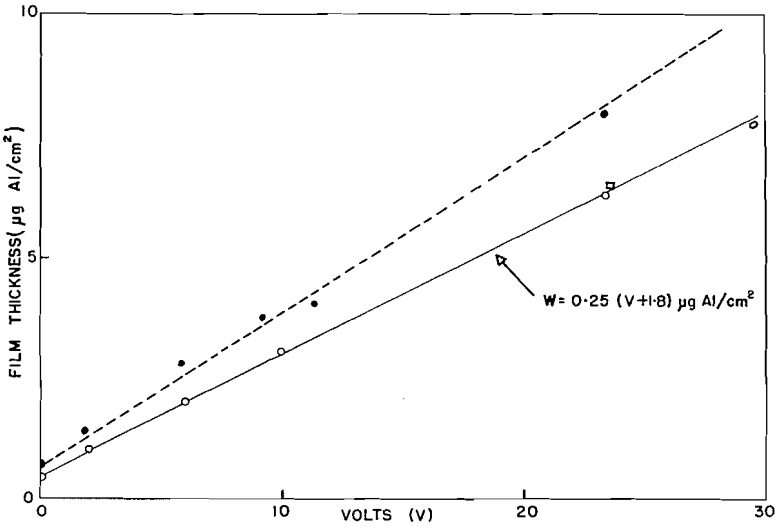

FIG. 2. Graph of film thickness (μg Al cm^{-2}) vs. the applied voltage (V). Number of preanodizing treatments: ● none, ○ one, □ four.

been subjected to any preanodizing treatment. In both cases, a linear relationship was observed. However, with preanodized foils, the slope was considerably less. This can probably be interpreted as a reduction in the true surface area caused by the removal of a thick uniform oxide layer in the preanodizing treatment. No further reduction in surface area occurred even after three additional preanodizing steps. It was concluded, therefore, that one such treatment was sufficient to produce a very reproducible surface. All further work was carried out only with preanodized foils.

The relationship between film thickness (W) in micrograms of aluminum per square centimeter and the applied voltage (V) may be expressed as follows:

$$W = 0.25\times(V+1.8). \qquad [1]$$

The "effective" voltage (1.8 volts) required to account for the observed thickness at zero applied voltage agreed quite closely with the standard electrochemical potential of aluminum of 1.66 volts.

If the oxide consists largely of unhydrated Al_2O_3, as X-ray studies on thicker films suggest (9), then the above value of 0.25 μg cm^{-2} volt^{-1} for the weight of aluminum in the oxide film is equivalent to a total oxide film thickness of 0.475 μg cm^{-2} volt^{-1}. This is in good agreement with previously published values of 0.47 to 0.50 μg cm^{-2} volt^{-1} (8, 10, 11) which were observed at much higher voltages (30–580 volts) by determining the decrease in weight on stripping off the oxide.

In order to study the depth of penetration of radioactive ions in aluminum, it is necessary to know the total amount of aluminum removed in the anodizing plus stripping operation. In the above experiments, we have investigated only the amount that is removed during the stripping process, i.e. the thickness of the protective oxide film produced during the anodic oxidation. However, it has been suggested (12, 13) that the efficiency of the anodic current in forming Al_2O_3 may be considerably less than 100%, and that a significant amount of aluminum ion may escape into solution during the anodic process. This would cause the total thickness of aluminum removed to be somewhat greater than that expressed by equation 1.

Several runs were therefore carried out to investigate the existence and importance of this effect. Pieces of aluminum foil were irradiated briefly in NRX, and were then subjected to anodic oxidation and film stripping as before. The amount of Al^{28} activity in both the anodizing and the stripping solutions was measured, and the results are tabulated in Table II. Over the range studied (18–100 volts), the ratio of Al^{28} activities in the

TABLE II

Loss of Al^{+++} during anodizing

Applied voltage, volts	Al^{28} activity (c.p.m.) in:		Ratio, A/B
	Anodizing solution	Stripping solution	
	A	B	
18	2010	9900	0.20
18	1080	5080	0.21
18	1260	7400	0.17
100	8730	41,000	0.21

two solutions remained constant; hence it is evident that a correction of 20% must be applied to equation 1 to account for the loss of aluminum during the anodizing step. The total weight (W) of aluminum removed by anodic oxidation plus film stripping may be expressed as

$$W = 0.30\ (V+1.8). \qquad [2]$$

Due to the short half-life of Al^{28}, the counting rates after 10-minute anodizing treatment had become very small and this investigation could not be extended to lower voltages. However, it would seem reasonable to assume that the fraction of aluminum ions lost in the anodizing step would remain almost constant over the total voltage range of interest to us.

It may be concluded, from the above studies, that layers of aluminum as thin as 1 μg cm^{-2} may be removed rapidly and reproducibly. This would permit range-distribution studies in aluminum to be carried out with radioactive ions having kinetic energies as low as a few kiloelectron volts (see following paper).

Na^{24} *Recoil Atoms*

An additional check on the reproducibility of the anodizing and film-stripping techniques for removing layers of aluminum of known thickness was obtained by studying the distribution of the Na^{24} atoms produced by the (n,α) nuclear reaction on aluminum. Samples of aluminum, wrapped in cadmium to prevent thermal neutron side-reactions, were irradiated for 15 hours in the NRX reactor, and allowed to decay for at least 12 hours to eliminate the short-lived Mg^{27} and Al^{28} activities. The Na^{24} distribution as a

function of depth was then determined by removing successive layers of aluminum of various thicknesses and counting the resulting solutions. A well-type NaI crystal was used as previously, but with a pulse-height selector set to record only those γ-pulses that exceeded 2.0 Mev. Under these conditions, the total contribution from the most significant impurities in superpure aluminum (14), viz. Cu, Ga, Sc, Mn, La, and Co, amounted to less than 0.05% of the Na^{24} activity. It should be noted that, due to the small cross section for the (n,α) reaction, low counting rates of Na^{24} were involved: for example, with a 20-volt film, the Na^{24} activity was approximately 100 c.p.m., which is only three times the background counting rate. Consequently, statistical counting errors were rather large, in some cases, as high as 15%. Thicker oxide films (up to 150 volts) were used in order to reduce this error.

The $Al^{27}(n,\alpha)Na^{24}$ reaction is endothermic by approximately 3.3 Mev, and can only occur with high-energy neutrons. Since fast neutrons are not significantly attenuated in passing through a thin foil of aluminum, it is evident that the rate of production of Na^{24} atoms will be uniform throughout the foil. However, those formed within their recoil range of the surface will have a finite probability of escaping. The Na^{24} distribution, therefore, should increase at first with increasing depth below the original surface, and gradually approach a constant value. A graph of the actual distribution observed in a typical run is shown in Fig. 3. The thickness of each layer was calculated from the anodic voltage by means of equation 2. After about 5000 Å of aluminum was removed, the Na^{24} content did approach a constant value. In Table III, this constant value is compared with the average Na^{24} content for the whole foil. The latter quantity was determined by

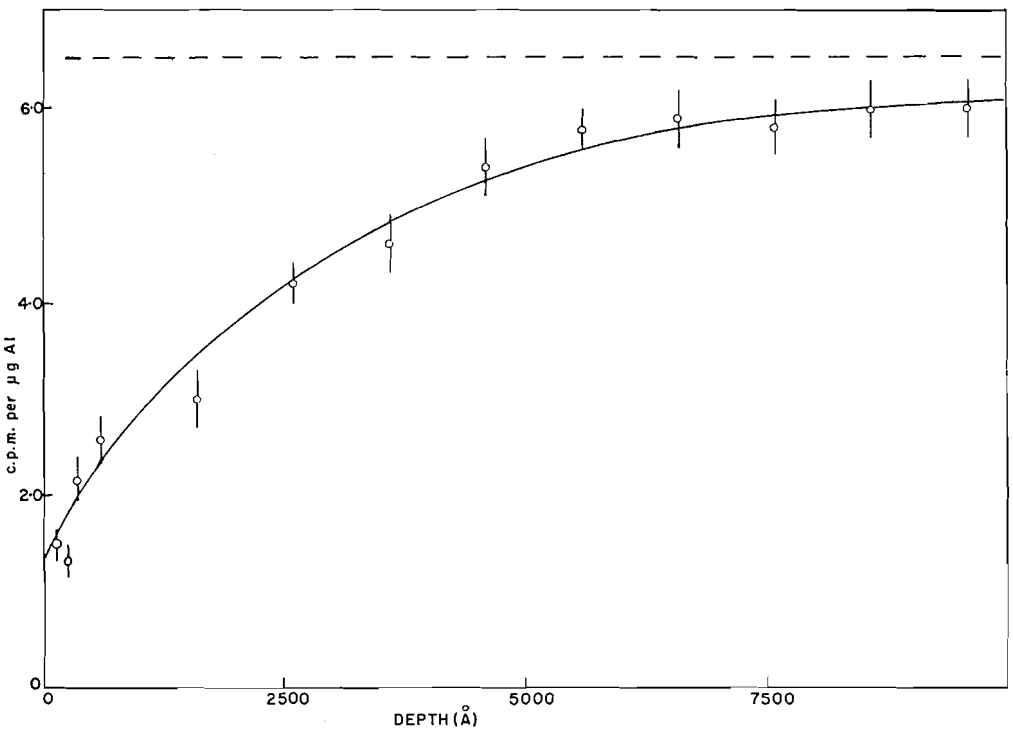

FIG. 3. Distribution of Na^{24} recoil atoms vs. depth below surface of foil. Dotted line represents average Na^{24} content of the whole foil.

TABLE III

Comparison of Na^{24} content in a thin layer with Na^{24} content for the whole foil

Run No.	Na^{24} content (c.p.m./μg Al) of:		Ratio, A/B
	Thin layer	Total foil	
	A	B	
2	5.49	5.78	0.95_0
3	4.34	4.62	0.94_0
4	4.55	4.89	0.93_0
5	5.50	5.40	1.0_2

completely dissolving a piece of the foil of known weight, and measuring the Na^{24} activity in a small aliquot. The agreement between the two confirms the validity of equation 2 up to at least 150 volts.

In one run, 25 successive layers were removed at an applied potential of 100 volts in order to test the reproducibility of the technique. In every fifth layer, the Na^{24} content was measured by counting both the anodizing and stripping solutions. Also, the foil was weighed in order to determine directly the average weight loss for the previous five layers. The results are summarized in Table IV. Both the weight loss and the Na^{24} content

TABLE IV

Reproducibility of anodizing process

Number of 100-v layers removed	Av. weight loss/100 v for previous five layers ($\mu g/cm^2$)	Na^{24} content in last layer (c.p.m./cm^2)
5	28.5	121
10	28.0	136
15	29.5	130
20	29.0	140
25	28.5	139
Calculated value per 100-v layer (from equation 2)	30.5	138

remained almost constant throughout, thereby indicating that the process may be repeated a large number of times without significantly affecting the voltage–thickness relationship. The somewhat lower value obtained in layer 5 for the Na^{24} content may be attributed to recoil loss which, according to Fig. 3, should be quite significant for the first six to eight layers. Good agreement was obtained between the observed values and those calculated from equation 2 both for the weight loss, and for the Na^{24} content per 100-volt layer. This provides an excellent cross-check on the validity of equation 2.

One might think that the variation of Na^{24} activity with depth, illustrated in Fig. 3, might be used to provide quantitative information about the range of the Na^{24} recoil atoms themselves; but, unfortunately, this was not possible. First of all, the recoil atoms were not collimated and therefore a geometric factor would have to be introduced to correlate the number of atoms escaping from a given depth below the surface with the range. This factor, in turn, would depend to some extent on the shape of the recoil track which, due to elastic scattering, would certainly not be linear.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Furthermore, the recoil atoms were not monoenergetic; their energy depended markedly on the energy of the incident neutron and on the angular correlation between it and the emitted α-particle. Using the most recent data for the (n,α) cross section (15) and for the neutron spectrum in NRX, it was estimated that 90% of the recoils would occur between 0.1 and 2.0 Mev, provided there is little or no correlation in the center of mass system between the direction of the incident neutron and the emitted α-particle. A strong angular correlation, although considered very unlikely in an (n,α) reaction, would shift the energy limits for the recoil atoms to much lower values (0.04 and 0.3 Mev, respectively).

It is evident from Fig. 3 that only a very small number of Na^{24} atoms, originating at a depth greater than 10,000 Å below the surface, manage to escape. This implies that the mean range of a 2-Mev Na^{24} atom in aluminum is somewhat less than 10,000 Å.

SUMMARY

Successive uniform layers of known thickness can be removed from an Al target by a two-stage process, consisting of anodic oxidation followed by chemical dissolving of the film. The thickness removed varies linearly with the applied voltage. Reproducible results were obtained with layers as thin as 1.0 μg per cm^2 (37 Å) of aluminum, which suggests that the method should be sufficiently sensitive for studying the range of radioactive ions with kinetic energies as low as a few kiloelectron volts.

ACKNOWLEDGMENTS

The authors would like to express their thanks to Dr. R. H. Betts for suggesting the problem, and for his interest and encouragement throughout the work.

THE RANGE OF ALKALI METAL IONS OF KILOELECTRON VOLT ENERGIES IN ALUMINUM[1]

J. A. DAVIES, J. D. MCINTYRE,[2] R. L. CUSHING, AND M. LOUNSBURY

ABSTRACT

A simple electrostatic accelerator capable of producing a monoenergetic beam of alkali metal ions at energies up to 100 kev has been used to study the range of Cs^{137} ions in aluminum as a function of energy. The median range (R_M) increases linearly with energy as predicted from the Bohr–Nielsen equation, but has a value about twice that predicted by this equation. Furthermore, the observed straggling about the mean value is not Gaussian in shape, but consists of an asymmetric peak with a pronounced exponential "tail". The possible significance of these results is discussed. Preliminary results are given for the range of 30-kev Rb^{86} and Na^{24} ions in aluminum.

INTRODUCTION

The present study has been undertaken as part of a program to obtain precise experimental measurements on the penetration depth and distribution of heavy atomic particles in matter at bombardment energies up to 100 kev. As pointed out by Nielsen (1) this is a velocity region of very considerable importance, both from the theoretical and practical viewpoint. The ion is moving sufficiently slowly for elastic nuclear collision to predominate over ionization as the principal mode of energy loss; hence range studies are of considerable interest for comparison with theoretical predictions of the cross section and mechanics of energy transfer in the elastic scattering process. Furthermore, since nuclear collision is far more effective than ionization in producing atomic displacements, this is also the region in which maximum radiation damage and sputtering should occur.

However, because of the experimental difficulties associated with measuring small depths of penetration, there have been until now almost no reliable experimental results reported on the range of heavy particles below 100 kev.

Our experimental technique consists in bombarding an aluminum target with a monoenergetic beam of radioactive ions of desired energy, and then determining the distribution of radioactivity as a function of depth by dissolving successive very thin uniform layers of aluminum of known thickness—using the electrochemical method described in the previous paper (2).

EXPERIMENTAL

The accelerator used for producing the beam of radioactive ions was designed and constructed specially for these range studies. Considerable economy and flexibility in design were achieved by carrying out the acceleration in two separate stages (see Fig. 1). In the first or low-energy stage, a beam of positive ions is produced in a thermionic-emission ion source A of the single-filament type (3). It consists of a tantalum ribbon upon which is evaporated a solution containing approximately 10^{-7} g of $(Cs^{137})_2SO_4$, and produces a beam of Cs^{137} ions at currents up to 10^{-6} amp. The filament is maintained at a positive potential of up to 5 kv in order to provide the first stage of acceleration. In the second stage, the beam passes between a set of four monitoring plates F, each of which is connected to an electrometer, and is then accelerated towards the target G,

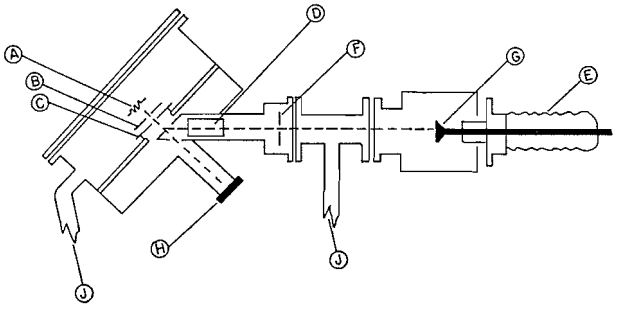

FIG. 1. Schematic diagram of ion accelerator: (A) ion filament, (B) grounded defining slit, (C), (D) beam-alignment plates, (E) high-voltage polystyrene insulator, (F) monitoring plates (4), (G) target, (H) Faraday cup, (J) to diffusion pumps.

which is maintained at any required negative potential up to 120 kv. In this way, the problem of maintaining an ion source at high voltage is eliminated. For energies up to 5 kev, the required voltage can be provided by the first stage alone, and in such cases the second stage is connected directly to ground.

Between the two stages, the beam passes between two pairs of plates C and D; an adjustable voltage is applied across each pair in order to align the beam on the target. One set of plates C deflects the beam through an angle of 30° in order to separate the ions completely from any neutral, and hence unaccelerated, atoms. The ion current is determined intermittently by reducing the deflecting voltage across C to zero, thereby permitting the ions to enter the Faraday cup H. The ion current is determined on a Keithley Electrometer Model 200 capable of measuring currents down to 10^{-13} amp with an accuracy of $\pm 2\%$.

In order to minimize radiation damage and contamination effects, it is desirable to bombard as large an area of the target as possible. Hence, there is no need to provide any focusing. Indeed, the cross-sectional area of the beam is considerably smaller than the normal target area (4 cm^2), and therefore, in most runs, the beam is traversed back and forth across the target to increase the bombarded area. This is accomplished by gradually varying the voltages on C and D during the bombardment until current begins to register on one or other of the monitoring plates at F. These four plates are positioned at 90° with respect to one another, and can be adjusted to define accurately the desired area of target to be bombarded. In Fig. 2, a curve of ion current falling on

two of these monitoring plates and on the target is shown as a function of the deflecting voltage across C.

A differential pumping system is used, consisting of two high-speed oil-diffusion pumps, one connected to the source chamber, and the other to the target chamber. The normal operating pressure along the path of the beam is about 2×10^{-6} mm. The total path length is 30 cm.

The adjustable accelerating voltage for the second stage is provided by a New Jersey Electronics 120-kv power supply Model HL-80 stabilized to $\pm2\%$.

PROCEDURE

Aluminum targets, approximately 2.5×2.5 cm, were cut from strips of 0.020-in. "super-pure" aluminum foil which had been carefully electropolished and preanodized to provide a reproducibly flat surface. The final stage of this treatment, removal of a thick anodic oxide film, was carried out immediately before the target was loaded into the accelerator in order to minimize the thickness of the surface oxide layer formed by action of air on the aluminum. After the bombardment was completed, the radioactivity of the target was measured to determine the number of Cs^{137} ions embedded in it, and then a series of uniform layers were removed by successive anodic oxidation and film stripping, as described in the preceding paper (2).

By varying the applied voltage in the oxidation step, layers of aluminum of any desired thickness from 37 Å to 1000 Å could be prepared for stripping. After one anodic oxide film had been stripped off, the target was rinsed with ethyl alcohol, allowed to dry, and counted. The process was then repeated until all the Cs^{137} ions had been removed from the target. The activity of the target was measured with an end-window flow-type proportional counter having a geometrical efficiency of approximately 30%.

The amount of Cs^{137} contained in each layer was determined from the decrease in the amount of residual radioactivity in the target. In some runs, to perform a mass balance, the Cs^{137} content in each layer was also determined directly by measuring the radioactivity in aliquots from the anodizing and film-stripping solutions. Good agreement was obtained between the two methods; however, in practice, the latter was much more tedious. Very small aliquots had to be used to avoid errors due to source thickness, and consequently the counting rates involved were very low. Therefore, in most of the runs, the Cs^{137} content per layer was determined solely from the decrease in target activity.

It should perhaps be noted that the depth of penetration of Cs^{137} ions into the target is sufficiently small to neglect any subsequent attenuation of the emitted β-particles. This was verified by placing a thin aluminum absorber (2 mg/cm^2) over the target. The counting rate decreased by 2.1%. Even at 50 kev, the average depth of penetration of Cs^{137} in aluminum was only 0.01 mg/cm^2, and hence the attenuation of β-particles was negligible.

RESULTS

A typical run illustrating the determination of the Cs^{137} distribution in a bombarded target is shown in Table I. The two different methods (columns 6 and 7) for obtaining the Cs^{137} activity in each layer are in satisfactory agreement. The thickness (W) per layer (column 3) has been calculated directly from the anodic voltage V by using the relationship from the preceding paper (2): viz. $W = 0.30\ (V+1.8)$. It will be noted that the first layer contains an extra 0.5 μg/cm^2. This represents a small correction term which is applied to all runs in order to take account of the oxygen that is present

during the bombardment as an oxide layer on the target surface, and which contributes therefore to the slowing down of the ion beam. The aluminum content of this oxide layer is included in the above expression for W. It is assumed that the aluminum and oxygen atoms have comparable stopping power for heavy ions. This assumption should be valid provided the ion range is considerably greater than 0.5 $\mu g/cm^2$.

The actual distribution of Cs^{137} ions in the target was observed to be markedly asymmetric. This may be seen more clearly in Fig. 3, in which the Cs^{137} content in each successive layer is plotted against the depth beneath the original surface. The existence of an appreciable, highly penetrating "tail" in the distribution curve is a characteristic feature of these range studies; as a result, the median range R_M, i.e. the thickness required to stop 50% of the incident ions, is somewhat greater than the most probable value R_P. Both R_M and R_P increase linearly with energy (Table II).

Typical distribution curves for Cs^{137} ions of various energies are shown in Fig. 4, in

TABLE II

Range of Cs^{137} ions in aluminum

which the residual activity remaining in the target has been plotted against the total thickness of aluminum removed. In each case, apart from an initial region, the activity falls off exponentially with depth. The half-thickness, $X_{1/2}$, of this exponential region also was observed to increase linearly with the energy of the incident ion.

In order to test the reproducibility of the technique, several runs were carried out at 30 kev under various experimental conditions (see Table III).

TABLE III

Test of reproducibility: 30-kev Cs^{137} ions in aluminum

Run No.	Ion current (μamp)	Total number of Cs ions	R_P ($\mu g/cm^2$)
1	40	0.56×10^{13}	4.4
2	40	4.7	4.8
3	40	20*	4.8
4	600	3.8	4.5

*4.0×10^{13} Cs^{137} ions, plus 16.0×10^{13} Cs^{133} ions.

In the first three runs, the duration of the ion bombardment was varied by a factor of 30 to investigate whether sputtering or radiation damage could alter significantly the initial distribution of the incident ions. The results indicate that prolonged bombardment does not change appreciably the observed value for the most probable range. In run 3, a further check on the absence of significant sputtering was provided by carrying out the bombardment in two stages: 4×10^{13} ions of Cs^{137} in the first stage, followed by a much larger number of inactive Cs^{133} ions in the second one. The observed distribution of Cs^{137} as a function of depth was identical with that in run 2, which showed clearly that the subsequent bombardment by inactive cesium had not changed the distribution of Cs^{137}. Furthermore, the radioactivity of the target was measured immediately before and after the second bombardment to determine whether any Cs^{137} had been sputtered from the target by the Cs^{133} ions. The observed decrease in activity was extremely small (0.3%), and in fact was not significantly greater than the statistical counting errors involved.

The absence of detectable sputtering or other secondary radiation damage in these range–distribution studies is not unexpected; even in run 3, the total number of ions striking the target was only 2×10^{14} and those were distributed over an area of 4 cm^2. From the observed distribution curves for 30-kev ions in aluminum, it can readily be shown that the maximum ratio of cesium atoms to aluminum atoms in the target was less than 10^{-3}. Therefore, each cesium ion would have to eject an unreasonably large number of aluminum atoms from the target to reduce significantly the observed depth of penetration.

Run 4 was carried out at much higher ion current in order to investigate whether the observed distribution depended on the rate of energy deposition. It is true that in these experiments the rate of energy deposition was extremely small, usually less than 10 milliwatts; but, due to the short range of the incident ions, the kinetic energy is dissipated in an extremely small volume, equivalent to a power input of approximately one kilowatt per gram. It was thought that this high heat flux might give rise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

to some secondary thermal effects. However, run 4 shows clearly that a 15-fold increase in the rate of energy deposition had no appreciable effect.

The distribution of Cs^{137} for each of the above runs is illustrated in Fig. 5. Within the statistical errors involved, the results for the four runs are indistinguishable.

Other Alkali Metal Ions

Some preliminary studies have also been carried out with 30-kev Na^{24} and Rb^{86} ions in aluminum. The results are illustrated in Fig. 6, and in Table IV. With both ions, a markedly asymmetric distribution curve is again observed. The energy dependence for these ions has not yet been investigated.

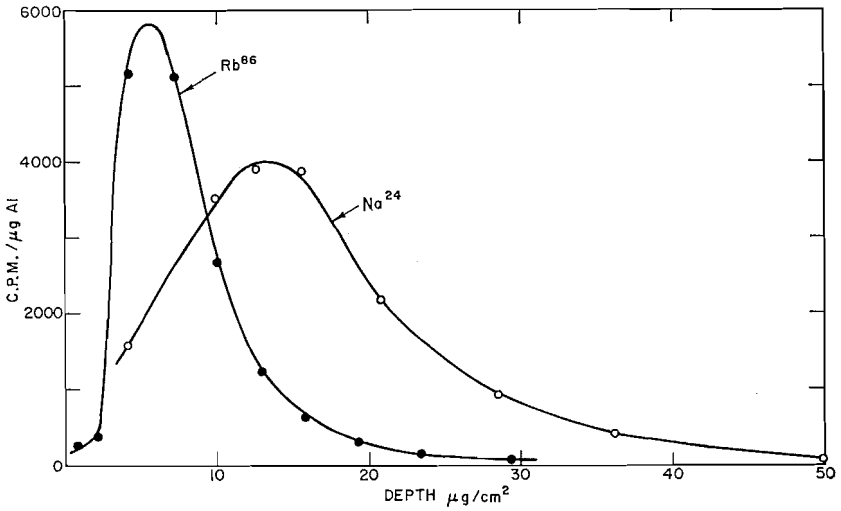

FIG. 6. Depth of penetration of 30-kev Rb^{86} and Na^{24} ions in aluminum.

TABLE IV

Range of 30-kev alkali-metal ions in aluminum

Ion	R_P (μg cm^{-2})	R_M (μg cm^{-2})	Range predicted by Bohr–Nielsen equation (μg cm^{-2})
Na^{24}	13.1	15.0	23.4
Rb^{86}	6.6	8.4	5.4
Cs^{137}	5.8	7.6	3.6
Na^{24}/Cs^{137}	2.2	2.0	6.5

DISCUSSION OF RESULTS

Bohr (4) has shown that the complicated many-body problem involved in slowing down an atomic particle can be simplified considerably by separating it into two distinct types of collision processes: electronic or inelastic collisions, in which energy is transferred to individual electrons, thereby causing ionization or atomic excitation; and nuclear or elastic collisions, in which momentum and kinetic energy are transferred to the stopping atom as a whole. The former process is the more important at high velocity such as in the initial portion of a fission-fragment or alpha-particle track; whereas, when the moving particle has a velocity less than that of the slowest orbital electrons in the stopping material (viz. $<2\times10^8$ cm/sec), nuclear collisions tend to predominate. The ion velocities used in the present work were considerably less than this critical velocity; hence, nuclear collisions should be the more significant process throughout the range.

Nuclear collisions may be subdivided further into various types depending on the relative magnitude of the collision diameter, the screening parameter, and the wavelength of the incident particle. A general treatment of the problem is therefore quite complicated. However, at the energies studied in the present work, it has been shown by Nielsen (1) that, over the entire range, the collision diameter, or minimum distance of approach in a head-on collision in an unscreened coulomb field, is considerably larger

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

than the screening parameter. Hence, the nuclear collisions occur in a screened coulomb field. Furthermore, over most of the range, the wavelength of the incident ion is much smaller than the screening parameter and classical orbital considerations may be applied. For such a system the following range–energy relationship has been developed (1, 5):

$$\frac{R}{E} = 0.60\,\frac{A_1+A_2}{A_1}\cdot\frac{A_2}{Z_2}\cdot\frac{(Z_1^{2/3}+Z_2^{2/3})^{\frac{1}{2}}}{Z_1}$$

where R is the range in $\mu g/cm^2$, E is the energy of the incident particles in kev, A_1, A_2 are the masses, and Z_1, Z_2 are the atomic numbers of the incident and target atoms respectively.

The predicted linear relationship between range and energy is observed for Cs^{137} ions in aluminum (Table II). A comparison of the absolute magnitude of the experimental and predicted values for the range of 30-kev alkali-metal ions is given in Table IV. Clearly, the theoretical values do have the correct order of magnitude, but the predicted variation from Na^{24} to Cs^{137} is several times larger than that observed. This discrepancy may be ascribed partly to the fact that the theory gives the total distance travelled by the particle in coming to rest, not merely the depth of penetration beneath the target surface. One important characteristic (1) of screened-field scattering is that the angular distribution is almost isotropic in the center-of-mass system, in contrast with coulomb scattering where small angular deflections predominate. As a result, the individual ion tracks will be far from linear; hence the predicted ranges must be reduced somewhat before comparing with the experimental values.

In the case of Cs^{137}, this correction term is quite small. The mass of the incident particle is more than five times that of the target atom; hence, to conserve momentum, it can be shown that the maximum deflection per collision is only 12°. On the other hand, with Na^{24}, where the mass ratio is close to unity, individual deflections as large as 90° are possible, and consequently the depth of penetration will be much less than the total path length.

Effect of Surface Area

One problem of some concern in the interpretation of these range studies is the possible effect of surface non-uniformity on the measured depth of penetration. Consider a small segment of surface (Fig. 7) inclined at an angle θ to the plane of the target. Let the area of the segment be ΔA. If the target is bombarded uniformly by a collimated beam of ions, then the number striking ΔA is given by $N(\Delta A \cos\theta/A')$ where N is the total number of ions striking the target and A' is the apparent or measured area. Each of these ions, in traversing a thin uniform layer of thickness δ, travels a distance $\delta/\cos\theta$. Hence, the sum of the distances travelled by all the ions striking the segment is given by $N(\Delta A/A').\delta$, which is independent of θ. Integrating over the whole target, and dividing by N, we find that the average distance travelled per ion is $\delta.(A/A')$, where A/A' is the ratio of the true to the apparent surface area of the target. It is obvious, therefore, that surface irregularities increase markedly the average path length travelled.

However, in calibrating the relationship between oxide film thickness and anodic voltage (2), it was not possible to measure the true film thickness δ, but only the apparent thickness δ'. It can readily be shown that $\delta' = \delta(A/A')$. Since the same type of surface was used in the preliminary calibration as in the subsequent depth of penetration studies, it can be seen that the average distance travelled per ion in traversing a uniform film is identical with the apparent film thickness. Consequently, the effects of non-uniformity cancel out in determining the average range.

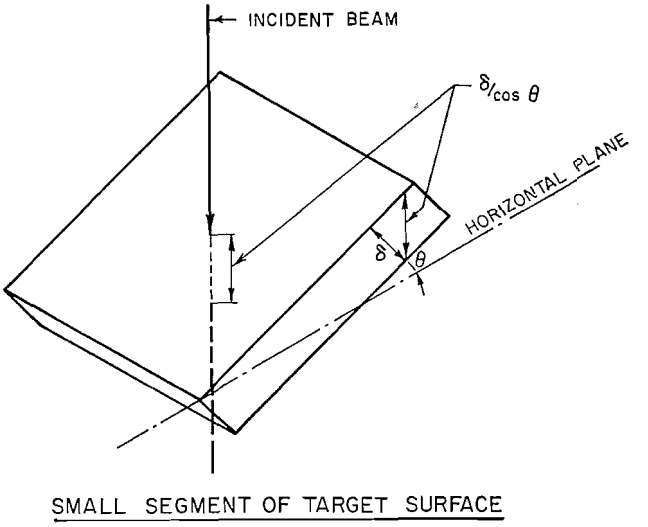

FIG. 7. Sketch to illustrate surface-area effect.

Of course, surface irregularities will introduce some straggling into the observed distribution, but this straggling should not be very marked: optically flat surfaces have been used throughout this work, and the preanodizing studies reported in the preceding paper (2) suggest that the ratio (A/A') is probably very close to unity.

A particularly interesting feature of our results is the observed asymmetric distribution. Some previous workers (6, 7) have assumed that the distribution of individual particle ranges about a mean value would be given approximately by an error curve:

$$W(R) = \frac{1}{\rho R_M \sqrt{2\pi}} \exp\left[-\frac{1}{2\rho^2}\cdot\left(\frac{R-R_M}{R_M}\right)^2\right]$$

with a straggling parameter

$$\rho^2 = \frac{4}{3}\frac{A_1A_2}{(A_1+A_2)^2}.$$

However, as noted by Bohr (4, p. 50), a Gaussian distribution occurs only when the maximum fractional energy transfer T_{max} per collision is very small: in other words, when $A_1 \gg A_2$. This assumption is certainly not valid when using an aluminum target. Even with Cs^{137}, where $A_1 = 5.1A_2$, T_{max} is almost 0.60; and, assuming isotropic scattering, T_{av} is approximately 0.30. Since the range varies linearly with the energy, this means that each ion, on the average, traverses one-third of its total range before the first collision. Furthermore, since the collision diameter increases with decreasing energy of the incident ion, the mean free path should decrease markedly with every collision. Obviously, the depth of penetration is determined primarily by the first few collisions. Under such conditions, it can be shown (see Fig. 8, and Appendix) that the distribution curve consists of an asymmetric peak with a highly penetrating exponential "tail"; the half-thickness of the exponential region is determined by the mean free path for the first collision.

With Cs^{137}, this exponential "tail" is in fact observed. Furthermore, the half-thickness varies linearly with the energy, as would be expected.

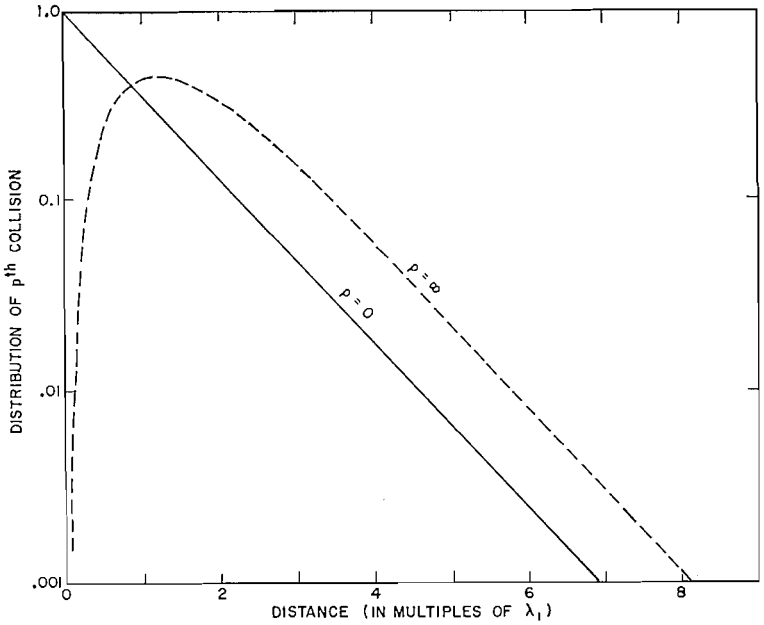

FIG. 8. Calculated distribution curves for large fractional energy loss per collision.

It is planned to extend these studies to somewhat higher energies, to other ions, and to other target materials in order to permit a more quantitative interpretation of the role of nuclear collisions in determining range–energy relations.

ACKNOWLEDGMENTS

The authors wish to acknowledge the invaluable assistance of Mr. G. Sims with the construction and operation of the ion accelerator, and with the subsequent radiochemical analyses. We are particularly indebted to Dr. R. H. Betts for his advice and encouragement throughout this work, and to Mr. G. C. Hanna for his help in developing the mathematical treatment in the Appendix.

APPENDIX

CALCULATED RANGE DISTRIBUTION FOR LARGE ENERGY TRANSFERS

Consider an experiment in which N particles have been shot into the absorbing material. Suppose $N_p(r)$ is the number of particles that made p collisions in penetrating a distance r. Then the number that reached $(r+dr)$ making p collisions is the sum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

those that reached r making p collisions without making a further collision in dr and those that reached r in $(p-1)$ collisions and did make a collision in dr. That is

$$[1] \qquad N_p(r+dr) = N_{p-1}(r)dr/\lambda_p + N_p(r)(1-dr/\lambda_{p+1})$$

where λ_p is the mean free path for the pth collision.

Writing $\mu = 1/\lambda$ gives

$$[2] \qquad (d/d_r)N_p(r) = \mu_p N_{p-1}(r) - \mu_{p+1}N_p(r).$$

This equation is the same, with r replacing time, as that governing a series of radioactive transformations, with the familiar solutions (8)

$$N_0(r) = Ne^{-\mu_1 r}$$

$$N_1(r) = N\mu_1\left(\frac{e^{-\mu_1 r}}{\mu_2-\mu_1}+\frac{e^{-\mu_2 r}}{\mu_1-\mu_2}\right)$$

etc.

and

$$[3] \qquad N_p(r) = N\mu_1\mu_2 \ldots \mu_p \sum_{n=1}^{p+1} \frac{e^{-\mu_n r}}{a_n}$$

where

$$a_n = \prod_{i=1}^{p+1} (\mu_i - \mu_n), \qquad i \neq n.$$

For the special case where the mean free path remains constant (i.e. where $\mu_1 = \mu_2 \ldots = \mu_p$), equation (3) becomes a Poisson distribution, which for large values of p is simply the familiar Gaussian curve. Such a condition would be approximately correct for a system in which the fractional energy loss per collision is small. However, where the energy transfer per collision is large, a very different type of distribution curve is obtained.

In order to illustrate this, let us take a somewhat idealized system in which the fractional energy transfer per collision is exactly 0.5. Clearly, in such a case, only the first few mean free paths contribute significantly to the total range. Since the mean free path is proportional to the energy, we may substitute in equation (3) the following relationship:

$$\mu_1 = \frac{1}{2}\mu_2 = \frac{1}{4}\mu_3 \ldots = \frac{1}{2^{n-1}}\cdot\mu_n.$$

The resulting series

$$\sum_{n=1}^{\infty} \frac{1}{a_n} [\exp -(2^{n-1})\mu_1 r]$$

is rapidly convergent and leads to the distribution shown in Fig. 8 by a dotted line: viz. an asymmetric peak, followed by an exponential region of half-thickness identical with that for the first collision.

The above treatment is greatly oversimplified and cannot be used for quantitative comparison with the observed distribution curves. No allowance has been made for variations in energy transfer from one collision to another, nor for the difference between the total path length and the depth of penetration.

ISOLATION AND STRUCTURE OF A NEW ALKALOID: ASPIDOCARPINE[1]

STEWART MCLEAN,[2] K. PALMER,[2] AND LÉO MARION

ABSTRACT

From the root bark of *Aspidosperma megalocarpon* Muell. Arg. a new alkaloid, aspidocarpine, has been isolated. It has the empirical formula $C_{22}H_{30}O_3N_2$ and contains an N-acetyl, one methoxyl group, and one active hydrogen. The alkaloid, a phenolic monoacidic tertiary base, has been shown by its properties, those of its derivatives, and the spectroscopic data, to contain an N-acetyl-6-methoxy-7-hydroxydihydroindole moiety. Oxidation of aspidocarpine with chromic acid gave rise to a product identical in all respects with apoaspidospermine obtained from the similar oxidation of aspidospermine. Since the structure of aspidospermine is known, the foregoing results establish the structure of the alkaloid aspidocarpine.

The root bark of *Aspidosperma megalocarpon* Muell. Arg., a tree that grows in British Guiana,[3] has been found to contain alkaloids. They mostly occur in the petroleum ether extract, and largely consist (0.06% of dry weight) of one base which it is proposed to designate aspidocarpine. Its empirical formula derived from the analytical figures of the base and its salts is $C_{22}H_{30}O_3N_2$. Aspidocarpine melts at 168.5–169.5°, and determination of functional groups revealed that it contains one acetyl group, one methoxyl, one additional C-methyl besides that arising from the acetyl, and one active hydrogen.

The ultraviolet spectrum of aspidocarpine contains maxima at λ_{max} 227 mμ, log ϵ 4.42, and λ_{max} 263.5 mμ, log ϵ 3.92. It resembles that of aspidospermine and suggests that the new alkaloid, like aspidospermine, contains the N-acetyl-indoline chromophore. The spectrum of aspidocarpine was not affected by the presence of mineral acid, but was profoundly changed by the addition of sodium hydroxide.

In the infrared the spectrum of aspidocarpine contains no apparent hydroxyl absorption, but shows a peak at 1632 cm^{-1} which, although weak and at a low wave-number, must be indicative of the carboxyl of an N-acetyl group. Since, however, the base does not contain a carboxylic group, but contains an active hydrogen and is soluble in sodium hydroxide, since, further, it produces a pale olive-green color with ferric chloride, it must be phenolic. If the phenolic hydroxyl and the N-acetyl group were located sufficiently close to one another to form a strong hydrogen bond the effect in the infrared would shift the hydroxyl and carbonyl absorption to lower wave-numbers. Hence any hydroxyl absorption would be shifted to and covered by the CH stretching absorption region. The situation would thus parallel that observed in demethylaspidospermine (1). Evidence that this assumption is indeed correct has been obtained by blocking the hydroxyl function and thus removing the possibility of hydrogen bonding. Acetylation of the hydroxyl group was carried out smoothly in acetic anhydride and pyridine. The product, O-acetylaspidocarpine ($C_{24}H_{32}O_4N_2$) shows bands in the infrared at 1768 cm^{-1} and 1204 cm^{-1} characteristic of a phenolic O-acetyl (2) and another band at 1666 cm^{-1} due to the carbonyl of the N-acetyl group.

The phenolic hydroxyl of aspidocarpine did not react with diazomethane under the usual conditions, a common occurrence with strongly hydrogen-bonded phenols, but methylation was readily effected by the use of alkaline dimethylsulphate at room tempera-

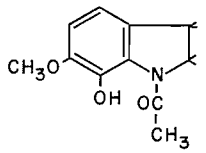
ture. The O-methylaspidocarpine ($C_{23}H_{32}O_3N_2$) thus produced showed a strong absorption band in the infrared at 1656 cm^{-1} due to the N-acetyl carbonyl. The ultraviolet spectra of both the O-acetyl and the O-methyl derivatives were not appreciably altered by sodium hydroxide. Thus when the phenolic hydroxyl is blocked and no hydrogen bonding is possible, the carbonyl absorption of the N-acetyl group in the infrared appears with its normal frequency and intensity.

The N-acetyl group was characterized by hydrolysis of the alkaloid with sulphuric acid, steam-distillation of the reaction mixture, and spot-testing of the ethylamine salt of the distilled acetic acid on a paper chromatogram.



O-Methylaspidocarpine was hydrolyzed with 10% hydrochloric acid to O-methyl-deacetylaspidocarpine ($C_{21}H_{30}O_2N_2$). The infrared spectrum of this product no longer shows any carbonyl absorption, but contains a band at 3335 cm^{-1} attributable to an imino group. Treatment of the product with acetic anhydride and pyridine regenerates O-methylaspidocarpine, thus confirming the presence of an N-acetyl group in the alkaloid.

Treatment of aspidocarpine with hydrobromic acid produced an extremely unstable material which could not be crystallized. This material gives a blood red color with ferric chloride, which is consistent with an aminodihydric phenol. The material must be O-demethyl-N-deacetylaspidocarpine because on acetylation it is converted to O,O-diacetyl-O-demethylaspidocarpine ($C_{25}H_{32}O_5N_2$). The latter has an infrared absorption spectrum containing bands at 1777 and 1767 cm^{-1} (C=O) and 1204 cm^{-1} (C—O—) due to two phenolic O-acetyl groups, as well as a band at 1668 cm^{-1} attributable to the non-bonded carbonyl of the N-acetyl group. This observation places the original methoxyl group of aspidocarpine in the aromatic ring. In support of this conclusion it has proved possible to hydrolyze selectively the O-acetyl groups of O,O-diacetyl-O-demethylaspidocarpine and isolate pure O-demethylaspidocarpine, $C_{21}H_{28}O_3N_2$, which has the characteristics of a dihydric phenol. In the infrared spectrum of this compound, as expected, the carbonyl absorption shows the effect of hydrogen bonding, and the hydroxyl region contains an absorption band attributable to the non-hydrogen-bonded hydroxyl group. Treatment of O-demethylaspidocarpine with diazomethane did not affect the original hydroxyl, which had already been shown to resist methylation by this method, but methylated the second hydroxyl, thus regenerating aspidocarpine.

O-Demethylaspidocarpine behaves as an ortho-dihydric phenol as shown by the following observations. With ferric chloride it produces initially an intense blue-green color, which on addition of sodium carbonate, changes to a very deep red, a color sequence characteristic of catechols. In a series of tests on the compounds already described it was observed that coupling with diazotized sulphanilic acid occurred whenever either the hydroxyl or the indoline nitrogen was free, but did not occur when both were substituted. This indicates that the positions in the benzene ring para to these two functions are unsubstituted. Attempts to oxidize aspidocarpine or O-demethylaspidocarpine with periodate by the method of Adler and Magnusson (3) failed to give any crystallizable products, but produced color sequences indicative of the formation of an ortho-quinone. The condensation of either the presumed crude quinone with ortho-phenylenediamine, or of O-demethylaspidocarpine with phosgene led invariably to amorphous products of doubtful composition. The product of the reaction with phosgene, however, showed in the infrared a peak at 1835 cm^{-1}, a value indicative of the formation of a cyclic carbonate. It is of some interest that O-methylaspidocarpine gives no color in the brucine test with

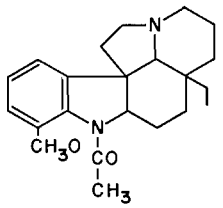
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

nitric acid and acetic acid, an observation in accordance with the model experiments of Lyons, Perkin, and Robinson (4), whereas aspidocarpine and O-demethylaspidocarpine both give a deep red color different from the characteristic brucinequinone color. The best evidence in favor of the ortho arrangement of the hydroxyl groups in O-demethylaspidocarpine came from an application of Jurd's method (5), which is based on the effect of buffered boric acid on the ultraviolet spectrum of a compound. The ultraviolet spectrum of O-demethylaspidocarpine shows a dramatic change in the presence of buffered boric acid and parallel experiments show that catechol undergoes a similar change while the other dihydroxybenzenes are unaffected. The spectrum of aspidocarpine is unaffected by buffered boric acid. The sum of the evidence therefore strongly favors partial structure I as representing rings A and B of aspidocarpine. The nuclear magnetic resonance evidence, discussed later, also supports this conclusion.

I

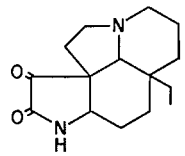
The close similarity between the chemistry of aspidocarpine and that of aspidospermine, as well as in the spectral properties of both alkaloids, is quite striking. The relationship in rings A and B has already been demonstrated. In the study of the saturated moiety of the molecule it has been found that the reactions of aspidocarpine parallel exactly those of aspidospermine including the rather remarkable rearrangements known to take place in the latter (6).

In line with aspidospermine (6, 7) aspidocarpine showed a high analytical N-methyl value (76% of calculated figure for one N-methyl) which later proved spurious, and still in keeping with other *Aspidosperma* alkaloids, O-methylaspidocarpine gave an N-methyl value considerably lower than that obtained with the alkaloid (24% of calculated value for one such group).



Aspidocarpine-N(*b*)-methiodide was readily prepared in dimethylformamide. It did not undergo the Hofmann degradation, however, but gave back aspidocarpine.

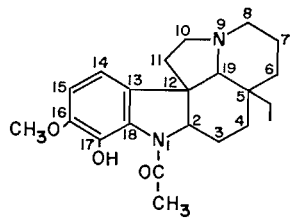
The von Braun degradation of aspidocarpine also produces a significant parallel with the behavior of aspidospermine in this reaction (6). Treatment of aspidocarpine with cyanogen bromide in chloroform (the reaction failed in benzene) gives rise to aspidocarpine bromocyanamide, $C_{23}H_{30}O_3N_3Br$, which exhibits the usual characteristics of this class of compounds, except that the normal solvolytic completion of the von Braun degradation fails since the bromocyanamide reverts to aspidocarpine even on reflux with ethanol.



These similarities between aspidospermine and aspidocarpine, coupled with their botanical relationship, suggested the possibility that they might differ only insofar as ring A was concerned. Ewins (8) had oxidized aspidospermine with chromic acid and had obtained a product, m.p. 193°, to which he tentatively assigned the structure of a keto-lactam (apoaspidospermine) resulting from the oxidative degradation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

aromatic ring. The structure of aspidospermine (II) recently determined by X-ray crystallography[4] (9) leads to structure III for apoaspidospermine,



II

III

which should also be the product of the similar oxidation of aspidocarpine. Ewins' analytical figures were not in agreement with this structure but in our hands the oxidation of aspidospermine with chromic acid yielded a product, m.p. 224–225°, which gave analytical figures in excellent agreement with those required by III ($C_{15}H_{22}O_2N_2$). Both the infrared and ultraviolet spectra of the oxidation product were consonant with the presence of a five-membered keto-lactam in the molecule. This product was most probably identical with Ewins' apoaspidospermine, although it was purer as shown by the higher melting point. Aspidocarpine when oxidized with chromic acid yielded a product which had the same optical rotation and the same melting point as apoaspidospermine, alone or in admixture. The infrared spectra and the X-ray powder diagrams of both products were exactly superimposable.

The identity of the oxidation products of aspidocarpine and aspidospermine establishes the structure of the saturated moiety of the former, and this, together with the demonstration of the presence of a hydroxymethoxy-N-acetyl-indole in the molecule, affords conclusive proof that the structure of aspidocarpine is

IV

represented by formula IV. The assignment of the structure of the saturated part of the molecule depends on the X-ray crystallographic analysis of aspidospermine (9), and it follows from the identity of the oxidation products obtained from both alkaloids.

Aspidocarpine has proved very suitable for examination by nuclear magnetic resonance[5] especially since the spectrum can be compared with that of aspidospermine, the structure of which has been conclusively established (9, 10).

[4]*We acknowledge with thanks the courtesy of Professor N. S. Nyburg, who communicated to us the structure of aspidospermine in advance of his publication.*

[5]*Spectra were obtained with a Varian Associates high resolution nuclear magnetic resonance spectrometer operating at 60 Mc/s frequency. Chloroform was employed both as a solvent and as an internal reference; its proton resonance was assigned a value of zero c.p.s. and the scale was fixed from the position of the associated* C^{13} *(natural abundance) peaks which were shown to have a value of* ± 105 *c.p.s.*

The significant features of the spectrum of aspidocarpine are:

(1) A single sharp peak at −215 c.p.s. with area equivalent to one proton. This is attributed to the internally hydrogen-bonded phenolic OH group.

(2) A triplet with strong central peak at 44 c.p.s. This multiplet produced by the aromatic protons is of the AB type (11) with a very small chemical shift and $J = 9$ c.p.s. The total area is equivalent to two protons.

(3) A quartet at 193, 198, 202, and 208 c.p.s. with a total area equivalent to one proton. This is attributed to the proton at C2. The structure shows the effect of splitting by the adjacent methylene protons and demonstrates the rigidity of ring C.

(4) A single sharp peak at 211 c.p.s. of area equivalent to three protons. This is attributed to the protons of the methoxyl group.

(5) A multiplet at 247, 255, 258, and 263 c.p.s. of which the 258 c.p.s. peak is the strongest and sharpest. These signals are more difficult to assign to particular protons, but are probably to be associated with the protons on carbons adjacent to the nitrogen at position 9. From the area under the curve, two or at most three protons are involved with this resonance. Since ring size is known to affect the position of proton resonance in saturated heterocyclic systems (12) it would be expected that the signals of the protons at C8 would be separated from those at C10. The most likely situation is that the protons at C10 (in a five-membered ring) are involved with this multiplet while the C8 protons (in a six-membered ring) appear in the general absorption above 300 c.p.s. The sharp peak at 258 c.p.s. may be part of the C10 resonance or, if the total area does in fact represent three protons, it may be caused by the proton at C19, which is common to a five-membered and a six-membered ring and is isolated from protons which could cause splitting.

(6) A single sharp peak at 303 c.p.s. with an area equivalent to three protons. It is attributed to the protons of the N-acetyl group.

(7) A sharp peak at 400 c.p.s. with an area corresponding to about two protons, but the peak is probably associated with some of the adjacent structure and is attributed to the methyl protons of the ethyl group.

A comparison of the spectrum of aspidospermine with that of aspidocarpine shows almost all the expected relationships.

(1) The OH peak at −215 c.p.s. is absent.

(2) The aromatic protons (now three) show a multiplet of the ABC type centered on 32 c.p.s., but a complete analysis is not possible since only nine separate peaks are observed.

(3) The quartet associated with the proton at C-2 now appears at 165, 171, 175, and 182 c.p.s. The shift from the corresponding values in aspidocarpine is associated with the nature of the N-acetyl group. In aspidocarpine the carbonyl of this group is hydrogen-bonded with the C17 hydroxyl and this certainly pulls the oxygen away from the C2 proton. In aspidospermine, hydrogen bonding does not occur and it can readily be seen from models that the acetyl group will take up a less hindered conformation.[6] Since a shift occurs the important deduction that can be drawn is that the assignment of the quartet to the C2 proton resonance is confirmed.

The remainder of the spectrum of aspidospermine is essentially the same as that of aspidocarpine except that the N-acetyl protons appear at 8 c.p.s. lower in the latter, an

[6]*There are two less hindered conformations that can be taken up by the acetyl group. In one conformation the carbonyl and the* C2—H *bond have a cis relationship but are trans in the other. A cis relationship would cause a shift to higher frequency and since the observed shift is to lower frequency the trans relationship is more probable. Stereochemical predictions from scale models are in agreement with this.*

effect probably produced by the hydrogen bonding with the acetyl carbonyl in aspidocarpine.

The spectrum of O-methylaspidocarpine has also given interesting information. Since the phenolic hydroxyl is blocked, hydrogen bonding is excluded in this derivative and the spectrum is very similar to that of aspidospermine except that there are two methoxyl peaks (210 and 215 c.p.s.) and the aromatic proton region shows a complete AB type (11) quartet centered on 39 c.p.s. with an area equivalent to two protons (chemical shift = 11.5 c.p.s. and $J = 8$ c.p.s.). The quartet associated with the C2 proton (166, 172, 176, 182 c.p.s.) is essentially the same as in the spectrum of aspidospermine. The relationship between the spectra in the aromatic region of aspidocarpine and O-methylaspidocarpine affords supporting evidence for the assignment on chemical grounds of substituents to positions 16 and 17. Since the oxygen function at position 17 is considered to be conclusively established, the original methoxyl group must be located at one of the three positions (14, 15, or 16). Position 15 meta to position 17 is excluded because the spectrum requires two adjacent protons. If in O-methylaspidocarpine the original methoxyl were at position 14 the protons at 15 and 16 would have almost identical environment, and a very small chemical shift would be expected. In fact the chemical shift in the O-methylaspidocarpine spectrum is greater than in the spectrum of aspidocarpine and the methoxyl must therefore be placed at position 16. The small chemical shift for the aromatic protons in aspidocarpine is explainable by the fact that the effect of a hydroxyl group on a proton para to it (i.e., at position 14) is almost the same as the effect of a methoxyl group (position 16) on a proton at its ortho position (i.e. position 15).

Conroy and his co-workers (6) have made an analysis of the spectrum of aspidospermine using a 40 Mc/s instrument, and while the major features of their spectrum correspond to those of ours (after the appropriate conversions of scale, etc.) there are several important differences. The peaks that we have assigned to the C2 and C10 protons are not easily seen in their chloroform solution spectrum, but are more evident when they used carbon tetrachloride as solvent. The peaks close to the N-acetyl and methoxyl signals which they assign to the CH_2 groups and the CH adjacent to the nitrogen do not appear in our spectrum.

EXPERIMENTAL

Melting points were determined on a Kofler micro hot stage. The infrared spectra were obtained with a Perkin–Elmer model 21 spectrophotometer, and the absorption is reported in wave numbers followed by a bracketed (m) or (s) to indicate medium or strong absorption. The ultraviolet spectra unless otherwise stated were determined with a Beckman model DU spectrophotometer.

Isolation of Aspidocarpine

The root bark of *Aspidosperma megalocarpon* Muell. Arg. (83.2 kg) was ground to a powder and percolated with petroleum ether (b.p. 95°–110°). The petroleum ether extract was concentrated under reduced pressure and the concentrate deposited the crude alkaloid in crystalline form. Aspidocarpine was purified by recrystallization from heptane and from methanol from which it separated as colorless prisms (50 g), m.p. 168.5–169.5°, $[\alpha]_D^{25}$ +140° (*c*, 2.3 in chloroform), pK_a, 6.55 (by titration with *p*-toluenesulphonic acid). Found: C, 71.18, 71.13; H, 8.10, 8.11; N, 7.52; act. H, 0.26; CH_3CO, 10.06; C—CH_3, 6.34; OCH_3, 8.28, 8.29; N—CH_3, 3.09 (spurious result); mol. equiv. 371, 374 (acid titration). Calc. for $C_{22}H_{30}O_3N_2$; C, 71.32; H, 8.16; N, 7.56; 1 act. H, 0.27;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1 CH_3CO, 11.61; 2C.CH_3, 8.12; 1 OCH_3, 8.38; mol. wt. 370. Infrared in chloroform: 1632, 1603, 1582 cm^{-1}, in nujol: 1637, 1605, 1587 cm^{-1}. Ultraviolet spectrum in 95% ethanol: λ_{max}, 228 mμ, log ϵ 4.42, 263.5 mμ, log ϵ 3.92, λ_{min} 249 mμ, log ϵ 3.80; after addition of a drop of aqueous sodium hydroxide: λ_{max} 224 mμ, log ϵ 4.29, 238 mμ, log ϵ 4.29, 308 mμ, log ϵ 3.65.

Aspidocarpine perchlorate, prepared in the usual manner separated from methanol as colorless needles, m.p. 280–282° (decomp.). Found: C, 56.38; H, 6.29; N, 5.93. Calc. for $C_{22}H_{30}O_3N_2.HClO_4$: C, 56.11; H, 6.64; N, 5.95%. Ultraviolet spectrum in 95% ethanol: λ_{max} 227 mμ, log ϵ 4.28, 262 mμ, log ϵ 3.82; λ_{min} 250 mμ, log ϵ 3.68.

Aspidocarpine hydrochloride crystallized from ethyl acetate–ethanol as colorless prismatic needles, m.p. 224–230° (decomp.). Found: C, 64.47; H, 7.52. Calc. for $C_{22}H_{30}O_3N_2.HCl$: C, 64.93; H, 7.63%.

The hydrobromide separated from methanol as prismatic needles m.p. 288–290°. Found: C, 57.82; H, 6.68. Calc. for $C_{22}H_{30}O_3N_2.HBr.O.5H_2O$: C, 57.38; H, 7.00%.

Aspidocarpine hydriodide crystallized in rectangular plates from methanol, m.p. 272–274° (decomp.). Found: C, 52.17; H, 6.09. Calc. for $C_{22}H_{30}O_3N_2.HI.0.5H_2O$: C, 52.08; H, 6.35%.

O-Acetylaspidocarpine

Aspidocarpine (281 mg) was dissolved in acetic anhydride (3 ml) containing pyridine (0.8 ml) and allowed to stand at room temperature for 6 hours. The solution was evaporated to dryness under reduced pressure, the residue dissolved in benzene and chromatographed on neutral alumina. Careful elution with benzene and evaporation of the eluate gave a crystalline product which separated from hexane–ether as colorless prisms, m.p. 165–167°, $[\alpha]_D^{25}$ −8.4° (*c*, 0.81 in chloroform). Found: C, 69.90; H, 7.78; CH_3CO, 20.25. Calc. for $C_{24}H_{32}O_4N_2$: C, 69.88; H, 7.82; CH_3CO (one OAc+one NAc) 20.86%. Infrared in chloroform: 1768 (s), 1666 (s) cm^{-1}. Ultraviolet (95% ethanol; Cary model 11M): λ_{max} (log ϵ) 223 mμ (4.53), 253 mμ (3.98), 292 mμ (3.61); λ_{min} (log ϵ), 240 mμ (3.89), 272 mμ (3.28). The spectrum was not appreciably affected by the presence of base.

O-Methylaspidocarpine

Aspidocarpine (1.040 g) was dissolved in dilute hydrochloric acid (20 ml) and the solution made basic by the cautious addition with stirring of 20% aqueous sodium hydroxide. A precipitate was first formed which redissolved after the solution had become basic. Methylation was carried out with methyl sulphate (5 ml) in the usual manner. The product which separated as the reaction proceeded was filtered off and washed with water. After two crystallizations from aqueous methanol it consisted of prismatic needles (0.752 g) m.p. 152–154° $[\alpha]_D^{25}$ −94° (*c*, 1.15 in chloroform). Found: C, 71.44; H, 8.10; CH_3O, 16.58; CH_3N, 0.94 (spurious). Calc. for $C_{23}H_{32}O_3N_2$: C, 71.84; H, 8.39; $2CH_3O$, 16.14%. pK_a 6.9 (titration with *p*-toluenesulphonic acid in 50% ethanol).

Infrared (chloroform): 1660 (sh), 1645 (s) cm^{-1}; in carbon tetrachloride, 1663 (s) cm^{-1}; in nujol, 1656 (s) cm^{-1}. Ultraviolet in 95% ethanol: λ_{max} (log ϵ) 224 mμ (4.60), 252 mμ (4.07), 288 mμ (3.44), λ_{min} (log ϵ), 244 mμ (4.03), 279 mμ (3.41). The spectrum was not appreciably affected by base.

O-Methyldeacetylaspidocarpine

O-Methylaspidocarpine (107 mg) was dissolved in 10% hydrochloric acid (5 ml) and the solution refluxed in an atmosphere of nitrogen for 3 hours. The cooled solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

made basic with solid sodium carbonate and immediately extracted with chloroform. After drying (sodium sulphate) the extract was evaporated to dryness and the residue dissolved in aqueous methanol from which it crystallized as white needles (50 mg), m.p. 151–152°. Recrystallization raised the melting point to 153–154°. $[\alpha]_D^{25}$ −4.9° (*c*, 1.03 in chloroform). pK_a 7.8 (titration with *p*-toluenesulphonic acid in 50% ethanol). Found: C, 73.95; H, 8.83; N, 8.65. Calc. for $C_{21}H_{30}O_2N_2$: C, 73.64; H, 8.83; N, 8.18%. Infrared in nujol 3335 cm^{-1}. Ultraviolet in 95% ethanol: strong end absorption, λ_{infl} 240 mμ, log ε 3.82, λ_{min} 268 mμ, log ε 2.97, λ_{max} 293 mμ, log ε 3.49. The spectrum was not appreciably affected by acid.

Treatment of a sample of O-methyldeacetylaspidocarpine with acetic anhydride and pyridine reconverted it to O-methylaspidocarpine in about 50% yield.

O,O-Diacetyl-O-demethylaspidocarpine

Aspidocarpine (731 mg) was refluxed with constant boiling hydrobromic acid (10 ml) in an atmosphere of nitrogen for 1 hour. The solution was evaporated to dryness under reduced pressure and the residue heated on the steam bath with acetic anhydride (15 ml) in an atmosphere of nitrogen for 3 hours. The solution was evaporated to dryness under reduced pressure and the residue dissolved in dilute aqueous sodium carbonate. This solution was extracted with ether and the extract washed with a little water and dried (sodium sulphate). Evaporation of the ether yielded a residue (757 mg) which crystallized from hexane–acetone as yellowish microcrystals (510 mg), m.p. 140–144°. After treatment with charcoal and recrystallization from the same solvent, the product consisted of colorless platelets, m.p. 144–145°, $[\alpha]_D^{25}$ +9.8° (*c*, 1.33 in chloroform). Found: C, 68.21; H, 7.19; CH_3CO, 30.36. Calc. for $C_{25}H_{32}O_5N_2$: C, 68.16; H, 7.32; $3CH_3CO$, 29.31%. Infrared in chloroform: 1777 (sh), 1767 (s), 1668 (s) cm^{-1} (in nujol, 1204 cm^{-1}).

O-Demethylaspidocarpine

The material was prepared first by controlled hydrolysis of O,O-diacetyl-O-demethylaspidocarpine but it was found more convenient to start with aspidocarpine and carry out the whole preparation in the same flask without isolating the intermediates in pure form.

Aspidocarpine (1.043 g) was treated successively with hydrobromic acid and acetic anhydride as described above for the preparation of the diacetyl derivative. After removal of the acetic anhydride, the crude residue was dissolved in methanol (25 ml) to which was added 20% aqueous sodium hydroxide (2.5 ml). The solution was refluxed in an atmosphere of nitrogen for 20 minutes and then evaporated under reduced pressure to a volume of about five milliliters. Crushed ice (ca. 5 g) was added, the solution made just acid with 5% sulphuric acid, then brought to pH 8 with aqueous sodium carbonate and finally thoroughly extracted with chloroform. The extract was dried (sodium sulphate) and the solvent removed by evaporation. The residue, a brown solid (0.845 g) was dissolved in a mixture of ether and benzene and passed through a short column of silica gel which was then eluted with a mixture of benzene (4 parts) and ether (1 part). Evaporation of the eluate yielded a colorless solid (0.676 g) which, on crystallization from aqueous methanol, formed needles, m.p. 130° with an apparent phase change and partial melting at 92–94°. Recrystallization from benzene produced colorless tablets, m.p. 130°, with softening above 125°. After drying *in vacuo*, found: C, 70.91; H, 8.17; N, 7.79. Calc. for $C_{21}H_{28}O_3N_2$: C, 70.76; H, 7.92; N, 7.86%. $[\alpha]_D^{25}$ +121° (*c*, 0.81 in chloroform). Infrared (nujol), 3330 (m), 1634 (s) cm^{-1}. Ultraviolet (pure ethanol): λ_{max} (log ε) 227 mμ (4.41),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

262 mμ (4.01), λ_{min} (log ε) 248 mμ (3.86). In the presence of buffered boric acid: strong end absorption, λ_{infl} (log ε) 258 mμ (4.08), λ_{max} (log ε) 290 mμ (3.56).

For the determination of the ultraviolet spectra in the presence of buffered boric acid a stock solution of O-demethylaspidocarpine (2.0 mg) in pure ethanol (10 ml) was prepared. Simple dilution of the stock solution afforded the solution used in determining the spectrum of the untreated substance. For the spectrum in the presence of buffered boric acid, the stock solution (1 ml) was added to a saturated solution of boric acid in ethanol (2 ml) and diluted to 10 ml with ethanol. Excess anhydrous sodium acetate was added, and the mixture was thoroughly shaken and allowed to stand for 20 minutes before use.

Treatment of O-demethylaspidocarpine in methanol with an ethereal solution of diazomethane reconverted it to aspidocarpine in 60% yield.

Aspidocarpine-N(b)-methiodide

Aspidocarpine (258 mg) was dissolved in dimethylformamide (5 ml) containing methyl iodide (3 ml) and heated under reflux on a steam bath for 4 hours. The solution was evaporated to dryness on a rotary evaporator and the yellow residue crystallized from methanol from which it separated as yellowish crystals (170 mg), m.p. 280–284° (decomp.). Recrystallization from the same solvent gave colorless rectangular plates, m.p. 288–290° (decomp.). Found: C, 52.93; H, 6.26. Calc. for $C_{22}H_{30}O_3N_2.CH_3I.O.5H_2O$: C, 52.98; H, 6.57%.

Aspidocarpine-N(*b*)-methiodide (34 mg) was refluxed for 30 minutes with a solution of potassium hydroxide (70 mg) in 95% ethanol (5 ml) in an atmosphere of nitrogen. The solution was evaporated to dryness under reduced pressure and the yellowish residue dissolved in water (5 ml). The aqueous solution was thoroughly extracted with ether, the extract washed with a little water, dried (sodium sulphate), and evaporated to dryness. The residue was a slightly discolored crystalline solid (17 mg) which, on recrystallization, proved identical with an authentic sample of aspidocarpine.

von Braun Degradation: Aspidocarpine Bromocyanamide

Aspidocarpine (215 mg) was refluxed with cyanogen bromide (416 mg) in chloroform (10 ml) for 24 hours. Evaporation of the solution left a white residue which was triturated with ethyl acetate. The insoluble fraction (70 mg) proved to be aspidocarpine hydrobromide. The ethyl acetate solution when concentrated deposited a colorless crystalline solid (133 mg), m.p. 167–169°, which formed needles, m.p. 170–171° on recrystallization from methanol. Found: C, 58.45; H, 6.33; N, 8.93. Calc. for $C_{23}H_{30}O_3N_3Br$: C, 57.98; H, 6.35; N, 8.81%. Infrared (nujol): 2218(m), 1633(s) cm^{-1}.

In a subsequent preparation, the alkaloid hydrobromide was removed by dissolving the crude mixture in chloroform and chromatography on a short column of neutral alumina.

Aspidocarpine bromocyanamide (73 mg) was refluxed for 6 hours with 95% ethanol (9 ml) in an atmosphere of nitrogen. The solution was concentrated to a small volume under reduced pressure, diluted with a little water, made basic with solid sodium carbonate, and extracted with chloroform. The extract, after drying over sodium sulphate, was chromatographed on a short column of neutral alumina and eluted with chloroform. The eluate yielded a solid product (60 mg) which, on crystallization from methanol, formed colorless prisms identical in every respect with aspidocarpine.

Chromic Acid Oxidation

(a) Aspidocarpine

The alkaloid (1.131 g) was dissolved in water (17 ml) containing sulphuric acid (3 ml) and heated on a steam bath. Chromium trioxide (1.8 g) dissolved in a little water was cautiously added over a period of about one hour. Heating was continued for a further hour and the hot solution subsequently made basic with hot aqueous barium hydroxide and filtered. The yellow filtrate was exhaustively extracted with chloroform and the dried (sodium sulphate) extract evaporated. A semisolid residue was left (0.169 g) which was dissolved in benzene, chromatographed on neutral alumina, and crystallized in a mixture of hexane and acetone from which it separated as yellowish microcrystals (76 mg), m.p. 222–224°. Recrystallization from the same solvent gave pale yellowish rods, m.p. 224–225°, $[\alpha]_D^{25}$ −132° (*c*, 1.03 in chloroform). Found: C, 68.87; H, 8.52; N, 10.63. Calc. for $C_{15}H_{22}O_2N_2$: C, 68.67; H, 8.45; N, 10.68%. Infrared (chloroform): 3410 (w), 1762 (s), 1728 (vs) cm^{-1}. Ultraviolet (95% ethanol): λ_{min} 227 mμ log ϵ 3.31, λ_{max} 252 mμ log ϵ 3.55, 336 mμ, ϵ 59. In the presence of a drop of dilute aqueous potassium hydroxide: λ_{min} 234 mμ log ϵ 3.28, λ_{max} 268 mμ log ϵ 3.48 (longer wave-length absorption not measured).

(b) Aspidospermine

Aspidospermine obtained from Inland Alkaloid Co., and recrystallized (1.020 g) was treated with chromic acid as described above, except that heating was continued for 8 hours. The crude product (0.105 g) proved more difficult to purify than the oxidation product of aspidocarpine. The crystalline product, m.p. 223–225°, has $[\alpha]_D^{25}$ −128° (*c*, 0.47 in chloroform). Its infrared spectrum contained the same peaks as that of the oxidation product of aspidocarpine and the X-ray diffraction patterns of both compounds were identical.

ACKNOWLEDGMENTS

The authors acknowledge their indebtedness to Dr. Maria Przybylska for the X-ray powder patterns and Dr. R. Norman Jones and Mr. R. Lauzon for the infrared spectra.

THE ELECTROCHEMICAL BEHAVIOR OF THE NICKEL OXIDE ELECTRODE

PART II. QUASI-EQUILIBRIUM BEHAVIOR[1]

P. L. Bourgault and B. E. Conway

ABSTRACT

The electrode potential of the nickel oxide electrode has been determined as a function of water and solute activity in aqueous solutions of potassium hydroxide. The electrode, which was charged to a mean state of oxidation corresponding to 50% Ni II and 50% Ni III, was examined after long periods of time and by cathodic and anodic e.m.f. decay measurements after polarization in order to establish the quasi-reversible potentials by two methods. The results are discussed in terms of the stoichiometry of the potential-determining reaction, and distinction between mixed and true reversible potentials is made.

INTRODUCTION

We have previously examined in part I (1) the kinetic behavior of the "overcharged" nickel oxide electrode with regard to rates of self-discharge and oxygen evolution. In the present paper we present data on the quasi-equilibrium potentials of the nickel oxide electrode in aqueous potassium hydroxide solutions. The behavior of the electrodes is referred to as "quasi-equilibrium" since the electrodes are continuously losing charge on open-circuit by the corrosion type of process described previously (1).

This can affect the electrode in two ways: firstly to produce a continuous but slow decrease of the state of oxidation of the oxide and secondly to give rise to an electrode potential which is more cathodic than the true equilibrium potential corresponding to the formal state of oxidation of the oxide. In fact, the potentials measured on open-circuit are analogous to mixed potentials observed in corrosion, since there is a slow anodic evolution of oxygen and a corresponding cathodic self-reduction of the oxide. This factor does not seem to have been realized in previous work (2, 3, 4). However, by suitable choice of conditions and methods of study it is possible to determine the potential of the electrode under conditions very near to equilibrium. Thus, if the electrodes are left in dilute potassium hydroxide (0.001 M) for several days, the potential ceases to change by more than 0.1 mv per hour and the potential of the electrode may then be examined as a function of potassium hydroxide activity without further significant self-discharge during the measurements. Also in the solutions of higher alkali concentration the electrode is more stable* since the open-circuit potential becomes less anodic to the reversible oxygen potential and the rate of self-discharge (already allowed to become small in the 0.001 M solution) becomes negligible.

Electrode potentials and stoichiometric reactions for the potential-determining reaction at the nickel oxide electrode have been discussed in earlier work by Forster (2) and Zedner (3) and more recently by Kornfeil (4). A potential of 0.49 v has been attributed to the nickel oxide electrode by Latimer (5), but no evidence that the potential-determining species (e.g. NiO_2) are those written by Latimer (5) has been given; in fact there is no evidence that NiO_2 exists as such in the electrochemically active material in the nickel

[1]*Manuscript received April 22, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

**This is not in contradiction to our previous findings (1); in the latter work we showed that the exchange currents for oxygen evolution became greater in the solutions of higher alkali concentration. In the present work the open-circuit potentials are lower in the stronger solutions so that the oxygen "overpotential" is relatively smaller and the self-discharge rate is hence less at the open-circuit potential.*

oxide electrode. The IV-valent state of nickel may exist in a non-stoichiometric oxide lattice in electrodes charged beyond the "$NiO_{1.5}$" composition but it is not possible at room temperature to achieve states of oxidation greater than about "$NiO_{1.7}$" (6), so that the oxide cannot be completely oxidized to the "NiO_2" state. In other work (2, 3) the stoichiometric reactions suggested are not in mutual agreement and the more recent work (4) contributes further serious discrepancies.

We have therefore examined the potential of partially charged nickel oxide electrodes at a controlled formal state of oxidation as a function of potassium hydroxide and water activity in aqueous alkali solutions by a polarization decay method in which the reversible potential is approached both from the anodic and cathodic directions. This method may be expected to give more reliable values of the electrode potential than those obtained by leaving the electrode on open-circuit for arbitrary periods of time. We have also compared data obtained by the decay method with the e.m.f. values from "stationary" potential measurements i.e. at very long times, and deduced the nature of the potentials which are measured by these procedures. From these determinations, the role of potassium hydroxide and water in the over-all potential-determining reaction can be evaluated.

EXPERIMENTAL

1. General

Nickel hydroxide electrodes were prepared in nickel sinters as described previously and charged anodically (7, 1) to the higher oxide for 30 hours at 25° C in aqueous potassium hydroxide (analytical grade) solutions of the concentrations indicated below, until an appreciable rate of oxygen evolution was maintained.

2. Reversible Potentials from Polarization Decay Measurements

Here the potentials of nickel oxide electrodes at a formal state of oxidation of $NiO_{1.25}$ were determined by extrapolating cathodic and anodic e.m.f. decay lines, plotted logarithmically in time, to the potential of their intersection. This procedure is analogous to the determination of reversible potentials by extrapolation of anodic and cathodic Tafel lines to zero overpotential (cf. 26).

The electrodes were prepared as described above and initially charged in solutions of KOH of various concentrations at 38.2 ma per gram of $Ni(OH)_2$ for 30 hours at 25° C. The electrodes were then left to stand on open-circuit to allow the surface pseudocapacity (8) to become discharged. The remaining bulk electrochemical capacity* was then determined by discharging the electrode at a constant rate such that the theoretical capacity (based on a state of oxidation "$NiO_{1.5}$") would be discharged in 5 hours. The observed charge held by the electrodes agreed with that expected theoretically to within 10% (this deviation simply means that a state of oxidation slightly different from $NiO_{1.5}$ is reached initially). On the basis of this determination, a charging rate i_c was then chosen such that the electrode would be oxidized to 50% Ni^{II}–Ni^{III} (i.e. $NiO_{1.25}$) in 1 hour. The charging was interrupted and the decay of potential was followed on open-circuit for 24 hours or more on a recording potentiometer. The charging was resumed at the rate i_c for 2 hours; after decay on open-circuit for several hours (to again discharge the surface capacity associated with oxygen evolution), discharging was commenced at the rate $-i_c$ for 1 hour so that the electrode regained a state of oxidation of "$NiO_{1.25}$". The discharging current was interrupted and the potential decay from this *cathodic*

**We use the term "capacity" here in the sense familiar in battery technology. We in fact determine the Faradaic charge, which can be withdrawn from the electrode by the current i_c passing for a measured period of time.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

polarization was followed for 24 hours, after which the remaining bulk electrochemical "capacity" was checked by complete discharge with the same current, $-i_c$.

This sequence of operations and the corresponding e.m.f.'s are shown schematically for a typical experiment (in 7.3 M KOH) in Fig. 1.

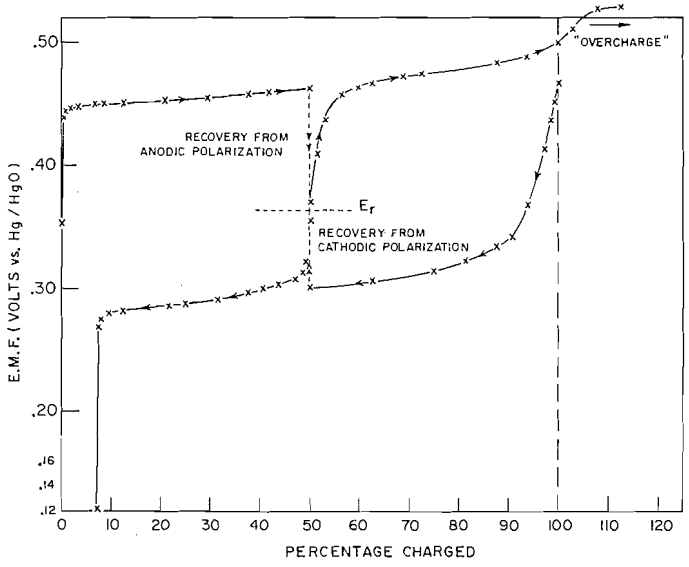

FIG. 1. Charging and discharging cycle for the nickel oxide electrode used in polarization decay studies.

3. Quasi-Equilibrium Potentials

In this series of measurements, electrodes were allowed to stand on open-circuit in 0.001 M aqueous KOH until the degree of charge corresponded to an approximate state of oxidation of "$NiO_{1.25}$". The electrodes were then transferred to other potassium hydroxide solutions by the following three alternative procedures:

(*a*) Six electrodes were transferred directly into solutions 14.6, 11.0, 7.3, 3.7, 1.46, and 0.146 M in KOH, respectively, which were stirred by bubbling purified oxygen. The e.m.f. of the electrodes was followed as a function of time (versus a Hg/HgO electrode) for 1 week.

(*b*) Six electrodes were transferred from the 0.001 M KOH to a solution of 14.6 M KOH where they were allowed to stand for about 24 hours; they were then transferred to solutions of 0.07, 0.146, 0.73, 1.46, 7.3, and 11 M KOH respectively and again the e.m.f. was recorded at regular intervals of time.

(*c*) (i) An electrode was taken from the 0.001 M KOH solution and then allowed successively to equilibrate in 0.07, 0.7, 3.65, 7.3, 11.0, and 14.6 M KOH solutions for periods of 2 hours during which the e.m.f. became constant to better than 0.5 mv per hour. A reverse series of measurements was then made by transferring the electrodes back from the concentrated to the more dilute solutions.

(ii) A similar series of e.m.f. values were obtained by transferring the electrode from the 0.001 M KOH directly to the strongest (14.6 M) solution and thence successively to the more dilute solutions and back again to the more concentrated ones.

From these measurements, the reversibility of the e.m.f. changes with changes of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

concentration could be judged. The sequence of changes of conditions and corresponding e.m.f. values can be seen by reference to Fig. 2.

The degree of oxidation of the electrodes was measured after the e.m.f. runs by discharging the electrodes at a controlled current (30 ma per gram of $Ni(OH)_2$) and hence determining coulometrically their electrochemical "capacity".

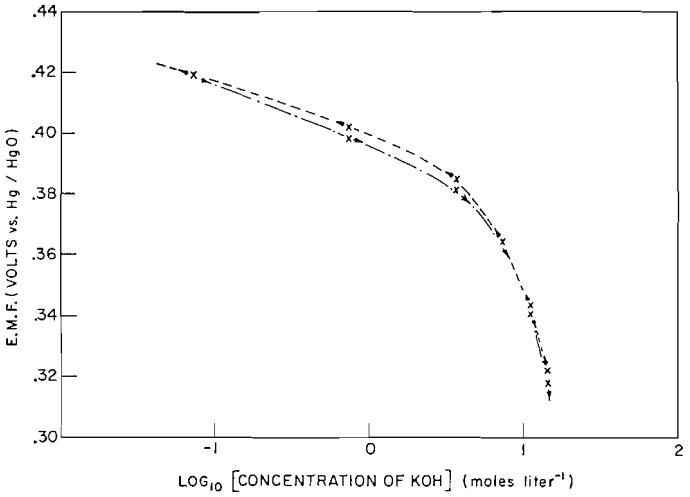

FIG. 2. Reversibility of e.m.f. of the nickel oxide electrode with successive changes of concentration. Arrows indicate sequence of changes for electrode initially put in strongest solution after being maintained in 0.001 *M* KOH.

4. Solutions

Aqueous solutions of analytical grade potassium hydroxide were made up by diluting a saturated (25° C) solution of potassium hydroxide kept in a "seasoned" closed "polythene" bottle. Concentrations were checked after runs by titration against standard acid. The water used had been prepared from distilled water by a further distillation from alkaline permanganate in a still provided with three glass spray traps. Use of potassium hydroxide recrystallized at −20° C gave results insignificantly different from those obtained with the analytical grade reagent.

Several experiments were also carried out in heavy water (99.76% D_2O) and in these cases, KOD solutions in D_2O were prepared by decomposing electrolytically prepared dry potassium amalgam with the heavy water. The nickel oxide electrodes for this part of the work were prepared by impregnating the sinters with a solution of nickel sulphate made up from the anhydrous substance by dissolution in deuterium oxide. The Ni_2SO_4 was obtained from the hexahydrate by heating it to constant weight (52 hours) at 600–700° C. Control runs were also carried out on electrodes prepared by the same method but using ordinary water as the solvent.

5. Measurement of e.m.f.

Potentials of the nickel oxide electrodes were measured against yellow mercuric oxide electrodes (9) in the same solutions by means of a Tinsley potentiometer and a Philips high input impedance recording potentiometer capable of measuring to 0.5 mv on a full scale of 100 mv on various voltage ranges.

RESULTS

1. Polarization Decay

The kinetic significance of measurements of decay of e.m.f. after cessation of a polarization has been treated previously (10, 11). Thus, the rate of decay of e.m.f. with (Naperian) logarithmic time gives the Tafel slope $-RT/\alpha F$ for the rate-determining mechanism involved in the discharge of the double-layer or surface capacity provided that this capacity is constant in the range of potentials over which the polarization decay occurs. At very long times of decay, the e.m.f. approaches the reversible potential asymptotically as discussed previously (11). Thus, plots of e.m.f. during decay from both anodic and cathodic polarization vs. the logarithm of the effective time of decay can be extrapolated to a potential where they intersect and this potential should approximate closely to the reversible potential E_r (unless other alternative processes can occur), which would theoretically be reached only after infinite time. Plots of decay of anodic and cathodic polarization as a function of time t plus θ, where θ is the semiempirical constant discussed previously (11, 1), are shown for the $NiO_{1.25}$ electrode in Figs. 3*a–d* and 4*a*, *b* for the indicated concentrations of potassium hydroxide. The quantity θ can be regarded as the time required for the potential of the electrode to fall from an infinite value to that at the commencement of decay of the polarization corresponding to passage of a current i_c. The constant θ is given by

$$\theta = Cb/2.3\ i_c \qquad [1]$$

where b is the Briggsian slope for the decay process and C is the capacity suffering discharge by the electrochemical process. The quantity θ is determined as described previously (1, 11) by an empirical procedure but is not involved in the kinetic equations determining the slope b and hence the extrapolated values of E_r.

In order to establish the effect of varying water activity at a constant KOH activity, one experiment was carried out in a saturated aqueous KF solution (25° C) 0.08 molar (i.e. approximately unit activity (see Discussion, Section 4)) in KOH. The anodic and cathodic decay lines are shown in Fig. 4*b*.

In the Figs. 3*a–d* and 4*a*, *b*, the extrapolated values of potential designated E_m or E_r (see below) are shown in the brackets on the ordinate axes and are indicated by dotted lines. Cases where inflections occur in the anodic lines are discussed in detail below.

Decay lines similar to those in Figs. 3*a–d* and 4*a*, *b* are also given in Fig. 5 for the nickel oxide electrodes in a 0.93 *M* KOD solution in deuterium oxide and the data shown are the means of two sets of values which agreed to ca. ±2 *mv*.

2. Quasi-Equilibrium Potentials

The potentials obtained by the procedure *c*(ii) described in Section 3 under Experimental are shown as a logarithmic function of molar concentration of KOH in Fig. 2. The results obtained from "backward" successive immersions agreed with those obtained by "forward" immersions as shown in this figure but some irreversibility occurs when the sequence of operations is carried out by immersing the electrode initially in dilute solutions (*c*(i)) followed successively by more concentrated solutions and then returned to the more dilute solutions. These values obtained in the "forward" direction by procedure *c*(i) are not therefore regarded as true equilibrium values.

In Fig. 6, comparison is made between the data obtained by procedure *b* (crosses)

(taking the e.m.f. attained 24 hours* after transfer of an electrode from a strong solution to a more dilute one) and the polarization decay method (circles) and it is seen that the polarization decay values tend to be significantly more positive (ca. 15–30 mv) to the Hg/HgO electrode than those obtained by procedure *b*. This is in fact to be expected

**The e.m.f. values obtained by procedure c are not used for comparison with the decay values since the times of equilibration may have been too short for electrolyte diffusion effects to have become negligible in the strongest solutions (see Appendix).*

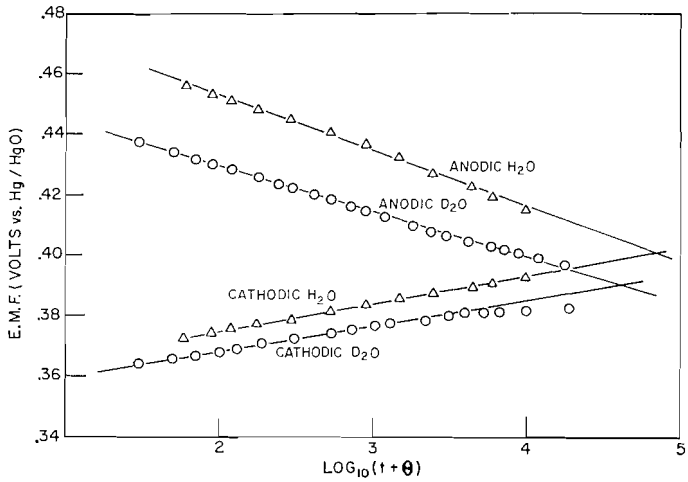

FIG. 5. Decay of e.m.f. from anodic and cathodic polarization in 0.93 *M* KOD/D_2O or KOH/H_2O.

since the values obtained by the latter procedure are the mixed potentials and will be depressed from the true reversible potential by the small cathodic polarization impressed on the electrode by virtue of its finite rate of self-discharge by the corrosion-type of process discussed previously (1).

3. Accuracy and Reproducibility

Owing to kinetic self-discharge effects and to the relatively complex method (7, and above) of preparation of the electrodes at a controlled state of charge, reproducibility of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

electrode potentials cannot be expected to be so good as that obtainable with primary standard half-cells, e.g. the Ag/AgCl electrode (12). However, replicate runs usually gave e.m.f. values (vs. the Hg/HgO electrode) reproducible to ±3 mv from either the polarization decay method or the procedure *b*.

The precision of the measurements was greater than this since potentials measured on the Tinsley and automatic recording potentiometers could be read to 0.2 mv and 0.5 mv, respectively, with a similar accuracy after standardization by means of a Weston cadmium cell. The temperature of the air thermostat used to house the cells during measurements was constant to ±0.1° C. The order of magnitude of the temperature coefficient of the e.m.f. of the nickel oxide – mercuric oxide electrode pair is 10^{-1} mv $°C^{-1}$ (13) so that the constancy of temperature provided was more than adequate to ensure insignificant errors of e.m.f. arising from temperature fluctuations.

DISCUSSION

1. *Nature of the Electrode Processes*

In the polarization decay studies, the aim was to disturb the equilibrium between reduced and oxidized forms of the nickel oxide in the semicharged electrode ("$NiO_{1.25}$") by passing an anodic or a cathodic current and then observing the decay towards the reversible potential of the oxide electrode. However, whilst passage of a current in either direction will cause a change in the formal degree of oxidation of the bulk material, for the reasons given below this process is found to be an *indirect* one.

The quantity θ, which can be determined empirically for the decay lines shown in Figs. 3 and 4, as described previously (11, 1), enables the surface capacity associated with the electrochemical processes involved in the decay of e.m.f. to be calculated (equation [1]) and the values found are between 500 (7 *M* KOH) and 3000 (0.01 *M* KOH) farads per gram of $Ni(OH)_2$. This capacity is very much larger by several orders of magnitude than any possible ionic double-layer capacity corresponding to the real area of the nickel in the sinter (5000 cm^2* in an electrode capable of supporting 1 g of $Ni(OH)_2$). On the other hand, the charge which can be withdrawn from this capacity over a given voltage range is very much smaller, by a factor of 50–100, than that which can be withdrawn as conventional electrochemical "capacity" from the bulk material over a comparable range of voltage.

The values of the capacity obtained from θ were checked by observations on the potential (E) – time (t) relations for build-up and forced decay of e.m.f. at constant current using the half-charged electrodes. Although there was some hysteresis between build-up and forced decay lines, the mean capacities obtained as $d(it)/dE$ from these measurements were comparable with the capacity values obtained from θ.

The above values of capacity must therefore be regarded as corresponding to a *surface* layer (14*a*) of intermediates (probably adsorbed radicals of OH or O) which participate in the process of oxidation of the bulk material. Conversely, the reduction of the bulk material proceeds by an opposite process, and the reactions observed in the cathodic and anodic polarization and their decay correspond, respectively, to removal and formation of this surface layer. The capacity associated with this layer may be referred to as a "surface capacity" in which the degree of charge must be changed before any chemical changes in the bulk oxide can be effected.

We may therefore qualitatively represent the behavior of the electrode upon charge or

**This value was kindly determined by Dr. C. Amberg of the National Research Council on an outgassed sample of sinter by the B.E.T. method.*

discharge by the electrical analogue shown in Fig. 7 where C_S is the surface capacity, C_B that corresponding to the electrochemically active bulk material, R_{O_2} the non-ohmic

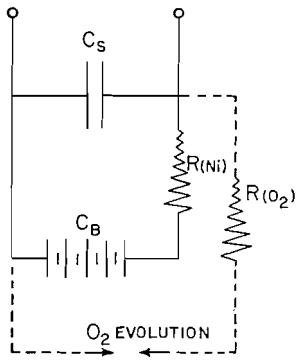

FIG. 7. Schematic equivalent circuit by which charging and discharging of electrode can be represented.

resistance corresponding to the reciprocal of the rate of electrochemical oxygen evolution, and R_{Ni} that corresponding to the reciprocal of the rate of oxidation or reduction of the bulk material by the chemisorbed species constituting the surface pseudocapacity.

When current is made to flow anodically into the system through the two schematic terminals at the top of the circuit (Fig. 7), C_S is first charged up and in the steady state, charge flows mainly through R_{Ni} with some "leakage" through R_{O_2}, giving, respectively, simultaneous oxidation of the bulk material (C_B) and some oxygen evolution. On open-circuit, following anodic polarization, oxygen evolution still occurs (but this can only be detected in the "over-charge" region (Fig. 1) as described previously (1)) and the remainder of the excess charge on C_S passes into C_B with resultant oxidation of the material. This indirect mechanism of charging is supported by the direction of the H/D isotope effect on the polarization on charging and discharging (Fig. 5), which is significantly *less* in D_2O than in H_2O. If H^+ or D^+ transfer steps (1, 6) were rate-determining in the oxidation or reduction of the bulk oxide the reverse isotope effect would be expected (20). The *faster* rate in D_2O is connected with the expected lower heat of solvation of OD^- than that of OH^- in the respective isotopic solvents (21).

Conversely, on cathodic polarization, C_S is discharged to potentials low enough for current to flow from C_B through R_{Ni} sufficient to maintain the current taken from the over-all system, the oxygen evolution rate then being negligible at these more cathodic potentials (it becomes significant in some cases only as the reversible or mixed potential is reached, e.g. in Fig. 3*d*). On open-circuit following cathodic polarization, C_S can be regarded as recharged by the current through R_{Ni} (less the small current corresponding to oxygen evolution) and this corresponds to the lower recovery lines shown in the Figs. 3*a–d* and 4*a*.

At long times after cessation of anodic or cathodic polarization, the potential across C_S would become equal to that set up across C_B if no leakage occurred through R_{O_2}, i.e. if no self-discharge were taking place, and the reversible potential of the electrochemically active material constituting C_B would then be measured by the potential at which the extrapolated logarithmic decay lines intersect. Inspection of the e.m.f. decay lines indicates, however, that in all but the most dilute solutions there are inflections in the anodic lines and at the highest concentrations (14.6 *M*) also in the cathodic line. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

raises the problem of how the extrapolations should be carried out, i.e. by extension of the upper lines in the region of low times (i.e. log $[t+\theta]$ in the range 1 to 3) or production of the lines after the longest periods of time (i.e. for log $[t+\theta] > 4$). We therefore now consider possible reasons for these inflections in the decay lines.

2. Form of the Decay Lines

(a) Oxygen Evolution Rates

The anodic decay lines for concentrations greater than 0.1 *M* KOH show an inflection from a low slope to a high slope with increasing time which is characteristic of *alternative* electrochemical reactions with different Tafel slopes as discussed by Parsons (14). From the foregoing, it is evident that the process alternative to the one with the lower slope could be oxygen evolution. At higher anodic potentials we have examined the kinetics of oxygen evolution (1, 15) and from these data it is possible to calculate what the rate of oxygen evolution will be in the range of potentials over which the polarization decay occurs at the semicharged electrodes. In Figs. 8*a* and 9*a* are shown the Tafel lines for the anodic oxidation (I) of the semicharged electrode and for oxygen evolution (II) in solutions of the same concentration. The solid lines show the polarization behavior based on i_0 and b values* for each of the alternative processes and the dotted line shows the calculated *total* rates† over the potential range where I and II have comparable rates. Figs. 8*b* and 9*b* show the same data plotted in terms of the e.m.f. decay lines, the dotted region corresponding to the total rate similarly drawn in Figs. 8*a* and 9*a* and the points the actual e.m.f.'s obtained during an experimental decay run. It is clear from these figures that between 0.1 *M* and 7.3 *M* the inflections in the anodic decay lines are adequately accounted for by the alternative oxygen evolution process which becomes (because of its higher b value) the predominant process at low potentials. We may note that the cathodic lines in Figs. 3*a–d* show no significant inflections; this would be expected since the alternative oxygen process is much slower at the more cathodic potentials. Calculations of the rates of the alternative oxygen evolution process indicate that the inflections in all the anodic decay plots up to 7.3 *M* KOH can be accounted for. However, in the 14.6 *M* KOH solution and in some experiments carried out at 0° C, the oxygen evolution rate is too slow by a factor of about 100 to influence the decay, yet an inflection is observed (Fig. 4*a*) and is also present now in the cathodic line. Furthermore, in the 14.6 *M* solution, the e.m.f. reached at long times is below the reversible oxygen potential so that the oxygen evolution process referred to above cannot be responsible for depressing the e.m.f. to this low value. The electrochemical charging or discharging reaction causes changes of the relative concentrations of water and KOH in the sinter (2, 3, 4) and we show in the Appendix that this effect brings about a concentration polarization in the porous electrode which falls off with time on open-circuit owing to diffusion and gives rise to the inflection in Fig. 4*a*.

(b) Mixed Potentials

From the above, it is seen that the potentials reached at the intersection of the decay lines for solutions up to 7.3 *M* in KOH (or at very long times) must be the mixed potentials corresponding to a finite rate of oxygen evolution and self-discharge on open-circuit. These potentials will be less anodic than the true reversible potentials. From the present data (Figs. 3*a–d*) and our other work (1, 15), we can obtain the polarization parameters

**The method of calculation of these parameters from the decay lines has been discussed previously (11, 1).*

†True surface areas of the oxide electrode being unknown, rates in these figures and in Fig. 10 are expressed in amp g^{-1} of $Ni(OH)_2$ *as discussed previously (1).*

i_0 and b for the cathodic and anodic partial "corrosion" reactions, respectively, in the self-discharge process; hence, the mixed potential and the net self-discharge rate at this potential may be calculated as shown in Fig. 10 for 7.3 M KOH solution. In this diagram,

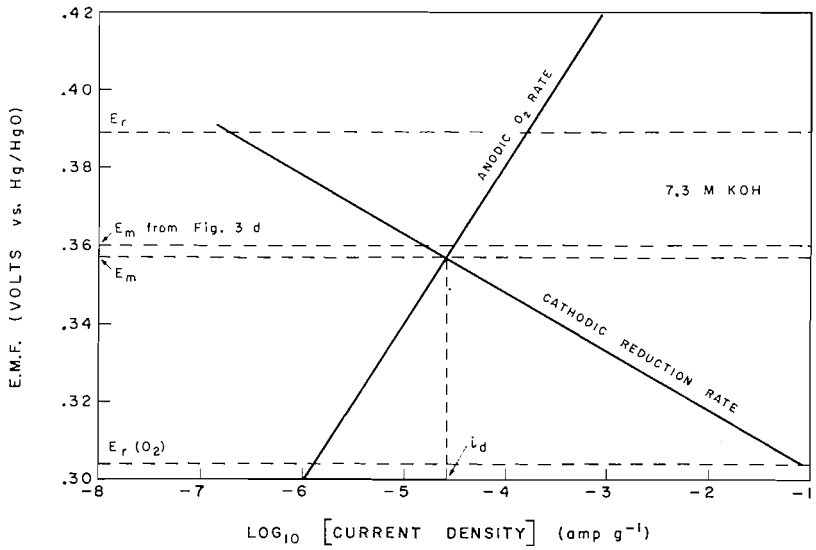

FIG. 10. Polarization lines for the partial reactions in the "corrosion" or self-discharge of the nickel oxide electrode in 7.3 M KOH (symbols are defined in text).

E_m is the steady-state mixed potential, E_r the ideal reversible potential, and i_d the net rate of "corrosion" or self-discharge. It is clear that any e.m.f. measurements (cf. 2, 3, 4) taken on open-circuit at long periods of time, except in the most concentrated solutions and at low temperatures, will not give the true reversible potential E_r but the steady-state *mixed* potential E_m, which will be lower than E_r by 5–30 mv. Similar figures to 10 may be drawn for the other concentrations of KOH and, except for the 14.6 M KOH solution, the extrapolated or long-time potentials will be E_m.

3. Assignment of Reversible Potentials

In solutions up to 7.3 M in KOH, the true reversible potentials E_r should be based on extrapolation of the whole region of the cathodic decay lines and that region of the anodic line before which oxygen evolution becomes a significant process, i.e. in the first 3.5 decades of $t+\theta$. The values of E_r thus obtained are shown as circles in Fig. 6 whilst the long-time values or those based on *all* the decay points (i.e. the E_m values) are indicated by crosses. They differ, as expected, by 5–30 mv. In the derivation of the Nernst equation for the electrode, it is clear that the E_r, and not the E_m values as usually used (2, 3, 4), must be considered.

In the 14.6 M KOH solution, the inflection in the decay line cannot be accounted for at all by the process of oxygen evolution, which is some 100 times too slow in the range of potentials concerned to affect the course of the decay curve. For this solution we can show (see Appendix) that the inflection arises from concentration changes in the electrode which fall off with increasing time after termination of the charging. In this solution and in the saturated KF, the values of potential corresponding to intersection of the cathodic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and anodic decay lines are therefore to be taken as the E_r values, there being no mixed potential in this case.

4. The Nernst Equation for the Electrode

From the above assignment of reversible potentials, we obtain a series of E_r values at various KOH concentrations. Using the data of Akerlöf and Bender (16), these E_r values can be expressed as logarithmic functions of activity of KOH and water. Three unknowns are then involved in the Nernst equation for the potential-determining electrode process viz., $E°$, and the two coefficients of the logarithmic activity terms. Using the data shown in Fig. 6 for E_r, we may obtain three (or more) simultaneous equations in E_r (experimentally determined), $E°$, ln a_{H_2O}, and ln a_{KOH}, which give, upon numerical solution, the following Nernst equation at 25° C for the cell

$$\text{Hg/HgO KOH } (a_{KOH}) \begin{cases} \text{NiO.OH*} \\ \text{Ni(OH)}_2\text{*} \end{cases}$$
$$\text{H}_2\text{O } (a_{H_2O})$$

where the * refers to unspecified and probably non-stoichiometric (22, 23, 24) quantities of associated water and adsorbed KOH:

[2] $$E_r = 0.420\ (\pm 0.002) - 0.004\ (\pm 0.001) \log_{10} [a_{KOH}] + 0.105\ (\pm 0.01) \log_{10} [a_{H_2O}],$$

which corresponds to the formal reaction

[3] $$[2\text{NiO.OH}]\ (0.14\text{KOH ads.}) + \text{Hg} + 3.56\text{H}_2\text{O} \rightleftarrows 2[\text{Ni(OH)}_2.1.28\text{H}_2\text{O}] + \text{HgO} + 0.14\text{KOH aq.}$$

It will be noted that in this equation terms both in KOH and water activity are required to represent the results, i.e. the dependence of E_r on KOH concentration cannot be quantitatively accounted for through the diminution of water activity with increasing KOH concentration. This residual dependence on KOH activity is consistent and in fair agreement with that deduced from previous work (4) and our own (see below) using a KOH/KF mixture. Chemically, adsorption of KOH at the higher oxide is not inconsistent with the general properties of higher oxides, which are usually more acidic than corresponding lower ones.

The dependence on water activity is, however, very much greater than that found in Kornfeil's work (4) and is moreover in the *opposite* direction to that found by him. Our results are in qualitative agreement with those of Zedner with regard to direction of the dependence of e.m.f. on water activity. It is unfortunate that Kornfeil's results are presented in an obscure fashion; thus, no *absolute* values of E_r as a function of concentration are stated and the dependence of e.m.f. upon concentration is expressed only as a fraction of the e.m.f. value for a 0.01 M KOH solution, i.e. $E°$ is not stated. Kornfeil's equation

[4] $$E = E° - 0.029\ (0.16 \log_{10} a_{H_2O} + 0.067 \log a_{KOH})$$

also predicts, using the data of Akerlöf and Bender (16), a minimum e.m.f. at 12 molal KOH, whereas in the present work and in that of Zedner (3) the e.m.f. continues to decrease rapidly with increasing concentration at high concentrations of KOH. Since we have no knowledge of the actual e.m.f. values in Kornfeil's work, it is difficult to seek an explanation of his anomalous results. It may be remarked, however, that the procedure used in his work was different to that used here and involved analytical determinations of the change of KOH and water concentrations relative to that of a KCl or KBr reference

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

electrolyte. The interpretation of results obtained by this method may be complicated by variation of adsorption of KCl on the electrode with changing KOH concentration and electrode potential. Thus it is well known that Cl^- ions are specifically adsorbed at electrodes particularly at potentials anodic to the potential of zero charge (25).

For the single electrode process at the nickel oxide electrode, equation [3] gives

[5] $[2NiO.OH]\ (0.14KOH\ ads.)+4.56H_2O+2e \rightleftarrows 2[Ni(OH)_2.1.28H_2O]+0.14KOH\ aq.+2OH^-.$

Equations derived by other workers expressed in corresponding form (cf. 4) to that of equation [5] are

$$2NiO.OH.H_2O+4H_2O+2e \rightleftarrows 2Ni(OH)_2.2H_2O+2OH^- \qquad \text{(Zedner)}$$

and

$$2NiO.OH.0.1H_2O+1.8H_2O+2e \rightleftarrows 2Ni(OH)_2+2OH^- \qquad \text{(Forster)}$$

from which it is seen that apart from the KOH adsorption not considered in the earlier work, our results with regard to dependence on water activity are in closest agreement with those of Zedner. Forster's results (2) differ from the above, possibly on account of the use of nickel oxide electrodes containing graphite. Kornfeil's equation

$$[2NiO.OH]\ (0.067KOH\ ads.)+0.84H_2O+2e \rightleftarrows 2Ni(OH)_2^*+2OH^-+0.067KOH$$

leads to an anomalously small role of water in the electrode process. Most of the above equations involve non-stoichiometric amounts of hydrate water and this is not inconsistent with available data (22, 23, 24) which indicate non-stoichiometric ranges of hydrate composition.

As an independent check on the validity of our equation [2], the measurements made (Fig. 4*b*) in saturated KF containing 0.08 *M* KOH enabled a value of E_r to be obtained at a low KOH activity (1.3*), and in which solution the water activity (determined directly by a differential vapor pressure measurement at 25° C) was also low at 0.30. The value of E_r observed experimentally in the KF/KOH mixture was 0.362 v whilst that calculated from equation [2] for the same conditions is 0.364 (6); the agreement is thus within the reproducibility claimed (see Results, Section 3)) in the present work.

Further work, in which the variation of e.m.f. has been studied with degree of oxidation, viz. at states of oxidation greater and less than "$NiO_{1.25}$" will be reported elsewhere.

APPENDIX

Diffusion Effects

We show here that the inflection in the anodic decay line for the 14.6 *M* KOH solution can be semiquantitatively accounted for by diffusion effects, which can arise in two ways: (i) from changes of e.m.f. of the electrode itself due to changes of KOH and water activity arising from Faradaic transport and the occurrence of the electrode reaction, and (ii) concentration polarization in the electrode arising secondarily from these concentration changes.

**The activity coefficient for* KOH *in the mixed electrolyte was taken as that for a solution of pure* KOH *having the same water activity as that (0.3) in the* KF *solution. This approximation is justified since at very high ionic strengths, the activity coefficient is determined to a large extent by ion–solvent interaction (19).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

During charging, the water and KOH activities near the interface of the electrode material will be higher and lower, respectively, than those in the bulk. After some time, a steady-state activity gradient of water and KOH will be set up in the electrode out towards the solution with a corresponding change in the electrode–solution potential difference. Upon termination of the charging, this activity gradient will fall to zero with attendant e.m.f. changes which will be superimposed on those arising from the "activation controlled" (17) electrode processes discussed above.

It is of interest to make a semiquantitative calculation to establish if these effects could account for the observed inflection in the decay lines in 14.6 *M* KOH.

(*a*) Model: a finite slab of thickness h is assumed (18) with homogeneous solutions at concentration C_b at the two slab–solution interfaces. (The porous electrode approximates to this since its dimensions were $2.5\times1.2\times0.1$ cm.) The integrated solution to the diffusion equation for this model is (18)

$$[6] \qquad \frac{\bar{C}-C_b}{C_1-C_b} = \frac{8}{\pi^2}\sum_{\nu=0}^{\infty}\frac{1}{(2\nu+1)^2}\exp\left[-\left(\frac{(2\nu+1)\pi}{h}\right)^2 Dt\right]$$

where $\bar{C}$ is the mean concentration of diffusing substance (diffusion constant D) at time t, C_1 the initial concentration (or in the present case, the mean steady state concentration of KOH during charging, prior to decay), and ν the order of the terms required in the Fourier solution of the diffusion equation.

(*b*) Calculation of concentration changes with time: we cannot make a rigorous calculation of concentration changes with time owing to the complexity of the diffusion problem in a real electrode. However, the following method involving two successive approximations will enable an estimate of the magnitude of the changes of concentration with time to be calculated. Diffusion will occur as soon as any changes of concentration are brought about by the electrolytic charging. At the end of this process, the average concentration in the sinter will hence be less than that which would have arisen had there been no diffusion *during* charging.

As a first approximation, we assume hypothetically that the latter condition obtains and that this results in a change of mean concentration $\Delta\bar{C}$. The fall of $\Delta\bar{C}$ (with no current passing) with time is then calculated from equation [6] and from this plot rates of change of mean concentration $d\bar{C}/dt$ can be calculated at various times. As a second approximation, we then obtain that value of $d\bar{C}/dt$ from the values discussed above, which corresponds to the rates of production of water and removal of KOH, respectively, during charging. This value of $d\bar{C}/dt$ will then be relevant to that time at which the current is interrupted for decay measurements. In the first approximation treatment, this rate of change of concentration would have been reached after a time t'. The subsequent decay of $\Delta\bar{C}$ with time t after the *actual* termination of charging is then calculated and plotted against t and this concentration change $\Delta\bar{C}$ after the times t would be equivalent to the same changes of concentration after times $t+t'$ in the first approximation calculation. This procedure will thereby allow approximately for the fact that during electrolysis some steady state change of concentration will tend to have been set up which will be less than that occurring if no diffusion took place. Two alternative values of D in equation [6] were taken as 10^{-6} and 3×10^{-7} cm^2 sec^{-1} in order to place limits on the resulting e.m.f. variation which could arise from uncertainties in the value of D. The above values were estimated from data at low concentration (19) by correction for the relative viscosity (η_r) of 14.6 *M* KOH ($\eta_r = 12$) and after empirical allowance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

for the fact that, in the porous electrode, the diffusion path length will probably be somewhat longer than that corresponding to the free linear diffusion and the fact that the channel area available for diffusion out of the electrode will be less than the projected area of the electrode. The values of D taken are probably of the right order of magnitude but cannot be regarded as more precise than this.

From the changes of concentration calculated by the above procedure, the total change of e.m.f., ΔE_c, with time, due to diffusion effects, can be calculated using equations [2] and the data given by Akerlöf and Bender (16) for concentration cells in KOH and water.

The calculated values of ΔE_c are shown for 14.6 M KOH in Fig. 4*a* as a function of time during decay and is seen that ΔE_c is comparable with the total anodic polarization observed and can hence account fairly well for the form of the inflected decay line in 14.6 M KOH. Similar considerations apply to the cathodic line where effects in an opposite direction will occur. It may be noted that no value of θ exists which can lead to linearity of the decay curve in Figs. 4*a* or 4*b*.

We can therefore conclude that the potential to be taken as the reversible one in 14.6 M KOH (Fig. 4*a*) is that corresponding to the intersection of the anodic and cathodic decay lines after the longest times. The same conclusions will apply to the results in saturated KF solution (Fig. 4*b*).

Diffusion effects will be much less significant in the more dilute and less viscous solutions since it may readily be shown that ΔE_c values are much smaller and the times over which diffusion equilibration is occurring are much shorter (owing to the higher diffusion constants) than those for the 14.6 M solutions. For the more dilute solutions, the inflections arise, as discussed above, from the alternative oxygen evolution process.

It can be shown that these effects in dilute solution are operative over periods of time comparable to θ (the time correction applied to allow for a finite charging rate). Thus diffusion effects are absorbed in the empirical assignment of θ. This will introduce some uncertainty in its value but will have no significant effect on the slope of the anodic and cathodic decay lines since θ in these cases is not larger than about 100 seconds.

HYDROGEN ATOM ABSTRACTION BY ETHYL-d_5 RADICALS. PART I[1]

P. J. Boddy[2] and E. W. R. Steacie

ABSTRACT

The photolysis of 3-pentanone-d_{10} has been used as a source of deuterated ethyl radicals and some of their hydrogen abstraction reactions studied over the temperature range 50–300° C.

The compounds neopentane, *n*-butane, and isobutane were chosen as representative of the basic structural features in the alkane series. The activation energies for abstraction ($E_8-\frac{1}{2}E_2$) are respectively 12.60±0.7, 10.4±0.75, and 8.9±0.6 kcal/mole and the pre-exponential factors ($\log_{10}(A_8/A_4)$) are 0.300±0.09, 0.082±0.09, and −0.334±0.066 where

$$2\ C_2D_5\cdot \rightarrow C_4D_{10}, \quad [2]$$

$$C_2D_5\cdot + \text{3-pentanone-}d_{10} \rightarrow C_2D_6, \quad [4]$$

$$C_2D_5\cdot + \text{hydrocarbon} \rightarrow C_2D_5H. \quad [8]$$

For abstraction of a deuterium atom from the ketone the values obtained are $E_4-\frac{1}{2}E_2 = 9.0\pm0.5$ kcal/mole and $(\log_{10}(A_4/A_2^{\frac{1}{2}})) = \bar{8}.36\pm0.20$ in agreement with previous investigations (1, 2).

The value of the disproportionation to combination ratio for C_2D_5 radicals is 0.0985±0.008 independent of temperature.

INTRODUCTION

Although a great deal of information has been obtained on the abstraction of hydrogen atoms from hydrocarbons by methyl radicals, there is little information on more complex alkyl radicals. The methyl radical work has led to the realization of a relationship between structural features of hydrocarbon molecule reactants and activation energy for abstraction of a hydrogen atom (3). This, however, has not in turn led to any good theoretical treatment of the problem probably, at least in part, because there is so little experimental data on the influence of the structure of the alkyl radical itself. There is published data on the abstraction by ethyl radicals from some unsaturated hydrocarbons in the C_6 and C_8 range (4) and this does throw light on the effect of bond multiplicity but not on the aspects of alkane structure.

The major difficulty with higher radicals is that of analysis of the reaction products. In the case of ethyl radicals, calculation of the rate constant for abstraction involves determination of small quantities of ethane, ethylene, and *n*-butane. This severely complicates investigation of some of the most interesting hydrocarbons.

The mechanism of 3-pentanone photolysis is known to be (5)

$$(C_2H_5)_2CO + h\nu \rightarrow 2C_2H_5\cdot + CO, \quad [1]$$

$$2C_2H_5\cdot \rightarrow C_4H_{10}, \quad [2]$$

$$2C_2H_5\cdot \rightarrow C_2H_6 + C_2H_4, \quad [3]$$

$$C_2H_5\cdot + (C_2H_5)_2CO \rightarrow C_2H_6 + \cdot C_2H_4COC_2H_5, \quad [4]$$

$$C_2H_5\cdot + \cdot C_2H_4COC_2H_5 \rightarrow C_4H_9COC_2H_5, \quad [5]$$

$$2\cdot C_2H_4COC_2H_5 \rightarrow (C_2H_4COC_2H_5)_2, \quad [6]$$

$$\cdot C_2H_4COC_2H_5 \rightarrow C_2H_4 + CO + C_2H_5\cdot, \quad [7]$$

$$C_2H_5\cdot + RH \rightarrow C_2H_6 + R\cdot. \quad [8]$$

Under suitable conditions the ethane from [3], and [4] can be assessed and hence the rate of [8] determined.

The situation can be greatly simplified by the use of labelled species. The use of deuterated hydrocarbon molecules is possible but does not lead to results directly comparable with the large number of experiments carried out with methyl and perfluoralkyl radicals and hydrogenated molecules without making certain assumptions about the relative reactivities of C—H and C—D bonds. A study has been made of the reaction between ethyl radicals and deuterium molecules (6) and from this the activation energy for abstraction from a hydrogen molecule deduced. The value obtained agrees reasonably well with that determined experimentally for ethyl-d_5 radicals and hydrogen (7).

A preferable experiment involves the use of a deuterated radical source with hydrogenated molecules. Current evidence suggests that insofar as activation energy for hydrogen atom abstraction is concerned, deuterated radicals behave identically with their hydrogenated counterparts within the present limits of experimental error (4, 8, 9). Analysis of products is greatly simplified since only reactions [4] and [8] need to be considered and from the ratio of (in this case) C_2D_5H/C_2D_6 the activation energy difference between [4] and [8] may be determined. (C_2D_6 from [3] is easily estimated.)

The reasonable assumption is made here that the mechanism outlined above for 3-pentanone-d_0 is entirely applicable to the photolysis and subsequent reactions of 3-pentanone-d_{10}, although the rate constants for the individual steps will, of course, be different.

EXPERIMENTAL

A conventional high vacuum apparatus was used with sections for storage, purification, reaction, analysis, and sampling of gases as previously described in papers from this laboratory. Mercury cutoffs were used at all points where absorption of organic vapors could lead to error.

The reaction system was a 10-cm-long quartz cell with an all glass circulating pump in the connecting tubing, the total volume being 196 ml. Both the cell and the metal valves isolating it from the rest of apparatus were contained in an air thermostat. The cell itself was surrounded by a cylindrical electric furnace which was maintained to within 1° C of the required temperature. Pressures were measured on a quartz spiral gauge within the thermostat.

Radiation from a Hanovia S-500 lamp was collimated by an aluminum cylinder and then brought to a parallel beam, which just filled the cell, with a quartz lens. A 2-mm-thick "Pyrex" filter removed radiation below 2900 Å.

The reaction products were distilled several times at −80° C to remove most of the unphotolysed ketone and involatile products, and then passed through traps at −165° C, −125° C, and −215° C in that order. Carbon monoxide passed straight through. C_2 hydrocarbons were collected at −215° C. The fraction between −125° C and −165° C was n-butane-d_{10} (this was measured only in experiments where the ketone was photolysed alone).

MATERIALS

3-Pentanone-d_{10} was obtained from Merck of Canada. It was degassed and stored in a blackened bulb behind a mercury cutoff. Small samples were further degassed before each run. The purity of the ketone is discussed below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

Neopentane, *n*-butane, and isobutane were all Phillips Research Grade materials. They were degassed and stored in the same way as the ketone. Their purities exceeded 98%.

TREATMENT OF DATA

1. Ketone

The low energy (15 v) mass spectrum of the ketone, showing only parent peaks, gave the following analysis, assuming equal sensitivities:

(1) $C_4D_{10}CO$ 93.7%,
(2) C_4D_9HCO 5.95%,
(3) $C_4D_8H_2CO$ 0.34%.

The peaks were small due to the low sensitivities at 15 v and the smallest peak was difficult to measure.

The normal (70 v) spectrum gave information on the relative abundance of species 1 and 2.

Parent peaks	95 pk/96 pk = 5.25%.
Propionyl peaks	61 pk/62 pk = 2.8% (≡ 5.6% of species 2).
Ethyl peaks	33 pk/34 pk = 2.5% (≡ 5.0% of species 2).

The latter two ratios include the effect of species 3 but since the values lie on either side of the direct ratio of the parent peak the effect of this appears to be well within the experimental error. An average value of 5.3% of species 2 was adopted. In view of the relative abundances of species 2 and 3 it was assumed that 3 was largely $(C_2D_4H)_2CO$ (since 0.0595^2 is very close to 0.0034, the value obtained at low energy). In previous work with this ketone, prepared by the same method (heavy water exchange with $(CD_3CH_2)_2CO$), it was logically assumed that the H atoms were mainly in the primary position (1). A similar assumption is made here.

The composition of the ketone used in the following experiments was therefore taken to be:

(1) $(C_2D_5)_2CO$ 94.4%,
(2) $CD_2HCD_2COC_2D_5$ 5.3%,
(3) $(CD_2HCD_2)_2CO$ 0.28%.

The relative abundance of 3 has been adjusted to $.053^2$.

2. Butanes

The butane produced in reaction [2] should have an isotopic composition similar to that of the original ketone. Only the 70 v spectrum was taken so no butane with two H atoms could be detected with accuracy. The ratio C_4D_9H/C_4D_{10} was in good agreement with the expected value of 0.053 over the whole range of experimental conditions. C_4D_{10} was taken as 94.4% of total butane in most runs, but the ratio was checked at intervals and found to be constant. The uncertainty introduced by not analyzing the $C_4D_8H_2$ was negligible.

3. C_2 Hydrocarbons

(a) Ethanes

C_2D_6 can arise in three ways:

(i) $C_2D_5\cdot$ + ketone → C_2D_6, which we wish to determine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

(ii) $C_2D_5\cdot + C_2D_5\cdot \rightarrow C_2D_6 + C_2D_4$; this can be estimated from the C_2D_4 after correction has been made for other sources.

(iii) $C_2D_5\cdot + C_2D_4H\cdot \rightarrow C_2D_6 + C_2D_3H$; this can be estimated from the C_2D_3H yield.

C_2D_5H can arise from:

(iv) $C_2D_5\cdot$ + hydrocarbon $\rightarrow C_2D_5H$, which we wish to determine.

(v) $C_2D_5\cdot$ + ketone $\rightarrow C_2D_5H$; an empirical correction curve for this is described later.

(vi) $C_2D_4H\cdot$ + ketone $\rightarrow C_2D_5H$ assuming the ketone composition given above and assuming that there is no different rate of photolysis, or reaction of the two types of radical about 3.0% should be $C_2D_4H\cdot$. Hence C_2D_5H from (vi) should be 3.0% of C_2D_6 from (i).

Preliminary results showed that the ratio of disproportionation to combination for ethyl-d_5 was about 0.1 compared with 0.14 for ethyl-d_0 radicals (5). The activation energy for these reactions is very close to zero, and the collision numbers cancel from each ratio. Assuming that the steric factors for combination in the two cases are equal since the radicals are so similar, then on a collision-for-collision basis C—H bonds break 1.4 times more frequently than C—D bonds in the disproportionation reaction. If these relative rates hold good for abstraction from $CD_2HCD_2\cdot$ and bearing in mind the head-to-tail mechanism of disproportionation (2, 15), the relative rates of abstraction of D and H stand in the ratio 2:1.4. Since $C_2D_4H\cdot$ represents about 3.0% of the total radical concentration then reaction (iii) above should represent $((2/3.4)\times 3.0\% =)$ 1.75% of the total disproportionation reaction. Since C_2D_4 is produced in all disproportionation reactions except (iii) and in negligible amounts in other ways below 197° C, the C_2D_4 yield can be taken to represent the total disproportionation. Figure 1, in which C_2D_3H/C_2D_4 from a series of experiments with the ketone alone is plotted vs. temperature, shows that in the range 50–150° C the ratio comes close to that predicted. At 180° C and above

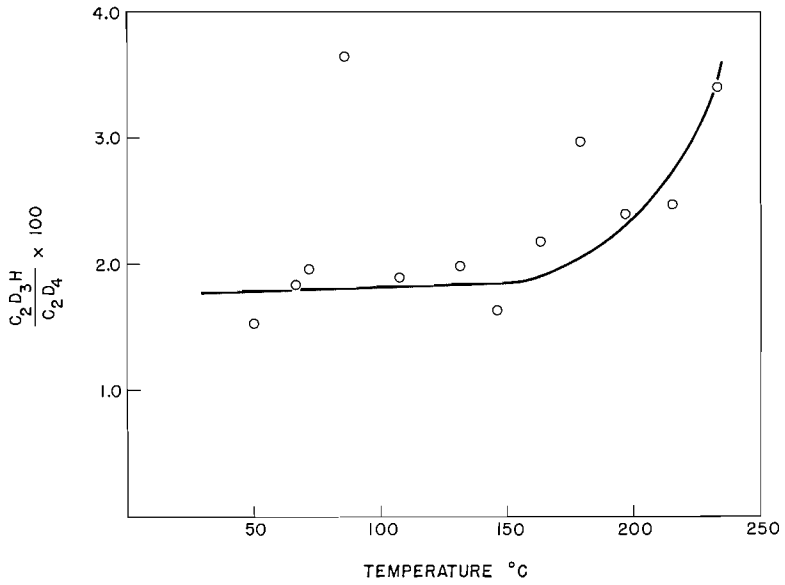

FIG. 1. Ratio of C_2D_3H to C_2D_4 in DEK-d_{10} photolysis.

For personal use only.

the ratio increases, probably due to decomposition of pentanonyl radicals, which would be hydrogen enriched if the hydrogen is primary. If there is no isotope effect on the decomposition, about 3% of the ethylene from this source would be C_2D_3H.

(vii) $C_2D_5\cdot + CD_2HCD_2\cdot \rightarrow C_2D_5H + C_2D_4$; on the basis of the above discussion this should be $((1.4/3.4)\times 3.0\% =)$ 1.25% of the total disproportionation reaction.

(viii) $CD_2HCH_2\cdot + C_2D_5 \rightarrow C_2D_5H + C_2D_4$, 3.0% of the total disproportionation.

Since the $C_2D_4H\cdot$ concentration is relatively low, interactions between these radicals and with impure ketone are not considered.

(*b*) *Ethylenes*

C_2D_4 can arise in four ways:

(ii) $C_2D_5\cdot + C_2D_5\cdot \rightarrow C_2D_6 + C_2D_4$, the major source when (ix) is not significant.

(vii) $C_2D_5\cdot + C_2D_4H\cdot \rightarrow C_2D_5H + C_2D_4$, 1.25% of the total disproportionation.

(viii) $C_2D_4H\cdot + C_2D_5\cdot \rightarrow C_2D_5H + C_2D_4$, 3.00% of the total disproportionation.

(ix) $\cdot C_2D_4COC_2D_5 \rightarrow C_2D_4 + CO + C_2D_5\cdot$; this reaction is of little importance below 200° C. Under these circumstances 4.25% of the C_2D_4 arises from (vii) and (viii), the remainder from (ii).

C_2D_3H can arise only in (iii) and is discussed above.

On the basis of these corrections the data was treated in the following way. The measured $R_{C_2D_6}$ was converted to that produced in (i) by subtracting the $R_{C_2D_4}$ from (ii) (i.e. 95.75% of the total $R_{C_2D_4}$) and $R_{C_2D_3H}$. $R_{C_2D_5H}$ was corrected by subtracting 3.0% $R_{C_2D_6}$ (vi) and 4.25% of the total $R_{C_2D_6}$ (vii) and (viii).

When this procedure had been carried out for the experiments in which the ketone was photolysed alone there was a small residue of C_2D_5H. This could have been largely removed by adjustment of the correction factors but it was preferred to treat it as a separate temperature-dependent correction due to reaction (v). The function $(R_{C_2D_5H\ \text{residual}})/(R^{\frac{1}{2}}_{C_4D_{10}}[\text{ketone}])$ is plotted vs. $1/T$ in Fig. 2, which was used as a correction curve for subsequent experiments. The results are not sufficiently precise to ascribe an activation energy and hence check the position of the H atom in the ketone molecule.

While the corrections are complex, they are generally not large and the final results are not greatly affected by the approximate nature of some of the corrections.

RESULTS

Ketone Photolysis

The data obtained for photolysis of the ketone alone are presented in Table I. Columns 10, 11, and 12 have been corrected as described. In the region where reaction [7] is negligible column 12 represents k_3/k_2. Below 197° C the values are in good agreement (0.0985 ± 0.008) and independent of temperature. At higher temperatures this value of k_3/k_2 is used to calculate $R_{C_2D_6}$ from [2] by measurement of $R_{C_4D_{10}}$ from [3]. The corrections described in the previous section are valid only when $R_{C_2D_4}$ from [7] is negligible. Experiments were carried out up to a temperature where the activation energy plot showed a curvature (300° C) indicating the onset of a systematic error in the correction.

It can easily be shown that in the valid range $(k_4/k_2^{\frac{1}{2}}) = R_{C_2D_6\ \text{corrected}}/R^{\frac{1}{2}}_{C_4D_{10}}[\text{ketone}]$.

The constants are those in the expression $13+\log_{10}(k_4/k_2^{\frac{1}{2}}) = C-(B.10^3/T)$.

The present results confirm the conclusion that there is negligible effect of isotopic substitution on the reactivity of ethyl radicals. It was important to redetermine the ketone data here since subsequent activation energies were measured relative to this.

Ketone and Hydrocarbons

The data from the experiments with neopentane, *n*-butane, and isobutane appear in Tables II, III, and IV.

Activation energies may be obtained in two ways. The most precise way is to consider the reactions [4] and [8]. The activation energy difference E_8-E_4 may be obtained by plotting

$$\log_{10}\frac{R_{C_2D_5H\ \text{corrected}}}{R_{C_2D_6\ \text{corrected}}}\cdot\frac{[\text{ketone}]}{[\text{hydrocarbon}]}\ \text{vs.}\frac{1}{T} \qquad \text{(Fig. 4).}$$

The isobutane curve falls off below 110° C. This was due to the use of too low an isobutane to ketone ratio and hence to too low a $R_{C_2D_5H}$ to $R_{C_2D_6}$ ratio leading through small errors in the correction factors to a large systematic error in $R_{C_2D_5H\ \text{corrected}}$. Increase of the relative isobutane pressure gave the point close to the drawn line ($1/T = 2.64$).

Least squares calculation gives:

For neopentane

$E_{8a}-E_4 = 3.6\pm0.2$ kcal,
$\log_{10}(A_{8a}/A_4) = 0.30\pm0.09$;

hence $E_{8a}-\frac{1}{2}E_2 = 12.6\pm0.7$ kcal,
$(A_{8a}/A_4) = 2.00\pm0.5$.

For *n*-butane

$E_{8b}-E_4 = 1.38\pm0.25$ kcal,
$\log_{10}(A_{8b}/A_4) = 0.082\pm0.09$;

hence $E_{8b}-\frac{1}{2}E_2 = 10.4\pm0.75$ kcal,
$(A_{8b}/A_4) = 1.21\pm0.27$.

For isobutane

$E_{8c}-E_4 = 0.1\pm0.1$ kcal,
$\log_{10}(A_{8c}/A_4) = \bar{1}.666\pm0.066$;

hence $E_{8c}-\frac{1}{2}E_2 = 8.9\pm0.6$ kcal,
$(A_{8c}/A_4) = 0.464\pm0.07$.

Alternatively, $R_{C_2D_4}$ may be used to calculate $R_{C_4D_{10}}$ from k_3/k_2 and then by plotting $\log_{10}(R_{C_2D_5H\ \text{corrected}}/R_{C_4D_{10}}^{\frac{1}{2}}$ [hydrocarbon] vs. $1/T$, $E_8-\frac{1}{2}E_2$ may be obtained directly. This method suffers from the very unfavorable value of k_3/k_2 which multiplies errors in $R_{C_2D_4}$ in the final expression. This limits the range of validity of the experiments since it is so sensitive to $R_{C_2D_4}$ from [7] and also increases the scatter over the range where the analysis is valid. The results plotted in Fig. 5 are, however, compatible with those from the first method.

The data for abstraction from the ketone in the presence of hydrocarbons is plotted in Fig. 6. The line is drawn to correspond to that in Fig. 3. In view of the greater complexity of these systems the agreement is considered satisfactory.

DISCUSSION

The results obtained for ethyl-d_5 radicals are compared below with those corresponding for methyl (9). In both cases the results are approximately corrected for the presence of primary hydrogen atoms in the two butanes by using the rate per primary hydrogen atom from the neopentane experiments. The behavior in the two cases is parallel in that there is a change in reactivity of about an order of magnitude as one goes from primary to secondary to tertiary hydrogen atoms.

iso-C_4H_{10}	8.9	6.1	5.7	7.6	42	37

NOTE: k_1 refers to $CH_3\cdot + RH \rightarrow CH_4 + R\cdot$.

The reduced activity of ethyl as compared with methyl is obvious but not surprising in view of the lower exothermicity of the ethyl abstractions. In fact, as can be seen from Fig. 7, the experimental values for both radicals lie on a good curve suggesting that at low values of ΔH both radicals have the same activation energy for the same value of ΔH based on some usually accepted figures for C—H bond energy (10). The uncertainty in the bond energies, however, introduces an uncertainty approaching 100% in the C—H bond energy difference for methane and ethane (ΔH). Electron impact methods although subject to criticism have been used to obtain more precise information on such differences (12). It can be seen from Table V that the activation energy difference (ΔE) for methyl and ethyl abstracting from neopentane is 2.6 kcal. It has been suggested that the constant α (in the expression $\Delta E = \alpha\Delta H$) should have a maximum value of 0.5 due to the symmetry of the reaction (11) and this leads to a minimum ΔH of 5.2 kcal. The same is true of the previously observed activation energies for abstraction by methyl from methane (16, 17) and ethane (18, 19), which also differ by about 2.6 kcal. The figure of 5.2 kcal is in excellent agreement with the electron impact value of 5.1±0.7 kcal. Hence the data suggests that α approaches a value of 0.5 at low negative values of ΔH and one assumes that this may be extended to endothermic reactions. The equation of the line is $E = 14.1+(\Delta H/2)$ (in kcal). The ΔE for methyl and ethyl abstractions from various hydrocarbons varies, but definitely seems to increase with the

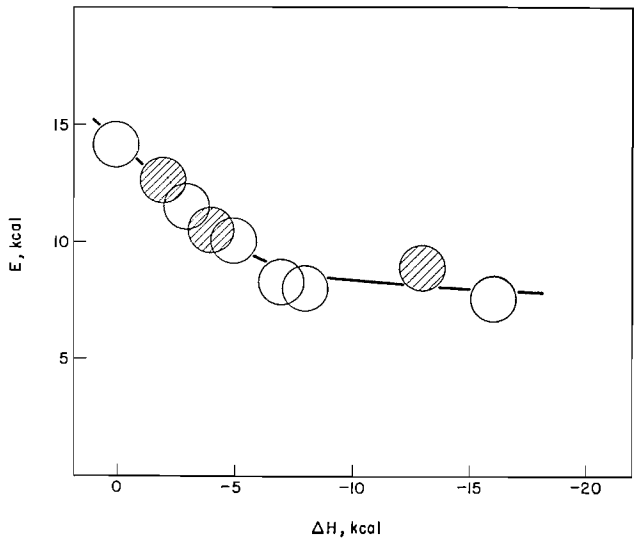

FIG. 7. Activation energy for H atom abstraction vs. ΔH, for CH_3 and C_2D_5 radicals.

strength of the bond broken. Since ΔE is 2.6 kcal for neopentane it should be at least this for ethane. Hence the activation energy for ethyl abstracting from ethane should be at least 14.1 kcal. (This is very close to the corresponding thermally neutral methyl abstraction from methane.) By assuming ΔH for ethane and neopentane to be 3.0 kcal (this is well within the accuracy of the photobromination experiments) and taking ΔH for methane and ethane as 5.2 kcal the following table may be constructed from the above equation.

TABLE VI

Radical abstracting from:	Activation energy in kcal		
	CH_4	C_2H_6	neo-C_5H_{12}
$CH_3\cdot$	14.1*	11.5*	10.0*
$C_2H_5\cdot$	16.7**	14.1	12.6*
neo-$C_5H_{11}\cdot$	18.2	15.6	14.1

Values marked * have been experimentally measured and agree closely with the equation. Value marked ** was estimated by the present authors to be greater than 16.0 kcal on the basis of an unsuccessful attempt to measure the activation energy of ethyl-d_5 abstracting from methane. The yield of C_2D_5H at the highest temperature was used with an assumed steric factor of 10^{-3} to calculate an approximate lower limit of the activation energy. Table VI is entirely consistent with the requirement that the activation energy difference between the forward and reverse reactions should equal ΔH.

An estimate is made of the activation energies for neopentyl radical abstractions. If these values are correct they may never be measured experimentally due to the radical decomposition and rearrangement occurring at the temperatures necessary to measure activation energies of this magnitude. There seems to be no reason not to include all alkyl radicals in this treatment since a ΔH of 5.0 kcal seems to make no difference in the methyl and ethyl case. Results with isopropyl and *tert*-butyl radicals are awaited

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

with interest. If the above argument is correct these radicals should have $\alpha = 0.5$ throughout almost the whole range of their abstraction from alkanes.

The result deduced in an earlier section that in the disproportionation of ethyl radicals C—H bonds break 1.4 times more frequently than C—D bonds is of particular interest. This figure is almost exactly equal to the ratio of C—H and C—D stretching frequencies in C_2H_6 and C_2D_6 (13). There is an empirical rule that in similar molecules corresponding vibrations stand in the same ratio (14). This is extended here to the assumption that the frequency ratio for a certain type of vibration in C_2H_6 and C_2D_6 is the same for a similar vibration in C_2H_5 and C_2D_5.

$$\frac{R_{\text{C—H break}}}{R_{\text{C—D break}}} = \frac{0.139}{0.0985} = 1.41.$$

	ν_1 (cm^{-1})	ν_5 (cm^{-1})
C—H stretch in C_2H_6	2899	2954
C—D stretch in C_2D_6	2083	2111
Ratio	1.39	1.40

It appears that there is good evidence here to definitely relate the steric factor of the reaction with the vibrational frequency of the reacting bond. There is probably at least one other term in the steric factor but here where the reactions are so similar it may be expected to be about equal in the two cases.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Mrs. Berneice Riem, who carried out the mass-spectral analyses and to Mr. R. Renaud, who prepared samples of C_2D_5H and $C_2D_4H_2$.

THE EFFECT OF SOLVENTS UPON EQUILIBRIA, SPECTRA, AND REACTION RATES[1]

S. BROWNSTEIN

ABSTRACT

It is shown that the effect of solvent upon a wide variety of equilibria, reaction rates, and spectral shifts may be described by the equation $\log (k_{solvent}/k_{ethanol}) = SR$. S is a constant related to the polarity of the solvent and R is a measure of the sensitivity of the system to change in solvent polarity. Tables of S and R are included.

INTRODUCTION

Many attempts have been made to correlate solvent effects with a physical property of the solvent (1–4). Most of these have involved a function of the dielectric constant of the solvent, but refractive index has also been used in an attempt to correlate spectral shifts (5). No satisfactory correlation with a physical property of the solvent could be obtained over an extended range of solvents, or solvent composition in a mixed solvent. This was attributed to specific solvent–solute interaction for some solvents and the ineffectiveness of dielectric constant as a measure of the hydrogen bonding ability of a solvent.

A linear relationship has been observed for the change in reaction rate of closely related reactions as the solvent is varied (6). However, by its nature it is limited to solvolysis reactions and hydroxylic solvents. A four-parameter equation has also been proposed for this group of reactions (7). A similar relationship has been observed in the solvent-dependent shift of certain infrared frequencies (8, 9). A correlation has also been found between solvent effects on solvolysis reactions, described by Y values (6), and ultraviolet spectral shifts, described by Z values (10). Again this cannot be readily extended, as it is formulated, to widely different situations. The success of Kosower's correlation of solvent effects upon solvolysis reactions and ultraviolet spectral shifts suggests the possibility of a semiquantitative correlation of solvent effect upon a wide variety of reactions, equilibria, and spectral shifts. Therefore, it should be possible to predict approximately the effect of changing solvent in a wide variety of cases.

It is the purpose of this paper to propose an equation for correlating solvent effects and to show how well this fits some of the results obtained by a variety of workers. Since the effect of solvent is to change the free energy of the product, activated complex, or excited state, relative to the initial state, a linear free-energy relationship similar to that proposed by Hammett for the reactions of substituted benzenes seems appropriate (11). Absolute ethanol will arbitrarily be chosen as the standard solvent. It appears suitable since much work has been done in this solvent and it is intermediate in dielectric constant and polarity.

Let us assume $\log(k_{solv}/k_{EtOH}) = SR$ where k is a reaction rate, equilibrium constant, or function of a spectral shift. S will be a constant characteristic of any given solvent or solvent mixture. For absolute ethanol it is defined as 0.000 by the above equation, since any other value would require all reactions to have $R = 0.000$. R is a constant characteristic of the sensitivity of a given reaction to solvent effects. The shift of the absorption maximum in 1-ethyl-4-carbomethoxypyridinium iodide (10) was arbitrarily chosen to have

[1]*Manuscript received April 29, 1960.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 5782.

$R = 1.000$. This reaction was chosen since data is available for a wider range of solvents than with most other reactions. With the choice of one standard solvent and one standard reaction, S and R values may be calculated for any reaction and any solvent. The present discussion is limited to a single temperature and 25° C, or room temperature, has been chosen. Although relative solvent polarities, and hence S values, will change with temperature the effect is probably small, since activation energies for a given reaction in various solvents are usually quite similar (6).

Reaction rates and equilibrium constants are exponentially proportional to the difference in free energy between initial and final states while shifts in frequency are directly proportional to energy differences. Therefore for shifts in spectral absorption

$$k = e^{\tilde{\nu}_{\text{max solv}}/\tilde{\nu}_{\text{max EtOH}}}.$$

Then

$$SR = \log \frac{e^{\tilde{\nu}_{\text{max solv}}/\tilde{\nu}_{\text{max EtOH}}}}{e^{\tilde{\nu}_{\text{max EtOH}}/\tilde{\nu}_{\text{max EtOH}}}}$$

$$= \frac{\tilde{\nu}_{\text{max solv}}}{\tilde{\nu}_{\text{max EtOH}}} - \frac{\tilde{\nu}_{\text{max EtOH}}}{\tilde{\nu}_{\text{max EtOH}}}$$

$$= \frac{\tilde{\nu}_{\text{max solv}} - \tilde{\nu}_{\text{max EtOH}}}{\tilde{\nu}_{\text{max EtOH}}}$$

In cases where the appropriate measurements have not been made in absolute ethanol as solvent, and it is not feasible to do them, the following procedure may be used.

$$S_1R = \log\left(\frac{k_{s1}}{k_{\text{EtOH}}}\right) = \log k_{s1} - \log k_{\text{EtOH}}$$

$$S_2R = \log\left(\frac{k_{s2}}{k_{\text{EtOH}}}\right) = \log k_{s2} - \log k_{\text{EtOH}}$$

Therefore

$$R(S_1 - S_2) = \log k_{s1} - \log k_{s2}$$

and

$$R = \frac{\log k_{s1} - \log k_{s2}}{S_1 - S_2}.$$

It is desirable to have results in several solvents grouped into two equal sets and use

$$R = \frac{\sum \log k_{s1} - \sum \log k_{s2}}{\sum S_1 - \sum S_2}.$$

In cases where k is a frequency this still does not remove the necessity of a measurement in absolute ethanol since

$$\log k_{s1} = \log e^{\tilde{\nu}_{\text{max } S_1}/\tilde{\nu}_{\text{max EtOH}}} = \frac{\tilde{\nu}_{\text{max } S_1}}{\tilde{\nu}_{\text{max EtOH}}}$$

and

$$R = \left\{\frac{\tilde{\nu}_{\text{max } S_1} - \tilde{\nu}_{\text{max } S_2}}{\tilde{\nu}_{\text{max EtOH}}}\right\}/(S_1 - S_2).$$

For these cases the data were plotted and the value found for the frequency at S equals zero was used for $\tilde{\nu}_{\text{max EtOH}}$.

EXPERIMENTAL

The data of Kosower (10) were used to determine 58 S values. In those cases where concentration of the pyridinium salt affected the spectral shift, the results were extrapolated to infinite dilution. Using these S values, R values were calculated for nine

reactions and these in turn were used to calculate a total of 158 S values. These S values were then used to determine 78 R values. These figures are given in Tables I and II. This does not constitute an exhaustive survey of the literature but is sufficient to show the range of values which can be expected.

A minimum of nine points were used to determine R values of reactions which were subsequently utilized to determine further S values. If the average deviation for these reactions was large, results from two or three reactions were averaged to obtain the additional S values. For the carbonyl absorption of acetone, dimethyl formamide, and methyl acetate in the infrared, data were obtained for additional solvents in this laboratory using a Perkin–Elmer model 21 spectrophotometer with a rock salt prism. It was calibrated immediately before use.

DISCUSSION

There is found to be a good fit of the proposed equation to the experimental data. Therefore, there is probably a characteristic of solvents, described here by S values, which is responsible for solvent effects in a wide variety of situations. However, this type of correlation necessarily averages out individual differences in solvents and reactions so it would be dangerous to attribute too much theoretical significance to the individual numbers. It obviously will not apply to measurements where there is a unique interaction between the solvent and the species which is being measured. Such a situation occurs with infrared spectral shifts when there is hydrogen bonding between the solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and some functional group of the substance whose spectrum is being determined. It also occurs when the solvent is able to complex with one of the species in a reaction whose rate is being determined. This type of correlation should nevertheless prove quite useful in transposing data, primarily spectroscopic, from one solvent system to another.

For the rates of 14 solvolysis reactions the average deviation from the individual R values was 19.4% for rates differing by up to 10,000 times. The R values for the individual reactions were all positive and varied between 9.9 and 35.9. For 32 infrared absorptions the average deviation from the individual R values was 27%. All R values were negative and ranged between -3.19 and $-.016$ except for two positive values and one case which did not fit the equation. These numbers correspond to a slight solvent shift and the experimental accuracy in determining the solvent shifts usually limited the accuracy with which the data fitted the equation.

For the spectral shifts of 15 ultraviolet absorptions the average deviation from the individual R values was 34%. There was no correlation in two instances. The R values were positive and ranged between .05 and 1.08 except for two negative values. It has been suggested that $\pi \rightarrow \pi^*$ transitions are affected differently by solvent change than $n \rightarrow \pi^*$ transitions (12). This can be stated more quantitatively by noting that $\pi \rightarrow \pi^*$ transitions are likely to have negative R values. The solvent corrections for Woodwards rules can also be stated in terms of R values (13). They correspond to saying the transitions usually have an R value of about 0.10, although chloroform does not seem to fit this scheme very well.

Magnetic-susceptibility-corrected solvent shifts of nuclear resonance spectra are also correlated by the same equation. The average deviation in individual R values for five proton resonance solvent shifts is only 13.6%. Little correlation is found with fluorine resonance shifts.

This type of correlation should be useful in correcting literature values of data in some solvent system to the system which an investigator finds convenient in his own work.

THE FLUORINE RESONANCE SPECTRUM OF PERCHLORYL FLUORIDE[1]

S. BROWNSTEIN

ABSTRACT

The first instance of observable spin–spin coupling with a chlorine nucleus is found in the fluorine resonance of perchloryl fluoride. The explanations of this, and of the very large chemical shift, are given.

When a nucleus of non-zero spin is bonded directly, or with a few intervening atoms, to another nucleus of non-zero spin, coupling of the two nuclear spins occurs via the bonding electrons. If the spin-coupled nuclei are magnetically non-equivalent, the spin coupling manifests itself by a splitting of the observed nuclear resonance peaks (1, Chap. 8). When a nucleus of spin 1/2 is coupled to a nucleus with spin greater than 1/2, spin coupling is not always observed in the resonance spectrum of the nucleus with spin 1/2. This is attributed to a rapid relaxation of the nucleus with spin greater than 1/2 due to interaction of its quadrupole moment with an unsymmetric electric field gradient. One would expect to see spin coupling when there is spherical symmetry about the nucleus of spin greater than one half, and this is observed (2). If the symmetry is less, the individual lines broaden and eventually coalesce into a single sharp line when the relaxation is rapid.

No examples have been reported of observable spin coupling of nuclei with chlorine, but sharp single peaks are always observed. Both chlorine-35 and chlorine-37 have spin 3/2 and appreciable quadrupole moments. Since chlorine is quite electronegative, unsymmetric bonds are to be expected in most of its compounds and rapid relaxation of the chlorine nuclear spin occurs. Three oxygens and a fluorine are tetrahedrally arranged about a central chlorine in perchloryl fluoride and the compound has no observable dipole moment (3). Relaxation of the chlorine nuclear spin should not be too rapid in this compound.

The fluorine resonance spectrum of perchloryl fluoride is shown in Fig. 1. It has a

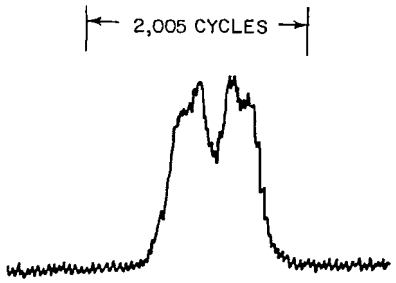

FIG. 1. Fluorine resonance of perchloryl fluoride.

chemical shift of 320 p.p.m. to low field from the fluorine resonance in trifluoracetic acid. The splitting between the two partially resolved lines is 310 cycles and the extrapolated line width, at half the height, for each line is 430 cycles. The signal is very weak requiring

Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5778.

40 decibels more of radio-frequency power to obtain the same signal intensity as that of trifluoracetic acid.

A correlation of chemical shift with the electronegativity of the atom or group to which fluorine is bonded has been demonstrated (4). The shift to low field is greatest the lower the electron density about fluorine, with the spherically symmetric fluoride ion occurring at highest field. The fluorine resonance shift in perchloryl fluoride is to lower field than any compound of fluorine, except for molecular fluorine. The lack of dipole moment for perchloryl fluoride suggests that the electronegativity of the perchloryl group approaches that of fluorine. Therefore the chemical shift is in agreement with previous observations.

Four lines of equal intensity are to be expected in the spectrum of a nucleus spin coupled to one other of spin 3/2. Since both stable isotopes of chlorine have spin 3/2 two sets of four lines will be expected with $J_{Cl^{35}}/J_{Cl^{37}} = \mu_{Cl^{35}}/\mu_{Cl^{37}} = .821/.683$ (1, p. 188). The relative intensities will be three to one. Combining the individual spectra gives a composite spectrum in which the intensity between the outside peaks is greater than between the center ones. This is illustrated in Fig. 2 for triangular peaks. A Gaussian

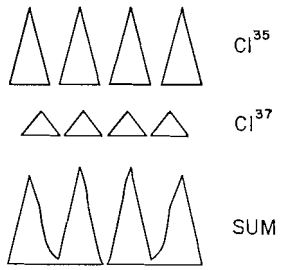

FIG. 2. Effect of isotopic composition upon the spectrum.

line shape would probably accentuate this. Possibly for this reason only two poorly resolved peaks are actually observed.

The lines of perchloryl fluoride have a width of 430 cycles whereas at the same sweep rate the resonance of trifluoracetic acid is immeasurably narrow. Therefore considerable broadening of the fluorine resonance is occurring due to rapid relaxation of the chlorine nuclear spin.

EXPERIMENTAL

Perchloryl fluoride was obtained from Pennsalt Chemicals Corporation, and used without further purification. The gas was condensed under vacuum into a 5-mm O.D. Pyrex tube which was then sealed. Upon warming to room temperature, a colorless mobile liquid remained in the sample tube.

The spectra were run on a Varian Associates high resolution nuclear magnetic resonance spectrometer Model V4300C operating at 56.4 Mc. The spectra were calibrated using audio side bands (5) counted with a Hewlett Packard Model 521C frequency counter. Since the observed chemical shift was beyond the normal sweep range of the instrument, the magnet current was varied after the instrument was calibrated. Because of hysteresis in the electromagnet, the chemical shift obtained in this manner will only be accurate within about 5 p.p.m. A radio-frequency power level of 50 db below 1/2 watt was required to produce an adequate signal. Variation of the power about this level gave no indication of saturation of the signal.

THE PREPARATION OF CYCLIC PEROXIDES AND THEIR DECOMPOSITION IN SOLUTION[1]

K. E. Russell

ABSTRACT

The cyclic dimers of sebacyl, dodecanedioyl, and tetradecanedioyl peroxide have been prepared, together with high yields of the corresponding high molecular weight polymeric peroxides. The decomposition of these peroxides in styrene and benzene solution has been studied. The results show that if diradicals are formed in the breakdown of the cyclic peroxides, they undergo self-termination before reacting with a significant number of styrene molecules. In the presence of low concentrations of 1,1-diphenyl-2-picrylhydrazyl (DPPH) in benzene solution, self-termination of diradicals is preferred to reaction with the hydrazyl.

INTRODUCTION

The main objective of this investigation was to study the reactions of diradicals obtained by the thermal breakdown of cyclic peroxides. Previous work (1, 2) has shown that phthalyl peroxide may be readily prepared by the reaction of phthalyl chloride with sodium peroxide, but that its decomposition in solution may be complex (2, 3). It was thus not possible to reach firm conclusions concerning the reactions of diradicals from studies involving this aromatic peroxide. Some cyclic aliphatic peroxides have now been prepared using the same experimental method. Attempts were made to isolate succinyl, adipyl, suberyl, azelayl, sebacyl, dodecanedioyl, and tetradecanedioyl peroxides, but low molecular weight cyclic peroxides were only obtained in the last three cases. Polymeric peroxides of high molecular weight were always obtained as the major reaction products.

The decomposition of the cyclic and linear peroxides in benzene solution was studied by direct analysis in order to show that there is no fundamental difference in the primary step of the breakdown. Measurements were made of the rate of polymerization of styrene using the various peroxides as initiators to determine to what extent the radical intermediates grow to give high molecular weight polystyrene. The decomposition of the peroxides in benzene solutions of 1,1-diphenyl-2-picrylhydrazyl (DPPH) was studied to give information concerning the reactions of the radical intermediates with DPPH.

EXPERIMENTAL

Materials

Chloroform was treated with concentrated sulphuric acid to remove alcohol and was washed twice with distilled water. Reagent grade (Fisher) benzene was used for the kinetic studies. Styrene was distilled at 15 mm pressure and subjected to two bulb-to-bulb distillations on the high vacuum line. DPPH was prepared by the method of Goldschmidt and Renn (4); it was heated *in vacuo* to 90° for 1 hour to remove complexed solvent. Succinyl, adipyl, sebacyl, and hexanoyl chlorides were Eastman Kodak materials.

Suberic, azelaic, dodecanedioic, and tetradecanedioic acids were converted to the corresponding acid chlorides by reaction with thionyl chloride. Thionyl chloride (2.4 moles per mole of acid) was used and the reaction was allowed to proceed for 3 days at 40°; excess thionyl chloride was distilled off at reduced pressure. The light yellow product was treated with activated charcoal. (This modification of the usual method was suggested by R. F. Liming, Distillation Products Industries.) The purity of the acid chlorides was

[1]*Manuscript received May 13, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

shown to be greater than 98.5% by allowing them to react with 6 *N* sodium hydroxide, adding 6 *N* hydrochloric acid equivalent to the sodium hydroxide, and determining the hydrochloric and dibasic acids present.

Preparation of the Peroxides

The peroxides were prepared by stirring a dilute aqueous solution of sodium peroxide with a dilute chloroform solution of the acid chloride. In a typical preparation, 20 g of disodium hydrogen phosphate hexahydrate and 0.01 mole of sodium peroxide were added to 110 ml of water at 0° C. A solution of 0.015 mole of acid chloride in 250 ml of chloroform was added and the mixture stirred vigorously. Further quantities of sodium peroxide, up to a total of 0.025 mole, were added over a period of 20 minutes. Stirring was continued for a further 30 minutes.

The chloroform layer was separated and washed twice with water, and the chloroform was evaporated with a stream of dry air at room temperature. The white solid obtained was extracted twice with low-boiling petroleum ether.

Significant yields of low molecular weight peroxide soluble in petroleum ether were obtained only in the cases of sebacyl, dodecanedioyl, and tetradecanedioyl peroxides. These materials were purified by recrystallization from petroleum ether and dried *in vacuo* at room temperature. Molecular weights were determined by measurement of the depression of the freezing point of pure benzene, and peroxide contents were determined by the method of Wagner, Smith, and Peters (5). Sebacyl peroxide: yield 4–6%, m.p. 19–21°. Anal. Calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.06; —O—O—, 16.0. Found: C, 60.16, 60.22; H, 8.07, 8.06; —O—O—, 15.8%. Mol. wt. 360, 370. Dodecanedioyl peroxide: yield 5–6%, m.p. 32–35°. Anal. Calc. for $C_{12}H_{20}O_4$: C, 63.15; H, 8.77; —O—O—, 14.0. Found: C, 63.17, 63.26; H, 8.78, 8.97; —O—O—, 13.8, 13.7%. Mol. wt. 429, 473. Tetradecanedioyl peroxide: yield 7–9%, m.p. 43–46°. Anal. Calc. for $C_{14}H_{24}O_4$: C, 65.56; H, 9.38; —O—O—, 12.5. Found: C, 65.54, 65.58; H, 9.65, 9.53; —O—O—, 12.1%. Mol. wt. 462.

In the attempted preparation of succinyl peroxide a low yield of chloroform-insoluble peroxide was obtained and very little peroxide remained in the chloroform layer even before evaporation. With other preparations the major product was a peroxide which was insoluble in petroleum ether. Molecular weight determination by depression of the freezing point of benzene indicated values greater than 3000; intrinsic viscosities of chloroform solutions of sebacyl, dodecanedioyl, and tetradecanedioyl peroxides varied between 0.3 and 0.5. These high molecular weight peroxides will be referred to as polymeric peroxides and individual peroxides as polysebacyl peroxide, etc. *When dry, polymeric peroxides explode on scratching or on heating. The sensitivity to percussion and the vigor of the explosion increase with the peroxide content of the polymeric peroxide.* Polyadipyl peroxide: yield 50%, m.p. 118–119° decomp. Polysuberyl peroxide: yield 75%, m.p. 116–118° decomp. Anal. Calc. for $C_8H_{12}O_4$: —O—O—, 18.6. Found: —O—O—, 18.3%. Polyazelayl peroxide: yield 70%, m.p. 104–105° decomp. Anal. Calc. for $C_9H_{14}O_4$: —O—O—, 17.2. Found: —O—O—, 17.0%. Polysebacyl peroxide: yield 85%, m.p. 112–113° decomp. Anal. Calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.06; —O—O—, 16.0. Found: C, 60.12, 60.22; H, 8.07, 7.95; —O—O—, 15.9, 15.8%. Polydodecanedioyl peroxide: yield 80%, m.p. 108–109°. Anal. Calc. for $C_{12}H_{20}O_4$: —O—O—, 14.0. Found: —O—O—, 13.7%. Infrared spectra were taken of the low molecular weight and polymeric sebacyl, dodecanedioyl, and tetradecanedioyl peroxides in chloroform solution using a Perkin–Elmer Model 21 spectrometer.

Decomposition Studies

The rates of breakdown of the peroxides in benzene and styrene solutions were determined by peroxide analysis. For styrene as solvent, about 0.04 g of peroxide was weighed and introduced into a reaction tube. Approximately 4 g of styrene was distilled into the tube, and after it was sealed off, the tube was placed in a bath at 60° for 1 hour or 2 hours. The remaining peroxide was then estimated (5). For benzene as solvent, the solutions were degassed twice before being placed in the bath at 60°.

In the polymerization studies, solutions of peroxide in styrene were made up as described above, and the polymerization allowed to proceed at 60° for 2 hours. The high molecular weight polystyrene was precipitated in methanol, filtered, and dried *in vacuo* at 60°.

The rates of disappearance of DPPH were studied using benzene solutions which were approximately 0.0004 *M* in DPPH and 0.005 *M* in peroxide. The solutions were degassed and were heated to 60° for periods of 20 minutes. Readings of optical density were taken at a solution temperature of 20° using a Fisher electrophotometer with a 650 mμ filter. The optical densities of a series of DPPH solutions of known concentration were also determined.

RESULTS AND DISCUSSION

The Structures of the Peroxides

The major product of the reaction between a dibasic acid chloride and sodium peroxide under the experimental conditions used in this work is a polymeric peroxide. Good yields of polyadipyl, polysuberyl, polyazelayl, polysebacyl, polydodecanedioyl, and polytetradecanedioyl peroxides were obtained. The average molecular weights of the polymeric peroxides are probably between 5000 and 10,000. They are almost certainly linear polymers.

Small yields of low polymers of sebacyl, dodecanedioyl, and tetradecanedioyl peroxides were isolated. Analytical data and molecular weight determinations suggest that these low polymers are cyclic dimers. It is possible that the products are mixtures of low polymers, e.g., cyclic monomer, dimer, and trimer. However, fractional crystallization did not appreciably affect the melting points of the products and it is probable that the peroxides are largely, if not completely, cyclic dimers. Confirmatory evidence for the nature of the low molecular weight products is provided by their infrared spectra. The spectra of corresponding low and high molecular weight products are identical except for slight differences in the intensities of some bands. This indicates that similar structural units are present in the dimer and polymer. There is no absorption in the O—H stretching frequency region in any of the spectra; the cyclic dimer is therefore not seriously contaminated by low molecular weight linear peroxides.

The production of cyclic dimer instead of monomer in the case of sebacyl peroxide is not surprising in view of the strain normally involved in 12-membered rings. Overberger and Lapkin (6) obtained the cyclic dimer, 3,12,15,24-tetraphenyl-1,2,13,14-tetraaza-1,13-cyclotetracosatetradiene, when they attempted to prepare the monomeric 12-membered ring compound. A dimer was also formed when they attempted to prepare the corresponding 14-membered ring compound. In the present work it was hoped that the 16-membered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ring of monomeric tetradecanedioyl peroxide would be formed more readily, but the molecular weight evidence indicates that formation of dimer is preferred to that of monomer.

Decomposition of the Peroxides in Solution

The thermal decomposition of the peroxides in benzene and styrene solution was studied by peroxide analysis. The peroxides investigated were the cyclic dimers and the high molecular weight linear polymers of sebacyl, dodecanedioyl, and tetradecanedioyl peroxide. These six peroxides all decompose at rates within the range 5.5 to 8.5%/hour in the two solvents at 60°. Since the cyclic peroxides decompose at approximately the same rates as the linear peroxides, it is reasonable to assume that homolytic cleavage of the peroxide link occurs as the initial step in both cases. The radicals so formed may eliminate carbon dioxide. Thermal decomposition of the polymeric peroxides gives rise to monoradicals and decomposition of the cyclic peroxides leads to diradicals.

The Peroxides as Initiators for the Polymerization of Styrene

The three cyclic dimers and their long-chain linear analogues were used as initiators for the polymerization of styrene at 60°. The measured rates of polymerization were converted to rates of initiation R_i by means of the relationship (7)

$$[1] \qquad R_p^2 = 3\times10^{-2}R_i .$$

In this work concentrations are expressed in moles/liter and time in seconds; for the peroxides, concentrations are given in moles/liter of monomer units. Values of $R_i/(I)$, where (I) is the concentration of peroxide, are given in Table I.

TABLE I

Rates of initiation of polymerization of styrene and rates of disappearance of DPPH at 60°

	$10^6 R_i/(I)$ sec^{-1}	$10^6 R_{DPPH}/(I)$ sec^{-1}
Polysebacyl peroxide	8.0	12.1
Sebacyl peroxide (cyclic dimer)	0.22	0.5
Polydodecanedioyl peroxide	7.9	11.0
Dodecanedioyl peroxide (cyclic dimer)	0.21	0.35
Polytetradecanedioyl peroxide	8.2	11.4
Tetradecanedioyl peroxide (cyclic dimer)	0.37	0.6
Hexanoyl peroxide	13.8	18

The three polymeric peroxides have a value of $R_i/(I)$ of 8×10^{-6} sec^{-1} within experimental error. The polymeric peroxides differ only in the number of methylene groups joined together in their repeating units, and unless this number is very small, significant differences between the rates for the three peroxides would not be expected. The value of $R_i/(I)$ for hexanoyl peroxide, a simple linear peroxide, is 13.8×10^{-6} sec^{-1}.

The rates of initiation of polymerization of styrene are very much lower when the cyclic dimers are used as initiators. The maximum rate is observed with tetradecanedioyl peroxide and this is only 4.5% of the rate observed with the corresponding polymeric peroxide. If the cyclic dimers decompose to produce diradicals, these diradicals undergo self-termination before they add on a significant number of styrene units. Other workers have reached a similar conclusion on the basis of theoretical and experimental studies. Zimm and Bragg (8) predicted that even large polystyryl diradicals would undergo self-termination more rapidly than addition of a styrene monomer unit. Tobolsky and Russell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(9) showed that the photochemical breakdown of a cyclic disulphide in styrene gave very little high molecular weight polystyrene, in contrast with the result obtained using a linear disulphide. Overberger and Lapkin (6) observed that the thermal decomposition of a 24-membered ring azo compound in styrene gave a relatively low yield of high polymer, and Cohen *et al.* (10) observed that a 6-membered ring azo compound behaved in a similar manner.

In previous studies it was not clear whether the small amount of high polymer formed arose from the growth of diradicals or of monoradicals originating from an impurity. This point can be investigated by comparing the degree of polymerization of the polystyrene produced by a cyclic peroxide with that predicted by the equation (11)

$$[2] \qquad \frac{1}{P_n} = C_m + \frac{K_t}{K_p^2} \times \frac{R_p}{[M]^2}.$$

This relationship applies to initiators which produce monoradicals and which do not undergo chain transfer with polystyryl radicals. P_n is the number average degree of polymerization, C_m is the chain transfer constant for styrene, K_t is the termination rate constant, K_p is the propagation rate constant, and [M] is the concentration of styrene. For samples of polystyrene produced using the three cyclic peroxides as initiators, the experimental and calculated values of P_n are very close to one another (see Table II).

TABLE II

Experimental and calculated degrees of polymerization of polystyrene

	Experimental DP	Calculated DP
Sebacyl peroxide (cyclic dimer)	4460	4100
Dodecanedioyl peroxide (cyclic dimer)	3400	3370
Tetradecanedioyl peroxide (cyclic dimer)	3360	3310

Johnson and Tobolsky (12) have pointed out that polystyrene produced by diradicals which fail to undergo self-termination will have a much larger degree of polymerization than that predicted by the above relationship. The small amount of polystyrene produced when the cyclic peroxides are used as initiators therefore originates from a monoradical-producing compound, which is probably a linear peroxide present as impurity in the cyclic dimer. Diradicals formed in the breakdown of the cyclic dimers appear to have a negligible chance of growing to high polymer.

Decomposition of Peroxides in the Presence of DPPH

DPPH has been used to measure the rate of formation of free radicals in the thermal decomposition of benzoyl peroxide (13). The decomposition of the cyclic peroxides in the presence of DPPH was investigated to determine whether self-termination of diradicals occurred before they could react with DPPH. The linear polymeric peroxides and hexanoyl peroxide were used as standards of comparison. The results obtained for $R_{DPPH}/(I)$, where R_{DPPH} is the rate of disappearance of DPPH, are given in Table I. The reactions were zero order with respect to DPPH in the concentration range studied. The values of $R_{DPPH}/(I)$ for the polymeric peroxides are almost 50% greater than the values of $R_i/(I)$. This difference is not necessarily significant as there is some uncertainty in the choice of constant for equation (1) and the experimental error in the DPPH work may be as high as 10%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The cyclic peroxides give very low values of $R_{DPPH}/(I)$. The observed rates may well be due to the reaction of DPPH with monoradicals from a small amount of linear peroxide present in the cyclic dimers. Diradicals from the cyclic peroxides thus undergo self-termination in preference to reaction with DPPH.

The high rate of self-termination of large diradicals is of importance in discussing the mechanism of the thermal polymerization of styrene. It appears likely that diradicals are formed in pure styrene (14), and that some of them have a sufficient lifetime to react with a further molecule of styrene (14) or with DPPH (15). This is only possible for small diradicals containing two styrene units where there are steric difficulties in self-termination. The probability of self-termination for larger diradicals is so great that the high polymer obtained in thermal polymerization must have been formed through an alternative monoradical process.

DETERMINATION OF DIELECTRIC CONSTANT IN BINARY ORGANIC SYSTEMS[1]

C. G. MILLER[2] AND O. MAASS

ABSTRACT

Measurements of the dielectric constants of binary systems have been made; hexane, benzene, toluene, acetone, isopropyl alcohol, and nitrobenzene have been used two at a time. It was the purpose to obtain accurate data for the dielectric constants for the 15 systems over the whole range of concentrations from 0 to 100%, with the absolute accuracy of 0.1%. It is claimed that the relative accuracy is of this order. From the data obtained regularities have been found which are expressed in the form of empirical equations which summarize the data. Tentative suggestions regarding theoretical conclusions are made in a number of cases.

INTRODUCTION

There are already extensive data in the literature concerning the dielectric constants of binary organic mixtures (1). These data have been obtained over a period of years by a number of investigators and by a number of different techniques. While some of the systems investigated in the present work have been recorded elsewhere, in most cases these studies are isolated in the sense of dealing with a single system and in some cases only a relatively small concentration range has been considered within a given system. In addition the data are reported at various temperatures.

The initial objective of the authors was to build up a body of self-consistent dielectric constant data at a single temperature in those mixtures which would cover a wide range of dielectric constant, and over the complete range of concentration in a given system, with a view to investigating subsequently electrolytic conductivity in such mixtures.

In the furtherance of this objective, measurements were made of the dielectric constant in two-component systems which may be of interest per se. The 15 systems reported comprise a systematic study of mixtures of six compounds taken in pairs and cover a range of dielectric constant (ϵ) from 2 to 35. In this presentation it is considered an advantage for comparative purposes that all systems have been studied with the same apparatus and technique.

While the authors are interested in establishing the accuracy of the absolute values of their results, it may be pointed out that whatever error there may be in the measurements will be relative and will not affect the general nature of the conclusions drawn.

Those inferences drawn from the dielectric constant data in regard to certain regularities were so interesting that it was considered useful to record these regularities, although at this stage the authors do not contemplate making any theoretical deductions.

To assist in interpreting the results of the dielectric constant measurements, the densities of the various mixtures were required and were determined experimentally where adequate data were not readily available in the literature.

The technique of the measurement of dielectric constant follows fairly closely that of other investigators and whatever changes have been made are recorded in the experimental section.

EXPERIMENTAL

A. Materials

Benzene and toluene (Mallinckrodt "Analytical Reagent"), normal hexane and cyclohexane (Phillips "Pure Grade") were all used without further purification. The dielectric constant was taken as the criterion of purity and its values for all the hydrocarbons agreed closely with the accepted values for the pure liquids.

Acetone (Mallinckrodt "Analytical Reagent") was dried by distillation from a large quantity of Drierite and allowed to stand over a small quantity of Drierite from which it was decanted for use.

Isopropanol (Eastman) was dried over freshly calcined lime and distilled from the lime immediately prior to each series of measurements.

Nitrobenzene (Eastman) was twice distilled in vacuum (less than 2 mm of mercury) and the distillate stored in a sealed container until used.

B. Apparatus and Procedure

The dielectric cell was of similar design and dimensions to that described by Gross and Taylor (2). The capacitor comprised two coaxial metallic cylinders, the medium under study filling the annular space between the cylinders. The outer cylinder was surrounded by a guard element which formed the body of the cell. These three elements were made from rhodium-plated brass. The assembly was held rigidly by teflon spacers and by a stainless steel lid which screwed down tightly and formed a part of the guard element. When assembled, the cell had an air capacitance of approximately 4.89 $\mu\mu$f and an internal volume of about 14 ml. The cell assembly was lowered into a grounded aluminum canister from which it was insulated electrically by a teflon ring, and the canister was immersed in a water thermostat maintained at 25°±0.01° C. The cell, once assembled and calibrated, was used for all measurements without disassembly.

Capacitance measurements were made by substitution on a capacitance bridge (General Radio type 716-C with guard circuit type 716-P4 and detector type 1231-BRF). Experiments on air and cyclohexane showed no variation in capacitance reading over the frequency range 1 kc/sec to 100 kc/sec. Accordingly the frequencies 1 kc/sec, 10 kc/sec, and 100 kc/sec were used indiscriminately throughout this work, the higher frequencies being preferred in the polar liquids where the dissipation factor was appreciable. All capacitance measurements were made by a reiterative method, sufficient readings being taken that the estimated probable error in the mean did not exceed 0.1% of the mean.

TABLE I

Cell capacitance using toluene

	C_i	B_0	Δ_{corr}	C_0	C_0-C_i
1	100.18	111.90	+0.02	111.92	11.74
2	199.96	211.70	−0.02	211.69	11.73
3	400.24	412.04	−0.01	412.03	11.79
4	599.58	611.34	+0.01	611.35	11.77
5	800.24	812.06	−0.02	812.04	11.80
6	1000.12	1011.90	+0.01	1011.91	11.79
	Mean				11.770±0.012

By way of illustration, in Table I is given the record of an actual experiment using toluene as the dielectric. In operation the variable capacitor of the capacitance bridge was set to an arbitrary value with the cell in parallel with it. The bridge was balanced, the

cell removed from the circuit, and the bridge rebalanced by means of increasing the capacitance of the variable capacitor. The difference in reading gives the capacitance of the cell. In Table I, C_1 is the reading of the variable capacitor with the cell in the circuit, B_0 the reading of the variable capacitor when the cell has been removed, Δ_{corr} the net correction as obtained from the bridge calibration and applied to B_0, C_0 the corrected value for B_0 (that is, $C_0 = B_0 + \Delta_{corr}$), and finally $C_0 - C_1$ represents the capacitance of the cell.

The probable error in the mean, ± 0.012, was estimated from the expression: $R = \pm 0.6745 \sqrt{\{\sum V^2/n(n-1)\}}$ where R is the probable error, V the individual deviations from the mean, and n the number of readings taken.

A correction for switch and lead capacitance was made by the same reiterative method and was applied to capacitance readings as follows:

Observed capacitance	$11.770 \pm 0.012\ \mu\mu f$
Switch correction	$-0.157_5 \pm 0.001_4\ \mu\mu f$
Net cell capacitance	$11.612 \pm 0.013\ \mu\mu f$
Cell constant (previously determined)	$4.887 \pm .005\ \mu\mu f$
Dielectric constant of toluene $\frac{11.612}{4.887}$	$= 2.376 \pm 0.005$

The dielectric cell was calibrated with air as the dielectric and cyclohexane was used as a secondary standard, as recommended by Hartshorn and his co-workers (3). Excellent agreement (0.1%) was obtained, and the true cell constant was taken as the mean, with the value obtained from cyclohexane given half-weight.

Density measurements were performed with a Westphal balance. The temperature of the liquid was measured to 0.2° C and the density corrected to 25.0° C, assuming the temperature coefficients of the pure liquids to persist in the mixtures.

All mixtures were prepared by volume, the temperature of the pure liquids being measured and the molar percentages calculated from the density data given by Timmermans (4).

RESULTS

A comparison between observed values of dielectric constant for the pure liquids (ϵ_{obs}) and the accepted values (ϵ_{ref}) as recorded by Maryott and Smith (5) is given in Table II. All the observed values are thought to be accurate to $\pm 0.2\%$ except that for

TABLE II

Dielectric constants of pure liquids at 25° C

Compound	ϵ_{obs}	ϵ_{ref}
n-Hexane	1.884 ± 0.004	1.882 ± 0.01
Benzene	2.281 ± 0.006	2.274 ± 0.002
Toluene	2.376 ± 0.005	2.379 ± 0.01
Isopropanol	19.13 ± 0.04	18.3 ± 0.4
Acetone	20.54 ± 0.04	$20.7_0 \pm 0.4$
Nitrobenzene	34.62 ± 0.07	34.82 ± 0.07

benzene, which is slightly high, due probably to a small amount of moisture in the sample. Hartshorn (3) has shown that traces of water in benzene cause a high dielectric constant and are extremely difficult to remove. No attempt was made to dry the benzene used in this work.

There is a notable discrepancy between the observed dielectric constant of isopropanol and that recorded by Maryott and Smith. However, these authors, when selecting the value 18.3 as the dielectric constant of isopropanol, neglected the value 20.1 recorded by Hennings (6) although they suggested that Hennings' value be considered in any future revision of the data. Since the interest in the present work lay largely in the relative variation of dielectric constant with composition, no attempt was made to resolve this discrepancy. All dielectric constant values, whether for mixtures or for pure liquids, are internally consistent to $\pm 0.1\%$.

In Table III (A, B, and C) are recorded the experimental determinations of the dielectric constants for the various mixtures. For each system the mole fraction refers to

the first named component and it is the more polar. Measured dielectric constants are plotted for selected systems in Fig. 1 (*a*, *b*, *c*). The curve for the nitrobenzene–acetone system is slightly convex upward; the system acetone–isopropanol exhibits a minimum in dielectric constant at about 0.35 mole fraction acetone; the system toluene–benzene shows a linear variation in dielectric constant with composition; all other systems studied show a downward convexity in the dielectric constant – composition curve. Typical examples of this latter behavior are shown in Fig. 1*a* for nitrobenzene–hexane and in Fig. 1*c* for the benzene–hexane and toluene–hexane systems.

Table IV (parts 1, 2, 3) contains the values of density (column 2) and dielectric constant (column 3) at the selected concentrations (column 1) of 0, 0.20, 0.40, 0.60, 0.80, and 1.00 mole fraction. As in Table III the mole fraction refers to the first-named component of each system. Experimental values of dielectric constant and density relative to molecular concentration were plotted on graphs from which the values at the selected concentrations were read. The error in the values thus derived can be expected to be at least as small as the error in any specific measurement.

Where density data for the mixtures were readily available no measurements were made. The density values taken from the literature were corrected by a constant amount over the whole concentration range in a given system in order to bring the densities of the pure liquids to the values given by Timmermans (4) and accepted in the remainder of this work. In only one system (acetone–benzene) was this correction of a significant magnitude, and amounted to about 0.2%. The systems so corrected were acetone–benzene (correction -0.0016) (7); nitrobenzene–benzene (correction 0.004) (7); and acetone–isopropanol (correction 0.0005) (8). Rakshit (9) has shown that density is a linear function of composition in the toluene–benzene system at 20° C. The densities for this system in Table IV have been calculated on the assumption of a similar linearity at 25° C.

For the remaining 11 systems the densities were determined experimentally as described

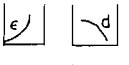
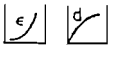
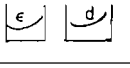
(*b*) Measured dielectric constants in acetone–isopropanol system.
(*c*) Measured dielectric constants in three hydrocarbon systems.

above. The temperature correction was small in all determinations and the accuracy of the density data is estimated at $\pm 0.1\%$ absolute.







In addition to the columns relating to molecular concentration, density, and dielectric constant, Table IV contains several columns which will be described fully in the discussion but which may be mentioned briefly here. The fourth column shows calculated values of dielectric constant based on a relationship which will be dealt with later, and the difference between this value and the observed is given in the fifth column. The next two columns contain calculated values of the so-called molecular polarizations of the mixture and of the relatively more polar component respectively. Finally, the values of K_1 and K_2 from the empirical relationship to be discussed below, together with a qualitative indication of the relative variation of the dielectric constant and of the density over the whole range of concentration are shown in column eight.

Also to be described in detail later is Fig. 2 in which are plotted the molecular polarization of the mixture and the molecular polarization of the more polar component as these are tabulated in columns 6 and 7, Table IV.

DISCUSSION

The application of the theory of dielectric constants of binary systems to the interpretation of experimental data has not been very fruitful. At best it can be said that theory has indicated certain trends which have been borne out. This is so, for instance, in regard to molecular polarization, which will be referred to later.

That density and dielectric constant of a medium are related has been indicated, at least in so far as pure compounds are concerned. In a two-component system certain relationships between dielectric constant and density have been suggested. Having this in mind, the relationship of dielectric constant with density which was observed was found to lend itself to algebraic expression within certain limits for a number of systems including those having a polar compound as one of the components.

In the following discussion ϵ_1 and ϵ_2 are the dielectric constants of the pure components of a binary mixture in which $\epsilon_2 > \epsilon_1$. The corresponding densities are d_1 and d_2; ϵ_{12} and d_{12} are dielectric constant and density respectively of the mixture. The first approach is that

$$\epsilon_{12} = \epsilon_1 + K(d_{12} - d_1). \qquad [1]$$

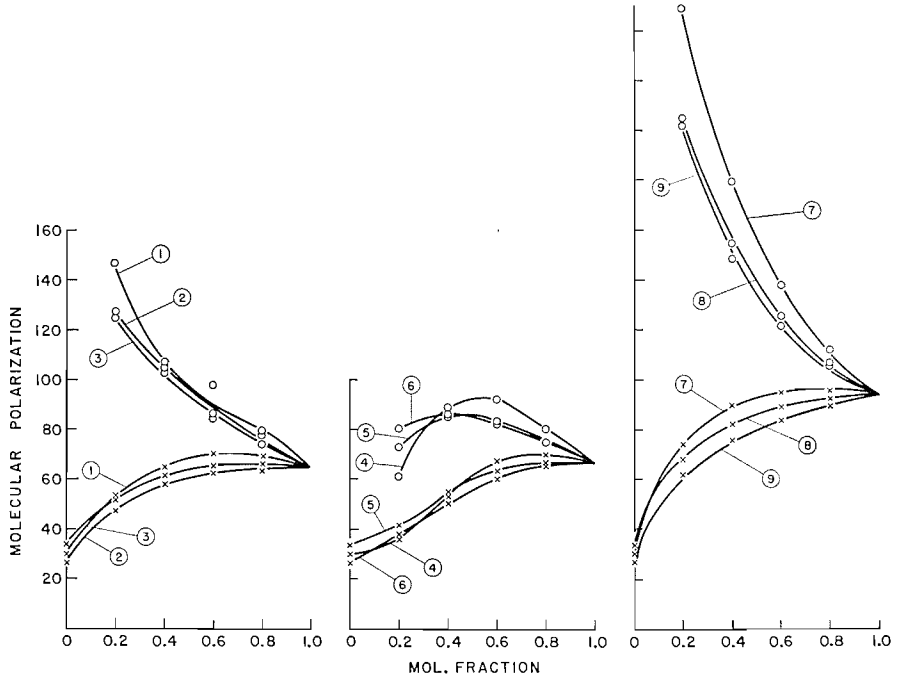

FIG. 2. Calculated values of molecular polarization.
$\times = P_{12}$, $\circ = P_2$. (1) Acetone–hexane. (2) Acetone–benzene. (3) Acetone–toluene. (4) Isopropanol–hexane. (5) Isopropanol–toluene. (6) Isopropanol–benzene. (7) Nitrobenzene–hexane. (8) Nitrobenzene–toluene. (9) Nitrobenzene–benzene.

This is in agreement within experimental error only in the system benzene–toluene. Even with the hexane–benzene and hexane–toluene systems this does not hold. However, if instead of the above simple relationship we use

$$[2] \qquad \epsilon_{12} = \epsilon_1 + K_1 (d_{12} - d_1) + K_2 (d_{12} - d_1)^2,$$

there is perfect agreement in the hydrocarbon systems betwen the calculated and observed results (Table IV, part 1).

Having found this perfect agreement between the empirical relationship (2) and the experimental results in a limited number of systems, an examination of the application of this to all the other systems examined was made.

From the qualitative graphical representation of the relation between dielectric constant and composition, and density and composition, respectively, made in the final column of Table IV it is obvious that the relative convex and concave curvature, as between dielectric constant and composition on the one hand and density and composition on the other, varies from system to system, and it might seem that no particular regularity could be expected. Nevertheless, when equation [2] is applied, this relationship is found to be in fairly good agreement with the experimental results as far as systems involving only one polar compound are concerned (Table IV, part 2) and even indicatively correct for systems involving two so-called polar compounds.

Calculations show that in the hydrocarbon systems (Table IV, part 1) equation [2] hold exactly. In Table IV (part 2) the average difference between observed and calculated values is 0.9% and in Table IV (part 3) 4.0%.

Reference to column 7, in Table IV, part 1, shows that the molecular polarization remains essentially constant with dilution for the hydrocarbons used in this work. This constancy can be made use of in the calculation of P_2, the molecular polarization of the more polar component.

Figure 2 contains three families of curves representing systems containing acetone, isopropanol, and nitrobenzene respectively. For each polar compound the three curves represent mixtures with the hydrocarbons taken in turn. These curves are plots of the calculated values of P_{12} and P_2 as given in Table IV (parts 2 and 3). There is an essential similarity for curves for all hydrocarbons. In benzene and toluene they are almost contiguous while an appreciable divergence is noted for hexane.

A difference in shape is noted in the P_2 curve for systems containing acetone and nitrobenzene as distinct from the systems containing isopropanol. The increase in molecular polarization of acetone and nitrobenzene with increasing dilution may be explained simply by postulating an association between the dipoles in concentrated solution, an association that results in a partial cancellation of the moments of the associated dipoles. As the dilution increases fewer of the molecules exist in the associated state and each exerts its own moment.

The behavior of isopropanol in giving maxima in the P_2 curves calculated for systems containing hydrocarbons is common to other alcohols as well (10). An explanation which has been advanced for this behavior in the past supposes that two different mechanisms of association exist in binary mixtures of alcohols and hydrocarbons. The first mechanism is similar to that advanced above and accounts for the portion of the P_2 curve to the right of the maximum. As the concentration of alcohol is still further reduced, however, the dominant form of association is one in which the alcohol molecules are lined up, perhaps in chains, in such a way that the moments reinforce each other. As this type of association is reduced with increasing dilution the effective moment of each molecule and hence the apparent molecular polarization is also reduced.

CONCLUSION

It has been shown that the dielectric constants of binary systems are dependent on their density and the polarity of each of the components. Certain regularities have been established by summarizing the results obtained in the form of empirical equations. Aberrations from these equations can in the main be attributed to so-called association of one of the components, an association that is affected by the concentration of the second component.

ACKNOWLEDGMENTS

The authors are indebted to Dr. D. W. Davidson, who suggested the design of the dielectric cell, and who provided much valuable discussion throughout the work, and to Mr. Gordon Graham for his technical assistance.

The rhodium-plating of the cell was very kindly undertaken by Avon Jewellery Limited, Belleville, Ontario.

THE POLYSACCHARIDES OF CRYPTOCOCCUS LAURENTII (NRRL Y-1401)

PART I[1]

M. J. Abercrombie, J. K. N. Jones, M. V. Lock,[2] M. B. Perry, and R. J. Stoodley

ABSTRACT

The extracellular polysaccharides produced by *Cryptococcus laurentii* have been isolated and shown to consist of (A) an acidic polysaccharide containing D-mannose, D-xylose, and D-glucuronic acid; (B) a neutral polysaccharide containing D-glucose only.

Preliminary structural studies on the acidic material suggest that it consists of a mannose-containing backbone with xylose and glucuronic acid as end groups, while the glucan contains $1 \rightarrow 3$, $1 \rightarrow 4$, $1 \rightarrow 2$, and (or) $1 \rightarrow 6$ linked residues.

INTRODUCTION

Much is known about the origin of sugars found in homopolysaccharides (1–11). On the other hand the origin of sugars in heteropolysaccharides has not been investigated to any great extent (12, 13).

As part of a program for investigating the biosynthesis of monosaccharides found in heteropolysaccharides, we have studied the extracellular polysaccharide produced by the yeast organism *Cryptococcus laurentii*.

This organism, kindly supplied by the United States Department of Agriculture, Peoria, Illinois, was chosen because it produced high yields of polysaccharides from a wide variety of sugar substances.

Cryptococcus laurentii was grown on an unbuffered casamino acids – salts medium with glucose as the main carbon source (14). An acidic and a neutral polysaccharide were isolated by the following procedure, which was considered unlikely to cause degradation of the polysaccharides. The cell-free solution was dialyzed and then passed through an ion exchange column to give a clear, light brown viscous solution. After the solution was concentrated, the polysaccharides were precipitated with ethanol and had $[\alpha]_D$ +27°. Chromatographic examination of the acid hydrolyzate showed sugars which moved at rates corresponding to mannose, xylose, glucuronic acid, and glucose. The sugars were obtained crystalline or as crystalline derivatives and were shown to be D-mannose, D-xylose, D-glucose, and D-glucuronic acid. The crude polysaccharide showed two peaks on electrophoresis in a veronal buffer. On addition of an aqueous solution of 'cetavlon' (cetyltrimethyl-ammonium bromide) to an aqueous solution of the polysaccharide an insoluble cetyltrimethyl-ammonium salt of an acidic polysaccharide was precipitated. This salt was dissolved in 10% aqueous sodium chloride solution and the sodium salt of the acidic polysaccharide was precipitated in ethanol. Chromatographic examination of the acid hydrolyzate of this material showed mannose, xylose, and glucuronic acid to be present. Electrophoresis in veronal and borate buffers showed a single peak: glass paper electrophoresis (17) showed a single spot. Further attempts at fractionation failed to give any separation. The supernatant from the cetyltrimethyl-ammonium precipitate was concentrated and added to ethanol. Mainly glucose and traces of mannose, xylose, and glucuronic acid were detected in the precipitated material (chromatography).

The acidic polysaccharide had $[\alpha]_D$ +21°; the molar ratio of mannose to xylose present

[1]*Manuscript received May 11, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario, Canada.

in this material was found to be 5:2 (18); titration of the polysaccharide with standard sodium hydroxide gave a uronic acid content of 14.4%. Determination of uronic acid content by the carbazole method (19) gave 11.8%.

On oxidation with sodium metaperiodate the acid polysaccharide consumed 1.10 moles of sodium metaperiodate and liberated 0.58 mole of formic acid per sugar residue. These figures appear to indicate that end group or $1 \rightarrow 6$ linked hexose only is oxidized since a sugar which contains hydroxyl groups on each of three contiguous carbon atoms will reduce 2 moles of periodate and yield 1 mole of formic acid per mole. However, glucuronic acid is present as an end group which is known to overoxidize easily. Hence no exact interpretation can be placed on these results. The oxidized material was reduced with sodium borohydride and hydrolyzed: chromatographic examination of the hydrolyzate showed mannose to be the only sugar present.

Hydrolysis of the acidic polysaccharide in the presence of Amberlite 1R-120 (H) resin removed considerable quantities of xylose without liberating mannose or glucuronic acid. This treatment was repeated with fresh resin until no more xylose was liberated. Chromatographic examination of the hydrolyzate of the resin resistant polysaccharide showed mannose, glucuronic acid, and some xylose. The mannose to xylose molar ratio (18) was determined and found to be 25:3; thus about 66% of the xylose had been hydrolyzed.

The results obtained from sodium metaperiodate oxidation and resin hydrolysis suggest that the polysaccharide consists of a resistant mannose containing backbone with xylose and glucuronic acid as end groups.

The glucan had $[\alpha]_D$ $+180°$ but was contaminated with traces of the acidic polysaccharide. It did not give a blue color with iodine nor was it hydrolyzed by β-amylase.

On oxidation with sodium metaperiodate the polysaccharide consumed 0.83 ± 0.07 mole of metaperiodate and liberated 0.14 ± 0.04 mole of formic acid per anhydro hexose unit. These results indicate that about 1 glucose residue in 10 contains hydroxyl groups in each of three contiguous carbon atoms and that about 40% of the glucose residues do not contain adjacent hydroxyl groups. The oxidized material was reduced with sodium borohydride and hydrolyzed. Chromatographic examination of the hydrolyzate showed glucose, erythritol, and glycerol to be present, suggesting the presence of $1 \rightarrow 3$, $1 \rightarrow 4$, $1 \rightarrow 2$, and (or) $1 \rightarrow 6$ linked residues.

EXPERIMENTAL

The following solvent systems (v/v) were used to separate sugars on paper chromatograms: (A) butanol:pyridine:benzene:water, 5:3:3:1; (B) ethyl acetate:acetic acid:water, 9:2:2; (C) butanol:ethanol:water, 3:1:1. Sugars were detected on paper chromatograms by spraying the chromatograms with either *p*-anisidine hydrochloride (20) or alkaline silver nitrate (21). Solutions were evaporated under reduced pressure at ca. 40° C. All optical rotations were measured in aqueous solution at $23° \pm 3°$ C unless otherwise stated.

Growth of Cryptococcus laurentii and Isolation of the Polysaccharide

The following two media were prepared and each was electrometrically adjusted to pH 7.0 with dilute potassium hydroxide solution: (i) 'Difco' bactocasamino acids (15 g), potassium nitrate (5 g), potassium dihydrogen phosphate (20 g), dipotassium hydrogen phosphate (15 g), magnesium sulphate heptahydrate (2.5 g), thiamine hydrochloride (5 mg), trace element solution (25 ml) (15), water (4l); (ii) glucose (250 g), water (1 liter). The trace element solution contained zinc sulphate heptahydrate (2.0 g), copper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sulphate pentahydrate (0.1 g), manganese sulphate monohydrate (1.5 g), ferrous sulphate heptahydrate (2.0 g), and distilled water (1 liter).

Medium (i) was equally distributed between 10 conical flasks (1 liter), the necks of which were plugged with cotton wool. Both media were steam-sterilized for 15 minutes at a pressure of 15 p.s.i. Aliquots (ca. 100 ml) of the glucose solution were added to each flask under sterile conditions and the solutions were innoculated with an aqueous suspension of *Cryptococcus laurentii*. The flasks were swirled on a mechanical shaker at 20°±2° C for 14 days, after which the culture medium had become extremely viscous.

The combined solution was diluted with water (2 vol.) and centrifuged on a Sharples ultracentrifuge to remove suspended yeast cells. The supernatant was dialyzed against tap water (3 days) and distilled water (1 day). The clear, light brown solution was passed through an Amberlite IR-120 (H) resin column: since the solution was slightly cloudy it was again centrifuged on the Sharples ultracentrifuge. The solution was concentrated on a continuous evaporator at 35° C until a highly viscous solution was obtained. This solution was poured into ice-cold ethanol (6 vol. containing 1% hydrochloric acid) with vigorous stirring. The fibrous white product, suspended in ethanol, was broken up in a Waring Blender: the finely divided material was washed with ethanol until free of chloride ions. This material was collected by filtration, dried *in vacuo* over calcium chloride, and had $[\alpha]_D$ +27° (yield 19 g, 8% based on glucose).

Chromatographic examination of the polysaccharide hydrolyzate in solvents A and B indicated the presence of mannose, xylose, glucuronic acid, and glucose.

Neutral Component Sugars of the Polysaccharide

The polysaccharide (500 mg) was heated with *N* sulphuric acid (50 ml) for 24 hours on a boiling water bath. The solution was neutralized ($BaCO_3$), filtered, and deionized by passage through an Amberlite IR-120 (H) resin column. The solution was concentrated to a syrup and fractionated by paper chromatography using solvent A. Extraction of the appropriate sections of the paper afforded crystalline D-xylose, m.p. 142–143°, $[\alpha]_D$ +17.6°; D-glucose, m.p. 145°, $[\alpha]_D$ +50°, which gave a N-*p*-nitrophenyl-β-D-glucosylamine (22), m.p. 185°, $[\alpha]_D$ −200° (pyridine); D-mannose (crystallized after seeding and standing 4 weeks), m.p. 133° C, $[\alpha]_D$ +13°, which gave D-mannose phenylhydrazone, m.p. 188°–190° C (mixture melting points with authentic samples showed no depression). The glucuronolactone failed to crystallize. A spot of the D-glucose solution gave a positive test when sprayed with the glucose oxidase reagent (23).

Free Electrophoresis of the Polysaccharide

The polysaccharide in solution at a concentration of 1.0% in veronal buffer (0.1 *M* barbital/sodium hydroxide pH 9.5) was subjected to electrophoresis in a Perkin–Elmer Model 38-A moving boundary apparatus (1° C). The polysaccharide solution was dialyzed against the veronal buffer for 48 hours to gain full equilibration of the ionic concentrations prior to electrophoresis. Figure 1 is the diagram obtained in the descending arm after 5 and 60 minutes. Two peaks were observed, a fast-moving peak and a stationary small peak. Electrophoresis was continued until the fast-moving peak had moved off the screen. Chromatographic examination of the hydrolyzate of the solutions contained in the solution, buffer, and middle arms of the electrophoresis cell showed that the fast-moving peak was an acidic polysaccharide containing mannose, xylose, and glucuronic acid. The stationary peak was a polysaccharide containing mainly glucose.

Fractionation of the Polysaccharide

The polysaccharide mixture was dissolved in water (5 liters): to this solution was

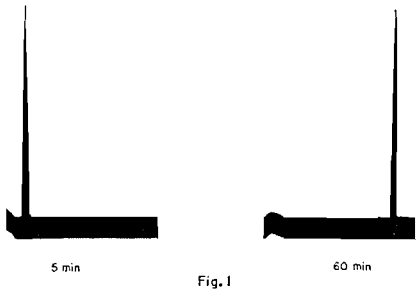

Fig. 1

Fig. 2

FIGS. 1 and 2. Free electrophoresis of polysaccharide.

added a 2.5% solution of 'cetavlon' with stirring until no further precipitate formed (15, 16). The white material was collected by centrifugation, washed well with water, and dissolved in 10% aqueous sodium chloride solution (500 ml). The solution was poured into ice-cold ethanol (6 vol.) and the precipitated polysaccharide was washed with 95% aqueous ethanol. The polysaccharide (sodium salt) was collected by filtration, dried *in vacuo* over calcium chloride, and had $[\alpha]_D$ +21°, ash 4.5%, and nitrogen content 0.1% (yield 17 g). Chromatographic examination of the hydrolyzate in solvents A and B indicated the presence of mannose, xylose, and glucuronic acid. The supernatant from the 'cetavlon' precipitate was dialyzed against tap water (4 days) and distilled water (1 day), concentrated, and poured into ice-cold ethanol. The small amount of white precipitate was collected by centrifugation, washed with ethanol, and dried (yield 1.0 g). Chromatographic examination of the hydrolyzate of this material indicated the presence of glucose and small quantities of mannose, xylose, and glucuronic acid.

Free Electrophoresis of the Acidic Polysaccharide

A 1% solution of the acidic polysaccharide in (i) borate buffer (0.05 *M* borate) and (ii) veronal buffer (as above) was subjected to electrophoresis. Figure 2 is the diagram obtained in the descending arm in each buffer: only a single peak was observed.

Glass Paper Electrophoresis

The glass paper electrophoresis was carried out as described by Smith and Lewis (17). A type 3371 B LKB power supply was used with 2 *N* sodium hydroxide as the electrolyte. The chromatogram was sprayed with sulphuric acid/*p*-anisidine. The electrophoresis was repeated (×4); in each case a single spot was observed.

Reduction of the Acidic Polysaccharide

The sodium salt of the acidic polysaccharide (100 mg, glucose-free) was dissolved in water (10 ml) and deionized by passing its solution through a small column of Amberlite IR-120 (H) resin. The solution was concentrated and lyophilized. The residual material was suspended in methanol and an ethereal solution of diazomethane was added with stirring until a permanent yellow color was obtained. The polysaccharide was collected by filtration, washed with methanol, and dissolved in water. An excess of sodium borohydride (50 mg) was added and the reaction was allowed to stand at room temperature for 5 hours. The excess sodium borohydride was destroyed by the addition of acetic acid: the solution was dialyzed against distilled water for 24 hours and then passed through an Amberlite IR-120 (H) resin column. The deionized solution was concentrated and the polysaccharide precipitated by pouring the solution into ice-cold ethanol. The polysaccharide was collected by centrifugation. A small portion of this (ca. 5 mg) was hydrolyzed with *N* sulphuric acid as previously described. Chromatographic examination of the hydrolyzate in solvent A indicated the presence of mannose, xylose, glucuronic acid, and glucose. When sprayed with the glucose oxidase spray (23), a spot of the hydrolyzate gave a positive reaction for glucose. The treatment with diazomethane and reduction with sodium borohydride was repeated twice until the chromatographic examination of the hydrolyzate showed that only a trace of glucuronic acid remained. The remainder of the polysaccharide (ca. 60 mg) was hydrolyzed with *N* sulphuric acid on a boiling water bath, neutralized ($BaCO_3$), filtered, and deionized by passage of the solution through an Amberlite IR-120 (H) resin column. The solution was concentrated to a syrup which was fractionated by chromatography on Whatman 3MM paper by the use of solvent A. The appropriate section of the paper containing glucose was eluted and the solution concentrated to a syrup. The syrup was dissolved in methanol (1 ml) containing a trace of hydrochloric acid and 10 mg of *p*-nitroaniline was added: the reaction mixture was heated on a boiling water bath for 10 minutes; on cooling yellow crystals appeared, m.p. 185° C (mixture melting point with authentic N-*p*-nitrophenyl-β-D-glucosylamine was not depressed).

Quantitative Estimation of the Component Sugars of the Acidic Polysaccharide

Samples of the polysaccharide (30–40 mg) were hydrolyzed in the usual way. The syrup obtained was fractionated by chromatography on Whatman 3MM paper by the use of solvent A. The appropriate sections of paper were eluted and the ratio of mannose to xylose was determined by the phenol – sulphuric acid method (18). The results indicated that mannose and xylose were present in the molar ratio 5:2.

The glucuronic anhydride content of the polysaccharide was determined by the carbazole method (19) and found to be 11.8%. The ash-free polysaccharide had an equivalent weight of 1215 (≡ 14.4% glucuronic anhydride), found by electrometric titration with standard alkali.

Sodium Metaperiodate Oxidation of the Acidic Polysaccharide

Accurately weighed samples of the polysaccharide (ca. 50 mg) were oxidized with aqueous sodium metaperiodate solution using standard procedures. The periodate uptake was estimated by the method of Neumuller and Vasseur (24) and the formic acid liberation by Andrews *et al.* (26). The results are collected in Table I.

When the oxidation with sodium metaperiodate was complete, ethylene glycol (3 ml) was added and the solution was dialyzed against distilled water for 24 hours. Sodium

TABLE I

Sodium metaperiodate oxidation of the acidic polysaccharide per anhydro residue

Time (hr)	HCOOH	IO_4
4.5	0.14	0.31
12.5	0.26	0.62
24.0	0.37	0.82
37.0	0.50	0.99
61.0	0.58	1.10
85.0	0.58	1.10
105.0	0.58	1.10

borohydride was added (50 mg) and the solution was left overnight and then dialyzed. The concentrated non-dialyzable material was hydrolyzed with *N* sulphuric acid in a sealed tube in a boiling water bath. Examination of the neutralized ($BaCO_3$) hydrolyzate on paper chromatograms showed mannose to be the only original sugar present.

Degradation of the Acidic Polysaccharide with Resin

The polysaccharide (500 mg) was dissolved in water (100 ml) and Amberlite IR-120 (H) resin (5 ml) was added. The reaction mixture was heated on a boiling water bath; at intervals, samples (ca. 1 ml) were withdrawn and examined chromatographically. Only xylose was detected; after 20 hours no apparent further release of xylose took place. The resin was removed by filtration and the solution concentrated and added to ice-cold ethanol, the precipitated polysaccharide (300 mg) was collected by centrifugation. The hydrolyzate of a small portion of this material (ca. 10 mg) was examined chromatographically; some xylose as well as mannose and glucuronic acid was present. The treatment with resin was repeated twice; only traces of xylose were removed by fresh resin: the weight of the polysaccharide remained constant during the two hydrolyses. The molar ratio of mannose to xylose was determined by the phenol – sulphuric acid method and found to be 25:3. Thus the hydrolysis of the polysaccharide with the resin had removed ca. 66% of the xylose without liberating mannose or glucuronic acid.

Examination of the Glucan

The glucan had $[\alpha]_D$ +180°: it did not give a blue color with iodine nor was it hydrolyzed with β-amylase.

Sodium Metaperiodate Oxidation of the Glucan

The oxidation of the glucan was carried out as described for the acidic polysaccharide. The results are collected in Table II. Extrapolation of the overoxidation part of the

curve to zero time gave a value corresponding to a metaperiodate uptake of 0.83±0.07 mole and a liberation of 0.14±0.04 mole of formic acid per anhydro hexose unit.

Hydrolysis of the Oxidized Glucan

The polysaccharide (50 mg) was oxidized with sodium metaperiodate as described. After 100 hours, ethylene glycol (5 ml) was added to destroy the excess periodate. The polyaldehyde was then reduced by the addition of a large excess of sodium borohydride and the solution stirred for 2 hours. The solution was acidified with dilute acetic acid and dialyzed against distilled water. The dialyzate, after concentration to dryness, was dissolved in *N* sulphuric acid and hydrolyzed for 10 hours. Chromatographic examination of the hydrolyzate in solvents A, B, and C, using *p*-anisidine hydrochloride and alkaline silver nitrate sprays, detected spots corresponding to glucose, glycerol, and erythritol.

Growth of Cryptococcus laurentii at pH 5, 7, and 9 and Isolation of the Polysaccharides

Culture media were prepared as before and each was adjusted to pH 5, pH 7, or pH 9. The media were treated in a similar manner to those described previously; after 12 days' shaking the solutions had become extremely viscous. The clear solutions were collected and the acidic polysaccharide and the glucan were isolated as previously described. The weights of the polysaccharides isolated from each growth media are shown in Table III.

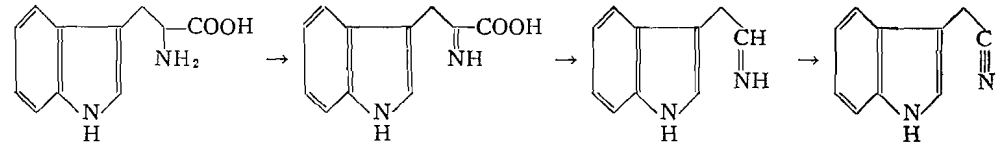
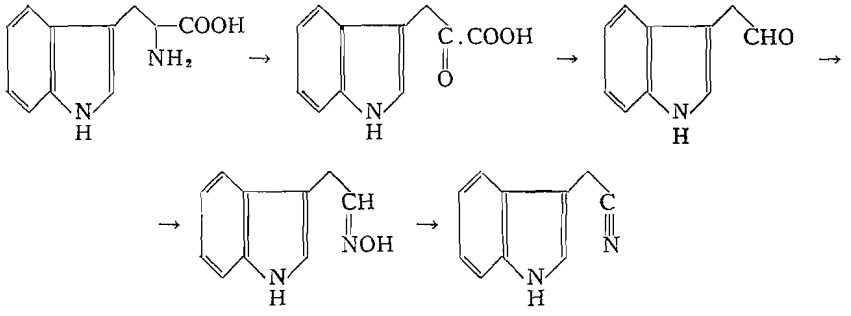
INDOLYL-3-PYRUVIC ACID OXIME AS THE PRECURSOR OF INDOLYL-3-ACETONITRILE[1]



A. Ahmad and Ian D. Spenser

ABSTRACT



Chemical and chromatographic evidence is presented compatible with the hypothesis that the auxin indolyl-3-acetonitrile is derived in plants from indolyl-3-pyruvic acid oxime (anti HO– –COOH) by a concerted reaction.

Since the discovery that indolyl-3-acetonitrile (IAN) occurs naturally (1) and shows auxin activity in certain plant species, two hypotheses of its biosynthetic origin have been proposed. Both of these postulate tryptophan as the parent substance, but differ in the intermediate steps whereby the alanyl side chain of the amino acid is modified to $-CH_2-CN$ in the nitrile.

Sequence A was the first to be put forward (1).

(A) 

Experimental work (2) has established that IAN is indeed derived enzymatically from tryptophan in watermelon slices and in *Avena* coleoptiles. Incubation of the tissues with α-C^{14}-tryptophan, followed by paper chromatographic analysis of extracts, gave rise to a number of radioactive spots, one of which was assigned to IAN. Another highly active spot was tentatively ascribed to indolyl-3-pyruvic acid, whose occurrence in plant extracts (3) had been the subject of controversy (4, 5, 6). A modified sequence of steps (sequence B) for IAN biosynthesis was suggested as a result of this tracer work (2).

(B) 

Neither of the two hypotheses is entirely satisfactory. The first step of sequence A has many biochemical analogies, but amino acid oxidases, the type of enzyme required to catalyze such a reaction, are comparatively rare in plant tissues (7). The final step, dehydrogenation of an aldehyde imine to a nitrile, is without known chemical or biochemical precedent, and even the second step is unusual since in biochemical systems

α-imino acids undergo rapid spontaneous hydrolysis to α-keto acids (8) rather than decarboxylation. The latter reaction is feasible, however, since in vitro primary amines catalyze α-keto acid decarboxylation (e.g. ref. 9) with the intermediate formation of N-substituted α-imino acids (Schiff's bases), which themselves readily decarboxylate (e.g. ref. 9). Such a mechanism, however, is no longer accepted for the enzymatic decarboxylation of α-keto acids (10).

Indirect evidence supporting the first step of sequence B, conversion of tryptophan to indolyl-3-pyruvic acid by transamination, has been accumulating (e.g. ref. 11). The only intermediate in sequence B which has not yet been found to occur is indolyl-3-acetaldoxime. Other oximes, and particularly α-keto acid oximes, have, however, been isolated from natural sources (e.g. ref. 12) and the formation of indolyl-3-acetaldoxime from indolyl-3-acetaldehyde and hydroxylamine is a tenable supposition, since indirect evidence for the occurrence of both these substances in plants is available (6 and 13 respectively). The fact that IAN biosynthesis from tryptophan is inhibited by dimedone, which is regarded as a specific aldehyde trapping agent, has been adduced as an important argument in favor of the implication of indolyl-3-acetaldehyde in the biogenetic sequence (14). The final step of sequence B, although easily accomplished chemically under vigorous, usually anhydrous, reaction conditions, is again without known biochemical analogy.

Neither sequence, however, accounts for the detection by Housley and Bentley (4, 15) of an acidic precursor of IAN in the water-soluble, ether-insoluble fraction of an extract of cabbage leaves. This precursor gave IAN when heated in aqueous solution pH 5.6 at 98–100° for 25 minutes. The same chemical reaction took place to some extent even at room temperature under basic, but particularly under acidic, conditions. Other data (16) also point to the occurrence of a water-soluble, ether-insoluble acidic precursor of IAN.

It should be noted that Housley and Bentley (15) do not present direct evidence bearing on the conversion of their precursor to the nitrile in vivo, but infer biological conversion on the basis of the precursor's growth-promoting properties and by analogy with its chemical behavior. Accepting this inference as a working hypothesis, it follows that any substance postulated as direct biological precursor of the nitrile should also be convertible to nitrile under mild chemical conditions. The identity of the precursor with either indolyl-3-acetaldehyde imine (sequence A) or indolyl-3-acetaldoxime (sequence B) must therefore be ruled out.

We have examined the chemical and chromatographic properties of synthetic indolyl-3-pyruvic acid oxime and have found them to be very similar to those of the IAN precursor described by Housley and Bentley. We wish to advance a new hypothesis for the biosynthesis of IAN (sequence C) with indolyl-3-pyruvic acid oxime as the key intermediate:

The first step in our sequence is identical with that of sequence B. The second step, in vivo conversion of α-keto acid to the corresponding oxime, is not a novel idea (13). Although indolyl-3-pyruvic acid oxime has not been isolated from natural sources, other

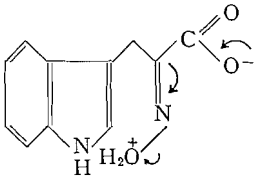
For personal use only.

α-oximino acids have been obtained from plants (17) and from micro-organisms (e.g. ref. 12) and it has been shown that compounds of this type may be utilized biologically (18, 19), whereas oximes of carbonyl compounds other than α-keto acids are relatively inactive (18, 20). A transoximase system, catalyzing the transfer of =N–OH between α-keto acids, has been detected in a variety of tissues (21). α-Keto acid oximes are thus known as biochemical intermediates.

The novel feature of our sequence lies in the postulated concerted conversion of indolyl-3-pyruvic acid oxime to IAN. We have found that this reaction takes place readily in aqueous solutions pH 1 to 7 at moderate temperatures, as required for an IAN precursor by the results of Housley and Bentley.

Not only indolyl-3-pyruvic acid oxime, but all other α-keto acid oximes we have tested, yield the lower nitrile and CO_2 under these reaction conditions. The generality of this phenomenon was first recorded by Bouveault and Locquin (22) but has since been almost entirely overlooked, except in isolated instances (23). Considering the ease with which the conversion takes place it is not surprising that reaction of α-keto acids with hydroxylamine under the usual conditions gives oxime in poor yield only and that occasionally (e.g., indolyl-3-glyoxylic acid (24)) no oxime, but only nitrile is obtained. It is probable that Bauguess and Berg (25) obtained a very impure sample of indolyl-3-pyruvic acid oxime (m.p. indefinite, >175°) by this method. The compound (m.p. 154° (decomp.)) was obtained in 59% yield (26) by nitrosation of ethyl α-acetyl-β-(3-indolyl)-propionate.

When heated in 0.05 *M* H_2SO_4 for 3 hours, indolyl-3-pyruvic acid oxime is converted to IAN in 95% yield. The same product (60% yield) is obtained directly when equimolar amounts of indolyl-3-pyruvic acid and hydroxylamine hydrochloride are refluxed in aqueous solution, pH 1.



In further confirmation of the ease with which IAN formation takes place, decomposition of oxime to nitrile was found to occur readily even at low temperature. Table I

TABLE I

Yield of IAN on incubation at 41.5° for 24 hours of 20 mg indolyl-3-pyruvic acid oxime in buffer solutions, pH 1–7

Buffer	Initial pH	Final pH	IAN obtained	
			mg	% yield
HCl/KCl	1.0	1.0	6.44	45.0
HCl/KCl	1.6	1.6	7.36	51.4
HCl/KCl	2.0	2.0	7.51	52.5
Phthalic acid/hydrogen phthalate	3.1	3.0	6.73	47.0
Hydrogen phthalate/phthalate	4.0	3.6	5.41	37.8
Hydrogen phthalate/phthalate	5.0	4.5	1.85	12.9
$H_2PO_4^-/HPO_4^=$	7.0	6.3	0.78	5.5

shows the yields of nitrile at various pH values, when a dilute solution of oxime was incubated at 41.5° for 24 hours. The yield of product was optimal at pH 2, decreased at lower pH values, and dropped with rise in pH, but even at pH 7 nitrile was obtained. Although the decreased yields at pH <2 may be due entirely to side reactions leading to destruction of the indole nucleus, this is not likely in view of the good yield of IAN at pH 1 at 100° but may be a consequence of the existence at pH 2 of maximal amounts of the zwitterionic species, which would be the most favorable for a concerted elimination

of carbonic anhydride and water from the oxime. At pH <2 the carboxylate group (pK_a 3.4) would be more than 96% protonated, whereas at pH >2 the oxime OH is unlikely to bear a proton.

A concerted elimination of this type requires an anti (HO– –COOH) stereochemistry of the oxime. Only in very few instances (phenylglyoxylic acid (27), oxaloacetic acid (28), and possibly phenylpyruvic acid (29), glyoxylic acid (30), and α-ketoglutaric acid (19)) have syn- and anti-isomers of α-keto acid oximes been described. The stereochemistry of these oximes has not been reinvestigated by modern methods, and therefore remains uncertain, but on the basis of their classical investigations both Hantzsch (27, 28) and Meisenheimer (31) concur that, where only one isomer is known, the favored stereochemical arrangement of α-keto acid oximes is anti (HO– –COOH), as now required to account for the facility of their conversion to nitriles in aqueous solution by a concerted acid catalyzed mechanism.

Having established that indolyl-3-pyruvic acid oxime yields IAN under mild chemical conditions, as demanded for a precursor according to Housley and Bentley, it remained to compare the behavior on extraction and chromatography of Housley and Bentley's precursor with that of the oxime. In Table II the chromatographic behavior of indolyl-3-

TABLE II

may be accounted for by concentration effects. At low concentrations the mauve color given by indolyl-3-pyruvic acid oxime with these two reagents was exceedingly transient.

Complete analogy was found in the behavior of synthetic oxime and IAN precursor on partition between solvents: using a solution of indolyl-3-pyruvic acid oxime (20 mg in 15 ml 95% ethanol, adjusted to pH 3.2 with dilute sulphuric acid) we duplicated the operations performed by Housley and Bentley in their treatment of those fractions of cabbage extract which contained IAN precursor. The details of this comparison are set out in the experimental section. Housley and Bentley fractionated cabbage extract into ether-soluble neutral, ether-soluble acidic, and water-soluble fractions by extraction with ether after pH adjustment. Their IAN precursor was found, by chromatography and bio-assay, mainly in the water-soluble, but also in the acidic ether-soluble, fraction. Elution of the IAN precursor from chromatograms and rechromatography led to a decrease in IAN precursor and an appearance of indolyl-3-acetonitrile. When we applied Housley and Bentley's procedures to indolyl-3-pyruvic acid oxime, results analogous in all particulars were obtained. In a number of their chromatograms Housley and Bentley detected two other growth active substances (R_f 0.10–0.20 and R_f 0.55–0.65, respectively, in 2-PrOH/NH_3). Chromatography of the ether extract of an acidified 5% $NaHCO_3$ solution of indolyl-3-pyruvic acid oxime gave, in addition to the expected spots of starting material and IAN, two weakly Ehrlich-positive spots of unknown nature with R_f ranges, 0.11–0.18 and 0.60–0.70, similar to those of Housley and Bentley. These growth active zones may thus have been due to artifacts derived from their acidic IAN precursor during extraction and chromatography.

The inhibition of IAN formation by dimedone, which has already been referred to, requires explanation. Since under mild conditions dimedone reacts specifically with aldehydes (e.g. ref. 32) it would appear that an aldehyde is implicated in IAN formation. This consideration led Gordon (14) to reject indolyl-3-pyruvic acid oxime as a possible intermediate in IAN biosynthesis in favor of indolyl-3-acetaldehyde. Preliminary experiments have now shown that Gordon's inference was based on insufficient evidence: whereas incubation of indolyl-3-pyruvic acid oxime at pH 2.0 and at pH 5.0, yielded IAN in 52.5% and 12.9% yield respectively (Table I), incubation of the oxime under similar conditions in the presence of dimedone did not yield detectable amounts of nitrile. Instead, the neutral ether-soluble fraction contained an oily yellow material of unknown structure which had no trace of –CN absorption at 2250 cm^{-1}, and showed, in addition to the indole bands at 280–288 mμ, an absorption band at 410 mμ, which disappeared in alkaline solution. Incubation of indolyl-3-pyruvic acid with dimedone, either in the presence or absence of hydroxylamine, gave rise to a similar yellow substance. When indolyl-3-acetonitrile was incubated with dimedone, starting material was recovered in 95% yield. Although the nature of the yellow dimedone adducts of indolyl-3-pyruvic acid and its oxime is as yet undetermined, it is clear that dimedone inhibits their conversion to indolyl-3-acetonitrile. This is consistent with Gordon's experimental results (14) on the inhibition of IAN formation from tryptophan in the presence of dimedone in *Avena* coleoptiles.

The auxin activity of indolyl-3-pyruvic acid oxime was compared with that of IAN and of indolyl-3-acetic acid in the *Avena* section (straight growth) test.[2] The oxime was found to have from 25% to 20% of the auxin activity of indolyl-3-acetic acid (compared

[2]*We are greatly indebted to Drs. J. Shen and S. A. Gordon, Argonne National Laboratory, Lemont, Illinois, for this study.*

on a molar basis) over a concentration range of 10^{-4} to 10^{-2} gram moles per liter (Fig. 1).

The chemical reactivity of indolyl-3-pyruvic acid oxime, the behavior of this substance on chromatography and solvent partition, and its biological activity thus correspond to the properties of the IAN precursor described by Housley and Bentley.

The evidence is compatible with the hypothesis that indolyl-3-pyruvic acid oxime is the biochemical precursor of indolyl-3-acetonitrile.

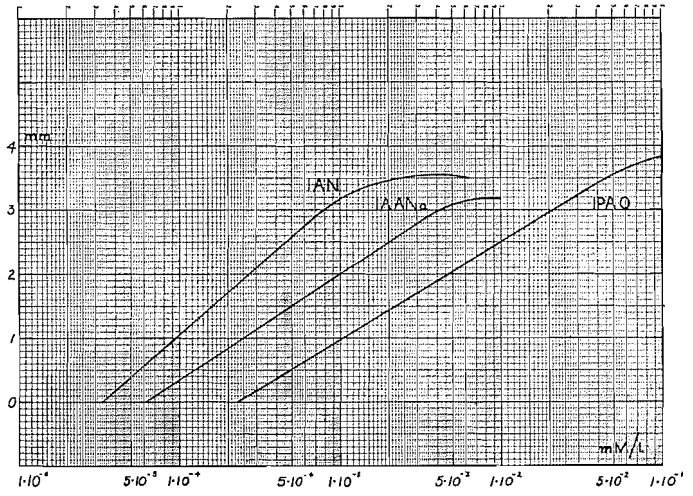

FIG. 1. Auxin activities of indolyl-3-acetonitrile (IAN), sodium indolyl-3-acetate (IAA.Na), and indolyl-3-pyruvic acid oxime (IPAO) in the *Avena* section (straight growth) test: 3-mm sections; medium: 0.01 *M* $NaHCO_3$, containing 2% w/v sucrose (2 ml); 20 hours.

Abscissa: concentration of auxin in millimoles per liter (log scale).

EXPERIMENTAL

Indolyl-3-pyruvic acid was prepared according to Bentley *et al.* (5). Indolyl-3-pyruvic acid oxime was obtained from indolyl-3-pyruvic acid (25) and also by nitrosation of ethyl α-acetyl-β-(3-indolyl)-propionate (26), melting at 157°, pK' 3.4 (i.e., pH at half equivalence in saturated aqueous solution), infrared absorption (Nujol) (cm^{-1}): 3360(s), 1690(s), 1620(m); ultraviolet absorption (λ_{max}, mμ (log ϵ)): 225(4.13), 274(3.83), 282(3.84), 290(3.77).

Indolyl-3-acetonitrile

(1) *From Indolyl-3-pyruvic Acid*

Indolyl-3-pyruvic acid (0.400 g, 0.00197 mole) and hydroxylamine hydrochloride (0.136 g, 0.00197 mole) in 30 ml water were refluxed 2.5 hours. The solution, which contained a small amount of dark brown precipitate, was filtered, allowed to cool, and extracted with ether (5 times 10 ml). The ether extract was washed with 5% sodium bicarbonate solution and with water, dried over Na_2SO_4, and concentrated, yielding indolyl-3-acetonitrile as an oily residue. The product was distilled at 100° and 10^{-3} mm and was obtained as a yellow oil (0.184 g, 60%), whose infrared (in $CHCl_3$ (cm^{-1}): 3450(s), 2250(s), 1615(m), 1455(s), 1350(s), 1330(s)) and ultraviolet (λ_{max}, mμ (log ϵ) in MeOH: 220(4.50), 273(3.78), 279(3.80), 288(3.68)) absorption was identical with that of an authentic specimen melting at 35–36°, prepared from gramine methiodide (33). The oil crystallized on seeding with a few crystals of the authentic sample.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A small portion of the oily product was converted to the picrate, melting at 127–128° (33).

(2) *From Indolyl-3-pyruvic Acid Oxime*

(i) At 100°.—The oxime (0.100 g, 0.00046 mole) was dissolved in 20 ml 0.05 *M* H_2SO_4 (0.001 mole) and the solution refluxed 3 hours in an atmosphere of nitrogen. On cooling, a small amount of dark sediment was filtered off, the solution was extracted with ether, the ether extract washed with 5% bicarbonate solution and with water, dried over Na_2SO_4 and concentrated, and the oily residue distilled at 100° and 10^{-3} mm to yield 0.068 g (95%) indolyl-3-acetonitrile as a light yellow oil, crystallizing on seeding with an authentic specimen.

(ii) At 40°.—A solution of oxime (0.020 g, 0.000092 mole) in 20 ml buffer solution was allowed to stand 12 hours at room temperature and then 24 hours at 41.5°. Buffers used were those of Clark and Lubs, HCl/KCl (pH 1, 1.6, and 2), phthalate (pH 3, 4, and 5), and $H_2PO_4^-/HPO_4^=$ (pH 7). Some discoloration was observed at pH 1–4. The solution was extracted with ether; the extract washed with 5% bicarbonate and water, dried over Na_2SO_4, and concentrated; the residue was dissolved in $CHCl_3$ and identified as indolyl-3-acetonitrile by its infrared absorption. The yield was determined by measuring the intensity of the ultraviolet absorption at 288 mμ of the product in methanol at suitable dilution. Results are summarized in Table I. Incubation of the oxime in the presence of dimedone (0.200 g) was carried out similarly and the reaction mixture was worked up for neutral products in the same way, except that dilute NaOH, instead of $NaHCO_3$ solution, was used for washing, to remove unreacted dimedone.

Solvent Fractionation and Chromatography of Indolyl-3-pyruvic Acid Oxime

Chromatography.—Solvents used in ascending paper chromatography on Whatman No. 1 paper were (*a*) 2-propanol/0.15 *M* ammonia (1:4), and (*b*) 1-butanol, saturated with 1.5 *M* ammonia. Chromogenic reagents applied were (i) Salkowski reagent: ferric chloride/perchloric acid (100 ml 5% aqueous $HClO_4$ and 2 ml 0.05 *M* $FeCl_3$); (ii) nitrous acid/nitric acid (1 g KNO_2 in 200 ml HNO_3, sp. gr. 1.42, diluted 10 times); (iii) Ehrlich's reagent (2 g *p*-dimethylaminobenzaldehyde in a mixture of 80 ml absolute ethanol and 20 ml HCl, sp. gr. 1.18) (15).

Solvent fractionation of the oxime according to the procedure used by Housley and Bentley (15) for the investigation of cabbage extract.—For purposes of comparison Housley and Bentley's operations and results at each stage are quoted in square brackets.

Preliminary Fractionation

(A) Indolyl-3-pyruvic acid oxime (20 mg) in 15 ml 95% ethanol adjusted to pH 3.2 with 0.05 *M* H_2SO_4, was stirred at −10° for 40 hours (fraction 1). Chromatography in 2-PrOH/NH_3, R_f 0.42, i.e., unchanged oxime. [Frozen ground cabbage was extracted for 40 hours at −10° with 95% ethanol acidified to pH 3.2 with H_2SO_4. Not chromatographed.]

(B) The pH of the solution was adjusted to pH 5 by addition of saturated aqueous $Ba(OH)_2$, $BaSO_4$ was filtered off and ethanol removed from the filtrate *in vacuo* at 30° (fraction 2). Chromatography in 2-PrOH/NH_3 gave a spot at R_f 0.42, i.e., unchanged oxime. The residual solution was mixed with 3 ml phthalate buffer, pH 3, and allowed to stand at room temperature 24 hours. [$Ba(OH)_2$ solution was added adjusting the pH to pH 5, the extract was filtered, ethanol removed at 35° *in vacuo* and the pH of the residual solution adjusted to pH 3 with dilute H_2SO_4. Not chromatographed.]

(C) The solution was exhaustively extracted with ether, yielding ether extract (fraction 3) and aqueous layer (fraction 4). Chromatography of the ether layer in 2-PrOH/NH_3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

gave spots R_f 0.42 (oxime) and R_f 0.90 (nitrile). The aqueous layer showed a spot at R_f 0.42 (oxime) only. [The solution was extracted with ether, yielding an ether-soluble fraction and a water-soluble fraction.]

The above experiments show that indolyl-3-pyruvic acid oxime is stable at pH 3.2–5 at $-10°$, but that it is partially converted to the nitrile at pH 3 and room temperature. They also show that the oxime is soluble both in ether and in water. Later steps were carried out with freshly prepared oxime in the requisite solvent.

Investigation of the "Ether-soluble" Fraction

(D) Indolyl-3-pyruvic acid oxime (10 mg) was dissolved in 5 ml ether giving a solution corresponding to fraction 3. This was extracted with 5% $NaHCO_3$ solution, yielding an ethereal and an aqueous layer. The ethereal layer was dried (fraction 6).

The aqueous bicarbonate layer was acidified to pH 3 with 0.05 *M* H_2SO_4. This solution was divided into two portions, one of which was extracted with ether immediately, and the ether layer washed and dried (fraction 5*a*), the other extracted with ether after 16 hours and the ether layer treated similarly (fraction 5*b*).

Chromatography of the "neutral" fraction 6 in 2-PrOH/NH_3 showed a single weak spot of R_f 0.90, i.e., indole-3-acetonitrile. The "acidic" fraction 5*b* showed an intense spot at R_f 0.90 (indole-3-acetonitrile), and a weak spot at R_f 0.41 (oxime). Fraction 5*a* showed a strong spot at R_f 0.90 (nitrile), a strong spot at R_f 0.42 (oxime), and in addition weakly Ehrlich-positive spots at R_f 0.60–0.70 (green, changing to yellow, changing to green), R_f 0.42–0.55 (purple, changing to green), and R_f 0.11–0.18 (blue green).

Evidently prolonged exposure to pH 3 had caused almost complete conversion of oxime to nitrile (fraction 5*b*), whereas during shorter contact with an acid medium (fraction 5*a*) conversion of oxime to nitrile was incomplete. The nature of the materials giving rise to the additional indolic spots in this fraction is obscure, but it is suggestive that Housley and Bentley report the occurrence, in a number of their chromatograms, of growth active materials of R_f 0.1–0.2 and 0.5–0.7 which could not be ascribed to recognized auxins. It is possible that these materials may have been breakdown products of their precursor, similar to the oxime breakdown products of fraction 5*a*. [The ether-soluble fraction from step C was washed, dried, concentrated, redissolved in ether, and extracted with bicarbonate solution. The ether layer gave a neutral fraction, containing growth active zones at R_f 0.46–0.90 (mainly IAN, but presumably some precursor, due to incomplete fractionation), whereas the bicarbonate layer, after acidification to pH 3, extraction into ether, and drying and evaporation of the ether layer, showed weak auxin activity at R_f 0.25–0.50 (precursor) and strong activity at R_f 0.54–0.89 (IAN).]

Investigation of the "Water-soluble" Fraction

(E) Indolyl-3-pyruvic acid oxime (10 mg) was dissolved in 5 ml water, giving a solution corresponding to fraction 4 (step C). Chromatography in 2-PrOH/NH_3 gave R_f 0.42 only. The area of the paper corresponding to the oxime was eluted with 4 ml water, and the eluate concentrated and rechromatographed with 2-PrOH/NH_3 and also with 1-BuOH/NH_3. The former chromatogram showed spots at R_f 0.42 (oxime) and R_f 0.90 (nitrile), the latter at R_f 0.16 (oxime) and R_f 0.90 (nitrile). During elution and rechromatography oxime had thus partially decomposed to nitrile. [The pH of the water-soluble fraction from step (C) was adjusted to pH 5.3 and the solution concentrated at 25°. Chromatography in 2-PrOH/NH_3 of the concentrate gave a precursor spot at R_f 0.4–0.5 and an IAN spot at R_f 0.8–0.9, the latter presumably due to previous acid treatment. The area on the chromatogram corresponding to precursor was eluted with 4 ml water at 5° and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the eluate rechromatographed with 2-PrOH/NH_3, where it showed R_f 0.4–0.5, and with *n*-BuOH/NH_3, where it gave R_f 0–0.15. In both the latter chromatograms an IAN spot at R_f 0.8–0.9 also appeared. Thus during elution and rechromatography precursor had partially decomposed to IAN.]

(F) Indolyl-3-pyruvic acid oxime (10 mg) was dissolved in 3 ml water and heated under reflux 25 minutes. On cooling, the solution was extracted with ether. Chromatography of the ether extract in 2-PrOH/NH_3 gave spots at R_f 0.42 (oxime) and R_f 0.90 (nitrile). Chromatography of the aqueous layer gave a weak spot, R_f 0.42 (oxime). [The pH of the water-soluble fraction from step C was adjusted to pH 5.3, the solution was concentrated at 25° and heated at 98–100° for 25 minutes, cooled, dissolved in 20 ml aqueous $NaHCO_3$, and the solution extracted with ether. Chromatography of the ethereal "neutral" fraction showed a weak auxin zone at R_f 0.29–0.44 (precursor which according to Housley and Bentley had entered this fraction due to incomplete separation) and a strong zone at R_f 0.7–0.95 (nitrile). Elution and rechromatography in 2-PrOH/NH_3 of the zone R_f 0.29–0.44 gave rise to more IAN. The aqueous phase was acidified to pH 3 and extracted with ether, yielding an "acidic" fraction, which on chromatography showed auxin activity at R_f 0.25–1.00 with activity peaks at R_f 0.85–0.92 (IAN, presumably derived from precursor due to acidification during fractionation) and at R_f 0.35–0.48 (presumably precursor, but ascribed by Housley and Bentley to indolyl-3-acetic acid, since this region gave a pink color with Salkowski's reagent).]

ACKNOWLEDGMENTS

We are greatly indebted to Dr. S. A. Gordon, Argonne National Laboratories, Lemont, Illinois, for placing at our disposal the manuscript, as yet unpublished, of a review on the biogenesis of auxin (14), and for testing the auxin activity of indolyl-3-pyruvic acid oxime.

Financial assistance by the National Research Council of Canada and by the Ontario Research Foundation is gratefully acknowledged. One of us (A. A.) wishes to thank the Colombo Plan authorities for financial support and the Pakistan Council of Scientific and Industrial Research for the award of a scholarship.

NOTES

A PROPOSED CRYOSCOPIC METHOD FOR DETERMINING THE HEAT OF COMPLEX FORMATION FOR A REACTION, $X + Y \rightleftharpoons Z$

P. A. D. DE MAINE*

Spectrophotometric methods (1, 2, 3) have been used frequently to determine equilibrium constant (K) and heat of formation (ΔH) values for complexes between dissimilar molecules in inert solvents. Scott (4) has reported that such values for K are not reliable; but he (4) and others (5, 6, 7) have noted that ΔH can be determined accurately with spectrophotometric data. Some workers (8, 9, 10) have suggested that the changes in absorption spectra used to determine ΔH (5, 6, 7, 4) arise from changes in the electrical properties of the solution and/or non-specific interactions between the unlike molecules. However, evidence that the changes in spectra are due to specific interactions between the molecules has been reported (11, 12, 13). Thus a non-spectrophotometric method for the determination of ΔH should prove helpful in elucidating the actual nature of the interactions.

If two unlike molecules, X and Y, interact thus,

$$X + Y \overset{K}{\rightleftharpoons} Z,$$

then

$$[1] \qquad K = N_Z/(N_X - N_Z)\,(N_Y - N_Z)$$

where N_Z, $(N_X - N_Z)$, and $(N_Y - N_Z)$ are the equilibrium concentrations in mole fraction units of Z, X, and Y respectively.

If K_f is the cryoscopic constant (degrees C/mole 100 grams of solvent) of the solvent, then for dilute solutions

$$[2] \qquad C_X + C_Y - C_Z = K_a(C_X + C_Y)/K_f,$$

where K_a is the apparent constant calculated for the mixed solute solution with the assumption that $C_Z = 0$.

$$[3] \qquad C_X = N_X\,100/M, \qquad C_Y = N_Y\,100/M, \qquad C_Z = N_Z\,100/M,$$

where M is the molecular weight of the pure solvent.

As N_X and N_Y are known, K and N_Z can be calculated for each mixed solute solution at its freezing point. With the van't Hoff equation (ΔH assumed to be independent of temperature) it can be shown that

$$[4] \qquad \Delta T_2 = \frac{\Delta H(\Delta T_1 - \Delta T_2)}{R(T_f - \Delta T_1)\ln\,(K_1/K_2)} + T_f.$$

K_1 and K_2 are values for the equilibrium constant, in mole fraction units, calculated for mixed solute solutions with freezing points of ΔT_1 and ΔT_2 °C, respectively, below the absolute freezing point (T_f °K) of the pure solvent.

*Present address: Chemistry Department, University of Mississippi, Oxford, Mississippi.

Plots of ΔT_2 versus $(\Delta T_1 - \Delta T_2)/\ln(K_1/K_2)$ for data with ΔT_1 constant should be linear with

$$\text{slope} = \Delta H/R\,(T_f - \Delta T_1), \quad [5]$$

$$T_f = \Delta T_2 \text{ intercept}. \quad [6]$$

Thus the absolute freezing point of the pure solvent (T_f °K) and ΔH can be determined with data obtained from measurements with a differential thermometer.

In deriving equations [4], [5], and [6] it has been assumed that (*a*) activities equal concentration; (*b*) ΔH is independent of temperature; and (*c*) both solutes have the same cryoscopic constant.

CRYSTALLINE *O*-METHYL ETHERS OF D-GALACTITOL*

C. T. BISHOP

During the course of some work on the separation of carbohydrate derivatives by gas–liquid partition chromatography it was found that anomeric methyl glycosides of methylated monosaccharides were separable (1). The ultimate objective of this work was application of gas–liquid partition chromatography to the structural investigation of polysaccharides; it appeared that the complex mixture of anomers that might be expected from methanolysis of a methylated polysaccharide could be avoided by reduction of the *O*-methyl monosaccharides to the sugar alcohols, which could then be separated as their acetates. It was later found that methanolysis of methylated polysaccharides did not yield as complex mixtures as had been anticipated so this approach was dropped. However, a number of partially methylated sugar alcohols were prepared for use as standard compounds; some of these are readily crystallized, sharp melting, and eminently suitable as characteristic derivatives of the parent monosaccharide. The opportunity is therefore taken to record the preparation and physical properties of 2,4-di-*O*-methyl-; 2,3,4-tri-*O*-methyl-; and 2,3,4,6-tetra-*O*-methyl-D-galactitol; these are derived from

*Issued as N.R.C. No. 5754.

CRYSTALLINE *O*-METHYL ETHERS OF D-GALACTITOL*

C. T. BISHOP

During the course of some work on the separation of carbohydrate derivatives by gas–liquid partition chromatography it was found that anomeric methyl glycosides of methylated monosaccharides were separable (1). The ultimate objective of this work was application of gas–liquid partition chromatography to the structural investigation of polysaccharides; it appeared that the complex mixture of anomers that might be expected from methanolysis of a methylated polysaccharide could be avoided by reduction of the *O*-methyl monosaccharides to the sugar alcohols, which could then be separated as their acetates. It was later found that methanolysis of methylated polysaccharides did not yield as complex mixtures as had been anticipated so this approach was dropped. However, a number of partially methylated sugar alcohols were prepared for use as standard compounds; some of these are readily crystallized, sharp melting, and eminently suitable as characteristic derivatives of the parent monosaccharide. The opportunity is therefore taken to record the preparation and physical properties of 2,4-di-*O*-methyl-; 2,3,4-tri-*O*-methyl-; and 2,3,4,6-tetra-*O*-methyl-D-galactitol; these are derived from

*Issued as N.R.C. No. 5754.

three *O*-methyl ethers of D-galactose which are found frequently as hydrolysis products of methylated polysaccharides (2).

EXPERIMENTAL

Reductions

The *O*-methyl-D-galactose (100 mg) was dissolved in methanol (3 ml) and potassium borohydride (15–16 mg) was added. The solution was kept at room temperature for 24 hours and then Amberlite IR-120 ion exchange resin was added with shaking until gas evolution ceased. The resin was filtered, washed with methanol, and filtrate plus washings were evaporated to dryness. Addition and evaporation of methanol were repeated six times to remove boric acid. The residues crystallized spontaneously when dried *in vacuo* over anhydrous calcium chloride. Yields were quantitative throughout.

2,4-Di-O-methyl-D-galactitol

This compound was prepared by reduction of 2,4-di-*O*-methyl-D-galactose, m.p. 103–104° C, $[\alpha]_D^{26} = +88° \pm 1°$ equilibrium value (*c*, 1.1% in water) (3). The crystalline reduction product was recrystallized from ethyl acetate to a constant melting point of 134–135° C (corr.), $[\alpha]_D^{28} = +23.5° \pm 0.5°$ (*c*, 2.04% in methanol). Anal. Calc. for $C_8H_{18}O_6$: C, 45.70%; H, 8.63%; OCH_3, 29.64%. Found: C, 45.59%; H, 8.31%; OCH_3, 29.80%.

2,3,4-Tri-O-methyl-D-galactitol

This compound was prepared by reduction of sirupy 2,3,4-tri-*O*-methyl-D-galactose, $[\alpha]_D^{25} = +110° \pm 2°$ (*c*, 1% in water), which had been characterized as its anilide (4, 5), m.p. 166–168° C, $[\alpha]_D^{26} = +42° \pm 3°$, equilibrium (*c*, 1% in methanol) and by conversion to 2,3,4-tri-*O*-methyl-D-galactonamide (5), m.p. 166–167° C, $[\alpha]_D^{26} = +35° \pm 3°$ (*c*, 0.8% in water). The crystalline reduction product was recrystallized from ethyl acetate to a constant melting point of 121–122° C, $[\alpha]_D^{26} = \pm 0°$ (*c*, 1.56% in methanol). Anal. Calc. for $C_9H_{20}O_6$: C, 48.20%; H, 8.93%; OCH_3, 41.50%. Found: C, 48.07%; H, 8.85%; OCH_3, 41.85%.

2,3,4,6-Tetra-O-methyl-D-galactitol

This compound was prepared by reduction of sirupy 2,3,4,6-tetra-*O*-methyl-D-galactose, $[\alpha]_D^{25} = +109° \pm 2°$ (*c*, 1% in water), which had been characterized as its anilide (6), m.p. 196.5–198° C, $[\alpha]_D^{25} = -137° \pm 1°$ (*c*, 2% in pyridine). The crystalline reduction product was recrystallized from cyclopentane to a constant melting point of 68–70° C, $[\alpha]_D^{27} = +12.5° \pm 0.5°$ (*c*, 2.25% in ethanol). Anal. Calc. for $C_{10}H_{22}O_6$: C, 50.40%; H, 9.31%; OCH_3, 52.32%. Found: C, 50.64%; H, 9.34%; OCH_3, 52.61%.

SPIROHEXANE

DONALD E. MCGREER

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.191.171.90 on 09/05/12
For personal use only.

In 1953 Slobodin and Blinova (1) reported an attempt to synthesize spirohexane by the treatment with zinc dust of 1,1-bis-(bromomethyl)-cyclobutane prepared from the corresponding diol and phosphorus tribromide. The only product isolated in the dehalogenation reaction was methylenecyclopentane. Rearrangement may have occurred in the dehalogenation step since similar rearrangements have been observed to occur as in the preparation of spiropentane (2). It is also possible that treatment of the diol leads to a rearranged dibromide since rearrangement has been noted in the treatment of cyclobutyl carbinol with phosphorus tribromide (3).

Spirohexane has now been prepared in good yield from 1,1-bis-(iodomethyl)-cyclobutane (I) and zinc in the presence of tetrasodium ethylenediaminetetraacetate to remove the zinc ions as formed in the reaction. This method was recently developed by Applequist *et al.* for the synthesis of spiropentane from pentaerythrityl tetrabromide (2). The 1,1-bis-(iodomethyl)-cyclobutane was prepared by the method of Schubert and Leahy (4) and its structure was checked by N.M.R., which showed two unresolved peaks with an area ratio of 2:3 at 104 and 260 p.p.10^8 from water due to the $—CH_2I$ and cyclobutyl hydrogens, respectively. The spirohexane obtained by treatment of I with zinc dust showed no absorption in the infrared spectrum in the region for multiple bonds and had a N.M.R. spectrum which showed two peaks in an area ratio of 3:2 at 289 and 459 p.p.10^8 from water due to the cyclobutyl and cyclopropyl hydrogens, respectively (5).

Spirohexane has also recently been prepared by the reaction of methylenecyclobutane and methylene iodide in the presence of a zinc–copper couple (6).

EXPERIMENTAL

An "Aerograph" vapor chromatography unit fitted with a 10-ft Ucon Polar column was used with helium as the carrier gas. The N.M.R. spectra were determined on a 40-Mc/s Varian spectrophotometer with field stabilizer VK 3506, and methylene chloride was used as an external standard.

1,1-Bis-(iodomethyl)-cyclobutane (I)

1,1-Bis-(iodomethyl)-cyclobutane, b.p. 76–78° at 0.3 mm, was prepared in 50% yield by the method of Schubert and Leahy (4). A N.M.R. spectrum (0.5 ml/ml of carbon tetrachloride) showed two peaks at 104 and 260 p.p.10^8 from water with peak areas in the ratio of 2:3, respectively.

Spirohexane

In a 250-ml three-necked flask fitted with a reflux condenser, stirrer, and dropping funnel was placed 21 g of disodium dihydrogen ethylenediaminetetraacetate, a solution of 7.4 g of sodium hydroxide in 13 ml of water, 40 ml of 95% ethanol, and 0.6 g of sodium iodide. The mixture was heated to reflux and 5.5 g of zinc dust was added followed by 6.3 g of 1,1-bis-(iodomethyl)-cyclobutane which was added dropwise over a half-hour period. The mixture was refluxed an additional hour and distilled through a wire gauze column to give 2.8 g, b.p. 56–79°. Separation of the distillate by vapor chromatography gave 0.94 g (60%) of spirohexane, b.p. 70°, n_D^{22} 1.4245, D_4^{24} 0.855. Found: C, 87.65; H, 12.00%. Calc. for C_6H_{10}: C, 87.73, H, 12.27%.

The infrared spectrum (liquid film) showed no bands in the region from 1500 to 2800 cm^{-1}. The N.M.R. spectrum (neat) showed two peaks at 289 and 459 p.p.10^8 from water with peak areas in the ratio of 3:2 respectively.

In addition to spirohexane the chromatogram of the crude product showed ethanol and an unidentified component for which the peak area was less than 3% of that for spirohexane.

Support for this research was received from the National Research Council of Canada and is gratefully acknowledged.

AMINONITRILES. II. SOME DERIVATIVES OF 2-AMINO-3-CYANOINDENE*

D. L. Garmaise and S. Gelblum

As part of a study on the relation between chemical structure and bacteriostatic activity, a series of 2-arylamino- (and aralkylamino)-3-cyanoindenes was prepared from the readily accessible 2-amino-3-cyanoindene.

The replacement of the unsubstituted amino group in β-iminonitriles (α-amino-β-cyanoethylenes) by anilino groups is normally accomplished (1, 2) by reacting the iminonitrile with the substituted aniline in acetic acid solution. This procedure was found to give variable results when applied to 2-amino-3-cyanoindene, and, in the case of 3-nitroaniline, 3-nitroacetanilide was isolated as the major product. Better results were obtained by heating the iminonitrile and the amine without solvent in the presence of the amine hydrochloride. The superiority of strong acid catalysis is to be expected in this type of nucleophilic addition to α,β-unsaturated systems (3). 2-(3,4-Dichlorobenzylamino)-3-cyanoindene was obtained in 95% yield by heating the iminonitrile and 3,4-dichlorobenzylamine with 5 mole% 3,4-dichlorobenzylamine hydrochloride. The 3,4-dichloroanilino derivative was prepared by simply fusing the iminonitrile with 3,4-dichloroaniline hydrochloride.

Although the action of concentrated sulphuric acid on 2-amino-3-cyanoindene gives 2-amino-3-carboxyindene in good yield (4), similar treatment of 2-(3,4-dichlorobenzylamino)-3-cyanoindene yielded the corresponding amide, 2-(3,4-dichlorobenzylamino)-indene-3-carboxamide, as the only identifiable product. The same amide was unexpectedly obtained when 2-amino-3-carboxyindene was heated with a mixture of 3,4-dichlorobenzylamine and its hydrochloride.

**Report No. 26.*

The infrared spectrum (liquid film) showed no bands in the region from 1500 to 2800 cm^{-1}. The N.M.R. spectrum (neat) showed two peaks at 289 and 459 p.p.10^8 from water with peak areas in the ratio of 3:2 respectively.

In addition to spirohexane the chromatogram of the crude product showed ethanol and an unidentified component for which the peak area was less than 3% of that for spirohexane.

Support for this research was received from the National Research Council of Canada and is gratefully acknowledged.

For personal use only.

Hydrogenation of 2-amino-3-carboxyindene with platinum oxide in ethanol at atmospheric pressure proceeded until 4 moles of hydrogen were absorbed. A single isomer of 1-carboxy-2-aminohydrindane, m.p. 171–172° C, was isolated.

2-(3,4-Dichlorobenzylamino)-3-cyanoindene was the only member of the series which showed appreciable bacteriostatic activity. It inhibited the growth of *M. pyogenes* var. *aureus*, *Sarcina lutea*, and *Streptococcus faecalis* at dilutions of 1:320,000, 1:160,000, and 1:40,000, respectively, as determined by the serial dilution tube technique. It was ineffective against Gram-negative organisms.

EXPERIMENTAL*

2-Amino-3-cyanoindene

o-Phenylenediacetonitrile (5) (31.1 g, 0.2 mole) was refluxed with sodium ethoxide (1.0 g, 0.015 mole) in ethanol (130 ml) for 1 hour. The product crystallized on cooling, yield 28.4 g (91%), m.p. 193–194° C (lit. reported m.p. 193° C (4)).

2-(3-Nitroanilino)-3-cyanoindene

A solution of 2-amino-3-cyanoindene (1.56 g, 0.01 mole) and 3-nitroaniline (1.38 g, 0.01 mole) in glacial acetic acid (30 ml) was refluxed for 2 hours. The solution was evaporated to dryness, and the residue was crystallized from dilute acetone to give 3-nitroacetanilide (1.32 g), m.p. 150–151° C, and the product (0.12 g, 4.4%), which melted at 225–226° C, after recrystallization from methanol. Anal. Calc. for $C_{16}H_{10}Cl_2N_2$: C, 63.80; H, 3.35; Cl, 23.54; N, 9.31. Found: C, 63.55; H, 3.35; Cl, 23.52; N, 9.54.

2-(3,4-Dichloroanilino)-3-cyanoindene

2-Amino-3-cyanoindene (1.56 g, 0.01 mole) and 3,4-dichloroaniline hydrochloride (1.98 g, 0.01 mole) were heated at 170–230° C for 25 minutes. Crystallization from ethanol gave the product melting at 200–203° C. Yield 2.27 g (75.5%). The analytical sample, m.p. 203–204° C, was prepared by recrystallization from methanol. Anal. Calc. for $C_{16}H_{10}Cl_2N_2$: C, 63.80; H, 3.35; Cl, 23.54; N, 9.31. Found: C, 63.55; H, 3.35; Cl, 23.52; N, 9.54.

2-(4-Chlorobenzylamino)-3-cyanoindene

A solution of 2-amino-3-cyanoindene (1.56 g, 0.01 mole) and 4-chlorobenzylamine (1.41 g, 0.01 mole) in glacial acetic acid (30 ml) was refluxed for 2 hours. The solution was evaporated to dryness and the residue was crystallized from dilute acetone to give the crude product, m.p. 164–167° C. Yield 1.51 g (54%). Crystallization from methanol raised the melting point to 173–174° C. Anal. Calc. for $C_{17}H_{13}ClN_2$: C, 72.73; H, 4.67; Cl, 12.63; N, 9.98. Found: C, 72.74; H, 5.02; Cl, 12.71; N, 10.15.

2-(3,4-Dichlorobenzylamino)-3-cyanoindene

A mixture of 2-amino-3-cyanoindene (15.6 g, 0.1 mole), 3,4-dichlorobenzylamine (17.4 g, 0.1 mole), and 3,4-dichlorobenzylamine hydrochloride (0.08 g, 0.005 mole) was stirred at 170–200° C for 1 hour. The mixture was cooled and triturated in ethanol (300 ml), giving the product melting at 178–179° C. Yield 30.0 g (95%). The analytical sample melted at 180–181° C after crystallization from dilute acetone. Anal. Calc. for $C_{17}H_{12}Cl_2N_2$: C, 64.77; H, 3.84; Cl, 22.50; N, 8.89. Found: C, 64.86; H, 4.08; Cl, 22.53; N, 8.92.

**All melting points are uncorrected. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois.*

2-Amino-3-carboxyindene

2-Amino-3-cyanoindene (2.0 g, 0.013 mole) was stirred in concentrated sulphuric acid (20 ml) for 1 hour, during which the temperature rose from 26° C to 35° C. The solution was poured onto crushed ice, and the resulting suspension was allowed to stand for 2 hours. The precipitate was filtered and extracted with 1 *N* sodium hydroxide solution (50 ml). Acidification of the alkaline extract gave the product melting at 186° C (decomp.). Moore and Thorpe (4) reported a melting point of 171° C. Anal. Calc. for $C_{10}H_9NO_2$: C, 68.55; H, 5.18; N, 8.00. Found: C, 68.38; H, 5.37; N, 8.17.

1-Carboxy-2-aminohydrindane

2-Amino-3-carboxyindene (0.485 g, 0.0028 mole) was hydrogenated at atmospheric pressure in ethanol (50 ml) in the presence of platinum oxide (5 mg). A total of 285 ml hydrogen (0.012 mole) was absorbed in 10 hours. The suspension was filtered and evaporated and the residue was crystallized from ethyl acetate (35 ml), giving the completely saturated product, m.p. 171–172° C. Yield 0.12 g (23.4%). Anal. Calc. for $C_{10}H_{17}NO_2$: C, 65.54; H, 9.35; N, 7.64. Found: C, 65.67; H, 9.51; N, 7.73.

A mixture of incompletely hydrogenated products, m.p. 121–123° C, was isolated from the mother liquors.

2-(3,4-Dichlorobenzylamino)-indene-3-carboxamide

I. 2-(3,4-Dichlorobenzylamino)-3-cyanoindene (4.0 g, 0.013 mole) was stirred in concentrated sulphuric acid (50 ml) for 2 hours. The solution was poured onto crushed ice, and the aqueous suspension was allowed to stand for 2 hours. The crude product was filtered and extracted with 1 *N* sodium hydroxide solution (50 ml). Crystallization of the insoluble fraction from methanol gave the pure amide, m.p. 164–165° C. Yield 0.84 g (20%). Anal. Calc. for $C_{17}H_{13}Cl_2NO_2$: C, 61.30; H, 4.24; Cl, 21.20; N, 8.41. Found: C, 61.20; H, 4.36; Cl, 21.04; N, 8.30.

Acidification of the alkaline extract did not yield any identifiable products.

II. 2-Amino-3-carboxyindene (1.0 g, 0.0057 mole), 3,4-dichlorobenzylamine (1.0 g, 0.0057 mole), and 3,4-dichlorobenzylamine hydrochloride (0.02 g, 0.0001 mole) were heated at 175° C for 20 minutes. The mixture was crystallized from ethanol (10 ml), giving the product melting at 164–165° C. Yield 0.90 g (47%). There was no depression on admixture with the product prepared as in I.

ACKNOWLEDGMENT

The authors wish to thank Dr. H. A. Baker, of Ayerst, McKenna and Harrison Limited, for determination of the bacteriostatic activities of these compounds.

Issued by THE NATIONAL RESEARCH COUNCIL OF CANADA

VOLUME 38 OCTOBER 1960 NUMBER 10

Symposium on Some Fundamental Aspects of Atomic Reactions

The papers that follow were presented at a symposium held at McGill University, Montreal, on September 6 and 7, 1960, under the auspices of the Physical Chemistry Subject Division of the Chemical Institute of Canada and organized by the chairman of the symposium, Dr. J. C. Polanyi of the University of Toronto. A few of the papers presented are not published here because of prior commitments.

The executive committee of the subject division wishes to express its gratitude to the symposium chairman, to McGill University for its generous co-operation in the use of its facilities, and to the Editor-in-Chief and staff of the Canadian Journal of Chemistry for their valuable assistance.

THE TRANSFER REACTIONS OF HALOGEN ATOMS[1]

G. C. FETTIS, J. H. KNOX, AND A. F. TROTMAN-DICKENSON

ABSTRACT

Extensive results on the reactions of fluorine, chlorine, and bromine atoms with alkanes and with some other molecules have been obtained from the study of competitive halogenations. The comparison of the A factors of the reactions provides an excellent test of the transition state theory. The activation energies of the bromine atom reactions can be combined with measurements of the activation energies for the reactions of alkyl radicals with hydrogen bromide to yield unusually reliable values of bond strengths. Information on the influence of polar effects on the activation energies of atomic reactions can be obtained from results on the reactions of fluorine and chlorine atoms with methyl halides.

The reaction of a halogen with a pair of hydrocarbons can be represented by the following steps:

$$\begin{aligned} X + R^1H &= XH + R^1 \\ R^1 + X_2 &= R^1X + X \end{aligned} \qquad [1]$$

$$\begin{aligned} X + R^2H &= XH + R^2 \\ R^2 + X_2 &= R^2X + X \end{aligned} \qquad [2]$$

In this paper we shall be concerned with the rate constants and Arrhenius factors for reactions [1] and [2] and for those of the reverse processes [−1] and [−2]. The relative values of k_1 and k_2 can be found by competitive methods in two ways. The first is the consumption method in which the amounts of R^1H and R^2H removed from a mixture during reaction with a halogen are determined. Then

$$\frac{k_1}{k_2} = \frac{-d[R^1H]/dt.\ [R^2H]}{-d[R^2H]/dt.\ [R^1H]}.$$

In practice this relation is used in its integrated form and the conversions are kept below about 20–30%. This method was particularly attractive before the development of gas chromatography for it was much simpler to analyze for small quantities of R^1H and R^2H than of the corresponding halides. It was employed by Pritchard, Pyke, and Trotman-Dickenson (1) to study chlorine atom reactions and later by Mercer and Pritchard (2) to study fluorine atoms.

[1]*Contribution from the Chemistry Department, Edinburgh University, Edinburgh 9, Scotland; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

The second method depends upon the measurement of the rate of formation of the halides formed. The rate constants are then obtained from

$$\frac{k_1}{k_2} = \frac{d[R^1X]/dt.\ [R^2H]}{d[R^2X]/dt.\ [R^1H]}.$$

The integrated form of the equation need not be used as the percentage conversions should be kept very low to avoid secondary reactions of the halides. Fortunately halides are not more than 10 times as reactive as their parent alkanes. This approach was first used by Hass, McBee, and Weber (3) in their studies of chlorinations. Their work was done on a large scale in flow systems, so that sufficient chlorides were formed for analysis by distillation. They worked at high temperatures. Some isomerization of the chlorides probably occurred so that the results do not agree well with those of later workers. Knox (4) applied gas chromatography to the problem and was able to reduce the scale of reaction by about 10^4 and at the same time improve the accuracy. The method has the great advantage that isomeric products can be distinguished and reactivities directly assigned to specific types of hydrogen atom. The attack on hydrogen is not simply followed because hydrogen halides are not easily determined by gas chromatography and are produced in reactions of all hydrogen-containing compounds.

Relative rate constants obtained by competitive methods can be placed on an absolute scale if the constant for one member of the series can be absolutely determined. Fortunately the rate constant for the attack of a chlorine atom on molecular hydrogen has been determined by three groups of workers whose results are in good agreement. Kistiakowsky and Van Artsdalen have carefully measured the rate of reaction of bromine atoms with methyl bromide and methane (5). No rate constant for a fluorine atom reaction has been measured. In this work it has been assumed that the value of the A factor calculated for the reaction of fluorine atoms with ethane is correct and that the activation energies for attack on hydrocarbons heavier than ethane are zero. The justification for these assumptions will be apparent in what follows.

Table I summarizes the results that have been obtained at Edinburgh, together with

TABLE I

a few other results of our own and of other workers. The experimental details and a full comparison of the results with the rather small number available from other sources are fully discussed in the original papers to which reference is made. With the notable exception of the bromination results of Van Artsdalen's group the present work is in excellent agreement with the small amount of recent work by other authors. Benson and Buss (6) have discussed at length the probable reasons for the unreliability of the results of Van Artsdalen's very careful work. These results were always suspect because they appeared to be out of line with those for all other atomic reactions.

The A Factors

According to transition state theory the A factor for a bimolecular reaction is given by

$$A = e^2.(kT/h) \exp [(\Delta S^{\ddagger}_{tr} + \Delta S^{\ddagger}_{rot} + \Delta S^{\ddagger}_{vib})/R].$$

The translational entropies of activation can be calculated exactly from the molecular weights of the reactants and complexes. The accuracy of the calculated value of the rotational entropy of activation is limited by the uncertainty of the exact configuration of the complex and, to a lesser degree, of the reactant. The C—H and C—C bond lengths have throughout been assumed to be 1.10 and 1.54 Å except that the half-order bonds $\diagdown$C—H—X$\diagup$ have been taken as 0.18 Å longer than the corresponding single bonds. The two extreme forms of the *n*-butane – halogen complexes in which the molecule is fully extended or completely curled up yield rotational entropies of activation that differ by less than 10%. Since intermediate configurations are much more profitable, it is unlikely that the error arising from assumptions about the configurations are as large as this.

The calculation of the vibrational entropies of activation is less certain and has a greater effect upon the result obtained. It has been assumed that many of the vibrations in RH will be little changed by the addition of the halogen atom and that their contributions to $\Delta S^{\ddagger}_{vib}$ will largely cancel. Only a few vibrations intimately connected with the part of the molecule to which the halogen atom is attached will give rise to important contributions. These vibrations are the C—H stretching and C—H wagging in the hydrocarbon which are replaced by five new vibrations in the activated complex. The C—H stretching becomes the reaction co-ordinate and the C—H wagging becomes the wagging of H—X against the rest of the hydrocarbon. The three additional vibrations are the symmetrical stretching of the C—H—X bonds and the doubly degenerate bending of the C—H—X bonds. Pitzer (11) deduced $\Delta S^{\ddagger}_{vib}$ for the reaction

$$Cl + H_2 = HCl + H$$

from the observed A factor and found that the bending and stretching frequencies were 560 cm^{-1} and 1460 cm^{-1} respectively. It has here been assumed that the force constants for these modes of vibration are the same for all the complexes and that the corresponding frequencies can therefore be calculated by classical mechanics for the different groups, R, and atoms, X.

The calculated and experimental A factors are compared for each type of halogen in Table II. In only one instance does A_{exp} differ from A_{calc} by more than a factor of 4. The transition state theory, therefore, accounts very well for the magnitude of the A factors. Even the deviations from the calculated values show a fairly regular pattern as can be seen by comparing the columns of ratios. This encourages us to think that the experimental results are adequate to sustain the test of a more precise theory if

*This value is assumed and the others for fluorine based on it.

one could be found. Since the deviations are more extreme for the heavier halogens, it is likely that the wagging of the H—X bond or the bending of the C—H—X bonds have not been correctly accounted for.

The Activation Energies

The activation energies of the reactions of the higher hydrocarbons with chlorine closely approach zero. It is not surprising that no differences between the activation energies for attack on the higher hydrocarbons by fluorine could be detected. There is probably no energy barrier to attack on these compounds.

The activation energies of the bromine atom reactions vary widely and are of greater interest because of the relation that they bear to the strengths of the bonds broken. The heat of reaction is related to the activation energies for the forward and reverse reactions by the equation

$$\Delta H_1 = E_1 - E_{-1}.$$

Since D(H—Br) is known, D(R^1—H) can be found if E_1 and E_{-1} are measured. At the moment, the values of E_{-1} are not accurately known and consequently the measurements do not yield the bond strengths directly. Until the E_{-1}'s have been determined it is convenient to use the Polanyi relation as a method of interpolation. This leads to the results shown below, which is based on the currently accepted values of D(Me—H) and D(Bu^t—H).

R	E_1	E_{-1}	D(R—H)
Me	18.3	1.8	102.5
Et	13.4	(2.5)	96.9
Pr^i	10.2	(3.1)	93.1
Bu^t	7.5	(3.6)	90.0

Information about E_{-1} can be obtained by photolysing a source of R^1 in a mixture of hydrogen bromide and iodine. The products are then analyzed for RH and RI. Hence

$$\frac{k_{-1}}{k_2} = \frac{R_{R^1H}}{R_{R^1I}} \frac{[I_2]}{[HBr]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

where k_3 refers to

$$R^1 + I_2 = R^1I + I. \quad [3]$$

So far preliminary experiments have been carried out with methyl ethyl ketone as the source of ethyl radicals. Hence we find that

$$E_{-1} - E_3 = 2.3 \text{ kcal mole}^{-1}.$$

It seems likely that the activation energies for the attack of radicals on iodine are very small and may well be zero. The value for ethyl agrees well with that listed above. Further investigations along these lines are clearly required.

Polar Effects

Although bond strengths largely determine the activation energies of the reactions of halogen atoms, polar effects are also important. This has been realized for some years. Recent experiments by Fredricks and Tedder (12) have extended our knowledge. We have attempted to study polar effects in the fluorination, chlorination, and less systematically, in the bromination of halogenated methanes. Fluorination is the most satisfactory because the reactions are so exothermic that the bond strengths are unlikely to be important, and all variations can be ascribed to the polar nature of the activated complexes. The available results are shown in Table III. The first conclusion to be drawn from the table is that more results are needed. The second is that there is little parallelism between the reactivities of the halogenated methanes and the α-hydrogen atoms in the halogenated *n*-butanes.

SURFACE-CATALYZED ATOM RECOMBINATIONS THAT PRODUCE EXCITED MOLECULES[1]

PAUL HARTECK, ROBERT R. REEVES, AND GENE MANNELLA

ABSTRACT

Various metal surfaces such as nickel, cobalt, copper, and silver give rise to a reddish uminosity in a stream of N- and O-atoms. Spectroscopic and photographic analysis of these glows indicate the formation of electronically excited molecules on the metal surface which diffuse into the gas phase and radiate. Two parallel processes are involved: the formation of an NO($B\,^2\Pi$), which results in NO β radiation, and the formation of an $N_2(A\,^3\Sigma_u^+)$, which, in collision, crosses into the $N_2(B\,^3\Pi_g)$ state and then radiates back to the $A\,^3\Sigma_u^+$, giving the N_2 first positive system. The N_2 first positive system observed here shows the strongest bands from $v' = 8$ and 6; these vibrational levels straddle the $A\,^3\Sigma_u^+$–$B\,^3\Pi_g$ potential energy curve crossing point. This crossing-over of N_2 molecules into the $(B\,^3\Pi_g)$ at this point may explain the observed strong $v' = 6$ transition in normal N-atom recombination if it is assumed that some of the N-atoms recombine into the $A\,^3\Sigma_u^+$ in addition to the $^5\Sigma_g^+$ state.

The N_2 second positive system ($C\,^3\Pi_u \rightarrow B\,^3\Pi_g$) has also been observed over copper in an N- and O-atom stream. This is most surprising since the $N_2(C\,^3\Pi_u)$ has about 1.4 ev more than D_{N_2}.

INTRODUCTION

A program of research in upper atmosphere chemistry has been underway in this laboratory for the past several years. This investigation has centered about the reactions of N-atoms and O-atoms. The results of this study to date have included determinations of the rate coefficients of the following reactions (1, 2, 3).

$$NO + O + M \rightarrow NO_2 + M \quad [1]$$

$$N + N + M \rightarrow N_2 + M \quad [2]$$

$$O + O + M \rightarrow O_2 + M \quad [3]$$

In order to determine the absolute atom concentrations necessary to obtain the rate constant in the second-order reactions [2] and [3], gas-phase titration procedures were developed for each of the atom species. A modified procedure was then developed which permitted the titration of mixed N- and O-atom streams in a single step. During some of the work with mixed N- and O-atom streams, silver foil was used to catalytically recombine the O-atoms, leaving the N-atoms unchanged. It was noticed in this work that a reddish glow appeared adjacent to the silver surface, particularly if the silver had contacted the orthophosphoric acid used to condition the walls of the decay tube. Further investigation showed that the glow was definitely in the gas phase and was not a corona, since it slowly faded out with the afterglows if the discharges were turned off. Further study of this glow showed it to be due to the surface-catalyzed recombination of N- and O-atoms to form electronically excited molecules.

DISCUSSION

It was subsequently discovered that cobalt and nickel also produced the luminosity, but much brighter than over the silver. The glow grew in size with decreasing pressure

[1]*Contribution from the Rensselaer Polytechnic Institute, Troy, New York; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960. The research reported in this document has been sponsored by the Geophysics Research Directorate of the Air Force Cambridge Research Center, Air Research and Development Command, under Contract No. AF19(604)-6128.*

and was unaffected by magnetic fields. Spectroscopic analysis showed the first positive system of N_2 and the NO β bands. The mixing of N- and O-atom streams had been observed to produce the same band systems by the gas-phase reactions

$$N(^4S) + N(^4S) + M \rightarrow N_2(^5\Sigma_g^+) + M \quad [2a]$$

$$N_2(^5\Sigma_g^+) \rightarrow N_2(B\ ^3\Pi_g)_{v=12} \quad [2b]$$

$$N_2(B\ ^3\Pi_g) \rightarrow N_2(A\ ^3\Sigma_u^+) + h\nu \text{ (1st positive)} \quad [2c]$$

and

$$N(^4S) + O(^3P) + M \rightarrow NO(B\ ^2\Pi) + M \quad [4]$$

$$NO(B\ ^2\Pi) \rightarrow NO(X\ ^2\Pi) + h\nu\ (\beta \text{ bands}) \quad [4a]$$

However, several important differences were apparent in the spectral analysis of the glows produced over the metals. The radiation from [2*c*] showed the strongest transitions to be from $v' = 12, 11, 10 \ldots$ The spectrum of the glow showed the most intense bands to be from $v' = 8$ and 6. Also, the mixing of N- and O-atom streams is observed to produce NO γ bands in addition to the β bands. No γ bands were observable on our plates.

Thus, it was apparent that the metal surface was catalytically recombining atoms into an electronically excited state. This molecule, instead of giving its energy of excitation and coming off the surface in the ground state, was actually diffusing into the gas phase and radiating. Since both N- and O-atoms appeared necessary to produce the glow, it was postulated that the primary molecule being formed was the $NO(B\ ^2\Pi)$. This species could be formed on the metal surface, diffuse into the gas phase, and then radiate or react with an N-atom to form $N_2(B\ ^3\Pi_g)$, which then radiated. The early work done on nickel produced glows which were several millimeters thick and the lifetime estimated from the diffusion distance was not inconsistent with the available estimates of the lifetime of the $NO(B\ ^2\Pi)$. However, cobalt produced a very enhanced glow at 1 mm pressure, which was 10–15 mm thick and which required only a very small amount of O-atoms. Photographic analysis of this glow using red and blue filters showed two parallel radiations: an intense blue extending only a few millimeters into the gas phase, and a red which extended very far out into the gas phase and which showed an unsymmetry due to the flowing stream which was not visible to the unaided eye. When nickel was used, a strong blue was evident and only a medium red; when cobalt was used, practically no blue appeared but the red was very large.

From these results it was concluded that two parallel processes were occurring on the surface. One involved the formation of $NO(B\ ^2\Pi)$ via [4]. This molecule leaves the surface and goes into the gas phase where it radiates. The thickness of the blue radiation is in excellent agreement with the diffusion distance calculated using the lifetime of 10^{-6} sec recently reported in the literature (4).

The second process occurring must involve the formation of an excited N_2 as the primary product. It is possible to explain the strong radiation from $v' = 8$ and 6 and the long lifetime of the species responsible for the glow by assuming that an $N_2(A\ ^3\Sigma_u^+)$ is formed on the surface. (In the case of cobalt, the small amount of O-atoms necessary to enhance the glow are probably required to condition the metal surface and permit the absorbed N-atoms which eventually form the excited molecule to be attached with an electron volt or less.) The $N_2(A\ ^3\Sigma_u^+)$ and $(B\ ^3\Pi_g)$ potential energy curves cross at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

about 8.5–9.0 ev or $v' = 8$–6. The metastable $N_2(A\ ^3\Sigma_u^+)$, which is the upper level of the well-known Vegard–Kaplan system, forms on the metal surface, diffuses into the gas phase and, by collision, crosses into the $(B\ ^3\Pi_g)$ state. This crossing-over would be at $v' = 8$–6 and the $N_2(B\ ^3\Pi_g)$ would immediately radiate back to the $(A\ ^3\Sigma_u^+)$. The lifetime of the species responsible for the red glow as calculated both from the diffusion distances and the linear velocity of the gas stream and the unsymmetry of the glow is about 10^{-3} sec. This would represent the time required by the $N_2(A\ ^3\Sigma_u^+)$ to relax vibrationally to the crossing point and by collision cross into the $(B\ ^3\Pi_g)$ state. Since the radiative lifetime of the $(A\ ^3\Sigma_u^+)$ is reported to be at least 10^{-2} sec (5), the time interval of 10^{-3} sec is sufficient for any necessary relaxation and the crossing-over to occur.

The $N_2(A\ ^3\Sigma_u^+)$–$(B\ ^3\Pi_g)$ crossing may have another interesting ramification in the presently accepted theory on N-atom recombination as outlined in [2*a*], [2*b*], and [2*c*] (6, 7). This theory postulates the $N_2(^5\Sigma_g^+)$–$(B\ ^3\Pi_g)$ crossing to be at $v' = 12$ and is supported by observations that bands from $v' = 12$, 11, and 10 are the most intense and the transition from $v' = 13$ is never observed in the nitrogen afterglow. However, an unusually intense band from $v' = 6$ has been discussed by several authors (8, 9). No really conclusive explanation has ever been offered for this observation. It is suggested that the lower levels of the $(B\ ^3\Pi_g)$ are populated by an analogous mechanism via the formation of a certain percentage of $(A\ ^3\Sigma_u^+)$ molecules in normal N-atom recombination.

From the observations and comparison of glows over cobalt and nickel, it appears that cobalt favors the formation of $N_2(A\ ^3\Sigma_u^+)$, while nickel favors the $NO(B\ ^2\Pi)$. The glows over nickel always appear a little bluish to the eye. In the case of $N_2(A\ ^3\Sigma_u^+)$ formation on the surface of cobalt, the reaction

$$N_2(A\ ^3\Sigma_u^+) + O\ ^3P \rightarrow NO(B\ ^2\Pi) + N(^4S) \qquad [5]$$

could account for some of the small amount of blue observed over cobalt. The $NO(B\ ^2\Pi)$ over nickel could similarly react,

$$NO(B\ ^2\Pi) + N(^4S) \rightarrow N_2(B\ ^3\Pi_g) + O(^3P), \qquad [6]$$

accounting for some of the first positive bands there. To what extent these exchange reactions occur is not known at the present.

A red glow with N- and O-atoms similar to those produced over silver, nickel, and cobalt has also been produced over copper, although it has been reported in the literature that electrolytically deposited copper can be used to extinguish the nitrogen afterglow (10, 11). The copper surface is slightly attacked. However, if the copper is maintained at approximately 15–20° C in a stream of N-atoms alone, the blue glow of the second positive system of nitrogen appears $(C\ ^3\Pi_u \rightarrow B\ ^3\Pi_g)$. This blue glow is less intense than the red glows observed earlier and extends about 2 mm into the gas phase. Transitions from the $(C\ ^3\Pi_u)$ state are indeed very striking, since the excitation of this level is about 11.2 ev, compared with D_{N_2}, which is only 9.76 ev. The mechanism for such a reaction must then necessarily involve three atoms or two excited species.

CONCLUSIONS

Surface-catalyzed excitation of N- and O-atoms can give rise to a number of excited species. What we originally believed to be a rather singular effect must now include the formation of $NO(B\ ^2\Pi)$, $N_2(A\ ^3\Sigma_u^+)$, and even $N_2(C\ ^3\Pi_u)$. We believe that this is the first recognition of this effect.

ON THE EXCITATION OF THE EMISSION SPECTRUM OF NCO IN SOLID MATRICES CONDENSED AT 4° K[1]

R. W. NICHOLLS[2] AND S. L. N. G. KRISHNAMACHARI[3]

ABSTRACT

Seventeen broad (~50 Å wide) spectral features have been excited in emission between 3000 Å and 4600 Å in the products of a microwave discharge through N_2 deposited on a cold (4° K) surface on which the discharge products of CO + N_2 had been previously condensed. The features which lie between 3650 Å and 4470 Å show close agreement with those observed in absorption by Dixon during the flash photolysis of NCO and assigned to the $A\ ^2\Sigma$–$X\ ^2\Pi_i$ transition. It therefore seems likely that the emission features arise from NCO also as a result of the reaction

$$N(^2P) + CO(X\ ^1\Sigma^+) \rightarrow NCO \begin{cases} A\ ^2\Sigma^+ \\ B\ ^2\Pi_i \end{cases}$$

at the solid surface.

1. INTRODUCTION

During the past few years, extensive spectroscopic studies have been made upon the luminosities arising from solids condensed between 1° K and 80° K from the products of microwave discharges maintained in a variety of gases, but mostly in N_2, A, O_2, and mixtures of them (1, 2, 3, 4, 5). Much of the work has been carried out with N_2–A mixtures (sometimes including a small oxygen impurity) (3, 5) and the spectra in these cases consisted almost entirely of atomic features of NI and OI and specific band systems of N_2, O_2, NO, and NO_2. Nearly all of the spectral features so far identified arise from transitions which, in the gas phase at least, are relatively forbidden (e.g. the "α" (^2D–^4S), and "μ" (^2P–^4S) features of NI; the "β" (^1S–^1D) feature of OI; the Vegard–Kaplan ($A\ ^3\Sigma_u^+$–$X\ ^1\Sigma_g^+$) system of N_2; the Herzberg ($A\ ^3\Sigma^+$–$X\ ^3\Sigma_g^-$) system of O_2; and the "M" ($^4\Pi$–$^2\Pi$) system of NO). Some allowed transitions (e.g. NO β ($B\ ^2\Pi$–$X\ ^2\Pi$); NO γ ($A\ ^2E$–$X\ ^2\Pi$) systems) have been reported (3). In general, however, the forbidden transitions predominate in the spectra of the solids because short-lived excited species decay radiatively during transit between the discharge and the cooled surface, while the longer lived metastable excited species are deposited and isolated from radiationless de-excitation influences before they can loose their energy.

It has therefore been thought worth while to attempt to excite forbidden transitions of other molecules, particularly those containing carbon, and also to attempt to excite in emission the spectra of polyatomic species. Most of the work on polyatomic spectra of low temperature solid matrices has so far been in absorption (6) although the "B" bands of NO_2 have been recognized in emission for some time.

This paper therefore describes some experiments with discharged N_2 + CO and the conditions under which NCO may be excited in the condensed solid. A subsequent paper (7) will discuss conditions under which CO_2^+ spectra can be excited.

The electronic spectrum of NCO was first observed in emission at low dispersion both in fluorescence from, and in discharges through, C_2H_5NCO, and later in absorption at much higher dispersion by flash photolysis of the same compound (8). Subsequent high dispersion studies by Dixon (9), of the absorption spectrum arising from flash photolysis of HNCO, lead to definitive identifications and rotational analysis of bands of the

$A\ ^2\Sigma^+$–$X\ ^2\Pi_i$ transition between 3603 Å and 4484 Å. Dixon (10) has recently analyzed bands of the $B\ ^2\Pi_i$–$X\ ^2\Pi_i$ transition between 2650 Å and 3200 Å using the same technique. Robinson and McCarty (11) have also reported identification of one strong absorption feature (at 4400 Å) of NCO in a low temperature solid condensed at 4.2° K from a discharge through N_2, O_2, and CH_4.

2. EXPERIMENTAL PROCEDURE AND RESULTS

Our experiments were carried out in a pyrex dewar flask, which has been described by Schoen *et al.* (12), in which the bottom of the central liquid helium container was a wedge-shaped "finger" on which the deposits were formed. All of the helium container except the terminal finger was protected against thermal radiation by a concentric cylindrical pyrex shield which contained liquid nitrogen. N_2 and CO gas flows were individually controlled by needle valves and were measured by floating ball flowmeters. The gas mixture was passed through a 2450 Mc/sec microwave discharge maintained at a few millimeters of pressure, and the discharge products flowed upwards through a "Wood" type light trap onto the liquid helium cooled finger. Prior to starting the discharge, the space around the finger was maintained at a vacuum of better than 10^{-6} mm Hg. During deposition it is believed that the pressure does not rise above 1 micron Hg.

The solid deposit formed on the pyrex finger exhibited a feeble blue luminescence over a wide range of N_2:CO mixtures. Its spectrum appears to be CO_2^+ and will be described elsewhere (7). After the solid condensed from the mixed gas stream had been built up for a few minutes, the CO flow was stopped and the deposition of discharged N_2 was continued. A marked surface color change from blue to bright yellow occurred in the luminescence from the deposit and the spectrum was easily recorded in a few minutes exposure of Kodak 103-F emulsion in a Hilger F/4 quartz spectrograph.

A typical spectrum is shown in Fig. 1 together with a mercury arc calibration. The spectrum consists of the atomic features "μ" (^2P–^4S) of NI at 3478 Å, "α" (^2D–^4S) of NI at 5228 Å, "β" (^1S–^1D) of OI at 5549 Å together with 18 broad (50 Å) features between 3000 Å and 4600 Å. Fifteen of these features (3206 Å–4600 Å) are relatively strong and three (3000 Å–3206 Å) are extremely weak. The wavelengths of the bands including their widths and estimates of intensity on a scale of 0 to 5 are given in Table I, and,

as is discussed below, there are good reasons for thinking that 17 of the bands are due to NCO. Owing to the diffuseness of the features there is perhaps a 10 Å uncertainty in the wavelengths.

DISCUSSION

Dixon's band-head wavelengths, transition assignments, and rough intensity estimates for the NCO $A\ ^2\Sigma^+–X\ ^2\Pi_i$ system are also given in Table I grouped for ease of comparison with our features. He used an intensity scale of 0 to 100 and we have only included bands with intensities greater than 5. Not only is a very strong correlation seen

PLATE I

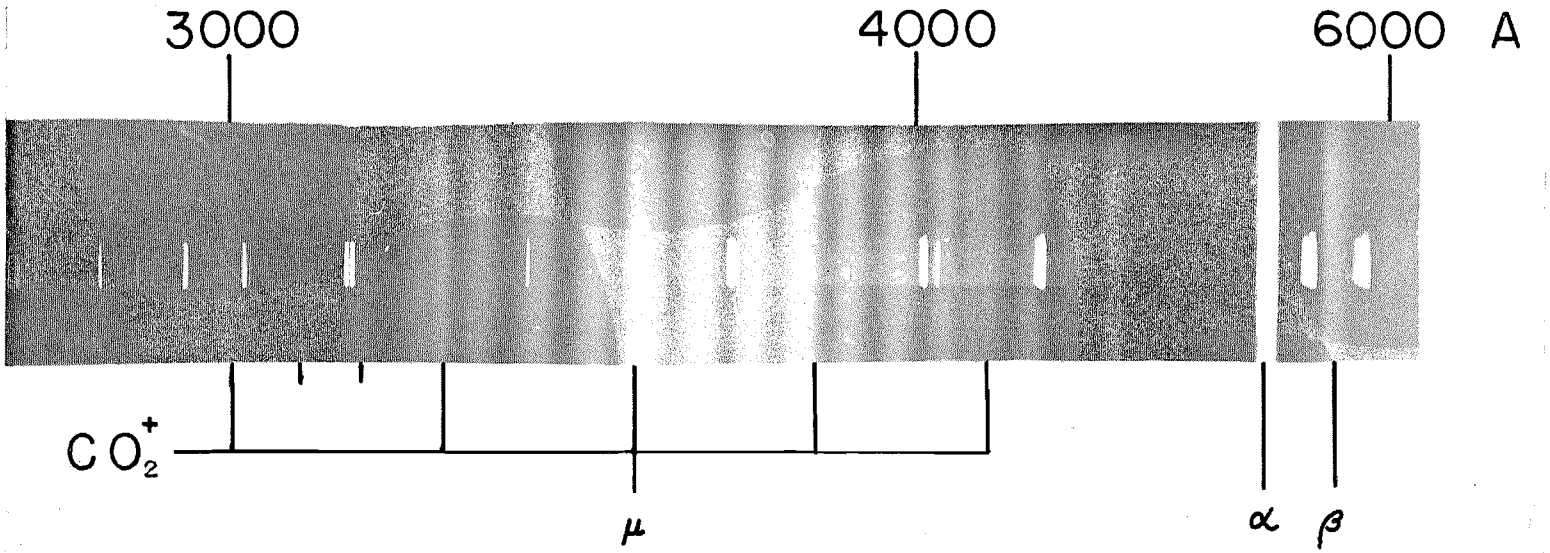

FIG. 1. Spectrum of luminosity arising from the action of discharged nitrogen on CO at 4° K.

in Table I between groups of Dixon's band heads and each of our features between 3650 Å and 4470 Å, but there is also good correlation between the spaces between our features and the regions where Dixon records absence of bands or very weak bands.

On this basis it seems very plausible to assign not only those of our features with which there is a strong correlation with those of Dixon to overlaps of strong NCO bands but also to assign those which lie between 3000 Å and 3630 Å and between 4560 Å and 4600 Å (which lie outside the range reported in absorption) to the same emitter.

Each of our features undoubtedly arises from the overlap of a number of adjacent bands whose rotational structure is not very extensive at the low temperature of the source. It will be observed in Fig. 1 that all or part of each of five features has been assigned to bands of CO_2^+. These assignments derive from experiments referred to above (7) on the spectra of condensed discharged CO + N_2. One CO_2^+ feature in Fig. 1 is also assigned in part to "μ" of NI. The three features between 3000 Å and 3165 Å are extremely weak and there is a possibility that there is a contribution to them from bands of the $B\,^2\Pi_i$–$X\,^2\Pi_i$ system of NCO reported by Dixon (10) to lie between 2677 Å and 3167 Å. In particular the 3140–3165 feature may be the strong 000–000 transition of this system. Alternatively these bands may be a continuation of the $A\,^2\Sigma$–$X\,^2\Pi_i$ system.

While the flash photolysis experiments involve the decomposition of HNCO into fragments, the mechanism operative in our experiments is almost certainly one of synthesis of NCO [either in the gas phase near the cold finger (no NCO spectrum is seen from the discharge itself), or as is more likely, on the surface of the cold finger itself]. This surface was prepared by deposition of discharged CO + N_2 and will therefore have a high concentration of ground state ($X\,^1\Sigma^+$) CO molecules on it. The surface was then treated with the discharge products of N_2, a significant number of which are N atoms in ^2P, ^2D, and ^4S (ground) states as is shown by the presence of "α" and "μ" in the spectra. Thus N + CO collisions occur at the surface. Dixon has pointed out (9) that

$$N(^2D) + CO(X\,^1\Sigma^+) \rightarrow NCO(X\,^2\Pi) \qquad [1]$$

and

$$N(^2P) + CO(X\,^1\Sigma^+) \rightarrow NCO\begin{cases} A\,^2\Sigma^+ \\ B\,^2\Pi_i \end{cases} \qquad [2]$$

are energetically possible and plausible processes. Before collision, the CO molecules were most probably in the $v = 0$ level, but the N atoms will collide with the kinetic energy of the discharge ($T \sim 300$–$400°$ K). NCO can therefore be formed in excited vibrational levels such as is required by the identifications of Table I. It may be remarked in passing that the possibility of forming NCO ($B\,^2\Pi_i$) by equation [2] makes reasonably plausible the possible assignment of our 3140–3165 feature to the strong (000–000) transition of the $B\,^2\Pi$–$X\,^2\Sigma$ transition.

It should not be overlooked that it may also be possible to form CON and CNO in the collision mechanism (equation [2]) and with our experimental arrangement. Further work on these possibilities is in progress.

ABSOLUTE RATE MEASUREMENTS OF O-ATOM REACTIONS WITH ETHYLENE AND WITH BUTANE[1]

L. Elias and H. I. Schiff

ABSTRACT

The absolute rate constants for the primary reactions of O-atoms with ethylene and with butane have been determined in a fast-flow system. The O-atoms were produced by electrodeless discharge of O_2 and allowed to react with the hydrocarbon introduced downstream. Addition of a small amount of NO to the gas stream enabled a photometric monitoring of the O-atoms in the reaction zone. The initial atom concentration was determined by NO_2 titration. The reaction could be stopped at any point in the reaction zone by means of a movable surface of cobalt oxide. The hydrocarbon concentration at any point could then be determined by condensation downstream and analysis of the products.

Rate measurements were carried out over the temperature range $-50°$ to $200°$ C. The rates were found to be consistent with a two-body mechanism. For O-atoms with ethylene,

$$k = 1.8(\pm 0.6)\times 10^{-11}\, e^{-1600/RT}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{sec}^{-1}$$

and for O-atoms with butane,

$$k = 5.0(\pm 1.6)\times 10^{-11}\, e^{-4200/RT}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{sec}^{-1}.$$

INTRODUCTION

Cvetanović has recently measured relative rate constants for the reactions of oxygen atoms with a series of olefins (1). This study enabled him to make interesting deductions about the effect of structure on the rates and mechanisms of these reactions. Absolute rate constants were estimated by comparison with the value for the reaction $O + NO_2$ reported by Ford and Endow (2), which was, in turn, based on the rate constant for the reaction $O + O_2 + M$, obtained by Benson and Axworthy (3) from their mechanism for the thermal decomposition of ozone.

Notwithstanding the high caliber of the work of these authors, it seemed desirable to measure the absolute value of the rate constant directly for one of these olefin reactions. It also seemed important to determine its activation energy and steric factor, since such data are virtually non-existent.

The present paper reports the measurement of the absolute rate constant and its temperature dependence for the reaction of O-atoms with ethylene. For comparison purposes, similar measurements were also obtained for the reaction of O-atoms with *n*-butane.

Principle of the Method

The rate constant of interest is that of the initial attack of an O-atom on an olefin molecule. The subsequent reactions are complicated and lead to a variety of products which depend on the ratio of atomic to molecular oxygen. Cvetanović has found, however, that the presence of molecular oxygen does not affect the rate of consumption of the olefin (4), which indicates that the initial O-atom attack is rate-determining. Consequently, no attempt was made in this work at a detailed product analysis.

The rate of disappearance of hydrocarbon can then be represented by a simple bimolecular equation,

$$[1] \qquad -\frac{d[\mathrm{RH}]}{dt} = k[\mathrm{O}][\mathrm{RH}].$$

Integration of this equation between reaction time limits t_1 and t_2 gives

$$[2] \qquad \ln\frac{[\mathrm{RH}]_1}{[\mathrm{RH}]_2} = k\int_{t_1}^{t_2}[\mathrm{O}]dt.$$

As a result of secondary reactions, [O] will be a complex function of time. However, in a well-defined flow system, time can be related to distance. [O] can then be measured along the length of the reaction vessel and the integral evaluated graphically. The rate constant is then obtained from the measurement of [RH] at times t_1 and t_2 and the value of the integral in that time interval.

The only assumptions involved in this method for determining k are that RH is neither reformed nor consumed in the secondary reactions. It is extremely unlikely that RH will be the product of any reaction of radicals resulting from the attack of O-atoms on the hydrocarbon. The radicals are also much more likely to react with O_2, which is present in large excess, than with the parent hydrocarbon. The validity of these assumptions, as well as the independence of the rates on $[O_2]$, is attested to by the good agreement of the relative rate constants for butane and ethylene obtained in this work with that obtained by Cvetanović (4) using a completely different technique, and in the absence of O_2.

EXPERIMENTAL

Apparatus

A conventional fast-flow system was used which incorporated the usual arrangement of fine-control needle valves and calibrated flowmeters. Molecular oxygen was dissociated to the extent of a few per cent by a microwave discharge in the manner described previously (5). Precautions were taken to exclude mercury vapor from the apparatus. The discharge tube was connected to the reaction vessel represented in Fig. 1. The latter consisted of a pyrex tube 16 mm i.d. and 30 cm long, surrounded by an outer jacket through which tap water could be flowed. The reaction vessel was thermostatted at higher temperatures by the vapors of appropriate liquids boiling in a flask attached to the apparatus at F and refluxing in a condenser attached at C. To achieve temperatures below 20° C, the outer jacket was replaced by a double-walled vacuum jacket, open at the top, into which could be placed suitable mixtures of ethanol and powdered dry ice.

A movable coil of platinum wire D_1, coated with cobalt oxide, served to remove all the atoms from the gas stream (5). It was mounted on a glass rod which could be moved axially along the reaction tube by rotation of the tygon-covered rod T, which pressed against it. This device was used to stop the reaction at selected positions, and thereby permitted an accurate control of the reaction time.

D_2 was a similar movable coil of copper wire (a less efficient catalyst for O-atom recombination) which was used to decrease the oxygen atom concentration by lowering it into the gas stream.

The hydrocarbon was introduced through the multiple jet J_1, which consisted of a small bulb in which five equally spaced small holes were blown in a plane transverse to the direction of the oxygen stream.

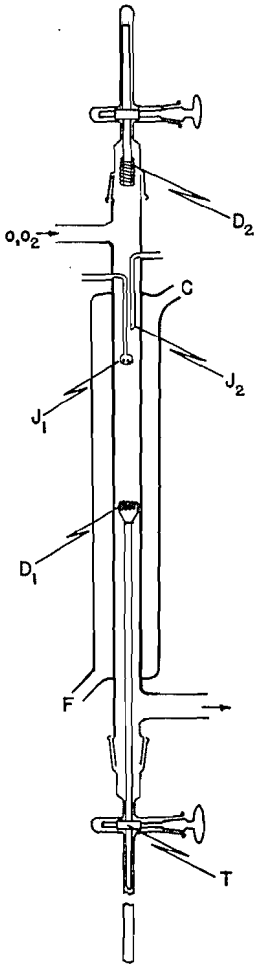

FIG. 1. Reaction vessel.

Materials

Linde tank oxygen rated to contain less than 0.1% N_2 was used without further purification. Matheson reagent grade ethylene and butane were 'trap-to-trap' distilled before use. Nitric oxide, also a Matheson product, was freed of NO_2 by passage through Caroxite, a commercial CO_2 absorbent. NO_2 was prepared by addition of O_2 to NO and stored with a small excess of O_2.

O-*Atom Measurement*

In previous studies in this laboratory (5, 6), O-atom concentrations were measured with an isothermal calorimeter. This technique could not be used in the present study, since preliminary experiments indicated that species produced in the secondary reactions liberated heat to the calorimeter. Consequently, a small amount of NO was added to the gas stream through J_2, and the resulting light emission used to monitor the O-atom concentration along the reaction tube. The change in [O] with time was measured photometrically in the manner suggested by Kaufman (7). The feasibility of this method depends on the following facts:

(1) The consumption of O-atoms by NO is relatively slow at these pressures, since it can be represented as occurring by the three-body process

$$O + NO + M \rightarrow NO_2 + M.$$

(2) The subsequent reaction

$$O + NO_2 \rightarrow NO + O_2$$

is fast and regenerates the NO so that the NO concentration remains essentially constant.

(3) The light emission is independent of the amount and nature of any third body and can be represented by

$$O + NO \rightarrow NO_2 + h\nu.$$

Thus for a given amount of NO the intensity depends only on the partial pressure of O-atoms.

The relative light intensity was measured by means of a IP21 photomultiplier tube. The phototube housing was mounted on rails and could be moved parallel to the reaction vessel. Collimating slits were used to limit detection of light from a 2-mm section of the reaction tube.

To convert the photometer readings to atom concentrations, it was only necessary to know the absolute value of [O] at one point in the reaction vessel. The value of $[O]_0$, the atom concentration at the inlet J_1, was determined by NO_2 titration. The NO flow was stopped, and an excess amount of NO_2 was added through J_1. The NO produced, which equals $[O]_0$, was trapped downstream with the excess NO_2. The trapped NO was determined by the amount of oxygen consumed in converting the mixture of the oxides to NO_2. It was found that NO could be trapped quantitatively at liquid nitrogen temperature only if the ratio of NO_2 to NO in the oxygen stream was greater than 2. Use of lower ratios resulted in some loss of NO by pumping and by oxidation in the trap. Blank experiments, in which synthetic mixtures of NO_2 and NO were introduced through J_1 with a molecular oxygen stream, showed that the uncertainty in the analysis was less than 2%.

The use of a Wratten 23A filter in front of the collimating slits of the phototube ensured that signal from the weak 'blue' flame resulting from the O-hydrocarbon reaction was negligible relative to that from the O–NO emission.

The presence of the small amount of NO did not affect the rate of the reaction under study, as evidenced from the constancy of the rate constant and the [O] decay curves when the NO flow was changed by a factor of 10 or more. In some experiments with butane the reaction flame was so feeble that the trace of NO formed in the discharge from the N_2 impurity in the oxygen was sufficient for accurate phototube readings. Rate constants determined using this 'afterglow' to monitor [O] were identical with those obtained when the glow was greatly enhanced by addition of NO.

This technique also provided a very sensitive visual test for the efficiency of coil D_1 in removing the atoms and stopping the reaction. A sharp discontinuity of the glow at the top of the coil indicated complete atom consumption. This discontinuity became more diffuse and extended further down the coil at higher atom flows.

Experimental Procedure

In a typical experiment the oxygen was passed through the discharge and the reaction tube for at least an hour to ensure that steady conditions had been achieved; $[O]_0$ was then determined by NO_2 titration. NO was then added through J_2, hydrocarbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

through J_1, and the O-atom profile determined photometrically. The NO flow was stopped, and the coil D_1 was introduced to stop the reaction at some position in the reaction tube. The products were then trapped downstream at liquid nitrogen temperature and removed for analysis when a sufficiently large sample had been collected. During this removal the gas leaving the reaction vessel was made to bypass the trap in order to leave the gas flow undisturbed.

The products were then distilled at $-90°$ C through a column of Caroxite. Mass spectrometric and gas chromatographic analyses showed that the effluent gas consisted only of unreacted hydrocarbon. This indicated that the Caroxite absorbed the oxygen-containing products which were volatile at $-90°$ C. The measurement of unconsumed hydrocarbon could thus be effected in a matter of minutes.

The procedure was then repeated with the coil D_1 at some new position. The determination of [RH] at several positions down the reaction tube permitted the evaluation of k by equation [2] for a variety of time intervals.

The presence of the coil D_1 in the reaction zone should not affect the rate measurements if it recombines atoms much faster than it catalyzes the reaction of O-atoms with the hydrocarbon on its surface. That this condition was fulfilled was shown by the following experiment. A reactant flow could be chosen which resulted in the complete consumption of O-atoms within the length of the reaction tube. For such experiments the coil D_1 was not needed to define the reaction zone. Since [O] decays to zero, no explicit knowledge of t_2 is required to evaluate the integral in equation [2]. The values of $[RH]_1$ and $[RH]_2$ are the concentrations at the inlet and that remaining after all the atoms are consumed. The rate constants obtained in these experiments were indistinguishable from those obtained when the coil was present. Although the presence of the coil evidently does not affect the initial reaction, it might well influence the course of the secondary reactions.

Since the reactions under study were quite exothermic, it was necessary to limit the reactant flow rates to prevent temperature rises which would increase the measured rate constant. Temperature measurements were effected by replacing the D_1 coil asesmbly by a thermocouple well. For the butane reaction, the flow rates used were such that the temperature increase in the reaction zone did not exceed 3 C°. Due to the lower activation energy of the ethylene reaction, a temperature rise of 10 C° could be tolerated without noticing an increase in the measured rate.

RESULTS AND DISCUSSION

Table I shows the results of an experiment in which the ethylene flow rate was sufficiently large to consume all the atoms within the reaction vessel. Columns 2 and 3 show the decrease in [O] and $[C_2H_4]$ with time. The coil D_1 was used to stop the reaction at positions 1, 2, and 5 cm from the jet J_1. The last number in column 3 is the value of $[C_2H_4]$ recovered in the absence of the coil. The rate constants shown in column 6 were calculated from equation [2] for the distance intervals shown in column 5. These results show that the presence of the coil does not affect the rate measurement and that there is no trend in the value of k with a 13-fold change in reaction time. These results also afford a very stringent test on the method, since the ratio of reactant concentrations differ by several orders of magnitude over the time intervals used. It will be noted that the ratio of O-atoms consumed to ethylene consumed (column 4) is never less than one. This is consistent with the basic assumption of the method, viz., that the ethylene is attacked only in the initial reaction. The fact that this ratio decreases and approaches unity at

O_2. Similar constancy for the value of k was obtained when the pressure was increased by addition of large amounts of inert gas to the oxygen. This result is significant since it has been shown that discharged oxygen contains a proportion of excited oxygen O_2*, which decreases with addition of helium (8). If ethylene were attacked by O_2* differences in k might be expected when helium is added. Constant values of k were, however, obtained with O_2–He mixtures from 3.5 to 100 mole% O_2.

Tables IV and V show the independence of k on the reactant concentrations for the C_2H_4 and C_4H_{10} reactions respectively.

These results clearly indicate that the rate-controlling steps in these reactions are second order, first order in each of the reactants.

Rate constants were determined for the C_2H_4 reaction over the temperature range −50° C to 192° C and for the n-C_4H_{10} reaction from −42° C to 160° C. Account was taken in the calculations of the effect of temperature on the concentrations and linear velocities of the reactants. The results are shown in Tables VI and VII and the Arrhenius plots in Fig. 2. These curves yield activation energies of 1.6±0.2 and 4.2±0.2 kcal/mole

for the C_2H_4 and n-C_4H_{10} reactions respectively, with corresponding pre-exponential factors of $1.8(\pm 0.6)\times 10^{-11}$ and $5.0(\pm 1.6)\times 10^{-11}$ cm^3 molecule^{-1} sec^{-1}.

The rate constant of 1.2×10^{-12} cm^3 molecule^{-1} sec^{-1} obtained for the C_2H_4 reaction at 25° C can be compared with Cvetanović's figure of 0.29×10^{-12} (1) and that of Ford and Endow of 0.76×10^{-12} (9). Since the last two values are derived indirectly from relative measurements using quite different experimental techniques, the agreement can be considered to be satisfactory.

The ratio of the rate constants for the ethylene and butane reactions was found to be 28 ± 3 at 25° C. Cvetanović (4) found this ratio to be 22 ± 5 from relative rate measurements. Again, the agreement is quite satisfactory.

Cvetanović (1) has suggested that the trend in rate constants for O-atom reactions with olefins is due to a trend in activation energy alone. On this basis his data would imply that the ethylene reaction has an activation energy 2.8 kcal greater than that of the 2,3-dimethylbutene-2 reaction. This is clearly inconsistent with the absolute value of 1.6 ± 0.2 kcal/mole for the value of E for the ethylene reaction found in the present work. It would therefore appear that the trend in k's for the olefin series must also involve a trend in steric factors.

PRESSURE DEPENDENCE OF ROTATIONALLY PERTURBED LINES IN THE ULTRAVIOLET BAND SPECTRUM OF CN[1]

H. P. Broida and Sidney Golden[2]

ABSTRACT

Intensity measurements of the components of rotationally perturbed lines ($K' = 4$, 7, 11, and 15) in the 0,0 transition of the violet system ($B\ ^2\Sigma^+$–$X\ ^2\Sigma^+$) of the CN formed in an "active" nitrogen flame have been made at pressures from 0.1 to 100 mm Hg. A simple kinetic model considering competition between formation, radiation, and collisional interchange of states gives a reasonable fit to the data over the entire range of measured pressures. At high pressures the intensity ratios of the components of rotationally perturbed lines depend only upon the radiative transition probabilities and at low pressures, only upon the relative rates at which they are populated. At intermediate pressures, the intensity ratios depend upon the collision frequency for the interchange of the rotationally perturbed states. The collision frequency determined in this manner is of the same order of magnitude as the gas kinetic collision frequency.

INTRODUCTION

The violet bands of CN ($B\ ^2\Sigma^+$–$X\ ^2\Sigma^+$) show intensity anomalies originating in the $v' = 0$ level of the $B\ ^2\Sigma^+$ state caused by perturbations of rotational levels with the $v' = 10$ level of the $A\ ^2\Pi_i$ state. Herzberg (1) first noticed that lines $K' = 4$, 7, and 15 of the 0,0 band of the violet system were greatly enhanced at low pressures in discharges and in "active" nitrogen flames. Beutler and Fred (2) found that the enhanced lines consisted of doublets and suggested that the anomalously high intensities of these lines are caused by interaction of these rotational levels with corresponding rotational levels of the $v' = 10$ (3)* level of the $A\ ^2\Pi_i$ state. This suggestion was confirmed by Wager's measurements (4, 5) of the perturbations in both the 10,4 band of the red system and the 0,0 band of the violet system. In addition he found another rotationally perturbed level, $K' = 11$, also consisting of a doublet. Recently, Kiess and Broida (6, 7) found that the enhancement of the perturbed lines was increased greatly at pressures below 1 mm Hg and that under conditions in which transitions from the $K' = 4$, 7, and 15 levels are enhanced in the violet system, lines from corresponding rotational levels in the $v' = 10$ state of the red system ($A\ ^2\Pi_i$–$X\ ^2\Sigma^+$) are weakened.

This paper reports the intensity measurements of the so-called *main* and *extra* lines of the rotationally perturbed pairs in the 0,0 transition of the violet system over a pressure range from 0.1 to 100 mm Hg. The *main* lines correspond to normally allowed transitions; the *extra* lines correspond to normally forbidden transitions. A mathematical model developed on the basis of kinetic considerations has been devised to fit the data. The ratio of the intensity of the extra line to that of the main line is expressed as a function of three parameters and the pressure. One parameter, $2k_M/k_E$, is the ratio of the radiative transition probability of the main line to that of the extra line. The factor of two appears as a result of the fact that the main line itself is an unresolved doublet. The k_M/k_E ratios found from measurements of the pressure variation of the intensity ratios for the lines $K' = 7$, 11, and 15 are in good agreement with the determinations of Wager (5) found from measure-

**The vibrational numbering of bands from the red system in earlier work must be increased by one unit (see, for example, Herzberg et al. (3)).*

ments of perturbed line displacements. Another parameter, α, is interpreted to mean that CN is formed in the upper state of the extra line at approximately three times the rate that CN is formed in the upper state of the main line. The third parameter, k_c/k_M, gives a rate of collisional depopulation compared with the rate of radiative transition.

EXPERIMENTAL PROCEDURE

CN emission was obtained by mixing "active" nitrogen with gases of compounds containing carbon in a simple reaction chamber similar to that of Wager (5) and of Kiess and Broida (6). Bright flames were observed at the point of mixing, and at lower pressures the flame filled the entire reaction tube (300 mm long and 45 mm diameter). Prepurified nitrogen (stated by the manufacturer to be of 99.997% purity) was taken from cylinders through float-ball flowmeters by means of Tygon tubing and was admitted by a stopcock into the discharge region. Pyrex glass (washed with soap, rinsed with a 12% solution of HF, and then rinsed with distilled water) was used in the remainder of the apparatus. Because CH_2Cl_2 gave the brightest flames in this burner (particularly at pressures below 1 mm Hg), it was used for most experiments. CH_2Cl_2 vapor was admitted to the reaction chamber through a stopcock from a graduated tube containing liquid CH_2Cl_2 (C.P.).

In most experiments, a 2450-megacycle electrodeless discharge (125 watts) was used to dissociate the nitrogen. A small percentage of nitrogen atoms (8) found in such discharges at pressures near 1 mm Hg. For pressures above 20 to 30 mm Hg, it was necessary to use a 800-watt generator.* In addition for some work below 0.2 mm, a spark discharge using 7μf and 3000 volts at 1 kilowatt with aluminum electrodes about 1 meter apart was found to give brighter reactions.

Pressure was measured with a Bourdon gauge which could be read to 0.05 mm Hg. A McLeod gauge was used for calibration and for measuring nitrogen pressures below 1 mm.

Spectra were recorded with a high resolution grating monochromator with photomultiplier detection.† This instrument, used with 7 micron slits, is able to resolve lines of 0.03 Å separation. Since peak heights were used for intensity measurements, relative intensities of lines closer than about 0.1 Å were not reliable.

Under the best conditions, for pressures between 0.2 and 20 mm Hg and for values greater than 0.1, intensity ratios were reproducible to about $\pm 2\%$. However, for weak flames at very low and very high pressures the reliability was not as good. For pressures lower than 0.1 mm Hg, errors of 50% in the intensity ratio were possible. These errors are associated with the very weak signals obtained.

EXPERIMENTAL DATA

Figures 1 and 2 illustrate the effect of pressure on the perturbed lines. With decreasing pressure the main lines, M, become increasingly enhanced so that at very low pressures they are more than 10 times the intensity of their neighbors. The extra lines, E, increase relative to the main lines. The extra lines occur on the short wavelength side of the main lines for $K' = 7$, 11, and 15 and on the long wavelength side of $K' = 4$. At the very lowest pressures, below 0.1 mm Hg, the extra lines at $K' = 7$, 11, and 15 were more than twice the intensity of the main lines.

Wager (5) has measured the separations of the extra lines from the perturbed main

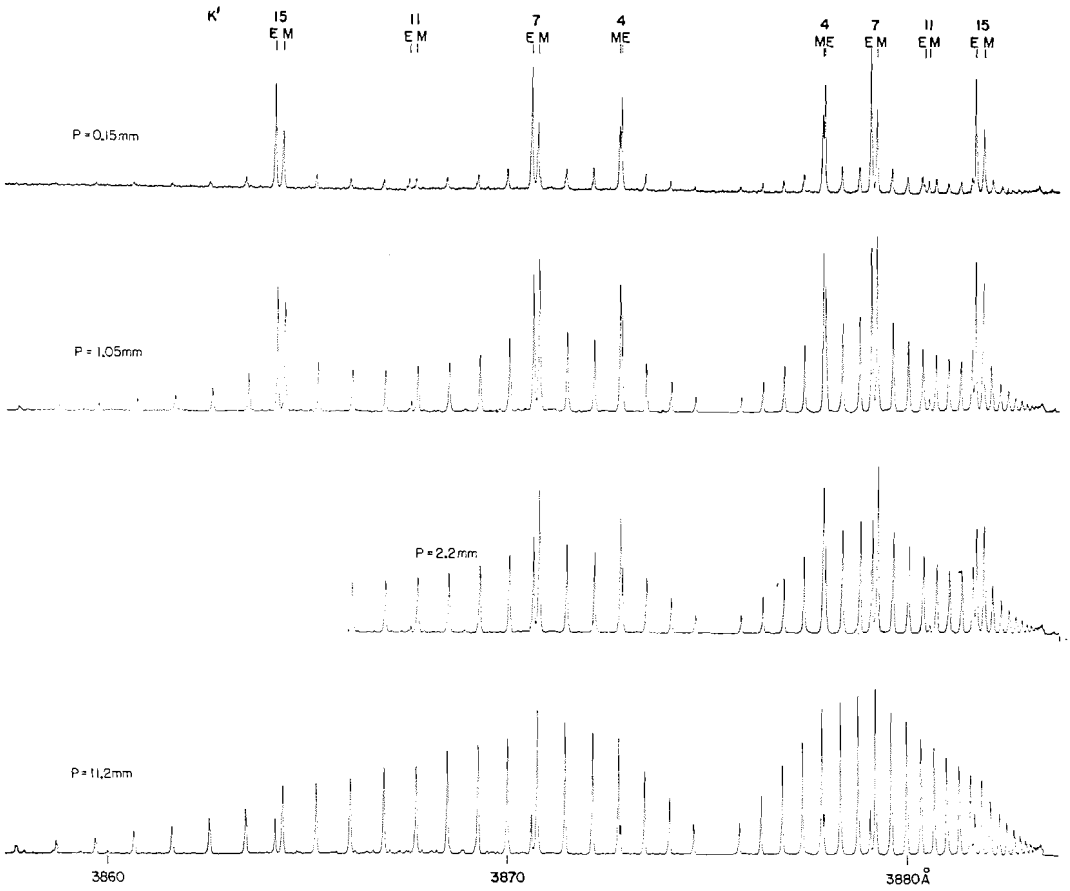

FIG. 1. Spectra of the violet CN emission from "active" nitrogen flames at several pressures.

lines to be -0.352, $+0.938$, $+1.177$, and $+1.212$ cm^{-1} respectively for $K' = 4, 7, 11$, and 15. Since the separation of lines from $K' = 4$ levels were not sufficiently resolved for reliable intensity measurements, intensity measurements on these lines have been excluded from detailed analysis.

Measured ratios of the intensity of the extra line, I_E, to the intensity of the main line, I_M, as obtained from peak height measurements at pressure from 0.08 to 100 mm Hg are shown in Figs. 3, 4, and 5. Pressure is the variable having the largest influence on I_E/I_M. The data have been obtained over a period of 18 months. Small effects on I_E/I_M caused by different relative amounts of CH_2Cl_2 and N_2 were noticeable but were too small for systematic measurement. No effects on the ratio were found to be caused by the type of discharge, the power in the discharge, the size or type of reaction chamber, flow rate, or the reactant.

The addition of appreciable amounts of argon or helium had a small but measureable effect on the ratio between 2 and 20 mm Hg. This is illustrated in Table I where I_E/I_M is given for various proportions of added helium. The effect of rare gas is the same whether it is added before or after the discharge. Other gases—N_2, O_2, CO, or CO_2—had little effect (much less than the rare gases) on I_E/I_M.

THEORETICAL MODEL

The model to be elaborated here is concerned mainly with the formation of CN molecules in those states which are affected by rotational perturbations. The energy relations of those states has been discussed in some detail by Wager (5). The upper states involved are degenerate doublets (or nearly so). However, only one of the spin components in the $B\ ^2\Sigma$ state and only one of the Λ components in the $A\ ^2\Pi$ state interact via a rotational perturbation (9). Thereby, the component derived from the $A\ ^2\Pi$ state acquires an enormously increased probability of transition to the ground state: this transition corresponds to the extra line. The other component of the $A\ ^2\Pi$ state is unaffected and has negligible intensity. By contrast, both components of the $B\ ^2\Sigma$ state have large transition probabilities, so that the main line that they produce is an unresolved doublet. However, the relative intensity of these doublets depends upon the relative rates at which they are being populated.

Figure 6 is a simplified energy level diagram indicating that the transitions associated with the doublets observed in the violet CN bands may be presumed to involve not only the radiative transitions, M and E, but also those ascribable to the formation of the CN molecule in the various states and those ascribable to non-radiative transitions. For simplicity, only non-radiative transitions between the members of each group of upper states are taken into account explicitly. The remaining possible non-radiative transitions are considered collectively in terms of the otherwise net rate of production into each of the pair of rotationally perturbed excited states. A diagram like Fig. 6 is applicable to each rotationally perturbed pair of states and the associated unperturbed state.

It is assumed that the various processes indicated schematically by the diagram occur with rates which are simply proportional to the appropriate concentration of relevant species. Thus, for example, the emission from the normally allowed member of the perturbed pair ($V' \rightarrow V$) would have an intensity equal to $k'_M[V']$, where $[V']$ is the concentration of CN molecules occupying the indicated state. Similarly, the rate at which CN molecules experience collisions which take them from one of the pair of perturbed states to the other, say ($V' \rightarrow R'$), is given by $k_{-c}\,[V']\,[N_T]$, where $[N_T]$ is the total concentration of species which are effective in inducing these non-radiative transitions.*

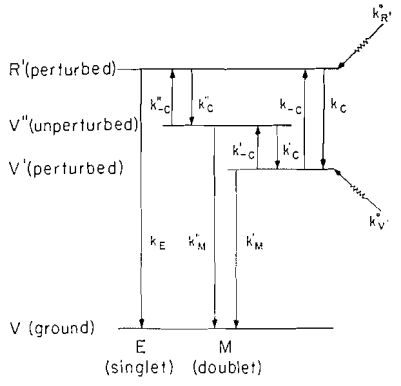

FIG. 6. Simplified energy level diagram, illustrating the transitions explicitly considered in the theoretical model involving the rotationally perturbed states of CN. The various k's refer to rate constants employed in the text.

**It may be noted that a more satisfactory expression which would take into account the different effectiveness of the individual species comprising the system would be exhibited in the form of a linear combination of their respective concentrations. Alternatively, the present simple form ascribes a composition dependence to the collisional rate constants.*

Because of the complexity of the production processes, the rates associated with them will not be given explicitly. Instead, $k^0_{R'}$ and $k^0_{V'}$ will be taken as the net rate of production into states R' and V' (apart from processes of collisional exchange) and will be assumed to depend upon the concentration and composition of the system. All rates are to be understood in terms of changes in concentration per unit time.

The intensity of radiation (neglecting self-absorption) emitted from the perturbed component of the main line ($V' \rightarrow V$) is given by

$$I'_{\mathrm{M}} = k'_{\mathrm{M}}[V'], \tag{1}$$

while for the unperturbed component ($V'' \rightarrow V$)

$$I''_{\mathrm{M}} = k''_{\mathrm{M}}[V'']. \tag{2}$$

Clearly, the intensity of the observed unresolved main line corresponds to

$$I_{\mathrm{M}} = I'_{\mathrm{M}} + I''_{\mathrm{M}}. \tag{3}$$

The intensity of the extra line ($R' \rightarrow V$) is given by

$$I_{\mathrm{E}} = k_{\mathrm{E}}[R']. \tag{4}$$

At any instant, the rates of change of molecules in the excited states are

$$\frac{d[V']}{dt} = k^0_{V'} + k_{\mathrm{c}}[R'][N_{\mathrm{T}}] + k'_{\mathrm{c}}[V''][N_{\mathrm{T}}] - k_{-\mathrm{c}}[V'][N_{\mathrm{T}}] - k'_{-\mathrm{c}}[V'][N_{\mathrm{T}}] - k'_{\mathrm{M}}[V'], \tag{5}$$

$$\frac{d[V'']}{dt} = k''_{\mathrm{c}}[R'][N_{\mathrm{T}}] + k'_{-\mathrm{c}}[V'][N_{\mathrm{T}}] - k'_{\mathrm{c}}[V''][N_{\mathrm{T}}] - k''_{-\mathrm{c}}[V''][N_{\mathrm{T}}] - k''_{\mathrm{M}}[V''], \tag{6}$$

$$\frac{d[R']}{dt} = k^0_{R'} + k_{-\mathrm{c}}[V'][N_{\mathrm{T}}] + k''_{-\mathrm{c}}[V''][N_{\mathrm{T}}] - k_{\mathrm{c}}[R'][N_{\mathrm{T}}] - k''_{\mathrm{c}}[R''][N_{\mathrm{T}}] - k_{\mathrm{E}}[R']. \tag{7}$$

The solution of these equations will give the dependence of the line intensities upon the total concentration and, hence, the pressure of the system.

However, it is not possible to solve the preceding equations without some explicit statement regarding the rates of production. In addition the complete solution of the equations is of interest only for transient circumstances, whereas the experimental conditions dealt with here are practically stationary. As a consequence, attention will be devoted only to the stationary solutions of the equations. To solve the equations, several assumptions will be introduced:

stationary hypothesis:

$$\frac{d[V']}{dt} = \frac{d[V'']}{dt} = \frac{d[R']}{dt} = 0; \tag{8}$$

collision hypothesis:

$$\begin{cases} k_{\mathrm{c}} = k_{-\mathrm{c}} \\ k'_{\mathrm{c}} = k'_{-\mathrm{c}} \\ k''_{\mathrm{c}} = k''_{-\mathrm{c}} \end{cases} \tag{9}$$

and

$$k_{\mathrm{c}} = k'_{\mathrm{c}} = k''_{\mathrm{c}}; \tag{10}$$

production hypothesis:

$$k^0_{R'} = \alpha k^0_{V'}, \qquad \alpha \text{ constant.} \tag{11}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The first assumption is justified on the basis of the experimental conditions. The second assumption partly conforms to microscopic reversibility which, however, is strictly applicable for conditions close to equilibrium. Equation [10] is introduced for simplicity. The third assumption also is introduced for simplicity. However, it is to be expected that the relative rates of production of CN molecules into the pair of perturbed states will vary with the mode of their production, especially when the latter is altered markedly (i.e., discharge vs. flame production). Since the radiative transition probabilities of the two components of the main line are the same,

$$k'_{M} = k''_{M} = k_{M}. \qquad [12]$$

Equations [5]–[7] are greatly simplified by substituting equations [8]–[12] and can be solved for the measured intensity ratio,

$$I_{E}/I_{M} = \frac{\alpha+(1+\alpha)(k_{c}/k_{M})[N_{T}]}{1+2(1+\alpha)(k_{c}/k_{E})[N_{T}]}. \qquad [13]$$

For indefinitely great pressures

$$(I_{E}/I_{M}) \rightarrow 1/2(k_{E}/k_{M}), \qquad [N_{T}] \rightarrow \infty, \qquad [14]$$

a result that is in accord with the notion that an equilibrium distribution among the various states should be achieved by the CN molecules at sufficiently high pressures. For extremely low pressures, on the other hand,

$$I_{E}/I_{M} \rightarrow \alpha, \qquad [N_{T}] \rightarrow 0, \qquad [15]$$

which is consistent with the hypothesis of production expressed in equation [11]. For sufficiently low pressures, one may expect that the rate of collisions in altering the populations in the various states becomes negligibly small, in which case the steady production must be equated to the rate of radiative transitions.

Equation [13] can be rearranged in a variety of ways and one form which is convenient for the subsequent analysis is the following:

$$\frac{\alpha-(I_{E}/I_{M})}{(I_{E}/I_{M})-1/2(k_{E}/k_{M})} = 2(1+\alpha)(k_{c}/k_{E})[N_{T}]. \qquad [16]$$

ANALYSIS OF EXPERIMENTAL DATA

The measured values of the intensity ratios have been subjected to an analysis in the light of the foregoing section and a reasonable fit is found. However, any fit of the data involving the empirical evaluation of three parameters cannot be weighted too heavily in judging the soundness of the theory. To achieve more confidence in the model described previously, the parameters must be compared with estimates of their values obtained from entirely different considerations of the phenomena. Such comparisons will be made in the course of the present section and give increased confidence in the general model.

Preliminary efforts at a least-squares analysis for the parameters were made but this approach was discarded because erratic values for the parameters resulted, one group of experimental data giving values of parameters seemingly unrelated to another group of data. Such discrepancies were caused by small effects due to changes in mixtures and flow rates of the reactants and to an inability to make sufficiently precise pressure measurements at low pressures.

The procedure employed to evaluate the parameters was an iterative one. It is evident

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that the asymptotic behavior at high and low pressures of the ratio of intensity I_E/I_M will give two parameters in equation [13]. Thus a preliminary value of α could be estimated from an extrapolated value of I_E/I_M at low pressures. The resulting value was employed in equation [16] to yield an expression which gave a linear extrapolation to high pressures, permitting an estimate to be made of k_E/k_M. The value resulting was then employed to obtain an expression which gave a linear extrapolation to low pressures, permitting a redetermination of the value of α. The iteration needed repetition only once to yield parameters which remained unchanged (to within 10%). With the final values of α and k_E/k_M obtained, the remaining parameter could be determined as an average value for all of the data. This procedure was carried through for the lines with $K' = 7$ and 15. The final plots for $K' = 7$ are given in Figs. 7 and 8 to illustrate the procedure for obtaining the asymptotic limits.

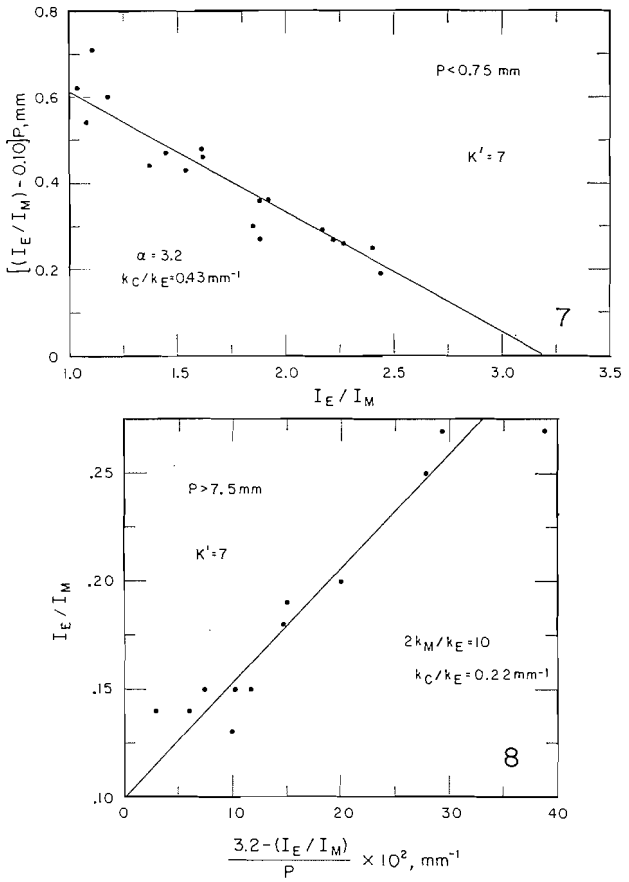

FIG. 7. The use of equation [13] to determine α.
FIG. 8. The use of equation [13] to determine $2k_M/k_E$.

The values of α which were obtained, as already indicated by the original data, suggested that the various lines exhibited a more-or-less uniform value of this parameter. To establish this, and eliminate the experimental uncertainties in the values of the pressure (at low pressures), the data were treated as in Fig. 9. The ratios of intensities of the lines

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

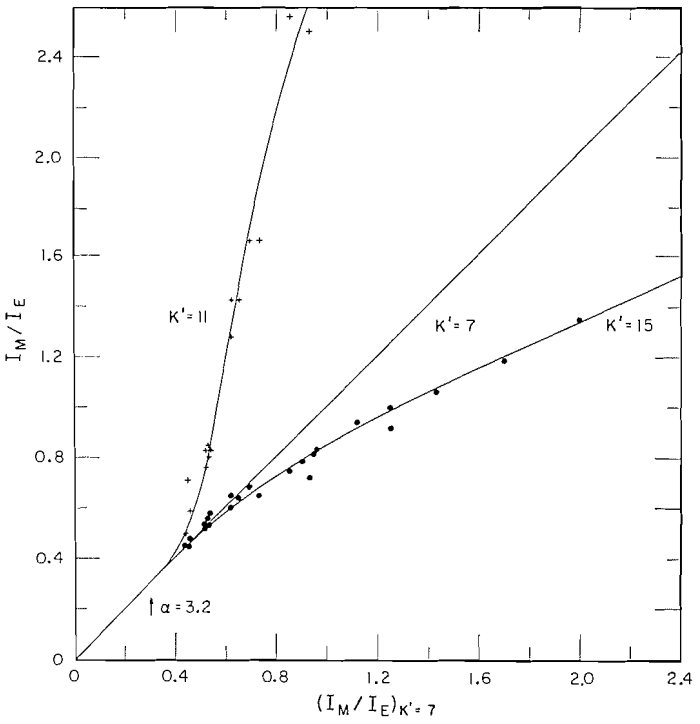

FIG. 9. Relations between intensity ratios at the same pressure for $K' = 7$, 11, and 15.

corresponding to $K' = 11$ and 15 have been plotted against the value for $K' = 7$, each point corresponding to the *same* value of the pressure, but differing, for any pair of lines, from point to point. It seems reasonable to suppose that for $K' = 7$, 11, and 15, α is approximately 3.2 since the curves for $K' = 11$ and 15 extrapolate smoothly to the value found for $K' = 7$.

With a more-or-less uniform value of α taken as 3.2 the analysis can be carried out to estimate k_E/k_M for the lines $K' = 7$, 11, 15 by extrapolation to high pressures. However, it is immediately apparent that the data for $K' = 11$ have a very small value of k_E/k_M from the low values of I_E/I_M at high pressures. The accuracy of the data do not permit a reliable estimate of k_E/k_M to be made for this line. As can be seen from equation [16], small values of k_E/k_M yield a pressure dependence (i.e. $[N_T]$) which is more reliably given by

$$\alpha-(I_E/I_M) \sim 2(1+\alpha)\,(k_c/k_E)[N_T](I_E/I_M), \qquad [17]$$

providing $k_E/k_M \ll 1$, which is apparently valid in the range of data where reliable estimates of I_E/I_M can be made. As a result k_c/k_E can be estimated from the data, but not k_c/k_M. The results obtained are summarized in Table II where $[N_T]$ has been measured in millimeters of mercury, for the lines with $K' = 7$, 11, 15.

The values of k_M/k_E obtained here from intensity measurements are uniformly one-half the values previously obtained by Wager (5) from wavelength measurements. However, Wager failed to consider that the main lines actually consist of doublets, only one component of which is affected by the rotational perturbation. It is evident that the frequency

TABLE II

Summary of the parameters

K'	α	$2k_M/k_E$	k_M/k_E (Wager)	k_c/k_M, mm^{-1}	k_c/k_E, mm^{-1}
7	3.2	10	10.6	0.068	0.34
11	3.2	>100 (est.)	130	—	1.13
15	3.2	5	5.6	0.104	0.26

displacements will be greater than those observed for the unresolved main line. Consequently the mixing of the two perturbed states will be greater than the values obtained by Wager, resulting in a smaller value of k_M/k_E. Better measurements of the perturbed line displacements should be possible from spectra obtained from flames at pressures near 0.1 mm Hg, so that the displacement of the main line will be less influenced by the unperturbed component.

The parameters have been incorporated into equation [13] for the ratio of intensities and the calculated curves are compared with the data in Figs. 3, 4, and 5 for pressures less than 100 mm, beyond which value the change in intensity ratio with pressure is very small. The fit to the data is relatively good.

One additional piece of information may be obtained from the data. The quantity k_c can be determined if the value of k_M is known (or that of k_E) or estimated. Since the ratio gives, when multiplied by the pressure, a measure of the ratio of collision frequency to the reciprocal of the radiative lifetime, these quantities may be evaluated independently. It is estimated from kinetic theory that a molecule of CN has approximately 10^6 collisions per second at 1 mm pressure and 300° K. Thus, for a radiative lifetime of 10^{-7} to 10^{-8} sec, it is estimated that $(k_c/k_M) \sim 0.1-0.01$ substantially in agreement with the observed values. Therefore, k_c is in fact a collision frequency corresponding essentially to the kinetic theory value. It seems unlikely that any more precise comparison can be made with the values obtained from our present analysis and those obtained otherwise. Rare gases (Table I) decrease k_c as compared with nitrogen.

DISCUSSION

The analysis of the experimental data provides support for the simple model which has been assumed; a competition between formation rates, radiative transitions, and collisional interchanges between the components of rotationally perturbed states seems adequate to account in a general way for the effect of pressure upon the relative intensities of the perturbed and extra lines in the emission spectrum of CN ($B\,^2\Sigma^+$–$X\,^2\Sigma^+$).

Nevertheless, the mathematical model, which has been presented, represents a great simplification of the actual state of affairs. This can be seen in part from the trends in the disparity between the data and the fitted curves. A more detailed examination would reveal that the parameters which have been used are better to be regarded as depending somewhat upon other parameters such as pressure. For example, k_c/k_E for the low-pressure extrapolation (Fig. 7) differs by about a factor of two from that for the high-pressure extrapolation (Fig. 8); fitting the whole range of pressures (Fig. 3 and Table II) gives intermediate values. Thus the results reported here represent some sort of average value. However, we should emphasize that the parameter α has been weighted in terms of low-pressure behavior. There seems to be no simple way of determining this quantity reliably under the opposite extreme of pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Because the model, which has been considered, has not dealt with the relative intensities of lines of different K's, the analysis is far from complete. In fact, since the anomalous intensities of the rotationally perturbed lines would seem to depend upon the actual rates of forming the CN in the several excited states, the present analysis, dealing with the *relative* rates of formation of specific pairs of these states, can only have a minor influence on that problem. Indeed the tacit use of a more-or-less constant value of α itself raises questions to which we have no ready answer.

ELECTROPHILIC CHARACTER OF OXYGEN ATOMS[1]

R. J. CVETANOVIĆ

ABSTRACT

The relative rates of reactions of oxygen atoms with a number of olefins in the vapor phase determined in previous work are summarized and supplemented by some additional results. The uncertainty in the values of the relative rate constants is now believed to be reduced to only a few per cent. A number of simple correlations observed previously have been re-examined on the basis of the more complete and more accurate list of values available at present. These correlations show a distinct electrophilic character of oxygen atoms in their reactions with olefins and their potential significance for the understanding of the finer details of these addition processes is discussed.

INTRODUCTION

Possibilities of finding simple correlations between reaction rates and physical properties of the reactants have been extensively explored at various times in the past with the object of establishing the factors which contribute to chemical reactivity. Thus, for example, considerations of the likely potential energy changes when two molecules interact have suggested linear dependence of activation energies on such quantities as heats of reaction or singlet–triplet excitation energies (1–6). In the case of metathetical reactions such views have found little experimental support. Some addition reactions, on the other hand, at least those involving a number of aromatic hydrocarbons (5, 6) and a somewhat restricted group of olefins (7), appear to show simple relations of this kind.

Reactions of atoms with series of structurally related compounds are particularly attractive for this type of investigation, especially if they can be studied under conditions where complications from solvent effects of variable magnitude can be eliminated. Solvent effects are of course absent in vapor phase reactions, but until very recently there were essentially no rate data for series of addition reactions in the vapor phase. An exception to this represented the reactions of H-atom additions to olefins, investigated by Robb and Melville (8). However, the work now in progress in this laboratory on these reactions at higher pressures and with the use of a different technique (9) reveals some differences in the values of the rate constants from those obtained by these authors. A discussion of the trends in reactivity in this reaction series has, therefore, to be delayed until the current work is completed.

Although free atoms as a rule possess unpaired electrons and thus have free radical character, they may be expected to react in particular reactions as either electrophilic, nucleophilic, or radical reagents. The type of the reactant character exhibited will be largely determined by the relative values of the electron affinities and ionization potentials of the atoms and their reaction partners.

In the past several years extensive information on the vapor phase reactions of oxygen atoms with olefins has been accumulated in this laboratory. Both the mechanism (10, 11) and the relative rates (12) have been investigated in considerable detail. The results of these studies show that ground-state oxygen atoms, which are diradicals, behave as distinctly electrophilic reagents in their reactions with olefins. The relative rates were found to exhibit approximate simple correlations with some physical properties of olefins

[1]*Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada; presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*
Issued as N.R.C. No. 5770.

and also to give linear "free energy" plots with the corresponding rates of some other electrophilic reagents studied in solutions. All such correlations show as a rule smaller or greater individual deviations from the basic trends. These deviations are only partly ascribable to experimental errors. In the present paper the earlier findings are summarized and supplemented by some additional experimental results with the particular object of obtaining further information on the extent and the nature of deviations from some of the observed correlations.

EXPERIMENTAL

Oxygen atoms were generated by mercury-photosensitized decomposition of nitrous oxide and the nitrogen produced served as an internal actinometer. A detailed study of this reaction (13) had shown that in this decomposition only nitrogen and oxygen atoms were initially formed. The oxygen atoms are in all probability in their ground, triplet $O(^3P)$ state. This is required by the spin conservation rule and is confirmed by comparisons with the analogous reactions with oxygen atoms generated by photolysis of nitrogen dioxide (14).

A circulating reaction system of total volume of 415 ml was used. The gases were circulated by means of an all-glass vertical plunger pump. The reaction cell was cylindrical, 5 cm in diameter and 10 cm long, and was illuminated by two low-pressure mercury lamps, one at each end of the cell. The reactant olefins were measured manometrically on a constant volume burette. By using mercury cutoffs instead of stopcocks the reactant olefins were kept from coming in contact with stopcock grease during the transfer into the reaction system and the run. Nitrous oxide was measured manometrically on a volume of 1000 ml before its introduction into the reaction vessel.

The rate constants of oxygen atom additions to olefins were measured relative to that of cyclopentene. In the cyclopentene reaction, ethylene is an important product while with the other olefins studied it is not formed or is produced at best only in very small amounts. At various olefin-to-cyclopentene ratios various amounts of ethylene are produced and the ratio of the rate constants can be calculated from the expression*

$$[1] \qquad k_1/k_2 = \log\{1-[\Delta N_2/(a_1)_1]+[\Delta C_2H_4/\alpha_2(a_1)_1]\}/\log\{1-[\Delta C_2H_4/\alpha_2(a_2)_1]\},$$

where subscript 2 refers to cyclopentene; $(a_1)_1$ and $(a_2)_1$ are the initial amounts of the competing olefin and cyclopentene, respectively; ΔN_2 and ΔC_2H_4 are the respective amounts of N_2 and C_2H_4 produced; and α_2 is C_2H_4/N_2 in the reaction of oxygen atoms with cyclopentene alone. In separate experiments α_2 has been found to be 0.270 at 26° C. The values of ΔC_2H_4 used in equation [1] have to be corrected for any ethylene produced from the competing olefin in the absence of cyclopentene. This is done by using the expression†

$$[2] \qquad (\Delta C_2H_4)_{\text{corrected}} = [(\Delta C_2H_4)_{\text{total}} - \beta\Delta N_2]/(1-\beta/\alpha_2),$$

where β is C_2H_4/N_2 in the absence of cyclopentene. In view of the relative magnitudes of α_2 and β these corrections are very small.

Of the reaction products only N_2 and C_2H_4 were of interest in the present work. Analyses were made therefore only for the non-condensible gases and the C_2 fraction. Both fractions were measured manometrically on a constant volume burette. The former was further analyzed by the use of a Cu–CuO furnace at about 250° (to remove CO and any H_2)

*Equation (5) of reference 12.

followed by mass spectrometric analysis to determine the small amount of CH_4 in the recovered N_2. The C_2 fraction was analyzed by mass spectrometer. A Le Roy still (15) followed by a "pump-out" trap was used to separate the two fractions from the rest of the products and the excess reactants present.

The reactants were of the best available grade and were degassed and bulb-to-bulb distilled *in vacuo* before use. Peroxides were removed from cyclopentene by filtering through an activated alumina column and rapid introduction into the vacuum apparatus. Large excess of nitrous oxide and high total pressures ensured no interference from chemical quenching reactions by the olefins.

RESULTS AND DISCUSSION

In the earlier work (12) it was found that *trans*-2-butene reacted somewhat more rapidly with oxygen atoms than *cis*-2-butene. However, the difference was almost comparable to the cumulative uncertainty in these determinations at that time and the reality of this observation was therefore in doubt. For this reason the relative rates of these two olefins have been redetermined with the use of the cyclopentene technique. This technique and the additional improvements in the handling of the reactants and the products have permitted appreciably more accurate determination of the relative rates than was originally possible. The results are given in Table I, in which the rate constants are determined relative to that of cyclopentene. It is seen that the rate of

addition of oxygen atoms to *trans*-2-butene is about 15% greater than it is for *cis*-2-butene. This is in approximate agreement with the previous finding although the difference between the two olefins is now found to be slightly smaller than in the earlier work.

Table I also includes the results of the determinations of the relative rate of reaction of oxygen atoms with *n*-hexene-1, which was not measured before. The particular interest in this compound in connection with the present work will be evident from the discussion which follows.

The temperature dependence of the relative rates of addition of oxygen atoms to several representative olefins has been recently determined. A full report on this work is being published elsewhere (16) and only a summary of the Arrhenius parameters obtained is given in Table II. In all cases the ratio of the pre-exponential factors (relative

TABLE II

Ratios of the Arrhenius pre-exponential factors and the differences in activation energies

to cyclopentene) is very close to unity. Within the experimental error the differences in reactivities in this reaction series appear then to be essentially entirely due to differences in the activation energies. In view of this any correlation of the logarithms of the rate constants for these reactions is to a good approximation equivalent to a correlation of the activation energies.

A list of the values available at present of the relative rate constants of the reactions of oxygen atoms with olefins at 25° C is given in Table III. As indicated in the table, besides several new determinations, most of these values are recent redeterminations and they agree very well with the previous values (12) which were in most cases obtained by

quite different techniques. The only exception to this is provided by *cis*-2-butene for which the rate constant determined in the present work is about 12% greater than previously found (12). It is believed that the present figures are accurate to within a few per cent in contrast to the previously estimated uncertainty of 10 to 15%.

The electrophilic character of oxygen atoms in their reactions with olefins is evident from the continuous increase in reactivity with increasing number of alkyl substituents on the doubly bonded carbon atoms, which primarily determine the electron-donating power, i.e. the basicity of olefins. Furthermore, in agreement with the electrophilic character of oxygen atoms their rate of addition to butadiene is comparable to that of two-substituted ethylenes while for radical reagents it would be expected to be much larger.

The logarithms of the relative rate constants of the reactions of oxygen atoms with olefins were previously found to be approximately linearly correlated with the following physical properties of the olefins (12): ionization potentials, heats of hydrogenation, and spectroscopic excitation energies. Also approximate linear free energy plots were obtained with some other series of electrophilic reactions (12), as well as approximate linear correlations with the theoretically derived excitation energies and bond orders (17). In view of the more complete and more accurate list of the relative rate constants for this reaction series now available (Table III), and additional literature information for some of the other reaction series considered, it is necessary to examine these correlations in somewhat greater detail.

In Fig. 1 are plotted logarithms of the relative rate constants for several series of electrophilic reactions against the ionization potentials of olefins. Of these series the oxygen atom additions to olefins are the only series of vapor phase reactions. The CCl_2 and CBr_2 series will be disregarded for the moment. It is seen that the bromination reactions give a good linear correlation. However, information is lacking for a greater variety of compounds that would permit finding out whether deviations shown by the oxygen atom and the peracetic acid series would appear in this case as well. In the latter two series it is found that the values of the rate constants for all the singly substituted ethylenes remain essentially constant and thus do not follow the trend in the ionization potentials. The same holds also for the two-substituted ethylenes.

In Fig. 2 relative rate constants are plotted against the excitation energies obtained by molecular orbital calculations (17). Excellent linear correlation is shown by the peracetic acid series. The same is also largely true for the oxygen atom and the bromination series, although in the former the value for tetramethyl ethylene is somewhat low and in the latter there is perhaps suggestion of a slight curvature. The value for the reaction of oxygen atoms with butadiene does not fit into this plot, although it does fit quite well into the ionization potential plot in Fig. 1 and the plot of the log k values against the bond orders in Fig. 3 (in these plots butadiene is indicated by squares instead of circles). The bond orders have been obtained by molecular orbital calculations (17) and they correlate well with the logarithms of the rate constants for the peracetic acid, oxygen atom, and bromination series, although the plots are slightly curved.

The deviations from the straight line plots in Fig. 1 for the oxygen atom and the peracetic acid series are as a rule larger for bigger substituents. Thus, for example, in the oxygen atom series the deviations for the monosubstituted ethylenes are in the order propylene < 1-butene < *n*-1-hexene, and similarly for the peracetic acid series the order is propylene < *n*-1-pentene < *n*-1-hexene < *n*-1-octene < *n*-1-decene. In view of this, the deviations could perhaps be ascribed to steric hindrance. However, it is significant that these deviations disappear in the plots against the theoretically derived excitation

energies and bond orders. The same is true for the "free energy" plots shown in Fig. 4. The plot of log k values for the peracetic acid reactions vs. log k_O (the values for the oxygen atom reactions) shows no deviations of this kind. It appears, therefore, that the trend in the ionization potentials is only an approximate measure of the basicity of olefins as determined, for example, by the trends in the oxygen atom reactions.

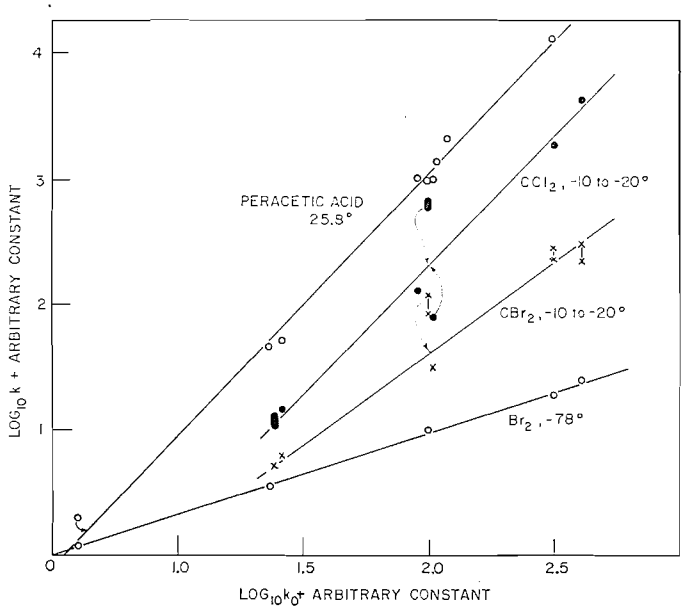

FIG. 4. Free energy plots for bromination, peracetic acid, CBr_2, CCl_2, and oxygen atom reactions with olefins. (Source of data: as given in caption of Fig. 1.)

There is little quantitative information on the basicity of olefins. The basicity towards silver ion was found by Winstein and Lucas (18) to decrease rather than increase with increasing alkyl substitution, presumably because of steric hindrance to the approach of the large ion to the π-electrons of the olefin. Brown and Brady (19) have measured Henry's law constants for olefin–HCl mixtures at −78° and the order of basicity found by these authors is qualitatively the same as the order of reactivity for the considered electrophilic reactions. Unfortunately the data cannot be used for a quantitative correlation. West (20) has recently obtained some quantitative information for the basicity of a number of olefins towards phenols from the shifts in the frequency of the O—H infrared band due to hydrogen bond formation. Plots of log k values against the frequency shifts due to hydrogen bonding of olefins with p-fluorophenol are given in Fig. 5. For the bromination series the available information is very incomplete. For the oxygen atom and the peracetic acid series there is a good correlation except that the shifts are exceptionally large for the α,α-disubstituted olefins* and therefore these compounds show large deviations. In addition to this irregularity, the experimental uncertainty in these values of about ± 6 cm^{-1} is relatively large for the purpose of quantitative correlations of this kind.

The mechanisms of reactions of electrophils with aromatic compounds have been extensively investigated. The mechanism of electrophilic aromatic substitution has been

**Possible reasons for this are discussed in reference 20. In Fig. 5 the frequency shift for 2-methyl-1-butene has been used for isobutene, for which the frequency shift was not determined.*

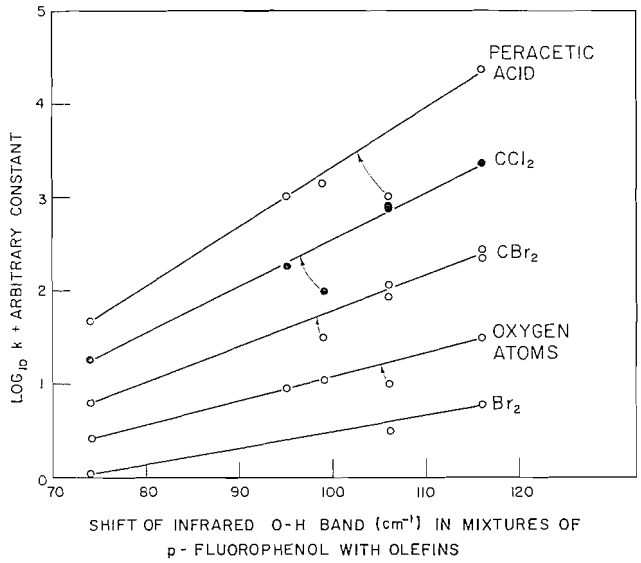

FIG. 5. Plot of log k values against the frequency shift of infrared O—H band in mixtures of p-fluorophenol with olefins. (Source of data: frequency shifts, reference 20; rate constants, as given in caption of Fig. 1.)

recently discussed by Brown (21) with the conclusion that it involves unsymmetrical inner charge-transfer complexes (or σ complexes) as stable intermediates, rather than outer complexes (or π complexes), in which only slight charge transfer to the electrophil occurs. He derived certain theoretical quantities (Z values) as indices of chemical reactivities of positions in aromatic compounds for a given electrophil. These are largely determined by the difference of the electron affinity of the electrophil and the ionization potentials of the aromatic compounds. An extension of this treatment to some electrophilic addition reactions appears to be contemplated.

In the case of oxygen atom addition to olefins there is indication that the rate of addition and the orientation are not governed by the same factors. This conclusion is based on the observation (11, 12) that in 2-pentene the addition takes place exclusively at the doubly bonded C-atom to which methyl group is attached (and not to the one to which ethyl group is attached) although the rates of addition to propylene and to 1-butene are the same and in both cases terminal addition occurs. Similarly the rates of addition to 2-butene and 2-pentene are again about the same. If the same factors governed the over-all reactivity and the orientation, about equal addition to the two doubly bonded C-atoms in 2-pentene would be expected. For these reasons it appears that the transition state responsible for the observed activation energies must occur quite early in the reaction process, perhaps as shown qualitatively in Fig. 6.

In their approach to an olefinic double bond, oxygen atoms experience at first a repulsion, but already at relatively large distances the electrostatic interaction leads to a lowering of the potential energy of the system. It seems necessary to assume that at this stage the atoms are not localized on one of the two doubly bonded C-atoms and the minimum at A in Fig. 6 is visualized as perhaps corresponding to a charge-transfer complex (using this term somewhat loosely). In this particular process the very exothermic transformation to the intermediate B is believed to occur rapidly and does not influence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

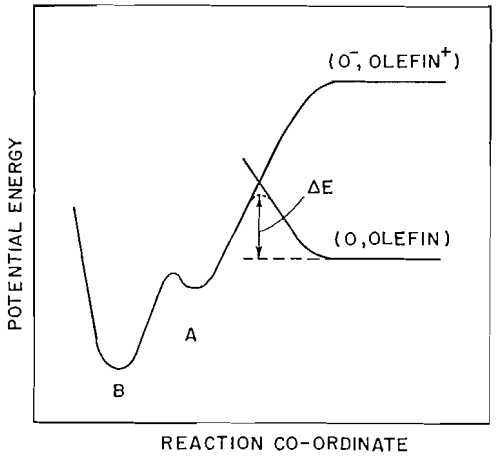

FIG. 6. Potential energy – reaction co-ordinate schematic diagram for the reaction of oxygen atoms with olefins.

the over-all rate of addition. In B the oxygen atom is localized on one of the two double-bond C-atoms and this intermediate is believed to be a triplet biradical (probably with some Zwitterion character) when the oxygen atoms reacting with the olefin are in their ground state (^3P). In agreement with this, both *cis*- and *trans*-epoxides are formed from internal olefins, and also intramolecular rearrangements to carbonyl compounds take place (11).

It is also possible that in some cases the transformation from A to B in Fig. 6 may be rather slow, in which case the observed rate is a composite quantity, as discussed in connection with a study of the rates of ozone addition to olefins in the vapor phase (22).

The diagram in Fig. 6 is of the type discussed in the Introduction and one could, therefore, adopt the usual assumptions (1–6) and from simple geometrical considerations arrive at the prediction of approximate linear dependence of the activation energies on such a property of the olefins as, for example, the ionization potentials. At the same time, some of these assumptions are very arbitrary and can only be justified by extensive agreement of experimental observations with the predictions. Moreover, the exact significance of the experimentally observed approximate linear correlations is uncertain since several physical properties of the olefins show approximately parallel trends.

The significance of the free energy plots in Fig. 4 has been discussed in some detail previously (12). In as much as in a plot of log k_1 vs. log k_2 the linear correlation persists over a temperature range, then in each one of the two reaction series either (*a*) the entropies of activation are to a good approximation equal for all the members of the series (isoentropic series), (*b*) the enthalpies of activation are equal (isoenthalpic series), or (*c*) there is linear correlation between the enthalpies and entropies of activation (compensating or additive enthalpy–entropy effect). In view of this, the slope of the free energy plot for peracetic acid and oxygen atoms represents the constant ratio of the activation energy differences for equal structural changes in the olefins multiplied by the inverse ratio of the absolute temperatures at which rate determinations have been made in the two series (cf. equation (14*a*) of reference 12) since both these series of reactions are approximately isoentropic. Any contributions of the solvent effects to the activation energies of the peracetic acid reactions must be small or to a good approximation constant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

for the considered cases. These conclusions perhaps also approximately apply to the other series of reactions considered here, although their temperature coefficients at sufficiently large temperature intervals are not known.

The good correlations in the free energy plots in Fig. 4 for the peracetic acid and bromination reactions, when plotted against the logarithms of the rate constants of the oxygen atom reactions, show that these values can serve as an empirical measure of the basicity of olefins as it manifests itself in such addition reactions. This is equivalent to defining Hammett σ and ρ functions for these processes (12).

The series of CBr_2 and CCl_2 reactions with olefins have been considered here for the sake of completeness. They show general electrophilic trends but at the same time there are some large systematic deviations in the plots in Figs. 1–5. Thus, for example, in Fig. 4 the rate constants for cyclohexene are too low and for isobutene they are too high. In the plot in Fig. 5, the discrepancy for cyclohexene remains while it disappears for the α,α-disubstituted olefins. This is due to the exceptionally high values obtained for infrared O—H band frequency shifts in mixtures of phenols with these latter compounds and it may perhaps be fortuitous. There is need for more extensive experimental information on these reaction series in order to ascertain in greater detail the extent and the nature of the deviations.

ATOMIC REACTIONS IN THE UPPER ATMOSPHERE[1]

JOSEPH KAPLAN, WILLIAM J. SCHADE, CHARLES A. BARTH, AND ALVIN F. HILDEBRANDT

ABSTRACT

The reaction rates of nine upper atmosphere chemical reactions have been analyzed with a digital computer. The dependence of the loss rates of atomic nitrogen and atomic oxygen as well as the relative concentrations of nitric oxide and nitrogen dioxide in the upper atmosphere are given. Using a flow system, nitrogen atoms were produced and then titrated by the addition of NO. The resulting nitrogen and oxygen atom densities were measured with an e.p.r. spectrometer. The dependence of the intensities of the nitrogen afterglow and the NO afterglow were related to the atom densities. An excitation mechanism for OI 5577 has been determined from the relation of the intensity of λ 5577 to the atom densities.

ATOMIC REACTIONS IN THE CHEMOSPHERE

In the upper half of the earth's chemosphere between 65 and 120 km, reactions involving atomic species constitute the predominant chemical activity. The atoms involved are those produced by the solar photodissociation of the molecular atmospheric gases, nitrogen, oxygen, and hydrogen. The atoms react with one another and with the remaining molecules that are present. The dominant upper atmosphere reactions between atomic nitrogen and atomic oxygen and their various molecular forms are described by the following nine equations:

$$N + N + M \rightarrow N_2 + M \quad [1]$$

$$N + O + M \rightarrow NO + M \quad [2]$$

$$O + O + M \rightarrow O_2 + M \quad [3]$$

$$N + NO \rightarrow N_2 + O \quad [4]$$

$$N + O_2 \rightarrow NO + O \quad [5]$$

$$O + O_2 + M \rightarrow O_3 + M \quad [6]$$

$$O + O_3 \rightarrow O_2 + O_2 \quad [7]$$

$$NO + O + M \rightarrow NO_2 + M \quad [8]$$

$$NO_2 + O \rightarrow NO + O_2 \quad [9]$$

In the first three reactions, atomic nitrogen and atomic oxygen recombine in three-body reactions. Atomic nitrogen also reacts rapidly with nitric oxide and more slowly with molecular oxygen in reactions 4 and 5. The formation and destruction of ozone are governed by reactions 6 and 7 and the formation and destruction of nitrogen dioxide, by reactions 8 and 9. The rate coefficients for reaction 1 and reactions 4 through 9 are available in the recent literature (1, 2). Recently, in an experiment at the Jet Propulsion Laboratory, the rate coefficients of reactions 2 and 3 have been measured (3).

The differential equations describing the rates of change of density of the various species are the following:

$$-[\dot{N}] = 2k_1[N]^2[M] + k_2[N][O][M] + k_4[N][NO] + k_5[N][O_2] \quad [10]$$

$$-[\dot{O}] = k_2[N][O][M] + 2k_3[O]^2[M] - k_4[N][NO] - k_5[N][O_2] + k_6[O][O_2][M] + k_7[O][O_3] + k_8[NO][O][M] + k_9[NO_2][O] \quad [11]$$

[1]*Contribution from the Institute of Geophysics, University of California, Los Angeles, California, and the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960. The research reported in this paper was sponsored in part by the Geophysics Research Directorate, Air Force Cambridge Research Center, Air Research and Development Command, under Contract No. AF 19(604)-2143, and in part by the National Aeronautics and Space Administration at the Jet Propulsion Laboratory.*

$$-[\dot{N}O] = -k_2[N][O][M] + k_4[N][NO] - k_5[N][O_2] + k_8[NO][O][M] - k_9[NO_2][O] \quad [12]$$

$$-[\dot{O}_2] = -k_3[O]^2[M] + k_5[N][O_2] + k_6[O][O_2][M] - 2k_7[O][O_3] - k_9[NO_2][O] \quad [13]$$

$$-[\dot{O}_3] = -k_6[O][O_2][M] + k_7[O][O_3] \quad [14]$$

$$-[N\dot{O}_2] = -k_8[NO][O][M] + k_9[NO_2][O] \quad [15]$$

This set of simultaneous, non-linear differential equations has been numerically integrated for several different initial conditions on the Jet Propulsion Laboratory's IBM 704 digital computer (3). The results of one of these numerical calculations may be seen in Fig. 1. Although the atom densities used in this calculation pertain to a laboratory

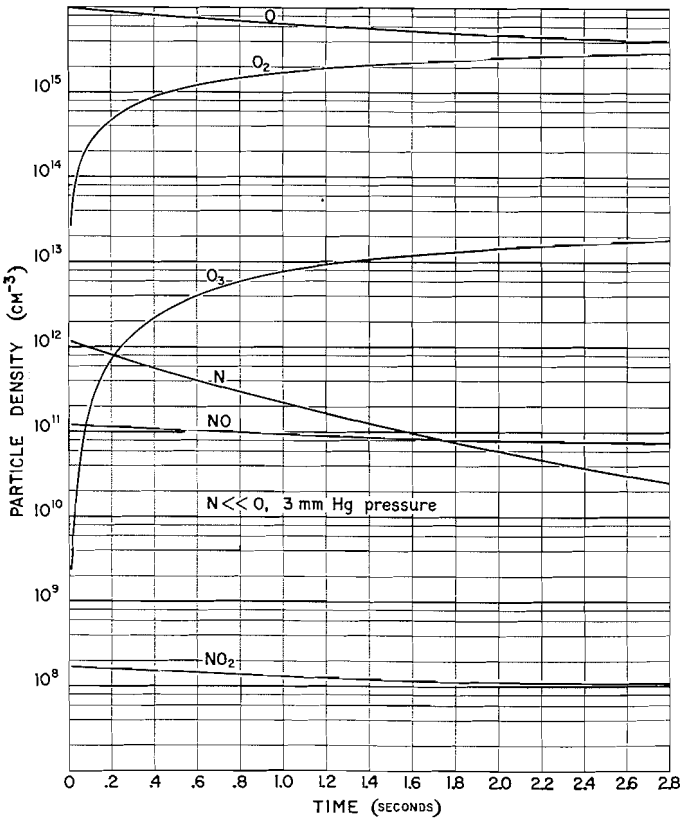

FIG. 1. Change of particle densities with time.

experiment, the conditions are analogous to those of the upper atmosphere in that the density of oxygen atoms is much greater than the density of nitrogen atoms. An analysis of the results of this numerical integration when applied to the chemosphere between 80 and 120 km gives the following results:

1. The rate of loss of atomic nitrogen is governed by its reaction with molecular oxygen, reaction 5.

2. The concentration of nitric oxide is determined by reaction 5 and the reaction of atomic nitrogen with nitric oxide, reaction 4. The density of nitric oxide is much less than, and proportional to, the density of the molecular oxygen present.

$$[NO] = k_5/k_4[O_2] \quad [16]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3. The concentration of nitrogen dioxide in the upper atmosphere is governed by the reactions of atomic oxygen with nitric oxide and nitrogen dioxide, reactions 8 and 9. The density of nitrogen dioxide is less than, and proportional to, the density of nitric oxide.

$$[NO_2] = (k_8/k_9)[M][NO] \qquad [17]$$

4. The rate of loss of atomic oxygen is determined by its three-body recombination, reaction 3.

ATOM DENSITY MEASUREMENTS

In some recent work at the Jet Propulsion Laboratory, atom densities of mixtures of nitrogen atoms and oxygen atoms have been measured with an electron paramagnetic resonance spectrometer (4). With this technique, atom densities as low as 5×10^{12} atoms/cm^3 have been determined. The nitrogen atoms are produced in a flow system by a 2450-mc microwave discharge operating at a total pressure of 3 mm Hg. The oxygen atoms were produced by titrating the atomic nitrogen with nitric oxide. The resulting mixture of atoms was pumped through the e.p.r. resonant cavity, which is located between the pole faces of an electromagnet. It is in this cavity that the atom densities are measured. The ground state of atomic nitrogen is ^4S with $J = 3/2$ and a Lande g factor of 2. Atomic oxygen has a ^3P ground state with a Lande g factor of 3/2. Both the $J = 2$ and $J = 1$ states of oxygen are measured.

The results of this study are shown in Fig. 2. The atom densities are plotted along the

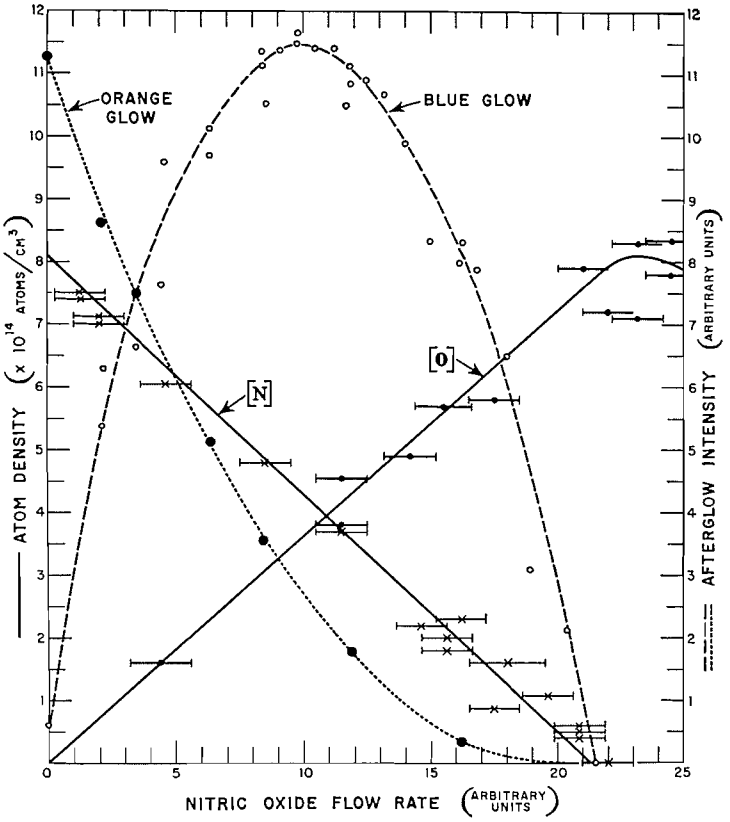

FIG. 2. Dependence of afterglow intensities on atom densities.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ordinate and the amount of NO added is plotted along the abscissa. Since the atomic nitrogen – nitric oxide reaction is very fast (1), for every nitric oxide molecule added, a nitrogen atom is converted into an oxygen atom before the gas enters the resonant cavity. Hence, the straight lines with slopes of 45° and −45° for the oxygen and nitrogen atom densities, respectively. Nitric oxide was continued to be added after all the nitrogen atoms were consumed. The loss of oxygen atoms on the right-hand side of the figure is governed by the nitric oxide – atomic oxygen reaction which is still taking place as the gas is pumped through the resonant cavity. Figure 1 is a decay study of the experimental conditions occurring near the minimum of nitrogen atom density and the maximum of oxygen atom density.

AFTERGLOW INTENSITY MEASUREMENTS

The intensity of the molecular nitrogen first positive bands that are emitted by the nitrogen afterglow is proportional to the square of the nitrogen atom density (5). In some work at the University of California, Los Angeles, it has been shown that the intensity of the nitric oxide beta bands is proportional to the product of the nitrogen atom density and the oxygen atom density (6). Using the preceding technique of addition of NO to atomic nitrogen, the atomic nitrogen density was decreased and the atomic oxygen density was increased. A simultaneous photometric recording of the intensities of the N_2 first positive bands and the NO beta bands provides data for interpreting the dependence of the intensity of the NO beta bands on the relative atomic densities of oxygen and nitrogen. A plot of I_b (intensity of NO beta bands) against the square root of the intensity of the N_2 first positive bands then yields a parabolic curve. This curve is consistent with the interpretation that the fast reaction 4 produces an increase in the atomic oxygen density which is equal in magnitude to the decrease in atomic nitrogen density, i.e.,

$$d[O] = -d[N]. \qquad [18]$$

Integration of 18 gives

$$[O] = [N_0] - [N], \qquad [19]$$

in which $[N_0]$ is the initial atomic nitrogen density before addition of NO and the initial atomic oxygen density is zero. Assuming that the emission of the beta bands follows a recombination of type 2, the intensity of the beta bands can be written

$$I_b = k_b[N][O][M]. \qquad [20]$$

Substitution of [19] into [20] gives

$$I_b = k_b[M][N]([N_0] - [N]) \qquad [21]$$

so that a plot of [21] against [N] produces the same parabolic curve obtained experimentally. The afterglow recombination mechanism 2 was also concluded in previous work (7). The dependence of the intensity of the N_2 first positive bands and the nitric oxide beta bands is plotted in Fig. 2 against flow rate of added nitric oxide. The parabolic shape of these curves illustrates their relationship to the nitrogen and oxygen atom densities.

Excitation of the atomic oxygen green line, OI 5577, which is a prominent spectral feature emanating from the upper atmosphere, has been studied recently by the addition of NO to active nitrogen (6). When atomic oxygen is added to atomic nitrogen by reaction 4, OI 5577 is found to be excited. As more NO is added to the system, the intensity of λ 5577 goes through a maximum value and decreases rapidly as the atomic nitrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

density approaches zero. An excitation mechanism which is consistent with the relation between the intensity of λ 5577 and the variation of the atomic species is found to be

$$N + N + O \rightarrow N_2 + O(^1S) \quad [22]$$

$$O(^1S) \rightarrow O(^1D) + \lambda\ 5577 \quad [23]$$

in which ^1S is the upper state and ^1D the lower state of atomic oxygen for the emission of λ 5577. When sufficient NO is added to the system so that all atomic nitrogen has been removed, a condition is obtained in which the only remaining atomic species is that of oxygen so that $[O] = [N_0]$ (see Fig. 2). Under this condition the excitation of OI 5577 should take place by the reaction

$$O + O + O \rightarrow O_2 + O(^1S) \quad [24]$$

$$O(^1S) \rightarrow O(^1D) + \lambda\ 5577 \quad [25]$$

which was proposed for the excitation occurring in the upper atmosphere (8). It has been found in the laboratory that reaction 22 is much more efficient than reaction 24 in the excitation of the ^1S state of atomic oxygen.

THREE-BODY RECOMBINATION OF GASEOUS IONS[1]

TAKAYUKI FUENO, HENRY EYRING, AND TAIKYUE REE

ABSTRACT

The recombination of gaseous ions in the presence of third bodies is assumed to follow a sequence of two bimolecular steps: $M + X^+ \rightleftharpoons MX^+$ and $MX^+ + Y^- \rightarrow XY + M$. The termolecular rate constants of the over-all processes are calculated for several ionized gases at various temperatures. For the calculation, the equilibrium internuclear separation and the corresponding binding energy of a complex ion, MX^+, are obtained by minimizing the interaction energy between M and X^+, which is approximated to the sum of the Lennard-Jones potential for the M–X interaction and the polarization energy between M and X^+. The recombination coefficients of some ionized gases at 288° K and various pressures are calculated and compared with the observed data. The agreement is found to be satisfactory. The limitations of this theoretical approach are discussed.

INTRODUCTION

The surplus energy evolved by the neutralization (or recombination) between positive and negative ions in a gaseous phase can be removed as radiation or taken up as the energy of excitation or homolytic dissociation of the recombination product (1, 2). Thomson (3) developed a gas-kinetic theory of the ion recombination occurring by the three-body process. The theory was based on the concept that two ions of opposite signs are only capable of recombination if either of the two ions collides with an uncharged molecule within a certain maximum distance from the other. The theory has proved very successful in the pressure range from 100 to 1000 mm Hg.

Recently, Bunker and Davidson (4) have proposed a kinetic theory to account for the rates of halogen atom recombinations in the presence of various third bodies. The theory assumes that an equilibrium concentration of intermediate complex is formed between halogen atoms and third bodies and that the collisions of the complexes with halogen atoms result in the halogen atom recombinations, releasing the third-body molecules. The dependence of the termolecular reaction rate constants upon temperature and third body has thus been interpreted quantitatively.

The present paper outlines a theoretical method of predicting the rates of the three-body recombinations of gaseous ions. The treatment pursues essentially the Bunker–Davidson theory for atom recombinations (4), except that, in our approach, the electrostatic nature of the recombining species is also taken into account. The theory is successfully applied to the calculation of the recombination coefficients for some ionized gases.

CALCULATION METHOD

An over-all three-body process of ion recombination, $X^+ + Y^- + M \rightarrow XY + M$, is assumed to be divided into a sequence of two bimolecular steps:

$$M + X^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MX^+ \qquad [i]$$

$$MX^+ + Y^- \xrightarrow{k_2} XY + M \qquad [ii]$$

where M denotes a third body. If MX^+ is a loose complex and M is in a large excess

[1]*Contribution from the Department of Chemistry, University of Utah, Salt Lake City, Utah; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

compared with X^+ and Y^-, then MX^+ will be in equilibrium with X^+ and M, undisturbed by step [ii]. Then the rate constant, k_t, for the over-all termolecular process can be approximated as (4, 5)

$$[1] \qquad k_t = K_1 k_2,$$

K_1 being the equilibrium constant for step [i].

Assuming that the complex MX^+ is an ion cluster, we now calculate the equilibrium constant, K_1. The complex may be loose enough so that M and X^+ are free to rotate and vibrate within the complex (6). Then, all the internal parts of the partition functions of the separated reactants will also appear in the partition function of the complex and will cancel out in the expression of the equilibrium constant, K_1, in terms of partition functions. Thus,

$$[2] \qquad K_1 = \frac{F_{t,MX^+} F_{v,MX^+} F_{r,MX^+}}{F_{t,M} F_{t,X^+}} e^{\epsilon_m/kT}$$

where ϵ_m is the binding energy of MX^+, and the subscripts t, v, and r indicate that the F's are respectively the translational, vibrational, and rotational partition functions of the substances indicated.

If we assume that the complex is a rigid rotor as well as a harmonic oscillator and that neither of the rotational and vibrational energies of the complex can exceed the binding energy ϵ_m, then (7)

$$[3] \qquad F_{r,MX^+} = \frac{8\pi^2 \mu_+ r_m^2 kT}{h^2} (1 - e^{-\epsilon_m/kT})$$

and

$$[4] \qquad F_{v,MX^+} = \frac{1 - e^{-\epsilon_m/kT}}{1 - e^{-\epsilon_v/kT}}$$

where μ_+ is the reduced mass of the complex, r_m the equilibrium internuclear distance between M and X^+ in the complex, and ϵ_v the vibrational quantum of the $M—X^+$ bond. Substituting all the partition functions into eq. 2, we obtain

$$[5] \qquad K_1 = \frac{h^3}{(2\pi\mu_+ kT)^{3/2}} \cdot \frac{8\pi^2 \mu_+ r_m^2 kT}{h^2} \cdot \frac{(1 - e^{-\epsilon_m/kT})^2 e^{\epsilon_m/kT}}{1 - e^{-\epsilon_v/kT}}.$$

For step [ii] of the recombination we assume that every collision between MX^+ and Y^- leads to the neutralization with the liberated energy which is carried away by the third body, M. Then, assuming that the steric factor for the collision is unity, we can write

$$[6] \qquad k_2 = Q \left\{ \frac{8kT(m + m_+ + m_-)}{\pi(m + m_+) m_-} \right\}^{\frac{1}{2}},$$

where Q is the effective collision cross section, and m, m_+, and m_- are the masses of M, X^+, and Y^-, respectively.

The feature of the collision cross section for ion recombinations is largely different from that of the usual gas-kinetic collisions, because of a considerable extent of coulombic attraction between the two recombining ionic partners. One charged particle can be captured by the other when the attraction exceeds the relative kinetic energy of the ion pair. If the gaseous ions are in thermal agitation, the largest permissible distance of approach, δ, for ions to recombine is (3)

$$[7] \qquad \delta = \frac{2e^2}{3kT},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where e is the electronic charge and δ is of the order of 10^{-6} cm at ordinary temperatures. The effective cross section, Q, for the ion recombination is given by

$$[8] \qquad Q = \pi\delta^2 = \frac{4\pi e^4}{9k^2T^2}.$$

From eqs. 1, 5, 6, and 8 we finally obtain the termolecular rate constant, after the proper cancellation,

$$[9] \qquad k_t = \frac{32\pi h e^4 r_m^{\,2}(m+m_+ +m_-)^{\frac{1}{2}}}{9\mu_+^{\frac{1}{2}} m_-^{\frac{1}{2}}(m+m_+)^{\frac{1}{2}}k^2T^2} \cdot \frac{(1-e^{-\epsilon_m/kT})^2 e^{\epsilon_m/kT}}{1-e^{-\epsilon_v/kT}}.$$

In order to obtain the values of k_t for recombining systems from eq. 9 it is necessary to evaluate the three parameters, r_m, ϵ_m, and ϵ_v. For evaluating the r_m and ϵ_m, both the X^+ and M are idealized as rigid spheres. If X and M are molecules with little or no permanent dipole, then the potential of interaction between X^+ and M will be reasonably approximated to the sum of the Lennard-Jones potential of interaction between the two neutral molecules and the polarization energy, i.e., the attraction between the static charge on X^+ and the dipole moment induced on M

$$[10] \qquad \epsilon_L(r) = 4\epsilon_0\left\{\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right\} - \frac{\alpha e^2}{2r^4}.$$

Here ϵ_0 and σ respectively denote the maximum depth of the potential well and the closest approach for the interaction between X and M, r is the internuclear separation of the MX^+ complex, and α is the angle-average polarizability of M. The equilibrium distance, r_m, and the corresponding binding energy, ϵ_m, of the complex can be obtained by minimizing the $\epsilon_L(r)$ with respect to r, provided that the values of ϵ_0, σ, and α are known.

The vibrational quantum, ϵ_v, can be calculated from [8]

$$[11] \qquad \epsilon_v = 2a\,(\epsilon_r\epsilon_m)^{\frac{1}{2}}$$

where $\epsilon_r = h^2/8\pi^2\mu_+ r_m^2$ and a is a parameter appearing in the Morse potential function for the complex in the form

$$[12] \qquad \epsilon_M(r) = \epsilon_m[\{1-e^{-a[(r/r_m)-1]}\}^2 - 1].$$

The value of a is obtainable, in principle, by making the Morse potential curve (eq. 12) fit the Lennard-Jones-type potential curve (eq.10). A practical method employed here for this purpose is setting the bond-stretching force constant, f_M, derived from the Morse function

$$[13] \qquad f_M = \left[\frac{d^2\epsilon_M(r)}{dr^2}\right]_{r=r_m} = \frac{2a^2\epsilon_m}{r_m^{\,2}}$$

equal to the force constant, f_L, from the Lennard-Jones-type function

$$[14] \qquad f_L = \left[\frac{d^2\epsilon_L(r)}{dr^2}\right]_{r=r_m} = \frac{24\epsilon_0}{r_m^{\,2}}\left\{26\left(\frac{\sigma}{r_m}\right)^{12} - 7\left(\frac{\sigma}{r_m}\right)^{6}\right\} - \frac{10\alpha e^2}{r_m^{\,6}}.$$

Thus, the three parameters, r_m, ϵ_m, and ϵ_v, involved in eq. 9 can straightforwardly be evaluated for the interacting systems for which the data of the relevant parameters, ϵ_0, σ, and α are available.

COMPARISON WITH EXPERIMENTS

It is experimentally established that the rates of recombination of gaseous ions are of a first order with respect to each concentration of positive and negative ions. The bimolecular rate constants, ρ, defined as

$$[15] \qquad \frac{d(X^+)}{dt} = \frac{d(Y^-)}{dt} = -\rho(X^+)(Y^-),$$

are usually called the recombination coefficients (1, 2). If the recombination takes place by the two-step mechanism assumed in this paper, the recombination coefficient should be equal to the product of the termolecular rate constant and the third-body concentration, i.e.

$$[16] \qquad \rho = k_t(M).$$

Over the pressure range from 100 to 760 mm Hg, the values of ρ for the recombinations in familiar gases such as CO, CO_2, SO_2, N_2O, and air have been observed to be proportional to the gas pressure (9). This observation indicates that over this pressure range the three-body process is the most important for the recombinations of ions at least in the cases of the above-mentioned molecular gases.

In order to obtain the value of ρ for recombining ions in a given gas, molecular configurations of X^+ and Y^- need to be specified. According to the mass spectroscopic experiments, most of the positive ions formed by electron impact with molecules are, in general, of the simple molecular type, i.e., the lowest appearance potential of a positive ion from a molecule corresponds to the simple removal of an electron without dissociation (10). Probably, a similar generalization applies to the ionizations of molecular gases resulting from the action of X-rays, a method which was often employed in earlier years (9, 11). Thus, it is assumed throughout the present paper that X^+ is the molecular ion formed by the removal of an electron from M.

Negative ions can be formed by the collisions of electrons with neutral molecules. However, it is not, as a rule, obvious what products result from the collisions. The best information has been given by mass spectroscopic studies. For instance, the most prominent negative ion observed in air and oxygen under pressures of 0.1 to 10 mm Hg has been identified to be O^-, instead of O_2^- (12). The atomic ion O^- is found to be the most abundant (or the only) negative ion also in the cases of CO (13), CO_2 (14), N_2O (15), NO (13, 15), NO_2 (16), and SO_2 (17). Thus, it appears very likely that the gaseous oxide molecules as well as oxygen molecules produce negative ions most effectively by the "resonance electron-capture dissociation (18)." In our calculation, therefore, Y^- is assumed to be the atomic ion O^- for all of the oxygen-containing molecules investigated.

According to the procedure described in the preceding section, all the potential parameters associated with the M—X^+ interactions were calculated for various gases. The data of the Lennard-Jones potential parameters, σ and ϵ_0, and the polarizability, α, for these gases were taken from the literature (19). All of the parametric values obtained are summarized in Table I.

Figure 1 shows the potential curves of interaction between CO_2^+ and CO_2 as a typical example of the M—X^+ interaction curves. The potential parameters used for drawing these curves are those listed in Table I. It is seen in Fig. 1 that the Morse curve somewhat deviates from the Lennard-Jones-type curve when the internuclear separation is fairly large compared with the equilibrium separation. However, any further modification of

the a-value in this respect will not be made here because it does not yield any serious change in the results obtained from the present approximation.

Using the parametric values given in Table I, the values of the equilibrium constant, K_1, and the reaction rate constants, k_2 and k_t, were calculated for several gases at 288, 600, and 1000° K. The results are given in Table II.

Inspection of the data in Table II indicates that the negative temperature-dependence of k_t is not only a consequence of the decreasing nature of K_1 with increasing temperature but it is also due to the same tendency of k_2. In fact, at relatively high temperatures, the latter constant appears to depend upon the temperature to the same extent as the former does.

For the gases listed in Table II, the values of ion-recombination coefficients, ρ, were calculated under varying pressures at 288° K. In Table III, the calculated values are compared with the observed data (9). Except for H_2 and air, the calculated values of ρ are too small by a roughly constant factor of 4. In the case of air the factor is about 6. Yet, the disagreement is not as bad as it sounds, in view of the crudeness of the approximations involved in the present theory. Generally the calculated values agree with experiment at least in order of magnitude. In this sense, therefore, the coincidence found for H_2 is considered as accidental.

DISCUSSION

(A) Termolecular Reaction and the Steady-State Treatment

Under the assumption of the stationary concentration of MX^+, the over-all rate of ion recombinations is expressed by

$$v = \frac{k_1 k_2 (M)(X^+)(Y^-)}{k_{-1} + k_2 (Y^-)}, \qquad [17]$$

which can be kinetically third order if $k_{-1} \gg k_2\,(Y^-)$. The last condition is fulfilled in the recombining systems investigated, in the following way:

Since k_{-1} is the rate constant for the unimolecular decomposition of MX^+, one may expect that $k_{-1} \simeq 10^{13} e^{-\epsilon_m/kT}\,\mathrm{sec}^{-1}$. If we choose $\epsilon_m = 1.4\times10^{-13}$ erg for a complex ion, then k_{-1} comes out to be ca. 3×10^{11} sec^{-1} at ordinary temperatures. On the other hand, the bimolecular rate constant, k_2, at 288° K is approximately 3×10^{-6} cm^3 ion^{-1} sec^{-1} for most gases investigated, as seen in Table II. Therefore, k_{-1} will be larger than $k_2\,(Y^-)$ until (Y^-) exceeds 10^{17} ions cm^{-3} (or 3.7×10^{-3} in mole fraction in a gas at the normal temperature and pressure). In many ionization phenomena the ion concentrations are much smaller than this limiting concentration, and so it is very probable that $k_2\,(Y^-)$ is sufficiently small compared with k_{-1}. In addition, the condition $k_{-1} \gg k_2\,(Y^-)$ is favored by high temperatures and low pressures, because k_2 has a negative temperature coefficient and (Y^-) will become smaller with decreasing pressure.

Obviously the theory is subjected to a serious restriction concerned with the steady-state hypothesis. In order that the time lag between the formation and destruction of MX^+ is negligible, the concentration of MX^+ as an intermediate should be at all times much less than that of X^+ as a reactant. To check this point, the concentration ratios, $(MX^+)/(X^+)$, were calculated from

$$\frac{(MX^+)}{(X^+)} = K_1(M) \qquad [18]$$

for the gases in question, using the values of K_1 given in Table II. The calculated ratios at 288° K and 1 atmosphere pressure are: H_2, 0.119; O_2, 0.106; air, 0.084; CO, 0.066; CO_2, 0.149; SO_2, 0.141; N_2O, 0.124. Although these ratios are not actually small compared with unity, they do appear to be small enough to neglect for the present purpose. This situation becomes more serious under higher pressures, because the concentration ratio increases proportionally with the increasing pressure. Therefore, under pressures much higher than 1 atmosphere, the over-all recombination cannot be approximated by $K_1 k_2 (M)(X^+)(Y^-)$ even if the condition $k_1 \gg k_2(Y^-)$ is satisfied.

Moreover, it has been shown experimentally that, although the recombination coefficients increase linearly with the increasing pressure up to approximately 1000 mm Hg, they attain the maximum values around this limiting pressure and then decrease

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

gradually as the pressure increases further (1, 2). Apparently, the latter phenomenon is not attributable to the three-body process. It is thus concluded that the present theory does not apply to the ion recombinations occurring under gas pressures higher than 1000 mm Hg.

(B) The Potential Parameters

As has already been described, all the potential parameters necessary for the calculation of K_1 are obtainable from the interrelations among these parameters provided that the values for ϵ_0, σ, and α are known. Thus the calculated data for the ion-recombination coefficients are essentially dependent upon these three parameters. Of the three, ϵ_0 is the least important, because the equilibrium separation, r_m, of an M—X^+ binding is usually close to σ where the Lennard-Jones potential is zero as seen in Table I. In other words, the maximum binding energy of the complex is mainly due to the polarization force at the separation, r_m, and it can even be approximated with a reasonable accuracy to the polarization force at the internuclear separation of σ (see Fig. 1 as an example). Thus, it should be noticed that the calculated values of the recombination coefficients are particularly sensitive to the empirical values of σ chosen.

The close agreement between theory and experiment found for the ρ's for hydrogen will break down with a more reasonable choice of the σ-value. In the calculation, σ (= 2.928 Å) was the closest approach for elastic collisions between hydrogen molecules, and the ion cluster H_2—H_2^+ was assumed to be stable at an internuclear separation, 2.591 Å, which was obtained by using the above value of σ. According to Eyring, Hirschfelder, and Taylor (6), however, an irreversible process

$$H_2 + H_2^+ \rightarrow H_3^+ + H \qquad [iii]$$

can take place very rapidly. Actually, it has been deduced from experiments that reaction [iii] occurs in nearly every collision between H_2 and H_2^+ (21). If we consider that the pre-neutralization equilibrium in the case of hydrogen is

$$H_2 + H_3^+ \rightleftharpoons H_2—H_3^+ \qquad [iv]$$

rather than

$$H_2 + H_2^+ \rightleftharpoons H_2—H_2^+, \qquad [v]$$

then the equilibrium internuclear separation in the intermediate complex will be larger on account of more bulkiness of H_3^+ than that of H_2^+. As a result, the binding energy of the complex and consequently the calculated values of K_1 and ρ will become correspondingly smaller.

(C) An Alternative Mechanism

So far the discussion has been confined to the recombination mechanism in which positive ions, X^+, are assumed to be equilibrated with their ion clusters prior to the neutralization with negative ions, Y^-. However, there is no definite reason why an alternative mechanism

$$M + Y^- \rightleftharpoons MY^- \qquad [vi]$$

$$MY^- + X^+ \rightarrow XY + M \qquad [vii]$$

can be eliminated from the consideration. Nevertheless, the mechanism does not seem very likely, because there would be a large possibility that the detachment of electrons (or ionization of MY^-) occurs on the collisions of MY^- with M. The possibility of this ionizaton is much larger than that of the second step [vii], because of the presence of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

large excess of M and the small electron affinities of the negative ions in general. The electrons thus liberated could collide with M to reproduce the negative ions Y^-, the concentration of which would therefore be maintained until they are neutralized with the partners, MX^+. There is then no participation of step [vii] in the ion recombinations. This point is, of course, still open to question and needs further consideration in the future.

A COMBINED FLASH PHOTOLYSIS AND SHOCK WAVE METHOD FOR THE STUDY OF BROMINE ATOM RECOMBINATION OVER A WIDE TEMPERATURE RANGE[1]

GEORGE BURNS AND D. F. HORNIG

ABSTRACT

A combined flash photolysis shock wave experiment is described in which bromine is first flash photolyzed, then compressed and heated by a shock wave, and finally allowed to recombine at the high temperature. Some of the problems connected with working in a shock tube used as a photolysis vessel are analyzed. The apparatus was used to measure recombination rates with argon as a third body at room temperature, to estimate the efficiency of bromine as a third body at room temperature, and to obtain a preliminary measurement of the recombination rate of bromine in the presence of argon at 950° K.

INTRODUCTION

The rate of the three-body recombination of both iodine and bromine atoms has been measured as a function of temperature between 300° K to 550° K by the flash photolysis method (1–4). Recombination rates have also been calculated from rates of dissociation and equilibrium constants in iodine, bromine, and oxygen (5–12). In every case the rate of recombination decreases with increasing temperature.

The source of this temperature effect has been the subject of considerable theoretical discussion and it may arise from several sources.

(*a*) An approximately $1/T$ temperature dependence appears in the statistical theories of Wigner (13) and of Keck (14).

(*b*) The fact that for attracting molecules the collision cross section decreases with increasing molecular velocity will produce a decrease in the rate as the mean velocity increases, similar to the effect on gaseous viscosities (15).

(*c*) If the reaction proceeds through the sequence

$$A + M \rightleftarrows AM$$

$$AM + A \rightarrow A_2 + M,$$

the fall-off may be attributed to the decreasing equilibrium concentration of the complex AM. This latter suggestion has been particularly in vogue recently (16–19). However, the existing experimental data do not cover a wide enough temperature range to make any unambiguous choices so it seemed important to extend the temperature range of direct recombination rate measurements.

It seemed possible to do this by using flash photolysis to dissociate the halogen molecule and a shock wave to heat the gas. Several variations of such an experiment might be considered.

1. If the gas is initially photolyzed and then heated, the photolysis is carried out at the initial gas density and the recombination is carried out at a gas density two to four times higher. This results in faster recombination, an important feature since it is only possible to maintain the high temperature for a limited time in the shock tube. An intrinsic limitation of this approach is that in order to observe recombination, the photolytic dissociation must exceed the equilibrium thermal dissociation behind the shock wave. In

[1]*Contribution from the Frick Chemical Laboratory, Princeton University, Princeton, N.J.; paper presented at the Symposium on Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

most experimental arrangements this would make it possible to reach temperatures in the vicinity of 2000° C.

2. If the gas is initially heated and then photolyzed the upper temperature limitation of the first approach is removed since the photolytic dissociation is added to the thermal dissociation. However, in this case the rates are from 2^3 to 4^3 lower for comparable initial conditions because of the density effect.

3. Either of the first two methods can be applied to a reflected shock wave. Reflected shocks have the advantage that higher temperatures and gas densities may be reached while at the same time the gas behind the reflected wave is not in motion. However, a variety of problems involving shock wave dynamics have complicated previous experiments with reflected waves (20, 21).

In designing an experiment, then, one must arrive at a suitable compromise among a variety of factors.

APPARATUS

A diagram of the apparatus utilized is shown schematically in Fig. 1. The low-pressure section, a 3-in. diameter pyrex glass shock tube, was filled with the bromine–argon mixture to be studied. When a cellulose acetate diaphragm (X), separating the low-pressure section from the helium-filled high-pressure section was punctured, a shock wave was sent through the low-pressure gas, compressing it and heating it to the desired temperature.

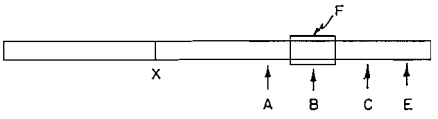

FIG. 1. Diagram of the apparatus.

By the time the disturbance reached station A a shock wave had been formed. Station A activated the time delay circuits which triggered the flash lamps (F), started the oscilloscope sweeps, etc. When the shock was about to enter the illuminated region the high-voltage condensers were discharged through the flash lamp, dissociating about 20% of the Br_2. The partially dissociated gas was subsequently compressed and heated by the shock wave. Since the gas behind the shock front was in motion the dissociated gas was carried down the tube and the optical absorption, from which the concentration of Br_2 could be measured, was studied at successive times by stations C and E.

The distance between the electrodes of the flash lamps was 25 cm; they were made of 1.9-cm diameter quartz tubes filled with xenon at a pressure of 100 mm Hg. The electrodes were made of 1/4-in. tungsten rods. In order to minimize the inductance the return lead from each lamp was made of copper foil covering the outer half of each tube. These lamps had an inductance of 1.8 microhenries and a resistive impedance of 1 ohm. The light pulse had a width at half peak intensity of 7 microseconds when a 3.75-μf condenser was discharged through a single lamp. The resistance and inductance of the rest of the circuit was negligible compared with those of the lamp.

Up to eight of these lamps were arranged in a ring, each parallel to the shock tube and separated from it by 1/8 inch, inside a reflecting box. They were operated in parallel and were capable of dissipating up to 4000 joules/flash in less than 10 microseconds. In order to make absorption measurements the eight lamps were separated into two groups of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

four and the measuring beam (B) was directed through the gap, at right angles to lamps and shock tube.

The flash lamps were each connected to separate capacitors. They were fired simultaneously by triggered spark gaps connected in series with the lamps. The spark gap electrodes consisted of a 1/4-in. diameter nickel hemisphere and a plane nickel electrode. The 2-mm diameter trigger electrode was inserted in a 4-mm diameter hole in the plane electrode. The trigger electrodes were pulsed by transformers which delivered approximately 6 kv with a rise time of 10 ± 1 microseconds. Using separate thyratrons to pulse the primaries it was possible to fire the eight flash lamps with a simultaneity of less than one microsecond.

Each measuring station (A, B, C, and E) consisted of a photomultiplier, an optical system, and an incandescent lamp source. Stations C and E were used to follow the changes in bromine concentration and to measure the shock velocity; A was used to trigger the flash lamps and to measure shock velocity. B was used only to study flash photolysis at room temperature. The rise time of the photomultiplier circuits was less than one microsecond and a square wave decayed 0.5% in 1 millisecond. Over the range of light intensities used the intensity measurements were accurate to within 1%.

At station B the intensity of the flash was roughly 10^5 times that of the incandescent source in the measuring circuit. Therefore care had to be taken to minimize the effect of scattered light which could damage the photomultiplier tube or at least affect its sensitivity. Aside from the strong peak there was a "tail" continuing for another 150 microseconds or so, which interfered with subsequent measurements. It was not established whether this was caused by continuing light output from the gas or by luminescence of the quartz walls of the flash lamps.

The main source of scattering was the glass wall of the shock tube. The effect of scattering was minimized by using a well-collimated optical system, relatively low photomultiplier voltage (190 v), and a relatively intense light source for the measuring circuit (8 v, 18-amp tungsten ribbon lamp). Measurements were all made at 4420 Å through an interference filter. The signal-to-noise ratio at station B was over 1000. Stations C and E were well removed from the flash lamps so that the problem of scattered light was less severe. The signal-to-noise ratio at these stations was about 300.

The low-pressure section of the shock tube was an 11-ft section of 3-in. I.D. pyrex pipe. The high-pressure section was a 6-ft section of 3-in. I.D. brass fitted with a knife-type plunger used to break the diaphragm, made of 10 or 15 mil cellulose acetate. The density in the flows in the shock wave was constant to within $\pm3\%$. This was probably the largest single experimental uncertainty leading to scatter in the experimental results.

The pressure of inert gas in the low-pressure section was measured with a mercury manometer and that of bromine, by a butyl phthalate manometer buffered with argon. The gases were thoroughly mixed in a 3-liter flask.

Although the system was originally vacuum tight, the strong shocks used caused leaks between sections of the shock tube which were very hard to eliminate. It is not believed that the air which was admixed with the argon could have produced an error over 1%.

STATIC EXPERIMENTS

In order to test the apparatus, measurements were first carried out at room temperature in a closed cell 3 inches in diameter and 27 cm long. Recombination constants in the rate equation $d[Br_2]/dt = k_{app}[Ar][Br]^2$ were measured over a 15-fold range in the [Br]/[Ar] ratio. All of the measurements were made at station B (Fig. 1). At each concentration

For personal use only.

ratio at least five traces of the scattered light and of scattered light plus deflection due to the changing Br_2 concentration were taken.

Further room temperature experiments were carried out using the shock tube itself as a reaction vessel (but with no shock wave). The results obtained in all of the static experiments are given in Table I. Both the absolute value of the experimental rate constant and the scatter in our data compare well with previously published work.

On the other hand, our data are in rather serious disagreement with those of Givens and Willard (4) as regards the dependence of the experimental rate constant on the $[Br_2]/[Ar]$ ratio. When this ratio was high our records showed a definite effect of heating by the flash and wave systems were set up in the closed reaction vessel (Fig. 2). We have

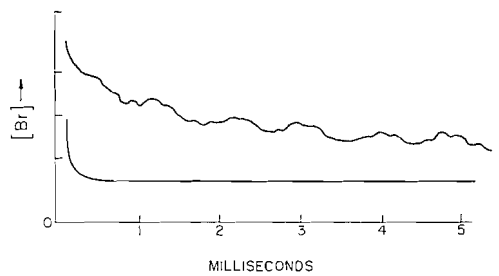

FIG. 2. Oscilloscope traces showing scattered light and recombination of bromine atoms in a closed vessel containing 1.92×10^{-4} moles/liter of Br_2 and 6.39×10^{-3} moles/liter of Ar. Vertical scale 4.5×10^{-6} moles/liter Br per small division.

For personal use only.

used the midpoint of the waves for measurement and it is hard to see how this can account for the disagreement. On the other hand, as regards this dependence, our results agree reasonably well with those of Strong and Basila (23) and Christie, Roy, and Thrush (24).

If both Br_2 and Ar act as third bodies for the recombination, the apparent rate constant is given by

$$[1] \qquad k_{app} = k_{Ar} + \frac{[Br_2]}{[Ar]} k_{Br_2}$$

so that the rate constant for Br_2 acting as a third body is obtained from the slope of Fig. 3. We have not taken enough data at high $[Br_2]/[Ar]$ ratios to obtain a reliable value of k_{Br_2}. It is plain, though, that the ratio of k_{Br_2}/k_{Ar} from our results (ca. 20) is much smaller than that of Givens and Willard (4). The values of k_{Br_2} reported recently are summarized in Table II.

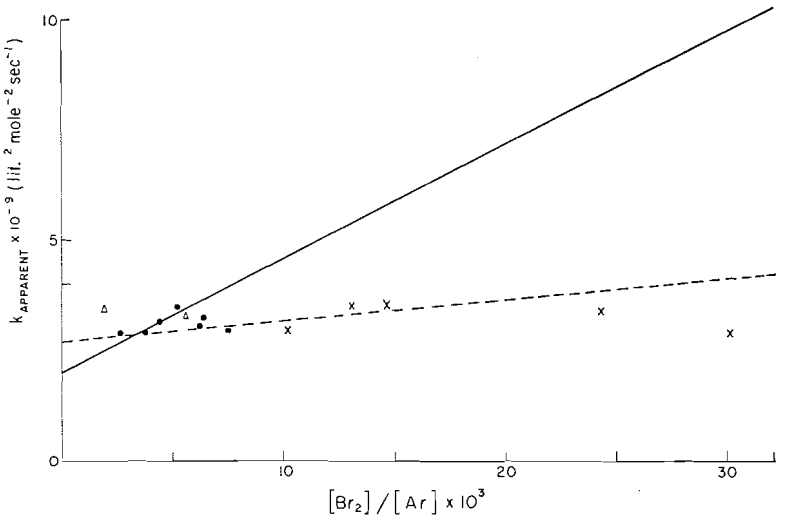

FIG. 3. Dependence of the recombination rate constant upon $[Br_2]/[Ar]$. Closed circles, oscilloscope trace shows no detectable waves; crosses, waves can be observed; triangles, experiments in shock tube used as a reaction vessel; solid line, dependence predicted from reference 4; dashed line, dependence predicted from reference 23 and reference 24.

TABLE II

Rate constant for bromine atom recombination with Br_2 as third body

Investigators	k_{Br_2}, l^2 mole^{-2} sec^{-1}
Strong and Basila (1958) (23)	49×10^9
Givens and Willard (1959) (4)	260×10^9
Christie, Roy, and Thrush (1959) (24)	48×10^9
This work	$<50 \times 10^9$

In order to determine this rate constant accurately more data must be taken at higher values of the $[Br_2]/[Ar]$ ratio. It would be particularly advantageous to use He instead of Ar as the diluent in such studies since He is about three times less efficient than Ar as a third body. In this case the slope of a plot similar to Fig. 3 could be determined with about three times more precision.

THERMAL EFFECTS

Heating by the Flash

When the flash dissociates the Br_2 the bromine atoms are released with a kinetic energy equal to the difference between the photon energy and the energy necessary to produce two $^2P_{3/2}$ atoms (45.6 kcal) or most often a $^2P_{1/2}$ and a $^2P_{3/2}$ atom (56.05 kcal). This excess kinetic energy is degraded to heat in a very few collisions. As a consequence the gas is heated from a few degrees to as much as 100° C, depending on the dilution and flash intensity, within the duration of the flash.

In a closed cell experiment in which the illumination is absolutely uniform, the only result is that the recombination is measured at a higher temperature. If the illumination is non-uniform there are further effects. The temperature, and hence the pressure, are increased more in the region of most intense illumination so that compression waves are propagated into the regions of less intense illumination, giving rise to oscillations in the record as sound waves are reflected back and forth through the cell. This phenomenon is illustrated in Fig. 2. Even if the wave motion is averaged there is an effect since the more intensely illuminated regions gradually expand while the less intensely illuminated regions are compressed, giving rise to a local gas density different from that to which the cell was filled. In particular, if the illumination is symmetrical about the midpoint of a cylindrical cell, the density, ρ_f, is given by the expression

$$\frac{\rho_f}{\rho_0} = \left(\frac{\bar{P}_f}{P_i}\right)^{1/\gamma} \qquad [2]$$

where $\bar{P}_f$ is the average final pressure in the tube, P_i is that immediately after the flash, and ρ_0 the gas density before the flash.

$$P_i = \rho_0 R T_i \quad \text{and} \quad \bar{P}_f = \rho_f R \bar{T}_f. \qquad [3]$$

Finally,

$$\begin{aligned} T_i - T_0 &= Q/C_v \\ \bar{T}_f - T_0 &= \bar{Q}/C_v \end{aligned} \qquad [4]$$

where Q is the excess kinetic energy produced in the Br atoms and C_v is the heat capacity. In a typical case in the experiments described in the last section, the illumination at the ends of the closed 27-cm cell was about 75% of that in the center. At the highest Br_2/Ar ratio $T_i - T_0$ was about 10° C while the corresponding $\bar{T}_f - T_0$ was about 9.1° C. In that case $\bar{P}_f/P_i = 0.993$ and $\rho_f/\rho_0 = (0.993)^{0.6} = 0.996$. The resultant errors are therefore not serious. We have not pursued this matter in the present experiments.

When the cell is open ended, as in a shock tube, the effects are much larger. In that case the initially heated gas expands until its pressure is back to the initial pressure so that equation [2] becomes

$$\rho_f = \rho_0 (P_i/P_0)^{1/\gamma} \qquad [5]$$

and for 10° C heating, $\rho_f = 0.98\rho_0$. Since a 2% density change by expansion would produce a change in the bromine absorption comparable to that produced by dissociation, it was considered necessary to study this initial heating experimentally in the shock tube.

The initial heating was studied under conditions where it would be maximized and the rate of recombination would be made negligible during the experiment, namely in pure bromine at low concentration ($0.44\text{–}0.77 \times 10^{-5}$ moles/liter). When pure Br_2 was photolyzed in the shock tube, a bromine absorption record similar to that in Fig. 4 was obtained

at station B. There was an abrupt decrease in the Br_2 concentration immediately following the flash because of the photolytic dissociation. This was followed by a slow further decrease which became much more rapid during the first millisecond. After about two milliseconds the gas was completely expanded and a new, relatively constant, value of $[Br_2]$ was reached.

It was clear that the second process was the anticipated expansion since the time at which it occurred was almost exactly equal to the expected time of arrival (1.3 milliseconds) of a sound wave from the edge of the illuminated region (where the expansion would be initiated). This conclusion was checked further by adding helium to the bromine to increase the velocity of sound and in that case the final plateau of Fig. 4 was reached in less than one millisecond.

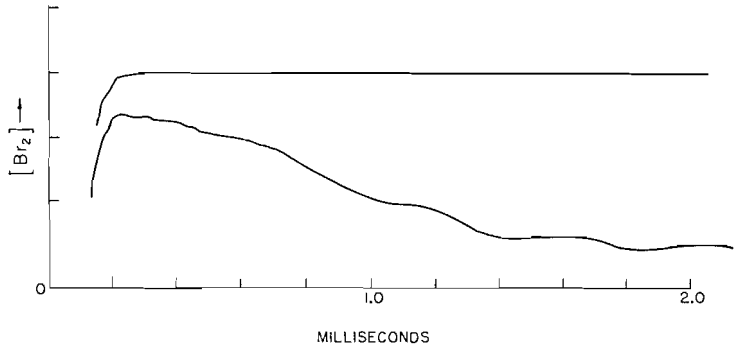

FIG. 4. Oscilloscope trace showing scattered light and expansion of bromine due to initial heating. Shock tube filled with 0.7×10^{-4} moles/liter Br_2. Vertical scale: 7.7×10^{-6} moles/liter Br_2 per division.

A final check that the phenomenon observed was indeed the expansion was obtained by observing the compression wave which the expanding gas in the illuminated region sent through the unilluminated part of the tube. The disturbance was observed at stations C and E; it was found that it propagated at a velocity almost exactly equal to that of sound in bromine and had its origin in the illuminated region at the time of the flash.

It was possible, therefore, to estimate the initial heating quantitatively from these experiments. The initial concentration, $[Br_2]_0$, was known from the initial pressure as well as from the optical absorption. The concentration, $[Br_2]_1$, immediately after the flash could be determined by extrapolating the record back to $t = 0$. Consequently

$$[Br]_1 = 2([Br_2]_0 - [Br_2]_1) \qquad [6]$$

and the degree of dissociation was

$$\alpha = ([Br_2]_0 - [Br_2]_1)/[Br_2]_0 \qquad [7]$$

If Q calories were released for each molecule dissociated, the temperature after the flash was

$$T_1 = T_0 + \frac{Q\alpha[Br_2]_0}{(1-\alpha)[Br_2]_0 C_{Br_2} + 2\alpha C_{Br}} . \qquad [8]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Hence Q could be determined if T_1 was known. T_1 could be determined from the temperature after the adiabatic expansion since

$$\frac{T_1}{T_t} = \left(\frac{[Br_2]_1}{[Br_2]_t}\right)^{\gamma-1}, \tag{9}$$

and T_t was known from the equation of state (if the final pressure equals the initial pressure),

$$\frac{T_t}{T_0} = \frac{[Br_2]_0}{[1+2\alpha][Br_2]_t}. \tag{10}$$

Hence Q could be determined from a single record similar to Fig. 4 since $[Br_2]_t$ could be measured from the final plateau.

Five experiments in pure Br_2 at a concentration of 0.75×10^{-4} moles/liter with four lamps firing yielded $Q = 9.6$ kcal/mole. Another set of four experiments at a concentration 0.48×10^{-4} moles/liter gave $Q = 5.7$ kcal/mole although the scatter among the determinations, using from one to four lamps, was only about 10%. The reason for the discrepancy is not known. However, the presence of as much as 1 mm Hg of air in the tube would account for it.

Because of the uncertainty in α caused by the difficulty in extrapolating to $t = 0$, another set of experiments was carried out in which argon was added to almost atmospheric pressure (3.88×10^{-2} moles/liter). The rate constant was determined in the usual way by plotting 1/Br vs. time. Extrapolating this straight line to $t = 0$ gave the initial concentration of Br atoms (8.6×10^{-7} moles/liter per flash lamp). Using the value of α determined in this way to fix the $t = 0$ point on another set of 35 runs in pure Br_2 at a concentration of 0.7×10^{-4} moles/liter gave $Q = 8.5$ kcal/mole.

These experiments were not carried further because our main interest was in high-dilution experiments where the heating and expansion effects were very small. Their importance lies in the fact that they show that the expansion is a smooth process and that it is possible to work quantitatively under conditions where the heating and expansion are large.

Recombination Heating

When recombination takes place the heat evolved warms the gas and in an open tube the consequent expansion may produce large effects. If the expansion is rapid enough so that inertial forces are significant the hydrodynamic conservation equations must be applied (8). When that is not the case there will be a free expansion of the heated gas at a constant pressure. We then have

$$\dot{[Br_2]} = \left(\frac{\partial Br_2}{\partial \alpha}\right)_{T,P}\dot{\alpha} + \left(\frac{\partial Br_2}{\partial T}\right)_{P,\alpha}\dot{T}. \tag{11}$$

For a three-body recombination

$$\left(\frac{\partial Br_2}{\partial \alpha}\right)_{T,P}\dot{\alpha} = k[Br]^2[M]. \tag{12}$$

From the equation of state

$$\left(\frac{\partial Br_2}{\partial T}\right)_{P,\alpha} = -\frac{[Br_2]}{T}. \tag{13}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For a constant pressure process

$$\dot{H} = \dot{q},$$

so that

$$[15] \qquad ([Br_2]C_{pBr_2}+[Br]C_{pBr}+[M]C_{pM})\,\dot{T} = Dk[Br]^2[M].$$

Therefore equation [11] becomes simply

$$[16] \qquad [\dot{Br_2}] = k[Br]^2[M]\left(1-\frac{D[Br_2]}{([Br_2]C_{pBr_2}+[Br]C_{pBr}+[M]C_{pM})T}\right).$$

Under conditions of high dilution this simplifies to

$$[17] \qquad [Br_2] = k[Br]^2[M]\left(1-\frac{D[Br_2]}{[M]C_{pM}T}\right).$$

It should be noted, therefore, that as recombination proceeds the Br_2 concentration may either decrease or increase. A similar situation exists for dissociation reactions and there both cases have been observed experimentally (8). In general, though, the bromine molecule concentration will increase during recombination when the gas is sufficiently dilute and decrease for pure Br_2 at any practicable temperature.

Cooling by the Walls

Norrish *et al.* (16) have called attention to the problem created by cooling at the walls. In a conventional photolysis cell the observations are made longitudinally. Cooling at the walls results in increased gas density near the walls and decreased density in the center of the tube where observations are made. In our apparatus observations were made transversely so that in first approximation the effect of cooling at the walls is averaged out, providing the cell is long enough so that the end walls are far removed. Consequently, we have for the present neglected this effect.

HIGH-TEMPERATURE MEASUREMENTS

Recombination measurements were made at 950° K in mixtures of 0.6% Br_2 in Ar. The low-pressure section of the shock tube was filled with bromine at a concentration of $(3.7\pm.05)\times10^{-5}$ moles/liter and argon at a concentration of $(6.05\pm.05)\times10^{-3}$ moles/liter. The total pressure was 11.4 cm Hg. The high-pressure section was filled with He at a pressure of three atmospheres. The strength of the shock wave produced when the diaphragm was ruptured was determined by measuring the time of passage between stations A, B, C, and E. All three shocks had an average velocity of 0.90 mm/microsecond over the 964-mm path from A to C. The third shock showed an average velocity of 0.92 mm/microsecond over the total path of 1297 mm so that its apparent velocity over the last 333 millimeters was 0.98 mm/microsecond. It is not yet known whether this represents experimental error or whether there was a genuine acceleration of the shock. Using the velocity 0.90 mm/microsecond (Mach number = 2.80), the compression ratio across the shock was 2.89 and the temperature behind the shock was 950° K. If the velocity was as high as 0.97 mm/microsecond (Mach number = 3.00) the corresponding numbers would be 2.99 and 1060° K.

The photolysis was carried out with eight lamps discharging a total of 32.25 mf at 10.4 kv. Since station B was not used, the initial Br atom concentration was determined in a separate photolysis on pure bromine at room temperature (no shock). Bromine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molecules (22%) were dissociated in the photolysis. The initial heating amounted to 5.3° C. The subsequent expansion would amount to 1% at 300° K and 0.34% at 950° K. Since the expansion should have been complete after about 750 microseconds it took place partially before and partially after the arrival of the shock wave at about 200 microseconds. Because of the high degree of dissociation the expansion had only a very minor effect on these measurements.

The rate constants were obtained from the initial bromine concentration, determined separately, and corrected for the expansion and the recombination which occurred before arrival of the shock (6%), plus the bromine atom concentration at the center of the pulse when it arrived at stations C (0.76 millisecond later) and E (1.30 milliseconds). The rate constants were corrected for the recombination heating, a correction of 7.7%.

The rate constants obtained on three high-temperature experiments were:

Expt.	Time range, milliseconds	k, l² mole⁻² sec⁻¹
I	0–0.76	6.4×10^8
	0.76–1.3	7.9×10^8
II	0–0.76	9.0×10^8
III	0.76–1.3	9.7×10^8
		Average $8.2\pm1.1\times10^8$

DISCUSSION

The most striking feature of previous work on bromine and iodine is that it was difficult to fit the low-temperature flash photolysis data and the high-temperature shock wave data to a single k vs. T curve. It was hoped that an intermediate temperature point might indicate where the difficulty lay. Furthermore, the various theoretical approaches suggest different forms of the k vs. T curve. The complex mechanism yields a function $k = Ae^{E/RT}$ whereas most other considerations yield functions of the form $k = B/T^n$.

The various measurements are therefore plotted as a function of temperature in Fig. 5; a straight line on the three representations shown would correspond to the functions: (A) $k = B/T^n$, (B) $k = Ae^{E/RT}$, and (C) $k = Ae^{-BT}$. The present work agrees reasonably well with the results of Willard and co-workers at room temperature but the rate constant at 950° K is substantially higher than would be predicted by extrapolation of their data.

A point of some interest is the fate of the $^2P_{1/2}$ atoms, which comprise roughly 50% of those produced in the initial photolysis, since they cannot lead directly to the formation of ground state molecules. If they were collisionally degraded to the $^2P_{3/2}$ state the 10.4 kcal released ought to appear in our experiments as heat and this does not seem to have been the case. They might, however, undergo a radiative transition and lose the energy as a photon. If their lifetime exceeds the recombination time (ca. 1 millisecond), though, all flash photolysis results would be in error unless the lifetime of the excited molecules produced from these atoms is short compared with the recombination time. This problem has been considered previously (16) but the evidence for neglecting this possibility does not seem conclusive to us.

If the $^2P_{1/2}$ atoms do not enter the observed recombination, the rate constants would be about four times greater and it should be noted that since the corresponding problem does not arise in thermal dissociation (e.g. in shock waves) this would help bring the flash photolysis and shock wave results into better agreement.

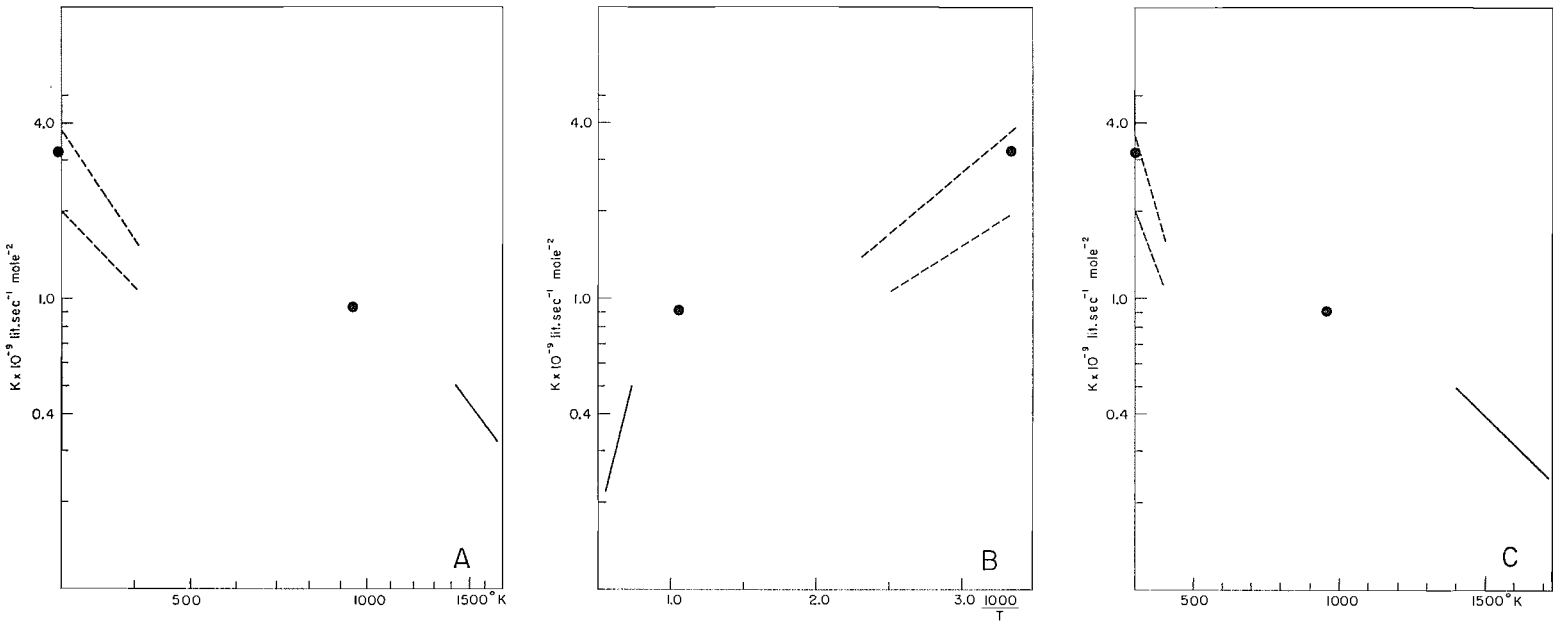

FIG. 5. Temperature dependence of recombination rate constant. (A) Log–log representation; (B) Arrhenius representation; (C) log k vs. T representation. Closed circles, present experiment; solid line, estimated from reference 12; upper dashed line, estimated from reference 2; lower dashed line, estimated from reference 4.

CONCLUSIONS

The combination of flash photolyses with the shock tube to obtain recombination rates at high temperatures appears quite feasible. All of the major problems, such as the various thermal effects, appear soluble and it has been possible to obtain preliminary results of reasonable accuracy for bromine recombination at 950° K. It now seems possible to reach higher temperatures, to improve the accuracy, and to work at lower dilutions.

THE ROLE OF Hg 6^3P_0 ATOMS IN MERCURY PHOTOSENSITIZATION

I. REACTIONS IN THE PRESENCE OF NITROGEN[1]

G. H. KIMBELL AND D. J. LE ROY

ABSTRACT

A quantitative investigation has been made of the factors affecting the concentration of mercury 6^3P_0 atoms formed by collisions of the second kind between mercury 6^3P_1 atoms and nitrogen. The absorption of 4047 Å (6^3P_0–7^3S_1) and the emission of 2656 Å (6^3P_0–6^1S_0) were studied in the pressure range 0.06 mm to 140 mm. Both types of measurement indicate that the forbidden line arises from spontaneous as well as collision-induced emission. The lifetime for spontaneous emission is estimated to be 4.2×10^{-4} sec.

The production of mercury 6^3P_0 atoms by collisions of the second kind between 6^3P_1 atoms and nitrogen is well known. The methods used to study their relative concentration and reactivity are of five main types.

The absorption of the line 4047 Å, corresponding to the transition 6^3P_0–7^3S_1, was first observed by Wood and Gaviola (1), and has been applied quantitatively by a number of others (2, 3, 4, 5). Correlation of the apparent concentration of 6^3P_0 atoms with cell geometry suggested that these atoms have a relatively long lifetime and are deactivated on the wall (2). With increasing nitrogen pressure the concentration reaches a maximum (3) and shows some indication of a fall-off at pressures above 20 mm (4).

As a result of the absorption of 4047 Å there is an increase in the population of the 7^3S_1 level. The intensity of the resulting emission of 4358 Å (7^3S_1–6^3P_1) and 5461 Å (7^3S_1–6^3P_2) has been used as a measure of the 6^3P_0 concentration (6).

Elevation of 6^3P_0 atoms to the 6^3P_1 level requires only 5 kcal per mole and can be brought about by collisions with nitrogen molecules. Because of the long lifetime of the former compared with that of the latter (1.1×10^{-7} sec), the emission of 2537 Å will continue for some time after the exciting radiation of that wavelength is cut off; its intensity can then be correlated with the concentration of 6^3P_0 atoms (5, 7, 8).

The liberation of electrons when 6^3P_0 atoms collide with metal plates has been used as a quantitative measure of their concentration (9, 10, 11), but the method may be complicated by the fact that Hg_2^+ ions appear to be produced homogeneously (4).

Although the transition 6^3P_0–6^1S_0 is forbidden by the usual selection rules, it has been observed by Wood (12) and others. Its wavelength *in vacuo* (2656.39 Å) lies close to the pseudotriplet, 2655.92, 2654.47, 2652.83, arising from transitions between the levels 7^1D_2, 7^3D_1, 7^3D_2, and the 6^3P_1 level, and can be separated from these only with a spectrograph of high dispersion. Laroze and Cojan (13) have tried to get around this difficulty by passing the light from the primary lamp through a filter designed to reduce the intensity of the pseudotriplet, relative to that of 2537 Å, by a large factor. Unfortunately, while this would reduce the rate of formation of $7D$ atoms from 6^3P_1 atoms, it would not affect their rate of formation by such processes as the absorption of 2535.5 Å by 6^3P_0 atoms to give 7^3D_1 atoms. Indeed, it was found in the present work that the intensity of the line 2654.47 Å increased very markedly in the presence of small amounts

[1]*Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario; presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

of nitrogen and was reduced below that of the forbidden line only at relatively high pressures.

EXPERIMENTAL

The apparatus in its present form was designed to permit measurements of the absorption of 4047 Å as well as of the emission of the forbidden line; its main features may be seen in Fig. 1. Two primary lamps of the low-pressure mercury-rare gas type were used.

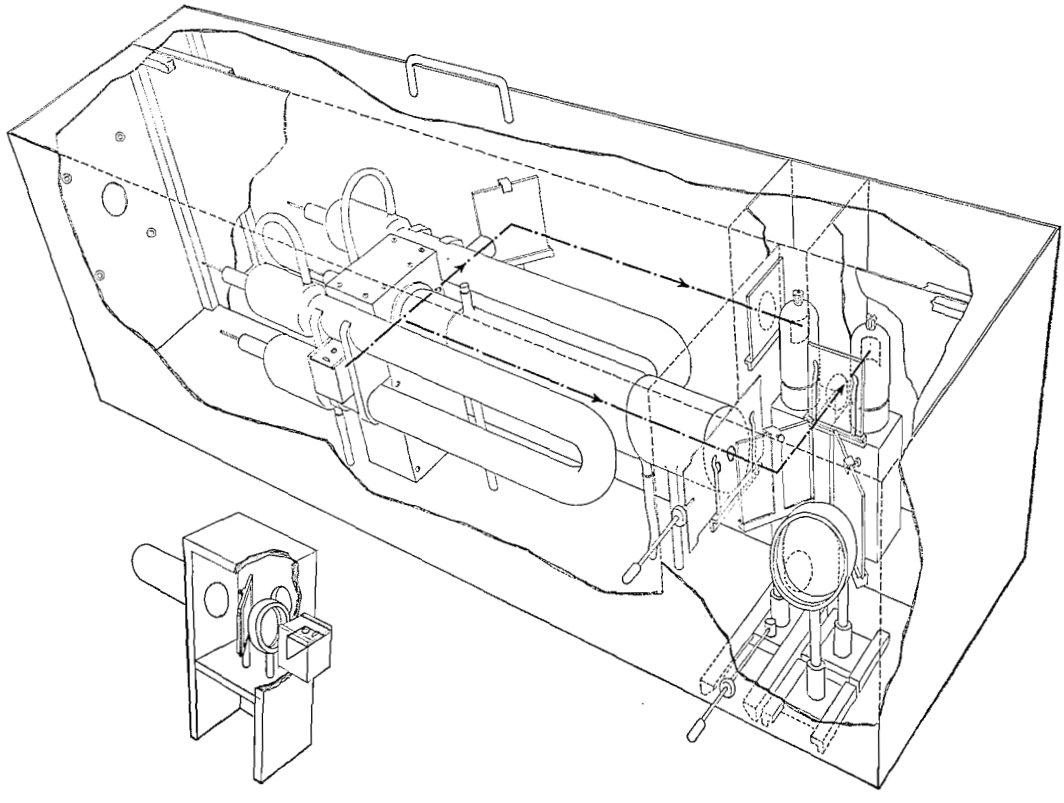

FIG. 1. Apparatus for studying absorption of 4047 Å and emission of 2656 Å by mercury 6^3P_0 atoms.

These were made entirely of fused quartz, including the jacketed electrode chambers, which were maintained at 29° C. The lamps were U-shaped and were mounted with their long axes parallel to that of the cell. The latter was also of fused quartz, and consisted of an outer tube 28 cm long and 5.5 cm O.D. and an inner tube 20 cm long and 3.1 cm I.D. The annular space between the tubes was filled with a filter solution of aqueous nickel sulphate, which removed essentially all of the 4047 Å radiation coming from the primary lamps (14). Close-fitting metal cylinders covered each end of the cell, leaving a central portion 18 cm long exposed to the light from the two lamps. Nitrogen and mercury vapor entered and left the cell through blackened side arms at each end of the cell, adjacent to the plane quartz windows.

To study the absorption of 4047 Å a beam of light from the end of one of the lamps was rendered parallel and then split into two roughly equal beams by a partially transmitting first surface mirror. One served as a reference beam, the other was passed longitudinally through the cell. The analysis beam was circular in cross section and 0.6 cm in diameter. By means of Corning filters each beam was made monochromatic before falling on separate GL-935 photocells. The photocell circuit used to measure the absorption of 4047 Å was similar to that described previously (15) except that the electrometer was a General Radio Type 1230-A.

The cell, lamps, photocells, etc. were mounted inside a metal box which was separated into lighttight shielded compartments by metal partitions. The cell compartment was flushed continuously with nitrogen to eliminate ozone formation.

Our procedure differed from that of previous workers in that we allowed the nitrogen and mercury vapor to flow through the cell continuously in order to avoid the build-up of impurities which might come off the walls of the cell. Nitrogen of the highest purity obtainable was passed over copper oxide at 250° C, over copper filings at 900° C, and then through a trap cooled with liquid air. After the gas had passed through a capillary flowmeter incorporating a mercury U-tube manometer, its pressure was lowered to the desired value by passing it through an Edwards LB-1 needle valve. An excess of mercury vapor was then added to the gas by passing it through a trap maintained at 40° C and containing a pool of mercury in the bottom and adherent drops of mercury on the sides. The mercury concentration in the gas was then adjusted to a value corresponding to saturation at 15.0° C by passing it through two long narrow traps kept at this temperature. After the gas had passed through the cell its pressure was lowered to the operating value for the diffusion pump by means of a second valve. The pressure in the cell was measured by a variable range mercury manometer connected to the cell through a stopcock connected to the exit tube.

Apparent concentrations of 6^3P_0 atoms (hereafter referred to as Hg^0 for simplicity) were obtained in terms of the optical density, $K^0L(Hg^0) = \log_{10}(I_0/I_t)$, in which K^0 is the extinction coefficient for the absorption of 4047 Å by Hg^0 atoms and L is the length of that part of the cell illuminated by the lamps. The measurements corresponding to I_0 (100%) were made by closing the needle valve on the upstream side of the cell and pumping continuously. Tests showed that no correction needed to be made for scattered light.

In making measurements on the emission of the forbidden line the diameter of the exit diaphragm of the cell was increased from 0.6 to 1.0 cm, the mirror which reflected the analysis beam of 4047 Å onto its photocell was slid out of place and the emitted light was allowed to fall on a quartz lens mounted over a hole in the side of the metal box. The conjugate foci of this lens were at the center of the cell and the slit of the spectrograph.

The spectrograph was of the Littrow type and had one 60° and one 30° prism. In the wavelength region of the forbidden line the dispersion was approximately two angstroms per millimeter. Plates were monitored by a recording microphotometer. Individual values of γ were obtained for each plate, using as standards the intensity of the forbidden line at a fixed pressure of nitrogen and various exposure times. Correction for the failure of the reciprocity law was made by using calibrated screens placed at the exit diaphragm of the cell. The screens were calibrated *in situ* using the optical arrangement for 4047 Å transmission measurements. The intensities of the forbidden line at various pressures of nitrogen were computed relative to the intensity for the standard pressure.

RESULTS AND DISCUSSION

The results on the absorption of 4047 Å for a wide range of nitrogen pressures are shown in Fig. 2. Assuming that K^0 is independent of nitrogen pressure, a dangerous

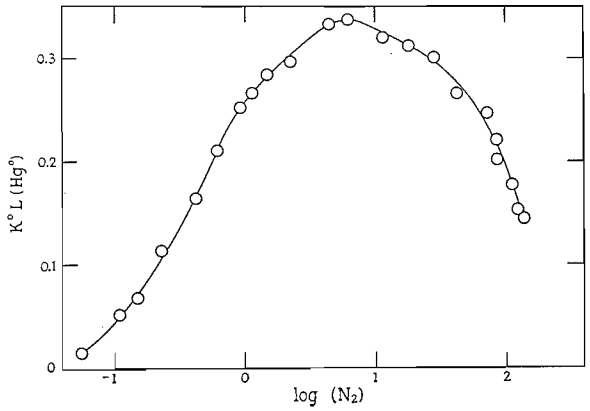

FIG. 2. Optical density, $K^0L(Hg^0)$, for the absorption of 4047 Å by mercury 6^3P_0 atoms as a function of nitrogen pressure.

assumption, it would appear that (Hg^0) reaches a maximum at about 5–10 mm and then falls off. On the other hand, the intensity of the forbidden line, shown in Fig. 5, is constant in the region 10–150 mm.

In order to make a kinetic analysis of the steady-state processes occurring in the cell under constant illumination the following reactions are considered; for simplicity 6^3P_1 atoms are referred to as Hg*, 6^1S_0 atoms as Hg.

$$Hg + h\nu^* = Hg^* \quad [1]$$

$$Hg^* = Hg + h\nu^* \quad [2]$$

$$Hg^* + N_2 = Hg + N_2 \quad [3]$$

$$Hg^* + N_2 = Hg^0 + N_2 \quad [4]$$

$$Hg^0 = Hg \text{ (on wall)} \quad [5]$$

$$Hg^0 = Hg + h\nu^0 \quad [6]$$

$$Hg^0 + N_2 = Hg + N_2 \quad [7]$$

$$Hg^0 + N_2 = Hg^* + N_2 \quad [8]$$

$$Hg^0 + N_2 = Hg + h\nu^0 + N_2 \quad [9]$$

Since the rate of [5] will be inversely proportional to the pressure of nitrogen it will be written as $k_5(Hg^0)/(N_2)$. The reactivation of Hg^0 atoms to the Hg* level by collisions with nitrogen has been observed by Samson (8) and others. The energy requirement would be 5.0 kcal per mole, close to the excess energy of the N_2 molecule formed in reaction [4]. However, the probability of such a molecule being deactivated by collisions with normal nitrogen molecules is far greater than its probability of undergoing reaction [8], except at very low pressures. Similar considerations apply to the excited nitrogen molecules formed in reactions [3] and [7]. It will therefore be assumed that the energy distribution in the nitrogen is essentially Boltzmann, and that the rate of reaction [8]

For personal use only.

will be given by $k_8(Hg^0)(N_2)$, with an activation energy of at least 5.0 kcal per mole.

For the steady state the above mechanism yields the following relation between (Hg^0) and (N_2):

$$\text{(i)} \qquad 1/K^0L(Hg^0) = A/(N_2)^2+B/(N_2)+C+D(N_2),$$

in which

$$A = k_2k_5/k_4I_a{}^*K^0L,$$

$$B = [(k_3+k_4)k_5+k_2k_6]/k_4I_a{}^*K^0L,$$

$$C = [(k_3+k_4)k_6+k_2(k_7+k_8+k_9)]/k_4I_a{}^*K^0L,$$

$$D = [(k_3+k_4)(k_7+k_8+k_9)-k_4k_8]/k_4I_a{}^*K^0L,$$

and $I_a{}^*$ is the rate of formation of Hg* atoms by reaction [1]. It is convenient to use an expression for $1/K^0L(Hg^0)$ rather than for $1/(Hg^0)$ since the former is obtained directly from the transmission measurements; consideration will be given later to the possible variation of K^0 with pressure.

(a) Absorption Measurements

While the general shape of the curve in Fig. 2 is in agreement with a function of the form given in (i), more detailed information can be obtained by examining the low-, medium-, and high-pressure regions. In Fig. 3 the quantity $(N_2)^2/K^0L(Hg^0)$ is plotted

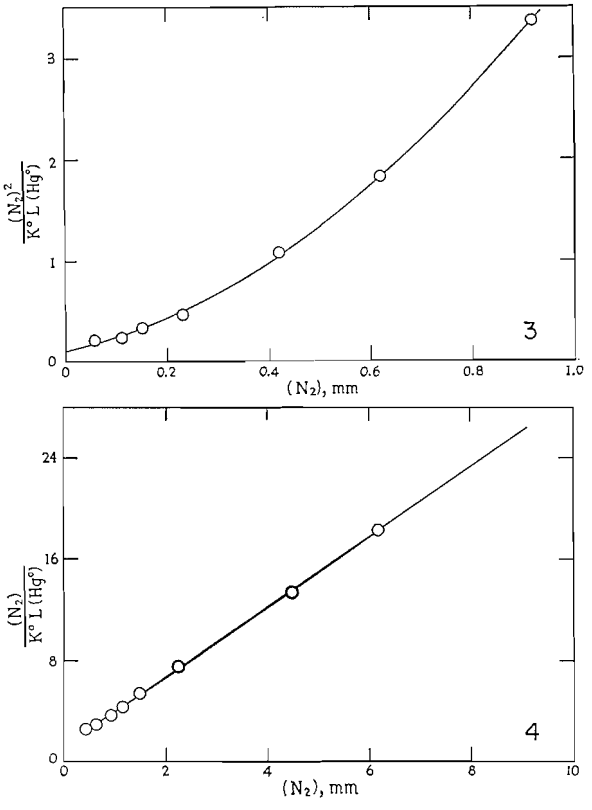

FIG. 3. $(N_2)^2/K^0L(Hg^0)$ as a function of nitrogen pressure in the low-pressure range.
FIG. 4. $(N_2)/K^0L(Hg^0)$ as a function of nitrogen pressure in the medium-pressure range.

against (N_2) for pressures below 1 mm. The smooth curve is plotted from the function $A+B(N_2)+C(N_2)^2$ in which the constants $A = 0.0974$ mm², $B = 1.171$ mm, $C = 2.597$ were obtained by the method of least squares.

In Fig. 4 the function $(N_2)/K^0L(Hg^0)$ is plotted against (N_2) for the pressure region 0.62 to 6.17 mm. The smooth curve is a plot of $A/(N_2)+B+C(N_2)$, in which $A = 0.0974$ as derived previously, $B = 1.116$, and $C = 2.780$. In this case the values of B and C were obtained by applying the method of least squares to the function $(N_2)/K^0L(Hg^0) - 0.0974/(N_2)$. To avoid crowding together of experimental points the lower part of the curve of Fig. 4, including the turnup is not shown. Although there is relatively little difference between the two sets of values of B and C, we prefer to use those corresponding to Fig. 4, since it is in this region that they play their most important role.

The value of D was obtained by taking the simple average of the quantity $[1/K^0L(Hg^0) - 0.094/(N_2)^2 - 1.116/(N_2) - 2.780]/(N_2)$ in the pressure region 9.26 to 137.0 mm; this was equal to 0.023 mm^{-1} with a mean deviation of 0.004.

Matland (16) obtained a value of approximately 0.4×10^{-16} cm² for σ^2 for the quenching of 2537 Å by nitrogen, corresponding to a value of 2.1×10^5 mm^{-1} sec^{-1} for (k_3+k_4). From the work of Alpert, McCoubrey, and Holstein (17) it would appear that with the mercury concentration and cell dimensions used in the present work there should be a negligible amount of imprisonment, and hence k_2 will be approximately 10^7 sec^{-1}. The quantity $(k_3+k_4)/k_2$ will then be 2.1×10^{-2} mm^{-1}. Since $B/A = (k_3+k_4)/k_2+k_6/k_5 = 11.4$, it follows that the first term can be neglected and that k_6/k_5 is equal to 11.4 mm^{-1}.

In order to evaluate k_6 it is necessary to obtain a relation between k_5 and the diffusion coefficient of Hg^0 atoms in nitrogen. Under steady illumination the relation between (Hg^0) and r, the radial distance from the axis of the cylindrical reaction cell is given by

$$\partial^2(Hg^0)/\partial r^2+(1/r)\partial(Hg^0)/\partial r-a(Hg^0)+b = 0, \tag{ii}$$

in which $a = [k_6+(k_7+k_8+k_9)(N_2)]/D^0$; $b = k_4(Hg^*)(N_2)/D^0$; and D^0 is the diffusion coefficient of Hg^0 atoms in nitrogen.

Since the cell is more or less uniformly irradiated by the four arms of the two U-shaped lamps, the radius of the cell is only 1.55 cm, and the partial pressure of mercury corresponded to saturation at 15° C, we feel justified in assuming that I_a^*, and hence (Hg^*), is uniform throughout the cell. This is supported by the work of Pinder and Le Roy (18) on the extinction coefficient for the absorption of 2537 Å by mercury, in which they used a lamp similar to those used in the present work. Actually, any decrease in (Hg^*) as r approaches zero will be partially compensated by an increase in the rate of reaction [8], since (Hg^0) will increase as r approaches zero.

The solution of (ii) is

$$(Hg^0) = \frac{b}{a}\left[1-\frac{\Sigma(\alpha\rho^2/4)^n/(n!)^2}{\Sigma(\alpha/4)^n/(n!)^2}\right], \tag{iii}$$

in which $\alpha = aR^2$, $\rho = r/R$, R is the radius of the cell, and the summations are for all integral values of n from zero to infinity. Since D^0 is inversely proportional to (N_2) it follows that a and α will approach zero as (N_2) approaches zero. Hence, at low pressures,

$$(Hg^0) \rightarrow bR^2(1-\rho^2)/4 \rightarrow \frac{k_4I_a^*(N_2)}{4k_2D^0}(1-\rho^2) \tag{iv}$$

or, at the axis of the cell,

$$(Hg^0) \rightarrow \frac{k_4I_a^*(N_2)}{4k_2D^0}. \tag{v}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Since the radius of the analysis beam is approximately one-fifth that of the cell, the average value of (Hg^0) in the beam will differ from that at the axis by a negligible amount. Comparison of (v) with the limiting low-pressure value of (Hg^0) given by (i) shows that

$$k_5 = 4D^0(N_2)/R^2. \qquad \text{(vi)}$$

Since there are no certain values of D^0 in the literature, we have used the data of Spier (19) on the diffusion coefficient of Hg in nitrogen. These were obtained under conditions similar to those of the present experiments: 1.12 to 1.75 mm pressure and 292.2° to 298.7° K. Assuming a square law dependence of D^0 on the temperature, and an inverse first-power dependence on the pressure, the average value of D^0 at 1 mm pressure and 25° C is 124 $cm^2\ sec^{-1}$, from which k_5 is calculated to be 206 $mm\ sec^{-1}$.

From this value of k_5 and the empirical values of A, B, and C, the following kinetic parameters were obtained: $k_6 = 2.35\times10^3\ sec^{-1}$ (i.e. natural lifetime is 4.25×10^{-4} sec); $(k_7+k_8+k_9) = 5.84\times10^3\ mm^{-1}\ sec^{-1} = 1.09\times10^{11}\ cm^3\ mole^{-1}\ sec^{-1}$. Assuming that $k_4 \gg k_3$ and that the coefficient D is not invalidated by pressure broadening, values of (k_7+k_9) and k_8 are found to be $2.32\times10^3\ mm^{-1}\ sec^{-1}$ and $3.52\times10^3\ mm^{-1}\ sec^{-1}$, respectively. Assuming that reactions [7] and [9] have no activation energy, their mean value of σ^2 is $4.5\times10^{-19}\ cm^2$. The value of σ^2 for reaction [8] is $31.5\times10^{-16}\ cm^2$, assuming an activation energy of 5.0 kcal per mole in the expression, $k_8 = \sigma^2(8\pi RT/\mu)^{1/2}e^{-E/RT}$; this appears to be high; whether or not this is the result of incomplete deactivation of excited N_2 molecules formed in reactions such as [3], [4], or [7] cannot be established until the possible influence of pressure broadening is ascertained.

The absorption measurements clearly indicate the occurrence of [6]; the lifetime of the 6^3P_0 state, with respect to emission was found to be 4.25×10^{-4} sec. This value was derived from experiments at pressures less than 1 mm, where errors from pressure broadening should be negligible, but involved the assumption that Hg^0 and Hg have the same diffusion coefficient. Whether or not we can conclude that there is also a collision-induced emission by reaction [9] is open to some question. Even if we neglect pressure-broadening effects in the high-pressure region it is possible to evaluate (k_7+k_9), but not k_9 alone. The constant intensity of the forbidden line in the high-pressure region, as shown in Fig. 5, would obtain if both k_7 and k_9 were equal to zero, but this would imply a very strong dependence of K^0 on nitrogen pressure in the region 10 to 137 mm.

(b) Emission Measurements

The effect of nitrogen pressure on the intensity of the forbidden line is shown in Fig. 5. According to the present mechanism the intensity should be proportional to $[k_6+k_9(N_2)](Hg^0)$. Qualitatively the results are in agreement with a relation of this form in which (Hg^0) is related to the nitrogen pressure by equation (i). However, it was necessary to assume a much larger value of D than that derived from the absorption measurements. The best agreement was obtained by using $A = 0.0974$, $B = 1.116$, $C = 2.78$, and $D = 2.0$, together with a value of 0.4 for k_6/k_9. The value of the latter is not in serious disagreement with that derived from the absorption measurements, which gave a value of 1.0 for $k_6/(k_7+k_9)$.

In comparing the results of the two series of experiments it must be borne in mind that although there is unequivocal evidence for pressure-dependent emission of the forbidden line, any conclusions about the particular form of the emission process will be influenced by the interpretation of the data given in Figs. 2 and 5. If the fall-off in

For personal use only.

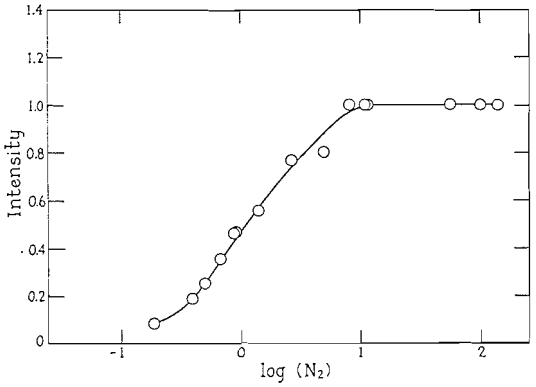

FIG. 5. Intensity of the forbidden line, 2656 Å, in arbitrary units as a function of nitrogen pressure.

$K^0L(Hg^0)$ at high pressures is due only to pressure broadening effects, then the coefficient D in equation (i) is actually zero; in which case all of the emission would have to be by reaction [6]. However, this would predict a considerably higher emission intensity below 10 mm than was actually found. On the other hand, if all emission is assumed to occur by reaction [9] it would not be possible to interpret the results of the absorption measurements in the low-pressure regions where pressure broadening effects are not likely to be serious. One factor that has not been taken into consideration is that the lamps were operated on 60-cycle alternating current, which might invalidate the use of the steady-state assumption.

Although it is evident that further work will have to be done in order to resolve the quantitative discrepancies between the two sets of measurements, the present work has shown that in any future attempt to interpret the behavior of mercury 6^3P_0 atoms cognizance must be taken of the spontaneous and collision-induced emission of the forbidden line.

The authors are grateful to the National Research Council of Canada for a Studentship (held by G. H. K.) and for a grant-in-aid of the research.

HIGH ENERGY REACTIONS OF ATOMIC HYDROGEN[1]

MICHAEL HENCHMAN,[2] DAVID URCH,[3] AND RICHARD WOLFGANG

ABSTRACT

The chemistry of hot hydrogen atoms has been studied using tritium of high kinetic energy as produced by nuclear recoil. The possibilities and limitations of this technique are discussed using a collision theory for reactions of atoms having a very high initial energy. Using this theory and certain experimental data, it is concluded that hot hydrogen atoms react to combine with organic molecules at very high collision efficiency (of the order of approximately 0.2 to 0.4) in the energy range 3–10 ev. There is no indication that collisions at much higher energies lead to combination. With most systems, e.g. alkanes, a wide variety of reactions is observed. The systematics of these hot reactions is discussed and evidence on their detailed mechanism is presented. It appears that most products are formed by a fast displacement of an atom or group by the hot hydrogen. There is no evidence for the formation of a common, internally equilibrated, collision complex which decays on a statistically determined basis to the various products. Instead, the course of the reactions seems largely governed by the direction and point of impact of the hot atom. Thus, stereochemical evidence indicates that axial approach of the hot hydrogen atom along the C—H bond axis leads to abstraction while approach at large angles to this axis results in displacement without Walden inversion. In some cases sufficient excitation energy is introduced in the hot displacement process to cause further decomposition of the primary product. This model of high-energy reactions is compared with that of thermal reactions and its general implications are briefly discussed.

Perhaps the severest limitation on the study of chemical kinetics has been the scarcity of data on high-energy interactions. Little information on such interactions is obtainable from results on thermally excited species. Thermal reactions generally have very low collision efficiencies which are sensitively dependent on the activation energy. As a consequence only those reaction modes with minimum activation energies are observed. In a sense these modes are only limiting cases of the high-energy situation. Here activation energies are no longer large compared with the energies available; consequently collision efficiencies should be higher and a much wider variety of reactions may be expected.

Thus up to a few years ago, the only known reaction between atomic hydrogen and methane was simple abstraction, as it proceeds with thermal hydrogen (1, 2)

$$D + CH_4 \rightarrow HD + CH_3\cdot$$

But other reactions of hydrogen atoms are quite conceivable; for instance, exchange

$$D + CH_4 \rightarrow CH_3D + H$$

or perhaps

$$D + CH_4 \rightarrow H_2 + CH_2D\cdot$$

and so on. These reactions are interesting and a priori one might expect them to occur at higher energies, where the system may follow paths on the reaction surface other than those going through the lowest saddle point.

There has been no shortage of interest in possible high-energy reactions. Rather, what has been lacking is the means of producing high energy or "hot" species under controlled conditions, where their elementary reactions might be studied. Some work has been done, generating hot atoms and radicals by photochemical dissociation; but, in general, these have still not been of sufficient energy to react in a qualitatively different manner from their low-temperature thermal counterparts (3). In principle, the ideal system for the

[1]*Contribution No. 1625 from the Sterling Chemistry Laboratory, Yale University, New Haven, Connecticut; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

[3]*Present address: Department of Chemistry, Queen Mary College, Mile End Road, London E1, U.K.*

study of high kinetic energy atoms and other species would be monoenergetic molecular beams of controllable energy. However, for work in what is chemically perhaps the most interesting energy range—of the order of 1 to 20 ev—it does not appear that present beam techniques are likely to give useful results for some time.

In the meantime it appears that high-energy recoils from certain nuclear reactions may provide systems in which high-energy atomic reactions may be studied under controlled conditions. In our laboratory we have used recoil tritium from the nuclear reaction $He^3(n,p)T$ as a source of hot atoms. This paper briefly surveys our recent and largely unpublished results and uses them as a basis for discussion of a model of hot atom reactions.

METHOD

The principle of the recoil method as used for hot hydrogen atoms is very simple (4). He^3 is mixed in a quartz ampoule with the gas whose reactions with hot hydrogen are to be studied. (A lithium salt may be substituted for He^3 in condensed systems.) Hot hydrogen in the form of recoil tritium is generated by exposure to neutrons. This will react to form trace quantities of various products which are labeled due to the radioactivity of the contained tritium. These products are then separated, generally by gas chromatography, and assayed using an internal flow proportional counter attached to the chromatography unit (5, 6). Any of the products may then be degraded to determine the intramolecular position of the tritium.

While this method is basically simple there are a number of pitfalls to be avoided. In the first place unless the nuclear reaction gives rise to a well-defined species, it becomes a difficult problem in itself simply to determine the nature of the reactant. Thus radiative neutron capture (n,γ reaction) usually yields a recoil species with an energy between 1 and 1000 ev, which may or may not be charged, and which may or may not be neutralized before undergoing "chemical" reaction. Fortunately the $He^3(n,p)T$ reaction yields ions of very high energy, 2×10^5 ev; neutralization of these ions occurs at 10^4 ev in non-ionic media; in an energy range well above that in which they may react to become chemically bound (4). This nuclear reaction is thus a well-defined source of atoms of essentially infinite energy, which lose energy by collision until they react or are reduced to thermal energies.

Secondly, the high-energy release associated with the nuclear reactions will cause gross radiation damage to the system and may build up a significant level of reactive impurities. This effect is controlled by using only a trace amount of recoil tritium—of the order of 10^{14} atoms—a device made possible, of course, by its radioactivity. The tracer level experiment has the further advantage of eliminating the confusing type of secondary process where more than one hydrogen atom is involved.

A final important point of technique is being able to distinguish between hot reactions and the thermal reactions of those atoms which have been collisionally deactivated (7). These thermal reactions are effectively eliminated by the addition of a small concentration of a scavenger, such as I_2, with which the thermalized species will react preferentially. On the other hand the hot reactions are unaffected since hot atoms have an effective lifetime of only a few collisions and are therefore unlikely to encounter the scavenger.

COLLISION KINETICS AND ENERGY DEPENDENCE

The main disadvantage of using nuclear recoil as a source of hot atoms is that the reactions occur over a range of energies, from the highest possible energy where combination may take place down to (but not including) the thermal region. It is for this reason that molecular beams are, in principle, preferable; they would make possible a direct and

explicit measurement of reaction probability as a function of energy. However, even if recoil atoms cannot be used to study reactions at a single energy, their distribution of energies is well defined and their collision kinetics can thus be treated analytically (7). In a sense the collision theory of hot atoms, briefly outlined below, is quite analogous to collision theories of thermal species whose Boltzmann energy distribution yields expressions such as the Arrhenius equation.

Kinetic Theory

Consider a system (7) of hot atoms which lose energy in successive collisions but may react to combine between energies E_2 and E_1. Above E_2 the collisions are too energetic to result in stable combination and E_1 is the minimum energy required for reaction. Let $n(E)dE$ be the differential probability of collision at energy E, f the probability that a collision will be with a reactive species, and $p(E)$ the probability that such a collision at energy E will result in combination. Then the total probability P that the hot atom will react during its lifetime is given by

$$P = \int_{E_2}^{E_1} fp(E)n(E)dE. \qquad [1]$$

$n(E)$ is evaluated assuming that the initial energy is much greater than E_2, that the reaction threshold E_1 is above thermal energies, and that the energy loss is as by elastic collisions. P can then be evaluated (7)

$$P = 1-\exp\left[-\frac{f}{\alpha} I\right] \qquad [2]$$

$$I = \int_{E_1}^{E_2} \frac{p(E)}{E} dE \qquad [3]$$

where α is the average logarithmic energy loss per collision. P, the total probability of hot reaction, is experimentally measurable and f and α may be calculated from the composition of the system. Similar considerations (7) lead to expressions for the total probability of hot reaction P_i to give a specific product i.

This detailed theory has been tested (7) using the reactions

$$CH_4 + T \rightarrow CH_3T + H, \qquad [4]$$

$$CH_4 + T \rightarrow CH_2T\cdot + H_2. \qquad [5]$$

f and α were varied by adding rare gas moderators. The effect of these is to reduce the total probability of hot reactions by reducing the number of collisions of the hot atom with methane. Figure 1 shows the probability of formation of CH_3T in the presence of

various amounts of He, Ne, A, and Xe. The points are experimental and the lines through them calculated from the kinetic theory. The fit is good within experimental error and the treatment is evidently a valid representation of the system.[4]

Energy Dependence

This model of hot reactions makes it clear that high-energy recoil atoms cannot supply explicit and absolute information on the energy dependence of the collision efficiency $p(E)$. As obtained from this treatment $p(E)$ is wrapped up in the definite integral I. The only energy information that can be directly obtained from the detailed theory is on the relative average energies at which various products are formed in a given system (7). Thus it appears that the two hot atom reactions of methane ([4] and [5]) proceed at about the same average energy.

Information on the energy range in which hot reactions can occur must come from calculations on the dynamics of the collision (which are quite difficult) and from the character of the reactions which are observed. Data on the lower energy limit (E_1) comes from experiments in which Hamill *et al.* (3) have observed that the hydrogen displacement reaction does not occur with photochemically generated hydrogen atoms of 1 to 2 ev. At the other limit, the only conceivable way in which a very high-energy hydrogen atom (>10–20 ev) can undergo displacement reaction [4] is by transferring most of its kinetic energy to the ejected hydrogen in a quasi-elastic or billiard-ball (8) collision. This would leave the incoming atom with sufficiently little energy so that it could be captured by the methyl group. (Such a process can be considered as essentially an atom–atom collision, where one of the atoms is held in a relatively shallow potential well to the rest of the molecule, with which it is then only weakly coupled.)

It has been calculated by Cross (9) that if displacement reaction [4] with CH_4 and CD_4 occurs by such a pure billiard-ball mechanism, there should be an isotope effect of about 3. No such large effect is experimentally observed, indicating that this type of mechanism is not important (9). Apparently reaction occurs in an energy range where valence bond coupling is strong, i.e. as far as transfer of momentum is concerned the incoming atom collides with the molecule, or a large part of it, instead of a single atom within it. This finding was not unexpected in view of the earlier observation that alkyl groups and halogen atoms as well as hydrogen atoms could be displaced. The tritium must therefore have a kinetic energy of the order of magnitude of valence bond energies. This conclusion is consistent with the products observed from other systems, for the energy deposited in a hot displacement reaction appears to be insufficient to cause extensive decomposition or rearrangement. This topic will be discussed later in this paper.

Collision Efficiencies

If, therefore, the conclusion is that the hot hydrogen reacts to combine while between 2 and 20 ev or, more likely still, while between 3 and 10 ev, the kinetic theory can be used to calculate collision efficiencies. From equation [3] the collision efficiency $p(E)$ averaged over the entire energy interval E_2 to E_1 is

$$\overline{p(E)} = \frac{I}{\ln(E_2/E_1)} \qquad [6]$$

For the methane system I has been measured to be 0.4 (7). Fortunately $\overline{p(E)}$ is quite insensitive to the energy range E_2/E_1. Using the values just quoted we find that for hot

[4]*Conversely, these considerations provide a further proof that the reactions studied are indeed hot. A fit cannot be obtained even if there is only a small contribution by thermal processes (7).*

atom reactions collision efficiencies are of the order of 0.2 to 0.4. These values are several orders of magnitudes higher than those for thermal reactions of a similar nature and are one of the distinguishing characteristics of hot atom reactions.

SYSTEMATICS OF HOT HYDROGEN ATOM REACTIONS

The reaction of hot tritium with hydrocarbons (4, 10, 11, 12, 13), alcohol (14), acetone (14), carboxylic acids (15), and various solid compounds (16) has been investigated. The types of reactions found are quite similar in all those systems. We can therefore use the results of a recent study (13) we have made of the alkane system as a representative example of the systematics of hot hydrogen displacement reactions. (Hot hydrogen addition reaction, as studied in alkenes (10), is a separate class of mechanism and will not be discussed here.)

As in most systems about two-thirds to three-quarters of hot hydrogen atoms in pure alkanes will undergo reaction before reaching thermal energies. The types of reactions found are as follows, in decreasing order of relative importance (butane is used as example):

(I) Hydrogen atom abstraction. This reaction, the only one observed at thermal energies, also occurs with hot hydrogen (although with a much higher collision yield).

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow \begin{matrix} CH_3CH_2\dot{C}HCH_3 \\ CH_3CH_2CH_2CH_2\cdot \end{matrix} + HT.$$

(II) Hydrogen atom displacement:

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow \begin{matrix} CH_3CH_2CH_2CH_2T \\ CH_3CH_2CHTCH_3 \end{matrix} + H.$$

(III) Replacement of alkyl group to form a degraded alkane:

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow \begin{matrix} CH_3T \\ CH_3CH_2T \\ CH_3CH_2CH_2T \end{matrix}$$

(IV) Replacement of two groups to form a radical. Either two hydrogen atoms or a hydrogen atom and an alkyl group may be displaced by the hot tritium atom, e.g.,

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow CH_3CH_2CH_2CHT\cdot.$$

The resulting radical may combine with iodine scavenger to form alkyl iodide. Alternatively it may decompose into a smaller radical and an alkene by breaking a C—C bond without rearrangement, e.g.,

$$CH_3CH_2CH_2CHT\cdot \rightarrow CH_3CH_2\cdot + CH_2CHT.$$

(This type of decomposition has also been observed with similar radicals made by hot atom addition to alkenes (10).)

These reactions account for essentially the entire yield. No built-up or rearranged products are formed. The relative importance of these various types of reactions with the alkanes are given in Table I. However, their relative probabilities vary sharply and in a specific manner from system to system. It is in this variation that we must look for clues to the mechanism.

MECHANISM

We have mentioned earlier that in high-energy processes the activation energies should become less important in determining the path of a reaction. This is reflected in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

result that 90±2% of the hot reactions are hydrogen abstraction or displacement and less than 10% involve displacement of an alkyl group. In other words the probability of C—H bond rupture is about four times greater than with the weaker C—C bond. This finding also implies that hot displacement reactions do not pass through a common intermediate or collision complex of sufficient lifetime to permit internal equilibration of energy, as has been suggested (17, 18). Such an intermediate would certainly be expected to decompose at least as often by breaking a weaker rather than a stronger bond. There appears to be no data supporting the supposition that hot displacement reactions do go through such quasi-equilibrated intermediates. For instance, if HT and $CH_2T\cdot$ were produced from methane by decomposition of a common activated complex, in which the incident and the CH_4 hydrogen atoms have become indistinguishable

$$T + CH_4 \rightarrow (CH_4T) \rightarrow \begin{matrix} CH_2T\cdot + H_2 \text{ or } CH_3\cdot + HT \\ CH_3T + H \quad \text{or } CH_4 + T \end{matrix}$$

their ratio $HT/CH_2T\cdot$ would be expected, on a purely statistical basis, to be 2:3. Even allowing for possible isotope effects the observed ratio of 9:1 hardly supports such a mechanism (4). Instead, all results are consistent with the hypothesis that the displacement reaction is a fast, direct, localized event occurring on a time scale comparable to a bond vibration ($\sim 10^{-14}$ sec).[5]

Stereochemistry of Hot Atom Displacement

If hot reactions are thus not controlled by energetics, or the statistically determined decay of a common collision complex, we must turn to stereochemical factors affecting displacement and abstraction processes, as the major determinant of hot atom reactions. For example, it appears to be a reasonable hypothesis that the C—H bond is attacked more readily than the C—C bond because of its greater exposure. Two related questions then arise: (*a*) Does hydrogen displacement proceed by a Walden inversion mechanism? and (*b*) What determines whether the hydrogen atom is displaced or abstracted? The answers to these questions have been sought in experiments on the retention of spatial configuration during hydrogen displacement.

The first experiment performed using hot tritium indicated that configuration was retained during hydrogen displacement. The system was glucose (19, 20) and it yielded a substantial amount of glucose labeled at hydrogen atoms attached to asymmetric carbon atoms. Had inversion occurred, other labeled hexoses would have been obtained instead. Retention of configuration has also been demonstrated in displacement at the hydrogen attached to the asymmetric center in alanine (21). However, since these experiments were carried out in the solid phase, they left open the possibility that the molecule was constrained to keep its configuration only by the crystal structure.

Experiments were therefore carried out on the retention of configuration in the vapor phase. The displacement reaction for gaseous optically active *sec*-butyl alcohol was studied. There is no change in configuration about the asymmetric carbon atom during the displacement of both the hydrogen bonded directly to it and those in the methyl and ethyl groups. These results actually show 90±10% retention of configuration.

With this information we can now discuss a more detailed model for the hydrogen abstraction and displacement, which together account for 90% of the hot reactions in

[5]*It is interesting to compare the fast displacement reactions with the addition reactions of hot hydrogen to double bonds in alkenes. In the latter case it can be clearly shown that a long-lived radical intermediate is formed (10). These well-defined intermediates may each decompose into two or three sets of alternative products.*

For personal use only.

alkanes. If Walden inversion is unimportant, it can be postulated that to react with a bound hydrogen, the incoming hot hydrogen must approach within a wide cone about the C—H bond axis (see Fig. 2). However, if the approach is directly along the C—H bond

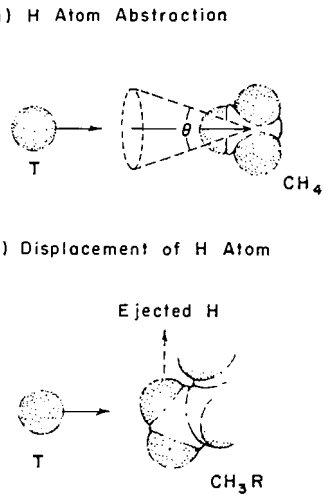

FIG. 2. Stereochemistry of the abstraction and displacement of hydrogen from an alkane.

axis, displacement could not occur as it would be difficult to juxtapose the positions of the H and T atoms. But abstraction of the H atom should be entirely possible for this approach. This is in accord with calculations of Gorin *et al.* (22), showing that axial attack along the C—H bond is the most favorable route for hydrogen abstraction. This mechanism is also consistent with the finding that abstraction from CH_2D_2 yields equal amounts of HT and DT (23). Thus we arrive at the tentative conclusion that hot hydrogen attack at small angles to the C—H bond, within a small inner cone about the bond axis, normally leads to abstraction, whereas approach at large angles, within a larger co-axial cone, usually results in displacement (see Fig. 2).

This model is crude and obviously oversimplified. But it can be tested. Consider a particular C—H in an alkane. Methyl or methylene groups attached to the carbon will obstruct those approaches of the hot atom at large angles to the C—H bond axis and will reduce the amount of displacement. Approaches at small angles will not be affected and hence there will be no steric obstruction of the abstraction reaction. We consider that the displacement reaction in methane is unobstructed and that replacement of one of these hydrogens by a methyl or methylene group reduces the amount of displacement at one of the remaining hydrogens, relative to that of abstraction, by a factor $(1-\Omega)$. Experimentally the ratio abstraction/displacement is found to be unity for methane. On this simple picture, for an alkane containing n hydrogens, of which n_1 are primary, n_2 secondary, and n_3 tertiary,

$$\frac{\text{abstraction}}{\text{displacement}} = \frac{n}{n_1(1-\Omega)+n_2(1-\Omega)^2+n_3(1-\Omega)^3}.$$

The experimental and calculated values of this ratio are plotted in Fig. 3 for all the alkanes listed in Table I and for cyclopentane. The value $\Omega = 0.45$ for the obstruction

[c]Not compatible with formation as direct consequence of a hot displacement reaction.

parameter gives the best fit. This is a simple-minded calculation with obvious shortcomings. The principal one is that it attributes the same amount of obstruction to any attached group, regardless of whether it is, say, methyl or isopropyl. Nevertheless, we suggest that the excellent correlation between calculation and experiment provides evidence for the detailed model used for hydrogen abstraction and displacement as well as the more general postulate that the course of the reaction depends primarily on the angle of approach and the point of impact of the hot atom.

Alkyl Group Displacement

It is tempting to try and generalize the hydrogen displacement mechanism for the displacement of larger atoms and groups. Such replacement has been shown to occur. Odum (24) finds that fluorine, chlorine, bromine, and iodine in alkyl halides have a high probability of being displaced by a hot hydrogen atom.

$$T^* + CH_3X \rightarrow CH_3T + X$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Rowland and co-workers have demonstrated the occurrence of hot hydrogen displacements of halogens and also of nitro groups in aromatic systems (25).

This would seem to indicate that degraded alkanes are formed by direct alkyl group displacement (reaction type III), e.g.,

$$CH_3CH_2CH_2CH_3 \rightarrow CH_3T \text{ or } CH_3CH_2T \text{ or } CH_3CH_2CH_2T.$$

In this single-step mechanism it is postulated that the hot hydrogen attacks the C—C bond in a direction nearly perpendicular to the bond axis. It would displace one group and combine with the other. This mechanism is consistent with the following results for the alkane system (13).

1. Displacement of an alkyl group is less probable than that of an H atom. This may be correlated with the greater steric obstruction of the C—C bond.

2. The amount of an alkane RT formed depends on the number of R groups in the reacting molecule. Thus the amount of methane formed from the pentanes increases in the order cyclopentane $<$ *n*-pentane $<$ isopentane $<$ neopentane.

3. In attacking a C—C bond the tritium preferentially combines with the smaller of the groups joined by the bond. This bias is more pronounced if the two groups are very dissimilar in size. Thus neopentane yields eight times as much methane-T as isobutane-T.

Although direct alkyl group displacement is not the only possible mechanism for the formation of the degraded alkanes (see footnote 6) it appears to be the most likely. Its validity would be established by showing that configuration is retained in the formation of the degraded alkanes.

The direct displacement mechanism can also account for the production of radicals (reaction type IV). Two atoms or groups would have to be displaced, e.g.,

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow H_2 + CH_3CH_2CH_2CHT.$$

This mechanism is plausible but there is as yet insufficient evidence to regard it as more than a tentative hypothesis.

EXCITATION ENERGY IN PRIMARY PRODUCT OF HYDROGEN DISPLACEMENT

It is likely that some of the energy of the incident hot atom will remain as excitation in the product of the displacement process. Although we have presented evidence that the point and direction of impact is the primary determinant of the reaction path, this excitation energy may also be a factor in determining the final product. That this energy is very unlikely to be large (of the order of 10 ev) is indicated by the very small yields of products requiring multiple bond rupture for their formation. Thus only traces of acetylene are formed by hot hydrogen reaction with alkanes; similarly, the yield of methylacetylene and allene by reaction with alkenes is less than 1% (10, 11, 13).

The excitation energy is sufficient to cause some decomposition of the product of the primary displacement especially in sensitive systems. Thus carboxylic acids tend to decarboxylate following hot hydrogen displacement (15), e.g.,

$$CH_3COOH + T^* \rightarrow CH_2TCOOH^* \rightarrow CH_3T.$$

The resulting decarboxylated hydrocarbon can presumably also be produced by direct displacement of —COOH. But the yield of this product decreases very rapidly with increasing chain length. This indicates that most of it must have been formed by decomposition of excited acid molecules. As the size of such molecules increases so does their lifetime (26) and it becomes more likely that they lose their energy by collision rather than decomposition.

Other systems also provide evidence for deposition of moderate amounts of excitation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

energy on displacement. When a hydrogen atom bound to the sp^2 carbon atom in cis and trans dichloroethylenes is replaced, configuration is lost in 30% of the events (13). This loss is probably due to rotation about the double bond requiring an activation energy of about 2 ev.

Reaction of hot hydrogen with cyclopropane yields at least 15% as much propylene as substituted cyclopropane (13, 17). The isomerization of cyclopropane to propylene has an activation energy of 3 ev. At the pressures at which the experiment was carried out, this would mean that about 4 ev of excitation had been introduced during hydrogen atom displacement.

The examples quoted are particularly sensitive systems, and even in them the fraction of the total products formed by rearrangement or decomposition of a species excited in the initial displacement is not large. In the more stable alkane systems, the only significant products, which could plausibly be formed by such decomposition, are the alkyl radicals (Systematics, reaction type IV), e.g.,

$$T^* + CH_3CH_2CH_3 \rightarrow CH_2TCH_2CH_3^* \rightarrow CH_2TCH_2\cdot + CH_3\cdot.$$

Radicals account for only about 5% of the total yield from alkanes and they could also have been produced by the two group displacement mechanism mentioned earlier.[6]

CONCLUSION

While the studies briefly outlined here represent only a small start towards understanding the chemical properties of hot hydrogen atoms, it does appear that the broad outlines of a mechanism are emerging. The significance of our findings may be summarized by comparing the model for hot reactions with that for thermal processes.

In thermal reactions only a small fraction $e^{-\Delta E/kT}$ (where ΔE is the activation energy) of species have sufficient energy for reaction. Even these species have barely sufficient energy and their only possible path over the energy surface must pass through a saddle point. This is evidenced by the fact that only a small fraction of collisions between species of sufficient energy result in reaction. This fraction p is, of course, the so-called steric factor and $pe^{-\Delta E/kT}$, the collision efficiency, is thus usually a very small number. By contrast we have shown that when a hydrogen atom with a kinetic energy of the order of 3 to 10 ev strikes a molecule, there is a high probability, approaching one-half, that it will react. This must in part simply result from the fact that all systems have energy in excess of the minimum activation energy, so that the factor $e^{-\Delta E/kT}$ approaches unity. What is more significant, however, is that many of the hot atoms have considerably more than the minimum energy for reaction. As a result, their possible paths over the reaction energy surface are not restricted to passage through the lowest saddle point, and a much wider

[6]*It may be proposed that degraded alkanes (Systematics, reaction type III) can be produced as a result of excitation energy left in hydrogen displacement and not by direct alkyl displacement. If decomposition of the primary product could yield hot radicals, these could form degraded alkane molecules by hydrogen abstraction (even in the presence of scavenger), e.g.,*

$$T^* + CH_3CH_2CH_2CH_3 \rightarrow CH_3CHTCH_2CH_3^* \rightarrow CH_3CHT\cdot^* \xrightarrow{\text{H abstraction}} CH_3CH_2T$$

This mechanism has difficulties however. An excited radical normally decomposes to a smaller radical and an alkene (10). To abstract hydrogen, the radical would therefore have to have kenetic rather than internal energy. The production of such species is rather improbable. Furthermore, to account for the distribution of products, e.g. the 8:1 ratio of methane-T: isobutane-T from neopentane, it would have to be postulated that the C—C bond broken was nearly always that closest to the site of the original displacement; in other words that there was little intramolecular energy transfer. Even so it is very difficult to account for the relative constancy, or even increase, in the ratio of total degraded alkanes to hydrogen substitution, that is observed with increasing chain length of the reacting alkane (Table I). However, a final decision on this mechanism must await data on the retention of configuration of the degraded alkanes. This and other alternative mechanisms can be finally excluded if it is shown that configuration is retained in alkyl displacement.

range of impact parameters can lead to reaction. Many different kinds of reactive collisions become possible. A variety of products may result, as illustrated by the alkane data, and their relative yields are not primarily governed by energy considerations. As a consequence, differences in chemical reactivity as conventionally understood become unimportant: for example, hydrogen atoms are about equally well displaced whether they are aromatic or aliphatic (23). Furthermore, the availability of excess energy may result in the products of the initial displacement being left with a range of excitation energies. There is, however, considerable evidence to suggest that these excitation energies are quite moderate. This is not unexpected for, in collisions, where the hot hydrogen has too much energy, it cannot lose enough momentum to combine.

This model is not consistent with the view that the course of hot reactions is governed by the statistically determined decay of a common intermediate or collision complex. Such a mechanism is essentially an extension of transition state theory of unimolecular decompositions. It has recently been proposed by Magee and Hamill (18) as possibly accounting for the reactions of low-energy hot atoms of photochemical origin. It seems unlikely that such a theory could be a valid representation of the reactions of atoms having more than about 2 ev of energy. Because of this excess kinetic energy, passage along the reaction co-ordinate is so rapid that there is insufficient time for internal equilibration of energy in the collision complex. The fate of this complex thus cannot be predicted by calculating the relative probabilities of decomposition, through various channels, of an equivalent internally equilibrated complex. Instead, the manner in which the collision complex disintegrates is determined by the particular manner in which it was put together.[7]

We thus postulate that the initial hot displacement reaction occurs by a fast ($\sim 10^{-14}$ sec) localized "direct" displacement. The course of this process is governed primarily by the direction and point of impact. These stereochemical considerations are of a different nature than that encountered in the "steric factor" of thermal reactions. In the thermal case it was simply a matter that with the minimal energy available only a certain approach could lead to reaction. With hot hydrogen, reaction appears likely for many types of approaches. What is governed by the stereochemistry is not so much whether reaction will take place but what kind of reaction will take place. An example is provided by the situation with alkanes, where approach co-axial to a C—H bond leads to abstraction, whereas approach at a larger angle results in displacement.

THE REACTIONS OF HYDROGEN ATOMS WITH SOME ORGANIC LIQUIDS[1]

R. B. INGALLS AND J. R. HARDY

ABSTRACT

Measurements have been made of isotopic exchange and deuterium pressure change during deuterium atom bombardment of *o*-terphenyl, toluene, and eicosane just above their melting points. The number of molecules of HD formed was larger than the number of molecules lost or gained by the gas phase. A mechanism of reaction of deuterium atoms with aromatic liquids is proposed.

INTRODUCTION

During studies of the radiation chemistry of some aromatic liquids (1), a need for a better understanding of the reactions of hydrogen atoms with aromatic molecules became apparent. There have been a number of studies of the action of hydrogen or deuterium atoms with aromatic or double-bond systems in the gas and solid phases reported (2), but reactions of hydrogen atoms in organic liquids have been largely neglected. Experimental difficulties encountered in such studies may be in part responsible for this state of affairs.

Hydrogen atoms are important intermediates in the radiation-induced formation of both high molecular weight products and hydrogen gas in aromatic and vinyl hydrocarbon systems (3). Therefore, a knowledge of their reactions is necessary for an understanding of the radiation chemistry of these materials. A knowledge of hydrogen atom reactions would also contribute indirectly to our knowledge of energy transfer and other important processes in radiation chemistry by allowing the separation of these reactions from other effects (4).

The work reported here is part of an effort to gain better understanding of the reactions of hydrogen atoms with aromatic materials by direct experimentation. Purified deuterium gas was dissociated into atoms on a hot tungsten filament. The gas, containing a small fraction of atoms, was cooled by indirect momentum transfer with thermostatted walls of the reaction vessel before impinging on the surface of the liquid under investigation. The gas consumed or formed during the reaction was measured, and the formation of HD was determined by mass spectroscopy.

EXPERIMENTAL

Deuterium gas, obtained from Stuart Oxygen Company, was further purified by storage as uranium deuteride. Its isotopic purity was determined by mass spectroscopy to be 99.5%.

Reagent grade toluene, obtained from Mallinckrodt, was distilled through a $2\frac{1}{4}$-ft glass-helix packed column and dried over calcium hydride. No impurities were detectable by gas–liquid partition chromatography.

Eastman Kodak white label eicosane and *o*-terphenyl were used without further purification. High-temperature gas–liquid partition chromatography indicated no impurities in the *o*-terphenyl and 2.4% of lower boiling impurities in the eicosane.

[1]*Contribution from the Research Department of Atomics International, A Division of North American Aviation, Inc., Canoga Park, California; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960. Work performed under A.E.C. Contract AT(11-1)-GEN-8.*

An appropriate quantity of deuterium gas was measured into the system and pumped into a 2-liter measuring volume and micromanometer head. The 2-liter volume and the micromanometer head were maintained constant within 0.2° C at about 36° C. After a period of about 15 minutes was allowed for temperature equilibration, the micromanometer head was isolated and the main portion of the gas was pumped into a 5-liter storage bulb. During the run, the deuterium gas was circulated from this bulb through the reaction cell (see drawing of reaction cell, Fig. 1). The storage bulb was designed so that mixing of the gas occurred during circulation.

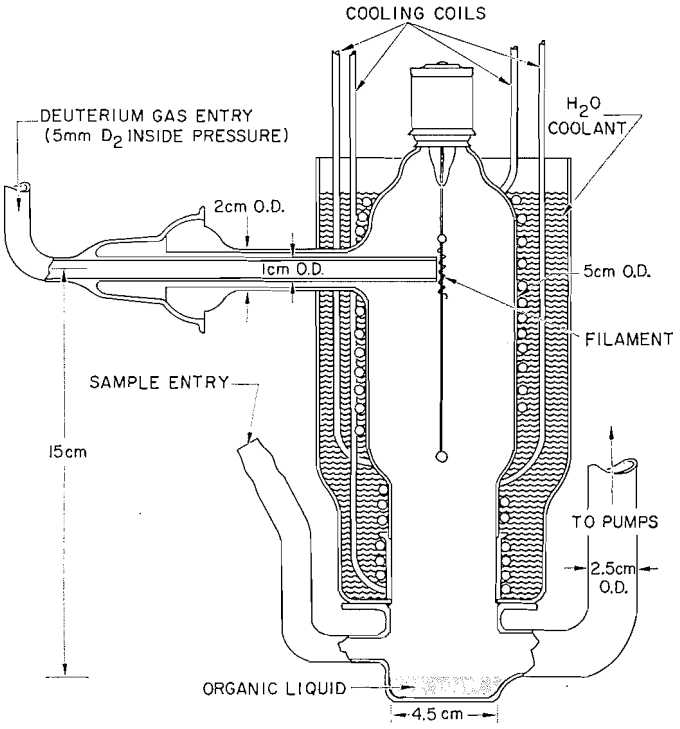

FIG. 1. Reaction cell.

It is important to understand that the pressure in the reaction cell during the run was about 5 mm of Hg* and that at this pressure, the mean free path of deuterium is nearly three orders of magnitude smaller than the dimensions of the reaction cell. Therefore, many of the deuterium atoms are prevented from getting to the wall to recombine while traveling the 15 centimeters from the filament to the surface of the liquid reactant. Indirect thermal contact with the thermostatted walls of the reaction cell does cool the gas, however, to within a degree or so of the temperature of the wall.

In order to prevent back diffusion of the organic vapors to the filament, a degassed sample was introduced into the reaction cell while the deuterium gas was being circulated. The reaction cell was brought to a constant temperature somewhat above the melting

**In order to pump deuterium rapidly at 5 mm, two mercury diffusion pumps were used in series. One was an 80-liter per second, three-stage pump and the other was a single-stage pump designed to pump into pressures up to 20 mm of Hg. The gas was pumped through the reaction cell at about 2 liters per minute when the inlet pressure to the big pump was maintained at about 0.2 mm of Hg by a controlled leak. Three traps were maintained at liquid nitrogen temperatures throughout the experiments.*

point of the sample which was stirred magnetically to increase the heat transfer with the bath. The filament was then brought up to temperature for an appropriate length of time. The gas was then pumped into the 2-liter bulb, permitted to come to temperature, and allowed to equilibrate with only one side of the micromanometer head. In this way, the pressure change which occurred during the reaction could be measured directly with the micromanometer to a precision greater than one part in a thousand. A sample of the gas was analyzed by mass spectroscopy for isotopic composition.

RESULTS

The experimental results are given in Table I. The values reported in the column headed % pressure per minute are equal to $(\Delta P \times 100)/(P \times T)$, where ΔP is the observed pressure change during the run, P is the pressure in the 2-liter measuring volume, and T is the length of the run in minutes. The corrected* increase in percentage of HD in the D_2 during the run divided by the time of the run in minutes is reported in the column headed % HD per minute.

A change in the geometry of the apparatus occurred between *o*-terphenyl runs 5 and 6. This did not significantly affect the ratio of HD formation to pressure change, although the rates of conversion dropped by approximately a factor of 4. Total conversion of the deuterium gas was about 10% in the runs with *o*-terphenyl and toluene, but was considerably less in the runs with eicosane. Blank runs with helium and *o*-terphenyl prove that cracking of the organic on the filament does not contribute to the results. This is not surprising in view of the low vapor pressure (less than 10 microns) of the materials at their melting point.† For the same reason, a gas phase reaction of organic vapors and deuterium atoms does not contribute significantly to the results.

The organic materials were examined by gas chromatography after reaction. A comparison of the sensitivity of the starting *o*-terphenyl and a 4.8-g sample from which 2.2×10^{-4} moles of HD had been produced indicated that exchange of deuterium for hydrogen had occurred in the *o*-terphenyl during the reaction. Using internal standards for comparison (5), the area under the curve for the starting material was $0.5\% \pm .05\%$ less than the area under the curve of the reacted material. This can be explained in terms of an increase in heat capacity and resulting increase in thermal conductivity of the *o*-terphenyl upon substitution of deuterium for some of the hydrogen (6).

No internal standard was used in the examination of the eicosane since impurities of the order of 2.4% were found in the unreacted material. The area under the curve for the impurity peaks was significantly reduced relative to the eicosane peaks in the reacted material. This effect may be due in part to substitution of deuterium and in part due to the selective reaction of the impurities.

Gas chromatographic examination of the reacted toluene revealed low yields of higher-boiling products. Bibenzyl was the major product, but its yield corresponded to only 1 mole per 10^4 moles HD formed. This indicates that abstraction of hydrogen from toluene is not important at these low temperatures (−80° C).

The values reported for the runs made with eicosane and toluene are preliminary and are intended only to support in a general way the results obtained with *o*-terphenyl. The eicosane results are open to question on two counts:

1. The conversions were low, decreasing our accuracy.

**A small correction for exchange on the walls was made based on results from blank runs.*

†This type of experiment is limited in applicability to materials of extremely low vapor pressures at the temperature of the reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

2. The 2.4% impurities in the eicosane may have been consumed disproportionately during the reaction.

The toluene runs were made at an earlier date and are more difficult experimentally so that the accuracy is probably not as high as in the runs with *o*-terphenyl.

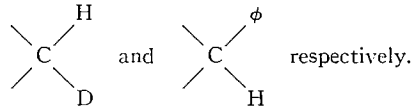
A more detailed study of these materials as well as several other classes of organic compounds is being planned.

DISCUSSION

The reaction of thermal deuterium atoms with liquid *o*-terphenyl at 60° to 75° C produces more molecules of HD than there are molecules lost from the gas phase. Similar results were obtained with toluene at −88° to −79° C (see Table I). We propose the following mechanism for these systems:

$$\dot{D} + \phi = \dot{\phi}D \qquad k_1 = 10^9 \exp -[(3\times10^3)/RT] \qquad [1a]$$

$$\dot{\phi}D + (n-1)\phi = \dot{\phi}_nD \quad n = 1, 2, 3, \ldots \qquad [1b]$$



$$\dot{D} + \dot{\phi}_nD = HD + \phi_n \qquad k_2 = 4\times10^{10} \qquad [2]$$

$$\dot{D} + \dot{\phi}_nD = \phi_nD_2 \qquad k_3 = 10^7 \qquad [3]$$

$$\dot{\phi}_nD + \dot{\phi}_nD = \text{high molecular weight products} \qquad k_4 = 10^6 \qquad [4]$$

$$\dot{D} + \dot{D} = D_2 \qquad k_5 = 10^{11} \qquad [5]$$

In this set of equations, ϕ represents a molecule of the substrate, $\dot{\phi}D$ and $\dot{\phi}_nD$ represent free radicals containing the structure

respectively.

The formation of D_2 by a reaction analogous to reaction [2] does occur, but it is slower than the production of HD for two reasons:

1. an isotope effect is expected for the reaction with $\dot{\phi}D$, which will favor the formation of HD (7); and
2. in reactions with $\dot{\phi}_nD$, $n = 2, 3, \ldots$, the deuterium is not likely to be in an activated position.

The production of D_2 by a reaction analogous to reaction [2] is not equivalent to reaction [5] since its rate depends on $(\dot{D})$ $(\dot{\phi}_nD)$ instead of $(\dot{D})^2$. However, we chose to neglect it in this treatment since its effects are small.

The values of the specific reaction rate constants chosen for reactions [4] and [5] are in agreement with the theory of bimolecular combination of two radicals (8). However, the rate constants for reactions [1*a*], [1*b*], [2], and [3] require some comment. Reaction [1*b*] is not specified since its value is not needed for the calculations we have made. It has been assumed that the rate constants for the reactions of $\dot{\phi}_nD$ are independent of n in order to simplify the treatment. The activation energy for reaction [1*a*] was chosen to be consistent with the values observed for the addition of hydrogen to double bonds (2), assuming reaction [3], which is a radical combination reaction, to have zero activation

energy. k_3 and the pre-exponential term in k_1 were chosen slightly lower than would be predicted theoretically in order to keep the value of k_2 (which as calculated depends on k_3 and k_1) well below the rate of collision between two particles.

*These rows refer to runs made using the same sample of organic liquid as used in the preceding run without purification.

The value of k_2 can be calculated from the experimental data in the following manner: HD is produced about three times as fast as molecules are lost from the gas phase in the experiments with *o*-terphenyl (see Table I). Therefore one can write the following relationship:

$$[6] \qquad k_2(\dot{\mathrm{D}})\,(\dot{\phi}_n\mathrm{D}) = 2\times 3\,[(k_1(\dot{\mathrm{D}})\,(\phi)+k_3\,(\dot{\mathrm{D}})\,(\dot{\phi}_n\mathrm{D})-k_2\,(\dot{\mathrm{D}})\,(\dot{\phi}_n\mathrm{D})].$$

Solving for k_2, we obtain

$$[7] \qquad k_2 = \frac{k_1(\phi)+k_3(\dot{\phi}_n\mathrm{D})}{7/6(\dot{\phi}_n\mathrm{D})}.$$

This expression for k_2 may then be substituted in the following steady-state equations:

$$[8] \qquad \frac{d(\dot{\mathrm{D}})}{dt} = I-k_1(\dot{\mathrm{D}})(\phi)-(k_2+k_3)(\dot{\mathrm{D}})(\dot{\phi}_n\mathrm{D})-k_5(\dot{\mathrm{D}})^2 = 0$$

and

$$[9] \qquad \frac{d(\dot{\phi}_n\mathrm{D})}{dt} = k_1(\dot{\mathrm{D}})(\phi)-(k_2+k_3)(\dot{\mathrm{D}})(\dot{\phi}_n\mathrm{D})-k_4(\dot{\phi}_n\mathrm{D})^2 = 0,$$

where I = rate of initiation of deuterium atoms in the liquid, to obtain the following set of equations:

$$I = (\dot{D})\,[(13/7k_1\,(\phi)+13/7k_3\,(\dot{\phi}_n D)+k_5\,(\dot{D})], \tag{10}$$

$$k_4\,(\dot{\phi}_n D)^2+13/7k_3\,(\dot{D})\,(\dot{\phi}_n D)-1/7k_1\,(\phi)\,(\dot{D}) = 0. \tag{11}$$

A numerical value of I which is necessary for the solution of equations [10] and [11] may be obtained by the following series of approximations.

The half life of the deuterium atoms is less than 10^{-7} seconds* in the reaction with *o*-terphenyl. Therefore the steady-state concentration of deuterium atoms is a strong function of the distance from the surface where the atoms are introduced into the liquid. An exact mathematical description of this reaction including the spatial distribution of radical concentrations is not available at this writing. We will therefore assume the reaction to be homogeneous in a small volume near the surface of the liquid.

The reaction volume, V, has been estimated to be about 10^{-4} cc.† The rate of initiation of deuterium atoms, I, is taken to be the number of moles of deuterium atoms that react per second divided by the reaction volume V. Therefore,

$$I = (10^{-7}\text{ mole sec}^{-1})/10^{-4}\text{ cc} = 10^{-3}\text{ mole sec}^{-1}\text{ cc}^{-1} = 1\text{ mole sec}^{-1}\text{ liter}^{-1}.$$

Using this value of I, equations [10] and [11] can be solved simultaneously by numerical methods yielding the values of 1.4×10^{-7} moles liter^{-1} and 8.8×10^{-4} moles liter^{-1} for the steady-state concentrations of deuterium atoms and $(\dot{\phi}_n D)$ radicals. $k_2 = 3.9\times10^{10}$ mole liter^{-1} sec^{-1} can now be obtained from equation [7]. This value of k_2 corresponds to a steric factor of about 0.1 if the reaction is considered to have a zero activation energy. There is some question as to whether this value is reasonable since there have been no values reported in the literature for analogous reactions. Even the steric factors for abstraction reactions from saturated hydrocarbons are not known unequivocally since various results have been reported (10).

Using this mechanism, results, qualitatively similar to those observed with *o*-terphenyl, are expected for toluene, if it is assumed that abstraction from the methyl group is not important at −80°C. This assumption can be justified as follows: It has been shown by several workers that, in a series of related elementary reactions, the energy of activation,

**Most of the deuterium atoms that enter the liquid react by reaction [1a] at the initiation rates used in the experiment. (This can easily be ascertained, assuming the proposed mechanism to be correct, by multiplying together the rate constants and appropriate steady-state concentrations to obtain actual reaction rates.) Therefore, the half life of the deuterium atoms in o-terphenyl is determined mainly by reaction [1a]. $k_1(\phi)$ is a pseudo first-order rate constant with a value of 4×10^7. Thus, the half life of a deuterium atom in o-terphenyl is approximately $\ln 2/k_1(\phi) \sim 10^{-7}$ sec.*

†A value for the volume V in which the reaction is considered to proceed is equal to the product of the surface area of the liquid (5 cm²) and the distance, Δx, the atoms diffuse in a time equal to their half life in the substrate (about 10^{-7} sec). To find Δx, we substitute approximate values for each of the terms in Ficks first law of diffusion

$$D\frac{d(\dot{D})}{dx} = F.$$

The numerical value of D, the Ficks law diffusion coefficient for the diffusion of deuterium atoms in liquid o-terphenyl, was found to have the approximate value of $D = 2\times10^{-3}$ by the absolute reaction rate theory (9). An approximation for the gradient of the deuterium atom concentration $d(\dot{D})/dx$ is the steady-state concentration of deuterium atoms in the reaction volume divided by Δx. An approximation of the steady-state concentration is the flux of deuterium atoms into the reaction volume (10^{-7} moles/sec) times the half life of the deuterium atoms (10^{-7} sec) divided by the reaction volume (5 cm² Δx). The flux F diffusing into the reaction volume from the surface is 10^{-7} moles/5 cm² sec.

Substituting these values into the diffusion equation, we obtain

$$2\times10^{-3}\frac{(10^{-7}\times10^{-7}-0)/5\Delta x}{\Delta x} = 10^{-7}/5.$$

Thus $\Delta x = 1.4\times10^{-5}$ and the reaction volume $V = 7\times10^{-5}$ cc $\sim 10^{-4}$ cc.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

E, of the reaction can be related empirically to the heat of reaction in a simple manner (11). For abstraction reactions, there is some evidence (12) for the relationship

$$E = 11.5 - 0.25Q$$

where Q is the exothermic heat of reaction in kilocalories per mole.

Taking the value 77.5 kcal for the heat of dissociation of the C—H bonds of the methyl group of toluene, the heat of reaction Q for

$$C_6H_5CH_3 + H = C_6H_5CH_2 + H_2 \quad + Q_1 \qquad [12]$$

is $Q_1 = 24.9$ kcal.* Thus, the activation energy for the abstraction of hydrogen from the methyl group of toluene is about 5.3 kcal, which is about 2.3 kcal higher than the activation energy required for reaction [1a] (see pp. 7 and 8). Therefore at −80° C reaction [1a] should be almost 400 times as fast as abstraction from the methyl group if the pre-exponential terms are equal. Low yields of bibenzyl (see p. 6) also indicate that abstraction from the methyl group is unimportant. The assumption that abstraction from the methyl group of toluene does not compete effectively with reaction [1a] therefore seems reasonable.

In calculating the products to be expected from the reaction with toluene, the only parameter which is not already specified is the initiation rate. The value of I for the work with toluene is probably quite similar to that for the experiments with *o*-terphenyl since $\ln 2/k_1$ (ϕ) and the net rate of deuterium conversion is similar. Thus, the initiation rate is probably similar and the ratio of the products is expected to be only slightly different due to the difference in k_1 at the lower temperature. Experimental results for toluene reported in Table I are similar to those of *o*-terphenyl within experimental error.

In the reaction with eicosane the ratio of the percentage of HD produced to the percentage of pressure increase is not very different from 2, the value to be expected if abstraction of hydrogen from the substrate were the only reaction involving deuterium atoms. This is not surprising since the abstraction of hydrogen by a deuterium atom from a saturated hydrocarbon proceeds with an activation energy of about 9 kcal (13), so that the lifetime of a deuterium atom in eicosane at 37° C should be about 10^{-4} seconds. Thus the reaction volume is some three orders of magnitude larger than in the case of *o*-terphenyl, and the initiation rate is therefore correspondingly lower. It can be shown that smaller amounts of products formed by the reaction of deuterium atoms with other radicals are to be expected at these lower initiation rates (14). Thus, the results obtained with eicosane are consistent with the concepts upon which the proposed mechanism is based.

The proposed mechanism has the additional advantage that it is in general accord with a number of seemingly unrelated results reported in the literature.

1. Very low values of the pre-exponential terms in the rate constants for addition reactions of atoms (and radicals) to double bonds have often been reported (12). These values correspond to steric factors of 10^{-3} to 10^{-5}.
This addition reaction

$$2\dot{D} + \phi = \phi D_2$$

is probably a two-step process composed of reactions [1a] and [3]. Since the second step is in strong competition with equations [2] and [4], the steric factor for the over-all hydrogenation reaction would be expected to be low. Thus, the low steric factors previously reported can be accounted for.

**If 89.9 kcal/mole is taken to be the value for the heat of dissociation of the methyl* C—H *bonds,* Q_1 *is 13.5 kcal.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

2. Deuterium-hydrogen exchange during the hydrogenation of olefins by atomic hydrogen at −195° C has been recently reported (15), indicating that HD can be formed by a low activation energy process. Since reaction [2] is strongly exothermic, it is likely to have a low activation energy.

3. In the radiation chemistry of benzene, it has been found that the formation of hydrogen gas increases more rapidly than does polymer formation with increasing L.E.T. (16). This increased hydrogen formation relative to polymer formation with increasing L.E.T. corresponds to an increase of products formed by reaction [2] relative to products formed by reactions [1*b*] and [4] as the initiation rate is increased. Thus, these results may be accounted for by the mechanism proposed in this paper.

4. During radiolysis experiments at low hydrogen atom initiation rates, exchange with perdeutero aromatic additives occurs to a very limited extent (17).

This mechanism predicts a value of the steady-state concentration of $\dot{\phi}_n$D which is subject to experimental verification. An attempt to test the mechanism by studying the steady-state concentration of the $\dot{\phi}_n$D radicals in this system by electron spin resonance spectroscopy will be made.

AN IMPROVED TECHNIQUE FOR THE OBSERVATION OF INFRARED CHEMILUMINESCENCE: RESOLVED INFRARED EMISSION OF OH ARISING FROM THE SYSTEM H + O_2[1]

P. E. Charters and J. C. Polanyi

ABSTRACT

A multiple reflection apparatus for the observation of infrared chemiluminescence is described. By means of this apparatus infrared emission from the system H + O_2 has been identified as being due to vibrationally excited OH radicals in levels $v = 1$, 2, and 3 of the ground electronic state. The resolved infrared spectrum of the OH fundamental has been observed for the first time without interference from other emission. The most likely source of excited OH is the reaction H + $HO_2 \rightarrow OH\dagger + OH$. The vibrational 'temperature' of OH† (vibrationally excited OH in its ground electronic state) in our system is in the region of $T_V = 2240°$ K. These findings are discussed in relation to Krassovsky's suggestion that reaction between H and O_2 could account for the Meinel hydroxyl bands in the night sky.

INTRODUCTION

Infrared emission arising from the gaseous system H + O_2, at room temperature, has been reported by Cashion and Polanyi (1). The emission consisted principally of three broad unresolved bands extending from 3400 to 4000 cm^{-1}, with maxima at 3600, 3730, and 3830 cm^{-1} (2.78, 2.68, and 2.61 μ). The intensity of the first peak could be varied, by varying reagent flows, independently of the other two, indicating that it was due to a separate emitting species. It was thought that this might be the hydroxyl radical, OH, with ν_0 for $v = 1 \rightarrow v = 0$ at 3570 cm^{-1} (2). The other two maxima were of constant relative intensity and it was suggested that these might be either the Q and R branches of the ν_3 O—H stretching fundamental of water (ν_0 at 3755.8 (3)) or alternatively the O—H stretching fundamental of the HO_2 radical. In either case the P branch would presumably be masked by the other emission, attributed to the hydroxyl radical.

Prior to the work described above, McKinley, Garvin, and Boudart (4) had observed visible and photographic-infrared regions of the spectrum from OH formed in the reaction H + O_3. They failed, however, to observe any emission whatever from the system H + O_2. They concluded, in agreement with suggestions made by Bates and Nicolet (5), and by Herzberg (6), that the reaction H + O_3 was responsible for the Meinel hydroxyl bands in the airglow (7). This result later received further support from a careful re-examination of the visible and photographic-infrared emission (8) and recently an examination of the infrared emission (9).

Krassovsky (10), however, has put forward the view (criticized by Bates and Moiseiwitsch (11)) that the evidence concerning the Meinel hydroxyl bands is more consistent with the formation of excited OH in a reaction H + O_2. He considered that this reaction, to be sufficiently exothermic, would have to involve vibrationally excited O_2. At first sight the results of Cashion and Polanyi (1) might appear to lend support to Krassovsky's view. The present investigation was undertaken in the hope of clarifying this point. In order to do this it was necessary in the first place to establish that the system H + O_2 does in fact give rise to vibrationally excited hydroxyl, and that the excited hydroxyl is present as a result of chemical reaction, not as a result of diffusion of reagents or products into the discharge or spreading of the discharge into the reaction zone. Once this has been

[1]*Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario; presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

done a comparison of the distribution of excited OH among vibrational levels with that observed in the upper atmosphere might help to decide whether the reaction could account for the Meinel hydroxyl bands.

At the same time it was hoped that the identity of the 3730 and 3830 cm^{-1} emission, due it was thought to H_2O or HO_2, could be established.

The apparatus used in this investigation represents a major departure from that used by Cashion and Polanyi; it will therefore be described in some detail. The system $H + O_2$ was used for the first trial of this apparatus since the reagents are relatively non-corrosive. In work presently being undertaken in this laboratory the same apparatus is being used for a re-investigation of the infrared emission from $H + Cl_2$ at pressures several orders of magnitude less than those at which detectable emission was obtained in the experiments of Cashion and Polanyi (12).

EXPERIMENTAL

Reaction Cell

A diagram of the reaction cell is given in Fig. 1. Partially dissociated hydrogen entered the cell from four Wood discharge tubes through 6 mm I.D. nozzles that protruded into

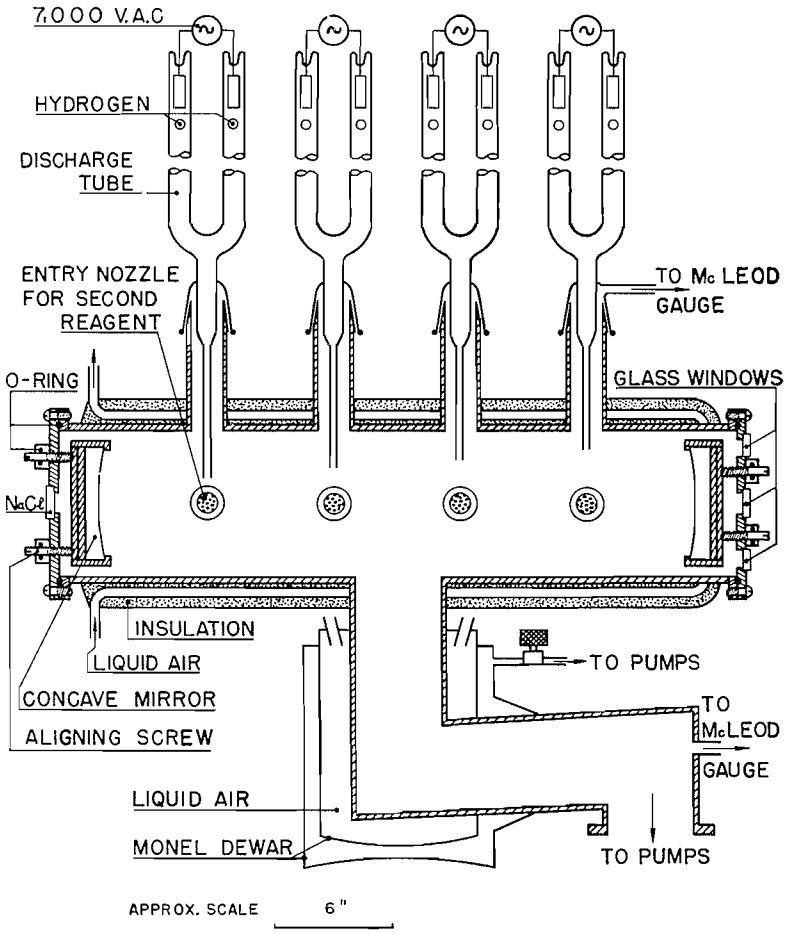

FIG. 1. Cross section of the reaction cell.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the cell to a point just above the cone of radiation visible to the spectrometer. Before use the discharge tubes (made from pyrex) were washed with dilute hydrofluoric acid and coated with an approximately 60% solution of phosphoric acid. The other reactant (in this case oxygen) diffused into the cell through sintered glass plugs placed in four side arms. These side arms ended flush with the walls of the reaction cell, since the cone of light with multiple reflection extended laterally across the entire diameter of the mirrors (see below). In each of the eight side arms linking the glass part of the apparatus to the reaction vessel, the connection was made through a 40/50 standard-taper metal cone and glass socket.

The cell itself consisted of a monel tube $6\frac{1}{4}$ in. I.D. $\times$ $23\frac{1}{2}$ in. long. The ends were sealed by $8\frac{1}{2}$ in. diameter monel plates held against "O" rings. The emission was viewed by the spectrometer through a sodium chloride window in the center of the front plate, the plate nearest the spectrometer. A vertical row of three glass windows in the back plate facilitated the alignment of the mirrors, mounted internally at either end of the reaction cell.

The reaction products passed out of the cell through a centrally located 4 in. I.D. monel pipe welded to the cell. A fixed metal dewar surrounded this pipe almost to the point where it entered an N.R.C. O.B.-4 booster pump (4 in. I.D.; 240 l./sec at 10^{-2} mm, falling to 50 l./sec at 10^{-1} mm). An Edwards "Speedivac" ISC450B pump (450 l./min) provided the backing pressure, and was connected to the diffusion pump through a Veeco valve ($1\frac{1}{2}$ in. port opening) and a length of $1\frac{1}{2}$ in. I.D. flexible steel tubing.

Monel was used throughout the cell and exit pipe to reduce corrosion when studying reactions involving halogens, and also to permit coating with phosphoric acid without deterioration of the metal surface. In practice it was found that phosphoric acid slowly reacted with the surface, and in the experiments described in this paper the cell was coated first with a thin layer of polystyrene and then with phosphoric acid over this base layer.

By switching leads on the four high-voltage transformers the reaction cell could be made earth for the high-voltage alternating current. The discharge then struck directly down into the reaction cell, filling the cell with the pink atomic hydrogen glow that was normally restricted to the U of the discharge tube.

Provision was made for cooling the entire cell by blowing liquid air through copper coils which followed a path back and forth along the length of the cell. The coils were clamped against the cell and were insulated by $1\frac{1}{2}$ inches of glass wool.

The mirror system consisted of four concave mirrors, all four having very closely matched radii of curvature; the system was identical with that suggested by Welsh and co-workers (13, 14) for use in high-resolution Raman spectroscopy. The radius of curvature of the mirrors in our system was 50.094 cm, diameter 14 cm, and average thickness 1.5 cm. The mirrors were made for us by the Perkin–Elmer Company of Norwalk, Conn., U.S.A. The dimensions were chosen so that the 15° cone of radiation accepted by the $f/4$ optical system of our spectrometer very nearly filled the back mirrors (furthest from the spectrometer). Each "pair" of mirrors (one pair at either end of the cell) was made from a single mirror which had been cut along a vertical axis so that the two halves could be adjusted separately and light could pass through a 0.5–2.0 mm (adjustable) slit-like gap between them. Under operating conditions the source optics of the spectrometer had its focal plane at a point centrally placed in the gap between the front pair of mirrors, on a level with the silvered surface of these mirrors. If the mirrors had not been present, only emitters within the 15° cone of light centered on the focal plane, emitting in the direction defined by the cone, would have contributed to the observed emission. With the

For personal use only.

mirrors present, a succession of such cones displaced laterally from one another fell within the line-of-sight of the spectrometer. This was the origin of the gain in intensity.

The mirror mounts, made entirely from monel, were based on a design due to Welsh and Shepherd (15). Each of the four mirrors, backed by springs, was held by clips to a plate. This plate was held by screws to a backing plate, the two plates being free to slide over each other for coarse horizontal and vertical alignment of the mirrors. The backing plate in turn was held down by springs on to three metal columns, two of adjustable height and a fixed one surmounted by a ball bearing. The adjustable columns extended into rods which passed through "O" rings and fine threads in the external end plates. By adjusting the two rods appropriate to any one of the four mirrors, that mirror could be aligned while the apparatus was under vacuum, and while chemiluminescent emission was being observed.

We wish to acknowledge here the skilled machining of Mr. Hans Hellenkamp, who constructed the reaction cell.

The efficiency of the multiple reflection system is markedly dependent on the reflectivity of the mirrors, approaching $1/1-r$ (r is the reflectivity) when the number of reflections is large. The mirrors in this apparatus were in contact with the reacting gases. To minimize deterioration they were first front-surface coated with silver (reflectivity 98.8% at 3 μ (16)) and then coated with ca. 1700 Å layer of cryolite or magnesium chloride. Coating was either carried out on an apparatus kindly made available by Professor H. L. Welsh and Professor J. C. Stryland of the Department of Physics, or was carried out professionally by Canadian Arsenals Ltd., Toronto.

Spectrometer

The spectrometer was a model 112G Perkin–Elmer double-pass grating instrument employing a Bausch and Lomb 300 groove/mm plane grating blazed at 3 μ in the first order. Several modifications were made in the instrument. A liquid-air-cooled lead sulphide detector was installed in the position provided by the makers for "external detectors". The housing for the cooled lead sulphide cell was identical with that described in a recent communication (17) .The detector itself has a sensitive surface 2.5 mm × 0.25 mm, sandwiched between two layers of sapphire. It was mounted *in vacuo* behind a sapphire window. The detector, made by Infrared Industries Inc., Waltham, Mass., U.S.A., had one half of peak sensitivity at 3.3 μ (ref. 17).

The source optics supplied by the makers was replaced by optics of slightly different design; the sequence of mirrors was reversed so that incoming radiation encountered first a spherical concave mirror (80 mm diameter, 294 mm radius) and then a plane mirror (55 mm square) placed close to the concave mirror. The source optics housing could then be reduced in size to 22 cm × 17 cm, eliminating the space between source optics and foreprism monochromater, normally occupied by an absorption cell. The source optics focus remote from the foreprism monochromater slit then fell at a point 14 cm from the front of the source optics housing, instead of being 2–3 cm from the housing as in the normal instrument. This alteration was necessary since the focal plane of the source optics must be brought to a point on a level with the front surface of the mirrors inside the reaction cell, 5.6 cm from the front (sodium chloride) window of the cell.

The gap between the front window of the cell and the front window of the source optics housing was bridged by a tube which was continuously flushed with dry air, as was the whole of the remainder of the path traversed by the radiation from the reaction cell through the spectrometer to the lead sulphide cell. This was of importance since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

emission was to be observed in regions of the spectrum where water vapor absorbs strongly.

To permit calibration without interference with the closed optical path linking the spectrometer to the reaction cell, the source optics was provided with a sodium chloride window at one side. A diagonal mirror within the source optics housing, mounted on an externally actuated swivel, could be swung into the optical path so that either a mercury lamp (for wavelength calibration) or a globar (for sensitivity calibration) could be viewed by the spectrometer.

The spectrometer was mounted on a table with provision for hydraulic lifting, and also for lateral and to-and-fro movement of the table top by means of adjusting screws. This degree of adjustment was required since the reaction vessel was rigidly attached to a separate rack carrying the reagent flow system and pumps. To facilitate the alignment of the spectrometer to the reaction cell, and the alignment of the multiple reflection system within the reaction cell, a light bulb was mounted permanently inside the spectrometer on a solenoid arm so that it could be moved into a position behind the foreprism monochrometer slit by closing a switch. This made possible rapid checks of alignment during the course of an experiment; at the same time a check could be made for deterioration of the mirrors, by counting the number of images formed at the front mirrors by the multiple cones of light within the cell (13, 14).

In the 112G spectrometer the grating table can swing through an angle of no more than 12°; to cover one order of the grating it is therefore necessary to insert "pins" into the grating table and thus obtain a coarse change in the range of angles being scanned. Changing pins necessitates removal of the entire grating monochromater housing, exposing the optics to the atmosphere. To avoid this we duplicated the pin mechanism at the lower end of the grating table shaft, beneath the instrument. Pins could then be rapidly inserted and removed without interfering with the flow of dry air through the apparatus.

Reagents

The hydrogen and oxygen flows were metered by measuring the pressure drops across two calibrated capillaries. Absolute pressure could be measured on a McLeod gauge just ahead of the cell and on one just beyond it (see Fig. 1); both of these pressure points were linked by wide tubing to the cell. The two pressures differed only slightly, but the former was taken as the true value since this measuring point was linked directly to the reaction cell through tubing in which no flow took place.

In most experiments the hydrogen was Dominion Oxygen Co. Electrolytic grade, 99.8% minimum purity. This was passed through a Deoxo unit guaranteed to reduce oxygen concentration to less than one part per million. In some experiments water was frozen out in a liquid air trap. The oxygen in most experiments was Linde Air Products Co., U.S.P. grade. However, to check for possible effects of slight impurities a portion of spectrum was retraced replacing both reagents simultaneously with Matheson research grade reagents. This grade of hydrogen contains less than the following mol.% impurities; oxygen 0.001%, nitrogen 0.03%, carbon dioxide 0.005%, water 0.001%. The oxygen contains less than the following percentage impurities; carbon dioxide 0.1%, carbon monoxide 0.01%, argon 0.01%, nitrogen 0.05%, hydrogen 0.01%, water 0.0002%.

RESULTS AND DISCUSSION

Figures 2 and 3 are reproductions of actual traces of the emission obtained in the 2950–3800 cm^{-1} (3.39–2.63 μ) and the 6600–7150 cm^{-1} (1.52–1.40 μ) regions of the spectrum. Four different grating slit widths were used in making these traces, varying from 0.400 mm for the strongest emission (section A of the trace) to 2.000 mm for the

weakest (section C of the trace). These data are recorded beneath the figures. No other emission was observed, though attempts were made to detect emission in the 3700–4000 cm^{-1} region, where Cashion and Polanyi observed emission (due to water vapor or HO_2) and at 5333 cm^{-1} where these workers observed emission due to atomic hydrogen. The experimental conditions applicable to these traces were hydrogen flow 2500 μmoles/sec, oxygen flow 1200 μmoles/sec, pressure in the reaction vessel 4.0 mm Hg, pumping by mechanical pump only, transit time through cone-of-sight 0.15 second. Reagents were standard grade hydrogen and oxygen used without drying of either reagent. The reaction cell was at room temperature and the mirrors were freshly coated.

Standard grade reagents were used since in a separate experiment it was shown that use of Matheson research grade reagents made no difference to the emission. Passing both reagents through liquid air traps also had no effect on the emission. Deliberately saturating both hydrogen and oxygen streams with water vapor, so that the partial pressure of water vapor in the discharge tube and reaction vessel became ca. 0.13 mm Hg, caused a 30% drop in emission intensity (in the region from 3400–3500 cm^{-1} that was scanned) but otherwise had no effect.

The region of spectrum from 3400–3500 cm^{-1} was traced at five total pressures ranging from 4.0 mm to 0.51 mm, while the molar inflow ratio of reagents was kept constant. The intensity of the emission was found to vary approximately linearly with total pressure.

An attempt was made to estimate the H atom concentration by measuring the heat liberated by atoms recombining at a hot tungsten filament placed in the reaction cell. The method used (Tollefson and Le Roy (18)) was first to clean the wire by prolonged heating in a stream of hydrogen passing through the cell, and then, by means of an a-c. bridge, to measure the rise in temperature of the wire as atoms recombined on it. Next, in the absence of H atoms, an external current was passed through the wire, and the current required to heat the wire to the same temperature as before was accurately measured. Knowing the resistance of the wire, the power liberated by the passage of the current could be calculated; this was identical with the power liberated by the recombining atoms. Knowing the surface area of the wire and assuming recombination at every collision the pressure of H in the gas could be calculated. The pressure measured was only ca. 5.10^{-3} mm of H at 4.0 mm total H_2 pressure with two discharge tubes running. We would expect 1.10^{-2} mm with all four tubes running. This constitutes a lower limit, but if correct it would mean that our H atom pressure may be only in the region of one third to one tenth of that obtained by Cashion and Polanyi (12, 17).

The spectrometer was calibrated using the lines of a low-pressure mercury lamp. The calibration was made under different conditions of slit width and chart speed to the actual trace. As a result the observed spectrum was found to be shifted bodily by 3 cm^{-1} to higher frequencies than the published values for OH. Accepting the published value (see below) for one line in the fundamental region ($P_1(2)$ of $1 \rightarrow 0$) and one in the overtone region (P_1 (3) of $2 \rightarrow 0$) and applying a correction for this apparent small shift, the remaining ca. 35 sharpest peaks fell within ± 0.5 cm^{-1} of the published values. The OH line frequencies were taken from an extensive compilation of OH frequencies made by Dr. H. P. Gush and Dr. E. H. Richardson on the University of Toronto digital computer. The calculation was based on spectroscopic constants obtained by Dieke and Crosswhite (19) and by Herman and Hornbeck (20). We are most grateful to Dr. Gush and Dr. Richardson for providing us with a copy of these tables.

The correspondence of the calculated frequencies with our observed lines leaves no doubt that we are observing emission due to three bands within the fundamental of OH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in its ground electronic state ($^2\Pi$, $v(1 \rightarrow 0)$, $v(2 \rightarrow 1)$, $v(3 \rightarrow 2)$) and two bands in the first overtone region ($^2\Pi$, $v(2 \rightarrow 0)$, $v(3 \rightarrow 1)$). At the narrower slit widths used in this work the lines of each band are well resolved into spin (but not lambda) doublets. All the lines in the spectrum can be accounted for as OH lines.

A striking feature of the spectrum is the complete absence of emission due to water vapor. The only previous observation of the fundamental infrared spectrum of OH has been in emission from flames, particularly in the work of Plyler and co-workers (21, 22, 23). The hydroxyl emission is accompanied by a strong water emission that tends to overlap many OH lines, and makes observation of the R branch of $1 \rightarrow 0$ impossible. Since water will be present in most systems in which OH is being formed, including the reaction system H + O_2 which we have studied, any non-specific method of excitation (thermal excitation, or excitation by electrical discharge) will give rise at the same time to H_2O and OH emission. In our system we are bound to postulate a highly specific method of excitation; this, of course, is most likely to be a chemical reaction. The specific nature of chemical reaction may well make infrared emission from chemical systems a valuable spectroscopic source of "clean" infrared spectra (cf. 24).

In some experiments the discharge was made to strike down into the reaction cell. Emission due to vibrationally excited water vapor was then observed. The appearance of water vapor emission could be due to physical excitation of the water molecules in the discharge.

We are able positively to identify this discharged-induced emission as being due to excited water molecules. If the unidentified emission observed by Cashion and Polanyi was also due to water, the question arises as to why water emission was not observed in the present investigation, under normal operating conditions. The answer may possibly lie in the fact that our reaction cell and discharge in normal operation are separated by 15–20 cm of narrow (6 mm I.D.) tubing and 15 cm of 28 mm I.D. tubing, whereas in Cashion and Polanyi's apparatus the discharge was separated by only 0.5 cm of 28 mm I.D. tubing from the cell. Back diffusion of water vapor into the discharge could perhaps have given rise to the emission observed by the earlier workers. However, this is far from certain. Our system also differs from theirs in other notable respects; the pressure in the present work was 10 times as high (but attempts to observe H_2O emission at lower pressure failed), the transit time was 0.25–0.10 times as great in our experiments, and the H atom pressure may have been as little as 0.1 times Cashion and Polanyi's.

The proximity of the discharge to the reaction cell in the work of Cashion and Polanyi probably accounts for the fact that they observed emission due to atomic hydrogen. They believed that this emission arose from electronically excited atomic hydrogen in their reaction cell, and not to reflected light from the discharge. This is in accord with the finding that in our system, where the discharge is removed to a distance from the reaction cell, emission from atomic hydrogen is absent. Moreover in our system the atomic hydrogen emission can be made to appear if the discharge is struck down into the reaction cell.

In our experiments we found no trace of any emission, either under normal operating conditions or with the discharge striking into the reaction cell, that could have been ascribed to the hydroperoxy radical, HO_2.

For reasons outlined above we consider that the vibrationally excited OH in our system is present as a result of some chemical reaction. The reaction between atomic hydrogen and ozone is a well-established source of vibrationally excited hydroxyl. However, it can be excluded in our system on several counts. The reagents entering the reaction cell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

certainly contained no ozone. It might be argued that after entering the reaction cell a very small amount of oxygen might have diffused up into the discharge and been converted to ozone. The argument would rest upon the fact that in a system such as ours traces of ozone might produce enough OH† (vibrationally excited hydroxyl in its ground electronic state) to account for the observed emission. But Herron and Schiff (25) have shown that the passage of pure oxygen at 2 mm pressure through a Wood discharge tube produces an amount of ozone which is below the limit of detection of a mass spectrometer. Furthermore, back diffusion into the discharge must be slight, and a very large gain in intensity would be expected if the discharge were brought down into the reaction cell. However, if there was an increase in the intensity of the OH† emission on striking the discharge down into the cell, it was a small increase (2 times or less, masked by water emission). Finally it should be noted that the vibrational "temperature" of OH† in our system (see below) is one-quarter that observed by Garvin, Broida, and Kostkowski in a recent examination of the H + O_3 emission in the infrared (their analysis was based on overtone transitions since they did not observe the OH fundamental bands) (9). Since their experiments were made in the same region of total pressures as ours, with considerable amounts of H_2, H_2O, and O_2 present in the system (ozone amounted to a few per cent), it seems most probable that the difference in vibrational temperature of the OH† in the two systems is due to a difference in the chemical processes by which it is produced.

The possibility exists that traces of NO_2 in the system might give rise to the observed weak emission since Cashion and Polanyi (26) found that this is a rapid reaction producing strong OH and H_2O emission. NO_2 would have to be formed in the discharge from air leaking into the apparatus. (An upper limit for the pressure of NO_2 that could conceivably be formed in this way is $\sim 10^{-5}$ mm.) However, in this case the emission should persist even if the O_2 flow is cut off, whereas the emission disappeared when this was done.

It would appear that the emission arises in some way from reaction between atomic hydrogen and molecular oxygen.

Reference has already been made to Krassovsky's (10) suggestion that reaction between atomic hydrogen and vibrationally excited oxygen might lead to the formation of vibrationally excited hydroxyl,

$$H + O_2\dagger \rightarrow OH\dagger + O \qquad Q = -16.7 \text{ kcal/mole.} \qquad [1]$$

Q is the heat of reaction assuming reagent and product molecules to be in their ground vibrational levels (D(O—O) = 118.0 (27), D(O—H) = 101.3 kcal/mole (28)). To account for the formation of OH† in $v = 3$ ($E(v = 3)$ = 29.2 kcal/mole) the oxygen molecule would have to have 45.9 kcal of vibrational energy. Recombination of atomic oxygen could lead to the formation of such highly vibrating molecules. (Fairly direct evidence for the formation of highly vibrating molecules as product of atomic association is to be found in reference 17.) Formation and recombination of O atoms should become far more important if the discharge strikes down into the reaction cell where O_2 is in plentiful supply. However, as already observed, no more than a small increase in intensity was obtained when this was tried.

It appears more probable that the primary reaction is

$$H + O_2 + M \rightarrow HO_2 + M \qquad Q = 47 \text{ kcal/mole,} \qquad [2]$$

for which strong evidence has been found by a number of authors. The work of Foner and Hudson (29) comes closest to our experimental conditions. They brought together

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

atomic H from a Wood discharge tube and oxygen at room temperature and examined the reaction mixture mass spectrometrically. At 30–40 mm pressure they obtained HO_2, OH, and H_2O as products, in the ratio 1.4:30:92. At 1 mm pressure (30) they detected no HO_2 but substantial amounts of OH and H_2O. It seems likely that HO_2 was also being formed in their low-pressure experiments, but was rapidly consumed. Foner and Hudson (30) have in fact suggested that at low pressure ($\sim$1 mm) HO_2 is formed, not, however, in the gas phase but at the wall. The HO_2, they believe, will then react with H at the wall, forming OH if the wall is at room temperature, or H_2O_2 if the wall is at liquid air temperature. We have tried cooling our reaction cell to liquid air temperature but have failed to obtain reproducible results, perhaps due to changes in mirror alignment or reflectivity. Nonetheless on three occasions out of four we have observed stronger OH emission from the cold cell (temperature $-185°$ C, measured on a thermocouple attached to the cell wall—the mirrors were probably only at $-10°$ to $-20°$ C). This increase in intensity is surprising in view of the fact that Foner and Hudson found that no OH is formed in a cold cell.

The volume-to-surface ratio in our cell is much greater than that in Foner and Hudson's small reaction tube. Taking our value for H (which is a minimum) we calculate that each HO_2 suffers at least 23 collisions with H for each wall collision. Burgess and Robb (31) have found the collision efficiency of this reaction at room temperature to be unity. If this is correct to within an order of magnitude, most HO_2 radicals in the room temperature system will react in the gas phase before reaching the wall. Foner and Hudson's suggestion that in the room temperature system OH is formed at the wall would require in the present case either that OH emits while adsorbed on the mirror surface (the only part of the "wall" in the line-of-sight) or that hydroxyl is desorbed at high vibrational temperature, i.e. as OH†. Neither of these processes seems likely, but neither can definitely be excluded.

Subsequent gas phase reactions, following the formation of HO_2, which could result in the production of vibrationally excited hydroxyl are

$$H + HO_2 \rightarrow OH\dagger + OH \qquad Q = 38 \text{ kcal/mole} \qquad [3]$$

$$H_2 + HO_2 \rightarrow OH\dagger + H_2O \qquad Q = 53 \text{ kcal/mole} \qquad [4]$$

with a very minor contribution from

$$2H + OH \rightarrow H_2 + OH\dagger \qquad Q = 103 \text{ kcal/mole.} \qquad [5]$$

($D(H—O_2) = 47 \pm 2$ kcal/mole is from Foner and Hudson (32), $D(HO—O) = 63$ kcal/mole from thermodynamic data (33).) Reaction [5] must be of relatively little importance in view of the fact that it involves a ternary reaction between three species present only in low concentration. The relative importance of [3] and [4] cannot easily be assessed. Using the data of Burgess and Robb (31), [3] is favored by having a collision efficiency 60 times that of [4]; however, this advantage may be offset in our system by a concentration ratio (upper limit) of H_2:H = 400:1. Leaving aside the uncertain question of the relative over-all rates of [3] and [4], reaction [3] seems a much more likely source of vibrationally excited hydroxyl since it conforms to the pattern followed by all known exothermic exchange reactions which produce vibrationally excited products: vibrational excitation appears in the new bond being formed and little if any appears in the residue of the molecule under attack.

Reaction [3] is of special interest since it is one in which an activated complex splits into two fragments of identical composition. It would be interesting to know whether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

these fragments are identical also in internal energy. If [3] is the origin of the OH† that we observe in $v = 3$ (and $v = 2$) we can confidently say that the internal energy is unequally distributed since even distribution would necessitate an endothermic reaction which would be slow at room temperature. This is shown in Table I. In the table Q_{TRV}

TABLE I

Heats of reactions forming OH† ($v = 2$, $v = 3$) from H + HO_2

Products of the reaction	Q_{TR} (= $Q_{TRV} - E(v)$) kcal/mole

[3] *f* OH† ($v = 2$) + OH† ($v = 1$)	8
[3] *g* OH† ($v = 2$) + OH	18

is the total heat of reaction (called Q above). Q_{TR} is the heat of reaction available for translation and rotation after the stated amount of energy has gone into vibration. It is clear from the table that the fastest reactions producing OH† in $v = 2$ and $v = 3$ involve uneven distribution of energy among the otherwise identical products. If then H + HO_2 is the principal source of OH† in $v = 2$ and $v = 3$ it would follow that the activated complex HOOH dissociates preferentially to OH† + OH. This would be in accord with the suggestion (Polanyi (34)) that in the activated complex of the exothermic exchange reaction the new bond being formed is extended relative to normal internuclear separation for the isolated product molecule, and that this extension persists in a large measure as the complex disintegrates forming highly vibrating product. For reaction [3] this might be written as, H + O—OH → H- - -O—OH → H—O† + OH.

Evidence has been adduced above which contradicts Krassovsky's suggestion that the reaction between atomic hydrogen and vibrationally excited oxygen could constitute an important source of vibrationally excited hydroxyl. In our view the most likely source of OH† is the reaction between atomic hydrogen and HO_2. This would rule out the possibility that reactions involving H and O_2 could account for the Meinel hydroxyl bands, since these bands involve OH† in vibrational levels $v \leqslant 9$, whereas the room-temperature reaction H + HO_2 could only produce OH† in levels $v \leqslant 4$.

There remains the possibility that the Meinel hydroxyl bands originating in vibrational levels $v \leqslant 4$ may arise, to a greater or lesser extent, from reaction between H and O_2. To investigate this possibility we have calculated the approximate relative population distribution among vibrational levels of OH in our system. The calculation has been made by comparing the intensities of corresponding rotational lines within different bands of the $\Delta v = 1$ sequence. The lines in question, their measured areas, their areas corrected to a common scale (corrected for change in slit width, transmissivity of the instrument, and sensitivity of the detector), the ratios of intensities (taken from these corrected areas), the ratios of transition probabilities, the ratios of populations, and the derived vibrational 'temperatures', T_V, are shown in Table II. The areas were corrected for change in transmissivity of the instrument and changing sensitivity of the detector, from one wavelength to another, by comparing an experimental trace of the globar taken with

the lead sulphide detector (at the same slit width as the chart being calibrated), with the theoretical trace to be expected from a detector of uniform sensitivity and a spectrometer of uniform transmissivity. The theoretical trace was calculated from the black-body formula using the temperature of the globar as measured on a calibrated optical pyrometer, and taking the emissivity of the globar at various wavelengths from the data of Silverman (35). Relative populations ($N_{v'}$) were then obtained from the relative intensities ($I^K_{v',v''}$) by means of the relation

$$\frac{(N_{v'})_2}{(N_{v'})_1} = \frac{(I^K_{v',v''})_2 \cdot (\nu^K_{v',v''} \cdot A_{v',v''})_1}{(I^K_{v',v''})_1 \cdot (\nu^K_{v',v''} \cdot A_{v',v''})_2}$$

where $(\nu^K_{v',v''})_1$ and $(\nu^K_{v',v''})_2$ are the frequencies of the lines being compared, and $(A_{v',v''})_1$ and $(A_{v',v''})_2$ are the Einstein transition probabilities appropriate to the bands. Ratios of Einstein transition probabilities were calculated from data given by Garvin and coworkers (8, 9). Our calculation involves the assumption that the rotational temperature is the same in all three bands, $v(1 \rightarrow 0)$, $v(2 \rightarrow 1)$, $v(3 \rightarrow 2)$. We neglect the effect of vibration–rotation interaction on the rotational line strength.

The distribution of vibrators among vibrational levels clearly corresponds to a lower temperature, $T_V \approx 2240 \pm 60°$ K at 4 mm pressure, than that derived by Chamberlain and Smith (36) for $v = 1$, 2, 3 of OH in the night sky, $T_V \approx 8000°$ K at a pressure of about 10^{-2} mm, or that obtained from the reaction H + O_3 in the laboratory, $T_V \approx 9250°$ K at pressures in the range 2–5 mm (9). Of the two laboratory systems, H + O_3 corresponds much more closely in vibrational temperature of the OH† product to the Meinel bands. However, the significance of this correspondence will remain uncertain until the H + O_3 system has been examined at a pressure in the region of 10^{-2} mm. We plan an investigation on these lines, making use of the apparatus described here.

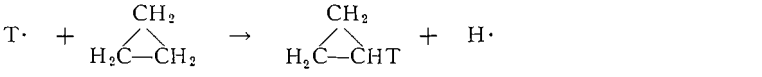
HOT ATOM REACTIONS AND RADIATION-INDUCED EFFECTS IN THE REACTIONS OF RECOIL TRITIUM WITH CYCLOPROPANE[1]

J. K. Lee, Burdon Musgrave, and F. S. Rowland

ABSTRACT

Recoil He^3 (n, p) tritium atoms have been reacted with cyclopropane in the gas phase under a variety of experimental conditions. The labeled hydrocarbon and molecular hydrogen products have been separated by gas chromatography and assayed by gas proportional counting.

The observed products show a strong dependence upon irradiation dose—cyclopropane is very inert toward reactions with hydrogen atoms and organic radicals, and the labeled olefinic products react preferentially, in effect as scavengers, with the reactive species from radiolysis of the parent molecule.



Energetic tritium atoms are able to react with cyclopropane to give labeled cyclopropane as a product without causing isomerization or decomposition of the molecule. The relative yields of cyclopropane and propylene are dependent upon the average collisional de-excitation times, indicating that a fraction of the labeled cyclopropane molecules are decomposing in times of approximately 10^{-9} seconds. Cyclopropane, propylene, ethylene, hydrogen, and small amounts of allene and methylacetylene are observed as "hot" products in the presence of gaseous free radical scavengers. Many additional compounds are found as the result of free radical and/or radiolysis reactions in the absence of scavengers.

The "hot" reactions are explained in terms of the single-step interactions of high kinetic energy tritium atoms with the cyclopropane molecules—the energy for endothermic and high activation energy processes is obtained from the recoil energy. The kinetic energy of the recoil atom at reaction is estimated to be of the order of 130 kcal/mole for some of the observed labeled compounds.

INTRODUCTION

The reactions of recoil tritium atoms from the nuclear reaction $He^3(n,p)T$ with saturated and unsaturated aliphatic hydrocarbons have been studied in detail in several laboratories, and the general outline of behavior is now well known (1–9). It will be assumed from these experiments, and from similar experiments with recoil tritium atoms from the $Li^6(n,\alpha)T$ reaction in condensed phases (10), that the recoiling atoms react predominantly while still "hot" in the sense of possessing excess kinetic energy from the nuclear recoil. As a result of this excess kinetic energy, the tritium atom is able to react at many positions in the molecule which are inaccessible to thermal hydrogen atoms (25° C) because of the high activation energies involved.

The cyclopropane molecule offers an interesting opportunity for further elucidation of the nature of these "hot" reactions because of its relatively high activation energy for substitution reaction—no deuterated cyclopropane was observed in mixtures of thermal deuterium atoms and cyclopropane (11)—and its ready thermal isomerization to propylene at temperatures in the range of 400–500° C (12). Preliminary experiments have already been reported which demonstrated that tritium-labeled cyclopropane can readily be obtained in good yield from the reactions of recoil tritium atoms with cyclopropane, as in reaction [1] (13).

[1]

More detailed experiments have now been carried out on the mechanism of reaction of energetic tritium atoms with cyclopropane. The most pertinent variables in these

[1]*Contribution from the Department of Chemistry, University of Kansas, Lawrence, Kansas; paper presented at the Symposium on Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960. Research supported by A.E.C. Contract No. AT-(11-1)-407.*

experiments have been the length of the irradiation, the pressure of cyclopropane, and the absence or presence of other gases, especially nitric oxide and/or helium, during the irradiation.

EXPERIMENTAL

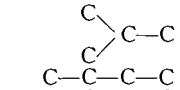
The experimental conditions of these experiments are quite similar to those established previously in our studies of olefinic hydrocarbons (9). Mixtures of He^3, cyclopropane, and any other gases to be added were prepared in a vacuum system, and sealed into irradiation tubes made of 20-mm I.D. Pyrex 1720 glass, in lengths of about 5–8 cm. He^3 was obtained from Oak Ridge and freed from tritium-labeled impurities by combustion over CuO at 600° C, and passage through a liquid nitrogen trap (14). The level of radioactive impurity gases in the He^3 after this purification was less than 50 d.p.m./cc S.T.P. of (T_2 + HT), and less than 50 d.p.m./cc S.T.P. of CH_3T or other aliphatic hydrocarbons. These activity levels are negligible in comparison to the neutron-induced radioactivity in each of the irradiated samples. The other gases were all obtained from the Matheson Company and have quoted purities of >99% for He and NO, and >99.5% for cyclopropane. Our measurements on the cyclopropane showed no detectable hydrocarbon impurities as large as 0.01%.

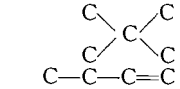
The irradiation tubes were exposed to neutrons in the instrument tunnel facility of the Brookhaven National Laboratory, which has a nominal flux of 2.8×10^9 n/cm² sec and an ambient temperature of about 30° C. Irradiations were carried out for periods of time varying from 2 hours to 6 days in this facility. The actual neutron flux during irradiation was somewhat reduced by neutron absorption in the Pyrex 1720 glass, and by self-shielding during simultaneous irradiation of many samples. Neutron flux calculations based on the observed tritium radioactivity fall in the range $0.5–1.0\times10^9$ n/cm² sec, as shown in Table I.

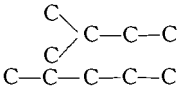
The distribution of radioactivity among molecular hydrogen and the various hydrocarbon molecules was obtained for each irradiated sample by gas chromatographic separation and flow proportional counting of the chromatographic effluent gas. Two or more aliquots were run on each sample, usually a large aliquot on a 50-ft dimethylsulpholane (DMS) column at 25° C, and a smaller aliquot on 10 ft silica gel at 85° C. The counting gas consisted of the helium carrier gas and methane in about a 50–50 mixture, the methane being added after the carrier gas had passed through a thermal conductivity detector for determination of macroscopic radiation damage. Further details have been given previously (15, 16).

Aliquots of some samples were run through a 50-ft safrole column in order to determine the relative contributions of *n*-butane – neopentane and cyclopropane–acetylene. In the usual dimethylsulpholane runs, the former pair are unseparated and acetylene is obscured by the large cyclopropane peak immediately preceding it. Acetylene contributions are also measured on the silica gel column, although they are partially obscured when propane is present in large amounts. The parent peaks usually overload the DMS column and emerge somewhat early; other components are practically unaffected by the overload of the parent compound.

RESULTS







Variation in Length of Irradiation

The yields of tritium radioactivity found in various molecules, measured relative to cyclopropane as 100, are shown in Table I for a series of irradiations carried out under

nearly constant conditions except for the length of the irradiation. As can readily be seen, the relative yields of several labeled unsaturated molecules fall, and the yields of the corresponding saturated aliphatic products increase, with increasing radiation time. The total number of counts actually measured in the cyclopropane peak and the flux estimate from the total observed tritium activity are also given in Table I for the irradiations. The shortest irradiations did not create much tritium radioactivity, and the quoted errors are calculated from the statistical uncertainty of the observed counts. For runs of 48 hours or longer, the statistical uncertainty is probably less than other possible errors. The irradiation times were varied from 2 to 138 hours; duplicate samples at 48 hours were separately irradiated several months apart and analyzed on both the dimethylsulpholane and safrole columns.

Nitric Oxide Experiments

The observed tritium distributions are given in Table II for a series of experiments carried out in the presence of nitric oxide. The usual role of nitric oxide in these experiments is to react with free radicals and thermal hydrogen atoms, and to remove them from the reacting system, thus protecting other recoil reaction products, e.g. propylene and ethylene, from secondary reactions with radiation-induced species. At the same time, all labeled compounds are eliminated which involve thermal atoms or radicals in

their production. Those labeled compounds which are unaffected by the presence of a radical scavenger are then assumed to be obtained from direct recoil reaction. A possible exception could occur if the direct reaction created a "hot" radical (e.g. ·CHT·), which was able to react very efficiently with the hydrocarbon molecule.

The nitric oxide experiments confirm hydrogen, ethylene, propylene, and cyclopropane

as products of recoil reaction, although the amounts observed are not always found in consistent ratios.

Pressure Effects

The tritium distributions have also been measured with a series of samples irradiated at various cyclopropane pressures from 7.9 to 80 cm Hg (plus 1–2 cm Hg of He^3) and are recorded in Table III. The practice of expressing all products in terms of the parent

yield is not very satisfactory for Tables II and III, for a comparison of the actual amounts of radioactivity observed in various compounds indicates that the percentage of labeled parent compound falls off with decreasing pressure. This parent fall-off is accompanied by an increase in the percentage of radioactivity observed as propane. There is no compound whose activity is necessarily constant through the pressure changes, although hydrogen is experimentally observed to be nearly so. We have chosen to hold the cyclopropane activity as 100 for comparison purposes. The column labeled estimated relative parent activity represents an estimate of the absolute change in the activity as cyclopropane.

Helium Moderator

The results of a series of runs carried out in the presence of moderator He^4, with and without nitric oxide as a scavenger, are shown in Table IV. The actual yield of labeled hydrogen is not very much affected by changes in He^4/cyclopropane ratio, but the yield of labeled cyclopropane falls markedly. Both propane and *n*-butane increase as the He^4/parent ratio is increased.

DISCUSSION

The distribution of tritium activity among the various possible molecular forms in a given system depends upon three separate steps:

(*a*) The primary reaction of the recoil tritium with a molecule of the medium. If, as is frequently true, this reaction occurs while the tritium atom possesses excess kinetic energy, this attack can be expected to be rather indiscriminate upon all species in the system. In lightly irradiated systems such as these, the "hot" reaction would then be with cyclopropane almost exclusively, for the total concentration of degradation products, free radicals, ions, etc. is always very small in comparison to the cyclopropane concentration. These "hot" reactions produce the initial recoil tritium yields.

(*b*) The "hot" product may itself be quite reactive, and be able to participate in further reactions in the system. This can happen if the "hot" product is either a labeled free radical, such as the $CH_2T\cdot$ or *sec*-$C_4H_8T\cdot$ suggested for other hydrocarbons (1, 3, 9), or if it is a molecule sufficiently vibrationally excited to undergo decomposition or isomerization. The identified stable labeled molecule will depend in each case on the further reactions of the radical or excited molecule involved. These reactions, unlike the "hot" reactions, can be strongly influenced by the presence or absence of reactive ions, atoms, and molecules from radiation degradation.

It is also possible to form a stable molecule in temperature equilibrium with the system which is able to undergo thermal chemical reactions with other molecules present. There have been no experimental indications of any such molecules in any of the hydrocarbon systems investigated in our laboratory. Furthermore, the known hydrocarbons do not react or undergo isotopic exchange over a period of several months at room

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

temperature, as confirmed by samples irradiated in duplicate and analyzed several months apart.

(*c*) The final distribution that is observed may also reflect subsequent alteration of the products of (*a*) and (*b*) by continued exposure to a radiation field. The perturbing effect of such radiation-induced reactions can readily be minimized, if the parent molecule is reasonably reactive toward radiation-produced species. If the parent molecule is rather inert, however, the brunt of the radiation damage may be borne by reactive product molecules present in low concentration, e.g. olefins, and will result in appreciable alteration in the observed amounts of these products.

The nitric oxide – scavenger experiments of Table II demonstrate that labeled hydrogen, cyclopropane, propylene, ethylene, and other molecules are all formed in the initial reaction of the "hot" tritium atom with cyclopropane. The experiments in the absence of nitric oxide show an appreciably different spectrum of labeled hydrocarbons, including substantial yields of a number of saturated aliphatic molecules that arise from the reactions of excited species, as in (*b*), or radiation alteration, as in (*c*).

Since reactions in both categories (*b*) and (*c*) are quite sensitive to the presence of radiation-produced reactive species in the rather unreactive cyclopropane, we must consider the radiation chemistry of the recoil system as well as the initial "hot" reactions with cyclopropane itself.

Radiation Effects

I. Ionization Processes

The recoil triton and proton from the $He^3(n,p)T$ reaction dissipate a total of 0.78 Mev for each tritium atom produced, and almost all of this energy is released as ionization and excitation in the gas phase. The identity of the ions, radicals, and atoms created by radiation effects can be estimated from the 70-volt mass spectra, as in the calculations of Futrell on *n*-hexane (17). Such a calculation, with the additional assumption that the ion–molecule reactions of $C_3H_5^+$ and $C_3H_6^+$ with cyclopropane go approximately as well as the corresponding reactions with propylene (18–20), clearly indicates the formation of substantial quantities of radiation produced ethylene and hydrogen atoms, as well as smaller yields of methyl and other radicals. Additional hydrogen atoms and or radicals will arise from the ion–electron or ion–ion recombination reactions.

II. Reactions of Hydrogen Atoms and Radicals

In pure cyclopropane, abstraction reactions such as [4] and [5] are the only important reactions that can occur for H atoms or radicals, except recombination as in [6].

$$H\cdot + \underset{H_2C-CH_2}{\overset{CH_2}{\diagup\diagdown}} \xrightarrow{k_4} H_2 + C_3H_5\cdot \qquad [4]$$

$$R\cdot + \underset{H_2C-CH_2}{\overset{CH_2}{\diagup\diagdown}} \xrightarrow{k_5} RH + C_3H_5\cdot \qquad [5]$$

$$R\cdot + R'\cdot \xrightarrow{k_6} R{-}R' \text{ (R can be H)} \qquad [6]$$

As irradiation proceeds and olefinic products begin to accumulate, the atoms and radicals may react with them, too, as in [7] and [8], and the actual course of reaction will depend upon the relative rates of the individual reactions [4] to [9] for the various radicals involved.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$H\cdot + C_nH_{2n} \xrightarrow{k_7} C_nH_{2n+1}\cdot \quad [7]$$

$$R\cdot + C_nH_{2n} \xrightarrow{k_8} R{-}C_nH_{2n}\cdot \quad [8]$$

Experimentally, it is observed that the sum of the relative yields of propylene and propane in Table I is reasonably constant over a factor of 70 in irradiation times, although the individual yields are changing. This observation strongly suggests that the most probable reaction for the removal of propylene from the system, and its lowered relative yield, is reaction [7] followed by the further addition of another hydrogen atom, probably by reaction [5] for the C_nH_{2n+1} radical. The sum of the yields for ethane plus ethylene is also nearly constant for different irradiation times—the ethylene concentration does not fall as smoothly as the propylene yield, but there are difficulties in separating the ethane and ethylene radioactivity at these low count rates.

A crude calculation of the kinetic behavior of atoms and radicals in the cyclopropane system can be made by assuming that

(*a*) H atoms and olefin are produced continuously by radiation effects on cyclopropane;

(*b*) olefin is removed only by reaction with H atoms, as in reaction [7], followed by reaction [5];

(*c*) H atoms are removed only by reactions [4] and [7], and rapidly reach a steady-state equilibrium.

Such assumptions lead to a predicted curve of olefin concentration versus time of irradiation which depends on the parameters: (1) radiation G values of hydrogen and olefin, and (2) the ratio k_4/k_7. The olefin reaches a steady-state concentration eventually, and since the total radioactivity produced rises linearly with time, the fraction of radioactivity found as olefin falls steadily (21).* The propylene yields of Table I agree quite well with the crude estimate obtained using the parameters: $k_4/k_7 = 8\times10^{-5}$, $G(H) = 5$, and $G(\text{olefin}) = 4$. These G values are reasonable ones, and the value of k_4/k_7 used is in good agreement with measured values for this ratio (11, 22, 23). The intercept for the propylene yield at zero irradiation time corresponds to zero initial production of labeled propane, and allows the additional conclusion that the sum of propylene plus propane yields is a satisfactorily accurate measure of the *total* production of propylene in the system by "hot" reactions. In the subsequent discussion of the "hot" reactions themselves, we shall use this sum of yields as a measure of the labeled propylene production in comparison to the labeled cyclopropane yield.

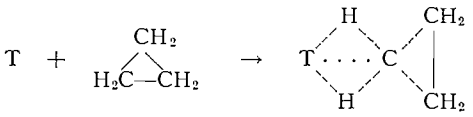
Tritium Reactions at High Kinetic Energy

Previous gas-phase experiments have led to a hypothesis for the reactions of high-energy recoil atoms with hydrocarbons that is able to explain the observed effects quite satisfactorily (1–9). The most important characteristics of this hypothesis are that the tritium atoms react

(*a*) as neutral atoms—the predominant charge state for a moving hydrogen nucleus at energies from 10^4 ev down;

(*b*) while possessing kinetic energy greatly in excess of average thermal energies, and hence are able to both react in a very few collisions and to undergo reactions that are highly endothermic and/or have high activation energies. Essentially, all positions in

**K. Yang and P. Gant (J. Chem. Phys. (in press)) have reported steady-state concentrations of ethylene in cyclopropane of about $10^{-3}\,x(\text{cyclo-}C_3H_6)$ for cyclopropane irradiated with beta particles from tritium decay.*

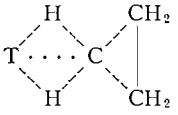


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

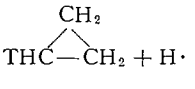
a molecule are approximately equally subject to attack by, and reaction with, the recoil tritium atom.

(*c*) the reaction usually takes place so rapidly that only one parent molecule is involved—the reaction is completed before energy can be removed from the system by collisions.

(*d*) the reaction takes place through a transition complex and does not require "cages" or combination with other radicals in order to produce most of the observed radioactive molecules.

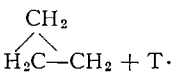


The recoil tritium reactions with both saturated and unsaturated positions of aliphatic molecules have been interpreted as involving momentarily a transition complex including the tritium recoil atom and all of the previously bonded substituents. This complex then decomposes by breaking one (or more) of these bonds, often leading to a stable molecule as a result. With cyclopropane, such a complex might be pictorially written as in [9] (without intending to indicate any specific details about the geometry and bonding involved).



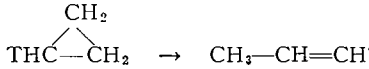
[9]

The lifetime of this complex is very short—it may only exist for one vibration or so, and equilibration of energy among the vibrated co-ordinates of the complex does not occur. The C_3H_6T complex above can break one of the bonds to the attacked carbon atom, with four possible reactions.



$$\rightarrow \quad HT + C_3H_5\cdot \qquad [10]$$

[11]



$$\rightarrow \quad CH_2T—CH_2—CH_2\cdot \qquad [12]$$

[13]

The tritium atom emerging from reaction [13] will usually be degraded in energy and will react again as a "hot" atom or a thermal atom depending upon the energy remaining. Undoubtedly a relatively high activation energy is required for the tritium atom to penetrate into the molecule far enough to bond even briefly to one of the carbon atoms. The relative yields of equations [10]-[13] may very well be strongly energy dependent.

The tritium-labeled cyclopropane from reaction [11] will usually be produced in an excited vibrational state, and, if this energy is sufficient, can undergo the isomerization reaction [14] for which the activation energy is 65 kcal/mole (24). Some tritium would be

[14]

expected in all hydrogen positions of the propylene. The labeled *n*-propyl radical from reaction [12] must be excited since the reaction is highly exothermic as shown in Table V.

TABLE V

Energetics of formation of "hot" products in recoil tritium reactions with cyclopropane

Reaction	ΔH (kcal/mole)
$T + \underset{H_2C-CH_2}{\overset{CH_2}{\diagup\diagdown}} \rightarrow$	
$\underset{H_2C-CHT}{\overset{CH_2}{\diagup\diagdown}} + H$	~0
$CH_3-CH=CHT + H$	−8
$CH_2=CHT + CH_3\cdot$	−20
$CH_2=CHT + \cdot CH_2 + H\cdot$	+83
$CH_2T-C\equiv CH + H_2 + H\cdot$	+31
$CH_2T-C\equiv CH + 3H\cdot$	+135
$CH_2=C=CHT + H_2 + H\cdot$	+32
$CH_2=C=CHT + 3H\cdot$	+136
ΔHf° used (isotopic differences ignored) (25–27)	
$\underset{H_2C-CH_2}{\overset{CH_2}{\diagup\diagdown}}$	+12.7
$CH_3-CH=CH_2$	+4.9
$CH_2=CH_2$	+12.5
$CH_3-C\equiv CH$	+44.3
$CH_2=C=CH_2$	+45.3
H	+52.1
$CH_3\cdot$	32.0
$\cdot CH_2$	83

This energy is sufficient to permit decomposition to labeled methyl and ethylene to occur readily,

$$CH_2T-CH_2-CH_2\cdot \rightarrow CH_2T\cdot + C_2H_4; \quad [15]$$

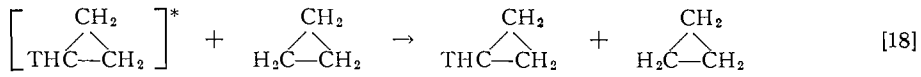
to hydrogen and propylene to occur less readily,

$$CH_2T-CH_2-CH_2\cdot \rightarrow CH_2T-CH=CH_2 + H\cdot, \quad [16]$$

and perhaps to decompose as in reaction [17] to a hydrogen atom and the trimethylene radical,

$$CH_2T-CH_2-CH_2\cdot \rightarrow \cdot CHT-CH_2-CH_2\cdot + H\cdot. \quad [17]$$

"Hot" Products



Cyclopropane

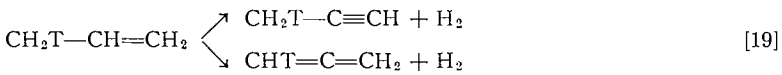
The identification of labeled cyclopropane among the radioactive products immediately indicates that reaction [1]—presumably by steps [9] plus [11]—is able to take place without further isomerization as in [14]. This failure to isomerize can be expected if the tritiated molecule is left with less vibrational energy than the 65 kcal/mole activation energy, or if the excess energy is not too great and can be removed by collision before isomerization.

The data of Table III show that the fraction of tritium activity found as labeled cyclopropane is greater at high pressures. (The results of Table IV show that the changes in He/Δ ratio of Table III are insufficient to explain the observed decreases in cyclopropane yield with decreased pressure during irradiation.) The increased cyclopropane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

yield at higher pressures is readily explained as a competition between the isomerization reaction [14] and the removal of excitation by collision:

[18]



De-excitation of the excited *n*-propyl radical is not a satisfactory mechanism, for this de-excitation will not lead to labeled cyclopropane, but rather to an aliphatic hydrocarbon.

An estimate of the excitation energy required for reactions [14] and [15] to be competitive depends on the efficiency of collisions in removing excess vibrational energy. Since the excess energy is quite large, the collision efficiency is probably very high, approaching unity. The rate of isomerization must then be of the order of 10^9 sec^{-1} in order to be competitive with gas collisions at 0.1 to 1.0 atmosphere pressure. Such a rate requires an excitation energy roughly double the activation energy for a molecule with 13 active degrees of freedom, and hence approximately 130 kilocalories/mole of internal energy. Almost all of this energy must be supplied from the original kinetic energy of the tritium, which must then have been at least 6–7 ev at the time of reaction. The possible alternate path to propylene by reactions [9] and [16] prevents additional conclusions about higher vibrational energies from being drawn from the experimental observation that substantial yields of propylene (plus propane) are found at the highest pressures used. Some information on the relative importance of the two paths to propylene formation could be obtained in principle by degradation of the propylene molecules in order to determine the intramolecular tritium distribution.

Ethylene, Allene, Methylacetylene, and Hydrogen

The unsaturated molecules ethylene, allene, and methylacetylene are all obtained in low yield from the recoil reactions in the presence of nitric oxide, as well as in its absence. Each of these molecules could arise from the decomposition of the excited intermediate by reactions other than [9] to [13], or by further decomposition of the propylene of [14] or [16], of the trimethylene radical from [17], or of the *n*-propyl radical from reaction [12].

Both allene and methylacetylene must be formed by a highly endothermic reaction, as shown in Table V. If the three hydrogen atoms that must be lost from the transition complex are all lost as separate atoms, a kinetic energy of more than 135 kcal/mole must be supplied by the recoiling tritium atom. The second possibility exists that two of these hydrogens are given off as H_2, as in reactions [19], from the unimolecular elimination of molecular hydrogen from an excited propylene molecule.

[19]

The over-all path by this sequence of reactions is only 31 and 32 kcal/mole endothermic, respectively. However, reactions such as [19] can be expected to have activation energies of the order of 40–60 kcal/mole, and again roughly double this energy would be required for decomposition before collisional deactivation. Hence, for either possible path to labeled methylacetylene or allene, an energy of about 120+ kcal/mole must be supplied from the kinetic energy of the recoil tritium. The unscavenged HT found in the nitric oxide systems may arise from an energetic hydrogen abstraction reaction. An alternate path that may be very important would be the intramolecular elimination of HT instead of H_2 from the excited propylene molecule, as in [19].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The excited *n*-propyl radical decomposition is exothermic over all in going to methyl plus ethylene, but the sequence of reaction [9] followed by [15] leads only to labeled methyl radical in the absence of some hydrogen transfer reactions in the excited radical. The decomposition of trimethylene diradical as in [20] is quite endothermic, but the energy requirements are no more severe than those for the formation of the other

$$\cdot CH_2—CH_2—CHT\cdot \rightarrow \cdot CH_2 + CH_2{=}CHT \qquad [20]$$

"hot" products. Since this reaction does not involve hydrogen transfer, it may be able to compete successfully. Furthermore, in the presence of so much excess vibrational energy, an excited trimethylene diradical for reaction [20] can probably be obtained readily by direct opening of the cyclopropane ring, as in [21]:

$$\begin{array}{l} CH_2 \\ /\ \backslash \\ H_2C—CHT \end{array} \rightarrow \cdot CH_2—CH_2—CHT\cdot \qquad [21]$$

Methylcyclopropane and Butene-1

Methylcyclopropane could presumably arise in this system by any of these three reactions:

$$\cdot CHT + \begin{array}{l} CH_2 \\ /\ \backslash \\ H_2C—CH_2 \end{array} \rightarrow \begin{array}{l} CH_2 \\ /\ \backslash \\ CH_2T—HC—CH_2 \end{array} \qquad [22]$$

$$CH_2T\cdot + \begin{array}{l} CH_2 \\ /\ \backslash \\ H_2C—CH_2 \end{array} \rightarrow \begin{array}{l} CH_2 \\ /\ \backslash \\ CH_2T—HC—CH_2 \end{array} + H\cdot \qquad [23]$$

$$CH_2T\cdot + \begin{array}{l} \cdot CH \\ /\ \backslash \\ H_2C—CH_2 \end{array} \rightarrow \begin{array}{l} CH_2 \\ /\ \backslash \\ CH_2T—HC—CH_2 \end{array} \qquad [24]$$

The recent experiments of Butler and Kistiakowsky demonstrate that a mixture of butenes would also be expected from reaction [22] under these experimental conditions (28). Since the yields of isobutylene and *cis*- and *trans*-butene-2 are negligible, the methylene insertion reaction is probably negligible, too. Reaction [23] is endothermic and would require a "hot" $CH_2T\cdot$ group. The observation of some labeled butene-1 in the presence of radical scavenger (Table II) is consistent with this reaction.

The radical recombination reaction seems quite likely since $C_3H_5\cdot$ radicals (of unspecified structure) will be expected in good yield from the abstraction reactions [4] and [5] by hydrogen atoms and radicals, respectively. Similarly, the recombination of methyl with allyl radical [26] is probably the source of the labeled butene-1 found in this system.

$$CH_2T\cdot + CH_2{=}CH—CH_2\cdot \rightarrow CH_2T—CH_2—CH{=}CH_2 \qquad [26]$$

Moderator Effect

Qualitatively, the changes in yields of cyclopropane and other molecules in the presence of He^4 (Table IV) are consistent with the removal of the excess kinetic energy of the recoil tritium in elastic collisions with the helium moderator. The energy loss reduces the probability of a large excess of vibrational energy, and hence of isomerization; it also reduces the probability of a successful reaction while still possessing the necessary activation energy for reaction with the cyclopropane molecule to form HT or labeled parent molecule. The more rapid decrease in the yield of labeled cyclopropane than of HT implies that the activation energy for the former is larger, as is also indicated by the thermal deuterium experiments of Schiff and Steacie.

For personal use only.

Wolfgang and Estrup have presented a theory of high-energy kinetics and have applied it quite successfully to the recoil reactions of tritium with methane (4). The reactions in the cyclopropane system are sufficiently complicated, however, that additional experiments are required on radiation effects and on collisional de-excitation in He^4–Δ mixtures before a suitable test of the applicability of the theory to this system can be made.

VIBRATIONAL DISEQUILIBRIUM IN REACTIONS BETWEEN ATOMS AND MOLECULES[1]

N. Basco and R. G. W. Norrish

ABSTRACT

Observations on the production of vibrationally excited oxygen molecules in the flash photolysis of nitrogen peroxide and of ozone have extended previous work on these systems. In the case of nitrogen peroxide it has been shown that oxygen molecules possessing the entire exothermicity of the reaction in the form of vibrational energy are produced. A new class of reactions is reported in which vibrationally excited hydroxyl radicals are produced under isothermal conditions by the reaction $O(^1D) + RH \rightarrow OH^* + R$, in which the energy for excitation is contributed by the electronic energy of the oxygen atom.

These and other cases of non-equilibrated energy distributions in reaction products and theories accounting for this phenomenon are reviewed.

The first clear indication that the energy distribution in a chemical reaction between an atom and a polyatomic molecule can differ appreciably both from equipartition and from the Maxwell–Boltzmann law was obtained by McKinley, Garvin, and Boudart (8), who showed that in the reaction

$$H + O_3 \rightarrow OH + O_2 \qquad + 80 \text{ kcal}$$

the hydroxyl radical was produced with up to nine quanta of vibrational energy (75 kcal). Soon after, Lipscomb, Norrish, and Thrush (4) detected oxygen molecules with up to eight quanta of vibrational energy (34 kcal) in the isothermal flash photolysis of nitrogen dioxide and chlorine dioxide and showed that these were produced in the reactions

$$O + NO_2 \rightarrow O_2 + NO \qquad + 46 \text{ kcal},$$

and

$$O + ClO_2 \rightarrow O_2 + ClO_2 \qquad + 61 \text{ kcal}.$$

Other examples of this process viz.

$$O + O_3 \rightarrow O_2^* + O_2$$
$$Cl + O_3 \rightarrow ClO^* + O_2$$
$$Br + O_3 \rightarrow BrO^* + O_2$$

were found by McGrath and Norrish (1, 6, 7) in the flash photolysis of ozone and of chlorine and bromine in the presence of ozone. From these results they arrived at the general conclusion (1) that the exothermic reaction between an atom and a triatomic molecule

$$A + BCD = AB + CD \qquad + Q \text{ kcal}$$

could lead to the accumulation of most of the energy Q in the newly formed bond AB.

More recently, several other examples have been reported by Cashion and Polanyi (2, 13, 14, 15), by Kaufman and Kelso (16), by Dressler (17), and by Thrush (18). These and other examples of this type of reaction are listed in Table I, which shows the exothermicity of the reactions (Q kcal/mole) together with the highest vibrational level observed.

The subject has been reviewed by McGrath and Norrish (1) and discussed from theoretical points of view by Polanyi (2) and by Smith (3). It is the purpose of this paper

[1]*Contribution from the Department of Physical Chemistry, University of Cambridge, Lensfield, Cambridge, England; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

TABLE I

Reaction	Q (kcal)	Highest level observed and energy in kcal/mole	Reference
$O + ClO_2 \rightarrow O_2^* + ClO$	61	8 = 34	4
$O + NO_2 \rightarrow O_2^* + NO$	46 (48)?	8 = 34	4
		11 = 45½ (12 = 49)?	5
$O + O_3 \rightarrow O_2^* + O_2$	138 $O(^1D)$	17 = 66½	6,7
	93 $O(^3P)$	19(?20) = 73	5

$X + Na_2 \rightarrow NaX^* + Na$	81 (X = Cl)		
	71 (X = Br)		
	54 (X = I)		
$Na + ClX \rightarrow NaX^* + Cl$	52? (X = Cl)	At least 48½	20
	39? (X = Br)		
	53? (X = I)		
$Na + HgX \rightarrow NaX^* + Hg$	75 (X = Cl)		
	71? (X = Br)		

to discuss various aspects of the production of vibrationally excited molecules in the reaction between an atom and a molecule in the light of our more recent results, which will now be briefly reported.

In the flash photolysis of ozone in the presence of ammonia, hydrogen, hydrogen chloride, methane, and water under isothermal conditions, we have observed in each case vibrationally excited hydroxyl radicals. So far, only the first and second excited levels have been detected, but further work is in progress. We suggest that the reaction in which they are produced is of the type

$$O(^1D) + RH \rightarrow OH^* + R.$$

These reactions are of particular interest for two reasons. Firstly, methane and ammonia provide the first examples of this type of reaction involving molecules more complex than triatomic and, secondly, because it is the first time that the electronic energy of the approaching atom has been shown to appear as vibrational energy of the product in otherwise thermoneutral or endothermic reactions. It should be noted that, though in the photolysis of ozone the reaction

$$O(^1D) + O_3 \rightarrow O_2^* + O_2$$

has been shown to be responsible for the production of O_2^*, the degree of vibrational excitation so far observed can be accounted for without involving the electronic energy. The observation of OH* in the systems described confirms the place ascribed to the $O(^1D)$ atom in the photolysis of ozone by McGrath and Norrish (7).

The question of the extent to which the heat of reaction in the general case

$$A + BCD \rightarrow AB + CD$$

can appear as vibrational energy in the products has interested us for some time. We considered it likely that the species AB could be formed with any allowed vibrational energy up to the maximum. Where the highest permitted vibrational level has not so far been observed, we suspected that this might be a consequence of experimental difficulties. Accordingly, we have started reinvestigating some of the systems previously studied by flash photolysis. In the photolysis of NO_2 and ClO_2 (4) it seemed rather a coincidence that the highest vibrational level of O_2* observed was 8 in each case though the exothermicities for the reactions

$$O + NO_2 \rightarrow O_2^* + NO$$

and

$$O + ClO_2 \rightarrow O_2^* + ClO$$

differed by 15 kcal.

In preliminary experiments with NO_2, we have now observed the 9th, 10th, and 11th (and 12th?) vibrational levels, the energy of the 11th level being equal to the exothermicity of the reaction. We have also observed very faintly the first and possibly the second vibrationally excited levels of NO, though this has yet to be confirmed.

In further studies on the flash photolysis of ozone, we have been able to observe the 18th and, very faintly, the 19th (and 20th?) vibrational level of O_2*. Further work on this system is expected to provide evidence in connection with the reaction,

$$O_2^{*}{}_{(v=7)} + O_3 \rightarrow O(^1D) + 2O_2,$$

which McGrath and Norrish (7) have proposed, to explain the high quantum yield in the photolysis of ozone with ultraviolet radiation. We have also extended observation to shorter wavelengths and have observed the 11th and 10th (9th?) vibrationally excited levels of O_2.

In reactions of the type

$$A + BCD \rightarrow AB + CD \quad + Q \qquad [1]$$

the evidence for the accumulation of most of the energy Q in the bond is thus quite convincing. We believe that the evidence now permits the generalization that, in all exothermic abstraction reactions, the heat of reaction will appear largely as vibrational energy of the products. However, the need for more experimental evidence is apparent and perhaps best illustrated by the fact that no reaction conforming strictly to equation [1] is yet known, B and D being either both hydrogen or oxygen atoms.

There is equally a need for theoretical treatments of the problem and here Polanyi (2) and Smith (3) have made significant contributions. Polanyi's valence bond resonance description of the activated complex ABC in the reaction

$$A + BC \rightarrow AB + C$$

leads to the prediction that almost the entire heat of reaction will appear as vibrational energy of the bond AB. The transition complex is presumed to be most stable when the two resonance forms

$$AB—C$$

and

$$A—BC$$

have equal energy. Since in an exothermic reaction the bond AB is stronger than BC, the internuclear separation AB in the complex will be larger than in the isolated molecule, while the internuclear distance in B—C will be that of the isolated molecule. Since the energy of the complex is generally accepted to be only 5 ± 5kcal greater than of the two resonance forms and assuming that the probability of the transfer of an appreciable amount of energy to C is very small, even when there is a chemical affinity between them, the molecule AB will be formed with very nearly the entire heat of reaction in vibration.

As well as the detection of molecules AB possessing nearly all the heat of reaction as vibrational energy, the most important experimental test of this model is to demonstrate that initially all the molecules are formed in the highest observed vibrational state. So far, in all cases, a distribution of energies has been observed and though, in the case of the reaction studied by Polanyi (14),

$$H + Cl_2 \rightarrow HCl^* + Cl$$

the energy distribution is reported (2) as corresponding qualitatively with a system relaxing from a high vibrational level, there is no certainty that all the HCl is initially formed with $v = 6$. Further, evidence has been furnished by Garvin, Broida, and Kostkowski (12) that in the reaction

$$H + O_3 \rightarrow OH^* + O_2$$

there is an appreciable production in all levels $v \leqslant 9$.

Restricted to the case A+BC, this model is a very plausible one and the experimental evidence strongly supports the idea that it is possible for at least some molecules to possess the entire heat of reaction.

It is not immediately apparent to what extent the model applies to the more general case

$$A + BCD \rightarrow AB + CD.$$

The probability of energy transfer between AB and CD in the transition complex may well be higher in this case, and this could result in the production of some molecules AB with appreciably less than the maximum possible vibrational excitation.

In a molecule of type BCB, the strength of the CB bond is not necessarily the same as in the isolated molecule CB. Where they differ appreciably, as, for example, in ozone and nitrogen peroxide, a considerable reorganization of the CB bonds must take place when an atom is abstracted. We consider it reasonable to suppose that the ease with which this reorganization takes place could depend on the nature of the molecule BCB and of the atom A and, perhaps more important, on the relative spacial configuration of the atoms at the moment of impact. The effect of this reorganization would be to reduce on the average the amount of energy available for vibrational excitation of the AB molecule, though, in any particular collision, there would always be a definite probability of producing the molecule AB vibrationally excited to the fullest extent. Thus, on this model the observed population of all possible vibrational levels is a consequence of the nature of the reaction itself rather than of deactivation of molecules initially produced entirely in the highest vibrational level. A quantitative estimate of the relative initial population of the various vibrational levels will have to take into account the variation in reaction probability with the direction of approach of the atom relative to the configuration of the molecule BCD and it seems likely that the reaction is most probable when there is the most favorable configuration for maximum vibrational excitation of AB.

For a non-linear molecule BCD, it is reasonable to expect a fraction (not necessarily constant) of the heat of reaction to appear as rotational energy as well as translational energy of AB and CD and this should also be true for an oblique collision of an atom with a linear triatomic molecule. It also seems possible on this model for the molecule CD to be vibrationally excited to some extent.

Smith (3) postulates a definite maximum value for the fraction of the heat of reaction which can appear as vibration. This is limited by a kinematic factor $\sin^2\beta$, where β is the angle of rotation required to take a co-ordinate system describing the reactants into one suitable for describing the products. The kinematic factor depends only on the masses M_A, M_B, M_C, and M_D of the atoms involved and can be calculated for the reaction

$$A + BC \rightarrow AB + C \left[\tan^2\beta = \frac{M_B}{M_A} + \frac{M_B}{M_C} + \frac{M_B^2}{M_A M_C} \right]$$

and

$$A + BCD \rightarrow AB + CD \left[\tan^2\beta' = \frac{M_B}{M_A} + \frac{M_B}{M_C + M_D} + \frac{M_B^2}{M_A(M_A + M_C)} \right].$$

The theoretical maximum value of the fraction of energy appearing as vibration in the second case then lies in the range $\sin^2\beta' - \sin^2\beta$, the latter value applying if the influence of D is neglected.

The model is a remarkably simple one and predicts accurately in several cases where good experimental data is available, e.g., 0.96–0.97 for

$$H + O_3 \rightarrow OH^* + O_2$$

and 0.986 for

$$H + Cl_2 \rightarrow HCl^* + Cl$$

compared with experimental values of 0.94 and 1.0.

He points out that it fails in the case of

$$I + Na_2 \rightarrow NaI^* + Na$$

where the predicted value of 0.576 gives the NaI* molecule insufficient energy for the reactions

$$NaI^* + Na \rightarrow NaI + Na^*$$
$$Na^* \rightarrow Na + h\nu$$

and suggests that there is either some peculiarity in the potential energy surface or the mechanism is in fact

$$Na + I_2 \rightarrow NaI^* + I$$

where $\sin^2\beta = 0.9$, but this is in disaccord with Evans' and Polanyi's original conclusion (20).

We consider that it again appears inadequate in the reaction

$$O + NO_2 \rightarrow O_2^* + NO$$

where it predicts a maximum value of the vibrational energy of 31–35.2 kcal, agreeing very well with the value of 34 kcal ($v = 8$) previously reported (4). Now that we have observed the 9th, 10th, and 11th vibrational levels, it seems that the agreement was fortuitous in this case. The agreement of theory with experiment in the case of ozone

is again not conclusive, since the evidence is strong in favor of the O atom being in the (^1D) state (7), whereas the exothermicity was calculated for the reaction of the O(^3P) atom. Further, since molecules with more than 17 quanta may react rapidly with O_3 (7) in the reaction

$$O_2^* + O_3 \rightarrow O(^1D) + 2O_2$$

the failure in previous work to detect them spectroscopically was evidence for their taking part in this reaction rather than for their not being produced. As we have shown, the threshold is not sharp and molecules with 18 and more quanta have now been observed.

Finally, the values of $\sin^2 \beta$ for the reactions of the type

$$O(^1D) + RH \rightarrow OH^* + R$$

described earlier are insufficient, except in the case of H_2, for the observed production of the vibrationally excited hydroxyl radical.

A third model accounting for the production of vibrationally excited molecules in the reaction

$$A + BCD \rightarrow AB^* + CD$$

has recently been proposed by Simons (21). He visualizes the atom A approaching B with such a velocity that, when A is finally brought to rest relative to B, the internuclear distance of A—B is very short compared with the equilibrium distance, so that on separation the molecule AB is vibrationally hot. The conditions necessary to achieve this are that the B—C bond is weak relative to AB so that dissociation of the complex (ABCD) occurs easily and little of the impact of A on B is transmitted to the C—D bond. There must be also an attractive force between A and B to overcome the normal repulsion of non-interacting particles. This model accounts for the ready production of O_2^* in the reactions

$$O(^3P) + NO_2 \rightarrow O_2^* + NO$$
$$O(^3P) + ClO_2 \rightarrow O_2^* + ClO$$

on the basis of electrons pin coupling between the paramagnetic species O(^3P) and NO_2 or ClO_2 resulting in attraction. In the case of ozone, the diamagnetic ozone molecule is considered as a weakly bound complex of $O_2(^3\Sigma)$ and O(^3P). Since the O_2—O bond is weak, the large internuclear distance favors the electron spin coupling. On this model the reaction

$$I + Na_2 \rightarrow NaI^* + Na$$

is particularly favored both on account of the low bond energy of the Na_2 molecule and the strong coulombic attraction between Na and I. Only qualitative tests of this model are possible and the author cites the reactions

$$O + SO_2 \rightarrow SO + O_2$$

and

$$O + Cl_2O \rightarrow O_2 + Cl_2$$

as being cases where the necessary conditions do not obtain, and therefore where vibrationally excited molecules should not be produced. He considers the failure of Oldershaw and Norrish (22) and of Edgecombe, Norrish, and Thrush (23) to observe O_2^* in these systems as evidence for the model. In our opinion, a more detailed consideration of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

experimental conditions under which both these reactions could have occurred shows that in neither case could an appreciable concentration of O_2^* have been produced for reasons quite unconnected with the proposed model. Firstly, in the photolysis of SO_2 itself, the oxygen atom produced is necessarily $O(^3P)$ and O_2^* could obviously not be produced in the reaction

$$O(^3P) + SO_2 \rightarrow SO + O_2 \qquad -12 \text{ kcal.}$$

In the photolysis of SO_3, the sequence

$$SO_3 \rightarrow SO_2 + O(^1D)$$
$$O(^1D) + SO_2 \rightarrow O_2 + SO \qquad +33 \text{ kcal}$$

would, we believe, result in the production of O_2^* ($v \ll 7$) if it occurred. Considering the low absorption coefficient of SO_3 and the possible alternative primary photolysis step

$$SO_3 + h\nu \rightarrow SO + O_2$$

only low concentrations of SO_2 and $O(^1D)$ would be present. It is therefore unlikely that a detectable concentration of O_2^* would be produced in this system even if the reaction itself were efficient. In any case, the oxygen atoms would probably react preferentially with the much larger amount of SO_3 present than with SO_2. One should also take into account that observation below about 2270 Å was particularly difficult in view of the continuous absorption and, at longer wavelengths, transitions from $v'' < 4$ are weak. It would therefore have been difficult to detect a low concentration of O_2^*.

A somewhat stronger case might have been made for failure of the reaction

$$O + SO_3 \rightarrow O_2^* + SO_2$$

to produce a detectable concentration of O_2^*, but even here some of the above arguments still apply and provide a satisfactory explanation which does not involve the inherent unlikelihood of the reaction itself.

In the other example quoted by Simons, the photolysis of Cl_2O, it should be noted that the reaction

$$O + Cl{-}O{-}Cl \rightarrow O_2 + Cl_2 \qquad +76 \text{ kcal}$$

is not of the type A + BCD. Requiring the breaking of two bonds, it is easy to visualize that the entire exothermicity of the reaction is not, in any case, available for vibrational excitation of the oxygen molecule.

There are other good reasons accounting for the failure to observe excited species in this system. The primary reaction might well be

$$Cl_2O \xrightarrow{h\nu} Cl + ClO$$

as well as

$$Cl_2O \rightarrow 2Cl + O$$

and the oxygen atom concentration may be low and would be further reduced by the reaction

$$O + Cl_2O \rightarrow 2ClO,$$

the concentration of ClO* being below detectable limits.

In our opinion, therefore, the negative evidence from the two systems considered does not test the model proposed by Simons. Objections to it are firstly that the argument he applies to the reaction

$$O + O_3 \rightarrow O_2^* + O_2$$

does not seem plausible when the atom involved is the $O(^1D)$ and, secondly, that it appears impossible to reconcile it with the occurrence of the reactions

$$O(^1D) + RH \rightarrow OH^* + R$$

It is profitable to consider further to what extent the available experimental evidence provides tests for theoretical models. The information required is:

1. Conclusive evidence of the reaction in which the vibrationally excited species is produced.
2. Certainty that all the vibrational levels produced have been observed or, failing that, a convincing explanation of the absence of certain levels.
3. The relative populations of the various vibrational levels and this as a function of experimental conditions; in particular, the distribution of vibrational energies in the molecules at the instant of formation and the subsequent variation with time.
4. The presence or absence of vibrational energy in the other species produced in the case of an atom and a polyatomic molecule.
5. Whether the electronic and kinetic energy of the abstracting atom can contribute to the vibrational energy of the bond formed.

The evidence for the proposed mechanism of formation of the excited species in the reactions considered is on the whole quite strong but, in some cases, far from conclusive. Even where the mechanism is well established, it is worth while to re-examine the arguments in favor of the proposed mechanism and to consider alternatives.

The production of O_2^* in the flash photolysis of NO_2 and of ClO_2 provides particularly well-established examples of the reaction

$$O + OXO \rightarrow O_2^* + XO.$$

An alternative mechanism, considered at the time, was that the O_2 molecule was initially formed in the $^1\Delta_g$ or $^1\Sigma_g^+$ electronic states and that the higher vibrational levels of the $^3\Sigma_g^-$ ground state were populated by collision-induced radiationless transitions, or by magnetic dipole radiation. This was rejected on the ground that such transitions, involving the breaking of two selection rules, would be unlikely to occur sufficiently rapidly to account for the results. Whether these rules are relaxed sufficiently in the presence of low pressures of ClO_2 and ClO or of NO_2 and NO is again doubtful, except, possibly, while the configuration approximates closely to the transition complex (O—O—X—O). In the extreme this reduces to the accepted mechanism and could only be distinguished from it if the calculated distribution of vibrational energies differed in the two cases.

In the case of ozone, the evidence (7) strongly supports the proposed mechanism

$$O(^1D) + O_3 \rightarrow O_2^* + O_2 \qquad +138 \text{ kcal.}$$

The possibility of the reaction,

$$O(^1D) + O_3 \rightarrow O_2(^3\Sigma_g^-) + O_2(^3\Sigma_u^-) \qquad -3 \text{ kcal,}$$

postulated by Benson (24) in connection with a photon-propagated chain decomposition of ozone, is, however, worth considering.

Population of high values of v'' by the process

$$O_2(^3\Sigma_u^-)(v' = 0) \rightarrow O_2(^3\Sigma_g^-)$$

is expected on the Franck–Condon principle and the observed apparent maximum in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

vibrational energy distribution at $v'' = 13$ or 14 may be consistent with this mechanism. The endothermicity of the reaction is not a strong contrary argument in view of a probable low or zero value for the activation energy.

In most cases, vibrational levels corresponding in energy to the full exothermicity of the reaction have not been observed. It seems that the reason for this is more likely to be found in the limitations of present experimental techniques rather than in any fundamental restriction on the proportion of energy which can appear as vibration.

We hope to test this both by further work on systems previously studied by flash photolysis and by investigating new systems. As we have seen, preliminary results in the NO_2 system show that all energetically possible vibrational levels are produced and that the ClO_2 system should be capable of providing a definite test. The ozone system is much more difficult and the evidence available strongly suggests that direct observation of vibrational levels appreciably higher than those already reported is unlikely. On account of the diffuseness of the threshold, it should be possible to follow the decay of molecules with vibrational energy $\geqslant 70$ kcal which seem to participate in the reaction,

$$O_2^*(v'' > 17) + O_3 \rightarrow 2O_2 + O(^1D),$$

and so provide a direct test of this reaction. So far, only the 18th level has been observed with sufficient intensity for quantitative measurements; but it may be possible to achieve this with the 19th and 20th levels. It is again doubtful whether possible failure to observe vibrational levels higher than the second in the reaction

$$O(^1D) + RH \rightarrow OH^* + R$$

will be theoretically significant because of rapid physical deactivation and chemical reaction. The concentration of molecules in these levels is likely to be small and the low transition probabilities for absorption from those levels makes the systems experimentally difficult.

There is little definite information on the initial distribution of vibrational energy and on its variation with time. In spite of the theoretical advantage of better time resolution in flash photolysis, the only indication that the distribution changes with time is to be found in the observation of Lipscomb, Norrish, and Thrush (4) that the half-lives for the levels with $v'' > 6$, which are slightly shorter than those with $v'' = 6$, which are likewise shorter than those with $v'' < 6$. The same authors concluded from the slow rate of vibrational energy transfer that the energy distribution observed at the shortest time was that actually produced in the reaction. The closely similar distribution for the ClO_2 and the NO_2 systems at the shortest times is equally significant. No marked changes of intensity distribution with time in the case of O_2^* formed from ozone have been reported, though it is evident that in all cases much more detailed information is needed. The experimental difficulties are, however, considerable. It may well be possible to extrapolate the results obtained in flow systems to infinite flow rate and zero pressures and an attempt to do this had been planned (14). Provided that this can be unambiguously correlated with zero time, important information may be expected.

In flash photolysis, completely reliable information could only be expected when the half-life of the excited species is very long compared with the flash times and, except in the case of O_2^* produced in the ClO_2 system, it is not clear that this condition has not so far been met. As well as the errors involved in long extrapolations and the averaging effect if the flashes are comparatively long, the possibility that the initial distribution may be changed by absorption of radiation may have to be considered. The present evidence,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from flash photolysis, incomplete as it is, supports the hypothesis of an initial distribution rather than population of all levels from the highest observed level.

On any model which predicts that, in some collisions, only part of the energy can appear as vibration in AB, the question of whether any part of the excess can appear as vibration in the bond C—D can be considered. The suggestion cannot be directly tested in the case of ozone itself and the presence of ClO* and NO* has not been reported in the ClO_2 and NO_2 systems, nor of O_2*, in the reactions of chlorine and bromine atoms with ozone. In the last-mentioned case, this could be a consequence of the experimental conditions and might also be explained in the case of ClO_2 by the approximate equality of the ClO bond strengths in ClO and ClO_2. In the case of NO_2, the probable rapid deactivation of NO* by NO_2 and the experimental difficulty of observing a weak NO* spectrum in the presence of a strong O_2* spectrum makes the negative evidence of its not having been reported previously inconclusive on this point. The observation of the first and possibly also the second excited vibrational levels of NO in our reinvestigation of this system is also inconclusive, as it has not been possible yet to show definitely how they are produced. The other case where there is evidence of vibrational energy in the bond CD is equally uncertain. Oldershaw and Norrish (22) in the flash photolysis of SO_3 observed bands arising from the levels $v'' = 0$, 1, 2, and 3 of SO, though the system was at near room temperature, and they suggested that this might arise from the reaction

$$O(^1D) + SO_2 \rightarrow SO^* + O_2 \qquad +33 \text{ kcal}$$

As we have pointed out, this reaction is an unlikely source of a detectable concentration of O_2*, but it is conceivable that, under their experimental conditions, a probably smaller concentration of SO* could be observed. It is also possible that SO* may be produced in the initial photochemical split

$$SO_3 \xrightarrow{h\nu} SO + O_2.$$

The participation of the electronic energy of the approaching atom in the vibrational energy of the bond formed is an interesting possibility. It can easily be imagined in the case of ozone if the oxygen molecule formed in the excited $^3\Sigma_u^-$ electronic state, but, unfortunately, it cannot be directly proved in this case unless the vibrational energy of the oxygen can be shown to exceed 93 kcal. In the absence of a convenient electronic state, the evidence is limited to the reactions

$$O(^1D) + RH \rightarrow OH^* + R$$

where the energy of vibration must come from the $O(^1D)$ atom if this mechanism is accepted. There seems to be, at present, no evidence for the participation of the kinetic energy of the approaching atom in vibrational excitation, except possibly the observation of the 12th vibrational level of oxygen in the flash photolysis of nitrogen peroxide (5). Recent work (19) has established the first N—O bond strength in NO_2 to be not greater than 71.2 kcal/mole and this makes the exothermicity of the reaction

$$O + NO_2 \rightarrow NO + O_2$$

a maximum of 48 kcal, which is insufficient in itself to excite the 12th vibrational level in oxygen (49 kcal/mole).

The production of vibrationally excited species under isothermal conditions both by flash photolysis and the atomic flame technique provides a potentially powerful method for studying vibrational energy transfer and the chemical reactions of these species.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

There is reason to believe that endothermic reaction is facilitated if one of the molecules possesses vibrational energy, e.g., in the reactions

$$H + O_2 \rightarrow OH + O \qquad [25]$$

$$O_2 + O_2 \rightarrow O + O_3 \qquad [26]$$

$$O_2 + O_3 \rightarrow 2O_2 + O(^1D) \qquad -69 \text{ kcal} \qquad [27]$$

though there is no evidence from the flash photolysis of ozone for the reaction

$$O_2 + O_3 \rightarrow 2O_2 + O(^3P) \qquad -24 \text{ kcal}$$

and the effect of this reaction, if it occurs, on the observed population of the various vibrational levels of O_2* has not been considered in the preceding discussion.

The reaction

$$OH(v'' \geqslant 2) + H_2 \rightarrow H_2O + H \qquad +16 \text{ kcal}$$

has been proposed by Garvin, Broida, and Kostowsky (12) in the H atom / ozone flame to account for the large increase in line intensities of the upper levels as the mole fraction of hydrogen increases. According to their views, the lower levels, being present in higher concentrations, are preferentially removed, and the upper levels are repopulated by further reaction of the hydrogen atoms with ozone. However, it is not clear if this explanation is satisfactory if, as was reported, the hydrogen atoms were initially present in excess. It is hoped that more evidence will be obtained from a further study of the O_3/RH systems by flash photolysis.

Finally, the field covered by this review is an exciting one and much remains to be done. We are confident that the work now being planned in various laboratories will lead in the near future to a greatly increased understanding of the important fundamental principles involved.

SEVEN MECHANISMS IN THE PHOTOLYSIS OF NO_2 BETWEEN 3100 AND 3700 Å[1]

HADLEY FORD

ABSTRACT

Nitrogen dioxide has been photolyzed by various investigators under seven different limiting conditions, all at wavelengths between 3100 and 3700 Å. The results are reviewed and discussed in terms of two general mechanisms, both of which quantitatively relate the experimental data. The mechanisms differ in that one postulates that atomic oxygen attacks NO_2 in two ways, yielding NO and O_2 in one case and excited NO_3 in the other. The excited NO_3 can decompose to form atomic oxygen and NO_2; it can be deactivated, or it can react with NO_2. The second mechanism postulates a single mode of attack on NO_2 by atomic oxygen, again yielding excited NO_3. The NO_3 can decompose to form NO and O_2; it can be deactivated, or it can react with NO_2. Of the two mechanisms the first seems more consistent with the thermal reactions of NO_2 and NO_3. It is believed that both the linear and the triangular NO_3 play important roles in the photolysis.

INTRODUCTION

The photolysis of nitrogen dioxide has been investigated (1–7) at various wavelengths of light and with varying pressures of NO_2 and inert gases. Quantum yield measurements are reasonably complete and consistent. It now appears that below 3700 Å atomic oxygen is an important product of the primary photochemical process. This report discusses the photolysis in terms of the following reactions:[2,3]

$$h\nu + NO_2 \rightarrow NO + O \quad [1]$$

$$O + O_2 + M \rightarrow O_3 + M \quad [2]$$

$$O + NO_2 + M \rightarrow NO_3 + M \quad [3]$$

$$O + NO_2 \rightarrow NO_3^* \quad [3a]$$

$$NO_3^* + M \rightarrow NO_3 + M \quad [3b]$$

$$O + NO_2 \rightarrow O_2 + NO \quad [4]$$

$$NO_3^* \rightarrow O_2 + NO \quad [4a]$$

$$NO_3^* \rightarrow NO_2 + O \quad [4b]$$

$$O + NO + M \rightarrow NO_2 + M \quad [5]$$

$$NO_3 + NO \rightarrow 2NO_2 \quad [6]$$

$$O_3 + NO \rightarrow NO_2 + O_2 \quad [7]$$

$$NO_3 + NO_2 \rightarrow N_2O_5 \quad [8]$$

$$N_2O_5 \rightarrow NO_3 + NO_2 \quad [9]$$

$$O + NO_2 + NO_2 \rightarrow O_2 + NO + NO_2 \quad [11]$$

$$NO_3^* + NO_2 \rightarrow O_2 + NO + NO_2 \quad [11a]$$

$$O_3 + NO_2 \rightarrow NO_3 + O_2 \quad [12]$$

Some of these reactions have been studied by Ford and Endow (6), who obtained the relative rates of reactions [2], [3], [4], and [5]. Using Benson and Axworthy's (9) rate

This paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under joint sponsorship of the Department of the Army, Ordnance Corps (under Contract No. DA-04-495-Ord 18), and the Department of the Air Force; presented at the Symposium on Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

[2]*The numbering of reactions is consistent with ref. 6.*

[3]*It is entirely possible that some of the reactions can be replaced by alternatives which will also explain the results.*

constant for reaction [2], a quantitative mechanism was proposed. Since then, the rate constants have been measured and reported by others (9–12), and agreement is quantitative within the limits of precision for each rate constant.

Later (7), it was shown that the relative concentration of atomic oxygen calculated from k_1, k_2, k_3, k_4, and k_5 was actually observed over a wide range of concentrations of NO_2, NO, and O_2. This meant that k_3+k_4 was correct, relative to k_2 and k_5. Other work has isolated k_4 from k_3, and the value of k_4 has been independently determined and found to agree with the value previously reported.

As has been emphasized by Leighton and Perkins (13), however, it is possible that none of the assumed reaction mechanisms is precisely correct. It is the purpose of this report to discuss the interrelationships of the various reactions and to show how they relate experimental results in the photolysis of NO_2 below 3700 Å.

Seven mechanisms are discussed which have many steps in common; and, in general, as experimental variables are gradually changed, the shift from one mechanism to another is also gradual. Each mechanism is a special case of a generally satisfactory mechanism. It is assumed in the discussion that in the wavelength region of from 3100 to 3700 Å the mechanisms are not wavelength dependent. Even so, small changes in the primary quantum yield with wavelength would produce small changes in the rate constants.

Because of the great complexity of the many interrelated mechanisms and reactions, the mechanisms are discussed in the order of increasing complexity, rather than decreasing generality. It is believed that this should make for easier reading.

THE PRIMARY PROCESS

The appearance of fluorescence at wavelengths above 3700 Å, but not at shorter wavelengths, led Norrish (14) to the hypothesis that dissociation occurred only on the short-wavelength side of 3700 Å.

$$h\nu + NO_2 \rightarrow NO + O \qquad [1]$$

To test this hypothesis Norrish photolyzed NO_2 in the presence of hydrogen, and since water was not produced, he concluded that reaction [1*a*] was the primary process at all wavelengths.

$$h\nu + NO_2 \rightarrow NO_2^* \qquad [1a]$$

Norrish then assumed oxygen was produced by

$$NO^* + NO_2 \rightarrow NO + NO + O_2. \qquad [14]$$

This is analogous to a similar reaction in the thermal decomposition of NO_2:

$$NO_2 + NO_2 \rightarrow NO + O_2 + NO. \qquad [14a]$$

Light in reactions [1*a*] and [14] provides the energy for activation which is provided by thermal collisions in reaction [14*a*]. A rate constant for reaction [14] can be estimated by assuming it is the same as, or greater than, the pre-exponential factor of reaction [14*a*]. Thus from the data of Rosser and Wise (15)

$$k_{14} \geqslant 3 \times 10^9 \text{ liter mole}^{-1} \text{ sec}^{-1}.$$

The absence of water as noted by Norrish is explained by the extremely small collision yield for the reaction of atomic oxygen with hydrogen when compared with the collision

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

yield with NO_2. No water would be expected even if reaction [1] proceeded with a quantum yield of unity.

Hall (4), on the other hand, found that when mixtures of isotopically enriched oxygen and normal NO_2 were irradiated at 3130 Å, isotopic scrambling occurred to about the extent expected from the data of Ogg (16). Essentially no scrambling was present at 4047 Å. Hall concluded that reaction [1] was the primary process at 3130 Å and that reaction [1*a*] was the process at 4047 Å.

Later, Ford and Endow photolyzed NO_2 at 3660 Å, using trace amounts of NO_2 in nitrogen at 1 atm pressure, and found a quantum yield of 0.69 for NO_2 disappearance. Under these conditions

$$NO_2^* + M \rightarrow NO_2 + M \qquad [15]$$

should remove reaction [14] as a possibility. The authors assumed that reaction [1] had a quantum yield of one, and that reaction [3] followed by reaction [6] led to a decreased efficiency, which, by reaction [4], would otherwise have led to $\Phi = 2$ for nitrogen dioxide disappearance.[4] The agreement between the rate constant the authors reported for reaction [3] and that reported by Kaufman (10) for

$$O + SO_2 + M \rightarrow SO_3 + M \qquad [16]$$

$$k_3 = 1.0\times10^{11} \text{ liter}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$

$$k_{16} = 3.0\times10^{10} \text{ liter}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$

gives credence to the belief that the inefficiency is caused by reaction [3] and not by a decrease in the rate of reaction [1] with increasing pressure.

DISCUSSION OF MECHANISMS

Mechanism I

This is the limiting mechanism for the condition $(NO)/(NO_2) \rightarrow \infty$ in the presence of a third body. The mechanism is given by reactions [1] and [5],[5] which predict a quantum yield of zero. Experimentally, the conditions of mechanism I have been approached by Ford and Endow (6), who found the following relationship when trace amounts of NO_2 were photolyzed in nitrogen at 1 atm pressure:

$$\text{(A)} \qquad \frac{1}{\Phi_{NO_2}} = 1.45+0.178\frac{NO}{NO_2}.$$

Thus for high values of $(NO)/(NO_2)$, $\Phi_{NO_2} \rightarrow 0$. Since the rate of reaction [5] is now well known (7–12), mechanism I becomes an important source of atomic oxygen at known, low concentrations.

In the limiting case of $(NO)/(NO_2) \rightarrow \infty$ the concentration of atomic oxygen is given by

$$\text{(B)} \qquad (O) = \frac{KI\Phi(NO_2)}{k_5(NO)(M)}.$$

The absorption coefficient has been measured by Hall and Blacet (17); the light intensity can be measured by any one of several methods, and k_5 has been reported by several investigators.

[4]Φ *is the over-all quantum yield of* NO_2 *disappearance;* Φ_{O_2} *is the over-all quantum yield of oxygen production.*
[5]*Although this is the simplest mechanism discussed, at least one alternative is possible. A discussion of the alternative mechanism is given in ref. 11.*

Author	Reference	k_5
Kaufman	10	2.0×10^{10}
Ford and Endow[6]	7	1.8×10^{10}
Ogryzlo and Schiff	11	1.8×10^{10}
Harteck, Reeves, and Manella	12	2.7×10^{10}

A value of k_5 of 6×10^9 was measured at 900 to 1000° K by Kaufman, Gerri, and Bowman (8), indicating a small, negative temperature coefficient. A value of 4.6×10^{13} calculated from the results of Kistiakowski and Volpi (18) is apparently in error, probably because the equations of a stirred flow reactor were not applicable as had been assumed. Since the values of k_5 of ref. 7, 9, and 10 cover a pressure interval of a few millimeters to 1 atm, the third-body dependence of reaction [5] is well established. Since the rate of reaction [17] is also known (7), reactions [1], [5], and [17] can be used to measure third-body efficiencies in reaction [5].

$$O + \textit{cis}\text{-2-pentene} \rightarrow \text{products} \qquad [17]$$

Mechanism II

This mechanism represents the low-pressure limit in the photolysis of NO_2. Following photolysis, NO and NO_2 would compete for atomic oxygen in bimolecular reactions. If Kaufman (19) is correct and reaction [5*a*] occurs only once in 10^7 collisions, restrictions on (NO/NO_2) should not be severe.

$$O + NO \rightarrow NO_2 + h\nu \qquad [5a]$$

The mechanism is given by reaction [1] followed by reaction [4], or alternatively, reaction [1] followed by reactions [3*a*] and [4*a*]. Kistiakowski and Volpi (18) reported a lower limit for the rate of reaction [4], which can be compared with that from ref. 7:

$$\text{Kistiakowski and Volpi: } k_4 > 9.5\times10^8 \text{ liter mole}^{-1} \text{ sec}^{-1},$$

$$\text{Ford and Endow: } \qquad k_4 = 2.1\times10^9 \text{ liter mole}^{-1} \text{ sec}^{-1}.$$

Because of the obviously large error in the value of reaction [5] calculated from the work of Kistiakowski and Volpi, the agreement may well be fortuitous. In the absence of presently unknown radiative processes, the conditions of mechanism II should lead to a quantum yield of two.

Mechanism III

Experimental conditions: trace concentrations of nitrogen dioxide, swamping concentrations of oxygen

$$[(NO_2)/(O_2) < 2\times10^{-6}]$$

at high third-body pressures (e.g., 1 atm). This condition is frequently found in the lower atmosphere and can be described by reactions [1], [2], and [7]. Since the rates of reactions [2] and [7] are both known (5, 9, 11, and 20) and the rate of reaction [1] can presumably be determined from the light intensity, the concentrations of atomic oxygen, ozone, nitric oxide, and nitrogen dioxide can be calculated for steady state and for approach to steady state. Since the rate of reaction [2] is known with much more accuracy than that

[6]*The value of k_2 reported in ref. 7 depends on the method of extrapolation of k_2 from the temperatures used by Benson and Axworthy to room temperature. From Benson and Axworthy $k_2 = 6.00\pm0.33\times10^7$ exp (600/RT) liter^2 mole^{-2} sec^{-1}; k_2 was obtained by direct substitution of the temperature (300° K) and with no assumption of a temperature dependence in the pre-exponential portion of k_2.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of reaction [7], calculated values of the steady-state concentrations of atomic oxygen should be considerably more accurate than those for ozone. Using Johnston and Crosby's (20) value for k_7 and assuming a primary quantum yield of unity, the ozone concentrations calculated were equal to those observed within a rather large combined experimental error (5).

Mechanism IV

Experimental conditions are the same as for mechanism III except that $(NO_2)/(O_2) > 10^{-6}$. Under these conditions when nitrogen dioxide is photolyzed below 3700 Å, the ozone concentration does not reach a constant steady-state value, but rather rapidly approaches a maximum concentration, and then this quasi-steady-state level gradually decreases. This decay is caused by atomic oxygen attacking nitrogen dioxide and converting the latter into nitric oxide. This, in turn, increases the rate of disappearance of ozone, by reaction [7], and causes the ozone level to decrease gradually. The mechanism, given in the terms of Ford and Endow, is [1], [2], [4], and [7]. In the same terms, reaction [3] followed by reaction [6] can be neglected. The reason for neglecting reactions [3] and [6] is that they have the effect of slightly decreasing the light intensity and not otherwise appreciably affecting the kinetics. Reactions [4] and [7], on the other hand, while proceeding even more slowly than reactions [3] and [6], have a profound effect on the steady-state ozone concentrations. The conditions of mechanism IV are the only known high-pressure conditions under which reaction [4] can be studied independently of reaction [3].

The observed rate of decay of the ozone concentration (17) and mechanism IV confirm that the rate of reaction [4] in nitrogen at 1 atm pressure was that reported by Ford and Endow (6). However, the relative concentrations of atomic oxygen observed in ref. 7 cannot be accounted for by reaction [4] alone. This is confirming evidence for the existence of reaction [3]. In polluted urban atmospheres generally $(NO_2)/(O_2) < 10^{-6}$, so that the conditions of mechanism IV are not met under average conditions.

Since steady-state conditions are not rapidly attained, (O) and (O_3) are functions of time over long time intervals. Atomic oxygen concentrations are given by

$$(O) = \frac{KI(NO_2)}{k_2(O_2)(M)} \qquad (C)$$

provided reaction [2] is fast compared with reactions [3] and [4]. Thus the concentration of atomic oxygen can be calculated if I, (NO_2), and (O_2) are known. The ozone concentration is approximated at any time by

$$(O_3)_t \cong \frac{KI(NO_2)_t}{k_7(NO)_t} \qquad (D)$$

and the rate of change of the steady-state ozone concentration by

$$\frac{d(O_3)_{ss}}{dt} \cong \frac{KIk_4(O)(NO_2)(NO_2)_1}{k_7(NO)^2}. \qquad (E)$$

The decay is slow because reaction [2] leads to a very low concentration of atomic oxygen. Reference 21, which will be published, discloses a more elegant approximation to the rate of ozone decay by this mechanism.

Mechanism V

Experimental conditions are the same as for mechanism III but with ozone added in trace amounts. The effect of added ozone on ozone formed during photolysis can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

explained only if reactions [1], [6], [7], [8], [9], and [12] are considered. Reaction [2] can be assumed to be fast (22). In this case the rate at which ozone is formed is given by reaction [1], which is known, and its rate of disappearance by reactions [7] and [12]. The over-all effect of photolysis is to suppress the ozone – nitrogen dioxide reaction. This is shown by the cancellation of all species in the following reactions:

$$h\nu + O_2 + NO_2 \rightarrow O_3 + NO \qquad [1a]$$

$$O_3 + NO_2 \rightarrow O_2 + NO_3 \qquad [12]$$

$$NO_3 + NO \rightarrow 2NO_2 \qquad [6]$$

The extent of this suppression was used to measure k_6k_8/k_9. Since k_8/k_9 is the equilibrium constant for the dissociation of nitrogen pentoxide, k_6 can be calculated using the value of K_{eq} reported by Schott and Davidson (25). Thus $k_6K_{eq} = 0.44\ sec^{-1}$ is in reasonable agreement with the value of $1.0\ sec^{-1}$ reported by Hisatsune, Ogg, and Crawford (23). This agreement gives quantitative confirmation of the validity of mechanism V. The resulting derived value of k_6 is 3.4×10^9 liter $mole^{-1}$ sec^{-1}.

Mechanism VI

This is the mechanism for the photolysis of nitrogen dioxide for conditions most frequently used and not involving trace reactant concentrations (1–4). The mechanism covers the millimeter pressure range for nitrogen dioxide with and without added inert gases. The following experimental facts must be explained:

1. In the millimeter pressure range the quantum yield of nitrogen dioxide disappearance[7] is constant and nearly equal to 2 (1–4).

2. In the photolysis of NO_2 in the millimeter pressure range the reciprocal of the quantum yields (either oxygen formation or nitrogen dioxide disappearance) is proportional to the pressure of added inert gas. Hall (4) has shown that

$$1/\Phi_{O_2} = 1+k(M).$$

3. At atmospheric pressure of inert gas, the quantum yield decreases with decreasing concentrations of NO_2, extrapolating to a finite value as $(NO_2) \rightarrow 0$, as shown by the data of refs. 4 and 6.

4. In the photolysis of NO_2 in the millimeter pressure range, the concentration of atomic oxygen is independent of the pressure of added inert gas. Proof of this seems definite if indirect. This conclusion is drawn from the data of Cvetanović (24), who photolyzed mixtures of *cis*-2-pentene, nitrogen dioxide, and nitrogen. Such directly found products as *cis*- and *trans*-β-pentene oxide formed at a rate which was independent of the pressure of added nitrogen over the internal of 0–400 mm. It is probable that the *cis*-2-pentene formed the oxides as a result of attack by atomic oxygen.

The facts can be explained by a variety of mechanisms, some of which can be ruled out on other grounds. The mechanism proposed by Ford and Endow for their conditions should be considered since their mechanism, consisting of [1], [3], [4], and [6], appears to yield quantitatively valid results.

Thus,

$$(F) \qquad 1/\Phi_{O_2} = 1+k_3(M)/k_4.$$

This is in the form reported by Hall. If it is assumed that NO_2, CO_2, and N_2 all have about the same efficiency as a third body, then from ref. 6,

$$(G) \qquad 1/\Phi_{O_2} = 1+2.6\times10^{-3}P_{NO_2,CO_2,N_2}$$

[7]*This assumes the previously mentioned stoichiometry:* $2NO_2 \rightarrow 2NO + O_2$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where the pressure is given in millimeters of mercury. Assuming quantum yield measurements are precise to within 10%, the effect of NO_2 pressure on the quantum yield would not be noticeable below 20 mm of NO_2. For CO_2 and propane being used as inert gases, the data from the work of Hall is shown in Fig. 1. The line calculated, using Ford and

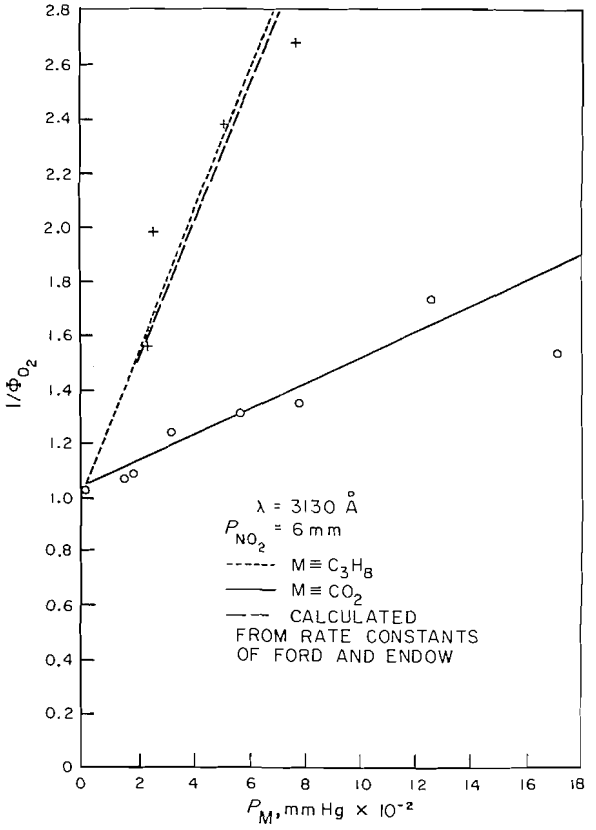

FIG. 1. Recpirocal quantum yield of oxygen appearance as a function of the pressure of added CO_2 and C_3H_8 from the data of hall.

Endow's values for k_3 and k_4 where nitrogen was used as a third body, is shown for comparison. It is obvious that CO_2 is not as efficient a third body as might reasonably have been expected from the rate constants of Ford and Endow and the mechanism given above. The mechanism predicts that the dependence of the quantum yield on added inert gas would be independent of the NO_2 concentration. This prediction is contrary to experimental results. Furthermore, according to this mechanism, the concentration of atomic oxygen is pressure dependent,

$$(H) \qquad (O) = \frac{KI}{k_3(M)+k_4},$$

neglecting the case where large amounts of NO are present and reaction [5] is important. With the values of k_3 and k_4 reported by Ford and Endow, the concentration of atomic oxygen would decrease by a factor of two in going from 0 mm to 400 mm of N_2. This is contrary to the observations of Cvetanović (24).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The facts can be explained by at least two mechanisms which have several steps in common. The two mechanisms are given below for direct comparison:

Mechanism VIA	Mechanism VIB
$h\nu + NO_2 \rightarrow NO + O$	$h\nu + NO_2 \rightarrow NO + O$
$O + NO_2 \rightarrow NO_3^*$	$O + NO_2 \rightarrow NO_3^*$
$NO_3^* + NO_2 \rightarrow NO + O_2 + NO_2$	$NO_3^* + NO_2 \rightarrow NO + O_2 + NO_2$
$NO_3^* + M \rightarrow NO_3 + M$	$NO_3^* + M \rightarrow NO_3 + M$
$NO_3^* \rightarrow NO + O_2$	$NO_3^* \rightarrow NO_2 + O$
	$O + NO_2 \rightarrow O_2 + NO$

The remaining steps, consisting of reactions [2], [5], [6], [7], [8], [9], and [12], would be common to both mechanisms. If the usual steady state can be assumed for NO_3, mechanism VIA gives

$$(I) \qquad 1/\Phi_{NO_2} = 1/2 + \frac{\frac{1}{2}k_{3b}(M)}{k_{4a} + k_{11a}(NO_2)}$$

or

$$(J) \qquad 1/\Phi_{O_2} = 1 + \frac{k_{3b}(M)}{k_{4a} + k_{11a}(NO_2)}.$$

So far as is known, the quantum yields at high pressures (e.g., 1 atm) decrease with decreasing NO_2 concentration and approach a finite value as $(NO_2) \rightarrow 0$. Equations (I) and (J) give the correct pressure dependence and the correct quantum yield at low third-body pressure.

Quantatively the significance of mechanism VIA can be seen from the work of Hall (4). Besides obtaining the data represented in Fig. 1, Hall measured the quantum yields of O_2 appearance at 1 atm total pressure of propane and at various partial pressures of NO_2. A summary of his data is given below:

Condition	$2\Phi_{O_2} = \Phi_{NO_2}$
1 atm CO_2, 6 mm NO_2	1.4
1 atm propane, 6 mm NO_2	0.7
1 atm propane, $P_{NO_2} \rightarrow 0$	0.2

The value of 0.2 was extrapolated from Hall's data by the author. From this data and equation (J)

$$k_{3b}(C_3H_8)_{1\text{ atm}} = 9.0k_{4a},$$

$$k_{11a}(NO_2)_{6\text{ mm}} = 3.8k_{4a},$$

$$k_{3b}(CO_2)_{1\text{ atm}} = 1.9k_{4a},$$

$$k_{3b}(N_2)_{1\text{ atm}} = 1.9k_{4a} \text{ (see ref. 7).}$$

If the mechanism is correct, CO_2 and N_2 are equally effective in deactivating excited NO_3. The pressure dependence of the quantum yield at constant NO_2 concentration and the dependence of the quantum yield on the concentration of NO_2 at 1 atm total pressure of propane give the same ratio for k_{11a} to k_{4a} within experimental error. At least formally,

For personal use only.

the assumed mechanism and measured rate constants determine the quantum yield for all pressures of CO_2, N_2, and propane and for all concentrations of NO_2, provided the system is at room temperature and the concentrations are in the regions that have been most frequently studied. The dependence of the quantum yields on third-body pressure and on NO_2 concentration at 1 atm pressure of added gas are given in Figs. 2 and 3.

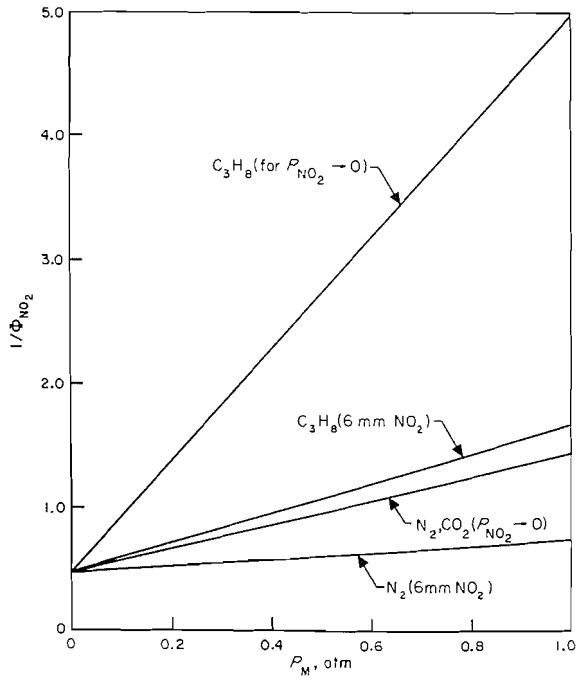

FIG. 2. Reciprocal quantum yields of NO_2 disappearance as a function of pressure of added gas.

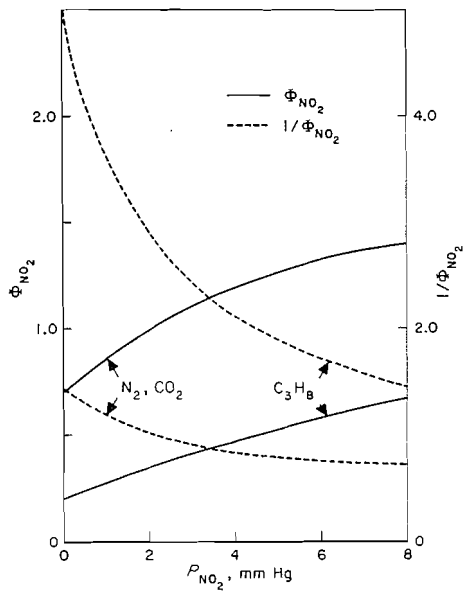

FIG. 3. Quantum yields of NO_2 disappearance as a function of NO_2 partial pressure.

In the absence of appreciable amounts of NO or O_2 the concentration of atomic oxygen is simply KI/k_{3a}, and therefore independent of pressure, as required.

Mechanism VIB requires one more reaction than VIA, gives less clear-cut results, and requires more assumptions but nevertheless seems to be the more convincing of the two mechanisms. In the absence of appreciable NO and O_2, and making the reasonable assumption that $k_{3c} \gg k_{3b}(M)$

$$\text{(K)} \qquad \frac{1}{\Phi_{NO_2}} = 1/2+\frac{\frac{1}{2}k_3(M)}{k_4+[k_4+k_{3a}][k_{11a}/k_{3c}](NO_2)}.$$

To fit the data of Hall to that of Ford and Endow

$$\text{(L)} \qquad [k_4+k_{3a}]k_{11a}/k_{3c} = 2.6\times10^{13} \text{ liter}^2 \text{ mole}^{-2} \text{ sec}^{-1}.$$

At trace concentrations equation (K) reduces to the form given by the mechanism of Ford and Endow,

$$\text{(M)} \qquad \frac{1}{\Phi_{NO_2}} = 1/2+\frac{k_3(M)}{2k_4}.$$

Thus, in fitting the two sets of data no changes are required in the values of k_3 and k_4 reported by the latter authors. This means that k_4 in equation (K) is known, leaving three unknowns in the one equation. The quantity, k_{3a}, is probably of the order of 5×10^{11} liter mole^{-1} sec^{-1} so that $k_4 \ll k_{3a}$. Or $k_{11a}/k_{3c} \cong 50$. A unimolecular decomposition of a diatomic molecule that might be of the order of 10^{13} sec^{-1}, whereas k_{3c} might be estimated at 10^9.

In this case $k_{11a} = 5\times10^{10}$ compared with a pre-exponential factor of 4×10^9 for the equivalent thermal reaction. It is, of course, easy to speculate about the relative values of the rate constants in equation (L), but the important point is that neither rate constants nor simple rate constant ratios can be calculated from available experimental data without additional assumptions. Quantum yields can be calculated and give the same dependence on pressure as shown by mechanism VIA (Fig. 2). Both mechanisms (VIA and VIB) can be used to calculate the dependence of the quantum yields on NO_2 concentration at 1 atm pressure of inert gas (Fig. 3).

For low concentrations of O_2 and NO, and for $k_{3b}(M) \ll k_{3c}$ the atomic oxygen concentration has the following dependence based on mechanism VIB:

$$\text{(N)} \qquad \text{(O)} = \frac{KI[k_{3c}+k_{11a}(NO_2)]}{k_4k_{3c}+k_{11a}[k_{3a}+k_4]}.$$

Thus, the concentration of atomic oxygen is not pressure dependent. The two mechanisms will be considered in more detail following a discussion of mechanism VII.

Mechanism VII

This mechanism is based on a study of the photolysis of nitrogen dioxide at trace concentrations in nitrogen at atmospheric pressure and with varying amounts of added oxygen, nitric oxide, and *cis*-2-pentene. The latter was used as a tracer for atomic oxygen (6, 7). The mechanism incorporates reaction [5] into the general scheme and permits quantitative evaluation of the rate of reactions [3], [4], and [5], or, alternatively, [3*a*]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and [5] from Benson and Axworthy's rate constant for reaction [2]. Under the experimental conditions, all reactions except perhaps [11*a*] were playing a significant role. Quantum yield measurements were delayed so that reactions [6], [7], [8], [9], and [12] would have gone to completion. Therefore the significant steps in interpreting the experimental results are either reactions [1], [2], [3*a*], [3*b*], [4*a*], and [5], or [1], [2], [3], [4], and [5]. The latter mechanism was proposed by Ford and Endow and is consistent with mechanism VIA.

Experimentally, Ford and Endow found that $1/\Phi_{NO_2}$ was proportional to $(NO)/(NO_2)$ and to $(O_2)/(NO_2)$, and they measured the proportionality constants. Extrapolating $(NO)/(NO_2)$ and $(O_2)/(NO_2)$ to zero separately, they obtained a limiting quantum yield of 0.69 for NO_2 disappearance. The following relation was derived:

$$(O) \qquad 1/\Phi_{NO_2} = 1/2+\frac{k_3(M)}{2k_4}+\frac{k_5(M)(NO)}{2k_4(NO_2)}+\frac{k_2(M)(O_2)}{2k_4(NO_2)},$$

based on reactions [1], [2], [3], [4], and [5]. An analogous expression, based on reactions [1], [2], [3*a*], [3*b*], [4*a*], and [5] is given by

$$(P) \qquad 1/\Phi_{NO_2} = 1/2+\frac{k_{3b}(M)}{2k_{4a}}+\frac{(k_{4a}+k_{3b})k_5(NO)(M)}{2k_{4a}k_{3a}(NO_2)}+\frac{(k_{4a}+k_{3b})k_2(O_2)(M)}{2k_{4a}k_{3a}(NO_2)}.$$

At low values of $(NO)/(NO_2)$ and $(O_2)/(NO_2)$

$$(Q) \qquad 1/\Phi_{NO_2} = 1.45 = \frac{k_{4a}}{k_{3b}(M)}.$$

Also

$$(R) \qquad \frac{k_5(M)[k_{4a}+k_{3b}(M)]}{k_{4a}k_{3b}} = 1.33\times10^{-3}$$

and

$$(S) \qquad \frac{k_2(M)[k_{4a}+k_{3b}(M)]}{k_{4a}k_{3b}} = 0.36.$$

From these ratios and Benson and Axworthy's rate constant k_2, the value of k_{3a} can be calculated:

$$k_{3a} = 6.0\times10^9 \text{ liter mole}^{-1} \text{ sec}^{-1}.$$

Beyond that, the data only give the ratio of k_{4a} to k_{3b}.

From the mechanism (reactions [1], [2], [3*a*], [3*b*], [4*a*], and [5]):

$$(T) \qquad k_4 = \frac{k_{4a}k_{3a}}{k_{4a}+k_{3b}(M)},$$

$$(W) \qquad k_3 = \frac{k_{3a}k_{3b}}{k_{4a}+k_{3b}(M)},$$

$$(X) \qquad k_{11} = \frac{k_{3a}k_{11a}}{k_{4a}+k_{3b}(M)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Thus k_{3a} is the low-pressure limit of k_4. The variations of k_4, k_3, and k_{11} as functions of the third-body pressure and of the pressure of NO_2 are given in Figs. 4 through 7.

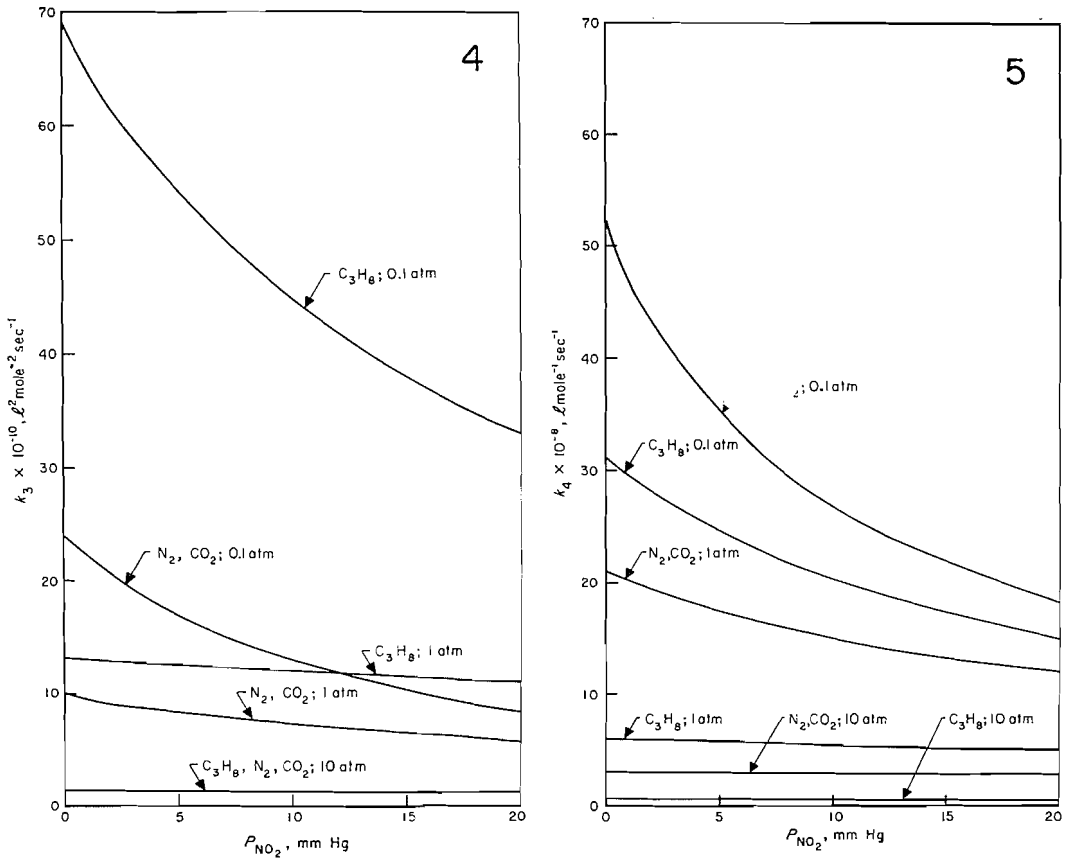

FIG. 4. Dependence of k_3 on NO_2 partial pressure at various partial pressures of matrix gas.
FIG. 5. Dependence of k_4 on NO_2 partial pressure at various partial pressures of matrix gas.

As it turns out, k_3, as given is constant with mechanism VIA. However, k_3 has a different definition consistent with VIB.

$$k_3 = \frac{k_{3a}k_{3b}}{k_{4b}+k_{3b}(\mathrm{M})}. \qquad \text{(Y)}$$

For the usual case $k_{4b} \gg k_{3b}(\mathrm{M})$ the three-body recombination reaction would have the usual form, and k_3 would be independent of pressure in the region of interest.

In both equations (W) and (Y) the steady-state concentration of NO_3^* was calculated neglecting reaction [11*a*], and consequently k_2 is a limiting value as $(NO_2) \rightarrow 0$.

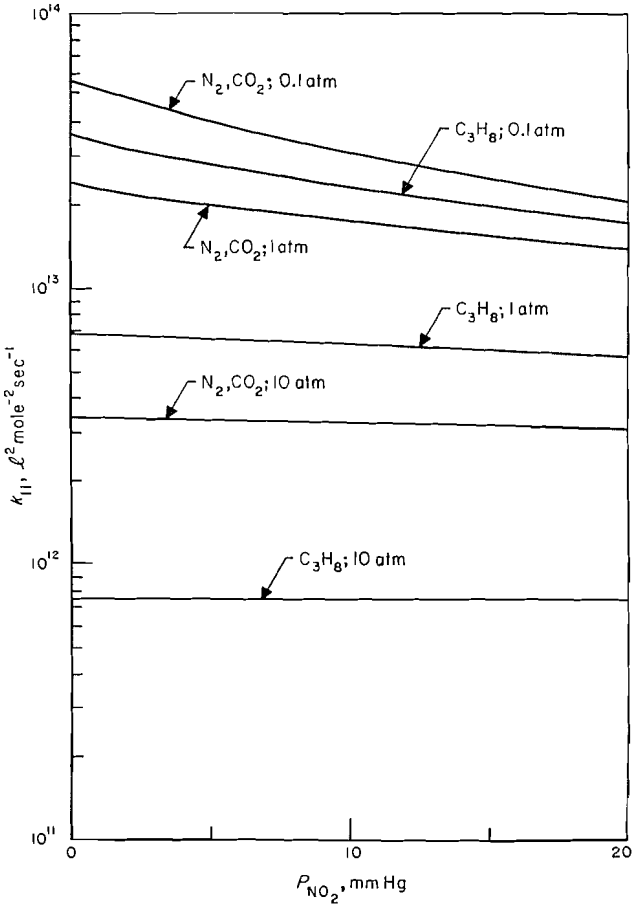

FIG. 6. Dependence of k_{11} on NO_2 partial pressure at various partial pressures of added gas.

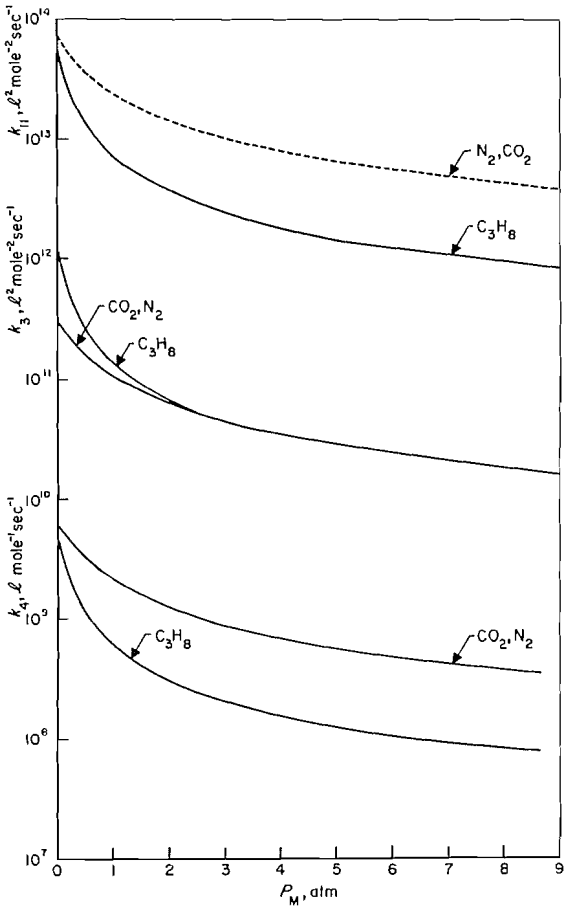

FIG. 7. Effective values of k_3, k_4, and k_{11}, based on the assumption that the excited-molecule mechanism is correct, for the case of $NO_2 \rightarrow 0$.

DISCUSSION

The difficulties and ambiguities in the mechanism can be summarized with the question: What happens when atomic oxygen attacks NO_2? The photolysis of NO_2 provides no definite answer. The situation can be somewhat clarified by considering other reactions of NO_2. Thus Schott and Davidson (25) agree with Ashmore and Levitt (26) that both of the following reactions occur in the thermal decomposition of NO_2:

$$NO_2 + NO_2 \rightarrow 2NO + O_2 \quad [10]$$

$$NO_2 + NO_2 \rightarrow NO_3 + NO \quad [13]$$

Similarly Huffman and Davidson (27) agree with Johnston (28) that the following reactions are important in the thermal decomposition of N_2O_5:

$$NO_3 + NO_2 \rightarrow NO + O_2 + NO_2 \quad [14]$$

$$NO_3 + NO_2 \rightarrow N_2O_5 \quad [8]$$

It is therefore of interest that Ford and Endow also postulated two reactions of atomic oxygen with NO_2:

$$O + NO_2 \rightarrow O_2 + NO \quad [4]$$

$$O + NO_2 + M \rightarrow NO_3 + M \quad [3]$$

The following appears to be a reasonable explanation of these reactions. When O, NO_2, or NO_3 attack NO_2, the approach to the NO_2 can follow either of two paths. The activated complex for each of the above cases would then be of the forms given below:

Reaction No.	Activated complex	Subsequent intermediate
[10]	ONOONO	OONO
[13]	$ONON\begin{matrix}O\\O\end{matrix}$	
[14]	$\begin{matrix}O\\O\end{matrix}NOONO$	OONO
[8]	$\begin{matrix}O\\O\end{matrix}NON\begin{matrix}O\\O\end{matrix}$	
[4]	OONO	OONO
[3]	$ON\begin{matrix}O\\O\end{matrix}$	

When the activated complex is of the peroxy form, decomposition either occurs to give OONO or O_2 and NO. Evidence for the peroxy form of NO_3 has been found by Benson (29), who has shown that the activation energy of [14] is less than the endothermicity by about 2 kilocalories. Benson explains this by a two-step process:

$$\begin{matrix}O\\O\end{matrix}NO + ONO \rightarrow ONO + OONO \quad [15]$$

$$OONO + M \rightarrow O_2 + NO + M. \quad [16]$$

Reaction [14] would be unusual as an elementary reaction because NO_2 is both a reactant and a product. According to this explanation, reaction [14] is composite, the first step consisting of an abstraction reaction which results in the peroxy form of NO_3. A similar explanation applies to the attack of atomic oxygen and NO_2 on NO_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In distinguishing between mechanisms, it would seem that [4*b*] is much more probable than [4*a*]. An attack on NO_2 by atomic oxygen by two paths rather than one has a geometrical and structural basis, and is analogous to the other reactions mentioned above. In the opinion of the author mechanism VII and the equivalent mechanism VIB best conform to our present understanding of the chemistry of NO_2.

THE PRODUCT EMITTER DIFFUSION FLAME: THE REACTION OF NITRIC OXIDE WITH OXYGEN ATOMS[1]

DAVID GARVIN, PAUL P. GWYN, and JULES W. MOSKOWITZ

ABSTRACT

The use of the Polanyi diffusion flame technique as a diagnostic test for the identification of reactions that lead to light emission is presented. There is developed the mathematical model needed for the interpretation of such flames in which a product is responsible for the emission that is studied. The method is applied to the systems in which oxygen atoms and nitrogen atoms react with nitric oxide. The rate constant of the reaction $O + NO + M \rightarrow NO_2 + M$ at 293° K was determined as $k = 1.4 \times 10^{17}$ (cc/mole)^2 sec^{-1}.

INTRODUCTION

The Polanyi diffusion flame technique has been used numerous times for the measurement of rates of very fast reactions (1–5). It is applied here to a system in which several reactions of nitric oxide occur, both to determine rates and as a diagnostic tool to determine the probable reaction, which is studied directly. In part, this paper presents an experimental confirmation for the mechanism of the 'airglow' or 'oxygen afterglow' that has been identified and studied intensively in the past few years (6–10), and, in addition, there is presented the model needed for the interpretation of diffusion flames in which a product is the emitting species. This model is applied to a determination of the rate of the O+NO reaction as it may be studied in two systems. Finally, there are reported several qualitative observations on related reactions.

DIAGNOSTIC STUDIES

It is usually essential that the elementary reactions that are studied by the diffusion flame technique be established by some independent means. In some cases an a priori knowledge of the possible reactions is sufficient, and in others product analysis is helpful. In any case, such information is needed for the interpretation of the experiments because the lifetime or spatial distribution of a very reactive species is used as the basis for the quantitative measurements.

The special geometry of the diffusion flame system imposes severe conditions on the reactions that can be studied: they must be very fast, i.e., occur at least once in 10^5 collisions, and must be homogeneous. In this method one reagent (y) is fed in small amounts through an orifice into a low pressure atmosphere containing its reaction partner (z) in considerable excess. At the low pressures employed y penetrates the atmosphere principally by diffusion and reacts with z before reaching any wall surface.

If, in a given system, one reaction leads to immediate emission of light, and the spatial distribution of this emission is to be studied, the particular reaction that is responsible for it can be identified by employing as y and z the possible reactant pairs in the system. The light-emitting reaction will give a small, well-defined zone of emission near the orifice while the other reactions will give, at best, a diffuse emission throughout the reactor. Where several sets of reagent pairs lead to emission, other criteria (such as rate and spectral studies) must also be used.

[1]*Contribution from the Frick Chemical Laboratory, Princeton University, Princeton, N.J. Based in part on theses submitted in partial fulfillment of the requirements for the degree of Bachelor of Arts at Princeton University by Jules W. Moskowitz, May 1956, and by Paul P. Gwyn, May 1957; presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

A favorable case for the application of this type of test is the system in which nitric oxide may react either with oxygen or nitrogen atoms. The following reactions have been shown to be important.

$$O + NO \rightarrow NO_2^* \quad [1]$$

$$NO_2^* \rightarrow NO_2 + h\nu \quad [2]$$

$$O + NO_2 \rightarrow O_2 + NO \quad [3]$$

$$N + NO \rightarrow N_2 + O \quad [4]$$

$$N + NO_2 \rightarrow NO + NO \quad [5]$$

$$\rightarrow N_2 + O_2 \quad [6]$$

The rate of [1] has been determined independently by Kaufman (8) and by Harteck, Reeves, and Mannella (10). NO_2 is the probable emitter, but has not been positively identified. Reaction [3] has been studied by the flash photolysis technique and an excited oxygen molecule shown to be a primary product (11). Dressler (12) found evidence for [4] in the nitrogen 'afterglow', the nitrogen molecule being in an excited state. Also, limited emission of the oxygen 'afterglow' (1) in systems containing nitrogen atoms and nitrogen dioxide require consideration of reactions [5] and [6]. The sequence [1], [2], [3] is generally considered to explain the long-lived 'afterglow' in impure oxygen in which traces of NO are produced along with much larger quantities of oxygen atoms by an electric discharge.

TABLE I

Observations of reaction zones in systems related to the NO–O reaction

Nozzle reagent	Atmosphere	Appearance of reaction zone
(*a*) $O + O_2$	Air	Diffuse glow throughout reactor
(*b*) NO	$O + O_2$	Diffuse glow throughout reactor
(*c*) $O + O_2$	NO (excess)	Stable flame, small zone near nozzle
	$NO + N_2$	
(*d*) $O + O_2$	NO_2 (excess)	No glow
(*e*) $O + O_2$	NO_2 (limited)	Glowing zone with dark center
(*f*) $N + N_2$ (active nitrogen)	N_2	Active nitrogen color, difficult to restrict
(*g*) $N + N_2$	NO (excess)	Stable flame, spectrum same as that of (*c*)
(*h*) $N + N_2$	NO_2	No zone, active nitrogen color diminished

Table I summarizes a number of observations made on these reactions using the usual diffusion flame arrangement. The behavior of (*c*) and (*b*) are consistent with the oxygen 'afterglow' mechanism. Reactions (*d*) and (*e*) agree with results found in oxygen atom titration experiments (8,10,13), and the behavior of (*e*) is to be interpreted as a sequence of [3] and [1]–[2]. Reaction (*g*) could be interpreted in terms of emission in [4], but the fact that the spectrum of (*g*) in the visible region is the same continuum as that produced by (*c*) is an argument in favor of the sequence [4]–[3]–[1]–[2]. This is in agreement with the other studies mentioned above.

These observations offer direct evidence that the reaction leading to emission in systems containing O and N atoms and an excess of NO is [1]–[2]. (When the supply of NO is limited and there is an abundant supply of N atoms the bands of NO are produced by atom recombination (14). These were not observed here.)

SPECTRA

Since our conclusions depend upon observation of the spectrum of the radiation produced in (*c*) and (*g*), the results of such studies are summarized here. Comparative spectra of the reaction zones in (*c*) and (*g*) were taken with a medium quartz Hilger Cornu type spectograph using Eastman Kodak type F plates to emphasize the red end of the spectrum. A continuum with faint banded structure extended from about 4400 Å to the plate limit (about 6600 Å). The intensity was not uniform, but the variations with wavelength were characteristic of the sensitivity of the emulsion, not of the flame. Similar spectra have been reported many times (7,8). A more extensive study of the airglow spectrum was made using a large aperture spectograph designed at the National Bureau of Standards (15).* With this instrument and films sensitive to the visible and the near infrared region the airglow spectrum was surveyed to beyond 11,000 Å. The continuum is strong out to the limit of the I-N emulsion (about 8900 Å) and continues to about 10,900 Å. No intensity measurements were made, but it was apparent that the continuum intensity was decreasing more rapidly than was the emulsion sensitivity as the long wavelength limit was approached. This spectrum should be studied in detail in any reinvestigation of the nitrogen dioxide spectrum.

System (*h*) was studied because reaction (5) is sufficiently exothermic to permit the production of NO in excited vibrational states that could lead to emission in the 1–2 micron region. An exposure of 144 minutes on I-Z film did not reveal any bands attributable to NO.

REACTION RATES: THE PRODUCT EMITTER DIFFUSION FLAME MODEL

There is presented in this section the mathematical model needed for the interpretation of diffusion flames in which a product molecule emits the radiation that is monitored. It has been used previously for the analysis of the $H+O_3$ system (16), and a similar treatment has been used recently by Rapp and Johnston (17) in connection with the nitric oxide – fluorine flame. The equations for the spatial distribution of reagents and intermediates are developed for the cases that may be applied to O+NO and N+NO. The modifications that must be introduced when the flame is photometered or photographed are then presented. In a following section the application to these systems is discussed.

The reaction scheme that is applicable to the O+NO system is

$$y+z \rightarrow w^* \qquad \text{rate} = k_1\,[z][y]$$

$$w^* \rightarrow w+h \qquad = k_2\,[w^*]$$

$$w^*+M \rightarrow w+M \qquad = k_3[M][w^*]$$

in which y is the nozzle reagent, z the atmosphere reagent (present at constant concentration), and M is any 'third body'. Following the development used for the temperature pattern method (3), treating the nozzle as a point source, the steady-state diffusion equations are

$$[7] \qquad -D_y\Delta^2[y] = -k_1[z][y]$$

$$[8] \qquad -D_w\Delta^2[w^*] = -(k_2+k_3[M])[w^*]+k_1[z][y]$$

We are indebted to the National Bureau of Standards for the opportunity to use this instrument, and to Dr. A. M. Bass for conducting these experiments.

with the boundary conditions

$$y \rightarrow 0 \quad \text{as} \quad r \rightarrow \infty, \qquad b = \int_0^\infty k_1[\mathrm{z}][\mathrm{y}]\, dV$$

$$w^* \rightarrow 0 \quad \text{as} \quad r \rightarrow \infty, \qquad b = \int_0^\infty (k_2 + k_3[M])[\mathrm{w}^*]\, dV$$

where D is a diffusion coefficient, b is the molar flow rate of the nozzle reagent, V is the volume, and r the radial distance from the nozzle. Spherical symmetry is assumed and equations [7] and [8] are solved in sequence by standard techniques. The solutions that satisfy the boundary conditions are

[9] $$[\mathrm{y}] = be^{-cr}/4\pi D_y r, \text{ where } c^2 = k_1[\mathrm{z}]/D_y$$

[10] $$[\mathrm{w}^*] = \frac{b}{4\pi D_w} \cdot \frac{c^2}{(a^2 - c^2)} \cdot \frac{e^{-cr} - e^{-ar}}{r}$$

where $$a^2 = (k_2 + k_3[\mathrm{M}])/D_w.$$

If w^* were stable and the nozzle reagent concentration were studied, as in the sodium diffusion flames, equation [9] would be used for the analysis. Where w^* is the emitter and the emission pattern is studied, two simple cases can be distinguished. If $a \gg c$, that is instantaneous emission or destruction,

[11] $$[\mathrm{w}^*] = \frac{b}{4\pi D_w} \cdot \frac{c^2 e^{-cr}}{a^2 r}$$

and then if $k_3[\mathrm{M}] \ll k_2$

[12] $$k_2[\mathrm{w}^*] = \frac{bc^2 e^{-cr}}{4\pi r}.$$

If $a = c$, i.e., the rates of formation and destruction of w^* are equivalent, the general expression for w^* goes to a limit of

[13] $$[\mathrm{w}^*] = \frac{bce^{-cr}}{8\pi D_w}$$

and then, if $k_3[\mathrm{M}] \ll k_2$

[14] $$k_2[\mathrm{w}^*] = \frac{bc^3 e^{-cr}}{8\pi}.$$

A scheme that is applicable to the case of N + NO is

$$y + z \rightarrow p + I$$

$$p + z \rightarrow w^* \qquad \text{rate} = k_4[\mathrm{z}][\mathrm{p}]$$

$$w^* \rightarrow w + h$$

$$w^* + M \rightarrow w + M$$

where I is an inert product, the other symbols have the meanings previously assigned,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and the same rate notation is associated with the same reagents. The diffusion equations for this case are [7] and

$$[15] \qquad -D_p\Delta^2[\mathrm{p}] = -k_4[\mathrm{z}][\mathrm{p}]+k_1[\mathrm{z}][\mathrm{y}]$$

$$[16] \qquad -D_w\Delta^2[\mathrm{w}^*] = -(k_2+k_3[\mathrm{M}])+k_4[\mathrm{z}][\mathrm{p}]$$

with the additional boundary condition

$$p \to 0 \quad \text{as} \quad r \to \infty, \qquad b = \int_0^\infty k_4[\mathrm{z}][\mathrm{p}]\, dV.$$

The solution of [7] remains the same, the solution of [15] is of the same form as [8], except that p replaces w^* and a new parameter $f^2 = k_4[\mathrm{z}]/D_p$ replaces a. (The last retains its same significance here, see eq. [10].) The solution for w^* is

$$[17] \qquad [\mathrm{w}^*] = \frac{bc^2f^2[(f^2-c^2)e^{-ar}+(a^2-f^2)e^{-cr}-(a^2-c^2)e^{-fr}]}{4\pi D_w r(f^2-c^2)(a^2-c^2)(a^2-f^2)}.$$

We record here both the simplification that corresponds to rapid formation of p, $c \gg f$, and a

$$[18] \qquad [\mathrm{w}^*] = \frac{bf^2[e^{-fr}-e^{-ar}]}{4\pi D_w(a^2-f^2)r},$$

which is of the same form as the general solution in the first case considered [10], and the simplification that specifies rapid destruction of w^* under the conditions leading to [18] $a \gg f$

$$[19] \qquad [\mathrm{w}^*] = bf^2e^{-fr}/4\pi D_w a^2 r$$

and if, as before $k_3[\mathrm{M}] \ll k_2$

$$[20] \qquad k_2[\mathrm{w}^*] = bf^2e^{-fr}/4\pi r,$$

which is identical in form with [12].

This completes the development of the concentration and emission density expressions needed here. Other less limited cases differ only in the terms preceding the exponentials.

We now turn to the question of the form of the pattern recorded on a photograph of such an emission zone, or, indeed, of the resonance zone produced in sodium diffusion flames. Ideally, such a photograph is a plane representation of the three dimensional zone, at each point of which there is an emission density $k_2[\mathrm{w}^*]$. Each point on the film represents a summation of the emission from a sequence of points in the flame. We shall assume that these points lie on a chord of the sphere that runs perpendicular to the plane of the film, and that all such points contribute radiation in proportion to their values of $k_2[\mathrm{w}^*]$. Since the flame is 'focused' onto the film, these assumptions should be moderately good. If v represents a distance from the center of the reaction zone in the plane parallel to the film, and u a distance perpendicular to this plane, the integration of the emitter density along u yields the emission recorded by the film (or a number proportional to it).

$$F(cv, av) = 2\int_0^\infty k_2[\mathrm{w}^*]\, du = \frac{bk_2c^2}{2\pi D_w(a^2-c^2)}\int_0^\infty \frac{e^{-cr}-e^{-ar}}{r}\, du$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which becomes upon substitution of $u = v \sinh$ and integration (for w^* given by [10] or [18] with f replacing c)

$$[21] \qquad F(cv,av) = \frac{bk_2c^2}{2\pi D_w(a^2-c^2)} [K_0(cv)-K_0(av)]$$

where $K_0(x)$ is a modified Bessel function of the second kind, for which tabulated values are available (18). For the case of instantaneous emission, equations [11] and [19], a particularly simple result is obtained

$$[22] \qquad F(cv) = bc^2K_0(cv)/2\pi.$$

When $a = c$ and equation [14] is employed

$$[23] \qquad F(cv) = bc^3vK_1(cv)/4\pi.$$

The general equation [21] can be simplified when emitter densities at large values of cv are considered. Then, the function $K_0(cv)$ is closely approximated by c^2e^{-cv}/v.

While the treatment given above completes the presentation needed here, its relationship to the classical sodium diffusion flame deserves mention (2). In such studies the 'edge' of the flame, that point at which the sodium resonance emission is just visible, is determined. This is compared to that concentration of sodium that is just visible in static experiments under similar conditions. Thus, instead of using the integral criterion

$$\int_0^\infty [y]\, du = A \int_0^\infty (e^{-cr}/r)\, du$$

the expression

$$[y]_R = A' e^{-cR}$$

is used. Since the factor c^2 present in [22] does not enter here (it must be considered in any analysis based on an absolute value of [y] or [w*]), the approximation is probably no worse than the neglect of spherical symmetry.

The important difference between the sodium flame and the product emitter flame is that in the latter a decrease in c or a reduces the apparent size of the reaction zone, while in the former a reduction in c may produce an apparent enlargement. In this respect, the product emitter flame behaves in a manner opposite to that of the sodium flame.

REACTION RATES: APPLICATION TO NITRIC OXIDE SYSTEMS

Studies of the O+NO and the N+NO systems were made in a conventional low-pressure flow system. In both cases the atom-bearing stream was the nozzle reagent and either pure NO or NO diluted with nitrogen formed the atmosphere. The NO (Matheson) was fractionally distilled before use. Tank oxygen was dried but not purified further. Nitrogen was passed over heated copper and dried before use. All gases were fed through critical orificii into the low pressure system from reservoirs, the pressures of which were adjusted to provide the desired flow rates. The reactor was a 4-in. diameter cylinder with plate glass ends through which the flame was photographed. The nozzles through which reagent y was introduced were pyrex tubes drawn down to an i.d. of 1 to 2.2 mm. The reactor pressure could be controlled by a valve near the mechanical oil pump that maintained the flow. Pressures within the reactor ranged from 0.5 to 2 mm Hg and were adjusted to provide flames 2 to 5 cm in diameter. In all cases higher pressures were needed to restrict the flames in the NO–N_2 mixtures than in pure NO.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The O+NO flames were photographed with a Leica IIe 35 mm camera, and the N+NO flames were recorded with a Zeiss $2\frac{1}{4}\times3\frac{1}{4}$ film pack camera. In both cases the ranges were adjusted so that the flame filled most of the film. In both cases Eastman Kodak XXX panchromatic film was used. For each set of flame pictures there was prepared a film calibration made by exposing a strip of film through a calibrated step wedge. The calibrations were processed at the same time as the corresponding flame pictures.

The flame negatives were densitometered using a Leeds and Northrup microdensitometer, traverses being taken across several regions of each flame so density maps could be prepared. These maps showed a slight elongation of the flame along the nozzle axis, this being noticeable only at small distances from the nozzle tip. After the plate densities were converted to exposures, plots of exposure versus distance from the center of the flame pattern were prepared. For this purpose only exposure values were used that were taken from points near a line perpendicular to the nozzle axis and passing through the center of the pattern.

These exposure–distance plots were analyzed in terms of the models presented in the last section. Examination of either equation [21] or [22] reveals that the *shape* of the function is determined by the behavior of the modified Bessel function. Thus, if a parameter c or two parameters, c and a, can be chosen so that the shape of the experimental curve can be reproduced, the rate constants may be obtained without knowledge of the molar flow rate of atoms through the nozzle. In this case, and in others involving unstable species, this is advantageous.

In all the cases studied here it was feasible to reproduce the experimental exposure–distance curves by means of a formula such as [22] containing only one rate parameter. For this reason, the general relation [21] has not been applied. The results of the experiments are given in Table II. The 'shape parameter' column may be interpreted as

TABLE II

Product emitter flame measurements of rates of the reaction of nitric oxide with oxygen atoms

c, a, or f. The final column represents $k/D = c^2/[z]$, see equation [9] where z is the NO concentration and the diffusion coefficient would have its value for a pressure of 1 mm Hg (that is, the reciprocal pressure dependence of the diffusion coefficient has been factored out). The average of k/D' for set a is $(4.1\pm2.4)\times10^7$, and for set b is $(4.7\pm2.0)\times10^7$ (arithmetic errors).

DISCUSSION OF RATE MEASUREMENTS

The equality of the average values of k/D' for the experiments using O and N atoms indicate that the same process is controlling in both systems. The spread of values in set *a*, Table II, must be attributed to experimental error. The spatial resolution on the 35-mm films used here was considerably less than for set *b*, where the larger films were used. In the latter the reproducibility in equivalent is much better. Here there is a slight suggestion that k/D' varies with the NO pressure, but this is far from certain.

For set *a*, the shape parameter may be identified as *c* as defined by equation [9] and for set *b* as *f* defined immediately before [17]. These then apply to equation [1], or its equivalent

$$O + NO + M \rightarrow NO_2 + M. \qquad [24]$$

In either case a value for the diffusion coefficient, D', must be supplied if the rate constant is to be extracted. This number is uncertain, due to our poor knowledge of the diameter of the oxygen atom. Here we assume a value of $250 = D'$. Then for equation [1], $k_1 = 1\times10^{10}$ cc/mole-sec. This value is tenable for the type of reaction considered but is 1000 times larger than other estimates (8,10). If [24] is assumed to dominate, $k_{24} = 1.4\times10^{17}$ $(cc/mole)^2$ sec^{-1} based on set *b*. This value is fivefold greater than that reported by Kaufman (8) and by Harteck, Reeves, and Mannella (10).

(An alternative interpretation of the shape parameter may be made because of the symmetry of the equations. If it is considered to be *a*, equation [10], either a value of $k_2 = 4\times10^2$ sec^{-1} or $k_3 = 7\times10^9$ $(cc/mole)^2$ sec^{-1}. The former is improbable for the decay of an excited NO_2, the latter is very low for a three-body recombination coefficient. Neither is tenable here.)

The interpretation of these flames in terms of [24] and the comparison with previous work provides an adequate justification for the model developed here for the product emitter flame. It is apparent that, as presently used as a photographic method, the precision is not high. A photometric application should markedly improve the technique. The fact that the rate, k_{24}, reported here is larger than has been determined earlier deserves some comment. The product emitter flame is a limiting case of a few oxygen atoms reacting with a large excess of NO. The more accurate work on this system has employed the reverse condition, a small amount of NO for many oxygen atoms. If there should be systematic errors in that work (and we have not found them), particularly reactions in the cycle that destroys and regenerates NO whose rates have not been considered but are only moderately fast, they would tend to reduce the apparent value of the rate. Some of the discrepancy may lie here, but most or all of it should be attributed to as yet unevaluated factors in this diffusion flame method.

SOME OBSERVATIONS ON THE RADIATIVE COMBINATION OF ATOMIC HYDROGEN WITH ATOMIC HALOGENS IN BURNER FLAMES[1]

L. F. PHILLIPS AND T. M. SUGDEN

ABSTRACT

When small quantities of gaseous molecular halogens chlorine, bromine, and iodine are introduced into the supply to premixed hydrogen–oxygen–nitrogen flames one of the most important spectroscopic features appearing is an apparently continuous emission in the visible, sometimes extending into the near ultraviolet. The intensity of this continuous emission has been studied as a function of amount of halogen, and of temperature, composition, and position with respect to the reaction zone in a wide variety of flames. In oxygen-rich flames it has been attributed to an over-all process,

$$X + X \rightarrow X_2 + h\nu,$$

where X denotes an atom of halogen; one of the atoms may be in an excited state. Most of the work concerns hydrogen-rich flames, where a very strong correlation between the intensity and the product [H][X] is obtained. The over-all process may be written as

$$H + X \rightarrow HX + h\nu.$$

The efficiency of this over-all process is measured as 1 quantum emitted for about 10^{10} ordinary kinetic collisions of the atoms. The mechanism is discussed from the aspects of direct radiative recombination and of stabilization by collision of an intermediate excited HX* before radiation.

INTRODUCTION

A rather convenient method for studying some gaseous reactions at high temperatures has been shown to be the addition of the reactant or reactants in small amount to premixed flames of hydrogen, oxygen, and nitrogen at atmospheric pressure (1, 2). Variation of the amounts of hydrogen and nitrogen relative to oxygen enables a range of burnt gas temperatures from 1500° to 2500° K to be covered. The composition of the flame gas may also be varied isothermally. Little or no disturbance is produced in such gases by small amounts of additives, and the main flame gases can be regarded as a medium or 'solvent' in which the reactions of the additive take place.

Hydrogen–oxygen–nitrogen flames have two advantages over most other flames for this kind of work. Firstly, a great deal is known about the burnt gases and the reactions proceeding in them in the absence of additives, and secondly, the radiation from such flames is either very weak or confined to rather narrow regions of the spectrum in the visible and contiguous near ultraviolet and infrared.

The premixed flame has a narrow reaction zone close to the burner, followed by a zone of hot burnt gas extending several centimeters downstream. The use of sintered metal or Mèker-type burners allows this reaction zone to be made almost flat, and parallel with the burner surface, and it is then possible to use the downstream direction as a variable for following reactions with time. The scale is such that 1 cm corresponds with times of about 1 millisecond. The effects of entrained air from the surroundings can be reduced by shielding the flame containing the trace additive with a second flame of similar composition but without additive. In this way the inner flame is protected over a distance of several centimeters.

The major part of the burning takes place in the reaction zone in a distance of a fraction of a millimeter. The relevant properties of the burnt gases are as follows. In general, the

[1]*Contribution from the Department of Physical Chemistry, University of Cambridge, Lensfield, Cambridge; paper presented at the Symposium on the Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, Que., September 1960.*

amounts of the free radicals H and OH emerging from the reaction zone are very much in excess (up to 1000 times for cooler flames) of the equilibrium ones for the measured temperatures (3, 4). This occurs because of the branched chain nature of the main process of combustion. These radicals recombine relatively slowly, as they proceed downstream, by reactions

$$H + H + M \rightarrow H_2 + M$$
$$H + OH + M \rightarrow H_2O + M$$

where M is a third body. This third body is usually a molecule of a major constituent of the burnt gases and, in the case of fuel-rich flames, as normally used in this work, will be H_2O, N_2, or H_2. Certain rapid, reversible, bimolecular reactions can occur, however, at such speeds that definite relations hold between the concentrations of the burnt gas molecules. The most important of these is (1, 5)

$$H + H_2O \rightleftharpoons OH + H_2; \qquad K_0 = ([OH][H_2])/([H][H_2O]).$$

This reaction proceeds so rapidly that the concentrations of H and OH are related to each other at all points in the burnt gases by the equilibrium law for K_0, in terms of $[H_2]$ and $[H_2O]$, both of which are large, and known with reasonable accuracy for fuel-rich flames.

Flame photometric methods for measuring [H] and [OH], based on the addition of very small amounts (1 part in 10^6 or less) of various metallic compounds to the flame gases, have been devised, and shown to be consistent and reliable (3, 6, 7, 8). The temperature of the flame gases (about 2000° K) can be measured to within 10° C. It can thus be seen that the flame gases can be used as a fairly controlled source of atomic hydrogen and hydroxyl radicals.

The other great advantage of these flames is that their normal radiation is limited to strong emission from OH in the near ultraviolet, H_2O vibration–rotation bands in the far red and near infrared, and a very weak, apparently continuous, spectrum extending across most of the visible region (9). This last has been shown by Padley to arise from (10)

$$H + OH \rightarrow H_2O + h\nu$$

although whether this is a true radiative combination, or whether an excited H_2O^* is formed and stabilized by collision, is not fully established. Spectra arising from additives often stand out strongly and allow of photometric investigations.

The emission resulting from addition of amounts up to 2% of the halogens chlorine, bromine, and iodine to hydrogen–nitrogen–oxygen flames, mainly fuel-rich, is discussed in this paper. Figure 1 shows typical exposures for the reaction zone of a flame of this kind with small additions of these halogens. The addition of iodine produces the well-known IO band system (11) in the visible quite strongly, and the addition of bromine produces the BrO bands (12), weakly. No ClO bands were detected in this work, although such a system has been found in other circumstances (13, 14). These halogen oxide bands became much weaker downstream from the reaction zone, presumably because of the decrease of atomic oxygen with distance.

The most important feature from the present aspect is, however, an apparently continuous spectrum extending from the red into the ultraviolet. In the case of chlorine it is clearly visible at shorter wavelengths than the (0,0) bandhead of OH at 3064 Å, but no very sharp short wavelength cutoff can be ascribed to it. These continua persist, with some reduction in intensity, into the burnt gas. This general type of continuous spectrum appears to be quite a common feature of flames. In particular, they occur when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

nitric oxide (15, 16), carbon monoxide (17, 18, 19), and alkali metals (8) are added in small quantities, and in these cases have been ascribed to

$$NO + O \rightarrow NO_2 + h\nu$$
$$CO + O \rightarrow CO_2 + h\nu$$
$$Na + OH \rightarrow NaOH + h\nu$$

respectively. The atomic hydrogen–hydroxyl continuum has been mentioned above (10). It is not known in most cases whether an excited intermediate molecule is stabilized. Better resolution of the spectra might show discrete structure, which would be evidence in favor of this stabilization.

These apparently continuous spectra given by the halogens have been studied in a wide variety of flames, their intensities being measured as functions of wavelength, flame gas composition, temperature, and position in the flame gases.

EXPERIMENTAL

The burner consisted of a bundle of fine silica tubes, each of about 0.5 mm internal and 1.0 mm external diameter. The whole bundle was 1.2 cm in diameter. It was supplied with premixed hydrogen, nitrogen, and air, which were individually metered by calibrated capillary-type flowmeters. The gases were mixed before passing to the burner. A diagram of the burner and its supply lines is shown in Fig. 2. Silica tubes were used in preference to metal ones on account of possible corrosion by the halogens, which were also supplied to the gas mixture before it entered the burner. The bundle of tubes was held together by Araldite cement. This 'experimental' flame was surrounded by a shield flame supplied by a similar gas mixture, except for the halogen, to reduce the effects of entrained air on the inner flame. The tubing for the shield flame was stainless steel hypodermic tube, again cemented with Araldite. The arrangement gave a stable, laminar flame with primary reaction cones about 0.5 mm high, i.e. the reaction zone was almost flat. The burner was water-cooled. The total flow to the burner was of the order of 1 cubic foot/minute and was adjusted to give a stable flame for each composition.

The temperature of the burnt gas was measured by the sodium D-line reversal method (20), which has been established to be reliable for these flames provided the measurements are made more than 1 cm downstream from the reaction zone, so as to avoid effects due to chemiluminescent excitation of the sodium (2). Sodium was added as a fine spray of concentrated aqueous sodium chloride solution from an atomizer operated by part of the air supply. Measurements of the reversal were made visually, using a tungsten strip filament lamp which was calibrated with a Cambridge optical pyrometer. A Hilger, glass prism, constant deviation spectroscope was used. The temperatures ranged from 1500° K to 2300° K, depending on the composition of the mixture; most of the flames were fuel-rich. Reproducibility was to within 10° C. The potassium resonance doublet at 7665 and 7699 Å is considerably less liable to chemiluminescence, as compared with thermal excitation (5), and was used photometrically to extend temperature measurements closer to the reaction zone than 1 cm.

Measurements of the concentration of atomic hydrogen in the burnt gas were made by the Na–Li method of James and Sugden (3, 21). This involves flame photometry of

FIG. 1. Emission spectra for addition of halogen to an H_2–O_2–N_2 flame. Hilger Medium Quartz Spectrometer with Ilford H.P.3 Plates. Exposures 1 hour. Observations made on the reaction zone. Flame $H_2/O_2/N_2 = 3/1/4$, $T \sim 2300°$ K. The extension of continua into the ultraviolet below 3064 Å is only visible on the original plate. The minimum in the green corresponds with a region of low plate sensitivity.

PLATE I

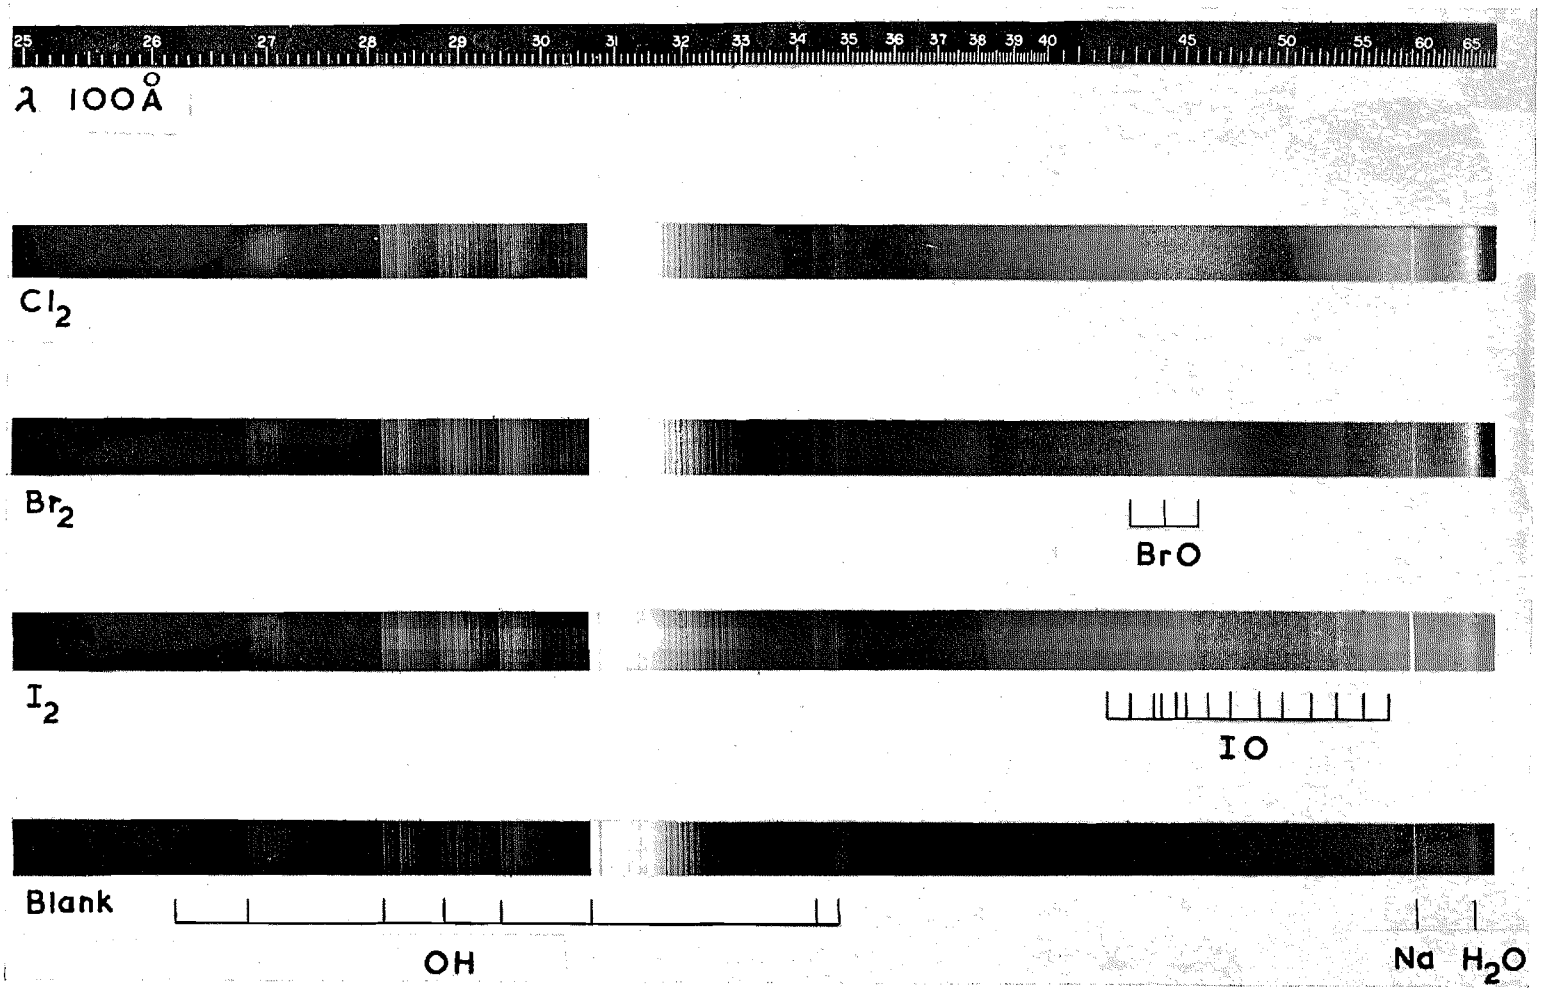

FIG. 1.

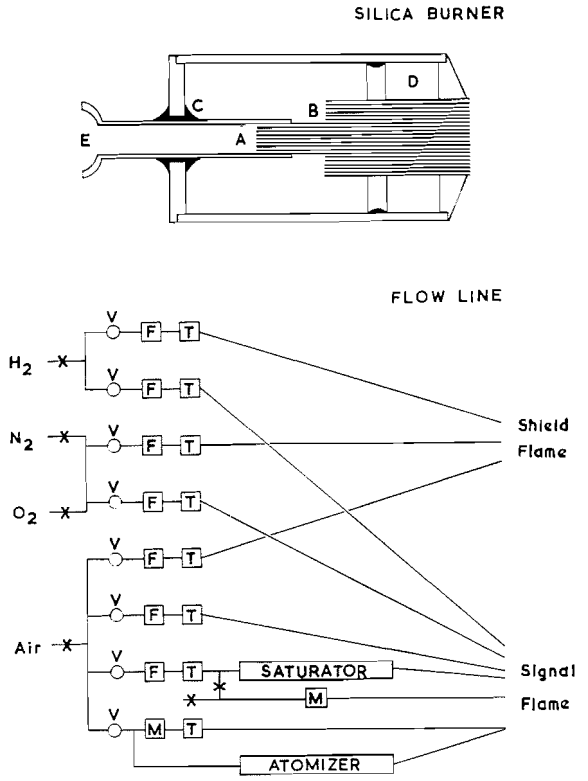

FIG. 2. Burner and supply lines. A is the 'experimental' flame with silica tubes, supplied from E. B indicates the stainless steel tubes for the shield flame (supply tubes not shown). C is a wax seal to eliminate strain. D is the water-cooling jacket, X tap, V needle valve, F flowmeter, M mercury manometer, T trap.

the emission from the resonance lines when equal amounts of sodium and lithium are introduced as salt sprays into the flame supply, the concentrations being sufficiently low to make self-reversal negligible. A significant amount of the lithium is removed as the very stable gaseous compound LiOH by the balanced reversible reaction

$$Li + H_2O \rightleftharpoons LiOH + H.$$

The NaOH molecule is much less stable, and the amounts of it formed can be neglected. The method leads to absolute values of [H] correct to within $\pm 20\%$, and to relative values for a series of flames to within $\pm 5\%$. The equilibrium constant of the reaction was calculated from a formula given by Smith and Sugden (22), with thermochemical data from Gaydon and Wolfhard (20), modified to correspond with a heat of dissociation of OH of 102.5 kcal/mole, as recommended by Gray (23). The method yields values of [H] in accordance with equilibrium ones in circumstances where equilibrium is known to obtain, i.e. at temperatures above 2400° K and at 3 cm from the reaction zone. It is valid provided that the emission of the resonance lines is thermal, a condition which holds reasonably well 1 cm or more downstream from the reaction zone.

To obtain [H] nearer to the reaction zone, the CuH photometric method of Bulewicz and Sugden (6) was adopted, as recommended by Padley and Sugden (2). This method is not absolute, but can be calibrated against the Li–Na method. It is apparently not subject to difficulties arising from chemiluminescence.

All photometric measurements were made by chopping the light from the flame with a sector disk at a frequency of 600 cycles/second before it fell on the entrance slit of the Hilger constant deviation glass spectrometer fitted with an IP 21 photomultiplier as detector. The output from this was amplified by a homodyne system, a reference signal being taken from the same chopping disk, and was finally presented as a meter reading. The wavelength sensitivity was obtained by calibration with a tungsten strip filament lamp running at known temperatures. The spatial resolution of the optical system allowed a section of the 'experimental' flame about 0.5 mm in height to be studied. The burner was mounted horizontally so that the image of a cross section of the flame filled the vertical entrance slit of the spectrometer.

Elementary halogens were added by the following means. For chlorine, cylinder supplies were transferred to a gas aspirator, where they were stored over brine. The gas was passed into the main flame gas supply by displacing the brine with a metered stream of air. Liquid bromine was contained over a sintered glass disk in a thermostatted saturator. A very small, measured proportion of the air supply was diverted through the sintered disk, and became saturated with Br_2 vapor. Independent tests showed saturation to be efficient. Iodine was contained in a similar saturator immersed in glycerol at 130° C, whereby it could be kept in liquid form. It was necessary to heat the connecting tubes to within a short distance of the burner to reduce condensation on the walls. Even so, some difficulty was experienced from this source. Vapor pressure data were taken from the International Critical Tables.

RESULTS AND CONCLUSIONS

1. *The Effect of Halogens on Temperature and Flame Composition*

The first point to be established is whether the addition of the halogen has any marked effect on the parameters of the main flame gases. Two of these have been examined, as being the most important—the temperature and the concentration of atomic hydrogen. Addition of 2% of chlorine causes an increase of temperature of 20–30° C. Since most of the measurements were made with amounts below 1%, the effects of change of temperature can be neglected, in first approximation. The addition of bromine and iodine had much smaller effects on the temperature than did that of chlorine. The effect of the addition of halogen on the concentration of atomic hydrogen has been estimated indirectly, since it is not possible to use the Li–Na method or the CuH method in the presence of halogen, on account of the formation of alkali halides in the one case, and of emission from gaseous cuprous halides in the other.

Addition of chlorine in amounts of the order of 0.1–1% of the gases causes a reduction of the intensity of the sodium D-line provided by adding a very small (1 part in 10^8) portion of sodium salt because of the formation of gaseous sodium chloride. By far the most stable compound of chlorine in hydrogen-rich flame gases is hydrogen chloride, and the added chlorine will be expected (see below) to be almost entirely in this form. The reaction by which sodium chloride is made will be the rapid reversible one of Na with HCl

$$Na + HCl \rightleftharpoons NaCl + H; \qquad \text{eq. const. } K_1.$$

This balance will be set up in the flame gases within a few microseconds. If [H] remains unchanged on addition of chlorine, then a plot of (I_0/I) against $[Cl]_0$ should be a straight line, where I_0 and I are the intensities of the sodium D-lines in emission without and with total added chlorine $[Cl]_0$ respectively, since $[Cl]_0 \sim [HCl]$, and thus

$$[Na]_0/[Na] = 1+(K_1[Cl]_0)/[H].$$

I is proportional to [Na] for sufficiently low concentrations of sodium to make self-reversal negligible. If [H] is dependent on $[Cl]_0$, curved plots should be obtained.

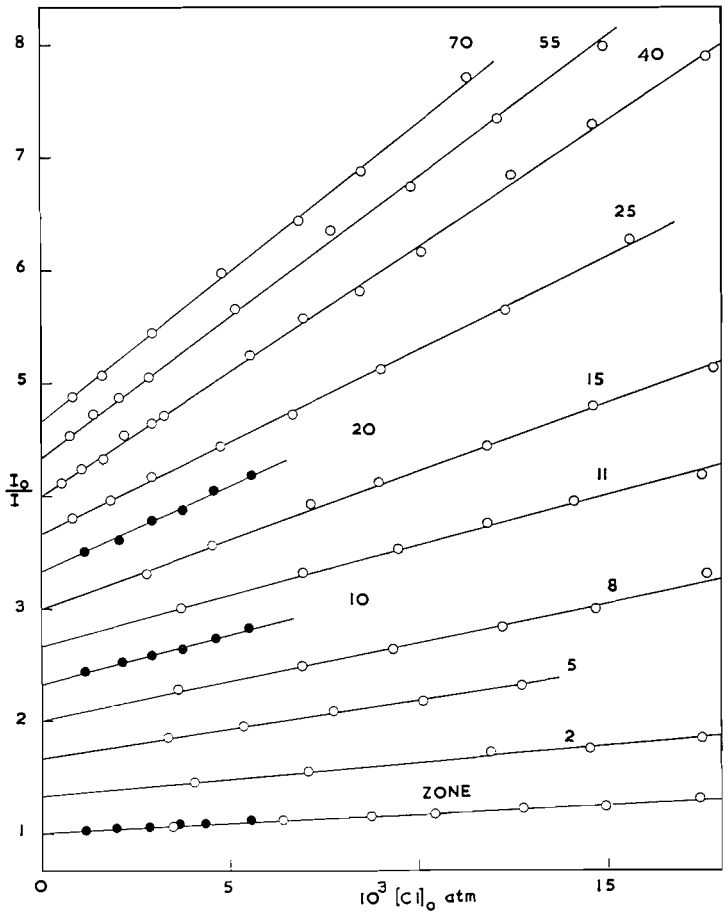

FIG. 3. (I_0/I) sodium D-lines against total added chlorine $[Cl]_0$ for a flame with $H_2/O_2/N_2 = 3/1/4$. The open circles are for addition of chlorine gas, and the full circles for addition of chlorine as chloroform. The numbers on the plots give distance in millimeters from the reaction zone. The lines (apart from that for the reaction zone) have been displaced vertically for clarity: without such displacement they have a common intercept. $M/1000$ NaCl solution sprayed from the atomizer.

Figure 3 shows typical plots of (I_0/I) against $[Cl]_0$. They are good straight lines. In the case illustrated they give evidence of decrease of [H] with increasing distance from the burner. There is thus good evidence that [H] is not significantly altered by the amounts of chlorine used. Earlier work (3) showed a slight initial curvature of plots of this kind, but this has been shown to arise from faults in the method of adding the halogens. Results with the same implication, that [H] is unaffected, hold for addition of bromine and iodine up to 0.5%. This greatly simplifies the analysis of the results to be described, insofar as they are connected with the concentration of atomic hydrogen. Some observations have also been made on the effect of chlorine on the intensity in emission of the (0,0) band of OH at 3064 Å. Two per cent of chlorine produced no significant effect. This is in agree-

ment with the absence of change in [H], since the two radicals are related to each other and the major constituents by

$$H_2O + H \rightleftharpoons H_2 + OH,$$

which is balanced.

2. The Halogen 'Continua'

Figure 4 shows some results on the emission from various hydrogen–oxygen–nitrogen flames to which amounts of less than 1% of chlorine, bromine, or iodine were added. They were taken at wavelengths, and in positions in the flame gases, where interference

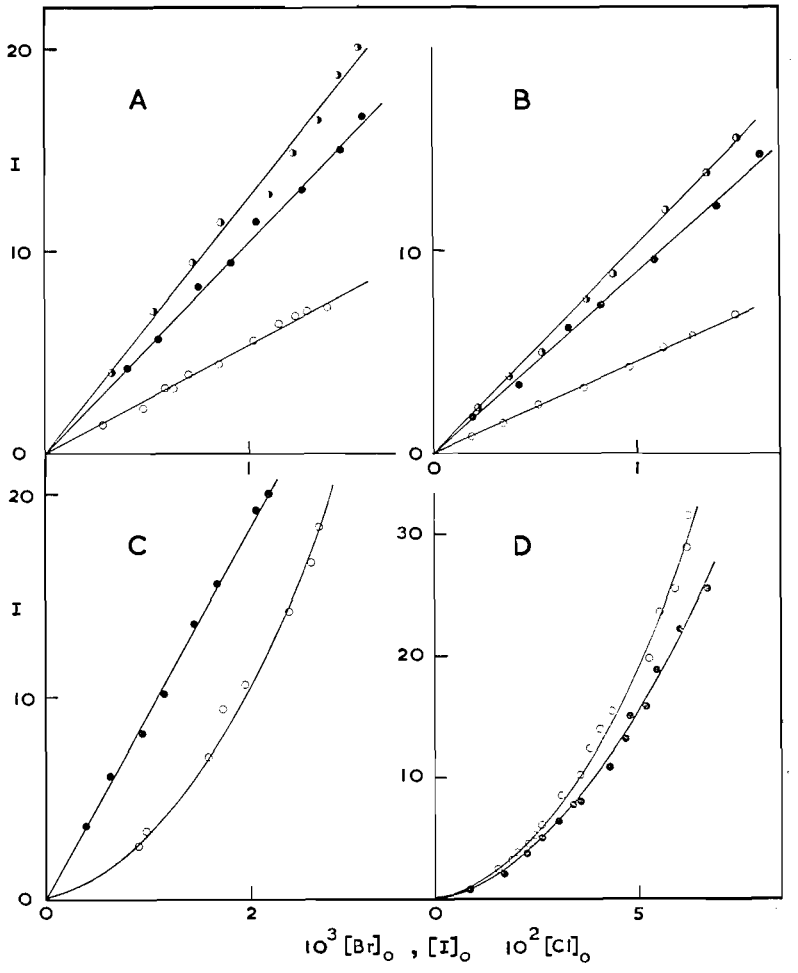

FIG. 4. Plots of intensity of halogen continua in H_2–O_2–N_2 flames as functions of total added halogen $[X]_0$. Waveband observed about 50 Å wide.

(A) Addition of chlorine. ○, flame $H_2/O_2/N_2 = 3/1/4$ at 10 mm from the reaction zone; ●, flame $H_2/O_2/N_2 = 3.5/1/5$ at 4 mm; ◑, flame $H_2/O_2/N_2 = 4.5/1/6$ at 2 mm. All at 4900 Å.

(B) Addition of bromine, all at 2 mm from reaction zone. Flame $H_2/O_2/N_2 = 3.5/1/5$: ○, for 6400 Å; ●, for 5500 Å; ◑, for 4900 Å.

(C) Addition of iodine. ○, flame $H_2/O_2/N_2 = 1/1/4$ at 8 mm; ●, flame $H_2/O_2/N_2 = 3/1/4$ at 2 mm. Both plots for 6400 Å.

(D) Flame $H_2/O_2/N_2 = 1/1/4$ at 8 mm and 4900 Å. ○, for addition of chlorine; ●, for addition of bromine.

For personal use only.

from known discrete spectra (such as that of IO) was negligible. The intensity of emission without added halogen was subtracted directly from the total reading. Wide slits were used, so that a section of about 50 Å was observed.

An important relation to the general flame composition is at once apparent. When a fuel-rich flame is used there is a direct proportionality between the observed intensity I and the total halogen $[X]_0$, whereas for a very oxygen-rich flame, I is proportional to $[X]_0^2$.

The heats of dissociation of X_2 halogen molecules are such that at flame gas temperatures, and with the amounts of halogen used, the proportion which would be expected, on thermodynamic grounds, to be present as X_2 are negligible. Molecules of this type entering the reaction zone would immediately be decomposed by reaction with atomic hydrogen, of which a great deal is present,

$$X_2 + H \rightarrow HX + X.$$

A subsequent very rapid, reversible, reaction

$$HX + H \rightleftharpoons H_2 + X; \qquad \text{eq. const. } K_2$$

then sets up a balance between atomic X and the hydride HX

$$[HX]/[X] = [H_2]/K_2[H]$$

and

$$[X]_0 = [HX] + [X].$$

The ratio $[HX]/[X]$ may thus be obtained from the known values of the equilibrium constant K_2, and the concentrations $[H_2]$ and $[H]$. The former of these concentrations is readily calculable for a fuel-rich flame with sufficient accuracy, and the latter has been measured. The result is that $[HX]/[X] \gg 1$ for chlorine in fuel-rich flames, $\ll 1$ for iodine, and is not far from unity for bromine. In oxygen-rich flames the value of this ratio will be very severely reduced since molecular hydrogen now becomes a very minor constituent and in this case hardly any hydride HX is expected, and for all the halogens $[X] \sim [X]_0$. Consideration of the dissociation energies of the XO molecules (24) shows that they will not take up an appreciable part of the total halogen in any of the present flames.

It is therefore suggested that the observed dependence of I on $[X]_0^2$ in a very oxygen-rich flame arises from the radiation being associated with an over-all process

$$X + X \rightarrow X_2 + h\nu.$$

Whether X_2^* is stabilized by collision with other molecules before emission ensues (i.e. whether X_2^* is associated with a potential curve with a minimum) cannot be decided from the observations, since at the flame temperatures the discrete structure expected in this event would be so rich as not to be resolvable by the spectrometer. It is interesting to note that Kondratiev and Leipunski (25) observed an apparently continuous spectrum from heated halogens in this region (blue-green). This they attributed to recombination of excited and normal halogen atoms. Similar continua were observed by Ludlam, Reid, and Soutar (26) in H_2–Cl_2 diffusion flames, and by Urey and Bates (27) in H_2–Cl_2 and H_2–O_2–X_2 flames, and were associated with the same origin.

The main interest of this paper, however, centers on the emission from hydrogen-rich

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

flames, where the results of Fig. 4 exclude the possibility of radiative recombination of two halogen atoms. The direct dependence of I on $[X]_0$ implies that the radiation emerges from a molecule or process in which only one atom of halogen is concerned. On an a priori basis the over-all effect

$$H + X \rightarrow HX + h\nu$$

deserves consideration, since Padley (10) has shown that in these flames a very similar spectrum arises from

$$H + OH \rightarrow H_2O + h\nu.$$

Neither the results of Ludlam *et al.* nor those of Urey and Bates exclude the possibility that such an effect gave rise to some of the emission which they observed.

3. Dependence of Intensities on [H]

The total halogen is effectively distributed between [X] and [HX] in fuel-rich flames,

$$[X]_0 = [X] + [HX] = [X]\{1+([H_2]/K_2[H])\}.$$

Then, if the intensity $I = k[H][X]$

$$I = (k[H][X_0])/\{1+([H_2]/K_2[H])\}.$$

In the case of chlorine $[HX]/[X] = [H_2]/K_2[H] \gg 1$, so that

$$I = (kK_2[H]^2[Cl]_0)/[H_2]$$

whereas for iodine $[H_2]/K_2[H] \gg 1$, and

$$I = k[H][I]_0.$$

One way of testing these expressions is to observe I as a function of distance downstream from the reaction zone. The decrease in [H] as this distance increases, due to recombination of the excess radicals, may be followed by flame photometric methods. The most convenient one is the CuH method of Bulewicz and Sugden (6), referred to in the experimental section. The intensity of the CuH band at 4280 Å when a very small amount of copper salt is added to the flame is directly proportional to [H]. Thus, the lowest plot of Fig. 5 is effectively one of $1/[H]$ against distance from the reaction zone for a particular flame. It is a straight line with slope characteristic of the velocity constants of the ternary recombination processes such as

$$H + H + M \rightarrow H_2 + M$$

The first plot of Fig. 5 is of $(1/I)^{\frac{1}{2}}$ for the chlorine continuum: it is linear, and has the same (slope/intercept) as the $1/[H]$ plot at the bottom. The third plot is of $(1/I)$ for the iodine continuum, and is again of the same form as the $1/[H]$ plot. Thus the predictions based on the law $I = k[H][X]$ are borne out. Both $(1/I)$ and $(1/I)^{\frac{1}{2}}$ are plotted for bromine. The former is a little too steep, and the latter not nearly steep enough. This is in good agreement with the calculated values of $[HX]/[X]$ in this flame at 6 mm of 22.5, 0.55, and 2×10^{-4} for X = Cl, Br, and I respectively.

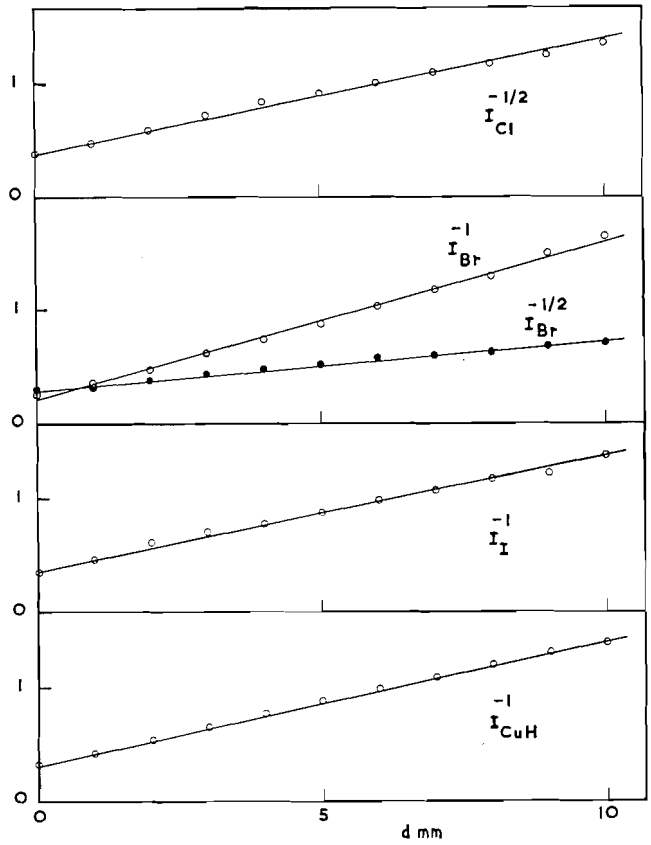

FIG. 5. Decay of intensity of I halogen continua with distance from the reaction zone for flame $H_2/O_2/N_2$ = 3.5/1/5, $T \sim 2000°$ K. Observed at 4900 Å for Cl_2 and Br_2 addition and at 6400 Å for iodine. $[Cl]_0 = 2 \times 10^{-2}$ atm, $[Br]_0 = [I]_0 = 2 \times 10^{-3}$ atm. Compared with decay of [H] as given by the intensity of the CuH band at 4280 Å.

A more complete test of the correlation of I with [H] (for iodine) or with $[H]^2$ (for chlorine) is obtained by plotting the values of all these quantities for the reaction zone (defined here as the point of maximum [H]) for a wide series of flames. One of the most convincing ways of doing this is to use the method of 'families', first introduced by James and Sugden (8). A 'family' is a set of flames for which $[N_2]/[O_2]$ in the unburnt gas is constant, usually integral: the flames within it have various $[H_2]/[O_2]$ values, ranging in this work from 2.5 (hot end of family) to 4.5 (cold end). Their properties are plotted conveniently against $1/T$, a line connecting members of a particular family. Thus figure 6 shows such plots for the functions $[H]_0$ and $[H]_0^2/[H_2]$, $[H]_0$ denoting the value of [H] in the reaction zone. It will be seen that one function gives clearly separated families, while the other produces characteristic overlapping. Figure 7 shows the intensity of the continua for chlorine, bromine, and iodine at constant total halogen concentration, plotted in the same way. The correlation of the iodine pattern with $[H]_0$, and that of the chlorine pattern with $[H]_0^2/[H_2]$ is very striking. Bromine is again intermediate in behavior. The case that the observed emission is given by $k[H][X]$ is thus a very strong one.

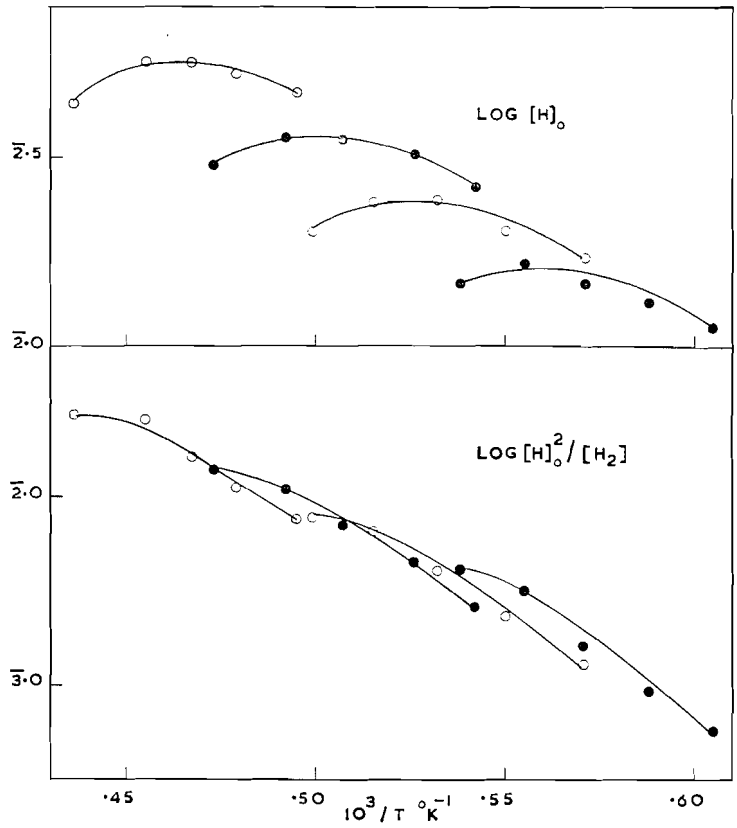

FIG. 6. Variation of $[H]_0$ and $[H]_0^2/[H_2]$ with flame composition. $[H]_0$ is the partial pressure (in atmospheres) of hydrogen atoms in the reaction zone. Flame families (N_2/O_2 in unburnt gas) 4, 5, 6, and 7. Points in each family are for unburnt H_2/O_2 ratios 2.5, 3, 3.5, 4, and 4.5. The temperature indicated is the steady value reached in the burnt gases after a time of ~1 millisecond.

4. The Efficiency of Emission in the Continuum

A figure for the number of quanta emitted per cubic centimeter/second, can be obtained by suitable integration over the whole of the continuum, and comparing the result with the known thermal emission from the sodium D-lines under conditions of known sodium concentration and no self-reversal. The result of this measurement is to establish that 1 quantum in the continuum for HCl is emitted for every 4×10^{10} normal kinetic collisions of H and Cl atoms in a flame at ca. 2300° K. This figure is subject to a number of limitations. Firstly, the intensity was only observed from about 3000 Å, where it becomes very weak, to 6500 Å, where it is still quite strong; any infrared contribution is ignored. Secondly, a mean collision diameter of 3 Å for H and Cl has been assumed in calculating the frequency of 'normal' collisions. Nevertheless, the above result for the "efficiency" of emission should be correct to an order of magnitude.

Figure 8 shows plots of relative k (where $I = k[H][X]$) obtained by computing $(I/[H][X])$, and indicates the way in which k varies with temperature. The plots show that it decreases markedly with increasing temperature for chlorine, at a rate corresponding to an exponential term with an energy of about 15 kcal/mole. The corresponding

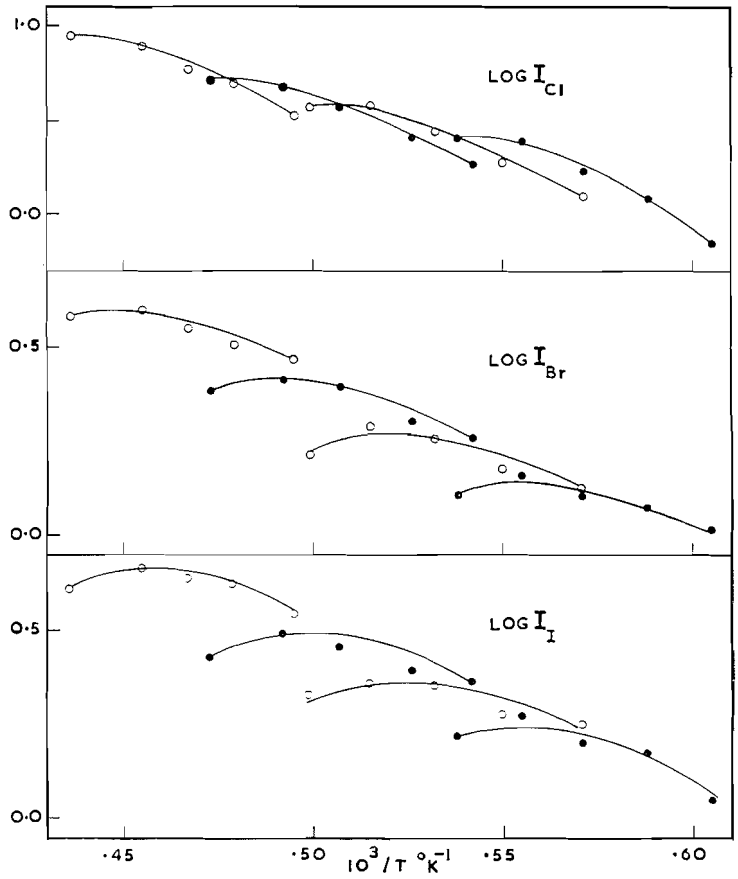

FIG. 7. Variation of intensities of halogen continua in reaction zone with flame composition. Families as in Fig. 6. $[Cl]_0 = 2\times10^{-2}$ atm, $[Br]_0 = [I]_0 = 2\times10^{-3}$ atm.

decrease for bromine is much smaller, and no decrease is observed for iodine, although in this case there is quite a high scatter on the points. These results do not refer to complete wavelength scans, but only to the emission at 4900 Å for chlorine and bromine, and 6400 Å for iodine. They must be interpreted with caution since the dependence of intensity distribution on temperature has not yet been fully explored.

DISCUSSION

Given that the intensity of the emission is proportional to [H][X], two types of mechanism appear possible.

(i) Direct radiative recombination from an upper electronic state which is arrived at by collision of atoms (ground state H and $^2P_{3/2}$ or $^2P_{1/2}$ atoms of halogen), without the intervention of any third body.

(ii) Stabilization of an intermediate HX* formed by collision of the atoms in the presence of a third body M. A typical scheme may be written

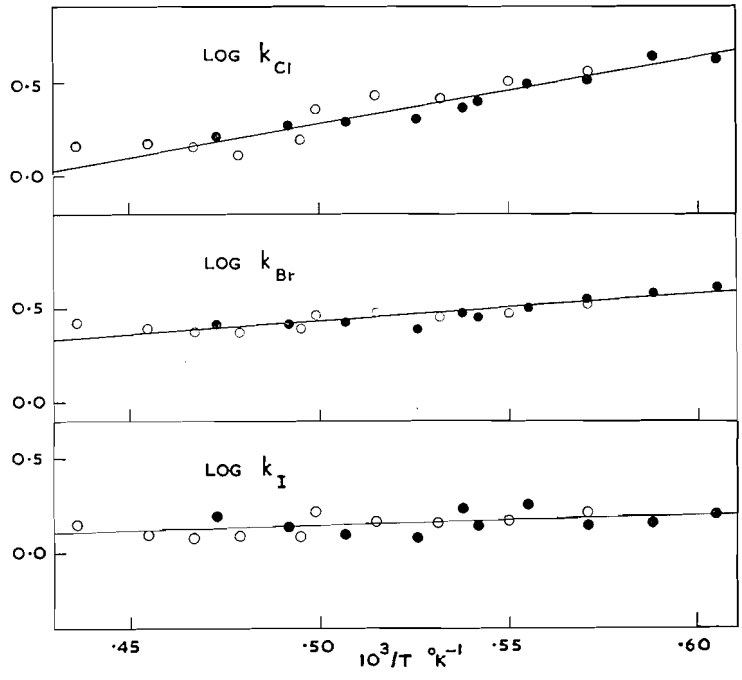

FIG. 8. Dependence of relative k, defined by I (continuum) = k[H][X] on temperature for the halogen continua in hydrogen-rich flames.

$$H + X + M \xrightarrow{k_1} HX^* + M,$$

$$HX^* + M \xrightarrow{k_{-1}} H + X + M,$$

$$HX^* + M \xrightarrow{k_2} HX + M,$$

$$HX^* \xrightarrow{k_3} HX + h\nu.$$

If the mean kinetic energy of approach of H and X, given by kT, is small compared with the vibrational spacing in the ground electronic state, then some fluctuations in intensity of emission corresponding with this spacing might be expected in case (i). It is interesting that Weizel, Wolff, and Binkele (28) observed multiple maxima in apparently continuous emission between the green and 2500 Å with hydrogen bromide in a weak uncondensed discharge. At flame temperatures kT is about one half of the vibrational spacing and such maxima might be obscured, giving an apparently smooth continuum. Case (ii) might be expected to give a somewhat more discrete spectrum, but if HX* has only a shallow minimum a large number of its vibrational states would be occupied, which, together with the number of rotational levels involved at flame temperatures could well make the result indistinguishable, with our resolution, from case (i).

The previously observed absorption spectra are of little use here, since only continua have been observed. Goodeve and Taylor (29, 30) obtain absorption continua for HBr and HI, which they consider are connected with dissociation to H($^2S_{1/2}$), Br($^2P_{3/2}$), and I($^2P_{3/2}$). Unfortunately the long wavelength limits lie above the dissociation energy, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

it is then impossible to say whether the HX* is in a completely repulsive state or not. These observations, as well as others by Trivedi (31), are discussed by Finkelnburg (32).

From the general kinetic point of view, case (i) leads to

$$I = k[H][X]$$

where k is the velocity constant of a single process, whereas case (ii) leads to

$$I = (k_3k_1[H][X][M])/(k_{-1}[M] + k_2[M])$$

provided that radiation is only a minor source of removal of HX* molecules. M may be different for the reactions leading to dissociation and deactivation of HX*, and so does not cancel directly. If dissociation predominates, $k_{-1}[M] \gg k_2[M]$ and [M] then cancels. Writing K_1, the equilibrium constant of $H + X \rightleftharpoons HX^*$, for k_1/k_{-1}, we have

$$I = k_3K_1[H][X] \quad \text{and} \quad k = k_3K_1.$$

If the heat of dissociation of HX* into $H(^2S_{1/2}) + X(^2P_{3/2})$ is ΔE^*, a positive quantity, then K_1 may be written

$$K_1 = Q_1 \exp(\Delta E^*/RT)$$

and a rough calculation, with reasonable rotational and vibrational parameters, leads to

$$K_1 = 10^{-23} \exp(\Delta E^*/RT) \text{ cm}^{-3}.$$

The experimental values of k are of the order of 10^{-21} cm^3 sec^{-1}, so that if $\Delta E^* =$ 10 kcal/mole, at 2000° the value of k_3 will be of order 10 sec^{-1}. This implies a highly forbidden transition; reference to the states indicating that $^3\Pi \rightarrow {}^1\Sigma$ would be the only one to fulfil such a requirement. Increments of ΔE^* by units of 10 kcal/mole have the effect of decreasing k_3 approximately by orders of magnitude, but the absence of discrete spectra implies that HX* cannot be very stable.

If deactivation predominates over dissociation, i.e. $k_2[M] \gg k_{-1}[M]$, k_3 is correspondingly increased, and the radiative lifetime shortened. It is improbable that this inequality would amount to a sufficient factor to make the radiative lifetime short enough for a fully allowed transition (order of 10^{-8} sec).

A very crude analysis of case (i) can be made as follows. The period of a molecular vibration is of the order of 10^{-13} sec, and this can be taken as the duration of a collision for a repulsive state. A normal radiative lifetime for electronic transition (10^{-8} sec) would then give an efficiency of order 10^{-5}, corresponding with k of order 10^{-15} cm^3 sec^{-1}. Again, therefore, the transition must be a highly forbidden one.

It is considered that the different variations with temperature found for the various halogens probably favor case (ii) insofar as ΔE^* could readily show a range of 15 kcal/mole among the halogens. No great temperature dependence of k_3 would be expected, nor of k for case (i), but the evidence presented here is not sufficient to allow of a final decision. It is of interest that the NO–O 'continuum' in flames has recently been shown (33) to derive, at least to some extent, from a mechanism of the general type (ii).

One of us (L. F. P.) is grateful for the award of a Shell Commonwealth Scholarship (New Zealand). We also wish to express our thanks to our colleagues in the Department of Physical Chemistry for useful discussions.

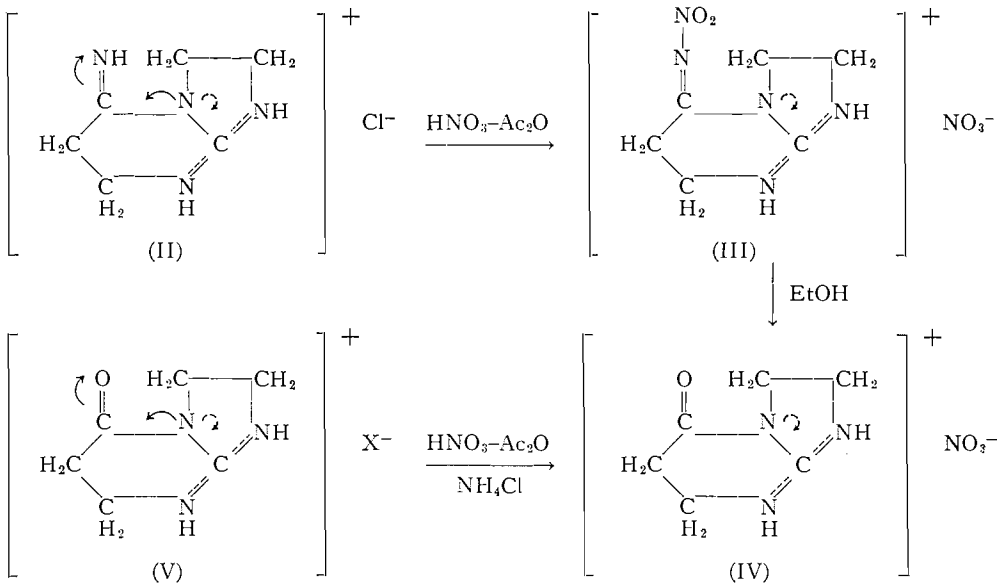
NITRATION OF BICYCLIC GUANIDINES[1]

A. F. McKay and M.-E. Kreling

ABSTRACT

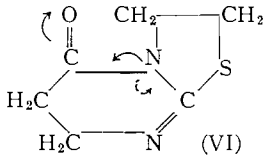
The course of the nitration of a bicyclic guanidine system has been shown to depend on substitution at an adjacent carbon atom. The pyrimidine ring in 5-keto-2,3,6,7-tetrahydro-5(H)-thiazolo(3,2-*a*)pyrimidine is opened more rapidly by benzylamine and ethanolic hydrogen chloride than the pyrimidine ring in 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine. These effects are interpreted in terms of the resonance ion structure at the ring junctions.

The bicyclic guanidine, 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine,[2] has been converted into 1-nitro-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium nitrate by nitration in absolute nitric acid – acetic anhydride medium (1). Nitration of the 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium ion is consistent with the presence of the guanidinium ion in its structure. The model of this bicyclic guanidinium ion may be represented diagrammatically by structure I. Atoms 1, 2, 3, 4, 5, 8, and 9 are



(I)

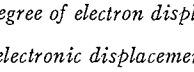
in the same plane, since the five-membered ring can be considered to be planar. A slight deviation of C atoms 2 or 3 from the plane of the ring would not contribute much to a relief of strain within this structure. A continuation of nitration studies on the 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine system has shown that an electronegative substituent such as oxygen or nitrogen on C_5 affects the nitration of the guanidine structure.

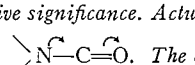


Nitration of 5-imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium chloride (II) in absolute nitric acid – acetic anhydride medium gave 5-nitrimino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium nitrate (III). The failure of the guanidine structure to nitrate is explained by the electron displacements within structure II. There are two opposing electron attractive forces working on N_4; one involves its participation in the guanidinium ion and the other in the electron displacement indicated by the curved unbroken arrows in structure II. These opposing forces give the resonance ion structure more of an amidinium ion character than a guanidinium ion character and the amidinium ion does not nitrate. Thus nitration occurs only on the 5-imino nitrogen. The same explanation is given for the failure of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine to nitrate.

5-Nitrimino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium nitrate (III) is converted into 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium nitrate (IV) on crystallization from ethanol. Because of this easy replacement of the nitrimino group, extreme care was required in the preparation of a pure sample of compound III.

[1]*Manuscript received June 8, 1960.*
Contribution No. 27 from the L. G. Ryan Research Laboratories of Monsanto Canada Limited, LaSalle, Que.
[2]*Named in accordance with the rules on nomenclature of fused ring systems given in The ring index, Am. Chem. Soc. 2nd ed., 1960. This compound was referred to as* Δ^8*-hexahydro-1,4,8-pyrimidazole in ref. 1.*





When 5-keto-2,3,6,7-tetrahydro-5(H)-thiazolo(3,2-*a*)pyrimidine (VI) was treated with an ethanolic solution of hydrogen chloride, a quantitative yield of 2-(β-carbethoxyethylamino)-2-thiazoline was obtained. Similarly benzylamine opened the pyrimidine ring of VI to give 2-(β-(N-benzylcarbamyl)-ethylamino)-2-thiazoline (2). Both ethanolic hydrogen chloride and benzylamine failed to open the pyrimidine ring of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (V) under similar conditions. The greater resistance of the pyrimidine ring to opening in V than in VI is due to the relative ease of electron displacements towards the carbonyl oxygen atom in these two systems. In V the opposing electron attractive force to the electron displacement indicated by the solid arrows[3] is greater than the opposing electron attractive force in VI. This is probably the main factor contributing to relative ease of opening the pyrimidine ring in these compounds although the slight difference in the conformations of the two ring systems also may make some contribution.

EXPERIMENTAL[4]

5-Keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-a)pyrimidine

2-(β-Carboxyethylamino)-Δ²-1,3-diazacyclopentene (m.p. 209–211° C with decomp.) was prepared in 73.2% yield and the acid was esterified with ethanolic hydrogen chloride as previously described (3). On evaporation of the ethanolic solution 2-(β-carbethoxyethylamino)-Δ²-1,3-diazacyclopentene hydrochloride was obtained as a viscous oil.

[3]*The solid and broken arrows in the graphic formulas are used only for differentiation in discussion and they have no quantitative significance. Actually the degree of electron displacement in the*  *system is greater than in*  . *The effects of electronic displacements and resonance on the chemical reactivity of the bicyclic guanidines are under investigation.*

[4]*All melting points are uncorrected. Analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.*

The above ester hydrochloride (10.3 g, 0.0465 mole) in absolute methanol (200 ml) was passed through a column of IRA-400 resin in the hydroxyl form. The resin column had been previously washed with absolute methanol. After the resin had been washed with absolute methanol (150 ml), the eluate and washings were evaporated to dryness *in vacuo*. The white crystalline residue weighed 6 g (92.8% yield). It melted at 141° C, resolidified, and melted at 148–149° C. This melting point was not changed by crystallization from absolute ethanol – ether (1:2) solution. Anal. Calc. for $C_6H_9N_3O$: C, 51.78; H, 6.52; N, 30.20%. Found: C, 51.53; H, 6.31; N, 30.34%.

The picrate (m.p. 248–249° C) of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*) pyrimidine was prepared in 95% yield from ethanol solution. Anal. Calc. for $C_{12}H_{12}N_6O_8$: C, 39.14; H, 3.29; N, 22.82%. Found: C, 38.93; H, 3.41; N, 22.75%.

5-Keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-a)pyrimidinium Nitrate

5-Keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (0.695 g, 0.005 mole) was added to a nitration medium consisting of 98% nitric acid (2.33 ml, 0.05 mole), acetic anhydride (4.72 ml, 0.05 mole) and ammonium chloride (0.6 g, 0.011 mole). After the reaction mixture was stirred at 32° C for 2 hours, it was poured into cold absolute ether (75 ml). The ether was decanted from the oil, which was washed twice with fresh portions of absolute ether. After the oil was triturated with absolute ethanol, crystals (m.p. 129.5–131° C) separated from the oil, yield 0.57 g (56.4%). One crystallization from absolute ethanol raised the melting point to 132–133° C. Anal. Calc. for $C_6H_{10}N_4O_4$: C, 35.65; H, 4.99; N, 27.71%. Found: C, 35.56; H, 4.88; N, 27.38%.

The picrate (m.p. 247–249° C), which was prepared from absolute ethanol solution in 91.8% yield, did not depress the melting point of a known sample of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine picrate (m.p. 248–249° C).

5-Imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-a)pyrimidine

2-Methylmercapto-2-imidazolinium iodide (14.64 g, 0.06 mole) and β-aminopropionitrile (4.2 g, 0.06 mole) in absolute ethanol (15 ml) were refluxed for 7 hours. Crystals (m.p. 192–198° C) separated from the solution on cooling, yield 7.43 g (46.5%). Several crystallizations from absolute ethanol raised the melting point to 201–203° C. Anal. Calc. for $C_6H_{11}IN_4$: C, 27.08; H, 4.17; N, 21.06; I, 47.69%. Found: C, 27.26; H, 4.08; N, 20.86; I, 47.43%.

Decreasing the reflux period in the above reaction in individual runs to 2 and 5.5 hours lowered the yields of 5-imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium iodide to 37.6 and 41% respectively.

The picrate (m.p. 228–231° C) was formed from aqueous solution. Recrystallization from water–ethanol (1:1) solution raised the melting point to 248–249° C. This picrate was shown by analysis and a mixed melting point determination to be identical with the picrate (m.p. 248–249° C) from 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*) pyrimidine. Thus the imino group of the original compound was hydrolyzed to a keto group during the formation of the picrate in aqueous solution.

A sample of 5-imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo-(1,2-*a*)pyrimidinium iodide (9.1 g, 0.034 mole) in absolute methanol (180 ml) was passed through a column of IRA-400 resin (Cl^- form) which had been washed thoroughly with absolute methanol. The column was washed with absolute methanol (150 ml) and the eluate was taken to dryness *in vacuo* under nitrogen. The hydrochloride salt was obtained in 98.9% (5.90 g) yield. One crystallization from absolute methanol – ether (1:1) gave crystals melting at 193–194° C. Anal. Calc. for $C_6H_{11}ClN_4$: C, 41.27; H, 6.35; Cl, 20.30; N, 32.09%. Found: C, 41.42; H, 6.36; Cl, 20.44; N, 31.89%.

An ethanolic solution of a sample of 5-imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo (1,2-*a*)pyrimidinium chloride on treatment with ethanolic picric acid gave a dipicrate (m.p. 218–220° C) in 77% yield. Anal. Calc. for $C_{18}H_{16}N_{10}O_{14}$: C, 36.25; H, 2.74; N, 23.49%. Found: C, 36.50; H, 2.96; N, 23.38%.

5-Nitrimino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-a)pyrimidinium Nitrate

5-Imino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium chloride (0.75 g, 0.0043 mole) was added to a nitration medium of 98% nitric acid (2.0 ml, 0.043 mole), acetic anhydride (4.06 ml, 0.043 mole), and ammonium chloride (0.3 g, 0.0056 mole) at 0° C. The temperature was raised to 32° C and the stirred solution was maintained at this temperature for 2.5 hours. When the solution was poured into cold absolute ether (75 ml) a sticky crystalline mass separated. The ether solution was decanted from the solid, which was washed with absolute ether (3×50 cc) by decantation. The solid was triturated with absolute ethanol (50 cc) and the crystals were recovered by filtration. After this process was repeated, the crystals were dried *in vacuo* at room temperature. The crystals melted at 152.5–153° C with decomposition, yield 0.45 g (42.6%). Anal. Calc. for $C_6H_{10}N_6O_5$: C, 29.27; H, 4.10; N, 34.13%. Found: C, 29.27; H, 4.32; N, 34.47%.

After a sample of the 5-nitrimino-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidinium nitrate was refluxed in ethanol for 1.5 hours, the crystals obtained on cooling the solution melted at 131–133° C. These crystals did not depress the melting point of a known sample of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine nitrate (m.p. 132–133° C). The infrared spectra of these two samples were also identical.

Attempts to Open the Pyrimidine Ring of 5-Keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo-(1,2-a)pyrimidine

(*A*) *With Benzylamine*

5-Keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (0.556 g, 0.004 mole) and benzylamine (0.43 g, 0.004 mole) in absolute ethanol (7 ml) were allowed to stand at room temperature for 17 hours. The solution was concentrated to 3 ml *in vacuo* and ether was added. The crystals (m.p. 141° C and 148–149° C) on admixture with the starting material gave no depression in melting point, yield 0.506 g (91%).

A similar experiment in which the reactants in ethanolic solution were refluxed for 3.5 hours gave an 81% recovery of starting material.

(*B*) *With Ethanolic Hydrogen Chloride*

A solution of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (0.278 g, 0.002 mole) in ethanolic hydrogen chloride (10 ml of absolute ethanol containing 79 mg, 0.0022 mole of hydrogen chloride) was refluxed for 2.5 hours. The cooled solution was divided into two equal parts. One part on treatment with ethanolic picric acid solution gave 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine picrate (m.p. 248–249° C) in 98% (0.36 g) yield. This picrate did not depress the melting point of a known sample of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine picrate (m.p. 248–249° C).

The second portion on standing in the cold gave crystals melting at 251.5–252.5° C, yield 120 mg (68.4%). The melting point of this sample of 5-keto-2,3,6,7-tetrahydro-1(H), 5(H)-imidazo(1,2-*a*)pyrimidinium chloride was not changed by crystallization from ethanol–ether solution. Anal. Calc. for $C_6H_{10}ClN_3O$: C, 41.04; H, 5.74; Cl, 20.19; N, 23.93%. Found: C, 41.18; H, 5.91; Cl, 20.00; N, 23.34%.

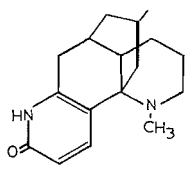
THE STRUCTURE OF LYCODINE[1]

W. A. Ayer and G. G. Iverach



ABSTRACT

The molecular formula of the *Lycopodium* alkaloid lycodine has been revised to $C_{16}H_{22}N_2$. Transformation of β-obscurine (I) into N-methyl lycodine has shown that lycodine is the pyridine analogue of des-N-methyl-β-obscurine and is represented by structure II (R = H). The transformation of β-obscurine into α-obscurine is also described.

The alkaloid lycodine was first isolated from *Lycopodium annotinum* L. in 1958 by Anet and Eves (1), who assigned to it a molecular formula $C_{17}H_{24}N_2$. Lycodine was shown to be a tetracyclic diacidic base containing a secondary nitrogen atom, a 5,6,7,8-tetrahydroquinoline system unsubstituted in the heterocyclic ring, and a C-methyl group.

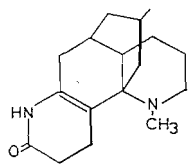
When structure I was advanced for β-obscurine (2) it was suggested that lycodine is formed by a similar biogenetic path,[2] with the exception that N-methylation has not occurred, and is represented by structure II (R = H). The correctness of this structure has now been confirmed by a series of experiments which are described in this communication.

The isolation of lycodine from *L. annotinum* L. involves a rather extended separation procedure (1). We have found that lycodine also occurs in *L. obscurum* L. and is readily separable by chromatography of the crude bases over alumina. Some lycodine was obtained directly by crystallization of the eluates. The remainder was separated from contaminating bases (mainly lycopodine and annotinine) by lithium aluminum hydride reduction, which transformed the contaminants into hydroxylic materials but did not affect the lycodine, followed by chromatography. The total yield of lycodine from dried plant material was approximately 0.003%.

I

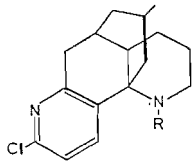
II

Structure II (R = H) requires that the formula of lycodine be revised to $C_{16}H_{22}N_2$. The analytical results quoted by Anet and Eves (1), especially those for the dipicrate of lycodine and the picrate of N-acetyl lycodine, do not clearly differentiate between the two possibilities. Our analytical results with lycodine and N-methyl lycodine, together with the preparation of N-methyl lycodine from β-obscurine ($C_{17}H_{24}ON_2$) described below, confirm the 16 carbon formulation. The proposed structure differs in two other respects from the partial structure advanced by Anet and Eves (1). Firstly, the more strongly basic nitrogen is attached to a carbon α to the pyridine ring. This attachment



[1]*Manuscript received June 13, 1960.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta. This work forms a portion of a thesis to be submitted by G. G. Iverach in partial fulfillment of the requirements for the degree of Master of Science.

[2]*Recently, Professor H. Conroy (3) has outlined a biogenetic scheme which accounts for the formation, from acetate units and ammonia, of all the Lycopodium alkaloids of known structure.*



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was regarded as improbable by the previous workers on the basis of a comparison of the pK_a's of the pyridine nitrogen atoms in lycodine and nicotine. We believe that the greater basicity (pK_a 3.97) of the pyridine nitrogen in lycodine as compared with that in nicotine (pK_a 3.35) is explained by the presence in lycodine of an electropositive substituent in the 2-position of the pyridine ring (4). Secondly, the C-methyl group of lycodine is not attached to a quaternary carbon atom. The assignment of the C-methyl group to such a grouping was made on the basis of the fact that the C-methyl peak in the nuclear magnetic resonance spectrum of lycodine is unsplit (1). The failure of the $\rangle CHCH_3$ peak to split is possibly attributable to the proximity of the aromatic ring, since in β-obscurine (I) the C-methyl peak is also unsplit, whereas in α-obscurine (III) the usual splitting occurs (2). In this connection, it is interesting to note that reduction of β-obscurine (I) with lithium and ammonia, a reagent which has been shown (5) to selectively reduce α-pyridones to the corresponding 3,4-dihydro-α-pyridones, yields α-obscurine (III).

It seemed at this point that structure II could be confirmed by direct transformation of β-obscurine (I) into lycodine (II, R = H) or, since some difficulty was anticipated in the removal of the N-methyl group of β-obscurine, into N-methyl lycodine (II, R = CH_3).

III

IV

Treatment of lycodine with formaldehyde and formic acid gave, in good yield, N-methyl lycodine (II, R = CH_3). The new base had no NH stretching band in the infrared and the ultraviolet spectrum was almost identical with that of lycodine. The nuclear magnetic resonance spectrum was similar to that of lycodine (1), with the addition of a strong (3-proton) signal at τ = 7.38 due to the N-methyl group (6). The C-methyl peak (at τ = 9.21) was again unsplit.

The transformation of an α-pyridone into the corresponding 2-chloropyridine is usually accomplished by the treatment with phosphorus oxychloride, phosphorus pentachloride, or a mixture of these two reagents (7). β-Obscurine was recovered unchanged after prolonged refluxing with phosphorus oxychloride and phosphorus oxychloride – phosphorus pentachloride. However, treatment with phosphorus pentachloride at 200° or, preferably, with phenylphosphonic dichloride (8) yielded an oily product whose spectral properties (ultraviolet maximum at 275 mμ, peak in the infrared at 1565 cm^{-1}) were consistent with those expected for the desired chloropyridine IV. The crude chloro compound was hydrogenated over platinum in acetic acid. Chromatography of the products gave N-methyl lycodine (41% yield from β-obscurine) and, unexpectedly, lycodine (23% yield). Presumably, loss of the N-methyl group occurred during the treatment with phenylphosphonic dichloride and the oily product was a mixture of the chloropyridines IV (R = CH_3) and IV (R = H). The appearance of a weak NH band at 3330 cm^{-1} in the infrared spectrum of the crude product is consistent with this view.

This transformation establishes that lycodine is the pyridine analogue of des-N-methyl-β-obscurine and, on the basis of the proposed (2) structure for β-obscurine, is represented by structure II (R = H).

EXPERIMENTAL

Ultraviolet spectra were measured in ethanol and, unless otherwise stated, infrared spectra in chloroform. Microanalyses are by Pascher Mikroanalytisches Laboratorium, Bonn, West Germany, and Micro-Tech Laboratory, Skokie, Illinois.

Isolation of Lycodine

Finely ground *L. obscurum* L. (10 kg) was extracted by the procedure of Manske and Marion (9). The crude alkaloids (9.3 g) yielded some lycopodine (2.0 g) on crystallization from ether. The mother liquors were dissolved in chloroform and placed on a column of basic alumina (150 g). Thorough elution with chloroform gave 3.75 g of basic material which was rechromatographed over alumina (100 g). Fraction A (2.1 g), eluted with benzene (900 ml), was mainly lycopodine. Fraction B (0.63 g), eluted with ether (850 ml), was a mixture of lycopodine and lycodine (as shown by infrared and ultraviolet measurements). Fraction C (0.17 g), eluted with 1:1 ether – methylene chloride (500 ml), contained annotinine, lycodine, and unidentified carbonyl-containing compounds. Crystallization of fraction B from pentane gave lycodine (172 mg). The residues from the crystallization were combined with fraction C, dissolved in ether, and reduced with lithium aluminum hydride in the usual manner. The product was chromatographed over alumina. Elution with benzene–ether gave crystalline lycodine (130 mg). The combined lycodine was recrystallized several times from pentane to give colorless blocks, m.p. 118–119°. Calc. for $C_{16}H_{22}N_2$: C, 79.29; H, 9.15; N, 11.56%. Found: C, 79.49, 79.33; H, 9.13, 9.09; N, 11.61, 11.47%; no N-methyl.

N-*Methyl Lycodine*

Lycodine (52 mg) was dissolved in 98% formic acid (0.25 ml) and formalin (0.25 ml) added. The solution was refluxed for 2 hours, then maintained at 50° for 12 hours. The reaction mixture was diluted with water (50 ml), basified with concentrated ammonium hydroxide, and extracted several times with chloroform. Evaporation of the dried chloroform extracts gave a pale yellow oil (0.05 g) which solidified on standing. Three recrystallizations from acetone gave N-methyl lycodine as colorless blocks (23 mg), m.p. 91–92°. Calc. for $C_{17}H_{24}N_2$: C, 79.63; H, 9.44; N, 10.93; one N—CH_3, 5.86%. Found: C, 79.61, 79.59; H, 9.36, 9.27; N, 11.25, 10.75; N—CH_3, 5.19%. Ultraviolet spectrum: λ_{max} 268 mμ (log ϵ = 3.61), shoulder at 275 mμ (log ϵ = 3.49). Infrared spectrum (Nujol): γ_{max} 3040, 1574, 1472, 812, 737 cm^{-1} (pyridine ring).

N-*Methyl Lycodine and Lycodine from β-Obscurine*

A solution of β-obscurine (168 mg, isolated from *L. annotinum* L. by established procedures (10, 11)) in phenylphosphonic dichloride (50 ml) was maintained at 200–210° for 45 minutes. The reaction solution was decomposed with ice and water and made basic by the addition of concentrated ammonium hydroxide. Chloroform extraction yielded the crude chloro compounds IV (R = CH_3) and IV (R = H) as a pale yellow oil (0.16 g), ultraviolet maximum 275 mμ, infrared peaks at 3330 cm^{-1} (NH) and 1565 cm^{-1} (pyridine ring). The oil was dissolved in glacial acetic acid and shaken with hydrogen (50 p.s.i.) in the presence of Adam's catalyst (100 mg) for 3 hours. The catalyst was filtered off and the filtrate concentrated, diluted with water, made basic with ammonium hydroxide, and extracted thoroughly with chloroform. Removal of the chloroform left a viscous yellow oil (0.12 g) which was chromatographed over basic alumina (3 g). Elution with benzene and crystallization from acetone gave N-methyl lycodine (65 mg), m.p. 91–92°. This did not depress the melting point of the N-methyl compound prepared from lycodine and their infrared spectra were identical.

Elution of the column with ether yielded a fraction (35 mg) which crystallized from acetone as colorless blocks, m.p. 115–116°. The infrared spectrum was identical with that of lycodine and a mixture melting point was undepressed.

α-Obscurine from β-Obscurine

A solution of β-obscurine (31 mg) in dry tetrahydrofuran (100 ml) was added during 1/2 hour to a vigorously stirred solution of lithium (0.1 g) in ammonia (40 ml). The solution was stirred for a further $2\frac{1}{2}$ hours, then the reaction mixture was evaporated to dryness. The residue was dissolved in aqueous HCl, washed with chloroform, basified, and extracted with chloroform. Evaporation of the chloroform left a solid residue which was chromatographed over alumina (1 g). Elution with chloroform and crystallization from methanol gave α-obscurine (20 mg), m.p. 285–287° (uncorrected). The mixture melting point with authentic α-obscurine was undepressed, and the infrared spectra of the two were identical.

Further elution of the column with chloroform–methanol (4:1) gave a fraction (7 mg) whose spectral properties were identical with those of β-obscurine.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for financial support, Professor Z. Valenta for the nuclear magnetic resonance spectrum, and Mr. R. N. Swindlehurst for many of the ultraviolet and infrared spectra.

SOME EQUILIBRIUM CONSTANTS OF TRANSITION METAL HALIDES[1]

M. W. Lister and P. Rosenblum

ABSTRACT

Measurements are reported on the formation of complex ions in solutions containing cupric and chloride or bromide ions, and solutions of nickel or cobalt with chloride. In each case the halide was present in very low amount. With copper a spectrophotometric method was used, and a cell voltage method with nickel and cobalt. The ionic strength was kept constant, but the temperature was varied. The data show difficulties of interpretation if it is assumed that only MX^+ ions (M is the metal, X is the halogen) are formed, the difficulties arising from the anomalous variation of the equilibrium constant with temperature, and from the general drift of the calculated constants from the e.m.f. measurements. Various explanations are considered and it is shown that postulation of M_2X^{+3} ions is at least a possible explanation.

A considerable number of measurements have been made on the dissociation constants of complex ions in aqueous solution, particularly those containing transition metals. In many cases, however, no very precise values have been obtained, or the effect of varying conditions, and especially the effect of temperature, has not been examined. The object of the present paper is to report results on the ions $CoCl^+$, $NiCl^+$, $CuCl^+$, and $CuBr^+$. The previous work on these ions will be briefly reviewed as each one is considered. The present work shows that the apparent equilibrium constants for $CuBr^+$, and to a lesser extent for $CuCl^+$, change with temperature in an anomalous manner. The possible cause of this is considered in some detail, since it is relevant to the use of spectrophotometric measurements generally for determining equilibrium constants.

The copper chloride and bromide systems were examined by means of a spectrophotometer, and the cobalt chloride and nickel chloride by means of cell voltages. The results on copper chloride and bromide will be given first, and then their explanation will be considered.

COPPER CHLORIDE MEASUREMENTS

This system has been the subject of many investigations of which the earlier ones are largely qualitative. Of recent investigations the most notable are those of Näsänen (1), who found a value of $K_1 = [CuCl^+]/[Cu^{++}].[Cl^-] = 0.90$ at 25° C; and of McConnell and Davidson (2), who found K_1 to be 1.30 at 25.2° C and 1.39 at 46.9° C, both at an ionic strength of 1.0. The discrepancy between these determinations was attributed by Kruh (3) to neglect of molecules of $CuCl_2$ (or other higher complexes) in Näsänen's calculations.

The present work largely confirms McConnell and Davidson's values. The experimental details are as follows. The optical densities of the solutions were measured by means of a Beckmann DU spectrophotometer, modified to allow water at constant temperature to circulate round the absorption cells. The temperature of the solutions being measured was thereby controlled to ±0.05° C or better.

The materials used were copper perchlorate and sodium perchlorate, supplied by the G. Frederick Smith Co.; sodium chloride (British Drug House's "analar" grade), twice recrystallized; and perchloric acid (Baker "analyzed" reagent). A stock solution of copper perchlorate (about 0.4 *M*), containing 0.1 *M* perchloric acid, was prepared, and analyzed iodometrically; other solutions were prepared by diluting the stock solution.

[1]*Manuscript received March 31, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

The results are given below in the form of tables of optical density at various copper concentrations. These original data are included because, as will be seen later, there are some difficulties in their interpretation, and their explanation is not entirely certain. Hence the original data are given so that any other possible explanations can be checked against them. All results were at an ionic strength of 2.00 (adjusted by sodium perchlorate), with a perchloric acid concentration of 0.300 M, and a sodium chloride concentration of 0.00748 M. The light path was 1.000 cm. Table I gives the optical densities. The comparison cell contained the same solution without the sodium chloride. Each measurement was repeated, and the setting at zero optical density for the comparison cell was checked after each measurement.

TABLE I

Optical densities of copper chloride at various wave lengths

COPPER BROMIDE MEASUREMENTS

As with copper chloride, earlier measurements were largely qualitative. Riley and Smith (4) used a cell, $Cu/CuSO_4/KNO_3/CuSO_4 + NaBr/Cu$, to obtain successive equilibrium constants; their value for K_1 was 2.1×10^6. Job (5) used spectrophotometric measurements to get 0.063 for K_1 (the first equilibrium constant). Näsänen (6), using a spectrophotometer, found K_1 to be 0.94 at 25° C. Farrington (7), in 1952, obtained 2.1 ± 0.25 for K_1, at $22\pm2°$ C and at unit ionic strength.

In the present work the reagents and method were the same as for copper chloride, except that recrystallized sodium bromide was used in place of sodium chloride. The results in Table II are for an ionic strength of 2.00, with perchloric acid at 0.300 M, and sodium bromide at 0.00839 M. As before, the light path was 1.000 cm, and the comparison cell contained the same solution without the sodium bromide.

DISCUSSION OF RESULTS

If we assume that, because of the high copper and low halide concentration, the only complex ion present is CuX^+ (X = Cl or Br), then the law of mass action gives

$$\frac{D/\epsilon_1}{(a-D/\epsilon_1)(b-D/\epsilon_1)} = K_1$$

where a is the total copper concentration,
b is the total halide concentration,
D is the optical density,
ϵ_1 is the extinction coefficient,
K_1 is the equilibrium constant for $Cu^{++} + X^- \rightleftharpoons CuX^+$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

If $a \gg b$, this can be rearranged (as was first done by Rabinowitch and Stockmayer for an analogous system (8)) to give

$$\frac{a}{D} = \frac{1}{K_1 b \epsilon_1} + \frac{a}{b\epsilon_1}.$$

Hence a plot of a/D for any wave length against a should give a straight line, from the slope and intercept of which K_1 and ϵ_1 can be found. The present data give at least nearly straight lines for this plot. If the best straight lines are drawn through the data by the method of least squares the calculated values of K_1 and ϵ_1 are as given in Table III.

TABLE III
Values of K_1

Compound	Temp., °C	295	290	285	280	275	270	265	260	Mean

	25	.923	.939	.984	.921	.943	.943	.946	.997	.952	0.95
	40	.913	.870	.884	.807	.804	.805	.844	.846	—	0.85

Two comments can be made on these results. At any one temperature, the K_1 values usually drift in a characteristic way with wave length, being higher at the high and low wave lengths and lower in the middle. This drift is not large, but it seems to be definite. Secondly, the average K_1 values give a rather unexpected change with temperature, in that the usual log K against $1/T$ plot is not linear. This is particularly marked with copper bromide, where K_1 at first rises with temperature and then falls. This is confirmed from the results in Table II, where the optical densities were followed in a more detailed way over a range of temperature. The mean values of K_1 calculated from Table II are

temp.:	12.0	20.0	25.0	30.0	35.0	40.0,
K_1:	0.72	0.85	0.98	0.96	0.89	0.83.

The corresponding values of the extinction coefficient for CuX^+ ions are given in Table IV.

TABLE IV

With $CuCl^+$ the absorption band advances steadily towards the red as the temperature is raised; this is what is to be expected if the band is widened at higher temperatures. However, with $CuBr^+$ the absorption maximum rises slowly at first and then rapidly at higher temperatures.

These results, particularly the effect of temperature on K_1, need further explanation. Various possibilities will now be considered.

1. Rapidly Changing Heat of Reaction

The equation $d \ln K/dt = \Delta H/RT^2$ will, of course, only give a linear relation between $\ln K$ and $1/T$, if it is assumed that ΔH is independent of temperature. If C is the specific heats of the products minus those of the reagents, ΔH will be of the form $\Delta H = B+CT$, where B is a constant. If C is assumed to be independent of temperature, then integration gives $\ln K = A - B/RT + (C/R) \ln T$, where A is an integration constant. Hence measurements of K at three (or more) temperatures will allow A, B, and C to be evaluated. If this is done for the K_1 values quoted above, for temperatures 12.0, 25.0, and 40.0° C, the results are

$$\Delta H = 30040 - 95.5T \qquad \text{for } Cu^{++}+Cl^- \rightleftharpoons CuCl^+$$
$$\Delta H = 134200 - 446.5T \qquad \text{for } Cu^{++}+Br^- \rightleftharpoons CuBr^+$$

or if T is in °C: $CuCl^+$: $\Delta H = 3960 - 95.5T$ (°C); $CuBr^+$: $\Delta H = 12260 - 446.5T$ (°C).

These values of C seem impossibly high, since C is the difference in specific heats of relatively simple ions in solution. It is true that the sign of C makes the specific heat of the two simple ions larger than that of the complex ion, as might be expected, but the difference seems impossibly large. If these effects are genuine, it might be expected that they would also show up in the specific heats of copper chloride solutions, on which some data are available. Marignag (9) gives the specific heat of copper chloride solutions as

molar ratio, water/copper chloride:	25	50	100,
specific heat/g solution:	.779	.864	.920 cal/°C.

It is very uncertain how these figures should be interpreted, but if the concentrations of Cu^{++}, $CuCl^+$, and Cl^- ions are calculated in each solution, and if it is assumed that each ion has a certain specific heat/gram molecule, and that these are strictly additive (the specific heat of the water present being taken as that in pure water), then the above results require the specific heats/gram molecule of each ion to be $Cu^{++}-171$, $CuCl^+-21$, Cl^-+49 cal/°C. Hence the difference in specific heats between $CuCl^+$ and $Cu^{++} + Cl^-$ is +101 cal/°C. Although this is large, it is of the wrong sign to explain the equilibrium constant results. Thus quite apart from the question of the justification of treating specific heat results in this simplified way, the specific heats do not support the view that the heat of reaction changes rapidly with temperature.

2. Deviations from the Beer–Lambert Law

It is necessary to assume the accuracy of the Beer–Lambert law in colorimetric investigations of complex ions, since otherwise no evaluation of equilibrium constants would be possible. Evidence for the Beer–Lambert law is obtained from the internal consistency of results, but it is usual to avoid having any very high concentration of the colored species present, since deviations are generally small at low concentrations. In the present work, the $CuCl^+$ concentration varied from about 7 to 15×10^{-4} M, and the $CuBr^+$ concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

from 8 to 18×10^{-4} M. It can be calculated that if the equilibrium constant for $CuBr^+$ was really unchanged with temperature, and its apparent rise and fall were entirely due to variations in the extinction coefficient, then the extinction coefficient of $CuBr^+$ would have to change by about 10% over the range of concentration given above (at any one temperature). This seems to be too rapid a change for such small concentrations.

3. Occurrence of Other Complex Ions

Another, and perhaps more plausible, possibility is that some other complex ion occurs in those solutions. Since the copper concentration is high and halide low, the only reasonable suggestion is that the ion Cu_2X^{+3} (where X is a halogen) is present. Ions of this type have not been often postulated, but they are not really inherently improbable, since halogen atoms are known to hold two metal atoms together in various compounds, for instance Al_2Cl_6. One other consideration shows that this is a possible ionic type: suppose that CuX^+ is purely an ion pair association, with r the distance between ionic centers, then the electrostatic energy of formation of CuX^+ is $2e^2/r$, where e is the electron charge. Similarly for Cu_2X^{+3} the energy is $2e^2/r$, but for Cu_3X^{+5}, assumed to be flat, it would be $-0.93e^2/r$. Hence CuX^+ and Cu_2X^{+3} might be stable, but probably not Cu_3X^{+5}. This, of course, is an oversimplified picture, since covalent binding is ignored, but it gives a qualitative indication of what to expect.

If we postulate the existence of Cu_2X^{+3}, then this introduces a new equilibrium constant $K_2 = [Cu_2X^{+3}]/[Cu^{++}]^2[X^-]$ and the extinction coefficient for Cu_2X^{+3}. Using the same nomenclature as earlier, this modifies the equation for a/D to

$$\frac{a}{D} = \frac{1+K_1a+K_2a^2}{b(K_1\epsilon_1+K_2\epsilon_2a)}$$

and if K_2 and a are not too large this gives approximately

$$\frac{a}{D} = \frac{1}{bK_1\epsilon_1}\left\{1+\left(K_1-\frac{K_2\epsilon_2}{K_1\epsilon_1}\right)a+\left[K_2-\frac{K_2\epsilon_2}{\epsilon_1}+\left(\frac{K_2\epsilon_2}{K_1\epsilon_1}\right)^2\right]a^2\right\}.$$

In theory any four measurements should suffice to evaluate K_1, K_2, ϵ_1, and ϵ_2, but it is better to combine all the data at one wave length to get the best values of these quantities. The plots of a/D against a are nearly straight lines, but many of them show a slight curvature. Accordingly the best equation of the type $a/D = A+Ba+Ca^2$ was fitted by the method of least squares to the experimental data, thus giving numerical values of A, B, and C. A comparison of the two expressions for a/D shows that

$$K_2-K_1\left(\frac{B}{A}\right) = \frac{C}{A}-\left(\frac{B}{A}\right)^2.$$

A, B, and C, of course, vary with wave length. Hence a graph of B/A against $C/A-(B/A)^2$ should give a straight line, using data at one temperature but various wave lengths, since K_1 and K_2 are constants. As will be seen, these graphs were in fact moderately good straight lines, although the points were somewhat scattered. The small curvature of the original a/D graph makes the accuracy rather low. The best straight line was drawn through the values of B/A plotted against $C/A-(B/A)^2$; this gives K_1 and K_2, and the extinction coefficients can be found as $\epsilon_1 = 1/K_1Ab$, and $\epsilon_2 = (K_1-B/A)/K_2Ab$.

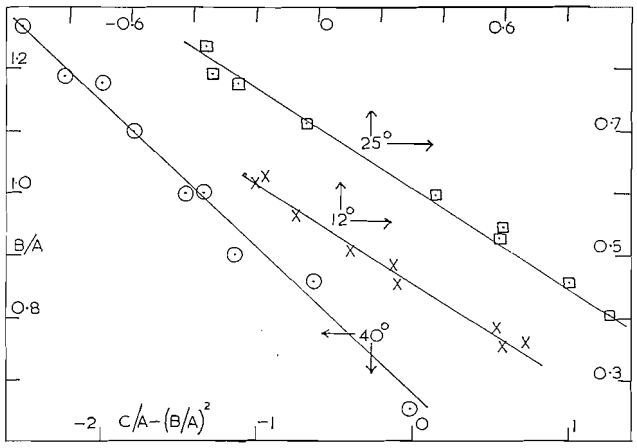

FIG. 1. Copper bromide.

The results of this treatment were as follows. Figure 1 gives the graph of B/A plotted against $C/A-(B/A)^2$ for copper bromide at various temperatures. The points are at least approximately linear. The constants calculated from these lines are as follows:

Copper bromide			Copper chloride		
Temp.	K_1	K_2	Temp.	K_1	K_2
12° C	3.08	1.73	12° C	3.92	3.40
25° C	3.56	2.31	25° C	5.47	5.21
40° C	4.15	2.77	40° C	7.35	7.79

For copper bromide, log K_1 plotted against $1/T$ gives a reasonably good straight line corresponding to $\Delta H = 1.9$ kcal; log K_2 gives only a moderately straight line corresponding to ΔH of about 3.0 kcal. For copper chloride, these give reasonably linear log K against $1/T$ plots: ΔH from K_1 is 4.0 kcal, and 5.2 kcal from K_2.

The calculated extinction coefficients are as follows:

Copper bromide		305 mμ	300	295	290	285	280	275	270	265
ϵ_1	12° C	50	68	75	86	94	95	91	78	62
	25° C	66	82	98	109	118	120	110	97	77
	40° C	78	91	113	125	131	127	120	99	77
ϵ_2	12° C	244	278	359	396	438	440	395	349	301
	25° C	267	315	374	431	444	431	384	330	268
	40° C	384	479	502	555	600	601	517	467	377

Copper chloride		295 mμ	290	285	280	275	270	265	260
ϵ_1	12° C	16	22	31	46	66	98	144	187
	25° C	17	23	35	50	71	106	152	192
	40° C	—	28	39	57	82	116	158	194
ϵ_2	12° C	68	87	113	158	259	375	496	758
	25° C	93	123	142	196	342	494	620	887
	40° C	—	163	239	328	477	682	948	1293

For personal use only.

Although the behavior of the equilibrium constants is as might be expected, the extinction coefficients are sufficiently surprising to cast doubt on the interpretation of the experimental results through the postulation of Cu_2X^{+3} ions. In particular the absorption maxima for $CuBr^+$ and Cu_2Br^{+3} increase with temperature, and for Cu_2Br^{+3} the increase is disproportionately large at 40° C. The copper chloride results are less unusual, since the absorption only shifts to longer wave lengths at higher temperatures. However, in both cases ϵ_2/ϵ_1 seems unduly large, particularly at the absorption maximum for copper bromide.

To sum up, the linearity of the plots of B/A against $C/A-(B/A)^2$, and the more regular behavior of K_1 and K_2 with temperature favor an explanation in terms of Cu_2X^{+3}; against it is the anomalous behavior of the extinction coefficients. Thus, although there is some support for a suggestion of Cu_2X^{+3} ions, the matter cannot be definitely decided.

Cobalt and Nickel Chloride

Because of the striking color change when cobaltous ions form complexes with chloride, this system has been the subject of considerable investigation, starting with the early work on ion migration by Donnan and Bassett (10). Job (11), using a spectrophotometer, obtained evidence for $CoCl^+$ and $CoCl_3^-$, with K_1 for $CoCl^+$ equal to 4.5×10^{-3}. In 1949, Bobtelsky and Spiegler (12) investigated cobalt chloride in ethanol water mixtures, and similar measurements were made by Katzin and Gebert (13), and by Barvinok (14): these workers all found evidence of $CoCl_2$ and $CoCl_4^{--}$. Moore and Kraus (15) used anion exchange resins to investigate cobalt (II) in hydrochloric acid solutions, and obtained evidence for $CoCl_3^-$ and $CoCl_4^{--}$. However, Moore, Gootman, and Yates found evidence only for $CoCl_2$ from vapor pressure measurements (16).

The situation with respect to nickel chloride is similar, though there is less early work. Kiss and Csokan in 1941 (17) investigated nickel chloride in hydrochloric acid, obtaining evidence for $NiCl_4^{--}$ in concentrated solution. Moore and Kraus (15) examined its ion exchange behavior, obtaining evidence that anionic species were formed only to a very small extent. Beaver, Trevorrow, Estill, Yates, and Moore (18) examined nickel chloride in 2-octanol obtaining evidence for $NiCl_2$ and $(NiCl_2)_n$, and for complex ions. Herber and Irvine in 1956 (19) found evidence for $NiCl_3^-$ and $NiCl_4^{--}$ by ion exchange, but optical measurements indicated only $NiCl^+$ up to high hydrochloric acid concentrations.

The present work was undertaken initially to investigate the extent of formation of the first complex, $CoCl^+$ or $NiCl^+$, and the variation of this with temperature. However, as will be seen below, the results also provide evidence of the existence of ions of the type M_2Cl^{+3}, where M is the metal.

In the first instance, spectrophotometric measurements were made. However, even up to 0.12 M chloride, the effect of chloride was so slight over the range 240–900 mμ, that this method seemed to offer no prospects of success. In fact, one must conclude either that $NiCl^+$ is not formed, or that its absorption spectrum is very like that of Ni^{++}. The situation with cobalt was found to be very similar. Accordingly measurements were made by another method, by the use of the e.m.f. of cells, to decide between these two alternatives. Here evidence for MCl^+ was obtained, and it seems to be necessary to conclude that for both nickel and cobalt the spectrum of MCl^+ is very like that of M^{++}.

Apparatus and Method

The measurements made were on the e.m.f. of the cell: Ag, AgCl/NaCl+$M(ClO_4)_2$+$NaClO_4$/NaCl+$NaClO_4$/AgCl, Ag, where M is cobalt or nickel. The two electrolytes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

were adjusted to the same ionic strength and acidity by means of sodium perchlorate and perchloric acid. The sodium chloride concentrations in the two solutions were the same; so the only difference was the presence in one side of cobalt or nickel perchlorate, with an adjustment of the sodium perchlorate concentration to keep the ionic strengths equal. The sodium perchlorate was much more concentrated than the chloride (0.008 *M*).

The silver/silver chloride electrodes were prepared as recommended by Janz and Taniguchi (20). The electrodes so prepared gave voltages of 0.02 mv or less when placed in the same solution, this difference being found and allowed for in the subsequent calculations. The two sodium chloride solutions were separated by a salt bridge, sodium perchlorate being used for this. The voltage was measured on a Leeds and Northrup K-2 potentiometer. The cell, of course, was at constant temperature during use. Nickel and cobalt perchlorate from the G. Frederick Smith Co. were used in making up the solutions: the concentrations of the solutions were determined by E.D.T.A. titration for cobalt with murexide indicator (21), and by dimethylglyoxime for nickel.

RESULTS

The observed e.m.f. are given in Table V. In interpreting these results it has to be assumed that the liquid junction potentials cancel as a result of the similar concentrations and ionic strengths of the solutions on each side of the salt bridge. This assumption is

	25	1.83	2.25	3.05	3.44	3.84	4.29	4.61	5.05	
	40	2.10	2.55	3.43	3.87	4.31	4.77	5.22	5.73	

NOTE: Ionic strength = 2.0; $[HClO_4] = 0.300$ *M*.

supported by the consistency of the equilibrium constants calculated from the results. The voltages were very steady with time, which supports this assumption. In the calculations below it was assumed that the great excess of sodium perchlorate made it the effective conductor of the current. Since all runs were made with very low chloride concentration and relatively high metal, it is reasonable to assume (as for copper) that the complex ions are MCl^+ (formation constant K_1) and M_2Cl^{+3} (formation constant K_2). If, as before, a is the total metal concentration, and b the total chloride, and if $a \gg b$, and if u is the concentration of free chloride in the solution containing cobalt or nickel, then it is easily shown that $b/u = 1+K_1a+K_2a^2$. But b/u is the ratio of the chloride in the two solutions, and, assuming that the activity coefficients are equal at the same ionic strengths, then

$$E = \frac{RT}{nF} \ln(b/u)$$

where E is the cell voltage. Hence b/u can be found. The first equation can be rewritten: $(b/u-1)/a = K_1+K_2a$. If only MCl^+ is formed $(b/u-1)/a$ will be constant; otherwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

it should increase linearly with a. Table VI gives the calculated values of $(b/u-1)/a$.

These values of $(b/u-1)/a$ are approximately linear when plotted against a, although there is evidently some random error. If the best straight line is drawn through them by the method of least squares, the following constants are obtained.

Compound	Temp.	K_1	K_2
$CoCl_2$	12° C	.611	.263
	25° C	.666	.274
	40° C	.711	.327
$NiCl_2$	12° C	.508	.426
	25° C	.569	.407
	40° C	.620	.409

The K_1 values give ΔH as 1.0 kcal for $Co^{++} + Cl^- \rightarrow CoCl^+$, and 1.25 kcal for $Ni^{++} + Cl^- \rightarrow NiCl^+$. It is impossible to calculate heats of reaction for the formation of M_2Cl^{+3}, except to say that here ΔH must be very small. Thus, if this interpretation of the results is correct, the complexes M_2Cl^{+3} are formed nearly as easily as MCl^+. While this interpretation is certainly possible, it cannot be considered as proved.

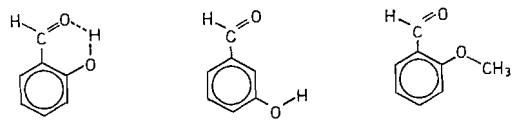
THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART V. INTRAMOLECULAR HYDROGEN BONDING IN ANILINES AND PHENOLS[1]



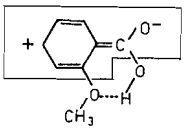
J. C. Dearden[2] and W. F. Forbes[3]

ABSTRACT

Information concerning intramolecular hydrogen bonding in phenols and anilines can be obtained from ultraviolet spectra by a variety of methods. One method is to note the spectral changes observed between the corresponding *o*-substituted phenols and anisoles. A second method is to compare the spectral changes between *o*-substituted phenols or anilines and the corresponding meta isomers. A third method is to note the absence of an appreciable spectral change, on altering the solvent conditions, which may also indicate the formation of an intramolecular hydrogen bond. The conclusions deduced from the three methods confirm previously stated generalizations concerning the nature of the hydrogen bond. One notable exception is that the spectral changes ascribed to the intramolecular hydrogen bond in *o*-nitrophenol can be explained in terms of an electrostatic model of the hydrogen bond.

INTRODUCTION

Intramolecular hydrogen bonds are known to cause bathochromic wavelength displacements in some of the absorption bands of the ultraviolet spectra. In order to obtain a quantitative measure of this effect for intramolecularly bonded phenols or anilines such as salicylaldehyde (IA), a reference compound must be available against which the wavelength displacement can be measured. This reference compound may be provided either by the corresponding *m*-isomer, for example *m*-hydroxybenzaldehyde (IB), or by the otherwise similar O-methyl- or N-methyl-substituted compound, for example *o*-methoxybenzaldehyde (IC). In the absence of interfering interactions both methods



IA IB IC

should afford similar results. Moreover, some of the absorption bands of systems containing an intramolecular hydrogen bond should be less affected by competitive intermolecular hydrogen bonding between solute and solvent molecules than otherwise similar, but non-intramolecularly bonded, molecules.

However, the following considerations may affect the reliability of the observed spectral changes: (i) The absorption band under consideration may be determined by that part of the chromophoric system which does not contain the intramolecular hydrogen bond and consequently this absorption band will not be appreciably affected by intramolecular hydrogen bonding. For example, the similarity of the benzoic acid *B*-bands for *o*-methoxybenzoic acid and benzoic acid is explained by assuming that the intramolecular hydrogen bond in *o*-methoxybenzoic acid does not appreciably affect the

II

resonance form of type II, which can be assumed to determine predominantly the observed absorption band (see ref. 1). (ii) Steric interactions and other proximity effects, which almost always operate in *o*-disubstituted benzene derivatives, may be appreciably different in the intramolecularly hydrogen-bonded compound and in the reference compound. For example, in cyclohexane solution the nitrobenzene *B*-band of *o*-nitroanisole shows a hypsochromic wavelength displacement of ca. 11.5 mμ from this same band in *m*-nitroanisole (2*a*). This hypsochromic displacement is associated with steric and other short-range interactions between the methoxy and the nitro groups. It follows that *o*-nitroanisole cannot be assumed to provide a satisfactory reference compound for estimating intramolecular hydrogen bonding in *o*-nitrophenol. (iii) The absence of spectral changes with change of solvent may be caused by a strong intermolecular hydrogen bond, but it may *also* be caused by steric hindrance preventing solvent–solute interaction. For example, *o*-substituted phenols such as 2,6-di-*tert*.butyl phenol in which the ortho substituents are large, do not show the usual wavelength displacements if the spectra are determined in cyclohexane and ethanol solution, presumably because the large *o*-substituents prevent solvent–solute interactions (cf. ref. 2*b* and references cited there).

The purpose of the present paper is to summarize the spectral changes which can be ascribed with some degree of confidence to intramolecular hydrogen bonding, and to deduce from the data certain generalizations concerning the intramolecular hydrogen bond in phenols and anilines.

THE INTRAMOLECULAR HYDROGEN BOND IN SOME ORTHOSUBSTITUTED PHENOLS AND ANILINES

Salicylaldehyde

The relevant ultraviolet and infrared spectra of salicylaldehyde (IA) and *m*-hydroxybenzaldehyde (IB) are listed in Table I. The intense infrared carbonyl band at 1666 cm^{-1} for salicylaldehyde occurs at lower frequency than for *m*-hydroxybenzaldehyde (1700 cm^{-1}) or for benzaldehyde (1709 cm^{-1}) (see Table I) and this then indicates an intramolecular hydrogen bond in salicylaldehyde (cf. also refs. 3, 4, 5, 6).* It may also be noted that the O—H stretching frequencies of phenol and salicylaldehyde occur near 3600 and 3200 cm^{-1} respectively (7). Salicylaldehyde may therefore be taken as an example of an intramolecularly hydrogen-bonded compound where, moreover, steric interactions are likely to be small. In *n*-hexane solution, the benzaldehyde ultraviolet *B*-band of salicylaldehyde shows a slight bathochromic wavelength displacement compared with the same *B*-band in *m*-hydroxybenzaldehyde and this displacement is accompanied by an increase in the maximal extinction coefficient (ϵ_{max}) from 9500 to 11,700 (see Table I). In the corresponding methoxybenzaldehydes no significant wavelength displacement is

**The other infrared bands listed in Table I are presumably to be associated with aromatic* C—H *vibrations which usually occur in this region; it is worth noting that for benzaldehyde and salicylaldehyde at least three fairly intense bands occur in this region. It is therefore possible, though considered unlikely, that the band at 1644 cm^{-1} in salicylaldehyde also represents a carbonyl band.*

m-Hydroxybenzaldehyde	Ether			249 *253–254*	9,700 *9,200*	308 *311* *316*	3,250 *3,200* *3,050*	—	—

*See also ref. 2*b*. †Band nomenclature in this and subsequent tables is as generally used in ref. 2. ‡Values in italics represent inflections in this and subsequent tables. §In 0.1 *N* ethanolic NaOH this band occurs at ca. 232 mμ. It is therefore believed to be a phenolic *B*-band (see ref. 2*b*).

observed between the *o*- and *m*-isomers and the increase in ϵ_{max} on passing from the *m*- to the *o*-isomer is from 9200 to 10,500, that is, somewhat less than for the hydroxybenzaldehydes (see ref. 2*a*). Since, therefore, steric interactions in *o*-methoxybenzaldehyde do not give rise to appreciable wavelength displacements, the small wavelength displacement in the *B*-bands between salicylaldehyde and *m*-hydroxybenzaldehyde may be taken as an indication of intramolecular hydrogen bonding in salicylaldehyde as shown in IA.

The phenolic *B*-band also shows a slight bathochromic displacement (2 mμ) relative to the same band in *m*-hydroxybenzaldehyde and this displacement may also be related to hydrogen-bond formation. Three possible factors may account for this latter spectral change: (i) the displacement may occur because the hydrogen atom tends to become detached from the phenolic hydroxy group in the course of hydrogen-bond formation and hence the absorption maximum may tend towards that of the phenolate ion, (ii) the displacement may occur because of steric or other reasons since the hydrogen bond may cause the hydroxy group to rotate from its normal position in phenol (cf. ref. 2*b*), and (iii) the hydrogen bond may affect the vibrational levels of the hydroxy group in such a way as to cause the observed spectral change. *C*-Band data of salicylaldehyde and the other compounds studied are listed in Table I and subsequent tables. Their significance will be discussed in the Concluding Remarks.

The spectrum of salicylaldehyde compared with that of *o*-methoxybenzaldehyde is altered in a similar way. That is, compared with *o*-methoxybenzaldehyde both *B*-bands are again shifted to longer wavelength and these wavelength displacements are of the same order as between salicylaldehyde and *m*-hydroxybenzaldehyde (see Table I).

Next, it may be noted that the ultraviolet spectra of salicylaldehyde in cyclohexane and ether solution are more similar than, for example, the spectra of *m*-hydroxybenzalde-

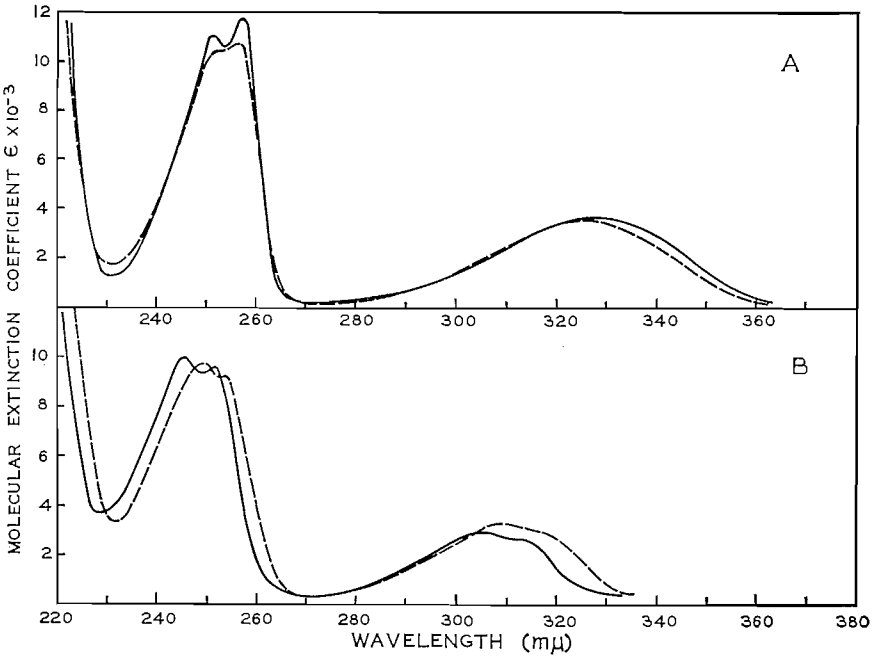

FIG. 1. The spectra of (A) salicylaldehyde and (B) *m*-hydroxybenzaldehyde in *n*-hexane (———) and ether (– – –) solutions.

hyde in these two solvents (see Fig. 1). The lack of any appreciable spectral change, particularly in the *C*-band, accompanying the solvent change for the spectrum of salicylaldehyde may again be ascribed to the presence of a strong intramolecular hydrogen bond.

All the above-mentioned spectral changes for salicylaldehyde can therefore be rationalized in terms of an intramolecular hydrogen bond, which can be schematically represented as shown in structure III.

III IV

o-Hydroxyacetophenone

The relevant ultraviolet spectral data are listed in Table II. The infrared spectrum of *o*-hydroxyacetophenone again shows the presence of an intramolecular hydrogen bond (cf. refs. 8, 9, and references cited there). It may also be noted that whereas the carbonyl band of *o*-hydroxyacetophenone does not show a doublet, the infrared carbonyl bands of compounds like *m*-hydroxyacetophenone (ν_{max} 1688 and 1678 cm^{-1}), *o*-chloro- and *o*-bromo-acetophenone (10) do show doublets in carbon tetrachloride solution. If structure IV indeed represents the predominant form of *o*-hydroxyacetophenone one would anticipate a number of similarities between the ultraviolet spectra of salicylaldehyde and *o*-hydroxyacetophenone and these are in fact observed (see Table II and cf. Table I).*

o-Nitrophenol

The infrared hydroxyl band of *o*-nitrophenol shows one intense band at 3209 cm^{-1} with only low-intensity absorption at higher frequency (see Fig. 2). The position of this band (see ref. 9, p. 84, Table VI and refs. 11 and 12) as also the absence of any observed concentration dependence of the band (see Experimental) indicates that the band corresponds to an intramolecularly hydrogen-bonded form. The NO_2-valence

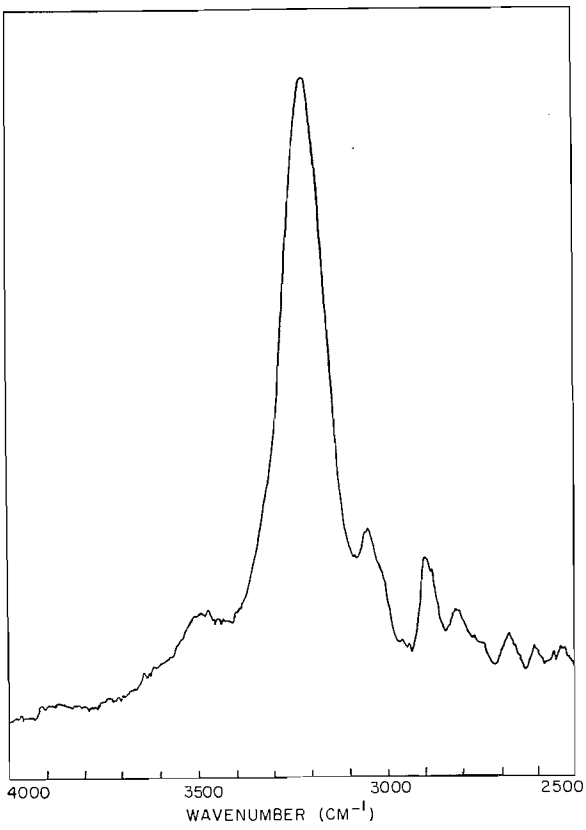

FIG. 2. The —OH stretching absorption band (3209 cm^{-1}) of *o*-nitrophenol, due to intramolecular hydrogen bonding (0.20 molar solution in carbon tetrachloride).

**The slightly greater displacement in o-hydroxyacetophenone compared with the o-methoxy compound is probably caused by steric interactions in the latter compound. This suggestion also receives support since for o- and m-methoxyacetophenones the acetophenone B-bands are no longer similar as they are for the corresponding benzaldehydes, but the o-isomer now absorbs at shorter wavelength indicative of steric interactions (see ref. 2a).*

vibration, for reasons which will be discussed later, is not particularly influenced by intramolecular hydrogen bonding (cf. ref. 12).

TABLE III

Main ultraviolet maxima for *o*-nitrophenol and reference compounds

o-Nitroanisole	Ethanol	ca. *231*	*5,000*	257	3,200	319	2,350

The relevant ultraviolet data are listed in Table III and again confirm the presence of an intramolecular hydrogen bond in *o*-nitrophenol. The nitrobenzene *B*-band of *o*-nitrophenol compared with that of *m*-nitrophenol is more appreciably displaced (by 12.5 mμ) and intensified (see Table III). Compared with *o*-nitroanisole even larger wavelength displacements are observed but steric interactions preclude the use of *o*-nitroanisole as a suitable reference compound (see Introduction). The phenolic *B*-band data (see Table III) also show the anticipated wavelength displacements (see previous sections) but show a surprisingly large decrease in the ϵ_{max} value for the *o*-isomer. Next, the absence of appreciable wavelength changes for *o*-nitrophenol on changing the solvent from cyclohexane to ether and ethanol may also again be taken as evidence for a strong intramolecular hydrogen bond (see Table III and Fig. 3).

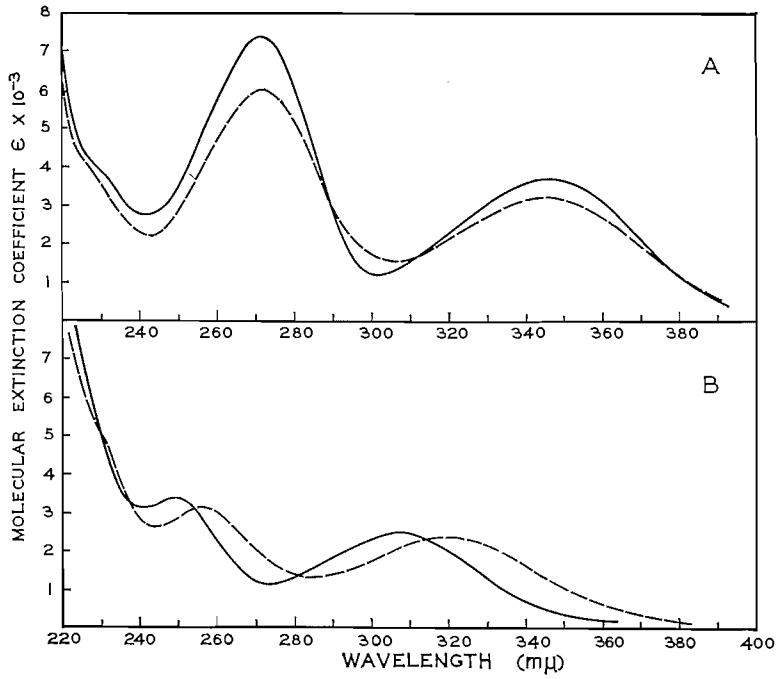

FIG. 3. The spectra of (A) *o*-nitrophenol and (B) *o*-nitroanisole in cyclohexane (———) and ethanol (– – –) solutions.

As previously shown, the wavelength displacement between *o*-nitrophenol and *o*-nitroanisole cannot be used directly as a measure of the intramolecular hydrogen bonding because of steric interactions in *o*-nitroanisole. However, additional substituents in the benzene ring, not vicinal to the nitro or methoxy substituents, are unlikely to affect these steric interactions; hence the above-mentioned wavelength displacements may be used as a measure of the strength of the intramolecular hydrogen bond in compounds of the type as listed in Table IV, where comparison with a *m*-isomer is not possible. The spectra of the compounds listed in Table IV were collected in order to investigate whether a substituent in the absence of additional steric interactions affects the strength of an intramolecular hydrogen bond.

The infrared frequency displacements listed in Table IV indicate that the intramolecular hydrogen bond is progressively strengthened by a chloro and a methoxy substituent, if these substituents are *para* with respect to the nitro group (cf. ref. 9, p. 84, Table VI). This strengthening of the intramolecular hydrogen bond, for a *p*-methoxy substituent, would also have been anticipated from benzoic acid data since a *p*-methoxy substituent apparently strengthens the dimeric hydrogen bond in benzoic acid (1). Moreover, using resonance symbols, both *p*-chloro- and *p*-methoxy substituents would be anticipated to give rise to increased contributions of resonance forms of type V which might be expected to favor the formation of an intramolecular hydrogen bond.

The ultraviolet spectral changes (if expressed in wave numbers) show approximately parallel effects. That is, 5-chloro or 5-methoxy substituents give rise to slightly larger

V

frequency displacements between the nitrobenzene *B*-bands of the phenol and the anisole (indicative of a stronger intramolecular hydrogen bond) whereas the opposite effect is observed for 4-methyl, 4-methoxy, or 4-chloro substituents (see Table IV). The data in Table IV also show that the spectra of intramolecularly hydrogen-bonded compounds are again generally only slightly affected on being determined in ethanol solution.

A simple explanation to rationalize the spectral changes is as follows: The negative charge on the NO_2 oxygen atom is increased by a *p*-methoxy or a *p*-chloro substituent and this enhanced charge formation occurs for *both* nitrophenol and nitroanisole; it accounts for the bathochromic displacement in the ultraviolet nitrobenzene *B*-band for 5-methoxy- and 5-chloro-nitrophenol and for the corresponding anisoles relative to these bands in nitrophenol or nitroanisole. This increased negative charge on the NO_2 oxygen atom, only for the *o*-nitrophenol, now also attracts the hydrogen atom of the hydroxyl group and this accounts for the lower frequency of the O—H vibration in both 5-methoxy- and 5-chloro-2-nitrophenol relative to *o*-nitrophenol. The closer proximity of the hydrogen atom, however, does not apparently affect appreciably the negative charge on the NO_2 group in the ground state (see below), and this phenomenon can be explained by assuming an electrostatic model for *this* hydrogen bond.* This model for *o*-nitrophenol also accounts for the infrared NO_2 vibrational frequencies which are remarkably constant (1530 ± 2 cm^{-1}) for the following compounds: *o*-nitrophenol, *o*-nitroanisole (cf. also ref. 12 for the

*Since a "covalent" contribution would be anticipated to affect the negative charge on the nitro group it should be noted that this model does of course not necessarily hold for other intramolecularly bonded systems (cf., for example, the carbonyl bands described in the previous section which are appreciably affected by a vicinal hydroxy group).

reported, but unexplained similarity of the NO_2 vibrational frequency for these two compounds), 5-methoxy-2-nitrophenol, 4-methoxy-2-nitrophenol, 4-methyl- and 5-methyl-2-nitrophenol, and 4-chloro-2-nitrophenol* (see also Concluding Remarks) and ref. 13 for a discussion of the infrared N—O stretching frequencies).

Salicylic Acid

The relevant ultraviolet and infrared spectra are listed in Table V. The monomeric infrared carbonyl band for salicylic acid occurs at lower frequency than for benzoic acid or for *o*-methoxybenzoic acid (see Table V) and this then again indicates an intramolecular hydrogen bond involving the carbonyl oxygen atom (see also refs. 6, 14).

TABLE V

Ultraviolet *B*-bands and infrared carbonyl bands of salicylic acid and reference compounds

Compound	Solvent	Ultraviolet maximum*		Infrared carbonyl band† (in carbon tetrachloride), ν_{max} (cm^{-1})
		λ_{max}(mμ)	ϵ_{max}	
Salicylic acid	Cyclohexane	239	8,000	1,691
m-Hydroxybenzoic acid	Cyclohexane containing ca. 1% ether	233–234	6,800	Insufficiently soluble
Benzoic acid	Cyclohexane	230	12,500	1,744
o-Methoxybenzoic acid	Cyclohexane	230	8,300	1,749

*Spectra are determined at concentrations at which the monomeric species are believed to predominate (see ref. 1).
†Monomeric bands from ref. 1.

Supporting evidence for this hydrogen bonding is also obtained from the ultraviolet data listed in Table V, which show that the benzoic acid *B*-band in salicylic acid is bathochromically displaced compared with the same band in *m*-hydroxybenzoic acid; for the *o*- and *m*-isomers of methoxybenzoic acid on the other hand, the *m*-isomer absorbs at slightly longer wavelength (2*a*). Moreover, salicylic acid in ether is reported to absorb maximally at 237 mμ, ϵ = 7800 (15) which is close to the absorption of the monomeric species in cyclohexane solution (see Table V).†

TABLE VI

Main ultraviolet maxima for *o*-aminobenzaldehyde and reference compounds

Compound	Solvent	Aniline *B*-band		Benzaldehyde *B*-band		*C*-band	
		λ_{max}(mμ)	ϵ_{max}	λ_{max}(mμ)	ϵ_{max}	λ_{max}(mμ)	ϵ_{max}

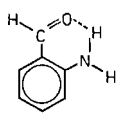
m-Aminobenzaldehyde*	Cyclohexane containing ca. 0.2% ether	228	17,500	ca. *244* ca. *257*	*9,000* *7,500*	331.5	2,000
Benzaldehyde	Hexane	—	—	242 *248*	14,000 *12,000*	279–280 289	1,200 1,000
Aniline*	Cyclohexane	234	9,000	—	—	289	1,900

*Data from ref. 2*e*.



**The same band in 5-chloro-2-nitrophenol occurs only at slightly lower frequency (ν_{max} 1521 cm^{-1}). It might also be noted that the infrared* O—H *vibrational frequencies listed in Table IV for various substituted nitrophenols are not proportional to the relevant* σ *values.*

†*Dannenberg (15) assumes that the intramolecular hydrogen bond causes a wavelength displacement of 16* mμ *but this value is probably too large since it is obtained by comparing the maximal absorptions of salicylic and o-methoxybenzoic acids; that is steric interactions, as mentioned in the Introduction may operate in the latter compound and these will tend to increase the apparent wavelength displacement ascribed to the intramolecular hydrogen bond.*

For personal use only.

o-Aminobenzaldehyde

The relevant ultraviolet data are listed in Table VI, and these data show that the wavelength displacements between the *o*- and *m*-isomers may again be taken as evidence of intramolecular hydrogen bonding. An interesting difference between the spectra of amino and hydroxy compounds is that only for the amino compounds are the ϵ_{max} values of the benzaldehyde *B*-band substantially decreased in the *o*-isomer compared with the ϵ_{max} values of the *m*-isomer (see Table VI, and compare also later tables). A possible explanation is that the intramolecular hydrogen bond prevents the alignment of the carbonyl group in the same plane as the benzene ring since steric interactions are well known to give rise to intensity decreases. A coplanar alignment would be expected to lead to a large ϵ_{max} value, and hydrogen bonding of type VI would have been expected to facilitate this same alignment. However, if the above explanation (i.e. the hydrogen bond preventing coplanar alignment) concerning the ϵ decrease is correct, it is necessary to postulate that the six-membered ring system, involving the intramolecular hydrogen bond as shown in structure VI, is not entirely coplanar. Another more general interpretation is that the coplanar hydrogen-bonded confirmation causes some of the "normal" transitions to be "forbidden." A third explanation may be provided by supposing that

VI

VII

there is a tendency for *both* N-hydrogen atoms to form intramolecular hydrogen bonds as shown in structure VII, and that in this process both the NH_2 and CHO groups are twisted out of the plane of the benzene ring. A similar explanation—that is, *two* hydrogen bonds being formed at the expense of coplanarity—may also hold for the intensity decrease observed for the *B*-band of *o*-aminobenzoic acid (see Table IX) and for the ϵ decrease as observed for the phenolic *B*-band in *o*-nitrophenol (see Table III and also Concluding Remarks).

o-Aminoacetophenone

Infrared data have previously indicated (10, 16) the presence of an intramolecular hydrogen bond for this compound and the present ultraviolet spectra support this hypothesis (see Table VII); that is, the acetophenone *B*-band relative to the same band

TABLE VII

Main ultraviolet *B*-bands and infrared carbonyl bands of *o*-aminoacetophenone and reference compounds

		Ultraviolet maxima						Infrared carbonyl bands* (in carbon tetrachloride)	
		Aniline *B*-band		Acetophenone *B*-band		*C*-band

For personal use only.

in the *m*-isomer is bathochromically displaced. The intensity of the *B*-band in *o*-aminoacetophenone is again decreased (cf. Table VI). Although the ultraviolet spectrum of *o*-aminoacetophenone is not completely unaffected on altering the solvent from cyclohexane to ethanol, the observed spectral changes are less than for the corresponding *m*-isomer and particularly the ϵ values remain strikingly similar.

The ultraviolet data for this compound have also been determined by Lutskii and Dorofeev (17), who obtain spectral data similar to those obtained by us for *o*- and *m*-aminoacetophenone. Lutskii and Dorofeev also show that for the corresponding N,N-dimethyl derivatives a *hypsochromic* wavelength displacement is obtained in the acetophenone *B*-band if the spectrum of the *o*-isomer is compared with that of the *m*-isomer. This is not unexpected and suggests the presence of steric interactions in the *o*-isomer of N,N-dimethylaminoacetophenone. It follows that the latter compound is unsuitable as a reference compound for measuring the strength of the intramolecular hydrogen bond in *o*-aminoacetophenone.

o-Nitroaniline

Infrared data for *o*-nitroaniline, as judged primarily from the N—H stretching frequencies, have been assumed to show the *absence* of an intramolecular hydrogen bond in this compound (18, 19). The NO_2 vibrational frequencies are again only slightly, or not at all, lowered in the *o*-isomer compared with these same frequencies in the *m*-isomer of nitroaniline (12, 18, 19). However, this evidence cannot perhaps be regarded as entirely conclusive since some interaction would be expected to occur between the two *o*-substituents in *o*-nitroaniline, and since also there is some evidence for this interaction from other infrared data (see refs. 20, 21). The question whether a hydrogen bond exists in the ground state of *o*-nitroaniline must therefore remain undecided although, as pointed out by Dyall and Hambly (18), there is at present no unambiguous evidence of such a hydrogen bond in *o*-nitroaniline.

TABLE VIII

Main ultraviolet maxima for *o*-nitroaniline and reference compounds

Compound	Solvent	Aniline *B*-band		Nitrobenzene *B*-band		*C*-band	
		$\lambda_{max}(m\mu)$	ϵ_{max}	$\lambda_{max}(m\mu)$	ϵ_{max}	$\lambda_{max}(m\mu)$	ϵ_{max}
o-Nitroaniline	Cyclohexane	228	18,000	271	5,000	375	5,000
m-Nitroaniline	Cyclohexane	234	15,300	ca. *266*	*4,000*	345	1,950
Nitrobenzene	Cyclohexane	—	—	252	9,000	ca. *280*	*1,500*
o-Nitroaniline	Ethanol	232	17,000	279	5,000	408	5,500
m-Nitroaniline	Ethanol	234	18,000			380	1,600
m-Nitroaniline	Ether	235	19,000	ca. *277*	*4,600*	373	1,800

This uncertainty is also reflected in the ultraviolet spectra (see Table VIII). On the one hand, a bathochromic wavelength displacement (of ca. 5 mμ) between the *o*- and *m*-isomers is observed in the nitrobenzene *B*-band; on the other hand, this *B*-band spectral change is less for *o*-nitroaniline than for *o*-aminoacetophenone, and on changing the solvent from cyclohexane to ethanol both *B*- and *C*-bands are appreciably more displaced for *o*-nitroaniline than for *o*-nitrophenol or *o*-aminoacetophenone.

A possible explanation is that the electronic perturbations, loosely ascribed to intramolecular hydrogen bonding, are of only minor importance *in the ground state* (cf. ref. 18 and also the dipole moment data for 2,4-dinitroaniline of Smith and Walshaw (22)), but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that these perturbations become more important in the electronic excited state and in this way give rise to the observed ultraviolet spectral changes. Even on this interpretation, however, it seems probable that intramolecular "hydrogen bonding" in *o*-nitroaniline is weaker than in most of the other *o*-amino or *o*-hydroxy compounds discussed in this paper.

o-Aminobenzoic Acid

The wavelength displacements between *o*- and *m*-isomers of aminobenzoic acid in ether and ethanol solution are ca. 8 and 6.5 mμ, respectively, for the ultraviolet benzoic acid *B*-band. The *C*-band ϵ_{max} values are appreciably larger in the *o*-isomer (see Table IX). These observations can in a general way be related to the existence of intramolecular hydrogen bonding or related interactions in *o*-aminobenzoic acid.

TABLE IX

Main ultraviolet maxima for *o*-aminobenzoic acid and reference compounds*

CONCLUDING REMARKS

In all the above *o*-substituted anilines or phenols, which may contain an intramolecular hydrogen bond, a bathochromic wavelength displacement of between 5 and 12.5 mμ (690 and 1780 cm^{-1}) is observed in the *B*-band compared with the *B*-band absorption in the corresponding *m*-isomer. (See Tables I–IX; the *B*-band referred to is the *B*-band associated with transitions involving predominantly that mono-substituted benzene derivative in which the substituent is electron-withdrawing.) Since for most of these compounds an intramolecular hydrogen bond is generally believed to be present, this suggests that intramolecular hydrogen bonding or related interactions contribute to this wavelength displacement. If this interpretation is correct this also indicates that intramolecular hydrogen bonding or related interaction give rise to approximately the *same* amount of electronic perturbation for most of the compounds discussed ($\Delta\nu$ = 1175 ±215 cm^{-1}), except that for *o*-nitroaniline the observed wavelength displacement is smaller (690 cm^{-1}) and larger for *o*-nitrophenol (1780 cm^{-1}).

Evidence which can be interpreted in terms of an intramolecular hydrogen bond affecting *all* the above-mentioned compounds in a similar manner can also be deduced from the corresponding *C*-band spectral changes (see Tables I to IX). Apart from bathochromic wavelength displacements, the intensity of the *C*-band is also consistently increased in the *o*-isomer but this increase is not exclusively caused by intramolecular hydrogen bonding since it is very pronounced for *o*-nitroaniline compared with *m*-nitroaniline, although *o*-nitroaniline is not believed to contain a strong intramolecular hydrogen bond. Moreover, this intensity increase in the *C*-band is also observed for compounds like *o*-methoxyacetophenone compared with *m*-methoxyacetophenone (2*a*) although *no* intramolecular hydrogen bond is possible in the former compound. This suggests that *C*-band spectral changes are less reliable than *B*-band spectral changes in estimating the strength of an intramolecular hydrogen bond (cf. also ref. 2*d*).

The absence of an appreciable spectral change on determining the ultraviolet spectrum of a molecule in cyclohexane and ether or ethanol solution also provides support for the supposed presence of a strong intramolecular hydrogen bond. This argument is particularly convincing if the *m*-isomer or other reference compound shows an appreciable spectral change on altering the solvent in an identical manner (see Figs. 1 and 3 and Tables I, II, III, IV, and VII); only for *o*-nitroaniline the observed wavelength displacements point *against* the presence of an intramolecular hydrogen bond (the intensity values, however, again remain similar for the spectrum of *o*-nitroaniline in cyclohexane and ethanol). As anticipated, the concept of competitive hydrogen bonding is also indicated by some of the infrared data. For example, on determining the O—H vibrational band for a number of phenols under various solvent conditions, phenol affords frequency displacements of up to 300 cm^{-1}, *p*-nitrophenol affords frequency displacements of over 400 cm^{-1}, whereas the frequency displacements in *o*-nitrophenol for the same solvent range are never greater than 66 cm^{-1} (11). For salicylaldehyde both carbonyl band frequencies as also band intensities remain similar in carbon tetrachloride, chloroform, *n*-butanol, and even in acetonitrile (23).

There is also other evidence that the above eight compounds do not contain a similar intramolecular hydrogen bond. For example for phenols the ϵ_{max} value of the *B*-band not associated with the phenol or aniline system is usually increased substantially in the *o*-isomer compared with the same band in the *m*-isomer (see Tables I to V), but this same ϵ_{max} value is generally *reduced* for *o*-substituted anilines. Next, the other *B*-band, associated with the phenol or aniline chromophore, is only slightly affected if the spectrum of the *o*-isomer is compared with that of the *m*-isomer; however, a small *bathochromic* wavelength displacement is usually observed for the *o*-substituted phenol (see Tables I–III), whereas a small *hypsochromic* displacement is observed for *o*-aminoacetophenone (see Table VII). *o*-Nitroaniline may be exceptional since a slight bathochromic displacement is observed relative to the *m*-isomer and also since for *o*-nitroaniline the ϵ_{max} value of this band is increased (cf. Table VIII and other tables). Moreover, infrared spectral changes are also dissimilar. For example, the data in reference 6 show that the estimated frequency displacements of the O—H stretching bands are different for *o*-nitrophenol, salicylaldehyde, and salicylic acid. The reason for these differences remains obscure. A possible partial explanation is that the formation of N—H- - -O bonds tends to twist the carbonyl group out of the plane of the benzene ring, possibly to form hydrogen bonds or related interactions with *both* of the hydrogen atoms of the NH_2 group as shown in structure VII. This could account for some of the spectral differences observed between *o*-substituted anilines and phenols, but does not account for the anomalous spectral changes in *o*-nitroaniline. There is incidentally no evidence that an intramolecular O—H- - -O bond is stronger than an intramolecular N—H- - -O bond although precisely this relationship is indicated for the corresponding *inter*molecular hydrogen bonds (24).

Perhaps the most important deduction is that the data provide no evidence for other than an electrostatic linkage in the compounds discussed in this paper. That is, covalent-type hydrogen-bonded structures tend to be excluded for *o*-nitrophenols because the N—O stretching vibrations remain practically unaffected by the intramolecular hydrogen bond or related interactions for a number of substituted *o*-nitrophenols and for *m*-nitrophenol. (A covalent-type linkage would be expected to affect the N—O bond order and consequently the infrared stretching bands.) For some of the other compounds studied in this paper, for example *o*-hydroxy- and *o*-amino-acetophenone, the carbonyl

stretching vibration *is* altered, presumably by the formation of the intramolecular hydrogen bond or related interaction, but this does not necessarily provide evidence for a covalent linkage since an electrostatic linkage might also affect the negative charge on the carbonyl oxygen atom and hence the bond order of the carbonyl group.* In fact it must be supposed that the N—O bond order remaining unaffected in *o*-nitrophenol represents a somewhat exceptional behavior which *cannot* be explained readily in terms of a covalent linkage; it *can*, however, be explained in terms of an electrostatic linkage if it is assumed that the relatively large negative charge on the NO_2 oxygen atom is only slightly affected by the comparatively smaller positive charge on the neighboring hydrogen atom of the OH or NH_2 groups. For other compounds a variety of evidence has been obtained; some indicates a covalent type of linkage or at least that covalent forces play a considerable part (cf. for example, refs. 1, 6, 26), while other evidence, like the present data, may be assumed to indicate a predominantly electrostatic type of linkage (25).

Assuming that the change in the O—H stretching vibration provides the most sensitive method of determining the strength of an intramolecular "hydrogen bond" we may now attempt to summarize our observations. We can thus suppose that the interactions loosely referred to as intramolecular hydrogen bonding tend to attract the hydrogen atom(s) of the OH or NH_2 groups towards the adjoining negative center; this gives rise to the changes in bond order of the O—H or N—H bonds and consequently to the changes in the corresponding infrared vibrational bands. The bond order of the group containing the negative charge is not necessarily affected in the ground state but appears to be affected in the electronic excited state. Such a mechanism accounts for the ultraviolet spectral changes and also seems reasonable since the presence of a vicinal positive charge on the hydrogen atom might be expected to affect the bond order of the N—O bond to a greater extent in the electronic excited state than in the ground state.

EXPERIMENTAL

The ultraviolet absorption spectra were determined as described in previous parts of this series of papers (1, 24).

The infrared spectra were determined on a Unicam SP100 double-beam spectrophotometer using a NaCl prism and diffraction grating at the following solute concentrations: The spectrum of *o*-nitrophenol was determined at solute concentrations of 0.2 *M* and 1.0 *M*, and the spectra of the other *o*-nitrophenols were determined at concentrations of 0.2 *M*. The spectrum of salicylaldehyde was determined at solute concentrations of 0.05 and 0.25 *M*, the spectrum of benzaldehyde at 0.05 *M* and the spectra of *m*-hydroxybenzaldehyde and *m*-hydroxyacetophenone were determined in saturated solutions.

The phenols and anilines were either commercially available materials or prepared by standard methods as described in the literature. The compounds were purified by distillation or recrystallization until their melting points or boiling points and refractive indices showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher), spectroanalyzed carbon tetrachloride, or commercially available absolute ethanol suitable for spectroscopy.

**However, intramolecularly hydrogen-bonded systems containing a carbonyl group have been reported in which no effect of the hydrogen bonding on the carbonyl stretching frequency was observed (25).*

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART VI. THE EFFECT OF STERIC INTERACTIONS ON THE INTRAMOLECULAR HYDROGEN BOND IN *o*-NITROPHENOL[1]

J. C. DEARDEN[2] AND W. F. FORBES[3]

ABSTRACT

Intramolecular hydrogen bonding occurring in *o*-nitrophenol is discussed with special reference to the effects of the steric interactions on the absorption bands and on the bonding. An alkyl substituent vicinal to the OH group, or a methyl group vicinal to the NO_2 group appears to strengthen the intramolecular hydrogen bond in *o*-nitrophenol. The O—H vibrational stretching frequency in *o*-nitrophenol appears to be more susceptible to steric than to mesomeric interactions, and a methyl substituent vicinal to the nitro group in *o*-nitrophenols is found to give rise to a characteristic O—H stretching vibration band. For 6-*t*-butyl-2-nitrophenol, a special, "protected" hydrogen bond is postulated. In some of the *o*-nitrophenols, intermolecular hydrogen bonding gives rise to appreciable ultraviolet intensity decreases presumably because of increased steric interactions.

INTRODUCTION

In the previous paper (1), it was shown that spectral data confirm the generally held opinion that *o*-nitrophenol possesses an intramolecular hydrogen bond; it was also shown that the spectral effects ascribed to this hydrogen bonding could be adequately explained in terms of an electrostatic model. That is, it may be assumed that the NO_2-group because of its negative charge merely attracts the hydrogen atom of the OH-group and that there is no need to postulate the presence of a covalent contribution since the infrared NO_2 stretching bands remain practically unaffected for a number of substituted *o*-nitrophenols, for *o*-nitroanisole, and for *m*-nitrophenol.

The purpose of the present paper is to investigate how steric interactions affect the spectral changes ascribed to intramolecular hydrogen bonding in various sterically hindered nitrophenols.

THE SPECTRA OF *o*-NITROPHENOL AND *o*-NITROANISOLE

The greatly reduced maximal extinction coefficient in the nitrobenzene *B*-band (for band nomenclature used, see ref. 2 and other papers in that series of papers, and ref. 3) of *o*-nitroanisole (λ_{max} 250 mμ, $\epsilon = 3400$) compared with that of *o*-nitrophenol (λ_{max} 271 mμ, $\epsilon = 7350$), *m*-nitrophenol (λ_{max} 258.5 mμ, $\epsilon = 6100$), and *m*-nitroanisole (λ_{max} 262 mμ, $\epsilon = 6100$) (all in cyclohexane solution) suggests the operation of steric interactions in *o*-nitroanisole. If intramolecular hydrogen bonding were wholly responsible for the relative intensity increase in *o*-nitrophenol compared with the intensity in *o*-nitroanisole, a similar intensity increase should be observed for *o*-nitrophenol compared with *m*-nitrophenol but this is not found to be so. Since, further, a hypsochromic wavelength displacement of 21 mμ occurs for this same band in *o*-nitroanisole compared with *o*-nitrophenol (12 mμ compared with *m*-nitroanisole), whereas the infrared NO_2 stretching vibrations remain approximately constant (1530 ± 2 cm^{-1}) this suggests that the energy levels of the nitrobenzene groups in the two compounds are as shown in Fig. 1.

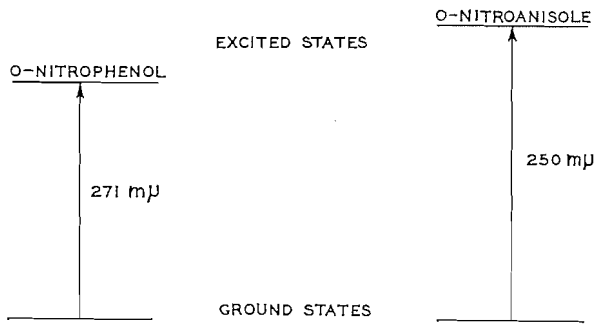

FIG. 1. Schematic representation of ground and excited states for nitrophenol and nitroanisole.

Figure 1 illustrates that the ultraviolet hypsochromic wavelength displacement is to be ascribed to the potential energy being raised predominantly in the electronic excited state of *o*-nitroanisole, and a contributing factor to this may be a slight twist in the interplanar angle between the NO_2-group and the benzene ring. Moreover, this slight change in interplanar angle may cause some of the transitions in *o*-nitroanisole to become "forbidden" and this may contribute to the observed loss of absorption intensity in this compound (4, 5, 6). It remains to explain the well-known appreciable frequency displacement in carbon tetrachloride solution for the infrared O—H band in *o*-nitrophenol (ν_{max} 3209 cm^{-1}) compared with that of *m*-nitrophenol (ν_{max} ca. 3500 cm^{-1}) on the basis of this model, but this has previously been done (1) by assuming that the negative charge on the NO_2-group attracts the hydrogen atom and thus weakens the O—H bond and consequently causes absorption at lower frequency.

THE SPECTRA OF *o*-NITROPHENOL, 6-METHYL-2-NITROPHENOL, AND 6-*t*-BUTYL-2-NITROPHENOL

The spectra of *o*-nitrophenol, 6-methyl-2-nitrophenol, and 6-*t*-butyl-2-nitrophenol are listed in Table I.

Table I shows that, as judged by the infrared O—H stretching bands, an alkyl substituent ortho to the OH group in *o*-nitrophenol apparently strengthens the intramolecular hydrogen bond. Moreover, this effect, associated with strengthening of the intramolecular hydrogen bond, is more pronounced for a *t*-butyl than for a methyl substituent. The effect of the alkyl substituents on the infrared O—H band is also paralleled by the effect on the ultraviolet maximal wavelengths, which are progressively displaced to longer wavelength (i.e. to lower frequency) with increased size of the alkyl substituent (see Table I). The above spectral changes therefore suggest that the introduction of alkyl substituents vicinal to the OH group in *o*-nitrophenol may be assumed to provide an example of steric facilitation of hydrogen bonding (for other examples of steric facilitation of hydrogen bonding see ref. 7 and cf. also refs. 8, 9, and footnote 14 of ref. 10).

However, there are some significant differences between the spectra of 6-methyl-2-nitrophenol and 6-*t*-butyl-2-nitrophenol (see Table I). First, doublet formation occurs in both infrared stretching bands for the 6-methyl compound but not for 6-*t*-butyl-2-nitrophenol or *o*-nitrophenol. The most obvious cause of this observed band splitting is conformational heterogeneity, but it is difficult to conceive of two different conformational isomers in 6-methyl-2-nitrophenol. Next, the ultraviolet data show that for *o*-nitrophenol and 6-*t*-butyl-2-nitrophenol the maximal wavelengths are altered only

*Band assignment doubtful; this band may be a —C—H stretching band, or may correspond to associated molecules.

slightly on changing the solvent from cyclohexane to ethanol. However, for 6-methyl-2-nitrophenol an appreciable wavelength change is observed with change of solvent (see Table I), and incidentally the ϵ_{max} values are greatest for the *B*-band and smallest for the *C*-band of 6-methyl-2-nitrophenol. These changes can partly be explained by assuming that competitive intermolecular hydrogen bonding occurs for 6-methyl-2-nitrophenol (which gives rise to the observed wavelength displacement on determining the spectrum in cyclohexane and ethanol), but that such competitive intermolecular hydrogen bonding does not occur for 6-*t*-butyl-2-nitrophenol presumably because of the bulk effect of the *t*-butyl group. If this interpretation is correct it must also be assumed that for *o*-nitrophenol competitive intermolecular hydrogen bonding is of less importance. The reason for this may be that only for 6-methyl-2-nitrophenol (in which steric facilitation of hydrogen bonding occurs), but not for *o*-nitrophenol, steric interactions are increased by this competitive intermolecular hydrogen bonding. It may be noted that 6-*t*-butyl-2-nitrophenol therefore occupies a somewhat unique position among *o*-nitrophenols possessing adjacent alkyl groups (see also following sections), since only for this compound is there observed no wavelength displacement on determining the ultraviolet spectrum in cyclohexane and ethanol. This, in turn, suggests a stronger, "protected" hydrogen bond and this hypothesis also receives support from the greater frequency displacement (142 cm^{-1}) observed for the O—H stretching band and from examination of scale models of 6-*t*-butyl-2-nitrophenol.

THE SPECTRA OF *o*-NITROPHENOL, 3-METHYL-2-NITROPHENOL, AND 3,4-DIMETHYL-2-NITROPHENOL

The relevant spectral data are listed in Table II.

It may first be noted that the infrared O—H stretching vibration bands of all *o*-nitrophenols containing a methyl group vicinal to the nitro-group are different from these bands in other *o*-nitrophenols. This is illustrated in Fig. 2.

Figure 2 shows that 3-methyl-substituted 2-nitrophenols afford a broad O—H absorption band in the 3350–2900 cm^{-1} region as opposed to the more intense, sharp bands observed for the other *o*-nitrophenols. This broadness of the bands suggests that 3-methyl-substituted *o*-nitrophenols give rise to strong intramolecular bonds (cf. ref. 11), presumably again because of steric facilitation of the hydrogen bond. Apart from these diffuse O—H stretching bands, 3-methyl-substituted 2-nitrophenols also afford a sharp band which occurs at lower frequency, and which is ascribed to —C—H stretching bands. The displacement of the infrared O—H stretching band for 3-methyl-2-nitrophenol ($\Delta\nu = +41$ cm^{-1}) again indicates steric facilitation of hydrogen bonding but the displacement for the O—H band of 3,4-dimethyl-2-nitrophenol ($\Delta\nu = -136$ cm^{-1}) is in the opposite direction. This suggests that buttressing interactions also affect the intramolecular hydrogen bond in some way (see below). The infrared NO_2 symmetrical stretching band of 3-methyl- and 3,4-dimethyl-2-nitrophenol again shows some signs of band splitting. Moreover, there is some indication that in sterically hindered *o*-nitrophenols the intensity of the symmetrical NO_2 stretching band decreases slightly relative to the same band in *o*-nitrophenol, presumably because of steric interactions (cf. ref. 13).

The ultraviolet spectra in cyclohexane solution first indicate that a 3-methyl group causes a slight twist of the nitro-group away from the plane of the benzene ring as judged by the reduced ϵ_{max} value of the nitrobenzene *B*-band (see Table II). The ϵ_{max} value of 3-methyl-2-nitrophenol is slightly *greater* than that of *o*-methylnitrobenzene in isooctane

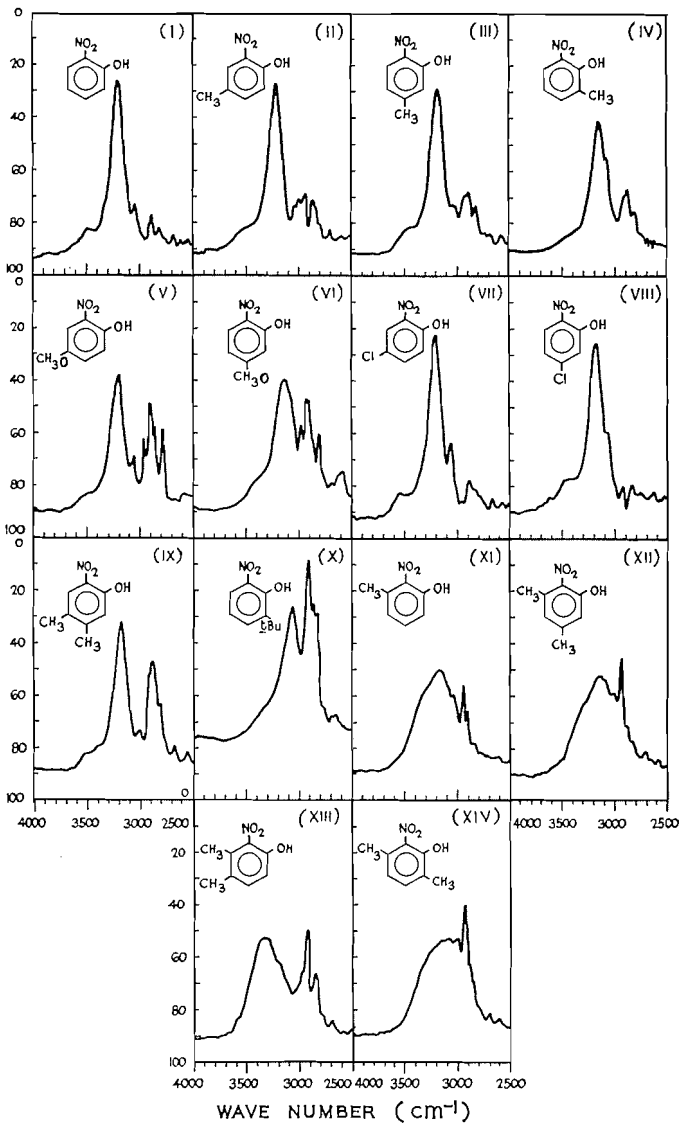

FIG. 2. The infrared O—H stretching vibration bands at concentrations of 0.2 molar in carbon tetrachloride solution of (i) *o*-nitrophenol, (ii) 4-methyl-2-nitrophenol, (iii) 5-methyl-2-nitrophenol, (iv) 6-methyl-2-nitrophenol, (v) 4-methoxy-2-nitrophenol, (vi) 5-methoxy-2-nitrophenol, (vii) 4-chloro-2-nitrophenol, (viii) 5-chloro-2-nitrophenol, (ix) 4,5-dimethyl-2-nitrophenol, (x) 6-*t*-butyl-2-nitrophenol, and (xi) 3-methyl-2-nitrophenol, (xii) 3,5-dimethyl-2-nitrophenol, (xiii) 3,4-dimethyl-2-nitrophenol, (xiv) 3,6-dimethyl-2-nitrophenol. (Fine structure observed in these O—H bands may be caused by intermolecular hydrogen bonding.)

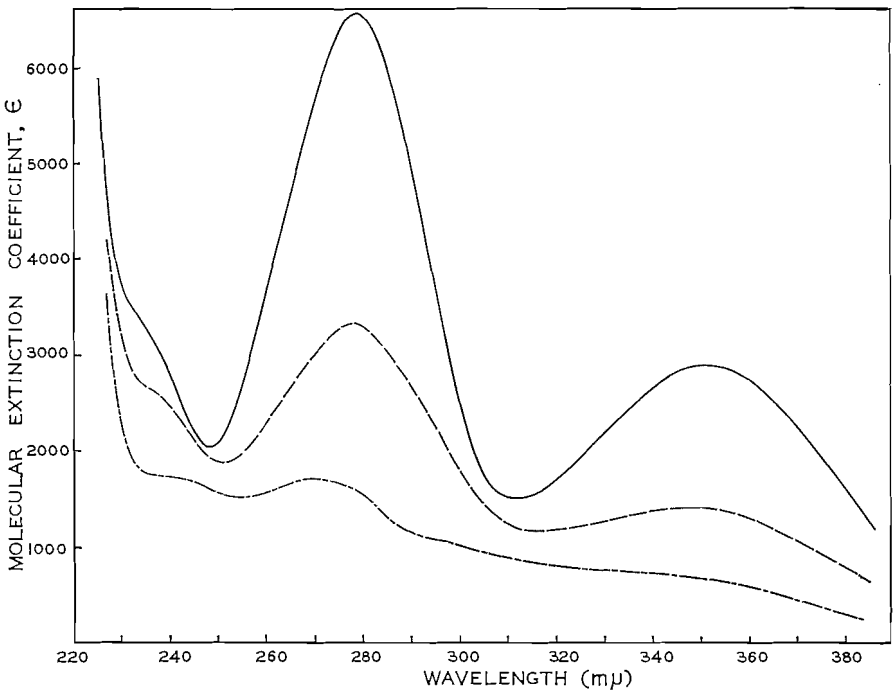
solution whereas in cyclohexane solution the ϵ_{max} value of *o*-nitrophenol is less than that of nitrobenzene (cf. Table II and ref. 2), and this may imply that the intramolecular hydrogen bonding tends to keep the NO_2-group in a position coplanar with that of the benzene ring. In 3,4-dimethyl-2-nitrophenol the ϵ_{max} value of the nitrobenzene *B*-band is yet further decreased, indicative of a buttressing effect of the 4-methyl on the 3-methyl

group (see Table II and cf. ref. 12). In ethanol solution, the ϵ_{max} values of all three bands in both 3-methyl- and 3,4-dimethyl-2-nitrophenol are drastically reduced, and a similar but less pronounced effect is observed for 3-methyl-2-nitrophenol in ether solution (see Table II and Fig. 3). Both 3-methyl- and 3,4-dimethyl-2-nitrophenol again give rise to



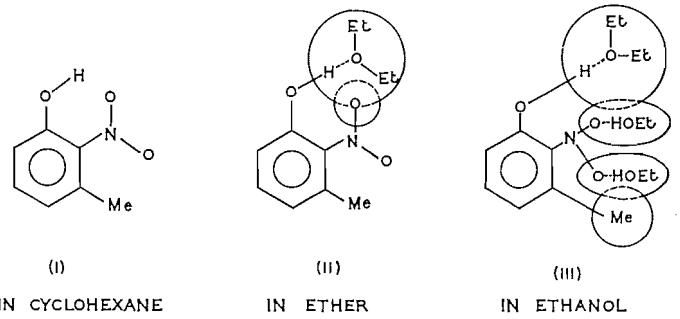


FIG. 3. The spectrum of 3-methyl-2-nitrophenol in cyclohexane (———), ether (– – –), and ethanol (– · – · –).

appreciable wavelength displacements when the solvent is altered, which indicates competing solvent–solute interactions.

The hypothesis of a coplanar conformation facilitating hydrogen bonding also receives support since this coplanarity is disturbed in ethanol *or* ether solution, as judged by the greatly reduced ϵ_{max} values of the 3-methyl-substituted compounds (see Table II), although ether presumably interacts predominantly with the OH-group only. It may thus be assumed that ether interacts competitively with the OH-group and in this way weakens the intramolecular hydrogen bonding, and that as a result of this weakening, there occurs the above-mentioned non-planarity between the nitro-group and the benzene ring. This is further illustrated by structures I, II, and III, which schematically indicate the effect of competing intermolecular hydrogen bonding on the intramolecular hydrogen bond and on the steric interactions present in 3-methyl-2-nitrophenol (cf. also the *B*-band intensities of *o*-nitrophenol in different solvents and later discussion). The steric facilitation of hydrogen bonding relative to *o*-nitrophenol, which is again observed for 3-methyl-2-nitrophenol as judged from the infrared O—H bands, may be ascribed to the NO_2-group – OH-group distance being decreased probably through the NO_2-group being *bent* towards the OH-group.

THE SPECTRA OF 3-METHYL-2-NITROPHENOL, 3,5-DIMETHYL-2-NITROPHENOL, 4,5-DIMETHYL-2-NITROPHENOL, AND 3,6-DIMETHYL-2-NITROPHENOL

The relevant spectral data are listed in Table III.

The infrared O—H vibrational stretching frequencies of the compounds listed in Table III again afford the expected changes in as much as only 4,5-dimethyl-2-nitrophenol, which does not possess a 3-methyl substituent, shows a sharp absorption band (see Fig. 2). It may be noted that the effect of steric interactions on this O—H band is larger than the effect of mesomeric interactions on the same band. Thus, the data in Tables II and III show that only in 4,5-dimethyl-2-nitrophenol is the O—H stretching band (ν_{max} 3191 cm^{-1}) reasonably close to that in *o*-nitrophenol (ν_{max} 3209 cm^{-1}) and in the previous paper of this series it was shown that the O—H bands in 4-chloro-2-nitrophenol (ν_{max} 3216 cm^{-1}), 4-methoxy-2-nitrophenol (ν_{max} 3216 cm^{-1}), 4-methyl-2-nitrophenol (ν_{max} 3218 cm^{-1}), and 5-chloro-2-nitrophenol (ν_{max} 3182 cm^{-1}), 5-methoxy-2-nitrophenol (ν_{max} 3144 cm^{-1}), 5-methyl-2-nitrophenol (ν_{max} 3185 cm^{-1}) all occur fairly close to the O—H band in *o*-nitrophenol (see ref. 1), whereas steric interactions give rise to larger frequency displacements (cf. Tables I, II, and III). It is also worth noting that in dimethyl-substituted *o*-nitrophenols frequency displacements in the infrared O—H stretching band are approximately additive, except as for the previously mentioned 3,4-dimethyl compound. Thus, relative to the O—H band in *o*-nitrophenol, the O—H band in 3-methyl-2-nitrophenol is displaced by 41 cm^{-1} and the relevant band in 5-methyl-2-nitrophenol by 24 cm^{-1}. Adding these displacements affords a calculated value of 65 cm^{-1} for the frequency displacement in 3,5-dimethyl-2-nitrophenol, which is identical with the observed frequency displacement of the infrared O—H band in 3,5-dimethyl-2-nitrophenol relative to the same band in *o*-nitrophenol. Similarly, for 3,6-dimethyl-2-nitrophenol the "calculated" frequency displacement is 96 cm^{-1} while the observed frequency displacement is 109 cm^{-1}, and the "calculated" frequency displacement for 4,5-dimethyl-2-nitrophenol is 15 cm^{-1} while the observed displacement is 18 cm^{-1}. These displacements incidentally are not quantitatively related to the wavelength displacements observed in the ultraviolet *B*-bands; at best, a rough semiquantitative relation holds for compounds where there is no steric effect, that is, for *o*-nitrophenols which have substituents only in the 4- or 5-positions.

Next, a substituent in the 4-position causes absorption at slightly higher frequency, whereas a substituent in the 5-position causes absorption at slightly lower frequency than for 2-nitrophenol (cf. ref. 1). This latter observation may in general terms be related to the ability of an electron-donating substituent in the 5-position to enhance the negative

(IV)

charge on the NO_2-group by means of mesomeric interaction as shown in structure IV, which, as discussed in ref. 1, tends to facilitate the intramolecular hydrogen bond.

Related, though less pronounced effects are observed for the NO_2 stretching vibrations as follows. The asymmetrical NO_2 stretching vibrational frequency remains approximately constant, although it may be noted that for 4,5-dimethyl-2-nitrophenol the band occurs at slightly lower frequency (1525 cm^{-1}; see Table III) than for *o*-nitrophenol (ν_{max} 1532 cm^{-1}). This may be a general effect for *o*-nitrophenols possessing a substituent in the 4- or 5- positions since 3,4-dimethyl-2-nitrophenol (ν_{max} 1524 cm^{-1}), 4-methoxy-2-nitrophenol (ν_{max} 1528 cm^{-1}), and 4-chloro-2-nitrophenol (ν_{max} 1530 cm^{-1}) also absorb at slightly lower frequency than *o*-nitrophenol. 4-Methyl-2-nitrophenol absorbs at ν_{max} 1532 cm^{-1} like *o*-nitrophenol, and *o*-nitrophenols possessing *only* a substituent in the 5-position also tend to absorb at lower frequency than *o*-nitrophenol, for example 5-chloro-2-nitrophenol (ν_{max} 1521 cm^{-1}), 5-methyl-2-nitrophenol (ν_{max} 1529 cm^{-1}), and 5-methoxy-2-nitrophenol (ν_{max} 1529 cm^{-1}), but all other *o*-nitrophenols discussed show the asymmetric NO_2 stretching band at higher frequency.

Similar effects are observed for the symmetrical NO_2 stretching vibration near 1315 cm^{-1} except that comparisons are sometimes more difficult because of band splitting and also because 5-methoxy-2-nitrophenol absorbs at slightly higher frequency (1317 cm^{-1}) than *o*-nitrophenol, although it might have been expected to absorb at lower frequency. Thus it seems that the effect of both electronic and steric interactions on the NO_2 vibrational stretching bands are small but that there is a tendency for electron-donating substituents in the 4- or 5-positions to cause absorption at lower frequency and for steric interactions, brought about by substituents in the 3- or 6-positions, to cause absorption at higher frequency.

The ultraviolet spectra listed in Table III give rise to the expected wavelength displacements when it is remembered that the ultraviolet *B*-bands are particularly susceptible to mesomeric interactions. This presumably accounts for the nitrobenzene *B*-band absorption at longer wavelength for 3,5-dimethyl-2-nitrophenol in cyclohexane solution. In ethanol solution the previously discussed decrease in the ϵ values of the 3-methyl-substituted 2-nitrophenols is again observed (see Table III). The spectral changes with change of solvent for a number of *o*-nitrophenols and *o*-nitroanisoles are also listed in Table IV.

Table IV shows that changing the solvent from cyclohexane to ethanol causes a bathochromic wavelength displacement of ca. 6 mμ (ca. 900 cm^{-1}) in nitrobenzene accompanied by a slight intensity decrease (2). In sterically hindered nitrobenzenes, such as 2,4- or 2,5-dimethoxynitrobenzene, this bathochromic wavelength displacement of the nitrobenzene *B*-band appears to be increased to ca. 8–10 mμ (ca. 1200–1300 cm^{-1}). In cyclohexane solution, an intensity decrease occurs for this band in 2,4-dimethoxynitrobenzene relative to the same band in nitrobenzene and this decrease is considerably more pronounced in the 2,6-dimethoxynitrobenzene. An intermediate intensity value is observed in the 2,5-isomer, probably because of a buttressing effect (cf. ref. 12) and because in 2,4-dimethoxy-, but not in 2,5-dimethoxy-benzene, can the mesomeric effect of the

p-methoxy substituent be expected to cause increased double-bond character in the C—N bond, which in turn may lead to increased coplanarity and increased absorption intensity. The low intensity value of the 2,6-isomer shows that two substituents, one on either side of the nitro-group, produce a much larger steric effect than one such substituent, which in turn implies that the interactions on the nitro-group do not only involve a twisting effect on a symmetrical nitro-group. (If these interactions merely caused a symmetrical nitro-group to twist out of the plane of the benzene ring, two like substituents would be expected to cause changes in the conformation of the nitro-group similar to those caused by a single substituent.) Changing the solvent incidentally does not appreciably affect the absorption intensity for 2,4-dimethoxy- or 2,5-dimethoxynitrobenzene. Next, for intramolecularly hydrogen-bonded molecules, such as *o*-nitrophenol and 5-methyl-2-nitrophenol, only small wavelength changes and small intensity decreases are observed on changing the solvent from cyclohexane to ethanol. For 6-methyl-2-nitrophenol a hypsochromic wavelength displacement is observed on changing the solvent from cyclohexane to ethanol and this suggests, as previously noted, that the intramolecular hydrogen bond has been affected by the 6-methyl substituent. It may be noted that the wavelength displacements are in a different direction from those observed for ordinary nitrobenzenes, and this could be because the intramolecular hydrogen bond in 6-methyl-2-nitrophenol is partially inhibited by changing the solvent. Direct steric interactions, it may be noted, are unlikely to be entirely responsible for this hypsochromic wavelength displacement since changing the solvent affects the absorption intensity only slightly.

In 3-methyl-2-nitrophenol, however, changing the solvent from cyclohexane to ethanol produces a very large intensity decrease comparable to the intensity decrease observed for 2,6-dimethoxynitrobenzene in cyclohexane solution, and this may be related to the observation that in both compounds the nitro-group has two large neighboring groups.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In this case, however, it must further be assumed that the ethanol molecule attaches itself to the OH-group, and in this way increases the effective size of the OH-group. These general hypotheses are supported by the *B*-bands of 2-nitroresorcinol in cyclohexane and ethanol solution since in the latter there occurs a hypsochromic wavelength displacement accompanied by a considerable intensity decrease; steric interactions and the inhibition of part of the intramolecular hydrogen bonding would be expected to give rise to precisely these spectral changes.

Summarizing, the above-mentioned and previous data all suggest that in most 3-methyl-substituted 2-nitrophenols the NO_2-group is partly twisted out of the plane of the benzene ring, and also that solvent–solute interactions become important for 3-methyl- or 6-methyl-substituted 2-nitrophenols. These latter interactions tend to weaken the intramolecular hydrogen bond and may also increase the effective size of the NO_2- and OH-groups.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP500 spectrophotometer as described in previous parts of this series of papers (1, and references cited there). For each compound at least two independent sets of observations were made. The accuracy of λ_{max} values is estimated to be ± 1 mμ, and the precision of ϵ_{max} values $\pm 5\%$ or better. Values were reproducible in most cases to $\pm 2\%$.

The infrared spectra were determined on a Unicam SP100 double beam spectrophotometer using a NaCl prism and diffraction grating. The day-to-day reproducibility was better than ± 2 cm^{-1} for sharp bands. The spectra were determined in carbon tetrachloride at solute concentrations of about 0.2 *M* in cells of path lengths of 0.1 and 0.5 cm.

Most of the compounds were synthesized according to directions obtained from the literature. All the compounds, except 6-*t*-butyl-2-nitrophenol, have previously been described in the literature. 6-*t*-Butyl-2-nitrophenol, prepared by a modification of the method of Gibson (14) distilled under vacuum as a bright golden oil, b.p. 122° at 7 mm, $n_D^{22.5}$ 1.5562. Found: C, 61.7; H, 6.9; N, 7.5%. $C_{10}H_{13}O_3N$ requires C, 61.5; H, 6.7; N, 7.2%.

The solvents used were spectroanalyzed cyclohexane (Fisher), spectroanalyzed carbon tetrachloride, and commercially available absolute ethanol suitable for spectroscopy.

ACKNOWLEDGMENTS

The authors are greatly indebted to Mr. D. L. Coffen for very competent technical assistance in the preparation of some of the compounds and in the determination of the infrared spectra, and to Miss N. Joan Smith for determining some of the ultraviolet absorption spectra. Thanks are also due to Dr. A. W. Baker, Dow Chemical Company, Pittsburgh, California, U.S.A., for a generous sample of 3,5-dimethyl-2-nitrophenol.

The authors also wish to thank the Fisheries Research Board of Canada for financial support, since part of this work was carried out under a contract between the Fisheries Research Board of Canada and the Memorial University of Newfoundland. Finally the assistance of the National Research Council in support of these studies is again gratefully acknowledged.

RADICAL TERMINATION MECHANISMS IN BULK POLYMERIZATION[1]

B. L. Funt and W. Pasika[2]

ABSTRACT

The termination mechanism in the bulk polymerization of styrene and vinyl acetate initiated by α,α'-azobisisobutyronitrile has been investigated. C^{14}-Labelled initiators were employed and activities of samples were determined by internal liquid scintillation counting. Measurements of fractionated and unfractionated polystyrene showed an average of 1.94 and 2.04 tagged fragments per molecule, respectively, and indicated termination by combination at 60° C. For polyvinyl acetate 1.06 fragments were found per molecule, indicating termination by disproportionation at 60° C.

One of the features of vinyl addition reactions, which is still subject to considerable uncertainty, is the mode of termination of growing chains. It is universally accepted that termination reactions must occur as the result of the interaction of two radicals, but the mechanism of this termination, whether by direct combination or by disproportionation, has only been investigated for a few systems, and has not been proved unequivocally even for these.

Nevertheless the mode of termination is of primary importance in kinetic analysis of data, in the assignment of termination constants and the prediction of molecular weights. Unless the mode of termination is understood, these quantities are subject to an uncertainty of a factor of two.

Two sensitive methods exist for the solution of this problem. Bamford and Jenkins (1) have described a technique of coupling preformed polymer possessing suitably reactive end groups. Alternatively with the use of radioactive initiators, it is possible to determine the number of initiator fragments present per polymer molecule (2, 3, 4). Since each initiator fragment found generated a chain, then in the final polymer the presence of two initiator fragments per polymer molecule would indicate the exclusive occurrence of combination, and of one initiator fragment of disproportionation.

Previous studies have not yielded completely conclusive results. For methyl methacrylate, the monomer subjected to the most intensive study, early work by Arnett and Peterson (5) using tagged initiators, indicated combination, whereas Bevington *et al.* (3) found a predominance of disproportionation. Ayrey and Moore (6) also found disproportionation and combination, but their results were not in exact agreement with those of Bevington.

It is reasonable to assume that for most monomers, termination reactions by combination and disproportionation can be considered as competitive reactions, each with a definite rate constant and activation energy. It is our intention to investigate this problem in detail, and the present report represents our first work in this direction.

The systems styrene and vinyl acetate, initiated with α,α'-azobisisobutyronitrile (AIBN), were chosen for this preliminary study.

EXPERIMENTAL

Materials

α,α'-Azobisisobutyronitrile (AIBN) dicyano C^{14} was obtained from the Commissariat à L'Énergie Atomique, Saclay, France, and possessed a specific activity of 200 μc/g. It

[1]*Manuscript received June 3, 1960.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.
[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*

was suitably diluted with inactive AIBN, dissolved in benzene to an activity of 1 μc/ml, and the mixture purified by the method of Ikamura and Motoyama (7).

Styrene, obtained through the courtesy of the Dow Chemical Company, was washed three times with 5% NaOH solution, three times with distilled water, dried over $CaSO_4$, slightly prepolymerized, and then distilled under reduced pressure (8).

Vinyl acetate, obtained from Carbide and Carbon Chemicals, was twice distilled at atmospheric pressure under an argon atmosphere. Prior to the second distillation it was refluxed for 1 hour under argon to destroy peroxides.

Scintillation grade *p*-terphenyl and 1,4-di-2-(5 phenyl oxazolyl)benzene (POPOP) were obtained from Nuclear Enterprises Ltd., Winnipeg, and were employed without further purification.

Methods

Polymerization

The monomers, with appropriate amounts of initiator added, were placed in Pyrex tubes and degassed by a series of freezing–thawing cycles under vacuum. The tubes were evacuated and sealed, and the 20-ml charges placed into a thermostatted water bath at 60.0° C. Samples were polymerized to approximately 10% conversion and blank experiments (without initiator) were performed for all samples to determine whether thermal uninitiated polymerization was also occurring.

In order to determine that the polymerizations were following established mechanisms, samples were isolated and weighed at different degrees of conversion, and it was found that the kinetics accurately obeyed the expected linear dependence of rate of polymerization on the square root of the AIBN concentration.

Isolation and Purification of Polymers

After polymerization the polystyrene was dissolved in methyl ethyl ketone and precipitated in methanol. Polyvinyl acetate was precipitated in a 25/75 methanol–water mixture (5), redissolved in acetone, and precipitated in *n*-hexane. The polymer was finally isolated by the freeze-drying method (9).

Molecular Weights

Molecular weights were primarily determined by viscometry, employing an Ubbelohde viscometer, with benzene and acetone as solvents for polystyrene and polyvinyl acetate respectively.

Values of K and α employed in the Staudinger equation were 1.03×10^{-4} and 0.74, respectively, for fractionated polystyrene (10), 2.62×10^{-4} and .68 for unfractionated polystyrene (11), and 1.76×10^{-4} and .68 for fractionated polyvinyl acetate (12). At a later stage a bank of five Stabin–Immergut osmometers was in operation in our laboratory (13), and where the amount of sample available was sufficient, number average molecular weights were also obtained by osmometry.

Radioassay Technique

One of the objectives of this work was to test the suitability of internal liquid scintillation counting techniques for tracer studies of this type. The scintillation counting method provides a greater inherent sensitivity, will accommodate larger samples and hence of lower specific activity, and allows energy discrimination and the concomitant reduction in background counting rate. A further important advantage in the present work is that it eliminates the necessity of sample combustion, and purification of CO_2 gas required for Geiger techniques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The active samples of polymer were dissolved directly in 20 ml of a liquid scintillator containing 2.0% *p*-terphenyl and 0.04% POPOP in xylene and counted.

The counting assembly consisted of a DuMont 6292 photomultiplier, a cathode follower, linear non-overloading amplifier, a pulse height analyzer, a scaler, and a stabilized high-voltage supply, and was similar to units employed in previous work (14). The liquid scintillator cell was $1\frac{1}{2}$ inches in diameter and 2 inches high. It was surrounded by a magnesium oxide powder reflector and was fitted with a bubbling device for the removal of dissolved oxygen (15, 16) to improve its luminescent output.

RESULTS

It was first necessary to determine whether the quenching effects of added polymer would seriously affect the counting rates and thus lead to spurious results. Figure 1 shows

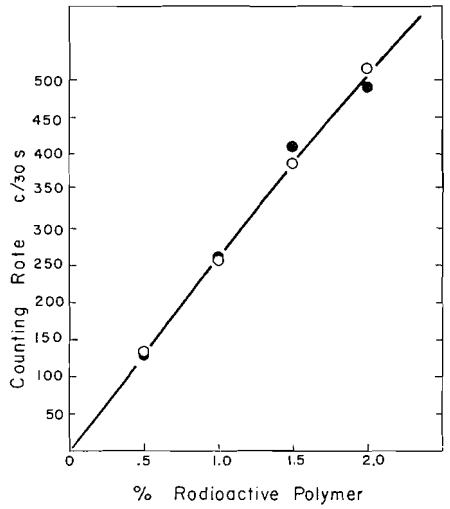

FIG. 1. Proportionality between counting rate and concentration of radioactive polymer. Solid and open circles denote duplicate experiments.

the data obtained for a tagged polystyrene sample and it can be seen that the counting rate is proportional to the amount of active polymer up to 2% concentration. It was therefore considered convenient and satisfactory to work with solutions of 1% polymer in the liquid scintillator.

The efficiency of separation of polymer from occluded initiator was tested by adding 0.2 μc of active AIBN to 0.5 g of inactive polystyrene and repeatedly precipitating the polymer from methyl ethyl ketone with methanol. For no separation one would expect 13,200 c.p.m. per 0.1500 g polymer. The counts obtained were 76 c.p.m. after one precipitation and 20 c.p.m. after two precipitations. This indicated that a double precipitation was adequate.

For the polymer samples a pulse height analyzer lower gate of 15 kev was employed and checks were made with an internal standard of C^{14} (17, 18) to detect any possible variations in counting efficiencies due to electronic drift or quenching action.

The results for unfractionated polystyrene are presented in Table I.

In order to determine whether the number of AIBN fragments incorporated in the final polymer was influenced by molecular weight, a sample of polystyrene prepared with

high and low molecular weight material, respectively, and sample 1 was fractionated into four parts labelled 1A to 1D.

The data for polyvinyl acetate polymerized at 60.0° C are presented in Table III.

DISCUSSION

The data in Tables I and II indicate that in the thermal reactions polystyrene radicals terminate by mutual combination and that the method of termination is independent of molecular weight over the range investigated. These findings are in agreement with Bevington's studies of the photopolymerized system (3), and with Bamford and Jenkins conclusions based on coupling of preformed polymer (1). Although early work (19, 20, 21) had assumed termination by combination, this cannot be construed to be the current picture, and the present results are therefore considered to extend and confirm the current views of the mechanism of termination in styrene.

In many respects the data presented here for styrene appear to be in surprisingly close agreement with the simple picture presented. It is recognized that the presence of thermal reaction, or of chain transfer to polymer or initiator, could tend to vitiate the results. After this investigation had been essentially completed it was possible to check the molecular weights of a few samples by osmometry, although the amounts of samples available were not sufficiently large for optimum conditions of osmotic measurement. Sample 16, for example, yielded a molecular weight of 61,700 by osmometry vs. 56,200 from viscosity data. The agreement is within 10% and is well within the limits necessary to discard a disproportionation mechanism in favor of one by combinaion.

The results for vinyl acetate, in Table III, indicate one initiator fragment per polymer molecule and hence the occurrence of disproportionation. Previous investigation of this system by Burnett, George, and Melville (22) indicated an unusual variation in the number of fragments from 1.6 to 6.0 per molecule at temperatures from +27 to −38° C.

Chain transfer to polyvinyl acetate is known to occur and might be expected to affect the results. However, it should be noted that if a growing radical $IR\cdot$ were to abstract an H atom from a dead polymer molecule then $IR\cdot_m + IR_n \rightarrow IR_{(n+r)} + IR_m$ one initiator fragment per molecule would still remain and the results would be indistinguishable from those in the absence of branching if disproportionation is predominant.

A few preliminary experiments with vinyl acetate performed at 30° C showed spurious results and indicated an increase in the number of tagged fragments above a value of 3. Time did not permit an investigation of this effect in further detail as part of this work, and the few results obtained were considered tentative and were not included in the tabular presentation. A more detailed study of the variation of termination mechanism with temperature and of the determination of competitive rate constants for termination by combination and disproportionation for some systems has now begun in our laboratories.

THE SEPARATION OF SOME INORGANIC IONS BY HIGH-VOLTAGE ELECTROMIGRATION IN PAPER[1]

R. A. BAILEY[2,3] AND L. YAFFE

ABSTRACT

A number of inorganic ions have been separated by high-voltage electromigration in paper. The systems considered include some of particular radiochemical interest, such as Sr–Y, Ba–La, Mo–Tc, Pb–Bi–Po, as well as the alkali metals, some elements of the first long period, and other metals. Background electrolytes were usually solutions of complex-forming organic acids.

INTRODUCTION

Numerous references to the separation of inorganic ions by electromigration in paper (paper electrophoresis) have appeared over the last 10 years. The present work deals with a number of separations which were performed while making a general study of the method with a view to applying it to routine radiochemical separations. As such, it deals with a fairly large number of systems, and is a preliminary survey. It does not consider in detail the effects of varying such factors as the concentration and pH of the background electrolyte solution, which would be necessary if the optimum conditions for any separation were to be determined. Nevertheless, some striking results were obtained even with this rather arbitrary choice of conditions, illustrating the power of the method. The technique of electromigration has some specialized advantages. However, as a general method of separating small amounts of inorganic material, it can compete with other means, such as ion exchange, only on the basis of speed. Therefore a very high voltage technique was adopted, and solutions of low conductivity were used. This has permitted a number of separations to be made in 10 minutes or less.

Many of the ions studied are of adjacent atomic number, since these are often of chief interest radiochemically.

EXPERIMENTAL

The technique used was basically the same as that employed for quantitative measurements of zone mobility (1). An apparatus capable of withstanding much higher voltages was used, however, and for these qualitative results much less attention was paid to details which are important for zone mobility determinations.

A closed strip technique was used wherein the paper was placed between two cooling plates. These were of aluminum, $40\times10\times1/4$ in. in size. Copper tubing was bolted to the backs of both plates to allow the circulation of cooling water. Electrical insulation was provided by a strip of mica 4 in. wide running the length of each plate. This was extended to the edges of the plates at the high-voltage end to prevent arcing from the paper. Mica combines a higher electrical breakdown potential with a greater heat conductivity than most other practical materials. The strip was built up as a lamination of thin sheets 4×4 in. in size glued together; the thickness was 0.016 in. at the high-voltage end but somewhat less over most of its length. This insulation proved to be quite suitable. It could withstand a potential of 10,000 volts, and it had the additional advantage that, if the paper did char, the mica was not damaged. The mica was protected by a thin sheet of polyethylene or polyvinylchloride which could be replaced readily.

In order to obtain the good contact between the paper and the cooling surface, which is necessary at high voltages, about 140 lb of lead weights was placed on the upper plate.

No electrolyte reservoirs were employed. The electrodes were of platinum foil and were in direct contact with the ends of the paper strip. They could be placed at any distance from the ends of the plates to give any desired migration distance up to the full length of the plates. Electrical connections were made to them by means of aluminum or copper ribbons. Products of electrolysis were trapped by means of suitable buffer solutions.

A d-c. power supply giving a continuously variable, well-filtered output of up to 10 kv was used as a source of voltage.

A number of the ions studied were radioactive; such substances are easily detected and identified. They were located after separation by means of a Geiger counter for β-radiation, or a scintillation counter for γ-rays. The strip was either cut into sections, 1 cm broad, or measured intact with a scanning device. The latter is much less tedious, but it is not as sensitive toward very low levels of radioactivity such as may be found if a zone 'trails'. Alpha particles were detected by a 2π-proportional counter operated at its α-plateau voltage. In all cases the identity of the various zones was confirmed by means of the γ-ray spectra of the migrants, or by their relative rates of decay.

Many experiments were carried out with inactive migrants when radioactive nuclides were not available and when simple chemical tests could be used. Such tests may fail to show low-concentration regions, but they are satisfactory in most cases, and are fast and simple. The reagents used were rubeanic acid – NH_3 for Co(II) and Ni(II); NH_4SCN for Fe(III); alizarin–NH_3 for Al(III), Ga(III), and In(III); and dithizone for the remainder of the inactive ions.

The concentration of the inactive solutions was 0.01 M or less, while the radioactive solutions were much more dilute. Most ions were in solution as the nitrate, sometimes with a slight excess of nitric acid, but with other substances capable of forming stable complexes absent. Ten microliters of each migrant solution was normally used.

A number of temperatures were employed in this work. The comparatively low temperatures, which many workers have used to achieve adequate cooling, were found to be unnecessary with our apparatus; the best operation was obtained at 35–40° C. Since higher temperatures lead to higher zone mobilities, they may result in more rapid separations.

RESULTS AND DISCUSSIONS

The separations made with inactive materials are shown as reproductions of a tracing of the strip; those with radioactive substances are shown as histograms. The heavy vertical line in the former indicates the starting position. The relative heights of the peaks on the histograms are not significant since the detection efficiency varies for the different nuclides. The conditions of each separation are indicated in the figure captions. Except where indicated otherwise, Whatman No. 3MM chromatography paper was used, and the absorbance used was about 1.1 ml/g.

The first series of separations are of the following groups of cations in several organic acid background electrolytes:

(*a*) Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Ga(III);
(*b*) Ag(I), Cd(II), In(III);
(*c*) Hg(II), Tl(I), Pb(II), Bi(III);
(*d*) Zn(II), Cd(II), Hg(II);
(*e*) Al(III), Ga(III), In(III).

Oxalic acid gave the best results in most cases, but citric, tartaric, and lactic acids were investigated as well. The latter two gave superior separations of aluminum, gallium, and indium. Complex formation occurs in most of these systems, although often it is not strong enough to cause the migrant to behave as an anion. Table I gives the migration sequences in the systems used. Figures 1 to 3 illustrate some of the separations achieved.

(D) Separation of Hg(II), Pb(II), and Bi(III) using a zone of 0.1 *M* HBr in a strip moistened with 0.01 *M* oxalic acid; nominal voltage gradient 80 v/cm, 30 minutes, 39° C. Tl(I) was separated in the same experiment, but is not shown; it has moved far toward the negative electrode.

TABLE I

Migration sequences of a number of ions in several electrolyte solutions

Acetic acid of concentration 1–2 *M* Tl(I), Co(II), Ni(II), Zn(II), Ga(III), Cd(II), Pb(II), Cu(II), In(III), Fe(III):
0.01 *M* oxalic acid Tl(I), Cd(II), Co(II), Zn(II), Ni(II), Pb(II): In(III), Cu(II), Al(III), [Ga(III)+Fe(III)], In(III)
0.015 *M* citric acid Tl(I), Cd(II), Co(II), [Ni(II)+Zn(II)] [Pb(II)+Cu(II)]: Fe(III), [Al(III)+In(III)], Ga(III)
0.1 *M* tartaric acid Tl(I), Cd(II), [Co(II)+Zn(II)], Ni(II), Pb(II), Cu(II), Al(III), In(III), Ga(III): Fe(III)
0.1 *M* lactic acid Tl(I), Cd(II), [Co(II)+Zn(II)], Ni(II), Pb(II), Cu(II), Al(III), [Fe(III)+Ga(III)]:
In addition, Ag(I), Hg(II), and Bi(III) are adsorbed by the paper and are found near the starting position in these electrolytes.

NOTE: Ions in parentheses have similar mobilities; the relative rates were not determined.
The starting point is indicated by the symbol :. Ions to the left of this move as cations, those to the right as anions.

No difficulty was encountered in separating most of these ions in at least one of the electrolytes used. Ternary mixtures could be resolved very rapidly. Only systems involving silver, or mercury and bismuth, gave difficulty. These ions are strongly adsorbed by the paper and either will not move from the starting position, or trail back to it. In the case of silver, this may be the result of a reduction of small amounts of the silver by certain groups in the paper. In 0.01 *M* oxalic acid, indium formed two anionic zones, indicating that two complex species are formed which are not in rapid exchange with one another. This does not interfere with separations. The results can also indicate the relative tendency

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of complex formation of some of the ions. Thus, zinc seems to form stronger complexes than cadmium, and gallium stronger complexes than aluminum or indium, in the solutions used here.

Silver, when present in small enough amounts, remains at the starting position except when complexed strongly, as with ammonia. As the amount of silver present is increased, it tends to move toward the cathode, but leaves a low-concentration trail back to the starting point. The latter was detectable when radioactive Ag^{110} was used. Although in the separation of silver, cadmium, and indium no difficulty is encountered if a very small amount of silver is present (Fig. 1F), the extended zone formed with a larger quantity may overlap the zones of the other ions, since the mobility of the moving silver is high. In order to achieve a satisfactory separation in the latter case, some means of retaining all of the silver near the starting position is required.

By adding hydrochloric acid to a narrow zone on the cathode side of the starting position, all of the silver is precipitated or adsorbed between this zone and the initial position. If the hydrochloric acid is sufficiently dilute that complex formation with the other ions is slight, these ions pass through this zone with little interference (although the indium zone does tend to become elongated). A second procedure consists of adding a little potassium cyanide to the migrant solution before application to the paper. The $Ag(CN)^-$ ion is sufficiently stable to prevent any cationic motion of the silver. Separations utilizing these techniques are illustrated in Figs. 2A and 2B respectively.

Since both Hg(II) and Bi(III) remain near the starting position, they cannot be separated from one another in the electrolytes used here with ordinary filter paper. That the failure to move is due to interaction with the cellulose is shown by the results in 0.1 *M* tartaric acid in glass fiber filter paper (Fig. 3C). Both ions are anionic here, and they are separated. In the same electrolyte with cellulose paper, bismuth forms a streak toward the anode but does not leave the starting point entirely, while the mercuric ion moves scarcely at all. Glass paper may also yield a separation of lead from mercury and bismuth, but the fourth member of this group, thallium, is adsorbed and trails, hence overlapping the lead zone. Separation of all four ions in cellulose paper can be brought about by utilizing the bromide complexes, which were studied for mercury, lead, and bismuth by Pucar (2). A small zone of 0.1 *M* hydrogen bromide serves to separate these ions (Fig. 3D). The part of the strip moistened with another electrolyte (oxalic acid in this case) serves for the migration of any ion which leaves the hydrogen bromide zone without involving the high conductance of a strip completely moistened with hydrogen bromide. Tl(I) is a much faster cation than the rest and is readily separated from them.

A number of ions considered above were also studied in lactic acid by Sato *et al.* (3).

The behavior of Cr(III), Mn(II), Fe(III), and Co(II) in the strong chelating agents ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA), hydroxyethylethylenediaminetriacetic acid (HEDTA), and 1,2-diaminocyclohexanetetraacetic acid (DCTA) was investigated and a number of separations accomplished. Examples are shown in Fig. 4. Further data on the electromigration in these systems are given in Table II. The anionic complexes formed are slow and hence do not lend themselves to rapid separations. Diffuse and multiple zones were also encountered.

Separation of the alkali metals was also attempted. Potassium, rubidium, and cesium have very similar mobilities, and could not be completely separated under the conditions employed. Sodium was readily separated from the rest. Other workers have obtained similar results (4, 5, 6). Only Gross (7) has reported a separation of potassium, rubidium,

and cesium. Figure 5 shows typical results obtained. Alkali metal ions are readily separated from others in strong complexing agents. Figure 6 shows some separations of alkali metals and other univalent cations in NH_4OH–EDTA solutions. Silver forms multiple zones in this electrolyte, probably because of competition between the EDTA and the ammonia in forming complexes.

(C) Separation of Cs, Ba, and La in 1% citric acid; 160 v/cm, 8 minutes, 33° C.

Separation of the molybdate and pertechnate ions are shown in Fig. 7. The former, as Mo^{99}, was obtained as a product of nuclear fission, while Tc^{99m} is its radioactive daughter, and is present in 'carrier-free' form. In non-basic solution, the $MoO_4^=$ ion may be precipitated as molybdic acid, which probably accounts for its occurrence near the starting position in ammonium acetate and acetic acid solutions. Figure 7C shows its migration in NH_4OH, where no precipitation takes place. $MoO_4^=$ is slightly faster than TcO_4^- but, even after a movement of 40 cm, they are not completely separated. The cross-hatched region, measured immediately after separation, includes both molybdenum and technetium

activities, while the blackened region, measured 5 days later, includes none of the technetium present initially, since the half-life of Tc^{99m} is only 6 hours. Tc^{99} was not detected.

Separations of rubidium, strontium, and yttrium in acetic and citric acids are shown in Figs. 8A and 8B. Similar separations of cesium, barium, lanthanum were attempted, but barium invariably exhibited a trail back to the starting point when it moved as a cation (Fig. 8C). The cause of this is not known, but it may be due to precipitation of small amounts of barium by traces of sulphate in the paper. Further separations of strontium and yttrium, and of barium and lanthanum, in EDTA solutions, are shown in Figs. 9 and 10 respectively. In all of these experiments, the yttrium and the lanthanum were 'carrier-free'.

The separation of RaD, RaE, and RaF (Pb^{210}, Bi^{210}, and Po^{210}) was also investigated. Both bismuth and polonium tend to be adsorbed by the paper and trail. RaD can be separated from the other two in oxalic, citric, tartaric, lactic, or acetic acids, and separation of RaF from the rest may be accomplished in EDTA solution. In this, and in the other chelating agents used, RaD and RaE move with similar mobilities, so that it was not found possible to separate all three ions in one run under these conditions.

Sato *et al.* (3, 8) have reported the separation of lead, bismuth, and polonium in lactic acid, but the bismuth and polonium zones seem to overlap here also.

RELAXATION OF SURFACE PRESSURE AND COLLAPSE OF UNIMOLECULAR FILMS OF STEARIC ACID[1]

W. Rabinovitch, R. F. Robertson, and S. G. Mason

ABSTRACT

A study has been made of the time variations of π–A isotherms of stearic acid films at air/water interfaces using an automatic recording surface balance of the vertical pull type. The existence of coherent films below molecular areas of 22 sq. Å/molecule has been found to be dependent on the temperature, rate of compression, and the history of compression of a given film. The behavior at or near collapse, the decrease in π with time after sudden compression (relaxation), and the increase in π with time after sudden expansion (recovery) have been studied.

The results have been interpreted on the basis of structural changes in the monolayer.

INTRODUCTION

Although extensive studies have been made on the pressure–area (π–A) isotherms of simple long-chain fatty acids spread as unimolecular films at the air/water interface, little attention has been given to the possible time-dependency of these mechanical properties. By analogy with three-dimensional viscoelastic systems, it is not surprising that the π–A isotherms of two-dimensional systems should be time-dependent. This dependency has been observed experimentally under conditions of slow manual compression for stearic and other fatty acid films (1, 2, 3) and with automatic compression and surface pressure recording techniques for films of palmitic (4) and stearic (5, 6) acids.

The collapse of stearic acid films may occur with compression to 19 sq. Å/molecule surface area (5, 6, 7) or before this area is attained (1). In more definitive studies of collapse Muller (8) has suggested that a stearic acid film collapses by a stepwise wrinkling leading to the formation of numerous strata. Kimball and Ries (9) have reported the appearance of long wrinkles two molecules deep (100 Å) in electron micrographs of collapsed hexatricontanoic acid monolayers.

In the present study the π–A – time relations of stearic acid films have been investigated up to and beyond the collapse region in an attempt to elucidate the molecular processes associated with the formation and collapse of unimolecular films. Studies have been made of: (*a*) the effect of compression rate on the π–A isotherm, (*b*) the variation of π with time after repeated compressions and expansions of the film at molecular areas between 19 and 24 sq. Å, and (*c*) the effect of repeated compressions on the π–A isotherm of the same film.

EXPERIMENTAL PART

The Film Balance

Description

The surface pressure measurements were made with an automatically recording film balance of the Wilhelmy type. The balance incorporated a null-balance feature activated by the electronic servo-mechanism of Mauer (10) applied to a chainomatic balance. This surface balance was found to be capable of rapid and precise response to increasing or decreasing surface pressure.

[1]*Manuscript received June 10, 1960.*

Contribution from the Department of Chemistry, McGill University, and the Pulp and Paper Research Institute of Canada, Montreal, Que. Based on work conducted under Extramural Grant No. 2031-08 of the Defence Research Board of Canada. Presented at 43rd Annual Conference, Chemical Institute of Canada, Ottawa, Ontario, June 1960.

A Wilhelmy dipping plate is suspended by a nichrome wire from the bottom of the left-hand pan of a chainomatic balance. A galvanometer mirror attached at the fulcrum of the balance beam reflects a light beam from a source onto the separate twin cathodes of a phototube in a bridge circuit. The phototube senses the magnitude and direction of minute displacements of the balance arm from a given equilibrium position and translates the displacements into a proportional electrical voltage of corresponding polarity. By applying this voltage to the input of a direct-coupled amplifier an output current of corresponding magnitude and phase is obtained. This current is led through a solenoid whose field exerts a force on a magnet concentric with the solenoid and suspended from the right-hand pan connection of the chainomatic balance. The magnet is so oriented in the solenoid that the polarity opposes the displacement of the balance beam from equilibrium. When a vertical force is applied to the balance pan the system can be maintained continuously in equilibrium by this instantaneous self-balancing action. The balancing current was passed through a decade resistance and the resulting voltage was recorded by a multiple-span strip chart recorder (Minneapolis-Honeywell-Brown, Extended Range, Type 153).

Calibration

A clean dipping plate suspended from the nichrome wire was allowed to dip into a clean substrate surface and the initial zero reading of the balance was obtained after taring. A calibrating weight was placed on the balance pan and the positive deflection of the recorder was adjusted to full scale by the decade resistance. Normally the calibrating weight was chosen to give $\pi = 25$ or 50 dynes/cm for the full 10 in. chart width; however, the multiple-span feature of the recorder made it possible to extend the range to 50 inches when desired.

Characteristics of the Surface Balance

The surface balance response was highly stable over long periods of time (10 hours) and was linear within 0.1% for loads from 0 to 300 mg. Beyond 300 mg the instrument was not self-balancing with the size of magnet (1/4×3 in.) employed. The response time of the balance to rapidly changing surface pressure was limited by the response time (4.5 seconds) of the recorder pen for full-scale deflection.

With the conventional Wilhelmy surface balance in which the depth of immersion is changed by manipulation, measurement of decreasing values of π becomes uncertain since the downward movement of the dipping plate into the substrate may cause the contact angle to deviate from zero (11, 12). Since, however, vertical movement is negligible ($<10^{-2}$ cm) in this balance it was possible to measure both increasing and decreasing π to within ± 0.1 dynes/cm.

The Trough Assembly

A description of the air thermostat and barriers employed can be found in earlier publications (13, 14). The film area could be varied by stepwise manual compression or by a motor-driven barrier-moving device which provided either a fixed trough traverse time of 10 seconds or a variable traverse time of from 10 minutes to several hours.

Materials

The stearic acid (m.p. 69° C) used in these experiments was obtained from the Defence Research Chemical Laboratories, Ottawa, Canada. A stock solution of 0.00418 M stearic acid was prepared in benzene and used in all experiments. At the standard initial area of 880.9 sq. cm, 0.1 ml of this solution formed a film at 35 sq. Å/molecule initial area. All substrates were 0.01 N HCl aqueous solution.

Experimental Techniques

The dipping plate and teflon-coated trough and barriers were cleaned with chromic acid and rinsed with copious quantities of distilled water. After the trough and barriers were placed in the thermostat, the substrate solution was added, the dipping plate installed, and the balance brought to its equilibrium zero position. The surface was then checked for contamination by advancing the barrier from its initial position to one corresponding to an area 1/4 to 1/8th of the initial area. An increase in pressure of less than 0.25 dyne/cm during this compression was taken as the criterion of a clean surface. The system was left for several hours for temperature equilibration with the barrier at its initial position and then checked for surface contamination again before a film was spread.

RESULTS

Effect of Compression Rate on the π–A Isotherms

The pressure–area (π–A) isotherms were obtained on 0.01 N HCl substrates at 25° C over a range of compression rates from 0.04 to 2.43 sq. Å/molecule per minute. The results for three freshly spread monolayers are given in Fig. 1. Curve 1 of this figure is the

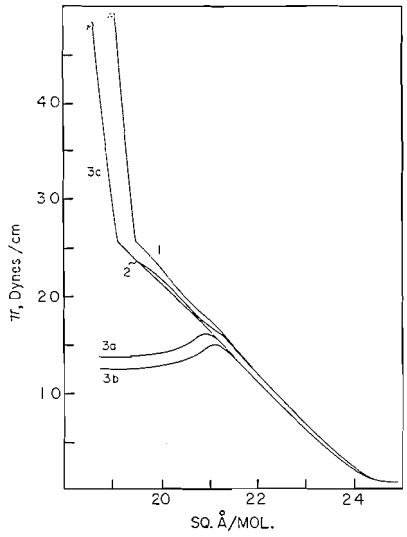

FIG. 1. Isotherms (25° C) of stearic acid monolayers determined at the following continuous compression rates in sq. Å per molecule/minute: 2.43 (curve 1), 0.213 (curve 2), 2.43 after a 7-hour rest period (curve 3). Curves 3*a* and 3*b* were obtained by slow manual stepwise compression as explained in the text, and 3*c* by recompression at 2.43 sq. Å/molecule per minute after expansion and resting for 7 hours at 35 sq. Å/molecule.

isotherm obtained from a film initially at a molecular area of 35 sq. Å under continuous compression at a rate of 2.43 sq. Å/molecule per minute and curve 2 is the isotherm of a similar film compressed at the rate of 0.213 sq. Å/molecule per minute. The isotherms represented by curves 3*a* and 3*b* were obtained by 30 stepwise compressions, each of 0.2 sq. Å/molecule, in the range 25 to 19 sq. Å/molecule of the surface area. The film initially at 35 sq. Å/molecule was compressed rapidly to 25 sq. Å/molecule and then by steps with 5 minutes between each compression. The surface pressure was noted immediately after each compression and immediately before the next. Curves 3*a* and 3*b* are the isotherms obtained on plotting these two values of the surface pressure. After the slow stepwise

compression the film was rapidly expanded to 35 sq. Å/molecule, left for 7 hours, and then recompressed continuously at a rate of 2.43 sq. Å/molecule per minute to obtain curve 3*c*. The significance of these observations is discussed later.

Surface Pressure Relaxation and Recovery

A study was made of the variation with time of the surface pressure at constant area after sudden compression and expansion. Adopting the customary nomenclature, the decrease in π with time after rapid compression is called pressure relaxation, and the increase in π with time after rapid expansion is called recovery.

All experiments were made at 25° C with the film at an initial area of 35 sq. Å/molecule. This monolayer was rapidly compressed or expanded between molecular areas of 24 and 21 sq. Å, and the pressure recorded as a function of time t at each intermediate area. The details of the experimental operations for one typical film are given in Table I and the results are given as plots of π vs. t in Figs. 2 (A, B, C, D), 3, and 4.

TABLE I

15	22	23	"	"	19	4	14
16	23	24	"	"	10	2A	15
				Total time = 335			

NOTE: Initial area = 35 sq. Å/molecule. Initial π = 0.17 dynes/cm. Temperature = 25° C.

At areas of 24, 23, and 22 sq. Å/molecule the pressure relaxation is shown in Figs. 2 and 3 to be 0.13 dyne/cm in 10 minutes. At 21 sq. Å/molecule, however, the relaxation is 1.7 dynes/cm in 10 minutes (a 10-fold increase) and after 2 hours the pressure has decayed by about 5 dynes/cm. On subsequent expansion the pressure recovery is of the same order as the relaxation (Fig. 4). The curves obtained for both the relaxation and recovery seem to indicate that these two phenomena reflect properties of the monolayer and are not the result of slow solution and diffusion of film molecules into the substrate.

Surface Pressure Relaxation at 19 sq. Å/molecule

At a compression rate of 2.43 sq. Å/molecule per minute the monolayer attained a surface pressure before collapse in excess of 45 dynes/cm at a molecular area of about 19.5 sq. Å (Fig. 1, curve 1). Other workers (5–7) have reported maximum surface pressures from 55 to 62 dynes/cm at molecular areas near 18.5 sq. Å for stearic acid films compressed

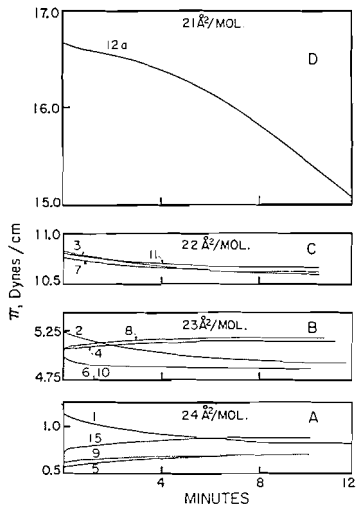

FIG. 2. Relaxation and recovery curve over 10 to 12 minutes. See Table I for details of curves.

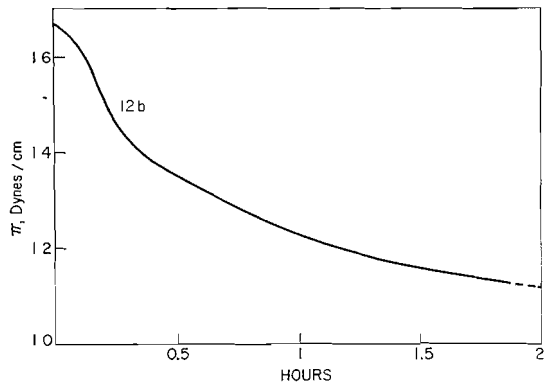

FIG. 3. Relaxation curve over a 2-hour period at 21 sq. Å/molecule (see Table I).

at rates in excess of 3 sq. Å/molecule per minute. To examine pressure relaxation at the pressure maximum obtained on rapid compression, a film initially at an area of 35 sq. Å/molecule was compressed at a rate of 2.43 sq. Å/molecule per minute until the pressure maximum was attained and the surface pressure recorded with time at constant area. Figure 5 shows the π–A isotherm (part A) and the relaxation plot (part B), respectively, for a film at an initial pressure maximum of 45 dynes/cm and a molecular area of 19.2 sq. Å.

It is apparent from Fig. 5 that on decreasing the molecular area from 19.5 to 19.2 sq. Å during compression, 7.5 seconds were required for the film pressure to increase from 25 to 45 dynes/cm, but on stopping the barrier 12 seconds were required for the pressure to decay from 45 to 25 dynes/cm at 19 sq. Å/molecule. The rate of pressure decay changed markedly (20-fold) at 25 dynes/cm reflecting the similar discontinuity in the isotherm at 25 dynes/cm pressure. This behavior was demonstrated a number of times with different films.

Part B: Relaxation of π at constant area of 19.2 sq. Å/molecule.

Isotherms on Repeated Compressions and Expansions

The π–A isotherms were obtained for films subjected to repeated compressions and expansions. After spreading a film to an initial area of 35 sq. Å/molecule the monolayer was compressed at a rate of 2.43 sq. Å/molecule per minute to the maximum pressure and immediately re-expanded to 35 sq. Å/molecule and left at this molecular area for

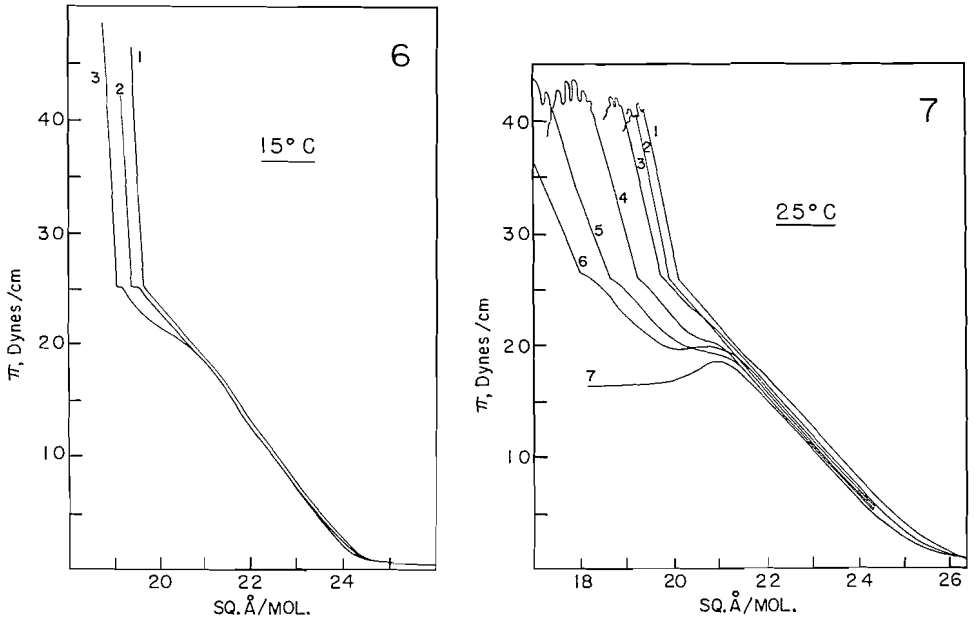

FIG. 6. Isotherms of a repeatedly compressed and expanded film at 15° C. Curve numbers represent the sequence of compressions.

FIG. 7. Isotherms of repeatedly compressed and expanded film at 25° C. Curve numbers represent the sequence of compressions.

1 hour to permit respreading. After this time interval the film was recompressed as before. Figures 6 and 7 are the isotherms obtained from such a series of compressions and subsequent expansions at 15° C and 25° C respectively. The curves are numbered according to the sequence of compressions.

The isotherms obtained with successive compressions are very similar to those obtained by varying the rate of compression (Fig. 1). The highly incompressible solid phase persists on the 15° C isotherm after three compressions but is shifted to smaller molecular areas with each compression (Fig. 6). The shift in area results from a change in the slope of the isotherm just before the appearance of the solid phase of constant compressibility similar to that apparent in Fig. 1. At 25° C the shift of the solid phase to progressively smaller areas with succeeding compressions becomes strikingly evident (Fig. 7). Not only does a marked change occur in the shape of the isotherm before the appearance of the solid phase, as found in varying the compression rate (Fig. 1), but the slope of the isotherm and hence the compressibility of the solid phase change with each compression and finally the phase disappears (Fig. 7, curve 7). There is some indication of a change in slope in the solid phase isotherm itself (Fig. 7, curve 5).

DISCUSSION

Heller (4) has reported that the shape of the π–A isotherm of palmitic acid monolayers depends on the rate of compression of the film. A similar dependence with stearic acid monolayers is indicated in Fig. 1, in which substantially the same film compressibility from molecular areas of 24.5 to 21 sq. Å is shown; below 21 sq. Å/molecule, however, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

marked divergence is apparent in the shape and slope of the curves. At the highest compression rate (2.43 sq. Å/molecule per minute) the highly incompressible solid phase of stearic acid monolayer is evident (Fig. 1, curve 1). When the compression rate was reduced to 0.213 sq. Å/molecule per minute (Fig. 1, curve 2) the isotherm was identical with curve 1 until a 21 sq. Å/molecule area was reached and a more compressible intermediate film appeared. With slow manual compression (Fig. 1, curves 3*a*, 3*b*) the slope of the isotherm was again identical with the others until reaching 21 sq. Å/molecule, but on further reduction of the molecular area neither the solid film nor the intermediate film appeared. Further, pressure relaxation, essentially absent at molecular areas greater than 21 sq. Å/molecule, became measurable at smaller molecular areas when slow compression was used (Fig. 1, curves 3*a*, 3*b*).

The absence of the solid phase in curves 2, 3*a*, 3*b* of Fig. 1 seems to be associated with the compression rate, since 7 hours after slow compression the film readily exhibited the highly incompressible solid phase (Fig. 1, curve 3*c*). The maximum pressure attained before collapse seems similarly dependent on the rate of compression (Fig. 1); collapse occurred at surface pressures varying from 15 to 49 dynes/cm and from 21 to 19.4 sq. Å/molecule as the rate of compression was increased. The work of Dervichian (6) on stearic acid films, which reports a pressure maximum of 61 dynes/cm at 18.6 sq. Å/molecule under an estimated compression rate of 18 sq. Å/molecule/min, corroborates these findings.

The point of collapse near 21 sq. Å/molecule for slowly compressed monolayers appeared as an inflection on the isotherm obtained under rapid compression (Fig. 1). Inflections of this type have been reported for stearic acid (15) and behenic acid (16) and have been related to the appearance of a second-order phase transition in the film. The nature of this transition point is obscure, Adam (17) suggesting that the head group packing beneath the film is responsible for the effect.

According to Vold (18) a molecular cross-sectional area of 25.2 sq. Å can be calculated from the volume swept out during the rotation of vertically oriented fatty acid molecules of the stearic type with the head groups close-packed and planar in the water surface (Fig. 8(*a*)). The discontinuity found at 25 sq. Å/molecule in the π–A isotherms of stearic acid monolayers is assumed to reflect the appearance of such a surface configuration with free rotation permitted. When the film molecules are identically oriented on the surface but no longer free to rotate, the molecular cross-sectional area, now ovoid, is calculated to be 20.5 sq. Å for the most efficient packing (Fig. 8(*b*)). The π–A isotherm of stearic acid on compression from 25 to 21 sq. Å/molecule can be assumed to reflect the progressive inhibition of free rotation until at the lower area rotation is completely restricted. At this point the compressibility of the film would depend on the compressibility of the head groups only and should decrease markedly. The discontinuity in the π–A isotherm at 21 sq. Å/molecule does in fact reflect this change to a lower compressibility. As the lateral compression continues and the film approaches collapse, the planar configuration of the head groups (Fig. 8(*c*)) should give way to a multiplanar one as head groups are forced to a position either above or below the original plane (Fig. 8(*d*)). Finally some of the stearic acid molecules may invert under lateral compression to form a second molecular layer (Fig. 8(*e*, *f*)) with ensuing collapse.

If the inversion process requires time, the appearance of the solid film on rapid compression may be the consequence of insufficient time for inversion between the moment at which 21 sq. Å/molecule area was reached and the moment of general collapse of the film.

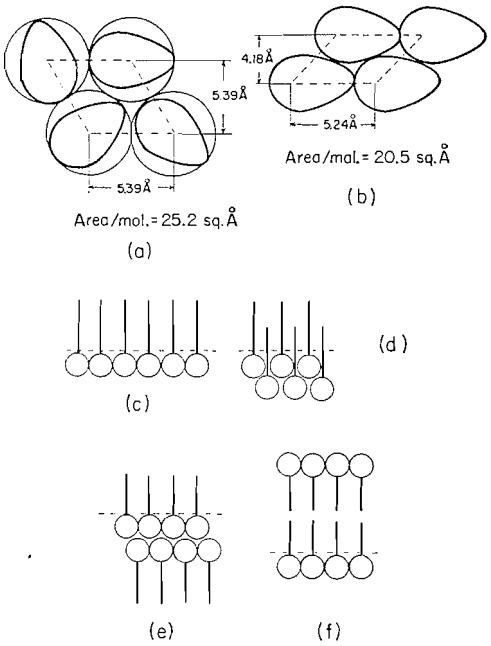

FIG. 8. Possible configuration of stearic acid monolayers.
(*a*) At 25 sq. Å/molecule, free rotation (18). (*b*) At 21 sq. Å/molecule, no rotation (18).
(*c*) Planar configuration at 21 sq. Å/molecule. (*d*) Below 21 sq. Å before inversion.
(*e*, *f*) Possible modes of inversion below 21 sq. Å/molecule.

As the compression rate is decreased the time per unit change in area after attaining 21 sq. Å/molecule increases and the time available for inversion increases. Consequently the inversion process can occur to an extent dependent on the particular compression rate employed. With intermediate compression rates a competition can occur between the processes of solid film formation and inversion resulting in the π–A isotherm of variable compressibility found by experiment. At very low rates of compression the time available for inversion is so great that the film molecules can invert at a rate at least equal to the compression rate and no solid or intermediate film is formed.

The variation in slope and hence compressibility illustrated in Figs. 6 and 7, obtained by successive compressions and expansions, can also be explained by a process of inversion. With rapid compression to areas below 21 sq. Å/molecule a small fraction of the molecules may invert but not in sufficient numbers to alter the apparent compressibility of the solid phase. With subsequent expansion the inversion process may be reversed but the molecules involved retain a configuration on the surface favorable to rapid inversion on subsequent compression. On immediate recompression these molecules rapidly invert and others follow, thus increasing the fraction of film molecules conditioned for rapid inversion in the next expansion–compression cycle. The over-all effect of this mechanism would be an apparent increase in the inversion rate with each successive compression until the rate of the inversion process approaches the rate of compression and no solid film appears (Fig. 7).

ANIONIC POLYMERIZATION OF STYRENE[1]

D. J. Worsfold and S. Bywater

ABSTRACT

A study of the kinetics of the initiation and propagation reactions in the polymerization of styrene by butyllithium in benzene solution has been made. The initiation has been shown to be first order in styrene and 0.155 order in butyllithium, the propagation to be first order in styrene and half order with respect to active chain ends. The apparent activation energies of the two reactions have been shown to be 18,000 calories and 14,300 calories respectively. The ultraviolet absorption spectra of colored species produced has been measured and compared with others found in similar systems.

The polymerization of styrene by butyllithium in benzene solution is an anionic chain reaction comprising initiation and propagation steps. Chain termination is negligible if the starting materials are rigorously purified and the reaction is carried out in a high vacuum system. Previous kinetic studies on this system have followed only the rate of monomer consumption (1, 2). Since, however, the reaction is complicated by the fact that initiation and propagation rates are of comparable magnitude under many experimental conditions, it seemed desirable to study the initiation and propagation steps separately. The method employed to follow the reaction was photometric using the known absorption bands of styrene and the absorption band of the polystyryl anion measured as described later. Because of the high extinction coefficient of both compounds, the concentration ranges studied were lower than previously used or overlapped their lower concentration range.

EXPERIMENTAL

The butyllithium was supplied by Foote Mineral Company as a 16% solution in a heptane/pentane solvent mixture.

The purification of the styrene has been described before (3).

Reagent grade benzene was stirred for a week with concentrated sulphuric acid, washed with water, with dilute sodium hydroxide solution, and again with water. It was distilled from phosphorus pentoxide onto calcium hydride, degassed, and stored under vacuum. The benzene was distilled in the vacuum system as needed to a smaller reservoir containing butyllithium from which the solvent had been removed by pumping. From here it was transferred to the reaction vessel by distillation.

The techniques used in the handling of the reactants under high vacuum have been described before (3) and entailed using small fragile glass bulbs of the reactants, and glass-covered magnetic bars for breaking them. All reaction vessels were washed with a solution of butyllithium in benzene and rinsed by refluxing as before, after all the reactant bulbs had been sealed inside and the vessels evacuated.

It was necessary to dilute the stock butyllithium solution by a factor of 50 or more before it could be used. A milliliter of the stock solution was transferred by hypodermic syringe in a dry nitrogen box to a fragile glass bulb, connected to a stopcock, that previously had been evacuated and reopened in the dry box. The bulb was then pumped and sealed off. This butyllithium was diluted 50 times and sealed into a large number of similar bulbs in a vacuum apparatus by the methods referred to above. It had been

[1]*Manuscript received June 3, 1960.*

Issued as N.R.C. No. 5921.

determined previously that handling 1 milliliter of the stock solution by syringe in this manner destroyed less than 2% of the butyllithium.

Lithium analyses were performed spectrophotometrically using a solution of "Thorin" on aliquots of the lithium polystyryl solution after the benzene had been evaporated on a hot plate, and the polymer burned off at a temperature of less than 500°. Higher temperatures seemed to cause loss of lithium. The analysis is reputed to have an accuracy of 3%.

The optical cells used were made of 1-cm sq. clear quartz tubing, and could be converted to 1-mm cells with appropriate square quartz blocks. The cells were calibrated with potassium chromate solution. The spectra were measured on a Beckman DU spectrophotometer.

To show that the absorption band of the polystyryl salt obeyed Beer's law, the optical cell was connected to a graduated tube, with benzene in a reservoir joined to the cell and tube. The optical density of a solution of the polystyryl lithium salt at 335 mμ was measured over a 10-fold range of dilution, and the dependence was shown to be linear. Styrene was estimated at 291 mμ after a correction for the tail of the polystyryl ion band was applied.

The vessels used for the kinetic experiments, and for the determination of the spectra of the lithium polystyryl salt, are shown in Fig. 1, which is thought to be self-explanatory. The volume of reaction mixture was about 50 milliliters. Only one bulb of catalyst was used, but successive additions of styrene were achieved by breaking in turn up to three bulbs of styrene. This enabled the propagation step to be followed separately after

measurements of the optical density at 335 mμ had indicated that chain initiation was complete. The breaking of successive bulbs of styrene after this point could sometimes decrease the optical density by 1 to 2% due to the presence of residual impurities. Otherwise once it had attained a steady value, it remained constant during the course of a kinetic run (about 4 hours) and only decreased slowly over a period of weeks. This indicates that chain termination is negligible in this system under the experimental conditions used.

The reactions were carried out at 30.3°, except those for the temperature dependence, which were carried out over the range 10.0°–30.3°.

RESULTS

The spectrum of the colored species produced by the action of butyllithium on styrene in benzene solution was found to consist of a single absorption band centered at 334 mμ, with a long wavelength wing extending into the visible region which gives the solution its yellow color. The short wavelength wing was lost in the accompanying polystyrene bands below 280 mμ. Assuming that the structure of this species is $[\text{———}CH_2CHPhCH_2\overset{-}{C}HPh.\overset{+}{L}i]$, the extinction coefficient of the polystyryl ion was determined by analysis of the solution for lithium. The results are shown in Table I.

To confirm that each butyllithium molecule initiated one polymer molecule, the molecular weights of three of the polymers from the kinetic experiments were determined viscometrically using a viscosity – molecular weight relationship determined using monodisperse polystyrenes (4). The conditions of preparation were such that the initiation reaction was completed rapidly compared with the propagation reaction, and the three polymers could be expected to have a low $\bar{M}_w/\bar{M}_n$ ratio. The molecular weights calculated from the butyllithium and total styrene concentrations, assuming no chain transfer, are compared with the experimental values in Table II. The first two polymers were terminated by methanol, the third by exposure to air. The last entailed two separate additions of styrene.

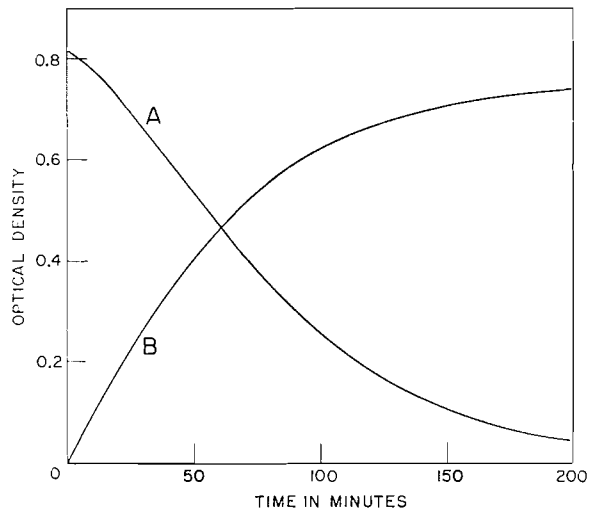

FIG. 2. Typical reaction curves of initiation reaction.
A. Disappearance of styrene measured at 291 mμ.
B. Appearance of polystyryl ion at 335 mμ.
Initially, [styrene] = 1.39×10^{-2} moles/liter; [butyllithium] = 1.10×10^{-3} moles/liter.

The reagent consumption curves of a typical initiation reaction are shown in Fig. 2.

The initial rates of formation of the colored species were determined from the plots of optical density versus time. The plots are usually not strongly curved and the initial tangent could probably be drawn with an accuracy of 5% or better. The results are shown in Table III.

Consideration of the first section suggests that the rate of formation of polystyryl

anions is first order in styrene, the second section shows the rate to increase very slowly with butyllithium concentration. A plot of $\log_{10}$ (initial rate/[styrene]) against $\log_{10}$ [butyllithium] is relatively insensitive at such low orders, but appears to give $0.155 \pm 10\%$ for the order with respect to the butyllithium for concentrations between 5×10^{-5} M and 4×10^{-2} M (Fig. 3). This is close to an order of 1/7 or 1/6, and for convenience, and with

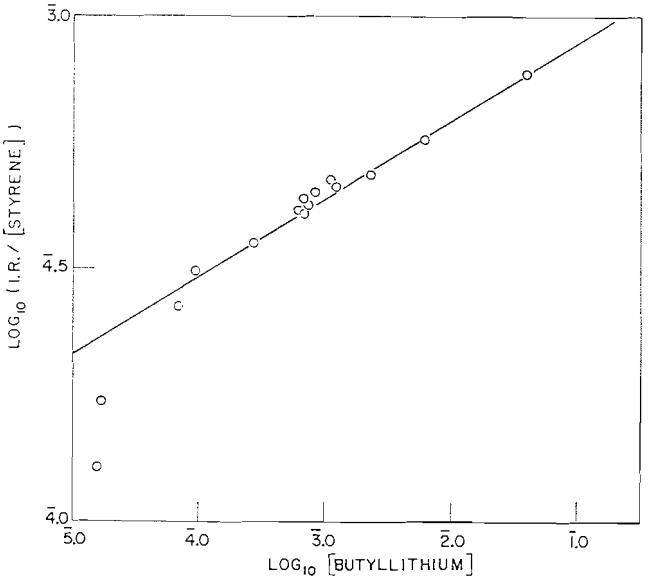

FIG. 3. Dependence of initiation rate on butyllithium concentration.

some theoretical justification the latter figure has been used subsequently. The two runs at concentration below 2×10^{-5} M showed deviation from this behavior, their rates being too low.

Plotting initial rate/[lithium butyl]$^{1/6}$ against [styrene] for the seven runs with butyllithium concentration between 6×10^{-4} M and 1.2×10^{-3} M gives a good straight line over the range of styrene concentration 3×10^{-3} M to 3×10^{-2} M (Fig. 4). Thus the over-all expression for the initial rate of formation of polymer chains, or consumption of butyllithium is given by

$$d\,[\text{butyllithium}]/dt = -k_1\,[\text{butyllithium}]^{1/6}\,[\text{styrene}]$$

and the values of k_1 calculated for individual kinetic experiments are given in Table III.

If sufficient monomer were present, the optical density at 335 mμ would increase to a maximum and then remain constant, at which point it was assumed that all the butyllithium had reacted to form active chains. The propagation reaction, once all the chains had been initiated, was followed by the consumption of the residual monomer, or by the consumption of further bulbs of styrene broken into the reaction mixture. Here, of course, the method of initial rates could not be used. The rate of consumption of monomer, however, followed a first-order course over a matter of at least four half-life times, at which point the precision of the analysis was the limiting factor. A logarithmic plot of this first-order rate against the initial butyllithium concentration (equal to the number

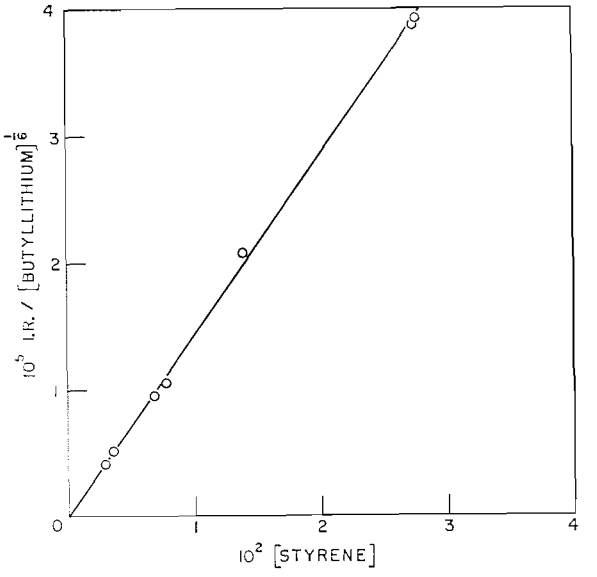

FIG. 4. Dependence of intiation rate on styrene concentration.

of polystyryl ions present) showed a good half-order dependence of the rate on the butyllithium concentration (Fig. 5). The kinetic equation for the propagation reaction is then

$$d\,[\text{styrene}]/dt = -k_2\,[\text{styrene}]\,[\text{butyllithium}]^{1/2}.$$

The temperature dependence of the initiation reaction was found to correspond to an apparent activation energy of 18,000 calories, that of the propagation reaction to 14,300

calories, for the temperature range 10.0°–30.3°. The appropriate mean rate constants calculated assuming the same kinetics apply at the lower temperatures are shown in Table IV. The half-order dependence on the butyllithium concentration of the first-order disappearance of monomer in the pure propagation reaction was confirmed at all four lower temperatures, but not the orders of the initiation step.

DISCUSSION

The absorption band of the lithium polystyryl compound in benzene with a maximum at 334 mμ is very similar to the absorption band of the similarly prepared compound in tetrahydrofuran, which has a maximum at 340 mμ and extends rather more into the visible region. The absorption bands of the lithium compounds cut off much more sharply than do the absorption bands of the sodium and potassium polystyryl salts in tetrahydrofuran which have a maximum at 343 mμ and extend so far into the visible region to give their solution a red color, whereas the lithium salts are yellow. All the bands are sufficiently similar to suppose that they are due to the same species, the polystyryl anion, somewhat modified by the environment composed of the solvent and gegenion. The integrated area under the band of the lithium polystyrene salt in benzene, extrapolated where it is lost in the bands of polystyrene, has about 85% of the corresponding area of the sodium compound in tetrahydrofuran. If the arguments of Evans *et al.* (5) concerning similar bands of carbonium ions are valid, this would suggest that the ionic nature of the C—metal bond is very little reduced in changing to the less favorable conditions of dielectric constant and alkali metal ion. There was no change in the optical density of solutions at 335 mμ in the temperature range 10° to 30°, suggesting that there is no temperature-dependent equilibrium between ionic and nonionic forms in this range.

The most straightforward schemes that can be suggested to explain the kinetics found for the reaction of butyllithium with styrene are as follows:

$$\text{Initiation}\begin{cases}(\text{Li Bu})_6 \rightleftharpoons 6\ \text{Li Bu} & [1]\\ \text{Li Bu} + \text{styrene} \rightarrow \text{Bu(M)}_1^-\ \text{Li}^+ & [2]\end{cases}$$

$$\text{Propagation}^*\begin{cases}(a)\begin{cases}[\text{Bu (M)}_n^-\ \text{Li}^+]_2 \rightleftharpoons 2\text{Bu(M)}_n^-\ \text{Li}^+ & [3]\\ \text{Bu (M)}_n^-\ \text{Li}^+ + \text{styrene} \rightarrow \text{Bu(M)}_{n+1}^-\ \text{Li}^+ & [4]\end{cases}\\ (b)\begin{cases}\text{Bu (M)}_n^-\ \text{Li}^+ \rightleftharpoons \text{Bu(M)}_n^- + \text{Li}^+ & [5]\\ \text{Bu (M)}_n^- + \text{styrene} \rightarrow \text{Bu(M)}_{n+1}^- & [6]\end{cases}\end{cases}$$

The subscript 6 applied to the butyllithium aggregate is probably an average.

A strong argument in favor of the first propagation scheme can be made on the basis of the behavior in the sodium naphthenide catalyzed polymerization of α-methylstyrene in tetrahydrofuran. Here the propagation step is close to first order in initiator (6). Conductivity measurements on the sodium polystyryl salt (3) indicate that it exists largely in the form of ion pairs in this solvent. Both facts suggest that the ion pair is the reactive species in this solvent. Molecular weight determinations in boiling ether (7) suggest that lithium benzyl and lithium phenyl exist in the form of dimers so presumably lithium polystyryl would be expected also to be dimerized in solvents of low dielectric constant. The heat of dissociation of the dimer $(\text{Bu(M)}_n^-\text{Li}^+)_2$ would have to be in this

**In the first scheme (a) it is assumed that the reaction is due solely to ion pairs in equilibrium with ion pair dimers, and in the second scheme (b) it is due solely to the extremely low concentration of free ions which are in equilibrium with the ion pairs. The equilibria 1, 3, and 5 are normally predominantly on the left-hand side of the equations.*

For personal use only.

case somewhat over 10 kilocalories as the apparent activation energy of the propagation step (14,300 calories) would be composed of its heat of dissociation and the actual activation energy of the propagation step. The latter is presumably low as was the case in tetrahydrofuran solution. A heat of dissociation of this magnitude is not incompatible with the apparent high stability of alkyl and aryl lithium complexes in solutions of low dielectric constant. On the other hand, similar arguments applied to the second propagation step infer a similar heat of dissociation of the ion pair into kinetically free ions. This appears to be much too low for this process in benzene solution.

The activation energy of the initiation step of 18,000 calories would consist of an activation energy and a dissociation energy of the same type. The activation energy of attack of the comparatively covalent butyllithium on styrene would be expected to be higher than that of the propagation step, thus allowing a similar heat of dissociation of butyllithium. One difficulty which applies to the initiation scheme is the great dilutions at which the butyllithium aggregates must remain in the form of hexamers. The experimental results suggest no significant breakdown above a concentration of 5×10^{-5} M. Several studies of the degree of association of ethyllithium and butyllithium in ether and benzene by measurement of freezing point depression or boiling point elevation (8, 9, 7) have indicated a value of about six in the concentration range down to 1/10th molar. One other study under identical conditions (10) indicated a degree of association of two. A study of the infrared spectra of ethyllithium and butyllithium (11) was interpreted to show that in benzene or hexane on dilution, the hexamer fairly rapidly dissociated to dimer and monomer in the same concentration range. Further work on this topic is obviously desirable before adequate comment can be made on the low order of the initiation step with respect to butyllithium.

An attempt can be made at analysis of the system for the over-all disappearance of monomer during the period which both consecutive reactions are occurring. Whatever the detailed mechanism, the kinetic scheme may be written

$$C+M \rightarrow M_1^- \quad \frac{d[\mathrm{M}^-]}{dt} = k_1[\mathrm{C}]^{1/6}[\mathrm{M}]$$

$$M_n^- + M \rightarrow M_{n+1}^- \quad \frac{d[\mathrm{M}]}{dt} = -k_2[\mathrm{M}^-]^{1/2}[\mathrm{M}]$$

where $[\mathrm{M}^-] = \Sigma[\mathrm{M}_n^-]$, using the rate constants shown in Table IV.

TABLE IV

Summary of rate constants

Temp., °C	$k_1\times10^4$, liters$^{1/6}$ mole$^{-1/6}$ min^{-1}	k_2, liters$^{1/2}$ mole$^{-1/2}$ min^{-1}
30.3	14.0	0.929
25.0		0.563
20.0	4.68	0.387
15.0		0.265
10.0	1.45	0.155

The complete solution of the differential equations of consecutive, competing reactions is only available for the simplest of cases, and not for this particular case. It is possible to obtain a partial solution by eliminating the variable time, leaving C and M as the variables, and also with the simplification of ignoring monomer consumption in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

initiation stage. Then by treating the resultant equation as two separate binomial series it is possible to obtain

$$[M_0-M] = \frac{k_2}{k_1} C_0^{4/3}\left(\frac{2}{3}\left[\frac{M^-}{C_0}\right]^{3/2}+\frac{1}{15}\left[\frac{M^-}{C_0}\right]^{5/2}+\frac{1}{36}\left[\frac{M^-}{C_0}\right]^{7/2}+\frac{91}{5832}\left[\frac{M^-}{C_0}\right]^{9/2}\cdots\right)$$

for $0 \leqslant M^- < C_0$

and

$$[M_0-M] = \frac{k_2}{k_1}C_0^{4/3}\left(\frac{6}{5}\left[\frac{C_0-M^-}{C_0}\right]^{5/6}-\frac{6}{22}\left[\frac{C_0-M^-}{C_0}\right]^{11/6}-\frac{6}{136}\left[\frac{C_0-M^-}{C_0}\right]^{17/6}-\frac{6}{368}\left[\frac{C_0-M^-}{C_0}\right]^{23/6}\cdots\right)$$

for $0 < M^- \leqslant C_0$.

The latter expression converges more rapidly than the first, but taking the first part for $0 \leqslant M^- \leqslant C_0/2$ and the second for $C_0 \geqslant M^- \geqslant C_0/2$, only four terms or less are necessary to evaluate either.

From these equations it should be possible to plot $[M_0-M]$ against the computed values of the right-hand side for values $[M^-/C_0]$ in the initiation reaction, and thus evaluate k_2/k_1 from the resultant straight lines. This was done whenever possible and the value of k_2/k_1 at 30.3° for eight of the runs was 522, compared with 665 obtained from the k_1 of the initial rates, and the k_2 of the pure propagation reaction. Again at the lowest butyllithium concentration the ratio was abnormal being twice the mean, and not included in the the mean.

The discrepancy between the two values of k_2/k_1 is probably no more than the experimental error, but it could be due to the excess butyllithium complexing with the propagating species and depressing the rate, as was suggested by Tobolsky (1). This would lower the k_2/k_1 ratio obtained under conditions where both reactions were occurring simultaneously. But for the reaction with the highest concentration of lithium butyl (3.88×10^{-2} moles/liter), where it is in large excess (only 2% reacted whilst most of the monomer was consumed), the value of k_2/k_1 is only 30% lower than the mean, although it had the largest deviation by a factor of two. This is taken to indicate that the propagation reaction is very largely independent of the excess butyllithium, because if the kinetics were changed appreciably the equations above would not hold as well as they do.

From the form of these equations it is seen that, as is expected of a reaction with an order of less than one, the initiation reaction goes to completion at a finite monomer consumption. For any given starting butyllithium concentration, it is possible to calculate the required initial monomer concentration to ensure all the butyllithium has reacted, with the qualification that when the unreacted butyllithium concentration approaches 10^{-5} M, the kinetic scheme is no longer valid. For an initial catalyst concentration C_0 to react completely, the monomer concentration must equal $0.84\ C_0^{4/3}\ k_2/k_1$. Taking a mean value at 30° of 600 for k_2/k_1 and a value of $C_0 = 0.01$ M, the initial monomer concentration must be 1.08 M for complete reaction; for 50% of the butyllithium to react the monomer concentration must be 0.326 M. At points before all the butyllithium has reacted, it is possible to compute that the ratio $\bar{M}_w/\bar{M}_n \sim 1.28$; further consumption of monomer will decrease this ratio.

This implies that at initiator concentrations greater than 0.01 molar and using a molar solution of monomer the reaction will exhibit the combined characteristics of the initiation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and propagation reaction. It will not be possible to study the propagation reaction separately even at later stages in the reaction. Due to the low order in butyllithium the rate of styrene consumption will appear to be largely independent of initiator concentration. A semiquantitative study of the complex kinetic equations shows that the percentage conversion will be a linear function of time over a fairly wide conversion range and that the apparent order with respect to initial monomer concentration will be between one and two. Generally speaking therefore our kinetic scheme is compatible with the results of O'Driscoll and Tobolsky (1) even though we have postulated a different propagation step and the absence of chain termination.

A comparison with the paper of Welch (2) is somewhat more difficult. Although he claims to have followed the propagation reaction only, it seems from the analysis given above that his highest concentration reactions were performed under such conditions that he could not free the propagation reaction from the initiation reaction by his experimental procedure. This is supported by the appearance of his typical first-order polymerization plot at the highest concentration, which curves in a way that would be predicted. The apparent change to zero order in butyllithium at concentrations above 0.02 M could well be due to the reasons outlined above. It should be noted, however, that our experiments do not show that a decrease in order of the propagation reaction at these concentrations does not occur, as all the kinetic runs on this reaction were conducted well below them. In fact such a decrease in order is quite possible as higher aggregates are likely to form in more concentrated solutions, although the measurements of Wittig *et al.* (7) did not show this.

The first-order dependence found by Welch for the propagation step on lower concentrations of butyllithium is at variance with the half order found in this work. The reason for this probably lies in the different methods of analysis for active chain ends. The optical method used here is simpler and more direct than that used by Welch since he calculated the butyllithium concentration from the viscosity of the polymer produced. Although the method of Welch is basically sound, it would require a far more rigorous technique to be truly effective. This Welch demonstrated when, using as he described extreme precautions in his procedure, he found agreement with the molecular weight–viscosity relationship of Szwarc *et al.* (12), who noted a discrepancy of a factor of about two between it and the true relationship. By picking individual points from the graph in the paper of Welch, it is possible to calculate the rate constants to fit the kinetic equation in this paper, and it is found that they are generally about 25% lower than the constant found at 20° here. Although his results for the lower half of his concentration range show considerable scatter, they are a reasonable extension of the half-order dependence on butyllithium.

HYDROGEN BONDING IN THE AMINE HYDROHALIDES

III. NEAR-INFRARED SPECTRA OF ALIPHATIC AMINE HYDROHALIDES[1]

P. SAUVAGEAU AND C. SANDORFY

ABSTRACT

The first overtones of the $\overset{+}{N}H_n$ (n = 3, 2, or 1) stretching fundamentals are very weak and difficult to locate. Binary combinations between $\overset{+}{N}H_n$ stretching and $\overset{+}{N}H_n$ bending vibrations and also $\overset{+}{N}H_n+CH_n$ stretching–bending combinations fall into the 4600–4400 cm^{-1} area for primary and secondary amine hydrohalides and are much stronger. The intensity of these combination bands is not due to the anharmonicity of the potential surface but to the electrical anharmonicity of bending vibrations.

INTRODUCTION

There is a fargoing analogy between the vibrations of $\overset{+}{N}H_3$ and $\overset{+}{N}H_2$ groups on the one hand and CH_3 and CH_2 vibrations on the other and the most characteristic bands of the near-infrared spectra of both aliphatic hydrocarbons and alkylammonium ions are combinations between CH_n and $\overset{+}{N}H_n$ stretching and CH_n and $\overset{+}{N}H_n$ bending vibrations (n = 3, 2, or 1).

Let us suppose first that these vibrations are completely localized in the respective functional groups. Then, as a CH_3 group has C_{3v} symmetry, the asymmetric stretching vibrations (near 2967 cm^{-1}) will be doubly degenerate and the symmetric one (near 2872 cm^{-1}) non-degenerate. The first overtone of the former may split into two levels, belonging to irreducible representations A_1 and E because of anharmonicity. The latter will give one overtone of symmetry A_1. Transitions from the ground state to all these levels are allowed. The combination of the two stretching vibrations (E) is also allowed. Thus we expect to find four bands in the 5800 cm^{-1} area. This argument holds for the $\overset{+}{N}H_3$ group as well. For the hydrogen bonded species the asymmetric and symmetric stretching vibrations appear to be close to each other. They are also close to the stretching vibrations of the CH_3 group (1, 2, 3).

For the CH_3 bending vibrations again the asymmetrical one (near 1460 cm^{-1}) is degenerate (E) and the symmetrical one (near 1375 cm^{-1}) is non-degenerate (A_1). Thus again there are four binary combinations. The same applies to the $\overset{+}{N}H_3$ group with its bending bands lying close to 1600 and 1500 cm^{-1}.

Combinations between one stretching and one bending vibration yield certain new features. If the two asymmetrical vibrations are combined, A_1, A_2, and E states result. Transition from the ground state to A_2 is forbidden, so two bands remain. The two symmetrical vibrations would give one allowed totally symmetrical combination. The sum of the asymmetrical stretching vibration and the symmetrical bending vibration would give one level (E); the sum of the symmetrical stretching vibration and the asymmetrical bending vibration would also give one level. Together, five bands would result.

Contribution from Département de Chimie, Université de Montréal, Montréal, Qué.

Can. J. Chem. Vol. 38 (1960)

The situation is simpler for localized CH_2 or $\overset{+}{N}H_2$ vibrations. Under C_{2v} symmetry all vibrations are non-degenerate and all binary combinations between stretching and bending bands are allowed. This would yield three bands due to combinations of the stretching vibrations, one overtone for the bending vibration and two stretching–bending combinations. (As a general reference see (4).)

Analogous combinations between one $\overset{+}{N}H_n$ and one CH_n vibration are also expected to occur and could fall into the same part of the spectrum.

Interactions between individual groups in the molecule and between molecules in the crystal may split the bands and further complicate the spectrum. All intermolecular effects are much more likely to influence $\overset{+}{N}H_n$ vibrations than CH_n vibrations, as the former are affected by hydrogen bonding.

Under the resolution of our instrument, separation of all the expected bands would be impossible and we have to restrict ourselves to interpret the most conspicuous features of the spectra.

EXPERIMENTAL

The near-infrared spectra were measured by a Beckman DK-1 spectrometer, mounted with a fused-silica prism. The hydrohalides were taken in the form of hexachlorobutadiene mulls. With some of these compounds it is quite difficult to obtain spectra which are free of scattered light. For this reason no complete series of hydrochloride, hydrobromide, and hydriodide spectra could be obtained in every case.

The fundamentals were measured previously in this laboratory, using a Perkin–Elmer model 112 instrument with LiF and CaF_2 prisms.

RESULTS

Cyclohexylamine, piperidine, and triethylamine hydrohalides were chosen as representatives of aliphatic primary, secondary, and tertiary amine hydrohalides. Figures 1, 2, and 3 give the near-infrared spectra of one of the hydrohalides measured as a hexachlorobutadiene mull together with the spectrum of the related amine in liquid phase. The spectra of some other hydrohalides and of some related hydrocarbons were measured as well and will be referred to incidentally in the text. No detailed discussion of these seems to be warranted, however.

No originality is claimed for the spectra of the amines and the hydrocarbons. As to previous literature concerning them, we deem it sufficient to refer to review papers by Kaye (5) and Wheeler (6).

Tables I, II, and III summarize the fundamentals and binary combinations relevant to the discussion. Care should be exercised in considering the exact values of the frequencies of the fundamentals. There is a considerable amount of band overlapping in these spectra, especially in the 3000–2800 cm^{-1} region. Bands due to hydrogen bonded $\overset{+}{N}H_n$ groups are usually quite broad and carry several other bands atop themselves, making assignments difficult. Furthermore, it may be said because of reasons given in the introduction that the hydrohalide spectra offer many opportunities for Fermi resonance and the apparent peaks might be modified by it. Fermi resonance is very likely to occur frequently in the near-infrared spectra too, where binary combinations often coincide with ternary and

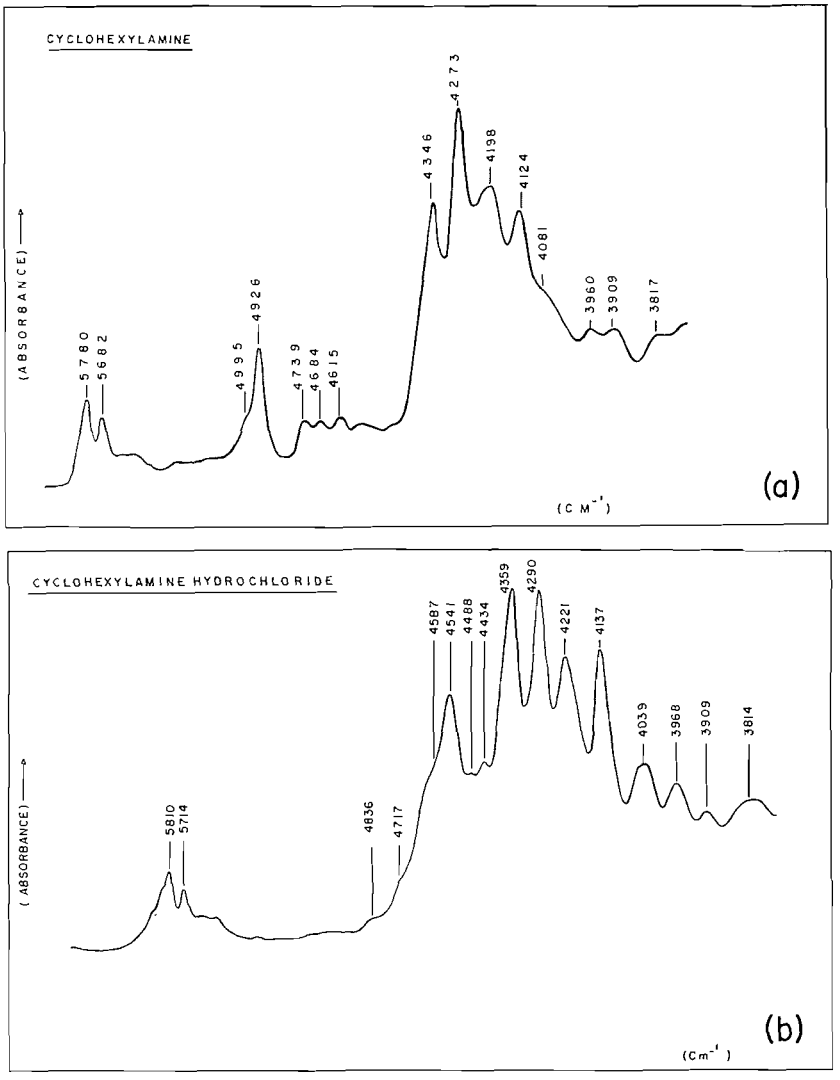

FIG. 1. Near-infrared spectra of cyclohexylamine (above) and cyclohexylamine hydrochloride (below).

other higher combinations. The tables do not contain all the observed bands, only those necessary to discuss our specific problem, the assignment of the first $\overset{+}{N}H_n$ overtones, the $\overset{+}{N}H_n$ stretching plus $\overset{+}{N}H_n$ bending combinations, and the analogous $CH_n+\overset{+}{N}H_n$ combinations. They should be regarded together with the respective figures. Intensities are given by usual symbols. Capital letters are used for the fundamental region, lower case letters for the overtone region. There is a factor of about 100 between the two scales. A "very strong" overtone would be considered as "weak" (at most) on the scale applied to the fundamentals. Indexes *a* and *s* stand for asymmetrical and symmetrical respectively.

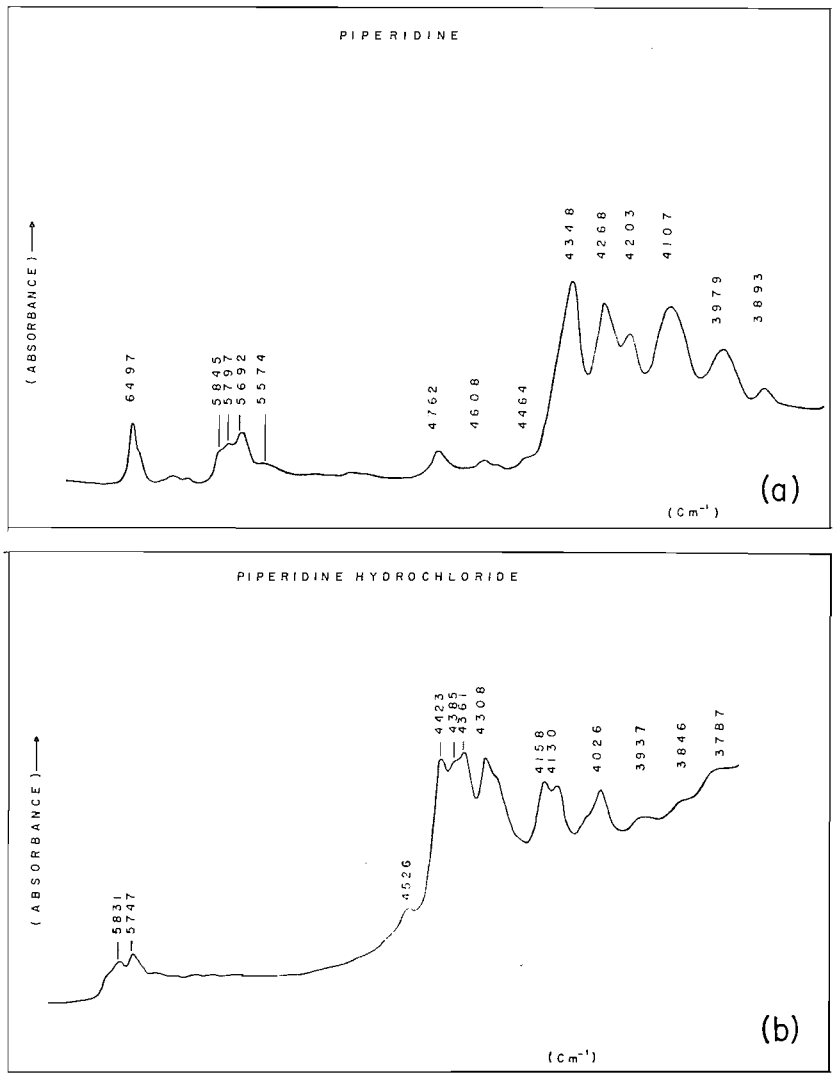

FIG. 2. Near-infrared spectra of piperidine (above) and piperidine hydrochloride (below).

DISCUSSION

G. and L. Herzberg examined the near-infrared spectrum of methyl iodide in the vapor state and established the main features pertaining to the methyl group (7). (For other methyl halides see ref. 4, p. 312.) The near-infrared spectra of liquid paraffins exhibit similar characteristics. There is a series of strong bands between 4400 and 4000 cm^{-1} due to combinations between a CH_n stretching vibration from the 2900 cm^{-1} area and a CH_n deformation vibration. These bands are much stronger than the first overtones of the stretching vibrations which are near 5800 cm^{-1}. In methyl iodide (7) the shift of the latter bands from the sum of the observed fundamentals is of the order of 40 to 50

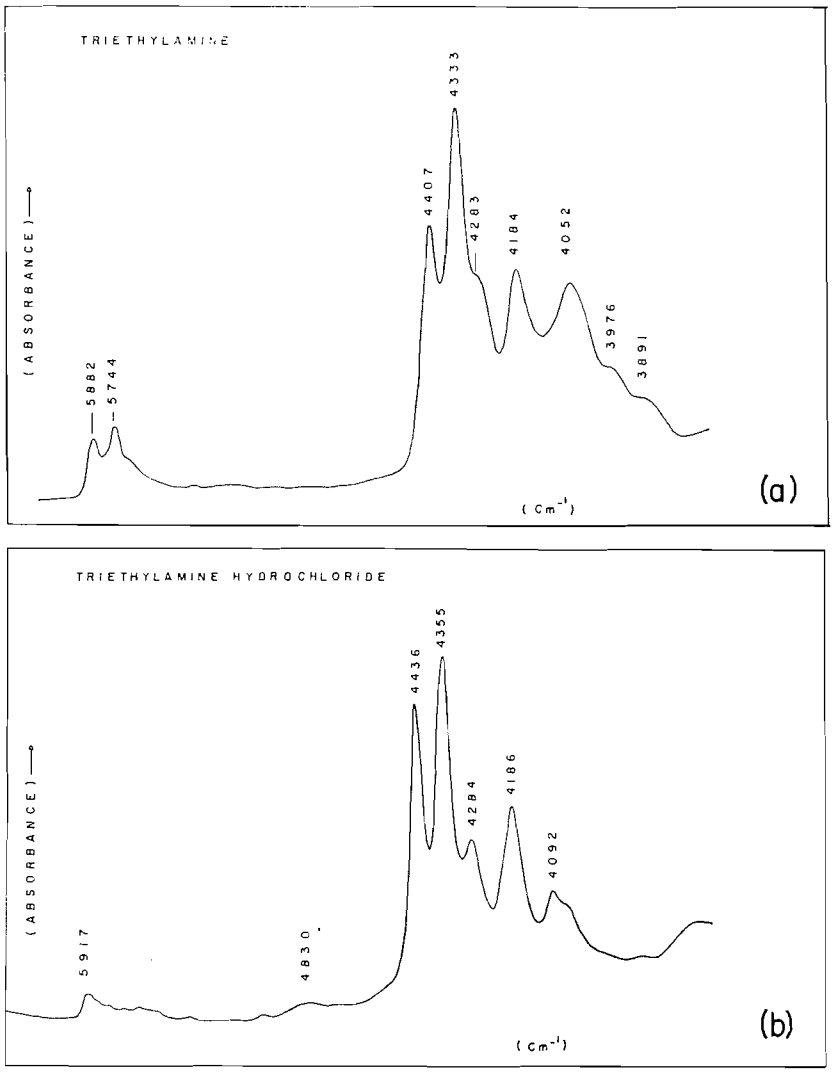

FIG. 3. Near-infrared spectra of triethylamine (above) and triethylamine hydrochloride (below).

cm^{-1}, while for the former it is only of the order of 10 to 30 cm^{-1}. This is related to the expected higher mechanical anharmonicity of the stretching vibrations but it also shows that the relatively high intensity of the combination tones in the 4400–4000 cm^{-1} area is not due to mechanical anharmonicity or, in particular, to high anharmonicity constants between stretching and bending vibrations. Therefore, electrical anharmonicity of the bending vibrations involved should explain the higher intensity of these bands.

It is important that no strong band appears above about 4400 cm^{-1} in saturated hydrocarbons. In the hydrohalides these CH_n stretching+CH_n bending summation bands

are sometimes found as high as 4430 cm^{-1}. We shall not discuss here ternary and higher combinations.

Cyclohexylamine Hydrohalides

In liquid cyclohexylamine (Fig. 1) the 4400–4000 cm^{-1} and the 5800 cm^{-1} areas are very similar to what they are in the spectra of the hydrocarbons and must be due mainly to binary combinations of CH_n vibrations. A medium strong band at 4926 cm^{-1} (with a shoulder at about 4995 cm^{-1}) represents the expected NH_2 stretching+NH_2 bending combinations. Combinations between NH_2 stretching and CH_2 bending vibrations can explain the weaker bands at 4739, 4684, 4615 cm^{-1}. The first NH_2 overtone is at 6502 cm^{-1} (not shown in the figure).

A conspicuous new feature in the spectrum of cyclohexylamine hydrochloride is a strong band at 4541 cm^{-1} with several shoulders and weaker bands at 4488 and 4434 cm^{-1} (Fig. 1).

The asymmetrical $\overset{+}{N}H_3$ stretching band near 2980 cm^{-1} and the asymmetrical $\overset{+}{N}H_3$ bending band near 1615 cm^{-1} are very probably split by removal of their degeneracy, and their frequencies are modified by Fermi resonance with other close-lying bands. Instead of the bending band we actually find a group of four bands at 1620, 1618, 1615, and 1610 cm^{-1}.

Table I contains the fundamentals and the main binary combinations down to about 4300 cm^{-1} with the proposed assignments. The main contributor to the 4600–4500 cm^{-1} absorption is very likely the asymmetrical $\overset{+}{N}H_3$ stretching+asymmetrical $\overset{+}{N}H_3$ bending combination (or combinations). The second largest contribution appears to come from the CH_2 stretching+$\overset{+}{N}H_3$ asymmetrical bending combinations. Minor contributions may come from many other combinations.

In other instances there are two well-defined peaks in this area:

Cyclohexylamine	hydrochloride	4587 sh	4541
	hydrobromide	4593	4541
	hydriodide	4630 sh	4525
		4591	
Tertiary butylamine	hydrochloride	4625 sh	4505
		4575	
	hydrobromide	4625	4484
		4566	
	hydriodide	4612	4468
		4570	
		4535	
Ethylamine	hydrochloride	4598	4525
	hydrobromide	4619	4525
	hydriodide	4617	4521

No one is a single band. This is clearly seen in the case of tertiary butylamine hydriodide where the higher frequency band is split into three well-distinguishable bands.

The value of the 4600–4500 cm^{-1} area for the identification of *primary* amine hydrohalides should be emphasized.

We have to look now for the first overtones of (and combination between) the $\overset{+}{N}H_3$ stretching vibrations. No significant band appears, however. One explanation may be that they coincide with the CH_3 and CH_2 overtones. This is how Waldron (1) interpreted the near-infrared spectrum of methylamine hydrochloride.

Assigning the 4600–4500 cm^{-1} bands to the stretching overtones (and not to the stretching–bending combinations as we did) does not seem to be reasonable. We measured the spectrum of 1.28 *M* ethanol in carbon tetrachloride. The associated OH stretching fundamental is at 3360 cm^{-1}, its first overtone at 6329 cm^{-1}. This amounts to a shift of about 400 cm^{-1} from the sum of the fundamentals. If the overtones for $\overset{+}{N}H_3$ are at 4600 cm^{-1}, this would correspond to a shift of almost 1400 cm^{-1}.

Thus we are led to think that the $\overset{+}{N}H_3$ stretching overtones are covered by the CH_2 overtones being broad an even weaker than the latter. The weakness of the overtones and their slight anharmonic shift shows that in this case hydrogen-bonding causes only a slight increase in mechanical anharmonicity. In complete analogy with the hydrocarbons the electrical anharmonicity of the bending vibrations appears again as mainly responsible for the relatively high intensity of the combination tones. This is in line with our previous conclusions relative to the infrared spectra of amine hydrohalides (3).

Reference should be made here to papers by Russell and Thompson (8) and Moccia and Thompson (9), who stressed the importance of electrical anharmonicity for the intensity of the overtones in the case of the NH and OH groups respectively.

Piperidine Hydrohalides

In the near-infrared spectrum of piperidine (Fig. 2, Table II), the first overtone of the NH stretching vibration is at 6497 cm^{-1}, the CH_2 stretching overtones are at their usual

places, the band at 4762 cm^{-1} may be assigned to the NH stretching + NH bending summation tone (this frequency seems to be somewhat low). The weaker bands at 4608 and 4464 cm^{-1} represent probably $NH+CH_2$ combinations. The strong CH_2 combination tones do not go higher than 4348 cm^{-1}.

In the spectrum of the hydrochloride a strong new band appears at 4423 cm^{-1} (with a shoulder at 4385 cm^{-1}) which must be due to the $\overset{+}{N}H_2$ stretching + CH_2 bending combinations. There is a weak band at 4526 cm^{-1} to which the $\overset{+}{N}H_2$ stretching + $\overset{+}{N}H_2$ bending and the CH_2 stretching + $\overset{+}{N}H_2$ bending combinations must contribute.

In diethyl amine hydrohalides the band between 4600 and 4500 cm^{-1} is stronger but still much weaker than in the primary amine hydrohalides. This must be linked to the lack of degenerate asymmetrical $\overset{+}{N}H_n$ stretching and bending vibrations.

The first overtones of the $\overset{+}{N}H_2$ stretching vibrations are again apparently too weak and are hidden by the CH_2 stretching overtones.

Triethylamine Hydrohalides

In the amine itself the strong CH_n combination tone of highest frequency is at 4407 cm^{-1} and shifts to 4436 cm^{-1} in the hydrochloride. In the hydrochloride the $\overset{+}{N}H$ stretching fundamental is near 2600 cm^{-1} and the $\overset{+}{N}H$ deformation band of highest frequency is at 1446 cm^{-1}. Therefore, we would expect an $\overset{+}{N}H$ stretching + $\overset{+}{N}H$ bending summation band near 4000 cm^{-1} and the overtone of the $\overset{+}{N}H$ stretching band well below 5200 cm^{-1}. No one of them can be clearly distinguished, however (Fig. 3, Table III). There are several broad but weak bands between 5600 and 4600 cm^{-1} and the one at 4830 might well be the $\overset{+}{N}H$ stretching overtone. A look at the spectrum shows, however, that this cannot be asserted with any degree of certainty. Nor can we say whether there is a splitting due to a double well potential surface, which is a possibility here as the tertiary amine hydrohalides form significantly stronger hydrogen bonds than the primary and secondary ones (2, 3). The $\overset{+}{N}H$ stretching + bending combination should coincide with a CH_n combination band between 4100 and 4000 cm^{-1}. Actually, the shape of the latter undergoes changes due to hydrohalide formation. CH_n stretching + $\overset{+}{N}H$ bending combinations could explain a shoulder near 4370 cm^{-1} in the hydrobromide and hydriodide.

The weakness of the first overtones of the $\overset{+}{N}H_n$ fundamentals appears to be a common phenomenon for all aliphatic amine hydrohalides.

SPHERICAL AGGLOMERATION OF BARIUM SULPHATE[1]

H. M. SMITH[2] AND I. E. PUDDINGTON

ABSTRACT

The mechanical agglomeration of barium sulphate suspended in organic media into essentially spherical masses has been studied. The presence of a small quantity of water is necessary for the phenomenon to occur. This is regarded as a bridging agent that forms liquid lenses between the particles and binds them together. An equilibrium is set up for this water between the surface of the solid and the bulk suspending medium. The methods of formation of the spherical agglomerates are discussed and their properties examined.

INTRODUCTION

Flocculation of the solid constituents, which is frequently desirable to promote more rapid settling in suspension, almost invariably results in a large increase in the final volume of the sediment obtained. An exception to this general behavior was reported by Stock (1), who observed that when dried, finely divided barium sulphate suspended in dry benzene in cylindrical containers was shaken with a reciprocating motion, discrete spheres of 0.5 to 1.0 mm in diameter were formed. These settled rapidly to a volume considerably less than that obtained from an equal amount of the suspension that had not been shaken. It was tentatively suggested that the phenomenon was owing to the tendency of the hydrophilic barium sulphate to aggregate in such a way that a minimum surface was exposed to the hydrophobic benzene. Thus the phenomenon was considered to be somewhat analogous to the formation of droplets when two immiscible liquids are shaken together.

The pronounced flocculating influence of small quantities of water on suspensions of solids having hydrophilic surfaces in organic media has been frequently reported (2, 3, 4, 5). A few preliminary experiments demonstrated that the phenomenon observed by Stock (1) did not occur if the system were thoroughly dry and the present work was undertaken to ascertain the conditions necessary for the formation of spherical agglomerates with barium sulphate suspended in benzene and, if possible, to give an indication of how the technique might be applied to other systems.

EXPERIMENTAL

Procedure

Suspensions were prepared by weighing 4-g portions of pure barium sulphate directly into sample holders which were subsequently sealed to a vacuum system equipped with facilities for B.E.T. surface area measurements. The barium sulphate was freed from water by heating the samples to 200° C and reducing the pressure to about 10^{-5} mm Hg. B.E.T. surface areas (6) were determined in the usual way. The nitrogen adsorption isotherms were all of the reversible S-type, characteristic of adsorption on a non-porous solid. A known volume of benzene, usually about 20 ml, was then condensed from a doser into the sample holder and, similarly, water was added if desired in quantities from 2 mg upwards. After being sealed off, the vessel was shaken for a period of 12 hours or more. For most of the work a mechanical horizontal shaker that had a frequency of

4 cycles per second with a displacement of 6 cm was used. Visual observation of the specimens usually showed no further change after about half an hour but the longer shaking period was convenient and it ensured that equilibrium was reached. The sedimentation volume of the barium sulphate was determined from calibrations on the sample container. Readings were taken after the suspension had been allowed to settle under gravity for a week although little change was observed after 48 hours.

A number of qualitative experiments were also carried out using flat-bottomed, stoppered cylindrical containers in which 4 g of the barium sulphate had been dried in an oven at 200° C overnight and cooled in a vacuum desiccator. The liquids were added rapidly and the tubes quickly stoppered before they were placed in the shaker. This method enabled a wider range of systems and conditions to be studied without the tedious experimentation with the vacuum system. Blank runs were always performed in order to check against accidental contamination from the atmosphere. Twenty milliliters of the suspending liquid was normally used with 0.1 ml of bridging agent.

Water in the supernatant benzene was determined by the Karl Fischer method (7). The saturation value of water in benzene at 25° C determined in the work was 0.046% w/v. This value is the same as that calculated from the nomogram given by Davis (8) based on data determined by Jones and Taylor (9) using a tritium oxide analysis method.

Preparation of Materials

Reagent grade, thiophene-free benzene was shaken and left in contact with calcium hydride for 2 weeks. After the benzene was passed through a column containing dried silica gel, alumina, and calcium hydride into a distillation flask containing more calcium hydride, it was finally distilled into a storage vessel which had been previously dried by heating under reduced pressure. Benzene was distilled from the storage vessel into the prepared system when required.

Other organic liquids were reagent grade and dried for several weeks over anhydrous calcium sulphate before use.

Deionized water was obtained from an Amberlite MB1, mixed bed ion exchange column and placed in a small water storage flask. Dissolved gases were substantially removed from the water by evacuation of the system for 1/2 hour.

Barium sulphate was prepared from reagent grade barium chloride. The chloride was first dried at 140° C and then washed with absolute ethyl alcohol to remove traces of strontium and calcium, followed by drying again at 140° C. It was dissolved in warm water and reagent grade concentrated sulphuric acid was added with stirring. After settling, the barium sulphate was washed many times with distilled water and finally with equilibrium water. Spectrographic analysis revealed fewer impurities in the specimen than the reference material (Johnson, Matthey & Co. Ltd. spectroscopically pure barium carbonate). The purified barium sulphate was crushed in an agate mortar and passed through a 200-mesh sieve before being sealed onto the vacuum system in its container. Electron micrographs showed that the particle size was mostly in the range 0.2 to 1 micron diameter. The particles were approximately spherical but had some flat faces on them extending up to 0.5 micron in length.

RESULTS

Preliminary runs showed that no agglomeration took place when the system contained no water. With small additions of water voluminous flocs were formed after agitation but it was only with further additions of water that spherical agglomerates were apparent.

Experiments were conducted with identical 4-g portions of barium sulphate using different amounts of benzene and water to determine the distribution of water between the barium sulphate and benzene. The results are given in Table I. From the analyses of the supernatant liquid, the water associated with the barium sulphate was calculated.

TABLE I

Distribution of water between barium sulphate and benzene

Benzene used, ml	Total water added, g	Water in benzene, % w/v	Water with $BaSO_4$, g/100 g	Water in benzene / Total water
18.35	0.0049	0.013	0.0633	0.026
18.10	0.0069	0.017	0.0953	0.025
35.25	0.0110	0.016	0.1333	0.015
16.52	0.0097	0.019	0.1633	0.020
36.91	0.0219	0.041	0.1695	0.019
34.27	0.0288	0.046	0.3258	0.016
17.61	0.0231	0.046	0.3743	0.020
17.53	0.0235	0.041	0.4083	0.017

The ratio water in benzene (g/ml)/total water added (g) was found to be approximately constant below the saturation point of the benzene, the average value being 0.020.

Further experiments established the amount of water associated with the barium sulphate over the complete range of water content where flocculation and spherical agglomeration occur. Figure 1 shows the sedimentation volume of the settled barium sulphate

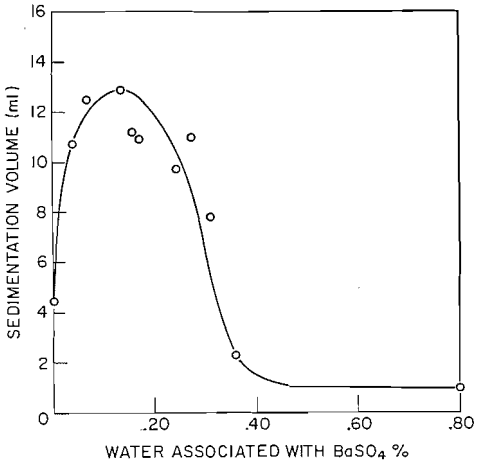

FIG. 1. The effect of water on the sedimentation volume of barium sulphate.

as a function of its water content. It is seen that, with the first additions of water, flocculation causes the settled volume to increase. On further additions the volume decreases with some of the particles forming spherical-shaped clusters. Finally, when enough water has been added, good spherical agglomerates are formed. For the area of barium sulphate considered here, 18 sq. meter/g, the necessary amount of water to form completely spherical agglomerates is 0.3125 g/100 g. If the water is less than this amount, only partial spherical agglomeration occurs. Taking the area of the water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

molecule as 10.5 sq. Å, the above water is only sufficient to give an average monolayer coverage of about 60% with the specimen considered here.

Qualitative experiments were carried out using benzene to which small amounts of nitromethane, nitrobenzene, or acetonitrile were added. These three substances would not promote the spherical agglomeration without a small quantity of added water. However, since much less water was necessary under these conditions to give agglomeration, these three substances enhanced considerably the effect of the water.

Good spheres of barium sulphate were formed on agitation when the following liquids containing the appropriate amount of water were substituted for benzene: toluene, nitrobenzene, diethyl ether, chloroform, carbon tetrachloride, *n*-hexane, cyclohexane. If systems were rigorously dried, however, no agglomerates were apparent.

The effect of shaking at reduced temperatures was studied using the technique of the qualitative experiments with toluene as the suspending medium. The tubes were cooled by placing them in a copper jacket which had circulating ethylene glycol in a surrounding cooling coil. A run at $-2°$ C gave the same result as the blank shaken at room temperature with good agglomerates being formed. A run held over the range $-17°$ to $-20°$ C gave no spheres and the barium sulphate remained virtually unchanged. It is to be noted that collision of the particles probably causes the temperature at the point of impact to rise and, although the outside of the tube was kept below $-17°$ C, higher temperatures may have existed at the interfaces of colliding particles. The conclusion may be drawn from the above experiments, however, that for spherical agglomeration to occur the water must be in a liquid form and free to form the linkages between the particles.

Knacke and Pohl (10) report that in the formation of granules by standard pelletization processes, added salts in the binding liquid result in stronger granules. The increased strength was attributed to salt bridges being formed. Experiments using normal and saturated (25° C) reagent grade sodium chloride solutions in place of water gave agglomerates which appeared not to differ from the blank run where only water was used.

The effect of different modes of shaking for the production of the spheres was reviewed. Although a detailed study involving different rates of motion was not made, each method was tested under conditions which appeared most favorable for the formation of agglomerates. Reciprocating horizontal shaking as described gave the best results. Rolling end-over-end gave good agglomerates but rather smaller in size. With horizontal rolling, dense agglomerates formed which were less spherical and uniform in size than those given by the other methods of agitation. Longitudinal rocking through a circular path gave few agglomerates and these were neither spherical nor uniform in size. Vibration applied to the tube gave negative results. Apparently motion that allows the initial flocs to roll with not too much impact or shear is desirable for the densification to occur. No difference in behavior was noted when the diameter of the cylindrical glass containers was varied from 15 to 45 mm, each being filled to the same height. Rendering the surfaces of the tubes lyophobic with "dri-film" eliminated the very fine coating of barium sulphate that normally occurs. It is probable that in all the experiments with untreated tubes, the glass surface adsorbs water which binds a small amount of the barium sulphate. The amounts of water and barium sulphate involved with this effect were not important in the over-all quantitative runs, however.

When the spherical agglomerates were drained of their supernatant liquid and left to dry in the air, good free-flowing particles were obtained. They could be transferred without dusting and withstood a force of the order of 10^5 dynes before being crushed. No difference was observed when the particles were maintained for 24 hours at a pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 10^{-5} mm Hg, and heating at 200° C for 24 hours at this pressure produced no visible effect.

When immersed in water, some of the dried spheres rapidly shattered but most remained unaltered. There was no change after 24 hours. This shattering was probably due to a large hydrostatic pressure being set up in any small pores present. Similar results were obtained when benzene was added to the dried spheres. It is apparent that, once formed, the spherical aggregates retain their shape when allowed to air-dry, the ultimate particles being held together by fairly strong forces.

If the barium sulphate spheres were drained of their supernatant liquid and, before they had dried, a large volume of water was added, the particles lost their spherical shape leaving a creamy suspension of barium sulphate. The bridging liquid appears to bind the particles into agglomerates by virtue of surface tension forces which disappear when the interface is removed through the addition of excess bridging liquid.

X-Ray analysis showed no detectable change in crystal structure or cell size with the formation of the spheres. It appeared, however, that the spheres were of somewhat greater crystalline perfection than the original material and thus the treatment appears to have stimulated a recrystallization or its equivalent.

Increasing amounts of water beyond the minimum necessary for spherical aggregation increases the diameter of the agglomerates. The results were somewhat erratic, however, due to differences with the initial formation. If particles group in different ways initially, a direct relationship between added water and diameter of formed spheres would not be expected. With a run in which 0.50 g of water was added, the barium sulphate formed into one sphere of approximately 1.2 cm in diameter. Further additions of water resulted in the solid adhering to the walls of the tube in a sticky mass, the spherical form of the agglomerate being lost. A continued increase of water resulted in a separate aqueous phase in which the barium sulphate remains.

Apparent density measurements on two groups of six particles, having mean diameters of 0.3 and 0.8 mm, respectively, gave values of 2.7 and 2.9 g per cc. The void volume of the spheres is therefore about 30 to 35%. The two samples, examined microscopically, were remarkably good spheres and quite uniform in diameter. A possible mechanism by which the spheres grow was suggested by the examination of a third sample, where, apparently, slightly more water was present in the system than the amount required for the compact spheres that were initially formed and sufficient excess was available to flocculate a number of these spheres into groups of two, three, or four by the Kruyt and van Selms mechanism. Further agitation had compressed these into dumbells, disks, tetrahedra, etc. in which the outlines of the original spheres were clearly visible. Obviously further mechanical action could form these into new spheres with volumes approximately simple multiples of the spheres originally formed. Were the process to be carried out on a lyophilic suspension in which the particles become partially desolvated by the bridging liquid, considerable increase in the size of the spheres might be expected with continued shaking owing to the excess of bridging liquid made available by the shrinkage of the solid.

DISCUSSION

Apparently the added small quantity of water displaces organic solvent from part of the barium sulphate surface. An equilibrium is set up between the water molecules on the barium sulphate surface and in the organic solvent. When the solid particles are brought in sufficiently close proximity by the agitation, the adsorbed water links the

For personal use only.

particles by forming a water lens or bridge between them. With the first additions of water, the particles are held together in loose clusters, voluminous flocs being formed. However, with further additions of water more linkages are possible and with the aid of mechanical agitation the particles are able to assume a more closely packed pattern and ultimately an over-all compact, spherical shape. The flat faces of the ultimate particles may have some significance in the amount of bridging liquid necessary. As still more water is added larger spheres which require more junctions per unit volume are formed with the extra bridging liquid. Where organic liquids, along with water, act as a bridging agent, it is probable that the water promotes the adsorption of both species on the solid surface. There is, as before, an equilibrium set up with the organic suspending medium.

The barium sulphate/benzene/water system is well suited for the observation of the phenomenon. The barium sulphate has a very low solubility in both benzene and water as well as being chemically inert to both liquids. The water acting as the bridging agent has a low solubility in the benzene and in this system the benzene is saturated with water before spherical agglomerates are formed. This is not regarded as being essential to the phenomenon but depends on the relative affinities of the solid and organic medium for the bridging liquid.

Other systems meeting these requirements should show the phenomenon and the success of obtaining the spherical agglomerates will depend on how readily these factors are met.

ACKNOWLEDGMENT

Grateful acknowledgment is made to J. R. Farnand for continued help and many useful suggestions in this work.

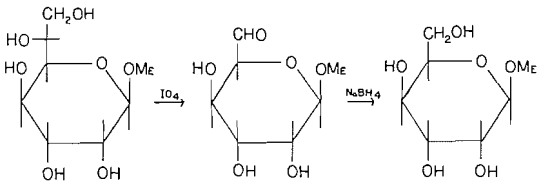
A NEW SYNTHESIS OF METHYL β-D-GULOPYRANOSIDE[1]

N. J. Antia and M. B. Perry

ABSTRACT



The oxidation of 1 mole of β-D-glycero-D-gulo-heptopyranoside with 1 mole of sodium metaperiodate, followed by reduction with sodium borohydride, gave rise to crystalline methyl β-D-gulopyranoside. The method provides a new synthetic route to the D-guloside and, thence, to D-gulose. The possibility of utilizing this reaction scheme as a general convenient method for preparing the relatively rare aldohexoses as well as for "labelling" carbon atom 1 of these compounds is discussed.

It was shown recently by Perry and Pietak (1) that the periodate oxidation of aldoheptoses proceeds in nearly discrete stages, with the sugars being oxidized in their cyclic forms. Consumption of the first mole of oxidant per mole was correlated with the almost exclusive scission of the C_6–C_7 (exocyclic) bond of the heptose. This observation appeared to be of great potential value for the facile synthesis of hexoses not readily available. The controlled oxidation of 1 mole of the heptose with 1 mole of periodate would be expected to yield the corresponding hexodialdose, which would require a selective reduction of the —CHO group at C_6 to give the corresponding hexose. The reduction step was considered to present insuperable difficulties and, accordingly, we turned our attention to the application of the reaction sequence to the heptosides, where such selective reduction would not be required. An analogous series of reactions was used by Foster, Davies, and Crumpton (2) in their conversion of heptose units in polysaccharides to hexose units.

Methyl β-D-glycero-D-gulo-heptopyranoside had been prepared by Fisher (3) and a proof of its pyranoside structure had been offered by Haworth, Hirst, and Stacey (4). We have prepared the heptoside by the method of the latter authors, but have found difficulty in separating it from contaminating heptose. One mole of the methyl β-D-glycero-D-gulo-heptopyranoside (I) was oxidized with 1 mole of sodium metaperiodate in unbuffered medium, and the product (II) was directly reduced with an excess of sodium borohydride. After deionization with ion-exchange resins, crystalline methyl β-D-gulopyranoside (III) was isolated in 30% yield. Attempts to isolate the guloside from the borohydride reduction reaction without recourse to resin deionization, by acetylation with acetic anhydride/pyridine or by *p*-nitrobenzoylation, failed to yield crystalline material. The D-guloside was shown (*a*) to be homogeneous, by paper chromatography in three solvent systems, and (*b*) to be identical with a sample obtained from Dr. Isbell (5, 6). The identity was established by comparison of infrared spectra and by mixed melting point determination. The pyranoside structure of the D-guloside was confirmed by periodate oxidation studies (2 moles of periodate consumed, 1 mole of formic acid liberated). Mineral acid hydrolysis of the D-guloside gave predominantly a reducing sugar identified as gulose from paper chromatographic evidence.

The synthesis reported above suggests that other heptosides may similarly be converted to the corresponding hexosides, and the method appears to offer a convenient, general, synthetic route for the conversion of heptoses to hexoses. The particular value of this synthetic method lies in (*a*) the simplicity and ease of preparation, in quantity, of the relatively rare hexoses, and (*b*) the possibility of selectively "labelling" a hexose

[1]*Manuscript received May 16, 1960.*
Contribution from the Chemistry Department, Queen's University, Kingston, Ontario.

I II III

at carbon atom 1 by starting with a *1*-C^{14}-heptose. Obviously the preparative value of the method will be governed by the ease of availability of aldoheptoses. Both classical Kiliani/Fischer cyanohydrin synthetic method (7) and the more recent nitromethane/Nef reaction scheme of synthesis (8) provide convenient preparative routes to aldoheptoses from aldohexoses. Both of these methods effect the addition of a one-carbon fragment to the carbon atom 1 of the hexose. The incoming carbon atom may be "labelled" by the use of $HC^{14}N$ or $C^{14}H_3NO_2$. In this way, a readily available hexose (e.g., D-glucose) may be converted to a *1*-C^{14}-aldoheptose (e.g., D-glycero-D-gulo-heptose) which, by the application of the synthetic scheme described above, may be further converted to the desired *1*-C^{14}-hexose (e.g., D-gulose).

EXPERIMENTAL

All melting points reported are uncorrected.

Paper chromatography was performed by the descending method on Whatman No. 1 paper, using the following solvent systems:

solvent I: 1-butanol/ethanol/water (3:1:1 v/v);
solvent II: 1-butanol/pyridine/water (10:3:3 v/v);
solvent III: ethyl acetate/acetic acid/water (9:2:2 v/v).

The following sprays were used to detect the sugars on the chromatograms: (A) 2% solution of *p*-anisidine hydrochloride in 1-butanol, (B) 1% solution of silver nitrate in acetone, followed by 2% ethanolic sodium hydroxide, and (C) saturated aqueous solution of potassium periodate followed, 6 minutes later, by benzidine reagent (9). The rate of movement of the sugars on the chromatograms is given relative to that of 2,3,4,6-tetra-*O*-methyl-D-glucose (R_{TMG}) or of rhamnose (R_{Rha}).

Methyl β-D-Glycero-D-gulo-heptopyranoside

The glycoside was prepared by refluxing D-glycero-D-gulo-heptose (m.p. 190–192°) with 3–5% methanolic hydrogen chloride for 24–48 hours. Yields of the crude crystalline product were of the order obtained by Haworth, Hirst, and Stacey (4). After two recrystallizations from alcohol, the glycoside had a melting point of 166–168°, $[\alpha]_D^{20}$ −72°±2° (*c*, 1.1 in water). Paper chromatography in solvents I and II showed the presence of a heptose. Treatment of the glycoside in aqueous solution with Dowex 1-X2(OH) (by agitation with the resin at room temperature for 20 hours, followed by passage of the solution down a column of the resin) effected removal of most of the contaminating heptose, but traces were still detectable. The treated glycoside crystallized from alcohol as colorless prisms with the same melting point and optical rotation as given above. The following R_{TMG} values were observed for the heptoside: solvent I, 0.33; solvent II, 0.35; solvent III, 0.41.

Methyl β-D-Gulopyranoside

The calculated quantity of an aqueous solution of sodium metaperiodate (49.18 ml, 0.045 *M* $NaIO_4$) was added slowly to a stirred solution of methyl β-D-glycero-D-gulo-heptopyranoside (0.4935 g) in water (25 ml) cooled to 0°. After addition was complete, the solution was agitated for 2 hours at room temperature and allowed to stand overnight. The solution was next cooled to 0°, and a solution of sodium borohydride (0.8 g) in water (25 ml) was added slowly, with mechanical agitation. The solution was agitated for 2 hours at room temperature and allowed to stand overnight. The pH of the solution was adjusted to 5 by the addition of 50% aqueous acetic acid with mechanical agitation and cooling. After 1 hour at room temperature, a test sample showed no reduction of Fehling's solution (absence of reducing sugar as well as of borohydride). The solution (160 ml) was divided into halves at this stage. One half was used for the attempted isolation of the D-guloside by (*a*) acetylation and (*b*) *p*-nitrobenzoylation. The other half was passed successively through columns of Amberlite IR-120(H) and Duolite A-4(OH) ion-exchange resins. The pH of the eluent from the latter column was ca. 3–4 and it was found necessary to deionize the solution further by passing it through Dowex 1-X2(OH) resin. This solution (pH7) was evaporated to dryness *in vacuo* and the residual boric acid was removed as methyl borate by repeated evaporation *in vacuo* with methanol. The residue was next extracted with ethanol, the ethanol-insoluble material being rejected (negative reaction to Molisch reagent). The ethanol extract (0.22 g) was taken up in boiling ethanol, allowed to cool, and ethyl acetate was added to incipient turbidity. The solution was allowed to crystallize at 0–5° for 4 days. Methyl β-D-gulopyranoside crystallized as prisms (0.065 g), m.p. 178–180°, $[\alpha]_D^{20}$ −87.9° (*c*, 1.03 in water). The mother liquors failed to yield any further crystalline product. The over-all yield of the D-guloside was ca. 30% of the theoretical. Isbell (6) has given the following constants for the D-guloside, m.p. 176°, $[\alpha]_D^{20}$ −83°. A mixed melting point determination of the D-guloside with Isbell's sample showed no depression. The infrared spectra (KBr disk) of the D-guloside samples were identical.

The attempted acetylation of the D-guloside with acetic anhydride and pyridine failed to give a crystalline product, although Isbell (5) has described a crystalline tetraacetate.

Paper chromatography of the D-guloside showed (*a*) complete absence of reducing sugars, and (*b*) a homogeneous product having the following R_{TMG} values: solvent I, 0.44; solvent II, 0.51; solvent III, 0.51.

Periodate oxidation studies: The D-guloside (19.4 mg) was oxidized at 0–4° with an aqueous solution of sodium metaperiodate (5 ml, 0.1 *M* $NaIO_4$), the total volume of the reaction mixture being adjusted to 100 ml with distilled water. Aliquots (5 ml) of the reaction mixture were taken at the time intervals stated in Table I, in order to determine the periodate consumed and the formic acid liberated. These determinations were carried out by standard methods.

TABLE I

Periodate oxidation of methyl β-D-gulopyranoside

Oxidation period, hours	Periodate uptake, moles per mole	Formic acid release, moles per mole
1	1.92	0.94
2	2.02	0.94
4	2.02	0.96
21	1.98	0.96

D-Gulose

The D-guloside (10 mg) was hydrolyzed with *N* HCl (10 ml) (refluxed for 2 hours), the mineral acid was neutralized with silver carbonate, and the product was worked up in the usual manner. No attempt was made to crystallize the D-gulose or to prepare a derivative.

Paper chromatography of the product showed the presence of a reducing sugar as the major component, along with traces of what may be 1,6-anhydro-D-gulose, oligosaccharides, and polymeric material formed by the acid treatment. The reducing sugar was identified as D-gulose by comparison of R_{Rha} values with those of D-mannose (see Table II). Thomas (10) has shown that these two sugars are virtually inseparable on paper chromatograms in the solvent systems used.

TABLE II

R_{Rha} values of some reducing sugars

Sugar	Solvent system		
	I	II	III
D-Gulose	0.54	0.52	0.74
D-Mannose	0.62	0.55	0.80
D-Glycero-D-gulo-heptose	0.41	0.31	0.69

ACKNOWLEDGMENTS

The authors wish to express their thanks to the National Research Council for financial assistance (Grant No. 706); to Dr. H. S. Isbell, National Bureau of Standards, Washington, D.C., for kindly supplying an authentic specimen of methyl β-D-gulopyranoside; and to Professor J. K. N. Jones, for his interest and advice.

EXPERIMENTAL STUDIES OF SOLUTION PROCESSES

VI. EFFECT OF SOLVENT ON INFRARED ABSORPTION SPECTRA[1]

P. A. D. DE MAINE,[2] L. H. DALY, AND M. M. DE MAINE[2]

ABSTRACT

Here are reported infrared absorption data between 4000 cm^{-1} and 700 cm^{-1} near 19° C for methanol, *n*-propanol, isopropanol, cyclohexanol, benzyl alcohol, diethyl ether, anisole, 1,4-dioxane, diisopropyl ether, nitromethane, acetone, *p*-xylene, benzene, and hexane as pure substances and in carbon tetrachloride solution. Band frequencies accurate to within 1 cm^{-1} are reported. Except for the 3340 cm^{-1} band in dilute MeOH solutions no frequency shifts were observed even with gross changes of the electrical properties of the solutions. Molar extinction coefficients at absorption maxima are discussed briefly.

INTRODUCTION

During the last 5 years several workers have reported results of experimental and theoretical investigations of solvent effects on infrared absorption spectra. Excellent summaries of these data are found in Spectrochimica Acta (1, 2, 3, 4, 5) and in Annual Reports of the Chemical Society (6). Thompson (5), la Lau (4), and Bellamy (1) have shown that the Kirkwood–Bauer–Magat equation (7, 8) cannot be used to explain many frequency shifts observed for different solvents. Bellamy *et al.* (9, 10) have demonstrated that the frequency shifts observed for X—H and carbonyl stretching vibrations result from specific interactions between solute and solvent molecules.

De Maine (11) has reported that all the band frequencies for nitromethane dissolved in carbon tetrachloride do not shift even for gross changes in solution composition. However, Brown (2) has quoted the work of Bayliss *et al.* (12) as evidence that for non-polar solvents the frequency shifts appear to depend only on the dielectric constant of the solvent, as predicted by the Kirkwood–Bauer–Magat equation (7, 8).

La Lau (4) has shown that the Debye (13) or Onsager (14) equations for the integrated band intensities must be replaced by a more complicated expression which cannot be handled easily. Coulson (3) has attributed changes of the integrated band intensities with solvent to small changes in the term $\partial\mu/\partial Q$ (μ, dipole moment; Q, normal co-ordinate) which does not necessarily cause a frequency shift. Thompson (5) has quoted numerous workers to support his assertion that neither the Debye equation (13) nor the Onsager equation (14) gives a satisfactory explanation for changes in band intensities with solvent.

In this work we report band frequencies for five alcohols, four ethers, acetone, benzene, nitromethane, *p*-xylene, and hexane as pure substances and in carbon tetrachloride solution. No frequency shifts are observed even with gross changes in the composition of the solutions.

EXPERIMENTAL

Solutions were made by diluting the pure substance with carbon tetrachloride to the required volumes. Actual concentrations were calculated with density data for the pure solvents (15) as described elsewhere (16). The concentration ranges and number of samples studied are given in Table I.

TABLE I

Data of experiments with the solvents indicated

Compound	Source	Grade	Concentration range (moles/l.)	Cell length	No. of samples
Carbon tetrachloride	Fisher	Spectrograde	—	.028	—
Methanol	Fisher	Spectrograde	.019–24.75	.028, 5.00	36
n-Propanol	Fisher	Cert. reagent	.107–13.39	.028	13
Isopropanol	Fisher	Cert. reagent	.105–13.08	.028	13
Cyclohexanol	Fisher	Reagent	.095–12.10	.028	12
Benzyl alcohol	Fisher	Cert. reagent	.078–9.70	.028	12
Diethyl ether	Mallinckrodt	Anal. reagent	.077–9.63	.028	12
Diisopropyl ether	Eastman Kodak	Red Label	.057–7.10	.028	12
1,4-Dioxane	Fisher	Spectrograde	.094–11.70	.028	12
Anisole	Fisher	Reagent	.074–9.21	.028	12
Nitromethane	Eastman Kodak	Spectrograde	.278–18.51	.028	20
Actone	Fisher	Cert. reagent	.109–13.64	.028	11
p-Xylene	Eastman Kodak	White Label	.065–8.11	.028	11
Benzene	Mallinckrodt	Reagent	.090–11.25	.028	11
Hexane	Fisher	Spectrograde	.061–7.65	.028	11

All measurements were made with a Perkin–Elmer Model 21 double-beam infrared spectrophotometer with sodium chloride optics. Absorption by carbon tetrachloride was cancelled by use of a variable path-length cell filled with pure carbon tetrachloride in the reference beam. Base lines were obtained with both cells filled with carbon tetrachloride before each set of measurements. Samples were run starting with the most dilute and increasing the concentration of solute. The decreasing concentration of solvent was compensated for by a decrease in the path length of the cell in the reference beam.

Each sample was scanned from 4000 cm^{-1} to 700 cm^{-1}. The temperature was $19\pm2°$ C. Repeated measurements showed that band frequencies between 2000 cm^{-1} and 700 cm^{-1} could be reproduced to within 1 cm^{-1}. At higher frequencies (4000 to 2000 cm^{-1}) reproducibility was within 4 cm^{-1}. No changes in the spectra of samples were observed even after 8 hours.

RESULTS

Dielectric constants, refractive indices, and observed band frequencies for the 15 pure solvents studied are given in Table II. Except for the center of the hydrogen bond band (near 3340 cm^{-1} in pure alcohols), no measurable frequency shifts were observed for any band of any solute – carbon tetrachloride pair studied, even for large changes in the electrical properties of the solutions.

In agreement with other workers, we observed that the broad band with center near 3340 cm^{-1}, which is common to all alcohols (Table II), does not shift measurably in passing from the pure alcohol to carbon tetrachloride solutions with near 0.200 mole per liter of methanol, *n*-propanol, isopropanol, cyclohexanol, or benzyl alcohol. Figure 1 provides data for the methanol – carbon tetrachloride system. In carbon tetrachloride solutions with alcohol concentration less than about 0.200 M, the hydrogen bond band first changes shape and on further dilution, it disappears. Figure 2 illustrates these changes for methanol – carbon tetrachloride, together with the isolation of a weak band near 3640 cm^{-1} which is observed first in a 1.485 M methanol solution and which shows no measurable frequency shift on further dilution of the methanol solution with carbon tetrachloride.

Extinction coefficients at all absorption maxima were calculated for all solutions studied.

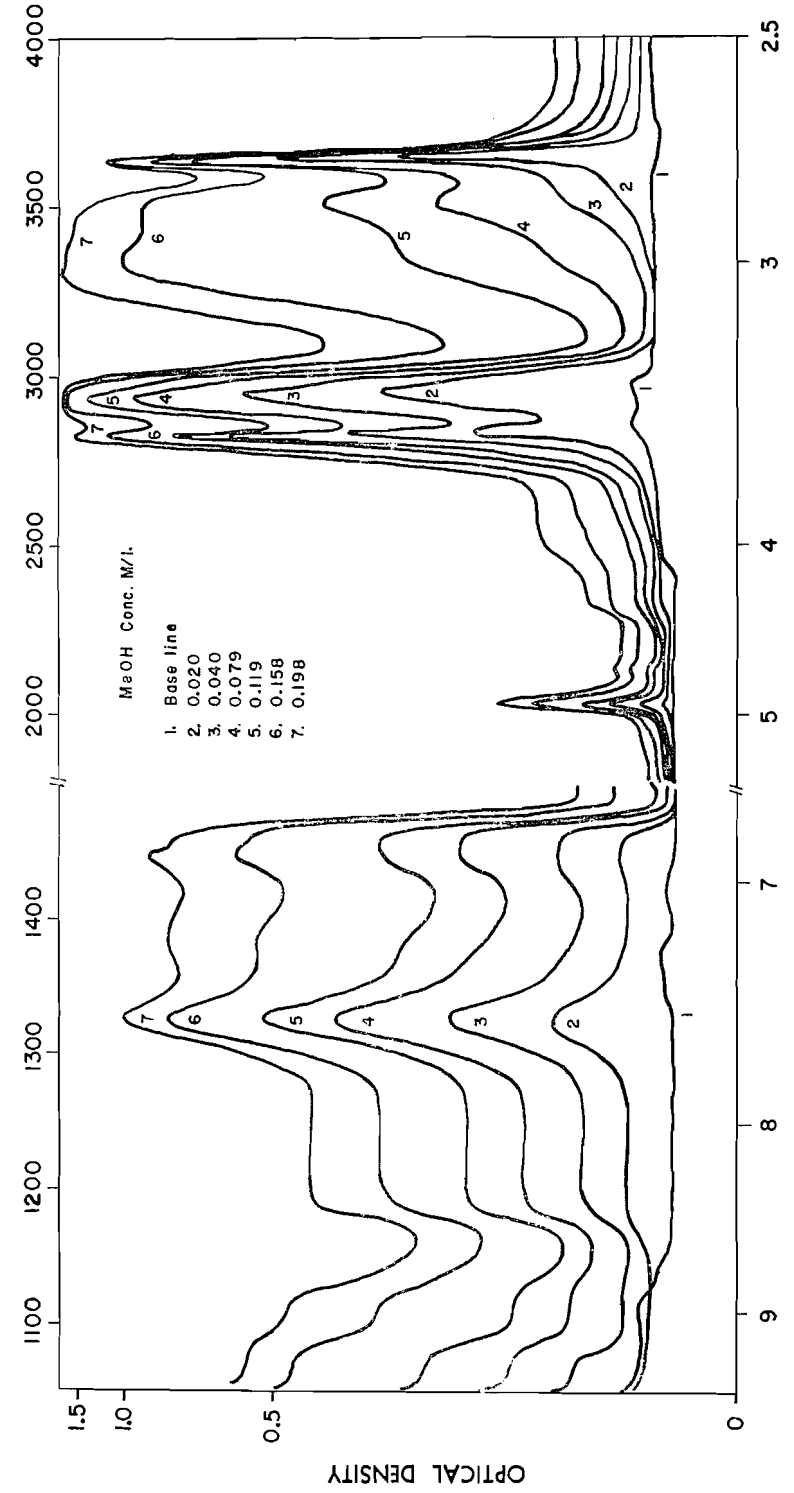

FIG. 2. Infrared absorption spectra between 1275 cm^{-1} and 4000 cm^{-1} for dilute solutions of methanol in carbon tetrachloride near 19° C. Absorption by carbon tetrachloride has been subtracted. Cell length is 5.000 mm. Methanol concentrations are indicated.

Within a 10% limit of reliability all bands between 3100 and 800 cm^{-1} for methanol, *n*-propanol, isopropanol, cyclohexanol, benzyl alcohol, nitromethane, acetone, hexane, and *p*-xylene obey Beer's law. In agreement with other workers we observed that the broad band with center near 3340 cm^{-1} (hydrogen bond band) increases with increasing alcohol concentration. This increase together with the changes in band shape reported for the dilute methanol solutions can be explained in terms of partial and reversible polymerization of alcohol molecules. The weak band with center near 3640 cm^{-1}, reported for the dilute methanol solutions, appears to obey Beer's law.

At increased concentrations of the ethers and of benzene, the extinction coefficients measured at the band centers decrease uniformly. For diethyl ether, anisole, benzene, 1,4-dioxane, and diisopropyl ether, average decreases of 50, 25, 24, 21, and 20%, respectively, were observed in the concentration range of 0.1 *M* to pure substance.

DISCUSSION

These data cannot be explained with the Kirkwood–Bauer–Magat equation (7, 8) or with any modification of this equation (17) since the band frequencies are independent of the electrical properties of the solutions. As a variety of alcohols have been examined, and as the 3340 cm^{-1} band common to all is not perturbed at alcohol concentrations greater than near 0.20 *M*, it seems that frequency shifts previously reported may arise from specific interactions between solute and solvent molecules rather than from the average electrical properties of the solution.

Inherent difficulties already described by la Lau and Thompson have prevented a thorough examination of theories which predict intensity variations with solution changes. That all the bands for alcohols (except 3340 cm^{-1}) apparently obey Beer's law, while those of the ethers and benzene do not, may be of special interest.

ACKNOWLEDGMENT

Special thanks are due to Dr. F. C. Nachod of Sterling-Winthrop Research Institute, Rensselaer, N.Y., for the loan of a variable path-length cell.

ALKALOIDS OF LYCOPODIUM FAWCETTII. PART II[1, 2]

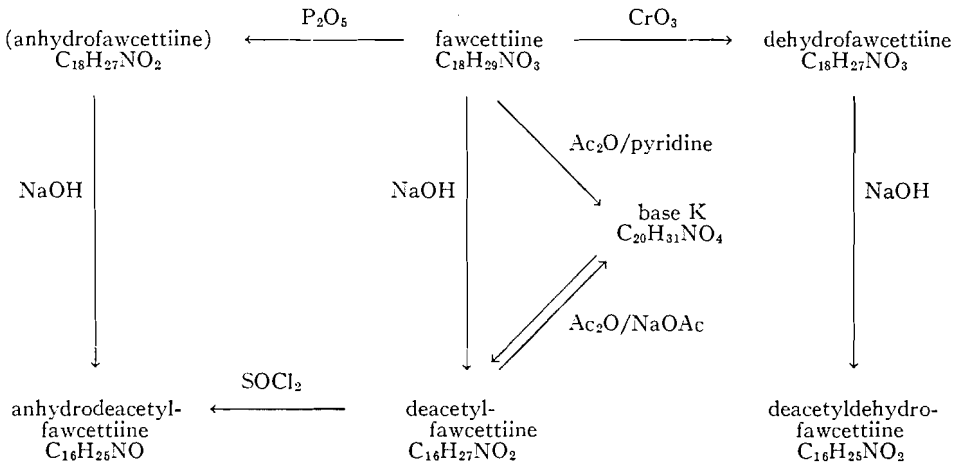
R. H. BURNELL, B. S. MOOTOO, AND D. R. TAYLOR

β-Lofoline and fawcettiine are shown to be identical. Hydrolysis of bases from *Lycopodium fawcettii* gave rise to lycofoline and a smaller amount of an α-obscurine like base. Milder extraction procedures afford four new bases, base M, $C_{17}H_{27}NO_2$; base O, $C_{20}H_{31}NO_5$; base K, which is acetylfawcettiine, $C_{20}H_{31}NO_4$; and base N, which is diacetyllycofoline, $C_{20}H_{29}NO_4$. The isolation of fawcettiine from *Lycopodium clavatum Linn.* gathered in Jamaica is also reported.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

After the initial extraction of this species (1) it was decided that a detailed study of deacetylfawcettiine was necessary and a slightly modified procedure was used to isolate this base. The stronger bases from the plant were hydrolyzed before being separated and the deacetylfawcettiine was then obtained by chromatography over alumina. These operations afforded another crystalline base, $C_{16}H_{25}NO_2$ (m.p. 140–141°), which we had not previously isolated. From the infrared spectrum and analyses it was learned that base H is an unsaturated tertiary base containing two hydroxyl groups. In a recent paper on the alkaloids of *Lycopodium annotinum* (2), Anet and Khan described an unsaturated base, lycofoline, which is identical with that described above.

Small quantities of another base which shows a great similarity to α-obscurine (3) were also obtained but insufficient material prevents a positive identification at this stage.



Using the procedures of Manske and Marion (4) for the extraction of lycopodiums affords an extremely dark crude product, a large portion of which proves to be intractable. We have found that cold percolation with dilute tartaric acid gives not only a cleaner, more readily purified extract but also affords a higher yield of tractable base. The new procedure gives rise to different proportions of the previously recorded bases (1) but base B (Marion's L.30 (5)) has not been found. Base E, $C_{17}H_{25}NO_2$, was not found in any quantity but a very similar substance base M, $C_{17}H_{27}NO_2$, was obtained. This base gives by far the least soluble perchlorate and can only be satisfactorily recrystallized from water. Like base E, base M shows a distinguishing ammonium band at 2000 cm^{-1} in the infrared (as does lycopodine).

The crude base from the tartaric acid extraction was distributed between chloroform and buffer in nine funnels and from this operation a significant quantity of a crystalline base (base J) was obtained. Analyses show a molecular formula $C_{18}H_{29}NO_3$ and melting point, mixed melting point, and infrared comparison have shown the substance to be β-lofoline, also reported by Anet and Khan (2). β-Lofoline perchlorate is indistinguishable from fawcettiine perchlorate in the infrared and shows the same melting point but fawcettiine had never been obtained crystalline and its perchlorate consistently analyzed for the monohydrate, $C_{18}H_{29}NO_3 . HClO_4 . H_2O$, whereas using the same conditions for drying prior to analysis, β-lofoline perchlorate analyses for $C_{18}H_{29}NO_3 . HClO_4$. However, a mixed melting point determination on the two perchlorates gave no depression, showing the two to be identical. We would like to retain the name fawcettiine for this base since it represents the major alkaloid of the species. Hydrolysis of crystalline β-lofoline gives deacetylfawcettiine (1).

Oxidation of fawcettiine with chromium trioxide gave a six-membered ring ketone,

[1]*Manuscript received June 1, 1960.*
Contribution from Chemistry Department, University College of West Indies, Jamaica, B.W.I.
[2]*Part I: Burnell, reference 1.*

dehydrofawcettiine ($C_{18}H_{27}NO_3$) which could be readily hydrolyzed to deacetyldehydrofawcettiine, $C_{16}H_{25}NO_2$, m.p. 145–147°. The more readily eliminated hydroxyl group in deacetylfawcettiine has been shown to be that present as the free hydroxyl in fawcettiine since the dehydration product from fawcettiine can be hydrolyzed to the previously obtained anhydrodeacetylfawcettiine, $C_{16}H_{25}NO$. These, and other transformations mentioned later, may be summarized:

The most highly oxygenated base isolated from *L. fawcettii*, base O (m.p. 181–182°), has the molecular formula $C_{20}H_{31}NO_5$ and from spectral and analytical results contains two O-acetyl residues and a hydroxyl group.

The greatest difference between the methanol and tartaric acid extractions was found in the weaker bases. Base F was obtained only in small amounts while two diacetate bases not previously described represented the bulk of the weak base fraction. Countercurrent distribution over 120 tubes did not completely separate these two bases and since neither crystallizes nor forms the usual crystalline salts, characterization was extremely difficult. Neither compound shows hydroxyl absorption in the infrared but both show bands corresponding to O-acetyl frequencies. Hydrolysis of one, base K ($C_{20}H_{31}NO_4$), affords deacetylfawcettiine and O-acetyl determinations show two such residues to be present in the base. Acetylation of fawcettiine with acetic anhydride and pyridine gave rise to base K, which can also be prepared from deacetylfawcettiine by refluxing in acetic anhydride containing sodium acetate.

The other diacetate weak base, present in much smaller quantity, gives rise to lycofoline on hydrolysis and the absence of hydroxyl absorption in the infrared, supported by the analogy of the other acetylated bases shown to be present in the plant, suggests that this unstable compound is represented by the formula $C_{20}H_{29}NO_4$, i.e. diacetyllycofoline.

Tartaric acid extraction of locally collected *L. clavatum* Linn. led to the isolation of fawcettiine and smaller quantities of lycopodine. Several other bases which have been obtained from this plant will be described in a future publication.

EXPERIMENTAL

All melting points are uncorrected and the infrared spectral figures are for Nujol mulls unless otherwise stated. Paper chromatography means in all cases No. 4 Whatman

paper employing pyridine, ethyl acetate, water (2.3:7.5:1.65), the bases being spotted as the hydrochlorides.

Base H *(Lycofoline)*

The stronger bases from a methanolic extraction (see ref. 1) were hydrolyzed with 5% methanolic sodium hydroxide. The base was extracted (3.9 g) and then run over a column of ethyl acetate washed alumina in benzene. Elution with 20% chloroform in benzene gave white crystals (1.0 g), m.p. 140°, a sample of which was sublimed for analysis, m.p. 141°. Calc. for $C_{16}H_{25}NO_2$: C, 73.0; H, 9.6; N, 5.3; O, 12.2. Found: C, 73.0; H, 9.4; N, 5.2; O, 12.3.

The infrared showed both absorption in the OH stretching region (3350 cm^{-1}) and a weak band due to unsaturation (1675 cm^{-1}). The trace was identical with that published for lycofoline (2) and a mixed melting point (140–141°), kindly performed by Dr. Anet, with lycofoline (m.p. 142°) showed no depression.

Base I

Elution of the column (above) with 50% chloroform in benzene afforded another crystalline base (100 mg), m.p. 300° (decomp.). The ultraviolet spectrum showed λ_{max} 252 mμ, log ϵ (based on the molecular weight of α-obscurine) 3.77. The infrared spectrum, which was not identical with that of α-obscurine, had peaks at 3480 (OH), 3200 (NH), and 1662 (lactam C:O) cm^{-1}.

Further elution of the column with chloroform gave deacetylfawcettiine (1.1 g).

Extraction of L. fawcettii with Tartaric acid

The dried, ground plant (18 kg) was percolated with 3% tartaric acid solution and the aqueous percolate then evaporated at 40° to a manageable volume. Neutral impurities were removed by ether extraction and after basification with ammonia, the crude base (28.0 g) was obtained by ether extraction. The base was shaken between chloroform and phosphate buffer, pH 5.3, in nine 1-liter separatory funnels, and the stronger bases in funnels 1–7 (12.4 g) was distributed again between chloroform and acetate buffer, pH 5.6, in a 120-tube multiple extractor. The weight curve (Fig. 1) showed three peaks but paper chromatography showed a larger number of bases to be present.

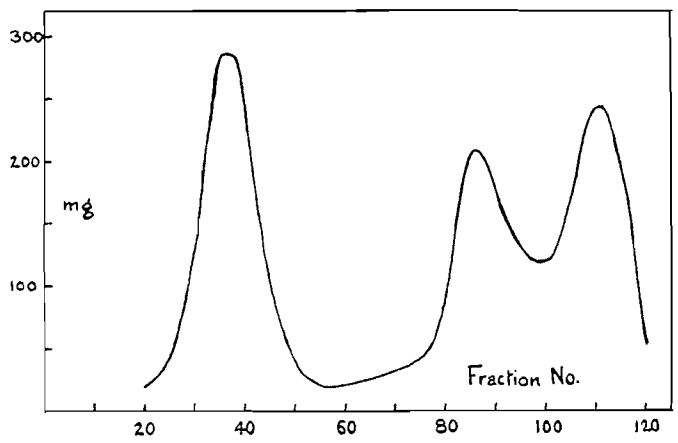

FIG. 1. Countercurrent distribution of strong bases with the system chloroform–buffer of pH 5.6.

Base A

Tubes 25-50 contained only base A (1).

The material from tubes 77–97 (3.18 g) was a mixture of three bases as shown by paper chromatography, so it was shaken between chloroform and phosphate buffer, pH 5.9, for 60 transfers. Complete separation was not obtained but from the central part of the distribution a crystalline base appeared.

Base O

The base was sublimed for analysis, m.p. 181–182°. Found: C, 65.7; H, 8.7; N, 3.9; O, 22.1; O—Ac, 23.9. $C_{20}H_{31}NO_5$ requires: C, 65.7; H, 8.6; N, 3.8; O, 21.9; $(O—Ac)_2$, 23.6. Infrared peaks at 3180 (bonded OH) and 1725 and 1235 (O—Ac) cm^{-1}.

Base M

The acetone mother liquors from base O were made slightly acidic with perchloric acid affording a sparingly soluble perchlorate, m.p. 280–282° (from water). Found: C, 54.1; H, 7.2; N, 3.8; O, 25.3; Cl, 9.3. $C_{17}H_{27}NO_2.HClO_4$ requires: C, 54.0; H, 7.4; N, 3.7; O, 25.4; Cl, 9.4. Infrared peaks at 3420 (OH), 2010 (NH), and 1692 (C:O) cm^{-1}.

The third base in this fraction is as yet uncharacterized.

The material (4.18 g) from the third peak of the first distribution (tubes 99-120, Fig. 1) was shown to contain one major and one minor component by paper chromatography, other than smaller amounts of the bases found in the second peak. Distribution between chloroform and phosphate buffer, pH 7.4, gave a central peak fraction containing the major base (2.33 g), which crystallized from an acetone solution.

β-Lofoline (*Fawcettiine*)

The base was sublimed for analysis, m.p. 172–173°. Calc. for $C_{18}H_{29}NO_3$: C, 70.3; H, 9.5; N, 4.6; O, 15.6; active H, 0.33. Found: C, 70.4; H, 9.6; N, 4.5; O, 15.8; active H, 0.34. Infrared peaks at 3470 and 3100 (OH) and at 1730 and 1710 (C:O) cm^{-1}. In carbon tetrachloride solution the infrared spectrum showed only weak hydroxyl absorption and only one carbonyl band at 1733 cm^{-1}.

The methiodide was prepared in methanol, m.p. 293–296°. Calc. for $C_{19}H_{32}NO_3I$: C, 50.8; H, 7.2; N, 3.1; I, 28.2; N—Me, 3.2. Found: C, 51.1; H, 7.2; N, 3.2; I, 28.4; N—Me, 3.0.

The perchlorate was recrystallized from acetone, m.p. 272–275°. Calc. for $C_{18}H_{29}NO_3.HClO_4$: C, 53.0; H, 7.8; N, 3.4; Cl, 8.7. Found: C, 53.2; H, 7.5; N, 3.4; Cl, 8.5. Mixed melting point with fawcettiine perchlorate (m.p. 272-275°) gave no depression.

Hydrolysis of β-Lofoline

β-Lofoline (175 mg) was hydrolyzed in methanolic sodium hydroxide giving white solids (160 mg), m.p. 207–208°. A sublimed sample gave an infrared spectrum identical with that of deacetylfawcettiine, and admixture with an authentic sample caused no lowering of the melting point.

Anhydrodeacetylfawcettiine from Fawcettiine

Excess phosphorus pentoxide was added to fawcettiine (100 mg) in dry benzene and the mixture gently refluxed for 6 hours and then allowed to stand at room temperature overnight. The mixture was poured into cold water, and the solution was then made basic with solid sodium carbonate and the organic base removed by extraction with carbon tetrachloride. The pale oil obtained could not be made to crystallize nor could the perchlorate be obtained crystalline so the product was sublimed and then hydrolyzed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in ethanolic sodium hydroxide. The base, extracted with chloroform after dilution of the reaction mixture with water, gave a crystalline hydrochloride showing an infrared spectrum superimposable on that of anhydrodeacetylfawcettiine hydrochloride (1).

Dehydrofawcettiine

Fawcettiine (530 mg) in pyridine (8 ml) was added to excess chromium trioxide / pyridine complex prepared in the usual manner. After 1 hour at room temperature, the reaction mixture was poured into water, made strongly basic with ammonia, and extracted with chloroform. The chloroform solution was extracted with 10% hydrochloric acid, which was then basified with ammonia and re-extracted with chloroform giving a dark brown oil (300 mg) which showed, in addition to unchanged fawcettiine, another spot of greater R_f on paper. The crude product was chromatographed on ethyl acetate washed alumina and afforded, in the benzene eluate, a colorless oil (220 mg) which solidified on standing. The solid was sublimed, m.p. 134–137°. Found: C, 71.0; H, 9.4; N, 4.5; O, 15.5; C—Me, 9.4. $C_{18}H_{27}NO_3$ requires: C, 70.8; H, 8.9; N, 4.6; O, 15.7; $(C—Me)_2$, 9.8. Infrared peaks at 1700 (six-membered ring ketone) and 1725, 1240, and 1220 (O—Ac) cm^{-1}. No absorption in the hydroxyl region.

The methiodide was recrystallized from methanol/acetone, m.p. 267–268° (inserted at 240°).

Deacetyldehydrofawcettiine

Dehydrofawcettiine (120 mg) was dissolved in methanol (5 ml) and a solution of sodium hydroxide (1 g) in methanol (3 ml) and water (5 ml) was added. After 6 hours at room temperature, the solution was diluted with water and extracted with chloroform, yielding a white solid which after sublimation, melted over the range 145–147°. The acetate peaks were absent in the infrared spectrum but both hydroxyl (3080 cm^{-1}) and carbonyl bands (1708 cm^{-1}) were present. The substance was characterized as the methiodide prepared from the base (20 mg) in methanol (10 ml) and recrystallized from methanol/acetone, m.p. 308–309° (inserted at 240°). Found: C, 50.0; H, 7.0; N, 3.6; I, 31.8. $C_{16}H_{25}NO_2.CH_3I$ requires: C, 50.4; H, 7.0; N, 3.5; I, 31.3.

Acetylfawcettiine

Fawcettiine (100 mg) was acetylated in acetic anhydride/pyridine at room temperature for 12 hours. The product was sublimed to remove traces of pyridine and a white semisolid (m.p. ca. 110°) was obtained. In the infrared the substance showed no hydroxyl absorption but could not be crystallized from any solvent. A portion was sublimed for analysis, m.p. 116–117°. Found: O—Ac, 25.4. $C_{20}H_{31}NO_4$ requires: $(O—Ac)_2$, 24.6. Mixed melting point, paper chromatography and identical infrared spectra show acetylfawcettiine to be base K (see below).

Weak Bases

The weak base from the nine-funnel distribution (11 g) was distributed between chloroform and acetate buffer, pH 3.2, for 120 transfers. The first 27 tubes contained neutral material (1.96 g) and no significant quantities of base were encountered until tubes 52–78 (0.75 g) containing base N and 84–102 (1.91 g) mostly base K.

Base N

This substance failed to crystallize or form crystalline salts. It was not completely stable to sublimation but showed only one relatively slow-moving spot on paper. Hydrolysis (of tube 52) in methanolic sodium hydroxide for 24 hours at room temperature gave

a solid base which sublimed readily, m.p. 140°. Comparison of the infrared spectrum of the hydrolysis product with that of lycofoline showed them to be identical and a mixed melting point confirmed this. The infrared spectrum of base N shows no hydroxyl peak but a broad carbonyl band 1725–1740 cm^{-1} with complementary absorption at 1235 cm^{-1}. A shoulder at 1660 cm^{-1} is due to the carbon–carbon double bond.

Base K

The material (1.91 g) was run over alumina in benzene giving a white solid which solidified after sublimation, showed homogeneity on paper, but did not crystallize from solvents. The base was resublimed for analysis, m.p. 117°. Found: O—Ac, 24.7; N, 3.8. $C_{20}H_{31}NO_4$ requires: $(O—Ac)_2$, 24.6; N, 4.0. Infrared absorption at 1725 (C:O) and a broad peak at 1240 cm^{-1}.

Hydrolysis of base K gave an almost quantitative yield of deacetylfawcettiine as shown by the infrared spectrum, m.p. 207° and mixed melting point 207°. Base K was the major product when deacetylfawcettiine was acetylated in refluxing acetic anhydride containing sodium acetate.

Extraction of L. clavatum Linn.

Through the dried, ground plant material (4.5 kg) was percolated aqueous 3% tartaric acid solution until no alkaloid could be detected using a potassium iodide/platinic chloride spray. The crude base (7.5 g) was obtained as described earlier and then distributed between chloroform and phosphate buffer, pH 5.3 (25 transfers). Three distinct fractions were obtained, tubes 20–25 (fraction A, 2.89 g) containing one main strongly basic component. Tubes 5–19 were combined (fraction B, 1.71 g) as were tubes 1–4, but this last fraction has not been investigated further.

Fawcettiine

Fraction A (2.18 g) was distributed between chloroform and phosphate buffer, pH 7.17 (20 transfers), and from the weight curve and paper chromatography it appeared that tubes 9–15 contained a single component. The perchlorates obtained from these tubes were combined and recrystallized from acetone/ether, m.p. 271–275° (500 mg). Mixed melting point and infrared comparison showed this derivative to be fawcettiine perchlorate.

Lycopodine

Fraction B (1.71 g) after countercurrent extraction afforded a perchlorate, m.p. 281–282° (550 mg). The infrared spectrum and no depression in the melting point on admixture with an authentic sample showed this to be lycopodine perchlorate.

ACKNOWLEDGMENTS

The authors express their thanks to Dr. F. A. L. Anet, Ottawa, for performing the mixed melting points and one of the authors (D. R. T.) wishes to acknowledge financial support in the form of a Postgraduate Scholarship from T. Geddes Grant Ltd., Kingston, Jamaica.

SYNTHÈSES D'ACIDES AMINOBUTYRIQUES

1. ACIDES ALKYLAMINO-2 AMINO-4 BUTYRIQUES[1]

RÉAL LALIBERTÉ ET LOUIS BERLINGUET

ABSTRACT

The syntheses of eight 2-alkylamino-4-aminobutyric acids are described. The starting material is 4-butyrolactone, which is opened with potassium phthalimide to give 4-phthalimidobutyric acid. After bromination the 2-bromo-4-phthalimidobutyric acid, obtained in excellent yield, is treated with aliphatic amines in alcoholic medium to give the desired substituted 2,4-diaminobutyric acids, which were characterized as the monohydrochlorides and the di(phenylcarbamates). Three of them cyclized easily to give the corresponding hydantoins. In the course of the reaction, substituted diamides of phthalic acid were isolated and characterized.

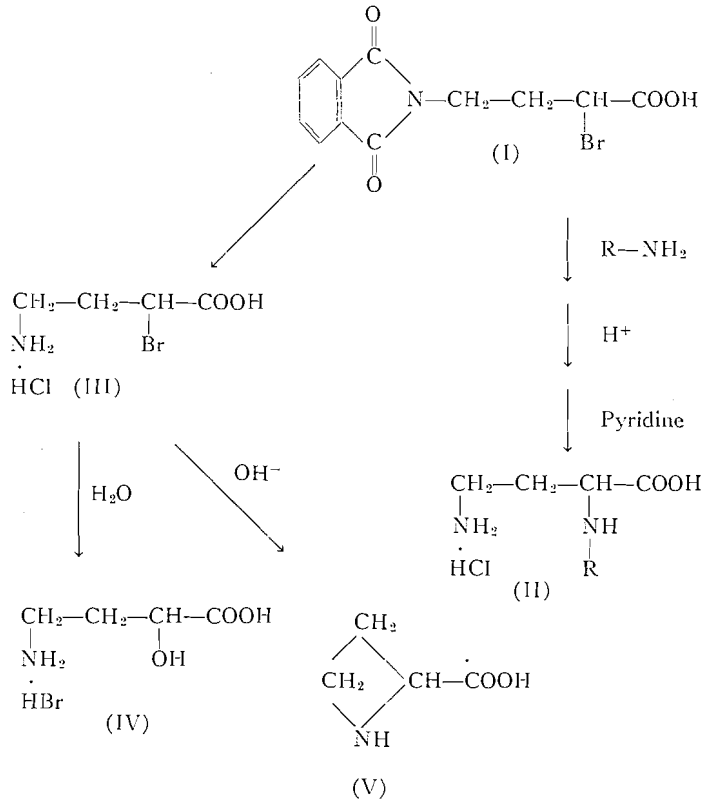
INTRODUCTION

Les dérivés aminés de l'acide *n*-butyrique retiennent l'attention depuis quelques années. En particulier, on connaît maintenant le rôle très important de l'acide amino-4 butyrique (GABA) (1, 2) dans le système nerveux central des mammifères et sa distribution généralisée chez tous les êtres vivants: levures (3), plantes et protéines animales (4). Des études ont aussi été faites sur les propriétés physiques et le rôle biologique de l'acide amino-2 butyrique ainsi que des acides amino-2 hydroxy-4 butyrique (5) et diamino-2,4 butyrique (6). Ces substances sont des intermédiaires normaux dans le métabolisme de quelques acides aminés. L'acide diamino-2,4 butyrique est absorbé très rapidement par la cellule intacte (7).

Vu l'importance biologique de ces composés, nous avons voulu préparer une série de dérivés N-alkylés de l'acide diamino-2,4 butyrique pour les soumettre à des essais biologiques.

La synthèse de ces dérivés présente des difficultés. Si l'on désire obtenir l'acide diamino-2,4 butyrique symétriquement substitué, on peut, en théorie, utiliser un acide butyrique dihalogéné. Mais des essais récents (8, 9, 10) montrent qu'une amination directe en position 4 est difficile à cause de réactions secondaires.

Si l'on veut obtenir l'acide diamino-2,4 butyrique substitué sur l'un des azotes, il faut, lors de la synthèse, bloquer l'atome d'azote qui doit rester exempt de substituants. Ainsi Christensen (7), en partant de dérivés *p*-toluène-sulfonyles de l'acide diamino-2,4 butyrique, a préparé quelques dérivés méthylés, soit en position 2, soit en position 4.



Nous avons voulu utiliser comme produit de départ une substance facilement accessible: la butyrolactone-4. Talbot, Gaudry et Berlinguet (11), Frankel (6) ainsi que Zaoral (12) ont préparé avec de bons rendements l'acide phtalimido-4 butyrique. Nous avons bromé cet acide (Zaoral) (12) en position 2, puis nous avons remplacé l'halogène par réaction avec les amines aliphatiques voulues.

La fonction amine primaire en position 4 se trouve protégée par le radical phtalimidé, lequel peut être hydrolysé une fois la réaction terminée ou peut être scindé par aminolyse lors de la réaction pour donner le diamide de l'acide phtalique.

Théoriquement, dans cette synthèse à partir de l'acide bromo-2 phtalimido-4 butyrique (I), plusieurs réactions sont possibles. Il peut y avoir amination, hydroxylation si la réaction se fait en milieu aqueux ou encore cyclisation si le groupe phtalimide est scindé.

[1]*Manuscrit reçu le 26 mai 1960.*
Contribution du Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Qué.

En plus de l'acide diamino-2,4 butyrique substitué désiré (II) on peut donc avoir, comme produit de la réaction, l'acide hydroxy-2 amino-4 butyrique (IV), l'acide bromo-2 amino-4 butyrique inchangé (III) et l'acide azétidine-carboxylique-2 (V) (9).

Dans les synthèses rapportées ici, la chromatographie et l'électrophorèse sur papier nous ont permis de constater la présence, après hydrolyse des produits d'amination, d'une faible quantité d'acide hydroxy-2 amino-4 butyrique en plus de l'acide diamino-2,4 butyrique voulu. La purification de ce dernier produit se fait facilement par cristallisation dans l'éthanol.

Zaoral (12) n'a pas réussi à substituer l'atome de brome de l'acide bromo-2 phtalimido-4 butyrique par de l'ammoniaque. Nous avons repris cette réaction et, à l'aide de la chromatographie sur papier, nous avons pu mettre en évidence la présence dans ces conditions d'une grande quantité d'acide hydroxy-2 amino-4 butyrique ainsi qu'un peu des acides bromo-2 amino-4 butyrique et diamino-2,4 butyrique. Il semble qu'avec l'ammoniaque il y ait hydrolyse du groupe phtalimidé et hydroxylation en position 2 plutôt que substitution comme dans le cas des amines.

Pour favoriser l'amination nous avons condensé les amines en milieu alcoolique. Sauf dans le cas de la méthylamine et de l'éthylamine, les rendements sont meilleurs en solution alcoolique qu'en solution aqueuse.

Certaines amines sont des bases assez fortes pour couper le radical phtalimidé en milieu alcoolique. Dans ces cas on recueille, après la réaction, les diamides correspondants de l'acide phtalique. Nous avons caractérisé les diamides suivants: N,N′-dibutyl phtalamide, N,N′-dicyclohexyl phtalamide et N,N′-diisopropyl phtalamide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

La température optimum pour les substitutions semble être 20° C. Les rendements sont sensiblement les mêmes, que l'on utilise l'acide halogéné ou son ester méthylique.

Nous avons caractérisé huit nouveaux acides amino-4 butyriques portant en position 2 une fonction amine secondaire ou tertiaire. Nous en avons fait les di(phénylcarbamates) et nous avons noté que trois d'entre eux se cyclisent très facilement pour donner les hydantoïnes correspondantes.

PARTIE EXPÉRIMENTALE

Acide phtalimido-4 butyrique

On peut faire la réaction dans la diméthylformamide (Talbot, Gaudry et Berlinguet) (11) ou sans solvant (Zaoral) (12). Dans ce cas, on ajoute lentement (30 minutes) à de la butyrolactone-4 (70.0 g, 0.81 mole) maintenue entre 180° et 200° de la phtalimide de potassium (150.0 g, 0.81 mole). On chauffe le mélange pendant 30 minutes, puis on dissout la masse dans 1 litre d'eau. On ajoute alors 200 ml d'éthanol et on refroidit. L'addition lente d'acide chlorhydrique concentré accompagnée d'une forte agitation précipite l'acide phtalimido-4 butyrique. Rendement brût: 160 g (85%). Il n'est pas nécessaire de recristalliser le produit pour les manipulations suivantes, p.f. 112°–115°* (lit. p.f. 117°–118°) (13). Anal. Calc. pour $C_{12}H_{11}O_4N$: N, 6.00%. Trouvé: N, 6.31%.

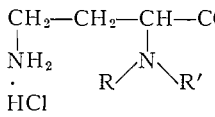
Acide bromo-2 phtalimido-4 butyrique

Dans un ballon muni d'un réfrigérant, on place 62 g (0.27 mole) d'acide phtalimido-4 butyrique, 1 g de tribromure de phosphore, 1 g de phosphore rouge amorphe et 250 g (1.55 moles) de brome dissous dans 200 ml de CCl_4. On chauffe à reflux pendant 18 heures. Après avoir évaporé le solvant et l'excès de brome, on lave le solide avec du benzène. Le résidu est dissous à chaud dans l'éthanol. L'addition d'eau permet la cristallisation de l'acide bromo-2 phtalimido-4 butyrique. Rendement: 80 g (96%), p.f. 150–152°. Une seconde cristallisation dans l'acétate d'éthyle donne un point de fusion de 157° (lit. 157–158°) (12). Anal. Calc. pour $C_{12}H_{10}BrO_4N$: N, 4.5; Br, 25.6%. Trouvé: N, 4.5; Br, 25.7%.

Acides alkylamino-2 amino-4 butyriques

On place dans une fiole conique 40 g (0.125 mole) d'acide bromo-2 phtalimido-4 butyrique et 200 ml d'éthanol. À la suspension refroidie, on ajoute en agitant un excès d'amine (environ 1.0 mole). La méthylamine, l'éthylamine et la diméthylamine sont en solution aqueuse de sorte que le mélange réactionnel est un mélange eau–alcool. Les autres amines réagissent en milieu alcoolique. On laisse en contact en agitant de temps à autre. Après 5 jours, les solutions sont évaporées à sec sous vide. On hydrolyse à reflux le résidu avec 500 ml d'acide chlorhydrique concentré pendant 12 heures. En refroidissant, l'acide phtalique cristallise. Après l'avoir filtré (21 g) on évapore à sec sous vide. On dissout le dichlorhydrate de l'acide diaminé dans l'éthanol chaud. On précipite le monochlorhydrate par addition de 9 ml de pyridine. Le monochlorhydrate obtenu est recristallisé deux fois par dissolution dans 75 ml d'eau chaude et addition de 400 ml d'éthanol. Le Tableau I contient la liste des acides alkylamino-2 amino-4 butyriques préparés. Dans le cas de la diméthylamine, il faut substituer la triéthylamine à la pyridine pour isoler l'acide diméthylamino-2 amino-4 butyrique libre.

Di(phénylcarbamates) des acides alkylamino-2 amino-4 butyriques



On peut caractériser les acides diaminés en les transformant en di(phénylcarbamates). Dans 5 ml de NaOH 4 *N* (0.02 mole), on dissout 1.68 g (0.01 mole) du monochlorhydrate

**Les points de fusion ne sont pas corrigés.*

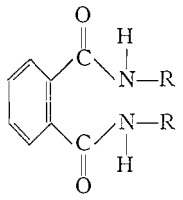
—C_6H_{11}	172	13.3	13.3



Le groupe phénylcarbamate en position 2 de la chaîne éthyle placée en position 5 du noyau de l'hydantoïne peut être hydrolysé par ébullition avec l'acide chlorhydrique concentré. On obtient ainsi le chlorhydrate de la méthyl-1 phényl-3 (amino-2 éthyl)-5 hydantoïne. On peut le cristalliser de l'alcool par addition d'éther, p.f. 227–228°. Anal. Calc. pour $C_{12}H_{16}N_3O_2Cl$: N, 15.6; Cl, 13.2%. Trouvé: N, 15.4; Cl, 13.3%.

Diamides de l'acide phtalique

Lors de la condensation de l'acide bromo-2 phtalimido-4 butyrique avec les amines primaires en solution alcoolique, il y a aminolyse du groupe phtalimidé et formation des diamides correspondants. On les isole en ajoutant à la solution 300 ml d'eau. On peut obtenir ainsi les N,N′-dibutyl phtalamide, N,N′-dicyclohexyl phtalamide et N,N′-diisopropyl phtalamide. Ces composés peuvent être recristallisés dans l'isopropanol. Leurs constantes physiques sont données dans le Tableau IV.

TABLEAU IV

CONDUCTANCES OF AQUEOUS SOLUTIONS OF SODIUM HEXANOATE (SODIUM CAPROATE) AND THE LIMITING CONDUCTANCES OF THE HEXANOATE ION, AT 25° C AND 35° C[1]

A. N. Campbell and J. I. Friesen[2]

ABSTRACT

The equivalent conductances, densities, and viscosities of aqueous solutions of sodium hexanoate have been determined at 25° C and 35° C at concentrations ranging from 0.0003 *M* to saturation.

The limiting equivalent conductances of the hexanoate ion have been determined as 27.37±0.04 mhos at 25° C and 34.69±0.05 mhos at 35° C.

The Robinson–Stokes and the Falkenhagen–Leist equations have been applied to the data. The Robinson–Stokes equation reproduces the data within 0.7 mho up to 0.5 *M* at 25° C when $\mathring{a}$ = 13 Å. At 35° C the data are reproduced within 0.5 mho up to 0.05 *M* with $\mathring{a}$ = 10 Å. The Falkenhagen–Leist equation reproduces the data at 25° C within 0.4 mho up to 0.1 *M* with $\mathring{a}$ = 5.5 Å. An $\mathring{a}$ = 4.0 Å reproduces the 35° C data within 0.5 mho up to 0.05 *M*.

From the form of the conductance curves and from an estimation of the apparent molecular weight it was concluded that the hexanoate ion does not form ionic micelles.

This research, in which the conductances of sodium hexanoate solutions have been determined, was part of a program in which it was intended to measure the conductances of the sodium salts of the fatty acids. It was thought that, proceeding up the homologous series, the increasing size of the anions might eventually lead to a situation where the anion was essentially motionless and non-conducting. On the other hand, it was known that, after a certain number of carbon atoms in the chain is reached, micelle formation occurs and that therefore the increasing size of the anion might be to some extent counterbalanced by the increased electrical charge; hence, even the largest ions would exhibit appreciable conductance. The limiting conductances of the hexanoate ion at two temperatures were determined, from the results in very dilute solution, and the results from concentrated solutions were compared with results calculated by means of the Wishaw–Stokes (1) and the Falkenhagen–Leist (2) equations. These equations have been quoted so frequently by us that they need not be stated again here.

EXPERIMENTAL

n-Hexanoic acid was obtained from the Eastman Kodak Company and purified by redistillation. The refractive index agreed very closely with the figure given in the literature. To prepare the sodium salt the acid was neutralized with an alcoholic solution of sodium hydroxide and the solution was evaporated until the salt crystallized out. The salt was then recrystallized twice from alcohol, dried at 110° C, ground in an agate mortar, and stored in an oven at 110° C.

Attempts to determine the purity of the salt by titration with hydrochloric acid, using a Fisher titrimeter, failed. Finally, the salt was analyzed by conversion to sulphate. The method, which is crude, gave a result corresponding to 99.5% sodium hexanoate. Had the salt contained either sodium carbonate or sodium hydroxide, the result would have been high rather than low.

Solutions were prepared in two ways. For concentrations ranging from 0.02 *N* to saturation, at least 2.3 g was weighed to 0.2 mg and the resulting solution weighed to

[1]*Manuscript received May 16, 1960.*
Contribution from the Chemistry Department, University of Manitoba, Winnipeg, Manitoba.
[2]*Holder of N.R.C. Bursary, 1959–60.*

0.2 mg, if it weighed less than 120 g, or to 10 mg, if it weighed more than 120 g; all weighings were reduced to vacuum. The weight concentration was therefore known to 0.01%. Dilute solutions were prepared by successive additions of salt to a known amount of water. At least 0.02 g of salt was weighed on a microbalance to 2μg. A maximum of six additions was made so that the weight concentrations were known to 0.01%.

For the more concentrated solutions, distilled water, having a specific conductance less than 5×10^{-6} mhos/cm, at 25° C, was used as solvent. For the medium concentration range, water from a Barnstead still was first passed through an Amberlite N-3 mixed bed ion exchange resin and then "equilibrated" with the carbon dioxide of the atmosphere by shaking for at least half an hour. The specific conductance was then about $2\text{–}3\times10^{-6}$ mhos/cm, at 25° C. For the very dilute region, water from the still was purified by bubbling purified nitrogen through it for several hours. The specific conductance was then 2 to 3×10^{-7} mhos/cm.

The electrical measurements were made on a Jones bridge and all the refinements of good work were applied. The technique has been described frequently. Four conductance cells, all of the type described by Jones and Bollinger (3), were used, and they had cell constants varying from 1.4409 to 443.76.

The conductances of very dilute solutions were determined in a cell of the Shedlovsky type (4). The constant of this cell was determined with potassium chloride, using the equation of Fuoss (5)

$$\Lambda = 149.93 - 94.65\sqrt{C} + 58.74C \log C + 198.4C.$$

From this equation, Λ for KCl at 25° C can be calculated for any given low concentration. But

$$\Lambda = 1000\, A/CR$$

where R is the measured resistance of the cell and A the cell constant. In this way the cell constant for the Shedlovsky cell was found to be 0.43246. We have pointed out, in previous papers, that it is easy to show, by means of the Washburn equation (6) that the effect of temperature on cell constant is, for cells of conventional geometry, exceedingly slight. In the present case, the constant of the Shedlovsky cell changes by 0.004%, for a 10-degree rise in temperature. It is therefore quite permissible to use, at 35° C, cell constants determined at 25° C.

For the more concentrated solutions, thermostats of conventional type were used. All thermometers were calibrated against a platinum-resistance thermometer. For the very dilute solutions, where the Shedlovsky cell was used, a more complicated thermostat, containing about six gallons of bleached petroleum oil and housed in a double-walled insulated box, was used. Stirring was by means of a circulating pump. Temperature was controlled by a mercury–toluene regulator and thyratron relay as described by Swinehart (7) and it was read directly on a platinum-resistance thermometer. In all cases, the temperature was known to about 0.005° C and it was constant within 0.002° C. When this thermostat was operated at 35° C, the air above the bath was maintained just above 35° C to prevent distillation of solvent into the exposed section of the cell.

Viscosity measurements were made with two viscometers of the Cannon and Fenske type (8), in which drainage and kinetic energy corrections are negligible. They were calibrated with water at the two temperatures. The reproducibility of run times was not better than 0.05%. Density and viscosity measurements were not made on the six most dilute solutions, since these were made up by successive additions of salt to the Shedlovsky-type cell.

DISCUSSION

After a careful consideration of all possible errors, we conclude that our equivalent conductances have a maximum possible error of $\pm 0.1\%$.

Limiting equivalent conductances are usually obtained either by the classical Kohlrausch method, in which equivalent conductance is plotted against the square root of the concentration, or by the Shedlovsky (4) or some other, method of extrapolation. Both the Kohlrausch and the Shedlovsky methods were used by us. In very dilute solutions hydrolysis is appreciable and correction was made for this by the method of Campbell and Bock (9). This method calculates x, the degree of hydrolysis, from the expression

$$x = -\frac{K_h}{2C} + \sqrt{\frac{K_h^2}{4C^2} + \frac{K_h}{C}},$$

where K_h is the hydrolysis constant and C is the stoichiometric concentration, and assumes that the equivalent conductance of free acid or base, as the case may be, is the limiting equivalent conductance of acid or base. It then follows that

$$\Lambda_{exp} = (1-x)\Lambda_{corr}+x\Lambda_{base}.$$

Thus Λ_{corr}, the equivalent conductance of the unhydrolyzed salt, can be calculated. The hydrolysis constants were obtained from the data of Everett, Landsman, and Pinsent (10). At 25° C, $K_h = 7.25\times10^{-10}$ and at 35° C, $K_h = 1.57\times10^{-9}$.

The Kohlrausch method gave for the limiting equivalent conductance of sodium hexanoate at 25° C a value of 77.47±0.04 mhos, and at 35° C a value of 96.23±0.05 mhos. The Shedlovsky extrapolation method gave the values 77.84 and 96.71 mhos, respectively. The Shedlovsky values are distinctly higher. Similar behavior was observed by Bock (9) for ammonium salts. Since the Shedlovsky method is empirical and the deviations from a straight line in the Kohlrausch plot are small (maximum deviation 0.05%, by the method of least squares), we think the Kohlrausch values are the ones that should be accepted.

The limiting conductances of the sodium ion, according to Benson and Gordon (11), are 50.10 mhos at 25° C and 61.54 mhos at 35° C. Subtracting these values from the values obtained for sodium hexanoate, the limiting conductance of the hexanoate ion results as 27.37±0.04 mhos at 25° C and 34.69±0.05 mhos at 35° C.

It now appears that there is little theoretical justification for the application of Wishaw–Stokes and the Falkenhagen–Leist equations to the region of concentrated solution. Nevertheless, the manner in which these equations predict the experimental results is surprising. We note in particular the results of Campbell and Paterson on lithium chlorate (12) where the observations were pushed right up to the molten salt, without serious discrepancy. We therefore find it of interest to apply these equations to our results and we have done so in the present instance. In this case, however, both equations appear to be useless. Both conductance equations were programmed on a Bendix G-15 D computer, in such a way that the best $\mathring{a}$ was found for each concentration. An $\mathring{a}$ value was then chosen in the dilute region (usually about 0.1 N), and this $\mathring{a}$ value was then used to calculate a conductance value for each concentration.

The 25° C data, based on the Wishaw–Stokes equation, are given in columns 3 and 4 of Table III. Two values of $\mathring{a}$, viz. 13 Å and 20 Å, were used in these calculations. Even in the very dilute region, the calculated and observed conductances differ by as much as 0.3 mho. When $\mathring{a}$ = 13 Å is used, the calculated and observed conductances agree within 0.7 mho up to a concentration of 0.5 M but for higher concentrations the calculated values differ markedly from the experimental results. For $\mathring{a}$ = 20 Å, the deviation becomes large for a concentration of 0.02 M. Below this concentration, the agreement is similar to that observed for $\mathring{a}$ = 13 Å. The reason for the similarity in the dilute region, despite the large difference in $\mathring{a}$ values, is that the equation becomes very insensitive to a change in $\mathring{a}$ value at lower concentrations.

The results with the Wishaw–Stokes equation at 35° C are given in columns 3 and 4 of Table IV, using $\mathring{a}$ values of 10 and 17 Å. Again, the agreement between observed and calculated values in the dilute region is only within 0.5 mho. For $\mathring{a}$ = 10 Å, the conductance values are reproduced within 0.5 mho up to a concentration of 0.05 M. For $\mathring{a}$ = 17 Å, the agreement is somewhat better in the dilute region but the region now extends only to 0.004 M. The calculated values for the higher concentrations again deviate very markedly from the experimental values.

The results of the calculations at 25° C based on the Falkenhagen–Leist equation are given in columns 5 and 6 of Table III. In the dilute region this equation reproduces the data rather well, the deviations being less than 0.1 mho up to 0.05 M and 0.4 mho at 0.1 M, when $\mathring{a}$ = 5.5 Å. For the larger value, $\mathring{a}$ = 7.0 Å, the deviation becomes appreciable at 0.02 M. Above 0.1 M, the equation fails rather badly.

Columns 5 and 6 of Table IV give the 35° C data obtained with the Falkenhagen–Leist equation. Behavior similar to that observed at 25° C is also observed here. The data are reproduced within 0.5 mho up to 0.05 M, with $\mathring{a}$ = 4.0 Å, and within 0.8 mho, for $\mathring{a}$ = 6.0 Å.

Compared with their behavior in regard to lithium chlorate, both equations perform very poorly. Moreover, the $\mathring{a}$ values are so large as scarcely to have any physical significance, at least with the Wishaw–Stokes equation, where the best value of $\mathring{a}$ is 10 Å, or greater. All conductance equations for the region of higher concentration must contain some function of the viscosity since undoubtedly a moving ion encounters a greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

resistance than it would in pure water or a very dilute solution. In the absence of a precise knowledge of the form of the viscosity function, theoretical investigators have been reduced to the necessity of dividing their calculated result by the relative viscosity of the solution and this has of course been done in all the calculations given here. If this were not done, a ludicrous result would be obtained for the very concentrated and very viscous solutions. In this connection it is perhaps significant that while the viscosity of sodium hexanoate solutions does not rise as high, at saturation, as that of lithium chlorate at saturation (an ideal salt for this kind of treatment), at comparable concentrations the viscosity of sodium hexanoate is much higher than that of lithium chlorate. This is exemplified in Fig. 1, where the viscosities of the aqueous solutions of the salts, at 25° C,

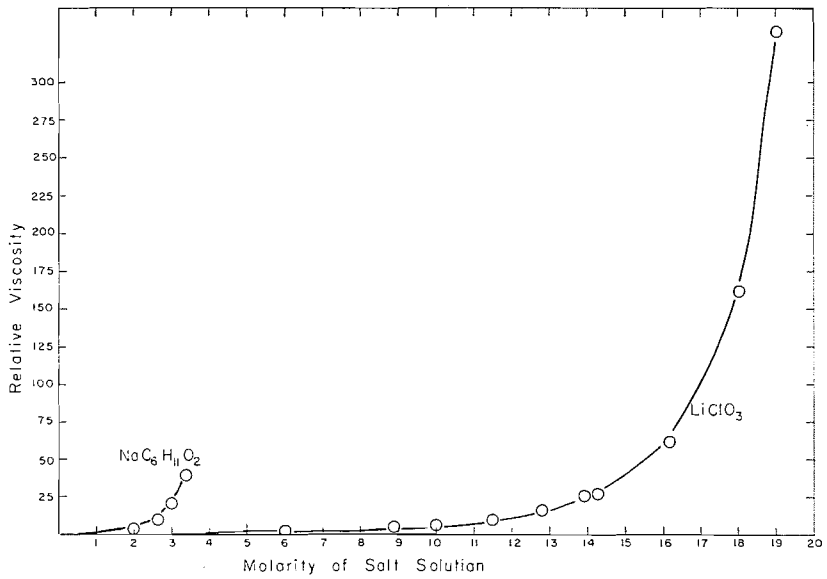

FIG. 1. Viscosity of sodium hexanoate and of lithium chlorate solution at 25° C.

are plotted against molar concentration. The graph shows that a saturated, or almost saturated, aqueous solution of sodium hexanoate, has a molarity of 3.45 but its viscosity equals that of a 15 *M* solution of lithium chlorate. If some power of the viscosity other than unity were used, the results might be brought into harmony, not only with one another, but with smaller $\mathring{a}$ values. In the absence, however, of any theoretical indication as to what form the viscosity correction should take, there seems no point in further speculation.

An obvious explanation of the large $\mathring{a}$ values would appear to exist in the assumption of micelle formation. According to McBain (13), solutions of colloidal electrolytes exhibit approximately ideal behavior until a certain concentration, characteristic of the substance, is reached. Marked deviation from ideal behavior then sets in rather suddenly. The sodium salts of the fatty acids belong to the class of compounds which exhibit this behavior. Smith and Robinson (14), employing the isopiestic vapor pressure method, conclude that the butyrate ion is the first of the fatty acid series to exhibit tendency toward micelle formation: micelle formation was observed for the hexanoate ion. On the other hand, McBain and co-workers (15) measured the conductance of the potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

salts of the fatty acids and observed that anomalous curves were first obtained with potassium laurate (C_{12}). When our own figures for the equivalent conductance of sodium hexanoate are plotted against concentration, the curves do not show the minima characteristic of salts which form micelles. Again, if the specific conductance is plotted against concentration, there should be a "break" or sharp change of direction, at the critical micelle concentration, but no such "breaks" occur.

To clinch the question of whether or not micelle formation occurs in solutions of sodium hexanoate, we determined the apparent molecular weight of sodium hexanoate in solutions of different concentration, by the method of freezing point lowering. The liquid in equilibrium with ice at various temperatures was analyzed by evaporation to dryness. The results are given in Table V. The apparent molecular weights correspond to

TABLE V

Concentration, g salt/100 g H_2O	Apparent molecular weight
1.0517	69.2
5.1895	67.0
10.287	63.0
17.298	59.5

complete dissociation of the salt and give no evidence of micelle formation. It is strange that the apparent molecular weights decrease with increasing concentration but colligative behavior cannot be expected at these high concentrations and the activity coefficients are not known. Hence, in our opinion, micelle formation cannot be considered an explanation of the very large values of $\mathring{a}$.

THE PREPARATION OF L-ARGINYL DIPEPTIDES OF ASPARAGINE, GLUTAMINE, AND SOME BASIC AMINO ACIDS[1]

CASIMIR BERSE, LUCIEN PICHÉ, AND AKIRA UCHIYAMA

ABSTRACT

The synthesis of the following dipeptides is described: L-arginyl-L-asparagine acetate, L-arginyl-L-glutamine acetate, L-arginyl-L-lysine diacetate, and L-arginyl-L-ornithine diacetate. The two former were prepared by coupling a mixed anhydride of α-carbobenzoxy-ω-nitro-L-arginine directly with L-asparagine or with L-glutamine; catalytic hydrogenolysis of the resulting intermediates gave the dipeptides. The two others were obtained by combining α-carbobenzoxy-L-arginine with ω-carbobenzoxy-L-lysine methyl ester hydrochloride or with ω-carbobenzoxy-L-ornithine methyl ester hydrochloride in the presence of N,N′-dicyclohexylcarbodiimide; saponification and hydrogenation was necessary to uncover the resulting dipeptides.

Arginine is a universal constituent of proteins and is found in most of the physiologically active polypeptides. Its introduction in synthetic peptides has presented unusual difficulties caused by the strongly basic character of the guanidino group (1). The arginyl peptides, in which the carboxyl group of arginine is involved, were not prepared until three groups of workers reported initial success almost at the same time in 1953 (2, 3, 4). Although a variety of these compounds have now been synthetized by appropriate methods (5–8), the arginyl dipeptides containing basic amino acids have not hitherto been described; L-arginyl-L-arginine is the only exception (9).

Two methods were adapted to the combination of arginine with L-asparagine and L-glutamine or with L-lysine and L-ornithine respectively. In the first of these, α-carbobenzoxy-ω-nitro-L-arginine (6, 10) was converted to a mixed anhydride (11) by the action of ethyl chloroformate in the presence of an equimolar amount of tri-*n*-butylamine; it was then condensed directly with L-asparagine or with L-glutamine in alkaline solution. Catalytic hydrogenolysis of the resulting intermediates removed the carbobenzoxyl and nitro groups and resulted in the respective dipeptides; these were crystallized as the acetates.

The synthesis of L-arginyl-L-lysine and of L-arginyl-L-ornithine was attempted by the same procedure: the mixed anhydride of ethyl carbonate and α-carbobenzoxy-ω-nitro-L-arginine was condensed with ω-carbobenzoxy-L-lysine methyl ester hydrochloride and with ω-carbobenzoxy-L-ornithine methyl ester hydrochloride. Saponification of the resulting covered dipeptide esters was successful but the carboxylic compounds resisted hydrogenolysis in acidic, neutral, or basic media.

An alternate procedure based on the previous experience of Boissonnas *et al.* (15) was adopted. In this procedure the guanido group of α-carbobenzoxy-L-arginine is protected by a proton (2, 3) while condensation is carried out with N,N′-dicyclohexylcarbodiimide (12). Use of the proton to cover the guanido group avoided the necessity for hydrogenolysis of the nitro group and in contrast to previous experience of the authors (7) gave satisfactory yields of the protected dipeptides. The esters obtained by condensation of α-carbobenzoxy-L-arginine with ω-carbobenzoxy-L-lysine methyl ester or with ω-carbobenzoxy-L-ornithine methyl ester were saponified in the usual manner. Hydrogenation in 10% acetic acid over palladium catalyst converted the carboxylic intermediates into arginyl dipeptides; these were isolated as the diacetates.

EXPERIMENTAL

*α-Carbobenzoxy-ω-nitro-*L*-arginyl-*L*-asparagine*

Ethyl chloroformate (2.44 ml, 20 mmoles) was added to a solution of α-carbobenzoxy-ω-nitro-L-arginine (7.06 g, 20 mmoles) (5, 6, 10) and tri-*n*-butylamine (2.8 ml, 20 mmoles) in dry dioxane (50 ml). After 10 minutes, L-asparagine (2.64 g, 20 mmoles) in 0.4 *N* sodium hydroxide (50 ml) was added to the mixture at 10°. Carbon dioxide gas was given off vigorously. The mixture was shaken for 15 minutes at 10°, and then it was acidified to Congo red with *N* hydrochloric acid. Dioxane was evaporated *in vacuo* in the water bath, water was decanted, and the resulting oily product was triturated with cold acetonitrile until crystallization occurred. The compound was recrystallized from a mixture of N,N-dimethylformamide and acetonitrile. Yield 4.6 g (48%), m.p. 201°, $[\alpha]_D^{25}$ +6.2 (*c*, 4.17 in N,N-dimethylformamide). Anal. Calc. for $C_{18}H_{25}O_8N_7$: C, 46.25; H, 5.39; N, 20.98. Found: C, 46.27; H, 5.46; N, 20.88.

L-*Arginyl-*L*-asparagine Acetate*

α-Carbobenzoxy-ω-nitro-L-arginyl-L-asparagine (2.12 g, 4.53 mmoles) was dissolved in 0.1 *N* sodium hydroxide (4.65 ml). Palladium catalyst was added and the mixture was shaken with hydrogen for 5 hours. The catalyst was filtered off; pH of the solution was 8.6; it was brought to 5–6 with glacial acetic acid, then the solvent was evaporated until dryness *in vacuo* at 30–40°. The resulting product was washed with absolute ethanol and treated with N,N-dimethylformamide. On standing, the residue crystallized. The compound was recrystallized from aqueous methanol. Yield 1.2 g (75%), m.p. 260° (decomp.), $[\alpha]_D^{25}$ +11.1° (*c*, 0.83 in water). Anal. Calc. for $C_{12}H_{24}O_6N_6$: C, 41.34; H, 6.95; N, 24.13. Found: C, 41.32; H, 7.07; N, 24.16.

*α-Carbobenzoxy-ω-nitro-*L*-arginyl-*L*-glutamine*

This compound was prepared from α-carbobenzoxy-ω-nitro-L-arginine (3.53 g, 10 mmoles) and L-glutamine (1.46 g, 10 mmoles) in the manner described for α-carbobenzoxy-ω-nitro-L-arginyl-L-asparagine; the product was crystallized several times from a mixture of a small amount of absolute ethanol and methylene chloride. Yield 2.8 g (45%), m.p. 168°, $[\alpha]_D^{25}$ −0.5° (*c*, 3.8 in N,N-dimethylformamide). Anal. Calc. for $C_{19}H_{27}O_8N_7$ (1/2 H_2O): C, 46.65; H, 5.72; N, 19.99. Found: C, 46.72; H, 5.91; N, 19.97.

L-*Arginyl-*L*-glutamine Acetate*

α-Carbobenzoxy-ω-nitro-L-arginyl-L-glutamine (2 g, 4.16 mmoles) was dissolved in a mixture of water (2 ml), methanol (2 ml), and glacial acetic acid (20 ml). The compound was hydrogenated for 12 hours at room temperature and at atmospheric pressure over 1 g of 10% palladium on carbon. The catalyst was filtered off and the solvent was evaporated *in vacuo* at 40–50°. The residue was crystallized from methanol–acetone. Yield 1.0 g (66%), m.p. 160°, $[\alpha]_D^{25}$ +19.2° (*c*, 3.87 in water). Anal. Calc. for $C_{13}H_{26}O_6N_6$ (1/2 H_2O): C, 42.16; H, 7.35; N, 22.65. Found: C, 42.34; H, 7.11; N, 22.67.

*α-Carbobenzoxy-ω-nitro-*L*-arginyl-ω-carbobenzoxy-*L*-lysine Methyl Ester*

α-Carbobenzoxy-ω-nitro-L-arginine (3.53 g, 10 mmoles) was dissolved in dry dioxane (100 ml) and tri-*n*-butylamine (2.4 ml, 10 mmoles) was added. The solution was cooled to 10° C; ethyl chloroformate (0.96 ml, 7.8 mmoles) was added with stirring and the solution was kept at 11–12° for 15 minutes. The product was then added to 150 ml of N,N-dimethylformamide containing 3.31 g (10 mmoles) of ω-carbobenzoxy-L-lysine methyl ester hydrochloride (13, 14). The mixture was shaken for 2 hours at room temperature and the solvent was evaporated at 40–50°. The residue was dissolved in ethyl acetate,

and the solution was washed successively with *N* hydrochloric acid, water, *N* sodium bicarbonate and water, dried over sodium sulphate, and evaporated to dryness *in vacuo*; it was then treated with isoamyl alcohol – methylene chloride (1:50). The resulting crystals were washed with ether and recrystallized from N,N-dimethylformamide–water. Yield 3.9 g (62%), m.p. 104°, $[\alpha]_D^{25}$ −2.5° (*c*, 4.64 in N,N-dimethylformamide). Anal. Calc. for $C_{29}H_{39}O_9N_7$: C, 55.35; H, 6.25; N, 15.58. Found: C, 55.28; H, 6.32; N, 15.39.

*α-Carbobenzoxy-ω-nitro-*L*-arginyl-ω-carbobenzoxy-*L*-lysine*

α-Carbobenzoxy-ω-nitro-L-arginyl-ω-carbobenzoxy-L-lysine methyl ester (6.35 g, 10.01 mmoles) was dissolved in methanol (20 ml) and *N* sodium hydroxide (20 ml, 20 mmoles) was added. The mixture was shaken for 3 hours; the alkaline solution was washed with ethyl acetate, then acidified to Congo red with *N* hydrochloric acid; the oily residue crystallized on standing. It was recrystallized from hot water or aqueous methanol. Yield 4.7 g (77%), m.p. 159°, $[\alpha]_D^{25}$ +3.8° (*c*, 1.44 in N,N-dimethylformamide). Anal. Calc. for $C_{28}H_{37}O_9N_7$: C, 54.80; H, 6.07; N, 15.93. Found: C, 54.55; H, 6.19; N, 15.74.

*α-Carbobenzoxy-*L*-arginyl-ω-carbobenzoxy-*L*-lysine Methyl Ester Hydrochloride*

α-Carbobenzoxy-L-arginine (3.08 g, 10 mmoles) (15, 17) and ω-carbobenzoxy-L-lysine methyl ester hydrochloride (3.65 g, 11 mmoles) were suspended in N,N-dimethylformamide (10 ml) containing diethyl phosphite (2 ml) and the mixture was stirred for 2 hours (15). To this solution was added N,N-dicyclohexylcarbodiimide (3.10 g, 15 mmoles). The mixture was stirred for 2 days at room temperature, then it was cooled to −10°; N,N-dicyclohexylurea precipitated and was filtered off. The urea was washed with a small amount of N,N-dimethylformamide which was combined with the filtrate. The solvent was removed *in vacuo*. The residue was triturated several times with anhydrous ether; it was then dissolved in methylene chloride (200 ml). The solution was washed with *N* ammonium hydroxide, water, *N* hydrochloric acid and water, and it was dried over sodium sulphate; the solvent was removed *in vacuo*. The crude product thus obtained was crystallized from methylene chloride – ether. It was recrystallized from the same solvent and again recrystallized from ethanol–ether. Yield 4.05 g (65%), m.p. 131°, $[\alpha]_D^{25}$ +9.9° (*c*, 5.69 in N,N-dimethylformamide). Anal. Calc. for $C_{29}H_{41}O_7N_6Cl$: C, 56.00; H, 6.66; N, 13.62. Found: C, 57.40; H, 7.01; N, 13.88.*

*α-Carbobenzoxy-*L*-arginyl-ω-carbobenzoxy-*L*-lysine Hydrochloride*

Sodium hydroxide (4 *N*, 2 ml, 8 mmoles) was added to α-carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-lysine methyl ester hydrochloride (2.6 g, 4.2 mmoles) dissolved in methanol. The mixture was shaken at room temperature for 2 hours. The solution was diluted with water (2 ml), acidified with concentrated hydrochloric acid under cooling. Methanol was evaporated *in vacuo*. The product precipitated as an oil and crystallized on standing. It was recrystallized from hot water. Yield 1.53 g (60%), m.p. 205° $[\alpha]_D^{25}$ +27.8° (*c*, 1.82 in N,N-dimethylformamide). Anal. Calc. for $C_{28}H_{39}O_7N_6Cl$: C, 55.50; H, 6.50; N, 13.83. Found: C, 56.19; H, 7.12; N, 13.83.*

L-*Arginyl-*L*-lysine Diacetate*

(*a*) A number of attempts towards the hydrogenation of α-carbobenzoxy-ω-nitro-L-arginyl-ω-carbobenzoxy-L-lysine in methanol containing acetic acid or ammonium hydroxide or in neutral methanol, over palladium catalyst in the usual manner, were unsuccessful.

**In view of the poor agreement of the analytical data the other properties of the compound are subject to question. However, the intermediate at this stage of purity was suitable for the synthesis of* L*-arginyl-*L*-lysine diacetate.*

(*b*) α-Carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-lysine hydrochloride (1 g, 1.64 mmoles) was dissolved in methanol (20 ml) containing 10% by volume of glacial acetic acid. The compound was hydrogenated for 3 hours at room temperature and atmospheric pressure over palladium catalyst. The catalyst was removed by filtration and the filtrate was evaporated to dryness *in vacuo*. The residue was crystallized from methanol–acetone. Yield 0.41 g (58%), m.p. 167°, $[\alpha]_D^{25}$ +5.1 (*c*, 3.41 in water). Anal. Calc. for $C_{16}H_{33}O_7N_6$: C, 45.48; H, 8.11; N, 19.99. Found: C, 45.59; H, 8.24; N, 20.61.

α-Carbobenzoxy-ω-nitro-L-arginyl-ω-carbobenzoxy-L-ornithine Methyl Ester

This compound was prepared from α-carbobenzoxy-ω-nitro-L-arginine (3.53 g, 10 mmoles) and ω-carbobenzoxy-L-ornithine methyl ester hydrochloride (3.46 g, 10 mmoles) (16) in the manner described for α-carbobenzoxy-nitro-L-arginyl-ω-carbobenzoxy-L-lysine methyl ester hydrochloride. The product was recrystallized from methanol – methylene chloride (1:100 by volume). Yield 3.53 g (58%), m.p. 88°, $[\alpha]_D^{25}$ −16.2° (*c*, 1.0 in N,N-dimethylformamide). Anal. Calc. for $C_{28}H_{37}O_9N_7$: C, 54.70; H, 6.06; N, 15.91. Found: C, 54.35; H, 6.20; N, 15.85.

α-Carbobenzoxy-ω-nitro-L-arginyl-ω-carbobenzoxy-L-ornithine

α-Carbobenzoxy-ω-nitro-L-arginyl-ω-carbobenzoxy-L-ornithine methyl ester (7.00 g, 14 mmoles) was dissolved in methanol (20 ml) and *N* sodium hydroxide (20 ml, 20 mmoles) was added. The mixture was shaken for 3 hours. The product was isolated in the usual manner and recrystallized from hot water. Yield 4.9 g (72%), m.p. 185°, $[\alpha]_D^{25}$ −12.7° (*c*, 0.77 in N,N-dimethylformamide). Anal. Calc. for $C_{27}H_{35}O_9N_7$: C, 54.00; H, 5.86; N, 16.31. Found: C, 53.81; H, 5.84; N, 16.25.

α-Carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-ornithine Methyl Ester Hydrochloride

This compound was prepared from α-carbobenzoxy-L-arginine (3.08 g, 10 mmoles) and ω-carbobenzoxy-L-ornithine methyl ester hydrochloride (3.80 g, 11 mmoles) in the manner described for α-carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-lysine methyl ester hydrochloride. The crude product was precipitated from ethanol–ether and was recrystallized from methylene chloride – ether. Yield 3.73 g (62%), m.p. 122°, $[\alpha]_D^{25}$ +4.6 (*c*, 4.78 in N,N-dimethylformamide). Anal. Calc. for $C_{28}H_{39}O_7N_6Cl$: C, 55.30; H, 6.48; N, 13.85. Found: C, 55.51; H, 6.60; N, 13.88.

α-Carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-ornithine Hydrochloride

α-Carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-ornithine methyl ester hydrochloride (1.00 g, 1.75 mmoles) was saponified in the manner described for α-carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-lysine hydrochloride. The product was recrystallized from hot water. Yield 0.61 g (58%), m.p. 103–106°, $[\alpha]_D^{25}$ +3.5° (*c*, 1.72 in N,N-dimethylformamide). Anal. Calc. for $C_{27}H_{37}O_7N_6Cl$: C, 54.70; H, 6.29; N, 14.17. Found: C, 54.48; H, 7.03; N, 13.80.

L-Arginyl-L-ornithine Diacetate

α-Carbobenzoxy-L-arginyl-ω-carbobenzoxy-L-ornithine hydrochloride (1.00 g, 1.68 mmoles) was dissolved in methanol (10 ml) containing 10% by volume of glacial acetic acid. The compound was hydrogenated for 3 hours at room temperature and atmospheric pressure over the palladium catalyst. The final product was obtained in the manner described for L-arginyl-L-lysine diacetate. Yield 0.53 g (77%), hygroscopic. The crude product (0.52) in 5% acetic acid (50 ml) was applied to the top of the curtain of the continuous flow paper electrophoresis cell (Spinco Model CP) and was carried downward by acetic acid solution (5%, 16 liters). Sample feed rate was 0.8 ml/hour. The acetic

For personal use only.

acid solution was maintained at 1° C and the curtain temperature was 10° C. Power supply was 30 milliamperes and 500 volts. The curtain came to equilibrium after 2 hours. Collection of the sample solution was started 1/2 hour after the first fraction reached the drip point. Thirty-two (32) test tubes were used to collect the solution. Duration of a typical run was 65 hours. The curtain was then dried and developed with ninhydrin.

The sample solution in test tubes No. 27 to 32 was combined and the solvent was evaporated *in vacuo* at 40–50° C. The residue was precipitated from methanol–ether. Yield 0.36 g (53.9%), $[\alpha]_D^{25}$ +9.6 (*c*, 2.9 in water). Anal. Calc. for $C_{15}H_{22}O_7N_6$: C, 44.11; H, 7.90; N, 20.60. Found: C, 44.14; H, 8.05; N, 20.49.

PROTON MAGNETIC RESONANCE ABSORPTION IN ANHYDROUS POTASSIUM STEARATE[1]

R. F. GRANT[2] AND B. A. DUNELL

ABSTRACT

The proton magnetic resonance absorption in anhydrous potassium stearate has been measured over the temperature range −190° C to 182° C. Abrupt changes in line width have been found between 55° C and 62° C, and between 170° C and 171° C; these changes correspond approximately to known phase transitions. The reduction in line width and second moment with rising temperature is discussed.

INTRODUCTION

Like other alkali metal salts of long-chain fatty acids, potassium stearate passes through several transitions between solid state phases that exist in successive temperature ranges below the melting point. These transitions have been observed by various experimental methods, dilatometry (1, 2), differential calorimetry (3), and light transmission studies (4). They are, however, not so well understood in potassium stearate as in the sodium salts, for which it has been shown that the lowest temperature transitions (from a crystalline or curd phase to a waxy phase) correspond to the appearance of considerable structural disorder in the paraffin chain portion of the molecules (5, 6, 7). One infers from this appearance of disorder that the low-temperature transition may represent the onset of considerable motion in the paraffin chains. Since proton magnetic resonance has been useful in determining the nature of molecular motion in solid long-chain paraffin compounds (8, 9, 10), a magnetic resonance investigation of the lower-temperature transitions in anhydrous potassium stearate was made.

EXPERIMENTAL METHOD AND RESULTS

The potassium stearate used in this investigation was prepared from Eastman Kodak White Label grade stearic acid. This acid, which had a freezing point of 68.1° C, was purified by repeated crystallization at −20° C from freshly distilled acetone (11) until the freezing point was raised to 69.1° C. The purified acid was dissolved in hot ethanol and titrated with an ethanolic solution of potassium hydroxide, using phenolphthalein as the indicator. The potassium stearate precipitate was dried at 105° C and then fused under vacuum to remove traces of water and alcohol. When cool, the fused soap was crushed and fused again under vacuum in 10-mm o.d. Pyrex sample tubes; dry nitrogen was admitted to the vacuum system and the sample tubes were sealed off.

The nuclear magnetic resonance spectrometer and sample thermostat have been described previously (12). The temperature of the sample was measured with a thermocouple inserted in a well in the side of the sample tube.

Figure 1 shows the variations of the proton magnetic resonance line width of potassium stearate as a function of temperature. Following the common usage, we have taken the line width as the separation, in gauss, of the points of maximum and minimum slope

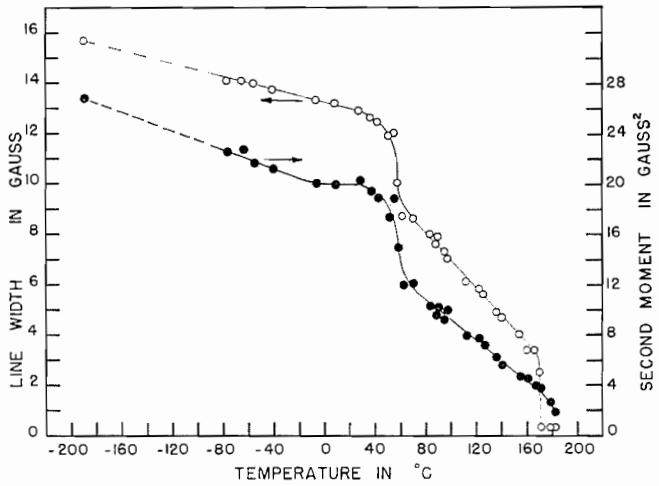

FIG. 1. Line width and second moment of potassium stearate as functions of temperature. Open circles, line width; filled circles, second moment.

on the resonance absorption line. Figure 1 also shows the corresponding variations of the second moment values with temperature. The second moments were obtained from the experimental derivative curves by the convenient method described by Powles (13) and were corrected for the effects of modulation (14).

It can be seen from Fig. 1 that there is an abrupt change in both line width and second moment between about 55° and 62° C and that there is a second discontinuity in line width between 170° and 171° C. At 171° C the line width is determined by depth of modulation and field inhomogeneity. The second moment shows no abrupt change at this temperature since the wings of the resonance line are only slightly narrowed, or decreased in intensity, as Fig. 2 shows.

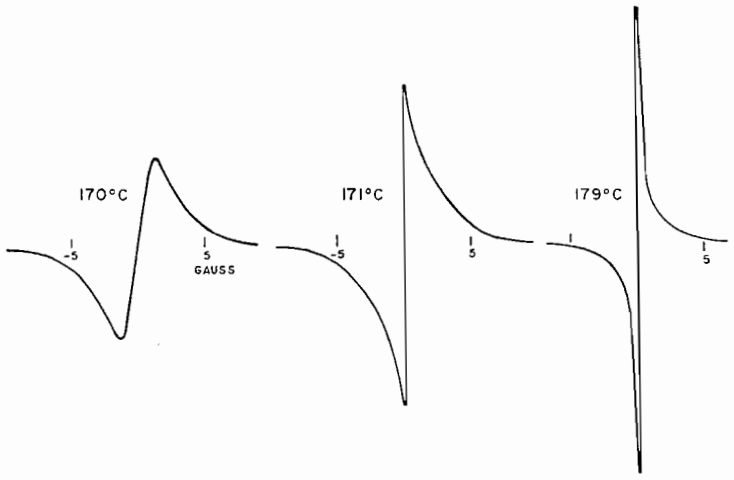

FIG. 2. Line shapes for potassium stearate near the phase transition at 170° C.

DISCUSSION

It is generally agreed that anhydrous potassium stearate passes through at least three phase transitions before melting (1–4). The lowest-temperature transition is variously located between 50° and 80° C; dilatometrically at 51° C by Vold (1) and with two changes in density at 65° and 80° C by Puddington and his co-workers (2), calorimetrically at 57° C by Ravich and Nechitaylo (3), and with X-ray studies at 78° C by Lomer (15), who has also measured the lattice parameters of the crystalline lower temperature B phase and crystalline higher temperature C phase. At least two other transitions occur before the substance melts to an isotropic liquid at 353° C (4), one in the range 160° to 170° C, and the other in the range 265° to 270° C (1–4). The positions at 160° and 170° C of the discontinuities observed in the n.m.r. line width agree with the transition temperatures observed by other techniques. Some indication of the nature of the low-temperature transition and of the solid phases may be obtained from a study of the second moment of the n.m.r. signal.

It can be shown that the rigid lattice second moment of the proton magnetic resonance for a polycrystalline sample (16, 17) is given by

$$S = \frac{716}{N} \sum_{j>k} r_{jk}^{-6}$$

where N is the number of protons whose interactions are considered and r_{jk} is the distance in angstrom units between any two protons j and k (9). In using this particular formula, it is assumed that the interactions of magnetic nuclei other than the protons in potassium stearate, such as the potassium nuclei and the nuclei of C^{13} and O^{17} in natural abundance, make a negligible contribution to the second moment.

An X-ray diffraction investigation of the A form of potassium caprate has indicated that the alternate carbon atoms in the zigzag paraffin chain are 2.60 Å apart (18), which would suggest that the bond angles differ slightly from the tetrahedral angle usually considered for long-chain paraffins. Moreover, electron diffraction studies on solid paraffin compounds have shown that the H—C—H bond angle may be about 107° and that the C—H bond length is about 1.12 Å (19, 20). A model of the paraffin chain part of potassium stearate, constructed using these bond parameters, and assuming that the C—C bond length is 1.54 Å (20), yields an intramolecular second moment of 18.0 gauss^2. The model in which tetrahedral bond angles and a C—H bond length of 1.094 Å are used gives an intramolecular second moment of 18.9 gauss^2. The intermolecular contribution will differ even less from the contribution for the non-tetrahedral model, and the total difference in second moments between the two is approximately within the error of experimental determination of second moment. If the experimental second moment of 26.8 gauss^2 at −190° C represents rigid lattice conditions, then the intermolecular second moment should be about 8.8 gauss^2.

Only the unit cell dimensions and the angle of tilt of the paraffin chains have been reported for potassium stearate (15). However, in the solid, the soap molecules are usually arranged such that the carboxylate ends form an electrically balanced ionic double layer, with the paraffin chains sticking out parallel to each other from both sides of this layer. If the paraffin chains were arranged parallel to one another with their long axes parallel to the *ac* planes and tilted at the angle $\tau = 53°$ (15) to the plane *ab* containing

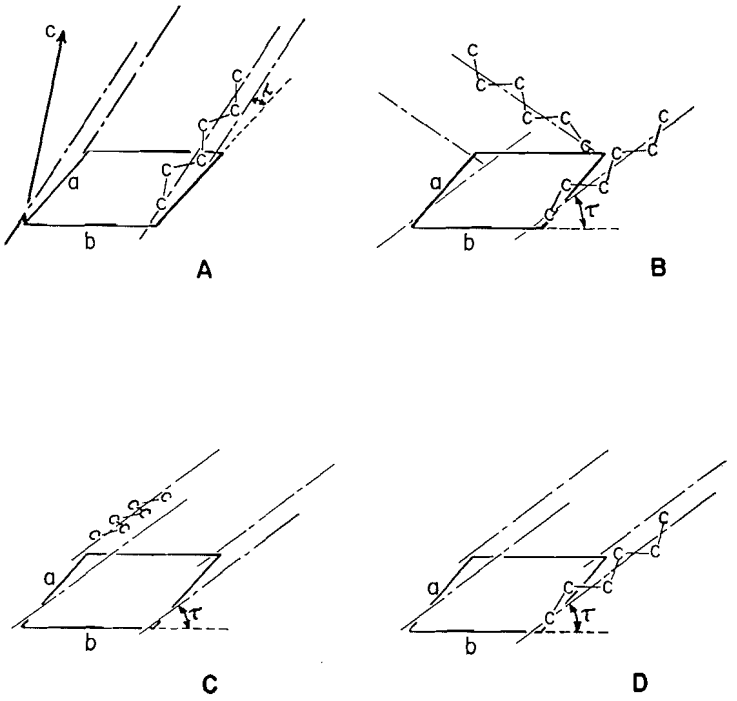

FIG. 3. Possible orientations of the hydrocarbon chains in the potassium stearate unit cell. The dot-and-dash lines — - — - represent the long axes of the hydrocarbon chains, and τ is the angle of tilt of 53° with respect to the plane *ab*.

the polar ends, as shown in Fig. 3A, some of the interhydrogen distances between chains would be reduced to values much less than the van der Waals diameter for a hydrogen atom, 2.4 Å (21). This arrangement has been dismissed as highly improbable. If the paraffin chains are inclined at 53° to the *ab* plane and arranged with their long axes parallel to *bc* planes, at least three reasonable values of the intermolecular second moment at 25° C may be obtained: 5.9 gauss^2 if the chains are not parallel to one another but are arranged in a crisscross fashion (Fig. 3B) as in the A phase of potassium caprate (18), 6.6 gauss^2 if the chains are parallel to one another and the plane of the C—C—C bonds is parallel to the *a*-axis (Fig. 3C), and 8.1 gauss^2 if the chains are parallel to one another and the plane of the C—C—C bonds is parallel to the *b*-axis (Fig. 3D). At −190° C the values are 6.2, 8.7, and 8.9 gauss^2 if one corrects the unit cell dimensions for thermal contraction using the coefficient of expansion given by Lomer (15). The first of these possibilities is considered less probable than either of the other two because of the poorer agreement between its calculated second moment of either 24.2 gauss^2 or 25.1 gauss^2 (non-tetrahedral or tetrahedral bond angles, respectively) at −190° C and the observed value of 26.8 gauss^2. The difference between the two remaining arrangements decreases with decreasing temperature because dimensional change in the *a* direction is much greater than in the *b* direction (15). The calculated value of the rigid lattice second moment may, then, be given as 27.2±0.5 gauss^2 depending mainly on whether or not tetrahedral bond angles are assumed in the hydrocarbon chain, and based on the arrangement of chains in the unit cell which gives best agreement with the experimental second moment of 26.8 gauss^2.

In considering the decrease of the line width and of the experimental second moment with increasing temperature, one must take note of recent modifications of the theory of Gutowsky and Pake (22), according to which theory both of these phenomena are to be expected as molecular reorientation becomes sufficiently rapid. Andrew and Newing (23) have discussed in detail the argument that the second moment must theoretically remain constant independent of the extent of molecular motion, pointing out that although the main central portion of the spectrum narrows, there is increased intensity in the wings of the spectral line because of production of side bands by modulation of the Larmor frequency by the molecular reorientation. Under some experimental conditions, however, the intensity of the side bands or the wings of the spectral line is comparable to or less than the noise level in the spectrometer. Thus the wings, which keep the second moment at its rigid lattice value, are not observable experimentally and the experimental second moment falls according to the earlier theory of Gutowsky and Pake. In the spectra of potassium stearate there were no indications of extended wings from the spectrometer with signal-to-noise ratio of 30. Further, the change of second moment with temperature effectively parallels the change in line width. Correlation frequencies can be calculated from the change of line width, which is not affected by the side bands, with temperature following the theory of Gutowsky and Pake (22). These agree substantially with correlation frequencies calculated from change of the observed second moment with temperature. One concludes, then, that the sensitivity and noise level of the spectrometer used in this work were such that side bands were not observed under any conditions, and our interpretation follows that of the original theory.

The experimental second moment at 25° C is 20 gauss^2, whereas the predicted rigid lattice value at this temperature is between 24.6 and 27 gauss^2 depending on the structure assumed. If the end methyl groups in potassium stearate reorient about their C_3 axes, a form of motion which is probably the first to take place with rising temperature in paraffins (9), the intramolecular second moment is reduced to 16.3 gauss^2 (17.1 gauss^2 for tetrahedral bond angles) (24). If the intermolecular contribution is reduced by a corresponding proportion, the total second moment should be between 22.2 and 24.4 gauss^2. Although zero-point vibrational motions may decrease the calculated second moment a little more (25), it will probably not be sufficient to give agreement with the experimental value of 20.0 gauss^2 at 25° C (12). It is suggested that the paraffin chains twist about their longitudinal axes in a torsional oscillation with amplitude somewhat in excess of the zero-point rocking vibration of the CH_2 groups. The relationship of the reduction of second moment to the amplitude of such oscillation has been calculated (8). Since each paraffin chain is clamped at one end in a strongly bonded salt layer, the amplitude of oscillation should increase along the chain with distance from this layer.

The line width and second moment change between 55° C and 62° C probably corresponds to the transition between the B and C crystalline phases (1, 2, 4). The known unit cell dimensions at 75° C (15) give an intermolecular second moment of about 6 gauss^2 if the paraffin chains are tilted at 53° C to *ab* and lie parallel to the *bc* plane. Thus the predicted rigid lattice second moment changes by about 2 gauss^2 between 25° C and 75° C, whereas the experimentally observed change is about 10 gauss^2. On going from the B to the C phase between 55° C and 62° C the experimental second moment is reduced by about 7 gauss^2, and hence greatly increased molecular motion, corresponding to more than 5 gauss^2 decrease in second moment, must accompany this change in structure. The complete reorientation of the potassium stearate molecules about the longitudinal axes of the paraffin chain portions would reduce the intramolecular second moment to 5.0

gauss^2 if reorientation of the end methyl groups about their C_3 axes also occurred (22, 24). The total second moment would then be 6.7 gauss^2 (8), which is the value at 130° C. There would be a further reduction of the second moment if there were reorientation about other axes in the molecule (24), which might be brought about by a bending motion of the twisting or rotating chain.

The sudden narrowing of the line width between 170° C and 171° C is probably associated with the phase transition reported to occur between 160° C and 170° C. This narrow line width must indicate comparatively great freedom of molecular motion in all directions, for most of the interaction between the proton pairs has been averaged out. However, the small change in the second moment at 171° C suggests that the molecules maintain their mean positions in the lattice (26) and that molecular motion is not yet isotropic. Infrared (6) and X-ray studies (7) on some sodium soaps suggest that a similar change in structure occurs when the temperature is raised above the "supercurd sub-waxy" transition at about 117° C. The transition between 160° C and 170° C reported in potassium stearate may therefore represent the beginning of a waxy-type phase.

CONSTITUTION OF A GLUCOMANNAN FROM THE WOOD OF EASTERN WHITE PINE (PINUS STROBUS L.)[1]

M. O. Gyaw and T. E. Timell

ABSTRACT

Glucomannans have been isolated from the wood of eastern white pine (*Pinus strobus* L.) by two different methods, the ratios of mannose to glucose being 3.8:1 and 2.7:1, respectively. The yields, based on the mannose content of the wood, were 70 and 50%. Partial acid hydrolysis gave 4-*O*-β-D-mannopyranosyl-D-mannose, 4-*O*-β-D-mannopyranosyl-D-glucose, 4-*O*-β-D-glucopyranosyl-D-mannose, 4-*O*-β-D-glucopyranosyl-D-glucose, *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose, and *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose. The fully methylated polysaccharide on hydrolysis gave a mixture of di-*O*-methylhexoses, 2,3,6-tri-*O*-methyl-D-mannose, 2,3,6-tri-*O*-methyl-D-glucose, and 2,3,4,6-tetra-*O*-methylhexose (mostly mannose) in a mole ratio of 4:61:21:1. The number-average degrees of polymerization of the methylated and the nitrated glucomannans were 96 and 93. On the basis of this and other evidence it is concluded that the glucomannan contains at least 90 mannose and glucose residues linked together by (1 → 4)-β-glycosidic bonds to linear macromolecules. The nature and relative composition of the oligosaccharides obtained on partial hydrolysis indicate that very few of the glucose residues are contiguous. The glucomannan is compared with similar polysaccharides from the wood of other gymnosperms.

In recent years it has become evident that the mannose residues in the wood of gymnosperms largely originate from glucomannan (1) or galactoglucomannan (2) heteropolymers. Glucomannans are the main hemicelluloses of softwoods and have lately been isolated from several species. A previous investigation (3) dealt with an arabino-4-*O*-methylglucuronoxylan from the wood of white pine (*Pinus strobus* L.). The present paper is concerned with the isolation and properties of a glucomannan from the same species.

RESULTS AND DISCUSSION

White pine wood (11.7% mannose residues) was delignified with acid chlorite (4) to give a holocellulose which still contained at least 5% lignin. Extraction with aqueous sodium hydroxide containing borate (5) gave a mixture of hemicelluloses which was not amenable to resolution by complexing with copper (6). Better results were obtained by the barium hydroxide method (7), but the precipitated glucomannan still contained 6.4% galactose residues which could not be removed by further treatments.

A glucomannan from Scots pine (*Pinus sylvestris* L.) was recently also found to retain galactose residues which could be removed only after complete elimination of residual lignin (8). The present crude glucomannan had an ultraviolet spectrum indicative of the occurrence of lignin, and the latter was accordingly eliminated by treatment with chlorine and ethanolamine (9). The hemicellulose obtained on copper complexing of the delignified material contained less than 2% galactose residues. Evidently, the lignin left in the crude hemicellulose acted as a binding agent between the main glucomannan component and other polysaccharides containing galactose residues. Whether the association was of a chemical or physical nature could not be decided on the basis of the present evidence.

The purified glucomannan, $[\alpha]_D$ −32°, contained glucose and mannose residues in a ratio of 1:3.8 and amounted to 10.6% by weight of the wood. Osmotic pressure measure-

ments on the nitrate derivative (10) gave a number-average degree of polymerization of 82. The polysaccharide consumed 1.0 mole of periodate per hexose residue, thus suggesting the presence of (1 → 4)-glycosidic bonds.

In an alternative method of isolation of the glucomannan, wood meal was delignified with acid chlorite until the Klason lignin content was less than 1%. A hemicellulose mixture containing 5 parts of pentosan and 3 parts of hexosan was removed by extraction with aqueous potassium hydroxide. The residue, when extracted with sodium hydroxide containing borate, gave a hexosan containing only 3% xylose residues in a yield of 7% of the original wood. One precipitation with barium hydroxide lowered this yield to 6%. The glucomannan thus obtained contained 3% galactose residues and had a ratio of mannose to glucose of 2.7. Its number-average degree of polymerization was 93.

It is evident from this and other investigations (1, 11, 12) that the relative proportions of mannose and glucose residues in glucomannans are apt to vary considerably with the mode of isolation of these hemicelluloses. Of the two methods used here, the second was by far the least time-consuming and is preferable in spite of the somewhat lower yield. It is well known that prolonged treatment of wood with acid chlorite entails loss of carbohydrates (13, 14). In isolation of softwood hemicelluloses, this factor has to be weighed against the desirability of eliminating the lignin as completely as possible.

A portion of the glucomannan isolated by the first method was partially hydrolyzed with aqueous formic acid (15). The sugar mixture obtained was resolved on a column of charcoal–Celite (16) by gradient elution (17) with aqueous ethanol (18). Twelve oligosaccharides were collected, some of which were further purified by paper chromatography. Five of the oligosaccharides were crystallized and were fully identified, namely 4-*O*-β-D-mannopyranosyl-D-mannose (mannobiose), 4-*O*-β-D-glucopyranosyl-D-mannose, 4-*O*-β-D-glucopyranosyl-D-glucose (cellobiose), *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose, and *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose. Two sugars could not be crystallized but were tentatively characterized as a (1 → 4)-β-linked *O*-mannosyl glucose and an *O*-glucosyl-*O*-mannosyl mannose. The paucity of material available prevented a characterization of the other oligosaccharides, all of which were evidently tri- or tetrasaccharides.

The mannobiose, mannosyl glucose, and glucosyl mannose have previously been isolated from many coniferous woods (12, 15, 19–24). The mannotriose has been obtained crystalline from loblolly pine (15) and white spruce wood (24) and was probably also present in glucomannan hydrolyzates from western hemlock (21), red cedar (22), and spruce sulphite pulp (23). The mannotetraose has been isolated previously only from vegetable ivory (25) and from white spruce wood (24). A mixed trisaccharide, apparently very similar to the compound obtained here, has been obtained from a spruce pulp (23).

The mannobiose was obtained in the highest yield (14.7%), followed by glucosyl mannose (5.4%), mannotriose (3.8%), mannotetraose (2.3%), mannosyl glucose (1.0%), and cellobiose (0.3%). Some of these results can undoubtedly be explained by the different stability towards acids of the glycosidic bonds, for example the five times higher yield of glucosyl mannose as compared with mannosyl glucose. This explanation cannot account, however, for the low yield of cellobiose which probably is more stable towards acids than any other of the oligosaccharides isolated. Low yields of cellobiose have been noticed on several occasions when softwood glucomannans were partially hydrolyzed (15, 23, 24, 26).

The glucomannan was methylated to completion and subsequently hydrolyzed to a mixture of sugars which was resolved on a charcoal–Celite column by gradient elution with aqueous ethanol. A mixture of di-*O*-methylhexoses, a tri-*O*-methylmannose, a tri-*O*-methylglucose, and a mixture of tetra-*O*-methylhexoses were obtained in a molar ratio of 4:61:21:1. The first fraction probably contained 2,6-di-*O*-methyl-D-glucose as its main component (8, 27). The following, and main, fraction was identified as 2,3,6-tri-*O*-methyl-D-mannose through its crystalline aniline and di-*p*-nitrobenzoate derivatives (28, 29). The tri-*O*-methylglucose crystallized and was also identified through its di-*p*-nitrobenzoate ester as 2,3,6-tri-*O*-methyl-D-glucose (29). The last fraction on demethylation gave mannose and a small quantity of glucose. Treatment with aniline, followed by repeated recrystallization, gave pure 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine (30). This fraction consisted therefore predominantly of 2,3,4,6-tetra-*O*-methyl-D-mannose. The molar amount of this compound corresponded to one non-reducing end group per 87 hexose residues.

From the evidence adduced a simplified structure can now be assigned to the glucomannan present in the wood of white pine. The isolation of the two 2,3,6-tri-*O*-methyl-D-hexoses shows that the polysaccharide is composed of $(1 \rightarrow 4)$-linked D-mannopyranose and D-glucopyranose residues. The negative rotation of the original and the methylated hemicelluloses indicates that the hexose residues are present in the β-modification. The average number of hexose residues present in the methylated macromolecule was 96 while 87 such residues occurred for each non-reducing end group. An average number of 0.10 branch points per molecule was thus indicated. This number is so low, however, that the glucomannan might be regarded as essentially linear. Mannose residues apparently constituted the preponderant portion of the non-reducing end groups.

The nature of the hexose oligosaccharides isolated corroborate these conclusions. The low yield of cellobiose, in conjunction with the absence of any higher glucose oligosaccharides, show that very few of the glucose residues in the glucomannan were contiguous. The relatively high yields of mannobiose, mannotriose, and mannotetraose indicate that the glucose residues were probably interposed between blocks of contiguous mannose residues.

The mannose-to-glucose ratios of 2.7 and 3.8 found here are similar to those reported for other softwood glucomannans, such as (2.5) red cedar (22), (3) western hemlock (1, 21), (2.7) loblolly pine (15), (3.1–3.7) Scots pine (8, 31), (3.5–4) Norway spruce (27, 32), (2.5) Sitka spruce (12), and (3) white spruce (24, 33).

The evidence presently available concerning the linear or branched nature of softwood glucomannans is not conclusive. Glucomannans from red cedar (22), western hemlock (21), and Sitka spruce (12) are stated to be essentially linear, whereas similar glucomannans from Scots pine (8) and Norway spruce (27) are reported to be branched. The number-average degree of polymerization found here (93) is within the same range as the values observed for glucomannans from (130) western hemlock (21), (70–115) Scots pine (32), (68–100) Norway spruce (27), and (107) white spruce (24). All these polysaccharides were obtained after delignification of the wood with acid chlorite. In view of the now well-established depolymerizing action of this reagent on polysaccharides (9, 34), it seems almost certain that none of the above values represented the molecular magnitude of the native glucomannans. On the basis of previous results (34), an original number-average degree of polymerization of 200 for the present glucomannan does not appear unlikely.

CONCLUSIONS

The main structural features of the two preponderant hemicelluloses in the wood of white pine have now been established. One of these polysaccharides, which amounts to approximately 7% of the wood, is a (1 → 4)-β-linked xylan containing numerous single side chains of either (1 → 2)-α-linked 4-*O*-methyl-D-glucuronic acid or (1 → 3)-linked L-arabinofuranose residues. The other hemicellulose, which accounts for 10–14% of the wood, is a neutral (1 → 4)-linked hexosan containing about three times as many β-D-mannose as β-D-glucose residues. Both polysaccharides are linear or only slightly branched and both contain at least 100 but probably closer to 200 sugar residues in their native state.

The occurrence in the wood of gymnosperms of a predominant, neutral glucomannan together with an arabino-4-*O*-methylglucuronoxylan is apparently of early botanical origin. The same arrangement is found also for the wood of the now monotypical *Ginkgo biloba* (35), a phylogenetically far older gymnosperm (upper Carboniferous) than the present-day conifers. In contrast, the hemicelluloses of the botanically much younger arborescent angiosperms are characterized by the presence of a predominating 4-*O*-methylglucuronoxylan while the neutral glucomannan here has been relegated to a much more inconspicuous role.

EXPERIMENTAL

All specific rotations are equilibrium values and were determined at 20° C. Melting points are corrected. Evaporations were carried out *in vacuo* at 40–50° C.

Paper Chromatography

The following solvent systems (v/v) were used for separating the sugars: (A) ethyl acetate – acetic acid – water (9:2:2), (B) butan-1-ol – pyridine – water (10:3:3), (C) butan-1-ol – pyridine – water (6:4:4), and (D) butanone–water (89:11). Whatman No. 1 or, for preparative purposes, No. 3MM filter papers were used. Paper electrophoresis was carried out with Whatman No. 3MM filter paper in 0.05 *M* borate buffer at 750 or 2000 volts. *o*-Aminodiphenyl was used as a spray reagent and also for quantitative sugar analysis (36).

Isolation of a Mixture of Hemicelluloses

The preparation and properties of the wood sawdust used have been described previously (3). Extractive-free wood meal (40–60 mesh, 200 g) was suspended with stirring in water at 75–80° C. Acetic acid (20 ml) and sodium chlorite (60 g) were added and the reaction was allowed to proceed for 1 hour, when the same amounts of reagents were added. After a total time of 4 hours, the holocellulose was recovered by filtration, washed with water and then with ethanol, and dried in the air. Yield: 151 g, 75.5% of the wood. This process was repeated several times with new wood.

Chlorite holocellulose (300 g) was shaken with 17.5% (w/w) aqueous sodium hydroxide, to which 4% of boric acid had been added, in an atmosphere of nitrogen at room temperature for 3 hours. The alkaline solution was removed by filtration through fritted glass and the solid residue was washed with 17.5% sodium hydroxide (3 liters). Washing with aqueous acetic acid, water, and ethanol gave an alpha-cellulose (109 g). The alkaline solutions were poured into ice-cold ethanol (15 liters) containing glacial acetic acid (3 liters). The precipitate formed was recovered by filtration, washed in succession with

80% aqueous ethanol, ethanol, and petroleum ether (b.p. 30–60° C), and finally dried *in vacuo* to give a crude hemicellulose (118 g, 29.7% of the wood). Constituent sugars were galactose (3%), glucose (13%), mannose (41%), arabinose (8%), and xylose (35%).

Isolation of a Crude Glucomannan

The mixture of hemicelluloses (100 g) was dissolved in 5% sodium hydroxide (4 liters). The solution was centrifuged and a minor amount of insoluble material was removed. Saturated aqueous barium hydroxide (4 liters) was added dropwise with constant stirring (7). The precipitate formed was recovered on the centrifuge, washed twice with 5% sodium hydroxide, suspended in ice water, and acidified with acetic acid. The solution was poured into four times its volume of ethanol and the precipitate was recovered in the usual way. Yield: 68 g, 20.2% of the wood. Constituent sugars were galactose (6.4%), glucose (17.5%), mannose (70.3%), and xylose (5.8%). Further treatments with barium hydroxide or Fehling's solution (6) failed to alter the galactose content. The ultraviolet spectrum of the product exhibited a band at 280 mμ.

Purification of the Glucomannan

Glucomannan (35 g) was dissolved in water (3 liters). Gaseous chlorine was introduced into the solution at +6° C for 5 minutes (9). The solution was poured into ethanol (12 liters) and the recovered hemicellulose was suspended in ethanol (3 liters) containing 3% monoethanolamine for 5 minutes at 70° C. The polysaccharide was recovered by centrifuging and washed three times with ethanol after which it was added to water (3 liters). This delignification process was repeated three times. The polysaccharide was finally treated twice with Fehling's solution to yield a purified product (18 g, 10.4%). Analysis indicated the presence of galactose (2%), glucose (20%), and mannose (78%).

Isolation of a Glucomannan by an Alternative Method

Extractive-free wood meal (1385 g) was delignified with acid chlorite in the usual way (4) for 4 hours. The holocellulose (962 g, 69.6%) was extracted with 24% potassium hydroxide as described previously (3) to yield a mixture of hemicelluloses (155 g, 15.0%), containing 37% of hexosans. The solid residue (780 g) was shaken with 17.5% aqueous sodium hydroxide, to which 4% boric acid had been added, at room temperature for 5 hours. The alkaline solution was recovered by filtration and the residue was washed thoroughly with water. The filtrate and washings were poured into four times their volume of a 4:1 mixture of ethanol and acetic acid. The precipitate was recovered in the usual way to give a glucomannan (96 g, 7.0% of the wood), containing glucose and galactose (23%), mannose (68%), and xylose (3%). One precipitation with barium hydroxide (7) gave a product (83 g, 6.0%) which contained galactose (3%), glucose (26%), and mannose (71%). Specific rotation, $[\alpha]_D$ −32° (*c*, 1.0 in 10% sodium hydroxide).

Partial Hydrolysis of the Glucomannan and Resolution of the Hydrolyzate

A portion of the glucomannan obtained by the first method (10 g) was dissolved in 90% formic acid and diluted with water to 45% (100 ml). The solution, $[\alpha]_D$ −27°, was heated at 97° C for 3 hours when the specific rotation was +15° (after heating for 7 hours, $[\alpha]_D$ was +39°, equilibrium). Formic acid was removed by repeated evaporation from water after which the residue was boiled under reflux with 0.5 *N* sulphuric acid (320 ml) for 10 minutes for elimination of formate esters. The acid was neutralized with barium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

carbonate and the solution obtained after filtration through Celite was deionized with Amberlite IR-120 (H^+) and Dowex 1-X4 (acetate) exchange resins.

A portion of the hydrolyzate (7.5 g) was added to the top of a Darco G-60 charcoal – Celite column (9) (1:1, w/w, 6×64 cm) and the sugars were removed by gradient elution (17) with aqueous ethanol (18) in the following order: water → 2% aqueous ethanol (3 liters each), 2% ethanol → 10% ethanol (4 liters), 10% ethanol → 20% ethanol (4 liters), and 20% ethanol → 40% ethanol (2 liters). The eluate was collected in 20-ml fractions at intervals of 30 minutes.

Identification of Sugars

All sugars were chromatographically identical with authentic specimens (solvents A, B, and C).

(1) Monosaccharides

A mixture of glucose and mannose in addition to minor amounts of xylose (2890 mg) was first obtained. The sugars were characterized only by paper chromatography (solvents A and B).

(2) 4-O-β-D-Mannopyranosyl-D-mannose

Hydrolysis of this fraction (1015 mg), the first oligosaccharide to be removed from the charcoal column, indicated the presence of mannose only. The mannobiose, after recrystallization from methanol, had a melting point and a mixed melting point of 209–210° C, $[\alpha]_D$ −8° (*c*, 3.5 in water) (37). The X-ray diffraction pattern and infrared diagram were identical with those from an authentic specimen.

(3) 4-O-β-D-Mannopyranosyl-D-glucose

This sirupy disaccharide (73 mg) had $[\alpha]_D$ +29° (*c*, 2.4 in water) (38) and on hydrolysis yielded equal amounts of glucose and mannose. After reduction with sodium borohydride only mannose was obtained on hydrolysis. The mannosyl glucose could not be induced to crystallize.

(4) 4-O-β-D-Glucopyranosyl-D-glucose

This fraction (107 mg) was a mixture of a disaccharide and a tetraose. Resolution by paper chromatography (solvent C) gave pure cellobiose (23 mg), $[\alpha]_D$ +35° (*c*, 1.0 in water). Recrystallization from methanol gave a melting point and a mixed melting point of 234–235° C (39).

(5) O-β-D-Mannopyranosyl-(1 → 4)-O-β-D-mannopyranosyl-(1 → 4)-D-mannose

This trisaccharide (262 mg) on hydrolysis gave mannose and on partial hydrolysis mannobiose and mannose. Analysis by the method of Peat, Whelan, and Roberts (40) suggested a degree of polymerization of 2.8. The product crystallized from ethanol, m.p. and mixed m.p. 165–168° C, $[\alpha]_D$ −25° (*c*, 2.4 in water) (41).

(6) 4-O-β-D-Glucopyranosyl-D-mannose

Hydrolysis of this disaccharide (373 mg) gave equal amounts of glucose and mannose. The compound crystallized from ethanol, m.p. and mixed m.p. 134–137° C, $[\alpha]_D$ +10° (*c*, 4.0 in water) (42). The octaacetate derivative had a melting point and a mixed melting point of 201° C, $[\alpha]_D$ +34° (*c*, 1.0 in chloroform).

(7) O-Glucosyl-O-mannosyl Mannose

This fraction (285 mg), $[\alpha]_D$ −8° (*c*, 6.6 in water), on hydrolysis yielded glucose and mannose in a ratio of 1:2. Reduction with sodium borohydride followed by hydrolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

gave equal amounts of glucose and mannose. The degree of polymerization of the compound was 2.9 (40). Partial hydrolysis with formic acid gave mannobiose, glucosyl mannose, glucose, and mannose.

*(8) O-β-*D*-Mannopyranosyl-(1 → 4)-O-β-*D*-mannopyranosyl-(1 → 4)-O-β-*D*-mannopyranosyl-(1 → 4)-*D*-mannose*

At this stage, elution of the column gave a mixture of trisaccharides which was not further examined (941 mg). Subsequent elution gave a mixture of higher oligosaccharides (1034 mg) which, on resolution by paper chromatography (solvent C), yielded a pure mannotetraose (114 mg). The compound on recrystallization from aqueous ethanol had a melting point and a mixed melting point of 232–234° C, $[\alpha]_D$ −31° (*c*, 1.0 in water) (25). Partial hydrolysis gave mannotriose, mannobiose, and mannose.

Methylation of the Glucomannan

Glucomannan (19 g) was dissolved in 30% (w/w) aqueous sodium hydroxide (400 ml) in an atmosphere of nitrogen, and dimethyl sulphate (200 ml) was added dropwise at 0° C over a period of 8 hours (43). This treatment was repeated twice. The reaction mixture was neutralized with sulphuric acid, concentrated to 1 liter, and dialyzed against running water for 1 week. The polysaccharide solution was concentrated to 200 ml and freeze-dried for 2 days, yielding a powder of partially methylated glucomannan (18 g, OCH_3, 26.8%). The product was dissolved in dry dimethyl formamide (44). Silver oxide (50 g) and methyl iodide (50 ml) were added and the mixture was shaken at 30° C for 20 hours. The same amounts of reagents were added and the reaction mixture was again shaken for 20 hours. The insoluble, grayish mass was washed on the centrifuge with chloroform. The solution obtained was washed with 5% aqueous potassium cyanide (3×300 ml) and then with water (3×500 ml). After drying over anhydrous sodium sulphate, the chloroform solution was concentrated to 200 ml and poured slowly with stirring into petroleum ether (2 liters) to yield a white powder (14 g).

After one more methylation as above, the product was methylated according to Purdie (45) with methyl iodide (200 ml) and silver oxide (80 g). The final product had $[\alpha]_D$ −21° (*c*, 1.0 in chloroform). Anal. Calc. for a fully methylated glucomannan: OCH_3, 45.3%. Found: OCH_3, 45.0%. The infrared spectrum of the polysaccharide indicated the absence of hydroxyl groups.

Hydrolysis of the Methylated Glucomannan and Resolution of the Hydrolyzate

The fully methylated polysaccharide (4.0 g) was boiled under reflux with 0.7 *N* methanolic hydrogen chloride for 12 hours. Most of the methanol was removed and *N* hydrochloric acid (120 ml) was added. The solution was refluxed for 7 hours, neutralized with silver carbonate, filtered through Celite, treated with hydrogen sulphide, and again filtered. Chromatographic examination (solvent D) of the sirupy hydrolyzate (3.6 g) revealed the presence of di-, tri-, and tetra-*O*-methylhexoses.

A portion of the sirup (3.4 g) was added to the top of a Darco G-60 charcoal – Celite column (5×56 cm) and subjected to gradient elution with 4 liters each of 5% aqueous ethanol → 20% ethanol and 20% ethanol → 40% ethanol.

Preliminary Characterization of Di-O-methylhexoses

Paper electrophoresis indicated the presence of three components in the fraction first eluted from the charcoal column (156 mg). The principal component gave only glucose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

on demethylation with hydrobromic acid (46). It was chromatographically and electrophoretically indistinguishable from 2,6-di-*O*-methyl-D-glucose. The other two components were electrophoretically similar to 2,4- and 3,6-di-*O*-methylglucose.

Identification of 2,3,6-Tri-O-methyl-D-mannose

The second fraction (2400 mg) was further purified by paper chromatography (solvent D). The sirup had $[\alpha]_D$ −12.6° (*c*, 2.6 in water) (47). A portion of the compound (100 mg) was converted to the 1,4-di-*p*-nitrobenzoate derivative (80 mg), m.p. and mixed m.p. 187–188° C, $[\alpha]_D$ +33° (*c*, 1.0 in chloroform), after recrystallization from ethanol (29). Recrystallization from ethyl acetate gave needles, m.p. 187–188° C. The 2,3,6-tri-*O*-methyl-*N*-phenyl-D-mannopyranosylamine had a melting point of 125° C, $[\alpha]_D$ −152° (*c*, 0.6 in methanol) (28).

Identification of 2,3,6-Tri-O-methyl-D-glucose

The third fraction (814 mg) on recrystallization from ethyl ether had a melting point and a mixed melting point of 120–121° C, $[\alpha]_D$ +70° C (*c*, 1.0 in water) (47). The 1,4-di-*p*-nitrobenzoate derivative (29), on recrystallization from methanol, had a melting point and a mixed melting point of 189–190° C, $[\alpha]_D$ −34° (*c*, 0.7 in chloroform).

Identification of 2,3,4,6-Tetra-O-methyl-D-mannose

The fourth fraction (43.7 mg) on demethylation yielded glucose and mannose and was a mixture of the 2,3,4,6-tetra-*O*-methyl derivative of glucose and mannose, $[\alpha]_D$ +4.8° (*c*, 4.4 in water). The infrared spectrum of the sirup agreed closely with that of 2,3,4,6-tetra-*O*-methyl-D-mannose. Treatment with aniline gave 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine, m.p. and mixed m.p. 145–146° C (30), after three recrystallizations from ethyl ether.

Periodate Oxidation of the Glucomannan

Glucomannan (150–200 mg) was oxidized for various lengths of time in the dark at 30° C with 0.05 *M* sodium metaperiodate (50 ml). The consumption of periodate was measured by the excess arsenite method. The molar consumption of periodate per hexose residue was 1.0.

Preparation of the Nitrate Derivative of the Glucomannan

Glucomannan (1 g) was treated with a mixture of nitric acid, phosphoric acid, and phosphorus pentoxide (64:26:10, w/w) at +17° C for 1 hour (48). The reaction mixture was poured into aqueous acetic acid (1:1) cooled to −16° C. The nitrate was recovered by filtration and washed with water until the washings were neutral. Yield, 90%; nitrogen content (49), 13.56%. A duplicate experiment gave a product with the same nitrogen content and in the same yield.

Determination of the Number-Average Molecular Weight of the Methylated and the Nitrated Glucomannans

The osmometers were of the modified (49) Zimm–Myerson (50) type. The membranes were of gel cellophane and the solvent was a mixture of chloroform and ethanol (9:1, v/v) for the methylated and *n*-butyl acetate for the nitrated glucomannan. The temperature was 30±0.01° C and the static method of measuring the osmotic height was used. The results obtained are summarized in Table I.

CATIONIC POLYMERIZATION OF ETHYLENE OXIDE

IV. THE PROPAGATION REACTIONS[1]

G. T. MERRALL, G. A. LATRÉMOUILLE, AND A. M. EASTHAM

ABSTRACT

Studies of the boron-fluoride-catalyzed reaction of ethylene oxide with simple alcohols and low molecular weight polyglycols indicate three ways in which chain growth could occur, but only one of these is considered to be important after the initial stages of polymerization. The rate of disappearance of monomer reaches a maximum at a molecular weight of about 400. A mechanism is proposed to account for both polymerization and depolymerization and it is shown how equilibrium between these two reactions could result.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The polymerization of ethylene oxide by boron fluoride is a complex process in which the propagation reaction must compete with an apparently independent depolymerization reaction. The depolymerization process, as discussed in the previous paper (1), breaks down the polyglycol to dioxane seemingly through a chain reaction propagated by oxonium ions acting upon the ether linkages in the polymer molecule. The polymerization on the other hand appears to occur through a stepwise addition of monomer to the terminal hydroxyls of the polymer chain. A study was therefore undertaken of the reaction of ethylene oxide with alcohols in the presence of boron fluoride in an effort to obtain a mechanism for the propagation and to observe the transition from propagation to depolymerization. This paper presents the results of these studies.

EXPERIMENTAL

Ethylene chloride, ethylene oxide, and boron fluoride were prepared for use as previously described (2). Volatile alcohols were dried by distillation from their magnesium alcoholates in the usual way and ethers were dried over sodium metal or calcium hydride. Wherever the reactants were sufficiently volatile they were stored on the vacuum system and transferred by distillation. The polyglycols were either stirred under high vacuum for several hours or dissolved in dry ethylene chloride and pumped free from solvent before use.

Molecular weights were determined by viscosity measurements as before, but in a few cases were confirmed by freezing point depressions in benzene. Where hydroxyl content of the polymer was important, end group analysis by acetylation with acetyl chloride in pyridine, according to the method of Smith and Bryant (3), was used. All three methods gave satisfactory agreement.

Reactions were carried out in ethylene chloride solution at 20° C. Rates were followed either by the decrease in vapor pressure of ethylene oxide as described in the earlier work, or by a dilatometric method. The dilatometers were so constructed that they could be dried and filled under vacuum and then transferred to a constant temperature bath while exposing only the capillary tip to the atmosphere. Absolute contractions were not determined but the contraction per unit of oxide appeared to be constant over the range of the experiments. The two methods gave good agreement wherever they could be compared.

RESULTS AND DISCUSSION

Before discussing the reaction of ethylene oxide with alcohols, it is necessary to draw some conclusions as to the probable distribution of boron fluoride in a system containing both hydroxyl and ether groups. We know (4) that boron fluoride with water forms both monohydrates and dihydrates and that the second molecule of water is held, at least in the crystal, as the hydronium ion,

$$BF_3 \overset{H_2O}{\rightleftharpoons} BF_3{:}H_2O \overset{H_2O}{\rightleftharpoons} H_3\overset{+}{O} \ldots \overset{-}{B}F_3OH.$$

The dihydrate is much the more stable of the two complexes but in the corresponding alcoholates this difference in stability appears to be much smaller. Ethers yield 1:1 compounds with boron fluoride but in the presence of alcohols they yield ternary complexes, analogous to the dihydrates, in which the ether is held by hydrogen bonding,

$$ROH{:}BF_3 + R'_2O \rightleftharpoons RO{:}BF_3 \ldots HOR'_2 \rightleftharpoons ROH + R'_2O{:}BF_3.$$

Obviously then, in a solution of hydroxyl and ether groups such as one has with the polyglycols, the boron fluoride will be present as an equilibrium mixture of several complexes and, since the reaction rates will depend on the concentrations and reactivities of the various species present, a rigorous interpretation of the kinetics will require an accurate knowledge of all the equilibrium constants. Information of this kind is not available nor is it likely to be for some time to come so a few simple experiments were conducted in an effort to obtain some idea of the relative importance of the various complexes.

The relative basicities of a few ethers towards boron fluoride were examined by equilibrating the ethers in ethylene dichloride solution against dimethyl ether and boron fluoride. The concentration of free dimethyl ether in solution was obtained from its vapor pressure and the position of the equilibrium was then calculated from the known initial concentrations of all reactants. Constants obtained in this way held very well over about a fivefold range of concentrations and, where comparison could be made, were in good agreement with values calculated from the data of Brown and Adams (5) for the thermal dissociation of boron fluoride etherates. A few values of the relative basicities are listed in Table I.

TABLE I

Dimethyl ether	1
Di-*n*-butyl ether	0.16
Dioxane (molar basis)	0.115
Tetrahydrofurane	25.

Ethylene oxide unfortunately could not be examined because of its high reactivity, but the dimethyl ether of diethylene glycol, $CH_3OCH_2CH_2OCH_2CH_2OCH_3$, is of some interest because of its similarity to the polyglycols. In our experiments this molecule was found to add only two molecules of boron fluoride and of these one seemed to be held quite loosely. At low boron fluoride concentrations, however, the triether was quite basic with a relative basicity, on a molar basis, of about 0.4. In a similar manner a little information was obtained about the ternary complexes. If one adds dimethyl ether to a solution of equimolar amounts of boron fluoride and *n*-butanol, then an amount of ether equal to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the boron fluoride is removed from the solution. Since addition of further alcohol regenerates some ether, an equilibrium of the type

$$ROBF_3 \ldots H \ldots OR'_2 + ROH \rightleftharpoons ROBF_3 \ldots H \ldots HOR + R'_2O$$

seems indicated so, on the assumption that any binary complexes present are in low concentration compared with the ternaries, an equilibrium constant can be obtained. This constant was found to hold surprisingly well over the short range of concentrations which could be examined and indicated that the dimethyl ether was about 1.5 times as basic as *n*-butanol towards the acid ROH:BF_3. From subsequent experiments it seems likely that at high ratios of ether to alcohol serious interference from the binary ether – boron fluoride complex may occur, but as much of our work has been carried out at low values of this ratio, we feel justified in assuming that the catalyst will be present largely as the ternary complex in most of our reaction mixtures. Furthermore, as alcohols and ethers seem to have rather similar basicities, we must expect that a mixture of ternary complexes will be present.

Ethylene oxide reacts with simple alcohols to give the β-alkoxyethanols which can in turn react with further monomer. Since the latter reaction is several times more rapid than the initial one, rates must be obtained either from initial slopes or from experiments at high alcohol/oxide ratios. The results obtained with *n*-butanol are shown in Table II

but essentially similar results were obtained with ethanol. The rate of the reaction decreases with increasing alcohol concentration. From our previous discussion it seems most probable that this decrease is due to an increase in the concentration of boron fluoride dialcoholate, so we may suppose that the rate is governed by the following reactions,

where reaction [1] is the unimolecular rearrangement of a ternary complex of all three reactants while reaction [2] is a bimolecular reaction between ethylene oxide and the boron fluoride dialcoholate. The rate expression for this system, assuming only ternary complexes, is found to be

$$-\frac{d(\text{oxide})}{dt} = (BF_3)(\text{oxide})\,\frac{k_1K_1+k_2(\text{ROH})}{K_1(\text{oxide})+(\text{ROH})}$$

which, when assigned the following values for the constants, $K_1 = 0.1$, $k_1 = 9$ min^{-1}, and $k_2 = 0.4$ liter mole^{-1} min^{-1}, gives the calculated rates shown in Table II. The agreement with the experimental values is good but since there are three constants to adjust such agreement does not mean a great deal. The real test of the mechanism would perhaps be an independent measurement of the equilibrium constant K_1, i.e. of the basicity of ethylene oxide and this, as noted above, we were unable to obtain. The above kinetic value of K_1 suggests that the oxide is about 1/10th as basic as *n*-butanol and hence about 15 times less basic than dimethyl ether, so is in agreement with qualitative experiments (6) which indicate that epoxides are among the least basic of the simple ethers.

The reaction of ethylene oxide with a simple alcohol is the first step in an addition polymerization in which the second and third steps can be represented by the reactions of the monoethyl ethers of glycol (Cellosolve) and diethylene glycol (Carbitol), respectively. The results of some dilatometric experiments with these alcohols are shown in Fig. 1; vapor pressure measurements were in reasonable agreement with the dilatometric measurements at the higher alcohol concentrations but diverged at the lower ones. The rate measurements show a minimum with both Cellosolve and Carbitol at low alcohol concentration. We have examined this region carefully and feel that the minimum is probably real but admittedly it could be due to a breakdown of the dilatometric method in this region or to experimental errors which tend to accumulate at low alcohol concentrations. If it is real, it would appear that the increasing rate at very low hydroxyl concentrations corresponds to an extension of the curve for *n*-butanol to low alcohol concentrations, i.e. to a region where reaction [1] is dominant. This view receives some support from the fact that no minimum is evident in runs with a polyglycol of molecular weight 600 (Fig. 1) where the contribution from reaction [1] would be reduced markedly by the competition of the polymer ether groups for the boron fluoride. While the presence of the minimum is disturbing, its presence should not be allowed to obscure the most important conclusion from these results, namely, that a clear change in mechanism, not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

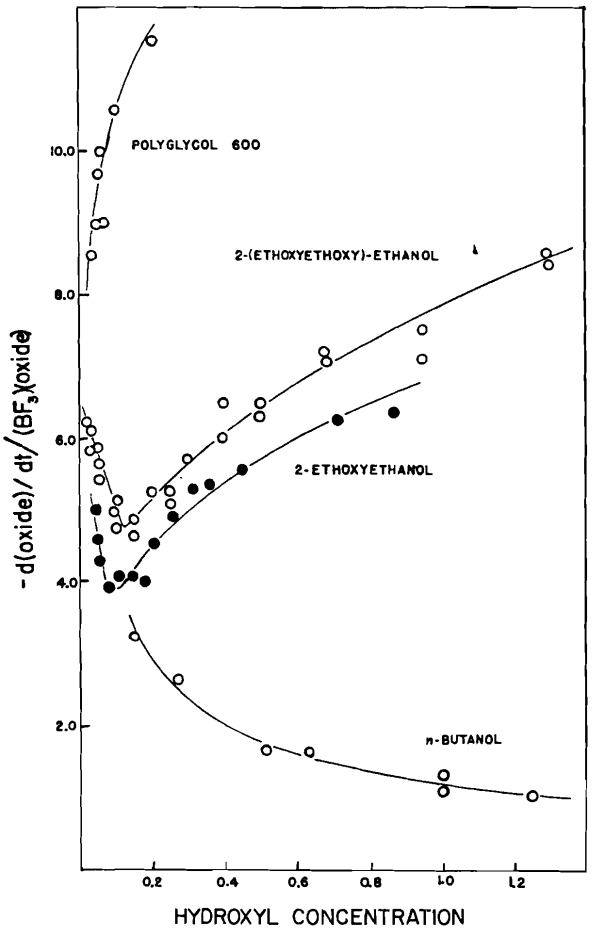

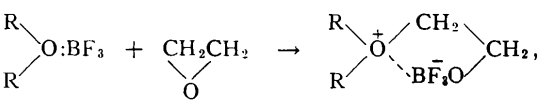

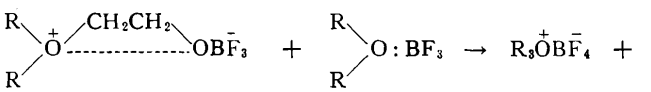

FIG. 1.

merely a change in rate, has occurred in passing from the simple alcohols to the β-ether alcohols. This change must be due to the presence of the ether groups and suggests that an oxonium ion type of reaction is important even at this early stage of the polymerization.

Meerwein and his co-workers have shown (7) that epoxides react, both rapidly and quantitatively, with anhydrous ethers and boron fluoride to form the inner oxonium salts,

which can then react with further etherate to form the tertiary salts,

The inner salts differ from the tertiaries in being very unstable and insoluble so most probably account for the precipitation and discoloration we observe in the absence of

hydroxyl groups. It may be that the hydroxyl groups decompose the inner salts as formed, but an alternative explanation is possible and would account for other aspects of the polymerization process. Klages and Meuresch (8) showed that ether complexes of very strong acids will react with diazomethanes to form tertiary oxonium salts, both rapidly and quantitatively,

$$R_2O\text{-------}HBF_4 \quad + \quad R'CHN_2 \quad \rightarrow \quad R_2\overset{+}{O}CH_2R'\text{-------}\overline{BF_4} \quad + \quad N_2.$$

The acid–ether complexes here are closely similar to the alcohol–ether – boron fluoride complexes encountered in the present work so if ethylene oxide could replace the diazomethane, tertiary oxonium ions would be formed directly according to the reaction

$$RO{:}BF_3\text{--------}H\text{-------}OR'_2 \quad + \quad \underset{\diagdown O \diagup}{CH_2-CH_2} \quad \xrightarrow{k_4} \quad R'_2\overset{+}{O}CH_2CH_2OH\text{--------}\overline{BF_3}OR. \qquad [4]$$

A reaction of this form seems best able to account for the rapid reaction of ethylene oxide with the lower ether alcohols and may be considered as an exact analogue of reaction [2], differing from it only in the stability of the product; in reaction [2] the catalyst is regenerated immediately

$$RO{:}\overline{BF_3}\text{-------}H\text{—}\overset{H^+}{\underset{|}{O}}R \quad + \quad \underset{\diagdown O \diagup}{CH_2CH_2} \quad \xrightarrow{k'_2} \quad RO\overset{H^+}{\underset{|}{C}}H_2CH_2OH\text{--------}\overline{BF_3}OR \qquad [2]$$

whereas in reaction [4] the oxonium ion is sufficiently stable that it must be decomposed by reaction with a hydroxyl group, i.e.

$$R'_2\overset{+}{O}CH_2CH_2OH \quad + \quad ROH \quad \xrightarrow{k_5} \quad R'_2O \quad + \quad RO\overset{H^+}{\underset{|}{C}}H_2CH_2OH. \qquad [5]$$

The net effect of this formation and destruction of the oxonium ion is to lengthen a chain by one oxide unit so we now have three processes which can lead to chain growth, reactions [1], [2], and [4, 5], all of which must be considered as important in the reaction of Cellosolve and Carbitol. The system is obviously too complex for complete kinetic analysis but under conditions of high alcohol/oxide ratios, as in some of the dilatometric experiments, reaction [1] should not be important and the boron fluoride will be distributed between two ternary complexes,

$$ROH\cdot BF_3\cdot\text{alcohol}/ROH\cdot BF_3\cdot\text{ether} = K_2,$$

according to whether hydrogen bonding takes place at an alcohol or ether group. The value of K_2 will be governed by the ratio of ether to alcohol groups in the molecule and not by the concentration of the ether–alcohol; it will decrease as the chain grows longer. If steady-state conditions were to apply to the oxonium ion, the rate expression for the system would be

$$-\frac{d(\text{oxide})}{dt} = \frac{k'_2K_2+k_4k_5}{K_2+1+\dfrac{k_4(\text{oxide})}{k_5(ROH)}}(BF_3)(\text{oxide}),$$

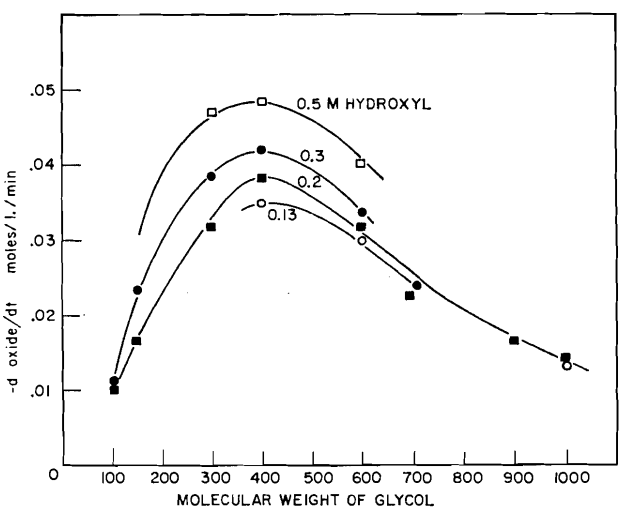
or if reaction [5] were very rapid compared with [4]

$$-\frac{d(\text{oxide})}{dt} = \frac{k'_2K_2+k_4}{K_2+1}(BF_3)(\text{oxide}).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These very similar expressions are in agreement with the observed first-order dependence on boron fluoride and ethylene oxide but require that the rate be independent of hydroxyl concentration. It is evident in Fig. 1 that at the higher alcohol concentrations where reaction [1] can be disregarded, the rates do in fact tend towards such independence without actually achieving it. This failure of the rate expressions is probably due to the high rate of reaction [4], which invalidates the assumptions used in deriving them.

Extension of these results to low molecular weight polymers is not simple. Rate expressions of the type just considered suggest that as the molecular weight increases and K_2 becomes very small, the reaction should reduce to a simple second-order process. In fact, however, at high molecular weights (3000–4000) the rate of oxide disappearance becomes very slow and independent of monomer concentration. For reasons detailed in the previous paper (1), we believe that this slow zero-order rate is due to the formation of stable oxonium ions which do not react directly with ethylene oxide with the result that reaction [5] becomes rate controlling. (In solutions of high molecular weight polymer the hydroxyl concentration is, of necessity, low.) Between the two extremes of the very low and the high molecular weight polyglycols the rate of reaction of oxide with the glycols, at constant hydroxyl concentration, passes through a maximum at a molecular weight of about 400. The order in oxide at moleculer weights below the maximum is always one or nearly so, but at higher molecular weights it drops off steadily. If, as we believe, the order is determined by the relative rates of reactions [4] and [5], then it is legitimate to compare initial rates of oxide disappearance and this is done in Fig. 2 for initial concentrations of boron fluoride and ethylene oxide of 0.012 M and 0.55 M, respectively.



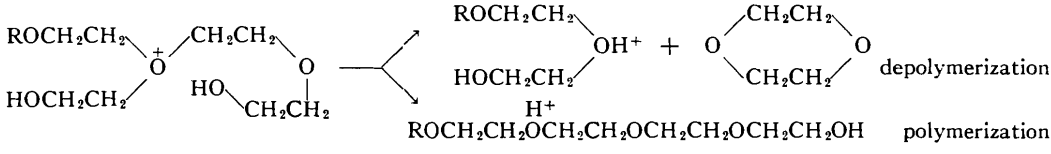


FIG. 2.

It was stated earlier that the increase in rate in passing from the simple alcohols to the ether alcohols is most probably due to a contribution from a reaction proceeding via oxonium ions. On the other hand, the decrease in both rate and order at higher molecular weights is almost certainly due to the presence of stable oxonium ions, so the problem is to resolve this apparent conflict in a way which will account for the rate maximum at molecular weight 400. Dilatometric experiments with low molecular weight polymer and very small amounts of monomer suggest strongly that reaction [4], oxonium ion formation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is very fast even at molecular weights well above 400 (Fig. 1), so the over-all rate must be governed largely by reaction [5]. It follows that reaction [5] must be especially rapid in the molecular weight range 200–400 and since there seems no reason why reaction between an oxonium ion and *any* terminal hydroxyl group should be molecular weight dependent, this conclusion suggests that internal reaction, i.e. reaction of the oxonium ion with the hydroxyls of its own chain, is important at low molecular weights. Once reached, this conclusion seems quite reasonable for we know that an oxonium ion readily attacks the oxygen atoms of its own chain (dioxane formation), so with low molecular weight polymer there is a high probability that the oxygen attacked will be that of a hydroxyl group. With triethylene glycol, for example ($HOCH_2CH_2OCH_2CH_2OCH_2CH_2OH$, mol. wt. 150), no other reaction is possible, but with higher polymers one or more dioxane units may have to be eliminated before the attack at hydroxyl is possible. The reaction could take place in two ways, one leading to polymerization and the other to depolymerization,

$ROCH_2CH_2OCH_2CH_2OCH_2CH_2OCH_2CH_2OH$

but from the point of view of rate it does not matter which occurs since both lead to destruction of the oxonium ion. Our evidence suggests, however, that polymerization is favored for we could detect no dioxane in the product of the reaction between the monoethylether of triethylene glycol and an equimolar amount of triethyloxonium fluoroborate.

According to the reaction scheme here proposed, the increasing rate at low molecular weights is due primarily to a transition from reaction [2] to reaction [4]. With continued chain growth, however, reaction [5], which is composed of two parts corresponding to internal and external termination, becomes steadily slower as internal termination becomes less and less probable. Since the probability of internal termination should be inversely related to the molecular weight, it is not surprising that the maximum rate occurs at a definite molecular weight at all hydroxyl concentrations. More surprising perhaps is the relatively small contribution of the external to the total termination.

With a reaction mechanism for guidance, the conditions governing molecular weight equilibrium can be considered. If equilibrium were to occur at molecular weights above about 1500, the situation would be relatively simple because it could be assumed that all termination occurred by the external route and the order in oxide could be taken as zero, with all the catalyst in the form of oxonium ion. The rates of dioxane formation and monomer disappearance would be given approximately by

$$d(\text{dioxane})/dt = k_6(\text{oxonium ion}),$$

$$-d(\text{oxide})/dt = k_7(\text{oxonium ion})(\text{ROH}),$$

and would be related at equilibrium as

$$2d(\text{dioxane})/dt = -d(\text{oxide})dt.$$

It follows that equilibrium would occur at a hydroxyl concentration equal to $2k_6/k_7$ but it would be an equilibrium in the sense that if a polymer were added to the reaction so as to give a hydroxyl concentration of $2k_6/k_7$, then that polymer would neither grow nor depolymerize. At higher hydroxyl concentrations growth would occur and at lower concentrations the polymer would disappear.

In practice equilibrium occurs at molecular weights where the order in oxide is less than about 0.5 but certainly not zero, and where internal termination is still a major part of the total termination. If the oxide concentration were important in determining the equilibrium, then the molecular weight should rise to a maximum in the course of a polymerization and fall off again as the monomer concentration declines. We have found some evidence for a maximum of this kind but it is scarcely greater than the error in the weight measurements, so the concentration of oxide will be ignored in the present discussion. The contribution of internal termination to the equilibrium, on the other hand, cannot be ignored and unfortunately cannot be expressed with our present information. It obviously will become smaller as the molecular weight increases and may perhaps be roughly inversely proportional to the molecular weight, in which case the total termination rate would be given by

$$-d(\text{oxonium ion})/dt = [k_7(\text{ROH}) + k_8/(\text{mol. wt.})](\text{oxonium ion})$$

which in turn, assuming that reaction [5] is rate controlling, would be the rate of oxide disappearance. Accordingly at equilibrium

$$2k_6(\text{oxonium ion}) = [k_7(\text{ROH}) + k_8/(\text{mol. wt.})](\text{oxonium ion})$$

giving

$$(\text{mol. wt.})_{\text{equilib}} = k_8/[2k_6 - k_7(\text{ROH})].$$

This treatment is obviously exceedingly crude but is interesting in that it suggests that the equilibrium molecular weight should be somewhat dependent on the hydroxyl concentration for this in fact seems to be the case (Table III).

TABLE III

Hydroxyl concentration	Approx. final molecular wt.
0.03	525
0.06	600
0.12	750
0.20	800
0.61	1000

A reaction as complex as this one will require a great deal of work before it yields any exact solutions and we do not pretend that the reaction schemes presented in this and the preceding paper are any more than preliminary ones. They do, however, seem to account in a qualitative and fairly logical way for almost all of our observations on the boron fluoride catalyzed polymerization of ethylene oxide. Perhaps the most interesting problem which remains unexplained is the difference in behavior of the various Friedel–Crafts catalysts in this polymerization, for the reaction schemes proposed do not seem to account satisfactorily for the fact that stannic chloride, and perhaps antimony pentachloride, can produce much higher molecular weight polymer than boron fluoride.

AN IMPROVED PREPARATION OF ω-HYDROXY ALIPHATIC ACIDS AND THEIR ESTERS[1]

D. G. M. Diaper and D. L. Mitchell[2]

ABSTRACT

Reductive cleavage of the ozonides of aliphatic acids and their esters by sodium borohydride or by hydrogenation produces ω-hydroxy aliphatic acids and ω-hydroxy aliphatic esters, respectively, in high yields.

INTRODUCTION

ω-Difunctional aliphatic compounds have found much employment in the synthesis of higher aliphatic compounds. Among these, substances having two different terminal functions are the most favored, and probably the most important reagents for chain extension are the esters of the ω-halogeno acids. These compounds, in various chain-lengths, were required for condensation with malonic ester derivatives in the preparation of branched alkanedioic acids (1, 2, 3, 4) in this laboratory. With the exception of those members of the series of very short chain-length, only one ω-bromo acid, 11-bromo-undecanoic, is easily available and this substance is best prepared by the peroxide-catalyzed addition of hydrogen bromide to 10-undecenoic acid (5). The latter compound is unique among the terminal unsaturated acids in that it is available in quantity and this method of preparation cannot be regarded as a method of general applicability. Use of the more common unsaturated acids with non-terminal olefinic linkages as starting materials for the preparation of ω-hydroxy acids and ω-bromo acids was first explored by Adams (6, 7), who ozonized the esters and isolated ω-aldehydo esters. These compounds were then reduced to give the esters of the ω-hydroxy acids. A practical difficulty in preparations of this type is the inevitable oxidation of a portion of the aldehydo ester to the half ester of the corresponding dicarboxylic acid. Contamination of intermediates with substances in the dicarboxylic acid series is undesirable as such compounds are usually high melting and insoluble and therefore difficult to remove. It is desirable, therefore, to obviate the sensitive aldehyde intermediate by exploitation of the new metal hydride reagents (8) and by selective reductive cleavage of the ozonide-ester prepare the hydroxy ester without isolation of the aldehyde. A similar observation on the preparation of primary alcohols by the borohydride cleavage of ozonides appeared while this work was in progress (9).

We have compared the high-pressure hydrogenolysis of certain ozonides with their reductive cleavage by sodium borohydride and the results are summarized in Table I. Yields of hydroxy ester were found to be superior when the borohydride was used and the products were also of higher purity as indicated by a narrow boiling range and ease of crystallization of the phenylurethane. When the scale of the preparation was increased, the yield by borohydride cleavage remained the same but the yield by high-pressure hydrogenation diminished. Sodium borohydride is still an expensive reagent and it may therefore be more economical to use the hydrogenation method on a large scale.

*Method (*a*) by sodium borohydride reduction, method (*b*) by Raney nickel catalyzed hydrogenation.

The working solvent employed for ozonizations has customarily been chloroform, carbon tetrachloride, acetic acid, ethyl acetate, or light petroleum. We have found absolute methanol, ethanol, and isopropanol to be convenient solvents and have used sodium borohydride in the same solvent, thus performing the ozonization and reductive cleavage in one sequence. The alcohol chosen as a solvent for the ozonolysis of an ester was that corresponding to its alkyl radical for it was found that transesterification took place if a different alcohol was employed. Presumably the basic environment of the borohydride reduction step made this transesterification possible.

A limitation on the use of methanol as a solvent is the rapid decomposition of sodium borohydride in this solvent. This can be obviated by reversing the usual order of addition and employing solid borohydride in place of an alcoholic solution.

It may be seen that 9-hydroxynonanoic acid may be obtained either from oleic acid or from linoleic acid. Using the former starting material, difficulties were encountered in freeing the hydroxy acid from the concomitant nonan-1-ol either by the method of Sousa and Bluhm (8) or by the steam-distillation method here described. When linoleic acid is the starting material, the other cleavage products are of lower molecular weight and therefore more easily removed.

10-Hydroxydecanoic acid was obtained in two ways from 10-undecenoic acid. The direct ozonization–borohydride method gives good yields and a high degree of purity. In the second method, undecenoic acid was esterified and reduced by the Bouveault–Blanc process, giving 10-undecen-1-ol without saturation or migration of the olefinic linkage. The acetate of the latter was then ozonized and the aldehyde thus obtained was oxidized to the corresponding acid, 10-acetoxydecanoic acid. This was then saponified. In the first method the carboxylic acid function of the starting material is retained and in the second it becomes the primary alcohol function of the end product.

The structure of (+)-ricinoleic acid as 12-hydroxy-9-octadecenoic acid (10) and most likely possessing the D-configuration (11) has been established by degradation studies (12, 13) and by synthesis (14, 15, 16). Early ozonolysis experiments performed on ricinoleic acid produced 3-hydroxy-nonanoic and nonanedioic acids and the corresponding aldehydes, which were characterized by the formation of crystalline derivatives (17, 18). These experiments supported the Goldsobel formula. We have found that sodium borohydride reduction of the ozonide of (+)-ricinoleic acid formed a hitherto unknown laevorotatory diol with boiling point, refractive index, and infrared spectrum very similar to those of racemic (±)-nonane-1,3-diol. The latter compound was synthesized by a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Reformatsky condensation of *n*-heptanal and ethyl bromoacetate followed by lithium aluminum hydride reduction of the intermediate ethyl 3-hydroxynonanoate which was not isolated. Although racemic (±)-nonane-1,3-diol formed a crystalline mono-*N*-phenylcarbamate and bis-*N*-phenylcarbamate, attempts to form these crystalline derivatives from the optically active isomer were unsuccessful.

EXPERIMENTAL

Melting points were uncorrected. Infrared spectra were determined on 5% solutions in chloroform. Hydrogenations were carried out in a high-pressure autoclave equipped with a stirrer.*

10-Hydroxydecanoic Acid by the Sodium Borohydride Reduction Method

A stream of ozonized oxygen was bubbled through a solution of 10-undecenoic acid (undecylenic acid, b.p. 176–178° C/23 mm, 39.7 g) in absolute methanol (40 ml) at 0° C until an aliquot test portion no longer decolorized a dilute solution of bromine in a glacial acetic acid. The ozonide solution was then added dropwise to an ice-cold solution of sodium hydroxide (12.5 g) and sodium borohydride (17 g) in 50% aqueous ethanol (300 ml). A gentle evolution of hydrogen resulted and stirring was continued at room temperature for at least 10 hours. The methanol and ethanol were removed by distillation under reduced pressure and at a bath temperature of 40° C or less, and the alkaline aqueous solution was then added dropwise with stirring to an excess of ice-cold dilute hydrochloric acid (1.5 liters). The precipitated 10-hydroxydecanoic acid was collected by suction filtration, washed thoroughly with portions of ice-cold water, and dried under reduced pressure to constant weight (37.0 g, 91%). The yield was not reduced when the scale of the experiment was doubled. Recrystallization twice from benzene gave a product of constant melting point, 77° C, and mixed melting point 75.5–77° C (lit. 75.5–76.5° C (19)).

10-Hydroxydecanoic Acid by the Pressure Hydrogenolysis Method

A solution of the ozonide from 10-undecenoic acid (37.4 g) in ethanol was hydrogenated at room temperature and 2000 p.s.i. for 3 hours using Raney nickel W-2 catalyst (20). The temperature was increased to 130–150° C and the hydrogenation was continued a further 5 hours. The product was isolated by solvent removal, conversion to the sodium salt, and precipitation by pouring the alkaline solution into ice-cold dilute hydrochloric acid. The slightly syrupy crude product (33.6 g) was recrystallized from benzene – light petroleum to give a product (21.4 g, 56%) with a melting point of 75° C.

Ethyl 10-Hydroxydecanoate

The ozonide from ethyl 10-undecenoate (ethyl undecylenate) (20.4 g) in absolute ethanol (200 ml) was prepared according to the above method. The solution was added to sodium borohydride (6.0 g) in absolute ethanol (300 ml) as before and allowed to stand for 24 hours in a loosely stoppered flask at 5° C. After removal of most of the ethanol under reduced pressure, the product was taken up in ether (1500 ml), washed with acid and alkali in the usual manner, and dried. The product (19.7 g, 94%) distilled† at 114–115° C/0.07 mm and crystallized in the refrigerator (m.p. 15° C, thermometer immersed), n_D^{24} 1.4460.

Reduction of the ozonide from methyl 10-undecenoate (24.9 g) with a cold (3%)

*Superpressure Division of American Instrument Company, Inc., Silver Springs, Maryland, U.S.A.

†*A test for ozonide (i.e. starch iodide paper) and a safety shield are recommended for this distillation. In a preliminary experiment, when the borohydride reduction step was acidified after 5 minutes of reduction, the isolated crude product decomposed explosively during distillation presumably due to unreduced ozonide present.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ethanolic solution of sodium borohydride (9 g) for 30 hours produced ethyl 10-hydroxydecanoate (22.2 g, 82%). The derived *N*-phenylcarbamate had a melting point and a mixed melting point of 52–54° C.

The derived *N*-phenylcarbamate of ethyl 10-hydroxydecanoate melted at 52–54° C after two recrystallizations from heptane. The ethyl ester of 10-hydroxydecanoic acid was prepared; it formed a *N*-phenylcarbamate of melting point 52–54° C and mixed melting point 52–54° C. Both specimens gave an identical infrared absorption spectrum. Anal. Calc. for $C_{19}H_{29}O_4N$: C, 68.1; H, 8.7; N, 4.2. Found: C, 67.4; H, 8.8; N, 4.3.

Ethyl 10-hydroxydecanoate was also prepared from ethyl 10-undecenoate (25.2 g) by the ozonolysis–hydrogenation method described above. The product (18.4 g, 71%) was purified by two distillations and had a boiling point of 106–108° C/0.04 mm and n_D^{22} 1.4410.

Large-scale experiments (ca. 100 g of ozonide) produced a less pure product boiling over a 10° C range in yields of 40 to 66%.

The derived *N*-phenylcarbamate (m.p. 52–54° C) was prepared but did not crystallize readily.

9-Hydroxynonanoic Acid

The ozonide from linoleic acid* (50 g) in absolute ethanol (100 ml) was added dropwise to an aqueous alcoholic solution (1:1, 100 ml) of sodium hydroxide (20 g) and sodium borohydride (15 g). The solution was stirred for 48 hours, and it was acidified and extracted with ether (3×200 ml). The ethereal extracts were steam distilled until most of the alcohols had been removed. The product was recovered by ether extraction, was crystallized from benzene – light petroleum (13 g, 42%) and had a melting point of 43–45° C. Recrystallization from ethyl acetate raised the melting point to 50–51° C [lit. m.p. 53–54° C (corr.) (6), and m.p. 51–51.5° C (21)].

When the above procedure was carried out with oleic and elaidic acids, crude 9-hydroxynonanoic acid was obtained in 50% and 74% yields, respectively. The product obtained from oleic acid was difficult to purify by crystallization. Poor yields and resinous products in the ozonization of oleic acid and its esters have been attributed to excessive temperatures of ozonization (22).

Methyl 9-Hydroxynonanoate

Methyl oleate (20.6 g) in methanol (200 ml) was ozonized as described above. To minimize the borohydride–methanol reaction, however, the order of addition was reversed, the borohydride (9 g) being added in 0.5-g portions during 5 hours. Distillation at 0.1 mm produced two fractions: (*a*) b.p. 80–100° C (7.2 g) (72%), n_D^{22} 1.4340 (lit. for nonan-1-ol, n_D^{20} 1.4338 (23)); (*b*) b.p. 103–109° C/0.1 mm, 11.75 g (88%), n_D^{21} 1.4433. The derived *N*-phenylcarbamate melted at 53–54° C and had a mixed melting point of 53.5–55.5° C [lit. methyl 9-hydroxynonanoate *N*-phenylcarbamate 53–54° C (6)].

Methyl 9-hydroxynonanoate was also prepared from methyl oleate by the ozonization–hydrogenation technique and from methyl linoleate by the borohydride and catalytic hydrogenation methods. The yields are listed in Table I. Examination of the forerun (b.p. 80–105° C/0.2 mm) from the latter preparation by gas-liquid chromatography indicated the presence of at least two components.

Ethyl 9-Hydroxynonanoate

The ozonide from ethyl linoleate (b.p. 148–153° C/0.4 mm, n_D^{20} 1.4573) (50.15 g) in absolute ethanol was divided equally into two parts. One part was reduced by the dropwise

**Nutritional Biochemicals Corporation, Cleveland 28, Ohio (linoleic acid, 75%).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

addition to sodium borohydride in absolute ethanol and gave a product (12.1 g, 73%) with a boiling point of 110–118° C/0.2 mm and n_D^{21} 1.4441. Anal. Calc. for $C_{11}H_{22}O_3$: C, 65.3; H, 11.0. Found: C, 65.6; H, 11.0. The second portion was reduced by the two-stage hydrogenation described above and gave a product (10.8 g, 65%) with a boiling point of 110–120° C/0.1 mm and n_D^{18} 1.4415.

When both specimens were warmed with one-half by weight of phenyl isocyanate, the derived *N*-phenylcarbamate was obtained (m.p. 59–60° C). Recrystallization from 2,2,4-trimethylpentane – benzene raised the melting point to 60–61.5° C. Anal. Calc. for $C_{18}H_{27}O_4N$: C, 67.3; H, 8.5; N, 4.5. Found: C, 67.5; H, 8.6; N, 4.7.

Isopropyl 9-Hydroxynonanoate

The ozonide from isopropyl oleate (b.p. 225–227° C/22 mm, n_D^{22} 1.4491) (32 g) was reduced with sodium borohydride in isopropanol according to the above method. The product (15 g, 70.5%) had a boiling point of 116–120° C/0.4 mm and $n_D^{25.5}$ 1.4399. Anal. Calc. for $C_{12}H_{24}O_3$: C, 66.6; H, 11.2. Found: C, 66.8; H, 11.3.

The derived *N*-phenylcarbamate was recrystallized from 2,2,4-trimethylpentane and had a melting point of 66.5–68° C. Anal. Calc. for $C_{19}H_{29}O_4N$: C, 68.1; H, 8.7; N, 4.2. Found: C, 68.3; H, 8.8; N, 4.1.

10-Hydroxydecanoic Acid by the Ozonization of the Acetate of 10-Undecen-1-ol

10-Undecen-1-ol (from ethyl undecylenate by Bouveault–Blanc reduction (24)) was acetylated by the acetic anhydride method of Chuit (25) in 83–86% yield. The acetate was ozonized in 20-g portions in acetic acid (40 cc) and the ozonide was reduced by the zinc dust – ether – water method of Adams (7). 10-Acetoxydecanal was obtained as a pungent oil, b.p. 113–118° C/0.3 mm, and was not purified before oxidation. Its oxime was obtained from ethanol as colorless prisms, m.p. 67.5–68° C. Anal. Calc. for $C_{12}H_{23}O_3N$: C, 63.0; H, 10.0; N, 6.1. Found: C, 63.0; H, 9.85; N, 5.7. Its *p*-nitrophenylhydrazone was obtained as yellow needles from aqueous acetic acid, m.p. 118° C. Anal. Calc. for $C_{18}H_{27}O_4N_3$: C, 61.9; H, 7.75; N, 12.0. Found: C, 61.8; H, 7.65; N, 11.5.

Oxidation of 10-acetoxydecanal (15 g) to the corresponding acid was performed in 65–68% yield by passing air through a rapidly stirred mixture of the aldehyde with 200 cc of 20% aqueous manganous chloride solution. The product, 10-acetoxydecanoic acid, isolated with the aid of ether and potassium carbonate, melted at 34.5–36° C and a 15–30% recovery of unchanged aldehyde was effected. By saponification of 10-acetoxydecanoic acid in aqueous–ethanolic potassium hydroxide, 10-hydroxydecanoic acid, m.p. 74–74.5°, was obtained and found to be identical with the product described above.

(−)-Nonane-1,3-diol

After ozonolysis of ricinoleic acid (26 g, $[\alpha]_D^{22}$ 16.3°, *c*, 14.1, ethanol) and sodium borohydride reduction in aqueous alkaline methanol as described above, there was obtained an aqueous solution which was extracted with ether. From the extract of non-acidic products was obtained (−)-nonane-1,3-diol (10.0 g, 72%, b.p. 98–105°/0.1 mm). Two further distillations produced a colorless liquid with a boiling point of 97–99° C/0.1 mm, $n_D^{23.5}$ 1.4506, $[\alpha]_D^{22}$ −6.0° (neat liquid), and $[\alpha]_D^{22}$ −6.3° (*c*, 10, ethanol).

The product had an infrared absorption spectrum identical with that of (±)-nonane-1,3-diol prepared by the method described below. The infrared spectrum was also very similar to those of octan-1-ol and octan-2-ol with the major difference being a stronger absorption at the stretching frequency due to hydroxyl (3420 cm^{-1}).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Examination of the product by gas–liquid chromatography indicated the presence of at least three impurities which constituted approximately 6% of the product. This material was fractionally distilled in a Piros–Glover microdistillation still* with seven fractions being collected with n_D^{25} 1.4483, 1.4490, 1.4495, 1.4500, 1.4500, 1.4500, 1.4500, respectively. Anal. Calc. for $C_9H_{20}O_2$: C, 67.45; H, 12.6. Found: C, 67.3; H, 12.6.

Attempts to prepare the *N*-phenylcarbamate from fractions 4, 5, 6, or 7 resulted in the formation of a gel. This phenomenon of gel formation was also observed on the slightly impure product.

(±)-Nonane-1,3-diol

n-Heptanal (57 g) and ethyl 1-bromoacetate (83.5 g) were condensed by a standard Reformatsky procedure. After the reaction was complete, the solution was filtered from the unreacted zinc granules and the volume of the filtrate was adjusted to 300 ml with dry ether. The ethereal solution was added dropwise to an ethereal suspension of excess lithium aluminum hydride at such a rate that a gentle reflux was maintained. After the solution had been heated under reflux for an additional 2 hours, the residual lithium aluminum hydride was decomposed by the addition of excess ethyl acetate (100 ml). After 0.5 hour, water was added and a voluminous froth developed. The froth was suspended in ether and cold dilute hydrochloric acid was added until the solution was strongly acidic. The ethereal layer was separated and washed successively with water, sodium hydrogen carbonate solution, and water. Evaporation of the ether left an oil which distilled at 97–99° C/0.04 mm (42 g, 52.5%). A second distillation gave a main fraction with a boiling point of 97–99° C/0.1 mm and n_D^{23} 1.4512. Anal. Calc. for $C_9H_{20}O_2$: C, 67.45; H, 12.6. Found: C, 67.4; H, 12.6.

Bis-N-phenylcarbamate of (±)-Nonane-1,3-diol

Equal weights of phenyl isocyanate and (±)-nonane-1,3-diol were warmed to 60° C for 8 hours. Upon cooling, the product crystallized and was recrystallized from 2,2,4-trimethylpentane, m.p. 85–85.5° C. Examination of the infrared spectrum indicated the absence of the hydroxyl band. Anal. Calc. for $C_{23}H_{30}O_4N_2$: C, 69.3; H, 7.6; N, 7.0. Found: C, 69.3; H, 7.7; N, 7.2.

N-Phenylcarbamate of (±)-Nonane-1,3-diol

(±)-Nonane-1,3-diol was mixed with one-half by weight of phenyl isocyanate and the solution was stored at room temperature for 6 hours, then gently warmed to 60° C for 0.5 hour. The crystalline product was recrystallized from 2,2,4-trimethylpentane and melted at 83–84.5° C. The melting point was depressed upon admixture with the above bis-*N*-phenylcarbamate. Examination of the infrared spectrum indicated the presence of bands due to OH and NH stretching frequencies in approximately equal intensity. Anal. Calc. for $C_{16}H_{25}O_3N$: C, 68.8; H, 9.0; N, 5.0. Found: C, 69.0; H, 9.1; N, 5.0.

STEROIDS

PART IV. CONDENSATION OF CHOLESTAN-3-ONE AND CHOLESTANE-3,6-DIONE WITH FORMALDEHYDE[1,2]

TED H. WAID AND ALFRED TAURINS

ABSTRACT

Cholestan-3-one and cholestane-3,6-dione were allowed to react under the conditions of the Mannich reaction with paraformaldehyde and amine hydrochlorides. The products obtained proved to be methylene-bis-ketones, and were formulated as di(2,2′-3-oxocholestanyl)methane and di(4,4′-3,6-dioxocholestanyl)methane respectively.

DISCUSSION

In the steroid series, the Mannich reaction has been applied to compounds containing an activated methylene group in ring D, or in the aliphatic side chain attached to C_{17} (1, 2) and also to certain estrogens (3). A 21-aminomethyl, and several 16-aminomethyl and 2-dialkylaminomethyl steroid derivatives, have been prepared in this way.

The present investigation was undertaken in order to study, by means of the Mannich reaction, the reactivity of hydrogen atoms in rings A and B of certain steroidal ketones. The steroidal materials selected for study were 5-cholesten-3-one (I) (4), 4,4-dimethyl-5-cholesten-3-one (II) (5), 4-cholesten-3-one (III) (4, 6), cholestan-3-one (IV) (7, 8), and cholestane-3,6-dione (V) (9).

The procedure used for the Mannich condensations that were attempted consisted in allowing the amine and paraformaldehyde to react, then adding the keto compound gradually. Paraformaldehyde was used instead of a 40% aqueous solution of formaldehyde because of the very low solubility of oxosteroids in water. The amines and hydrochlorides used in the reactions were morpholine, piperidine, and dimethylamine.

It was thought that if the isomerization of the double bond in 5-cholesten-3-one (I) from C_5 to C_4 could be avoided, then the hydrogen at C_4 should be particularly active due to the activation by the adjacent double bond and the keto group. In all the attempts to react morpholine with the Δ^5-3-one (I) and paraformaldehyde, brown, viscous oils, which could not be crystallized, and did not contain nitrogen, were obtained. Efforts to condense piperidine under similar conditions, using absolute ethanol, *n*-butyl alcohol, and isoamyl alcohol as solvents, also resulted in the formation of oils. When morpholine, piperidine, or dimethylamine hydrochloride was used in place of the free amine in the foregoing reaction, a viscous oil was obtained, and the unreacted amine hydrochloride was recovered in high yield.

In view of these results, it was felt that the high degree of reactivity of the methylene group in position 4 of 5-cholesten-3-one (I) might be responsible for the rapid formation of oily substances under various conditions. It was decided, therefore, to examine the reactivity of the methylene group in 2-position in a compound in which position 4 would be rendered inactive. Under conditions similar to those employed previously, 4,4-dimethyl-5-cholesten-3-one (II) failed to react with morpholine, piperidine, their hydrochlorides, or

[1]*Manuscript received May 2, 1960.*

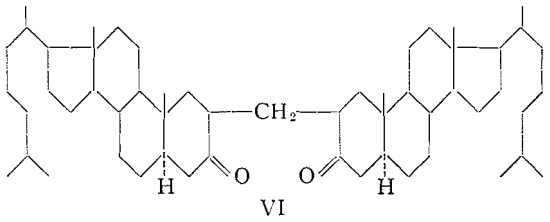
dimethylamine hydrochloride, and was recovered unchanged after 4 hours refluxing in isoamyl alcohol.

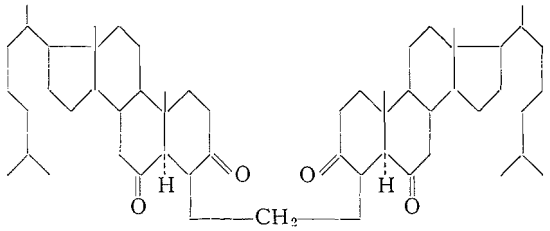
Unreacted starting material also was recovered in high yield from the reactions of 4-cholesten-3-one (III) with paraformaldehyde and morpholine or piperidine. Since bromination of III occurs under enolizing conditions (10), it was concluded that the ketone was not sufficiently enolized by the secondary amines to participate in the reaction. In the reactions of III with morpholine, piperidine, and dimethylamine hydrochlorides, after refluxing for 1/2 hour in isoamyl alcohol, *n*-butyl alcohol, or absolute ethanol, non-crystalline oils were isolated. The absence of the characteristic odor of formaldehyde in the reaction mixtures indicated that the oils were a condensation product of III with formaldehyde.

By analogy with the acid-catalyzed halogenation of ketones (11, 12), an electrophilic substitution, it was presumed that the Mannich condensation in the cases of cholestan-3-one (IV) and cholestane 3,6-dione (V) would proceed via enolization of the ketones. Since the enol forms of IV and V were not stabilized by conjugation, as was the case in the unsaturated ketones, it was expected that the acidic hydrogen atoms of the saturated ketones would exhibit less reactivity.



When cholestan-3-one (IV) was refluxed in isoamyl alcohol for 20–30 minutes with paraformaldehyde and morpholine hydrochloride, a product melting at 208–210° and containing no nitrogen was obtained in a 35% yield. An identical material was produced when piperidine hydrochloride was substituted for the morpholine hydrochloride. The product appeared to be a condensation product of IV with formaldehyde and, on the basis of the analytical results and a comparative study of infrared spectra, was formulated as a methylene-bis-ketone. In the infrared spectrum of cholestan-3-one (IV), the carbonyl band appeared at 1710 cm^{-1}. The band of medium intensity present at 1425 cm^{-1} was considered to be due to the C–H scissoring vibrations in an unsubstituted methylene group at C_2 or C_4 in a 3-oxosteroid (13, 14). In the spectrum of the reaction product, two carbonyl bands occurred at 1735 cm^{-1} and 1700 cm^{-1}. The absorption due to methylene groups adjacent to the ketone appeared at 1413 cm^{-1}, and was of weak intensity. This spectroscopic evidence was interpreted as indicating that the new compound contained two residues of cholestan-3-one joined by a methylene bridge in either 2 or 4 position. It was noted that bromination of cholestan-3-one with bromine in acidic medium takes place in 2-position (15). Since an aldol condensation in basic or acidic medium proceeds through enolization, it is reasonable to postulate that the linkage in the methylene-bis-ketone is between the carbon atoms in 2-position. Consequently the compound was designated as di(2,2′-3-oxocholestanyl)methane (VI).

When morpholine and piperidine were used in place of their hydrochlorides in the foregoing reaction, the starting material IV was recovered unchanged. Both the ketone (IV) and the amine could be considered as competing nucleophilic reactants with regard to the electrophilic reagent formaldehyde. When the amine hydrochloride was used in the reaction, the ketone was the only nucleophilic species present, and condensation with the formaldehyde occurred.



A non-nitrogenous product melting at 242–242.5° was obtained in a 21% yield (based on V) when cholestane-3,6-dione (V) was refluxed with paraformaldehyde and morpholine or piperidine hydrochloride for 45 minutes in isoamyl alcohol. The analytical results and the infrared absorption spectrum inferred a methylene-bis-ketone structure. In the infrared, the dione (V) absorbed at 1710 cm^{-1} and with low intensity at 1420 cm^{-1}. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spectrum of the condensation product exhibited two bands in the carbonyl region at 1727 cm^{-1} and 1710 cm^{-1}. The band due to methylene groups was shifted to 1425 cm^{-1} and existed as a shoulder on the more intense band at 1465 cm^{-1}. In V, there are methylene groups at positions 2, 4, and 7 adjacent to keto functions. The reactivity of the hydrogen atoms belonging to these methylene groups was evaluated by a consideration of other substitution reactions. Bromination of the dione (V) with 3 moles of bromine in acidic medium leads to the formation of 4,7-dibromo-4-cholestene-3,6-dione (VII) (16). Apparently an initial electrophilic attack occurs at position 4 in this reaction. Therefore it was considered that the linkage in the methylene-bis-ketone was between the carbon atoms in 4-position, and the compound was formulated as di(4,4′-3,6-dioxocholestanyl) methane (VIII).

VI

VIII

When the free amines were used in place of their hydrochloride salts, the unreacted dione (V) was recovered. The ketones IV and V also were recovered unchanged when they were allowed to react with paraformaldehyde in neutral or acidic media.

Two alternative mechanisms are offered to explain the condensation of cholestan-3-one (IV) and cholestane-3,6-dione (V) with formaldehyde. Scheme A (Fig. 1) represents an abnormal Mannich condensation in an acid–base catalyzed system. Although there is no proof of an intermediate Mannich base, several similar reactions leading to methylene-bis-molecular compounds are known to respond to alkaline and acidic catalysis in much the same manner as the Mannich reaction (17–20). According to the mechanism (Fig. 1), a carbonium ion (ix) is formed from formaldehyde and the secondary amine through the intermediate methylene-bis-amine (v) or methylolamine (vi). This cation combines then with the anion (iv) derived from the ketone as in a normal Mannich reaction. Formation of the cation (ix) is promoted by hydrochloric acid, and that of the anion (iv) by the amine present in the system. Then cleavage of the C—N bond occurs with the loss of amine and formation of the carbonium ion (xii). Such a possibility has been clearly demonstrated by Hellman (21), who reviewed and studied extensively the use of Mannich bases for alkylations. In the final step, the cation (xii) condenses with the anion (iv) to give the methylene-bis-ketone (xiii).

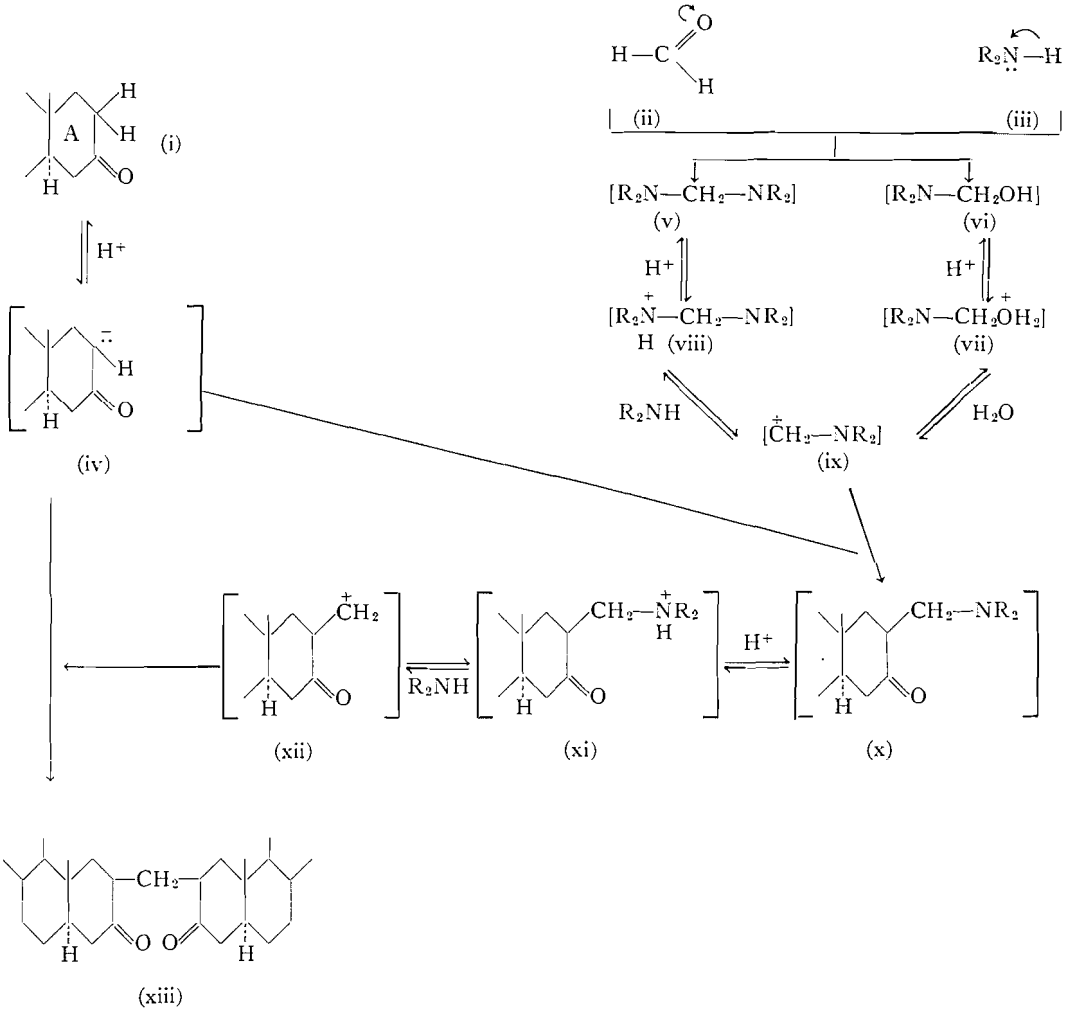

FIG. 1. Scheme A: mechanism proposed for an abnormal Mannich reaction.

The alternative mechanism is presented (Fig. 2) in view of the uncertainty about whether a secondary amine derived from its hydrochloride participates actively in the reaction or acts only as a buffer toward the hydrochloric acid. This mechanism accounts for an acid-induced aldol condensation of formaldehyde with the oxosteroid. In the first step, a transition state complex (ii) is formed which rearranges to a β-ketomethylol (iii). The latter is unstable in acidic medium, and gives, upon protonation, an oxonium ion (iv) which by loss of a molecule of water affords a carbonium ion (v). Finally the carbonium ion combines with the carbanion (vi) derived from the ketone (i) to give the methylene-bis-ketone (vii).

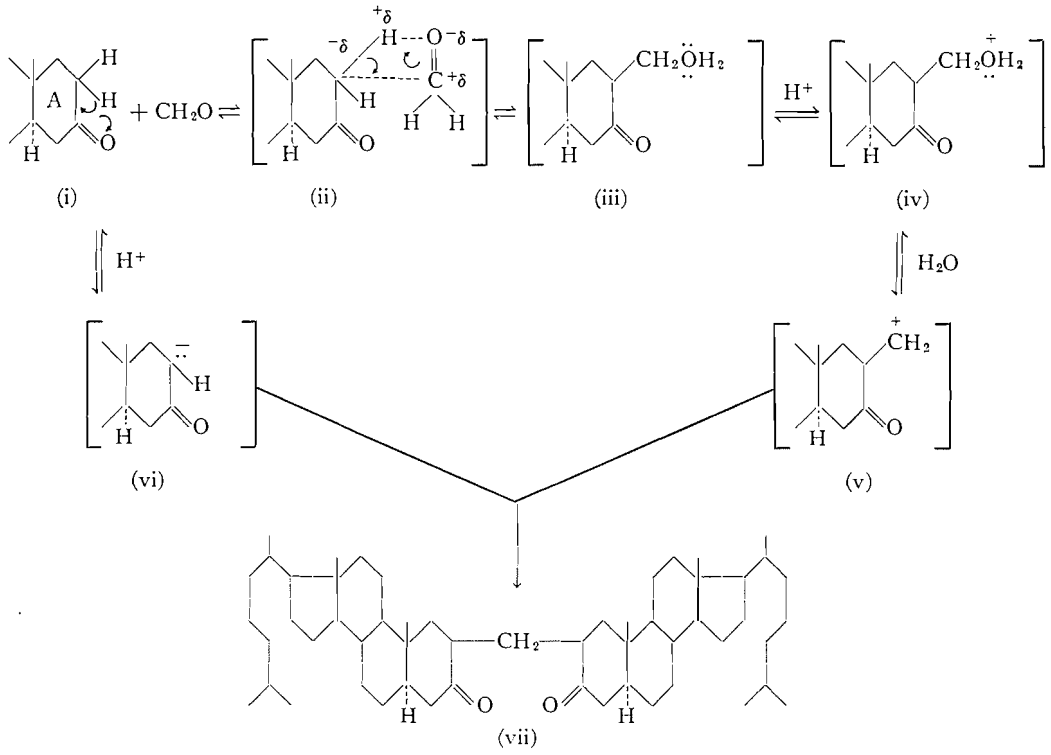

FIG. 2. Scheme B: mechanism proposed for an abnormal Mannich reaction.

EXPERIMENTAL

The melting points were determined in a Thiele-Dennis melting-point tube containing Dow Corning silicone fluid No. D.C. 550 and are uncorrected. The analyses were performed by the Schwarzkopf microanalytical laboratory, Woodside, N.Y., U.S.A. All infrared spectra were determined on a Perkin–Elmer Model 21 double-beam spectrometer equipped with a sodium chloride prism.

The secondary amines were dried by refluxing over sodium hydroxide pellets for 6 hours, distilling, and storing over solid sodium hydroxide. The hydrochloride salts of the amines were prepared by addition of a calculated amount of dilute hydrochloric acid to the amine with cooling, evaporation to dryness, and recrystallization from absolute ethanol.

Attempted Condensation of 5-Cholesten-3-one (I) with Paraformaldehyde and Secondary Amine Hydrochlorides

In a nitrogen atmosphere, morpholine hydrochloride (0.185 g), paraformaldehyde (0.04 g), and isoamyl alcohol (6 ml) were stirred for 20 minutes at room temperature. The mixture was heated to reflux, and all solids dissolved. During the next hour, 5-cholesten-3-one (I) (0.58 g) was added in portions, and refluxing was continued for an additional hour. The brown solution was allowed to cool to room temperature, and the long needles which separated were filtered off and dried. The material (0.15 g) melted at 171–172°, and the mixed melting point with an authentic sample of morpholine hydrochloride was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

undepressed. The filtrate was shaken with 4% hydrochloric acid (10 ml), diluted with water, and extracted with ether. The brown ethereal extract was dried, and then allowed to stand with decolorizing carbon Nuchar-C190-N for a few hours at room temperature with occasional shaking. After filtration, the solvent was evaporated *in vacuo*, and the tarry brown residue was dried over phosphorus pentoxide. The oil contained no nitrogen, possessed a tendency to form films, and resisted all attempts of crystallization.

The aqueous layer was made alkaline with saturated sodium carbonate solution, and extracted again with ether. The ethereal extract was washed with water, dried, and evaporated to dryness. No residue remained.

Similar results were obtained when the molar ratios of the ketone, paraformaldehyde, and morpholine hydrochloride were varied from 1:1:1 to 1:2:3 and 1:5:7.5. The refluxing time was varied from 15 minutes to 2 hours in each case. The results were not affected when absolute ethanol or *n*-butanol was substituted for isoamyl alcohol under the previously described conditions. When dimethylamine and piperidine hydrochlorides were used in place of morpholine hydrochloride in the foregoing experiments, film-forming oils which could not be crystallized resulted in all cases. These oils contained no nitrogen. In each experiment, the major part of the amine salt was recovered.

Attempted Condensation of 4,4-Dimethyl-5-cholesten-3-one (II) with Paraformaldehyde and Morpholine Hydrochloride

When II, morpholine hydrochloride, and paraformaldehyde were heated in isoamyl alcohol for 4 hours under the conditions described in the previous procedure, morpholine hydrochloride was recovered in a 75% yield.

Similar results were obtained when piperidine and dimethylamine hydrochlorides were used in place of morpholine hydrochloride, and also when morpholine itself was used.

Attempted Condensation of 4-Cholesten-3-one (III) with Paraformaldehyde and Secondary Amine Hydrochlorides

The procedure outlined for the attempted condensations of 5-cholesten-3-one (I) was followed, and morpholine, piperidine, and dimethylamine hydrochlorides were used. The molar ratios of the ketone, paraformaldehyde, and amine salts were varied from 1:1:1 to 1:2:3 and 1:5:7.5. Absolute ethanol, *n*-butanol, and isoamyl alcohol were employed as solvents, and the refluxing time was varied from 1/2 hour to 2 hours in each case. Brown viscous oils, possessing film-forming tendencies were the only isolable products in all instances. The oils contained no nitrogen, and could not be crystallized.

Attempted Condensation of 4-Cholesten-3-one (III) with Paraformaldehyde and Secondary Amines

When the conditions outlined for the condensation reaction of 5-cholesten-3-one (I) were employed, using either piperidine or morpholine, an 80% recovery of the starting material III was achieved. When the refluxing time was extended to 2 hours or longer, a brown amorphous material which could not be crystallized resulted in each case. Varying the molar ratios of the reactants did not affect the course of the reaction.

Di(2,2'-3-oxocholestanyl)methane (VI)

A mixture of cholestan-3-one (IV) (0.58 g), paraformaldehyde (0.05 g), morpholine hydrochloride (0.2 g), and isoamyl alcohol (2.5 ml) was heated to reflux, with stirring, in a nitrogen atmosphere. All solids dissolved when the temperature reached 115°, after 5 minutes heating. When the solution had been refluxed for 20–30 minutes, solid material precipitated. The mixture was allowed to cool to room temperature, and was refrigerated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

overnight. The product (0.33 g) was isolated. It was a white crystalline solid, melting at 205–207° to a deep brown liquid. Recrystallization from benzene provided di(2,2′-3-oxocholestanyl)methane (VI), m.p. 208–210°, ν_{max} 1725, 1700 cm^{-1} (C=O). Anal. Calc. for $C_{55}H_{92}O_2$: C, 84.18; H, 11.73. Found: C, 83.86; H, 11.64%.

A similar yield of VI was obtained in an analogous reaction in which piperidine hydrochloride was substituted for morpholine hydrochloride.

When the reaction was carried out in absolute ethanol, and refluxing was maintained for 2 hours, unreacted cholestan-3-one (IV) was recovered in 95% yield. The yield of product was unaffected by a change in the molar ratio of ketone (IV) to paraformaldehyde from 1:1 to 2:1.

Di(4,4′-3,6-dioxocholestanyl)methane (VII)

In a nitrogen atmosphere, a mixture of cholestane-3,6-dione (VI) (0.60 g), paraformaldehyde (0.05 g), morpholine hydrochloride (0.2 g), and isoamyl alcohol (3 ml) was stirred, and heated to reflux. All solids dissolved when the temperature reached 105°. After 45 minutes refluxing, the solution was dark yellow. Crystalline material separated on cooling of the solution to room temperature. The mixture was treated with water (0.5 ml), and the organic layer was separated, dried over anhydrous magnesium sulphate, and evaporated to dryness *in vacuo*. The solid residue was crystallized from acetone (250 ml) yielding soft needles (0.254 g) melting at 214–217°. Recrystallization from acetone provided di(4,4′-3,6-dioxocholestanyl)methane (VII), m.p. 242–242.5°, ν_{max}^{nujol} 1727, 1710 cm^{-1} (C=O). Anal. Calc. for $C_{55}H_{88}O_4$: C, 82.51; H, 11.83. Found: C, 82.09; H, 11.82%.

The yield of product was not affected by varying the molar ratio of ketone and paraformaldehyde from 1:1 to 2:1. In dioxane the reaction was complete after 60–70 minutes' refluxing. The yield of product was considerably lower than when isoamyl alcohol was the solvent.

ACKNOWLEDGMENT

The authors wish to acknowledge the assistance of Dr. B. G. Ketcheson in the preparation of this manuscript.

CATALYTIC OXIDATION OF CARBON MONOXIDE PRESENT IN LOW CONCENTRATIONS[1]

S. Sourirajan[2] and Mauro A. Accomazzo

ABSTRACT

The oxidation of carbon monoxide present in low concentrations has been studied in the presence of the CuO–Al_2O_3 (1:1) catalyst using 1,000–10,000 p.p.m. of CO in air in the temperature range 120°–322° C, and gas space velocities ranging from 8,000–16,000 hr^{-1}. It was found that for the entire concentration range studied, the percentage of oxidation of CO at a given temperature was independent of its initial concentration and at temperatures above 200° C, more than 95% of CO was removed by oxidation at all gas space velocities up to 16,000 hr^{-1}. A simple first-order rate equation was found to fit the experimental data well. The presence of water vapor in the reactant gas was found to have no effect on the efficiency of the catalyst at temperatures above 225° C. The possible practical utility of the above catalyst for the removal of carbon monoxide present in auto exhaust gases was tested using a six-cylinder Chevrolet engine run on leaded gasoline fuel. It was found that under all conditions of engine operation, more than 99% of carbon monoxide present in the exhaust gases was removed by catalytic oxidation when the initial temperature of the catalyst bed was kept at or above 220° C.

INTRODUCTION

The development of suitable catalysts for the efficient oxidation of carbon monoxide present in low concentrations in the exhaust gases emanating from various combustion sources is of particular importance as a possible method of air pollution control. An extensive literature is available on the heterogeneous oxidation of carbon monoxide (1, 2). The object of this investigation is to study the efficiency and the practical utility of the copper oxide – alumina (1:1) catalyst for the oxidation of low concentrations of carbon monoxide, in view of the proved effectiveness of the above catalyst for the total oxidation of hydrocarbons (3).

EXPERIMENTAL DETAILS

The apparatus used was similar to the one described earlier (3). The carbon monoxide gas was mixed with air before entering the catalyst bed, which was placed in a vycor glass reactor tube enclosed in a furnace. The gas flow rates were measured by appropriate flowmeters which were initially calibrated. The lower section of the vycor tube, filled with porcelain beads, served as a preheater for the reactant gases. The temperature of the catalyst bed was measured by means of a thermocouple. The gases flowing through the preheater and reactor tube could be sampled both immediately before and after passing through the catalyst bed. The carbon monoxide content of the samples was analyzed by a combustible analyzer developed by Miller (4). It consisted essentially of two cells constituting the two arms of a Wheatstone bridge arrangement; the combustion of the gas sample material took place on the surface of a hot platinum wire in one of the cells, and the resistance change resulting from the increase in temperature due to combustion measured the concentration of the combustibles in the gas mixture entering or leaving the catalyst bed. The instrument, coupled to an automatic recorder, was initially calibrated for different concentrations of carbon monoxide. The analyzer gave results reproducible within 1%.

The concentration of carbon monoxide in the reactant gas ranged from 1,000–10,000 p.p.m. in diluent air. The temperature of the catalyst bed was varied from 120°–322° C

[1]*Manuscript received June 24, 1960.*

[2]*Present address: Institute of Geophysics, University of California, Los Angeles 24, California.*

and the gas space velocities (volume of gas per hour per volume of catalyst) ranged from 8,000 to 16,000 hr^{-1}. During the reaction, the furnace controls were set so that the temperature gradient across the different parts of the catalyst bed was less than 10° C. Under steady-state conditions, the highest temperature of the catalyst bed (taken as the reaction temperature), the gas flow rate, and the carbon monoxide concentrations in the gases entering and leaving the catalyst bed were recorded and the efficiency of the catalyst for the oxidation of carbon monoxide was evaluated.

The catalyst was prepared as follows. Copper hydroxide was precipitated on the alumina carrier from a hot dilute aqueous solution of copper nitrate by the addition of an excess of sodium hydroxide. The precipitate was then filtered and washed free of alkali. The wet solid mass was then extruded, dried, and pelleted. The composition of the catalyst was $CuO:Al_2O_3 = 1:1$. The catalyst material was heated in the reactor at 450° C for a period of 12 hours in a current of air before use in the experiments. The surface area of the catalyst, as determined by the B.E.T. method, was 128 square meters/g, and its pore volume, as determined by the helium–mercury method, was 0.56 cc/g. The mean radius of the pores in the catalyst, as calculated from its known surface area and pore volume measurements assuming cylindrical pores, was 87 Å. Twenty-five cubic centimeters of catalyst material was used in all these experiments.

EXPERIMENTAL RESULTS AND DISCUSSION

Efficiency of the Catalyst

Tables I and II give the experimental results obtained on the oxidation of carbon monoxide present in the concentration range of 1,000 to 10,000 p.p.m. in diluent air in the presence of the copper oxide – alumina catalyst described above. Figures 1 and 2 show the effect of temperature and gas space velocity, respectively, on the extent of oxidation. Most of the experiments were carried out at a gas space velocity of 10,000 hr^{-1} or more in order to simulate comparable conditions for practical utilization of the catalyst in air pollution control devices. The results showed that (i) for the entire concentration range studied, the percentage of oxidation of CO at a given temperature was independent of its initial concentration and (ii) at temperatures above 200° C, more than 95% of CO was removed by oxidation at all gas space velocities up to 16,000 hr^{-1}. Thus, the above copper oxide – alumina catalyst was found to be a very efficient one for the oxidation of CO present in low concentrations.

Rate Equation for Reactor Design

Garner, Gray, and Stone (5) investigated the nature of the interaction of carbon monoxide and oxygen on the surface of the copper oxide catalyst through surface conductivity and heat of adsorption measurements. They found that in the temperature range 100°–270° C, the rate-controlling step in the adsorption of oxygen on plane surfaces was first order. When a mixture of carbon monoxide and oxygen was admitted to the catalyst surface, the first process was always the saturation of the surface with carbon monoxide. They also observed that the rate of oxidation of carbon monoxide in the presence of the copper oxide catalyst was independent of carbon monoxide pressure and proportional to the oxygen pressure. They hence concluded that the $CO–O_2$ reaction occurred on the catalyst surface saturated with carbon monoxide.

The experimental data obtained in this work, however, show that the rate of catalytic oxidation of CO present in low concentrations by excess oxygen, is more nearly first order

For flow reactors,

$$[1] \qquad \frac{V_R}{F} = \int_0^Z \frac{dZ}{r},$$

$$[2] \qquad r = -\frac{dC}{d\theta} = kC^nC_{O_2}^m.$$

When the oxygen concentration is much in excess,

$$[3] \qquad kC_{O_2}^m \approx k' = f(T)$$

therefore

$$[4] \qquad \frac{V_R}{F} = \int_0^Z \frac{dZ}{k'C^n}.$$

At any point in the reactor where a conversion of fraction Z has taken place, the concentration of carbon monoxide can be written as

$$[5] \qquad C = C_0(1-Z).$$

Hence at constant temperature,

$$[6] \qquad \frac{V_R}{F} = \frac{1}{k'C_0^n}\int_0^Z \frac{dZ}{(1-Z)^n}$$

$$[7] \qquad = \frac{1}{k'C_0}\ln\frac{1}{1-Z} \qquad \text{for } n = 1.$$

Since

$$[8] \qquad F = QC_0\frac{T}{T_1}$$

equation [7] becomes

$$[9] \qquad k'\frac{V_R}{Q} = \frac{T}{T_1}\ln\frac{1}{(1-Z)}.$$

Hence a plot of V_R/Q vs. $(T/T_1)\ln[1/(1-Z)]$ should be a straight line (with slope = k') passing through the origin. Such plots are shown in Fig. 3, and the graphs obtained are seen to be nearly straight lines justifying the essential validity of equation [9].

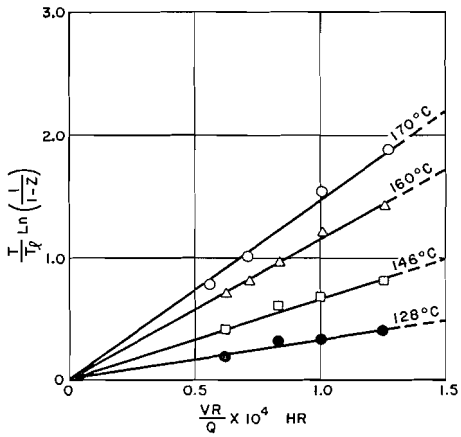

FIG. 3. Apparent first-order plot for the catalytic oxidation of carbon monoxide present in low concentrations.

Assuming

$$k' = f(T) = Ae^{-E/RT} \quad [10]$$

the plot of ln k' vs. $1/T$ should be a straight line with slope $= -E/R$. Such a plot is shown in Fig. 4 which is also seen to be nearly a straight line giving an apparent activation

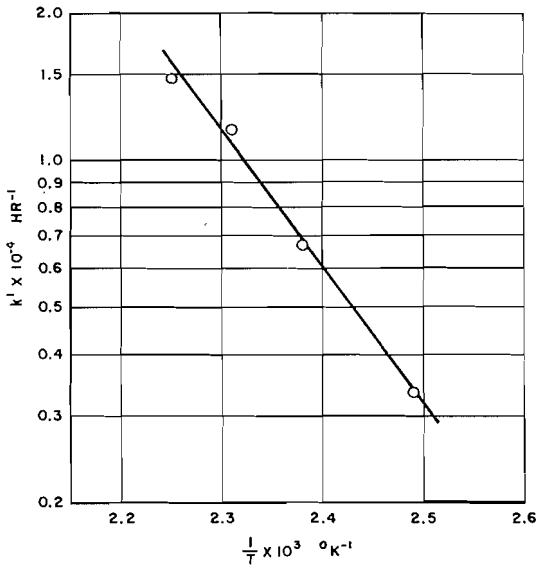

FIG. 4. Variation of reaction rate constant with temperature.

energy of 12.8 kcal/g.mole with $A = 3.1\times10^{10}$ hr^{-1}. Thus

$$r = Ae^{-E/RT}C \quad [11]$$

is found to be a simple rate equation useful for reactor design applicable to the experimental data reported previously for the catalytic oxidation of carbon monoxide present in low concentrations.

Experiments with Water Vapor in Reactants

It is known that water vapor retards the catalytic oxidation of carbon monoxide (6). Since considerable amounts of water vapor may be present in gases issuing from various air-polluting sources, it is important to consider the efficiency of the above CuO–Al_2O_3 catalyst for the oxidation of CO in presence of water vapor. With 2000 p.p.m. of CO in air saturated with water vapor at the laboratory temperature (i.e., with water vapor in the feed = 3.0%) experiments were carried out on the effect of temperature on the extent of oxidation at a gas space velocity of 10,000 hr^{-1}. The results obtained are given in Fig. 5.

It was found that the presence of water vapor did retard the rate of reaction at lower temperatures, but it had no effect at temperatures higher than 225° C. Thus, at temperatures higher than 225° C, CO present in air in low concentrations, even with a large relative proportion of water vapor, was almost completely removed by oxidation in presence of the above CuO–Al_2O_3 catalyst.

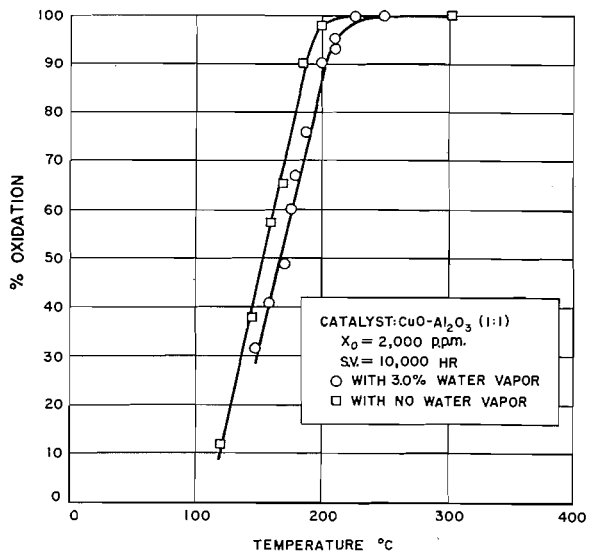

FIG. 5. Effect of water vapor and temperature on the catalytic oxidation of carbon monoxide.

Experiments with Auto Exhaust Gases

The possible practical utility of the above catalyst for the removal of carbon monoxide present in auto exhaust gases was then tested. For this purpose, a 1955 six-cylinder Chevrolet engine coupled to an eddy current dynamometer was used. The engine was run on leaded gasoline fuel. The air/fuel ratio in the engine was determined by a DuMont type 932 exhaust gas analyzer. Part of the exhaust gases from the engine was cooled to room temperature, mixed with excess air (2 to 4 times that needed for complete combustion), and then passed through the catalyst bed initially kept at 200°–220° C, at a gas space velocity of 10,000 hr^{-1} at 25° C. The amount of carbon monoxide present in the engine exhaust gases was determined by orsat analysis, and that present in the gases leaving the catalyst bed was determined by means of a Mines Safety Appliance carbon monoxide indicator (using hopcalite catalyst) capable of analyzing CO within 50 p.p.m. Under the different engine conditions tested, the concentration of CO in the exhaust gases ranged from 1.5–7%; as soon as the air-mixed exhaust gases from the engine entered the reactor, the temperature of the catalyst bed increased rapidly due to reaction and attained steady-state conditions within 10 minutes. The experimental results obtained under the varying conditions of engine operation are recorded in Table III. It was found

TABLE III

Data on the use of the CuO–Al_2O_3 (1:1) catalyst for the removal of carbon monoxide present in auto engine exhaust gases

that under all conditions of engine operation, more than 99% of carbon monoxide present in the exhaust gases was removed by catalytic oxidation. Thus, the above CuO–Al_2O_3 (1:1) catalyst was found to be practically useful for the almost complete removal of CO present in the auto exhaust gases. Coupled with the fact that the above catalyst was already shown to be effective for the removal of hydrocarbons present in low concentrations (3), the experimental results reported in this paper indicate the possibility of developing a practical antismog catalyst containing copper oxide for the simultaneous oxidation of both hydrocarbons and carbon monoxide present in low concentrations in gases issuing from various air-polluting sources.

A CHEMICAL PROCEDURE FOR DETERMINATION OF THE C^{14} DISTRIBUTION IN SOME LABELLED CARBOHYDRATES[1]

M. J. Abercrombie and J. K. N. Jones

ABSTRACT

A chemical procedure for the determination of the labelling in the terminal carbon atoms of some unsubstituted carbohydrates using 20 mg of material is described. The procedure has been tested on D-glucose-1-C^{14}, D-glucose-6-C^{14}, D-glucose-2-C^{14}, and D-glucuronolactone-6-C^{14} with satisfactory results.

A procedure based on the work of Smith *et al.* for the degradation of hexoses via the methyl glucopyranosides is described and has been applied to D-glucose-1-C^{14} and D-glucose-6-C^{14} with satisfactory results. These procedures have been designed to give barium carbonate as the final product in each determination.

INTRODUCTION

There are many procedures for determining C^{14} distribution in carbohydrates described in the literature (1–14), but of these only two afford a complete determination of the labelling on a millimole scale (11, 13). The remainder either require large amounts of material or do not give the labelling in all of the carbon atoms. Gunsalus and Gibbs have described a fermentation procedure with *Leuconostoc mesenteroides* (11) for the degradation of glucose and Altermatt, Blackwood, and Neish (12) have extended the method to the degradation of xylose. Although this procedure yields satisfactory results it is limited to those sugars which the organism will ferment. Boothroyd, Brown, Thorn, and Neish have described chemical procedures for the determination of the C^{14} labelling in glucose (13) and xylose (14) (see also 10). This method is applicable to many sugars.

A limitation to the methods available for radioactive degradation procedures is the type of counting apparatus available. If counting of barium carbonate plates is the only method available then the combustion of large molecules, such as dimedone and phenylhydrazone derivatives, is not always suitable, since the labelled moiety becomes diluted with large quantities of unlabelled carbon material.

The first part of this paper describes a method by which the C^{14} labelling in the terminal position of any unsubstituted carbohydrate may be determined on a minimum of material (20 mg). This quantity is the amount required to give 30 mg of barium carbonate for each of the three determinations involved.

The sodium metaperiodate oxidation of sugars has (16, 17) been extensively studied in this (15) and other laboratories. It has been shown that complete oxidation of an aldohexose to 5 moles of formic acid (C 1–5) and 1 mole of formaldehyde (C-6) takes place rapidly at pH 8.0 (15) (phosphate buffer). Hough *et al.* (17) have shown that the oxidation of glucuronic acid proceeds smoothly to give 1 mole of carbon dioxide (C-6) and 5 moles of formic (C 1–5) at pH 3.6 (acetate buffer). The borohydride reduction of oligosaccharides and subsequent metaperiodate oxidation carried out *in situ* without isolation of the intermediatory glycitol derivative has been studied (18). These methods when applied to monosaccharides gave a method for determining the labelling in the terminal carbon atoms.

The specific activity of the sugar can be determined by the complete combustion of the material to carbon dioxide (C 1–6). Metaperiodate oxidation and oxidation of the formic acid liberated to carbon dioxide with mercuric acetate (7) gives the specific activity of carbon atoms 1–5. Similarly reduction with borohydride and metaperiodate oxidation

of the glycitol *in situ* gives the specific activity of carbon atoms 2–5. Thus by difference the labelling in C-1 and C-6 can be determined. Although the determination of activities by difference has been criticized by many workers it can be seen from Table II that the results obtained from the above procedure are within ±2% of those expected. The figures in Table I show that the results are reproducible within ±2% except in the determinations where the activity is very small.

*Degradation by method A. †Degradation by method B.

The above method requires a minimum of material since the activity of the formic acid and not the formaldehyde is determined. The quantity of formic acid liberated is fivefold that of the formaldehyde in the metaperiodate oxidation and twice that of the formaldehyde in the borohydride/metaperiodate oxidation. Thus the same quantity of barium carbonate is obtained from a fifth and a half as much sugar respectively.

The second part of this paper describes a chemical method for the degradation of any aldohexose, using a single sample of material, for determination of the activity in each of the six positions.

The method is outlined in Fig. 1. Smith *et al.* have studied the metaperiodate oxidation of methyl glycosides (19) and have isolated the dialdehyde (II), characterized the triol (III), and isolated derivatives of glycerol and glycolic aldehyde (IV). Neish *et al.* (13) attempted to make use of these products for a degradation procedure, but found that C-2 was contaminated by C-1 due to enolization of the glycolic aldehyde.

In the present work the procedure was carried a stage further to give glycerol and ethylene glycol (V). These compounds have been characterized as glycerol tris-*p*-nitrobenzoate and ethylene glycol-bis-*p*-nitrobenzoate. The glycerol / ethylene glycol mixture is obtained in high yield (95% based on the methyl glycoside).

A considerable amount of time was spent devising methods for the separation of glycerol and ethylene glycol. The best method of separation would be to use gas-phase chromatography with a column that could separate milligram quantities. Separation on resin columns (20) has been attempted but only a partial separation has been obtained to date. The components can be separated satisfactorily on a cellulose column using butanol/ethanol/water, 6:2:1. Excellent separation is achieved by paper chromatography when the same solvent mixture was used but in the ratio 3:1:1. In the latter two

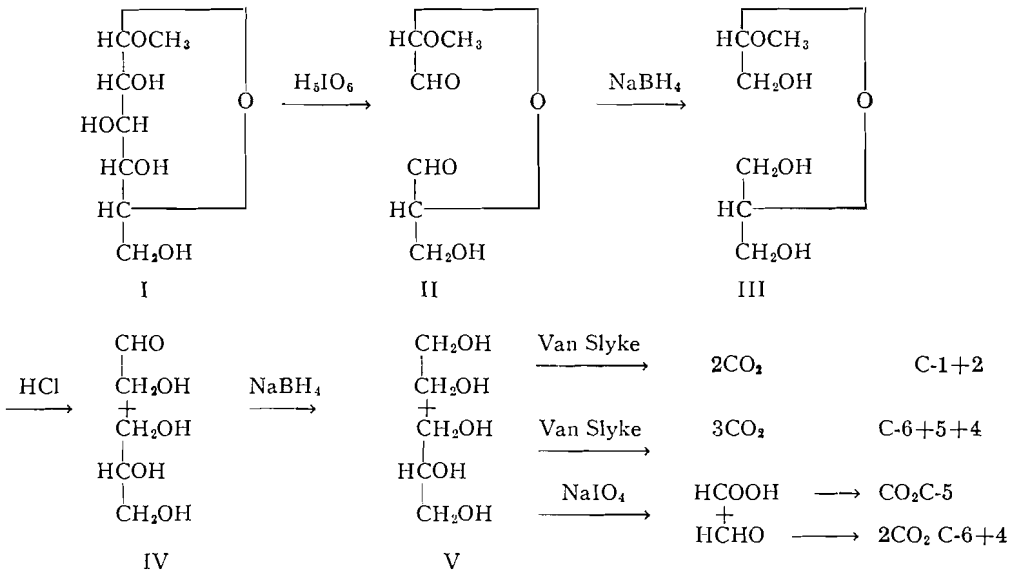

FIG. 1.

techniques 95% or better recovery of glycerol was obtained but the recovery of ethylene glycol was considerably less (50–65%).

The activity of the ethylene glycol was determined by combustion (C 1+2). The glycerol was oxidized with aqueous sodium metaperiodate to give 2 moles of formaldehyde (C 6+4) and 1 mole of formic acid (C-5). This degradation procedure gives us the labelling in C (1+2), C-3, C-5, and C (4+6). Since the labelling in C-1 and C-6 can be obtained from a small quantity of material as described at the beginning of this paper the C^{14} labelling in all six carbon atoms of the aldohexose can be determiued. The results are collected in Table II.
