THE MECHANISM OF ORGANOMERCURIAL OXIDATION BY MERCURIC SALTS[1,2]

J. H. ROBSON AND GEORGE F WRIGHT

ABSTRACT

It has been shown that the oxidation of organomercuric salts by inorganic mercuric salts is inhibited by oxygen, accelerated to some extent by acids, and will form esters as products even in the presence of much water. Moreover, the system will polymerize acrylonitrile. These evidences of free radical participation are substantiated by the formation of the same products when pernitrous acid replaces inorganic mercuric salt in the system. Kinetic studies show that radicals are involved in a self-regenerating chain in which active monomeric mercurous salt seems to be the carrier.

It has been shown previously (1) that the oxidation of organomercuric salts in which the anion is nitrato is much more facile than maintains for systems in which the salts are acetates. Because of this difference in reactivity we have found it convenient to discuss the nitrato and acetato systems separately.

THE OXIDATION OF ORGANOMERCURIC NITRATES

In the earlier publication (1) it was shown that the reaction of benzylmercuric nitrate with mercuric nitrate in methanol led to benzyl methyl ether and benzyl nitrate. Additional examples have now been sought. Although *n*-butylmercuric nitrate will not react, cyclohexylmercuric nitrate in methanol containing mercuric nitrate gives an 8% yield of methoxycyclohexane and a 31% yield of cyclohexyl nitrate.

Of greater interest is the observation that benzylmercuric nitrate with mercuric nitrate in water yields not only benzyl alcohol, benzaldehyde, and benzoic acid but also benzyl nitrate. Similarly cyclohexylmercuric nitrate with mercuric nitrate in water gives not only a 40% yield of cyclohexanol and a trace of formylcyclopentane (to be explained in a forthcoming publication) but also a 21% yield of cyclohexyl nitrate. The formation of these nitrate esters in aqueous solution is unusual even though these reaction systems are not entirely homogeneous. To be sure benzylmercuric chloride has been found (2) to yield benzyl nitrite and nitrate in nitric acid but little water was present in that system. Certainly cyclohexanol with mercuric nitrate in dilute nitric acid does not form cyclohexyl nitrate according to infrared spectral examination. Indeed the formation of appreciable amounts of nitrate esters under conditions where they should be absent or minimal if they were constituents of heteropolar or ionic equilibria indicates strongly that these nitrate esters are formed by a homopolar or free-radical mechanism.

Of course the generality of the reaction whereby organomercuric nitrates are oxidized by mercuric nitrate is not established by the reactions in aqueous solutions, especially since the second-order kinetics of the non-aqueous reaction (1) cannot be demonstrated in the aqueous systems because of their inhomogeneity. Therefore, direct evidence for the participation of radicals in the methanolic systems has been sought. In the first instance this investigation has involved methanolic mercuric nitrate alone.

It has been shown by Waters and Merz (3, 4) and by Uri (5) that mercuric salts are reduced to the mercurous state in aqueous sulphuric acid containing various organic substrates when Fenton's reagent (6, 7) is added. The significance of the substrate is shown by the absence of reduction when mercuric nitrate in aqueous solution is treated with Fenton's reagent. As was expected, we find that methanolic mercuric nitrate is rapidly reduced to the mercurous level when hydrogen peroxide is added, if, also, a trace of ferrous salt is present. Methanolic mercuric nitrate also is reduced to mercurous nitrate when isobutyryl peroxide is added. The mercurous salt is quite stable in these media and metallic mercury is never detected.*

The reduction of mercuric to mercurous nitrate implies oxidation of the methanolic medium. Since the over-all reaction of mercuric nitrate with an organomercuric nitrate causes oxidation of the latter, it is reasonable to presume that reduction of the inorganic salt forms free radicals from the substrate which in turn act upon the organomercurial. In order to test this presumption we have treated alkylmercuric nitrates (which are stable toward demercuration in acids) with a peracid instead of mercuric nitrate. Although *n*-butylmercuric nitrate is so inert under these conditions that eventual reaction does not lead to recognizable products, we have been successful with cyclohexylmercurials.

Thus pernitrous acid (8, 9, 10, 11) is formed from sodium nitrite and hydrogen peroxide in aqueous medium. When cyclohexylmercuric nitrate is added to this system (together with some methanol for solubilization) mercurous salt is formed. The mercurous salt yield (52%) is not meaningful because Hg^+ is partly oxidized by this medium but it indicates that accompanying radicals are involved in the 30% yield of cyclohexanol and the 25% yield of cyclohexyl nitrate, which are obtained together with some cyclohexanone.

FORMATION AND PERSISTENCE OF RADICALS IN THE MERCURIC NITRATE - ORGANOMERCURIC NITRATE SYSTEM

Although a radical source such as pernitrous acid will convert cyclohexylmercuric nitrate to cyclohexanol and its nitrate ester, and Fenton's reagent will reduce mercuric nitrate in a manner which should produce radicals in and from the substrate, it remains to prove that radicals are formed and do persist in the actual system of organomercuric salt and inorganic mercuric salt.

There is some evidence that the initiation of the radical reaction may arise in the organomercurial itself, since a methanol solution of diphenylpicrylhydrazyl is bleached by each of a series of organomercuric nitrates. When the mercurial is present in large excess the bleaching of the hydrazyl proceeds at a first-order rate (Fig. 1). A series of such hydrazyl bleaching rates are shown in Table I together with the second-order rates for reaction of the same mercurials with mercuric nitrate. It may be seen that there is a rough correlation. Complete agreement cannot be expected because the first-order rate of hydrazyl bleaching would only be the first, inducing, step in the reactions that comprise

**It may be noted that mercuric acetate is not reduced under comparable conditions. Of course a complete reduction would not be expected since mercurous acetate is oxidized by peroxides. However, in the absence of any reduction one recalls Waters' observation that a radical chain reaction does not ordinarily proceed via acetato radicals.*

the second-order oxidation. Nevertheless, the correspondence in relative rates for 6 of 10 entries in this table indicates that radicals are involved in the second-order oxidation.*

If radicals are involved in the oxidation of organomercuric nitrates by mercuric nitrate then these radicals ought to be detectable. To this end we first prepared 2-hydroxycyclohexylmercuric nitrate *in situ* by treatment of cyclohexene with 1 equivalent of mercuric

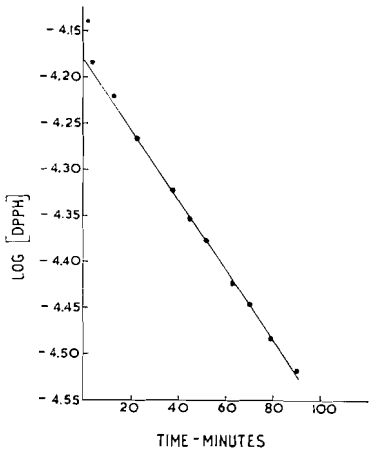

FIG. 1. The reaction of benzylmercuric nitrate (0.01 *M*) and diphenylpicrylhydrazyl (0.000081 *M*) in methanol at 25° C.

TABLE I

Comparison of reaction rates of nitratomercurials with diphenylpicrylhydrazyl and with mercuric nitrate

Nitratomercurial	1st order DPPH reaction ($k\times10^3$)	2nd order oxidation reaction ($k\times10^2$)
1. α-1-Nitratomercuri-2-methoxy-1,2-diphenylethane	21.4	30.0
2. Cyclohexylmercuric nitrate	17.1	2.11
3. Benzylmercuric nitrate	8.85	1.79
4. Isopropylmercuric nitrate	7.60	1.79
5. β-2-Methoxycyclohexylmercuric nitrate	3.03	—[a]

9. 1-Phenyl-1-nitratomercuri-2-methyl-2-methoxypropane	2.44	1.74
10. β-1-Nitratomercuri-2-methoxy-1,2-diphenylethane	0.76	1.47

[a]Too slow to be measured.

It is of interest that since submission of this manuscript a monomeric mercurous salt has been postulated (Weinmayer, V. J. Am. Chem. Soc. **81, 3590 (1959)) as an intermediate in the photolysis of oxyalkylmercuric halides. The specificity of methanol or water as the substrate is remindful of the reactions which we have described in the present publication. Moreover the coupling reaction which Weinmayer describes must have been preceded by a homolytic fission into radicals the presence of which are implied in any explanation of the hydrazyl bleaching reaction.*

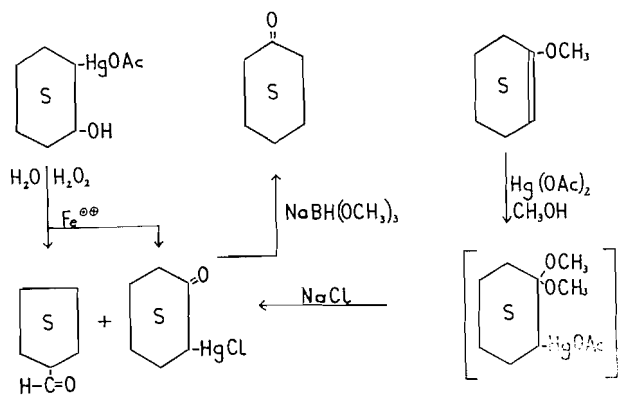
nitrate in aqueous solution and then added acrylonitrile. No polymer was formed during 24 hours. On the other hand, when another equivalent of mercuric nitrate was added together with the polyacrylonitrile polyarylonitrile, the system became turbid after 40 minutes and a 4% yield of acrylonitrile was obtained after 3 hours. Moreover, the turbidity appeared immediately and the yield of polymer was 7% when the system was deaerated before addition of mercuric nitrate and acrylonitrile. Finally the yield of polymer was increased to 24% by inclusion of 4 mole per cent of N,N′-methylene-bis-acrylamide as a cross-linking agent. These yields of polyacrylonitrile (with characteristically diffuse X-ray diffraction pattern) persuade us (12) that radical-induced polymerization has occurred, especially since the same behavior was observed with acrylonitrile and Fenton's reagent in an aqueous medium.



THE OXIDATION OF ORGANOMERCURIC ACETATES

More critical for a study of the oxidation are the reactions of organomercuric acetates with mercuric acetate. The rates of reaction are much slower (sometimes immeasurably so) than are the comparable reaction rates with nitrate salts. Variations which induce or accelerate reaction are more definitive for the systems containing acetate than they are for the system containing nitrate salts. However, the same type of product is obtained in either circumstance.

For example, cyclohexylmercuric acetate in methanol reacts with peracetic acid to give some (8%) mercurous acetate together with the mercuric acetate (73%) which would be expected to be formed by peracetic acid oxidation of mercurous salt. To be sure the organic product is not the expected cyclohexanol but, instead, is cyclohexanone in 75% yield. However, it would appear from the next paragraph that a secondary alcohol can be oxidized by peroxidic reagents in systems containing salts of mercury.

The participation of radicals is more apparent in the reaction of 2-hydroxycyclohexylmercuric acetate with Fenton's reagent. The expected products are mercurous salt and formylcyclopentane if the reaction proceeds like that of 2-hydroxycyclohexylmercuric nitrate with mercuric nitrate in water. Both of these products are obtained. The yields are low because of a by-product, 2-acetoxymercuricyclohexanone (isolated as its chloromercurial), which would appear to have been formed by the action of hydrogen peroxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12

on the original 2-hydroxycyclohexylmercuric acetate in the system containing metallic salts. The identity of the ketomercurial, which has been reported previously (13), has been established by its reduction to cyclohexanone by means of sodium trimethoxyborohydride and by its synthesis from 1-methoxycyclohexene. Parenthetically it is of interest that sodium trimethoxyborohydride reduces the chloromercuri group preferentially with respect to the carbonyl group.

If the action of peroxy compounds on organomercuric salts leads to products like those obtained by action of mercuric salts in primary alcohols then it is reasonable to postulate that mercuric salts in alcohols are sources of radicals which act upon the organomercurials. The postulation is supported by the observation (Table II) that mercuric acetate and mercuric nitrate in methanol undergo reduction to the mercurous salts to the extent of 14% and 36% respectively at 50° in 80 to 90 hours. Since formaldehyde cannot be detected during these reductions, one may assume that the oxidation of the substrate leads to radicals which decompose to a multiplicity of simple fragments that have not been characterized.

TABLE II

The effect of acids on the reduction of mercuric salts in methanol at 50°

Expt. No.	Salt	Acid	Time (hours)	% reduction
1	0.2 *M* $Hg(OAc)_2$	None	82	14
2	0.2 *M* $Hg(OAc)_2$	0.2 *M* $BF_3{\cdot}Et_2O$	24	100
3	0.2 *M* $Hg(OAc)_2$	0.2 *M* p-$MeC_6H_4SO_3H$	85	46
4	0.2 *M* $Hg(OAc)_2$	0.2 *M* HNO_3	85	42
5	0.2 *M* $Hg(OAc)_2$	0.34 *M* $HClO_4$	70	60
6	0.2 *M* $Hg(NO_3)_2$	None	88	36
7	0.2 *M* $Hg(NO_3)_2$	0.2 *M* HNO_3	88	13

As may be seen in Table II these slow reductions are accelerated by acids, of which the most effective is boron fluoride. At first glance one might presume that the accelerations involve ionic rather than radical reactions. However, the effective participation of ionic species is doubtful in view of earlier studies of the over-all oxidation (1).

These earlier studies, involving variations in salt concentration, indicated that ionic species were not directly involved. Moreover, the effectiveness of the acid used in the over-all reaction seemed to be unrelated to its extent of dissociation insofar as acid strengths in methanol are known. The same divergence may be observed in Table II. Indeed a comparison of experiments 4, 6, and 7 leads to a suspicion that the rate of reduction depends upon the extent to which a basic salt of a relatively strong acid is present. This suspicion may be expressed in terms of the following formulation of competing equilibria.

$$\begin{array}{ccccccc} HgX_2 & \rightleftharpoons & HX & \rightleftharpoons & HX & \rightleftharpoons & MeOH \\ + & & + & \pm HY & + & & + \\ MeOH & & MeOHgX & & MeOHgY & & HgY_2 \end{array}$$

It is evident that the maximum amount of the most reactive basic salt (say MeOHgY) will be dependent upon the strengths and concentrations of HX and HY.

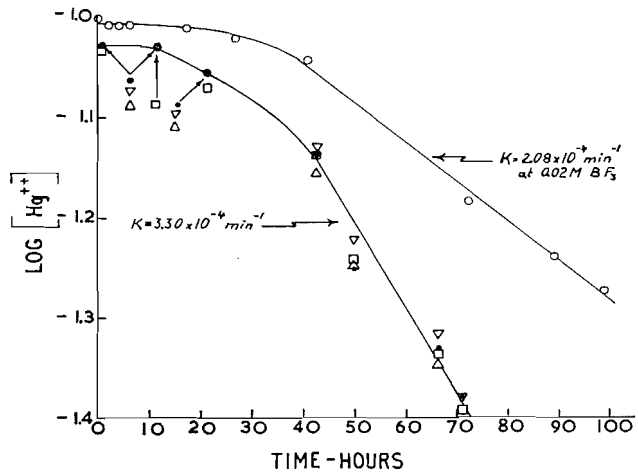
There ought to be kinetic significance from the evidence of Table II, and from that of Shearer and Wright (1), that the mercuric acetate – methanol system is affected by acids in the same way as is the organomercuric acetate – methanol – mercuric acetate system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

This significance is not easily apparent in the kinetically second-order reaction of organomercuric acetates with mercuric acetate in methanol because these reactions are very slow. However, as Shearer and Wright (1) showed, the oxidation is accelerated by addition of an acid like boron trifluoride to a rate that is satisfactory for kinetic study. The catalyzed reaction is kinetically first order.

Shearer and Wright specified the catalyzed reaction as first order in respect of the organomercurial and this opinion would seem to be at variance with the present evidence that the over-all oxidation is directly dependent upon the behavior of mercuric acetate in methanol. However, we have found the conclusion of Shearer and Wright to be incorrect. The over-all oxidation of organomercuric acetate by mercuric acetate in methanol containing boron trifluoride is first order with respect to mercuric acetate and not to the organomercurial.

The rate of reaction of mercuric acetate with methanol is negligible within a reasonable time in absence of boron trifluoride. The rate becomes measurable when 20 mole% of this catalyst is added. This rate is higher when 40 mole% of boron trifluoride is included but (see Fig. 2) is not increased by further addition of catalyst. The rate of disappearance



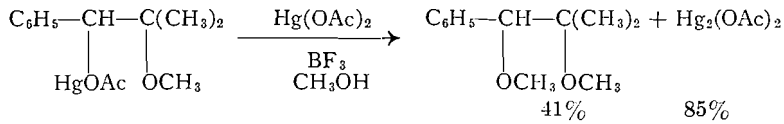


FIG. 2. Boron fluoride etherate catalysis of reduction of mercuric acetate (0.10 *M*) in methanol at 25° C. [$BF_3 \cdot Et_2O$]: ○, 0.02 *M*; □, 0.04 *M*; △, 0.06 *M*; ●, 0.08 *M*; ▽, 0.10 *M*.

of mercuric salt with 20 mole% of catalyst is found to be identical ($k = 2.08 \times 10^{-4}$) with the rate of appearance of mercurous salt, as it was determined in a separate experiment. Moreover (see Table III), this rate is unaltered when the methoxymercurials of *trans*-stilbene (in several concentrations) and of β,β-dimethylstyrene are included.*

**The products from experiments 1–6 inclusive have been described previously. We have now found the expected phenylisobutane diether by a separate experiment which includes the reagents of experiment 7, Table III. Except for the fact that these reactions of acetate salts yield only ethers and not esters they are similar to the reaction of the analogous nitrates.*

reference 1 is included as the line drawn through squares) show that the reaction is first order with respect to mercuric acetate and is independent of the concentration of the organomercurial. Thus it is understandable, as is shown in Table IV, that the oxidation rates of the mercurials prepared *in situ* (1) from *cis*- and *trans*-stilbenes are practically identical. Of course these rates are greater than those shown in Table III because the boron fluoride concentration is higher relative to the molarity of mercurial.

It would appear from these results that the rate-determining step in the acid-catalyzed oxidation of organomercuric acetates by mercuric acetate is the oxidation–reduction of mercuric acetate in methanol. But the over-all reaction seems to involve radicals, so one may speculate that a homopolar fission of the methoxymercuric salt is occurring

$$\mathrm{MeOHgX} \longrightarrow \mathrm{MeO}\cdot + \cdot\mathrm{HgX}.$$

Evidence for radicals in the mercuric acetate – methanol system is afforded because an induction period occurs before mercurous salt appears. It may be seen in Fig. 4 that this induction period may be shortened markedly by removal of dissolved oxygen from the system. Of course the inhibition by oxygen also indicates that radicals are involved in the induction step.

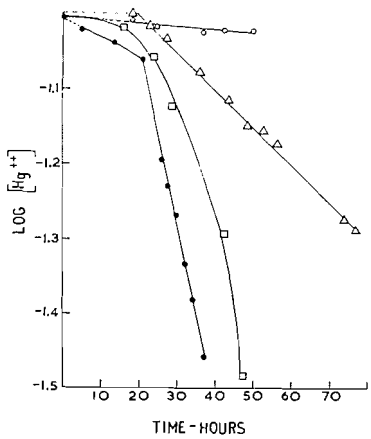

FIG. 4. System: Mercuric acetate (0.10 *M*) and boron fluoride etherate (0.02 *M*) in methanol at 25° C. ○, under oxygen; △, under air; □, deaerated three times; ●, deaerated four times.

Since the long period of induction does not occur in the over-all oxidation, it seems probable that inducing radicals are more prevalent in the presence of an organomercuric salt than they are in its absence. This supposition is borne out by the evidence of Fig. 5.

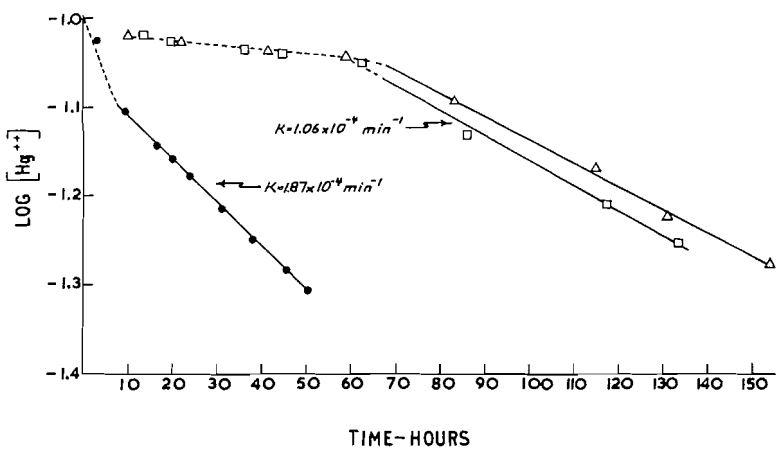

FIG. 5. System: Mercuric acetate (0.10 *M*) and boron fluoride (0.02 *M*) in methanol at 25° C. Additive: 0.05 *M* α-2-methyl-2-methoxycyclohexylmercuric acetate, ●; 0.05 *M* *n*-butylmercuric acetate, △; 0.05 *M* α-2-methoxycyclohexylmercuric acetate, □.

Here it is shown by the inclusion of organomercurials that *n*-butylmercuric acetate, which cannot be oxidized in the mercuric acetate – boron fluoride – methanol system, does not alter the inhibition. Neither does α-2-methoxycyclohexylmercuric acetate, the reaction of which is very slow in this system. On the other hand, the addition of 2-methyl-2-methoxycyclohexylmercuric acetate (which is oxidized rapidly in systems where the reagent concentration is stoichiometric) markedly shortens the induction period. Evidently it is acting here as a scavenger for oxygen.

THE MECHANISM OF THE OXIDATION

In summary of the evidence which now has been presented it is suggested that for several reasons mercuric salt in methanol very slowly undergoes a homopolar fission into anionomercury radicals and a radical (acetato, nitrato, methoxy, or hydroxy) deriving from the salt or its solvolysis product in water or methanol. This behavior is expressed in equations [i], [ii], and [iii]. The radical population generated by any one of these three reactions must be so low at room temperature (especially when mercuric acetate without boron fluoride is involved) that "breeding" of a chain reaction is largely prevented by oxygen. The decomposition of some organomercuric salts into radicals, as is expressed by equation [iv], should be more extensive according to the rate at which diphenylpicrylhydrazine is bleached (Fig. 1). The elimination of inhibition by oxygen seems to be confirmatory.

$$HgX_2 \rightleftarrows X\cdot + \cdot HgX \quad [i]$$

$$HgX_2 + ROH \rightleftarrows ROHgX + HX \quad [ii]$$

$$ROHgX \rightleftarrows RO\cdot + \cdot HgX \quad [iii]$$

$$R'HgX \rightleftarrows R'\cdot + \cdot HgX \quad [iv]$$

$$\cdot HgX + ROHgX \rightarrow RO\cdot + Hg_2X_2 \quad [v]$$

$$RO\cdot + R'HgX \rightarrow R'OR + \cdot HgX \quad [vi]$$

$$\cdot HgX + HgX_2 \rightarrow X\cdot + Hg_2X_2 \quad [vii]$$

$$X\cdot + R'HgX \rightarrow R'X + \cdot HgX \quad [viii]$$

$$RO\cdot \rightarrow H\cdot + (R \text{ minus } H)O \quad [ix]$$

$$H\cdot + ROHgX \rightarrow ROH + \cdot HgX \quad [x]$$

$$RO\cdot + H\cdot \rightarrow ROH \quad [xi]$$

$$2\cdot HgX \rightarrow Hg_2X_2 \quad [xii]$$

$$2\cdot HgX + O_2 \rightarrow XHg{-}O{-}O{-}HgX \quad [xiii]$$

These meager reactions ([i]–[iv]) cannot account for the rates at which organomercuric salts can be oxidized by mercuric salts. However, an explanation is afforded by consideration of a novel particle, anionomercury radical. If this half of a mercurous salt reacts with a basic mercuric salt according to equation [v] or with the non-solvolyzed mercuric salt by equation [vii], then stable (dimeric?) mercurous salt is formed together with a radical. This radical may be RO· (R = H or Me) from the solvolyzed salt in water or an alcohol, say methyl alcohol, or it may be X· (nitrato from mercuric nitrate or else the dead radical, acetato). If the live radicals, RO· or NO_3· were to react with the organomercuric salt according to reaction [vi] or [viii], products such as alcohols, methyl ethers, or nitrate esters would be obtained together with the anionomercury radical. But this radical would then promote reactions [v] and [vii], thus establishing a self-sustaining chain. The continuation of this radical chain would therefore depend upon a supply of new anionomercury radical according to equations [i], [iii], and [iv] in order to compensate for depletion of the radical according to equations [xii] and [xiii]. Other radical-depletion reactions are suggested by equations [ix], [x], and [xi].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

The anionomercury radical which is postulated here is envisaged as an active form of monomeric mercurous salt. The idea of this monomer is not unprecedented. A low concentration in equilibrium with the dimer has been postulated on the basis of spectroscopic evidence (14), and an apparent contradiction in favor of the dismutation into mercuric ion and free mercury (15) may only show that the monomer itself is an unstable species which may dismutate.

$$Hg_2X_2 \rightleftharpoons 2HgX \longrightarrow HgX_2 + Hg^0.$$

Certainly the dismutation reaction is well known. The intermediacy of the monomer has been suggested as a boundary state in the calomel electrode (16, 17), and the position of mercury in the periodic classification of elements is appropriate for the P → O electron shell transition which would allow of the temporal active state, ·HgX. Actually an unspecified active mercurous state has been suggested for the radical-like behaviors of the Eder reaction (18), which resembles closely the reaction that we have reported here and which we have described as a regenerative radical chain.

In our opinion the catalytic effect of acids does not conflict with our conception of a regenerative radical chain. Of course electron attraction within a group does so weaken a bond that ionic dissociation occurs. But such electrical field deformation may also equalize electron sharing in a bond, so that it becomes amenable to homopolar fission. Perhaps the best known example of this equalization influence is found in the effect of acidity upon redox potentials. Also it is significant that some of the homopolar reactions of diazotized amines are promoted by boron fluoride.

There remains the necessity to explain why the accelerating effect of boron fluoride on the organomercuric acetate – methanol – mercuric acetate system shifts the kinetic behavior from the second order observed for the uncatalyzed reaction (or for the reaction of the nitrate salts) to a first-order rate. An explanation may be offered in terms of equations [v] and [vi]. In absence of the accelerating action of boron fluoride the reaction according to equation [vi] will be rate controlling and hence will require both basic mercuric salt and organomercuric salt, each as first-order participants. But if boron fluoride catalyzes the reaction of equation [vi] (by labilization of the C—Hg bond in the organomercurial) then the anionomercury radical will be ample for the reaction of equation [v]. In this circumstance the regenerative chain ([v] and [vi]) will depend only on the concentration of the basic mercuric salt.

One might question why the co-ordinative tendency of boron fluoride ought not also labilize the basic mercuric salt of equation [v]. If this labilization occurred to an appreciable extent the explanation presented above would not be valid. We believe it to be fortuitous that the difference in co-ordination of boron fluoride with methanolic mercuric acetate versus the organomercuric acetates that we used was sufficiently great as not to vitiate the first-order kinetics. But we would not expect to be so fortunate with other organomercuric salts. Indeed, the poor kinetic studies of the earlier report (1) may in retrospect be explained on this basis.

STEREOCHEMICAL ASPECTS OF THE OXIDATION

If this oxidation of organomercurials is indeed homopolar then the unique characteristic is its stereospecificity. Moreover, the stereospecific reaction occurs with inversion if the recent assignment of configurations for 2-methoxy-1,2-diphenylethylmercuric salts is correct (19). In terms of the Werner concept of substitution (commonly called Sn_2) the stereospecific substitution via radicals may seem to be anomalous in the sense that nucleophilic attraction is absent in the neutral radical.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

Of course the original Werner concept of concise co-ordination as an intermediate state of substitution by inversion has now largely been superseded by the idea of a dynamic transition. In the latter view the assignment of electrical polarity is much less significant than is required by co-ordination, even if it is ephemeral. Indeed a transition state for equation [vi] in which radicals are involved may be described as a concerted coupling and decoupling of spin, exemplified in Fig. 6.

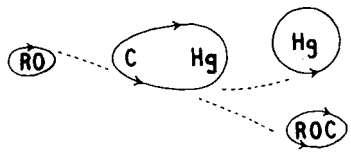

FIG. 6.

Of course it is surprising that the necessity for specification of this mechanism has not arisen previously among examples of Walden inversion. Perhaps the complexity of the usual radical reaction has disguised any stereospecificity. Indeed, the mechanism (Fig. 6) which we have proposed may turn out to be exemplified among the stereospecific polymerizations which are radical-induced and propagated.

The authors wish to thank the National Research Council of Canada for funds in aid of this investigation.

EXPERIMENTAL*

Reagents and Equipment

Mercuric acetate was purified by crystallization from dilute acetic acid. Mercuric nitrate (Merck reagent) was used as such; analysis showed that it contained 105.56% (gravimetric) and 104.94% (volumetric) of mercuric ion assuming anhydrous mercuric nitrate. Thus it was actually a basic salt. Absolute nitric acid (better than 99%) was distilled, water-white. Dry methanol (from magnesium methoxide) contained less than 0.002% water (Karl Fischer titration). Spectra were determined with Beckman DK-1, IR-4, and IR-5 instruments. Kinetic studies at 25° were controlled to ±0.1°.

The Reduction of Mercuric Acetate in Methanol with Boron Fluoride Etherate

(*a*) *Kinetics*

The rate of disappearance of mercuric acetate was determined by volumetric analysis for mercuric salt using the method of titration with potassium iodide and mercuric nitrate. This was necessitated by the fact that mercurous salts were not completely removed as the acetate when appreciable amounts of boron fluoride were present in the methanol solutions and would have interfered with analysis by thiocyanate titration. The rate data are plotted in Fig. 2, from which the first-order rate constants were calculated. The experiment involving 1 mole equivalent of boron fluoride is given as representative.

Mercuric acetate (3.1876 g, 0.01 mole) was dissolved in 75 ml of dry methanol, and 1.260 ml (0.01 mole) of freshly distilled boron fluoride etherate added. The volume was made up to 100.00 ml and the sample thermostatted at 25±0.1°. Aliquots (4.00 ml) were added to 10 ml of 2 *M* hydrochloric acid and filtered through Celite to remove mercurous chloride. The filtrate and washings were diluted to 70 ml with water, 10.00 ml of 0.2 *M*

**Melting points have been corrected against reliable standards. X-Ray diffraction patterns are reported using* Cu(K_α) Ni-*filtered radiation in Angstroms at relative intensities* [I/I_1].

For personal use only.

standard potassium iodide solution added, and then titrated with mercuric nitrate solution. The latter, used as the primary standard, was freshly prepared each 24 hours by dissolving 5.4152 g of mercuric oxide in 6.3 ml of concentrated nitric acid and diluting to 500 ml.

The rate of this reaction, using 0.02 *M* boron fluoride, was checked by analyzing gravimetrically for mercurous salt. A series of solutions containing 0.7950 g (0.0025 mole) of mercuric acetate and 0.070 g (0.0005 mole) of boron fluoride was made up to 25.00 ml in methanol and held at 25°. Periodically samples were rinsed out of the volumetric flasks with 25 ml of water containing 2 ml of 8 *M* nitric acid and then 2.0 ml of 5 *M* sodium chloride added. The mercurous chloride was recovered by filtration, using about 0.5 g of previously dried and accurately weighed Celite to facilitate the operation. The filtrate was made basic and mercuric oxide separated in the same manner. The precipitates were dried 4 hours at 50°/1 mm, giving the following data.

TABLE V

Gravimetric rate data

Time (hours)	Wt. Hg_2Cl_2 (g)	Wt. HgO (g)	Total [Hg] (*M*)
0	0.0000	0.5402	0.0998
11.50	0.0078	0.5365	0.1002
33.50	0.0461	0.4989	0.0998
41.25	0.0548	0.4893	0.0995
57.25	0.1320	0.4195	0.0999
67.25	0.2062	0.3348	0.0969
81.75	0.2744	0.2764	0.0976
129.75	0.3925	0.1598	0.0960

When this data was plotted similarly to that shown in Fig. 2, the rates, based on the mercurous and mercuric determinations respectively, were 2.08×10^{-4} min^{-1} and 2.14×10^{-4} min^{-1}.

Kinetics of the Oxidation of trans-Stilbene and its Methoxymercurial with Mercuric Acetate and Boron Fluoride Etherate in Methanol

(*a*) *Initially Alkene*

A suspension of 0.450 g (0.0025 mole) of *trans*-stilbene and 2.3902 g (0.0075 mole) of mercuric acetate in 40 cc of dry methanol was shaken 1 hour, causing nearly complete solution of the solids. Boron fluoride etherate (0.126 ml, 0.001 mole) was added and the volume made up to 50.00 ml, whereupon a brief shaking caused complete solution. This was then thermostatted at 25°, zero time being taken as that of boron fluoride addition.

(*b*) *Initially Mercurial*

Quantities of 2.235 g (0.005 mole) of β-2-methoxy-1,2-diphenylethylmercuric chloride (20) and 0.835 g (0.005 mole) of silver acetate were shaken with 25 ml of dry methanol for 1 hour then filtered to remove 0.716 g (100%) of silver chloride. To the filtrate was added 1.593 g (0.005 mole) of mercuric acetate and 0.126 ml (0.001 mole) of boron fluoride etherate. After it was diluted to 50.00 ml, the whole was shaken a few minutes to cause complete solution and kept at 25°.

In both cases (*a*) and (*b*) the analytical procedure used was the mercuric nitrate titration described above.

The Oxidation of 1-Phenyl-2-methoxy-2-methyl-propylmercuric Acetate with Mercuric Acetate and Boron Fluoride

(*a*) *Kinetics*

The rate of oxidation of this mercurial was determined by the method described above

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

and is given in Table II. The actual rate data is plotted in Fig. 3 together with the comparable experiments with stilbenes described above.

(*b*) *Products of the Reaction*

A 10.0-g (0.025 mole) quantity of 1-phenyl-2-methoxy-2-methylpropylmercuric chloride (21) was converted to its acetato analogue with 4.17 g (0.025 mole) of silver acetate in 200 ml of dry methanol (yield of silver chloride 99%). To the acetatomercurial was added 15.9 g (0.05 mole) of mercuric acetate and 6.3 ml (0.05 mole) of boron fluoride etherate, and the solution kept at 50° for 24 hours. After it was cooled to 0° and filtered from 6.02 g of solid (presumed to be mercurous acetate and testing black with alkali). the solution was concentrated to 40 ml by distillation at 15–20° under reduced pressure, and diluted with 200 ml of water. After the addition of just sufficient 8 *M* nitric acid to dissolve all solids, the suspension was extracted with chloroform (3×50 ml). The aqueous phase gave 9.51 g of chloroform-insoluble mercurous chloride when excess sodium chloride was added. Distillation of the chloroform extract yielded 2.01 g (41%) of crude 1-phenyl-1,2-dimethoxy-2-methylpropane, b.p. 94–96°/8 mm, m.p. −4.0 to +1.5°, n_D^{20} 1.4972. Literature values for this compound (1) are b.p. 94–100°/8 mm, m.p. 8–11°, n_D^{20} 1.4980.

Inhibition of Mercuric Acetate – Methanol Reaction

The data of Fig. 3 were obtained by the analytical methods described above with solutions of 1.5935 g (0.005 mole) of mercuric acetate in 100 ml of dry methanol to which 0.126 ml of boron fluoride etherate was added at zero time in a magnetically stirred flask at 26–27°. Duration of experiment was 50 hours. The reaction under oxygen was maintained at 17–19 lb absolute pressure and a yellow turbidity was observable at termination. Deaeration experiments were conducted by flushing system and solution with nitrogen, cooling by liquid air bath to incipient solidification, evacuation at 0.1 mm until cessation of bubbling, followed by complete solidification with 10 minutes of continued evacuation. The system was then warmed to 25° and pure nitrogen was admitted, followed by boron fluoride etherate. The relative first-order rates are: under oxygen, negligible; under air, $k = 1.97\times10^{-4}$ min^{-1}; after four deaerations, $k = 9.28\times10^{-4}$ min^{-1}.

Acceleration of Mercuric Acetate – Methanol Reaction

The experiment recorded in Table IV for acceleration by nitric acid is typical. A solution containing 0.935 g (0.0029 mole) of mercuric acetate, 0.120 ml of absolute nitric acid, and 15.0 ml of dry methanol was kept at 50° for 85 hours. After the solution was cooled to 0°, sufficient 8 *M* nitric acid was added to dissolve any precipitated solid, and excess sodium chloride solution (5 *M*) was added to precipitate 0.289 g (42%) of mercurous chloride. When the filtrate was basified, 0.272 g (58%) of mercuric oxide was obtained. The combined recovery of mercury salts was always 100±2%.

The Ultraviolet Absorption Spectra of Mercury Salts in Methanol

(*a*) *Mercuric Nitrate*

A solution of mercuric nitrate (2×10^{-4} *M*) in dry methanol showed no absorption maxima above 230 mμ. At shorter wave lengths total absorption occurred. Over a period of 100 hours an absorption peak appeared at 242 mμ, which was shown to be due to mercurous nitrate. When 4 mole equivalents of sodium acetate were added to this solution, the peak at 242 mμ was immediately replaced by one at 236 mμ due to mercurous acetate.

When a solution of mercuric nitrate (2×10^{-4} *M*) and absolute nitric acid (8×10^{-4} *M*) was freshly prepared it showed no absorption maxima above 230 mμ, but after 24 hours a peak had appeared at 290 mμ, and there was no absorption at 242 mμ attributable to mercurous nitrate. The addition of 4 mole equivalents of mercurous acetate to this solu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

tion shifted the 290-mμ absorption to 275 mμ. This latter absorption region was not observed in any of the mercuric and mercurous acetate solutions.

These spectra of mercurous nitrate solutions, showing only the maxima at 242 mμ, are not changed upon addition of 2 equivalents of sodium acetate. However, when the solutions had been left standing 100 hours the appearance of absorption at 290 mμ was observed.

(*b*) *Mercuric Acetate*

A solution of mercuric acetate (2×10^{-4} *M*) showed no maxima below 230 mμ when freshly prepared. Over a period of 9 days a peak appeared at 236 mμ, identical with that found with mercurous acetate (2×10^{-4} *M*). When a similar solution containing nitric acid (4×10^{-4} *M*) was aged 10 days, only the absorptions appeared due to mercurous nitrate (242 mμ) and the unidentified mercuric species (290 mμ).

The 236-mμ peak found for mercurous acetate was shifted to 242 mμ (mercurous nitrate) upon addition of 2 equivalents of nitric acid.

Oxidation of Cyclohexylmercuric Nitrate with Mercuric Nitrate

(*a*) *In Methanol*

A 10.00-g (0.0313 mole) quantity of the chloromercurial was converted to the nitrato analogue with silver nitrate in 450 ml of methanol. To this solution was added 10.18 g (0.0313 mole) of mercuric nitrate and 1.32 ml (0.0313 mole) of absolute nitric acid. After 38 hours, the solution was cooled to 0°, diluted with 400 ml of water, and 15 ml of 5 *M* sodium chloride added. Filtration gave 12.79 g (87%) of chloroform-insoluble mercurous chloride. The filtrate was extracted with ether (6×75 ml) which was washed with dilute base, water, dried, and distilled, giving a fraction, b.p. 25–41°/2–3 mm, n_D^{20} 1.4522, wt. 1.06 g. This material gave a positive nitrate ester test with benzidine (22) and a negative test for carbonyl compounds. A chromatoplate analysis was made on silicic acid, eluting with commercial hexane; comparison with pure compounds showed that methoxycyclohexane and cyclohexyl nitrate were present. When these pure compounds and the product mixture were submitted for infrared spectral analysis (courtesy of Canadian Armaments Research and Development Establishment, Quebec) the mixture was found to represent yields of 31% of cyclohexyl nitrate and 8% of methyl cyclohexyl ether.

(*b*) *In Water*

A 20.00-g (0.0627 mole) quantity of the chloromercurial and 10.65 g (0.0627 mole) of silver nitrate in 500 ml of dry methanol were stirred 1 hour, filtered from 8.98 g (100%) of silver chloride, and the filtrate taken to dryness as rapidly as possible at 20–25°. The grey residue was dissolved in 100 ml of chloroform, filtered from 0.58 g of grey solid, and again concentrated at reduced pressure to give 20.00 g (0.058 mole) of white crystals presumed to be the nitratomercurial. To this was added 140 ml of water, 18.82 g (0.058 mole) of mercuric nitrate, and 7.5 ml of 8 *M* nitric acid (0.060 mole). After it was stirred 16 hours the mixture was extracted with ether (6×50 ml), and 2.51 g (0.0125 mole) of metallic mercury separated from the aqueous phase. Addition of excess sodium chloride to the aqueous phase gave 24.5 g (0.103 mole) of mercurous chloride, which was totally insoluble in chloroform.

The ether extracts, washed with dilute sodium hydroxide which produced some mercuric oxide, then with water till neutral, were dried and distilled to give two fractions: (1) b.p. 15–40°/37 mm, wt. 0.38 g; and (2) b.p. 65–84°/42–3 mm, wt. 4.14 g. The infrared spectra of both fractions were nearly identical and indicated them to be mainly a mixture of cyclohexanol and cyclohexyl nitrate. Fraction 2 was analyzed by this means, using the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

hydroxyl band at 3450 cm^{-1} (ϵ = 98.1) for the alcohol and the strong covalent nitrate band at 1650 cm^{-1} (ϵ = 1090) for the ester. Each of these bands is free from contribution of the other component. Solution spectra in cyclohexane were used at concentrations of about 0.1 g/ml for the alcohol and 0.015 g/ml for the ester. Fraction 2 was thus found to be 43% by weight of ester and 55% alcohol. Hence fractions 1 and 2 represent yields of 40% and 21% respectively of cyclohexanol and cyclohexyl nitrate. The following principal absorption bands (cm^{-1}) were observed. Cyclohexanol: 3450, 2910, 1458, 1375, 1338, 1290, 1239, 1145, 1095, 1052, 1011, 991, 952, 930. Cyclohexyl nitrate: 3050, 2900, 1650, 1465, 1325, 1283, 1240, 993, 941, 915, 862.

A portion of fraction 2 (0.10 g) was treated with dinitrophenylhydrazine reagent to give 12 mg of the hydrazone of formylcyclopentane, m.p. 149–152°, which melting point was raised by mixture with an authentic sample.

Another portion of fraction 2 (1.92 g) was reduced with zinc and iron in acetic acid by the method of Dewar and Fort (23) to give 1.17 g of only one fraction, b.p. 158–160°, m.p. 16–22°. A test with diphenylamine was negative for nitrate ester. When this cyclohexanol (0.57 g, 0.0057 mole) was treated with 1.2 g (0.0057 mole) of α-naphthylisocyanate, there was obtained 1.53 g (100% crude yield) of urethane, m.p. 126–130°; this melting point was raised upon admixture with authentic urethane of m.p. 130–131°.

Under otherwise comparable conditions (except that the system was homogeneous) replacement of the mercurial by cyclohexanol did not lead to any cyclohexyl nitrate.

Oxidation of Benzylmercuric Nitrate with Mercuric Nitrate in Water

Benzylmercuric chloride (10.00 g, 0.0306 mole) was converted to the nitrate salt with silver nitrate in 90 ml of methanol. After filtration of silver chloride (100%), the filtrate was rapidly concentrated at reduced pressure to dryness. To this was added a clear solution prepared from 60 ml of water, 6.63 g (0.0306 mole) of mercuric oxide, and 11.15 ml (0.0918 mole) of 8.2 *M* nitric acid. After the solution was stirred for 10 hours, the reaction mixture was extracted with ether (5×25 ml). Then excess sodium chloride (5 *M*) was added to the aqueous phase to precipitate 11.63 g (81%) of mercurous chloride, which tested black with alkali and was chloroform-insoluble. The ethereal extracts were water-washed until neutral, dried, and concentrated to 2.46 g of yellow oil. Now, 1.000 g of this oil was chromatographed on a 10×250-mm column, using a 2:1 silicic acid:Celite adsorbent which had been activated at 150°. Two main fractions were obtained, one of which, wt. 0.360 g, tested positively for both a carbonyl and a nitrate ester (diphenylamine test) component. The second fraction contained no nitrate ester. The first fraction was dissolved in 15.0 ml of dry ethanol, and then 1.43 ml (0.025 mole) of glacial acetic acid and 0.59 g (0.0034 mole) of Girard's P reagent was added. After standing 15 hours the solution was poured into 50 ml of cold water containing 1.19 g (0.0112 mole) of sodium carbonate and was extracted in the cold with chloroform (4×20 ml). These extracts were washed with water, dried over magnesium sulphate, and concentrated to give 0.288 g of benzyl nitrate, m.p. −23 to −17.5°, n_D^{20} 1.5192. A mixed melting point with authentic benzyl nitrate (m.p. −17 to −15°, n_D^{20} 1.5205) was raised to −19 to −16°. The yield of benzyl nitrate was 15%.

In an identical experiment the oil obtained by ether extraction was distilled, taking a 2.36-g fraction, b.p. 65–100° (mostly boiling at 90–100°) at 30 mm. Treatment of 0.47 g of this oil with phenylisocyanate gave 0.39 g of the phenylurethane of benzyl alcohol, m.p. 76–78° (lit. value, m.p. 78° (24)). This indicates a 16% yield of the alcohol. From the oil there was also obtained a trace amount of benzaldehyde, separated as its dinitro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

phenylhydrazone, and identified by mixture melting point. Upon standing 2 days the oil also deposited about 20 mg of benzoic acid crystals, also identified by mixture melting point.

Reactions of Mercuric Nitrate with Radical Sources

(*a*) *With Hydrogen Peroxide*

When 0.01 mole each of mercuric nitrate and hydrogen peroxide (Becco 90%) were added to 40 ml of dry methanol a test showed no formation of mercurous salt (test with sodium chloride) after 4 hours, but the addition of 3–4 mg of ferrous sulphate heptahydrate initiated an exothermic reaction. After the solution was stirred for 20 hours, 7 ml of 8 *M* nitric acid was added to give complete solution and mercurous chloride and mercuric oxide were recovered using sodium chloride and sodium hydroxide respectively, in 60% and 40% yield. When the above was repeated using 0.10 g of ferrous salt, a nearly explosive reaction resulted. However, the same amounts of reagents, in water instead of methanol, using 5 mg of ferrous salt, produced no mercurous salt after 10 hours. It was shown that mercurous nitrate in methanol was unchanged by hydrogen peroxide and ferrous salt.

(*b*) *With Isobutyryl Peroxide in Methanol*

A 0.83-mmole quantity of mercuric nitrate in 5.0 ml of dry methanol was stirred for 12 hours with 5.0 ml of an 0.17 *M* solution of isobutyryl peroxide (25) in methanol. This system was analyzed by the method of Price (26). A test for peroxide was now negative. Addition of water, sufficient nitric acid to dissolve solids, and excess sodium chloride gave 0.12 g (62%) of mercurous chloride. Addition of excess base now gave no mercuric oxide.

Reactions of Mercury Acetates with Radical Sources

No mercurous salt was formed when 0.01 mole each of mercuric acetate and hydrogen peroxide in 40 ml of methanol was treated with 5 mg of ferrous sulphate. Indeed a 36% conversion to mercuric salt was observed when a solution of 0.005 mole of mercurous acetate and 0.01 mole of 90% hydrogen peroxide in 40 ml of methanol containing 5 mg of ferrous sulphate was stirred for 5 hours. This conversion was detected by subsequent addition of 90 ml of water and 10 ml of 5 *M* aqueous sodium chloride, then sufficient 8 *M* nitric acid to just dissolve the orange-colored solid. After filtration of 1.76 g (64%) of mercurous salt the filtrate was basified to yield 0.77 g of mercuric oxide. The conversion to mercuric salt was complete when 0.05 mole of peracetic acid in 10 ml of chloroform was refluxed with 0.01 mole of mercurous acetate in 20 ml of methanol during 4 hours.

Reaction of Cyclohexylmercuric Nitrate with Pernitrous Acid in Water–Methanol

A system was prepared at 0° containing 300 ml of dry methanol, 300 ml of water, 0.06 mole of the nitrato–mercurial, 0.009 mole of 8 *M* nitric acid, and 0.09 mole of 90% hydrogen peroxide. This suspension was warmed to and maintained at 25° while a solution of 4.56 g (0.066 mole) of sodium nitrite in 60 ml of water was added dropwise during 20 minutes. Now the serial addition of the same amounts of nitric acid, hydrogen peroxide, and then (slowly and dropwise) sodium nitrite was repeated thrice, and the mixture cooled to maintain the temperature at 25°. The reaction mixture was then extracted with ether (8×50 ml), the extracts dried and distilled to give 5.51 g of oil. Treatment of a sample of this oil with dinitrophenylhydrazine gave the derivative of cyclohexanone, m.p. 150–153°, identified by mixture melting point. Infrared analysis of the oil was made by the method described above for analysis of the products of oxidation of cyclohexylmercuric nitrate with mercuric nitrate. Thus the crude product contained 32% and 39% by weight

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

respectively of cyclohexanol and cyclohexylnitrate. These results indicate respective yields of 30% and 25% for these products in the pernitrous acid oxidation.

The original reaction mixture, after ether extraction, was treated with excess sodium chloride solution to yield 7.41 g (52%) of chloroform-insoluble mercurous chloride (black with alkali).

Reaction of α-2-Hydroxycyclohexylmercuric Acetate and Fenton's Reagent in Water

A solution containing 0.10 mole of cyclohexene, 0.10 mole of mercuric acetate, and 200 ml of water was stirred 2 hours, at which time a test with base indicated that no mercuric salt was present. Now, over a 2-hour period, there was added, simultaneously and equivalently, 10 ml of water containing 0.10 mole of hydrogen peroxide and 0.10 mole of ferrous sulphate heptahydrate. The resulting suspension was stirred 68 hours, then extracted with ether (4×50 ml). Distillation of the dried ethereal extracts gave one fraction, b.p. 90–140°, which upon redistillation yielded 1.19 g of product, b.p. 130–138°, n_D^{20} 1.4390. It was identified as formylcyclopentane (23%) via its dinitrophenylhydrazone, m.p. 153–155°, whose mixture melting point with an authentic specimen was not depressed.

To the aqueous phase was added 0.10 mole of 5 *M* sodium chloride. The precipitate, after drying, was extracted with 150 ml of hot chloroform to give 7.07 g of chloroform-soluble solid. This solid melted at 138–140° with decomposition, and could be recrystallized from acetone without change in melting point. Assuming it to be 2-chloromercuricyclohexanone, the yield was 23%. This compound has been reported by Nesmeyanov (13) to melt at 134–135°. The X-ray diffraction pattern was: [10] 6.70, 5.05, 4.99; [8] 3.49; [7] 2.99; [5] 2.36; [2] 3.78, 3.29, 3.11. Calc. for C_6H_9ClHgO: C, 21.62; Found: C, 22.1.

Oxymercuration of 1-Methoxycyclohexene

After 5 hours a system comprised of 1.12 g (0.01 mole) of 1-methoxycyclohexene (27) (n_D^{20} 1.4569, b.p. 140–141° at 750 mm), 3.18 g (0.01 mole) of mercuric acetate, and 25 ml of methanol was treated with 3.8 ml of 10% aqueous sodium hydroxide. After filtration the solvent was removed under reduced pressure. The residue was treated with 5 ml of saturated aqueous sodium chloride and alkali was added to pH 6. After 1 day the precipitated oil had solidified, 2.64 g, m.p. 99–102°. This crude material was dissolved in chloroform and diethyl ether was added. Further purification (difficult because decomposition occurred slowly with deposition of calomel) was effected by solution in dioxane and reprecipitation by addition of water, 0.25 g, m.p. 128–129.5° (with decomp.). Although the sample is impure its X-ray diffraction pattern shows identity with 2-chloromercuricyclohexanone.

Although cyclohexanone in dilute alkali is reduced to cyclohexanol by sodium trimethoxyborohydride it was possible to convert chloromercuricyclohexanone (m.p. 134–135°) to cyclohexanone, b.p. 150–160° (760 mm), n_D^{20} 1.4477, in 53% yield. A solution of 1.66 g (0.005 mole) of the mercurial in 1 ml of 6 *M* alkali at 0° was treated with 0.64 g (0.005 mole) of sodium trimethoxyborohydride during 1 hour. Distillation of the ether extract yielded 0.26 g which was converted to the 2,4-dinitrophenylhydrazone, m.p. 156–158°, not depressed by admixture with an authentic sample.

Kinetics of the Reaction of Diphenylpicrylhydrazyl (DPPH) with Nitratomercurials in Methanol

The first-order rates listed in Table I were obtained from plots of log [DPPH] versus time, an example of which is shown in Fig. 1. The reaction of DPPH and cyclohexylmercuric nitrate is given here as an example of the method.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

A quantity of 1.595 g (0.005 mole) of cyclohexylmercuric chloride (freshly recrystallized, m.p. 162–163° decomp.) and 0.850 g (0.005 mole) of silver nitrate in 40 ml of methanol was shaken for 30 minutes, then filtered to remove silver chloride (0.714 g, 100%). The filtrate was added to a freshly prepared solution of 16.0 mg of DPPH in 400 ml of methanol and the whole made up to 500 ml. The per cent transmittance at 510 mμ was then measured at appropriate time intervals, using a new sample of the stock reaction solution for each measurement. The molecular extinction coefficient mentioned above (ϵ = 10,220) was determined for a solution of DPPH (32.0 mg/l.) and used for calculation of the DPPH concentration. The spectrum of the solution in which the absorption maxima of DPPH had completely decayed was identical with that of a solution of diphenylpicrylhydrazine in the 440- to 800-mμ region.

Kinetics of the Oxidation of Nitratomercurials with Mercuric Nitrate in Methanol

The second-order rate constants (calculated on the basis of the rate of loss of mercuric nitrate) are presented in Table I. In each case the nitratomercurial was used. To exemplify the procedure, the experiment with cyclohexylmercuric nitrate is described.

A quantity of 0.998 g (0.00313 mole) of cyclohexylmercuric chloride was converted in the usual manner to its nitrato analogue in 25 ml of dry methanol. (If any additive was to be present, it was dissolved in this solution at this point.) The nitratomercurial solution was then added to 1.016 g (0.00313 mole) of mercuric nitrate in 10 ml of dry methanol which had been shaken for 10 minutes previously to disintegrate the lumps. Upon adding 0.260 ml (0.00626 mole) of absolute nitric acid the solution became homogeneous and was immediately diluted to 50.00 ml with dry methanol. From this there were removed 5.00-ml samples which were placed in tared centrifuge tubes. These rubber-stoppered samples were thermostatted at 25° and analyzed as follows.

Four milliliters of 2 *M* hydrochloric acid was added, the sample allowed to stand 10 minutes with occasional stirring to allow complete deoxymercuration of any oxymercurial present, then centrifuged. The precipitate was then thoroughly washed successively with 5-ml portions of water, methanol, and twice with chloroform. A slender glass rod (3 mm diameter) was found to be satisfactory for stirring in these operations and was easily rinsed free of particles with methanol. When solid particles tended to remain at the liquid–air interface, they were readily centrifuged down by first floating a layer of methanol or ether on the top. The sample was dried at 110°, then finally at 56°/1 mm, and weighed as mercurous chloride.

The rate data was plotted as the reciprocal of $[Hg^{++}]$, the latter referring to the mercuric nitrate concentration. Values for $[Hg^{++}]$ were calculated from the relationship

$$[Hg^{++}] = 0.0625 - [Hg_2Cl_2],$$

it being assumed that for each equivalent of mercuric nitrate which had reacted 1 equivalent of dimeric Hg_2Cl_2 was formed.

Formation of Polyacrylonitrile in the Oxidation System: Acrylonitrile – Cyclohexene – Mercuric Nitrate – Nitric Acid – Water

(*a*) *In Air*

A solution of 2.71 g (0.0125 mole) of mercuric oxide, 3.14 ml of concentrated nitric acid (0.050 mole), and 23 ml of water was prepared. To this was added 0.51 g (0.00625 mole) of cyclohexene and the mixture shaken 5 minutes to dissolve the alkene, whereupon 0.66 g (0.0125 mole) of freshly distilled acrylonitrile was added. After 40 minutes the solution became turbid and at 60 minutes the suspended material coagulated upon swirling. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

3 hours there was filtered 0.026 g (4% of monomer) of solid. This material gave a diffuse X-ray pattern having no diffraction lines. A sample was decomposed in hot concentrated nitric acid and then the solution made basic; there was no precipitate, indicating that the material contained no mercury.

(*b*) *Deaerated*

The above procedure was repeated except that the solution of mercuric nitrate, nitric acid, and water was deaerated three times prior to addition of the other reagents. After 3 hours the yield of insoluble polymer was 7%, which material had a similarly diffuse X-ray pattern.

(*c*) *With Methylene-bis-acrylamide Added*

This reaction was repeated a third time as outlined in the first procedure, adding 0.10 g (0.65 mmole) of methylene-bis-acrylamide. Within 5 minutes the solution had become opaque and after 3 hours it had set to a gel. Centrifugation gave 0.176 g (24% yield based on total available monomer) of solid which did not contain mercury (demonstrated by decomposition with a sulphuric – nitric acid mixture). The product gave a diffuse X-ray pattern.

Polyacrylonitrile

To a solution of 0.65 ml (0.01 mole) of acrylonitrile in 20 ml of water was added 0.10 ml of 90% hydrogen peroxide and 1–2 mg of ferrous sulphate heptahydrate. After 1 hour there was no visible change so 2 ml of 8 *M* nitric acid was added. The solution rapidly became turbid and after 12 hours, filtration gave 0.28 g (43%) of polyacrylonitrile. This polymer corresponded to those produced as is described above, in that it was insoluble in most common solvents, had no melting point but charred above 300°, and gave no distinct X-ray diffraction pattern after 8 hours' exposure.

Attempted Polymerization of Acrylonitrile in the Presence of 2-Hydroxycyclohexylmercuric Nitrate

A solution was prepared of 1.352 g (0.00625 mole) of mercuric oxide, 1.57 ml of concentrated nitric acid, and 23 ml of water. Cyclohexene (0.63 ml, 0.00625 mole) was added and the whole shaken for 30 minutes, at which time the homogeneous solution gave a negative test with base for mercuric ion. To this was added 0.81 ml (0.0125 mole) of acrylonitrile. A faint opalescence slowly developed, but after 1 day this had not increased to a degree which allowed separation of a solid phase.

Cyclohexylmercuric Acetate and Peracetic Acid in Methanol

A solution of 0.05 mole of peracetic acid in chloroform was added to 0.01 mole of cyclohexylmercuric acetate in 20 ml of dry methanol. After 7 hours of reflux a peroxide test was negative. The mercurous acetate was filtered off and was converted by treatment with sodium chloride to 0.20 g (8%) of calomel. The filtrate was diluted to 80 ml with water and was 4 times extracted with a total of 80 ml of chloroform. The aqueous phase yielded 1.58 g (73%) of mercuric oxide when it was treated with alkali. The chloroform phase was distilled to yield only the solvent and then 0.74 g (75%) of cyclohexanone, b.p. 150–55°, n_D^{20} 1.4497, which was characterized as the 2,4-dinitrophenylhydrazone m.p. 154–5°, mixture m.p. not depressed.

THE AUTOOXIDATION OF ORGANOMERCURIC SALTS[1]

J. H. Robson and George F Wright

ABSTRACT

It has been found that besides the homopolar bimolecular oxidation of alkylmercuric salts which has been reported previously an alternative unimolecular reaction of heteropolar character may occur. The product of this heteropolar reaction is the alkene, but it probably proceeds through an alkylmercury cation since reaction in benzene leads to the Friedel–Crafts type of product. Like the homopolar reaction, the heteropolar reaction is accelerated by electron withdrawal of the anionic part of the salt. Indeed, it is believed that both mechanisms are operative among many of the mercuric salt oxidations of alkenes which previously have been reported.

The oxidation of organomercuric salts by means of mercuric nitrate and mercuric acetate plus boron fluoride (1) has recently been re-examined (2). This reaction is now believed to involve a self-sustaining radical chain in which anionomercury radical (monomeric mercurous salt) is the chain carrier. The expectation that such a reaction would be inhibited by oxygen is in fact realized. This inhibition is exemplified by an induction period which occurs especially when the system comprised of mercuric acetate and boron fluoride in methanol is used as the oxidizing medium. It is evident that if there were an oxidation reaction of different mechanism, which was not inhibited by oxygen, then this latter alternative reaction would occur preferentially. Although the alternative is not observed when the mercurial to be oxidized is sufficiently reactive (as is the case with many oxymercurials), it has been observed with simple alkylmercurials.

The reaction under present consideration differs from the homopolar reaction (1, 2) in several respects. First, it does not require an inorganic mercuric salt and therefore may be classed as an autooxidation of an alkylmercuric salt. Secondly, mercury rather than mercurous salt seems to be one product while the other is the alkene to be expected if the elements of hydrogenmercuric salt were to be eliminated from the mercurial. The reaction is not entirely a general one (we have been unable yet to oxidize a primary alkylmercuric salt), but the secondary and, especially, the tertiary mercurials are oxidized with relative ease.

Typical is the reaction of cyclohexylmercuric acetate with boron trifluoride in methanol. After 90 hours at 25° the system yields 90% of the mercury as the metal. After removal

TABLE I

Autooxidation of cyclohexylmercuric salts (0.10 mole) to cyclohexene (isolated by subsequent conversion to 2-methoxycyclohexylmercuric chloride) at 50° with catalysts (0.04 mole) in several media

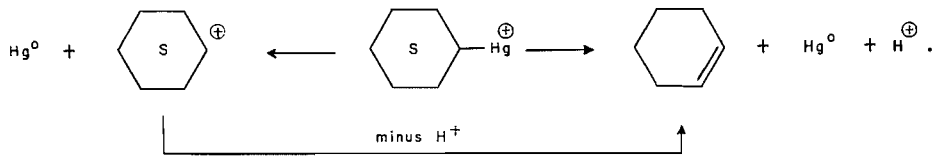
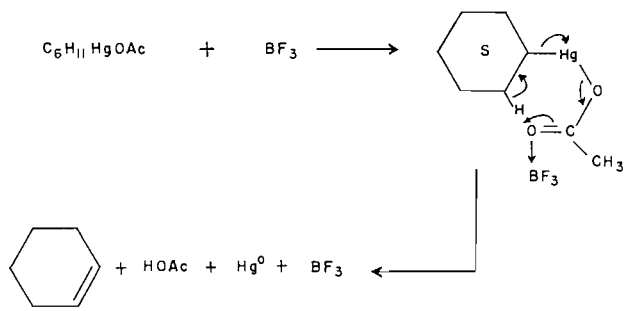
of this metal, the presence of cyclohexene in 89% yield may be demonstrated by its conversion to α-2-methoxycyclohexylmercuric chloride when mercuric acetate is added.



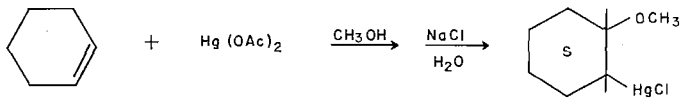
Although the autooxidation of the secondary alkylmercuric salt described above does not occur in absence of boron fluoride (expt. 1, Table I) it may be seen from this table that the Lewis acid must function only by increasing the polarity of the cyclohexylmercuric acetate. Thus the trifluoroacetate and the nitrate undergo the reaction without any boron fluoride. The reaction of the nitrate is especially notable because this salt reacts readily in the presence of an equivalent of mercuric nitrate in methanol by the homopolar path (2) to yield cyclohexyl nitrate and methoxycyclohexane. Contrariwise, the chloride does not undergo reaction, as might be expected in view of the stability of organomercuric chlorides.

The autooxidation reactions of Table I might be described in terms of an ionization



[i]

in which the cation is unstable and decomposes according to the following alternative modes



[ii]

However it is probably significant that neither phenylmercuric acetate nor *n*-butylmercuric acetate in methanol precipitate metallic mercury in presence of boron fluoride. It is possible that a stereomechanism such as is shown below is operative rather than reaction via free ions.

It might be expected, if mercuric acetate were added to the cyclohexylmercuric acetate system in methanol, that the homopolar reaction would occur to give methoxycyclohexane and mercurous acetate as the products. When 2 equivalents of mercuric acetate are included the organic product is α-2-methoxycyclohexylmercuric acetate, indicating that cyclohexene is the initial product. Thus initial excess of mercuric salt does not appreciably diminish the catalytic effect of boron fluoride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

To be sure, the other product is not elemental mercury but, rather, mercurous salt. However this is not surprising because the metal ought to react rapidly with mercuric acetate according to the known dismutation (3, 4).

$$Hg^0 + Hg(OAc)_2 \rightleftarrows Hg_2(OAc)_2 \xrightarrow{NaCl} Hg_2Cl_2$$

The maintenance of the heteropolar reaction under the conditions of the homopolar reaction may be explained in two ways. First, cyclohexylmercuric acetate, unlike the analogous nitrate salt, is not sufficiently reactive toward radicals. Secondly, the heteropolar reaction is not inhibited by oxygen. Therefore no induction period is involved such as is found in systems of mercuric acetate and unreactive organomercuric salts when the homopolar reaction occurs. This lack of an induction period is seen in Fig. 1 where the

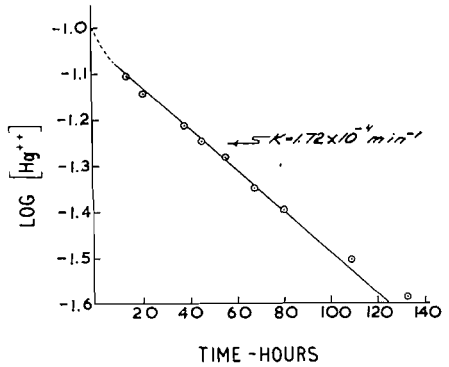


FIG. 1. System: mercuric acetate (0.10 m), cyclohexylmercuric acetate (0.05 m), and boron fluoride etherate (0.02 m) in methanol at 25° C.

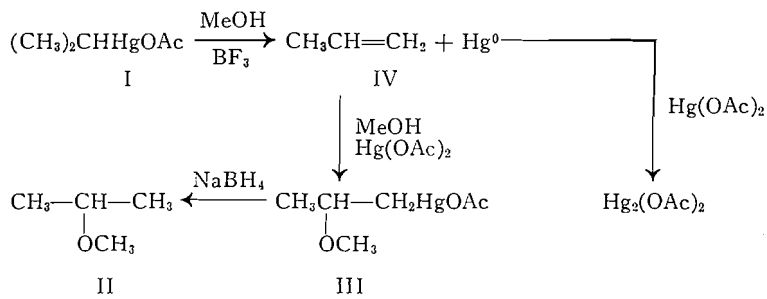
actual concentration of mercuric acetate at a certain time is defined as the difference between twice the experimentally determined value and the initial value.

$$[Hg(OAc)_2]_t = 2[Hg^{++}\text{obs.}] - [Hg(OAc)_2]_0$$



This calculation is valid because the oxymercurial formed *in situ* is decomposed prior to titration.

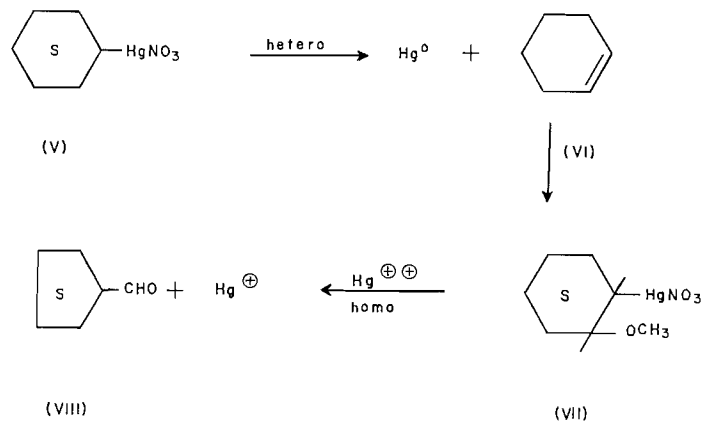
Inspection of Fig. 1 shows that the experimental data do not justify the first order slope that is drawn through part of the points. An attempt to fit the data to second order kinetics has been equally unsatisfactory. These discrepancies are not unexpected since the yield of α-2-methoxycyclohexylmercuric salt is only 75% while the yield of mercurous salt is 105%. Indeed it would be expected that upon the termination of its induction period the reaction of mercuric acetate plus boron fluoride in methanol (2) would commence to form mercurous salt and radicals. If a reactive organomercurial were present the homopolar reaction would then proceed concomitantly with the heteropolar reaction. This duality does not occur with the unreactive cyclohexylmercuric acetate but an example will be seen later in this report.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

Of course it might be postulated that the oxidation of organomercuric salts proceeds by three rather than two mechanisms. It has been assumed that free alkene is formed and then oxymercurated when mercuric acetate is included in the organomercuric acetate – boron fluoride – methanol system. Alternatively, a third mechanism might be postulated in which oxidation occurred at the carbon adjacent to the acetatomercuri group. In this circumstance the formation of an oxymercurial would not be presumptive for initial formation of an alkene.

This alternative is not valid according to the reaction of 2-propylmercuric acetate (I) with boron fluoride and 2 equivalents of mercuric acetate in methanol. The product has been shown (by its reduction using sodium trimethoxyborohydride to 2-methoxypropane, II) to be 2-methoxy-1-propylmercuric salt (III) rather than 1-methoxy-2-propylmercuric salt, which would be the product of oxidation of 2-propylmercuric salt at the neighboring carbon atom. The over-all reaction may be formulated as follows.

Therefore it would seem that the recognizable product from this type of oxidation derives from the alkene such as IV rather than by a third mechanism involving α-oxidation of the alkylmercuric salt.



The actual experiment, which was not terminated until all of the 2 equivalents of mercuric acetate had been consumed, does not conform stoichiometrically with the formulation outlined above. The yield of mercurous salt is 130% of that expected by this formulation, while the yield of 2-methoxypropylmercuric chloride is only 32%. A similar discrepancy has been observed in the less-definitive oxidation of 3-pentylmercuric acetate. No definite kinetic order can be specified for these reactions. While no products other than the methoxymercurials are present in sufficient quantity for isolation it is significant that none of the original alkylmercuric salt is recoverable.

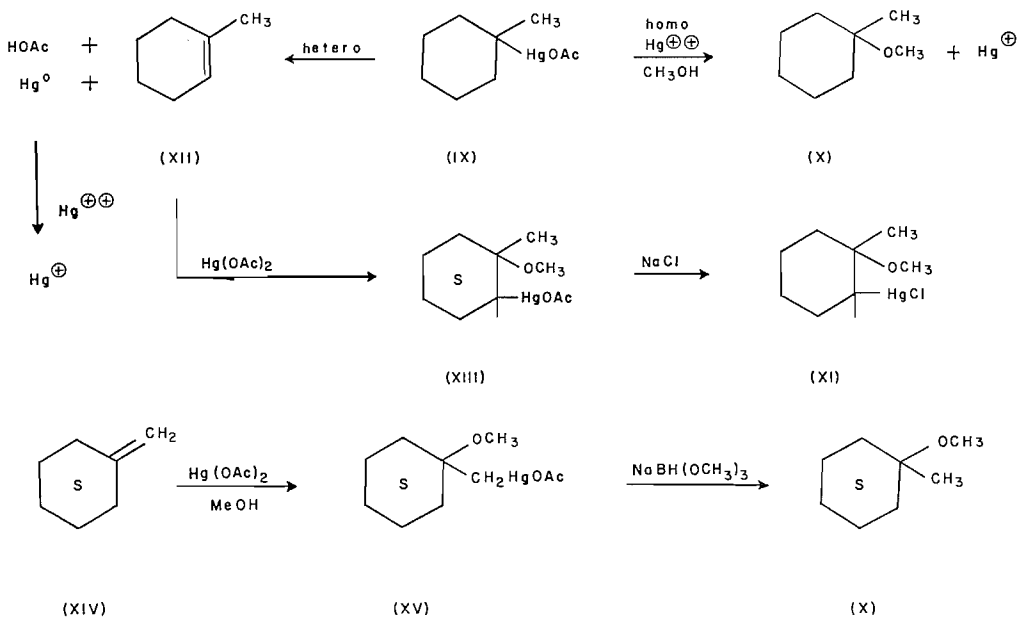
These deviations from stoichiometry may be attributed to the concomitant decomposition of mercuric acetate plus boron fluoride in methanol which establishes a radical chain if a susceptible organomercuric salt is present. While 2-propylmercuric acetate does not possess this susceptibility any more than does the cyclohexyl analogue it may be expected that the products of alkene oxymercuration (and especially the oxymercurials of pentene-2) will resemble 2-methoxy-2-methyl-1-phenylpropylmercuric acetate (2) more than they do the relatively stable α-2-methoxycyclohexylmercuric salt. The homopolar side reaction therefore consumes the oxymercurial derived from the alkene which is the initial product of the heteropolar reaction. It is evident that these homopolar side reactions may be minimized by deliberate oxygen inhibition.

A typical example of simultaneous reaction involving the two mechanisms has been reported in the previous publication (2) since it involves the opposite situation—where the homopolar reaction is the major one and the heteropolar reaction is minor. A small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

amount of formylcyclopentane (VIII) has been observed (2), besides the main products, cyclohexanol and its nitrate ester, when cyclohexylmercuric nitrate (V) is homolytically oxidized by mercuric nitrate. Undoubtedly this trace of aldehyde (1) is formed by a separate homopolar oxidation of 2-methoxycyclohexylmercuric nitrate (VII) which is derived *in situ* from cyclohexene (VI). This alkene will be formed by the heteropolar oxidation of V such as is reported in Table I.

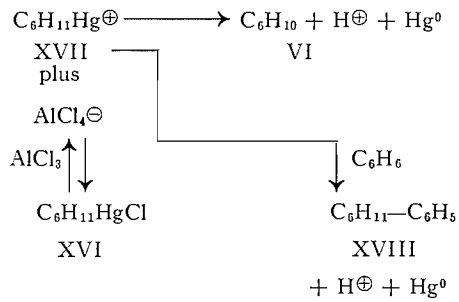
The simultaneous homopolar and heteropolar process on a single mercurial is shown also in the single instance of reaction with a tertiary alkylmercuric salt which we have been able to carry out. With this 1-methyl-1-cyclohexylmercuric salt no boron fluoride is required. Even the chloride survives only a few hours at 25° before it decomposes to metallic mercury and an oil. The acetatomercurial (IX) cannot be isolated but we have prepared it *in situ* by addition of silver acetate to a slurry of 1-methyl-1-chloromercuricyclohexane in a solution of mercuric acetate (2 equivalents) in methanol. It is evident from the rapidity of reaction that electron repulsion in the alkyl group precludes the necessity for electron attraction by a Lewis acid.



Three products have been isolated from a complex mixture. The isolated non-mercurial has been shown to be 1-methoxy-1-methylcyclohexane (X, estimated yield 25%) by comparison of its physical constants (5) and its R_f on a chromatoplate (6). This product is the expected one from the homolytic oxidation described in earlier reports (1, 2).

Not all of the substances containing mercury have been separated from the mixture of products, and the yields of substances which have been isolated are not significant because of the difficulties of separation. Several per cent of 2-methoxy-2-methylcyclohexylmercuric chloride (XI) has been isolated, which indicates that the heterolytic autooxidation also has been taking place via XII and XIII.

Another organomercuric salt was also isolated but it has not been identified. It is not 1-chloromercurimethyl-1-methoxycyclohexane (XV) because this substance has been synthesized for the purpose of comparison from methylenecyclohexane (XIV) (7) and its structure has been proved by reduction to 1-methoxy-1-methylcyclohexane.



This non-identity should not be construed as evidence that XV is not present in the mixture of products obtained from 1-methylchloromercuricyclohexane. It does show that the oxidation is more complex than may be shown by the formulation which is outlined above. But of prime significance is the evidence that when the C—Hg linkage is sufficiently weak the electron-withdrawing action of a Lewis acid is not required. Moreover, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

reaction shows that the lability of the C—Hg bond is specifically neither homo- nor hetero-polar, but rather is responsive to the environment in which it exists.

Nevertheless, the effect of the electron-withdrawing agent is profound. Thus it may be seen in Table I that cyclohexylmercuric chloride (XVI) is stable in methanol in presence of hydrochloric acid; also it is stable in benzene – hydrogen chloride. However the addition of 0.4 equivalent of aluminum chloride induces reaction in benzene to a 75% yield of cyclohexylbenzene (XVIII).

The reaction may proceed via the cyclohexylmercuri cation (XVII), or else cyclohexene (VI) may be an intermediate. Certainly the same product is obtained by treatment of cyclohexene in benzene with aluminum chloride. On the other hand the product is not cyclohexene but, rather, a polymer when the reaction is carried out in cyclohexane rather than benzene. Neither cyclohexene nor bicyclohexyl is detectable. In further extensions of the reaction *sec*-butylmercuric chloride yields *sec*-butylbenzene, but *n*-butylmercuric chloride does not react.

DISCUSSION

Although the heteropolar autooxidation of organomercurials has not been reported previously there are numerous papers dealing with the oxidation of alkenes by mercuric salts. In our opinion all of these oxidations involve an oxymercurial as an intermediate. Only one of these, the reaction of safrole with mercuric acetate (8, 9), may be explained as a homopolar oxidation of the intermediate. The remainder (references 10–17 inclusive) may be explained on the basis of the products in terms of heteropolar autooxidation of an intermediate oxymercurial. To be sure a concomitant homopolar oxidation cannot be precluded in these oxidations. The yield of product typical of heteropolar autooxidation is not high, so the unidentified by-products may well be the result of homopolar oxidation. Indeed it is possible that the yield of the desired products might be augmented by sufficient oxygen concentration to inhibit the homopolar reaction. In this instance a single equivalent of mercuric acetate per mole of alkene ought to be sufficient, especially if boron fluoride were added as well.

The authors acknowledge financial aid from the National Research Council of Canada, which has been used to support this investigation.

EXPERIMENTAL*

Autooxidation of Cyclohexylmercuric Acetate

(*a*) *In Methanol*

A solution of cyclohexylmercuric acetate (0.005 mole) was prepared by filtration of silver chloride (quantitative) after a solution of cyclohexylmercuric chloride (0.005 mole, 1.60 g) in 50 ml of methanol was treated with 0.005 mole (0.84 g) of silver acetate. The filtrate was then treated with 0.002 mole (0.25 ml) of boron fluoride etherate and was maintained at 50° for 24 hours. Then the cooled system was filtered to remove metallic mercury (0.99 g, 99%) and the filtrate was treated with 1.60 g (0.005 mole) of mercuric acetate. After 30 minutes the system, chilled to 0°, was treated with 100 ml of water and 2.5 ml of 5 *M* aqueous sodium chloride. Filtration gave 88% (1.52 g) of α-2-methoxycyclohexylmercuric chloride, m.p. 112–113°, identified by mixture melting point. When the same experiment was carried out at 25° during 72 hours the yield of mercury was 90%, and 84% of the organomercurial was obtained. Expt. 5, Table I, shows an identical experiment except that trifluoroacetic acid was used instead of boron fluoride etherate.

(*b*) *In Methanol with 2 Equivalents of Mercuric Acetate*

This reaction was followed kinetically. A solution of 0.005 mole of cyclohexylmercuric acetate in 50 ml of methanol was prepared from 1.595 g (0.005 mole) of cyclohexylmercuric chloride and 0.834 g (0.005 mole) of silver acetate. After quantitative removal of silver chloride, 0.252 ml (0.002 mole) of boron trifluoride etherate and 3.188 g (0.01 mole) of mercuric acetate were added. The solution was made up to 100 ml with methanol and was maintained at 25°. Analyses were made by removal of mercurous salt and unchanged cyclohexylmercurial by dilute hydrochloric acid according to the method described previously (2). We used 3-ml aliquots and allowed the solution before filtration to stand 30 minutes to ensure complete decomposition of the 2-methoxycyclohexylmercuric salt. The filtrate was titrated for unchanged and regenerated mercuric salt. The results are shown in Fig. 1.

**Melting points have been corrected by reference to reliable standards. X-ray patterns are reported in Å at intensities $[I/I_1]$ using* Cu K_α *(Ni-filtered) radiation.*

A duplicate reaction system was maintained *in toto* for 37 hours at 50° and then was filtered to remove 5.48 g (105%) of mercurous acetate. The filtrate was diluted with 200 ml of water plus 10 ml of 5 *N* aqueous sodium chloride, and then was five times extracted with 25-ml portions of chloroform. Evaporation of the extracts left 2.62 g (75%) of α-2-methoxycyclohexylmercuric chloride, m.p. 113–114°, identified by mixture melting point. The absence of β diastereomer was shown by solution of 0.5 g in 8 ml of methanol to which 0.2 ml of concentrated hydrochloric acid was added. After the solution was swirled for exactly 1 minute 1 ml of 6 *M* aqueous sodium hydroxide and then 8 ml of water were added quickly. After filtration through Celite the filtrate was acidified by carbon dioxide and finally by acetic acid. There was no precipitation of β diastereomer.

(*c*) *In Benzene*

The solution of cyclohexylmercuric acetate (0.005 mole) in methanol was evaporated to dryness under reduced pressure and then was dissolved in 50 ml of benzene containing 0.002 mole (0.25 ml) of boron fluoride etherate. After 15 hours at 50° the system was cooled and filtered to remove 0.87 g (87%) of metallic mercury. The filtrate distilled totally, showing that no mercurial remained. The distillate was treated with 100 ml of methanol and 1.60 g (0.005 mole) of mercuric acetate. After 15 hours the system was evaporated under reduced pressure (20–25°) and the residue, dissolved in water–methanol, was treated with sodium chloride to yield 1.27 g (73%) of α-2-methoxycyclohexylmercuric chloride, m.p. 108–111°, identified by mixture melting point.

(*d*) *In 2,5-Dioxahexane*

In an otherwise identical system dioxahexane replaced benzene. After 160 hours at 50° the cooled system was filtered to remove 0.71 g (71%) of metallic mercury. Vacuum distillation at 20° left 15 ml which, treated with aqueous sodium chloride, yielded 0.34 g (21%) of cyclohexylmercuric chloride. The distillate, treated with 60 ml of methanol and 0.005 mole of mercuric acetate for 30 minutes, was again vacuum-evaporated. Treatment of the residue with aqueous sodium chloride yielded 1.01 g (73%) of α-2-methoxycyclohexylmercuric chloride, identified by mixture melting point.

Autooxidation of Cyclohexylmercuric Trifluoroacetate

The silver trifluoroacetate used in this experiment was prepared from silver oxide and trifluoroacetic acid (0.354 mole). After evaporation at 0.1 mm the residue was dissolved in benzene (75 ml), and 50 ml of hexane was added. The precipitate was evidently a complex with benzene since 25.2 g, finely ground, was reduced in weight to 22.2 g at 55° (0.1 mm). The X-ray diffraction pattern was: [10] 6.10, 3.60; [8] 2.33; [7] 2.58; [5] 3.00; [4] 2.70; [2] 3.31, 2.50; [1] 4.74, 3.95, 3.11. Calc. for $C_2F_3O_2Ag$: Ag, 48.84. Found: Ag, 48.55, 48.68.

The mercurial was prepared from 0.005 mole (1.60 g) of cyclohexylmercuric chloride and 0.005 mole (1.11 g) of silver trifluoroacetate in 50 ml of methanol; the silver chloride was filtered off. After 22 hours at 50° the system was processed as was described for the acetate – boron fluoride experiments to yield mercury (92%) and α-2-methoxycyclohexylmercuric chloride (70%).

Autooxidation of Cyclohexylmercuric Nitrate

A solution of 0.005 mole of cyclohexylmercuric chloride in 50 ml of methanol was treated with 0.005 mole (0.85 g) of silver nitrate and the silver chloride was filtered off. Subsequent processing, like the acetate, after 1 day at 50° yielded mercury (97%) and α-2-methoxycyclohexylmercuric chloride (73%).

Reaction of Organomercurials with Hydrogen Chloride

A 94% recovery of isopropylmercuric chloride was effected after 1-hour reflux with 4 ml concentrated hydrochloric acid in 15 ml of methanol; similarly with cyclohexylmercuric chloride. The same behavior was observed at 25° for 1 day with hydrogen-chloride-saturated methanol. In none of these instances was inorganic mercury detectable. On the other hand, 1 g (0.0031 mole) of benzylmercuric chloride in 15 ml of hydrogen-chloride-saturated methanol at 50° for 24 hours yielded only 0.39 g (39%) of unchanged chloromercurial (mixture melting point) upon dilution with water. The basified filtrate yielded 0.35 g (53%) of mercuric oxide.

Reaction of Phenylmercuric Acetate with Boron Fluoride

A solution of 0.005 mole of phenylmercuric acetate, 0.002 mole of boron fluoride etherate, and 50 ml of dry methanol was held at 50° for 24 hours but no metal precipitated. Subsequently 98% of the original mercurial was recovered as phenylmercuric chloride, m.p. 250–251°, mixture melting point not lowered.

Isopropylmercuric Chloride

This preparation is reported as typical for alkylmercuric halides since the procedure is simplified beyond others reported in the literature, while the yields are oftentimes better, especially for some unstable halogenomercurials.

The filtered Grignard reagent from 0.20 mole of isopropyl chloride in 120 ml of dry ether was stirred while 0.24 mole (64.8 g) of dried mercuric chloride was added in portions during 2 hours. The resulting suspension was stirred for 24 hours, more dry ether being added if necessary to ensure efficient stirring. Then 250 ml of water was added cautiously and the ether was removed while the system (below 10°) was stirred under reduced pressure. The final slurry was filtered, air-dried, and dissolved with trituration in 400 ml of chloroform at 25°. After a final brief temperature increase to 45° the solution was filtered and the filtrate was evaporated under reduced pressure leaving 47.6 g (86%) of isopropylmercuric chloride, m.p. 94.5–95.5°, not raised by recrystallization from commercial hexane or 85% aqueous methanol. Calc. for C_3H_7HgCl: C, 12.9; H ,2.53. Found: C, 13.0; H, 2.71. This product in methanol could be converted to the nitrate salt by means of silver nitrate and thence by treatment with sodium bromide to isopropylmercuric bromide, m.p. 90.5–91.5°. A mixture melting point with the chloromercurial was depressed to 77–82°.

Cyclohexylbenzene

A solution of 1.59 g (0.005 mole) of cyclohexylmercuric chloride, 0.27 g (0.002 mole) of aluminum chloride, and 50 ml of benzene was stirred for 6 hours and then was decanted from 0.77 g (77%) of metallic mercury. The solution was then washed with water until it was neutral, during which time 0.22 g (19%) of mercurous chloride separated. The non-aqueous layer was distilled up to 80° to prove that the distillate contained no cyclohexene (test with mercuric acetate and methanol) and then was distilled further, b.p. 108–110° at 12 mm, 0.66 g (75%), m.p. 4.5–6.5°. This product was identified by mixture melting point with an authentic sample prepared from cyclohexene, hydrogen chloride, aluminum chloride, and benzene (18).

When this experiment was carried out in cyclohexane rather than benzene, 92% of the mercury was precipitated as metal, but only a gummy mass with no cyclohexene or bicyclohexyl was obtained as the organic product.

For personal use only.

sec-Butylbenzene

A slurry of 8.00 g (0.027 mole) of *sec*-butylmercuric chloride (19), 1.49 g (0.0112 mole) of aluminum chloride, and 100 ml of dry benzene was stirred for 15 hours and then decanted onto ice. The metallic mercury was separated (3.66 g, 67%). The benzene phase, washed with dilute alkali and then water, was dried (magnesium sulphate) and distilled, b.p. 170–173° (750 mm), 2.74 g (75%), n_D^{20} 1.4908 (20). When *n*-butylmercuric chloride was used instead of the secondary isomer it was recovered quantitatively.

2-Methoxypropylmercuric Chloride

(*a*) *From Isopropylmercuric Acetate*

A quantity of 2.79 g (0.01 mole) of isopropylmercuric chloride in 50 ml of methanol was converted to the acetate by means of silver acetate (0.01 mole). After filtration of the silver chloride, 6.38 g (0.02 mole) of mercuric acetate and 0.50 ml (0.004 mole) of boron fluoride etherate were added together with methanol to a total volume of 100 ml. After 37 hours at 50°, 6.26 g of mercurous acetate was filtered off and the chilled filtrate was diluted with 120 ml of water to which 10 ml of 5 *M* aqueous sodium chloride was then added. The resulting suspension was 5 times extracted with chloroform (125 ml total), and the aqueous phase was then filtered to remove 0.52 g of mercurous chloride (total Hg_2^{++}, 0.0132 mole or 132%). Vacuum evaporation of the chloroform left 1.00 g (32%) of yellow oil, m.p. −15° to −12.5°. Three crystallizations from methanol (2.5 ml per g) raised the melting point (−9 to −7.5°), and a mixture melting point with the authentic specimen described below was not lowered.

(*b*) *From Propene*

Propene gas was bubbled into a stirred suspension of 15.9 g (0.05 mole) of mercuric acetate in 75 ml of methanol at 0° at such a rate that a slight positive pressure was maintained in the closed system. When the pressure rose sharply and the test for mercuric ion was negative, the system was poured into 150 ml of cold water and 15 ml of 5 *M* aqueous sodium chloride was added. The oil was taken up by four extractions with a total of 120 ml of chloroform. The extract was dried (calcium chloride) and vacuum-evaporated, 15.24 g (99%), m.p. −7 to −4°. Three crystallizations from methanol (3 cc per g) left 10.4 g, m.p. −5.5 to −4.5°. After several days at −10° this substance started to decompose, yielding calomel. The organomercurial was analyzed by a micro method (21). Calc. for C_4H_9ClHgO: Hg, 64.9; Cl, 11.47. Found: Hg, 64.8; Cl, 11.63.

2-Methoxypropane

(*a*) *From 2-Methoxypropylmercuric Chloride*

A solution of 7.15 g (0.025 mole) of 2-methoxypropylmercuric chloride in 35 ml of water plus 5 ml of 6 *M* aqueous sodium hydroxide was chilled to 0° while 6.39 g (0.05 mole) of sodium trimethoxyborohydride was added during 1 hour. The system was then warmed to 60° to distil the ether into an ice-cold receiver. Redistillation gave 1.20 g (65%) of 2-methoxypropane, b.p. 32–33°, d_4^{25} 0.720, n_D^{20} 1.3532.

(*b*) *From 2-Propanol*

Sodium (0.16 g-atom, 3.68 g) was dissolved in 125 ml of dry 2-propanol. Then 17 g (0.12 mole) of methyl iodide was added and the solution was refluxed for 1 hour. Distillation gave 6.7 g (75%), b.p. 32–33°, d_4^{25} 0.719, n_D^{20} 1.3532. A similar preparation of 1-methoxypropane gave constants as follows: b.p. 38°, d_4^{25} 0.727, n_D^{20} 1.3584.

3-Chloromercuripentane

This substance was prepared from 3-chloropentane (22) by the general method for alkyl chloromercurials outlined above, 79% crude yield, m.p. 18–20°. Crystallization from commercial hexane (3 ml per g) raised the melting point to 21.3–21.7°. The substance was unstable and formed calomel slowly at 25°. Mercury analysis was effected by Walton's method (23). Calc. for $C_5H_{11}ClHg$: C, 19.5; H, 3.62; Hg, 65.3. Found C, 18.9; H, 3.61; Hg, 65.1.

Mixture of Vicinal Methoxypentylmercuric Chlorides

(*a*) *From 2-Pentene*

A solution of 2-pentene (b.p. 36–36.5°, n_D^{20} 1.3816) (24) and 4.47 g (0.014 mole) of mercuric acetate in 12 ml of dry methanol gave a negative test for mercuric ion within 15 minutes. The solution was poured into 24 ml of water containing 4 ml of 6 *M* aqueous alkali and the whole was filtered through Celite for clarification. To the chilled filtrate was added 3 ml of 5 *M* aqueous sodium chloride and then gaseous carbon dioxide was added until precipitation of oil was complete. The oil was collected in chloroform and the extract was evaporated leaving 3.36 g (71%) of non-crystallizable oil. The infrared spectrum (2–15 μ) showed the following absorption bands (cm^{-1}): 2950(s), 1465(m), 1382(m), 1326(m), 1196(m), 1185(m), 1152(m), 1080(s), 1028(w), 992(w), 921(w), 886(w), 832(w), 802(w), 758(w).

(*b*) *By Autooxidation of 3-Acetatomercuripentane*

A solution of 3-chloromercuripentane (3.07 g, 0.01 mole) in 30 ml of dry methanol was converted to the acetatomercurial by treatment with an equivalent of silver acetate. After removal of silver chloride (100%), 6.38 g (0.02 mole) of mercuric acetate and 0.50 ml of boron fluoride etherate were added. The system was made up to 100 ml with methanol and maintained for 44 hours at 50°. Then 5.81 g of mercurous acetate was filtered off, and the chilled filtrate was diluted with 120 ml of cold water followed by 10 ml of 5 *M* aqueous sodium chloride. Five extractions with chloroform removed the oxymercurials leaving 0.13 g of calomel filterable from the aqueous phase (total Hg_2X_2 0.012 mole, 120%).

The crude oxychloromercurial was purified by solution in aqueous alkali followed by treatment of the filtered solution with gaseous carbon dioxide. The product, recovered by chloroform extraction, gave an infrared spectrum superimposable upon that obtained by the product of procedure (*a*).

1-Methylcyclohexylmercuric Chloride

Fractionally distilled 1-methyl-1-chlorocyclohexane (25) (b.p. 77.5–78.0° at 73 mm, n_D^{20} 1.5484), 0.5 g in 5 ml of dry ethyl ether was stirred with 0.73 g (0.03 g-atom) of magnesium. This metal (stored under dry ether until it was used) had previously been activated by treatment with bromobenzene from which it was subsequently freed by thorough washing by dry ether.

After the reaction had commenced (cloudiness) a solution of 3.2 g of the chloride (total 0.027 mole) in 30 ml of dry diethyl ether was added during 8 hours. After 12 hours of further stirring 7.60 g (0.028 mole) of mercuric chloride was added rapidly. The suspension was stirred for another 7 hours, then was diluted with 70 ml of chloroform and the whole was filtered. Vacuum evaporation of the filtrate left a crystalline mass which was dissolved at 25° in 25 ml of acetone. This solution at −80° precipitated 0.92 g of white needles. A second similar crystallization from acetone gave 0.79 g (9.4%) of 1-methyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

cyclohexylmercuric chloride, no definite melting point. The X-ray diffraction pattern was [10] 9.50; [6] 4.02; [5] 3.70; [4] 4.60, 3.49; [3] 4.89, 3.29, 2.85; [2] 4.44, 4.29. Calc. for $C_7H_{13}ClHg$: C, 25.2; H, 3.93; Hg, 60.2. Found: C, 25.3; H, 3.70; Hg, 60.2, where the analysis for mercury was that of Whitmore and Sobatzki (26). The substance decomposed quickly at 25° but was stable for a few days at −70°.

1-Methylcyclohexylmercuric Acetate with Mercuric Acetate in Methanol

A slurry was prepared by dissolving 5.83 g (0.0183 mole) of mercuric acetate in 45 ml of dry methanol, then adding 1.55 g (0.0093 mole) of silver acetate and finally 3.09 g (0.0093 mole) of 1-methyl-1-chloromercuricyclohexane. The system was stirred 4 hours and then a gray solid was filtered off. This solid was shaken with 40 ml of 13% aqua ammonia to dissolve the silver chloride and leave 3.70 g (0.0178 mole) of mercurous oxide.

The methanolic filtrate at 0° was diluted with 100 ml of water, and 3 ml of 5 *M* aqueous sodium chloride was added. This diluate was extracted seven times with a total of 175 ml of ether. The extract was washed four times with a total of 120 ml of 1 *M* aqueous sodium hydroxide and then with water until the non-aqueous phase was neutral.

The combined alkaline and aqueous washing was filtered to remove 0.83 g (0.0038 mole) of mercuric oxide. The filtrate was acidified with carbon dioxide and then four times extracted with a total of 100 ml of chloroform. Vacuum evaporation of this extract left 1.52 g, m.p. 70–120°. Extraction with 3 ml of commercial hexane left an insoluble fraction which was crystallized from 3:7 water–methanol (8 ml per g), 0.57 g, m.p. 122–124°. This unidentified mercurial is base-soluble and easily demercurated by the action of methanolic hydrogen chloride. It is not 2-methoxy-2-methylcyclohexylmercuric chloride, described below.

The hexane-soluble part of the crude product extraction was evaporated and the residue was crystallized repeatedly from commercial hexane (20 ml per g), 0.06 g (3%), m.p. 79–80°, which was identified by mixture melting point with an authentic specimen (27).

The ether phase from which the alkaline phase containing the mercurials was separated was dried with magnesium sulphate and then distilled, 0.29 g, b.p. 130–140°. Redistillation gave 0.11 g (25% crude, 9% redistilled) of 1-methoxy-1-methylcyclohexane, b.p. 140–150°, n_D^{20} 1.4422. The identity with an authentic sample (b.p. 147–149°, n_D^{20} 1.4427) prepared according to Triebs' procedure (5) was established by a chromatoplate analysis in which silicic acid was the adsorbent and benzene was the eluant. The chromatogram was developed by use of a nitric – sulphuric acid spray.

1-Chloromercurimethyl-1-methoxycyclohexane

Hexahydrobenzyl acetate was pyrolyzed to methylenecyclohexane by Arnold's method (7). This alkene (0.96 g, 0.01 mole) and 3.19 g (0.01 mole) of mercuric acetate were shaken for 1 hour in 12 ml of dry methanol, then the system was chilled, diluted by 35 ml of cold water, and 3.0 cc of 5 *M* aqueous sodium chloride was added. The 3.33-g (91% crude) yield, m.p. 59–64°, was thrice crystallized from commercial hexane (8 ml per g), m.p. 68.3–69.0°. Calc. for $C_8H_{15}ClHgO$: C, 26.5; H, 4.16. Found: C, 26.6; H, 4.30.

A solution of 6.9 g (0.019 mole) of this mercurial in 4 ml of 6 *M* aqueous sodium hydroxide plus 35 ml of water was stirred at 0° while 4.85 g (0.038 mole) of sodium trimethoxyborohydride was added during 30 minutes. The ether extract of this system was then dried with magnesium sulphate and distilled, 1.73 g (71%), b.p. 145–148°, n_D^{20} 1.4414. This 1-methoxy-1-methylcyclohexane was identified by chromatoplate and also by comparison with the sample prepared by Triebs' method (5) according to the following

HYDROGEN BONDING IN THE AMINE HYDROHALIDES

II. THE INFRARED SPECTRUM FROM 4000 TO 2200 CM^{-1} [1]

C. BRISSETTE AND C. SANDORFY

ABSTRACT

The infrared spectra of a number of amine hydrohalides have been measured in the lithium fluoride region.

Hydrogen bonding and the torsional oscillations of the $\overset{+}{N}H_3$ groups influence these spectra characteristically. The $\overset{+}{N}$—H - - - X^- stretching frequencies give broad or fairly broad bands. They are near 3000 cm^{-1} for aliphatic primary amine salts. The corresponding band lies at somewhat lower frequencies for secondary amine salts and much lower for tertiary ones. The aromatic amine hydrohalides exhibit these bands at lower frequencies than do the aliphatic amine salts of the same order. There is a shift to higher frequencies in the series hydrochloride, hydrobromide, hydriodide.

All these spectra contain a number of sharper bands which may or may not coincide with the hydrogen-bonded stretching bands. These are combination bands involving mainly deformation vibrations, and they shift to lower frequencies, throughout the series hydrochloride, hydrobromide, hydriodide.

The importance of electrical anharmonicity for the appearance of these bands is stressed. The hydrogen bonds in amine hydrohalides appear to be largely electrostatic in character.

INTRODUCTION

The infrared spectra of ammonium halides were investigated by Wagner and Hornig (1, 2) and by Plumb and Hornig (3, 4). A primary aliphatic amine hydrohalide, methylamine hydrochoride, was treated by Waldron (5). Tertiary amine hydrohalides were discussed by Lord and Merrifield (6). More recently Chenon and Sandorfy (7) discussed some general aspects of the infrared spectra of amine hydrohalides measuring the spectra of a number of aliphatic and aromatic primary, secondary, and tertiary amine hydrochlorides, hydrobromides, and hydriodides. (This paper will be referred to henceforth as I.)

This series of compounds offers particular advantages for the study of hydrogen bonding. By studying the different hydrohalides of the same amine we can introduce a gradual change in hydrogen bond energy and by considering the amines of different order we can vary from one to three the number of hydrogen atoms which may be affected by hydrogen bonding. The effect of the more distant molecular environment may be studied by taking various aromatic and aliphatic amines. The effect of the net charges on the end atoms may also be examined.

In paper I, a general review of the subject was given. At present we intend to consider the high frequency part of the infrared spectrum (4000 to 2200 cm^{-1}) in more detail. This will lead us to a closer look at the nature of hydrogen bonding in these cases.

EXPERIMENTAL

A Perkin–Elmer model 112 single beam – double pass instrument was used with a lithium fluoride prism.

The whole instrument was put under a dry nitrogen atmosphere in order to eliminate atmospheric water and CO_2 absorption. All the spectra were taken in both nujol and fluorocarbon oil mulls. No significant differences were observed between the spectra taken in these two media.

RESULTS

The spectra of the three hydrohalides of the following amines were measured.

(*a*) Aliphatic primary amines: ethylamine, *n*-butylamine, *sec*-butylamine, isobutylamine, *tert*-butylamine, cyclohexylamine.

(*b*) Aliphatic secondary amines: diethylamine, di-*n*-butylamine, piperidine.

(*c*) Aliphatic tertiary amines: triethylamine, tri-*n*-butylamine.

(*d*) Aromatic primary amines: aniline, α-naphthylamine, β-naphthylamine.

(*e*) Aromatic secondary amines: diphenylamine, N-methylaniline.

(*f*) Aromatic tertiary amines: pyridine, N,N-dimethylaniline, N-methyl diphenylamine.

Tables I and II give one typical example for each of classes (*a*) to (*f*). The data concerning the bands located between 2200 and 1900 cm^{-1} are taken from paper I (sodium chloride prism).

INTERPRETATION OF THE SPECTRA

(*A*) *Aliphatic Primary Amine Salts*

It was not possible under the low resolution of the sodium chloride prism and with a number of CH_3 and CH_2 groups present in the molecules to disentangle the coincident CH_3, CH_2, and $\overset{+}{N}H_3$ or $\overset{+}{N}H_2$ absorption near 3000 cm^{-1}. This remains difficult using the lithium fluoride prism. It is quite clear, however, that in the case of aliphatic primary and secondary amine salts there is a strong and fairly broad band system in partial coincidence with CH_3 and CH_2 bands. This band system must contain the two $\overset{+}{N}H_2$ or $\overset{+}{N}H_3$ stretching bands or, in the case of the latter, the three stretching bands if the symmetry is lower than C_{3v}.

The spectra of the aliphatic primary amine salts, shown in Table I, bear a great resemblance to those of the ammonium halides (1, 2, 3, 4) and seem to be quite analogous to the spectrum of methylamine hydrochloride discussed by Waldron (5), who measured this spectrum at 300° K, 90° K, and 230° K. At each of these temperatures the compound exists in a different phase designated α, β, and γ in this order. In the α-phase he found the two $\overset{+}{N}H_3$ and the two CH_3 stretching frequencies near 3000 cm^{-1} giving a broad feature in the spectrum and only two or three bands down to 2000 cm^{-1}. The band near 2000 cm^{-1} which we found in all the primary aliphatic amine hydrohalides is significantly absent from the spectrum in the α-phase.

Waldron was able to assign practically all the bands using the analogy with ethane. Under C_{3v} symmetry the antisymmetrical $\overset{+}{N}H_3$ and CH_3 stretching and bending vibrations and the $\overset{+}{N}H_3$ and CH_3 rocking vibrations are doubly degenerate and the torsional oscillation is forbidden, though it might appear in combinations. Actually in the α-phase no splitting of the degenerate bands occurs and the torsional oscillation is absent, indicating threefold symmetry. In the β-phase the torsional oscillation was found by Waldron at 487 cm^{-1}, a strong band appears at 2075 cm^{-1} and a series of sharp bands appear between 2800 and 2400 cm^{-1}. In the γ-phase the situation was similar but the torsional oscillation band was not actually found. The main point is that the low temperature phases have no threefold axis and therefore the degenerate bands split.

Now, it is very interesting that all our primary amine hydrohalide spectra closely resemble Waldron's low temperature spectra although they have all been measured at room temperature. The natural explanation is that because of the bulky groups linked to the nitrogen atom none of our compounds possesses C_{3v} symmetry nor a threefold axis.

vs = very strong. s = strong. m = medium. w = weak. vw = very weak. * = "centre of gravity".

The band near 2075 cm^{-1} was assigned by Waldron to a combination band between the torsional oscillation (487 cm^{-1}) and the antisymmetrical bending vibration of the $\overset{+}{N}H_3$ group (1580 cm^{-1}); the sharp bands between 2800 and 2400 cm^{-1} were assigned to combinations between various $\overset{+}{N}H_3$ and other deformation bands. This can now be generalized to all the aliphatic primary amine hydrohalides whose spectra are reported here.

The sharp bands between 2800 and 2400 cm^{-1} generally accompany the strong combination band near 2000 cm^{-1}. The splitting of the former and the high intensity of the latter both appear to be connected with the lowering of symmetry, although the combination tone near 2000 cm^{-1} is allowed under C_{3v} symmetry. The lowering of the intensity of the bending bands in the 1600–1500 cm^{-1} area found by Waldron seems to be a related phenomenon.

The characteristic shift toward lower frequencies of the bands between 2800 and 2400 cm^{-1} in the order Cl→Br→I is definitely confirmed by our new measurements and is explained making use of the above assignments. This shift is in the $\overset{+}{N}H_3$ *deformation* bands. The $\overset{+}{N}H_3$ stretching bands should then shift in the opposite direction giving the strongest hydrogen bond with the chloride ion and the weakest with the iodide ion. Unfortunately it is quite impossible to establish this prediction because of the considerable amount of band overlap which takes place in the 3000 cm^{-1} region. The cyclohexylamine salts give relatively the best chance of resolving the $\overset{+}{N}H_3$ stretching bands since there we have only CH_2 groups, and no CH_3 groups. In fact the cyclohexylamine hydriodide has the $\overset{+}{N}H_3$ bands well separated from the CH_2 bands while the hydrobromide and hydrochloride give only strong shoulders. A consideration of the spectra of the N-deuterated and perfluoro-alkyl analogs could solve this problem and work is going on in this laboratory in this direction.

The above interpretation is, however, in line with our findings on amine salts of other classes and therefore seems very probably correct (see below).

The band near 2000 cm^{-1} shifts in the same direction but more rapidly in the hydrohalide series Cl→Br→I than do the upper sharp bands. This must be due to the fact that its two components shift individually in the same direction.

There are two or three weak bands above the $\overset{+}{N}H_3$ stretching bands up to about 3200 cm^{-1}. These can be readily assigned to the first overtones of the bending vibrations located in the 1600–1500 cm^{-1} area or to a combination of them.

The interpretation of the sharp bands between 2800 and 2400 cm^{-1} as combination tones involving deformation modes (which differs from the assignment suggested in paper I) appears to be the key to the understanding of these spectra. Indeed, their characteristic shifting with different hydrohalides provides us with a method of distinguishing between $\overset{+}{N}$—H--X^- stretching bands and deformation bands. Combinations involving C—H or C—C vibrations should be distinguishable as well, since these should shift very little, or not at all, when the type of hydrohalide is varied from hydrochloride to hydriodide.

(*B*) *Aliphatic Secondary Amine Salts*

In the spectra of the secondary amine salts the $\overset{+}{N}H_2$ stretching bands are found at lower frequencies overlapping the CH_3 and CH_2 stretching bands from the low frequency side.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

The situation is not entirely clear, however, because of the high degree of overlapping.

There are no bands near 2000 cm^{-1} in the spectra of diethylamine and di-*n*-butylamine hydrohalides. In piperidine hydrohalides there are two or three weak bands in this part of the spectrum and at the same time a greater number of sharp bands appear in the 2800–2400 cm^{-1} region. The bands near 2000 cm^{-1} are probably due to combinations between the $\overset{+}{N}H_2$ bending vibration below 1600 cm^{-1} and some low frequency vibration. Proof should come from the low frequency part of the spectrum.

The bands of the secondary amine hydrohalides tend to be somewhat broader than those of the primary amine hydrohalides.

(*C*) *Aliphatic Tertiary Amine Salts*

As was stated in paper I, the center of gravity of the broad $\overset{+}{N}H$ absorption region of the hydrohalides of a given tertiary amine shifts towards higher frequencies in the order Cl→Br→I. This shift is in the reverse direction to that of the sharp bands between 2800 and 2400 cm^{-1} in the primary and secondary amine salts.

In all likelihood this absorption region is due to the $\overset{+}{N}H$ stretching band. Then it can be seen that since the hydrochloride has the lowest $\overset{+}{N}H$ stretching frequency the chloride ion gives the strongest hydrogen bonds.

The centers of the bands are at considerably lower frequencies than are the $\overset{+}{N}H$ stretching frequencies in the primary and secondary amine hydrohalides, being found at about 2600 and 2450 for the hydrochlorides of triethylamine and tri-*n*-butylamine respectively. Although we do not know exactly the frequency range of the unassociated $\overset{+}{N}H$ stretching band, it is quite clear that tertiary amine hydrohalides form stronger hydrogen bonds than do the primary and secondary amine salts. This is consistent with the fact that in this case the positive charge is distributed only between the nitrogen atom and one hydrogen atom, rather than two or three hydrogen atoms.

No broad bands appear in superposition with the CH_3 and CH_2 stretching bands in the tertiary amine salt spectra and this further confirms the assignment of the $\overset{+}{N}H$ stretching band in all these cases.

There are a great number of sharp bands superimposed on both sides of the main band center, and it is significant that those sharp bands which can be followed hydrochloride to hydrobromide to hydriodide exhibit a slight shift toward lower frequencies in the order Cl → Br → I just as do the sharp bands in the primary and secondary aliphatic salts. This shows again that these are combination bands involving $\overset{+}{N}H$ deformation bands and that the broad stretching band shifts in the opposite direction. Other bands of similar origin are in coincidence with the broader $\overset{+}{N}H$ stretching bands and it is difficult to follow their shifting.

As expected, no band appears near 2000 cm^{-1}, since there is no possibility of torsional oscillations of the tertiary amine group.

(*D*) *Aromatic Primary Amine Hydrochlorides*

The two main bands in aniline hydrochloride have their maxima at 2810 and 2570 cm^{-1} respectively, the upper one having a strong shoulder on the high frequency side. In the two other salts the separation is even larger. Since in the aliphatic case the antisym-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12

For personal use only.

metrical and symmetrical $\overset{+}{N}H_3$ stretching vibrations are almost coincident, it seems to be unlikely that the two main maxima in aniline hydrochloride correspond to these bands.

The upper maximum of aniline hydrochloride shifts toward higher frequencies in the order $Cl \rightarrow Br \rightarrow I$ but less than in the case of the tertiary amine hydrohalides. The lower maximum (with two peaks), however, shifts toward lower frequencies showing that these are not $\overset{+}{N}H_3$ stretching bands but combination bands involving fundamentals of $\overset{+}{N}H_3$ deformation vibrations and that the upper band which is stronger and broader must contain the two or three $\overset{+}{N}H_3$ stretching frequencies. There is a close analogy here with the "satellite" bands of carboxylic acid dimers discussed by Bratož, Hadži, and Sheppard (9).

As was pointed out in paper I, since aniline is a very weak base, it is possible that we have two potential minima of comparable depths for the hydrogen-bonded $\overset{+}{N}H_3$ stretching motions with a low barrier between them. If this is the situation, tunnelling of the proton may occur and the $\overset{+}{N}H_3$ stretching bands (or rather only the antisymmetrical one) (see ref. 3) may split. Blinc and Hadži (10) interpreted in this fashion the spectra of KH_2PO_4-type compounds and Detoni and Hadži (11) those of sulphinic acid.

A similar explanation, however, could hardly explain the two main bands of the aniline hydrohalides. It would be contradicted by the above described shifting of these bands and it is rendered improbable, too, by the large separation between them. A splitting by double-well mechanism is still possible if both bands resulting from the splitting are contained in the broad upper band. There is more indication for this in the spectra of α and β naphthylamine salts which otherwise resemble the spectrum of aniline. More work is needed to elucidate this problem.

The main point is that these spectra actually resemble the aliphatic analogues more closely than it may appear at first sight and follow the same general pattern.

In all the aromatic primary amine *hydrochlorides* there is a strong combination tone near 2000. Comparison with the amines themselves shows that these are unlikely to belong to the well-known combination bands of the aromatic compounds (12). However, torsional oscillations should be again possible in these cases.

(*E*) *Aromatic Secondary Amine Hydrohalides*

Diphenylamine hydrohalides have interesting spectra. The main band is at much lower frequencies than it is in aniline. Again the center of gravity shows the upward shift in going from Cl^- to I^- but the other sharp bands show the downward shift.

Surprisingly there is a well-formed doublet in the 2000 cm^{-1} area. This may be a combination between some low frequency vibration and the $\overset{+}{N}H_2$ bending band near 1550 cm^{-1}.

The N-methylaniline hydrohalide spectra show the same general features but the $\overset{+}{N}H_2$ stretching bands are in the 2800 cm^{-1} region.

(*F*) *Aromatic Tertiary Amine Hydrohalides*

N-Methyl diphenylamine and pyridine give very strong hydrogen bonds; N,N-dimethylaniline gives somewhat weaker ones, probably for steric reasons.

The centers of gravity of the $\overset{+}{N}H$ stretching bands move upwards (except in the case

of N,N-dimethylaniline where the hydrochloride and hydrobromide have $\overset{+}{N}H$ stretching bands at about the same place), and the sharp bands show the above described slight downward shift.

The $\overset{+}{N}H$ stretching bands in this group of salts are at rather low frequencies and this shows again that weak bases and tertiary bases form the strongest hydrogen bonds and that this is accompanied by greatly broadened bands.

The two bands in pyridine salts near 2000 cm^{-1} constitute a difficult problem. We tentatively assign them to combination tones usually found in spectra of aromatic compounds.

We see that the spectra of aromatic amine hydrochlorides differ from the aliphatic salts inasmuch as the hydrogen bonds are usually stronger and the bands are broader in the former, but the differences are not really of a fundamental nature.

DISCUSSION AND CONCLUSIONS

Among the factors which determine the energy of a hydrogen bond are the following: attractive electrostatic forces operating in an X—H---Y system, repulsions between the end atoms, and delocalization of the Y lone pair and X—H bonding electrons (13, 14, 15). The usually high intensity of hydrogen-bonded X—H stretching bands is explained by considering the variation of bond polarity during the vibrational motion and the increasing amount of delocalization when the bond is shortening (16, 17).

Concerning the energy of the hydrogen bond we suggest that in the case of amine hydrohalides it is largely electrostatic as would be expected because of the presence of net charges. The amount of positive charge left on the hydrogen-bonded protons is important in determining shifts going from hydrochlorides to hydrobromides and hydriodides. This was treated in more detail in paper I.

Although the absolute intensities were not measured, it was observed that the amine hydriodides have usually the weakest spectra. Since delocalization would give them the highest intensity this is further evidence that these hydrogen bonds are largely electrostatic in character.

The width of the bands and the appearence of many bands when hydrogen bonding is present are certainly the most interesting of the related problems and have received much attention. It has been suggested that the great anharmonicity of the potential surfaces is the cause of the appearance of many overtones and combination tones (18). The importance of anharmonicity for the various phenomena connected to hydrogen bonding cannot be overestimated. It is, however, very likely, as Bratož and Hadži pointed out, that only the parts of the potential surface pertaining to the XH stretching vibrations are very anharmonic and that the parts pertaining to the bending vibrations are only slightly anharmonic. It might, therefore, be suggested that those combination bands which are found in the XH stretching region accompanying the "real" XH stretching bands should be combinations between the latter and some other bands of lower frequency. This is, however, obviously not the case. In Waldron's interpretation of methylamine hydrochloride all the bands around the broad "real" stretching bands are overtones or combination tones involving bending vibrations. This is confirmed by the present results and especially by the direction of the frequency shift from hydrochloride to hydrobromide to hydriodide of all the sharper bands, which is in the opposite sense from that occurring for the broad true $\overset{+}{N}H$ stretching bands. Bratož, Hadži, and Sheppard (9) reached similar conclusions for carboxylic acid dimers and Newman and Badger for certain amides (19).

Combination tones due to deformation vibrations may coincide with the "real"

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

hydrogen-bonded stretching band and broaden and complicate it further. This is the case in the spectra of many secondary and tertiary amine hydrohalides. In other cases they may appear non-coincident giving a clearer spectrum as in ammonium salts and primary aliphatic amine hydrohalides.

If the sharp bands which appear in the $\overset{+}{N}H$ stretching region were interpreted as combinations between the "real" stretching bands and some low frequency band (possibly the series of harmonics of the XY bridge frequency) then they would have to be difference tones and thus they should disappear or become very weak at low temperatures. Waldron's work shows quite clearly, however, that this does not happen.

The pronounced ability of the bending bands to form combination tones may appear unusual because of the low mechanical anharmonicity of the deformation vibrations involved. (Fermi resonance could only be involved to explain their relatively high intensities where they fall close to the $\overset{+}{N}H$ stretching bands; this, however, is very often not the case.) It is interesting to note in this respect that the free amines, which form only weak hydrogen bonds, exhibit a few such bands in the 2800–2400 cm^{-1} area (see Tables I and II). It seems likely, therefore, that the mechanical anharmonicity of the potential curve due to hydrogen bonding is not the main cause of the appearance of these combination bands. Since the only other factor which might cause them to appear is electrical anharmonicity, we conclude that this latter effect must be very important in hydrogen-bonded molecules especially for bending vibrations, and that it is responsible for much of the fine structure. W. E. Thompson and Pimentel (20) reached similar conclusions in a study of the association between chloroform and cyclohexylamine.

RÉSUMÉ

Les spectres infrarouges d'un certain nombre d'halogénures d'amine ont été mesurés.

La formation de liaisons hydrogène et les oscillations torsionnelles des groupements $\overset{+}{N}H_3$ influencent ces spectres d'une manière charactéristique. Les vibrations de valence du groupe $\overset{+}{N}$—H---Y^- donnent des bandes larges ou assez larges. Elles se trouvent autour de 3000 cm^{-1} chez les sels des amines aliphatiques primaires. Elles apparaissent à des fréquences un peu plus basses chez les sels d'amines secondaires et beaucoup plus basses chez les tertiaires. Les sels halogènes des amines aromatiques ont ces bandes à des fréquences plus basses que les sels d'amines aliphatiques de la même catégorie.

Il y a un déplacement vers les hautes fréquences dans l'ordre chlorhydrate, bromhydrate, iodhydrate.

Tous ces spectres contiennent un certain nombre de bandes plus minces qui coincident ou non avec les bandes de valence $\overset{+}{N}$—H---Y^-. Ce sont des tons de combinaison faisant intervenir des modes de déformation. Ils se déplacent vers les fréquences basses dans l'ordre chlorhydrate, bromhydrate, iodhydrate.

L'importance de l'anharmonicité électrique faisant apparaître ces bandes est soulignée.

L'énergie de la liaison hydrogène vient surtout de contributions électrostatiques.

COMPLEX COBALT PERIODATES[1]

M. W. LISTER AND Y. YOSHINO[2]

ABSTRACT

A number of complex cobalt periodates have been prepared. Sodium periodatocobaltate (III) $Na_5H_2Co(IO_6)_2.10H_2O$ is obtained as green crystals when cobaltous and periodate ions react in the presence of alkaline sodium hypochlorite. Somewhat similar potassium, barium, and lanthanum salts are described. Various methods of demonstrating that the cobalt is trivalent, including the observation that sodium periodatocobaltate (III) is diamagnetic, are described. The free acid $H_7Co(IO_6)_2$ can be obtained in solution, and measurements have been made on its ionization constants. Observations have been made on the stability of these compounds, and the stability constant of the periodatocobaltic ion (in alkaline solution at 60° C) has been shown to be in the neighborhood of 10^{18}.

Some years ago one of the writers of this paper noted that complex periodates of trivalent copper could be prepared by oxidizing divalent copper to trivalent copper by means of sodium hypochlorite in the presence of sodium or potassium periodate (1). The compounds so obtained were the same as those prepared earlier by Malatesta, using persulphate oxidation (2). Evidence for the existence of the copper complexes and measurements on their stability were obtained from the fact that copper was a much less efficient catalyst for the decomposition of sodium hypochlorite if periodate was present; the complex salt did not catalyze this reaction while uncomplexed copper did. It was noted at the same time that the catalysis by cobalt salts was also much decreased if periodate was present, and this suggested that a similar cobalt compound might be formed. The present paper describes the preparation of compounds of this sort, and gives a description of some of their properties.

(*1*) *Preparation of Compounds*

(*i*) *Sodium Periodatocobaltate* (III)

The general method used to prepare sodium periodatocobaltate (III) was as follows: cobalt sulphate (or chloride) solution was mixed with sodium periodate and enough dilute sulphuric acid to dissolve this relatively insoluble salt. The mixture was then poured into a considerable excess of alkaline sodium hypochlorite with vigorous stirring. A dark green precipitate formed, which was centrifuged off, washed with a little cold water, and then largely redissolved in dilute sodium hydroxide. The solution was filtered, and the complex periodate reprecipitated by adding alcohol. It was then filtered off, washed, and dried.

In some cases the initial precipitate was small in size and almost black (probably containing mostly cobalt (III) hydroxide). If this was filtered off, the filtrate was dark green and slowly deposited green crystals of the complex periodate. In every preparation, considerable loss of yield was caused by precipitation of cobalt (III) hydroxide, and it was essential to recrystallize the product to free it from this compound.

In a typical preparation, 14 g of sodium periodate, $Na_2H_3IO_6$, was dissolved in 75–100 ml of water with a minimum of nitric acid present to effect solution. Five grams of cobalt chloride hexahydrate was added. Meanwhile, 15 g of sodium hydroxide was dissolved in 50 ml of 1.5 *M* sodium hypochlorite. The two solutions were mixed, and the green precipitate was separated by centrifuging. The precipitate was washed with a little cold water, and then stirred into 400 ml of dilute (about 0.1 *M*) sodium hydroxide. The

[1]*Manuscript received August 18, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.
[2]*National Research Council Postdoctorate Fellow.*

insoluble portion was filtered off, and alcohol was added to the filtrate. The sodium periodatocobaltate (III) precipitated. The yield after a further recrystallization was 3.7 g.

(*ii*) *Analysis*

The method of analysis was as follows. A weighed sample was dissolved in water, and enough sulphur dioxide was bubbled in to cause complete reduction to iodide. The solution was briefly boiled to remove excess sulphur dioxide, and silver nitrate was added in excess. The precipitated AgI was filtered off, dried at 100° C, and weighed. This gives the iodine content. Excess potassium iodide was added to the filtrate, and silver iodide was filtered off. Cobalt was precipitated from the filtrate, either as cobalt anthranilate or as cobalt sulphide by ammonium carbonate and hydrogen sulphide. In the latter case the precipitate was digested with sulphuric acid, evaporated, and the residue of $CoSO_4$ was weighed. For sodium, a sample was dissolved in aqueous sulphur dioxide as before, and the cobalt removed as sulphide. The filtrate was evaporated with a little sulphuric acid, and the residue (after treatment with ammonium carbonate to remove $NaHSO_4$) was weighed as Na_2SO_4.

A second, more convenient, method was developed later. The sample was reduced by sulphur dioxide, the excess being boiled off as before. The solution was passed through a column of a cation exchange resin (14 cm long by 1 cm diameter of Dowex 50S-X8 in 50–100 mesh) in its hydrogen form. The effluent contains the iodide, which was estimated as AgI as before. The resin was eluted with 0.4 *N* HCl which removes the sodium. This liquid was then evaporated, and the residue of NaCl weighed. Finally the resin was eluted with 2 *N* HCl which removes the cobalt, and this was converted to the anthranilate or sulphate for weighing.

The water in the sample was measured by the loss in weight at 150° C.

The result of a typical analysis follows. Found: Na, 14.3; Co, 7.33; I, 31.25; H_2O, 22.3%. Theoretical for $Na_5H_2Co(IO_6)_2.10H_2O$: Na, 14.34; Co, 7.35; I, 31.65; H_2O, 22.47%.

In many samples the cobalt was a little high (up to about 8%), presumably because of contamination by cobalt hydroxide.

Another check on the sodium content was made by passing a solution of sodium periodatocobaltate (III) through an anion exchange resin in its chloride form. The complex displaces chloride into the effluent solution, and by using known amounts of the complex it was found that five chlorides (measured by silver nitrate titration) were displaced by 1 molecule of complex.

$$5RCl + Na_5H_2Co(IO_6)_2 \rightarrow R_5H_2Co(IO_6)_2 + 5HCl$$

where R represents the ion exchange resin.

Further evidence supporting this formula will be given later.

(*iii*) *Potassium Periodatocobaltate* (III)

A very similar compound was obtained using the potassium instead of the sodium salts in the method given above. The potassium compound, however, is more soluble than the sodium salt, so it needed more alcohol to precipitate it. The salt, after being dried over calcium chloride, is hygroscopic, and readily picks up water, at least in humid weather. An alternative method was to pass the sodium salt in solution through a cation exchange resin in its hydrogen form, when free periodatocobaltic acid is obtained. This was then neutralized by potassium hydroxide, and precipitated with alcohol.

The analysis, done by the same methods as for the sodium salt, gave as follows. Found: K, 22.6; Co, 8.60; I, 32.8; H_2O, 7.45%. Calc. for $K_4H_3Co(IO_6)_2.3H_2O$: K, 21.8; Co, 8.21; I, 35.3; H_2O, 7.52%. This preparation was made in somewhat less alkaline solution than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

for the sodium salt, which may account for the lower alkali metal content. Like the sodium salt, this compound gave small green crystals.

(*iv*) *Barium Periodatocobaltate* (III)

The barium salt was prepared in various ways, and gave different compounds depending on the conditions. Firstly, the sodium salt was converted into the free acid by passing through a cation exchange resin in its hydrogen form. The free acid was neutralized to pH = 11.5 by carbonate-free sodium hydroxide, and then barium chloride solution was added. This was done under nitrogen to avoid contamination with barium carbonate. A green precipitate formed which was filtered off, washed, and dried. The analysis was as described above, except that the barium was weighed as $BaSO_4$. The results were as follows. Found: Ba, 37.5; Co, 6.55; I, 25.8; H_2O, 9.58%. Calc. for $Ba_5[H_2Co(IO_6)_2]_2.10H_2O$: Ba, 36.5; Co, 6.27; I, 26.9; H_2O, 9.51%.

In acid solutions a different precipitate was obtained. If the free complex acid (pH about 2.5) was mixed with barium chloride solution, a green precipitate was formed of rather variable composition. It gave a Ba/Co ratio of close to one, but the iodine content was lower than that expected if the I/Co ratio is 2 as in the compounds described above. Several samples gave analyses close to $Ba_2H_5Co_2(IO_6)_3.5H_2O$. However, the results were sufficiently variable that it cannot be considered that this has been established as a definite compound.

(*v*) *Lanthanum Periodatocobaltate* (III)

This compound was prepared by converting 1.6 g of the sodium salt to the free acid by cation exchange, and adding 50 ml of 0.1 *M* lanthanum nitrate. The green precipitate analyzed as follows. Found: La, 21.0; Co, 9.28; I, 29.7; H_2O, 16.4%. Calc. for $La_2Co_2H_3(IO_6)_3.12H_2O$: La, 21.6; Co, 9.18; I, 29.7; H_2O, 16.8%.

It is interesting to note that another iodine-to-cobalt ratio is present. Possibly the lanthanum as another trivalent atom is capable of taking the place of cobalt in the compound.

At high pH (by adding lanthanum nitrate to the sodium complex) the green precipitate, however, had approximately the 2:1 ratio for iodine to cobalt found in the sodium complex. The analyses most nearly agreed with $La_4[H_3Co(IO_6)_2]_3.18H_2O$. However, no way of recrystallizing this compound (or the barium compounds) was found, for it is insoluble in water, and decomposed by acids.

(*2*) *Valency of Cobalt*

In the formulae quoted above it was assumed that the cobalt was trivalent. This is certainly the valency that one would expect for cobalt complexes formed under oxidizing conditions. However, these formulae are supported by various experimental results, which will now be given.

(*i*) *Oxidation of Iodide*

It was found that the corresponding copper compounds oxidized iodide ions in acid solution. The amount of iodine liberated depended on whether the acid was added before or after the iodide. If the iodide was added first, the copper was reduced by it from copper (III) to copper (I). If acid was added first, it decomposed the compound to give copper (II), and later addition of iodide only reduced copper (II) to copper (I). Hence, in the latter case less iodine was liberated, and from the ratio of the amounts the valency of the copper in the original compound could be deduced.

The same method was applied to sodium periodatocobaltate (III). The difficulty here is that the complex acid is so stable that prolonged boiling with acid is needed to decompose

it. However, it can be done, and then on adding iodide the cobalt remains as Co(II) and only periodate is reduced. If iodide is added first, the equivalent weight of sodium periodatocobaltate (III) is 1/17 of its molecular weight (eight iodines are liberated for each periodate, and one for Co(III) to Co(II)).

The observed equivalent weights were:

(1) Potassium iodide added first, obs. equivalent weight = 47.0, calc. equivalent weight = 47.15 (mol. wt./17).

(2) Acid added first, obs. equivalent weight = 50.7, calc. equivalent weight = 50.1 (mol. wt./16).

These results support a formula with trivalent cobalt.

(ii) Reduction by Sulphur Dioxide

A rather similar experimental confirmation comes from the reduction of the compound by aqueous sulphur dioxide. Here the sulphur dioxide is oxidized to sulphuric acid, and after unused sulphur dioxide has been boiled out, the acid can be titrated with sodium hydroxide. If bromcresol green is used as indicator, the cobalt ions do not interfere in the titration. It was found that 1 g-equivalent of sulphuric acid was produced by 67.0 g of the compound. The weights calculated for different cobalt valencies are: Co(II) 73.0; Co(III) 66.8; Co(IV) 61.6. Hence these results support trivalent cobalt, and the equation for the reduction is:

$$2Na_5H_2Co(IO_6)_2 \cdot 10H_2O + 17SO_2 \rightarrow 5Na_2SO_4 + CoI_2 + 10H_2O + 12H_2SO_4.$$

(iii) Reduction by Ferrous Sulphate

Sodium periodatocobaltate (III) can be titrated with ferrous sulphate in acid solution. A solution of the complex salt in about 1.0 *N* sulphuric acid was used, and the titration was followed potentiometrically. The cell used was: $Pt/Na_5H_2Co(IO_6)_2$ in acid/Hg_2Cl_2 in saturated KCl/Hg. With more dilute sulphuric acid (about 0.1 *N*), some precipitate formed in the early part of the titration, and the results were somewhat erratic. Sodium periodate also gives a similar titration, and it is then reduced to sodium iodate; some results of this titration are given for comparison. The results given below are the voltages relative to the saturated calomel electrode, so −0.242 v (3) must be added for voltages relative to the standard hydrogen electrode.

(*a*) Titration of 0.00503 *M* sodium periodatocobaltate (III) in 1.0 *N* sulphuric acid against 0.0913 *M* ferrous sulphate at 25° C. Moles Fe^{++}/moles $Na_5H_2Co(IO_6)_2$ and e.m.f. (volts): 0 (−1.023), 0.91 (−1.023), 1.82 (−1.019), 2.72 (−1.006), 3.18 (−1.002), 3.63 (−0.996), 3.99 (−0.987), 4.36 (−0.962), 4.72 (−0.889), 5.08 (−0.770), 5.45 (−0.675), 5.81 (−0.617), 6.17 (−0.584), 6.53 (−0.569), 7.26 (−0.556), 9.08 (−0.549).

(*b*) Titration of sodium periodate in 1.0 *N* sulphuric acid at 25° C. Moles Fe^{++}/moles $Na_2H_3IO_6$ and e.m.f. (volts): 0 (−1.045), 0.49 (−1.041), 0.98 (−1.031), 1.38 (−1.002), 1.57 (−1.016), 1.77 (−1.012), 1.97 (−0.732), 2.16 (−0.619), 2.36 (−0.588), 2.56 (−0.577), 2.95 (−0.570), 4.91 (−0.560).

In the second titration the voltage at the point where the periodate is half reduced is −1.033, or −1.275 relative to a standard hydrogen electrode. This is lower than Abel and Smetana's (4) result for this potential (−1.51 v), or Latimer's (5) estimate of it from the chemical behavior of periodic acid. Only about 0.05 v of this discrepancy can be attributed to partial ionization of the periodic acid. It seems probable that the electrode did not take up the true equilibrium potential for this system. Similarly, the apparent standard electrode potential for the reduction of the complex ion is between −1.19 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

-1.20 v relative to hydrogen, but again this may not be the true equilibrium potential. A reaction of this sort involving transfer of oxygen may well be a slow reaction.

However, the number of molecules of ferrous sulphate reacting is quite definite. The inflection occurs at 2 molecules for sodium periodate (i.e. reduction to iodate) and 5 for sodium periodatocobaltate (III). This is what is required for trivalent cobalt:

$$2Na_5H_2Co(IO_6)_2 + 10FeSO_4 + 10H_2SO_4 \rightarrow 4NaIO_3 + 5Fe_2(SO_4)_3 + 3Na_2SO_4 + 2CoSO_4 + 12H_2O.$$

(iv) Magnetic Properties

Measurements were made of the magnetic susceptibility of the sodium compound, by means of a Goüy apparatus of the conventional type. Both the solid and an aqueous solution were used. The results in aqueous solution cannot be very accurate, since the sodium periodatocobaltate (III) is not very soluble in water, and hence a dilute solution had to be used. The results made $\chi = -570(\pm 100)\times 10^{-6}$ per g-molecule of compound, from the solution measurements.

In the solid state, the degree of purity of the sample had a considerable effect on the result, the sample becoming more diamagnetic as it was recrystallized. It is evident that most samples contain traces of a paramagnetic impurity, probably cobalt oxide. The purest sample gave a susceptibility of -290×10^{-6}/g-molecule. It is difficult to make a precise theoretical calculation for this number, since the contributions of the atoms, particularly the iodine in this valency state, are not too certain. However, Angus's expression (6) predicts a value of about -350×10^{-6}/g-molecule. In any case it is clear that the compound is diamagnetic, as is generally found for Co(III) compounds.

(3) Spectrum of Sodium Cobalt Periodate and of Periodate-cobaltic Acid

Solutions of sodium periodatocobaltate (III) are green. The absorption spectrum shows a maximum at 625 mμ, and a minimum at 535 mμ. The absorption rises steadily towards the violet and falls towards the red. Values for the extinction coefficients, measured on a 5×10^{-3} *M* aqueous solution by means of a Beckmann D.U. spectrophotometer, are for sodium periodatocobaltate (III), λ (ϵ): 320 (2340), 340 (1440), 360 (1085), 380 (687), 400 (550), 420 (389), 440 (275), 460 (206), 480 (153), 500 (100), 510 (79.5), 520 (69), 530 (64), 540 (64.5), 550 (68.5), 560 (75.5), 580 (93), 600 (108), 610 (111.5), 620 (112.5), 630 (113), 640 (109), 650 (103), 675 (75.5), 700 (47), 750 (17), 800 mμ (11). The absorption in the violet starts at much longer wave lengths than does the similar absorption of periodate ions alone. KH_4IO_6, λ (ϵ): 260 (320), 280 (236), 300 (150), 320 (45), 340 mμ (4). $K_3H_2IO_6$, λ (ϵ): 290 (395), 300 (272), 310 (182), 320 (113), 340 (35), 360 mμ (8).

In acid solution the spectrum is somewhat altered. This change seems to take place in at least two stages. If acid ($HClO_4$) is added, and the spectrum is rapidly measured, it is found to be as follows, 3.35×10^{-3} *M* sodium periodatocobaltate (III) in 3.35×10^{-2} *M* perchloric acid, λ (ϵ): 450 (193), 460 (162.5), 480 (116.5), 500 (87.5), 520 (70.5), 540 (67.5), 560 (73), 580 (85), 590 (88), 600 (90.5), 610 (91), 620 (90.5), 630 (87.5), 650 (76), 675 (57), 700 (38), 750 (18), 800 mμ (12). The maximum is shifted to 610 mμ, and the maximum and minimum are less well marked. After this initial rapid change a slow further change occurs which will be considered in the next section on the stability of these compounds.

(4) Stability of Sodium Periodatocobaltate (III) *and of Periodatocobaltic Acid*

(i) Stability of Free Acid

If sodium copper (III) periodate is acidified, decomposition rapidly occurs to give Cu^{++} ions. It was expected that a similar reaction might occur with cobalt. However, the

acid proved much more stable, and required at least several hours of boiling with dilute sulphuric acid to give fairly complete decomposition to Co^{++} ions. At room temperature, solutions of periodatocobaltic acid (obtained by passing a solution of the sodium periodatocobaltate (III) through the hydrogen form of a cation exchange resin) can be kept for months.

As mentioned above, the absorption spectrum at first changes very rapidly if a solution of the sodium salt is acidified with perchloric acid. After this there is a further, moderately slow, change, taking place over a time of the order of 100 minutes at room temperature. This second stage in the decomposition is not simply decomposition to Co^{++} ions, as the spectrum after it has occurred is still fairly similar to that of sodium periodatocobaltate, and the rate of the process is much faster than that of the formation of Co^{++}. The rate of this second stage was examined a little more closely. Since the color change at any wave length is quite small (e.g. in one sample the color density changed from 0.381 to 0.353), it was only possible to get a rough measurement of the rate. If we assume that one colored species is slowly turning into another, and that the extent of the change is proportional to the change in the optical density, then the results indicate that this is a first-order reaction, with a rate constant about 0.03 min^{-1} at 30° C. The rate is very little affected by the hydrogen ion concentration, and has a fairly low temperature coefficient. Since the precise nature of this change is unknown, it did not seem to be worth while to get more than a rough estimate of its speed.

(*ii*) *Dissociation of Sodium Periodatocobaltate* (III)

In the work on the copper complexes referred to above it was possible to measure the stability of the complex (i.e. the equilibrium constant of the reaction: complex $\rightleftharpoons$ copper +periodate ions) by measuring the rate of oxygen evolution from sodium hypochlorite solution containing various amounts of copper and periodate. It was assumed that only the simple copper ions acted as a catalyst of this decomposition, and this assumption led to consistent values of the equilibrium constant.

An attempt to make similar measurements with the cobalt compound encountered difficulties. In the first place, if relatively small amounts of a cobalt salt and a periodate are added separately to a solution of sodium hypochlorite, some of the cobalt always remains as the black insoluble cobaltic oxide. This causes relatively rapid oxygen evolution. This cannot be considered to prove that the equilibrium is much in favor of the simple ions, since, if sodium periodatocobaltate (III) solution is added, almost no gas is evolved as a result. It seems reasonable to assume that the very insoluble cobaltic oxide reacts so slowly that equilibrium is not reached. With copper, on the other hand, the metal is present as the soluble $NaCu(OH)_4$. Whether equilibrium is reach when a solution of sodium periodatocobaltate (III) is added is uncertain; that is equilibrium for the reaction: $Co(HIO_6)_2^{-5} \rightleftharpoons Co^{+3} + 2HIO_6^{-4}$. The most that can be said is that no precipitate appears, and the rate of oxygen evolution does not rise appreciably with time.

The increase in the rate of gas evolution when the cobalt complex was added is so small that only a very rough value for this equilibrium constant can be obtained by this method. For instance, a solution containing an average concentration (during the measurement) of sodium hypochlorite of 1.495 *M* evolved oxygen at the rate of 0.1778 ml (at S.T.P.)/min per liter of solution, when its temperature was 60° C. When the solution was made 6.52×10^{-5} *M* in sodium periodatocobaltate (III), the rate of evolution was 0.1696 ml (S.T.P.)/min per liter; the average concentration of sodium hypochlorite was 1.416 *M*. The rate/$[ClO^-]$ is 0.1189 without sodium periodatocobaltate (III), and 0.1199 with it. The weight of cobalt which would produce this increase can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

calculated from earlier data (7), and is 7.5×10^{-7} g of uncomplexed cobalt. From the volume of solution (767 ml) the concentration can be obtained, and as two periodates are combined with each cobalt, the equilibrium constant can be calculated. The result is K = [complex]/[Co(III)].[periodate]^2 = 3×10^{18}. Other measurements gave somewhat lower values (down to 3×10^{17}); the cause of this lack of consistency is undoubtedly the very small differences (e.g. 0.004 ml/min) in the rate of oxygen evolution due to the cobalt compound.

However, it is plain that the cobalt compound is more stable than the copper compound where the corresponding equilibrium constant is 1.25×10^{10} at 40° C. For sodium periodatocobaltate the constant is in the neighborhood of 10^{18} at 60° C. These measurements are for dilute alkaline (about 0.1 M) solution, in which the precise chemical form of the uncomplexed cobalt is uncertain.

(*5*) pH *Measurements*

Since periodatocobaltic acid is reasonably stable, measurements were made to discover its ionization constants, and its general behavior in acid base titrations.

A solution of the free complex acid was prepared by passing the sodium salt through the hydrogen form of a cation exchange resin. The solution was 3.35×10^{-3} M and had a pH of 2.25 measured on a Beckmann pH meter with glass electrode. This makes the hydrogen ion concentration (or activity) 5.6×10^{-3}. This is not far off two hydrogen ions per molecule, so the first two ionization constants must be fairly large (if the first two ionization constants were the same, they would both have to be 1.0×10^{-2} to give the above pH). This conclusion is supported by the fact that when a solution of the free complex acid was run through an anion exchange resin (Dowex 1-X4) in its chloride form, slightly above two chlorides were displaced per molecule of periodatocobaltic acid:

$$[H_3O^+]_2[H_5Co(IO_6)_2^{--}] + 2RCl \rightarrow R_2[H_5Co(IO_6)_2] + 2H_3O^+ + 2Cl^-.$$

Under similar conditions phosphoric acid liberated 0.90 chloride per molecule ($pK_1 = 2.12$).

On titrating periodatocobaltic acid with sodium hydroxide the curve in Fig. 1 was obtained. This has inflections at 2 and at 4NaOH added per molecule. The first inflection

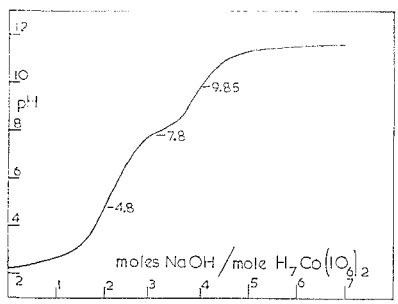

FIG. 1.

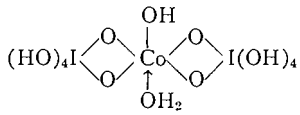
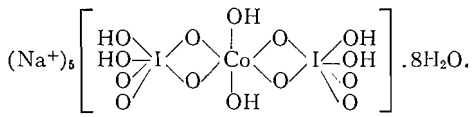
(2NaOH) is at a pH of 4.8, and the most horizontal part of the curve, between 2 and 4NaOH is at a pH of 7.8. Since the pH at an inflection point is the mean of the pK_a values on either side of it, the inflection at 2NaOH makes pK_3 = 7.6 (taking pK_2 to be 2.0 as found above). This agrees reasonably with the pH of 7.8 at 3NaOH. pK_3 and pK_4 must be fairly similar, and their average value is about 7.7. The inflection at 4NaOH has a pH of 9.85, making pK_5 = 12.0.

An almost identical titration curve was obtained by adding perchloric acid to a solution



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

of $Na_5H_2Co(IO_6)_2$ and titrating the liberated acid with sodium hydroxide; or (in reverse) by titrating $Na_5H_2Co(IO_6)_2$ with perchloric acid.



To sum up, pH measurements do not distinguish between the first and second ionization constants of periodatocobaltic acid, or between the third and fourth. The first two hydrogens ionize easily with an average pK value of 2.0; the next two pK values average 7.7. The fifth ionization constant is small with $pK_5 = 12.0$. These values are not very different from those for periodic acid ($pK_1 = 1.6$, pK_2 about 7). The jump in pK is very much what is generally found for ionization of successive OH groups attached to a central atom (compare phosphoric acid with successive pK values of 2.1, 7.2, and 12.3). It is, of course, to be expected that pK_1 and pK_2 should be similar, since this presumably involves ionization of two hydrogens from remote, but identical, parts of the molecule.

(6) General Remarks

It is not yet possible to write a detailed formula for sodium periodatocobaltate (III). There can be little doubt that it contains a complex ion, but it is uncertain whether each periodate is attached by three or two oxygens to the cobalt. Since the co-ordination of cobalt (III) is generally six, in the latter case the other places would have to be taken by water, or OH^-. The acid–base behavior indicates that the two periodate groups are identical in the free acid, and if each periodate is attached by three oxygens it is difficult to write a symmetrical formula. Hence it is perhaps a little more likely that each periodate is attached through two oxygens. This would make the free periodatocobaltic acid:

and the sodium periodatocobaltate (III):

It must be admitted that these formulae are quite speculative; but it is worth noting that the pH behavior can be explained by formulae such as the above, while, if each periodate is attached by three oxygens, it seems impossible to do so.

SOME PROPERTIES OF SILICA DISPERSIONS[1]

A. F. Sirianni, F. W. Meadus, and I. E. Puddington

ABSTRACT

When silicic acid sols are formed from solutions of sodium silicate by acid neutralization, a pronounced minimum in the time required for the sol–gel transformation is observed if the titration is stopped near pH 8. If the sol is prepared by electrodialysis, a similar minimum is obtained when the operation is stopped at about pH 5.5. Intermediate values for the minimum are found if the original silicate solution is partially dialyzed followed by neutralization with acid. When the water content of the gels is replaced by liquid hydrocarbons, maximum interaction between the silica particles occurs when the aqua gel has been formed or conditioned at pH 5.5 regardless of the method of preparation of the sol. A minimum in electrophoretic mobility and a maximum in sedimentation rate of the particles are observed at a similar pH value. These properties are modified considerably if the system is thoroughly dehydrated.

INTRODUCTION

A previous investigation (1) of the flow properties of dispersions of finely divided silica in hydrocarbon oils revealed a pronounced and unexpected maximum in the yield value when the silica used had been gelled or conditioned in aqueous solutions of about pH 5 prior to its suspension in oil. Both maximum yield values in suspensions and minimum times for sol–gel transformations might normally be expected to be associated with the maximum degree of interaction between the solid particles of the dispersion. It was surprising, therefore, that the minimum time of set for silica sols, which occurs at about pH 8 when sodium silicate solutions are neutralized with acid (2, 3, 4), did not coincide with the isoelectric point of silicic acid, which is about pH 5 (5). Since minimum gelation times for silica sols prepared by different methods have been variously reported in the pH range 5 to 8 (6), it seemed worth while to re-examine some of the conditions that may influence both this phenomenon and the flow properties of non-aqueous suspensions of the gels.

EXPERIMENTAL

Two types of sodium silicate were used: N grade containing about 28.7% SiO_2, 8.9% Na_2O, with 62.4% water and Metso Granular containing 28.3% SiO_2, 29.4% Na_2O, and 42.3% water. Both of these silicates are produced by the Philadelphia Quartz Co. Concentrated solutions were centrifuged to optical clarity prior to dilution to suitable concentrations for experimental purposes.

Substantially cation-free silica sols were prepared by electrodialysis using an American Instrument Co. electrodialyzer fitted with screen platinum electrodes of equal area and a cellophane #600 semipermeable membrane. The cathode compartment of the cell was washed continuously with fresh water to suppress electrolysis owing to a build-up of sodium hydroxide in the compartment. The cathode was positioned about 6 mm from the cellophane membrane to keep the cell resistance as low as possible. Changes in pH in the anode compartment as dialysis proceeded were followed by periodic measurements with a Beckman meter. When the desired pH was reached, the sol in the anode compartment was drained into a clean 600-cc Pyrex beaker prior to shutting off of the current. The beakers containing the sol were sealed with saran wrap.

Sols were also prepared by titrating the sodium silicate solutions to desired pH values with sulphuric acid solution. These sols necessarily contained the sodium sulphate formed during the titration.

[1]*Manuscript received July 7, 1959.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5450.

The time of set of the sol was taken as the period between the sol preparation and the time when polymerization and flocculation had proceeded sufficiently for the system to adhere to the sides of the beaker when it was tilted through 45°.

In a number of instances the flow properties of dispersions of particular gels were examined when the water of the aqua gel had been replaced by liquid hydrocarbon. These dispersions were prepared by adding to the mechanically broken gel, after as much water as possible had been removed by vacuum filtration, a mutual solvent for oil and water in an amount slightly in excess of the quantity required to form an azeotrope with the water that remained. The desired quantity of oil was then added and the water and residual solvent removed by evaporation, the final temperature being raised to 125° C for several hours to reduce the free water and solvent content of the system to a minimum. The operation was completed by mechanically homogenizing the system to produce a uniform paste of the silica in the oil. The aqua gels were normally aged for 24 hours prior to displacing their water content with oil. *n*-Propyl alcohol was a satisfactory mutual solvent for oil and water and the final product contained about 5% by weight of silica dispersed in an oil with a viscosity of about 0.6 poise. Viscometric measurements were carried out as previously described (1).

Gels prepared by acid titration were in most instances washed virtually free from salts with distilled water before dispersing them in the oil.

Electrophoretic measurements were conducted on portions of the pastes used for the rheological work diluted with medicinal oil to give a silica concentration of about one per cent. The measurements were carried out as described by Agius and Mulvey (7). The mobility was taken as the plateau in the velocity vs. time curve that appeared within 24 hours after starting the experiment.

Sedimentation experiments were carried out in vertical Pyrex tubes of 20 mm i.d. The suspensions were portions of the samples used in the electrophoretic determinations.

RESULTS AND DISCUSSION

Typical data relating gelation time for dialyzed sodium silicate and the pH of the sol are shown in Fig. 1. A pronounced minimum occurred at about pH 5.5, and this was substantially independent of the type of sodium silicate used, the concentration range explored, or the source of the water used in washing the cathode compartment of the cell. Softer gels with no odor of chlorine and gelation times up to 500 times longer were obtained when conductivity water was substituted for tap water in the washing procedure. The minimum time of set increased from 9 to 22 hours when the silica concentration was reduced from 4.15 to 2.92% and conductivity water was used to wash the cathode compartment. With a tap water wash the minimum time of set for a sol containing 3.6% SiO_2 was 4 minutes. These observations are consistent with those of Hurd and co-workers (8) on the effect of impurities and solids concentration on the time of set.

Since the behavior of a series of gels prepared by titration of sodium silicate solutions with sulphuric acid agreed with the results of previous investigations in that the minimum gelation time was about 4 seconds at a pH of 7.9 for a sol containing 3.6% SiO_2, it is apparent that the difference in the pH for minimum gelation time for these sols is owing to the presence of electrolytes from the reagents used in their preparation. It is quite possible, however, that the ions from different acids could modify the magnitude of the effect.

Two further series of gels prepared by partial electrodialysis, followed by titration with sulphuric acid to the desired end points, showed that the pH of minimum gelation time decreased regularly as the amount of electrolyte in the final sol was reduced.

The flow properties of 5% by weight dispersions of silica in hydrocarbon oil are

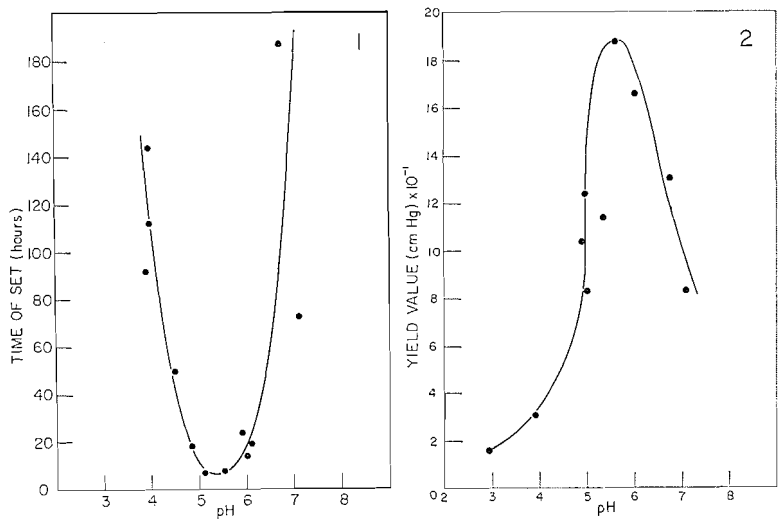

FIG. 1. Dependence of gelation times for dialyzed sodium silicate solutions on the pH of the sol.
FIG. 2. Yield values of 5% dispersions of silica in hydrocarbon oils as a function of the pH at which the silica was prepared.

indicated in Fig. 2. This shows the change in yield value of the dispersion as a function of the pH at which the sol–gel transformation occurred. A very pronounced maximum in the yield value was found at about pH 5.5 and this was independent of the method of gel preparation. Since the yield value of the pastes and the setting of gels both indicate interaction between the solid particles forming the structure, it seems that the behavior of silica in oil and in aqueous media is rather similar. The yield value of the silica-oil pastes was modified only slightly by the presence of sodium sulphate, and comparable flow properties were found when the gels were prepared by dialysis and by acid precipitation with or without the removal of the sodium sulphate. On the other hand, the aqua gels were considerably softer when prepared by dialysis using a conductivity water wash of the cathode cell and it would appear that electrolytes exert a strong flocculating influence on the polymerized silicic acid. Their inertness in oil is probably owing to their almost complete insolubility in that medium. A maximum in the elastic properties has also been observed for silica gels prepared near the point of minimum gelation time when the sols were formed by acid neutralization (9). This, too, is indicative of a high degree of adhesion between the flocculated particles.

The sedimentation rates and electrophoretic mobility of silica dispersed in oil are shown in Fig. 3. The maximum sedimentation rate which occurs at the same pH value as the maximum yield value in the more concentrated pastes strongly suggests a high degree of flocculation, and this, in turn, is indicative of higher particle interaction at this point. That the improved stability of the sols containing silica prepared above and below pH 5.5 is probably electrical in origin is suggested by the electrophoretic behavior. The mobility is essentially zero at the pH of maximum particle interaction in an electric field of about 70 v per cm with a velocity of migration rising sharply on either side of this minimum. The direction of particle motion indicates opposite charge on the silica on either side of the minimum and this is supported by the fact that the mixtures prepared from equal quantities of positively and negatively charged sols showed flocculation properties similar to those of the neutral sols. However, since some agitation is necessary to prepare the suspensions, and the oil has a very high electrical resistance, the possibility of the charges

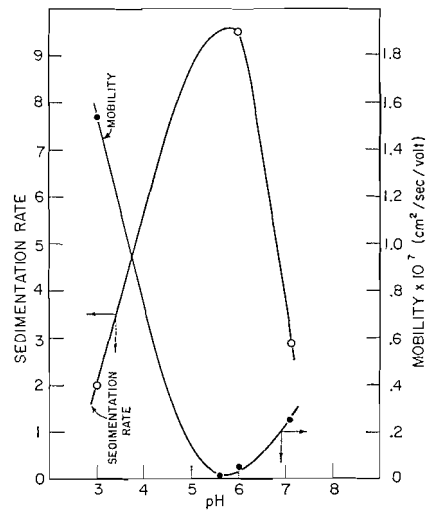

FIG. 3. Sedimentation rates and electrophoretic mobilities of finely divided silica prepared at different pH values in liquid hydrocarbons.

arising from the relative motion of the solid and the liquid cannot be ruled out completely. In those systems showing the highest mobilities there was a tendency for the velocity of migration to decrease after about 40 hours in the electrophoretic cell. No corresponding change in the sedimentation velocity of the more stable suspensions was observed, however, and the adsorption of oil-soluble ionic substances such as traces of hydrocarbon oxidation products is perhaps a more reasonable explanation for the apparent particle charge.

Although the amounts of water in these preparations must be small, traces of water have been observed to exert an influence on the electrical properties of non-aqueous systems (10), and the amounts desorbed from container walls may be important. To assess this point, the suspensions used in the sedimentation and in the electrophoretic work were diluted in their containers with 10% of toluene, which was then removed by boiling off at atmospheric pressure. This treatment had the general effect of making the sedimentation and electrical properties more uniform and similar in magnitude to those at the isoelectric point. It would thus appear that traces of water may exert an appreciable influence on the electrical properties of non-aqueous suspensions probably because of the enhanced ionizing power of the organic liquid containing it. No significant changes in the flow properties of more concentrated suspensions could be observed, however, after a similar treatment. The increased particle interaction is thus not sufficient to have an appreciable effect on the yield value.

THE RELATIVE ENTHALPIES OF CONCENTRATED POTASSIUM HYDROXIDE SOLUTIONS[1]

WENDELL J. BIERMANN

ABSTRACT

Measurements were made of the heats of neutralization of concentrated solutions of potassium hydroxide with hydrochloric acid, with an estimated accuracy better than one part per thousand. From this information it was possible to calculate relative enthalpy data for potassium hydroxide solutions up to 16 molal.

INTRODUCTION

The relative enthalpies of potassium hydroxide solutions have been measured calorimetrically in the relatively dilute range by Richards and Rowe (1), and over an extended concentration range by Bender and Akerlof (2), using an electromotive force method similar to the work of Akerlof and Kegeles (3) with sodium hydroxide solutions, and presumably of comparable accuracy. Because, as aptly pointed out by Harned and Owen (4), electromotive force data must be regarded as hypothetical until substantiated by other evidence, it appeared desirable to verify these high concentration values by calorimetric measurement.

As has been previously established (5, 6), heat of neutralization measurements can supply data from which relative enthalpy values can be derived conveniently and reliably, provided necessary auxiliary data are available. Because of the availability of both suitable equipment and the prerequisite data, the heats of neutralization of potassium hydroxide solutions by hydrochloric acid solutions were measured over a wide concentration range. This information was utilized in the computation of the relative enthalpies of potassium hydroxide solutions over a concentration range of 3 to 16 molal.

EXPERIMENTAL AND RESULTS

The calorimetric equipment and general method of operation have been described previously (5, 7). Reagent grade potassium hydroxide was freed of carbonate by standard procedures, and reagent grade hydrochloric acid was used without further treatment. Stock solutions were diluted as required with conductivity water and the diluted solutions analyzed gravimetrically by the precipitation of an equivalent amount of silver chloride.

The heat liberated in the bomb reaction differs from the desired quantity, the heat of neutralization of potassium hydroxide solution by hydrochloric acid solution, both at the same molal concentration m and 25.00° C, because of simultaneous heat effects, the most important being caused by:

(1) The solution of hydrogen chloride from the vapor phase after completion of the reaction.

(2) Dilution effects due to the impracticability of adjusting the concentrations of the reactants to exactly the same molality.

(3) A slight excess of one reactant being experimentally unavoidable; hydrochloric acid was therefore added in slight excess, thus minimizing the error due to any residual carbonate in the base. An enthalpy change is involved in the dilution of this excess acid.

[1]*Manuscript received August 25, 1959.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Canada.

TABLE I

Heats of neutralization of potassium hydroxide solutions by hydrochloric acid as observed experimentally

Reactant concentration (moles solute/kg solvent)	Observed heat of neutralization (defined calories at 25.00° C)	Reactant concentration (moles solute/kg solvent)	Observed heat of neutralization (defined calories at 25.00° C)
15.985	−21,448	10.126	−17,693
	21,437		17,692
14.961	20,838	9.034	17,213
14.915	20,816		17,194
	20,817		17,186
12.960	15,593	7.000	16,255
	15,596		16,257
12.023	18,963	6.987	16,251
	18,965		16,260
11.005	18,195	4.990	15,383
	18,212		15,378
10.969	18,181	3.113	14,605
	18,177		14,616

(4) A reaction temperature other than 25.00° C, except in the fortuitous case of the calorimeter being exactly 25.00° C when the reaction is initiated.

The heats of neutralization reported in Table I have been computed from the heats of the bomb reactions by "correcting" them for the above-mentioned heat effects. Experimental conditions were carefully controlled so that these corrections were small and the uncertainties involved in their calculation are negligible compared to experimental errors. Smoothed values of the heats of neutralization at integral values of the concentration are shown in Table II.

TABLE II

Smoothed values of the heats of neutralization of potassium hydroxide by hydrochloric acid

Molality	Heat of neutralization (defined calories)	Molality	Heat of neutralization (defined calories)	Molality	Heat of neutralization (defined calories)
3	−14,560	8	−16,715	12	−18,945
4	14,965	9	17,185	13	19,620
5	15,390	10	17,635	14	20,255
6	15,815	10.56	17,885	15	20,865
7	16,260	11	18,200	16	21,450

The only auxiliary data whose reliability could significantly affect the accuracy of the heats of neutralization are the specific heats of the product solutions, which were used in computing the heat capacity of the system. Values of the specific heats of potassium chloride solutions over the pertinent concentration range are available from Randall and Bison (8), Bousfield and Bousfield (9), and Galagoleva-Cherbou (10). When compared graphically, the average deviation of the experiment points was less than 0.1% from the mean curve, an insignificant error with respect to the use.

Calculation of the relative enthalpies of potassium hydroxide solutions from the smoothed heat of neutralization data involves the use of the relationship:

$$\Delta H_N = \Delta H^\circ_N + [L_2(KCl)_{m'} - L_2(KOH)_m - L_2(HCl)_m] + (55.51/m) \times [(m/m' L_1(KCl)_{m'} - L_1(KOH)_m - L_1(HCl)_m]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

at concentrations below the saturation concentration of potassium chloride. When the solubility of potassium chloride is exceeded, the enthalpy relationship takes the form:

$$\Delta H_N = \Delta H^\circ_N + [L_2(KCl)_{sat} - L_2(KOH)_m - L_2(HCl)_m] + \{(1 - m_{sat})/m'\} \times [H_{solid} - H_2(KCl)_{sat}] + (55.51/m)\,[m/m'\,L_1(KCl)_{sat} - L_1(KOH)_m - L_1(HCl)_m]$$

where "m" is used to designate the molality of the reactants, m' is used for $(55.51\ m)/(111.02+m)$, and m_{sat} is used to indicate the molality of saturated potassium chloride solution, 10.56 moles per kilogram of solvent. ΔH_N refers to the heat of neutralization at a reactant molality m, and ΔH°_N the heat of neutralization at infinite dilution. Supplementary data used were: heat of dilution data for potassium chloride solutions from Lange *et al.* (11), relative enthalpy data for hydrochloric acid solutions from Akerlof and Teare (12) and Sturtevant (13), and the heat of neutralization at infinite dilution was taken as −13.32 defined kilocalories (7). Differential heat of solution of potassium chloride was taken from Wüst and Lange (14); as macrocrystalline potassium chloride was produced in the present work, their initial and final states correspond to those encountered here.

Table III contains the relative partial molal enthalpies of solvent and solute, and the relative enthalpies per mole of solute for potassium hydroxide solutions at integral values of the solute concentration over the range 3 to 16 molal, calculated as described above.

TABLE III

Relative enthalpies of potassium hydroxide solution, defined kilocalories at 25.00° C

m	L_1	L_2	L	m	L_1	L_2	L
3	−.018	+ .63	+ .30	10	−.370	+3.43	+1.38
4	.035	.91	.42	11	.475	4.02	1.57
5	.061	1.24	.56	12	.612	4.67	1.84
6	.098	1.59	.69	13	.690	5.01	2.07
7	.146	2.00	.84	14	.771	5.36	2.29
8	.206	2.45	1.02	15	.855	5.67	2.51
9	.280	2.93	1.20	16	.942	5.98	2.71

DISCUSSION

Analysis of the results and a consideration of the contributing sources of error lead to the conclusion that the heat of neutralization values obtained are uncertain to less than 0.1%.

Further confidence in the reliability of the heat of neutralization data is obtained from a study of the discontinuity in the heat of neutralization versus concentration curve. At a reactant concentration of 10.56 molal, a discontinuity appears due to the precipitation of potassium chloride. The experimentally determined upper and lower sections of the curve fall within 5 calories of each other when extended to this point, and the change of slope is 283 units, compared with the calculated value of 270 units.

The average deviation between these relative molar enthalpies and those reported by Akerlof and Bender is about 100 calories, which is similar to the discrepancy between the Akerlof and Kegeles values and the calorimetric values of Bertetti and McCabe (16) for sodium hydroxide solutions.

A DETAILED STUDY OF THE SAMUEL–MAGEE MODEL FOR THE RADIATION CHEMISTRY OF WATER

PART II. KINETICS OF RADICAL REACTIONS IN THE TRACKS OF DENSELY IONIZING PARTICLES[1]

P. J. Dyne and J. M. Kennedy

ABSTRACT

The kinetics of recombination of H and OH radicals, formed in liquid water along the track of a densely ionizing particle in the manner suggested by Samuel and Magee, have been studied using an electronic computer. The variation in yields with track density is in good qualitative agreement with experiment. Arguments are advanced to show that the energy required to produce one effective radical pair in liquid water is about 20 ev. Discussions are presented of the effects of scavenger concentration and its depletion at the center of the track, track diameter, the value of the rate constant for the recombination of H atoms and OH radicals, and the value of $G(-H_2O)$ as a function of track density.

1. INTRODUCTION

This paper presents calculations performed on the Chalk River Datatron Computer on the kinetics of diffusion and recombination of H and OH radicals formed in water along the track of a densely ionizing particle, such as a proton or an α-particle. According to the model suggested by Samuel and Magee (1) these radicals are formed by the dissociation of excited water molecules which, in turn, result from the ionization and excitation brought about by the ionizing particle. These radicals have similar spatial distributions, lying in a uniform column along the track of the particle. The concentration of these radicals falls off rapidly across the axis of the column according to a Gaussian or some similar distribution. The diffusion processes are, accordingly, described in a cylindrical co-ordinate system.

In the tracks of lightly ionizing particles (fast electrons) the excitation is localized into small clusters or spurs containing a few (four to eight) radical pairs. These spurs have spherical symmetry and the diffusion process is described in a spherical co-ordinate system. In a previous paper (2), which will be referred to as Part I or (I), we presented calculations of the kinetics of recombination of H and OH radicals in these small spurs. The present paper is an extension of the techniques and arguments used in Part I to cylindrical tracks. The reader is referred to Sections 1 and 2 of Part I for a more detailed introduction to the topic.

2. THE TRACK EQUATION

We adopt the convention that the hydrogen atom is species 1, with diffusion constant D_1, recombination rate constant k_{11}, and concentration C_1, which is a function of time and space. The OH radical is species 2 with constants D_2, k_{22}, C_2, etc. The rate constant for recombination of H and OH radicals is k_{12}. The radical scavenger is species 3, with diffusion constant D_3; the rate constants for reaction of scavenger with radicals 1, 2 are k_{13}, k_{23} respectively.

The track equations governing the kinetics of reaction and diffusion are:

$$[1] \qquad \partial C_1/\partial t = D_1\nabla^2 C_1 - 2k_{11}C_1^2 - k_{12}C_1C_2 - k_{13}C_1C_3$$

$$[2] \qquad \partial C_2/\partial t = D_2\nabla^2 C_2 - 2k_{22}C_2^2 - k_{12}C_1C_2 - k_{23}C_2C_3$$

$$[3] \qquad \partial C_3/\partial t = D_3\nabla^2 C_3 - k_{13}C_1C_3 - k_{23}C_2C_3.$$

For personal use only.

These equations differ from those used for γ-ray spurs in three respects.

(*a*) The Laplacian refers to cylindrical, not spherical co-ordinates.

(*b*) There is no weighting function in front of the terms $k_{11}C_1^2$ and $k_{22}C_2^2$. In a γ-ray spur containing, say, five radicals, the bimolecular rate is given by $4/5\ k_{11}C_1^2$, since one radical can only react with four others. The cylindrical tracks are long and so N, the number of radicals in the track, is large and the weighting function $(N-1)/N$ is not significantly different from unity.

(*c*) The introduction of equation [3], which describes the depletion of scavenger at the center of the track and its replacement by diffusion from the bulk of the liquid.

The yields of hydrogen and hydrogen peroxide are the values of

$$\int_0^\infty\int_0^\infty k_{11}C_1^{\,2}\,dv.dt \quad \text{and} \quad \int_0^\infty\int_0^\infty k_{22}C_2^{\,2}\,dv.dt,$$

respectively, while

$$\int_0^\infty\int_0^\infty k_{12}C_1C_2\,dv.dt$$

is the amount of H_2O re-formed in the track. The numerical method is described in the Appendix.

3. THE CHOICE OF CONSTANTS

Rate constants and diffusion constants are chosen essentially as in Part I. They are $D_2 = 2\times10^{-5}$ cm²/sec, $D_1 = 8\times10^{-5}$ cm²/sec, $k_{11} = 6.0\times10^{-12}$, $k_{12} = 15\times10^{-12}$, $k_{22} = 4.5\times10^{-12}$ cc/molecule sec.[2] Constants k_{13} were taken as 1.0×10^{-11} cc/molecule sec, D_3 was taken as 2×10^{-5} cm²/sec. If it is assumed that the radicals have a Gaussian distribution, the track radius is expressed by the parameters β_1, β_2 where $C_1(r) = (N_1\beta_1^2/\pi)\exp(-\beta_1^2r^2)$. N_1 is the number of radicals/Å. For initial studies we have taken $1/\beta = 10^{-7}$cm = 10 Å for species 1 and 2. In the following discussion it is, at times, more illustrative to use the parameter $R = 1/\beta$, which can be visualized as the "radius" of the track. The "concentration" of scavenger in the initial calculation is $10^{-3}\ M$ (6.0×10^{17} molecules/cc). As experimental rate constants of scavengers are nearer 10^{-10} cc/molecule sec rather than the value of 10^{-11} which we use in the calculation, the equivalent experimental concentration of scavenger is nearer $10^{-4}\ M$.

The track density is expressed by the parameters N_1 and N_2, the number of radicals/Å. Cases were examined over the range 0.1–10 radicals/Å. We have converted the number of radicals/Å to L.E.T. (Linear Energy Transfer) (ev/Å) using the arbitrary figure of an energy deposition of 10 ev to give one radical pair. This value is derived from Firestone's measurement of $G(-H_2O) = 11\pm1$ (3) for the decomposition of water vapor (Part I, Section 4). If, for instance, $N_1 = N_2 = 0.2$ radicals/Å then this corresponds to a particle track with an L.E.T. of 2 ev/Å. Our L.E.T. values should not be used too literally because, as will be shown in subsequent discussion, the value of 10 ev/radical pair is a minimum value. The effective value in liquid water may be nearer 20 ev/radical pair.

[2]*The rate constants k_{11}, k_{22} were defined in an inconsistent manner in Part I. The value of k_{11}, for instance, in the normal chemical definition gives the number of reactions* $H + H \rightarrow H_2$. *The value of k_{11} used in the program was used to calculate the number of hydrogen atoms removed by recombination and is therefore a factor of 2 greater than the rate constant defined "chemically". The rate constants k_{11} and k_{22} tabulated in Table I of Part I are just twice the "chemical rate constants" for each case, e.g. the initial case "A" has "true" chemical rate constants, $k_{11} = 6\times10^{-12}$, $k_{22} = 4.5\times10^{-12}$, $k_{12} = 30\times10^{-12}$. This differs essentially from the initial case defined in Part II in that k_{12} is larger by a factor of two. This error in definition does not affect the results and conclusions of Part I.*

4. THE CALCULATIONS

The detailed results of the calculations are presented in Table I. The numbers to the left of the double line are the constants which specify the individual case: those to the right are the yields of molecular products and scavenged radicals. These are expressed as fractions of one initial radical pair. The yields of H_2 and H_2O_2 are expressed as the number of atoms or radicals which have recombined to give these molecular products. The numbers of molecules, H_2 and H_2O_2, formed are half these numbers. The number of water molecules re-formed is $[H_2O^*]$, the net decomposition of H_2O is $[-H_2O]$. The yields defined in this manner, symbolized by enclosure in square brackets, obey these stoichiometric relationships:

$$[H_2] + [H_2O^*] + [H] = [H_2O_2] + [H_2O^*] + [OH] = [H_2O^*] + [-H_2O] = 1.$$

(The yields for γ-ray spurs in Part I were expressed as the number of radicals, etc., per spur. They are identical with the yields defined above when divided by the number of radical pairs/spur.)

The final yields at infinite time are estimated numerically as follows. If the number of radicals recombined at times t_A and t_B are N_A and $N_B(t_B > t_A)$ then the number of radicals recombined at infinite time is $N_\infty = N_B + 9.5(N_B - N_A)$. This formula is justified in the Appendix. The yields of radicals which escape recombination are small and obtained by difference between two larger numbers, e.g. $[OH] = [-H_2O] - [H_2O_2]$. Small errors in estimating the molecular yields make larger errors in the radical yields. The radical yields, particularly at high L.E.T., have consequently rather low numerical precision.

The results of a typical calculation are shown in Fig. 1. The features of interest are firstly, the time scale during which significant reaction takes place—four orders of magnitude are plotted—and secondly, the large amount of total recombination which occurs in 10^{-9} seconds as compared with the extent of recombination in γ-ray spurs (Fig. 1, Part I). The effects of diffusion control are shown by the crossing of the curves for $[H_2]$ and $[H_2O_2]$. Initially $[H_2]$ is greater than $[H_2O_2]$ because $k_{11} > k_{22}$. After 10^{-10} seconds, however, hydrogen atoms have been removed from the center of the track so that $k_{11}[H]^2$ is less than $k_{22}[OH]^2$, and the yield of H_2O_2 becomes greater than that of H_2.

NOTE: The columns to the left of the double line refer to the parameters of the track and are explained in Sections 3 and 4. The columns to the right of the double line give the computed yields defined in Section 4.

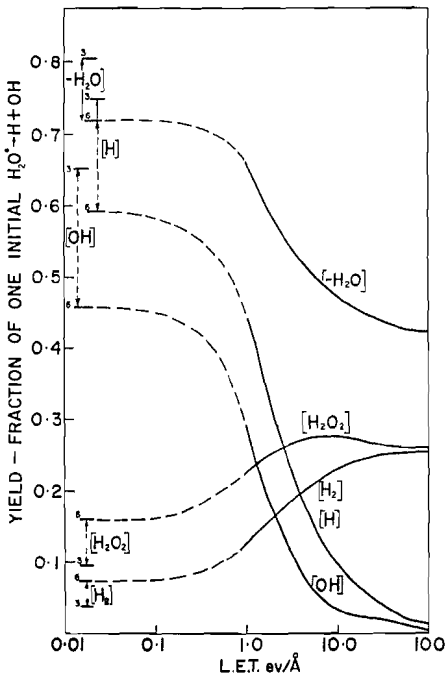

FIG. 2. Variation in yields with track density. The solid lines at the right of the figure are obtained from cases A–F. The yields at the left of the figure, plotted at L.E.T. of 0.02 ev/Å are for spherical spurs with three or six radical pairs/spur. The dotted lines are interpolations; no calculations have been made in this region. The scale of L.E.T. is arbitrary and can only be compared qualitatively with Fig. 3. For further details see text.

5. VARIATION IN YIELDS WITH TRACK DENSITY

The variation in yield with track density is shown in Fig. 2. The solid curves cover the range 0.1–10 radical pairs/Å and are derived from cases A–F (Table I). These cases use the rate constants, diffusion constants, and other parameters chosen for the "initial case" in the previous section. Note again that the scale of linear energy transfer in ev/Å is obtained from the track density using the arbitrary value of 10 ev/radical pair. Yields for γ-ray spurs for the same choice of rate constants and diffusion constants are plotted at a value of 0.02 ev/Å (corresponding to Compton recoils generated by ~1-Mev γ-rays). Values for both three and six radical pairs/spur are shown.

The yields are expressed as the number of molecules or radicals formed per initial H_2O dissociated. These are identical with the figures given in Table I except that the values of $[H_2]$ and $[H_2O_2]$ are divided by two. The yields as plotted are proportional to G-values (molecules/100 ev). The dotted portions of the curves in Fig. 2 lie in the region where the track expands partly in spherical and partly in cylindrical geometry. The present calculations do not cover this range and the curves have been drawn on the assumption that there is an asymptotic approach of the yields to the values for isolated spurs.

The calculations have been carried over the extreme range for which the cylindrical approximation is valid; at a track density as low as 0.1 radicals/Å and with a value of 10 Å for the modulus of the Gaussian, the track may be more correctly visualized as a series of spherical spurs which are just overlapping or touching. The errors involved are probably small because of the short time which elapses before such a track expands to a

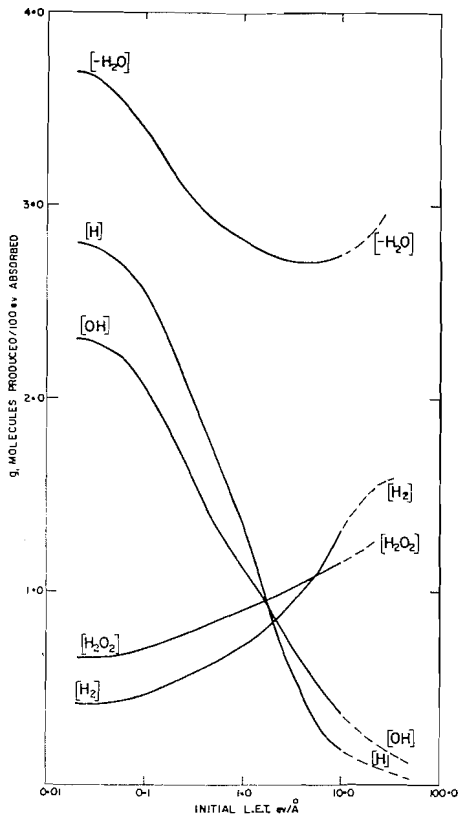

FIG. 3. Experimental variation in yields with initial track density. The figure shows smoothed, idealized curves based largely on the data of Schwarz, Caffrey, and Scholes.

uniform cylinder and because of the relative insensitivity of the yield to the initial track diameter. The errors will be in the direction of underestimating the amount of recombination.

Figure 2 is qualitatively in good agreement with experiment and may be compared with Fig. 3, which presents the experimental data for pure water in a somewhat idealized fashion. Figure 2 should also be compared with Figs. 2–16, reference 13, which present similar curves for acid solutions. The experimental curves are similar and differ mainly in numerical details.

Both in theory and experiment the yields of radicals decrease and the molecular yields increase with increasing L.E.T. In very dense tracks the radical yields are virtually zero. At the same time the ratio of the molecular yields $[H_2O_2]/[H_2]$ decreases. At low L.E.T. $[H_2O_2] > [H_2]$ but at high L.E.T. they approach equality. In the calculation the inequality arises because of the greater diffusion constant chosen for hydrogen atoms; this removes hydrogen atoms more rapidly from the high-density region of the track where the bulk of bimolecular recombination takes place. In the highest-density cylindrical tracks the effects of diffusion are reduced and the yields are not very different from those predicted by homogeneous kinetics.

The small maximum in the calculated value of $[H_2O_2]$ is another consequence of the more rapid diffusion of hydrogen atoms. The studies in Part I showed that $[H_2O_2]$ was strongly influenced by the availability of hydrogen atoms which compete for OH radicals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

by the $H + OH \rightarrow H_2O$ recombination. The maximum in $[H_2O_2]$ occurs where the diffusion of H atoms is becoming significant, their removal from the center of the track increases the availability of OH for recombination to H_2O_2, and consequently $[H_2O_2]$ shows a slight maximum. The effect is quite small and would be difficult to observe experimentally. The calculated maximum is only significant in illustrating the kinetic complexities of the system and the somewhat unexpected effects of competing processes.

It is possible that the experimentally observed increase in $G(H_2)$ at high L.E.T. (see Fig. 3 and ref. 4) making $G(H_2) > G(H_2O_2)$ could be the result of similar kinetic effects if k_{11} were made much larger than the values chosen here. A few calculations (not specified in Table I) showed, however, that the changes in the constants required to produce such an effect were too drastic to be reasonable.

(a) The Energy Scale

The calculated value of $[-H_2O]$ varies from ~0.8 for a γ-ray spur containing initially three radical pairs to ~0.5 for a track having 0.5 radical pairs/Å. Combining these figures with the value of ~10 ev/initial radical pair we find $G(-H_2O)$ (molecules/100 ev) to be ~8 for γ-rays and ~5 for a particle track with L.E.T. of 5 ev/Å. These values are greater, by a factor ~2, than the experimental values. $G(-H_2O)$ for γ-rays in neutral water is 3.7 (2). For 11-Mev α-particles in neutral water $G(-H_2O)$ is 2.57 (4). The energy required to produce one radical pair must be ~20 ev/radical pair (essentially double our initial estimate) to give agreement with experiment.

The same conclusion has been reached by both Schwarz, Caffrey, and Scholes (4) and Burton and Kurien (5). Both these groups of workers estimated *initial* values of $G(-H_2O)$, designated G^0, from experimentally determined values of $G(-H_2O)$, $G(H_2)$, and $G(H_2O_2)$. This was done by putting

$$G(H_2O^*) = G(H_2) + G(H_2O_2). \qquad [4]$$

$G(H_2O^*)$ is the yield of water re-formed in the track and is equivalent to $[H_2O^*]$ in our terminology.[3] The values of G^0 are obtained by putting

$$G^0 = G(-H_2O) + G(H_2O^*).$$

The assumption of equation [4] is equivalent, in these calculations, to putting $k_{11} = k_{12} = k_{22}$ and $D_1 = D_2$. The constants used in this paper would make $G(H_2O^*) \simeq 1.3(G(H_2) + G(H_2O_2))$ so that the approximation is not unreasonable. With these assumptions Schwarz *et al.* found $G^0 = 4.4$–4.7 in neutral solution for Co-60 γ-rays increasing to 6.1 for 3.5-Mev α's. In acid solution Burton and Kurien found $G^0 = 6.3$–6.7 for Co-60 γ-rays and 50-kev X-rays, and $G^0 = 7.3$ for α-rays with an average energy of 3.4 Mev.

The constancy of G^0-values over a fair energy range in both series of experiments supports the validity of the calculation. A value of $G^0 \simeq 5$ corresponds again to an energy requirement of ~20 ev/radical pair. It follows, therefore, that the value of ~10 ev/radical pair, obtained experimentally by Firestone (3) from studies in water vapor, is not directly applicable to liquid water.

The gas-phase and liquid values of the initial radical yield may be reconciled if it is assumed that there is a very high initial probability of an H, OH pair recombining in the first few diffusion steps. The effective radical pair yield is then less than the instantaneous initial value (4).

[3]*Burton and Kurien use a modified relation* $G(H_2O^*) = (N-1)/N\,(G(H_2) + G(H_2O_2))$ *for* γ*-ray spurs where N is the number of radical pairs/spur.*

(*b*) *The Variation of* $G(-H_2O)$ *with L.E.T.*

The value of $[-H_2O]$ falls with increasing L.E.T. as do the experimental values of $G(-H_2O)$ in pure water. The experimental ratio $G(-H_2O)$ γ-rays/$G(-H_2O)$ 11.5-Mev α-rays is 1.4 (4). The calculated ratio using the "initial" rate constants and diffusion constants for a track with 0.5 radicals/Å is 1.4 if the γ-ray spur contains six radical pairs and 1.6 if the spur contains three radical pairs. This we regard as being in qualitative agreement with experiment. The values obtained in acid solution are in less satisfactory agreement. Burton and Kurien (5) report a value of 1.12 for the ratio of $G(-H_2O)$ γ-rays/$G(-H_2O)$ 5.3-Mev α-rays in 0.8 N H_2SO_4; significantly different from the values in neutral water and from our quoted calculations.

The calculated value of this ratio is, however, a sensitive function of the value chosen for k_{12}. A plot of the ratio of $[-H_2O]$ for a γ-ray spur containing six radical pairs to $[-H_2O]$ for cylindrical tracks with $N_1 = N_2 = 0.5$ radical pairs/Å, is shown in Fig. 4. A value of 1.1 for this ratio is obtained with $k_{12} = 0.5\times10^{-11}$, 1/8 of the value chosen in the initial series of calculations. This figure is derived from cases M, N, and O and some calculations on γ-ray spurs not published in Part I.

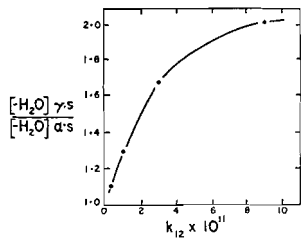

FIG. 4. The variation in $[-H_2O]$ as a function of k_{12}, expressed as the ratio $[-H_2O]$ γ's/$[-H_2O]$ α's for spherical spurs with six radical pairs/spur and cylindrical tracks with $N_1 = N_2 = 0.5$/Å.

The kinetic scheme used here to describe the Samuel–Magee model does, therefore, predict a reduction in $[-H_2O]$ in pure water with increasing L.E.T. which is qualitatively in agreement with experiment. The change in this and other yields with pH shows, however, that this kinetic scheme is incomplete. The observed pH effects may, *inter alia*, be equivalent to processes which, in effect, change the value of k_{12} in the simple kinetic scheme.

An increase in $G(-H_2O)$ at high L.E.T. has been observed by several workers. This has been qualitatively explained by Schwarz, Caffrey, and Scholes (4). It is supposed that the H and OH radicals from the dissociation of 1 water molecule are initially so close together that there is a fairly high probability of these two radicals recombining. At very high ionization densities however, the density of excited water molecules, and hence of H and OH radicals, is so high that one hydrogen atom is more likely to recombine with another hydrogen atom than to recombine with the OH from which it was dissociated. If this competing reaction for formation of H_2O_2 and H_2 is at all favorable then $G(-H_2O)$ will increase at high track densities.[4] This process could also explain the difference between the initial radical yields in the gas and liquid phases; in the gas phase the recombination of H and OH formed from 1 individual water molecule would

[4]*This explanation neglects the opposite effect where* H *atoms are closer to* OH *radicals produced from neighboring excited water molecules. This effect would decrease* $G(-H_2O)$ *as the track density increases and could exactly counterbalance the effect described above. This comment underlines the complexity of radical correlation effects.*

be less probable. Effects of this nature could be formally incorporated into the kinetic scheme of the model by the introduction of time-dependent rate constants. A procedure for doing this has been advanced by Monchick, Samuel, and Magee (11).

6. THE EFFECT OF SCAVENGER CONCENTRATION

The reduction in yields of molecular products as the concentration of scavenger is increased is calculated in cases G, H, I, J. The changes in the yields, expressed relative to the yield at the lowest concentration of scavenger, are shown in Fig. 5. The curve is qualitatively very similar to that for γ-ray spurs (I, Fig. 12) but the quantitative effect is somewhat smaller for cylindrical tracks than for the γ-ray spurs. This difference is also shown in the calculations of Ganguly and Magee (6). This arises because of the competition between the scavenging processes and the recombination processes. In the cylindrical tracks the recombination reaction occurs to a greater extent, and a given concentration of scavenger will have less effect here than in a spherical spur.

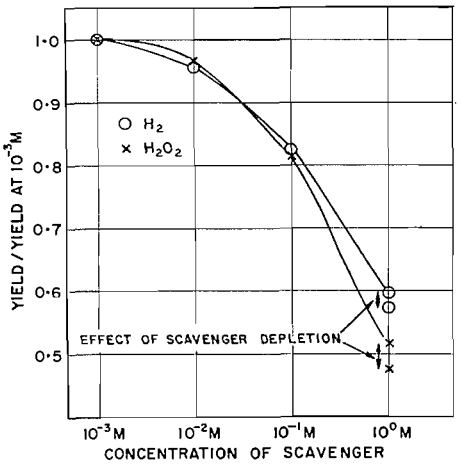

FIG. 5. Effects of scavenger concentration on the molecular yield. The abscissa is the ratio of $[H_2]$, $[H_2O_2]$ at the plotted scavenger concentration to the yield at "10^0 M". $k_{1S} = k_{2S} = 1\times10^{-11}$ (cases G, H, I, J). The two lower points at 10^0 M represent the relative yields obtained if depletion of scavenger at the center of the track is neglected (case K).

Schwarz, Caffrey, and Scholes (4), Burton and Kurien (5), and Senvar and Hart (10) have made extensive studies of yields as a function of scavenger concentration and have found good agreement with the one-radical calculations of Ganguly and Magee and those of Fricke and Flanders (8). These simpler calculations are, at the present time, more suitable for experimental comparison than our two-radical calculations because of the smaller number of parameters in the calculation.

Figure 5 shows that the yields of $[H_2]$ and $[H_2O_2]$ are changed at varying rates by the addition of scavenger. The curve for $[H_2]$ is at first lower than that for $[H_2O_2]$, but rises above it again at higher scavenger concentrations. This effect is numerically small and barely significant. In comparing these results with experiment it should be noted that, in these calculations, the scavenger reacts with both species simultaneously. In many experimental cases the scavenger reacts primarily with one species (e.g. halide ion with OH) and the other radical is removed by a secondary product (e.g. hydrogen atom by halogen atom). The over-all scavenger effects will also be affected by the competition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

between the primary recombination steps. For these reasons a detailed study of effects of scavenger concentration with variation in track density and differing values of k_{13} and k_{23} has been deferred until more experimental data is available.

The effect of depletion of scavenger can be seen from case K. Here k_{13} and k_{23} and C_3 have been chosen in such a way that the effective concentration of scavenger—measured by the products $k_{13}C_3$ and $k_{23}C_3$—is the same as in case J even though C_3 is greater by a factor of 10^3. The recombination is, in effect, taking place in a constant concentration of scavenger so that there is no significant depletion of the scavenger. As expected, the effect of scavenger is greater if depletion at the center of the track is neglected, i.e. the values of $[H_2]$ and $[H_2O_2]$ are less in K than they are in J. The effect is, however, small, changing the yields by only 5–10%. Qualitative arguments, comparing the initial concentration of radicals in the spur ($\sim$10 M) with the concentration of scavenger, suggest that the effect would be quite large. The direct comparison of the initial concentration of radicals is therefore somewhat misleading. It should be noted that the major fraction of recombination takes place before much scavenging has taken place, i.e. the two reactions are not competing on an equal basis until some appreciable time has elapsed. During this time the track has expanded and reduced the concentration of radicals quite sharply. At longer times the effect of depletion at the center of the track is counteracted by the diffusion of radicals to regions of higher scavenger concentration.

The relatively small effects due to diffusion of scavenger are also demonstrated by comparing L and J. The diffusion constant for the scavenger D_3 is reduced by a factor 4 in L, and the yields are unchanged within the numerical accuracy of the calculation.

7. VARIATION IN YIELDS WITH TRACK DIAMETER

The geometrical factors in the diffusion process for spherical spurs and cylindrical tracks make a considerable difference in the sensitivity of yields to spur or track radius. In spherical spurs the yields are quite sharply reduced when R_1 and R_2 ($R = 1/\beta$ where β is the modulus of the Gaussian, see Section 3) are increased by a factor of 2. In cylindrical tracks, however, the yields are relatively insensitive to the initial track radius. The molecular yields change by only about 3% in cases P, Q, and R where R_1, R_2 change from 5 Å to 20 Å. For spherical spurs the yields are reduced by 60–80% over the same range (A, S, T, Table I, Part I). In spherical spurs where R_1 only is increased, R_2 being kept constant, $[H_2]$ decreases and $[H_2O_2]$ increases. A different effect is observed for cylindrical tracks. Here $[H_2]$, $[H_2O_2]$, and $[-H_2O]$ all increase as R_1 increases (Q, S, T). At the same time [H] increases and [OH] decreases. These effects arise because of the insensitivity of the yield to the initial spur radius and to the behavior of the recombination term $k_{12}(H)(OH)$, which affects the yields of $[H_2]$ and $[H_2O_2]$ strongly. By making R_1 greater than R_2 the value of this term is decreased and more like radicals are available for recombination. A comparison between γ-ray spurs and cylindrical tracks is made in Table II.

TABLE II

Ratio of yields for R_1 = 10 Å to R_1 = 25 Å, (R_2 = 10 Å)

These results are of considerable interest in connection with the interpretation of the different yields in light and heavy water. The most recent experimental work on the system is summarized by Dainton (7). For γ-rays it appears that $G(H_2) > G(D_2)$, $G(-D_2O) > G(-H_2O)$, and G(radicals D_2O) > G(radicals H_2O). The discussion in Part I on these isotope effects was related to earlier experimental work which suggested that $G(-D_2O) < G(-H_2O)$ and is consequently superseded by the experimental work reported by Dainton and his co-workers.

Dainton suggests that the change in yields can be explained by assuming that, initially, D atoms are more widely dispersed than H atoms, i.e. $R_1(D) > R_1(H)$. The first line in Table I shows that a change in this direction does decrease $[H_2]$ and increase $[-H_2O]$ for γ-ray spurs. The effect is, however, partially inverted for cylindrical tracks, $[H_2]$ is increased as R_1 is increased. Measurement of D_2 yields for densely ionizing particles may therefore shed some light on the origin of isotope effects in water. It should also be noted that this change in R_1 affects the yield of $[H_2O_2]$ as well so that one would expect $G(H_2O_2) < G(D_2O_2)$. This inequality is found experimentally in some, but not all, of the aqueous systems which have been studied.

The mechanism proposed by Dainton to account for the larger displacement of D atoms requires some hydrogen atoms to be formed by the process: $e^-_{aq} + H_2O \rightarrow H + OH^-$. The Samuel–Magee model as originally proposed discounts this type of process.

8. GENERAL CRITIQUE OF THE SAMUEL–MAGEE MODEL

The original model proposed by Samuel and Magee can be modified in many ways without, in principle, changing the basic idea, namely that the radical and molecular yields arise from a bimolecular, diffusion-controlled reaction of H and OH. The inclusion of reactions between radicals and molecules and the concept of spatial correlation of the radicals (leading to time-dependent rate constants) are minor modifications to the kinetic scheme of the model. The principal criticism of the model is still that the mechanism of formation of free radicals H and OH from the initial ionized state ($H_2O^+ + e$(100 ev)) is neither established nor understood (12).

The model was originally advanced to explain the separation between radical and molecular yields of water. The relative values of these yields have been shown to be correctly predicted in a qualitative sense in the one-radical calculations cited elsewhere in this paper (1, 6, 8). The relative values of the yields of H_2O, H_2O_2, H, OH are qualitatively predicted in the two-radical versions of the model described in this series of papers. The variation of molecular yields with scavenger concentration has been predicted semiquantitatively in several treatments (6, 8, 9). The variation in yields with ionization density is, in its broad features, correctly predicted in the calculations of Ganguly and Magee and the two-radical model in this paper. These successes of the model are powerful arguments in favor of its validity. To be more specific, one can conclude from the comparison of theory and experiment that H_2 and H_2O_2 are formed by kinetically similar mechanisms and that these are bimolecular diffusion-controlled reactions, probably simple recombinations H + H, OH + OH, and H + OH.

On the other hand, the model, in the simple formulation discussed here, predicts neither the variations in yield with pH, nor the details of the yields at high-track density (inversion of the relations $[H_2] < [H_2O_2]$ and the increase in $G(-H_2O)$) and does not explain the isotope effects. (We reject large *ad hoc* variations in rate constants as "explanations" of such effects.) Variations in yields with pH require the introduction of reactions involving hydrogen ions. These, however, are an elaboration of the kinetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

scheme and so do not alter its essence. Variations in yield at high-track density may also be explained by radical–molecule reactions, and/or by taking into account the spatial correlation of free radicals. These, again, elaborate the kinetic scheme, but do not, in principle, alter the model. The isotope effects cannot apparently be explained without some significant change in the kinetic scheme or of the constants and parameters in the system.

One of the more significant conclusions of these papers is that the use of gas-phase data to deduce the initial structure of spurs and tracks is, at best, misleading. Even after exercising the caution necessary when deducing a mechanism from kinetics, the qualitative successes of the model are very striking and lead us to believe that it describes correctly the majority of processes occurring in the life history of spurs and tracks. The model only does this, however, for spur sizes and radical densities that are significantly different from those deduced from gas-phase data. In Part I arguments are developed, from gas-phase data, showing that the "average" spur resulted from an energy deposition of 65 ± 10 ev and contained $\sim$6 radical pairs/spur. The calculations in this part show, however, that an energy deposition of $\sim$20 ev is required to produce one "effective" radical pair. This invalidates the use of Firestone's measurements on the radiolysis of water vapor to estimate the energy required to produce a radical pair in liquid water and, further, makes either the validity or the relevance of cloud-chamber data to determine the energy deposition/spur open to question. The discussions to be found in ref. 12 are still very pertinent to the present state of knowledge.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the benefit of helpful and critical discussions with Dr. R. H. Betts.

APPENDIX

DIFFUSION WITH RECOMBINATION IN CYLINDRICAL GEOMETRY

(*1*) *The Equations*

The concentrations C_i of three types of particles are given by

$$[1] \qquad \frac{\partial C_i}{\partial t} = D_i\nabla^2 C_i - \sum_j k_{ij}C_iC_j,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

where the D_i are diffusion constants and the k_{ij} are rate constants for recombination reactions. The operator ∇^2 is the cylindrical Laplacian:

$$\nabla^2 \equiv \frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}.$$

Initially the particles of types 1 and 2 are confined to a small cylindrical region, while those of type 3 are uniformly distributed through all space:

$$C_i(r,0) = \frac{N_i\beta_i^2}{\pi} e^{-\beta_i^2 r^2}$$

for $i = 1, 2$.

[2] $$C_3(r,0) = C_3,$$

where N_i is the number of particles per unit length and β_i the range parameter for type i.

We assume throughout that $k_{33} \equiv 0$.

The problem is the evaluation of the losses of particles (per unit length) due to the various modes of recombination:

[3] $$L_{ij}(t) = \int_0^t dt \int_0^\infty 2\pi k_{ij} C_i C_j r\, dr = \int_0^t \lambda_{ij}(t)\, dt.$$

(2) Co-ordinate Transformations

Before attempting the numerical solution of the system [1] it is useful to make several changes of variable. We define new dependent variables by

[4] $$X_i = t^{\frac{3}{4}} r^{\frac{1}{2}} C_i,$$

and introduce the expanding radial co-ordinate by

[5] $$\rho = r/(D_1 t)^{\frac{1}{2}}$$

where (by convention) D_1 is the larger of D_1 and D_2.

Equation [1] is transformed into

[6] $$t\frac{\partial X_i}{\partial t} = \Delta_i\left[\frac{\partial^2 X_i}{\partial \rho^2}+\frac{1}{4\rho^2}X_i\right]+\tfrac{3}{4}X_i+\frac{\rho}{2}\frac{\partial X_i}{\partial \rho}-\frac{1}{\rho^{\frac{1}{2}}D_1^{\frac{1}{4}}}\sum_j k_{ij}X_iX_j.$$

These transformations are similar to the ones used previously in spherical geometry. Their utility arises from the fact that in the absence of recombination terms the solution that is initially

$$C_1(r,t_0) = A\, e^{-\beta_1^2 r^2}$$

at time t_0 makes the right side of (6) vanish provided t_0 is chosen so that

$$4\beta_1^2 D_1 t_0 = 1.$$

Thus the numerical work is devoted to examination of that part of the behavior that is not simple outward diffusion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

It is straightforward to verify that in the absence of recombination the equation for X_3 reduces to

$$t(\partial X_3/\partial t) = X_3$$

or

$$[7] \qquad X_3 = \frac{t}{t_0} X_3(t_0).$$

The increase in X_3 is a consequence of the fact that in real space C_1 and C_2 at any point decrease like $1/t$ due to outward diffusion, so that the transformation that keeps these constant gives an apparent increase in X_3 corresponding to constant C_3.

Finally, it is expeditious to introduce a new time variable x such that equal increments in x correspond to expanding steps in t. This is related to the physical fact that as time proceeds the concentrations and their gradients decrease, and we can afford to pursue them more vigorously. After some numerical experiments the choice made for spherical geometry was adopted.

$$[8] \qquad t = t_0 e^x.$$

The final form of [6] is

$$[9] \qquad \frac{\partial X_i}{\partial x} = \Delta_i\left[\frac{\partial^2 X_i}{\partial \rho^2}+\frac{1}{4\rho^2}X_i\right]+\frac{3}{4}+\frac{\rho}{2}\frac{\partial X_i}{\partial \rho}-\frac{1}{\rho^{\frac{1}{2}}D_1^{\frac{1}{2}}}\sum_j k_{ij}X_iX_j.$$

(3) Solution of the Equations

The method of integration follows closely the method used for spherical geometry. Tables of X_1, X_2, X_3 at 40 values of ρ were used, and the space derivatives evaluated using the relations

$$\frac{\partial^2 X^{(n)}}{\partial \rho^2}+\frac{1}{4\rho^2}X^{(n)} = \frac{1}{h^2}[X^{(n+1)}-T_nX^{(n)}+X^{(n-1)}]$$

$$[10] \qquad \frac{\rho}{2}\frac{\partial X^{(n)}}{\partial \rho} = \frac{nT_n}{8}[X^{(n+1)}-X^{(n-1)}]$$

where h is the interval in the variable ρ, and

$$T_n = \left(1-\frac{1}{n}\right)^{\frac{1}{2}}+\left(1+\frac{1}{n}\right)^{\frac{1}{2}}.$$

The choice of T_n is related to a quirk of cylindrical geometry. The usual formula for the second derivative is

$$\frac{\partial^2 X^{(n)}}{\partial \rho^2} = \frac{1}{h^2}[X^{(n+1)}-2X^{(n)}+X^{(n-1)}].$$

Now for large n,

$$T_n = 2-\frac{1}{4n^2}+\text{terms of order } \frac{1}{n^4};$$

hence the use of T_n in place of 2 compensates for the inclusion of $(1/4\rho^2)X$ in the Laplacian. Also, for small n, $X \sim \rho^{\frac{1}{2}}$, and its derivatives are not well represented by finite difference formulas due to the singularity at $\rho = 0$. The choice of T_n makes the formulas exact for the function $X = \rho^{\frac{1}{2}}$, and hence compensates for this difficulty.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

When [12] is substituted into [11], we are left with a set of 120 first-order differential equations for $X_i^{(n)}(x)$ for $i = 1, 2, 3$, and $n = 0, 1, \ldots.39$. The integration is carried out by the second-order "midpoint" method already used for spherical geometry.

The initial conditions and boundary conditions are obtained from [2], applying the co-ordinate transformations [4] and [5].

$$X_i^{(n)}(0) = t^{\frac{3}{4}} r^{\frac{1}{2}} \frac{N_i \beta_i^2}{\pi} e^{-\beta_i^2 r^2}$$

for $i = 1, 2$. With $t = t_0$ and $\rho = nh$

$$X_i^{(n)}(0) = \frac{N_i \beta_i^2 t_0}{\pi} (nh)^{\frac{1}{2}} (D_1)^{\frac{1}{4}} e^{-\beta_i^2 D_1 t_0 n^2 h^2}. \tag{11}$$

It follows that $X_1^{(0)} = X_2^{(0)} = 0$ for all time, and we also impose the condition that $X_1^{(39)} = X_2^{(39)} = 0$ for all time. Naturally, h must be large enough that this cutoff at "infinity" leads to negligible error.

The initial condition for X_3 is

$$\begin{aligned} X_3^{(n)}(0) &= t^{\frac{3}{4}} r^{\frac{1}{2}} C_3 \\ &= t_0 (nh)^{\frac{1}{2}} D_1^{\frac{1}{4}} C_3. \end{aligned} \tag{12}$$

Again $X_3^{(0)} = 0$ for all time. For the outer point $X_3^{(39)}$ we note that since X_1 and X^2 vanish here and $k_{33} \equiv 0$ there is no recombination. Thus equation [8] applies at the outer point, and

$$\begin{aligned} X_3^{(39)} &= X_3^{(39)}(t_0)\, t/t_0 \\ &= X_3^{(39)}(t_0)\, e^x. \end{aligned} \tag{13}$$

(4) The Integrals

For the loss integrals, we use

$$L_{ij} = \sum_x \lambda_{ij}(x),$$

where the loss during any interval Δx is

$$\begin{aligned} \lambda_{ij} &= \frac{dt}{dx} (\Delta x) \int_0^\infty 2\pi k_{ij} C_i C_j r\, dr \\ &= 2\pi D^{\frac{1}{2}} (\Delta x) \int_0^\infty k_{ij} X_i X_j\, d\rho \end{aligned} \tag{14}$$

after applying the transformation [4], [5], [8].

Similarly, the current values of the numbers of particles per unit length may be obtained from

$$\begin{aligned} N_i(x) &= 2\pi \int_0^\infty C_i r\, dr \\ &= 2\pi D_1^{\frac{1}{2}} \int_0^\infty X_i^{\frac{1}{2}} D_1^{\frac{1}{4}}\, d\rho. \end{aligned} \tag{15}$$

The integrands in [14] and [15] are available as tables obtained during the solution of the equations. The integrals are evaluated by Simpson's rule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

(5) Input and Output

The input data are defined by a choice of

$$\begin{array}{lllll} & t_0, & h = \Delta\rho, & \Delta x, & \\ k_{11}, & k_{22}, & k_{12}, & k_{13}, & k_{23}, \\ D_1, & D_2, & D_3, & & \\ N_1, & N_2, & \beta_1, & \beta_2, & C_3. \end{array}$$

It has been found that $\Delta x = 0.02$ is about the largest value that avoids instability in the solutions; $h = 0.3$ is a convenient choice. The value of t_0 depends on the physical parameters; it must set the pace of the co-ordinate system expansion to the pace of the actual diffusion. The "theoretically best" value is

$$t_0 = \tfrac{1}{4}\beta_1^2 D_1,$$

but it has been found that a rather smaller value

$$t \approx \tfrac{1}{6}\beta_1^2 D_1$$

avoids certain difficulties arising from the outer boundary conditions.

After every few steps in x (10 steps in most of the production runs), the following quantities are printed.

Elapsed time

$$\begin{array}{lllll} L_{11} & L_{12} & L_{13} & N_1 & \Sigma_1 \\ L_{22} & L_{12} & L_{23} & N_2 & \Sigma_2, \end{array}$$

where Σ_i is the sum of the four other quantities in its row. Σ_i should be independent of t, and its constancy is a check on the stability of the solution.

(6) Extrapolation to $t = \infty$

The printed results emerge at equal increments in x. It turns out that if the results for L_{11}, L_{12}, L_{22} are plotted as a function of the variable

$$y = e^{-x/2} = \sqrt{t_0/(T+t_0)}\ ,$$

where T is the elapsed time, they lie very nearly on a straight line for small y (large T). Thus for any of these terms,

$$L_\infty = L_F + \frac{y_F}{y_{F-1} - y_F}(L_F - L_{F-1})$$

$$= L_F + \frac{1}{(y_{F-1}/y_F) - 1}(L_F - L_{F-1}),$$

where L_F and L_{F-1} are the last and the penultimate values.

Now $y_{F-1}/y_F = e^{\frac{1}{2}\Delta x}$, and we have used $\Delta x = 0.2$. Thus

[16] $$L_\infty = L_F + 9.5\,(L_F - L_{F-1}).$$

It should be remarked that there is no particular justification for this recipe other than the empirical straightness of a line. At best, L_∞ given by [16] may contain one more significant figure than would be obtained by taking $L_\infty = L_F$.

THE RADIOLYSIS OF SOME ORGANIC HALOGEN COMPOUNDS IN AQUEOUS SOLUTION[1]

R. J. Woods and J. W. T. Spinks

ABSTRACT

Dilute aqueous solutions of some halogen-substituted ethanols, acetaldehydes, and acetates have been irradiated with Co^{60} gamma rays, and the yield of acid products determined. Irradiations were carried out using air-saturated solutions and also solutions from which the air had been displaced by nitrogen or hydrogen. The acid yields are correlated with the structure of the organic compounds.

INTRODUCTION

The action of ionizing radiations on certain organic chloro-compounds has been studied extensively, both in aqueous solution and as two-phase systems with water, with a view to their use as chemical dosimeters, though little consideration has been given to the chemical reactions taking place (1). Two-phase systems of chloroform or tetrachloroethylene with water have received most attention; when irradiated in the presence of air both give high yields of hydrochloric acid which are directly proportional to the dose of radiation received. The acid is formed by a chain reaction and the yields are dependent on the temperature, dose rate, and energy of the incident radiation, and are lowered by traces of impurities. These variables curtail the usefulness of the systems for dosimetry; their effect may be reduced by increasing the proportion of water in the system, for example by using dilute aqueous solutions of the organic compounds, though the amount of acid formed by a given dose of radiation falls if this is done. However, the ease with which acid can be determined in an aqueous solution suggested that it would be worth while to measure the acid formed from solutions of other organic halogen compounds on irradiation, and attempt to correlate the yield of acid with the structure of the compound. The halogen-substituted hydrocarbons are normally only slightly soluble in water but by substituting a suitable group, which for convenience will be referred to as the functional group, in the molecule, water-soluble compounds can be obtained. The present study employs a series of halogen-substituted ethanols, acetaldehydes, and acetates in which the functional groups are hydroxymethyl, aldehyde, and carboxylate respectively.

The compounds were irradiated as 0.1 molar solutions of the neutral compounds and 0.1 normal solutions of the barium salts of the substituted acids. Yields of acid were determined by titration with aqueous alkali and yields of halide ion, other than fluoride, by titration with silver nitrate solution; fluoride was estimated by a colorimetric method. Results are given to show the effect upon the acid yield of varying the dose rate and of displacing the air normally present by nitrogen or hydrogen, since previous work had shown that the yield from trichloroacetaldehyde (chloral) (2) and tribromoacetaldehyde (bromal) (3) was dependent upon the dose rate and the presence of oxygen. Some estimates of the oxygen consumed during radiolysis are given.

Experiment showed that the halogen was liberated as halide from every compound examined, though the yields of fluoride from fluorine-substituted compounds were generally

[1]*Manuscript received August 31, 1959.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.

low. The acid yields are discussed with reference to the structure of the compounds irradiated. The use of these halogen-substituted compounds in chemical dosimetry is discussed briefly.

EXPERIMENTAL

Materials

The distilled water used was redistilled from alkaline permanganate and then from acid dichromate solutions and stored in Pyrex bottles.

Reagent grade chemicals were used when these were available commercially. Materials of lower grade, and products prepared in the laboratory, were purified by crystallization to constant melting point or by repeated distillation, until the main fraction had a boiling range of less than 2° C. The purity of several of the bromo-compounds could be checked by treating them (10–20 mg) with excess 0.1 *N* sodium hydroxide solution and titrating the excess of alkali after a suitable interval (see Table VI) (cf. ref. 3). Equivalent weights determined in this way are given after the preparation of the appropriate compound. Whenever possible the radiolysis yields from two separate batches of a given compound were compared; in no case were there serious differences in yield between the different samples.

Reagent grade chloroform was washed 10 times by shaking with distilled water, distilled, and stored under water, in the dark.

Trifluoroacetaldehyde

Trifluoroacetaldehyde hydrate (fluoral hydrate), prepared from trifluoroacetic acid (4), was fractionated and the fraction, b.p. 103–105° C, dehydrated with hot, concentrated sulphuric acid. The gaseous fluoral was absorbed in a little less than the theoretical amount of water and the crystalline hydrate, which separated, filtered off, and dried over phosphorus pentoxide, m.p. 66–66.5° C.

Bromoacetaldehydes

The bromoacetaldehydes were prepared by brominating paraldehyde (5); omitting the sulphur catalyst, since this increased the quantity of tarry residue formed without markedly improving the yield of products, and distilling the volatile products from the reaction vessel under reduced pressure and as rapidly as possible when the reaction was complete. The distillate was carefully fractionated under reduced pressure to give monobromoacetaldehyde, b.p. 52–53° C/57–62 mm, dibromoacetaldehyde, b.p. 61–64° C/58–62 mm, and tribromoacetaldehyde (bromal), b.p. 43–45° C/4–5 mm.

The proportions of the three bromoacetaldehydes formed varied with the proportions of the reactants used and with the conditions of the bromination. For example, when 1360 g bromine (8.5 moles) was added dropwise to 193 g paraldehyde (equivalent to 4.4 moles of acetaldehyde) diluted with 400 ml carbon tetrachloride over a period of 4 hours and the mixture warmed to 50° C for a further 1 hour the products were 124 g monobromoacetaldehyde (1.0 mole), 300 g dibromoacetaldehyde (1.5 moles), and 179 g bromal (0.65 mole). The theoretical quantity of bromine, added to the paraldehyde – carbon tetrachloride mixture while it was being cooled with a cold-water bath, gave monobromoacetaldehyde in 80% yield. The proportion of bromal in the products could be increased by using a molar ratio of bromine to paraldehyde of 3:1 and stirring the reaction mixture at 50° C for several hours after adding the bromine: the products always included some dibromoacetaldehyde.

Both monobromoacetaldehyde and dibromoacetaldehyde polymerized on standing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

and, for convenience, were converted into the stable hydrates immediately after distillation by being stirred with a small excess of water. Seed crystals to initiate crystallization of monobromoacetaldehyde hydrate were obtained by distilling a portion of the aldehyde–water mixture; the distillate (b.p. 97°/720 mm) crystallized in the condenser. Monobromoacetaldehyde hydrate crystallized from water as needles; m.p. between 61 and 95° C, depending upon the rate of heating. Dibromoacetaldehyde hydrate crystallized from water as needles, m.p. 61–61.5° C. (Found: equiv. wt., 75.1. Calc. for $C_2H_4O_2Br_2$: equiv. wt., 73.3.) Bromal hydrate, m.p. 54° C. (Found: equiv. wt., 294. Calc. for $C_2H_3O_2Br_3$: equiv. wt., 299.)

Tribromoacetic Acid

Fuming nitric acid (30 ml) was added dropwise, through a reflux condenser, to bromal (100 g) which was warmed to about 70° C with a warm-water bath. When the addition was complete (15 minutes) the temperature of the water bath was raised to 90–100° C and the reaction mixture kept at this temperature for 3 hours. Removal of the volatile materials by distillation under reduced pressure (90° C/30 mm) left a residue of white crystals which were recrystallized from a mixture of benzene and light petroleum to give tribromoacetic acid as white plates (88 g), m.p. 127.5° C, unchanged by further recrystallization. Found: equiv. wt., 291. Calc. for $C_2HO_2Br_3$: equiv. wt., 297. A further quantity of pure acid was recovered from the mother liquors (5 g; total yield 88% theoretical).

Dibromoacetic Acid

(*a*) Fuming nitric acid (15 ml) was added cautiously to dibromoacetaldehyde hydrate (26 g) contained in a flask fitted with a reflux condenser and heated in a boiling-water bath. The heating was continued for 1 hour after the acid had been added. The products were fractionated under reduced pressure, and the fraction collected, b.p. 123–125° C/17 mm (20.4 g; 77% theoretical). Found: equiv. wt., 221. Calc. for $C_2H_2O_2Br_2$: equiv. wt., 218. The acid solidified on standing (m.p. about 36° C) and could be crystallized, with difficulty, from light petroleum. The crystals were very deliquescent and the acid was more conveniently purified by distillation.

(*b*) (Cf. ref. 6, which gives the preparation of dichloroacetic acid from chloral hydrate.) To a solution of bromal hydrate (45 g) in water (45 ml), warmed to 50° C, were added calcium carbonate (15.3 g) and a solution of sodium cyanide (1 g) in water (3 ml). The mixture was shaken and allowed to stand at room temperature until its temperature, which slowly rose to 74° C after the cyanide had been added, started to fall. Isopropanol (1–2 ml) was added to curb frothing and the mixture gently refluxed for 20–30 minutes, cooled, and extracted with ether. The ether extract was dried over magnesium sulphate, the ether evaporated, and the residue fractionated under reduced pressure to give dibromoacetic acid, b.p. 109–111° C/10 mm (24.9 g; 76% theoretical) as a colorless liquid which rapidly solidified. Found: equiv. wt., 222.

Substituted Ethanols

2,2,2-Trichloroethanol was prepared by reducing chloral with either aluminum isopropoxide (7) or lithium aluminum hydride (8); both reactants gave the pure alcohol, b.p. 148° C/705 mm, 73° C/35 mm, in about 65% yield.

Reduction of bromal in a similar manner with either aluminum isopropoxide or lithium aluminum hydride gave 2,2,2-tribromoethanol as colorless crystals, m.p., after recrystallization from water or a mixture of benzene and light petroleum, 78° C. Found: equiv. wt., 93.5. Calc. for $C_2H_3OBr_3$: equiv. wt., 94.3. The yields of pure alcohol were about 60% and 20% respectively.

Reduction of dibromoacetaldehyde with aluminum isopropoxide gave 2,2-dibromoethanol, b.p. 66–67° C/3 mm (57% theoretical). Found: equiv. wt., 101. Calc. for $C_2H_4OBr_2$: equiv. wt., 102.

Chlorodifluoroacetic Acid and Dichlorofluoroacetic Acid

These acids were obtained from L. Light and Co. Ltd., Poyle Trading Estate, Colnbrook, Bucks, England, and were redistilled before use. The chlorodifluoroacetic acid had b.p. 124–126° C and the dichlorofluoroacetic acid b.p. 156–158° C.

Barium Salts

The acids were generally irradiated as solutions of the barium salt so that the pH of the solutions would be comparable to those of the neutral halogen compounds. The salt solutions were prepared either from the pure crystalline salt or by making up a standard solution of the acid in the presence of an excess of pure barium carbonate, subsequently filtering off the excess carbonate, and drawing a current of moisture-saturated air through the solution to bring it into equilibrium with the atmosphere. The crystalline salts were prepared by adding an excess of pure barium carbonate to aqueous solutions of the pure (chloroacetic) acids, filtering off the excess carbonate, and allowing the neutral solutions partially to evaporate at room temperature; higher temperatures caused some decomposition. The crystals deposited were collected, washed with water, and dried over phosphorus pentoxide; the barium content was determined gravimetrically by precipitation with dilute sulphuric acid. Found: Ba, 30.3, 30.3. Calc. for $C_4O_4Cl_6Ba$: Ba, 29.7%. Found: Ba, 35.8, 35.6. Calc. for $C_4H_2O_4Cl_4Ba$: Ba, 34.95%. Found: Ba, 41.0, 41.0. Calc. for $C_4H_4O_4Cl_2Ba$: Ba, 42.35%. The yield of acid obtained on irradiation was the same by whichever method the salt solution was prepared.

The calcium salts of dibromo- and tribromo-acetic acids and of trichloroacetic acid, prepared by adding calcium carbonate to a standard solution of the acid, were also irradiated, with results in good agreement with those obtained using solutions of the barium salts.

Irradiations

Irradiations were carried out using Co^{60} sources of about 1 and 90 curies, respectively. Dose rates were measured using the ferrous sulphate dosimeter (9), assuming a G value of 15.5 for the formation of ferric ion.

As far as possible solutions were prepared immediately before use; the pH of the solutions was measured using a Beckman model M pH meter. Aliquots (3.0 ml) were irradiated at room temperature in stoppered glass test tubes, 13×100 mm, supported in lucite blocks arranged concentrically about the 90-curie source or else supported in a water bath surrounding the 1-curie source.

The acid formed on irradiation was determined as described earlier (3), by titration with either 0.1 N sodium hydroxide solution (bromophenol blue) or 0.01 N silver nitrate solution (eosin). Occasionally the bromophenol blue was partially bleached when added to solutions which had been irradiated for a long time, the color change making it difficult to decide when the irradiated solution being titrated matched the color of the blank. The difficulty could be partly overcome by allowing the irradiated solution to stand for 1 or 2 hours before being titrated, and may be caused by peroxides formed on irradiation; neither bromine nor chlorine have been detected in the irradiated solutions. It was noted previously (3) that solutions of bromal might be titrated up to 24 hours after irradiation without change in the titer. When potassium iodide was added to solutions of bromal which had been irradiated, a little iodine was liberated immediately and larger amounts

For personal use only.

were liberated on standing; the iodine was estimated by titration with 0.1 *N* sodium thiosulphate solution using a starch indicator. Iodine formed in solutions of iodoacetate by irradiation was estimated in the same way.

If the compound being irradiated was relatively stable to alkali, for example the substituted acetates, the acid formed could be titrated using an indicator changing color at a higher pH than bromophenol blue; bromocresol purple, bromothymol blue, and phenolphthalein were used to determine acid products that would not be neutralized at the bromophenol blue end point. However, difficulty was sometimes experienced in reaching a stable end point with these indicators, when it appeared that alkali-labile products were being slowly hydrolyzed by the alkali added; stable end points could be reached eventually by adding alkali as required, over a period of several minutes.

Fluoride was estimated by its action in bleaching a zirconium–alizarin red lake, measured with a photoelectric colorimeter (Megregian–Maier method) (10).

Solutions irradiated in the absence of air were treated before irradiation by passing a stream of either nitrogen or hydrogen through aliquots of the solution contained in irradiation tubes sealed with rubber serum-bottle caps. The gases were introduced into the tubes through a glass capillary which was pushed through the rubber cap, and escaped through a hypodermic needle inserted in the cap; a piece of adhesive tape effectively sealed the small holes left when the capillary and needle were removed. Traces of oxygen were removed from the nitrogen by passage through an alkaline solution of sodium hydrosulphite containing a catalytic amount of anthraquinone 2-sulphonate and from the hydrogen by passing it through a catalytic deoxidizer. Both gases were washed with water before being passed into the aliquots, which were purged for from 10 to 20 minutes; the shortest period of purging to ensure consistent results was about 5 minutes. An air-saturated solution of bromal gave the same yield of acid when irradiated in tubes sealed with glass stoppers or rubber serum-bottle caps.

Fluoral hydrate solutions were irradiated in both glass test tubes and in lusteroid tubes; the same acid yield was found in both cases.

The acid produced, in terms of microequivalents per liter, was plotted against the dose in kilorads and the slope of the straight line measured to give the acid yield in microequivalents per liter per kilorad. Each point on the graph was the average value of the acid produced for two or three duplicate irradiations; from 6 to 10 points were used to determine the slope of the line. Acid yields were found to be reproducible to $\pm 10\%$, or better, with different batches of material and for duplicate determinations at intervals of several months.

RESULTS

Acid yields in terms of microequivalents per liter per kilorad were multiplied by 0.945 to convert them to *G* values; the factor was derived in a similar manner to the factor used previously (3) to convert acid yields from microequivalents per liter per kiloroentgen to *G* values; it also includes a small correction for the difference in energy absorption of the ferrous sulphate dosimeter solution and the solutions of the halogen compounds. The errors introduced by using a single, average, value of the conversion factor for the solutions of slightly different density and electron density were estimated to be not more than 1% and may be discounted in view of the larger experimental uncertainty already present.

Acid Yield from Air-saturated Solutions

Table I gives the yield of acid from the compounds studied, determined by titration with sodium hydroxide solution, and, in parentheses, the yield of halide ion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The indicator used in the acid–base titrations, bromophenol blue, was such that strongly acid products, for example the halogen-substituted acetic acids, would be neutralized while weak acids, acetic acid and carbon dioxide, would not. When both acid yield and halide yield (other than fluoride) were determined for the same compound it was found that the acid yield was the larger for the substituted aldehydes and alcohols and the smaller for the substituted acids. The acid yield was greater than the halide yield by about 18% for air-saturated solutions of bromal hydrate (cf. ref. 11) and tribromoethanol and by about 25% for solutions of dibromoacetaldehyde, showing that besides hydrobromic acid appreciable quantities of other strongly acid products are formed from these compounds; these products are probably bromine-substituted acetic acids. It has been reported that the yield of acid from aqueous solutions of chloral hydrate is about 30% greater than the yield of chloride when they are irradiated with either Co^{60} gamma rays (12, 13) or Sr^{90} beta rays (13). No systematic attempt has been made to determine weakly acid products from our irradiations; a single determination of the acid formed from a solution of bromal hydrate (1020 rads/min) using both bromophenol blue and bromocresol purple as indicators gave a 17% greater yield with the latter indicator; carbon dioxide was removed from the solution before titrating. The yield of acid from the bromoacetates was from 30 to 50% lower than the yield of bromide, part of the organic acid originally present being converted to neutral products during the irradiation; carbon dioxide in the products was estimated approximately and was found sufficient to account for the loss of the acid groups by decarboxylation. Irradiated solutions of dibromoacetate and tribromoacetate, freed of carbon dioxide and titrated with alkali, gave the same titer when either bromophenol blue or phenolphthalein was used as indicator; thus weakly acid products were not formed and the bromoacetic acid originally present was not, in effect, neutralized by being converted to a much weaker acid. The negative G value shown for trifluoroacetate means that more acid was lost by decarboxylation than was formed by breakage of the carbon–fluorine bond.

Poor results were obtained when monobromoacetate was irradiated at low dose rates because of partial hydrolysis of the acid during the long periods of irradiation; at higher dose rates the irradiation times were shorter and the hydrolysis less important. Iodine liberated from monoiodoacetate appeared partly as iodide ion and partly as molecular iodine; the G values for each are given in Table I.

Hayon and Weiss (14) have irradiated monochloroacetic acid solutions with X-rays and report G_{Cl^-} values from 2 to 8 for air-saturated solutions (0.01 to 1 M) and 0.9 for deaerated solutions (0.1 M). They also report G_{Cl^-} 6 to 16 for deaerated solutions of trichloroacetic acid over the concentration range 10^{-2} to 1 molar (cf. Table III).

The concentration of the chloroform solution was limited to that of a saturated solution at the temperature of the experiment, i.e. 0.07 molar. However, both 0.07 molar and 0.1 molar solutions gave the same acid yield in the following instances: trichloroethanol, irradiated at 1020 and 17 rads/min, and chloral hydrate and trichloroacetate, irradiated at 1020 rads/min, and the G values for chloroform are directly comparable with the other values in Table I. Taplin (1) gives G_{acid} 25.5 and Teplý and Bednář (15) G_{Cl^-} 25.8 ± 1.3 for air-saturated chloroform solutions irradiated under conditions comparable to those for the values in Table I; the latter authors determined the acid produced in several ways and it appears that for chloroform the yield of acid and the yield of chloride are the same. Teplý and Bednář also give G_{CO_2} 8.4 for air-saturated chloroform solutions and G_{Cl^-} 6.3 for solutions from which the air had been displaced by nitrogen.

†A saturated aqueous solution of chloroform was used; 0.07 *M*.

a straight line was obtained whose slope was a measure of the yield of acid. If the irradiation was continued long enough a rather abrupt change in the slope of the line occurred, the slope after the break corresponding to a lower yield, or *G* value, than that found initially. The break has been correlated with the point at which oxygen originally present in the solution has been used up (2, 3), the rather abrupt nature of the change in slope showing that the concentration of oxygen is not important. After the break was reached the yield of acid was that from a solution deficient in oxygen; the break did not appear with irradiations in which the acid was formed very slowly, for example solutions of monochloroacetate irradiated at low dose rates, when sufficient oxygen could diffuse into the solution to meet the needs of the reaction. Apart from such cases the break was found with solutions of all of the halogen compounds studied.

Table II gives the acid yield from solutions of bromal hydrate both before and after the break corresponding to exhaustion of the oxygen present; the latter yields were variable, from experiment to experiment, since the rate at which oxygen diffused into the solutions was not controlled. For comparison acid yields are included for solutions from which the air had been displaced by nitrogen; these yields were lower than those for the oxygen-depleted solutions, though the difference became smaller as the dose rate was increased, increasing the rate of the radiolysis reactions but not the rate of oxygen diffusion. In Table III are given acid yields from solutions saturated with either air or nitrogen.

Acid yields obtained from nitrogen-saturated and hydrogen-saturated solutions are

compared in Table IV. In the presence of hydrogen the ratio of hydroxyl radicals to hydrogen atoms, formed initially in definite proportions by the action of the radiation upon the water, may be altered in favor of the hydrogen atoms by the reaction (16),

$$OH + H_2 \rightarrow H + H_2O. \qquad [1]$$

Hydrogen atoms and hydroxyl radicals would be expected to react differently with the halogen compounds and the absence of any marked difference between the yields for nitrogen- and hydrogen-saturated solutions suggests that at the low hydrogen concentrations used (about 10^{-3} M) the hydroxyl radicals react with the organic molecules in preference to hydrogen.

The ratio of the acid produced to the oxygen consumed could be estimated approximately from the position of the break in the graph, assuming that the solutions irradiated contained dissolved oxygen equal in amount to that in water under the same conditions of temperature and pressure; Table V gives some values estimated in this way. The values are the average for four or five experiments except for bromal hydrate when 30 values, distributed between the three dose-rate ranges shown, were available; the values were generally reproducible to within ± 0.5 unit, though they were not precise enough to show a consistent difference in a ratio when it was determined from the yield of acid and the yield of bromide separately. For bromal hydrate the ratio increased as the dose rate was increased; increasing the dose rate lowers the chain length of the chain-reaction forming acid and it may be inferred that less oxygen was consumed, relative to the amount of acid produced, in the chain-terminating steps than in the propagating steps. The values given in Table V show a tendency for less acid to be formed, relative to the oxygen used up, as the functional group was changed from $-CH(OH)_2$ (or H) to $-CH_2OH$ and —COOH. The ratio was also lowered when a bromine atom of bromal hydrate was replaced by hydrogen to give dibromoacetaldehyde. Teplý and Bednář (15) give a ratio for chloroform of 3.9–4.7 equivalents of hydrochloric acid formed per molecule of oxygen used up, estimated in the same way.

TABLE V

Ratio of the acid produced to the oxygen used up*

Compound	Acid groups estimated	Dose rate (rads/min)	Equivalents of acid gained / Molecules of oxygen used up
$Br_3C.CH(OH)_2$	HBr and total acid	9–18	3.0 ± 0.5
		160–450	3.6
		880–1460	4.0
$Cl_3C.CH(OH)_2$	Total acid	1020	4.1
Cl_3CH	Total acid	1020	4.2
$Br_3C.CH_2OH$	HBr and total acid	9–1020	3.6
$Cl_3C.CH_2OH$	Total acid	1020	3.1
$Br_3C.COOH$	HBr	1020	2.8
$Cl_3C.COOH$	Acid change	1020	2.3
$Br_2CH.CH(OH)_2$	HBr and total acid	390–1020	2.2

*Air-saturated 0.1 molar solutions, pH 3.5–5, $21 \pm 2°$ C. The acids were irradiated as 0.1 normal solutions of the barium salt.

Peroxides have been detected in irradiated solutions of the substituted acetates and of bromal hydrate; potassium iodide added to the latter solutions gave some iodine immediately and a greater amount on standing for several hours, the iodine formed immediately corresponded to hydrogen peroxide present in solution and that formed on standing to organic peroxides present. The concentration of hydrogen peroxide in the bromal solutions (dose rate 1020 rads/min) reached a low equilibrium value and then remained constant, but the concentration of organic peroxide increased in proportion to the dose of radiation received with a G value of about 12.

Effect of Dose Rate

The effect of changing the dose rate upon the yield of acid products has been examined by determining yields at two or three standard dose rates (cf. Tables I, II, and III). In the absence of oxygen, changes in dose rate had only a slight effect; a larger effect was observed in the presence of oxygen but only for those compounds which gave a high yield of acid products, indicative of a chain reaction, and then only at those dose rates at which the chain reaction was postulated. Dibromoacetaldehyde (Fig. 1) and tribromoethanol, for example, showed a dose rate dependency at dose rates in the region of 17 rads/min, but the acid yields were almost independent of dose rate between 450 and 1020 rads/min.

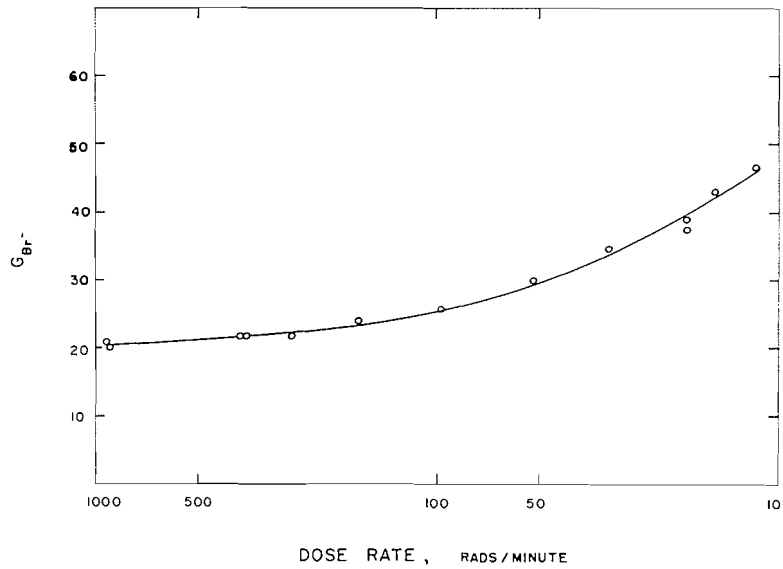

FIG. 1. Variation in G_{Br^-} with dose rate. Irradiation of 0.1 molar dibromoacetaldehyde hydrate solution, pH 4.2, 19° C.

Other work has shown that for dose rates in the range 1 to 60 rads/min G_{acid} for chloral hydrate (2) and bromal hydrate (3) was inversely proportional to the square root of the dose rate. The present work shows that this relationship is not obeyed closely at higher dose rates and it is possible that the yield of acid becomes independent of the dose rate as this is increased still further. The square root relationship was explained by postulating a chain reaction in which the termination step was the combination of two of the chain-propagating free radical intermediates to give a stable product; as the dose rate is increased the concentration of free radicals becomes greater and the chain length shorter. When the concentration of radicals becomes sufficiently high the chain length will approach unity and, unless the radicals interfere with the propagating steps, the acid yield will approach a constant value as the dose rate is increased. It is noteworthy that G_{acid} values for dibromoacetaldehyde and tribromoethanol, when they have reached the stage of being almost independent of dose rate, and some other dose rate independent G_{acid} values in Table I are greater than the sum of the probable G_H and G_{OH} values for water (about 5–6) and hence, if these inorganic radicals are responsible for the chemical changes occurring upon irradiation, each inorganic radical must be able to initiate reactions leading to the formation of several molecules of acid.

Action of Alkali on the Halogen Compounds

Most of the halogen compounds listed in Table I react readily with dilute aqueous alkali and these reactions were used as the basis for estimating the purity of several of the bromo-compounds (cf. ref. 3); a summary of the results is given in Table VI.

TABLE VI

Reaction of bromo-compounds with aqueous alkali*

Compound	Equiv. NaOH neutralized / Mole of compound	Estimated time for complete reaction
$Br_3C.CH(OH)_2$	1.0	Less than 1 minute
$Br_2CH.CH(OH)_2$	3.0	3–5 minutes
$BrCH_2.CH(OH)_2$	About 1.5	1–2 hours
$Br_3C.CH_2OH$	3.0	5 hours
$Br_2CH.CH_2OH$	2	5 hours
$BrCH_2.CH_2OH$	1	5–10 minutes
$Br_3C.COOH$	1.0	Neutralized immediately, about 3% hydrolysis and fission in 4 hours
$Br_2CH.COOH$	1.0	Neutralized immediately, about 1% hydrolysis in 18 hours
$BrCH_2.COOH$	2.0	Less than 1 minute

*Excess 0.1 *N* sodium hydroxide solution, titrated after reaction using phenolphthalein as indicator.

DISCUSSION

Effect of Structure on Acid Yield

Table I shows that for air-saturated solutions of the compounds studied the acid yield falls as (*i*) a halogen atom is replaced by hydrogen or by a more electronegative halogen, and (*ii*) as the functional group is changed from $-CH(OH)_2$ to $-CH_2OH$, to $-COO^-$. The acid yield from the one substituted hydrocarbon included, chloroform, is the same as that from the corresponding alcohol, trichloroethanol, in which the hydrogen is replaced by a hydroxymethyl group. Although acid yields may be changed by altering the dose rate, the relative position of the compounds if arranged in order of increasing acid yield is, in general, the same at any dose rate. Displacement of oxygen from the solutions by either nitrogen or hydrogen (Tables III and IV) lowers the acid yields but the relative position of the compounds is almost unchanged.

The carbon–halogen bond dissociation energy for the halogen-substituted methanes (Table VII) falls as the number of halogen substituents is increased and is lower for the less electronegative halogens. It is reasonable to assume that the carbon–halogen bond strength in the three groups of compounds studied, aldehydes, alcohols, and acid anions, will vary within each group in the same manner as in the substituted methanes as the number and nature of the substituting halogen atoms is changed. Thus, the greatest yields of acid are obtained on irradiation of the compounds which would be expected to have the lowest carbon–halogen bond dissociation energies, based upon the structure of the substituted methyl group present.

Chemical evidence leads to a similar conclusion; it is found that the compounds giving the greatest yield of acid on irradiation are those from which the halogen can be removed most readily by chemical reduction, and changes in halogen substitution which were found to lead to greater acid yields on irradiation also facilitate the removal of halogen by reduction. The effect of increasing halogen substitution, for example, upon the ease of reduction is shown by the action of zinc upon the chloroacetic acids (18); with this

For personal use only.

reagent the chlorine atoms in trichloroacetic acid may be replaced one at a time by hydrogen, but each succeeding replacement requires longer or more vigorous treatment. A similar stepwise reduction of trichloroacetic acid can be achieved electrochemically by using cathodes with increasing hydrogen overpotential or by using progressively greater cathode potentials (ref. 19, pp. 47, 91). This is well illustrated by the polarography of trichloroacetic acid (Table VIII). The acid shows two waves corresponding to the removal of first one, and then a second, chlorine atom; the second wave, at the more negative half-wave potential, being the same as that obtained with dichloroacetic acid. The final chlorine could not be reduced under the conditions used though all three bromine atoms could be removed from tribromoacetic acid, the increasing half-wave potential for each succeeding step showing that reduction is progressively more difficult. The table also shows that bromine may be removed from a bromoacetic acid more readily than chlorine from the analogous chloroacetic acid.

The postulate that substituents influence the acid yield on irradiation through their effect upon the strength of the carbon–halogen bond would require the acid yield to increase with the following changes in the functional group, $-COO^- < H < -CH_2OH < -CH(OH)_2 < -COOH$, in accordance with the increasing electron attraction shown by these groups, and similar to their effect on the ease of removal of halogen from a trichloromethyl group, as demonstrated by polarography (Table IX). In practice it was found that the carboxylate ion gave lower yields of acid than the alcohols and these, in turn, lower yields than the aldehydes. However, isolated irradiations of the free substituted acids have indicated that though these give higher yields than the anions they give lower yields than the alcohols and aldehydes, despite the predicted lower carbon–halogen bond strength in the acids. It seems clear that the functional group may affect the acid yield in other ways besides its indirect action upon the strength of the carbon–halogen bond. The explanation probably lies in the possibility of radical attack at either of the two carbon groups present; the susceptibility of the functional group to such attack and the nature

of the radical formed from it might then be more important than its indirect effect through the neighboring carbon group. The lower ratio of acid (or halide) produced to oxygen consumed as the functional group is changed from —$CH(OH)_2$ to —CH_2OH and —COO^- (Table V) suggests that more oxygen is used up through attack at the functional group with the latter compounds. The radicals formed from the acid groups, R.COO· and, by decarboxylation, R·, would also be expected to be less reactive than those formed from the alcohol and aldehyde, R.ĊHOH and R.Ċ$(OH)_2$.

Mechanism

The first step in the interaction of ionizing radiation and a dilute aqueous solution is the absorption of the radiation by the water to give both molecular and free radical products. For Co^{60} gamma irradiation the molecular products, hydrogen and hydrogen peroxide, are formed with G values of about 0.4 and 0.8 respectively (26); they are unreactive, compared to the free radical products, and the low concentrations produced are not likely to react directly with the organic solutes used here. The radical products are formed with higher G values, about 2.7 and 2.0 for hydrogen atoms and hydroxyl radicals respectively (26; neutral solutions), and are believed to be responsible for most of the chemical action observed.

For convenience the initial reactions between the primary radicals and the solute may be divided into attack at either the substituted methyl group or the functional group. Attack at the substituted methyl group might be as follows;

$$X_2HC.R' + H \rightarrow HX + XH\dot{C}.R' \quad [2]$$

$$+ OH \rightarrow HOX + XH\dot{C}.R' \quad [3]$$

$$+ OH \rightarrow H_2O + X_2\dot{C}.R' \quad [4]$$

$$+ H \rightarrow H_2 + X_2\dot{C}.R' \quad [5]$$

where X is a halogen atom and R′ either —CH_2OH, —$CH(OH)_2$, or —COO^-. A disubstituted halogen compound is shown for the purposes of illustration; this could equally be a mono- or tri-substituted group, though in the latter case reactions involving hydrogen abstraction, reactions [4] and [5], would not be possible.

Breaking of the carbon–halogen bond during the initial reactions is supported by the relationship between the strength of this bond and the yield of halide on irradiation, particularly in those cases where a chain reaction is not postulated. The removal of halogen by hydrogen atoms (reaction [2]) is analogous to the reduction of halogen compounds at a cathode and during polarography, for which hydrogen atoms have been suggested as the active intermediates (cf. ref. 19, p. 47, and ref. 27). Removal of the halogen by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

hydroxyl radicals (reaction [3]) is less likely and it has been shown (15) that carbon tetrachloride does not react with chemically produced hydroxyl radicals though chloroform does, presumably by hydrogen abstraction (reaction [4]). Polarographic data (Table VIII) suggest that hydrogen atoms are more likely to abstract halogen (reaction [2]) than hydrogen (reaction [5]) unless the halogen is firmly bound.

The primary inorganic radicals will also react with the functional groups present, the most probable reaction being hydrogen abstraction by the hydroxyl radicals. Most of the hydrogen atoms would be expected to react with the halogen-substituted group; polarography of the halogen-substituted aldehydes (28) shows that the halogen group is reduced in preference to the aldehyde group, both acids and alcohols are reduced less readily than the aldehydes. Hydrogen abstraction from an alcohol and an aldehyde hydrate would give the radicals $R.\dot{C}HOH$ and $R.\dot{C}(OH)_2$ respectively and electron transfer between an anion and a hydroxyl radical the carboxylate radical, $R.COO\cdot$.

The subsequent reactions of the organic radicals are uncertain. If oxygen is not present they may combine in pairs to give stable products or react with the solute, though the yields of acid products are relatively low and the extent of the reaction must be limited. The products obtained by irradiating solutions of the substituted acetic acids appear to be similar to those formed by anodic oxidation, in which carboxylate radicals are believed to be intermediates (ref. 19, p. 97, and refs. 29, 30). For example the products formed by irradiating an aqueous solution of monochloroacetic acid in the absence of air include carbon dioxide, carbon monoxide, formaldehyde, and hydrochloric acid (14), all of which are formed at the anode when the solution is electrolyzed (31, 32); in addition glyoxylic acid was identified among the radiolysis products and small amounts of chlorine, methylene chloride, and chloromethyl chloroacetate among the electrolysis products.

Oxygen markedly increases the yields of acid obtained on irradiation and is believed to add to the organic radicals, $R'\cdot$, to give relatively unreactive peroxy radicals, $R'O_2\cdot$, which may be unstable and break down to give a mixture of products or be converted to a more reactive alkoxy-type radical, $R'O\cdot$. The radical $R'O\cdot$ may itself be unstable and break down to give a mixture of products. The higher acid yields in the presence of oxygen can arise from the breakdown of oxygenated radicals and products to give acid materials or from the formation of reactive radicals which are able to sustain a chain reaction. The active radicals might be of the type $R'O\cdot$ or be inorganic radicals formed by the breakdown of unstable organic radicals.

Some evidence for the formation and subsequent breakdown of peroxy radicals during radiolysis arises from the formation of free fluoride from the fluorine-substituted acetates. Very little fluoride is formed from trifluoroacetate, even in the presence of oxygen (Table I), showing that the carbon–fluorine bond is not readily broken under the conditions of the irradiations. Chlorodifluoroacetate gives a greater yield of both fluoride and acid on irradiation (Table I); the yield of fluoride falls when the oxygen is absent (Table III). The carbon–fluorine bond can be broken chemically by substituting a hydroxyl group onto the carbon carrying the fluorine, when hydrolysis of the fluorine takes place in the presence of water, or by forming a free radical with the free electron on the fluorine-substituted carbon atom and allowing this to add oxygen to form a peroxy radical which will break down in the presence of water to give the fluorine as hydrogen fluoride (33). The chlorine present in chlorodifluoroacetate offers a point of attack not present in trifluoroacetate, and loss of the chlorine gives a radical which may react with either a hydroxyl radical or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

oxygen and subsequently break down, i.e.,

$$\cdot CF_2.COO^- + OH \xrightarrow{H_2O} HOOC.COO^- + 2HF \quad [6]$$

or

$$\cdot CF_2.COO^- \xrightarrow{O_2,\ H_2O} HOOC.COO^-,\ 2HF. \quad [7]$$

The lower yield of fluoride in the absence of oxygen suggests that the changes represented by reaction [7] occur.

Iodoacetate gives a lower yield of acid (measured by $G_{I^-} + G_{I_2}$) than either monobromoacetate or monochloroacetate, though a higher yield might be expected in view of its weaker carbon–halogen bond. The concurrent formation of molecular iodine from the iodoacetate suggests that some of the initiating radicals (H and OH) are converted to less reactive iodine atoms by reaction with iodide ions or molecular iodine and so prevented from reacting with the iodoacetate. An equimolar amount of potassium iodide added to a bromal hydrate solution before irradiation prevented the formation of any acid products but gave molecular iodine with a G value of about 10. This is higher than the value for solutions of iodide alone (G_{I_2} about 1.7) and suggests that some organic radicals are formed and converted to peroxides before reaction with iodide or iodine occurs to terminate the reaction. Bromide and chloride are without effect since the chain reactions involved in the radiolysis of bromal and chloral hydrates are not hindered by the increasing concentrations of bromide and chloride ions respectively as the irradiations progress.

Organic Halogen Compounds in Dosimetry

The liberation of acid from organic halogen compounds upon irradiation has been used as the basis for methods of detecting and measuring ionizing radiation (1). The compounds most generally studied have been chloroform and tetrachloroethylene, usually in the form of the pure organic liquid overlayered with water. If a pH indicator dye is added to the aqueous layer the acid formed may be estimated visually or by means of a photoelectric colorimeter, or it may be estimated by any of the standard methods for determining strong acids. However, before the water-soluble acid can be estimated in the aqueous layer it is necessary to hydrolyze acid-precursors, generally acid chlorides, dissolved in the organic phase and extract the acid formed into the aqueous layer, a procedure that may require shaking or stirring for periods ranging from minutes to hours (cf. ref. 34). By using carefully purified materials the two-phase systems can be made sensitive to small doses of radiation of the order of 1.0 to 10 rads. The integral dose that such a system can measure is limited by the amount of oxygen present, and once this has been used up by the radiolysis reactions the yield of acid falls to a small value. Larger doses of radiation can be measured by adding small quantities of inhibitors, generally aliphatic or aromatic hydroxy compounds, which lower the amount of acid formed, and of oxygen used up, for a given dose of radiation received by the system. Exhaustion of the oxygen present still imposes an upper limit to the dose that can be measured unless steps are taken to introduce fresh oxygen while the irradiation is in progress.

The two-phase systems suffer from the disadvantage of being rather dependent upon the energy of the incident radiation. This may be largely overcome by using dilute aqueous solutions of organic halogen compounds, for example, chloral hydrate (12). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

greatest yields of acid have been obtained from aqueous solutions of chloral hydrate, bromal hydrate, and tribromoethanol; the yields shown in Table I may be increased by using more concentrated solutions (cf. refs. 3, 12) but they are generally lower than the yields from the two-phase systems. These solutions, in common with the two-phase systems, are broken down by chain reactions initiated by the radiation. The reactions are very susceptible to traces of impurities and the chain length, and hence the yield of acid is dependent on the dose rate and the temperature. These features associated with the chain reaction are undesirable in chemical dosimetry, though almost impossible to avoid, since the chain reaction itself is essential if small doses of radiation are to lead to the relatively large quantities of product that are required for a convenient determination. Among the water-soluble compounds, traces of impurity have proved particularly troublesome with bromal hydrate; chloral hydrate and tribromoethanol are available commercially for drug use and little difficulty would be expected, or has been experienced, in obtaining reproducible results with them.

If the greatest sensitivity is not required, it is possible to choose a system for which the acid yield is independent of dose rate; chloroform, in aqueous solution, is undoubtedly the first choice on the grounds of availability, ease of purification, and ease of preparation of the solution, though the acid yield is low compared to that from chloral or bromal hydrates, or the two-phase systems. Aqueous solutions have the advantage that any acid-precursors formed are hydrolyzed immediately and the acid products can be titrated to a sharp end point as soon as the irradiation is finished. In addition, chloroform has the advantage over the two-carbon compounds listed in Table I that only one acid product is formed, thus avoiding confusion that might arise between the yield of halide and the total yield of acid.

Acid formed from the non-polar compounds when they are irradiated in aqueous solution can be determined conveniently from the electrical conductivity of the solution (12, 15). By this means the acid formed can be measured continuously, at a distance, while an irradiation is in progress and the integral dose confirmed after the irradiation by titrating the acid formed.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the Atomic Energy Control Board for continued financial support and to Mr. E. C. Bailey for the fluoride analyses.

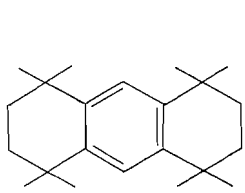
CYCLIALKYLATIONS OF ALKYL BENZENES WITH OLEFINS AND ALKYL HALIDES[1]

L. Ross C. Barclay, J. W. Hilchie, A. H. Gray, and (in part) N. D. Hall

ABSTRACT

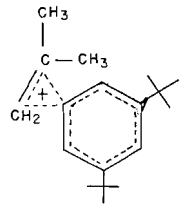
A revised mechanism is given for the formation of octamethyloctahydroanthracene from 1,3,5-tri-*t*-butylbenzene and *t*-butyl chloride. 1,3,5-Tri-*t*-butylbenzene reacts with isopropyl chloride to yield an octamethylhydrindacene which also forms when 1,3,5-triisopropylbenzene is cyclialkylated with isobutene. 1,3,5-Triisopropylbenzene is cyclialkylated with 2-methyl-2-butene to yield a decamethylhydrindacene. Treatment of 1,3,5-triisopropylbenzene with 2-chloro-2,4,4-trimethylpentane yields a hydrocarbon, $C_{23}H_{38}$, most probably 1,1,3-trimethyl-5,6-diisopropyl-3-neopentylindan. Structures assigned to the cyclialkylation products are based on ultraviolet, infrared, and mass spectroscopic data, and in some instances classical syntheses. Mechanisms are suggested to account for these reactions.

INTRODUCTION



In this paper, a revision is presented for a mechanism to account for cyclialkylation of 1,3,5-tri-*t*-butylbenzene with *t*-butyl chloride to form octamethyloctahydroanthracene (I). In addition, similar cyclialkylations are applied to some other systems. For example, treatment of 1,3,5-tri-*t*-butylbenzene with isopropyl chloride under Friedel–Crafts conditions yielded an octamethylhydrindacene (III). 1,3,5-Triisopropylbenzene reacted with isobutene in the presence of isopropyl chloride also to produce III. Under similar conditions, triisopropylbenzene and 2-methyl-2-butene yielded a decamethylhydrindacene (IV). Treatment of triisopropylbenzene with 2-chloro-2,4,4-trimethylpentane yielded another new compound, $C_{23}H_{38}$, which also was formed by cyclialkylation of triisopropylbenzene with 2,4,4-trimethyl-1-pentene in the presence of isopropyl chloride. The compound $C_{23}H_{38}$ apparently is 1,1,3-trimethyl-5,6-diisopropyl-3-neopentylindan (V). The structures given to the cyclialkylation products are based on ultraviolet, infrared, and mass spectroscopic data, and in some instances on classical syntheses. Mechanisms are suggested to account for the cyclialkylations.

DISCUSSION



In an earlier publication (1), a mechanism was proposed for the formation of 1,1,4,4,-5,5,8,8-octahydroanthracene (I) from 1,4-di-*t*- or 1,3,5-tri-*t*-butylbenzene and *t*-butyl chloride involving the formation of a primary tri-*t*-butylbenzene carbonium ion and cyclialkylation with isobutene. Condon (2) proposed an alternative mechanism for the formation of I. His mechanism requires that this cyclialkylation takes place through the 2,4,4-trimethylpentyl carbonium ion which apparently rearranges through a protonated cyclopropyl carbonium ion to the dimethylhexyl carbonium ion. It has been demonstrated by Barclay and Hilchie (3) that this dimethylhexyl system can displace *t*-butyl groups from 1,4-di-*t*-butylbenzene to produce I. However, a more adequate test of Condon's mechanism would be to carry out alkylations of aromatics with 2-chloro-2,4,4-trimethylpentane to find if the initial 2,4,4-trimethylpentyl ion rearranges to the required 2,5-dimethylhexyl system under conditions favorable for the formation of I. According to Condon's mechanism, it would be expected that I should form from benzene or the *t*-butylated benzenes and 2-chloro-2,4,4-trimethylpentane in at least as good a yield as reported (4) for the preparation of I from the *t*-butylated benzenes and *t*-butyl

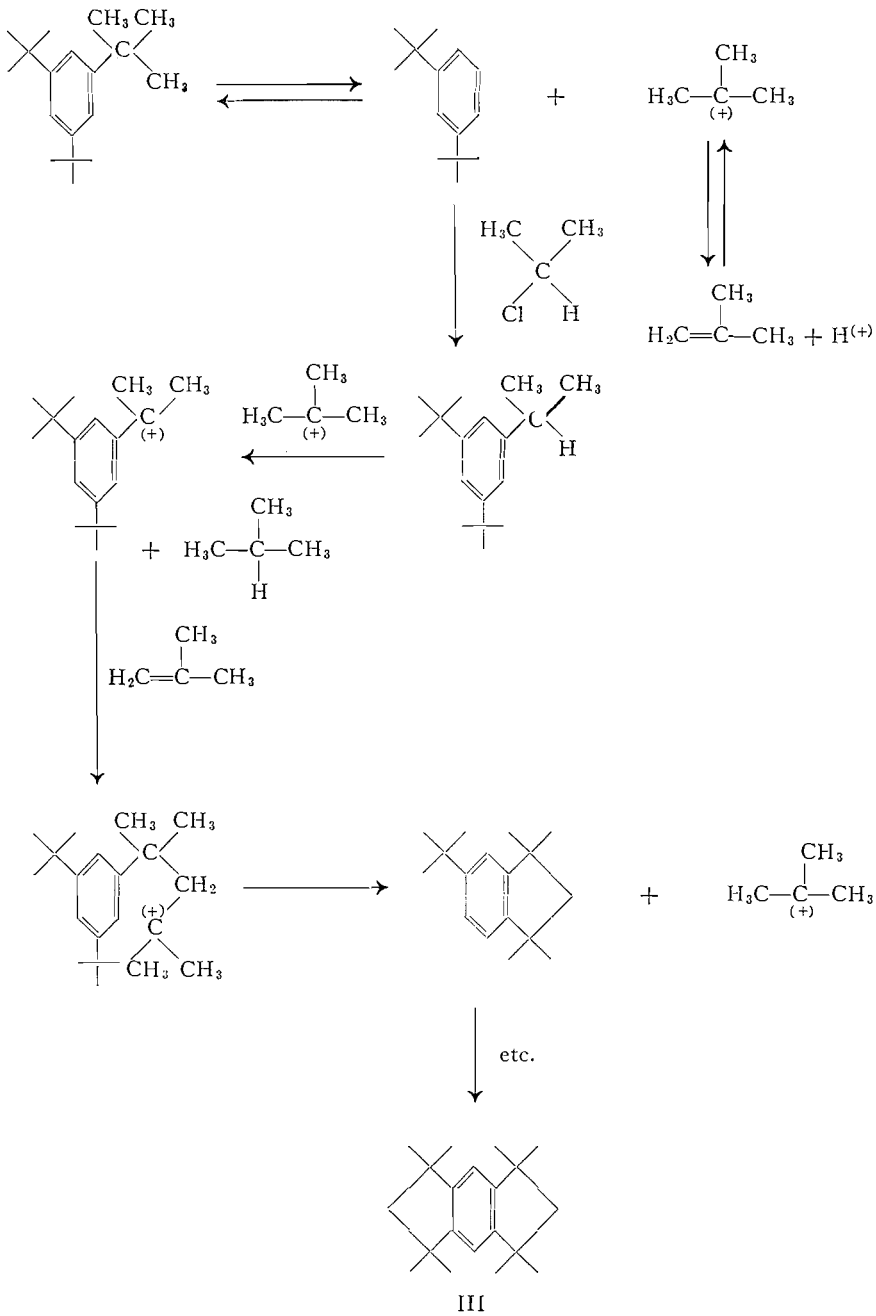
[1]*Manuscript received September 8, 1959.*
Contribution from the Department of Chemistry, Mount Allison University, Sackville, New Brunswick.

chloride. Benzene and 1,4-di-*t*-butylbenzene were therefore treated with 2-chloro-2,4,4-trimethylpentane under a variety of conditions which might be expected to cause cyclialkylation. However, no cyclialkylation products such as I could be detected in the reaction products. These negative results cannot be entirely conclusive but it does appear unlikely that this cyclialkylation proceeds via the 2,4,4-trimethylpentyl ion. The only objection to the initial mechanism proposed by Barclay and Betts (1) is that it involves a high energy primary carbonium ion. However, this neophyl ion could have a more stable bridged structure (II) where the neighboring phenyl group participates in the displacement of the hydride ion from a primary carbon.

(I)

(II)

Similar cyclic bridged phenonium ions have been postulated by Cram (5) for a variety of reactions and by Schmerling and co-workers (6) to explain aluminum-chloride-catalyzed isomerizations of alkyl benzenes. Recently, Douglas and Roberts (7) postulated removal of a hydride ion from the β-carbon of propyl benzene with "anchimeric assistance from the phenyl group" to produce a phenonium ion intermediate analogous to II. In our reactions the ion II would be expected to react with isobutene at the unsubstituted CH_2 group rather than at the more hindered branched position of II and therefore I is the octamethyloctahydroanthracene which forms.



In an effort to extend these cyclialkylations to other systems, 1,3,5-tri-*t*-butylbenzene was treated with isopropyl chloride under Friedel–Crafts conditions. A compound of parent mass 270 was isolated corresponding to $C_{20}H_{30}$. This compound was dehydrogenated to yield an anthracene derivative, indicating that $C_{20}H_{30}$ is tricyclic. The infrared spectrum showed bands attributed to *t*-butyl groups and a band of 11.35 microns attributed to 1,2,4,5-tetrasubstitution. From this evidence it was proposed that this compound is 1,1,3,3,5,5,7,7-octamethylhydrindacene (III). The structure suggested for $C_{20}H_{30}$ was confirmed by a classical synthesis by the alkylation of 1,1,3,3-tetramethylindan with 2,4-dimethyl-2,4-pentanediol.

A general mechanism to account for the formation of III from 1,3,5-tri-*t*-butylbenzene and isopropyl chloride is outlined on page 96.

It is proposed that isopropyl groups replace *t*-butyl groups by a dealkylation–alkylation reaction. Then a hydride ion transfer from an isopropyl group to a *t*-butyl carbonium ion sets up a carbonium ion on a side chain which is alkylated with isobutene. The resulting cation will then cyclize with the elimination of an ortho *t*-butyl group. The remaining *t*-butyl group is replaced by isopropyl which in turn is cyclialkylated so that III is the final product. This interpretation is supported by the fact that 1,3,5-triisopropylbenzene is cyclialkylated with isobutene in the presence of isopropyl chloride (as a hydride ion acceptor) to give a good yield of III.

The mechanism for the formation of III might also be described by the condensation of isobutene and an isopropyl cation to form the 2,4-dimethylpentyl carbon skeleton.

III

The latter could possibly replace isopropyl or *t*-butyl groups and form III. However, attempts to prepare III in this way by the alkylation of 1,4-di-*t*-butylbenzene with 2-chloro-2,4-dimethylpentane failed. It is therefore unlikely that the reaction proceeds by this alternative mechanism.

The formation of polymethylhydrindacenes was extended to another system by cyclialkylating 1,3,5-triisopropylbenzene with 2-methyl-2-butene in the presence of isopropyl chloride. In this case a high melting (245–245.6°) hydrocarbon ($C_{22}H_{34}$) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

obtained with an ultraviolet spectrum practically identical with that of III. The infrared spectra of these hydrocarbons were also very similar. Both had bands at 7.75, 8.10, and near 8.5 microns attributed to *t*-butyl groups. The main difference was due to bands appearing in the spectrum of the higher melting sample at 8.9 microns and in the 9.4- to 10-micron region which were absent in III. Both compounds had a strong band at 11.35 microns attributed to 1,2,4,5-tetrasubstitution. Therefore, the higher melting compound most probably has the decamethylhydrindacene structure IV and would form from 1,3,5-triisopropylbenzene as follows.

IV

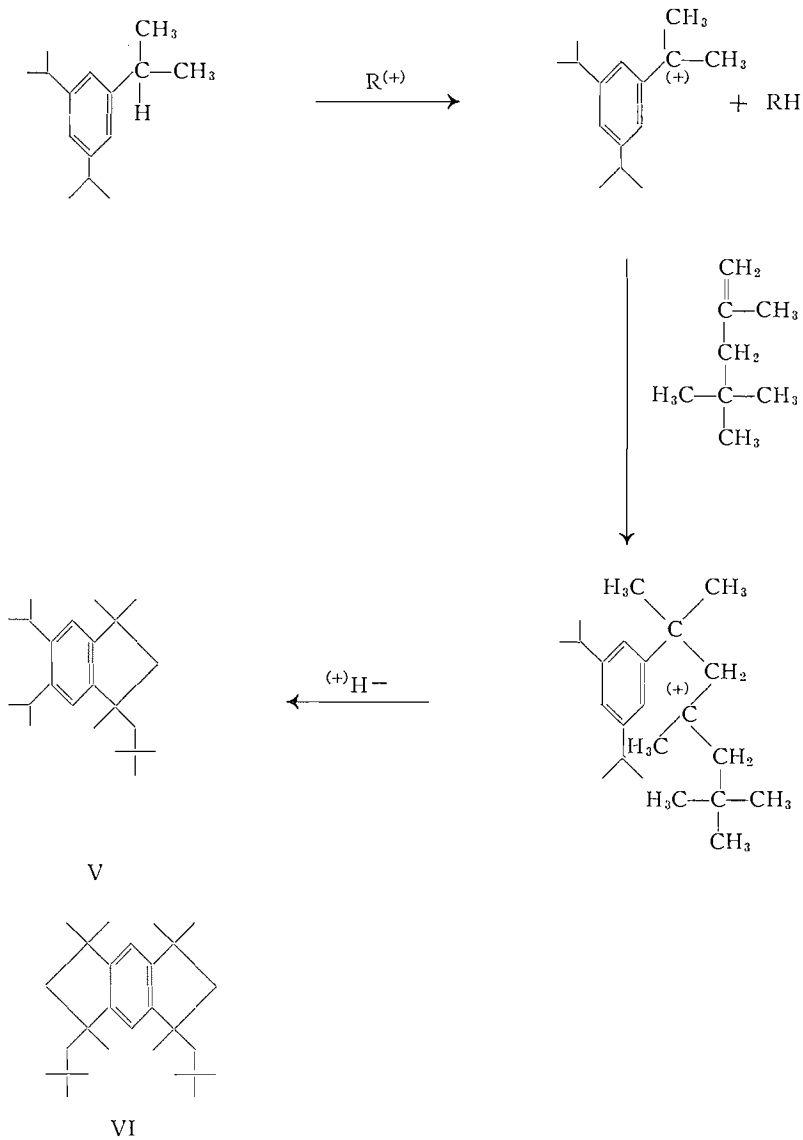
The cyclialkylations outlined above have some similarity to the reaction discovered by Ipatieff, Pines, and Olberg (8) for the formation of 1,3,3,6-tetramethyl-1-*p*-tolylindan

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

from *p*-cymene and a number of different olefins in the presence of sulphuric acid or hydrogen fluoride. Schlatter also reported similar reactions in the formation of 1,1,3,3,5-pentamethylindan by the *t*-butylation of *p*-cymene (9) and of the side product 1,1,3,3,-5,6-hexamethylindan from the alkylation of 1,2-dimethyl-4-*t*-butylbenzene (10). All of these cyclialkylations illustrate how highly branched, condensed ring systems can be produced in essentially a one-step process from relatively simple starting materials. The so-called classical syntheses of these hydrocarbons on the other hand often involve many steps which often proceed in poor yields. That these processes must have practical significance is evident in some recent patents (11, 12, 13) on the production of polyalkyl indans from styrene compounds. Many of these branched hydrocarbons are of practical importance to the perfume industry and the petroleum industry.

Although 2-chloro-2,4,4-trimethylpentane failed to cyclialkylate benzene or 1,4-di-*t*-butylbenzene, it reacted with 1,3,5-triisopropylbenzene to give an interesting unexpected result. A crystalline product was isolated from which two compounds were separated. The main component was a compound of m.p. 101–102° (V). A small amount of another compound, m.p. 203–205° (VI), was also separated.

The mass spectrum analysis of V showed that it consists mainly of a compound of mass 314. There was also a large peak at mass 243 which corresponds to a loss of C_5H_{11} from the compound of mass 314. The infrared spectrum of V showed bands attributed to isopropyl groups and to tetrasubstitution. Dehydrogenation of this compound in a sealed tube at a high temperature yielded a product whose ultraviolet spectrum indicated the presence of a substituted naphthalene.



Although VI was not available in sufficient amount for a complete analysis, the mass spectrum indicated a parent mass of 383 and a peak at mass 311 corresponded to the loss of a C_5H_{11} group from a compound of mass 383. The ultraviolet spectrum of VI was practically identical with that of octamethylhydrindacene indicating that VI is most probably a similar polyalkyl hydrindacene.

The structures shown on page 99 for V and VI seem logical to explain the analyses discussed above. Reaction mechanisms are illustrated to account for the formation of these compounds.

In the reactions outlined on page 99 the olefin involved in the cyclialkylation is 2,4,4-trimethyl-1-pentene since only this isomer would lead to structures V and VI which lose a neopentyl fragment during the mass spectroscopic analysis. This olefin is not the expected one according to the classical Saytzeff rule by which the proton is expected to be eliminated from the CH_2 group to form 2,4,4-trimethyl-2-pentene. However, Whitmore and Rohrmann (14) have found that the corresponding alcohol, dimethyl-neopentylcarbinol, dehydrates to yield 2,4,4-trimethyl-1-pentene. In both cases the neopentyl group does not take part in the elimination. Both of these "unusual" eliminations can be explained if one assumes that the factor governing the course of elimination here is inhibition of close approach of a proton acceptor to the hindered CH_2 group.

The 1,2,4,5-formulation for V makes it possible to offer an explanation of why this dicyclic compound forms in better yields than the tricyclic compound, VI. Usually in these cyclialkylation experiments the tricyclic compound forms very readily and it is difficult to isolate dicyclic compounds analogous to V. However, further cyclialkylation of V in this case would not readily take place because the bulky olefin (trimethyl-1-pentene) would be hindered from alkylating an isopropyl group by an adjacent isopropyl group. The 1,2,4,5-orientation for V is also favored by its ultraviolet spectrum which is very similar to the spectrum of 1,2,4,5-tetraisopropylbenzene. The latter showed bands

V

VI

at λ_{max} 2770 Å, ϵ = 649 and λ_{max} 2682 Å, ϵ = 586, while V had bands at λ_{max} 2760 Å, ϵ = 749 and λ_{max} 2677 Å, ϵ = 690.

As a check for the structure suggested for V and the mechanism involving the postulated olefin 2,4,4-trimethyl-1-pentene, experiments were carried out on the alkylation of 1,3,5-triisopropylbenzene with this olefin in the presence of isopropyl chloride. This reaction did produce a compound identical with V and in high yield.

EXPERIMENTAL

The melting points were obtained with a Fisher–Johns apparatus equipped with a microscope, and are uncorrected. Ultraviolet spectra were recorded on a Beckman DK-2 ratio recording spectrophotometer using spectro-grade cyclohexane as the solvent.

The infrared spectra were recorded on a Perkin–Elmer Model 137 instrument using purified carbon disulphide as the solvent. Some of the infrared spectra were determined by an independent laboratory. The mass spectroscopic measurements were made in another laboratory on a special high temperature inlet mass spectrometer. The ultimate analyses were determined by the Schwarzkopf Microanalytical Laboratory, New York.

In all of the cyclialkylation experiments the progress of the reactions was followed by means of the recording ultraviolet spectrophotometer. Aliquots were taken from the reaction mixtures at short time intervals, the aluminum chloride complexes decomposed in water, and spectra were recorded immediately. In this way the course of the reaction was followed with a time lag of not more than a few minutes. Significant changes, such as changes in positions of alkyl groups on the benzene ring, the formation of di- or tricyclic products, and in some instances the introduction of a conjugated double bond were quite easily detected. Thus the reaction could be terminated at an appropriate time to permit isolation of the desired products or intermediates.

The Reaction of 1,3,5-Tri-t-butylbenzene with Isopropyl Chloride

Isopropyl chloride was prepared almost quantitatively by heating isopropyl alcohol with an equal volume of a saturated solution of zinc chloride in concentrated hydrochloric acid while passing through hydrogen chloride. The product was distilled off the top of a reflux condenser on formation.

1,3,5-Tri-*t*-butylbenzene, prepared as described by Barclay and Betts (4), (6.6 g, 0.027 mole) and isopropyl chloride (5.8 g, 0.074 mole) were stirred together and cooled to below 0°. Nine grams of aluminum chloride (0.067 mole) was added in small portions over a period of 2 hours. After 7 hours reaction time, the brown complex which formed was decomposed in cold water. A white solid (4.6 g) was formed which was filtered and recrystallized from ethanol–benzene. After five recrystallizations the melting point was 220–222.5°. Calc. for $C_{20}H_{30}$: C, 88.84; H, 11.16; molecular weight, 270. Found: C, 88.53, 88.64, 88.61, 88.96; H, 11.04, 11.10, 10.78, 11.04.

This compound showed a peak in the mass spectrometer corresponding to a parent mass of 270. There was also a large peak at 255 attributed to the loss of a methyl fragment.

The infrared spectrum of this compound, both in carbon disulphide solution and in potassium bromide pellets, showed a series of bands in the 1200- to 1500-cm^{-1} region attributed to *t*-butyl groups. In the ultraviolet spectrum there were bands at λ_{max} 2810 Å, ϵ = 4725; λ_{max} 2760 Å, ϵ = 4243; λ_{max} 2715 Å, ϵ = 3760; and λ_{max} 2670 Å, ϵ = 2700.

This compound was dehydrogenated by heating 1 g of it with 2 g of selenium powder in a sealed tube for 40 hours at 400°. The product fluoresced under an ultraviolet light. The ultraviolet spectrum indicated that it is a substituted anthracene.

A solution of 0.55 g of this hydrocarbon in a mixture of 25 ml of glacial acetic acid and 15 ml of acetic anhydride was treated with 1 ml of fuming nitric acid and heated at 70° for 3 hours. Distillation of the solvent mixture left a crude nitro derivative which was contaminated with some unreacted hydrocarbon. Repeated recrystallizations from acetone yielded colorless crystals, m.p. 275–277°.

Cyclialkylation of 1,3,5-Triisopropylbenzene with Isobutene

Isobutene was generated by dropping 85% phosphoric acid on warm *t*-butyl alcohol. The gas thus produced was passed through an ice trap, a bubbler containing 85% phosphoric acid, and a calcium chloride tube. This was then bubbled into the reaction mixture which contained 12.5 g of 1,3,5-triisopropylbenzene, prepared as described by

Gustavson (15), 9.6 g of isopropyl chloride (0.122 mole) as a hydrogen acceptor, and 16.3 g of aluminum chloride (0.122 mole). The reaction was cooled to below 0° in an ice–salt bath and the gas was allowed to pass through for 5½ hours. The reaction was decomposed on water and allowed to stand overnight. The organic material was extracted with ether. The ether was distilled off and the residue recrystallized from ethanol–benzene. A solid was obtained which weighed 9.8 g (59% yield). After five recrystallizations the melting point was 218–220°. The melting point was not lowered when the product was mixed with the product of alkylation of 1,3,5-tri-*t*-butylbenzene with isopropyl chloride.

Synthesis of 1,1,3,3,5,5,7,7-Octamethylhydrindacene (II)

1,1,3,3-Tetramethylindane was prepared, as described by Bogert and Davidson (16), starting with diacetone alcohol and benzene. Diacetone alcohol was prepared as described in ref. 17. 2,4-Dimethyl-2,4-pentanediol was prepared as described by Franke and Kohn (18) from diacetone alcohol and methyl magnesium iodide.

The indane (1.24 g, 0.007 mole) and the diol (0.94 g, 0.007 mole) were dissolved in 4 ml of carbon disulphide. Aluminum chloride (0.95 g, 0.007 mole) was added in small portions over a period of ½ hour. A complex began to form almost immediately after the addition of aluminum chloride. The mixture was stirred for 15 minutes, and then another 0.95 g of aluminum chloride was added slowly. The reaction was allowed to proceed for a total of 4 hours. It was then poured into water and the organic material was extracted with ether. On concentration of the ether, 1.75 g (88% yield) of crude crystals was obtained. These crystals were purified by recrystallization from ethanol–benzene three times to yield a material of m.p. 218.5–220°.

The melting point of the synthetic hydrindacene did not lower when mixed with the product of the cyclialkylation reactions described in previous sections. The ultraviolet absorption spectrum of the synthetic compound, II, was identical with the spectrum of the cyclialkylation product. The X-ray diffraction patterns of the synthetic product and the cyclialkylation product were also identical.

Cyclialkylation of 1,3,5-Triisopropylbenzene with 2-Methyl-2-butene

Isopropyl chloride (5.0 g, 0.05 mole) was cooled to −5° in a three-neck flask. Then aluminum chloride (3.33 g, 0.025 mole), and a mixture of 2-methyl-2-butene (4.0 g, 0.05 mole) and 1,3,5-triisopropylbenzene (5.0 g, 0.025 mole), were added slowly to the cooled reaction mixture. At the end of 4 hours, the reaction mixture was decomposed in cold water and allowed to stand overnight. The semisolid hydrocarbon layer was filtered to yield 4 g of crude product. Four recrystallizations from ethanol–benzene produced colorless crystals, m.p. 245–245.6°. Calc. for $C_{22}H_{34}$: C, 88.51; H, 11.49. Found: C, 88.10, 87.96; H, 11.08, 11.24. In the mass spectroscope, this compound showed a parent mass of 298 corresponding to $C_{22}H_{34}$.

The ultraviolet spectrum of this material had bands at λ_{max} 2800 Å, $\epsilon = 4760$; λ_{max} 2747 Å, $\epsilon = 4170$; λ_{max} 2705 Å, $\epsilon = 3680$; λ_{max} 2660, $\epsilon = 2680$.

The Reaction of 1,3,5-Triisopropylbenzene with 2-Chloro-2,4,4-trimethylpentane

1,3,5-Triisopropylbenzene (5.2 g, 0.025 mole) and 2-chloro-2,4,4-trimethylpentane (7.5 g, 0.050 mole) were placed in a three-neck flask and cooled to below 0° in an ice–salt bath. Aluminum chloride (6.7 g, 0.050 mole) was added in small portions with stirring over a period of 1½ hours. After 8 hours reaction time, the reaction mixture was poured into water and allowed to stand overnight. The solid material which separated was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

filtered and recrystallized from benzene–ethanol. Forty milligrams of a compound with a melting point of 203–205° separated out in the first crop of crystals. The melting point of this compound was lowered when mixed with octamethyloctahydroanthracene (I) or when mixed with octamethylhydrindacene (III). The ultraviolet spectrum of the compound of m.p. 203–205° showed maxima at the same wavelengths as observed for III. In the mass spectrometer this compound showed a parent mass of 383 with a peak at mass 311 corresponding to the loss of a C_5H_{11} fragment.

On concentration of the original benzene–ethanol solution, 1.2 g of a second compound with m.p. 101–102° separated. Calc. for $C_{23}H_{38}$: C, 87.82; H, 12.18; molecular weight, 314. Found: C, 88.44, 88.53; H, 11.87, 11.88.

The mass spectrum of the lower melting compound showed a parent mass of 314. There was also a large peak at mass 243, corresponding to the loss of a C_5H_{11} fragment. The infrared spectrum of this compound in a potassium bromide pellet showed two strong bands of equal intensity at 7.28 and 7.37 microns attributed to isopropyl groups. There was also a strong band at 11.45 microns attributed to 1,2,4,5-tetrasubstitution. The ultraviolet spectrum of this compound showed bands at λ_{max} 2760 Å, $\epsilon = 749$ and λ_{max} 2677 Å, $\epsilon = 690$.

A sample of the compound of m.p. 101–102° (0.2 g) was dehydrogenated by heating with an equal weight of selenium powder in a sealed tube at 320° for 10 hours. The crude product was dissolved in cyclohexane and chromatographed on alumina using cyclohexane as eluant. The chromatograph fractions all showed a strong band in the ultraviolet spectrum at 2280 Å with weak absorption in the 2800 Å region containing some fine structure much like the alkyl naphthalenes.

Cyclialkylation of 1,3,5-Triisopropylbenzene with 2,4,4-Trimethyl-1-pentene

The 2,4,4-trimethyl-1-pentene used in these experiments was obtained from Matheson, Coleman and Bell, East Rutherford, N.J. It was also prepared by fractionating diisobutylene (η_D^{20} 1.4102) in a Podbielniak column. The diisobutylene was prepared by the procedure of Whitmore and co-workers (19). The 2,4,4-trimethyl-1-pentene isomer was removed in the fraction which boiled at 101° (760 mm), η_D^{20} 1.4090. The literature values (19) are 101.2° (760 mm) and η_D^{20} 1.4082.

1,3,5-Triisopropylbenzene (10 g, 0.05 mole) was dissolved in 25 ml of carbon disulphide and cooled in an ice–salt bath to −10°. A mixture of isopropyl chloride (5.6 g, 0.06 mole) and 2,4,4-trimethyl-1-pentene (5.6 g, 0.05 mole) was slowly added to the cooled, stirred solution over a period of 2 hours. Aluminum chloride (1.5 g, 0.01 mole) was added in small portions over the same period. From ultraviolet spectra run on various aliquots, the reaction product appeared to be formed in high yield after approximately 1 hour. After 2 hours reaction time, the carbon disulphide layer was poured into crushed ice and the organic layer extracted with ether. In concentrations of the ether extract, there was obtained 2 g of crystals and 5 g of semisolid material. The latter showed approximately the same ultraviolet spectrum as the crystalline material. The crude material was recrystallized from ethanol to yield colorless needles, m.p. 105–106.5°. This product was found to be identical with the product from alkylation of 1,3,5-triisopropylbenzene with 2-chloro-2,4,4-trimethylpentane by mixed melting points and ultraviolet spectra.

THE PHOTOLYSIS AND THE FLUORESCENCE OF PERFLUORO DIETHYL KETONE[1]

G. GIACOMETTI,[2] H. OKABE,[3] S. J. PRICE,[4] AND E. W. R. STEACIE

ABSTRACT

The photolysis and the fluorescence of $C_2F_5COC_2F_5$ have been studied at various temperatures, concentrations, and wavelengths. There is a strong dependence of the photochemical yield and to a lesser extent of the relative fluorescence yield on these factors. The reaction products are solely CO and C_4F_{10}. The fluorescence is excited by light of the wavelength region between 2537 Å and 3650 Å. The fluorescence band lies in almost the same wavelength region as that of CF_3COCF_3 and the relative fluorescence yield is slightly less in the higher concentration region. This behavior closely follows the pattern for CF_3COCF_3 and, hence, may be discussed by the same mechanism. A comparison is made of the primary photochemical reaction among fluorinated ketones.

INTRODUCTION

The photolyses of CF_3COCF_3 (1) and $C_3F_7COC_3F_7$ (2) have been investigated earlier in this laboratory. It was found that the dissociation takes place via an electronically excited species and that CO and fluorocarbons, formed by recombination of CF_3 and C_3F_7 radicals, are the sole products. The primary photochemical yield can be obtained directly from the rate of CO formation.

The fluorescence efficiency of CF_3COCF_3 has been studied in connection with the photolysis and a mechanism of the primary process has been presented (3, 4). Fluorescence has been observed also during the photolysis of $C_3F_7COC_3F_7$ but to such a small extent that no measurements have yet been made (unpublished observation by H. Okabe). In view of the simplicity of the mechanism it seems of interest to extend the investigation to other fluorinated ketones. The main purpose of this work is to study the photolysis and the fluorescence of $C_2F_5COC_2F_5$ and to see if the proposed mechanism (4) can be applied to this compound.

EXPERIMENTAL

The apparatus and experimental procedure have already been described (2, 3, 4). The quartz reaction cells used were 10 cm in length for photolysis and 15 cm for fluorescence experiments. The light source was a Hanovia S-500 lamp operated on a regulated supply. Radiation of 2640 Å was isolated for the photolysis experiments by means of a Corning 9863 filter and 5 cm of chlorine (100 mm Hg). The transparency band of this combination has a maximum at 2640 Å. Light in the 2537 Å region is also transmitted but is negligibly absorbed by the ketone. The $C_2F_5COC_2F_5$ was supplied by Dr. Leitch of this laboratory and later by Merck and Co. of Canada. The ketone was carefully distilled on a Podbielniak column (b.p. 26° C) and dried on P_2O_5. It was then degassed by bulb-to-bulb distillation under vacuum. A typical mass spectrometric cracking pattern is shown in Table I. Samples supplied for the early stages of this work showed the same mass spectro-

†These peaks are not attributed. They are usually found in mass spectra of fluorinated hydrocarbons (see N.B.S. Reports).

graph except for relative amounts of trace impurities. Later samples contained significant quantities of benzene and some unidentified bromine compound. These were removed by partition chromatography using a fluoroester column (Fluid 316, Fluoroester Lubricant, Petroleum Chemicals Division, E.I. DuPont De Nemours and Co., 30% by weight on Fisher Scientific Company Columpak) maintained at −15° C. On a 200-cm column, 10 mm i.d., with a hydrogen flow rate of 120 cc/min the appearance time of the ketone was 17 minutes.

Following photolysis runs, carbon monoxide was pumped from the products at −210° C. The unreacted ketone and other photolysis products were collected together owing to the impossibility of a separation by low temperature distillation. In the later stages of the photolysis work the condensable products were analyzed by gas chromatography using a 3-foot alumina column (80–100 mesh) at 25° C. The ketone appears to be completely adsorbed by the column. The retention volume of C_4F_{10} is about 600 cc but this varies considerably with the amount of ketone on the column and with the moisture content of the alumina used. All quantum yields were determined using acetone as an actinometer.

The fluorescence spectrum was taken with a Hilger intermediate quartz spectrograph on a Kodak 103_a-B plate. The relative fluorescence yield, Q, in arbitrary units, is obtained from the following equation (4).

$$Q = \frac{D_f - D_f^0}{D_t^0 - D_t} \frac{S_t T}{\lambda_t}$$

where D_f is the galvanometer deflection for the fluorescence light emerging from the center of the cell, D_f^0 is the deflection for scattered light from the empty cell, D_t and D_t^0 are the deflection for the transmitted light with and without the gas in the cell respectively, S_t is the spectral sensitivity of the phototube to the transmitted light of wavelength λ, and T is the % transmission of an exit window. This equation is approximately valid when the absorption of the gas is not large.

RESULTS

The absorption spectrum was recorded with a Cary spectrometer. The spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

extends over a wavelength region between 2500 Å and 3600 Å. Some structure is observed between 3000 Å and 3500 Å. The molar extinction coefficient, k, in l. mole^{-1} cm^{-1} is shown in Table II.

TABLE II

The molar extinction coefficient, k, (l. mole^{-1} cm^{-1}) of $C_2F_5COC_2F_5$ at various wavelengths

Wavelength (Å)	k at 23° C
2640	3.50
3130	22.3
3340	14.3

The coefficient at 3130 Å is about three times as large as that of CF_3COCF_3.

Photolysis

The results of runs in which the condensable products were analyzed by adsorption chromatography are shown in Table III. Within experimental error the quantum yields based on CO and on C_4F_{10} are identical. Hence CO and C_4F_{10} would appear to be the sole products of the photolysis. As an additional check runs have been performed at room temperature up to 50% decomposition and the products, after elimination of CO, analyzed on the mass spectrometer. The peak at mass 147 was used for the ketone and peaks at masses 150 and 169 for C_4F_{10}. The total spectrum was that predictable from the sum of the two pure samples except for very minor discrepancies (for instance the ratio 150/169 was slightly altered in the presence of the ketone). The quantity of C_4F_{10} was equal within 5% to the CO produced. No peaks attributable to other products were noticed. Furthermore, the total number of moles of gas collected from the cell after the long runs was always found, after removal of CO, to be equal to the initial number of moles of ketone introduced. All this is in agreement with the exclusive formation of CO and C_4F_{10}.

The primary photochemical yield, based on the rate of CO production, was measured at various temperatures, concentrations, and wavelengths. Figure 1 illustrates quantum yield vs. concentration at four temperatures. Light of wavelength 3130 Å was used for

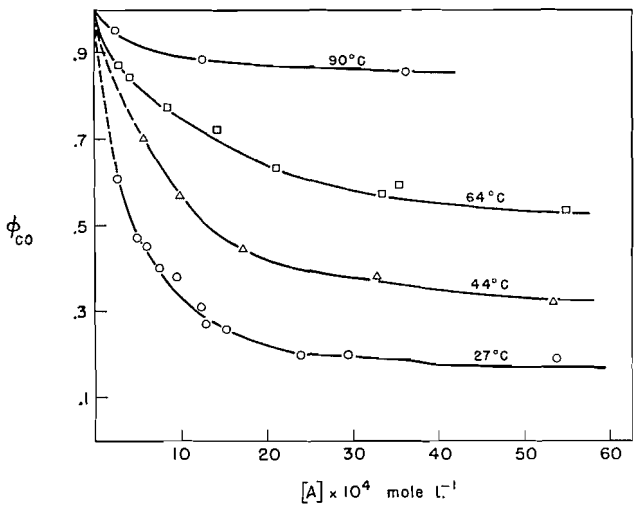

FIG. 1. The photochemical yield at various temperatures vs. concentration at 3130 Å.

60	26.0	0.56	0.57

3650 Å. The fluorescence band extends over the wavelength region between 3500 Å and 5000 Å with a broad maximum at about 4100 Å. There is little effect of temperature on the position and the apparent intensity distribution of the band.

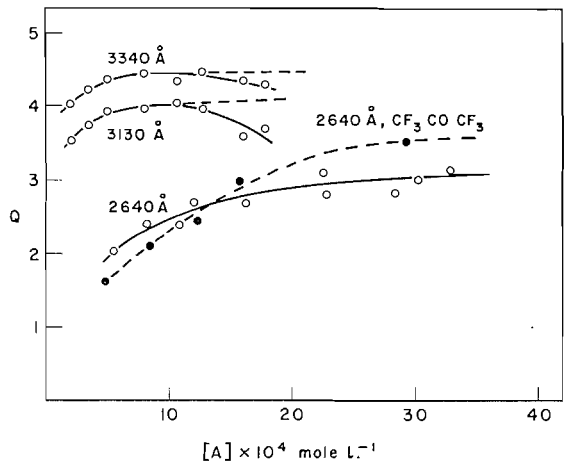

FIG. 4. The relative fluorescence yield at various wavelengths vs. concentration at room temperature; the curves are those of $C_2F_5COC_2F_5$ unless otherwise noted.

Figure 4 shows the concentration dependence at room temperature of Q at various wavelengths. For comparison Q for CF_3COCF_3 at 2640 Å is added. The apparent decrease of Q beyond the concentration of 10×10^{-4} moles per l. at 3130 Å and 3340 Å is undoubtedly due to the invalidity of the equation used in its calculation, which holds only when the absorption is less than 50%. The temperature dependence of the fluorescence yield was measured over the range from room temperature to 190° C. The fluorescence yield decreases with an increase of temperature with a negative temperature coefficient of about 0.7 kcal per mole, when light of 3130 Å and a concentration of 52×10^{-4} mole per l. are used.

DISCUSSION

The photochemical and the fluorescence behavior of $C_2F_5COC_2F_5$ as a function of temperature, concentration, and wavelength closely resembles that of CF_3COCF_3, namely:

(1) The mechanism of the photolysis is obviously the general one accepted for the other fluorinated ketones.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

(2) The photochemical yield, ϕ, increases and approaches unity as the concentration decreases. It increases with an increase of temperature and excitation energy. The yield has a larger concentration dependence at shorter wavelength over the moderate (10×10^{-4} mole per l.) and higher concentration range at the same temperature (Figs. 1 and 3).

(3) The fluorescence band extends over almost the same wavelength region. The relative fluorescence yield increases with an increase of concentration and with a decrease of excitation energy, approaching almost 70% that of CF_3COCF_3. The increase is larger at shorter wavelength (Fig. 4). The yield decreases as the temperature increases and the negative temperature coefficient is of the same order of magnitude. The mechanism may therefore be expressed by equations previously proposed (4).

[1] $$K + h\nu \rightarrow K_n$$

[2] $$K_n \rightarrow D$$

[3] $$K_n + K \rightarrow K_0 + K$$

[4] $$K_0 \rightarrow h\nu + K$$

[5] $$K_0 \rightarrow Z_0$$

[6] $$Z_0 \rightarrow D$$

[7] $$Z_0 \rightarrow K$$

where K, K_n, and K_0 designate the ground electronic state of $C_2F_5COC_2F_5$ and the nth and 0th vibrational levels of a singlet excited state from which the fluorescence originates. D denotes the dissociation products; Z_0 represents a molecule in the lowest vibrational level of another excited (probably triplet) state, from which dissociation and possibly internal conversion take place but not emission. From the above mechanism, the following equation is obtained:

[8] $$\frac{\phi}{1-\phi} = \frac{\alpha}{1-\alpha} + \frac{k_2}{k_3[K](1-\alpha)}$$

where α is the photochemical yield at infinite concentration. Figure 5 shows the relationship between $\phi/(1-\phi)$ and the reciprocal of the concentration at various temperatures and wavelengths. The data fit the equation well at 3130 Å, whereas at 2640 Å the equation is obeyed only approximately. In Fig. 5 the data at 3130 Å enable a reliable extrapolation to be made to $1/[A] = 0$, and hence the intercepts can be established with some certainty. Unfortunately, since the lines at 2640 Å are curved it is impossible to establish the value of the intercepts with any degree of certainty. The mechanism suggests that the intercepts should have the same values at both wavelengths, and the curves have been drawn in this way. It should be emphasized, however, that while the data are entirely consistent with common intercepts, they do not in any way establish this point. The rate of dissociation from upper vibrational levels of the singlet excited state, k_2, obtained from the slopes, is larger at the shorter wavelength. The values of α obtained from the intercept are given in Table IV. For comparison, α for CF_3COC_3F and $C_3F_7COC_3F_7$ are also given.

As can be seen from Table IV, α at the same temperature increases in the order CF_3COCF_3, $C_2F_5COC_2F_5$, $C_3F_7COC_3F_7$. If a plot is made of $\log\{(1/\alpha)-1\}$ vs. $1/T$ for

these compounds, apparent negative activation energies of 9.2, 8.9, and 7.8 kcal per mole are obtained for CF_3COCF_3, $C_2F_5COC_2F_5$, and $C_3F_7COC_3F_7$ respectively. If the mechanism is correct these energies correspond approximately to the activation energy differences between the dissociation and the internal conversion from the (triplet) state.

If a comparison is made of the photolysis at 27° C between $C_2F_5COC_2F_5$ and CF_3COCF_3 at 2640 Å, where the dissociation would mainly originate from higher vibrational levels, it is evident that ϕ for $C_2F_5COC_2F_5$ is smaller in the lower concentration region, but larger at higher concentrations. In other words, ϕ for $C_2F_5COC_2F_5$ has a smaller con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

centration dependence at this wavelength. From equation [8] this gives for $C_2F_5COC_2F_5$ a value of k_2/k_3 less than half that for CF_3COCF_3. Assuming the same rate of deactivation for both compounds, k_2 is much smaller in $C_2F_5COC_2F_5$. This suggests that since there are more vibrational degrees of freedom for $C_2F_5COC_2F_5$, there will be less probability that the energy will concentrate in the particular bond leading to dissociation.

Corresponding to the smaller concentration dependence of ϕ for $C_2F_5COC_2F_5$ at 27° C and 2640 Å, there is also less concentration dependence of Q at this temperature and wavelength (Fig. 4). It would be of great interest to find direct evidence of the two close-lying excited states of these molecules. It is possible that ultraviolet spectroscopy, performed under conditions such that no dissociation would occur (low temperature and moderate pressures), may supply the answer.

ACKNOWLEDGMENTS

The authors are indebted to Dr. L. C. Leitch of this laboratory for the supply of ketone, to Miss A. B. Thornton for the mass spectrometric analyses, and to Dr. K. O. Kutschke for much advice and discussion.

THE POLYSACCHARIDES OF FURCELLARIA FASTIGIATA

I. ISOLATION AND PARTIAL MERCAPTOLYSIS OF A GEL-FRACTION[1]

T. J. PAINTER

ABSTRACT

Addition of potassium chloride to an aqueous extract of the red alga *Furcellaria fastigiata* precipitated a polysaccharide containing residues of D-galactose and 3,6-anhydro-D-galactose in the approximate ratio 1.3:1. Approximately two monomer units in five bore sulphate half-ester groups. The fraction gave a single, sharp peak in the analytical ultracentrifuge. Partial mercaptolysis afforded the crystalline diethyl mercaptals of D-galactose, 3,6-anhydro-D-galactose, and 4-*O*-β-D-galactopyranosyl-3,6-anhydro-D-galactose (A); the respective yields were 27%, 20%, and 42% w/w of the recovered mercaptolysate. The polysaccharide resembles κ-carregeenin.

The red alga *Furcellaria fastigiata* (Huds.) Lamour. contains a hydrocolloid which is similar in properties to carrageenin (1, 2). The alga grows in the Baltic Sea, and is particularly abundant in the adjacent Kattegatt, where it is harvested for the manufacture of "Danish agar", or "furcellaran" (3). It is also reported to grow in the Gulf of St. Lawrence, Canada (4), in commercial quantities (5).

In 1943, Kylin showed that residues of D-galactose, and sulphate half-ester groups were present in the mucilage (6). More recently, Dillon, O'Colla, and co-workers found that residues of 3,6-anhydro-galactose were also present (7). The unfractionated mucilage was subjected to acetylative desulphation; examination of the degraded, sulphate-free product by methylation showed that the galactose residues were linked mainly through positions 1 and 3, but occasionally also through position 6 (7). In the present study, an attempt has been made to isolate a homogeneous polysaccharide from the mucilage, and to examine its structure by partial mercaptolysis.

In the first series of experiments, the milled alga was extracted with acetone, and then stirred for 2 hours with hot aqueous sodium acetate at pH 7. After three successive extractions of the residue in the same way, 73% of the dry weight of the alga had been removed as water-soluble products. Extraction in this manner appeared to be impeded by the presence of protein, of which the alga may contain 17–18% (N, 2.8%) (8). Furthermore, the extracts were contaminated with a brown pigment which could be removed only in part with decolorizing charcoal. In later experiments, when it was unnecessary to avoid slight degradation of the polysaccharides, both difficulties were overcome as described below.

A slurry of the alga in water, stirred at 75° C, was treated with dilute chlorous acid, added dropwise over a period of 30 minutes. During this time, the pH of the mixture fell slowly to 3.5. The pH was then brought immediately to 7 with sodium acetate, and extraction at 75° C was continued for 1 hour. In these cases, a single treatment caused dissolution of 88% of the alga, and the recovered polysaccharides were free from colored contaminants.

When potassium chloride (9, 10) was added to the aqueous extracts obtained by either method, a gelatinous precipitate was obtained of the potassium salt of a sulphated polysaccharide. This was collected and converted into the sodium salt by dialysis against aqueous sodium acetate. After three reprecipitations with potassium chloride in the same

For personal use only.

way, the purified product (sodium salt) had $[\alpha]_D$ $+75° \pm 2°$ in water. It contained residues of galactose (43.1%), 3,6-anhydro-galactose (30.3%), and half-ester sulphate (as SO_3Na) (20.1%).

When a solution of the polysaccharide in 0.1 *M* sodium chloride was examined in the analytical ultracentrifuge, a single, sharp peak was observed. Chromatography of an acid-hydrolyzate of the material indicated the presence of galactose, a trace of xylose, and a component having an R_f similar to that of 5-hydroxymethyl-2-furaldehyde. Upon isolation, the galactose crystallized extensively; the crystals were of D-galactose.

Total mercaptolysis of the polysaccharide with ethyl mercaptan and concentrated hydrochloric acid gave a high yield of the crystalline diethyl mercaptals of D-galactose and 3,6-anhydro-D-galactose, in the molar ratio 1.3:1. These compounds were further characterized by conversion, respectively, into crystalline D-galactose, and into 3,6-anhydro-D-galactose phenylosazone.

Mercaptolysis for a shorter period of time afforded the above-named mercaptals (47%), together with a large amount (42%) of a disaccharide mercaptal (A). This component (A) was isolated by chromatography of the mixture on a column of cocoanut charcoal (11), followed by preparative paper chromatography. It crystallized, and was identical with an authentic specimen of 4-*O*-β-D-galactopyranosyl-3,6-anhydro-D-galactose diethyl mercaptal, as prepared by the partial mercaptolysis of κ-carrageenin (12). The identity of the two compounds was confirmed by comparison of their crystalline hexa-*O*-acetyl derivatives.

Demercaptallation of (A) with mercuric chloride and cadmium carbonate in water afforded a reducing disaccharide (B), from which a crystalline phenylosazone was prepared. Reduction of (B) with aqueous sodium borohydride yielded a crystalline glycitol (C), which formed a crystalline hepta-*O*-acetyl derivative (D). The physical constants of (C) and (D) agreed well with those recently reported by Clingman and Nunn (13) for 4-*O*-β-D-galactopyranosyl-3,6-anhydro-D-galactitol, and for its hepta-*O*-acetate, respectively.

These results suggest that a part of the mucilage of *Furcellaria fastigiata* is made up of a homogeneous polysaccharide which consists essentially of residues of D-galactose and 3,6-anhydro-D-galactose. The traces of xylose detected in hydrolyzates of the polysaccharide may have arisen from contaminating xylan. No evidence for the presence of monomer units derived from the L-series of sugars was obtained.

The high yield of the disaccharide mercaptal (A) indicates that the two types of sugar residue must be very evenly distributed throughout the macromolecule. As an idealized picture, the polysaccharide could be considered to consist entirely of repeating units represented by the disaccharide (B); the 30% molar excess of D-galactose residues might have arisen from a contaminating galactan which escaped detection in the ultracentrifuge. It is equally probable, however, that the polymer has a rather less highly ordered structure, with occasional small groups of contiguous D-galactose residues in the chains; a small proportion of the 3,6-anhydro-D-galactose residues may be similarly grouped.

As a result of the highly labile nature of 3,6-anhydro-galactosidic linkages, an investigation of the present type provides little information about them, beyond the fact that most of them must be directed towards D-galactose residues in the polysaccharide. However, when these results are considered together with the methylation studies of Dillon, O'Colla, and co-workers (7), it appears probable that most of the 3,6-anhydro-D-galactose residues are linked to position 3 of D-galactose residues. The positive specific rotation of the polysaccharide suggests, moreover, that most of these linkages are in the α-configuration.

It would follow that the polysaccharide is similar to κ-carrageenin, although the sulphate content is somewhat lower. Another polysaccharide of this type was recently isolated from *Hypnea specifera* by Clingman and Nunn (13).

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper. For preparative work, large sheets (57×46 cm) of Whatman No. 3MM paper were used; in these cases, the solvent was supplied to the sheets through short strips (57×8 cm) of Whatman No. 1 paper, which were attached to the main sheets with staples. The irrigant was either (*a*) butan-1-ol–ethanol–water (3:1:1 v/v) or (*b*) butan-1-ol–pyridine–water (6:4:3 v/v). Reducing sugars were located on the chromatograms by spraying with *p*-anisidine hydrochloride in butan-1-ol (14). Sugar mercaptals were located by spraying with silver nitrate in acetone, followed by ethanolic sodium hydroxide (15). Chromatographic mobilities are calculated relative to the solvent front (R_f).

Optical rotations were measured at 21°±2° C; unless otherwise stated, the solvent was water. Melting points were determined with a Kofler block. Solvents were evaporated under diminished pressure at 30–45° C. X-Ray powder photography was carried out using chromium radiation and a vanadium filter; the powdered samples were mounted in the camera on lead-free glass fibers, to which they were attached with silicone grease. For sedimentation, a 0.2% w/v solution of the polysaccharide in 0.1 *M* sodium chloride was used. The ultracentrifuge, a Spinco Model E instrument, was operated at 59,780 r.p.m.

Sulphate was determined gravimetrically, after complete hydrolysis of the polysaccharide with 0.5 *N* hydrochloric acid (20 hours at 95° C), by precipitation as barium sulphate. Galactose and 3,6-anhydro-galactose were estimated by a modification (16, 17) of a method (18) for the simultaneous estimation of glucose and fructose. In an independent method, 3,6-anhydro-galactose was estimated selectively by a modification (16, 17) of the resorcinol method (19) for fructose. The results agreed well, and the figures given are averages.

Preparation of the Polysaccharide

The alga was collected near Pictou, Nova Scotia, in November, 1958. It was dried in a current of air at 45° C for 3 hours, and ground in a Wiley mill to pass a 20-mesh sieve. The product was extracted exhaustively with hot acetone, dried at room temperature, and used as follows.

Method (a)

The alga (100 g: 10% w/w moisture) was stirred in water (3 l.) containing sodium acetate (15 g) at 80° C for 2 hours. The mixture was then centrifuged while hot. The residue was extracted twice more in the same way, and then subjected to a final extraction for 6 hours. The final residue, when isolated and dried, weighed 21 g. The combined centrifugates (ca. 12 l.) were dialyzed against aqueous sodium acetate (0.1% w/v) for 24 hours. The solution was heated at 80° C with decolorizing charcoal (100 g) for 1 hour, and then filtered through Celite in a heated, sintered-glass funnel. To the clear, pale brown filtrate was added potassiun chloride (400 g) in water (2 l.); the solution was allowed to cool slowly to 4° C, while being vigorously stirred. The gelatinous precipitate was collected by centrifugation, and dispersed in aqueous sodium acetate (0.1% w/v; 5 l.). This mixture was dialyzed against aqueous sodium acetate until the gel had dissolved (60 hours). The solution was diluted to 10 l. with water, heated with charcoal, and filtered as before, and again treated with potassium chloride. The gel was collected and reprecipitated twice more in the same way. It was finally dispersed in water (3 l.) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

dialyzed against aqueous sodium acetate until it had redissolved. The solution was poured into ethanol saturated with sodium acetate (10 l.). The precipitate was collected, washed thoroughly with aqueous ethanol (80% v/v), followed by absolute ethanol, then by ether, and dried over silica gel in a vacuum desiccator. The yield of light brown, fibrous polysaccharide (F-1) was 15.0 g.

Method (b)

The alga (50 g; 10% w/w moisture) was stirred in water (2 l.) at 75° C for 10 minutes. A solution of chlorous acid was prepared by treating aqueous sodium chlorite (4% w/v) with an excess of Amberlite resin IR-120. This solution (150 ml) was added, uniformly and dropwise, to the above slurry over a period of 30 minutes. At 5-minute intervals, aliquot portions were withdrawn and cooled, and the pH was measured with a Beckman pH meter.

Time (minutes)	0	5	10	15	20	25	30
pH	7.2	6.7	6.3	5.7	5.0	4.3	3.5

The mixture was then neutralized with sodium acetate (30 g) and sodium carbonate (4 g), and stirring at 75° C was continued for 1 hour. Water (3 l.) was added, and the mixture was centrifuged at 40–50° C. The residue, when isolated and dried, weighed 5.4 g. The centrifugate was filtered through Celite at 80° C, and then treated with potassium chloride (200 g) in water (1 l.), and allowed to cool. The gelatinous precipitate was collected and purified as described in method (*a*), with the exception that no charcoal was used. The final yield of white, fibrous polysaccharide (Na salt) (F-2) was 10.5 g.

Preliminary Examination of the Polysaccharide (F-1)

The following analytical values were obtained: $[\alpha]_D$ +75°±2° (*c*, 0.2); ash, 14.6%; sulphated ash, 15.0%; SO_3Na, 20.1%; galactose (as $C_6H_{10}O_5$), 43.1%; 3,6-anhydrogalactose (as $C_6H_8O_4$), 30.3%. In the ultracentrifuge, a single, sharp peak was obtained which showed only slight spreading of the boundary.

A portion (1 g) was hydrolyzed with *N* sulphuric acid at 100° C for 12 hours. The solution was neutralized with barium carbonate, filtered, deionized (resins), and concentrated to a syrup (350 mg). Chromatography of the hydrolyzate in solvent (*a*) or (*b*) indicated the presence of galactose, a trace of xylose, and a component similar to 5-hydroxymethyl-2-furaldehyde. Separation of the galactose on a large chromatogram gave a syrup (260 mg) which had $[\alpha]_D$ +78° (*c*, 2.6). It crystallized from methanol, and after one recrystallization from the same solvent, the yield of pure crystals was 190 mg. They had m.p. 165–166° C, unchanged on admixture with pure α-D-galactose, and $[\alpha]_D$ +139° (by extrapolation) → +79° (24 hours) (*c*, 1.0).

Total Mercaptolysis of the Polysaccharide

The polysaccharide (F-2; 10 g) was stirred with concentrated hydrochloric acid (70 ml) at 0° C for 10 minutes. Ethyl mercaptan (25 ml) was added over a period of 1 hour. The mixture was then allowed to warm slowly to 10° C, and stirring at this temperature was continued. The flask was kept closed to minimize evaporation of ethyl mercaptan. After 24 hours, more ethyl mercaptan (25 ml) was added. After a total time of 96 hours, the mixture was cooled to 0° C, and ice-cold methanol (800 ml) was added. The resulting homogeneous solution was neutralized with lead carbonate, filtered, and the filtrate and washings were concentrated to a syrup. This was dissolved in absolute methanol (300 ml); the solution was cooled to 0° C, and the small deposit of inorganic salt was removed by filtration. The filtrate was concentrated to a syrup (11.5 g). Chromatography of this product in solvent (*a*), followed by the use of the silver nitrate spray reagent, indicated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

an intense black spot, R_f 0.65, corresponding to galactose diethyl mercaptal, and a light brown spot, R_f 0.90, corresponding to 3,6-anhydro-galactose diethyl mercaptal. Also detected were small spots corresponding to xylose diethyl mercaptal (R_f 0.77), to ethyl 1-thio-galactopyranoside (R_f 0.50), to free galactose (R_f 0.15), and to traces of reducing oligosaccharides (R_f 0–0.05).

(*i*) D-*Galactose Diethyl Mercaptal*

The above mercaptolysate was dissolved in water (100 ml), and the solution was cooled to 0° C, whereupon it solidified to a crystalline mass. This was lixiviated with ice-cold water. The crystals were collected (yield, 3.5 g), and recrystallized twice from methanol–ether. The pure product had $[\alpha]_D$ $-3.7°\mp0.5°$ (*c*, 0.7), and m.p. 141–141.5° C, unchanged on admixture with synthetic D-galactose diethyl mercaptal. The crystals (1 g), mercuric chloride (5 g), and cadmium carbonate (10 g) were heated in water (100 ml) for 2 hours at 50° C. The mixture was cooled and filtered, and the filtrate was saturated with hydrogen sulphide. Precipitated material was removed, and the solution was then neutralized with Amberlite resin IR-45. It was concentrated to a syrup (0.5 g), which was dissolved in a minimum of hot methanol. On cooling, crystals separated, and after recrystallization from methanol, the compound had m.p. and mixed m.p. with α-D-galactose, 165.5–166.5° C, and $[\alpha]_D$ +142° (by extrapolation) → +80° (14 hours) (*c*, 1.1).

(*ii*) *3,6-Anhydro*-D-*galactose Diethyl Mercaptal*

After collection of the D-galactose diethyl mercaptal, the aqueous filtrate was diluted to 500 ml with water, and then shaken 10 times with ether (10×200 ml) in a separatory funnel. The combined ether extracts (2 l.) were dried with Drierite, filtered, and concentrated to 200 ml. When ligroin (b.p. 35–60° C) (100 ml) was added, a flocculent mass of crystals separated; they were collected by filtration (yield, 2.4 g), and recrystallized twice from ether–ligroin. From the filtrate, a second crop (1.1 g) of crystals was obtained. The pure crystals had $[\alpha]_D$ $-9.8°\mp0.5°$ (*c*, 0.4), and m.p. 111.5–112.5° C, unchanged on admixture with a synthetic specimen (12) of 3,6-anhydro-D-galactose diethyl mercaptal. A mixture with 3,6-anhydro-L-galactose diethyl mercaptal (m.p. 110–111° C), prepared by the mercaptolysis of agar (20), had a melting range of 109–134° C.

A sample of the compound (100 mg) was heated in water (15 ml) with mercuric chloride (500 mg) and cadmium carbonate (1 g) at 50° C for 2 hours. The mixture was cooled and filtered, and the filtrate was extracted exhaustively with ether. It was then heated with phenylhydrazine (0.2 ml), sodium acetate (1 g), and acetic acid (1 ml) at 80° C for 2 hours. The flocculent yellow precipitate was collected and recrystallized from methanol. The product had m.p. 217° C, unchanged on admixture with 3,6-anhydro-D-galactose phenylosazone (12), and $[\alpha]_D$ +75° (15 minutes) → +54° (20 hours, constant) (*c*, 0.2 in methanol). For 3,6-anhydro-L-galactose phenylosazone, Araki and Hirase (21) report $[\alpha]_D$ −75° (initial) → −53° (24 hours) (in methanol–pyridine).

(*iii*) *Ethyl 1-Thio-*α-D-*galactopyranoside*

The aqueous solution remaining after the extraction of 3,6-anhydro-D-galactose diethyl mercaptal was concentrated to a syrup (3.2 g). Chromatography indicated the presence of three major constituents. The mixture was separated on large chromatograms, to yield D-galactose (0.5 g), D-galactose diethyl mercaptal (1.2 g), and the other component, having R_f 0.50 in solvent (*a*), (0.6 g). This last component was obtained as a syrup having $[\alpha]_D$ +280° (*c*, 2.5). It crystallized slowly on standing, and after three recrystallizations from butan-1-ol, it had $[\alpha]_D$ $+318°\pm2°$ (*c*, 0.6), and m.p. 152–153.5° C. For ethyl 1-thio-α-D-galactopyranoside, Fried and Walz (22) report $[\alpha]_D$ +320°, and m.p. 153.5–154° C. Calculated for $C_8H_{16}O_5S$: S, 14.3%. Found: S, 12.7%. Demercaptallation in the usual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

way afforded D-galactose, $[\alpha]_D$ +78°, characterized by conversion into its 1-methyl-1-phenylhydrazone, m.p. 189° C.

Partial Mercaptolysis of the Polysaccharide

The polysaccharide (F-1; 10 g) was stirred at 0° C with concentrated hydrochloric acid (70 ml) for 10 minutes. Ethyl mercaptan (30 ml) was then added, and stirring at 0° C was continued for 20 hours. The mixture was then stirred at 10° C for a further 24 hours. The mercaptolysate (10.5 g) was recovered as described above. It was dissolved in water (50 ml) and the solution was cooled to 0° C. Crystals (1.2 g) of D-galactose diethyl mercaptal separated, and were collected by filtration. The filtrate was diluted with water, and extracted by shaking with ether. From the extract, 3,6-anhydro-D-galactose diethyl mercaptal (1.8 g) was recovered. The remaining aqueous solution was then extracted exhaustively with ether in a liquid–liquid extractor for 3 days. From the extract, a further quantity of D-galactose diethyl mercaptal (0.8 g) was recovered. The aqueous layer was then concentrated to a syrup (6.0 g). On chromatograms developed in solvent (*a*), and sprayed with the silver nitrate reagent, the presence was shown of (*i*) a small, black spot, R_f 0.67, corresponding to galactose diethyl mercaptal; (*ii*) a very large, light brown spot having R_f 0.60; (*iii*) a dark brown spot, R_f 0.50, corresponding to ethyl 1-thio-galactopyranoside; (*iv*) three very small spots having R_f 0.42, 0.30, and 0.27 respectively; (*v*) a spot, R_f 0.15, corresponding to free galactose; and (*vi*) spots corresponding to traces of reducing oligosaccharides.

Isolation of 4-O-β-D-Galactopyranosyl-3,6-anhydro-D-galactose Diethyl Mercaptal (A)

Owing to overlapping of the spots, it was not possible to isolate the major component (A; R_f 0.60 in solvent *a*) of the mixture directly by paper chromatography. The mixture (6.0 g) was therefore adsorbed on a column (14×4 cm) of cocoanut charcoal (11). Elution with aqueous ethanol (5% v/v; 2 l.) displaced D-galactose (0.8 g). Aqueous ethanol (7.5% v/v) then displaced ethyl 1-thio-D-galactopyranoside (0.6 g in 8 l.), followed by D-galactose diethyl mercaptal (0.4 g in 10 l.). Elution with 20% v/v aqueous ethanol then displaced traces of reducing oligosaccharides, and the components with R_f 0.30 and 0.27 in solvent (*a*) (0.2 g in 5 l.). Finally, aqueous ethanol (50% v/v; 6 l.) eluted a mixture (3.8 g) containing ca. 90% of component (A). This last fraction was purified by preparative paper chromatography, to yield a viscous, colorless syrup having $[\alpha]_D$ +14° (*c*, 2.0). It was indistinguishable on chromatograms developed in solvent (*a*) or (*b*) from an authentic specimen of 4-*O*-β-D-galactopyranosyl-3,6-anhydro-D-galactose diethyl mercaptal, which was prepared from κ-carrageenin, and characterized by the late Dr. A. N. O'Neill (12). After drying over phosphorus pentoxide, it crystallized from absolute ethanol–ether, and had m.p. 116–117° C, undepressed on admixture with the authentic specimen.

A portion (100 mg) was heated at 80° C with pyridine (15 ml) and acetic anhydride (10 ml) for 1 hour. Excess of these reagents was then removed by distillation *in vacuo*, and the residue was washed by decantation with water. The residue crystallized from ethanol–water, and after three recrystallizations from the same solvents, the product had $[\alpha]_D$ +12° (*c*, 0.4 in chloroform), and m.p. 121.0–121.5° C, unaltered on addition of authentic 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2,5-di-*O*-acetyl-3,6-anhydro-D-galactose diethyl mercaptal (12). X-ray powder photographs of the two hexa-*O*-acetates were identical.

4-O-β-D-Galactopyranosyl-3,6-anhydro-D-galactose (B)

A portion (1 g) of the disaccharide mercaptal (A) was demercaptallated with mercuric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

chloride and cadmium carbonate in water in the usual way. Excess of mercuric chloride was removed by extraction with ether. The syrupy product (B; 0.7 g) reduced Fehling's solution in the cold, and restored the color to Schiff's reagent. Calculated for $C_{11}H_{19}O_9(CHO)$: reducing equivalent weight, 162. Found (by iodometric titration): 155.

A part of the syrup (25 mg) was heated in water (5 ml) with phenylhydrazine (0.1 ml), sodium acetate (0.5 g), and acetic acid (0.5 ml) at 80° C for 2 hours. On cooling, yellow crystals separated; they were collected, and after recrystallization from ethanol–ether, the product had m.p. 211–213° C, and $[\alpha]_D$ +110°±8° (*c*, 0.4 in methanol).

*4-O-β-*D*-Galactopyranosyl-3,6-anhydro-*D*-galactitol (C)*

The remainder of the above syrup (B), dissolved in water (20 ml), was treated with sodium borohydride (1 g), and the solution was allowed to stand overnight at room temperature. It was then treated with excess of Amberlite resin IR-120, and filtered. The filtrate and washings were concentrated to dryness, and boric acid was then removed by the repeated distillation of added methanol. The final residue (C; 0.6 g) crystallized spontaneously on cooling, and after recrystallization from methanol–ether, it had m.p. 172.5–173.5° C, and $[\alpha]_D$ +12.7°±1.0° (*c*, 0.12). For 4-*O*-β-D-galactopyranosyl-3,6-anhydro-D-galactitol, Clingman and Nunn (13) report m.p. 173–174° C, and $[\alpha]_D$ +15°. Calculated for $C_{12}H_{22}O_{10}$: C, 44.2%; H, 6.75%. Found: C, 44.64%; H, 6.80%.

A part of the product (C; 100 mg) was acetylated with pyridine and acetic anhydride in the same way as for (A). The product (D) crystallized from ethanol as strongly birefringeant needles, having m.p. 145.5–146.0° C and $[\alpha]_D$ −6.2°∓1.0° (*c*, 0.2 in chloroform). For 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-1,2,5-tri-*O*-acetyl-3,6-anhydro-D-galactitol, Clingman and Nunn (13) report m.p. 144–145° C, and $[\alpha]_D$ −7.6° (in chloroform). Calculated for $C_{26}H_{36}O_{17}$: C, 50.3%; H, 5.8%; Ac, 48.5%. Found: C, 50.02%; H, 6.01%; Ac, 48.10%.

ACKNOWLEDGMENTS

The author is indebted to Dr. J. W. Lorimer for help and advice in operating the ultracentrifuge, to Dr. O. Knop and Mr. R. D. McDonald of the Nova Scotia Technical College for X-ray powder photography, and to Dr. W. Yaphe for the colorimetric estimation of galactose and 3,6-anhydro-galactose. He is also grateful to Dr. Yaphe for his interest in this work.

CHEMISTRY OF THE TRIFLUOROMETHYL GROUP

PART I. COMPLEX FORMATION BY PHOSPHINES CONTAINING THE TRIFLUOROMETHYL GROUP[1, 2]

M. A. A. Beg and H. C. Clark

ABSTRACT

The formation of co-ordination compounds of $(CH_3)_3P$, $(CH_3)_2PCF_3$, $CH_3P(CF_3)_2$, and $P(CF_3)_3$, with boron trifluoride and platinum (II) chloride has been studied. The properties of the new compounds $(CH_3)_2PCF_3.BF_3$, $[(CH_3)_2PCF_3]_2PtCl_2$, $[CH_3P(CF_3)_2]_2PtCl_2$ are described, and it is hence concluded that the stabilities of the boron trifluoride compounds decrease in the order

$$(CH_3)_3P.BF_3 > (CH_3)_2PCF_3.BF_3 > (CH_3P(CF_3)_2BF_3 > P(CF_3)_3.BF_3),$$

while for the platinum (II) complexes the order of stability is

$$[(CH_3)_3P]_2PtCl_2 < [(CH_3)_2PCF_3]_2PtCl_2 > [CH_3P(CF_3)_2]_2PtCl_2 > ([P(CF_3)_3]_2PtCl_2).$$

These two orders are related to the electronegativity of the trifluoromethyl group and its influence on the bonding properties of the phosphorus atoms.

INTRODUCTION

While a range of organometallic and organometalloidal trifluoromethyl compounds has been prepared, little quantitative information is so far available for the trifluoromethyl group. Since its electronegativity will differ widely from that of a normal alkyl or aryl group, these organometalloidal compounds may be expected to show unusual properties. A study has therefore been made of the effect of the trifluoromethyl group on the donor properties of substituted phosphines. Two types of addition products may be formed: (*a*) those containing only a σ-bond from phosphorus to the acceptor atom, as for example in $F_3P.BH_3$, and (*b*) those in which both σ- and π-bonding occurs, usually between phosphorus and a transition metal, e.g. $(R_3P)_2PtCl_2$. The effect of the electronegative trifluoromethyl group on the formation of σ- and π-bonds will vary and may be investigated by examining the properties of these two classes of compounds.

EXPERIMENTAL

Preparation of the Phosphines

Trimethylphosphine was prepared by the method of Mann and Wells (1). This reaction normally gives low yields, but it was found that, with strong cooling of the reaction vessel in an acetone–solid CO_2 mixture, yields of 60% could be regularly obtained. The phosphine was isolated as the silver iodide complex, which, when warmed *in vacuo*, readily evolved the phosphine.

The reaction of trimethylphosphine with trifluoroiodomethane, as described by Haszeldine and West (2), was used to prepare dimethyl trifluoromethylphosphine, but yields higher than 33% based on CF_3I could not be obtained. The reaction appeared to commence below −78° and was virtually complete after the mixture had stood at room temperature for about 30 minutes. Apart from the desired product and an involatile residue of tetramethylphosphonium iodide, a volatile white solid identified as dimethyl bis(trifluoromethyl)phosphonium iodide, m.p. 60°, was also found. The latter compound (0.472 g) reacted with excess aqueous sodium hydroxide at room temperature to give fluoroform (0.235 g) corresponding to the loss of two CF_3 groups. Purification of the

[2]*Presented at the International Conference on Co-ordination Chemistry, London, April 1959.*

dimethyl trifluoromethylphosphine was best achieved by thermal decomposition of its silver iodide complex as described by Haszeldine and West.

Methyl bis(trifluoromethyl)phosphine was prepared by reacting tris-trifluoromethylphosphine with methyl iodide as described by Haszeldine and West (3).

The preparation of tris(trifluoromethyl)phosphine from phosphorus and trifluoroiodomethane followed the methods of earlier workers (4).

Commercial boron trifluoride was used after purification by vacuum distillation. Platinum (II) chloride was prepared by heating chloroplatinic acid to 325° in an atmosphere of nitrogen. The complexes described below were prepared by reacting the phosphines with boron trifluoride or platinum (II) chloride in sealed, evacuated tubes. The identities of the boron trifluoride derivatives were determined from the ratios of the reactants and those of the platinum (II) chloride complexes by standard methods of analysis. Saturation pressures were measured with an isoteniscope, the boron trifluoride compounds being prepared directly in its bulb in order to avoid decomposition with moisture.

Compounds with Boron Trifluoride

(*a*) *Trimethylphosphine.*—The phosphine (0.1995 g, 2.60 mmoles) reacted immediately with boron trifluoride (0.1927 g, 2.79 mmoles) to give a white solid. The recovery of excess trifluoride (0.0031 g) gave a ratio phosphine:boron trifluoride of 1:1. The compound $(CH_3)_3P.BF_3$ has been reported previously (5) but few of its properties have been described. It is decomposed slowly in moist air, and rapidly in water, acetone, and ethanol. It is only slightly soluble in chloroform and insoluble in carbon tetrachloride and carbon disulphide. The melting point is 126–130° (decomp.) and the saturation pressure is given by the equation $\log_{10} p$ (mm) $= 8.460-(2627/T)$ in the range 25°–100°, whence the heat of sublimation is 11.98 kcal mole^{-1}.

(*b*) *Dimethyl trifluoromethylphosphine.*—The phosphine (0.2952 g, 2.27 mmole) reacted with boron trifluoride (0.1589 g, 2.27 mmole) to give a white solid which melted below room temperature to a viscous liquid. The compound showed the same behavior towards moist air and polar solvents as its trimethylphosphine analogue. The melting or freezing point could not be precisely determined since supercooling to a glass occurred. Softening of the glass took place at approximately −9° C. The vapor pressure of the compound is given by the equation $\log_{10} p$ (mm) $= 10.354-(2146/T)$ whence the heat of vaporization is 9.68 kcal mole^{-1}.

(*c*) *Methyl bis(trifluoromethyl)phosphine.*—In this case, no reaction occurred after 120 hours at room temperature between the phosphine (0.2690 g) and boron trifluoride (0.0938 g). Cooling to −78° still allowed the boron trifluoride to be recovered and there was no sign of complex formation. Similarly, the treatment of tris(trifluoromethyl)-phosphine (0.3106 g) with boron trifluoride (0.1934 g) failed to reveal the formation of any complex.

Compounds with Platinum (II) *Chloride*

(*a*) *Trimethylphosphine.*—The complex $[(CH_3)_3P]_2PtCl_2$ has been prepared previously (6) but it was here prepared for comparison with its trifluoromethyl analogues. Direct reaction between the phosphine and platinum (II) chloride in the absence of a solvent was very slow. In a benzene suspension, reaction was more rapid although the yield was still low. Thus trimethylphosphine (0.195 g) shaken for 24 hours with platinum (II) chloride (0.3345 g) in benzene gave only 0.10 g of the complex, a 20% yield. Higher yields could be obtained by using the method described by Jensen (7) for the preparation of the

For personal use only.

corresponding triethylphosphine complex. This involved shaking an aqueous solution of potassium chloroplatinite (1.20 g) with the phosphine (0.43 g). The mixture was heated on a steam bath for 30 minutes, and the white complex was filtered, and washed with water, alcohol, and ether. Recrystallization from methanol gave a yield of 0.51 g, a 41% yield of bis(trimethylphosphine)dichloroplatinum (II). Found: Pt, 45.5; Cl, 17.0. Calc. for $[(CH_3)_3P]_2PtCl_2$: Pt, 44.7; Cl, 16.1%. The melting point is 324–326° and the dissociation pressure in the range 155–190° is given by the equation $\log_{10} p$ (mm) $= 6.510 - (2108/T)$, whence the heat of dissociation is 9.59 kcal mole^{-1}. The complex dissolves readily in chloroform, is sparingly soluble in ethanol, and almost insoluble in ether, benzene, and carbon tetrachloride. In water, particularly when heated, decomposition occurs and the free phosphine is evolved.

(*b*) *Dimethyl trifluoromethylphosphine.*—The reaction of the phosphine (0.412 g, 3.17 mmoles) with platinum (II) chloride (0.425 g, 1.59 mmoles) at room temperature for 48 hours in a sealed tube gave a pale yellow product, which was recrystallized from methanol to give white, needle-shaped crystals of bis(dimethyl (trifluoromethyl)-phosphine)dichloroplatinum (II). Found: Pt, 37.2; Cl, 13.2. Calc. for $[(CH_3)_2PCF_3]_2PtCl_2$: Pt, 37.1; Cl, 13.5%. The complex melted at 188–190° with decomposition and the dissociation pressure over the range 90–130° is given by the equation $\log_{10} p$ (mm) $= 7.969 - (2438/T)$ whence the heat of dissociation is 11.31 kcal mole^{-1}. It is soluble in alcohol, chloroform, and carbon disulphide and insoluble in ether, benzene, and carbon tetrachloride. It is not soluble in cold water, but reacts slowly with hot water to evolve fluoroform. Almost complete conversion (90%) to fluoroform is obtained on heating to 80° with 25% aqueous sodium hydroxide.

(*c*) *Methyl bis(trifluoromethyl)phosphine.*—This phosphine and platinum (II) chloride in a 2:1 ratio reacted only slowly and unreacted phosphine was always recovered from the reaction tubes. Extraction of the solid reaction product with carbon tetrachloride or methanol and evaporation of the extract gave yellow crystals of bis(methyl bis(trifluoromethyl)-phosphine)dichloroplatinum (II). Found: Pt, 29.9; Cl, 11.2. Calc. for $[CH_3P(CF_3)_2]_2$-$PtCl_2$: Pt, 30.7; Cl, 11.2%. The melting point is 85–87° and the dissociation pressure in the range 80–140° may be expressed as $\log_{10} p$ (mm) $= 4.885 - (1258/T)$ whence the heat of dissociation is 5.76 kcal mole^{-1}. The complex is soluble in carbon tetrachloride, ether, acetone, and alcohol, but is insoluble in water. Hydrolysis (50% approx.) to fluoroform occurs with 25% aqueous sodium hydroxide at 80°.

(*d*) *Tris(trifluoromethyl)phosphine.*—The following experiments were performed in attempts to prepare a platinum (II) complex. In all cases the reactants were completely recovered and no sign of complex formation was observed. (*i*) Direct reaction of the phosphine (0.175 g) and platinum (II) chloride (0.132 g) at room temperature. (*ii*) The passage of the phosphine in a stream of nitrogen over platinum (II) chloride heated to 200°. (*iii*) Reaction of the phosphine and platinum (II) chloride in methanol. Several experiments were performed under this last set of conditions and in all cases the methanol acquired a yellow color and a few colorless crystals appeared to be formed. All attempts to isolate a product were unsuccessful, apparently because of decomposition.

Dipole Moments

Because of the low solubility of the platinum complexes and also their tendency, in certain cases, to decompose slowly in the presence of moisture, accurate dipole moments were not calculated. The dielectric constants were measured with a simple Ebarch dielectric constant meter and dipole moments were calculated using Jensen's formula (8) for dilute solutions. The accuracy of the dipole moments is ± 0.5 D.

TABLE

DISCUSSION

The addition compounds formed by phosphines with boron trifluoride result from dative σ-bond formation from phosphorus to boron. Smaller secondary effects such as back co-ordination may also be involved but these are of only minor importance. Evidence from other series of BF_3 derivatives (9), comparable to that described here, reveals that a decrease in the electron-donating power of the co-ordinating base produces a corresponding decrease in the stability of the molecular addition compound. As a qualitative measure of stability, we have here employed relative volatilities. The vapor pressure equations quoted above show the lower volatility and greater stability of $(CH_3)_3P.BF_3$ as compared with $(CH_3)_2PCF_3.BF_3$. The trifluoromethyl group thus markedly reduces the donor properties of the phosphorus atom. This is in accordance with a higher electronegativity and a smaller inductive effect for the trifluoromethyl in contrast to the methyl group.

Since the adduct $(CF_3)_3P.BH_3$ does not exist (10) and since borine adducts are generally more stable than their boron trifluoride analogues, it is not surprising that methyl bis(trifluoromethyl)phosphine– and tris(trifluoromethyl)phosphine–boron trifluoride adducts could not be isolated.

The possibility that steric interaction by the much larger CF_3 group is responsible for the observed decrease in stability must also be considered, although the extent of such interaction is difficult to determine accurately. The steric requirements will certainly be greatest for tris(trifluoromethyl)phosphine for which Bowen (11) has shown the CPC angles to be 100° and the CF_3 groups all to lie on the same side of the phosphorus atom. Also since there is some rearrangement of the planar BF_3 molecule towards a tetrahedral configuration on formation of the co-ordinate bond, it would appear that steric interaction between the CF_3 groups and F atoms must be comparatively small. For the other phosphines with fewer CF_3 groups, steric interactions will be of even less significance. The observed decrease in stability of the BF_3 adducts is therefore not due to steric effects.

The infrared spectra of $(CH_3)_3P.BF_3$ and $(CH_3)_2PCF_3.BF_3$ could not be completely resolved so that full interpretation is not possible. However, in both cases the B—F stretching frequencies at 1450 and 1505 cm^{-1} in BF_3 were shifted to the 1175–1200 cm^{-1}. This is similar to the shifts observed for ketone–BF_3 complexes by Susz *et al.* (12). There is also a considerable shifting of bands in the 650–750 cm^{-1} region. Since both the BF_3 bending and P—C (aliphatic) stretching frequencies occur in this region and since no other similar spectra are available for comparison, assignments have not been made.

In phosphine – platinum (II) co-ordination compounds, in addition to the formation of dative σ-bonds from phosphorus to platinum, strong $d\pi$–$d\pi$-bonding is also possible and appears to be of considerable importance in determining relative stabilities. As an extreme

case, consider bis(trifluorophosphine)dichloroplatinum (II) $(F_3P)_2PtCl_2$ (13). Here the highly electronegative fluorine atoms reduce the electron donor properties of phosphorus, but at the same time cause considerable π-bonding which appears to involve the unshared *d*-electron pairs of platinum and the vacant 3*d* orbitals of the phosphorus atoms. The extent of this electron drift from platinum back to phosphorus is shown by the small dipole moment of 4.4 D. This indicates a *cis*-configuration and must be compared with values of 11–12 D for the *cis*-isomers of bis(trialkylphosphine)dichloroplatinum (II) complexes. Similarly, the substitution of trifluoromethyl for methyl groups may tend to give increased π-bonding between platinum and phosphorus although not to the same extent as phosphorus trifluoride.

The configurations of the complexes described earlier can be deduced from their colors, solubilities in polar and non-polar solvents, and their dipole moments. Bis(trimethylphosphine)dichloroplatinum (II) and bis(dimethyl trifluoromethylphosphine)dichloroplatinum (II) are obtained as the *cis*-isomers since they are white solids and have large dipole moments. Bis(methyl bis(trifluoromethyl)phosphine)dichloroplatinum (II) is isolated in the *trans*-form which is yellow-orange and has a zero dipole moment. It must be emphasized that these are the major components of reaction products prepared and recrystallized under the same conditions. In all three cases there were indications that the other isomer was also formed but only to the extent of less than about 5%. Since it is known that the isomer obtained under a given set of conditions may depend to some extent on relative solubilities, it would clearly be necessary to study in detail the *cis–trans* equilibria in order to determine unambiguously the relative stabilities of the isomers of the various complexes. However, since all our complexes could be prepared under identical conditions in the absence of solvents, the fact that different isomers are obtained with dimethyl trifluoromethylphosphine and methyl bis(trifluoromethyl)phosphine is significant and is discussed later.

The relative stabilities of these new phosphine complexes may be examined in several ways. Chemically, the trimethylphosphine complex appears the least stable since decomposition always occurs to a small extent during recrystallization from methanol, and to a much larger extent on reaction with warm water. Also, the solid compound always smells strongly of the free phosphine. In contrast the other two complexes were odorless solids which could be recrystallized without decomposition and which reacted only slowly with hot water. An accurate index of thermal stability is seen in the heats of dissociation calculated from the observed dissociation pressures, the values being 6.7 kcal $mole^{-1}$ for *cis*-$[(CH_3)_3P]_2PtCl_2$, 11.3 kcal $mole^{-1}$ for *cis*-$[(CH_3)_2PCF_3]_2PtCl_2$, and 5.8 kcal $mole^{-1}$ for *trans*-$[CH_3P(CF_3)_2]_2PtCl_2$. The process of dissociation probably involves the loss of a phosphine molecule and the formation of a dimeric bridged complex,

$$2(\text{phosphine})_2PtCl_2 \rightarrow 2\text{phosphine} + (\text{phosphine})_2Pt_2Cl_4$$

but it could alternatively result in the simultaneous loss of both phosphine molecules to give free platinum (II) chloride. Although the actual course of dissociation is unknown, the above values are considered a reasonable guide to relative stabilities of the platinum complexes and they show the order to be

$$(CH_3)_3P < (CH_3)_2PCF_3 > CH_3P(CF_3)_2[> P(CF_3)_3].$$

Points of particular interest are: (*a*) the increase and then decrease in stability in the series as CF_3 is substituted for CH_3; (*b*) the non-existence, under the conditions so far studied, of a Pt(II) complex of tris(trifluoromethyl)phosphine; and (*c*) the fact that, under

the same conditions, dimethyl (trifluoromethyl)phosphine gives the *cis*-isomer, while methyl bis(trifluoromethyl)phosphine produces the *trans*-isomer. In platinum (II) complexes the greatest degree of π-bonding is obtained when the two π-bonding ligands are *cis* to one another (14). Substitution of the first methyl group by the more electronegative CF_3 group thus appears to give greater stability to the complex by causing a greater increase in π-bonding than is offset by the reduction in strength of the σ-bond. This can also be seen by a comparison of the dipole moment of 13.1 D for $[(CH_3)_3P]_2PtCl_2$ with that of 9.2 D for $[(CH_3)_2PCF_3]_2PtCl_2$. For the complex of methyl bis(trifluoromethyl) phosphine there might be expected to occur one of only two possibilities: (*a*) introduction of the second CF_3 group on each phosphine might produce even greater stability; or (*b*) the reduction in strength of the σ-bond may more than offset any increase in π-bonding so as to give a less stable complex. In either case, one might expect that the *cis*-isomer would be obtained. The occurrence of the *trans*-isomer is therefore unexpected, and can satisfactorily be explained, together with the non-existence of a tris(trifluoromethyl)-phosphine complex, in terms of steric hindrance. When models are drawn using the usual values of atomic radii, it can be shown that 2 trimethyl(or indeed any alkyl)phosphine molecules can be placed *cis* to one another about a platinum atom, but not 2 tris(trifluoromethyl)phosphine molecules. The observed effects are certainly not just due to the decreased donor properties of the phosphines since the *cis*-isomer of bis(trifluorophosphine)-dichloroplatinum (II) is known and is more stable than its *trans*-isomer. The importance of steric effects for the trifluoromethylphosphines is also shown by the fact that nickel carbonyl derivatives have been obtained (15) in which no more than 2 of the carbon monoxide molecules can be replaced by tris(trifluoromethyl)phosphine. In contrast, the more electronegative and more weakly electron-donating but much smaller PF_3 molecule can occupy all four positions to give $Ni(PF_3)_4$ (16).

Although these stability orders for the boron trifluoride and platinum (II) chloride derivatives might well be investigated further by the determination of thermodynamic values, particularly the thermodynamic differences between *cis*- and *trans*-isomers, the present information does emphasize the high electronegativity of the trifluoromethyl group, as well as the importance of π-bonding in transition metal complexes.

HYDROGEN BONDING IN DIASTEREOISOMERIC α-β AMINOALCOHOLS: A REINVESTIGATION OF THE EPHEDRINES BY N.M.R.[1]

JAMES B. HYNE[2]

ABSTRACT

The results of an n.m.r. study of the diastereoisomeric ephedrine and ψ-ephedrine molecules in non-polar solvents are interpreted and discussed in terms of the relative stabilities of the intramolecularly hydrogen-bonded conformers.

INTRODUCTION

The presence of two different asymmetric centers in the ephedrine molecule accounts for the existence of four optically active forms of the molecule. Previous configurational analysis of the ephedrines (1, 2, 3) has established the configuration of the two centers in all four forms of ephedrine as summarized in Table I. Considerable chemical evidence has accumulated which suggests that there is preferred spatial distribution of the hydroxyl and amino functional groups in the ψ-ephedrines which differs from that in the ephedrines.

TABLE I

Configuration of the ephedrines

$C_6H_5\underset{\uparrow}{C}H(OH)\underset{\uparrow}{C}H(NHCH_3)CH_3$

C_O C_N

(+)-ψ-ephedrine	$C_O(+)C_N(+)$	(−)-ephedrine	$C_O(-)C_N(+)$
(−)-ψ-ephedrine	$C_O(-)C_N(-)$	(+)-ephedrine	$C_O(+)C_N(-)$

C_O, center configuration related to (+)- and (−)-mandelamide.
C_N, center configuration related to (+)- and (−)-alanine.

Emde (1) first suggested that this conformational difference existed and the work of Welsh (4), Nagai and Kanoa (5), and Fodor and Koczka (6) further suggested that in the ψ-ephedrines the hydroxyl and amino functional groups were spatially in a preferred gauche conformation, while in the ephedrines the *trans* disposition about the C_O—C_N bond was preferred. Close (7) explained the production of an oxazolidone from ψ-ephedrine on fusion with urea compared with an imidazolidone on similar treatment of ephedrine on the basis of a preferred gauche disposition of the hydroxyl and amino groups in ψ-ephedrine compared with *trans* in ephedrine. This conformational difference is reflected in the mechanism of ring closure to form the oxazolidone or imidazolidone, in the former case by elimination of ammonia and in the latter case of water. Everett and Hyne (8) reported approximate calculations of the energetically most favorable conformations for the two forms of ephedrine based on the repulsive interactions between non-bonded groups on the C_O and C_N centers and ignoring specific interactions between the hydroxyl and amino groups. These rough calculations give surprisingly good agreement with the chemical evidence showing that in the ψ-ephedrine the angle between the C_O—OH and C_N—$NHCH_3$ bonds, looking down the C_O—C_N axis, is 60° and in the ephedrine case 180°.

Phillips (9) has reported the X-ray crystallographic data on both ephedrine and ψ-ephedrine hydrochlorides. In these crystal lattices the hydroxyl and amino functional

[1]*Manuscript received October 6, 1959.*

[2]*Present address: Department of Chemistry, Dartmouth College, Hanover, N.H., U.S.A.*

groups were found to be gauche to one another in both forms of the hydrochloride. However, as Phillips points out, the presence of the chloride ion in the lattice probably constrains these groups to adopt a gauche conformation, but this need not apply under other conditions of aggregation of the ephedrine molecules. Kanzawa (10) has recently reported that the infrared spectra of (−)-ephedrine and (+)-ψ-ephedrine indicate a greater predominance of intramolecularly hydrogen-bonded species in solutions of the ψ-isomer in non-polar solvents, and interprets this observation in terms of the preferred gauche conformation of the hydroxyl and amino groups.

The development of high resolution n.m.r. techniques provides a further tool for the investigation of this type of problem, and although in the case of the ephedrines the conformational differences have already been convincingly demonstrated by other methods a reinvestigation by n.m.r. serves to establish the applicability of this technique to such problems. Various n.m.r. studies of the chemical shift associated with hydroxylic hydrogens have shown that the chemical shift depends upon the degree to which these hydrogens are involved in hydrogen bonding (11, 12, 13, 14). None of the previous n.m.r. studies of this kind, however, have considered the case where intramolecular hydrogen bonding is only possible in a particular conformer and the various conformers are separated by relatively low energy barriers resulting from steric hindrance to free rotation about a single bond. Clearly, the application of n.m.r. techniques to such problems would be of particular value in the many conformational problems associated with the stereochemistry of aminoalcohols, diols, and related systems. An additional advantage of the n.m.r. method over the infrared method lies in the fact that the n.m.r. technique involves measurement of the peak *position* which can be determined with considerably greater precision than the *areas* of infrared absorption peaks, which frequently overlap to a considerable extent.

If the conformational difference suggested by previous work is real then the ψ-ephedrine isomer should show a much higher degree of intramolecular hydrogen bonding which should be less sensitive to breakdown as a result of dilution compared with the ephedrine diastereoisomer in which there is a greater degree of intermolecular hydrogen bonding. A study of the chemical shift associated with the hydroxyl and amino hydrogens as a function of concentration should, therefore, reveal a difference in behavior in the two ephedrine forms. Furthermore, the intermolecular hydrogen bond might be expected to be more sensitive to temperature changes than the intramolecular bond. The results of the study of both the concentration and temperature dependence of the resonance frequency of the hydroxyl and amino hydrogens are reported in this paper.

N.M.R. SPECTRA

Spectra were measured with a Varian V 4300 spectrometer operated at a fixed frequency of 40 megacycles. Samples were spun in 12-mm inside diameter tubes and temperature maintained at 20°±1° except where otherwise specified. Chemical shifts, in c.p.s. from benzene as an external standard, were measured by standard side-band techniques with an accuracy of ±2 c.p.s. or better. Solutions were prepared by dilution of a master solution prepared by weight. Attempts to measure spectra in carbon tetrachloride as solvent were unsuccessful due to reaction of the ephedrines with the solvent and precipitation of hydrochlorides. A similar reaction was found to take place in chloroform but only after several weeks of standing and could not be detected when the solution was stored in the dark. Even under conditions of normal illumination no evidence could be found of reaction of this type during the normal period required to prepare solutions and take spectra.

A single peak only was observed for both the NH and OH hydrogens (ν_{obs}) at all except very low concentrations at which it was difficult to distinguish between real splitting and noise effects. The single peak probably arises from rapid exchange of the hydrogens catalyzed by trace amounts of acid in the solvent.

Concentration Dependence of ν_{obs}

Figure 1 shows the dependence of the chemical shift associated with the NH and OH hydrogens on the concentration, c, in chloroform expressed in moles per liter of solvent. The observed difference in behavior for the two diastereoisomeric forms can be summarized as: (*a*) at any given concentration the frequency observed (ν_{obs}) for ψ-ephedrine is always lower than that for ephedrine; (*b*) the rate of increase of ν_{obs} with dilution is initially greater in the ψ-ephedrine case; (*c*) the ν_{obs} for ψ-ephedrine appears to approach a limiting value at the lowest concentrations measured, but that for ephedrine shows no such behavior within the experimental range of concentrations studied.

Huggins, Pimentel, and Shoolery (12) have previously reported chemical shift behavior of a similar type in the n.m.r. spectra of *o*-, *m*-, and *p*-chlorophenol. The concentration dependence of the *o*-chlorophenol OH resonance frequency reaches a maximum value for the frequency at low concentrations, while that of the *m*- and *p*-chlorophenol continues to increase throughout the dilution range studied. These authors attribute the differing behavior to the ability of the *o*-chlorophenol to hydrogen-bond intramolecularly, a phenomenon which is prohibited in the *m*- and *p*-chlorophenols for steric reasons.

In the ephedrine systems we consider a cyclic equilibrium between three species: P, an intermolecularly hydrogen-bonded polymer characterized by an NH/OH frequency ν_P; H, an intramolecularly hydrogen-bonded monomer with frequency ν_H; and M, an unhydrogen-bonded monomer with frequency ν_M. Clearly, we could consider various types of polymer, but as was shown previously by Saunders and Hyne (14) a model of this type involving equilibria between various types of n-mers leads to a result which is experimentally indistinguishable from one assuming a monomer–dimer equilibrium only. Assuming that the frequencies associated with the various species P, H, and M are

approximately equal for both forms (i.e. $\nu_P(\psi\text{-ephedrine}) = \nu_P(\text{ephedrine})$ etc.) a knowledge of the values of these frequencies would enable a quantitative interpretation of the observed data in terms of the equilibria postulated. Unfortunately, however, these values are not available from the data since the limiting value of ν_{obs} in either case can not be assumed to be the value for any single species of monomer. Despite the lack of this precise information we can interpret the data qualitatively in terms of the relative values of the equilibrium constants for the various processes in the cyclic equilibrium.

From the data in Fig. 1 we can deduce the relative magnitudes of ν_P, ν_H, and ν_M. It is known that the frequency associated with hydrogen-bonded hydrogen is lower than that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

for unhydrogen-bonded hydrogen, therefore ν_P and ν_H must be less than ν_M. The relative values of ν_P and ν_H can be estimated from the observed slopes of the frequency versus concentration curves and the low concentration behavior. If ν_P and ν_H were equal, dissociation to hydrogen-bonded monomer H would not affect ν_{obs} and the observed greater slope of the ψ-ephedrine curve would be due entirely to easier dissociation to unhydrogen-bonded monomer M compared to the ephedrine case. This easier dissociation to unhydrogen-bonded monomer in the ψ-ephedrine system, however, is not in keeping with the observed behavior at low concentration. The approach to a limiting ν_{obs} which is considerably less than that observed for ephedrine clearly indicates that ψ-ephedrine does not dissociate more readily to the highest frequency monomer M. We therefore conclude that the relative order of magnitude of the frequencies must be $\nu_P < \nu_H < \nu_M$.

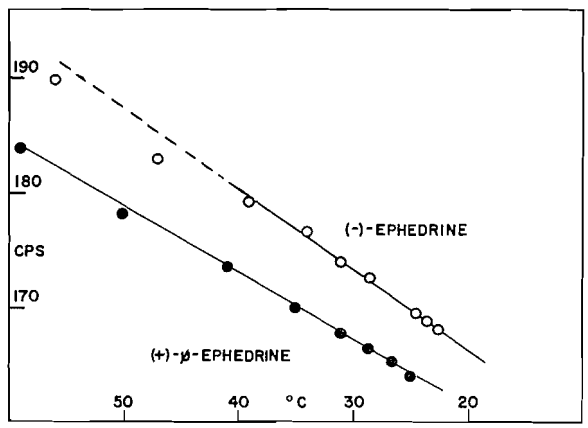

FIG. 1. The concentration dependence of resonance frequency for NH/OH hydrogens in c.p.s. from benzene (external) for ephedrine and ψ-ephedrine in chloroform solution. Concentration, c, in moles/liter.

The polymeric forms P of both ephedrines may dissociate to either one of two species, H or M. The data show that on initial dilution the ψ-ephedrine polymer dissociates more easily to the hydrogen-bonded monomer H with intermediate ν_H value. This will account for the greater observed slope and also the fact that at low concentrations the ν_{obs} tends to a limiting value which must be intermediate between that for ν_H and ν_M since both forms of the monomer exist in equilibrium. In terms of the dissociation constants this means that $K_{PH} > k_{PH}$ and $k_{PM} > K_{PM}$. That is, the hydrogen-bonded monomer of ψ-ephedrine is more stable relative to the unhydrogen-bonded monomer than the ephedrine counterpart, or $K_{HM} < k_{HM}$.

The concentration dependence of the NH/OH chemical shift for the two ephedrines therefore provides convincing evidence of the greater stability of the intramolecularly hydrogen-bonded ψ-ephedrine species, a conclusion which can only be rationalized in terms of the preferred gauche conformation of the hydroxyl and amino groups in the ψ-ephedrine diastereoisomer.

The Temperature Dependence of ν_{obs}

If, as has been suggested above, the ψ-ephedrine hydrogen-bonded species in the equilibrium mixture contain a greater proportion of intramolecularly hydrogen-bonded monomer than the ephedrine system at the same concentration, then the temperature dependence of ν_{obs} should differ in the two forms. This will only be true if the strengths of the inter- and intra-molecular bonds are different, but it seems reasonable to assume

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

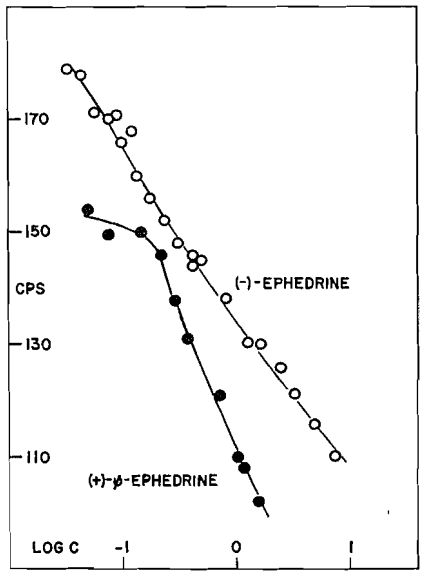

FIG. 2. The temperature dependence of resonance frequency for NH/OH hydrogens in c.p.s. from benzene (internal) for ephedrine and ψ-ephedrine in benzene solution.

that the intramolecular hydrogen bond will be less sensitive to temperature change than the intermolecular hydrogen bond. Figure 2 shows the temperature dependence of ν_{obs} for the two diastereoisomers in benzene solution. Benzene was used as a solvent rather than chloroform to avoid complication at higher temperatures arising from the reaction with solvent mentioned previously and in order to obtain a higher boiling solvent. Any shifts due to the anisotropy of the benzene will not seriously affect an argument based on the comparison of two isomers in the same solvent. The observed difference in temperature dependence is small but there is evidence at lower temperatures of a somewhat greater sensitivity to temperature in the case of ephedrine. Since only a proportion of the ψ-ephedrine hydrogen-bonded species will be intramolecularly hydrogen bonded and only these species will contribute to the reduction in temperature dependence compared with ephedrine the small observed difference is explicable. Furthermore, the intra- and intermolecular hydrogen bond strengths may differ by less than a kilocalorie and at most by no more than three or four. Although, in itself, the temperature dependence cannot be considered strong evidence for the preferred gauche conformation of the functional groups in ψ-ephedrine the small difference noted is in the direction to be expected on the basis of other evidence.

CONCLUSIONS

The concentration dependence of the chemical shift associated with the amino and hydroxyl hydrogens in the diastereoisomeric ephedrines provides good evidence for preferential residence of the ψ-ephedrine in the gauche form compared with the ephedrine isomer. Although the temperature dependence of the shift does not provide convincing evidence, the small effect noted does support the same conclusion. The work of Huggins, Pimentel, and Shoolery (12) on the chlorophenols has established the value of n.m.r. studies of intramolecular hydrogen-bonding phenomena where the hydrogen-bonded groups are not free to rotate by virtue of the order of the bond joining them. This work shows that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

the method can be extended to systems where the restriction arises from steric factors rather than bond order. Therefore, studies of the dilution effect on chemical shift can provide additional criteria for establishing preferred conformations arising out of rotation about a single bond where the degree and type of hydrogen bonding vary with the conformation.

ACKNOWLEDGMENT

The author expresses his thanks to Dr. Martin Saunders of this laboratory for his helpful discussion during the course of this work.

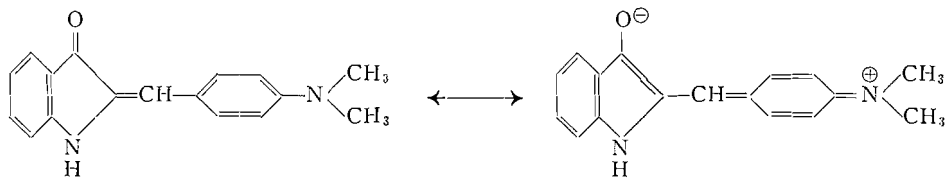
THE STRUCTURE OF 2-*p*-DIMETHYLAMINOBENZYLIDENEINDOXYL AND ITS SALTS[1]



R. A. ABRAMOVITCH[2] AND A. M. MARKO[3]

ABSTRACT

2-*p*-Dimethylaminobenzylideneindoxyl has been shown to have mainly the dipolar quinonoid structure (II), though quaternization takes place at the dimethylamino nitrogen atom in the unperturbed structure (I). This has been established by a study of its infrared and ultraviolet absorption spectra and by a comparison of these with those of its monohydrochloride, its methiodide, and of 2-benzylideneindoxyl.

A quantitative method of analysis of indican in urine has been devised (1) which involves the reaction of the indican-containing solution with *p*-dimethylaminobenzaldehyde and spectrophotometric measurement of the red color developed. The color was shown to be due to 2-*p*-dimethylaminobenzylideneindoxyl (I), which could be isolated as a purple crystalline solid exhibiting dichroism, and which was identical with the product prepared by Noelting (2) from indoxyl-2-carboxylic acid and *p*-dimethylaminobenzaldehyde. This compound is reported (2) to be a dyestuff and the deep color of the crystals was noteworthy. The ultraviolet absorption spectrum in 95% ethanol exhibited an intense band at 510 mμ (ϵ = 21,300) which did not seem to be compatible with the unperturbed structure (I). In dilute hydrochloric acid the color of the solution is a light orange-yellow, the intense band in the ultraviolet at 510 mμ being replaced by a weaker one at 497 mμ (ϵ = 15,620).

The deep color of 2-*p*-dimethylaminobenzylideneindoxyl would be understandable if canonical structure (II) was the main contributor to the resonance hybrid:

(I) (II)

Support of this suggestion was readily obtained from a consideration of the infrared and ultraviolet spectra of the base and some of its derivatives. In fact, the infrared spectrum of the solid dyestuff showed a medium-to-weak band at 1655 cm^{-1}. Because of the low intensity ($\Delta\nu_{\frac{1}{2}}$ for most of the bands in this region mentioned here are nearly comparable) and the position of this band, the band was considered unlikely to be due to the carbonyl group in (I). In fact, the ketonic carbonyl group in N-acetylindoxyl gives rise to a strong band at 1716 cm^{-1} and that in 1-methylindoxyl to a band near 1750 cm^{-1} (3). For the purpose of comparison the spectrum of 2-benzylideneindoxyl was recorded, and exhibited a strong conjugated carbonyl band at 1680 cm^{-1}. On the other hand, Edwards, Clarke, and Douglas (4) and Habgood and Marion (5*a*) have assigned a medium intensity band at 1668–1682

[1]*Manuscript received September 29, 1959.*

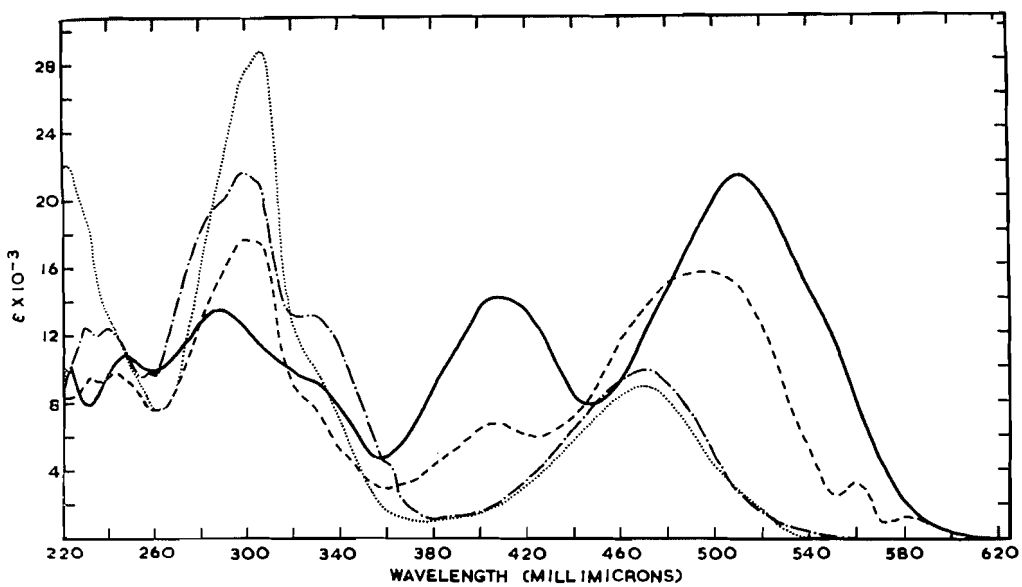
cm^{-1} to the grouping $C{=}\overset{\oplus}{N}\!\!<$ (see also Witkop and Patrick (5*b*)); such a grouping (conjugated in this case) is present in structure (II). The other bands observed in the 6-μ region may also be interpreted on the basis of structure (II): thus the strong bands at 1617 (sh) and 1607 cm^{-1} may be attributed to the conjugated C=C bonds and the band at 1558 cm^{-1} (s) to the highly conjugated enolate anion $\left(\begin{array}{c} O^{\ominus} \\ | \\ C{=}C \end{array}\right)$ (the enolate anion grouping is reported to give rise to a strong band at 1604 cm^{-1} (6)). Braunholtz, Ebsworth, Mann, and Sheppard (7) have shown that compounds containing an NMe or an $N\!<^{Me}_{Me}$ grouping exhibit a strong-to-medium band between 2760 and 2820 cm^{-1}. Salt formation or quaternization causes the disappearance of this band. No such band was observed in the infrared spectrum (KBr disk or hexachlorobutadiene mull) of 2-*p*-dimethylaminobenzylideneindoxyl. Evidence from ultraviolet absorption spectra also backs up the suggestion that (II) is the main contributory structure to the resonance hybrid. This evidence is as follows.

When a solution of 2-*p*-dimethylaminobenzylideneindoxyl in ethanol was treated with dilute hydrochloric acid, a marked change in color took place from reddish purple to yellowish orange. This was also accompanied by a change in the ultraviolet absorption spectrum (see Fig. 1). Thus, the intense band at 510 mμ underwent a hypsochromic shift



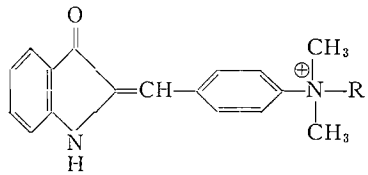


FIG. 1. ——— 2-*p*-Dimethylaminobenzylideneindoxyl in 95% ethanol. – – – 2-*p*-Dimethylaminobenzylideneindoxyl in 95% ethanol containing a small amount of HCl. —·—·— 2-Benzylideneindoxyl in 95% ethanol. ..... 2-*p*-Dimethylaminobenzylideneindoxyl methiodide in 95% ethanol.

to 497 mμ as well as a decrease in intensity. The intensity of the 407-mμ band also decreased, whereas the 288-mμ band underwent a bathochromic shift to 300 mμ as well as an increase in intensity. Since the monohydrochloride could not be isolated in a pure state and it was felt to be important to determine which atom had been protonated

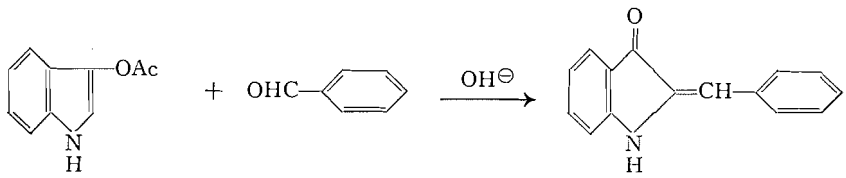
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

(the $-O^{\ominus}$ in (II) or the $-N(CH_3)_2$ in (I)), the crystalline methiodide was prepared instead. This showed a similar ultraviolet absorption to that of the hydrochloride with the changes above even more intensified, i.e. a stronger hypsochromic shift and decrease in intensity in the longer wavelength band, and an increase in the intensity of the shorter wavelength band. It is possible that the hydrochloride is only partially formed in solution and exists in equilibrium with the free base, or that there exists a tautomeric equilibrium between the N and O protonated forms, both of which hypotheses could explain the smaller hypsochromic shift observed.* This would indicate that in the formation of the salt, attachment of the proton or of the methyl group took place preferentially at the dimethylamino group of (I), thus resulting in a decrease in color due to the loss of the quinonoid structure, and to the fact that no resonating structures similar to (I) ↔ (II) can be written for (III) without invoking an inadmissible pentacovalent nitrogen atom.

(R = H or CH_3)

(III)

Support for structure (III; R = CH_3) was adduced from its infrared absorption spectrum which, unlike that of the parent 2-*p*-dimethylaminobenzylideneindoxyl, exhibited a strong band at 1686 cm^{-1} characteristic of the conjugated carbonyl group.



Conclusive supporting evidence for structures (II) (predominantly) and (III) assigned to the free base and salts respectively was obtained by a comparison of their ultraviolet absorption spectra with that of 2-benzylideneindoxyl (IV). Similar comparisons have very recently been carried out between *p*-dimethylaminoazobenzene and its methiodide, and azobenzene (9). Here the mesomeric effect of the dimethylamino group upon the ultraviolet absorption spectrum of the unsubstituted azobenzene is virtually nullified by quaternization, with the result that the spectra of azobenzene and *p*-trimethylammonium-azobenzene iodide are almost superimposable, whereas that of *p*-dimethylaminoazobenzene shows the expected bathochromic shift and increase in intensity due to the +M effect of the $-N(CH_3)_2$ group. When the ultraviolet absorption spectra of 2-*p*-dimethylaminobenzylideneindoxyl, its monohydrochloride, and its methiodide in ethanol were compared with that of 2-benzylideneindoxyl a comparable result to that reported (9) in the azobenzene series was observed (see Fig. 1). It is, therefore, concluded that though the quinonoid structure (II) is the main contributor to the structure of 2-*p*-dimethylaminobenzylideneindoxyl, quaternization occurs preferentially at the dimethylamino nitrogen atom.

When formation of the second conjugate acid of (II) was effected by dissolving the base in concentrated hydrochloric acid, the ultraviolet absorption spectrum changed markedly; the bands at 407 and 510 mμ in the base, and at 407 and 497 mμ in the monohydrochloride, disappeared and were replaced by a band at 380 mμ. This solution was unstable and the color soon faded.

2-Benzylideneindoxyl (IV) had previously been prepared by Baeyer by heating indoxylic acid with benzaldehyde at 120° (10). In the present work it was found more

**Yeh and Jaffé (8) have recently presented evidence that the formally related first conjugate acid of p-dimethylaminoazobenzene consists of a tautomeric mixture of the ammonium and azonium-quinoid forms.*

(IV)

convenient to obtain this compound by the condensation of indoxyl-*O*-acetate with benzaldehyde in aqueous alkali, the yield of product being nearly theoretical.

EXPERIMENTAL

The infrared spectra were measured in potassium bromide disks and in Nujol mulls using a Perkin–Elmer Model 21 double beam spectrometer with sodium chloride optics. Ultraviolet absorption spectra were determined using a Beckman DK 2 recording spectrophotometer.

2-p-Dimethylaminobenzylideneindoxyl

A filtered solution of crude indican (0.7 g) (from the oxidation of indole with potassium persulphate (11)) in water (150 ml) was treated with a 3% ethanolic solution of *p*-dimethylaminobenzaldehyde (75 ml), followed by 6 *N* hydrochloric acid (100 ml) whereupon the solution turned dark brown. After it was stirred for 1 hour the mixture was filtered and the purple solid (0.3 g) discarded (this may arise due to the presence of impurities in the crude indican). The filtrate was neutralized with 10% sodium hydroxide (25 ml) and saturated aqueous sodium acetate solution (200 ml), the precipitate (2.2 g) filtered, washed with water, and then with light petroleum. Unreacted *p*-dimethylaminobenzaldehyde was removed by washing with hot light petroleum (4×30 ml) and then once with hot ethyl acetate (20 ml). The last procedure resulted in the loss of some of the desired product. The product was recrystallized from benzene–cyclohexane giving long needles, m.p. 236–238°, which were green by reflected and red by transmitted light. Crystallization from alcohol gave purple needles. Noelting (2) reports m.p. 226°–227° for this compound while Gossner (12) reports 231–232°. Calc. for $C_{17}H_{16}ON_2$: C, 77.30; H, 6.11; N, 10.60. Found: C, 77.50; H, 6.08; N, 10.52. λ_{max} 248, 288, 407, 510, λ_{infl} 324 mμ; $\epsilon\times10^{-3}$ 10.89, 13.61, 14.21, 21.30, 9.54 (in 95% ethanol). λ_{max} 232, 244, 300, 407, 497, λ_{infl} 324 mμ; $\epsilon\times10^{-3}$ 9.48, 9.79, 17.70, 6.66, 15.62, 8.44 (in ethanolic hydrogen chloride).

Infrared spectrum (KBr disk) (main peaks only): 3240, 1655 (mw) (C=$\overset{\oplus}{\text{N}}$<, 1617 (sh) (s), 1607 (s) (conjugated C=C), 1558 (s) (C=C(–$O^{\ominus}$)–), 1545 (NH), 1526 cm^{-1}. Identical values were observed when the measurement was carried out on a Nujol mull.

Attempted Preparation of 2-p-Dimethylaminobenzylidene-N-acetylindoxyl

N-Acetylindoxyl (1.75 g) and *p*-dimethylaminobenzaldehyde (1.6 g) were boiled under reflux in 80% ethanol (25 ml) with 5 drops of concentrated hydrochloric acid for 5 hours. On cooling, the solution deposited crystals of 2-*p*-dimethylaminobenzylideneindoxyl, identical with those obtained above from indican. Working up the mother liquors only led to the isolation of intractable tars which, on chromatography on neutral alumina, could only be resolved into a number of tarry fractions which could not be induced to crystallize. When the reaction was carried out using piperidine as the catalyst instead of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

hydrochloric acid, similar results were obtained. The use of absolute instead of aqueous ethanol did not result in the isolation of any 2-*p*-dimethylaminobenzylideneindoxyl nor of any identifiable product.

2-p-Dimethylaminobenzylideneindoxyl Methiodide

This was prepared by adding an excess of methyl iodide to a suspension of 2-*p*-dimethylaminobenzylideneindoxyl in 95% ethanol; the flask was stoppered, shaken occasionally for 3 hours and left overnight. The purple solid gradually went into solution and the methiodide separated overnight as golden platelets which were recrystallized from ethanol after being washed with acetone. The product had m.p. 217–218° (after darkening at 204–205°). Calc. for $C_{18}H_{19}ON_2I$: C, 53.21; H, 4.68. Found: C, 53.02; H, 4.76. λ_{max} 306, 470, λ_{infl} 294, 326 mμ; $\epsilon \times 10^{-3}$ 28.70, 8.90, 24.50, 10.91 (in 95% ethanol). Infrared spectrum (Nujol mull) (main peaks only): 3300, 1686 (s) (>C=O) 1622 (s) (C=C), 1605 (s) (aromatic), 1589 (s), 1575 cm^{-1} (sh) (w).

2-Benzylideneindoxyl

Indoxyl-*O*-acetate (0.22 g) and benzaldehyde (0.135 g) in water (10 ml) containing 10 drops of 4 *N* sodium hydroxide were warmed on a water bath. A flocculent yellow precipitate began to separate immediately and the warm mixture was shaken until no more dark brown oil remained. The cooled product was extracted repeatedly with ether, the extract concentrated to a small volume, and cooled in a freezer at −17°. The crystals, which were obtained in nearly theoretical yield, were filtered and recrystallized at a low temperature from ether, yielding orange rods, m.p. 177–178°. Baeyer (10) reports m.p. 176° for this compound. λ_{max} 231, 241, 299, 470, λ_{infl} 284, 326, 358 mμ; $\epsilon \times 10^{-3}$ 12.50, 12.42, 21.60, 9.88, 19.10, 13.19, 4.60. Infrared spectrum (Nujol mull) (main peaks only): 3260, 1680 (s) (>C=O), 1625 (s) (C=C), 1604 (s), 1590 (s), 1560 cm^{-1} (sh) (m).

2-*p*-Dimethylaminobenzylideneindoxyl may be prepared conveniently and in high yield by substituting *p*-dimethylaminobenzaldehyde for benzaldehyde in this procedure.

ACKNOWLEDGMENTS

Financial support from the National Research Council (to R.A.A.) and from the Department of Public Health, Ottawa (to A.M.M.) are gratefully acknowledged. The authors are also indebted to Dr. L. Vining for the use of a recording ultraviolet spectrophotometer and to Mr. L. D. Johnson for technical assistance.

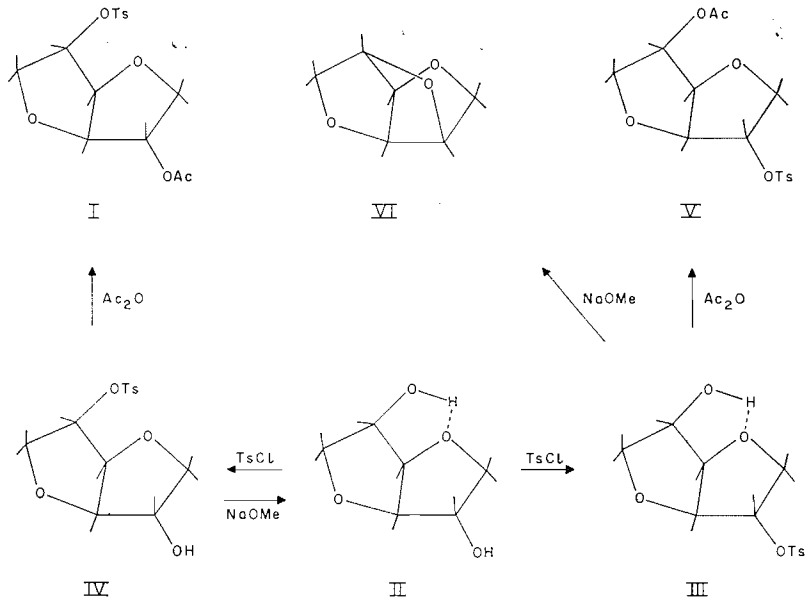
THE PREFERENTIAL TOSYLATION OF THE *ENDO*-5-HYDROXYL GROUP OF 1,4;3,6-DIANHYDRO-D-GLUCITOL[1]

R. U. LEMIEUX AND A. G. MCINNES

ABSTRACT



Reaction of 1,4;3,6-dianhydro-D-glucitol (isosorbide) with an equimolar amount of tosyl chloride in pyridine gave a fourfold greater yield of the *endo*-5-tosylate (IV) than of the *exo*-2-tosylate (III). Compound III reacted about 1.4 times more rapidly with tosyl chloride than did IV. The structures of III and IV were established by infrared spectroscopy and by their reaction with sodium methoxide. The *exo*-tosyloxy group of the monoacetate of III resists replacement by iodide ion.

Cope and Shen (1) reported the preparation of a mono-*O*-tosyl mono-*O*-acetyl 1,4;3,6-dianhydro-D-glucitol (mono-*O*-tosyl mono-*O*-acetyl isosorbide). Since the compound was converted (1) to 1,4;2,5;3,6-trianhydro-D-mannitol (VI) on treatment with sodium *t*-butoxide, it was concluded that the tosyl group in I was situated at the *exo*-2-position (compound V). However, Cope and Shen (1) reported unequivocal evidence that a transtosylation reaction can take place under these conditions and, consequently, the monotosylate may have had the tosyl group at the *endo*-5-position as shown in structure I. Recently, Jackson and Hayward (2) have shown the compound to undergo replacement of the tosyloxy group when heated with sodium iodide dissolved in acetic anhydride. This observation was taken as proof that the tosyloxy group was at the *endo*-5-position. It is conceivable, however, that the *endo*-acetoxy group of 2-*O*-tosyl 5-*O*-acetyl isosorbide (V) can participate in the solvolysis of the tosyloxy group to lead to a 2,5-bridged acetoxonium ion, which could then react with iodide ion to give the iodoacetate isolated by Jackson and Hayward (2). Thus, the reaction of the compound with sodium iodide could not be taken as unequivocal evidence that it possesses the structure I.

A consideration of a molecular model for isosorbide (II) shows that the *endo*-5-hydroxyl group is eclipsed with the oxygen atom which bridges the 1- and 4-positions, whereas the *exo*-2-hydroxyl is eclipsed only with hydrogen atoms. The non-bonded interaction between the eclipsed oxygen atoms should be especially unfavorable since it brings into close opposition carbon-to-oxygen bonds polarized in the same direction. This contention is supported by the fact that D-glucitol is converted more readily to the 1,4-anhydride which possesses a 2,3-*trans*-glycol, then to the 3,6-anhydride which possesses a 4,5-*cis*-glycol (3). It could be anticipated that the *endo*-5-hydroxyl group of isosorbide would be intramolecularly hydrogen bonded to the eclipsing 4-oxygen atom. This conclusion was supported by the observation (see below) that the *endo*-5-hydroxyl group of 2-*O*-tosyl isosorbide (III) in fact is involved in an intramolecular hydrogen bond.

Therefore, one might expect (1) that the *exo*-2-hydroxyl group of isosorbide (II) would undergo tosylation substantially more rapidly than the sterically shielded and hydrogen-bonded *endo*-5-hydroxyl group. *The main purpose of this communication is to show that precisely the opposite is in fact the case.* This observation clearly has an important bearing on the general subject of preferential esterification of alcoholic hydroxyl groups in the field of carbohydrate chemistry and in particular on the hazards of introducing

notions on the subject derived from studies of simple alicyclic alcohols into the field of carbohydrate chemistry.

Isosorbide (II) was reacted with 1 mole equivalent of tosyl chloride in pyridine at 5° for 40 hours (1, 2). The ditosyl derivative was obtained in 17.1% yield. The syrupy residue was chromatographed on silicic acid with chloroform as developing phase to yield a crystalline monotosylate (III) in 11.7% yield and an isomer (IV), which has resisted crystallization, in 45.4% yield. Acetylation of IV yielded the monotosyl monoacetate (I) previously prepared by Cope and Shen (1). Acetylation of the crystalline monotosylate (III) led to a mono-*O*-tosyl mono-*O*-acetyl derivative of II which has not crystallized. The structures of the monotosylates III and IV were readily established through their behavior in presence of sodium methoxide. Compound III consumed the base about 40 times more rapidly than IV at room temperature and led to the formation of 1,4;2,5;3,6-trianhydro-D-mannitol (VI). On the other hand, IV when heated in the presence of sodium methoxide was converted to isosorbide (II) in excellent yield. Clearly, therefore, compounds III and IV have the structures shown. This conclusion was supported by the fact that the compounds III and IV showed absorption maxima for the hydroxyl groups, in the infrared, at 3564 and 3624 cm^{-1}, respectively, when 0.0025 *M* in carbon tetrachloride. These results indicate intramolecular hydrogen bonding in compound III which can only be possible with the hydroxyl group at the *endo*-5-position. The *O*-acetyl derivative of III (V) was recovered in high yield after treatment with sodium iodide in refluxing acetic anhydride for 2.5 hours. Consequently, the acetoxy group of V is in fact not well disposed for participation in the dissociation of the tosyloxy group. We have confirmed the observation (2) that I undergoes facile replacement of the tosyloxy group by iodine under these conditions. It is of interest that compound I resisted refluxing in 4:1 acetic acid – acetic anhydride containing potassium acetate for 24 hours.

The phenomenon of the preferential tosylation of the *endo*-hydroxyl group of I was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

further substantiated by a study of the rates of tosylation of the monotosylates III and IV. The compound with the *endo*-hydroxyl group (III) reacted with tosyl chloride in pyridine at 25° approximately 1.4 times more rapidly than the isomer with the *exo*-hydroxyl group. It is not known whether or not this phenomenon is unique for the isosorbide structure. However, the literature suggests it may be of general importance in the esterification of polyhydric compounds. This matter is receiving further attention in this laboratory.

EXPERIMENTAL

Isosorbide (II) was prepared by the procedure of Montgomery and Wiggins (4). The white crystalline product melted at 62–63.5° (uncorr.) with $[\alpha]_D$ +44.6° (*c*, 1.78 in water) and +65° (*c*, 2.94 in pyridine). The reported values are m.p. 61.9–64°, $[\alpha]_D$ +44.8° (*c*, 2.22 in water) and +64.9° (*c*, 2.32 in pyridine) (5).

Reaction of Isosorbide (II) *with Tosyl Chloride*

Isosorbide, 13.2 g (0.905 mole), was dissolved in 100 ml pyridine and cooled to −5°. An equimolar amount of tosyl chloride (*p*-toluenesulphonyl chloride) was added and the reaction mixture stored at 5° for 46 hours. Any tosyl chloride present at the end of the reaction time was destroyed by the addition of 5 ml of distilled water to the reaction mixture, which was subsequently poured into 250 ml of distilled water and extracted with three 150-ml aliquots of chloroform. The combined chloroform extract was washed with concentrated hydrochloric acid to remove pyridine and then washed free of acid with distilled water. After drying over anhydrous sodium sulphate the chloroform solution was evaporated under reduced pressure at 50° to yield 22.6 g of a syrupy residue. The residue was dissolved in 100 ml 95% aqueous ethanol, and after the solution was left to stand overnight at 5°, 5.02 g of a white crystalline compound, m.p. 96–97° (uncorr.), was precipitated. The melting point and infrared spectrum of the substance were consistent with those expected for 2,5-di-*O*-tosyl isosorbide (6). The filtrate on evaporation under reduced pressure yielded 17.53 g of syrup.

The syrupy residue was chromatographed on 400 g silicic acid (Mallinckrodt) which had previously been activated at 120° for 24 hours. When the chromatogram was developed with chloroform, three fractions were cleanly separated in the following order: (*a*) a white crystalline compound, 2.00 g, the infrared spectrum of which was identical with that of 2,5-di-*O*-tosyl isosorbide; (*b*) a white crystalline compound (III), 3.18 g (11.7% of theory based on isosorbide), which after recrystallization from ethyl acetate melted at 108–109° with $[\alpha]_D$ +47.7° (*c*, 1.86 in chloroform); and (*c*) a colorless syrup (IV), 12.31 g (45.4% of theory), $[\alpha]_D$ +57.9° (*c*, 4.27 in chloroform). The total yield of ditosylate was 17.1% of theory.

A study, using a Beckman DK2 spectrometer, of the infrared spectra in the O—H stretching region of 0.0025 molar solutions of III and IV in carbon tetrachloride showed absorption at 3564 cm^{-1} and 3624 cm^{-1}, respectively. The latter is characteristic of the stretching vibration of a non-bonded secondary hydroxyl group, whereas the former shows a shift to lower frequency of 60 cm^{-1} which is characteristic of hydroxyl groups forming intramolecular hydrogen bonds.

Acetylation of 2-O-Tosyl (III) *and 5-O-Tosyl Isosorbide* (IV)

Samples of III, 1.74 g, and of IV, 5.31 g, were acetylated in pyridine with acetic anhydride at 5° to yield 1.80 g (90% theory) of 2-*O*-tosyl 5-*O*-acetyl isosorbide (V) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

5.70 g (94% theory) of 2-*O*-acetyl 5-*O*-tosyl isosorbide (I), respectively. V was a colorless oil, $[\alpha]_D$ +83.6° (*c*, 3.43 in chloroform), whereas I crystallized from methanol, 5.0 g (83% theory), m.p. 65.5–66° (uncorr.), and $[\alpha]_D$ +79.2° (*c*, 3.54 in chloroform). Reported (2) for 2-*O*-acetyl 5-*O*-tosyl isosorbide (I), m.p. 64–65° and $[\alpha]_D$ +77.9° (in chloroform). The nuclear magnetic resonance spectra of compounds I and V were in agreement with those expected for mono-*O*-acetyl mono-*O*-tosyl derivatives of isosorbide; furthermore, the infrared spectra were very similar. There could therefore be no doubt as to the composition of I.

Reaction of (III) *and* (IV) *with Sodium Methoxide*

The compounds III, 0.345 g (1.15 mmoles), and IV, 0.2905 g (0.97 mmole), were dissolved in 10 ml of methanol approximately 0.2 *N* in sodium methoxide and left standing at room temperature. At intervals, over a period of 72 hours, 1-ml aliquots were taken and titrated with 0.064 *N* hydrochloric acid. At the end of the reaction period, III had consumed 0.108 milliequivalent (94% theory) and IV 0.065 milliequivalent (17% theory) of the sodium methoxide. Assuming second-order kinetics, the ratio of the rate constants, k_{III}/k_{IV}, was approximately 40.

Compounds III, 0.2005 g (0.667 mmole), and IV, 0.4585 g (1.53 mmoles), were refluxed with 2 ml and 4 ml, respectively, of methanol approximately 1 *N* in sodium methoxide for 8 hours. After cooling to room temperature, the excess sodium methoxide was neutralized with solid carbon dioxide. The reaction mixtures were taken to dryness at room temperature under reduced pressure and the residues extracted with ether and acetone, respectively. After solvent removal, the residues were distilled under reduced pressure. Compound III yielded 0.0689 g (81% theory) of a crystalline compound, m.p. 68–68.6° the infrared spectrum of which showed no absorption in the O—H stretching or aromatic skeletal vibration regions and was consistent with that expected for 1,4;2,5;3,6-trianhydro-D-mannitol (VI). The trianhydride (VI) was reported (1) to melt at 66.5–67.2°. On the other hand, IV yielded 0.1566 g (70% theory) of a crystalline compound whose infrared spectrum was identical with that of isosorbide (II).

Rates of Tosylation

The rates of tosylation of III and IV were compared by reacting 0.2256 g (0.75 mmole) of the compounds with 2 mmoles of tosyl chloride in 5 ml of pyridine at 25°. One-milliliter aliquots of the solutions were taken at intervals and added to 5 ml of 90% aqueous pyridine and left standing for 5 minutes. Ten milliliters of distilled water was then added and the free acid determined by titration with 0.0882 *N* sodium hydroxide using phenolphthalein as indicator. A solution containing only tosyl chloride in the same molar concentration was used as control. The reaction of III was complete after 28 hours, whereas IV had reacted to the extent of 72% of theory after this time. Assuming second-order kinetics the ratio of the rate constants for the two reactions, k'_{III}/k'_{IV}, was approximately 1.4.

Reaction of Sodium Iodide with I *and* V

The compounds V, 1.43 g (4.2 mmoles), and I, 3.43 g (10 mmoles), were refluxed with 20 ml and 50 ml, respectively, of a 0.5 *M* solution of sodium iodide in acetic anhydride. After 2.5 hours the solutions were cooled to room temperature and the sodium tosylate was recovered by filtration and weighed as described by Jackson and Hayward (2). Compound V yielded 0.060 g (7.4% theory) and I yielded 1.78 g (92% theory) of sodium *p*-toluenesulphonate.

ADSORPTION EQUILIBRIA OF HYDROGEN, DEUTERIUM, AND THEIR MIXTURES. PART I[1]

D. BASMADJIAN[2]

ABSTRACT

Adsorption isotherms of hydrogen and deuterium have been measured at temperatures of 75–90° K and pressures up to 760 mm Hg on the following six adsorbents: charcoal (2), silica gel, and Linde molecular sieves type 4A, 5A, and 13X.

Deuterium was found to be adsorbed to a greater extent than hydrogen in all cases investigated, its isosteric heat of adsorption exceeding that of hydrogen by 50 to 300 cal/mole.

Binary adsorption isotherms were determined on the same adsorbents in the range 10–90% D_2 at temperatures of 75 and 90° K and a total pressure π of 750 and 200 mm Hg. The analyses were performed by the thermal conductivity method using thermistor sensing elements in a static system at atmospheric pressure. The device proved of exceptional stability, requiring no recalibrations and yielding an analytical accuracy of better than 0.02% deuterium content. The binary separation factors α were found to be constant over the concentration range investigated, with values for α varying from about 1.25 on charcoal to 2.54 on type 4A molecular sieves at 75° K and 750 mm Hg. The results suggest that the variations in α are due mainly to differences in chemical composition of the adsorbents rather than pore size, surface area, or origin of the materials.

INTRODUCTION

Among isotopes of the same element or compound the heavier species are usually preferentially adsorbed. The effect becomes more pronounced with decreasing molecular weight and experiments in this field have therefore mostly dealt with low molecular weight substances such as the neon (1, 2) and hydrogen isotopes. Separation of the latter by means of sorption has been investigated by a number of workers (Table I).

TABLE I

Summary of literature data on deuterium enrichment by sorption

Adsorbent	Temp., ° K	Pressure, mm Hg	Separation factor*	Ref.
(1) Binary equilibria

[2]*Present address: Assistant Professor, Department of Chemical Engineering, University of Ottawa, Ottawa, Ontario.*

The measurements usually consist in determining equilibrium separation factors (relative adsorptivities) α or analyzing the fractions obtained by slow desorption. A number of authors have also dealt with the gas chromatographic separation of the isotopes using supported palladium (10, 11) and type 5A Linde molecular sieves (12) as adsorbent.

From the results published so far, three major trends may be distinguished.

(*a*) Equilibrium separation factors show a marked increase with decreasing temperature and pressure, particularly at low values of the latter.

(*b*) By using the process of slow desorption, the equilibrium enrichment may be increased by factors as high as 1.7 (2).

The majority of data have been measured under conditions designed to yield maximum separations, i.e. pressures of 1 micron Hg or less and temperatures as low as 20° K. There are no published values of separation factors measured at temperatures and pressures suitable for use in the large-scale recovery of deuterium from natural hydrogen (75 to 100° K, 1 atm and above). The low values of α on charcoal at 77° K and 1 atm reported by Strange (4) give little reason to expect spectacular separations at these conditions and raise the problem of obtaining improved enrichments by means other than those mentioned above. The best prospects for achieving this appear to be in varying the adsorbent composition. Melkonian and Reps (2) have reported the enrichment on silica gel to be higher than on charcoal and it was thought to be of interest to measure separation factors on these and a number of other high capacity adsorbents at temperatures of liquid air and atmospheric pressure. In addition to charcoal and silica gel, measurements were made on the newly developed synthetic zeolites, Linde molecular sieves, which afford a means for determining any possible effects due to pore size. Single component isotherms of hydrogen and deuterium were also measured to provide additional data for the interpretation of the binary isotherms.

EXPERIMENTAL

The apparatus used is shown schematically in Fig. 1. Binary equilibria were determined by circulating hydrogen–deuterium mixtures of varying composition over the cooled adsorbent, equilibrium being assumed when the conductivity readings showed no further change (within $\pm 0.02\%$ D_2) over a period of $\frac{1}{2}$ hour. This was usually achieved within 2 to 3 hours after circulation was started. The adsorbed gases were then removed by means of the Toepler pump, and after the total volume was measured a sample was admitted to the conductivity cell for analysis. Single component isotherms were determined in the usual manner by admitting successive portions of the gases from a calibrated burette to the adsorbent. Pressures were measured by means of a McLeod gauge (below 5 mm Hg) and a U-tube manometer read to 0.05 mm Hg with a kathetometer. Constant readings were usually obtained within $\frac{1}{2}$ hour after the gases were admitted.

Liquid oxygen served as thermostat liquid, the appropriate temperature ($\pm 0.05°$) being maintained by pumping down the charge by means of aspirators through manually operated control valves. Temperatures were measured with calibrated oxygen and nitrogen manometers.

The binary gas mixtures were circulated by means of an oscillating mercury column contained in a side-arm between two ground-in glass valves. The reciprocating motion was generated by the alternating action of a vacuum pump and a solenoid relief valve.

Analytical Procedure

Analysis of the deuterium–hydrogen mixtures was carried out by the thermal conductivity method (13). Figure 2 shows a schematic diagram of the analysis cell and

Wheatstone bridge circuit. Considerable difficulty was experienced in eliminating the drift caused by the instability of the sensing elements and ambient temperature fluctuations. Platinum or tungsten wires used by previous workers (2, 6, 13–17) proved unsatisfactory as they required constant recalibration or elaborate precautions which resulted only in partial elimination of the drift (16). The danger, in addition, of a possible

reaction of the isotopes to HD in contact with the hot filaments led to the adoption of thermistors as sensing elements. These units, consisting of tiny, glass-coated beads of semiconducting oxides, could be completely stabilized by annealing at 100° C for a period of 3 weeks. The small size and low operating temperature of the elements makes it unnecessary to analyze at accurate reduced pressures, in order to minimize convection currents, as suggested by Trenner and others (14, 16). The bridge was balanced with both sides of the cell containing pure hydrogen at 1 atm and the current input set at approximately 5 ma. A Leeds Northrup type K-2 precision potentiometer was used to measure bridge unbalance, which varied almost linearly with deuterium content of the sample, ranging up to a maximum of 150 mv for pure deuterium. Current input was controlled within 10^{-6} amp by adjusting the potential drop measured across a standard resistance, and the cell was kept at constant temperature by pumping water thermostated to 1/50° C through the cell body. The analytical accuracy attained in this manner was better than $\pm 0.02\%$ deuterium content, the readings being reproducible over a period of several months. The performance exceeds that of previous units described in the literature and could quite possibly be improved even further if the device is used in a flow system (11, 12) where convection and ambient temperature changes become less important.

Since all the adsorbents used were found to catalyze ortho–para conversion, the calibrations were carried out with hydrogen which had previously been equilibrated over charcoal at the temperature to be used. An increase of 1% in para-hydrogen content was found to correspond to a decrease of 0.1% in deuterium concentration. Ortho–para deuterium conversion is small at the adsorption temperatures used and the difference in heat capacity at room temperature negligible (13). No change in the conductivity readings could therefore be detected. Prior to a series of runs each adsorbent was tested for possible preferential adsorption of ortho-hydrogen as suggested in a number of recent papers (5, 18, 19). A charge of pure equilibrated hydrogen was fractionally desorbed and the fractions analyzed. Conductivity measurements in all cases agreed within $\pm 0.02\%$ in terms of deuterium content. A number of tests were also made to establish the absence of catalytic HD-formation. It can be shown from calculations made by Trenner (16) that the formation of 1% HD from an equimolar mixture of hydrogen and deuterium should cause a change in conductivity reading corresponding to about 0.1% D_2. Mixtures of the isotopes were accordingly left in contact with various parts of the apparatus for a period of 12 hours. No change in the conductivity readings was observed. This is in agreement with the results reported by Gould *et al.* (8), who tested mercury, activated charcoal, and glass surfaces for possible catalytic effects. Burstein (20), however, has found rapid conversion of hydrogen and deuterium to occur on charcoal previously evacuated for 1 month at 950° C. The effect was attributed to the baring of active spots. As a precaution all the adsorbents used in this work were evacuated for no longer than 24 hours at a temperature of 180–200° C.

Materials Used

Deuterium.—Supplied by Stuart Oxygen Co., San Francisco. Purity better than 99.5%; used without further purification.

Hydrogen.—Supplied by Dominion Oxygen Co., Toronto. Purified over charcoal at liquid air temperature.

Helium.—Supplied by Dominion Oxygen Co., Toronto. Used without further purification in dead-space determination.

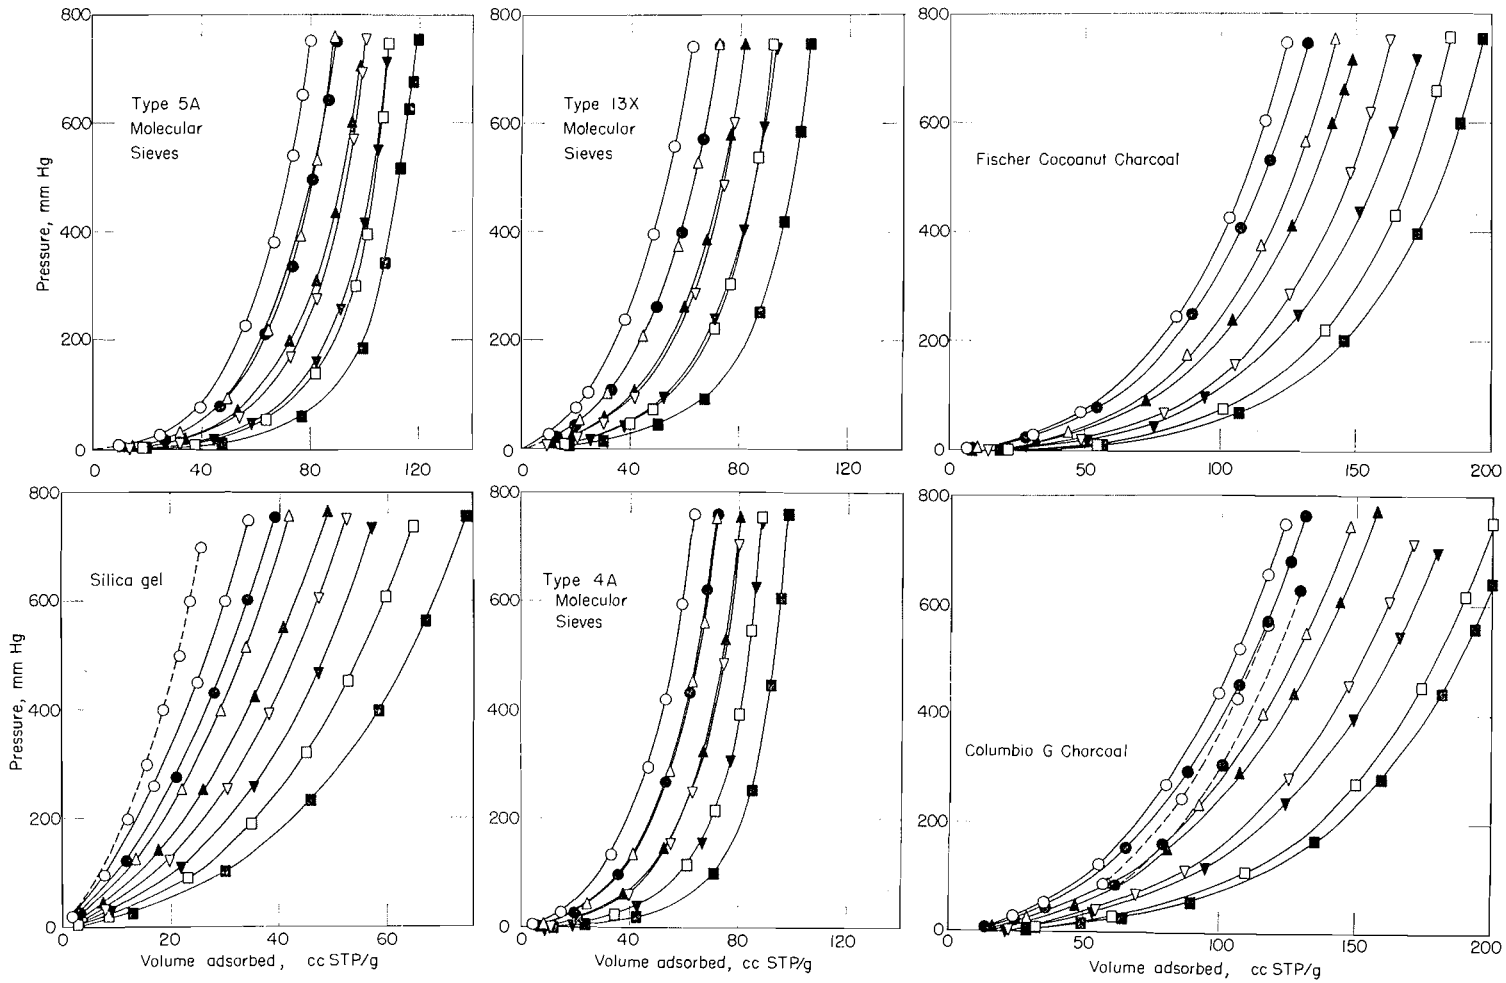

FIG. 3. Single component adsorption isotherms. Open symbols are for H_2, closed for D_2. Temperature (°K) for ○ and ●, 90; △ and ▲, 85; ▽ and ▼, 80; □ and ■, 75.---Ref. 22 (charcoal) and Ref. 23 (silica gel).

Adsorbents.—Columbia 'G' Charcoal, 12–20 mesh, 1250 sq. m/g, Carbide and Carbon Chemicals Co., New York. Fischer Cocoanut Charcoal, 12–20 mesh, 1100 sq. m/g. Supplied by Fischer Scientific Co., Toronto. Silica gel, 6–16 mesh, 750 sq. m/g, Fischer Scientific Co., Toronto. Molecular sieves type 4A, 5A, and 13X, 1/16-inch pellets containing approximately 20% inorganic binder, all 700–800 sq. m/g. Supplied by Linde Air Products Co., Tonawanda, N.Y.

Approximate formulae (21).—Type 4A: 0.96 $Na_2O \cdot 1.00\ Al_2O_3 \cdot 1.92\ SiO_2 \cdot xH_2O$ Type 13X: 0.83 $Na_2O \cdot 1.00\ Al_2O_3 \cdot 2.48\ SiO_2 \cdot xH_2O$. Type 5A is produced from type 4A through ion exchange of about 75% of the sodium ions by calcium ions. For a discussion of molecular sieve crystal structure, see Barrer (25).

Thermistors.—Type A33 matched thermistors, 2000-ohm nominal resistance. Supplied by Victory Engineering Corporation, Union, N.J.

RESULTS

Pure component adsorption isotherms of hydrogen and deuterium on the six adsorbents are shown in Fig. 3. Deuterium was found to be adsorbed to a greater extent than hydrogen in all cases investigated and both gases yield type I isotherms. The Freundlich and Langmuir equations were applied to the data but neither gave satisfactory agreement over the entire pressure range. The data of van Itterbeek and van Dingenen (22) (hydrogen and deuterium on "Carbotox" charcoal) and van der Waarden (23, hydrogen on silica gel) confirm the general trend of our isotherms.

Isosteric heats of adsorption were calculated from plots of log p versus $1/T$ at constant volume adsorbed. Straight lines were obtained in all cases over the entire temperature range. The heat of adsorption for deuterium was found to exceed that of hydrogen on all adsorbents, the difference tending to increase toward lower coverages (Fig. 4). The values found on charcoal compare well with the difference of 100 cal/mole calculated from the data of van Itterbeek and van Dingenen (22) and 80 cal/mole found by Beggerow (quoted by Melkonian and Reps (2)).

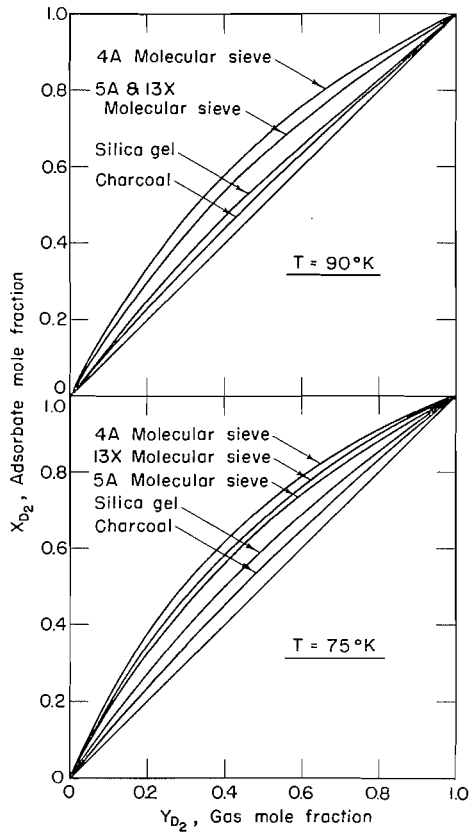

FIG. 5. Summary of binary adsorption equilibria (π = 750 mm Hg).

The binary data obtained in this work are summarized in Table II and Fig. 5. The results have been expressed in terms of the relative adsorptivity α which was found to be essentially constant over the entire concentration range investigated. More detailed graphs are given in Part II of this paper, where a comparison is made with values of α obtained directly from the single component data.

A number of qualitative conclusions may be drawn from the results:

(1) There seems to be little variation in the separation factors measured on chemically identical adsorbents of different origin. Values determined by us on two different charcoals are nearly the same as that reported by Strange (4) on a sample of unidentified origin and, as will be shown in a subsequent paper (II), similar values can be derived from the single component data measured on Carbotox charcoal by van Itterbeek and van Dingenen (22) and on sugar charcoal by Barrer and Rideal (24).

(2) The relatively high separation factors obtained on the molecular sieves do not appear to be due to any screening effect of the pores. Type 13X sieves with a nominal pore diameter of 13 angstrom give similar enrichment as type 4A, the pore size of which is close to the van der Waals diameter of hydrogen (2.4 angstrom).* A sample of 3A molecular sieves was also investigated but proved to have a negligible capacity for the two isotopes.

(3) The chemical composition of the adsorbent appears to have a marked effect on the separation factor, greater chemical heterogeneity tending to yield increased enrichment. The relative magnitude of α obtained on silica gel and charcoal agrees with the data of Melkonian and Reps (2), whose measurements at pressures of 1 micron Hg and less showed charcoal to be less effective than silica gel.

(4) The trend of increasing α with a decrease in temperature is confirmed by our results, but the lowest pressure used here (200 mm) was apparently not sufficiently small to reveal any effect on the separation factor.

The assistance received through a Research Foundation of Ontario Fellowship and grants by the School of Engineering Research, University of Toronto, is gratefully acknowledged. The author also expresses his appreciation to Dr. R. McIntosh and Dr. W. F. Graydon of the University of Toronto for a number of valuable discussions.

ADSORPTION EQUILIBRIA OF HYDROGEN, DEUTERIUM, AND THEIR MIXTURES. PART II[1]

D. BASMADJIAN[2]

ABSTRACT

An investigation has been made of the fundamental factors which determine isotope separation factors on adsorbents, based on hydrogen and deuterium isotherms reported in Part I. Through the use of a semiempirical thermodynamic approach, the binary separation factors α have been related to the single component isotherms ($p = f(v)$), and these in turn broken down into a number of terms involving the isosteric heat of adsorption q, temperature T, and surface coverage. If the less important contributions are neglected, the treatment leads to the following sequence of approximate relations:

$$[1] \quad \log \alpha \doteq \underset{[I]}{\frac{1}{(v_{H_2})_\pi} \int_0^{(v_{H_2})_\pi} \log\left(\frac{p_{H_2}}{p_{D_2}}\right)_v dv} \doteq \underset{[II]}{\frac{0.11}{(v_{H_2})_\pi} \int_0^{(v_{H_2})_\pi} \frac{q_{D_2} - q_{H_2}}{T} dv} \propto \underset{[III]}{\frac{\epsilon^0_{H_2} - \epsilon^0_{D_2}}{T}}$$

where ϵ^0 = total vibrational zero-point energy of adsorbed molecules.

The rigorous form of equation [I] agrees well with the experimental results, and semi-quantitative agreement with the data is shown by equation [II]. A qualitative discussion of [III] is given. It is suggested that the horizontal zero-point vibrations of the adsorbed species in some cases constitute an important contributing factor in addition to the vertical vibrations previously thought to be solely responsible for differences in isotope behavior.

INTRODUCTION

In a previous paper (1) we had reported data obtained from measurements of binary and single component adsorption isotherms of hydrogen and deuterium on a number of adsorbents. The surprisingly high separation factors which were obtained, particularly on type 4A molecular sieves, have led us to examine the fundamental factors which determine adsorption equilibria involving isotopes.

Differences in the sorption of isotopes are frequently attributed solely to zero-point energy effects. Sherman and Eyring (2) derived the expression

$$[2] \quad \frac{r_{H_2}}{r_{D_2}} = e^{(q_{D_2} - q_{H_2})/RT} = e^{(\epsilon^0_{H_2} - \epsilon^0_{D_2})/RT},$$

where r = rate of desorption, to explain the deuterium enrichment obtained by Gould *et al.* (3) by desorption from charcoal. Barrer and Rideal (4) obtained linear isotherms for hydrogen and deuterium on charcoal at a few millimeters of Hg and expressed their results in terms of the equation

$$[3] \quad \left(\frac{p_{H_2}}{p_{D_2}}\right)_v = e^{(q_{D_2} - q_{H_2})/RT} = e^{(\epsilon^0_{H_2} - \epsilon^0_{D_2})/RT},$$

where p = equilibrium pressure, v = volume adsorbed.

A more quantitative approach is achieved by the use of partition functions, but the advantages of this method are offset by the assumptions which have to be made in formulating the energy states of the adsorbed phase. Wheeler (5) applied the method to single component equilibria of the isotopes, assuming the adsorbed molecules to be

localized with 5 vibrational degrees of freedom relative to the surface. The result is described by the equation

$$[4] \qquad \left(\frac{p_{H_2}}{p_{D_2}}\right)_v = \frac{v_{m_{D_2}} - v_{H_2}}{v_{m_{H_2}} - v_{H_2}}$$

where v_m = monolayer volume.

In a recent note, White and Haubach (6) propose extending this treatment to the calculation of binary separation factors. The authors apparently assume Langmuir's mixed isotherm (7) to apply, postulating vertical vibrations as well as hindered rotation in the adsorbed phase. As a first approximation, zero-point energies only are considered, leading to qualitative agreement with some results obtained on alumina at 20° K.

One immediate difficulty in applying the above treatments arises from the fact that our data do not obey Langmuir's isotherm. Even if this were the case, it would not necessarily indicate that we are dealing with an energetically homogeneous surface justifying the use of the simple partition functions proposed by Wheeler, and White and Haubach. The formulation of more complex functions, on the other hand, would require a knowledge of surface energy distributions and other fundamental data which are difficult to obtain (see e.g. ref. 8). In the treatment given below we have sought to avoid these difficulties by employing a semiempirical thermodynamic approach involving variables which are easily obtained or estimated from the measured isotherms. The stepwise procedure consists in relating the binary separation factor α to the single component pressure ratio at constant volume adsorbed $(p_{H_2}/p_{D_2})_v$; this ratio is in turn expressed in terms of the difference in heat of adsorption of the two isotopes, system temperature, and surface coverage. The more significant of these, the heat of adsorption difference, is further broken down into the zero-point energies, adsorbent/adsorbate interaction potentials, and heat capacity integrals of the adsorbed isotopes. Each of these terms is discussed qualitatively as to its contribution to the total separation factor.

(a) Correlation of Binary and Single Component Data

Most theoretical treatments of this problem stipulate single component data which conform to a given isotherm equation, e.g., the Langmuir (7), Freundlich (9), or BET (10) isotherms. Our own data, which do not obey any of these equations, are represented by a modification of the correlation given by Lewis *et al.* (11):

$$[5] \qquad \frac{(v_{H_2})_\pi(\alpha-1)}{\alpha(v_{H_2}/v_{D_2})_\pi - 1} \log \alpha\left(\frac{v_{H_2}}{v_{D_2}}\right)_\pi = (v_{D_2} - v_{H_2})_\pi \log \pi + \int_0^{(v_{H_2})_\pi} \log p_{H_2}\, dv - \int_0^{(v_{D_2})_\pi} \log p_{D_2}\, dv.$$

The equation is based on the assumption that (*a*) α is independent of concentration, (*b*) the total binary adsorbate volume v_T is related to the adsorbate mole fraction X as follows:

$$[6] \qquad \frac{1}{v_T} = \frac{X_{H_2}}{(v_{H_2})_\pi} + \frac{X_{D_2}}{(v_{D_2})_\pi}.$$

The first of these was found to hold in the region 10–90% D_2 and will be assumed valid over the entire concentration range. The second assumption can be shown by an appropriate plot to be a close approximation of the linear relation found experimentally for our system:

$$[7] \qquad v_T = (v_{D_2} - v_{H_2})_\pi X_{D_2} + (v_{H_2})_\pi.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

The derivation given by Lewis *et al.* was repeated using equation [7] instead of [6]. The result, although considerably more complex, was found to be fully equivalent to the Lewis correlation.

For the purposes of this work it was found best to combine the two single component integrals in equation [5] into the pressure ratio $(p_{H_2}/p_{D_2})_v$, the residual term being evaluated by assuming log p to vary linearly with v over the short range in question. Thus:

$$[8] \qquad \frac{(\alpha-1)(v_{D_2}/v_{H_2})_\pi}{\alpha-(v_{D_2}/v_{H_2})_\pi}\log\frac{\alpha}{(v_{D_2}/v_{H_2})_\pi} = \frac{1}{(v_{H_2})_\pi}\int_0^{(v_{H_2})_\pi}\log\left(\frac{p_{H_2}}{p_{D_2}}\right)_v dv + \tfrac{1}{2}(v_{D_2}/v_{H_2}-1)_\pi \log\left(\frac{p_{H_2}}{p_{D_2}}\right)_{(v_{H_2})_\pi}.$$

It can be shown that for $\alpha < 4$ and $(v_{D_2}/v_{H_2})_\pi < 1.5$, the equation reduces to the approximate expression

$$[9] \qquad \log\alpha \doteq \frac{1}{(v_{H_2})_\pi}\int_0^{(v_{H_2})_\pi}\log\left(\frac{p_{H_2}}{p_{D_2}}\right)_v dv.$$

Plots of the ratio $(p_{H_2}/p_{D_2})_v$ versus v for the single component data reported previously are presented in Fig. 1. The curves show an initial sharp drop and appear to pass through a minimum at higher pressures. The general trend of the curves is confirmed by the data of van Itterbeek and van Dingenen (12) for hydrogen and deuterium on "Carbotox" charcoal. In terms of equation [9] the plots of Fig. 1 predict an increase in the separation factor α with decreasing total pressure π and temperature. This is confirmed by the high separations obtained by various authors on silica gel and charcoal at extremely low pressures and temperatures (see Part I, Table I). Our own binary data generally show excellent agreement with values of α calculated from equation [8] (see Fig. 2). The deviations observed in the case of the 4A molecular sieves are partly due

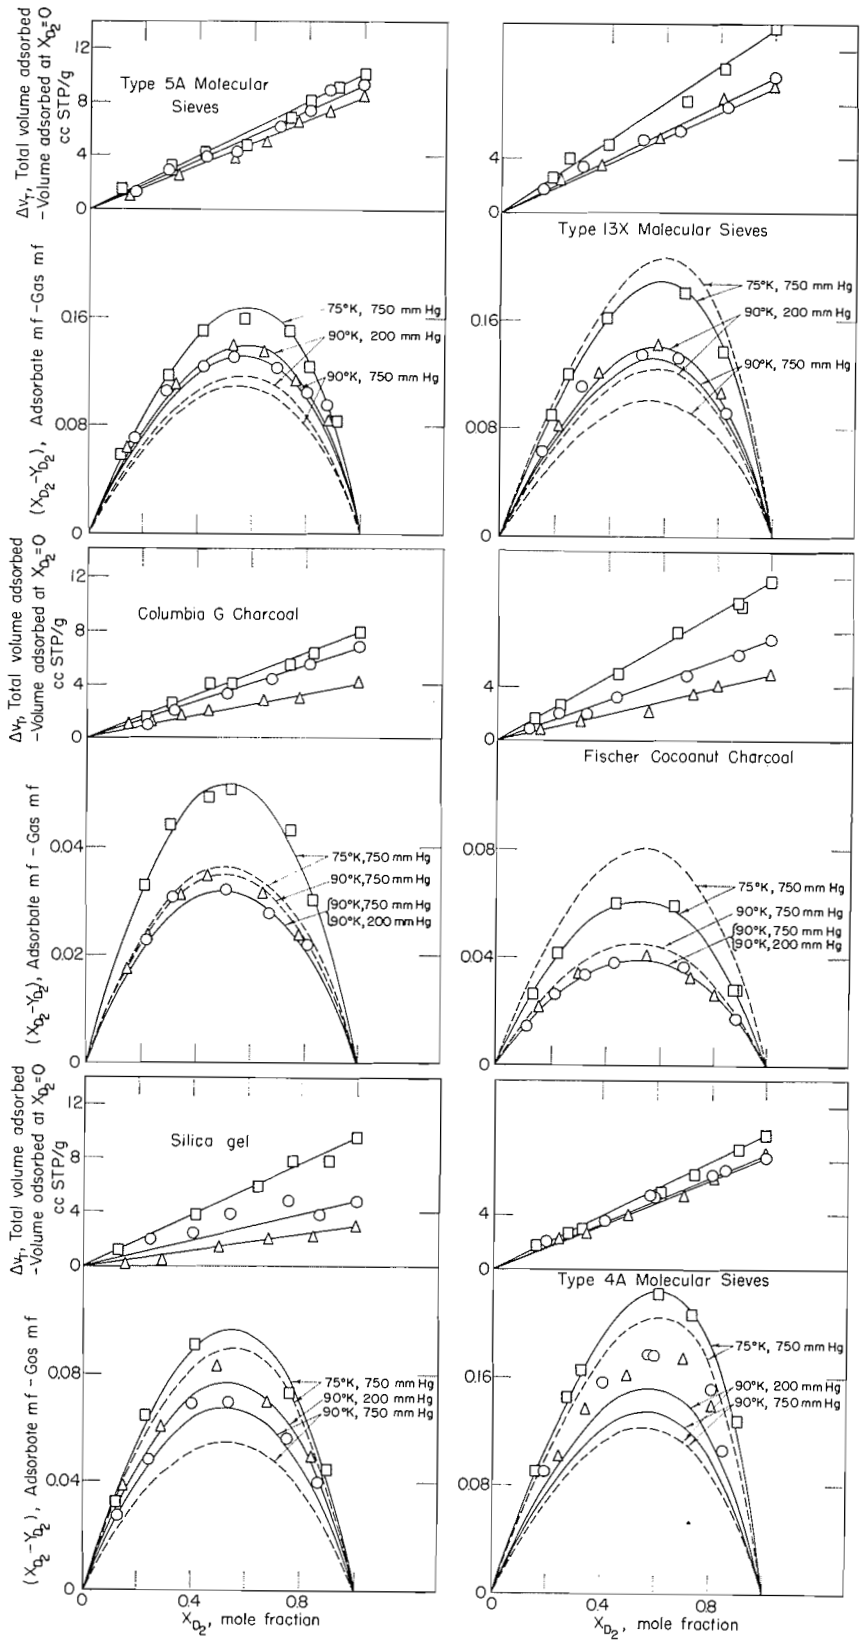

FIG. 2. Comparison of binary adsorption equilibria with equation [8] (———) and [9] (– – – – –). ○ $T = 90°$ K $\pi = 750$ mm Hg, △ $T = 90°$ K $\pi = 200$ mm Hg, □ $T = 75°$ K $\pi = 750$ mm Hg.

to the difficulty in extrapolating the pressure ratio to $v = 0$, and possibly also to a variation of α with composition at low concentrations.

Equation [9] is seen to be very similar to Raoult's Law for ideal liquid solutions, to which in fact it reduces by assuming p_{H_2}/p_{D_2} to be constant for all values of v. A slightly different form of this equation may be derived by postulating proportionality between gas and adsorbed phase mole fractions, Y and X, as follows:

$$[10] \qquad \begin{matrix} Y_{D_2}\pi = X_{D_2}(p_{D_2})_{v_T} \\ Y_{H_2}\pi = X_{H_2}(p_{H_2})_{v_T} \end{matrix} \quad \text{whence} \quad \frac{Y_{H_2}\cdot X_{D_2}}{Y_{D_2}\cdot X_{H_2}} = \alpha = \left(\frac{p_{H_2}}{p_{D_2}}\right)_{v_T}.$$

Values of α obtained from equation [10] agree less well with the experimental results than those calculated from the more accurate equation [8] (see Fig. 2). This underlines the importance of making allowance for the variation in the pressure ratio $(p_{H_2}/p_{D_2})_v$ with coverage.

(*b*) *The Pure Component Pressure Ratio*

We next proceed to express the pure component equilibrium pressure in terms of conventional thermodynamic functions. In the first instance this leads to the equation

$$[11] \qquad \Delta\mu = RT \ln p = \Delta H - T\Delta S.$$

(For an exact definition of the functions see, e.g., ref. 13*a*.)

The enthalpy term is in this case equivalent to the isosteric heat of adsorption q (13*a*), which is determined in the usual manner from a plot of $\log p$ versus $1/T$ at constant volume adsorbed. The entropy term is most conveniently evaluated by making use of a semiempirical correlation proposed by Everett (13*b*):

$$[12] \qquad \Delta S = \Delta S^* - R \ln \frac{\theta}{1-\theta}$$

where

$$[13] \qquad \Delta S^* = A \cdot q + B.$$

For a large number of gases on charcoal at 300° K, A was found to be equal to $0.38/T$ (14). Other systems give values of A between $0.45/T$ and $0.55/T$ (28), particularly at low temperatures, and a partial theoretical justification of this has been given by Drain and Morrison (14). Following Young (28), we have chosen the value of $0.50/T$ for A; B appears to be essentially independent of temperature below 90° K (13*b*), although this conclusion is based on rather scant data. The isotope pressure ratio then becomes:

$$[14] \qquad \log\left(\frac{p_{H_2}}{p_{D_2}}\right)_v = 0.11\,\frac{q_{D_2}-q_{H_2}}{T} + \log\frac{v_{m_{D_2}}/v_{m_{H_2}} - \theta_{H_2}}{1-\theta_{H_2}}$$

and

$$[15] \qquad \log\alpha = \frac{0.11}{(v_{H_2})_\pi}\int_0^{(v_{H_2})_\pi}\frac{q_{D_2}-q_{H_2}}{T}\,dv + \frac{1}{(v_{H_2})_\pi}\int_0^{(v_{H_2})_\pi}\log\frac{v_{m_{D_2}}/v_{m_{H_2}} - \theta_{H_2}}{1-\theta_{H_2}}\,dv.$$

A quantitative comparison with our data is rendered difficult by the high accuracy required in evaluating the heat of adsorption integral. Table I shows the results of some calculations based on approximate average values of $q_{D_2}-q_{H_2}$. The monolayer volume ratio was taken as 1.10 based on the low temperature isotherms of van Itterbeek and van Dingenen (12). Liquid molar volumes give a value of 1.20, solid molar volumes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12

one of about 1.15 (15). The pure component hydrogen coverage Θ_{H_2} was estimated from surface area measurements to vary from 0 to 0.3 for the cases investigated.

It is apparent that the term $(q_{D_2}-q_{H_2})/T$ constitutes the main contribution to the separation factor. Hence, as a first approximation:

$$\log \alpha \doteq \frac{0.11}{(v_{H_2})_\pi}\int_0^{(v_{H_2})_\pi}\frac{q_{D_2}-q_{H_2}}{T}\,dv. \qquad [16a]$$

Equations of a similar form

$$\alpha = A\cdot e^{\Delta q/RT} \qquad [16b]$$

have been suggested by several authors on a purely empirical basis (e.g. 16, 17). The experimental results of these workers are unfortunately difficult to interpret in terms of equations [14] and [15] due to the lack of data on single component isotherms.

(*c*) *The Heat of Adsorption Difference*

Having established that the separation factor is largely determined by the heat of adsorption difference, it is of interest to examine the factors which cause the large variation of $q_{D_2}-q_{H_2}$ on the various adsorbents investigated. The difference is conveniently broken down into a number of separate terms, following the treatment of Orr (18):

$$(q_{D_2}-q_{H_2})_T = \phi_{D_2}-\phi_{H_2}-(\epsilon^0_{D_2}-\epsilon^0_{H_2}) -\int_0^T C_{a_{D_2}}dT+\int_0^T C_{g_{D_2}}dT+\int_0^T C_{a_{H_2}}dT-\int_0^T C_{g_{H_2}}dT \qquad [17]$$

where ϕ = total interaction energy, C_a = adsorbate heat capacity, C_g = ideal gas heat capacity. Due to a lack of data, it is not possible to present more than qualitative conclusions on the contribution made by each term. Most authors are inclined to emphasize the importance of the zero-point energy difference. There is in fact some reason to believe that neither of the other two terms contributes appreciably to $q_{D_2}-q_{H_2}$. The intermolecular potentials of gaseous hydrogen and deuterium are known to be identical (19). Calculations based on the Kirkwood–Mueller equation (7) have shown the interaction potential of the isotopes with adsorbent surfaces to be nearly identical. Thus, as a first approximation, $\Delta\phi$ may be set = 0.

No measurements have been made of the heat capacities of either hydrogen or deuterium in the adsorbed state. A number of authors have, however, reported values for nitrogen (20, 22), oxygen (22), krypton (21), and argon (23) adsorbed on rutile over a temperature range extending from near 0° K to well above the normal boiling point. The results indicate that the difference of the heat capacity integrals

$$-\int C_a dT+\int C_g dT$$

for these gases does not exceed 100–200 cal/mole. On this basis, the algebraic sum of the isotopic heat capacity integrals (equation [17]) may be expected to be even smaller, if not completely negligible. At any rate, it would seem difficult to attribute heat of adsorption differences as high as 300 cal/mole solely to heat capacity effects.

(*d*) *The Zero-point Energy Difference*

The zero-point energy of a harmonic oscillator vibrating vertically to a surface is given by:

$$\epsilon^0_v = \frac{Nh}{\pi}\left(\frac{\phi}{4mr_0^2}\right)^{\frac{1}{2}} \qquad [18]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

h = Planck's constant and N = Avogadro's constant, where r_0 = equilibrium distance from surface and m = mass of isotope. Hence,

$$[19] \qquad q_{D_2} - q_{H_2} \doteq \frac{N \cdot h}{2\pi} \left\{ \left(\frac{\phi_{H_2}}{2mr_{0_{H_2}}^2} \right)^{\frac{1}{2}} - \left(\frac{\phi_{D_2}}{2mr_{0_{D_2}}^2} \right)^{\frac{1}{2}} \right\}.$$

While the order of magnitude of this expression agrees well with observed values of the heat of adsorption difference, it is difficult to account for its large variation with adsorbent composition solely on the basis of equation [19]. This would require a change in ϕ and r_0 incompatible with observed heats of adsorption or intermolecular van der Waals distances. It appears likely that other modes of energy may be involved, such as zero-point vibrations parallel to the surface or hindered rotation (6). Hill (24) has derived the following expression for horizontal vibrations on a surface with sinusoidal potential gradient:

$$[20] \qquad \epsilon_h^0 = Nh \left(\frac{V}{4ms^2} \right)^{\frac{1}{2}}$$

where V = maximum potential barrier, s = distance between potential minima.

Equations of similar form may be expected to hold for more complex surfaces.

In the case of charcoal at higher coverages, the horizontal contribution is probably negligible, calculations having yielded a surface potential periodicity for argon on graphite of only about 50 cal/mole (25). Silica gel has been shown to give lower surface diffusivities than charcoal, in spite of higher heats of adsorption on the latter (26). This is interpreted as proof that the former has higher surface heterogeneity, possibly due to its chemical structure, and horizontal zero-point vibrations may partly account for the higher α values observed.

Surface heterogeneity may also be used to explain in part the high separation factors measured on the molecular sieves. This may again be due to the presence of different types of atoms and ions in the adsorbent surface. In addition, however, it is to be expected that the small size of the intercrystalline voids (11A diameter, ref. 27) in which the main adsorption occurs will cause a considerable increase of the horizontal potential barrier. The large enrichment factors obtained by Melkonian and Reps (17), and others, at extremely low pressures can be similarly accounted for if the adsorption sites at these coverages are visualized as very narrow cracks.

The contribution due to hindered rotation (vertically to the surface) has been discussed briefly by White and Haubach (6). The ortho-hydrogen enrichment in the adsorbed phase reported by various authors (see Part I) indicates that the adsorbed

isotopes do in fact possess some form of hindered rotational motion. It would be difficult, however, to explain the observed variation of $q_{D_2}-q_{H_2}$ with adsorbent composition solely on this basis, since this would again require a change in r_0 or the vertical potential barrier incompatible with the physical facts. The measurement of surface diffusivities suggests itself as a possible means for confirming the importance of surface heterogeneity, as compared to potential barriers affecting the vertical rotation of the molecule.

IODINE COMPLEXES IN INERT SOLVENTS

XI. CRYOSCOPIC STUDY OF THE IODINE – NAPHTHALENE COMPLEX DISSOLVED IN CYCLOHEXANE[1]

P. A. D. DE MAINE AND P. J. SANTIAGO

ABSTRACT

Here is reported cryoscopic evidence of the specific interaction between naphthalene and iodine dissolved together in cyclohexane. Cryoscopic constants accurate to within 2% are given for iodine and naphthalene dissolved separately in cyclohexane or in benzene.

INTRODUCTION

Since publication of the work of Benesi and Hildebrand (2), many researchers have used their spectrophotometric method, or modifications like those proposed by Ketelaar *et al.* (9) or Andrews and Keefer (1), to show that iodine molecules react reversibly with many aromatic and aliphatic compounds to form one-to-one complexes in solution. In many cases, the spectrophotometric method has been used to determine the heats of formation of these complexes. However, except for the calorimetric work reported by Hartley and Skinner (7) and the determination of solubilities by Kortüm and Vogel (10) there appears to be no direct non-spectrophotometric evidence of specific interaction between iodine and aromatic molecules in solution.

De Maine and Peone (4) have reported that the heat of formation ($\Delta H = -1.63 \pm 0.25$ kcal/mole) of the complex, naphthalene–I_2, is independent of the inert diluent used. Solvents used were carbon tetrachloride, cyclohexane, *n*-heptane, *n*-hexane, and chloroform.

In the present work we report cryoscopic evidence for the specific interaction between naphthalene and iodine in cyclohexane.

EXPERIMENTAL

(*i*) *Chemicals*

Fisher reagent grade anhydrous magnesium sulphate was heated for 6 hours at 150° C. Mallinckrodt A.R. grade benzene and Fisher spectrograde cyclohexane were stored in glass-stoppered bottles containing magnesium sulphate for at least 1 week before use. Solvents were removed with a "propipette" from the storage bottles immediately before the start of the experiment.

Fisher resublimed iodine and certified reagent grade naphthalene were used without further purification.

(*ii*) *Procedure*

Before each experiment the cell and its glass attachments (described below) were soaked in concentrated nitric acid for at least 6 hours, then were washed with copious amounts of water, and finally were rinsed with anhydrous acetone or methanol. Then the clean cell and attachments were heated at 55–65° C for not less than 1 hour and then were blown with pure nitrogen (dew point less than −40° C). Twenty-five milliliters of the anhydrous solvent was pipetted into the assembled cell, which was placed in the modified, Precision Scientific Co., cryoscopic molecular weight apparatus. The Beckman

[1]*Manuscript received September 11, 1959.*
Contribution from the Chemistry Department, New York State College for Teachers, New York State University, Albany 3, New York, U.S.A.

Differential thermometer was transferred from an ice-water bath to the cell after the solvent was cool. Care was taken to avoid transfer of moisture. The freezing point of the solvent was determined by the procedure described in the operating instructions of Precision Scientific Co. (3737 Cortland St., Chicago 47, Illinois. Index TS-65920-1). Special care was taken to maintain a constant tube-stirrer velocity, to cool at a rate less than 0.1° C per minute, and to seed the solution at a fixed temperature below the freezing point. The maximum amount of supercooling permissible for each solution was determined separately.

The freezing point of each aliquot of solvent was determined at least three times. Then the solution was heated approximately four degrees centigrade above the freezing point, and an accurately weighed portion of the desired solid was introduced into the cell by means of a polyethylene, long-stemmed funnel and an adapted Burgess Vibra-Tool. One hour after addition of the solid the new freezing point was determined. (In separate experiments we have shown that all the iodine and naphthalene were dissolved in both solvents within 45 minutes.) This procedure was repeated with further addition of the solid materials.

All the operations described above were performed in a dry, cool atmosphere (relative humidity less than 20%, temperature 15° C), and precautions were taken to exclude moisture from the freezing solutions at all times. The relative freezing point could be reproduced to within 0.001° C.

(*iii*) *Instrumentation*

(*a*) *Description of Cell and Attachments*

The cell supplied by the manufacturers was replaced by one modified as follows. The stainless-steel tube-stirrer and brass stirrer-bearing were replaced by an all-glass assembly, which was fitted with a $CaCl_2$ drying tube. The thermometer was replaced by a Beckman Differential thermometer fitted with a male 24-40 ground glass joint, and an electromagnetic vibrator clamped to the metal ferrule. The vibrator was switched on a few minutes before measurement of the freezing point in order to obtain the quoted accuracy (within 0.001° C). We also found that glass dust from the stirrer-bearing could effect changes as large as 0.010° C over several hours. Special design of the stirrer assembly and lubricating techniques was necessary to eliminate this source of error.

(*b*) *Modifications of the Precision-shell, Cryoscopic Molecular Weight Apparatus*

To insure continuous operation of the instrument for periods up to 24 hours, modifications were made as follows. The small-bore, copper cooling-coil which surrounds the cell cavity and is immersed in the coolant was replaced by a cooling-coil made of $\frac{3}{8}$-inch internal diameter copper tubing. Ice water was pumped with a high capacity pump (greater than 1 gallon per minute) through the cooling-coil from a 5-gallon bath equipped with a high speed stirrer. The ice-bath pump and cooling-coil feed tubes were thoroughly insulated to minimize condensation. The coolant was commercial "Antifreeze".

RESULTS

More than 120 freezing points were each determined in duplicate with the instrument and procedure described above. With proper precautions to prevent moisture contamination of the solutions or hysteresis of the mercury in the Beckman Differential thermometer (13), the freezing points could be easily determined to within 0.001° C. The reproducibility obtained by us is considerably better than the 0.005° C quoted by the manufacturers (13).

In other experiments we have shown that the freezing point for solutions with single or mixed solutes does not change measurably even after several hours. The freezing points of fresh portions of each pure solvent did not vary by more than 0.002° C.

Cryoscopic constants (K_f = ° C for 1 mole dissolved in 100 g) for both solutes dissolved in each solvent were calculated with the standard formula (5). In these calculations the exact weights of solvent used were computed with densities estimated from published temperature–density equations (8). Such calculations have shown that K_f can be determined to high precision with small weights of the solute (Table I).

Typical data and K_f values for naphthalene dissolved separately in solutions of iodine plus cyclohexane are given in Table II.

NOTE: Cryoscopic constants (K_f) for naphthalene dissolved in iodine plus cyclohexane. Δt° C is the depression of the freezing point of the iodine solution observed on addition of the indicated weight of napthalene (w_N (g)) to 25 cc of the pure solvent with w_{I_2} g of iodine. K_f is in degrees centigrade for 1 mole dissolved in 100 g of solvent. K_f for napthalene alone is 218.6.

DISCUSSION

The new K_f value for naphthalene dissolved in benzene (51.4±0.7) is in good agreement with the accepted value of 51.2 (6, 11). However, the new value of K_f for cyclohexane (218.6±2.4) is significantly larger than the published values of 200 to 204 (6, 8, 11). The significantly lower K_f values reported for iodine in both solvents (Table I) cannot be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

attributed to partial polymerization of the solute, as has been suggested for other compounds in cyclohexane (12), because the K_f values are independent of the iodine concentration (Table I). Thus these low K_f values must be due to formation of solid solutions (5).

The significant decrease observed in the K_f values for naphthalene for the mixed-solute system (Table II) cannot be attributed to "salting-out" of either component because absorption spectra of these solutions show no sudden break when the temperature is lowered to near the freezing point. Also the saturation concentrations for both components dissolved separately in the pure solvent are significantly greater than the concentrations we studied. Thus the observed decrease for K_f must be due to specific interactions between iodine and naphthalene molecules in solution. This conclusion is in accord with published spectrophotometric work (3, 4, 14).

Calculations with data for naphthalene dissolved in iodine plus benzene solutions show that K_f decreases only slightly in the presence of iodine. (The maximum decrease observed was 2.5 for 0.7000 g of naphthalene dissolved in 21.98 g of benzene and 0.3000 g of iodine.) Calculations with spectrophotometrically determined values for the equilibrium constants for the separate reactions between iodine and benzene (2) or naphthalene (3, 14) show that in the competitive system less than 2% of the iodine will combine with the naphthalene. Thus the small decrease in K_f values can be understood.

No attempt has been made to calculate the equilibrium constant and hence ΔH for the reaction between iodine and naphthalene because of the different K_f values for iodine and naphthalene in cyclohexane.

CALCULATION OF HEATS OF SOLUTION IN SATURATED MIXED ELECTROLYTES[1]

Y. IYENGAR[2]

ABSTRACT

Theoretical equations have been derived for calculating heats of solutions of an electrolyte in its saturated system comprising one or more electrolytes. These expressions involve the application of "Harned's rule" concerning activity coefficients in mixed electrolytic solutions to an extension of van't Hoff's equation dealing with the temperature coefficient of solubility product in non-ideal systems. The commonly occurring case of mixed electrolytic pairs has been considered in detail. Application of theoretical equations to calculate the heats of solutions KCl, NaCl, and KNO_3 in the saturated systems KCl–NaCl–H_2O and KCl–KNO_3–H_2O is briefly discussed.

I. INTRODUCTION

A knowledge of the heats of solution of an electrolyte in its saturated system comprising one or more co-solutes is very useful in the computation of heat balances in processes involving steps such as the dissolution and crystallization of the electrolyte in these systems. Particularly of interest is the fact that the heat of crystallization of a salt is identified with its negative heat of solution at saturation.

Experimental data on heats of solutions in saturated solutions of mixed electrolytes are conspicuous by their absence. Even the data in fairly concentrated solutions are scarce (1–3). Such measurements are extremely difficult and tedious owing to the very slow rate of dissolution of a solute in a nearly saturated solution.

By a thermodynamic treatment involving the extension of van't Hoff's equation to non-ideal solutions, Williamson (4) derived expressions for calculating heats of solution of electrolytes at saturation in water. However, the influence of the presence of other electrolytes was not considered in his work.

The present work offers a theoretical method of calculating the heats of solution of a salt in saturated mixed electrolyte systems. The lack of experimental data in such systems lends considerable value to the theoretical solution.

II. GENERAL EQUATION FOR A PAIR OF ELECTROLYTES

(a) No Common Ions

Consider a system comprising a saturated solution of a pair of electrolytes having no ions in common between them. Let the properties of the species A and B be designated by the subscripts "1" and "2". The problem now is to derive expressions for evaluating heats of solutions of either A or B in a solution saturated with respect to both A and B.

From solubility relationships for component A

$$[1] \qquad P_1\gamma_1^{\nu_1} = P_{1(W)}\gamma_{1(W)}^{\nu_1}$$

where $P_{1(W)}$ and P_1 are the stoichiometrical solubility products of electrolyte A in water and in a solution saturated with respect to both A and B respectively, and $\gamma_{1(W)}$ and γ_1 are the corresponding mean activity coefficients. ν_1 is the total number of ions in 1 molecule of the electrolyte A.

[1]*Manuscript received August 19, 1959.*
Contribution from U.S. Borax Research Corporation, Anaheim, California, U.S.A.
[2]*Present address: Industrial Products Research Laboratory, Textile Fibers Department, E. I. du Pont de Nemours Co., Water Street, Newport, Delaware, U.S.A.*

Extending van't Hoff's equation to non-ideal systems of component A in the saturated A–B–H_2O system,

$$[2] \qquad \frac{d \ln P_1 {\gamma_1}^{\nu_1}}{dT} = \frac{\Delta H_{1(0)}}{RT^2},$$

where $\Delta H_{1(0)}$ is the differential heat of solution of A in pure water. Now, in the absence of a common ion,

$$[3] \qquad P_1 = (\nu_+{}^{\nu_+}\nu_-{}^{\nu_-}){m_1}^{\nu},$$

where ν_+ and ν_- are the number of cations and anions respectively in 1 molecule of the electrolyte and m_1 is the molality of A. Combining eqs. [3] and [2]

$$[4] \qquad \frac{d \ln m_1}{dT} + \left(\frac{d \ln \gamma_1}{dT}\right)_{\text{sat}} = \frac{\Delta H_{1(0)}}{\nu_1 RT^2},$$

where the subscript "sat" stands for "solution saturated with respect to both A and B".

Since the variation of γ_1 with temperature is also accompanied by changes in the ionic strengths μ_1 and μ_2 of A and B respectively,

$$\partial \ln \gamma_1 = \left(\frac{\partial \ln \gamma_1}{dT}\right)_{\mu_1,\mu_2} dT + \left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,T} d\mu_1 + \left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,T} d\mu_2,$$

whence

$$[5] \qquad \left(\frac{d \ln \gamma_1}{dT}\right)_{\text{sat}} = \left(\frac{\partial \ln \gamma_1}{\partial T}\right)_{\mu_1,\mu_2} + \left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,T} \frac{d\mu_1}{dT} + \left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,T} \frac{d\mu_2}{dT}.$$

Now,

$$[6] \qquad \left(\frac{\partial \ln \gamma_1}{\partial T}\right)_{\mu_1,\mu_2} = -\frac{\bar{L}_1}{\nu_1 RT^2},$$

where $\bar{L}_1$ is the relative partial molal heat content of A in a solution saturated with respect to both A and B. Combining eqs. [4], [5], and [6],

$$[7] \qquad \frac{d \ln m_1}{dT} + \left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,T} \frac{d\mu_1}{dT} + \left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,T} \frac{d\mu_2}{dT} = \frac{(\Delta H_{1(0)} + \bar{L}_1)}{\nu_1 RT^2}.$$

The variation of activity coefficients of salts in mixed electrolytes has been extensively investigated by Harned (5). Harned's rule, which has been successfully applied to several electrolyte pairs, can be written in the present context as

$$[8a] \qquad \ln \gamma_1 = \ln \gamma_{1(0)} - \alpha_1 \mu_2$$

$$[8b] \qquad \ln \gamma_2 = \ln \gamma_{2(0)} - \alpha_2 \mu_1,$$

where α_1, α_2 are constants at a given temperature, μ_1, μ_2 are the ionic strengths of A and B, and $\gamma_{1(0)}$, $\gamma_{2(0)}$ are the activity coefficients of A and B in their respective solutions in *water* at the *total* ionic strength $\mu = (\mu_1 + \mu_2)$.

Using eq. [8*a*],

$$[9] \qquad \left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu_1}\right)_{\mu_2,T} - \mu_2 \left(\frac{\partial \alpha_1}{\partial \mu_1}\right)_{\mu_2,T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T - \mu_2 \left(\frac{\partial \alpha_1}{\partial \mu}\right)_T.$$

Also

$$[10] \qquad \left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T - \mu_2 \left(\frac{\partial \alpha_1}{\partial \mu}\right)_T - \alpha_1.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

The activity coefficient $\gamma_{1(0)}$ of A in water at high ionic strengths (even exceeding the solubility of the salt in water) may be obtained by the empirical rule of Åkerlöf and Thomas (6), according to which

$$\ln \gamma_{1(0)} - \ln \gamma_{R(0)} = \beta_1 \mu, \qquad [11]$$

where $\gamma_{R(0)}$ is the mean activity coefficient of a reference electrolyte, and β_1 is a constant at a given temperature. The above relationship has been confirmed (6) for various electrolytes in concentrated solutions even up to saturation. Hydrochloric acid is generally used as the reference solute (R) since its activity coefficient is known over a very wide range of concentration (3–16 m) (7).

Differentiation of eq. [11] with respect to μ gives,

$$\left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T = \left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T + \beta_1. \qquad [12]$$

Substituting eqs. [9], [10], and [12] in eq. [7], and also using the mathematical identity,

$$\frac{d \ln m_1}{dT} = \frac{1}{m_1}\frac{dm_1}{dT},$$

$$\frac{1}{m_1}\frac{dm_1}{dT} + \frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T + \beta_1 - \mu_2\left(\frac{\partial \alpha_1}{\partial \mu}\right)_T\right] + \frac{d\mu_2}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T + \beta_1 - \mu_2\left(\frac{\partial \alpha_1}{\partial \mu}\right)_T - \alpha_1\right] = \frac{(\Delta H_{1(0)} + \bar{L}_1)}{\nu_1 RT^2}. \qquad [13]$$

β_1 can be determined from eq. [11] if the activity coefficients of electrolyte A and the reference electrolyte R at the same ionic strengths are known. Accurate values of β_1 may be obtained by plotting $\ln \gamma_{1(0)} - \ln \gamma_{R(0)}$ against μ and evaluating β_1 as the slope of this line.

α_1 may be evaluated from solubility data as follows.
Equation [1] may be written in the form,

$$\ln P_1/\nu_1 + \ln \gamma_1 = \ln P_{1(W)}/\nu_1 + \ln \gamma_{1(W)}. \qquad [14]$$

Substituting for

$$P_{1(W)} = (\nu_+^{\nu_+}\nu_-^{\nu_-})m_{1(W)}^{\nu},$$

$$P_1 = (\nu_+^{\nu_+}\nu_-^{\nu_-})m_1^{\nu},$$

$$\ln \gamma_{1(W)} = \ln \gamma_{R(W_1)} + \beta_1 \mu_{1(W)},$$

and for $\ln \gamma_1$ from eqs. [8a] and [11], where $m_{1(W)}$ is the solubility of A in water, and $\mu_{1(W)}$ the ionic strength of A at saturation in water, and $\gamma_{R(W_1)}$ is the activity coefficient of the reference electrolyte (R) at ionic strength $\mu_{1(W)}$, eq. [14] now becomes,

$$\ln m_1 + \ln \gamma_{R(0)} + \beta_1 \mu - \alpha_1 \mu_2 = \ln m_{1(W)} + \ln \gamma_{R(W_1)} + \beta_1 \mu_{1(W)},$$

whence

$$\alpha_1 = \frac{1}{\mu_2}[\ln (m_1/m_{1(W)}) + \ln (\gamma_{R(0)}/\gamma_{R(W_1)}) + \beta_1(\mu - \mu_{1(W)})]. \qquad [15]$$

Extending van't Hoff's equation to the non-ideal system of component B in saturated A–B–H_2O, the following expression analogous to eq. [13] may be derived going through similar steps.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

[16] $$\frac{1}{m_2}\frac{dm_2}{dT}+\frac{d\mu_2}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_2-\mu_1\left(\frac{\partial \alpha_2}{\partial \mu}\right)_T\right]+\frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_2-\mu_1\left(\frac{\partial \alpha_2}{\partial \mu}\right)_T-\alpha_2\right]=\frac{(\Delta H_{2(0)}+\bar{L}_2)}{\nu_2 RT^2},$$

where ν_2 is the total number of ions in 1 molecule of electrolyte B, and where β_2, α_2, $\Delta H_{2(0)}$, and $\bar{L}_2$ of B correspond to β_1, α_1, $\Delta H_{1(0)}$, and $\bar{L}_1$ of A.

β_2 and α_2 are given by expressions similar to eqs. [11] and [15]:

[17] $$\ln \gamma_{2(0)}/\ln \gamma_{R(0)} = \beta_2\mu$$

[18] $$\alpha_2 = \frac{1}{\mu_1}[\ln (m_2/m_{2(W)})+\ln (\gamma_{R(0)}/\gamma_{R(W_2)})+\beta_2(\mu-\mu_{2(W)})].$$

Further simplifications of eqs. [13] and [16] are possible by considering certain relationships between α_1 and α_2.

Harned and Owen (5) applied the Gibbs–Duhem equation to their rule (eqs. [8*a*], [8*b*]) and obtained, on the basis of Åkerlöf and Thomas' rule, eq. [11],

[19] $$\alpha_1-\alpha_2 = \text{constant},$$

whereas Glueckauf, McKay, and Mathieson (8, 9) obtained by thermodynamic considerations,

[20] $$\alpha_1+\alpha_2 = \text{constant}.$$

Equations [19] and [20] reveal that both α_1 and α_2 are constants independent of ionic strength of solution in concentrated solutions where Harned's rule is applicable. Since α_1 and α_2 are independent of μ,

$$(\partial\alpha_1/\partial\mu)_T = 0,$$

and

$$(\partial\alpha_2/\partial\mu)_T = 0,$$

whence eq. [13] becomes

[21] $$\frac{1}{m_1}\frac{dm_1}{dT}+\frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_1\right]+\frac{d\mu_2}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{d\mu}\right)_T+\beta_1-\alpha_1\right]=\frac{(\Delta H_{1(0)}+\bar{L}_1)}{\nu_1 RT^2}$$

and eq. [16] becomes

[22] $$\frac{1}{m_2}\frac{dm_2}{dT}+\frac{d\mu_2}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_2\right]+\frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_2-\alpha_2\right]=\frac{(\Delta H_{2(0)}+\bar{L}_2)}{\nu_2 RT^2}.$$

Denoting the left-hand sides of eqs. [21] and [22] by X and Y respectively, the equations can be rewritten as

[23] $$\nu_1 RT^2 X = \Delta H_{1(0)}+\bar{L}_1$$

[24] $$\nu_2 RT^2 Y = \Delta H_{2(0)}+\bar{L}_2.$$

Now, the heat of solution ΔH_{12} of A in a solution saturated with respect to both A and B is given by

$$\Delta H_{12} = (\bar{H}_{1(0)}-H_{1(s)})-(\bar{H}_1-\bar{H}_{1(0)}),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

where $\bar{H}_{1(0)}$ is the partial molal enthalpy of A in an infinitely dilute solution of A in water, $H_{1(s)}$ is the molal enthalpy of A in the solid state, and $\bar{H}_1$ is the partial molal enthalpy of A in a solution saturated with respect to both A and B.

Since

$$(\bar{H}_{1(0)}-H_{1(s)}) = \Delta H_{1(0)}$$

and

$$(\bar{H}_1-H_{1(0)}) = \bar{L}_1,$$

therefore

[24*a*] $$\Delta H_{12} = \Delta H_{1(0)}+\bar{L}_1$$

and similarly

[24*b*] $$\Delta H_{21} = \Delta H_{2(0)}+\bar{L}_2,$$

where ΔH_{21} is the heat of solution of B in a solution saturated with respect to both A and B. Combining eqs. [23], [24], [24*a*], and [24*b*]

[25] $$\Delta H_{12} = \nu_1 RT^2 X$$

[26] $$\Delta H_{21} = \nu_2 RT^2 Y.$$

Equations [25] and [26] indicate that the heats of solutions of either one of the components in a solution saturated with respect to the electrolyte pair A, B can be simultaneously calculated by knowing X and Y from the solubility and thermodynamic data of the saturated system A–B–H_2O.

(b) Common Ion Effect

For the case of an electrolytic pair with a common ion eqs. [21] and [22] become slightly modified. If the anion is assumed to be common between the two electrolytes A and B, P_1 (see eq. [3]) is now given by

[27] $$\begin{aligned} P_1 &= m_+^{\nu_+} m_-^{\nu_-} \\ &= ({}_1\nu_+ m_1)^{{}_1\nu_+}({}_1\nu_- m_1+{}_2\nu_- m_2)^{{}_1\nu_-}, \end{aligned}$$

where ${}_1\nu_+$ and ${}_1\nu_-$ are the number of cations and anions in 1 molecule of the electrolyte A respectively and ${}_2\nu_-$ is the number of anions in 1 molecule of B. Instead of eq. [4] we now have

[28] $$\frac{1}{\nu_1}[{}_1\nu_+ d\ln m_1/dT+{}_1\nu_- d\ln({}_1\nu_- m_1+{}_2\nu_- m_2)/dT]+(d\ln\gamma_1/dT)_{\text{sat}} = \Delta H_{1(0)}/\nu_1 RT^2.$$

Equation [21] now becomes

[29] $$\begin{aligned} \frac{1}{\nu_1}[{}_1\nu_- d\ln({}_1\nu_- m_1+{}_2\nu_- m_2)/dT+(dm_1/dT)({}_1\nu_+/m_1)]+(d\mu_1/dT)[(\partial\ln\gamma_{R(0)}/\partial\mu)_T+\beta_1] \\ +(d\mu_2/dT)[(\partial\ln\gamma_{R(0)}/\partial\mu)_T+\beta_1-\alpha_1] = (\Delta H_{1(0)}+\bar{L}_1)/\nu_1 RT^2 \end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

and eq. [22] becomes

$$[30]\quad \frac{1}{\nu_2}\left[{}_2\nu_- d\ln({}_1\nu_-m_1+{}_2\nu_-m_2)/dt+\left(\frac{dm_2}{dT}\right)\left(\frac{{}_2\nu_+}{m_2}\right)\right]+\frac{d\mu_2}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial\mu}\right)_T+\beta_2\right]$$
$$+\frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial\mu}\right)_T+\beta_2-\alpha_2\right]=\frac{(\Delta H_{2(0)}+\bar{L}_1)}{\nu_2 RT^2}.$$

Also from eqs. [14] and [27],

$$[31]\quad \alpha_1=\frac{1}{\mu_2}\left[\frac{{}_1\nu_+}{\nu_1}\ln m_1+\frac{{}_1\nu_-}{\nu_1}\ln({}_1\nu_-m_1+{}_2\nu_-m_2)-\ln m_{1(W)}+\ln(\gamma_{R(0)}/\gamma_{R(W_1)})\right.$$
$$\left.+\beta_1(\mu-\mu_{1(W)})\right].$$

Similarly,

$$[32]\quad \alpha_2=\frac{1}{\mu_1}\left[\frac{{}_2\nu_+}{\nu_2}\ln m_2+\frac{{}_2\nu_-}{\nu_2}\ln({}_1\nu_-m_1+{}_2\nu_-m_2)-\ln m_{2(W)}+\ln(\gamma_{R(0)}/\gamma_{R(W_2)})\right.$$
$$\left.+\beta_2(\mu-\mu_{2(W)})\right].$$

ΔH_{12} and ΔH_{21} may be calculated as before, by substituting X and Y for the left-hand side of eqs. [29] and [30] and using the eqs. [25] and [26].

III. 1:1 ELECTROLYTE PAIR

Equations [21], [22], [29], and [30] become considerably simple for the case of a pair of 1:1 electrolytes.

(a) No Common Ion

Consider the case when the 1:1 electrolytes A and B have no ions in common. Equations [11], [15], [17], [18], [21], and [22] remain practically unchanged except that ionic strengths (μ) become molalities (m)

$$\mu = m, \qquad \mu_1 = m_1, \qquad \mu_2 = m_2,$$

$$\mu_{1(W)} = m_{1(W)}, \qquad \mu_{2(W)} = m_{2(W)}.$$

Also

$$\nu = 2.$$

With these modifications and substitutions, ΔH_{12} and ΔH_{21} may be evaluated by eqs. [25] and [26].

(b) Common Ion Effect

Assume the anion to be common between the 1:1 electrolytes A and B. Since

$${}_1\nu_- = {}_2\nu_- = {}_1\nu_+ = {}_2\nu_+ = 1,$$
$$\mu_{1(W)} = m_{1(W)},$$
$$\mu_{2(W)} = m_{2(W)},$$

and

$$m = m_1+m_2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

eqs. [29] and [30] become greatly simplified to

$$[33]\quad \left(\frac{dm_1}{dT}\right)\left[\frac{1}{2m_1}+\frac{1}{2m}+\left(\frac{\partial \ln \gamma_{R(0)}}{\partial m}\right)_T+\beta_1\right]+\left(\frac{dm_2}{dT}\right)\left[\frac{1}{2m}+\left(\frac{\partial \ln \gamma_{R(0)}}{\partial m}\right)_T+\beta_1-\alpha_1\right] = \frac{(\Delta H_{1(0)}+\bar{L}_1)}{2RT^2}$$

and

$$[34]\quad \left(\frac{dm_2}{dT}\right)\left[\frac{1}{2m_2}+\frac{1}{2m}+\left(\frac{\partial \ln \gamma_{R(0)}}{\partial m}\right)_T+\beta_2\right]+\left(\frac{dm_1}{dT}\right)\left[\frac{1}{2m}+\left(\frac{\partial \ln \gamma_{R(0)}}{\partial m}\right)_T+\beta_2-\alpha_2\right] = \frac{(\Delta H_{2(0)}+\bar{L}_2)}{2RT^2}.$$

As before, the left-hand sides of these equations may be equated to X and Y respectively so that ΔH_{12} and ΔH_{21} may be evaluated from eqs. [25] and [26].

The expressions for α_1 and α_2 (eqs. [31] and [32]) also become greatly simplified to

$$[35]\quad \alpha_1 = (1/m_2)[\ln (m_1 m)^2 - \ln m_{1(W)} + \ln (\gamma_{R(0)}/\gamma_{R(W1)}) + \beta_1(m - m_{1(W)})]$$

$$[36]\quad \alpha_2 = (1/m_1)[\ln (m_2 m)^2 - \ln m_{2(W)} + \ln (\gamma_{R(0)}/\gamma_{R(W2)} + \beta_2(m - m_{2(W)})].$$

The expressions for β_1 and β_2 are similar to eq. [11] with μ being equal to molality.

IV. APPLICATION OF THEORY TO EXPERIMENTAL RESULTS

The above theoretical treatment has been applied to the saturated KCl–NaCl–H_2O and KCl–KNO_3–H_2O systems for calculating heats of solutions of both salts in each of the saturated systems.

Since both these are 1:1 electrolyte systems with common ions, eqs. [33] and [34] along with eqs. [25] and [26] are to be applied for calculation of heats of solutions. The data and calculations are given in Tables I and II.

V. DISCUSSION OF RESULTS

No experimental data are yet available on heats of solutions in nearly saturated salt pairs. However, the influence of added electrolytes on the heats of solutions of salts has been experimentally investigated (1, 2). Our calculations in saturated systems may be qualitatively reviewed in relation to the data in the unsaturated systems. Drucker's

work on KCl–NaCl–H_2O system indicates that the heat of solution of KCl was depressed from 4.4 kcal/mole in water (18° C) to 3.2 kcal/mole on the addition of 4.0 molar NaCl. This depression of 1.2 kcal/mole may be compared with the value of $\bar{L}_1$ (eq. [23]) which represents the relative partial molal heat content of NaCl in a solution saturated with respect to both KCl and NaCl.

$$\bar{L}_1 = 2RT^2X - \Delta H_{1(0)}$$
$$= 3.33 - 4.44 = -1.11 \text{ at } 18° \text{ C},$$

which is close to the observed depression. Since the system investigated by Drucker had about 0.2 molal KCl in it, it appears that $\bar{L}_1$ does not alter very much between this concentration and saturation (1.93 m). The data (2) on KCl–KNO_3–H_2O system are not extensive enough to evaluate heats of solutions at concentrations nearing saturation even by extrapolation. However, the high negative value of

$$\bar{L}_2 = 2RT^2Y - \Delta H_{2(0)} = -6.07 \text{ kcal/mole}$$

predicted by theory for a saturated KCl–KNO_3–H_2O system is justified by the trend of experimental results according to which (3) $\bar{L}_2$ in a solution containing 2.7 m KNO_3 and 0.27 m KCl is considerably large and negative ($\bar{L}_2 = 4.14 - 8.59 = -4.45$ kcal/mole).

ACKNOWLEDGMENT

APPENDIX

Heats of Solutions in Saturated Multicomponent Systems

The present treatment may be extended to multicomponent systems as follows: Consider a saturated system of 'n' components A_1, A_2, ... A_n. Extending van't Hoff's equation with respect to component A_1, whose properties are designated by subscript "1",

$$[A1] \qquad d \ln P_1\gamma_1^{\nu_1}/dT = \Delta H_{1(0)}/RT^2,$$

whence

$$[A2] \qquad \frac{1}{\nu_1}\frac{d \ln P_1}{dT}+\left(\frac{d \ln \gamma_1}{dT}\right)_{sat} = \frac{\Delta H_{1(0)}}{\nu_1 RT^2}.$$

Now,

$$[A3] \qquad \left(\frac{d \ln \gamma_1}{dT}\right)_{sat} = \left(\frac{\partial \ln \gamma_1}{\partial T}\right)_{\mu_1,\mu_2,\ldots\ldots\mu_n} +\left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,\mu_3,\ldots\ldots\mu_n,T}\left(\frac{d\mu_1}{dT}\right)$$
$$+\left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,\mu_3,\ldots\ldots\mu_n,T}\left(\frac{d\mu_2}{dT}\right)+\ldots\ldots+\left(\frac{\partial \ln \gamma_1}{\partial \mu_n}\right)_{\mu_1,\mu_2,\ldots\ldots\mu_{n-1},T}\left(\frac{d\mu_n}{dT}\right),$$

where $\mu_1, \mu_2, \ldots\ldots \mu_n$ are the ionic strengths of $A_1, A_2, \ldots\ldots A_n$ respectively. Now, assuming validity of Harned's rule (see eqs. [8*a*], [8*b*] of text)

$$[A4] \qquad \begin{aligned} \ln \gamma_1 &= \ln \gamma_{1(0)} - \alpha_1(\mu-\mu_1) \\ \ln \gamma_2 &= \ln \gamma_{2(0)} - \alpha_2(\mu-\mu_2) \\ \ln \gamma_n &= \ln \gamma_{n(0)} - \alpha_n(\mu-\mu_n), \end{aligned}$$

where μ, the total ionic strength $= (\mu_1+\mu_2+\ldots\ldots\mu_n)$. From [A4], equations analogous to [9] and [10] of text follow:

$$[A5] \qquad \left(\frac{\partial \ln \gamma_1}{\partial \mu_1}\right)_{\mu_2,\mu_3,\ldots\ldots\mu_n,T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T - (\mu-\mu_1)\left(\frac{\partial \alpha_1}{\partial \mu}\right)_T$$

and

$$[A6_1] \qquad \left(\frac{\partial \ln \gamma_1}{\partial \mu_2}\right)_{\mu_1,\mu_3,\ldots\ldots\mu_n,T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T - (\mu-\mu_1)\left(\frac{\partial \alpha_1}{\partial \mu}\right)_T - \alpha_1$$

$$[A6_n] \qquad \left(\frac{\partial \ln \gamma_1}{\partial \mu_n}\right)_{\mu_1,\mu_2,\ldots\ldots\mu_{n-1},T} = \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T - (\mu-\mu_1)\left(\frac{\partial \alpha_1}{\partial \mu}\right)_T - \alpha_1.$$

Further,

$$[A7] \qquad \left(\frac{\partial \ln \gamma_{1(0)}}{\partial \mu}\right)_T = \left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T + \beta_1$$

analogous to eq. [12] of text.

Substituting eqs. [A7], [A6$_1$]–[A6$_n$], and [A5] in eq. [A3] and also noting that

$$(\partial \alpha_1/\partial \mu)_T = 0$$

and

$$\left(\frac{\partial \ln \gamma_1}{\partial T}\right)_{\mu_1,\mu_2,\ldots\ldots\mu_n} = -\frac{\bar{L}_1}{\nu_1 RT^2},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

where $\bar{L}_1$ is the relative partial molal heat content of A_1 in the saturated multicomponent system,

$$[A8_1] \qquad \frac{1}{\nu_1}\frac{d\ln P_1}{dT}+\frac{d\mu_1}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_1\right]+\frac{d(\mu-\mu_1)}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_1-\alpha_1\right] = \frac{(\Delta H_{1(0)}+\bar{L}_1)}{\nu_1 RT^2}.$$

Equations similar to $[A8_1]$ may be written for the other components. In general,

$$[A8_n] \qquad \frac{1}{\nu_n}\frac{d\ln P_n}{dT}+\frac{d\mu_n}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_n\right]+\frac{d(\mu-\mu_n)}{dT}\left[\left(\frac{\partial \ln \gamma_{R(0)}}{\partial \mu}\right)_T+\beta_n-\alpha_n\right] = \frac{(\Delta H_{n(0)}+\bar{L}_n)}{\nu_n RT^2},$$

where, $P_1, P_2, \ldots . P_n$ are the stoichiometric solubility products and $\Delta H_{1(0)}, \Delta H_{2(0)}, \ldots . \Delta H_{n(0)}$ are the differential heats of solutions in water of $A_1, A_2, \ldots . A_n$ respectively. A knowledge of $\beta_1, \beta_2, \ldots . \beta_n$ and $\alpha_1, \alpha_2, \ldots . \alpha_n$ is necessary to evaluate the left-hand sides of eqs. $[A8_1]$ to $[A8_n]$. Now $\beta_1, \beta_2, \ldots . \beta_n$ are given by the equations of the type,

$$[A9] \qquad \ln \gamma_{n(0)} = \ln \gamma_{R(0)}+\mu\beta_n.$$

$\alpha_1, \alpha_2, \ldots . \alpha_n$ are evaluated as follows.

For the species A_n, the solubility relationship gives

$$[A10] \qquad \ln P_n/\nu_n+\ln \gamma_n = \ln P_{n(W)}/\nu_n+\ln \gamma_{n(W)}$$

where the subscript (w) indicates "solution in pure water". Substituting for $\ln \gamma_n$ from eqs. [A4] and [A9] and remembering that

$$\ln \gamma_{n(W)} = \ln \gamma_{R(W)}+\beta_n\mu_{n(W)},$$

where $\mu_{n(W)}$ is the ionic strength of A_n, we get on rearranging,

$$[A11] \qquad \alpha_n = [(1/\nu_n)\ln(P_n/P_{n(W)})+\ln(\gamma_{R(0)}/\gamma_{R(Wn)})+\beta_n(\mu-\mu_{n(W)})]/(\mu-\mu_n).$$

Now, denoting the left-hand sides of eqs. $[A8_1]$ to $[A8_n]$ by $X_1, X_2, \ldots . X_n$, respectively

$$[A12_1] \qquad \nu_1 X_1 RT^2 = \Delta H_{1(0)}+\bar{L}_1$$

$$[A12_2] \qquad \nu_2 X_2 RT^2 = \Delta H_{2(0)}+\bar{L}_2$$

$$[A12_n] \qquad \nu_n X_n RT^2 = \Delta H_{n(0)}+\bar{L}_n.$$

Now, if $\Delta H_1, \Delta H_2, \ldots . \Delta H_n$ are the heats of solutions of $A_1, A_2, \ldots . A_n$, respectively, in a system saturated with all the components

$$[A13_1] \qquad \Delta H_1 = \Delta H_{1(0)}+\bar{L}_1 = \nu_1 RT^2 X_1$$

$$[A13_2] \qquad \Delta H_2 = \Delta H_{2(0)}+\bar{L}_2 = \nu_2 RT^2 X_2$$

and in general

$$[A13_n] \qquad \Delta H_n = \Delta H_{n(0)}+\bar{L}_n = \nu_n RT^2 X_n.$$

Thus, knowing $X_1, X_2, \ldots . X_n$ from eqs. $[A8_1]$ to $[A8_n]$ it is possible to calculate the heats of solutions $\Delta H_1, \Delta H_2, \ldots . \Delta H_n$ of components $A_1, A_2, \ldots . A_n$ in their saturated multicomponent systems by means of eqs. $[A13_1]$ to $[A13_n]$.

ELECTRICAL EFFECTS ON THE C–O–C ASYMMETRICAL STRETCHING VIBRATION IN ANISOLES

G. K. GOLDMAN, H. LEHMAN, AND, C. N. R. RAO*

The infrared vibrational frequencies and the band intensities of several groups in related series of organic molecules have been found to be influenced systematically by substituents (1–4). In benzene derivatives of the type RC_6H_4X, where X is the functional group and R is a meta- or a para-substituent, linear relations have been found between reactivity constants of R with the vibrational frequency of X and also with the logarithm of the band intensity of X (1–4). Among the electron-donating groups, only the hydroxy and the amino groups have been studied in detail. Little is known about the electrical effects of substituents on the ether linkage (C–O–C) in anisoles. The 1200-cm^{-1} band in esters assigned to the C–O stretching vibration has been studied in a number of alkyl esters (5), but the results do not throw any light on the substituent effects. We have now investigated the electrical effects of substituents on the asymmetrical C–O–C stretching vibration (6) in parasubstituted anisoles.

All the compounds were purified before use. The infrared spectra were recorded in carbon tetrachloride solutions using a Perkin–Elmer, Model 21, spectrophotometer. The molarities of the solutions were kept constant at about 0.05 for all the compounds. The apparent molecular extinction coefficients (ϵ) at the maximal frequencies were calculated from the Beer's law.

The C–O–C asymmetrical stretching frequency in *p*-substituted anisoles increases with the electron withdrawing power of the *p*-substituent. The plot of the frequency

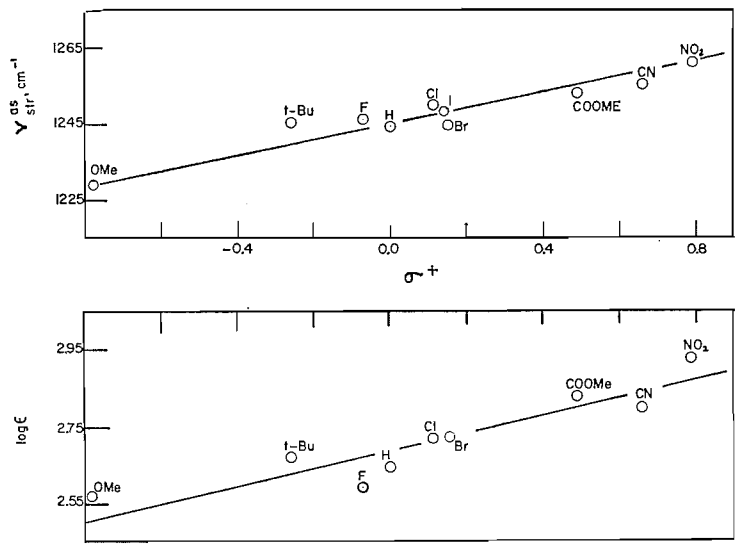

FIG. 1. Correlation of the C–O–C asymmetrical stretching frequency and the band intensity in para-substituted anisoles with the electrophilic substituent constants.

**To whom all the correspondence should be addressed at: Department of Physical Chemistry, Indian Institute of Science, Bangalore, India.*

against Brown–σ^+ values (7) is found to be linear (Fig. 1). The slope of the ν–σ^+ plot is about 21.

The plot of the logarithm of the apparent molecular extinction coefficients of the C–O–C asymmetric stretching frequency against the σ^+ values is also found to be fairly linear (Fig. 1). The band intensity increases with the electron-attracting ability of the *p*-substituent. The apparent half band widths did not seem to show any regular trend. It is interesting to note that the OH band intensity in substituted phenols also shows a similar behavior (8, 9). Since the band intensity of a stretching vibration is directly related to the electrical properties of the particular bond in question (i.e. bond moment and its direction), it appears reasonable that the prominent resonance structures in phenols (I) and in anisoles (II) should be similar:

I

II

The OH stretching frequency in *p*-substituted phenols (unlike the C–O–C stretching frequency in *p*-substituted anisoles) decreases with the increasing electron-withdrawing ability of the *p*-substituent. Of course, it is true that if two functional groups show similar trends of the band intensities with the reactivity constants, it does not follow that the trends of the frequencies will be similar.

describes the synthesis of N-(γ-DL-glutamyl)-*p*-aminosalicylic acid (II) and N-(L-pyroglutamyl)-*p*-aminosalicylic acid (III). The γ-compound (II) was prepared by treatment

(II)

(III)

of *p*-aminosalicylic acid with N-phthalyl-DL-glutamic anhydride (2), followed by hydrolysis of the intermediate with hydrazine. The reaction of phthalylglutamic anhydride with amines was known to give γ-derivatives (2) and additional evidence for this structure was furnished by the formation of a thiohydantoin when the product was warmed with ammonium thiocyanate and acetic anhydride (3).

The pyroglutamyl-derivative (III) was prepared either by treatment of *p*-aminosalicylic acid with L-pyroglutamyl chloride or by dehydration of N-(α-L-glutamyl)-*p*-aminosalicylic acid when heated above its melting point. Alkaline hydrolysis under a variety of conditions always resulted in cleavage of the side chain amide in preference to the cyclic amide linkage.

EXPERIMENTAL

N-(N-*Phthalyl*-γ-DL-*glutamyl*)-*p*-*aminosalicylic Acid*

A suspension of N-phthalyl-DL-glutamic anhydride (110 g) and *p*-aminosalicylic acid (65 g) in ethyl acetate (2 l.) was stirred at room temperature for 24 hours. The reactants slowly dissolved and then the product separated (120 g) m.p. 227–228° (decomp.). Crystallization from ethyl acetate yielded white needles, m.p. 229° (decomp.). Anal. Calc. for $C_{20}H_{16}N_2O_8$: C, 58.3; H, 3.9; N, 6.8. Found: C, 58.0; H, 4.0; N, 6.7.

N-(γ-DL-*Glutamyl*)-*p*-*aminosalicylic Acid* (II)

N-(N-Phthalyl-γ-DL-glutamyl)-*p*-aminosalicylic acid (41.2 g) in 1 *N* hydrazine hydrate (200 cc) was refluxed for 30 minutes and then cooled. Phthalyl hydrazide was filtered off and the filtrate evaporated to dryness under reduced pressure. The white residue which remained was crystallized from aqueous ethanol yielding the hydrazinium salt of the product (16 g), m.p. 172° (decomp.). Anal. Calc. for $C_{12}H_{18}N_4O_6$: C, 45.9; H, 5.8; N, 17.8. Found: C, 45.9; H, 5.7; N, 17.6.

The salt was treated with 1 equivalent of hydrochloric acid to yield the desired product, m.p. 225° (decomp.). Anal. Calc. for $C_{12}H_{14}N_2O_6$: C, 51.1; H, 5.0; N, 9.9. Found: C, 51.2; H, 5.1; N, 9.9.

1-Acetyl-2-thiohydantoyl-5-β-(3-acetoxy-4-carboxypropionanilide)

A mixture of N-(γ-DL-glutamyl)-*p*-aminosalicylic acid (1 g), ammonium thiocyanate (0.3 g), acetic anhydride (10 cc), and glacial acetic acid (1 cc) was warmed on a hot plate for ½ hour until a clear solution was obtained, and then evaporated under reduced pressure. The residual gum solidified after it was rubbed with water and a little ethanol. Two crystallizations from aqueous ethanol yielded white needles (0.3 g), m.p. 190° (decomp.). Anal. Calc. for $C_{17}H_{17}N_3O_7S$: C, 50.1; H, 4.2; N, 10.3; S, 7.8. Found: C, 49.5; H, 4.2; N, 10.1; S, 7.4.

N-(L-*Pyroglutamyl*)-*p-aminosalicylic Acid* (III)

(*a*) L-Pyroglutamic acid (38.7 g) was added to thionyl chloride (65 cc) and the mixture stirred at room temperature for 5 hours. The excess of thionyl chloride was evaporated under reduced pressure. Dry benzene was added to the residue and then evaporated under reduced pressure to remove the last traces of thionyl chloride. The crude acid chloride was dissolved in tetrahydrofuran (150 cc) and slowly added to a stirred suspension of *p*-aminosalicylic acid (45.9 g) in tetrahydrofuran (150 cc). The mixture was stirred at room temperature for 18 hours, and then the product (76.7 g) was filtered off. Purified material, m.p. 237–238° (decomp.) was obtained by dissolution in aqueous sodium bicarbonate, carbon treatment, and precipitation with hydrochloric acid. Crystallization from water yielded white needles, m.p. 242°–244° (decomp.). Anal. Calc. for $C_{12}H_{12}N_2O_5$: C, 54.6; H, 4.6; N, 10.6. Found: C, 54.7; H, 4.6; N, 10.4. $[\alpha]_D^{21}$ −7.5° (*c*, 5.0 in water).

(*b*) N-(α-L-Glutamyl)-*p*-aminosalicylic acid (4.3 g) was heated at 170° for 4 hours in an oil bath. The starting material melted at 160° and then resolidified. Crystallization from water yielded white needles (1.1 g), m.p. 242–243° (decomp.). The melting point was not depressed by admixture with the product from preparation (*a*).

6-*O*-ETHYL-D-GALACTOSE

G. G. MCKEOWN AND L. D. HAYWARD

In connection with some other work 6-*O*-ethyl-D-galactose was prepared as a sirup by ethylation of 1,2;3,4-di-*O*-isopropylidene-D-galactose followed by dilute acid hydrolysis of the isopropylidene groups. After standing for more than a year at room temperature this new sugar derivative crystallized and the opportunity was taken to record its melting point, equilibrium specific rotation, paper chromatographic behavior, and infrared spectrum.

The 6-*O*-ethyl-D-galactose appeared as a distinct, brown, non-fluorescent spot on paper chromatograms sprayed with *p*-anisidine hydrochloride reagent. This behavior appeared to be characteristic of 6-*O*-alkyl derivatives of galactose since it was shown by 6-*O*-methyl-D-galactose but not by the mono-1,2,3, or 4-*O*-methyl ethers (1). In the glucopyranose series the 2- and 6-mono-*O*-methyl ethers showed this same color reaction which was also distinct from the behavior of the 3- and 4-*O*-methyl compounds (2).

EXPERIMENTAL

Paper chromatograms were prepared with 1-butanol–ethanol–water (5:1:4 v/v) and were sprayed with *p*-anisidine hydrochloride reagent.

*6-O-Ethyl-1,2;3,4-di-O-isopropylidene-*D*-galactose*

Diacetone-D-galactose (1,2;3,4-di-*O*-isopropylidene-D-galactopyranose) was prepared from D-galactose in 34% yield (3), $[\alpha]_D^{20}$ −55.0° (*c*, 6.66 in chloroform) and gave a single

N-(L-*Pyroglutamyl*)-*p-aminosalicylic Acid* (III)

(*a*) L-Pyroglutamic acid (38.7 g) was added to thionyl chloride (65 cc) and the mixture stirred at room temperature for 5 hours. The excess of thionyl chloride was evaporated under reduced pressure. Dry benzene was added to the residue and then evaporated under reduced pressure to remove the last traces of thionyl chloride. The crude acid chloride was dissolved in tetrahydrofuran (150 cc) and slowly added to a stirred suspension of *p*-aminosalicylic acid (45.9 g) in tetrahydrofuran (150 cc). The mixture was stirred at room temperature for 18 hours, and then the product (76.7 g) was filtered off. Purified material, m.p. 237–238° (decomp.) was obtained by dissolution in aqueous sodium bicarbonate, carbon treatment, and precipitation with hydrochloric acid. Crystallization from water yielded white needles, m.p. 242°–244° (decomp.). Anal. Calc. for $C_{12}H_{12}N_2O_5$: C, 54.6; H, 4.6; N, 10.6. Found: C, 54.7; H, 4.6; N, 10.4. $[\alpha]_D^{21}$ −7.5° (*c*, 5.0 in water).

(*b*) N-(α-L-Glutamyl)-*p*-aminosalicylic acid (4.3 g) was heated at 170° for 4 hours in an oil bath. The starting material melted at 160° and then resolidified. Crystallization from water yielded white needles (1.1 g), m.p. 242–243° (decomp.). The melting point was not depressed by admixture with the product from preparation (*a*).

6-*O*-ETHYL-D-GALACTOSE

G. G. MCKEOWN AND L. D. HAYWARD

In connection with some other work 6-*O*-ethyl-D-galactose was prepared as a sirup by ethylation of 1,2;3,4-di-*O*-isopropylidene-D-galactose followed by dilute acid hydrolysis of the isopropylidene groups. After standing for more than a year at room temperature this new sugar derivative crystallized and the opportunity was taken to record its melting point, equilibrium specific rotation, paper chromatographic behavior, and infrared spectrum.

The 6-*O*-ethyl-D-galactose appeared as a distinct, brown, non-fluorescent spot on paper chromatograms sprayed with *p*-anisidine hydrochloride reagent. This behavior appeared to be characteristic of 6-*O*-alkyl derivatives of galactose since it was shown by 6-*O*-methyl-D-galactose but not by the mono-1,2,3, or 4-*O*-methyl ethers (1). In the glucopyranose series the 2- and 6-mono-*O*-methyl ethers showed this same color reaction which was also distinct from the behavior of the 3- and 4-*O*-methyl compounds (2).

EXPERIMENTAL

Paper chromatograms were prepared with 1-butanol–ethanol–water (5:1:4 v/v) and were sprayed with *p*-anisidine hydrochloride reagent.

*6-O-Ethyl-1,2;3,4-di-O-isopropylidene-*D*-galactose*

Diacetone-D-galactose (1,2;3,4-di-*O*-isopropylidene-D-galactopyranose) was prepared from D-galactose in 34% yield (3), $[\alpha]_D^{20}$ −55.0° (*c*, 6.66 in chloroform) and gave a single

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

yellow spot, R_f 0.88, on a paper chromatogram. A mixture of diacetone-D-galactose (5.04 g), acetone (10 ml), water (25 ml), and sodium hydroxide pellets (10 g) was heated to 55° C with vigorous stirring, and diethyl sulphate (13 ml) was added dropwise over a period of 45 minutes. The mixture was then heated at 85° C for 1 hour, cooled, and extracted with chloroform. The chloroform extract was dried (anhydrous sodium carbonate) and evaporated and the residue was distilled under reduced pressure from sodium carbonate (yield, 3.68 g, 66%). Hydrolysis of a sample with boiling 70% acetic acid and paper chromatography of the hydrolyzate showed that the sirupy distillate contained some unreacted diacetone-D-galactose. The developed chromatogram had a distinct, brown, non-fluorescent spot, R_f 0.40, for 6-*O*-ethyl-D-galactose plus a faint, yellow-brown, fluorescent spot, R_f 0.11, which corresponded to D-galactose. The sirup was redistilled from sodium hydroxide (b.p. 101–103° C at 0.2 mm) to give 2.63 g of a colorless product, $[\alpha]_D^{27}$ −57.6° (*c*, 4.90 in ethanol), which failed to crystallize.

6-O-Ethyl-D-galactose

6-*O*-Ethyl-1,2;3,4-di-*O*-isopropylidene-D-galactopyranose (783 mg) was dissolved in 80% acetic acid (10 ml) and heated on a steam bath for 15 hours. The hydrolyzate was evaporated to dryness *in vacuo* and the residue was refluxed with water (10 ml) for 5 hours to reverse any acetate formation. A chromatogram showed a trace of D-galactose in the product which was removed by passage through a cellulose column developed with butanol–water. The appropriate fractions when combined yielded a colorless glass (358 mg, 63.3%) which crystallized in pentagonal plates after standing at room temperature for 15 months. The reducing sugar derivative was recrystallized from anhydrous ethyl acetate to a constant melting point (104.5–105.0° C); $[\alpha]_D^{27}$ +88.6° (23 minutes) changing to +69.0° (constant at 148 minutes) (*c*, 2.10 in water). Anal. Calc. for $C_8H_{16}O_6$: C, 46.1; H, 7.7; OC_2H_5, 21.6%. Found: C, 45.8; H, 7.5; OC_2H_5, 21.8%.* The infrared spectrum of the compound (potassium bromide window) exhibited absorption maxima at the following frequencies (cm^{-1}): 3430, 2900, 1635, 1390, 1240, 1100, 970, 830, 800, 775.

We thank the National Research Council of Canada and the Sugar Research Foundation, New York, for research grants.

THE CHEMICAL COMPOSITION OF THE HEARTWOOD EXTRACTIVES OF LARIX LYALLII PARL.[1]

G. V. NAIR[2] AND E. VON RUDLOFF

ABSTRACT

The heartwood of Canadian Alpine larch was found to contain 4.8% acetone-soluble material. From this extract taxifolin and aromadendrin were isolated in 26% and 17% yield, as well as conidendrin in a small amount. About one-quarter of the extract was composed of esters of phthalic, ferulic, and fatty acids. After saponification β-sitosterol, nonan-2-ol, phthalic acid, and a mixture of fatty acids were isolated. Gas–liquid chromatography indicated the presence of palmitic, an unidentified C_{16}, stearic, oleic, linoleic, linolenic, an unidentified C_{20} acid, and two unidentified alcohols.

Recently we have reported on the chemical composition of the heartwood extractives of *Larix laricina* (Du Roi) K. Koch (tamarack) (1). This paper deals with the results obtained with a similar extract of another Canadian larch species, *L. lyallii Parl.* (alpine larch). This medium-sized tree is found in the high mountains of Western Canada, usually at an altitude of 5000 to 6000 feet. Botanical sources do not mention any particular resistance to decay of this wood, nor has it found any extensive commercial use. Acetone extraction of the heartwood of a mature tree from the Minnewanka district, Banff National Park, Alberta, gave a yield of about 4.8% soluble extractives. The fractionation scheme and yields of the various compounds isolated are shown in Fig. 1.

The two flavanonols (nomenclature (2)), taxifolin and aromadendrin, were isolated in 1.25% and 0.82% yield respectively (based on the dry weight of the wood). Thus, *L. lyallii* is an excellent source for these two compounds, especially so for the less common aromadendrin. Both flavanonols have previously been found in *L. decidua*, *L. leptolepis*, and *L. occidentalis* (3, 4, 5*a*, 5*b*), and Gripenberg (3) has shown that the distylin of *L. kaempferi* (5, 6) is a mixture of these two compounds. The isolation of these two flavanonols in the Canadian larch species *L. lyallii* and *L. laricina* (1) provides additional support to Erdtman's hypothesis (7) that closely related species of conifers have certain characteristic heartwood constituents in common, irrespective of geography, which are therefore of value in taxonomic classifications.

A small amount of conidendrin (0.03%) was also isolated. This lignan is widespread amongst conifers and other plants (2, 7) but has not previously been found in the wood of larches. The lignan lariciresinol has been isolated from the resin produced by *L. decidua* (7, 8).

About one-fourth of the extract of *L. lyallii* was found to consist of β-sitosterol, nonan-2-ol, and unidentified alcohols esterified with phthalic, ferulic, and a complex mixture of

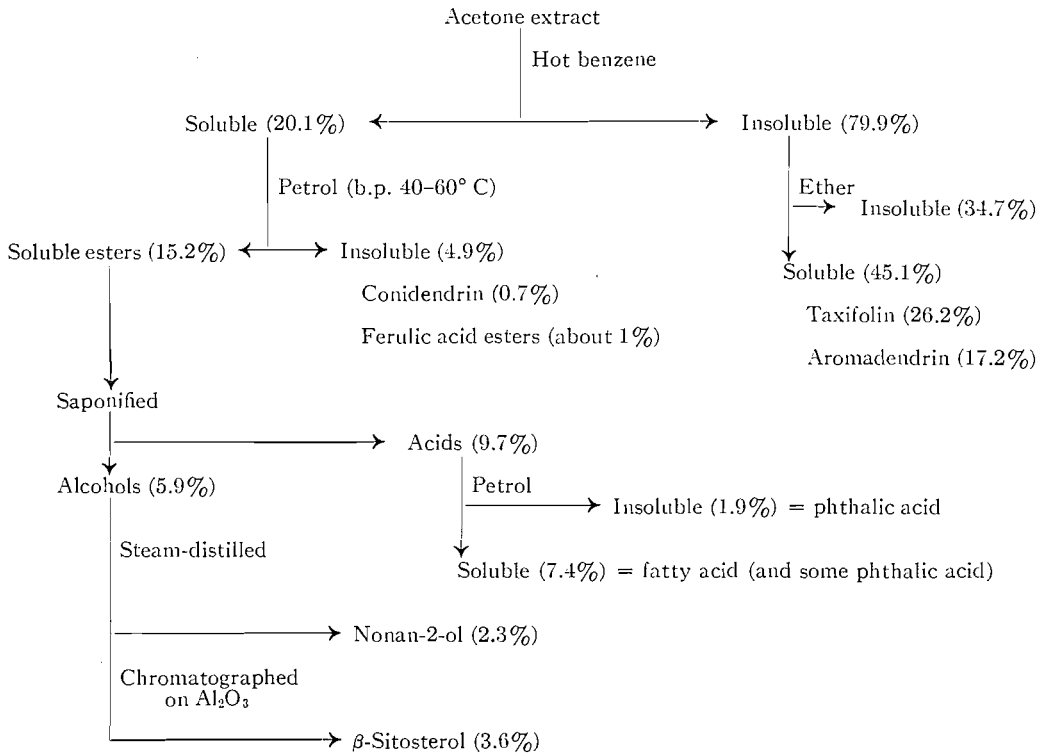

FIG. 1. Fractionation scheme and yields of components (based on the dry weight of acetone extract).

fatty acids. A mixture of esters composed of ferulic acid, nonan-2-ol, and an unknown alcohol of similar molecular weight was isolated from the petrol-insoluble portion (see Fig. 1). It hydrolyzed with difficulty, causing considerable degradation of the ferulic acid moiety, and its infrared absorption spectrum was similar to that of the eicosanyl ferulate isolated from the heartwood of *L. laricina* (1). The non-saponifiable portion was composed of a mixture of alcohols which failed to crystallize and which could not be resolved by distillation. Gas–liquid partition chromatography (GLPC) showed two peaks of about equal intensity corresponding to nonan-2-ol and an unidentified alcohol in the C_9-to-C_{10} region. Higher alcohols appeared to be absent.

The petrol-soluble esters were saponified and, from the resulting mixture of acids, phthalic acid was isolated by crystallization. The presence of phthalic acid in *L. lyallii* and *L. laricina* is noteworthy, since this aromatic acid is found only rarely in nature (1, 9, 10). The residual acid mixture was resolved by GLPC and peaks corresponding to palmitic, oleic, linoleic, phthalic, linolenic, and unidentified C_{16} and C_{20} acids were obtained. From the non-saponifiable portion, nonan-2-ol was obtained by steam distillation and β-sitosterol by chromatography on neutral alumina and crystallization. GLPC of the total non-saponifiable portion gave a major peak corresponding to nonan-2-ol and two minor peaks in the C_9-to-C_{10} and C_{16} region.

The extract contained no resin acids nor neutral terpenoid compounds, and differed from that of *L. laricina* in that free sugars and eicosanol were absent.

EXPERIMENTAL

Melting points were obtained with a Leitz hot stage microscope. All known compounds

were identified by mixed melting point and by comparing infrared spectra with those of authentic samples. Infrared spectra were recorded on a Perkin–Elmer model 21 double beam recording spectrophotometer, using the KBr disk method or the film technique. Gas–liquid partition chromatograms were obtained with a Beckman GC 2 chromatograph on $\frac{1}{4}$-inch columns of either washed silicone (11) or polyester (12) on C-22 firebrick, unless otherwise indicated.

Extraction of the Wood

The air-dried, milled wood (3.9 kg) (moisture content about 4.5%) was extracted with acetone in a Soxhlet extractor for 36 hours. The acetone extract was reduced to dryness in a rotary evaporator at about 50° C giving dark brown viscous material. The crude concentrated extract was dried *in vacuo* for several hours and then re-extracted with dry acetone and filtered. The filtrate was concentrated and dried as above to yield 178 g of acetone-soluble material (4.8% yield, based on the dry weight of the wood).

Preliminary color tests on the crude extract for flavanonols were positive, but precipitation tests with digitonin for sterols and cyclohexylamine for resin acids were negative. Paper chromatography (with impregnated paper (13), using petrol (b.p. 40–60° C) as the mobile phase and diazotized benzidine spray) provided no evidence for tropolones. Gripenberg's (3) chromatographic technique on paper using chloroform:ethanol:water (8:2:1, v/v) with addition of 2% acetic acid (1) showed spots corresponding to taxifolin and aromadendrin. A portion of the extract, after saponification, showed the presence of sterols, volatile constituents, and fatty acids, but no resin acids.

Separation of the Constituents

The crude extract (10.55 g) was triturated with hot benzene and filtered. The benzene-soluble matter (2.18 g) was further separated into petrol-soluble (b.p. 40–60° C) (1.65 g) and -insoluble (0.53 g) portions. The benzene-insoluble matter (8.6 g) was extracted with ether to yield 4.9 g of a phenolic mixture. The residue was ethanol-soluble and failed to yield crystalline material.

Isolation and Identification of Taxifolin and Aromadendrin

The ethereal extract of the benzene-insoluble portion was soluble in alkali but insoluble in bicarbonate. A paper chromatogram, using chloroform:ethanol:water (8:2:1 v/v) containing 2% acetic acid to prevent tailing (1), showed spots corresponding to aromadendrin (R_f 0.8) and taxifolin (R_f 0.6) when sprayed with bis-diazotized benzidine (14). The mixture (2.27 g) was resolved on a cellulose powder column (50×4.5 cm) using the same solvent mixture as eluent. Fractions of 20 ml were collected and tested individually by paper chromatography. Tubes 1–20 contained aromadendrin (0.44 g), m.p. 236–237° C (from chloroform), $[\alpha]_D^{25.4}$ +44.5 (*c*, 0.21; acetone–water) and tubes 41–153 gave taxifolin (0.89 g), m.p. 238–240° C (from water), $[\alpha]_D^{25.4}$ +45.21 (*c*, 0.11; water–acetone). Tubes 30–41 (0.845 g) contained about equal quantities of aromadendrin and taxifolin, bringing the over-all yield to about 17% and 26% respectively.

Isolation and Identification of Conidendrin and Ferulic Esters

The benzene-soluble portion (2.18 g) was evaporated to dryness and triturated with cold petrol (b.p. 40–60° C). The powdery, insoluble residue was filtered off, washed thoroughly with cold petrol, and dried. The crude product was crystallized from ethanol to give conidendrin (0.073 g), m.p. 238–239° C (lit. 255–256° C and 238° C (15)); $[\alpha]_D^{25.4}$ −59.43 (*c*, 1.1, acetone). It gave a green coloration with aqueous ferric chloride. Found: C, 67.08%; H, 5.95%. Calculated for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%. The mother liquor was chromatographed on a column of neutral alumina (M. Woelm, Eschwege,

activity grade I). Elution with ether produced a small amount of a mixture of fatty acid esters (infrared spectrum). When elution was continued with mixtures of petrol–ethanol (1:1 v/v) and benzene–ethanol (1:1 v/v) a liquid fraction was obtained, which had a well-defined infrared absorption spectrum which was similar to those of ferulic acid esters. The intensity of the C—H absorption in the 3000 to 2800 cm^{-1} region was relatively weaker than that for eicosanyl ferulate, but considerably stronger than that for methyl ferulate, indicating that the aliphatic chain of the alcohol moiety was of intermediate length. The material was hydrolyzed under reflux in a 2 *N* solution of potassium hydroxide in ethylene glycol monomethyl ether. Ferulic acid was identified in the saponifiable portion by paper chromatography. Attempts to crystallize the acid failed due to the presence of a considerable amount of degradation products. The non-saponifiable portion failed to yield a pure compound on distillation and crystallization attempts. GLPC on a polyethylene glycol column at 160° C gave two peaks of about equal area with retention times corresponding to nonan-2-ol and a C_9-to-C_{10} alcohol. Washing the column of neutral alumina with alcohol produced a small amount of conidendrin.

Petrol Extract

The petrol-soluble portion (1.65 g) was saponified under reflux with potassium hydroxide (3.4 g) in ethyleneglycol monomethyl ether (30 ml) for 3 hours. The reaction mixture was reduced in volume and worked up in the usual manner to give the non-saponifiable (0.64 g) and saponifiable (1.005 g) portions.

The non-saponifiable portion was steam-distilled and the distillate (1 liter) was saturated with sodium chloride and extracted thrice with ether. The ether extract was dried over Drierite and the solvent was distilled off to yield 0.25 g (2.3%) of a sweet-smelling, colorless liquid alcohol, b.p. 81–83° C at 15 mm, n_D^{25} 1.4390. The retention time of this alcohol on gas chromatograms was identical with that of nonan-2-ol. The non-volatile residue was extracted with ether and the ethereal solution evaporated after drying to give 0.4 g of a semisolid residue. This was chromatographed on a column of neutral alumina and eluted first with a 1:1 mixture of petrol (b.p. 40–60° C) and ether to yield a trace of unsaponified esters of fatty acid. Elution with a 1:1 mixture of ethanol–ether gave 0.39 g (3.6%) of a steroid material (positive Liebermann–Buchard reaction). Crystallization from alcohol gave β-sitosterol, having m.p. 136–137°.

Acid Mixture

The thoroughly dried acidic residue obtained after saponification of the esters was triturated with warm petrol (b.p. 40–60° C) and filtered. The petrol-insoluble portion (0.2 g, 1.9%) was crystallized from acetone, and gave phthalic acid, m.p. 201–202° C. The petrol-soluble portion (0.8 g, 7.6%) was re-esterified with diazomethane, and the methyl esters were analyzed by GLPC using the polyester column. Peaks corresponding to the following acids (in order of their retention times) were obtained: palmitic (5.9%); an unidentified C_{16} (5.7%); stearic (1.5%); oleic (18.2%); linoleic (34.7%); phthalic (22.1%); linolenic (3.4%); and an unidentified C_{20} acid (5.5%). The percentage composition was obtained by determining the area under the curve of each peak by the triangulation method.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mr. M. Granat for technical assistance, to Mr. M. Mazurek for the microanalyses, and to Miss I. M. Gaffney for the infrared spectra. We also wish to thank Professor H. Erdtman for authentic samples of flavanonols

THE ACTIVATION ENERGY FOR THE RECOMBINATION OF TRIFLUOROMETHYL RADICALS[1]

G. O. PRITCHARD[2] AND J. R. DACEY

ABSTRACT

By photolyzing mixtures of acetone and hexafluoroacetone, and measuring the rates of formation of the three ethanes, we have found $E_1 - \frac{1}{2}E_2 - \frac{1}{2}E_3 = -1070 \pm 100$ cal, which means that the activation energy for the recombination of CF_3 radicals is 2140 ± 200 cal, assuming zero activation energies for the other two radical recombinations, and that none of the ethanes is formed except by radical recombination.

INTRODUCTION

Although Ayscough (1) has shown that CF_3 radicals recombine on nearly every collision with a rate almost identical with that found for CH_3 radicals, he was unable to determine whether the recombination was temperature dependent or not. This problem is of theoretical interest since it has been suggested that due to the marked polarity of the C—F bond a potential barrier to CF_3 radical combination could exist, with a consequent small positive activation energy for the reaction (2). There is no such restriction for the recombination of simple alkyl radicals, and they are assumed to recombine with zero activation energy.

We have photolyzed mixtures of acetone and hexafluoroacetone over a temperature range from 29° to 169° C to see if we could detect any variation in the relative rates of formation of the three ethanes with temperature. Writing these rates as $R_{CH_3CF_3}$, $R_{C_2H_6}$, and $R_{C_2F_6}$ for the reactions

$$CH_3 + CF_3 \xrightarrow{k_1} CH_3CF_3 \qquad [1]$$

$$CH_3 + CH_3 \xrightarrow{k_2} C_2H_6 \qquad [2]$$

and

$$CF_3 + CF_3 \xrightarrow{k_3} C_2F_6, \qquad [3]$$

and assuming the activation energies for reactions [1] and [2] to be zero, i.e. $E_1 = E_2 = 0$, any variation in the ratio $R_{CF_3CH_3}/R^{\frac{1}{2}}_{C_2H_6} R^{\frac{1}{2}}_{C_2F_6} = k_1/k_2^{\frac{1}{2}}k_3^{\frac{1}{2}}$ (for steady-state conditions) will be caused by $E_3 \neq 0$, provided the above reactions are the only source of the ethanes in the system. (If $E_1 = E_2 = E_3$, and the steric factors for the three reactions are identical, the ratio reduces to 2.30, assuming $\sigma_{CH_3} = 3.5$ Å and $\sigma_{CF_3} = 4.0$ Å.)

EXPERIMENTAL

Hexafluoroacetone was obtained from the Merck Chemical Company as the hydrate. It was dehydrated with P_2O_5 and purified by low temperature fractionation. The acetone used was A.R. grade; it also was thoroughly dried and outgassed.

Mixtures of the ketones were photolyzed in the more or less standard high vacuum apparatus for experiments of this type. The light source was a B.T.H. high pressure lamp (ME/D, 250 watts), operated at constant intensity over the time of a run. The light beam was collimated by a single quartz lens and a stop. No filtering system, which would

For personal use only.

have reduced the light intensity considerably, was employed to isolate the 3130 Å radiation. With this arrangement it was found that convenient quantities of the ethanes were produced. The 175-cc cylindrical quartz reaction vessel was mounted in a furnace the temperature of which was held within ±1.5° C of the desired temperature.

Analysis of the reaction products was by low temperature fractionation, using a solid nitrogen trap and two Ward–LeRoy stills, a small Hg diffusion pump, and a combined Toepler pump and gas buret. CO and CH_4 were pumped off at −210° C. The C_2H_6, C_2F_6, and CF_3H were collected with the stills carefully regulated at −161° and −156° C respectively whilst the system was pumped in intermittent bursts of about 5 seconds in duration until a constant pressure of 10^{-3} mm Hg was obtained. After measurement, this mixture was analyzed mass spectrographically. (Reference gases were obtained commercially and purified if necessary.) The amount of CF_3CH_3 carried over using this technique was found to be less than 2% of the sample, although CO_2 was found to be present as well. The remainder of the reaction mixture was condensed in a tube containing carefully outgassed distilled water. The contents were allowed to warm up to room temperature, and shaken vigorously. The CF_3CH_3 was then distilled off at −130° C. This procedure removed all the CF_3COCF_3, which would otherwise contaminate the CF_3CH_3 samples. Trial experiments proved this method to be quantitative. Pure CF_3CH_3 was prepared by the reaction of SbF_3 on CH_3CCl_3 in a sealed bomb (3); this also served as a mass spectrometer standard. Mass spectrographic analysis of the CF_3CH_3 samples showed that they were essentially pure, but they also contained some CO_2.

RESULTS

The relevant data is collected in Table I. The quantities of CO_2 are the total amounts found; this was usually evenly divided between the two samples. They represent a 1%

CO_2 impurity in the hexafluoroacetone (detected in the mass spectrometer), but repeated treatment of the ketones with slaked lime failed to eliminate CO_2 altogether. The other volatile products, CO and CH_4, are not included in the table.

Assuming steady-state conditions, $R_{CF_3CH_3}/R^{\frac{1}{2}}_{C_2H_6}\ R^{\frac{1}{2}}_{C_2F_6} = k_1/k_2^{\frac{1}{2}}k_3^{\frac{1}{2}}$. An Arrhenius plot of the data is given in Fig. 1. A least squares treatment results in $(E_1 - \frac{1}{2}E_2 - \frac{1}{2}E_3) = -(1070 \pm 100)$ cal with the pre-exponential ratio $A_1/A_2^{\frac{1}{2}}A_3^{\frac{1}{2}} = 0.52 \pm 0.06$. Assuming $E_1 = E_2 = 0$, we have $E_3 = 2140 \pm 200$ cal. On the same graph are some identical measurements obtained by Sieger and Calvert (4) from the photolysis of CH_3COCF_3. They, however, consider these results to be unreliable, mainly due to the extremely small amounts of C_2F_6 which were obtained in the experiments.

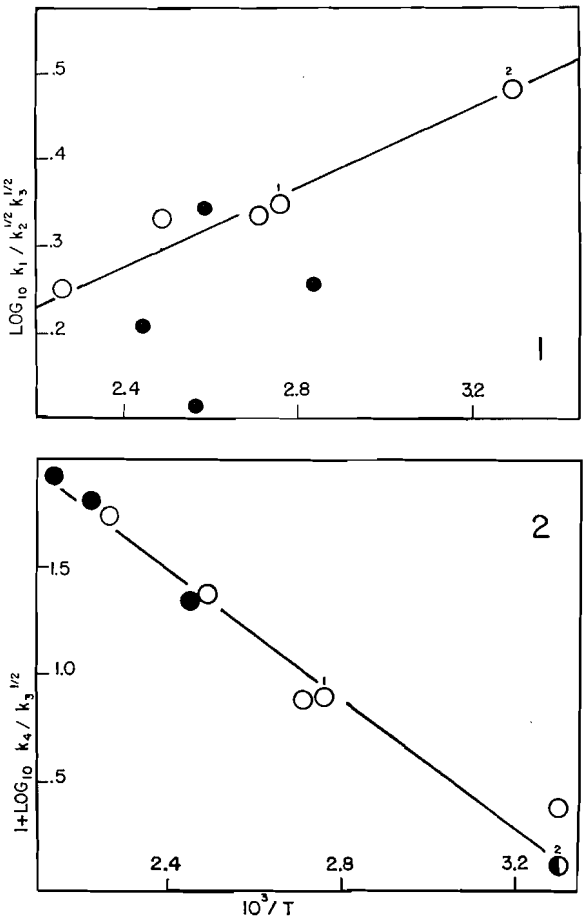

FIG. 1. Arrhenius plot of $k_1/k_2^{\frac{1}{2}}k_3^{\frac{1}{2}}$ versus $1/T$. (1) Average of two experiments. (2) Average of four experiments. ● Data of Sieger and Calvert from photolysis of CF_3COCH_3.

FIG. 2. Arrhenius plot of $k_4/k_3^{\frac{1}{2}}$ versus $1/T$. (1) Average of two experiments. (2) Average of six experiments. Shaded data not reported in Table I.

If all the CF_3H collected in our system is formed in the reaction

$$CF_3 + CH_3COCH_3 \rightarrow CF_3H + CH_2COCH_3 \qquad [4]$$

we have $k_4/k_3^{\frac{1}{2}} = R_{CF_3H}/R^{\frac{1}{2}}_{C_2F_6}$ [acetone]. Using the original acetone concentration in this expression, a least squares treatment of the Arrhenius plot of the function (Fig. 2) gives $k_4/k_3^{\frac{1}{2}} = 1.24\times10^4 \exp[-(6.9\pm0.1)\times10^3/RT]$ (mole/cc)$^{-\frac{1}{2}}$ sec$^{-\frac{1}{2}}$. This agrees well with a previous value of $E_4-\frac{1}{2}E_3$ of 8.0 kcal/mole (2), as it is possible from the manner in which it was computed that this latter figure is high by 1.5 kcal.

The shaded points in Fig. 2 represent six experiments not recorded in Table I because of the comparatively small amounts of C_2H_6 formed in these runs, which rendered the data unreliable. This was due to the fact that insufficient acetone was used, especially so at the higher temperatures, as the rate of photolysis of hexafluoroacetone is markedly temperature dependent up to 200° C (5). The point marked "2" represents the average of six experiments, half of which are recorded in Table I. The values of $k_4/k_3^{\frac{1}{2}}$ (excepting run 4, which is shown separately) obtained for all the six experiments were so close as to make them indistinguishable on the scale of the graph.

One remarkable feature of these experiments was that at room temperature the pressure dropped during the reaction and the total ethanes plus small quantity of methanes was only equal to about one-half the CO formed. Above 100° C the balance of radical products to CO was normal. No dark reaction occurs between the two ketones at 30° C, but when equal quantities (about 5 cm each) were illuminated for a period of hours the final pressure was approximately half the original pressure. The addition of CH_3 radicals to the carbonyl double bond in hexafluoroacetone has been discussed previously (6). The species $[CF_3CH_3COCF_3]$ could be stabilized at low temperatures by the addition of, rather than by the expulsion of, a radical, resulting in a loss in radical products. The participation of the CH_3CO radical, which is relatively stable up to a 100° C, cannot be precluded, but this would tend to give excess radical products. We are investigating this further.

Due to this effect it is difficult to estimate the exact percentage decomposition of the individual ketones in the experiments at room temperature, but about 5% of each was consumed. Material balance showed that about 5% or less acetone was decomposed in all the runs, but the decomposition of hexafluoroacetone increased to 10% at 100° C, and to 20% at 170° C. This latter figure is high for the application of steady-state conditions, so that the high temperature runs are probably less accurate.

The radical disproportionation reactions

$$CH_3 + CH_3 \rightarrow CH_4 + CH_2 \quad [5]$$

and

$$CF_3 + CH_3 \rightarrow CF_3H + CH_2 \quad [6]$$

have not been considered. Evidence for [5] is scant (7), but the occurrence of [6] cannot be ruled out. In some of the CF_3CH_3 analyses peaks at mass numbers 29 and 81 were obtained for which there appears to be no suitable explanation. Mass number 29 could possibly be from propane, but the residual at 43 was not really large enough to recommend propane as a constituent. It is worth speculating that propane could arise from the reaction of methylene with ethane if reaction [6] occurred.

DISCUSSION

If Ayscough's value (1) for k_3 at 400° K of 2.34×10^{13} $(mole/cc)^{-1}$ sec^{-1} is compared with the value calculated from collision theory of 1.5×10^{14} $(mole/cc)^{-1}$ sec^{-1} at 400° K, assuming $E_3 = 0$, the steric factor for reaction [3] is 0.16. If the steric factor is taken as unity E_3 becomes 1500 cal.

At the pressures used in our system there is no likelihood of third body restrictions affecting the radical recombination reactions and therefore no possibility of them exhibiting negative temperature coefficients (8, 9). If $E_1 \geqslant 0$, from the relationship $E_1-\frac{1}{2}E_2-\frac{1}{2}E_3 = -1070$ cal we have $E_2+E_3 \geqslant 2140$ cal. If $E_1 = 0$, and $E_2 = 700$ cal (the upper limit of Gomer and Kistiakowsky (10)), $E_3 = 1440$ cal. It is evident that many other combinations are possible; obviously all three activation energies cannot be identical, nor can they all be zero. If E_1 and E_2 are zero, or very nearly so, E_3 is of the order of 2 kcal. However, it is improbable that either E_1 or E_2 (and for that matter E_3) can be zero due to the slight temperature dependence of the collision number for a given reaction and the consequent small activation energy associated with it, which amounts to some 350 cal over the temperature range of our experiments. A value of E_1, E_2, or E_3 less than this could only occur if there was some third body restriction.

Shepp and Kutschke (11) have found an activation energy of 2.0 ± 1 kcal for ethyl radical recombination which they consider to be real, as they rate the possibility that there will be mutual repulsion of the C—H bond orbitals during C—C bond formation involving an energy barrier of the order of that due to hindered rotation, about 2 to 3 kcal. They suggest that CH_3 radical recombination is more favorable sterically, and that

the known temperature independence of the reaction (12) puts an upper limit of about 1 kcal on the activation energy, which could be due to the fact that the CH_3 radical is planar (13). The adjustment of two CH_3 radicals to the near tetrahedral arrangement in C_2H_6 could result in $E_2 > 0$. This is also true for E_3, if CF_3 is planar.

It is apparent in reactions where there is no significant potential energy barrier that the temperature dependence is due to several small factors of similar magnitude, which will tend to cancel each other if they are of differing sign. Thus the concept of "activation energy" is becoming more indeterminate in these cases. The most general conclusion that can be drawn is that all the three radical recombination reactions discussed here have a small positive temperature dependence, the greatest being attributable to reaction [3]. It is not clear what the effect, if any, of the C—F bond polarity is on this reaction, although the fact that E_3 is larger than E_1 or E_2 indicates that it could be of some consequence.

ACKNOWLEDGMENTS

We are greatly indebted to Dr. H. I. Schiff of McGill University, Montreal, for the mass spectrographic analyses, and to the Defence Research Board of Canada, under Grant 9530/13, for generous financial assistance.

THE INFRARED ABSORPTION SPECTRA OF UREA–HYDROCARBON ADDUCTS[1]

P. H. H. Fischer and C. A. McDowell

ABSTRACT

The infrared absorption spectra of the adducts formed between urea and hydrocarbons from *n*-heptane to *n*-hexadecane have been measured in the range 600 cm^{-1} to 4000 cm^{-1}. From a consideration of the crystal symmetries of urea and the urea–hydrocarbon adducts it has been possible to assign the various vibration frequencies. The band shifts observed are explained in terms of changes in bond lengths and bond angles.

INTRODUCTION

Urea forms adducts, or clathrates, with a variety of organic molecules such as hydrocarbons, esters, and organosilanes. X-Ray studies (1) have revealed the general details of the structures of hydrocarbon–urea adducts. There have also been infrared studies (2, 3, 4) which have supplemented this structural information. The results available show that whereas pure urea crystallizes with a tetragonal structure, when it forms an adduct it adopts a hexagonal crystal structure. In this way long channels are formed which allow the enclathrated hydrocarbon, or other molecule, to be located inside a cage of urea molecules held together by hydrogen bonds. Until quite recently little information was available concerning the physical state of the enclathrated hydrocarbon in these urea–hydrocarbon adducts. Nuclear magnetic resonance studies in these laboratories (5) have shown that the enclathrated hydrocarbon molecules have some vibrational and rotational, or torsional, freedom within the urea channels. We here report studies of the infrared absorptions spectra of a series of urea–hydrocarbon complexes. The aim of this work is to obtain information on the molecular motions of the trapped hydrocarbons, the stabilities of the complexes, and the structure of the hexagonal form of urea.

Apart from work by Stuart (2), who studied the N—H stretching frequencies of the urea–cetane adduct, and by Barlow and Corish (4) on the same adduct (among other classes of adducts), no other investigations of the homologous hydrocarbon–urea adducts seem to have been undertaken.

EXPERIMENTAL

The preparation of the adducts was accomplished by two different methods. (*a*) 1.25 g of A. R. grade urea (recrystallized), very finely powdered, was shaken with 15 ml of the respective hydrocarbon (Phillips, research grade) for periods ranging from 12 to 48 hours. Decantation, vacuum filtration for 30 seconds, and drying in filter paper gave a finely crystalline product. (*b*) 300 mg of hydrocarbon were placed in a vial with 10 ml of saturated urea–methanol solution and brought to boil. Cooling of the stoppered vial in a well-insulated Dewar flask yielded hexagonal crystals up to 35 mm in length.

The spectroscopic measurements were carried out on a Perkin–Elmer infrared spectrophotometer, model 21. The crystalline hydrocarbon–urea adducts were examined either by the potassium bromide disk method, or as Nujol and hexachlorobutadiene mulls.

RESULTS AND DISCUSSION

The spectra obtained (as KBr disks) are shown in Fig. 1. All complex spectra show similar changes from the spectrum of tetragonal urea, although in varying degree. Table I lists urea frequencies, both of the tetragonal and hexagonal structures.

Infrared studies (6, 8, 9) of urea have indicated that the molecule is planar and this has been confirmed by proton magnetic resonance studies (10). Thus the isolated urea molecule belongs to symmetry group C_{2v}. Ordinary urea crystallizes in a lattice of symmetry V_d^3 with 2 molecules per unit cell. Hence the site symmetry of the planar C_{2v} urea molecule is still C_{2v}, and the selection rules for the free molecule apply to the crystal as well (11). A free urea molecule with a planar C_{2v} structure has the following fundamental vibrational frequencies; $7a_1+2a_2+3b_1+6b_2$. All the vibrations are Raman active, but the two a_2 vibrations, a NH_2 wagging, and a NH_2 torsional oscillation are forbidden in the infrared spectrum. The hexagonal form of urea crystallizes with lattice symmetry $C_{6,2}$–D_6^2 (2) having 6 molecules per unit cell. There are consequently two distinct sets of sites having symmetry C_2 (with six equivalent sites per set). The selection rules of the free molecule do not apply to the crystal and an assignment of the vibrations based on C_2 symmetry is indicated (11). In this case, in contrast with the C_{2v} case above, all 18 fundamental vibrations are allowed in both the Raman and infrared spectra. The change in lattice symmetry from tetragonal to hexagonal allows the two formerly forbidden a_2 (NH_2) vibrations to appear in the infrared spectrum of the hexagonal structure.

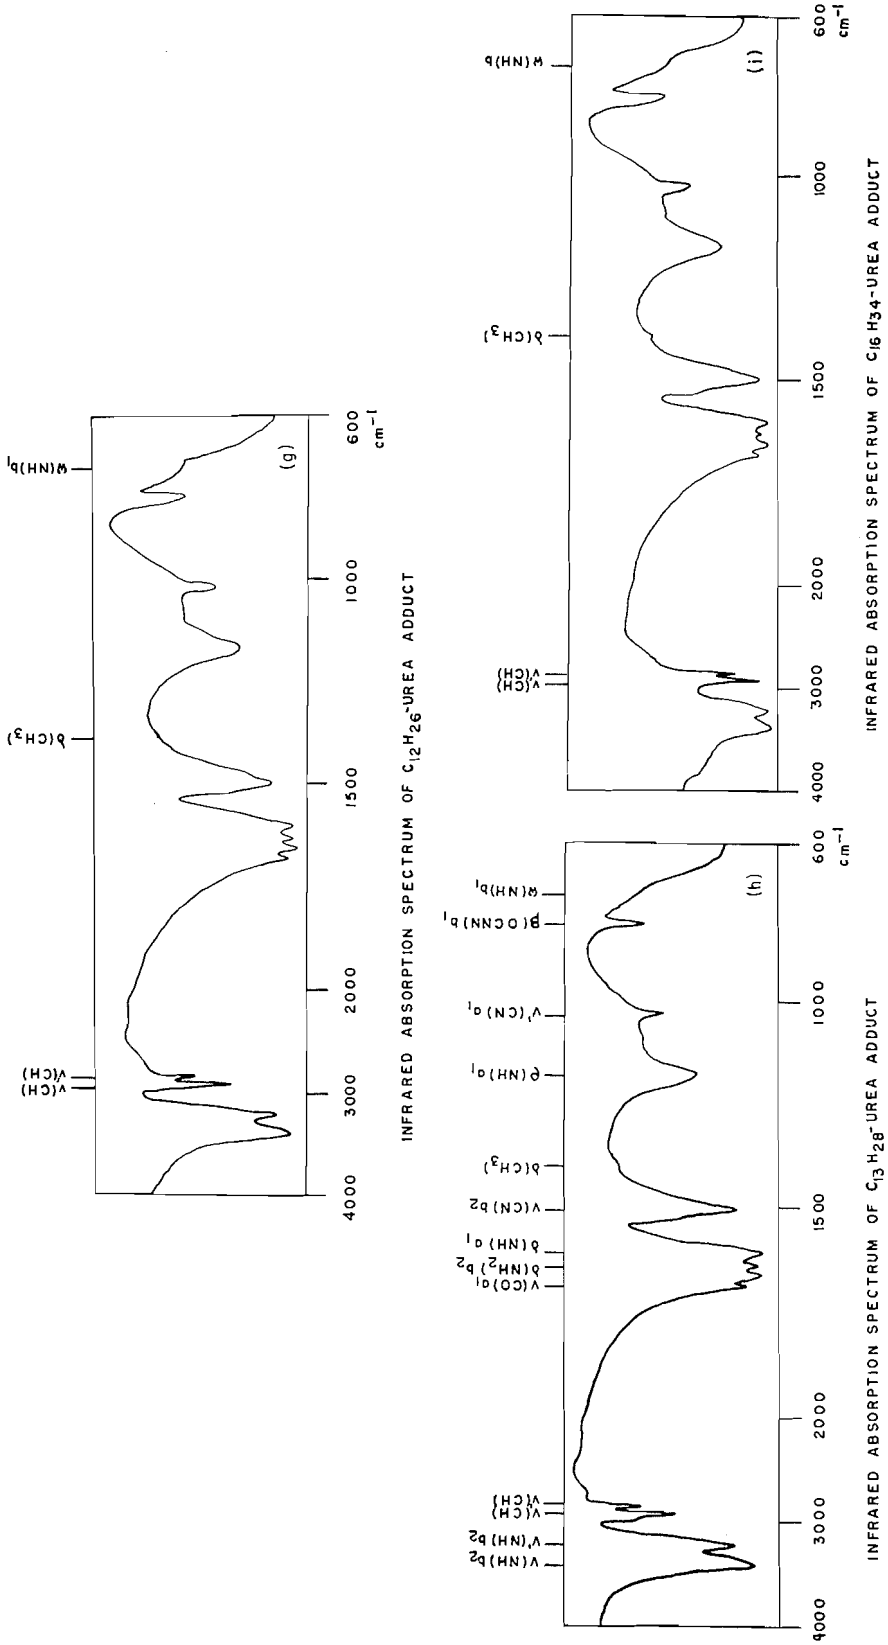

FIG. 1 (*g*), (*h*), (*i*).

The most striking change in the adduct spectra occurs in the N—H stretching frequency region. The out-of-phase vibration occurring at 3436 cm^{-1} in the tetragonal urea is lowered to 3420 cm^{-1}, whereas the in-phase vibration is shifted from 3333 cm^{-1} to 3220 cm^{-1} in going from tetragonal to hexagonal unit cell. An increase in the strength of the hydrogen bonds is apparent.

TABLE III

Bond distances in urea (1)

Bond	Hexagonal urea	Tetragonal urea
C—O	1.28 Å	1.25 Å
C—N	1.33	1.37 (ref.1) 1.335 (ref.12)
N—N	2.30	2.31
$N_1H \ldots O$	2.93	2.99
$N_2H \ldots O$	3.04	3.04

It seems reasonable to assume that the shorter hydrogen bonds of the tetragonal structure are situated in a much more favorable position for hydrogen bonding to occur during complex formation and that the stability of the adducts is mainly due to these bonds. Although crystallographic data shows no shortening of bond length of the longer hydrogen bonds, spectral analysis indicates a slight shortening.

The band at 1676 cm^{-1} is identified with the CO vibration and is explained by the lengthening of the C—O bond length. In this connection it may perhaps be mentioned that Krimm (13) found a correlation between the CO stretching frequencies in polypeptides and proteins, and the CO . . . NH angles. The raising of the C—N vibration frequency from 1464 cm^{-1} to 1492 cm^{-1} may be explained by the shortening of the C—N bond if the data of Smith (1) are accepted. However, Vaughan and Donohue (12) give a value of 1.335 Å for the C—N bond length in tetragonal urea; this value is very close to that given by Smith for hexagonal urea. Similar remarks apply to the finding that the symmetric C—N frequency is increased from 1000 cm^{-1} to 1014 cm^{-1}. It will be noticed that the intensity of the 1014 cm^{-1} band is greatly increased in the complex. The CO and CNH_2 groups have similar masses and due to resonance similar force constants. The CO group in the complex will be more highly polarized due to the stronger hydrogen bonding, and the C—O vibration, in phase with the C—N vibration, will tend to increase the intensity of the latter.

The slight raising of the skeletal out-of-phase bending frequency at 793 cm^{-1} (789 cm^{-1} in tetragonal urea) is explained by a somewhat larger deformational force constant, resulting from the decrease in the N—N distance. Other very small changes in the complex spectra are due to changes in the permanent dipole of the new structure.

From a study of Fig. 1 it is concluded that the spectra of the urea–tridecane and urea–hexadecane represent spectra of the pure complex, since only weak shoulders near 1465 cm^{-1} due to (CH_2) bending vibrations are present, and other bands found in tetragonal urea have been shifted, leaving no trace of the old band. In the case of the spectra of the heptane to dodecane adducts, it is noticed that a regular transition of intensity and degree of shift of bands has occurred. The continuous transition from the spectrum of pure urea to that of the pure complex is due probably to the instability of the lower hydrocarbon complexes. If the adduct had not been subjected to grinding, pressure, and vacuum during the pellet-making process, spectra resembling those of the pure complex would undoubtedly have been obtained. As some of the complex was presumably destroyed under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

such vigorous conditions, the spectra are likely those of varying proportions of pure urea and complex. Later experiments, using mulling techniques with Nujol and/or hexachlorobutadiene confirmed this, as spectra obtained resembled those of urea–tridecane and urea–hexadecane much more closely.

Although it would be expected that the spectrum of the octene-1 complex should resemble that of the octane complex, such was not the case. Rather, the spectrum of a more stable complex was obtained. An explanation for the greater stability may be that the labile electrons of the π-bond give the octene molecule enough polar character to permit dipole–dipole interactions. In an extreme case, there exists even the possibility of weak hydrogen bonding to the surrounding structure.

HALF-LIVES OF THE NUCLIDES Au^{195}, Pt^{195m}, AND Pt^{197} [1]

M. BRESESTI[2] AND J. C. ROY

ABSTRACT

The half-lives of Au^{195}, Pt^{195m}, and Pt^{197} have been measured. The radionuclides were produced by neutron irradiation in the NRX reactor at Chalk River and were radiochemically purified after the irradiation. The decay of the X rays and γ-radiations from Au^{195} and Pt^{195m} was observed with a NaI (Tl) detector, and the β-decay of Pt^{197} was observed with an anthracene detector. The half-lives are:

Au^{195}	199 ±3 days,
Pt^{195m}	4.08 ±0.12 days,
Pt^{197}	20.00 ±0.12 hours.

The errors quoted are the estimated reliability of the measurement and include the statistical counting error plus an estimated systematic error.

INTRODUCTION

Values differing by nearly a factor of two have been reported for the half-lives of both Au^{195} and the isomeric state of Pt^{195} whereas no precise measurement of the half-life of Pt^{197} has been made heretofore.

The half-life of Au^{195} has been reported to be 185±3 days by Wilkinson (1), who followed the decay of the radiations of Au^{195} with an end-window Geiger counter for 2 years. In a similar study Steffen *et al.* (2) obtained a value of 180±15 days after observing the decay of a source for 14 months. In contrast to these measurements, Cressman and Wilkinson (3) found a value of 90±10 days by following the decay of the conversion electron lines of the gamma rays of Au^{195}; the length of time of observation of the decay of the source is not mentioned by the authors.

DeShalit *et al.* (4), who followed the decay of the conversion electron lines of the gamma radiations of Pt^{195m}, reported a half-life of 3.8 days. Cork *et al.* (5) on examination of the conversion electron lines in a magnetic photographic spectrometer have deduced a half-life of about 6 days. Also a radioactivity in platinum observed by McMillan (6) ($t_{\frac{1}{2}}$ = 3.3 days), Hole (7) ($t_{\frac{1}{2}}$ = 3.5 days), and Haldar (8) ($t_{\frac{1}{2}}$ = 4.4 days) has been assigned to Pt^{195m} in the "Table of Isotopes" of Strominger *et al.* (9). Unquestionably these three values were obtained from sources containing Pt^{191}, Pt^{193m}, and Pt^{195m}, and in one case Au^{199} (6) and they cannot therefore be assigned with certainty to Pt^{195m}.

Earlier measurements on the half-life of Pt^{197} were done with sources contaminated with the other radionuclides of platinum and in some cases with a long-lived activity now known to be the 71-day Ir^{192} (10). The values reported by different workers are 18 (6, 4, 11); 17.4 (12); and 19 hours (8).

The present work was undertaken to reduce the uncertainties recorded in the earlier literature.

EXPERIMENTAL

(*a*) *Irradiation*

Au^{195}, Pt^{195m}, and Pt^{197} were produced by neutron irradiation of suitable targets in the NRX reactor at Chalk River.

Gold-195 was obtained by a $(n,3n)$ reaction on Au^{197}, the observation of which has

been reported recently by Eastwood and Roy (13). Early in the measurement of the radioactivity of Au^{195}, it was found that the source was radiochemically pure and that it could be used for half-life determination. Observations of the decay were begun 5 months after the end of the irradiation. Other gold isotopes produced in the irradiation, Au^{196}, Au^{198}, and Au^{199} had decayed to insignificance by this time.

The isomeric state of Pt^{195} was produced by the irradiation of platinum enriched to 60% in Pt^{195}. A filter of 0.076 cm of cadmium was used and under these conditions Pt^{195m} was produced by the (n,n') reaction on Pt^{195} and the (n,γ) reactions on Pt^{194}; the former is believed to be the more important reaction. The observations of the decay started about 15 days after the end of the irradiation; the Pt^{197} activities had decayed to a negligible level by this time.

Platinum-197 was obtained by a (n,γ) reaction on platinum metal enriched to 66% in Pt^{196}. Observations of the decay started 3 days after the end of the irradiation.

From the abundance of the other platinum isotopes and the values of the neutron cross sections (14) one can calculate that irradiations under cadmium of platinum enriched in Pt^{195} should give predominantly Pt^{195m} and correspondingly, irradiation of enriched Pt^{196} should give predominantly Pt^{197}. This arrangement substantially reduces the uncertainties associated with earlier work.

(*b*) *Purification*

The purification of the gold has already been described (13). The platinum metal was dissolved in aqua regia and the solution was evaporated to dryness. The residue was dissolved in 3 *N* HCl and washed 10 times with equal volumes of ethyl acetate containing gold carrier. The HNO_3 was eliminated from the aqueous solution by repeated evaporation and addition of concentrated HCl. The chloroplatinate in 3 *N* HCl was reduced to the platinic form with stannous chloride followed by an extraction with ethyl acetate. The ethyl acetate solution was washed five times with 3 *N* HCl and was then evaporated to a small volume (15). The sources of platinum were prepared by drying a few drops of the solution on an aluminum tray. Similarly, the gold source was prepared by deposition of the gold metal on an aluminum tray. All the sources were covered with a layer of Scotch tape to avoid loss of material.

(*c*) *Counting Techniques*

The decay schemes of Au^{195} (3) and Pt^{195m} (5, 16) are well known. The prominent radiation of these radionuclides is the 67-kev *K* X ray which arises mainly from *K*-capture and internal conversion of the 98-kev γ-ray in Au^{195} and from internal conversion of the 98- and 130-kev γ-rays in Pt^{195m}. In these measurements, the half-lives were obtained by following the decay of the *K* X ray and the 98-kev radiation with a 1 in. $\times$ 1 in. NaI (Tl) crystal coupled to an RCA 5919 photomultiplier tube. The γ-ray spectrum was displayed on a multichannel analyzer using an AEP-type 1444 linear amplifier with a resolving time of 0.5 μsec (17). The γ-ray spectra of Au^{195} and Pt^{195m} are shown on Fig. 1. Readings were taken about twice a month for Au^{195} and once or twice daily for Pt^{195m}. Before or after each reading the stability of the apparatus was checked with a source of Am^{241} ($t_{\frac{1}{2}}$ = 458 years). The strong 59.6-kev γ-ray of Am^{241} makes it a convenient and reliable standard. For the period over which the data were accumulated, the variations in the counting rate of the source of Am^{241} were random and fluctuated around a mean value. The standard deviation from this mean for the entire set of data was taken as a measure of the error due to the stability of the counter. It was 1.9% and 1.3% for the gold and platinum measurements respectively. There was no measurable counting loss due to the resolving time of the amplifier.

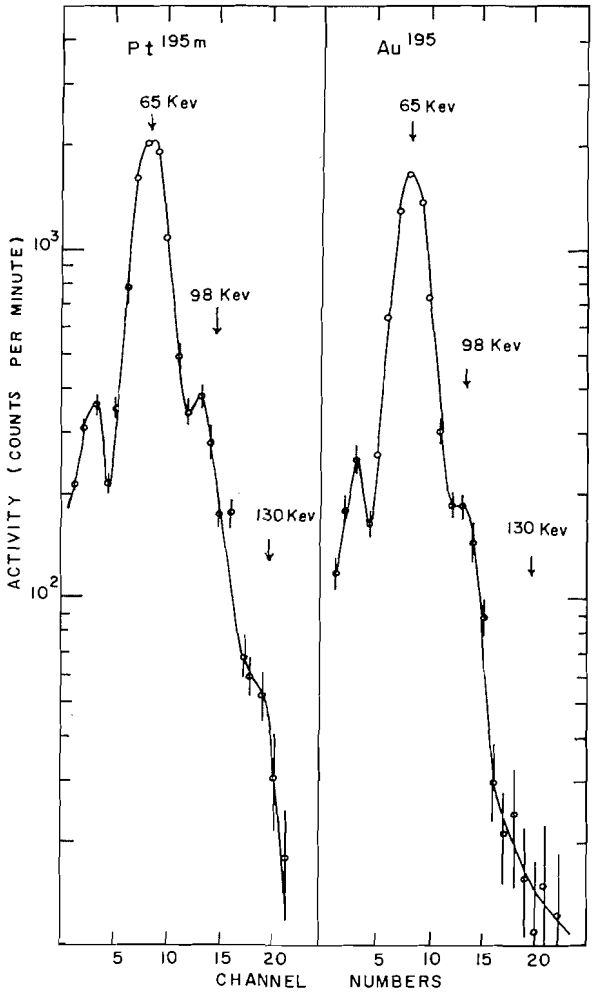

FIG. 1. Pulse-height distribution of Pt^{195m} and Au^{195} taken with 1 in. × 1 in. NaI (Tl) crystal.

The Pt^{197} activities were measured with an anthracene beta counter. The distance between source and window was 2.0 cm of air. The thickness of the window was 2.16 mg/cm² of aluminum, that of the Scotch tape covering the source was 9.0 mg/cm², and that of the source was a few mg/cm². These materials will absorb the conversion electrons emitted by other radionuclides of platinum present in small amount in the sources of Pt^{197}. The anthracene crystal was coupled to an RCA 6199 photomultiplier tube used with a linear amplifier–discriminator combination. The standard error due to the stability of the counter was measured to be ±0.5% by counting a source of Cs^{137} several days before and after the measurement. No dead time correction was applied because, for the highest initial counting rate obtained in the measurement, 1000 counts/sec, the counting loss was less than 0.3%. One half-life determination was also made using a conventional 2π-proportional counter.

RESULTS AND DISCUSSION

One source of Au^{195}, three sources of Pt^{195m} from two separate irradiations, and five

sources of Pt^{197} from four separate irradiations were used in the measurement. A study of the gamma-ray spectrum and of the absorption of the beta rays in aluminum was made for each source in order to detect the presence of possible impurities and to determine also the degree of interference of the other platinum activities.

In the range 25 kev to 2 Mev, only the radiations characteristic of the nuclide being measured could be observed. Platinum-191 has several gamma rays above 160 kev (16) which, if present in the sources of Pt^{195m}, could have been detected easily. Their absence in the sources of Pt^{195m} shows that the activity of Pt^{191} was less than 0.3%. The activity of Pt^{193m} was calculated to be less than 2% of that of Pt^{195m}. No beta rays could be observed in the sources of Au^{195} and Pt^{195m}. The soft conversion electrons emitted by these radionuclides were absorbed in the sources and Scotch tape covering them. The decay of the sources of Pt^{195m} and Pt^{197} were followed until the counting rate was just 1/10th of the background and in all cases no deviation from a linearity could be detected in the usual semilogarithmic plot. The backgrounds of the γ- and β-detectors were 50 ± 10 and 10 ± 1 counts/minute respectively. A further check was provided by dividing in two the time over which the decay of each source was observed and calculating the half-life for both parts. For the three radionuclides, the half-life calculated from each half of the data agreed with that calculated from the full data within the experimental error.

In the computation of the data each point was assigned an internal error formed by combining quadrically the statistical counting error and the error due to the stability of the counter. The half-life for decay of each source was calculated by the method of least squares, each point being weighted by the reciprocal of the squares of the assigned error. The data and the results of the computation are assembled in Table I. The external error

TABLE I

Summary of the half-life determinations

Radio-nuclide		Initial counting rate, counts/min	No. of points	No. of half-lives followed	Half-life	Internal error	External error
Au^{195}		6,000	34	2.1	199.04	1.54	1.05 days
Pt^{195m}	(1)	16,000	17	5.2	4.178	0.015	0.022 days
	(2)	9,300	14	3.1	3.998	0.024	0.012 days
	(3)	19,400	9	2.4	4.028	0.035	0.015 days
			Weighted average		4.083	0.015	0.060 days
Pt^{197}	(1)	54,200	62	6	20.113	0.018	0.019 hours
	(2)	43,200	50	5	19.930	0.019	0.025 hours
	(3)	62,300	44	6.3	19.977	0.016	0.023 hours
	(4)	49,200	30	4.5	19.661	0.027	0.050 hours
	(5)*	59,600	31	3.6	19.895	0.010	0.054 hours
			Weighted average		19.998	0.012	0.057 hours

*Half-life measured with a proportional counter.

listed in the last column is a measure of the deviation of the data from a least-squares fit. The weighted mean value is taken as the final half-life value and the larger of the internal or external error is taken as the final statistical error. The presence of other platinum activities, although in low abundance, could cause a small systematic error. It follows from the discussion that such a systematic error could be of the order of the statistical error. Therefore the statistical error is doubled and the half-lives are given as

Au^{195} 199 ± 3 days,
Pt^{195m} 4.08 ± 0.12 days,
Pt^{197} 20.00 ± 0.12 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The values of the half-lives of Au^{195} and Pt^{195m} found in this work are in fair agreement with those reported by Wilkinson (1), Steffen *et al.* (2), and deShalit (4) respectively. However, the present work does not support the values of 90 days (3) for Au^{195} and 6 days (5) for Pt^{195m}. The earlier approximate values of 18 (6, 4, 11), 17.4 (12), and 19 hours (8) are in reasonable agreement with the more precise value of 20.0 $\pm$0.12 hours recorded in this paper.

ACKNOWLEDGMENT

The authors would like to express their thanks to Dr. J. M. Kennedy for programming the Chalk River Datatron upon which the computations were carried out.

A METHOD OF INTEGRATION OF THE GIBBS–DUHEM EQUATION WHEN ACTIVITIES OF A SOLUTE ARE REQUIRED FROM THOSE OF THE SOLVENT[1]

M. L. LAKHANPAL[2] AND B. E. CONWAY

ABSTRACT

A new graphical method has been developed for integrating the Gibbs–Duhem equation for the case where activities of the solute are required from experimentally determined values of the activity of the solvent in a binary solution. This method has been applied to the determination of the activities of fractions of polyoxypropylene glycols in methanolic solutions. The accuracy of the procedure is discussed.

When partial thermodynamic functions are required for solute and solvent in a binary mixture from measurements of the vapor pressure of the solvent, it is necessary to utilize an integrated form of the Gibbs–Duhem equation. Whilst the integration of this equation by graphical or other means is easy when activities of the solvent are to be calculated from those of the solute, e.g. in the Tl–Hg case (1, 4) the reverse procedure, which is more often required, presents considerable difficulties since the function for integration then rises asymptotically to high values as the activity coefficient of the solvent tends to unity in dilute solutions and an unambiguous integration cannot then be carried out. For this case where activities of the solute are to be calculated from those of the solvent, approximate analytical methods (1) have been suggested but these can give erroneous results (1) for dilute solutions. It is therefore the purpose of this paper to report a new semiempirical graphical procedure for integration of the Gibbs–Duhem equation when *solute* activities are required. The method is illustrated by reference to thermodynamic measurements on the system polyglycol(mol. wt. 1955)–methanol, which we have recently carried out.

The Gibbs–Duhem equation

$$[1] \qquad \sum_i x_i d\mu_i = 0$$

gives, for a two-component system, the familiar relationship

$$[2] \qquad x_2 \, d \ln \frac{a_2}{x_2} = -x_1 \, d \ln \frac{a_1}{x_1},$$

where x_1, x_2 are the mole fractions; a_1, a_2 are the activities and μ_1 and μ_2 are the chemical potentials of the solvent and solute, respectively. Upon integrating equation [2] from the limit $x_2 = 0$ where a_2 is zero to any point $x_2 = x$, where a_2 is finite, the expression

$$[3] \qquad \ln \frac{a_2}{x_2} = -\int_{x_2=0}^{x_2=x} \frac{x_1}{x_2} d \ln \frac{a_1}{x_1}$$

is obtained. In the analytical method, the activities of the solute are determined by obtaining an empirical relationship by which the activities of the solvent can be expressed as a function of the composition of the two-component system (1, 2) so that [3] can be directly integrated and the activities of the solute calculated at various compositions. This procedure, however, necessitates very accurate knowledge of the experimental

activities of the solvent over a range of concentrations (particularly at low concentrations) sufficient to enable an empirical equation to be formulated which can be relied upon to represent the experimental behavior of limitingly dilute solutions. The graphical method consists in plotting the values of x_1/x_2 against log a_1/x_1 and determining the area under the curve between the limits indicated in equation [3]. The graph of the function x_1/x_2 vs. log a_1/x_1 is shown in Fig. 1 for solutions in methanol of a polyoxypropylene glycol fraction (number average mol. wt. = 1955), the experimental data for which have been obtained by differential vapor-pressure measurements which will be described in detail elsewhere (3). Since the curve of x_1/x_2 against log a_1/x_1 (see Fig. 1) is asymptotic*

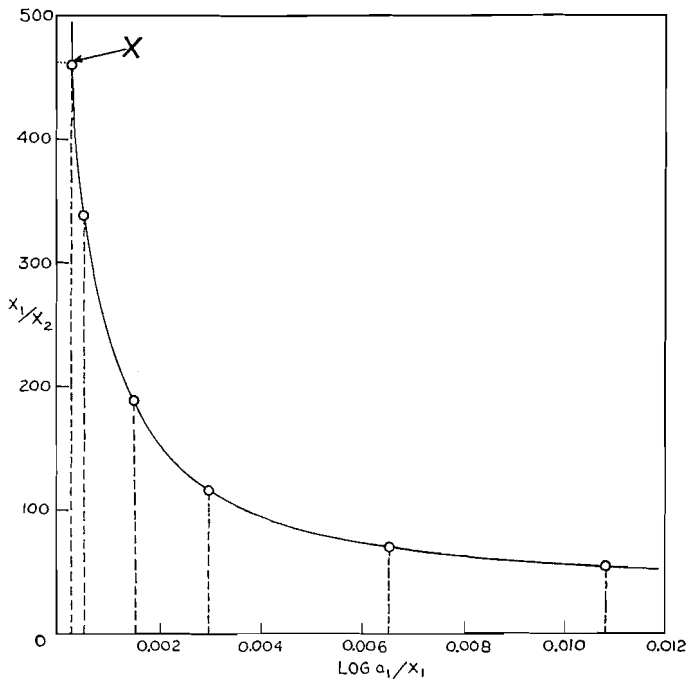

FIG. 1. Plot of the mole fraction ratio x_1/x_2 vs. log a_1/x_1 for solutions of polyoxypropylene glycol (mol. wt. 1955) in methanol.

to the axis of the ordinate x_1/x_2, it has to be extrapolated to an infinite value of x_1/x_2 in order to obtain the total area under the curve. The accurate assessment of the integral by measurement of the area under the extrapolated curve presents a practical difficulty particularly in the asymptotic region of the curve. Usually a rough approximation of this area is made or an extrapolation function is devised (1) which is often unsatisfactory in the dilute solution region.

In view of these difficulties, we have developed an alternative method for obtaining the integral to an infinite value of x_1/x_2 as log a_1/x_1 tends to zero. As in the graphical method mentioned above, the values of x_1/x_2 are first plotted against log a_1/x_1 (see Fig. 1). The area under the curve from a point X in the asymptotic region to an infinite value of x_1/x_2 is considered to be equal to an unknown constant C, so that the total integral up to

*When the activity of the "solute" is measured and it is desired to obtain the corresponding activity of the "solvent", for example in the system Tl–Hg (4), this difficulty does not arise since the function for integration becomes zero when $x_2/x_1 = 0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

any point on the curve is equal to C plus the area under the curve from the point X to that point. If C is first considered to be equal to zero, we obtain apparent first approximation values of log a_2/x_2. The values of x_2/x_1 are now plotted against the apparent values of log a_2/x_2 as shown in Fig. 2. It is found that the value of log a_2/x_2 for a value x_2/x_1

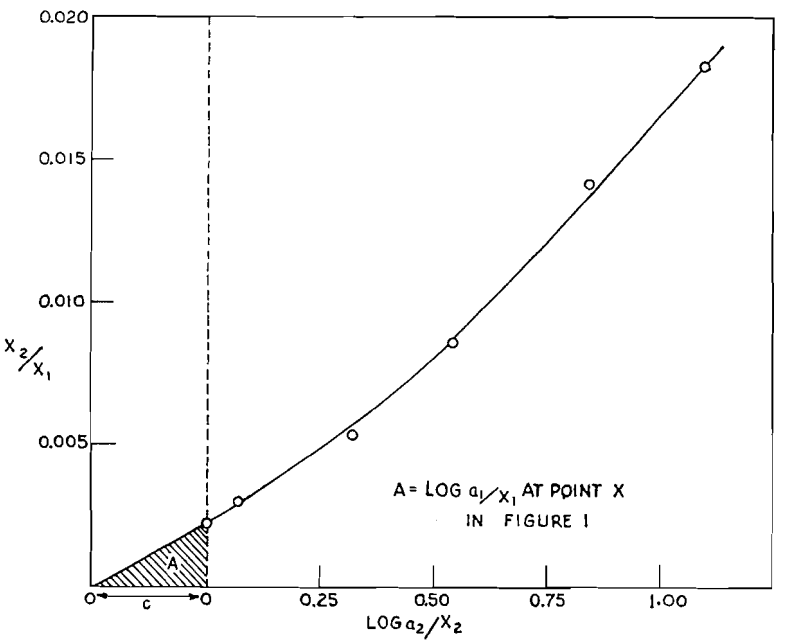

FIG. 2. Plot of the mole fraction ratio x_2/x_1 vs. log of the first approximation values of a_2/x_2 for solutions of polyoxypropylene glycol (mol. wt. 1955) in methanol.

corresponding to the point X in Fig. 1 is zero, so that the curve in Fig. 2 does not pass through the origin as it should do. This suggests that if we smoothly extend the curve back to the axis of abscissae, the point at which the curve meets that axis should be the actual origin. Hence all the apparent values of log a_2/x_2 must be increased by the constant C equal to the shift of the origin along the horizontal axis. Without any further information about the course of the curve in the region covered by extrapolation, there may be some uncertainty in the value of the constant C thus estimated. However, in order to make a more correct extrapolation it is possible to utilize the fact that the area A under the curve in Fig. 2 must be equal to log a_1/x_1 at the point X in Fig. 1, and this is known experimentally.

The above method makes it possible to compute the value of C and hence allows the determination of the values of a_2, the activity of the solute, corresponding to the various experimental values of a_1. The values of the constant C may be determined with an accuracy better than $\pm 5\%$ so that the values of log a_2/x_2 may be obtained with an accuracy increasing from about $\pm 4\%$ to better than $\pm 1\%$ for increasing values of the concentration of the solute. This enables the calculation of the activities of the solute to be made with an accuracy of better than $\pm 0.5\%$ in a_2. The accuracy of the above method of integration may be illustrated by applying it to the data on aqueous sucrose solutions discussed by Lewis and Randall (ref. 1, pp. 275–276). From the given values (1) of molal concentrations and ln a_1, we have calculated the values of ln a_1/x_1 shown in column 4,

TABLE I

Calculations of the activities of sugar in aqueous sugar solutions

m	x_1/x_2	ln a_1	ln a_1/x_1	ln a_2/x_2	ln a_1/x_1	ln a_1
0.050	1110	−0.00053	0.00037	−0.035±20%	−0.00002	−0.00092
0.172	322.7	−0.00013	−0.00013	−0.090±5%	−0.00013	−0.00324
0.454	122.3	−0.00871	−0.00056	−0.167±1%	−0.00055	−0.00870
1.009	55.01	−0.02002	−0.00201	−0.274±1%	−0.00194	−0.01995

Data taken from Lewis and Randall (ref. 1, p. 275).

Table I. The positive value of ln a_1/x_1 for the first concentration indicates that the value of a_1 is incorrect (as also concluded by Lewis and Randall). The last three concentrations (see Table I) were therefore used for the calculation of ln a_2/x_2 by the method described above and these values are given in column 5 of Table I. In order to test the validity of these calculated values of ln a_2/x_2, the values of ln a_1/x_1 were back-calculated from those of ln a_2/x_2 and are given in column 6. Considering that only three concentrations are available for these calculations the agreement of the values of ln a_1/x_1 in columns 4 and 6 of the table is very satisfactory. An estimate of the accuracy with which the values of ln a_2/x_2 can be obtained is also recorded in column 5.

An attempt has also been made to assess the approximate value of ln a_1/x_1 for the first concentration. The value obtained is −0.00002; the value of ln a_1 is therefore 0.00092 and it can be seen from Table I that this figure is accurate to about ±1%.

The above case has been examined in order to indicate the convenience and accuracy of this method of integration as applied to previously determined data which have also been treated by other methods of integration (1). The procedure reported here has some advantages in that it is convenient and not very sensitive to small inaccuracies in the determination of the experimental points for solutions in the region of low concentrations, whilst the special analytical extrapolation method described by Lewis and Randall is.

The method has enabled us to calculate the values of the activities of a number of different molecular weight fractions of polyoxypropylene glycol in methanolic solutions of various concentrations. The values of the activities of the solvent, a_1, and the corresponding activities of the solute, a_2, in solutions of the polymer of mol. wt. 1955 are reported in columns 3 and 4 of Table II as an example of the application of the method

THE OXYGENATED FATTY ACIDS OF THE OIL OF WHEAT STEM RUST UREDOSPORES[1]

A. P. TULLOCH

ABSTRACT

The principal oxygenated acid present in the oil of wheat stem rust is *cis*-9,10-epoxyoctadecanoic acid, and is accompanied by a small proportion of (+) *threo*-9,10-dihydroxyoctadecanoic acid.

INTRODUCTION

The component fatty acids of the oil from uredospores of *Puccinia graminis* var. *tritici*, race 15B, were described previously (1), and the present paper reports chemical evidence for the structure of the *cis*-9,10-epoxyoctadecanoic acid which was found in the oil. After preliminary experiments (1) had shown the presence of an epoxy acid in the mixture, the free fatty acids were treated with acetic acid according to Gunstone's procedure (2) and the acetoxy acid, produced from the epoxide, was hydrolyzed. A dextrorotatory dihydroxyoctadecanoic acid was isolated and separated into racemic and (+) *threo*-9,10-dihydroxyoctadecanoic acids by fractional crystallization. The melting point and rotation of the latter were practically the same as those reported by McGhie *et al.* (3) for the synthetic (+) acid. The dihydroxy acid obtained initially was oxidized with the permanganate–periodate reagent (4, 5), which afforded only azelaic and pelargonic acids. These results, and those reported before (1), establish that the acid contains a *cis* epoxy group at the 9,10 position, but some of the dihydroxy acid isolated could have been present in the original oil. Therefore, a fresh sample of oil was fractionated by countercurrent distribution as the methyl esters and found to contain 1.3% of (+) *threo*-9,10-dihydroxyoctadecanoic acid and about 27% of the epoxy acid. Oil from other spores collected in the field in 2 different years contained 4–5% of the (+) dihydroxy acid and 20–22% of the epoxy acid.

threo-9,10-Dihydroxyoctadecanoic acid has been found in small amounts in the oil of *Lycopodium clavatum* spores (6, 7) but not in conjunction with an epoxy acid. However, Bharucha and Gunstone (8) found that the seed oil of *Cephalocroton cordofanus* (Muell Arg.) contained, in addition to 62% of *cis*-12,13-epoxyoleic acid, 4% of *threo*-12,13-dihydroxyoleic acid. King (9) has prepared a *cis*-9,10-epoxyoctadecanoic acid (m.p. 59.5° C, $[\alpha]_D$ +0.29°) from the naturally occurring form of *erythro*-9,10-dihydroxyoctadecanoic acid; however, the epoxy acid isolated in the present work melts at 58.5–59.5° C and has $[\alpha]_D$ −0.25°, and is probably the enantiomorphic form.

Bharucha and Gunstone (10) and Gunstone and Morris (11) found that acetolysis of *cis*-12,13-epoxyoleic acid and of *cis*-15,16-epoxylinoleic acid is, to some extent at least, stereospecific giving dextrorotatory *threo*-dihydroxy acids. With the 9,10-epoxy acid a completely stereospecific ring opening would give either the (+) or (−) 9,10-dihydroxy acid with a specific rotation of ±26°. However, acetic acid treatment of the epoxy acid followed by hydrolysis gave only a very weakly dextrorotatory product showing that, for this type of reaction, when the epoxide group is in the central 9,10-position the two C—O bonds are broken with almost equal ease. Therefore, samples of oil which yielded appreci-

[1]*Manuscript received October 19, 1959.*
Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan.
Issued as N.R.C. No. 5478.

able amounts of (+) dihydroxy acid on acetolysis were assumed to have contained this acid before the reaction was carried out. In particular, the fatty acids from the 1951 spores, which gave a dihydroxy acid with a specific rotation of +12.4°, must have contained more (+) acid than usual, perhaps because of the age of the spores.

EXPERIMENTAL

Extraction of the oil was carried out as previously described (1, 12). Melting points were measured with a Leitz heating stage microscope. Infrared spectra were recorded in the manner described earlier (1). All rotations were measured in ethanol in a 1-dm tube.

Acetolysis of the Fatty Acids of the Oil

The oil, extracted from rust spores which had been collected in 1951, was saponified by refluxing with 5% ethanolic potassium hydroxide for 1 hour and the free fatty acids isolated in the usual way. The fatty acids (3.800 g) were refluxed with glacial acetic acid (50 ml) for 4 hours, the acetic acid taken off, the product hydrolyzed with 5% alcoholic potash, acidified, and the acids extracted with ether. Removal of the ether gave a mixture of acids (3.760 g) which was distributed between 100-ml portions of 80% methanol and petroleum (b.p. 40–60° C) in five stages. The two most polar fractions contained 1.230 g of gum which, on crystallization from ethyl acetate, gave *threo*-9,10-dihydroxyoctadecanoic acid (0.818 g), $[\alpha]_D^{24}$ +12.4° (*c*, 1.7). The methyl ester prepared by diazomethane treatment gave colorless prisms from acetone/petroleum (b.p. 60–80° C), m.p. 68–70° C. Calculated for $C_{19}H_{38}O_4$: C, 69.04%; H, 11.59%. Found: C, 68.77%; H, 11.31%. Five further crystallizations of the acid from ethyl acetate gave racemic *threo*-9,10-dihydroxyoctadecanoic acid (0.200 g), m.p. 96–97° C, not depressed by admixture with the synthetic acid (13) of m.p. 95–96° C. Calculated for $C_{18}H_{36}O_4$: C, 68.31%; H, 11.47%. Found: C, 68.59%; H, 11.54%. The infrared spectrum was indistinguishable from that of the synthetic material. The acid recovered from the mother liquor of the first two ethyl acetate crystallizations was crystallized four times from acetone, yielding (+) *threo*-9,10-dihydroxyoctadecanoic acid (0.062 g), m.p. 98.5–99.5° C; $[\alpha]_D^{26}$ +25.60° (*c*, 0.6) (lit. (3) gives m.p. 99.5° C and $[\alpha]_D$ +23.5° in methanol). Calculated for $C_{18}H_{36}O_4$: C, 68.31%; H, 11.47%. Found: C, 68.31%; H, 11.49%. The infrared spectrum showed some small differences from that of the racemic acid.

Oxidation of the Dihydroxy Acid

The acid (0.127 g) was dissolved in a solution of potassium carbonate (0.174 g in 132 ml water), and sodium periodate (0.360 g) and potassium permanganate (0.004 g) in water (64 ml) were added. After it was shaken for 24 hours the solution was acidified (dilute sulphuric acid), saturated with sodium chloride, and extracted seven times with ether. Evaporation of the ether gave a mixture of acids (0.156 g) which, on stirring with petroleum, b.p. 40–60° C, gave azelaic acid (0.079 g), m.p. 104–106° C, after crystallization from ethyl acetate, which was not depressed by authentic azelaic acid, m.p. 105–107° C. Distillation of the petroleum-soluble fraction gave pelargonic acid, b.p. 95–100° C (air bath)/0.1 mm, the infrared spectrum of which was indistinguishable from that of an authentic specimen. The *p*-bromophenacyl ester had m.p. 63.5–64.0° C, undepressed by the synthetic derivative, m.p. 63.5–64.5° C. Calculated for $C_{17}H_{23}O_3Br$: C, 57.47%; H, 6.52%. Found: C, 57.68%; H, 6.59%. The mother liquors of both fractions were converted to methyl esters and, examined by gas liquid phase chromatography using the apparatus described previously (1), appeared to contain only pelargonic and azelaic esters.

Isolation of the Oxygenated Acids

Spores were collected from rusted Stewart wheat grown in the greenhouse (controlled to temperatures of 60–75° F) in July 1959 and the oil was extracted. Methyl esters of the fatty acids were prepared by treating the oil (4.327 g) with diazomethane to esterify traces of free acids, and then refluxing with methanolic sodium methoxide (70 ml, from 0.5 g of sodium in 1 liter of methanol) for 50 minutes. The solution was poured off from the insoluble residue (0.194 g), acetic acid (0.15 ml) added, the methanol distilled off, water added to the residue, and the product extracted with ether. After the solvent was removed, the esters (3.995 g) were separated by 120-tube distribution between petroleum (b.p. 60–80° C) and 85% ethanol using a modified E.C. Apparatus Co. fractionator with 100 tubes and 20-ml capacity each phase. Fractions 16–35 (0.100 g) after crystallization from petroleum, b.p. 60–80° C, gave methyl (+) *threo*-9,10-dihydroxyoctadecanoate, m.p. 59–61° C, $[\alpha]_D^{24}$ +23.9° (*c*, 1.65) (lit. (3) gives m.p. 62° C and $[\alpha]_D$ +22.5° in methanol). Calculated for $C_{19}H_{38}O_4$: C, 69.04%; H, 11.59%. Found: C, 68.82%; H, 11.47%. Saponification of the sample gave (+) *threo*-9,10-dihydroxyoctadecanoic acid (0.053 g, 1.3%), m.p. 98–99° C, $[\alpha]_D^{23}$ +26.6° (*c*, 1.3).

Fractions 68–85 (1.087 g) consisted almost entirely of methyl *cis*-9,10-epoxyoctadecanoate, and crystallization from acetone at 0° C gave the pure ester as leaflets, m.p. 24.5–25.5° C. Calculated for $C_{19}H_{36}O_3$: C, 73.03%; H, 11.61%. Found: C, 72.98%; H, 11.73%. $[\alpha]_D^{26}$ +1.1° (*c*, 5.25). The infrared spectrum showed a *cis* epoxide peak at 825 cm^{-1}; synthetic methyl *cis*-9,10-epoxyoctadecanoate had a very similar spectrum with a peak at 826 cm^{-1} (14). The ester (1.087 g) was refluxed with 2% ethanolic potassium hydroxide for 30 minutes, water (200 ml) was added, followed by hydrochloric acid (*N*/2) until the mixture was just acidic, the solid product was filtered off and washed thoroughly with water. On drying, *cis*-9,10-epoxyoctadecanoic acid (0.989 g) was obtained and crystallized from acetone as colorless platelets, m.p. 58.5–59.5° C (lit. (9) 59.5° C) depressed to 53–56° C on admixture with the synthetic racemic acid (13), m.p. 58.3–58.8° C. Calculated for $C_{18}H_{34}O_3$: C, 72.43%; H, 11.48%. Found: C, 72.51%; H, 11.56%. $[\alpha]_D^{24}$ −0.25° (*c*, 17.00) (lit. (9) gives $[\alpha]_D^{19}$ +0.29°). The infrared spectrum had a *cis* epoxide peak at 845 cm^{-1} compared to 842 cm^{-1} for the racemic acid (14, 15). Fractions 86–112 contained the methyl esters of the other fatty acids of the oil (C_{12}–C_{18}) (1) (2.511 g), and the other fractions contained only very small quantities of material.

Conversion of the Epoxy Acid to threo-9,10-Dihydroxyoctadecanoic Acid

The *cis*-9,10-epoxyoctadecanoic acid (0.400 g) was refluxed with glacial acetic acid (25 ml) for 4 hours and the acetic acid removed under vacuum. The residual syrup (0.487 g) $[\alpha]_D^{24}$ +0.71° (*c*, 6.30) was hydrolyzed with alcoholic sodium hydroxide (3%) and the product (0.411 g) isolated in the usual way. Without purification the $[\alpha]_D^{25}$ was +1.11° (*c*, 5.60); one crystallization from ethyl acetate (15 ml) gave racemic *threo*-9,10-dihydroxyoctadecanoic acid (0.270 g), m.p. 94–95.5° C, which had an infrared spectrum closely similar to that of an authentic sample.

ACKNOWLEDGMENTS

The author wishes to thank Dr. G. A. Ledingham and Dr. H. J. Reisener for gifts of spores and Mr. L. L. Hoffman and Mr. T. M. Mallard for assistance with the collection of spores and the extraction of the oil. Microanalyses were by Mr. M. Mazurek and infrared absorption spectra by Miss I. M. Gaffney.

THE GAS HYDRATE OF BROMOCHLORODIFLUOROMETHANE[1]

D. N. Glew

ABSTRACT

An experimental study has been made of the saturation pressure – temperature lines of liquid bromochlorodifluoromethane, liquid bromochlorodifluoromethane – water, bromochlorodifluoromethane hydrate – water, and bromochlorodifluoromethane hydrate – ice systems, for which the characteristic equations are given. Two quadruple points for the hydrate systems have been located and solubilities of water in bromochlorodifluoromethane and bromochlorodifluoromethane in water determined. A systematic treatment of gas hydrate saturation pressure data to yield thermodynamic equations is indicated, and the thermodynamic functions for bromochlorodifluoromethane hydrate and its phase reactions are tabulated. Bromochlorodifluoromethane hydrate is shown to be a stoichiometric compound, and its thermodynamic functions are considered in relation to those of other gas hydrates.

INTRODUCTION

The gas hydrate clathrates, in which hydrate-formers are included in three-dimensional hydrogen-bonded water lattices, are of considerable interest in their own right and in the direct indication that they provide on the nature of the hydration shells confining aqueous non-electrolytes at lower temperatures (1, 2, 3).

Although the gas hydrates have been known for approximately 150 years their chemical formulae remained uncertain until 1951, when the structural work of Claussen (4) and the X-ray work of v. Stackelberg and Müller (5) elucidated the crystallographic structures of two distinct gas hydrate families based on two different fundamental water lattices. Recently two independent theoretical treatments (6, 7) have indicated that the formulae for the small molecule gas hydrates (Structure I) should change with temperature as a result of varying partial occupancy by the hydrate-former of available co-ordination sites within the hydrate water lattice.

It was therefore of interest to examine whether this partial occupancy obtained in the hydrates of larger molecules (Structure II) having the ideal crystallographic formula $M.17H_2O$. Furthermore, theoretical models for the gas hydrates have always assumed that the thermodynamic functions for the lattice water were little different from ice, in spite of the considerable difference of both hydrogen bond angles and separations (8). To obtain evidence for this assumption it was desirable to determine the heat capacity changes for hydrate formation, which would be considerably different from theoretical values for Structure II hydrates if the lattice water contributions were very different from ice, and/or if these hydrates were to exhibit significant changes of occupancy with temperature.

EXPERIMENTAL

Bromochlorodifluoromethane was purified in a Podbielniak low temperature distillation column and was analyzed as 99.9 mole% pure by mass spectrometry, the impurities being closely related halofluoromethanes. All water used was laboratory-once-distilled which had been passed through a mixed bed, demineralizing column.

The saturation pressure measurements were carried out with the condensed phases contained in either a simple unstirred 40-ml-capacity glass cell or a 100-ml glass cell equipped with a rotating paddle, which was driven magnetically. The pressure from the

[1]*Manuscript received September 17, 1959.*
Contribution No. 22 from the Exploratory Research Laboratory of Dow Chemical of Canada, Limited, Sarnia, Ontario, Canada.

saturation cell was transmitted via small bore glass tubing to a 1-cm I.D., U-type mercury manometer on which pressures were measured by cathetometer comparison with a stainless steel length standard accurate to ±0.02 mm at 100 mm and to ±0.04 mm at 1000 mm. All pressures were corrected to, and are quoted in, International mm Hg.

The vapor pressure cells were maintained at constant temperature using baths of melting methylene chloride −95°, subliming carbon dioxide −79°, melting chlorobenzene −45°, or a large capacity ethylene glycol – water thermostat between −30 and +10° C, the temperature of the vapor pressure cell being measured concurrently with the saturation pressure determinations. Temperatures were determined with a calibrated 65-ohm platinum resistance thermometer and standardized Müller bridge using a total bridge current of 2 ma and photoelectric amplifier–galvanometer as null detector. In the temperature range −20 to +10° C the precision of temperature difference measurement was ±0.001°, which, including ice-point errors and thermostat fluctuations, gives the temperatures reported an absolute accuracy of ±0.003° on the centigrade scale.

For vapor pressure measurement a 20-ml middle-fraction, from an original 40-ml freeze-outgassed sample of bromochlorodifluoromethane, was distilled into the evacuated vapor pressure cell, the sample was further freeze-outgassed and the cell was then isolated by mercury cutoff valve. For the experiments below −30° C the unstirred 40-ml cell immersed in the various cooling baths was used; the pressure and temperature were measured at regular intervals for periods of 4–10 hours, and some 20–30 independent readings were averaged in obtaining each of the experimental values recorded. Between −21 and 10° C, vapor pressure measurements were conducted in the 100-ml capacity cell immersed in the thermostat which maintained temperatures constant to ±0.002° C. The use of stirrer was unnecessary since the vapor pressure attained equilibrium within 1 hour, after which time a series of 4–6 pressure–temperature readings were taken to define each reported result.

In the preparation of the two-component water–bromochlorodifluoromethane systems, approximately 50 ml of freeze-outgassed water was transferred to the evacuated 100-ml cell maintained by the thermostat at +0.5° C. The stirrer was put into operation, the stirred water evacuated a further 30 minutes, the pumps isolated, and a 5-ml sample of freeze-outgassed bromochlorodifluoromethane distilled from a cold finger into the cell at 900 mm Hg pressure. After a short period gas hydrate formed and after the pressure had decreased to 600 mm Hg the cell and its contents were isolated by mercury cutoff valve.

Equilibrium measurements of (l_1l_2v), see Glossary of Symbols, were found to be most rapidly and reproducibly obtained by approaching equilibrium from higher temperatures, since removal of supersaturation was faster than attainment of saturation from the unsaturated condition. Thus, in obtaining equilibrium at a given temperature the thermostat was raised 0.7° C above this and the cell contents stirred rapidly for 4 hours, after which time the temperature was lowered to the required value and the stirring progressively moderated over a 6-hour period. The system was allowed to equilibrate a further 6 hours and then 4–6 equilibrium measurements were taken over a 4-hour period.

Kinetic measurements on (hl_1v) showed that equilibrium was generally attained with stirring after about 24 hours when approached from lower temperatures and pressures, as opposed to 48 hours when approached from higher temperatures. It was further observed that although the kinetic rates in different experiments varied irreproducibly, presumably due to uncontrolled factors such as hydrate crystallite size, proximity of crystals to liquid surface, quantity of freely suspended crystals in liquid phase, etc., equilibrium was attained in any single experiment with constant (or no) stirring according to a first-order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

rate law. When equilibrium measurements, which were approached from both lower and higher temperatures, were taken, the vapor pressure cell contents were stirred for 24–48 hours to come near to equilibrium, the stirrer was stopped, and the system left for a further 24 hours, after which 7–20 pressure–temperature readings were taken at regular intervals for a period 2–6 days, depending on the variability observed. To allow for the diurnal temperature variation of the unthermostatted mercury manometer and connecting tubing, all observed pressures were corrected to the average ambient temperature by applying a dead-volume correction. The precision of measurement of the pressures is essentially that of the length standard; however, the accuracy achieved over the 0–10° C range is certainly inferior, and is probably still due to lack of attainment of equilibrium.

Measurements on the solid (hs_1v), for which the stirrer was inoperative, showed that equilibrium was reached faster, 1–3 days, by approach from lower temperatures in which the hydrate decomposition reaction was involved. However, to confirm equilibrium, experiments from -5 to $-20°$ C were conducted starting both from below and above the required equilibrium temperatures, and the readings reported for each temperature represent averages of 25–42 separate measurements conducted over periods of 1 week or longer. The remaining results were derived from experiments approaching equilibrium from lower temperatures in which some 15 measurements were taken over 3-day periods. The improved absolute accuracy of the pressures measured for (hs_1v) is due both to the large number of readings taken at each temperature and to the reduced effect of ambient temperature variation. The apparent agreement shown in Table IV below $-10°$ C is fortuitous and cannot be considered significant since it is far beyond the ultimate accuracy ± 0.02 mm of the calibrated length standard.

The saturation pressure at $Q(hs_1l_1v)$ was determined by kinetic analysis of the first-order change of pressure with time exhibited when (hs_1v) initially at $-0.2°$ C was maintained in the thermostat set at $+0.013°$ C. The rate of melting of s_1 to l_1 was sufficiently slow that (hs_1l_1v) was observed for 30 hours, and the recorded pressure is an average of the "infinite time" pressures derived from six experimental measurements taken between 24 and 30 hours.

Liquid Bromochlorodifluoromethane – Vapor System

In Table I are presented experimental values for the saturation vapor pressure, p_2^0 International mm Hg, of liquid bromochlorodifluoromethane between -100 and $+10°$ C. In conjunction with the critical constants (9) the least-squares equation is derived,

$$[1] \qquad \log_{10} p_2^0 = -2106.200/T - 12.25100 \log_{10} T + 0.007417\, T + 38.47978$$

which is valid in the range -100 to $+154°$ C with $T°\,K = 273.16 + t°$ C. In the third column are shown back-calculated values using [1], from which a standard deviation of $\pm 0.0635\%$ is assigned to individual measurements. This error is unrealistically large for pressures between 366 and 1260 mm Hg and must be ascribed to inadequacy of the four-constant equation [1].

The normal boiling point derived from [1] is $-4.01 \pm 0.01°$ C. A liquid molar volume of 85 ml and a second virial coefficient of -722 ml, obtained respectively from the liquid densities (9, 10) and from the law of corresponding states (*vide infra*), lead to a compressibility factor of 0.9635, a heat content of vaporization of 5339 ± 30 cal_{15}/mole or 32.28 cal/g, and a Trouton constant of 19.8 cal/deg-mole. The statistical heat capacity of the ideal vapor from Gelles and Pitzer (11) yield heat capacities of 17.2 ± 0.1 and 23.1 ± 0.7 cal/deg-mole for the real vapor and liquid respectively at $-4.01°$ C.

Hydrate Molar Volume and Bromochlorodifluoromethane Second Virial Coefficient

In the calculation of the thermodynamic functions for bromochlorodifluoromethane hydrate from the saturation data to be presented, a knowledge of the associated phase volume changes and the bromochlorodifluoromethane vapor imperfections is essential.

[a]Critical point reference 9.

The molar volumes of liquid water $V_1^{l_1}$ and of solid ice $V_1^{s_1}$ have been taken from the critical compilation of Dorsey (12), whilst the derived values for the hydrate molar volume V^h and the bromochlorodifluoromethane second virial coefficient B_2 are presented here. Taken in order $t°$ C, V^h ml/mole, B_2 ml/mole; −20, 390.5, −816; −15, 391, −786; −10, 391, −757; −5, 391.5, −728; 0, 392, −701; +5, 392, −675; and +10, 392.5, −650. Values for V^h have been calculated from the cubic lattice spacing $a = 17.33$ Angstrom units at 0° C, measured by v. Stackelberg *et al.* (8, 13) for similar hydrates of CH_2Cl_2, $CHCl_3$, CCl_2F_2, and CCl_3F, using a coefficient of expansion for hydrate assumed equal to the volume coefficient $\beta = 153 \times 10^{-6}$ deg^{-1} for ice (12). Values for B_2 have been obtained from an assumed similarity with the second virial coefficients of CCl_2F_2 and CCl_3F (14), invoking the principle of corresponding states as applied to the reduced second virial coefficients (15), using the bromochlorodifluoromethane critical constants (9), $V_c = 232$ ml/mole at $t_c = 153.8°$ C.

Liquid Water – Liquid Bromochlorodifluoromethane – Vapor System

The liquid water (l_1) – liquid bromochlorodifluoromethane (l_2) – vapor (v), (l_1l_2v), three-phase system attains equilibrium at constant temperature according to the equation,

[2] $$H_2O\ (l_1) + CBrClF_2\ (l_2) \rightleftharpoons H_2O\ (v) + CBrClF_2\ (v)$$

$x_1^{l_1}$ $x_1^{l_2}$ $p_1(l_1l_2v)$

$x_2^{l_1}$ $x_2^{l_2}$ $p_2(l_1l_2v)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

in which $x_1^{l_1}$ and $x_1^{l_2}$ are the mole fractions of component 1, water, in phases l_1 and l_2; $x_2^{l_1}$ and $x_2^{l_2}$ are the mole fractions of component 2, bromochlorodifluoromethane, in l_1 and l_2; and $p_1(l_1l_2v)$ and $p_2(l_1l_2v)$ are the component 1 and 2 saturation partial pressures for the (l_1l_2v) equilibrium. Since $x_1^{l_2} \simeq 10^{-3}$ and $x_2^{l_1} \simeq 10^{-4}$ (*vide infra*), the experimental total pressure $P(l_1l_2v)$ is accurately represented by the sum of the Raoult law terms

$$[3] \qquad P(l_1l_2v) = p_1(l_1l_2v)+p_2(l_1l_2v) = p_1^0+p_2^0\,x_2^{l_2}$$

in which $p_1^0\,x_1^{l_1}$ is replaced by p_1^0 for pure l_1.
Rearrangement of [3], noting that $x_1^{l_2}+x_2^{l_2} = 1$, yields

$$[4] \qquad x_1^{l_2} = [p_1^0 + p_2^0 - P(l_1l_2v)]/p_2^0 = 1-p_2(l_1l_2v)/p_2^0$$

from which the saturation solubility of water in liquid bromochlorodifluoromethane is derived.

Calculation of $x_1^{l_2}$ from [4] requires values of p_2^0 at temperatures corresponding to the (l_1l_2v) measurements, and although equation [1] would appear suitable for this purpose its long temperature range and small number of constants make it a forcing equation, from which the experimental p_2^0 values show systematic deviations between -21 and 10° C. To provide a better representation of the experimental p_2^0 values between 4 and 10° C, and a relation for $p_2(l_1l_2v)$ between 9.4 and 10.4° C, the equations

$$[5] \qquad \log_{10} p_2(l_1l_2v) = -1197.8701/T+7.332245\pm0.000018$$

$$[6] \qquad \log_{10} p_2^0 = -1197.8701/T+7.332552\pm0.000070,$$

shown with their standard errors, have been derived as best fits of the data presented in Table II, using a slope factor defined by [1] at 7° C. In the fourth column of Table II are

TABLE II

Solubility of water in liquid bromochlorodifluoromethane

[a]Below 9.96° (l_1l_2v) metastable with respect to $(hl_{IV}v)$.

shown values of $x_1^{l_2}$, derived from $p_2(l_1l_2v)$ and p_2^0 from [6], on which there is a standard deviation ±0.00021. At an average temperature 9.86° C, which is near to $Q(hl_1l_2v)$ at 9.96° C (*vide infra*), equations [5] and [6] yield $x_1^{l_2} = 0.000707\pm0.000165$.

Although no comparable solubility measurement is available for water in liquid bromochlorodifluoromethane, this value is of the same magnitude although slightly larger than the mole fractions 0.00029 and 0.00042 reported (16) for water in the similar dichlorodifluoromethane and trichlorofluoromethane liquids.

Hydrate – Liquid Water – Vapor System

When the (l_1l_2v) system containing excess l_1 is cooled below 10° C it becomes metastable with respect to the (hl_1v) three-phase equilibrium, which is established according to the equation

[7] $$CBrClF_2.nH_2O\ (h) \rightleftharpoons nH_2O(l_1) + CBrClF_2\ (v)$$
$$p_1(hl_1v) \quad p_2(hl_1v)$$
$$x_1^{l_1}\ x_2^{l_1}$$

in which a solid bromochlorodifluoromethane hydrate phase h coexists with a dilute aqueous solution phase and a vapor phase. At constant temperature the system becomes invariant and its total pressure $P(hl_1v)$ attains a saturation equilibrium value, often called the "hydrate vapor pressure". This total pressure is adequately expressed by the relation

[8] $$P(hl_1v) = p_1^0 + p_2(hl_1v)$$

(cf. equation [3]) in which $p_2(hl_1v)$ is the saturation partial pressure of 2 for the (hl_1v) equilibrium.

In Table III are shown values for $p_2(hl_1v)$ and back-calculated values from the relation

[9] $$\log_{10} p_2(hl_1v) = 9963.8593/T + 144.056871 \log_{10} T - 385.31498$$

which has been derived by the method of least squares. The theory of errors indicates a standard error of ±0.0806% on individual pressure measurements which is significantly

larger than the precision of ±0.02 mm on the pressure measurement. At low pressures the standard error derives approximately equally from pressure measurement and effect of dead space, whilst at higher pressures the error is predominantly due to lack of attainment of equilibrium through diurnal temperature variation of the dead space.

Hydrate–Ice–Vapor System

When the (hl_1v) system is cooled below 0° C all excess l_1 freezes to give a solid ice phase s_1 and the (hs_1v) equilibrium is then established according to the equation

$$[10] \qquad \underset{}{CBrClF_2.nH_2O(h)} \rightleftharpoons \underset{p_1(hs_1v)}{nH_2O(s_1)} + \underset{p_2(hs_1v).}{CBrClF_2(v)}$$

At constant temperature the total pressure $P(hs_1v)$ attains a constant saturation value, equal to the sum of $p_2(hs_1v)$ and $p_1(hs_1v)$, of which the latter is the saturation sublimation pressure of ice (12).

In Table IV are presented values for $p_2(hs_1v)$ between 0 and −20° C which are represented by the equation

$$[11] \qquad \log_{10} p_2(hs_1v) = -1809.4253/T + 0.034379 \log_{10} T + 8.68372$$

with a standard error of ±0.0860% on single pressure determinations. In the third column of the table are shown back-calculated values for $p_2(hs_1v)$ from [11] using the experimental temperatures. Although few experimental values are given, each result represents multiple determinations approaching equilibrium from pressures above and below the saturation value.

Quadruple Points

In the present two-component system the end points of the (hl_1v) stability range at approximately 10 and 0° C are the respective invariant quadruple points $Q(hl_1l_2v)$ and $Q(hs_1l_1v)$, corresponding to the equilibrium coexistence of the four-phase systems (hl_1l_2v) and (hs_1l_1v).

The cut of the (l_1l_2v) and (hl_1v) three-phase lines (equations [5] and [9]) defines $Q(hl_1l_2v)$, with $p_2(hl_1l_2v)$ = 1262.65±0.58 mm Hg at $t(hl_1l_2v)$ = 9.96±0.03° C, above which temperature the hydrate cannot exist in the presence of a vapor phase. $Q(hl_1l_2v)$ is

TABLE IV

[b] = $Q(hs_1l_1v)$.

sometimes called the "hydrate critical point" which is a misnomer since, although this point is located at the highest temperature of coexistence of phases h and v, it does not necessarily represent the highest temperature at which hydrate can exist under hydrostatic pressure in the absence of a vapor phase (17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Direct experimental determination of the invariant point $Q(hs_1l_1v)$ has been made through kinetic analysis of the total pressure change observed during the isothermal phase reaction $(hs_1v) \rightarrow (hl_1v)$. These experiments gave a total pressure $P(hs_1l_1v) = 143.757 \pm 0.010$ mm Hg or $p_2(hs_1l_1v) = 139.181$ mm Hg. Substitution of this value for $p_2(hs_1l_1v)$ into equations [9] and [11] yields the temperatures $-0.003_6°$ and $+0.006_3°$ C respectively for the four-phase point, whilst the intersection of the (hl_1v) and (hs_1v) curves (equations [9] and [11]) gives $-0.006_9°$ C. On consideration of the lack of agreement of these three results, on which there are standard errors of $\pm 0.005°$ C, the experimentally determined four-phase temperature is taken as their mean $-0.001_4 \pm 0.005°$ C. Quantitative analysis of the l_1 phase at the termination of the experiment showed the presence of halogen acids depressing the experimental four-phase point by $0.001_4°$ C, from which the true quadruple temperature $t(hs_1l_1v) = 0.000 \pm 0.005°$ C.

Solubility of Bromochlorodifluoromethane in Water

The triple point of water (12), corrected for hydrostatic pressure, taken in conjunction with $Q(hs_1l_1v)$ at $0.000 \pm 0.005°$ C indicates a freezing point depression of $0.0084 \pm 0.005°$ C due to a mole fraction $x_2^{l_1} = 8.2 \times 10^{-5}$, which yields a Henry's law constant $H_2 = p_2(hs_1l_1v)/x_2^{l_1} = 1.7 \pm 1.0 \times 10^6$ mm Hg at 0° C for the solubility of bromochlorodifluoromethane in water. No other solubility determination is available for direct comparison, but the present value compares favorably with 4.1×10^6 mm Hg for dichlorodifluoromethane at 0° C extrapolated from the work of Parmelee (18). If it is assumed that the heat functions for the solubility of component 2 in l_1 are the same (3) as those for dichlorodifluoromethane (18), the temperature variation of H_2 in mm Hg is expressed by

$$\log_{10} H_2 = -10920/T - 72 \log_{10} T + 221.6298. \quad [12]$$

This equation is used to evaluate the solubility correction terms in [18].

Quantitative analysis of bromide and chloride ion concentration in phase l_1, by the mercuric nitrate – diphenyl carbazone method, showed hydrolysis of a mole fraction of 1.72×10^{-6} of bromochlorodifluoromethane over a period of 124 days, from which an upper limit of 2×10^{-9} (sec^{-1}) is set on the first-order velocity constant for hydrolysis of dissolved aqueous bromochlorodifluoromethane at 0° C.

Thermodynamic Functions for Hydrate Phase Reactions

Scheffer and Meyer (19) first indicated the exact use of the Clapeyron equation for obtaining the heat changes along the (hs_1v) and (hl_1v) saturation lines making due allowance for the small attendant vaporization heats of ice and water and solution heat of hydrate-forming gas. These workers, however, restricted their consideration to heat changes, being primarily interested in determination of the hydrate formula number n (*vide infra*, equation [23]). Here, in uniformity with modern usage, it was deemed desirable to indicate the systematic incorporation of correction terms necessary in obtaining other thermodynamic functions from hydrate equilibrium line data, and to define standard states in a manner convenient for comparison and conjunction with existent thermochemical tabulations. In this and other work the standard thermodynamic functions refer to condensed phases at 1 normal atmosphere pressure and to gaseous phases at 1 atmosphere fugacity; these standard functions are denoted by the usual superscript zero followed by a characteristic indication of phase. Standard changes of thermodynamic functions are represented in the normal way except that the phase reaction direction is included in parenthesis.

Consider the (hl_1v) equilibrium for which G_1, G_2, and G^h are the respective molar free

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

For personal use only.

energies of components 1 and 2 and of h throughout the system at absolute temperature T and total saturation pressure $P(\mathrm{hl_1v})$. At equilibrium, the molar free energy change for [7], denoted by $\Delta G(\mathrm{h} \rightarrow \mathrm{l_1v})$, is given by

$$\Delta G(\mathrm{h} \rightarrow \mathrm{l_1v}) = nG_1 + G_2 - G^{\mathrm{h}} = 0 \qquad [13]$$

in which the individual molar free energy terms are defined by

$$G_1 = G_1^{0\,\mathrm{l_1}} + RT \ln x_1^{\mathrm{l_1}} + [P(\mathrm{hl_1v}) - 1] V_1^{\mathrm{l_1}}, \qquad [14]$$

$$G_2 = G_2^{0\mathrm{v}} + RT \ln p_2(\mathrm{hl_1v}) + p_2(\mathrm{hl_1v}) B_2, \qquad [15]$$

and

$$G^{\mathrm{h}} = G^{0\,\mathrm{h}} + [P(\mathrm{hl_1v}) - 1] V^{\mathrm{h}}. \qquad [16]$$

In [14] and [16] $G_1^{0\,\mathrm{l_1}}$ and $G^{0\,\mathrm{h}}$ are the free energies for the condensed phases of pure $\mathrm{l_1}$ and of h at 1 atmosphere pressure, whilst $G_2^{0\mathrm{v}}$ is the free energy for an ideal gaseous component 2 having a fugacity of 1 atmosphere. Substitution of [14], [15], and [16] into [13] with replacement of $RT \ln x_1^{\mathrm{l_1}}$ by $-RTp_2(\mathrm{hl_1v})/H_2$ yields

$$-\Delta G^0(\mathrm{h} \rightarrow \mathrm{l_1v}) = RT \ln p_2(\mathrm{hl_1v}) + RT \ln \gamma(\mathrm{hl_1v}) \qquad [17]$$

with

$$RT \ln \gamma(\mathrm{hl_1v}) = p_2(\mathrm{hl_1v})[B_2 - nRT/H_2] + [P(\mathrm{hl_1v}) - 1][n V_1^{\mathrm{l_1}} - V^{\mathrm{h}}] \qquad [18]$$

where $\Delta G^0(\mathrm{h} \rightarrow \mathrm{l_1v})$ is the standard free energy change at 1 atmosphere for reaction [7] and $\gamma(\mathrm{hl_1v})$ is the over-all reaction activity coefficient.

A similar treatment applied to the $(\mathrm{hs_1v})$ equilibrium yields the parallel relations

$$\begin{aligned} -\Delta G^0(\mathrm{h} \rightarrow \mathrm{s_1v}) &= -(nG_1^{0\,\mathrm{s_1}} + G_2^{0\mathrm{v}} - G^{0\,\mathrm{h}}) \\ &= RT \ln p_2(\mathrm{hs_1v}) + RT \ln \gamma(\mathrm{hs_1v}) \end{aligned} \qquad [19]$$

and

$$RT \ln \gamma(\mathrm{hs_1v}) = p_2(\mathrm{hs_1v}) B_2 + [P(\mathrm{hs_1v}) - 1][n V_1^{\mathrm{s_1}} - V^{\mathrm{h}}] \qquad [20]$$

in which $\Delta G^0(\mathrm{h} \rightarrow \mathrm{s_1v})$ is the standard free energy change for reaction [10] and $\gamma(\mathrm{hs_1v})$ is the corresponding reaction activity coefficient.

In order to evaluate [18] and [20] n must be determined; the hydrate structural work of Claussen (4) and of v. Stackelberg (8, 13), together with the uncorrected heat content changes derived from [9] and [11] taken in [23], indicates that $n = 17$ for bromochlorodifluoromethane hydrate. With this preliminary value for n, $\gamma(\mathrm{hl_1v})$ and $\gamma(\mathrm{hs_1v})$ are calculated at each experimental temperature and the $p_2(\mathrm{hl_1v}).\gamma(\mathrm{hl_1v})$ and $p_2(\mathrm{hs_1v}).\gamma(\mathrm{hs_1v})$ terms (atmospheres) evaluated. The common logarithms of the reaction activity functions are fitted by the method of least squares to yield

$$\log_{10} p_2(\mathrm{hl_1v}).\gamma(\mathrm{hl_1v}) = 1156.5003/T + 69.766909 \log_{10} T - 174.95407 \qquad [21]$$

$$\log_{10} p_2(\mathrm{hs_1v}).\gamma(\mathrm{hs_1v}) = -1876.5722/T - 0.607407 \log_{10} T + 7.61080 \qquad [22]$$

from which the standard thermodynamic function changes are derived.

In Table V are presented the thermodynamic functions at 273.16° K for $(\mathrm{h} \rightarrow \mathrm{l_1v})$ and $(\mathrm{h} \rightarrow \mathrm{s_1v})$ derived from [21] and [22] using the gas constant $R = 1.986467$ $\mathrm{cal_{15}}$/deg-mole. The quoted limits of error are standard errors including variances from random error, solubility error, and a 5% uncertainty on the second virial coefficient. Although the free

energy, heat content, and entropy terms at 273.16° K are only slightly affected by variation of solubility and compressibility corrections, $\Delta Cp^0(h \rightarrow l_1v)$ is a sensitive function depending strongly on these corrections (cf. coefficients of $\log_{10} T$ in [9] and [21]), the errors on which contribute more than half the standard error quoted. The standard error on $\Delta Cp^0(h \rightarrow s_1v)$ is reduced, although based on fewer points, since this function is derived from lower pressure data independent of any solubility correction.

Derived indirectly from the heat content change relation

[23] $$\Delta H^0(h \rightarrow l_1v) - \Delta H^0(h \rightarrow s_1v) = n\Delta H^0(s_1 \rightarrow l_1)$$

in which $\Delta H^0(s_1 \rightarrow l_1)$ is the heat of fusion of water (12) (1435.7 cal_{15}/mole at 273.16° K); the hydrate formula number n is found respectively at −5, 0, and +5° C to be 16.99, 16.94, and 16.90±0.34 within a 90% confidence limit of error.

TABLE V

Thermodynamic functions for $CBrClF_2.17H_2O$ at 273.16° K

	$(h \rightarrow l_1v)$		$(h \rightarrow s_1v)$

$d(Cp^{0\,h})/dT$ cal/deg²-mole		1.29±0.83		

The hydrate standard entropy values presented are derived from Gordon's (20) spectroscopic entropy for water and from Gelles and Pitzer's (11) spectroscopic values for bromochlorodifluoromethane with n taken as 17.00. The two values of $Cp^{0\,h}$ quoted are strictly mean values at 278.05 $(h \rightarrow l_1v)$ and at 263.16° K $(h \rightarrow s_1v)$ and are derived from the properties of the pure components (11, 12, 20) at these temperatures.

DISCUSSION

The experimental value determined for n between −5 and +5° C for the present hydrate is equal to the ideal crystallographic value of 17 given by Claussen (4) and by v. Stackelberg (8, 13) the deviation being well within the 90% confidence limit of error. It had been expected that this work would show a possible significant deviation of n greater than 17, similar to the deviations discussed by Platteeuw and van der Waals (6) for the gas hydrates (Structure I) of small molecules: this, however, is apparently not the case for bromochlorodifluoromethane hydrate (Structure II).

The thermodynamic functions for the $(h \rightarrow s_1v)$ reaction are somewhat remarkable in their similarity with those for normal liquid evaporation, in spite of the complex nature of the hydrate decomposition process involving an environmental change of 17 moles of hydrogen-bonded lattice water. With our present structural knowledge of the hydrogen-bonded gas hydrate lattices (Structures I and II) the simplest interpretation of this similarity, always assuming that it is not fortuitous, is that the thermodynamic functions for the water within the hydrate lattices are little different from ice, whilst those for hydrate-former escape are comparable with liquid evaporation. Notwithstanding the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

differences, the analogy is further extended on recognition that the hydrate-former leaves a confining cell of high and nearly spherical symmetry, whereas in liquid evaporation the escape is from a cell with statistical spherical symmetry.

On the assumption of identity of the water functions, $\Delta H^0(\text{h} \rightarrow \text{s}_1\text{v})$ gives a direct measure of the over-all attractive energy of the hydrate-former with its lattice, primarily arising from interaction with its immediate 28-member water co-ordination shell and to a smaller extent with more distant water and hydrate-former neighbors. Consideration of the force field exerted at the hydrate-former by the hydrogen-bonded water co-ordination shell shows that the attractive energy derives predominantly from central fields of the α_1–α_2 dispersion type on which a smaller $\mu_2-\alpha_1$ induction effect is superimposed. The angularly dependent $\mu_1-\mu_2$ orientation and $\mu_1-\alpha_2$ induction effects do not arise because of high co-ordination shell symmetry and water dipole neutralization through hydrogen bonding, which reduces μ_1 to zero or to a higher multipole. For such a model it is reasonably expected that the nearly spherical bromochlorodifluoromethane hydrate-former should rotate classically within the approximately central force field of its water co-ordination shell, and that the interaction energy should be accurately calculable from theoretical considerations.

As early as 1902 de Forcrand (21), to evaluate $\Delta H(\text{h} \rightarrow \text{s}_1\text{v})$ for a number of unmeasured hydrate-formers, used an empirical gas hydrate entropy rule similar to the Trouton rule for liquids. Recently v. Stackelberg (22) demonstrated that $\Delta S^0(\text{h} \rightarrow \text{s}_1\text{v})$ at 0° C was approximated by the entropy of sublimation of the hydrate-former, ascribing a constant value of 22 cal/deg-mole; agreement with experimental data, however, was only moderate. Platteeuw and van der Waals (6) pointed out the failure of a constant valued $\Delta S^0(\text{h} \rightarrow \text{s}_1\text{v})$, and in their partially occupied lattice treatment, based on the Lennard-Jones and Devonshire cell model, achieved better agreement with experiment.

Here analogy is maintained with liquid evaporation as in the v. Stackelberg approximation (22) and $\Delta S^0(\text{h} \rightarrow \text{s}_1\text{v})$ is taken as an evaporation entropy term plus a further $R \ln e$ for the lack of communal entropy in the hydrate. However, the evaporation entropy term is not considered to be constant, but rather a function of hydrate former molar volume, which is geometrically related to the hydrate-former free volume within its nearly constant-volume co-ordination shell. Figure 1 illustrates such a relationship for the small molecule (Structure I) and large molecule (Structure II) gas hydrates, for which $\Delta S^0(\text{h} \rightarrow \text{s}_1\text{v})$ at 0° C has been plotted against V, the hydrate-former molar volume at the normal boiling point. From the figure it is immediately apparent that the hydrates fall into two distinct groups which present linear and parallel entropy change – volume relationships running over the range 22–27 cal/deg-mole. Furthermore, the hydrate-formers smallest with respect to their co-ordination polyhedra, H_2S, CH_4 (Structure I), and CH_3I (Structure II), all present $\Delta S^0(\text{h} \rightarrow \text{s}_1\text{v})$ values near to 22 cal/deg-mole, whilst the relatively larger hydrate formers C_2H_6, CH_3Br, and $CBrClF_2$, associated with smaller free volumes within their confining polyhedra, present larger values of 27 cal/deg-mole. The only real anomaly for the Structure I hydrates is the large entropy change for sulphur dioxide which might arise from specific interaction with its water co-ordination shell. For the Structure II hydrates the position of ethyl chloride is unexpectedly high, but here an experimental uncertainty of ± 3.5 cal/deg-mole on the entropy change could cover the discrepancy.

On the basis of stoichiometric hydrate formulae, using a simple, smoothed potential, hard sphere, free volume model, similar to the Eyring and Hirschfelder (23) treatment of liquids, and on the assumption that the thermodynamic functions for the hydrate lattice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

water remain unchanged irrespective of hydrate-former size, it can be shown that two different cavity sizes should give rise to two linear and parallel ΔS^0–V relations, similar to those shown in Fig. 1, for hydrate-former, hard sphere volumes between 3 and 73% of the cavity volume.

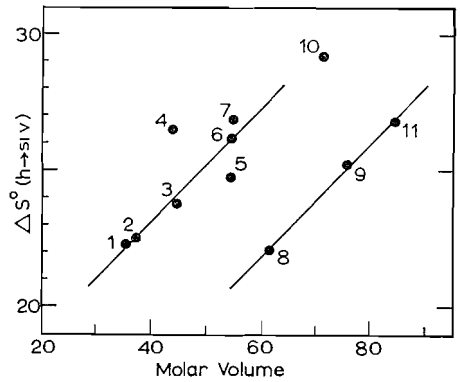

FIG. 1. Entropy change – volume correlation for gas hydrates.

Molar volumes at normal boiling point from International Critical Tables. McGraw-Hill Book Co., Inc., New York. 1933.

Consideration of the hydrate heat capacity is made on the basis of Pople's (24) theoretical analysis of the kinetic and potential energy terms contributing to the specific heat of a classical cell model liquid, as applied to the hydrate former within its co-ordination shell. If this analysis is used, assuming that the internal degrees of bromochlorodifluoromethane remain sensibly unchanged in the hydrate and that the lattice water has the same heat capacity as ice, ΔCp^0(h → s$_1$v) is given by $R(7/2-9/2$ or $7/2-10/2)$, i.e. -2 or -3 cal/deg-mole, which is in agreement with the experimental value. The error on the measured value is too large to consider the agreement better than satisfactory, but it should be considered that a variation of ±0.5 cal/deg-mole per hydrate water mole would change the experimental ΔCp^0(h → s$_1$v) to +6 or −10 cal/deg-mole. It is thus possible to state that, assuming the bromochlorodifluoromethane hydrate-former to behave as a classical rotator, the heat capacity of the hydrate lattice water does not differ from that of ice by more than ±0.3 cal/deg-mole, or alternatively assuming that the lattice water heat capacity is identical with ice, the hydrate-former behaves as a classical entrapped rotator within its co-ordination shell. With the second statement the increase of ΔS^0(h → s$_1$v) will derive mainly from reduction of translational free volume within its co-ordination shell, as implied by Fig. 1, rather than from increased hindered rotation.

Although not of great absolute significance the value of $d(Cp^{0\ h})/dT$ is positive indicating experimental consistency, and within experimental error is comparable with that of its components.

GLOSSARY OF SYMBOLS

Component 1, water:

l_1 liquid water phase

s_1 solid ice phase.

Component 2, bromochlorodifluoromethane:

l_2 liquid bromochlorodifluoromethane phase

h solid gas hydrate phase

v vapor phase.

$x_1^{l_1}$ mole fraction of component 1 in phase l_1.

$x_2^{l_1}$ mole fraction of component 2 in phase l_1.

$x_1^{l_2}$ mole fraction of component 1 in phase l_2.

$x_2^{l_2}$ mole fraction of component 2 in phase l_2.

(l_1l_2v) three-phase system consisting of l_1, l_2, and v.

(hs_1l_1v) four-phase system consisting of h, s_1, l_1, and v.

p_1^0 and p_2^0 saturation vapor pressures of pure components 1 and 2 respectively.

$P(l_1l_2v)$, $P(hl_1v)$, and $P(hs_1v)$, equilibrium total pressures exerted respectively by (l_1l_2v), (hl_1v), and (hs_1v).

$p_1(l_1l_2v)$, $p_1(hl_1v)$, and $p_1(hs_1v)$, component 1 partial pressures exerted respectively by (l_1l_2v), (hl_1v), and (hs_1v), in all cases taken equal to p_1^0.

$p_2(l_1l_2v)$, $p_2(hl_1v)$, and $p_2(hs_1v) \equiv P(l_1l_2v) - p_1^0$, $P(hl_1v) - p_1^0$, and $P(hs_1v) - p_1^0$, component 2 partial pressures exerted by (l_1l_2v), (hl_1v), and (hs_1v) respectively.

$Q(hl_1l_2v)$ and $Q(hs_1l_1v)$ invariant points for (hl_1l_2v) and (hs_1l_1v).

H_2 Henry's law constant for solubility of component 2 in l_1.

B_2 second virial coefficient of gaseous component 2.

X_1, X_2, and X^h, molar thermodynamic property X of components 1, 2, and of gas hydrate.

$X_1^{0\ l_1}$ and $X_1^{0\ s_1}$, standard molar thermodynamic property X of component 1, as pure l_1 and s_1 at 1 atmosphere pressure.

$X^{0\ h}$, standard thermodynamic property X of h at 1 atmosphere pressure.

$X_2^{0\ v}$, standard thermodynamic property of component 2 as vapor at 1 atmosphere fugacity.

$\Delta X(h \rightarrow l_1v)$ and $\Delta X(h \rightarrow s_1v)$, molar thermodynamic property change for reactions in the direction $(h \rightarrow l_1v)$ and $(h \rightarrow s_1v)$ respectively.

$\Delta X^0(h \rightarrow l_1v)$ and $\Delta X^0(h \rightarrow s_1v)$, molar thermodynamic property change for respective phase reactions with reactants and products in standard states.

SOME DEUTERIUM ISOTOPE EFFECTS

I. WATER SOLVOLYSIS OF METHYL-d_3 ESTERS[1]

J. A. LLEWELLYN,[2] R. E. ROBERTSON, AND J. M. W. SCOTT[2]

ABSTRACT

The α-deuterium isotope effect has been examined for the solvolysis of a series of esters containing a fully deuterated methyl group. The possible sources of the effect have been divided into "thermodynamic" effects which appear to favor more rapid reaction of the protium compound and "zero point" effects where stiffening of out-of-plane vibrations may account for the direction of the observed isotope effects. It appears that the inverse isotope effect may be a measure of the spatial restrictions placed on the hydrogen atoms on the carbon atom in the activated complex.

The substitution of deuterium for α-hydrogen in alkyl halides and substituted sulphonates has been shown to produce varying effects on reaction rates. Thus the solvolysis of methyl *p*-bromobenzenesulphonate in methanol and the reaction with methoxide ion are accelerated by α-deuteration (1). Isopropyl bromide reacting with ethoxide ion is apparently unaffected by this substitution (2), and phenyl ethyl toluenesulphonate solvolyzes in formic acid at a reduced rate when isotopically substituted at the α-hydrogen (3). Johnson and Lewis systematized these changes, suggesting that they were the consequence of the sensitivity of the C—H bending vibrations to the presence of entering and leaving groups and noted a decrease in the isotope effect, k_H/k_D, with increasing necessity for nucleophilic attack from the rear (1). From information available at the time they were unable to choose between several possible sources for the inverse isotope effect observed for methyl esters.

Streitwieser and co-workers (4) have observed a reduction in the acetolysis rate for cyclopentyl *p*-toluenesulphonate following α-deuteration. They have attributed this to the change in vibrational frequencies involving the α-hydrogen, produced by the difference in hybridization between initial and transition states, together with the effect of the leaving group which was postulated to stiffen the out-of-plane vibrations of the hydrogen.

Thus there appear to be three factors for consideration in assessing the zero-point contribution to the change in rate for nucleophilic displacements caused by α-deuterium substitution. These factors are: (*a*) the effect of the incoming group, (*b*) the effect of the leaving group, and (*c*) the change in hybridization.

Factors (*a*) and (*b*) will be related, inasmuch as bulky entering or leaving groups will be expected to stiffen the out-of-plane C—H bending modes. This effect will be modified by distance, but clearly, stiffening will increase the disparity in the energy levels of deuterium and hydrogen compounds in the transition state, and will produce changes tending to reduce the free energy of activation for the deuterium compound, compared with that of the protium compound. Reactions having the highest degree of nucleophilic interaction with large entering groups will presumably have the most stiffening.

The change in hybridization will also affect the characteristic frequencies but presents a problem in that even a qualitative decision concerning the effect is not simple. If we examine the force constants for molecules which can be considered to have C—H bonds analogous to those in the transition state, then we have a choice from a fairly wide range

of values. Added to this is the difficulty of deciding the hybridization of the transition state. If we reject the idea of an intermediate for the S_N2[3] reaction, the transition state will probably have three C—H bonds as sp^2 hybrids with entering and leaving groups interacting with the remaining p orbital.[4] The transition state of the S_N1 reaction will presumably occur before complete flattening of the carbon center linkages has occurred, and it might be considered that the C—H bonds are in a state between sp^3 and sp^2 with structure closer to tetrahedral when internal charge stabilization is more effective. Lower degrees of internal stabilization will mean that transition state C—H bonds are probably closer to sp^2 hybridization (6). From an examination of the force constants it appears that the stretching constants increase and bending constants decrease when hybridization changes from sp^3 to sp^2, although this is not invariably so. Some crude calculations which we have made indicate that the consequences of decreasing bending constants may outweigh the increase in stretching constant in terms of the zero-point energies, so that the change favors more rapid reaction of the protium compound. Since the hybridization change is most marked in the S_N2 reaction the effect should be pronounced in this case, but it will be offset by the closeness of the stiffening entering and leaving groups.

In the course of the present work we have examined the effect of deuteration on the reaction rates of a series of methyl esters solvolyzing in water (Table I). In the discussion

preceding this section it has been assumed that the only effective term in isotopic rate changes is the difference in zero-point energy change produced by the deuteration, but for the simpler esters and especially the methyl halides, this is not the case and other factors

[3]*The molecularity refers to the number of molecules undergoing covalent change and completely neglects the solvating molecules (5).*

[4]*The four original sp^3 hybrids become three coplanar sp^2 hybrids and the remaining p orbital combines with entering and leaving groups to give three M.O.'s two of which contain the four available electrons.*

must be considered. The problem of the alteration in reactivity for gas phase reactions has been dealt with extensively by Bigeleisen and co-workers (7). We have not adopted this treatment for our discussion because we are not sure of its application to reactions occurring in the liquid phase although other workers have made use of it as a basis for discussion (8, 4). We feel that discussion on a more naïve basis simplifies calculation of the effect of different models. Difficulties arise over the nature of the partition functions to be used in the description of the liquid systems, especially with respect to the transition state. Melander (9) uses the normal transition state equation with an added factor $\alpha/\alpha^{\neq}$ to compensate for the altered chemical potentials in the solution. This activity coefficient ratio is then considered as an increment ($\Delta F^{\neq}_{ex}$) to the free energy of activation. If a solute is strongly solvated, as in an ionic transition state, the alteration in chemical potential will be large and negative, and the stronger the interaction with the solvent the less will be $\Delta F^{\neq}$, so that reaction will be promoted for the species which is most strongly solvated in the transition state. A model for this interaction would be the C—H···O(H)(H) hydrogen bond, and the maximum value for this alteration would be the difference between hydrogen bonds involving deuterium and hydrogen in water.

Because of this difficulty we have proceeded by assessing the differences in the initial state of reaction, assuming that the gas phase differences which are calculated will be retained in the solution. Some justification for this is contained in a discussion of the nature of the solution. The free energy of the solution process may be considered in terms of the solute–solvent and solvent–solvent interactions. When a non-polar molecule is dissolved in water there is, in general, an increase in solvent–solvent interaction in the immediate vicinity of the solute, and the solute may be regarded as occupying a cavity in the solvent. The energy changes resulting from this process are more dependent on the properties of water than on those of the solute, and within a series, for example, alkanes, alkyl halides, alcohols, the free energy of solution is sensibly constant. Changes in enthalpy and entropy of solution oppose each other within the series and appear to be largely dependent on molecular volume so that the changes resulting from isotopic substitution would be expected to be negligible in the initial state. If we assume that the solute molecule rotates freely in the cavity in the water structure, and that the principal effect of solution is a reduction in the free volume available for translation, we arrive at the same conclusions. By factorizing the partition function into translational, rotational, and vibrational terms and making use of the relationships between the partition function and the thermodynamic properties, the following equations may be derived to represent the influence of isotope change on the initial state.

Translation

$$\delta F/T = 6.8635 \log M_D/M_H \text{ cal/mole deg}$$

(M = mass of compound in a.w.u.). δ is used to denote changes produced by isotopic substitution, and suffix D refers to the deuterium compound.

$$\delta H = 0$$

Rotation

$$\delta F/T = 2.2878 \log (ABC)_D/(ABC)_H \text{ cal/mole deg.}$$

$$\delta H = 0 \qquad A, B, C, \text{ moments of inertia.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Vibration

There will be a thermodynamic contribution, and an additional contribution from the decrease in zero-point energy. The thermodynamic terms will be:

$$\frac{\delta F}{T} = 1.9872\left(\sum \ln\left(1-e^{-hc\omega_D/kT}\right)-\sum \ln\left(1-e^{-hc\omega_H/kT}\right)\right)$$

$$\frac{\delta H}{T} = 1.9872\left(\sum \frac{hc\omega_H}{kT(e^{-hc\omega_H/kT}-1)}-\sum \frac{hc\omega_D}{kT(e^{-hc\omega_D/kT}-1)}\right).$$

The zero-point change will affect free energy and enthalpy in the same way and will be $\sum \frac{1}{2}hc\omega_H - \sum \frac{1}{2}hc\omega_D$ where ω_H and ω_D are the frequencies of the fundamental modes in wave numbers per cm for the two isotopic species.

Calculations for methyl halides yield the values in Table III from the data in Table II. For more complex molecules the following considerations will apply.

TABLE II

Data for calculation of initial state differences

Compound	Mass(a.w.u.)	Moments of inertia (a.w.u./Å) A	$B = C$
CH_3Cl*	50.5	3.31	38.48
CD_3Cl*	53.5	6.62	47.36
CH_3Br (19)	94.9	3.313	53.07
CD_3Br (19)	97.9	6.625	66.85
CH_3I (20, 21)	141.9	3.31	67.34
CD_3I (20, 22)	144.9	6.62	83.65

*Calculated from values of: Miller, S. L., Aamodt, L. C., Dousmanis, A., Townes, C. H., and Craitchman, J. J. Chem. Phys. 20, 1112 (1952). B value for CH_3Cl is in agreement with that of Gelles, E. and Pitzer, K. S. J. Am. Chem. Soc. 75, 5259 (1953), and a value given by Moelwyn-Hughes, E. A. Physical chemistry. The Pergamon Press, Ltd., London. 1957. p. 499, but disagrees with that given by Herzberg (ref. 12, p. 437).

TABLE III

Initial state differences calculated from data in Table II

Compound	Translational δF	Rotational δF
CH_3Cl	56	378
CH_3Br	32	394
CH_3I	21	384

(*a*) Deuteration will have little effect on the mass so that translational terms will be virtually unaffected.

(*b*) The moments of inertia will also be little affected by isotopic substitution so that rotational free energy will be unchanged. Deuteration will double the moment of inertia of the CH_3 grouping about a central axis perpendicular to the plane of the hydrogens, so that the possibility of contributions from internal rotation must be examined. A crude estimate may be made by considering the CH_3 group to be rotating with respect to a large mass (as in the *p*-toluenesulphonate ester).

The partition function for free rotation about a bond is

$$Q = \frac{(8\pi^3 I_r kT)^{\frac{1}{2}}}{\sigma h}$$

where I_r is the reduced moment of inertia for the system and σ the symmetry number.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

For symmetrical coaxial tops, with moments of inertia I_A and I_B

$$I_r = (I_A I_B)/(I_A I_B)$$

(this is obviously a crude approximation for the system being examined)

$$F = -RT \ln Q$$
$$\delta F = RT \ln Q_D/Q_H = \tfrac{1}{2}RT \ln I_{r(D)}/I_{r(H)}$$

identifying CH_3 and CD_3 in turn with I_A

$$\delta F = \frac{RT}{2} \frac{I_{CH_3}(I_{CD_3}+I_B)}{I_{CD_3}(I_{CH_3}+I_B)}$$

when $I_B \gg I_{CD_3}$

$$\delta F = \frac{RT}{2} \ln \tfrac{1}{2}$$

which will be about -238 cal/mole at 343° K.

In most cases the inequality above does not hold and rotation will not be free so that this value will be considerably reduced. More accurate assessment is probably not possible even if the height of the potential barrier hindering rotation was known (10). In the transition state the charge development may also hinder rotation despite the extension of the ester linkage and the net contribution to $\delta\Delta F^{\ddagger}$ will be the difference between two very small terms so that we feel justified in neglecting this issue.

The thermodynamic contribution of the vibrations is small so that inaccuracies here are probably unimportant, but the zero-point energy differences are the largest factor in the initial state differences so that this will be the principal source of error. The fundamental frequencies of the methyl and deuteromethyl halides have been established and using the values of Table IV the free energy and enthalpy changes have been calculated. From

TABLE IV

Fundamentals for methyl halides (cm^{-1})

	Degeneracy	CH_3Cl (12)	CD_3Cl (19)	CH_3Br (19)	CD_3Br	CH_3I (20)	CD_3I (20)
ν_1	(1)	2966	2161	2972	2157	2975	2135
ν_2	(1)	1355	1029	1305	993	1252	948
ν_3	(1)	732	695	611	578	533	493
ν_4	(2)	3042	2286	3057	2293	3061	2285
ν_5	(2)	1455	1058	1444	1056	1449	1070
ν_6	(2)	1015	775	955	712	882	665

these calculations it appears that initial state conditions strongly favor more rapid reaction of the protium compounds, although it is of interest to note that the thermodynamic enthalpy difference favors more rapid reaction of the deuterium compound by about 200 cal/mole for the alkyl halides.

In order to evaluate the consequences of isotopic substitution in the transition state, it is necessary to postulate a model or models for the calculation. The S_N1–S_N2 classification of the reaction will provide information concerning covalent interaction between the solvolyzing ester and a specific water molecule acting as a nucleophile, but will not specify the transition state. The experimental observations show that $\Delta H^{\ddagger}$, the enthalpy of activation, varies with temperature and this is interpreted as a consequence of the

change in heat capacity[5] on passing from initial to transition state. For many reactions this change does not appear to be readily detectable and in this case, it is largely attributable to the changes in the water molecules in the immediate vicinity of the reaction substrate. Current ideas suggest that these molecules are ordered (compared to the bulk of the water) in the initial state and less ordered (compared to the bulk of the water) in the quasi-ionic or ionic transition state. The magnitude of the heat capacity change suggests that more than one water molecule is involved in this disordering process (11, 18). Because these molecules have effect in determining the value of the heat capacity of the transition state it is not possible to disregard their presence in the calculations of the changes produced by isotopic substitution. For the evaluation of the thermodynamic changes caused by alterations in mass, a model containing a single water molecule will provide us with a maximum value and it may be stated with reasonable confidence that these contributions will actually be smaller. Proceeding on this basis a series of calculations reveal that the effect of mass increase on the translational contribution to $\delta F^{\ddagger}$ produces changes, which considered with the initial state values of δF, have very small, almost negligible, contributions to $\delta\Delta F^{\ddagger}$. The calculations for the effect of rotational contribution alterations were made for a series of models using different C—O, C—X distances, with the methyl hydrogens coplanar and carbon set at the C—H distance in ethylene (corresponding to sp^2 hybridization). The calculations indicated that alteration over a reasonable range of configurations did not seriously affect the outcome which showed $\delta\Delta F^{\ddagger}$ again in favor of the more rapid reaction of the protium compound. In the discussion of the initial state the possibility of internal rotation was considered and it appears that if a partial bond between carbon and oxygen has occurred, this effect may arise. Because of the symmetry of the system the potential energy will not be sensitive to the orientation of the two rotors CH_3 and H_2O and it seemed that for the case of the methyl halides, where the anionic moiety would have no moment of inertia about the internal axis, there might be an appreciable contribution. The model in Fig. 1 was

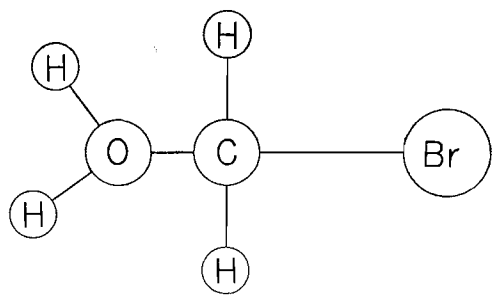

FIG. 1. Transition state model used for calculation of internal rotation contributions. O—H, 0.955 Å HOH 105°6′; C—H, 1.071 Å CH_3 coplanar; C—O, incipient bond formation; C—Br, incipient bond rupture

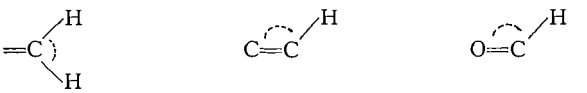
adopted, and assuming free rotation, a value close to -50 cal/mole at 343° K was calculated as a contribution to $\delta\Delta F^{\ddagger}$, i.e. reducing the free energy of activation for the deuterium compound. Generally speaking the calculations show that initial state differences favor more rapid reaction of the light compound. The effect of increased mass on the thermo-

[5]*$\Delta H^{\ddagger}$ is determined by identifying the gradient $(d \ln K)^{\ddagger}/(d\ 1/T)$ with $\Delta H^{\ddagger}/R$ and from the basic equation of transition state theory it can be readily shown that $\Delta H^{\ddagger} = E_0 + \int_0^T C_p^{\ddagger} dT - \int_0^T C_p dT$, where E_0 is the difference between the zero-point energy levels in initial and transition states.*

dynamic properties of the initial state will be paralleled in the transition state but will be reduced in size compared with the less massive initial state. Thus these transition state changes will tend to cancel the initial state changes, but will be less effective as the model postulated for the transition state becomes more complicated, and might be quite small where several water molecules are involved. Thus it seems that all these factors will increase the activation free energy of the deuterium compound relative to that of the protium compound with the exception of the internal rotation mentioned above.



We have omitted the part played by the vibrational contributions to $\delta\Delta F^{\ddagger}$ so that the nature of the vibrations of the transition state complex may be discussed separately. The results of our calculations indicate that the principal source of the inverse isotope effect probably lies in the altered vibrational frequencies which characterize the transition state. A substantial difference in the free energy of activation is present as a consequence of the initial state alterations in a direction which favors more rapid reaction of the protium compound. The direction of the isotope effect implies that the frequency sum for the transition state must exceed that of the initial state. The calculations which we mentioned earlier indicate that the simple hybridization change alters the frequencies downwards, that is, in a direction contrary to that expected from the rate alteration. If this is so, alternate sources of stiffening of the carbon–hydrogen vibrations must be sought, such as those proposed by Lewis and Johnson (1) and Streitwieser (4).

The presence of a nucleophile in close proximity to the coplanar methyl grouping, together with an additional contribution from the leaving group, appears to be a reasonable source of hindrance to out-of-plane carbon–hydrogen vibrations. As an extension of this hypothesis a correlation of the type noted by Lewis and Johnson would be expected. Since the hybridization change alone produces vibrational changes which would lead to isotope effects with $k_H/k_D > 1$, one would expect that with increasing hindrance to bending from increased nucleophilic interaction that the isotope effect would steadily decrease, pass through unity where α-deuteration would apparently have no consequences, and become less than one where the stiffening was extreme. The magnitude of the changes required to account for the experimental observations can be assessed if the frequencies of the fundamental vibrations of the transition state are estimated. The usual transition state theory represents the system as a mass point moving over a potential energy hypersurface. Translation along one co-ordinate in this hyperspace is associated with reaction and this translation is identified with one of the modes of vibration of the transition state complex. It seems a necessary condition that an incoming water molecule will be close to the carbon atom in the transition state and presumably the ester linkage will be extended so that movement in these two linkages will form part of the reaction co-ordinate. The effect that we have observed is small and thus it may be concluded that the reaction mode of vibration does not involve a normal mode which includes the movement of hydrogen in an important way so that the consequences of deuterium substitution on this mode will not be severe.[6] If it is concluded that the important changes will be those involving only the central CH_3 grouping then the problem is that of estimating the frequencies of the vibrations associated with this group. The bonds to the ester grouping and the incoming water molecule are assumed to be weak so that the effect of these groups on the in-plane vibrations can be neglected. The frequency sum for these vibrations for a coplanar CH_3 group was calculated assuming simple valence forces (12), and the effect of deuterium

[6]*An analogy can be drawn by considering the* ν_2 *and* ν_3 *vibrations of methyl iodide which can be described as the symmetrical* CH_3 *deformation frequency and the* C—I *stretching frequency, respectively. Deuteration produces an alteration of the frequency by factors of 0.76 where the vibration involves hydrogens in an important way, and only 0.92 where this is not so.*

assessed by using a modified mass correction (12, 4). By assuming that the isotope effect is derived from the large value of the frequency associated with out-of-plane bending, a force constant for this motion can be calculated for comparison with those encountered normally. These calculations are detailed in the Appendix. The fundamentals are ν_1, 2930; ν_2, 3120; ν_4, 1290 cm^{-1}, and the stiffened mode will have a value 2135 cm^{-1} to account for the observed isotope effect for methyl bromide. Calculating backwards, a value of $3.1\times10^5\ r^2$ dyne cm^2 can be derived for the out-of-plane bending force constant. This can be compared with the following values for bending modes in other molecules.

0.46 r^2 0.51 r^2 1.5 r^2 $\times10^5$ dynes/cm.

(N.B. These are all in-plane modes.)

The value that we have calculated is considerably higher than those above but does not render the stiffening hypothesis untenable since it represents a maximum where all the effect has been attributed to the stiffening of one mode. The presence of increments of charge on the constituent atoms of the group would increase the force constants for in-plane bending and stretching modes so that the aplanar bending need not be so stiff in order to account for the observed rate change.

CONCLUSIONS

The possibility that the deuterium compound is more strongly solvated in the transition state, and thus reacts more rapidly, is rejected because it fails to apply in cases where the opposing thermodynamic change (resulting from mass alterations) is quite small. Halevi's (13) suggestion that the potential surface is not invariant with respect to isotopic change cannot be dismissed (see below) but represents an unknown factor which does not appear essential in discussions concerning other systems where more precise statistical mechanics can be applied (17). It appears therefore that the observed inverse isotope effect can be attributed to stiffening of the C—H vibrations in the transition state which produces a decrease in the zero-level energy difference for the deuterium compound compared to the protium compound. This alteration counterbalances the change in the thermodynamic properties (arising from mass changes) which favors more rapid reaction of the light compound. The isotope effect varies with the nature of the group attached to the methyl group, but it is not clear whether the variation is a consequence of altered stiffening derived from changing size of the leaving group or changing degree of nucleophilic interaction by the entering water molecule. The sulphonates will presumably have similar effects in steric terms and do not show a variation in k_H/k_D which lies outside experimental error. The alteration in the methyl halide series follows the increase in leaving group size which is also the order of increase in the degree of nucleophilic attack if the rate ratio comparing OH^- attack in water with water solvolysis is accepted as a measure of this interaction (27).

The postulate that the alteration in $\Delta F^{\ddagger}$ is a consequence of opposing $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ changes leads to consideration of the possibility of experimental verification.

The temperature dependence of $\Delta H^{\ddagger}$ for methyl halide solvolysis has been examined by Heppolette and Robertson (18). Detailed examination of the Arrhenius E_a vs. T relationship indicated that the root mean square deviation of E_a from the derived smooth curve was ±90 cal for the methyl iodide solvolysis. If this value is taken as an index of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

precision with which $\Delta H^{\ddagger}$ can be measured, then experiments over a temperature range $t°$ will not reveal changes in $\Delta S^{\ddagger}$ which are less than $90/t$. The difference in gas phase entropies between CH_3I and CD_3I is slightly less than 2 e.u. in the range of experimental temperatures so that experiments 50° apart would just detect this change, but when the transition state difference is considered it is almost certain that the effect will not be detectable at the present level of experimental sensitivity.

Differential electron release would produce a reduction in E_0[7] favoring the heavy compounds we have examined here. Although there is considerable evidence to show that the substitution of deuterium for protium changes the ground state electron density configuration, it is uncertain whether these changes always imply differences in reactivity. Halevi (13–16) has measured isotope effects and interpreted them on the basis of electron release but some of these effects may be explicable in terms of the more usual phenomena associated with isotopic substitution discussed earlier, so that the significance of this factor in the cases discussed here is doubtful. Reasoning on the basis of electronegativity, isotope effects would be expected to increase along the series I, Br, Cl, sulphonates, and we find the reverse, but do not rule out this effect because a rapid saturation of this electron-releasing process might lead to the order observed in the experiments.

The thermodynamic contributions, which favor reduced reactivity of the deuterium compound, are greatest for the methyl halides and yet the inverse isotope effect is greatest for these compounds. A similar trend exists within the halides themselves and it is concluded that the more important factor is the vibration change produced by altered hybridization and stiffening by entering and leaving groups.

EXPERIMENTAL

The deuterated methyl methanesulphonate and methyl tosylate were synthesized according to the method of Morgan and Cretcher from CD_3OH (99.5%) supplied by Merck and Co. Ltd. of Montreal. The dimethyl sulphate was a pure sample supplied by Dr. Leitch of these laboratories. The methyl bromide and iodide were obtained from Merck and Co. Ltd. and were better than 99% isotopic purity.

Samples of both the normal and isotopic methyl chloride were prepared by heating the corresponding tosylate with an equal weight of anhydrous $CaCl_2$ in a suitable apparatus and collecting the evolved gas. The kinetic rates of hydrolysis for the normal material were shown to be identical with those previously obtained in a more extensive study in this laboratory (23).

Methyl nitrate was synthesized by the method previously used by Robertson and Laughton (24) and shown to be at least 95% isotopically pure by mass spectrometry.

Rate determination and other details of the kinetic studies were the same as those previously described by us (25).

APPENDIX

Calculations on the basis of a transition state model which contains only 1 water molecule interacting with methyl bromide and the deuterated analogue produce thermodynamic changes giving $\delta\Delta F^{\ddagger}$ 40 cal/mole at 343° K. The experimental value of $\delta\Delta F^{\ddagger}$ is -175 cal/mole so that if the transition state alteration in zero-point energy is the source of the inverse isotope effect then deuteration must account for this 215 cal/mole in addition to the 5647 cal/mole arising from the initial state zero-point differences.

For these vibrational calculations we consider only the ν_1, ν_2, ν_4, and ν_5 modes for the initial state which are those involving C—H bond vibrations in an important way (see Table IV). The ν_3 and ν_6 vibrations are strongly dependent on the X grouping and it is assumed that the errors involved in neglecting these in the initial state will be balanced by similar terms in the transition state, for vibrations involving bending with respect to the principal axis and stretching the C—O, C—X linkages. The purpose of this calculation is to show that the stiffening which must be postulated to account for the experimental observations does not lead to unreasonable values for the force constants involved. The model consists of a coplanar CH_3 group with the hydrogen atoms set at the C—H distance in ethylene with the stretching and in-plane bending force constants taken from the ethylene molecule.

A simple valence force treatment was then applied and the frequencies for the in-plane modes were calculated. By assuming that a mass correction can be applied to these vibrators the effect of deuterium substitution was assessed. From this information and the results of previous calculations a frequency for the out-of-plane bending mode was calculated which would account for the observations. Evaluation of the corresponding force constant enabled compromise with other systems.

A simple valence force treatment of the coplanar XY_3 molecule gives the following expressions for the fundamental frequencies.

$$\lambda_1 = k/m_y \quad [1]$$

$$\lambda_2 = (1+3m_y/m_x)\, k_\Delta/m_y r^2 \quad [2]$$

$$\lambda_4+\lambda_3 = (1+3m_y/2m_x)(k/m_y+3k_\delta/m_y r^2) \quad [3]$$

$$\lambda_3+\lambda_4 = 3(1+3m_y/m_x)(k/m_y^2 . k/r^2) \quad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

x = C; y = H; k, C—H stretching constant; k_Δ, aplanar bending constant; k_δ, HCH angle bending constant.

N.B. $4\pi c^2 M\nu^2 = 5.8894 . 10^{-2} . \nu^2 = \lambda$. This is treated in detail in Herzberg (12).

Using the values C—H stretch 5.1×10^5 dyne/cm, planar bend $0.3\times10^5 r^2$ dyne/cm, m_x = 12.011 a.w.u., m_y = 1.0008 a.w.u., r = 1.07 Å we may calculate ν_1, ν_3, and ν_4 leaving ν_2 the aplanar bending mode for later consideration.

The values obtained are

$$\nu_1\ 2930\ \text{cm}^{-1},$$

$$\nu_3\ 3120\ \text{cm}^{-1},$$

$$\nu_4\ 1290\ \text{cm}^{-1}.$$

Denoting the missing frequency by ν_2

$$\text{zero point energy} = \frac{1}{2}\left(\sum_i \nu_i\right) = (11750+\nu_2)/2\ \text{cm}^{-1}.$$

The initial state sums (for the frequencies mentioned earlier) are 13279 and 9830 cm^{-1} for protium and deuterium compounds respectively so that the zero-point change will be 1725 cm^{-1} ($\frac{1}{2}\sum_i \Delta\nu_i$). If the ν_2 vibration is to account for the effect then the zero point change in the transition state must be equal to the initial state zero point change plus the calculated thermodynamic changes plus the experimentally observed difference.

Applying the approximation $\nu_H = 1.35\nu_D$ the transition state zero point change is given by

$$\frac{1}{2}\sum\Delta\nu = \frac{11750+\nu_2}{2} - \frac{11750+\nu_2}{2\times1.35}$$

so that

$$\frac{11750+\nu_2}{2} - \frac{11750+\nu_2}{2.7} = 1725+75+22$$

where the second term (75 cm^{-1}) on the right-hand side represents the maximum value of the thermodynamic differences for methyl bromide and the third term (22 cm^{-1}) represents the experimental difference in $\Delta F^{\neq}$. The frequency of the stiffened mode is given by ν_2 = 2565 cm^{-1}, whence the force constant $k_\Delta r^2 = 3.12\times10^5$ dynes/cm for the out-of-plane vibration can be calculated using equation [2]. The only significance that we attach to these calculations is the more or less qualitative concept that the hybridization change produces a frequency sum decrease and that some degree of stiffening is required to change the zero-point energy in the appropriate direction to account for the observed effect.

It may be argued that a complete analysis of the transition state vibrations would be more effective but aside from the difficulty of carrying out such analyses for possible models, there remains the basic difficulty of definition of the reaction co-ordinate for a system such as this, superimposed upon the doubt whether it is capable of being identified with any of the normal modes of the transition state.

THE LUMINESCENCE OF COMPLEX MOLECULES IN RELATION TO THE INTERNAL CONVERSION OF EXCITATION ENERGY

PART II. N-HETEROAROMATICS[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

The relative fluorescence and/or phosphorescence yields of a number of methyl- and halogeno-quinolines, isoquinolines, and acridines have been measured as a function of the wavelength of the exciting light. In all cases the solvent was absolute ethanol. The results show that the efficiency of internal conversion processes between excited singlet states is extremely high in comparison to other intramolecular steps. The effect of substituted heavy atoms is discussed, as well as the fluorescence of the conjugate acids of the bases.

INTRODUCTION

In general, the fluorescence and phosphorescence quantum yields of aromatic molecules do not depend on which electronic state of the molecule is initially excited (6, 8, 9, 13, 25). In Part I of this series (9) some exceptional cases were reported and it was shown that this is not necessarily true if the excited molecule is free to isomerize. In these cases it was found that the quantum yield of fluorescence was considerably lower when the higher electronic states of the molecule were excited. Other exceptions are found with certain substances at very low pressure in the vapor phase. Under these conditions the molecule may photodissociate before the excess of vibrational energy is removed by collision. Consequently the fluorescence yield depends on the initial vibrational energy content which in turn is determined by the excitation energy. Another possible exception is that intramolecular energy transfer processes might occur within very short times (10^{-12} second). Should such a process as intersystem crossing, for example, occur at this rate it would probably compete favorably with the internal conversion process between electronic states. The result would be that the quantum yield of fluorescence would decrease and the quantum yield of phosphorescence would increase when the excitation energy was increased and successively higher electronic states were populated. An investigation of halogenated anthracenes (6) suggested that the last reason may be of importance. In particular, it was found that the fluorescence yield of dibromoanthracene was reduced to half its value when the excitation was directly into the higher electronic states.

The spectral similarity of anthracenic and naphthalenic systems to the analogous N-heteroaromatic molecules acridine and the quinoline isomers prompted the present experiments. The relative fluorescence and/or phosphorescence yields of a group of halogenated quinolines, isoquinolines, and acridines have been measured over a wide range of excitation wavelengths. Previous investigations of this type on heterocyclic molecules were mainly concerned with the larger molecular systems of biology and photosynthesis (7, 21), although more recently Weber and Teale (25) measured the quantum yield of fluorescence of 9-aminoacridine and found this to be constant over the range of exciting wavelengths 2100–4700 Å.

EXPERIMENTAL

The experimental arrangement, which was designed by Ferguson (6) and modified by the author (9), was essentially the same as that described in Part I. The excitation spectrum and absorption spectrum of each substance was determined before proceeding

[1]*Manuscript received September 14, 1959.*
Contribution from the Chemistry Department, the University of British Columbia, Vancouver, B.C.

to the yield determinations. In this way there was reasonable certainty as to the nature of the emitting species because luminescent impurities would have been readily detected in these experiments. Unless noted, the specimens were not examined in the long wavelength tail of the absorption band but from the wavelength of the first absorption maximum towards shorter wavelengths. Light from the hydrogen lamp was passed through a Beckman monochromater onto the sample, contained in a silica cell, and the luminescence was detected by a photomultiplier (RCA 5819). A filter was used to prevent the exciting light from reaching the photomultiplier. The filters used were benzyl alcohol (1.5 cm) or sodium nitrite (1.5 cm, saturated in water). The former cut off at approximately 3400 Å and the latter at 4000 Å. No luminescence could be detected from either filter. The benzyl alcohol filter was used for the fluorescence of the quinolines and isoquinolines, and the sodium nitrite filter for the green phosphorescence from these compounds and for the blue-green fluorescence from the acridines. Measurements were made of the excitation spectra of luminescence and of the relative quantum yields of fluorescence at different excitation energies. The experimental error in relative yields was about 3%. The concentration of the compounds investigated was sufficiently large that at least 99.9% of the exciting light was absorbed at each exciting wavelength. Thus any slight spectral shifts or sharpening of the spectra on cooling to liquid nitrogen temperatures would not have affected the quantum yield curves. In a few cases the separation of the phosphorescence and fluorescence emission was checked by using a Corning filter (No. 3486, cut off at about 4500 Å under the present conditions) in addition to the benzyl alcohol filter, and was found satisfactory.

RESULTS

(*A*) *Quinoline and Isoquinoline Derivatives*

Two emissions of different spectral location and apparent lifetime were observed for most of the compounds. The short-lived luminescence occurred in the region 3400–4000 Å. The longer-lived component, which appeared beyond 4000 Å, was observed only in rigid solutions. There was no doubt that each emission originated through the absorption of the incident radiation by the substance (of known absorption spectrum) under consideration. In the halogenated derivatives the phosphorescence and fluorescence could not be distinguished by qualitative observations of the apparent lifetime of the emission. This was to be expected by analogy with the corresponding naphthalenes where the phosphorescence lifetime decreases considerably as the atomic number of the substituted halogen is increased (14). However, there was no reason to suppose that the spectral location of the emissions would change by more than 1000–2000 cm^{-1} throughout the series, so the same filters were employed in these cases.

The compounds listed in Table I were investigated at room temperature and at the temperature of boiling nitrogen (−196° C). The range of excitation wavelengths over which the efficiencies remain constant are given in Table I.

(*B*) *Acridines*

The fluorescence from acridine is intense and lies in the visible region of the spectrum. The phosphorescence, on the other hand, is weak and probably lies in the near infrared. Craig and Ross (5) could find no triplet–triplet absorption of acridine although their experiments suggested that it is photochemically stable in a rigid glass. The weakness of the phosphorescence, its awkward spectral location, and the uncertain photochemical

TABLE I

Substances for which the fluorescence and phosphorescence yields are constant throughout the investigated range of exciting wavelengths

Substance	Exciting wavelength, mμ	
	Fluorescence	Phosphorescence
Quinoline	220–315	260–315
2-Methylquinoline	220–315	260–320
4-Methylquinoline	220–315	260–320
2-Chloroquinoline	250–320	260–320
6-Chloroquinoline	250–320	260–320
6-Bromoquinoline	250–320	260–320
Isoquinoline	220–315	260–315
3-Methylisoquinoline	220–315	260–315
4-Chloroisoquinoline	250–315	260–315
4-Bromoisoquinoline	250–315	260–315

behavior of the halogen derivatives suggested that with the present experimental arrangements no conclusive evidence could be obtained from the excitation spectra of phosphorescence. However, certain useful results were nevertheless obtained from the following fluorescence experiments.

The relative fluorescence yields of acridine, 9-chloroacridine, and 9-bromoacridine were determined as a function of the energy of the exciting light. The first two had constant yields over the range 230–395 mμ. The yield of 9-bromoacridine was considerably less than that of the other compounds. This may be contrasted with observations on the fluorescence yields of the bromoanthracenes, which suggested that there is no significant difference in yield between anthracene and 9,10-dibromoanthracene (19). The yield is so low for 9-bromoacridine that the excitation spectrum at room temperature resembles the *inverted* absorption spectrum. Presumably the bulk of the molecules in solution act as an inner filter to the incident light and the luminescing species is a minute amount of a photoproduct. At liquid nitrogen temperatures the fluorescence of 9-bromoacridine completely obscured the impurity luminescence, as indicated by the spectra of excitation and fluorescence. The fluorescence yield remained constant in a rigid ethanol glass over the range of exciting wavelengths 250–395 mμ. This result is in disagreement with that previously reported by the author (11) which appears to have been caused by the presence of a diacridinic photoproduct.

The absorption spectra of the halogenoacridines have not previously been examined in detail, although Zanker (28) determined the absorption and fluorescence spectra of acridine and the aminoacridines, and Mataga (15) computed the energy levels of acridine. The main difference in the spectra of anthracene and acridine is the intensity of the ^1L_b band in acridine and its feebleness in anthracene (2). It is of interest to compare the relative shifts of the ^1L_a and ^1L_b states and also the intensities of the bands on substitution of electron-donating halogen atoms. The energy of the 0–0 transition to the lowest ^1L_a state decreases through the series 9, X-acridine (X=H, =Cl, =Br) in the order 26,100 cm^{-1}, 25,150 cm^{-1}, and 24,140 cm^{-1} while the intensity does not change appreciably. On the other hand the energy of the transition $^1L_b \leftarrow {}^1A$ scarcely changes through the series while the intensity changes considerably. These results agree with those on the protonated and non-protonated N-heterocyclics (17, 28) and are similar to results obtained with the analogous substituted anthracenes (12).

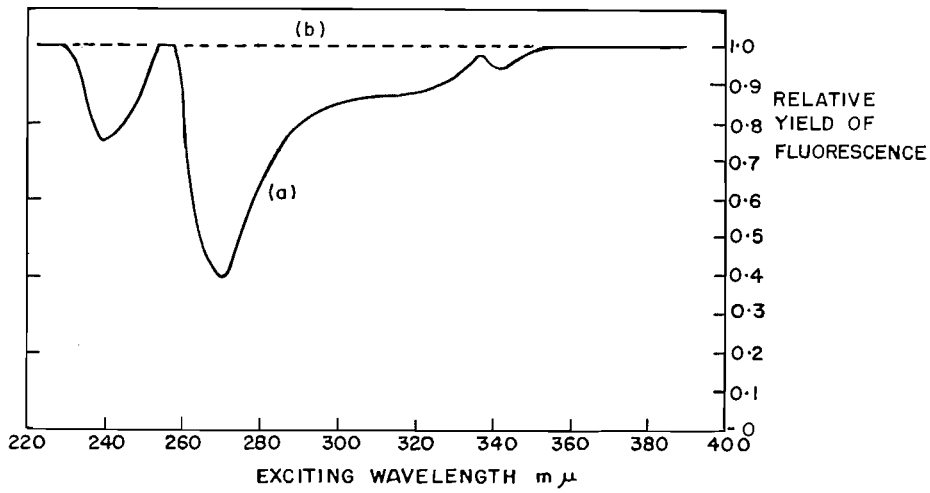

FIG. 1. The variation of the fluorescence yield of acridine conjugate acid with the wavelength of the exciting light. (*a*) No additional free acid. (*b*) Excess acid added.

(C) Luminescence of Conjugate Acids

A few experiments on the conjugate acids of all of the aforementioned bases were carried out. These included measurements of the absorption spectra, fluorescence spectra, and excitation spectra at room temperature and at liquid nitrogen temperature. In each case the quantum yield of fluorescence and/or phosphorescence was independent of the wavelength of exciting light over the same ranges as given in the previous section.

Some results which at first appeared anomalous were obtained for acridine conjugate acid. The excitation spectrum of fluorescence is shown in Fig. 1. In this experiment (concentration of acridine conjugate acid, 10^{-2} mole/liter; cell length, 1 cm; solvent, water) the curve would have been a straight line of zero slope and unit intercept if there had been only one emitting species. Consequently the curve shape must arise because there are two emitting species. These are the conjugate acid and the base with which it is in equilibrium.

As acid is added to this solution the yield becomes independent of excitation wavelength and eventually shows that only the conjugate acid is emitting with constant yield throughout the complete absorption range. The fluorescence of the base and its conjugate acid lie in slightly different spectral regions but both occur in a region where the photomultiplier response is not strongly wavelength dependent.

The results given in sections (*A*) and (*B*) indicate that the rule of the emitting level being the lowest of a given multiplicity is generally applicable to N-heterocyclic aromatic molecules. In each case the emitting level is the thermally equilibrated level of the lowest excited electronic state.

Quinolines and Isoquinolines

In alcohol solution it is likely that the fluorescent level is a $^1(\pi,\pi^*)$ state lying just below a $^1(n,\pi^*)$ state (22). The measurements, which extended throughout the absorption region of very concentrated solutions (that is, to energies comparable with the probable 0–0 transition), confirmed that internal conversion between these two states occurs with very high efficiency. The constancy of the yield also indicated that there is only one emitting species. This is an important observation in the light of recent work by Kasha and Mostafa

Amr Sayed (22), who showed that the orbital excitation types of the lowest electronic states of 2-ring N-heterocyclics may interchange on solvation. These authors found that the ratio of the phosphorescence to fluorescence yields was greatest when quinoline was dissolved in a non-hydroxylic (hydrocarbon) solvent and smallest when the solvent was an alcohol. This effect was attributed to hydrogen bonding. The fluorescence yields of hydrogen-bonded and non-hydrogen-bonded heteroaromatics are normally quite different (1, 16), the fluorescence yield of the latter being considerably greater since the emitting level is a $^1(\pi,\pi^*)$ state in which the probability of intersystem crossing is usually less than for a $^1(n,\pi^*)$ state (3, 23). As a hydroxylic solvent was used in this case all the emission presumably comes from hydrogen-bonded molecules.

The effect of small quantities of hydroxylic molecules on the relative fluorescence yield of quinolines, which will be discussed in detail in Part III, should be mentioned. When the excitation wavelength is longer than 3150 Å (beyond the first absorption maximum at 3140 Å) the quantum yield of fluorescence is no longer independent of the exciting energy. The yield *increases* as the excitation wavelength increases to 3300 Å and then remains constant at the higher value for longer exciting wavelengths. The amount of the increase is a function of the hydroxylic concentration. It is believed that this results from the dissociation of hydrogen-bonded molecules in the excited state. It appears that efficient mixing of the $^1(n,\pi^*)$ and $^1(\pi,\pi^*)$ states can occur when the solvent contains hydroxylic groups, that is to say when the lowest excited state is $^1(\pi,\pi^*)$ and the excitation is to levels beyond the first absorption maximum (3140 Å) as in the present work.

The phosphorescence in all cases was a $^3(\pi,\pi^*) \rightarrow {}^1A$ transition. It may also be concluded that the introduction of a bromine substituent into the ring system does not enhance intersystem crossing sufficiently for the process to compete favorably with internal conversion between excited states. The same general conclusions are known to be true for the analogous naphthalenes (6).

Internal Conversion

It may be asked why the internal conversion efficiency is independent of the excitation energy for bromoacridine but not for dibromoanthracene (6). These molecules are so similar that such a result is unexpected. An increase in spin orbital interaction due to the presence of a heavy atom could be brought about by altering the nodal distribution of π-electrons and hence the π-electron density in the region of the heavy atom. In most molecules this effect is not experimentally observable since the rate of intersystem crossing is much less than the rate of internal conversion between excited states (13, 20). The probability of intersystem crossing from the fluorescent state is measured by the ratio of the phosphorescence to fluorescence yield (13) while the probability of crossing from an upper state is given by the ratio of the phosphorescence to the internal conversion yield. For the cases under discussion this is presumed different from unity. The rate of upper state crossing k is given by

$$k = k_i \frac{(1-\phi)}{\phi} \geqslant 10^{13}/1 = 10^{13}\ \text{seconds}^{-1}$$

for 9,10-dibromoanthracene where the ratio $(1-\phi)/\phi$ is nearly unity (6) and where ϕ is the relative fluorescence yield. This value for k is much greater than that for most molecules. For example in the halogenated naphthalenes where heavy atom induced intersystem crossing is known to occur (14) the rate of intersystem crossing has a maximum value of about 10^{10} seconds^{-1}. There is no reason to believe that intersystem crossing via the upper states of molecules will be any more rapid than crossing from the first excited singlet state

in molecules where spin–orbit interaction is large. It is known that the fluorescent state of anthracenic molecules is particularly insensitive to heavy atom perturbation (18) so some enhancement is to be expected on excitation to a higher state. Also it has been shown that the process responsible for the reduction in the number of internal conversions when the excitation is in the upper state must occur at least 400 times faster than the apparent rate of fluorescence emission from the lowest singlet state (10). Thus the rate of removal of quanta from the upper state must be just below 10^{13} seconds^{-1}. Consequently, the phenomenon may not be explained as due to a slower rate of internal conversion due to unfavorable crossing of the excited state potential energy surfaces, as has been postulated in the case of azulene (24). It is possible that the increased efficiency of internal conversion in bromoacridine is connected with the presence of $^1(n,\pi^*)$ states. Theoretically these states lie quite close to each $^1(\pi,\pi^*)$ state, thus permitting internal conversion to occur through mixing of (n,π^*) and (π,π^*) electronic states.

Acridine Conjugate Acid

Although the base strengths of heterocyclic molecules differ in the ground and excited states (26), it is interesting that for acridine conjugate acid the constancy of the quantum yield of fluorescence throughout the regions where most of the light is absorbed by the conjugate acid (e.g. 2200–2300 Å, 2500–2600 Å, and 3500–3900 Å in Fig. 1) indicates that the base strength in the upper excited states is not much less than in the fluorescent state. The bimolecular rate constants for proton recombinations and additions in such systems (27) indicate that an excited acid molecule would probably lose its proton within 10^{-12} seconds. This implies that proton loss could compete favorably with internal conversion in such molecules if the base strength were low enough in the upper states. For acridine, the base strengths of the excited states are probably in the order ^1L_a > ground > ^1L_b, ^1B_b. This order was deduced from the electron densities at the N atom of the base in each excited state, using the Coulson definition of bond orders and charge densities (4). Alternatively one may consider the relative polarization directions of the transitions to these states, which are predicted to be short axis, short axis permanent, long axis, and long axis respectively (15). It is reasonable to assign a higher electron density at the nitrogen atom, hence a higher base strength, for the short axis polarized states. Thus it should be fairly simple to observe effects such as described above if the molecule chosen has greatly different base strengths in each of its electronic states. Of course it is also necessary that the proton recombination times for excited base molecules be of approximately the same magnitude as (or larger than) the fluorescence lifetimes of the base and its conjugate acid. Investigations of such systems will be important in order to determine the role of internal conversion. A more detailed discussion will be given in Part III, with special reference to quinoline.

The measurement of the fluorescence efficiency as a function of exciting light energy for a solution containing a base in equilibrium with its conjugate acid can make possible a calculation of the acid–base equilibrium constant of the acid–base reaction if the absorption spectra of the acid and of the base are known. The relative yield values such as these of Fig. 1 may be used in such calculations.

STUDIES IN THE WAGNER–MEERWEIN REARRANGEMENT

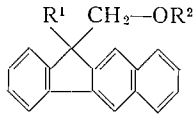
PART IV. DERIVATIVES OF BENZ[b]FLUORENE[1]

F. A. L. ANET AND P. M. G. BAVIN[2]

ABSTRACT

10-Methyl-10-benz[b]fluorenylmethyl tosylate[3] gave mainly 5-methylbenz[a]anthracene on formolysis, but the related alcohol gave a mixture of the 5- and 6-methyl isomers by reaction with phosphorus pentoxide. Reaction of benz[b]fluorenone with excess diazomethane gave 5-methoxybenz[a]anthracene as the only isolable product. The alkylation of methyl benz[b]-fluorene-10-carboxylate was studied.

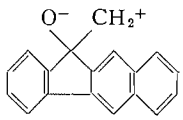
Collins and his co-workers have employed ^{14}C to study migratory aptitudes in Wagner–Meerwein rearrangements of polycyclic systems (1, 2, 3, 4). In particular, 10-benz[b]-fluorenylmethanol-11-^{14}C (I) was dehydrated by phosphorus pentoxide in boiling xylene to benz[a]anthracene (II), in which ^{14}C was found at carbon atoms 5 and 6 in the ratio 48:52 (3).



It seemed to us that similar information could be obtained without the use of ^{14}C, by using 10-methyl-10-benz[b]fluorenylmethyl tosylate (III), in which the carbon is labelled with a methyl group. On formolysis III gave almost pure 5-methylbenz[a]anthracene in about 60% yield. Examination of infrared spectra suggested the presence of traces of 6-methylbenz[a]anthracene (V) in the mother liquors from IV. However, the infrared spectra of IV and V were not sufficiently different to enable an accurate analysis to be made.

The greater migrating power of the naphthelenic over the benzenic ring in the formolysis of III is in contrast to the reaction of I with phosphorus pentoxide, where the two rings have about equal migrating powers. This may be due to the different experimental conditions leading in the case of Collins' work to a transition state more nearly approximating to a free carbonium ion which should have a low selectivity. In the case of the tosylate (III), formation of the benzanthracene probably occurs with participation of the aromatic ring in the ionization step, as in simpler systems studied by Cram (5). However, the reaction of 10-methyl-10-benz[b]fluorenylmethanol with phosphorus pentoxide gave nearly equal proportions of IV and V, in agreement with the results of Collins.

By reaction of benz[b]fluorenone with excess diazomethane, 5-methoxybenz[a]anthracene (VI) was obtained as the only isolable product, but in only fair yield (38%). The intermediate involved is almost certainly VII or a close approximation to it (6), so that this reaction is similar mechanistically to the Wagner–Meerwein rearrangement. A similar ring-expansion of benz[a]fluorenone has been reported (7), the only product isolated being 6-methoxychrysene. Thus in both of these examples the naphthalenic ring appears to have the greater migratory power.



Methyl benz[b]fluorene-10-carboxylate was not alkylated as smoothly as the fluorene analogue (8), the reaction failing with *t*-butyl bromide, though the methyl and isopropyl derivatives were readily obtainable.

EXPERIMENTAL

Methyl Benz[b]fluorene-10-carboxylate

Benz[b]fluorene (10 g) in warm benzene (150 ml) was added to a vigorously stirred solution of phenyl lithium (from 10.5 g bromobenzene and 1 g lithium) in ether (500 ml) under an atmosphere of dry nitrogen. The solution rapidly assumed a deep purple color. After half an hour it was poured onto powdered Dry Ice (500 g). Next day the mixture was acidified with dilute hydrochloric acid and steam-distilled to remove solvents. After cooling, the solid was collected, washed, and dissolved in hot 5% sodium carbonate solution (400 ml). Filtration with Norite and subsequent acidification gave the acid as a white solid. Esterification was effected by boiling for 4 hours with dry methanol previously saturated with hydrogen chloride. Concentration to 600 ml and cooling gave pale yellow prismatic needles of methyl benz[b]fluorene-10-carboxylate (8.7 g, 70%), m.p. 124–125°, raised to 126–126.5° by a further crystallization from acetone–methanol. (Lit. m.p. 117–118° (2).) Found: C, 83.23; H, 5.71. Calculated for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%.

Methyl 10-Methylbenz[b]fluorene-10-carboxylate

The preceding ester (5 g) was dissolved in methanol (100 ml) containing sodium methoxide (from 1 g sodium) to give a deep orange solution. Addition of excess methyl iodide caused a rapid change of color to pale yellow. Isolation of the product in the usual way and crystallization from acetone–methanol gave pale yellow prisms (4.07 g) m.p. 141.5–142.5°, raised to 142–143° by a further crystallization. Found: C, 83.23; H, 5.23%. Calculated for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59%.

Concentration of the original mother liquors gave a second crop (9.4 g) of almost pure material, raising the yield to 87%.

10-Methyl-10-benz[b]fluorenylmethyl Tosylate

The preceding ester (3 g) was reduced with an excess of ethereal lithium aluminum hydride. 10-Methyl-10-benz[b]fluorenylmethanol was obtained as a difficultly crystallizable oil, slow evaporation of a benzene–hexane solution affording small well-defined rhombs, m.p. 108.5–110°. The bulk of the oil was esterified with tosyl chloride (2.6 g) in dry pyridine. The product crystallized from benzene–hexane as small white needles (2.95 g), m.p. 118–119°; concentration of the mother liquors afforded a further 0.16 g. An analytical sample was obtained after a further crystallization, m.p. 118.5–119.5°. Found: C, 75.33; H, 5.35%. Calculated for $C_{26}H_{22}O_3S$: C, 75.35; H, 5.35%.

5-Methylbenz[a]anthracene

(*a*) In the best of several experiments, the once-crystallized tosylate (0.82 g) and 95% formic acid (100 ml) were boiled under reflux for 1 hour. Isolation of the product with chloroform gave a yellow gum, which was dissolved in hexane containing a little benzene and the solution passed through a column of activated alumina. Further elution with hexane and evaporation of the combined eluants gave crude 5-methylbenz[a]anthracene which crystallized from methanol as small white needles (0.28 g, 64%), m.p. 152–153°. (Lit. m.p. 155.9–156.9°, corr. (9).) The identity was confirmed by a mixed melting point with a sample of m.p. 154° and by comparison of infrared spectra. The melting point was strongly depressed by adding 6-methylbenz[a]anthracene.

Evaporation of the mother liquors gave material of m.p. 92–100° (0.08 g). The infrared spectrum showed a weak peak at 11.85 μ indicating the presence of a small proportion of the 6-methyl isomer, but attempts to isolate this through the picrate or by careful chromatography were unsuccessful.

(*b*) 10-Methyl-10-benz[b]fluorenylmethanol (0.5 g) and phosphorus pentoxide (1 g) in xylene (10 ml) were boiled under reflux for 4 hours. Purification of the product and examination of the infrared spectrum showed that there was present a mixture of about equal amounts of 5- and 6-methylbenz[a]anthracene.

Methyl 10-Isopropylbenz[b]fluorene-10-carboxylate

Methyl benz[b]fluorene-10-carboxylate (0.5 g) was alkylated using 3 equivalents each of isopropyl bromide and methanolic sodium methoxide. The product was a yellow oil which failed to crystallize, but passage of a hexane solution through a column of activated alumina and crystallization of the colorless fractions from acetone–methanol gave prisms, (0.4 g), m.p. 150–151°. Found: C, 83.40; H, 6.37%. Calculated for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%.

Further elution of the chromatogram gave a yellow oil (0.09 g) which formed a vermilion 2,4-dinitrophenylhydrazone. This was not characterized.

Attempts were made to *t*-butylate methyl benz[b]fluorene-10-carboxylate, as described for the fluorene analogue (8). The product was always contaminated with orange material which could not be removed by chromatography. Saponification to an acid followed by esterification with diazomethane also failed to yield a pure compound, so these experiments were discontinued.

5-Methoxybenz[a]anthracene

Benz[b]fluorene (1 g) was oxidized with sodium dichromate in acetic acid and a solution of the products in hexane passed through a column of activated alumina. Elution of the yellow band and crystallization from methanol gave yellow needles, m.p. 151–152° (0.7 g). (Lit. m.p. 152° (10).)

The pure ketone (0.5 g) was dissolved in methanol (100 ml) to which was added a large excess of ethereal diazomethane. Next morning the solvent was removed and the residue dissolved in hot heptane. The solution was passed through a column of activated alumina, elution being continued with the solvent until a fluorescent colorless band had been eluted. Evaporation and crystallization from benzene–hexane gave colorless needles (0.22 g) (38%), m.p. 165–166°. (Lit. m.p. 167–168° (11).) The melting point was not depressed on mixing with an authentic specimen, prepared by methylating 5-hydroxybenz[a]anthracene with diazomethane.

The only other material recovered from the chromatogram was unreacted ketone (0.11 g).

A SURVEY OF AMINO ACID CONTENT OF THE UREDOSPORES OF SOME RACES OF WHEAT RUST (PUCCINIA GRAMINIS)[1]

M. E. McKillican

ABSTRACT

The free and combined amino acids of seven samples of wheat rust were analyzed quantitatively by paper and column chromatography and compared with the amino acids present in uninfected wheat leaves. All races studied contained different proportions of free amino acids.

INTRODUCTION

The physiology of *Puccinia graminis* has been studied in some detail. For example, investigations of wheat leaf metabolism have indicated that diffusible substances spread from the fungal mycelium (1) and, as the parasite developed, the rise in oxygen consumption in the tissue of non-resistant wheat was found to occur later than in rust-resistant plants (2). This increase in respiration proved to be not merely an additive effect of the fungus respiration, but to be due to respiratory changes in the host tissues (3). In rust-susceptible wheat, decreased glycolic acid oxidase activity was shown to accompany the increased respiratory rate (4).

In contrast, the chemical constitution of the uredospores of *P. graminis* has been little investigated. The carotenoid pigments of the uredospores have been described (5) and studies made of a substance (6) or substances (7) that cause differentiation of infection structures. An examination of four races of wheat rust has shown a different total amino acid and sugar content for each race (8).

In the present work, the free and combined amino acids of seven samples of wheat stem rust uredospores are analyzed quantitatively by paper and column chromatography and compared with the free amino acids present in uninfected wheat leaves.

MATERIALS AND METHODS

The original rust cultures were obtained from the Plant Pathology laboratory in Winnipeg. The two-race mixtures and one sample of race 29, as well as the samples of field-collected wheat rust spores, were grown in Winnipeg. All races except the field-collected mixtures were grown on Little Club wheat in a greenhouse. Spores of all races were harvested when they reached maturity.

The free amino acids were obtained from the spores in the following manner: The uredospores were first extracted with ethyl ether for 20 hours to facilitate penetration of the aqueous solvent. Boiling water (20 ml per g) was then added to the sample and refluxed for 1 hour. The mixture was filtered, the filtrate cooled and poured into two volumes of ethanol. Any precipitate was removed by filtration. The extract was taken to small volume under reduced pressure, and the concentrate placed on a short (20 g) column of Dowex 50, 4% cross-linked, (50X4), 50–100 mesh, prepared according to Partridge (9, 10), and washed with 200 ml water. Acidic and neutral fractions were thus washed through, and the amino acid fraction (plus other weakly basic compounds) was then eluted from the Dowex 50X4 column with 0.2 *N* ammonium hydroxide. The ammonia was removed under reduced pressure and then *in vacuo* at 50° C.

[1]*Manuscript received June 22, 1959.*
Contribution No. 2 from the Genetics and Plant Breeding Research Institute, Research Branch, Canada Department of Agriculture, Ottawa, Canada.

A sample of uninfected leaves of Little Club wheat was freeze-dried and extracted in the same manner as the spores.

Individual amino acids were identified qualitatively by two-dimensional chromatography on Whatman No. 1 chromatographic paper. The sample was developed first with 80% phenol containing 0.04% 8-hydroxyquinoline, a small beaker of dilute ammonia being placed in the cylinder (11). The second solvent system was *n*-butanol – acetic acid – water 4:1:1 (12). The chromatogram was sprayed with 0.25% ninhydrin in *n*-butanol (13) to develop the color, or with isatin (14) to show proline and hydroxyproline and to help identify other amino acids by color differences between the effects of the two sprays.

The amino acid composition of the various races was determined as described by Moore and Stein (15). The concentration of amino acid in each fraction was estimated colorimetrically according to Moore and Stein (16) and Chinard (17).

Bound amino acids were released from the residue of the aqueous extraction by a 20-hour hydrolysis in 6 *N* hydrochloric acid used in the proportion of 25 ml per g of original sample (18, 19). The hydrolyzate was filtered and the hydrochloric acid removed from the filtrate by evaporation under reduced pressure. After the removal of most of the hydrochloric acid, a small amount of fine precipitate was present in the aqueous solution. This substance was slightly soluble in the Moore and Stein buffer pH 3.42 used initially on the column and, unless it was removed, the separation of the amino acids was not distinct. The hydrolyzate, after filtration (or centrifugation), was taken to dryness and stored over sodium hydroxide pellets to remove any remaining traces of free acid. An aliquot of suitable size (representing 0.2-g uredospores) was dissolved in buffer pH 3.42 and placed on the Moore and Stein column as in the case of the extract.

The individual amino acids in both the extract and hydrolyzate were identified by paper chromatography and by their position in the series of fractions from the Moore and Stein column. To calculate the percentage composition of a mixture of amino acids, the weight of each acid was expressed as a percentage of the total weight of the amino acids recovered from the column. This procedure was adopted to give a uniform basis of comparison among races.

After the over-all pattern of amino acid distribution had been noted, a synthetic mixture of amino acids was analyzed chromatographically to determine any limitations in the analytical methods.

RESULTS AND DISCUSSION

Each amino acid component of the synthetic mixture is recovered in essentially the same percentage of the total weight of amino acids in which it was present in the original mixture. When 10 mg of amino acids were applied to the column, 10.49 mg were recovered for an over-all efficiency of 104.9%.

By summing the weights of the amino acids in the fractions collected, the following information on over-all amino acid composition of *P. graminis* uredospores was obtained. Free amino acids made up approximately 0.5% of the original weight of spores and acid hydrolysis released a further 11% by weight of combined amino acids.

The proportions of free amino acids in the various races of rust studied are shown in Table I. Using the precision of recovery of the synthetic mixture as a model, appreciable differences in free amino acids were found between races. The variations in glycine and α-alanine contents separately, however, should be viewed with caution as the large amount of α-alanine present caused an overlapping of the peaks. There is also lack of resolution on the column of the peaks of tyrosine and phenylalanine.

*A Stem rust, field-collected and stored before analysis.
*B Stem rust, field-collected.

The greatest variation is shown by glutamic acid and aspartic acid. α-Alanine and glycine together show considerable variation although less is shown by the other α-amino-monocarboxylic acids, i.e. valine and the leucines. The other main constituent, γ-amino-butyric acid varies considerably as does serine while somewhat less variation is shown by the basic amino acids and those containing a benzene nucleus.

In contrast to the free amino acids, the bound amino acids in *P. graminis* uredospores are remarkably constant in composition from race to race.

On the basis of the results presented here, it would appear that the free amino acid content of uredospores, although its quantitative determination is tedious, might be considered a useful method for differentiating among races of wheat rust. For example, race 56 might be identified through its lack of glutamic acid and high content of aspartic acid and α-alanine. Similarly, the presence of large amounts of glutamic acid and low content of α-alanine and γ-aminobutyric acid might be used to identify race 48.

ACKNOWLEDGMENTS

The author appreciates the gift of rust cultures and samples from the Plant Pathology laboratory in Winnipeg; the co-operation of the Cereal Division, Central Experimental Farm, in providing greenhouse space; and the assistance of Miss S. G. Howsam and Mr. A. D. Gordon in carrying out the analytical work.

PHYSICOCHEMICAL STUDIES OF ALKALI LIGNINS

I. PREPARATION AND PROPERTIES OF FRACTIONS[1]

P. R. GUPTA[2] AND D. A. I. GORING

ABSTRACT

Alkali lignin was prepared by cooking periodate lignin with sodium hydroxide. Fractionation by gradual decrease of pH was not possible as most of the lignin was precipitated sharply at pH 4.4. Fractionation could be achieved by addition of non-solvents such as acetone, dioxane, or ethanol to an alkaline aqueous solution of the lignin, but the initial fractions when separated could not be redissolved. This difficulty was overcome by using barium chloride as a precipitant when all the fractions remained soluble. X-Ray analysis revealed no difference between the insoluble and soluble fractions.

The intrinsic viscosity of the fractions ranged from 0.027 to 0.585 g^{-1} dl. Reduced viscosities were considerably increased at lower ionic strength indicating that the molecule was a polyelectrolyte. The fractions possessed nearly constant methoxyl content (13%), visible absorption (0.28 cm^{-1} l. g^{-1} at 5460 Å), U.V. absorption (18 cm^{-1} l. g^{-1} at 2800 Å), neutralization equivalent (1.3 meq g^{-1}), and electrophoretic mobility (-12.6×10^{-5} cm^2 v^{-1} sec^{-1}). The partial specific volumes of a high and a low molecular weight fraction were 0.63 and 0.68 g^{-1} ml respectively.

INTRODUCTION

Various methods have been used to fractionate lignins and lignin derivatives. Attempts to fractionate lignin include fractional precipitations (1–6), fractional solution (7–9), dialysis (10–12), partitioning between two immiscible solvents (13, 14), chromatographic separation (15, 16), molecular distillation (17), and ultrafiltration (12).

Several early investigations on the isolation and purification of alkali lignin have been reviewed by Brauns (18) and Hägglund (19). In general, these workers were interested mainly in determining elementary composition and chemical constituents and no serious attempt was made to fractionate the lignin preparations as to particle size.

As far as is known, there have been no systematic studies of the solution properties of alkali lignins analogous to the work of Gardon and Mason (20), Goring *et al.* (21, 22), and McCarthy *et al.* (23, 24) on lignin sulphonates. The present investigation deals with the fractionation and subsequent physicochemical characterization of the fractions. In this paper, the development of the method of fractionation is described and measurements of U.V. and visible absorption, methoxyl content, neutralization equivalent, electrophoresis, viscosity, and X-ray diffraction are reported. Succeeding papers (25, 26) will deal with ultracentrifugal sedimentation analysis and the size and shape of the macromolecule.

Throughout the present work, emphasis has been laid on relatively mild treatment and careful purification. Cooking times were kept to the minimum required to render most of the lignin soluble. Ion exchange procedures, dialysis, and ultracentrifugation were used to purify the fractions from excess ions or colloidal debris. The difficulty of separating the alkali lignin from the soluble wood components was overcome by using periodate lignin as a starting material. Ritchie and Purves (27) have shown that the behavior of periodate lignin is similar to that of protolignin in many important respects, e.g., ethanolysis, hydrogenation, nitrobenzene oxidation, and bisulphite cooking. It is known that some methoxyl is lost but the phenyl propane chain is probably not broken.

Periodate lignin was, therefore, regarded as a suitable starting material for physicochemical investigations although comparison with lignins prepared directly from wood is planned as a subsequent extension of the work.

EXPERIMENTAL AND RESULTS

Materials

Periodate lignin was isolated from white spruce by a method similar to that of Purves and co-workers (27–29). The preparation has been described in a previous publication (21).

The sodium hydroxide solution was prepared from chemically pure reagent. Solvents were redistilled. Prior to distillation, dioxane was refluxed with sodium hydroxide pellets until no further brown precipitate was formed. The sodium bicarbonate – sodium hydroxide buffer was prepared by the method of Bates and Bower (30) to have an ionic strength, $\Gamma/2$, of 0.1 and pH 9.65.

Preparation of Alkali Lignin

About 100 g of the periodate lignin was homogenized manually in an agate mortar to pass a 150-mesh sieve.

Digestion was carried out in a stainless steel autoclave of 1.2-liter capacity fitted with a motor stirrer (21). The digestion was of 15-minute duration at 162° C with 10% NaOH solution. The lignin to liquor ratio was 1:50. The autoclave was heated to 162° C in 18 minutes, and cooled to room temperature in 5 minutes by immersing in cold water. The periodate lignin was first soaked with the cooking liquor in the autoclave for 17 hours. The reaction mixture was deaerated by evacuation prior to soaking and autoclaving. After digestion, it was centrifuged at 2000 r.p.m. for 30 minutes to separate the insoluble residue.

Lignin was precipitated from the centrifuged liquor by neutralizing with 20% HCl to pH 1.0. The precipitated lignin was washed with distilled water to pH 3.0, at which point it started dispersing in the wash water. The dispersed lignin was recovered using a Sharples ultracentrifuge. The lignin was then neutralized with NaOH to pH 7.0, when it dissolved giving a clear solution. The neutralized solution was filtered through a medium, sintered glass crucible, freeze-dried, and finally desiccated over magnesium perchlorate to give flakes of alkali lignin which were soluble in distilled water and in dilute sodium hydroxide.

The mother liquor from the acid precipitation of alkali lignin was light yellow in color and evidently contained some degraded lignin. This liquor was not investigated further.

Two batches of the alkali lignin were prepared. The second of these batches was obtained from three successive cooks. About 20 g of the periodate lignin was used for each cook. The yields of the insoluble residue, precipitated lignin, and lignin soluble at pH 1.0 are given in Table I. The neutralization equivalent, N_E (meq of Na per g of the precipitated lignin required for neutralizing to pH 7.0), is also included.

TABLE I

Recovery of alkali lignin

For personal use only.

By Mohr's titration, the chloride content of the precipitated lignin was less than 0.1%, and N_E by flame spectrophotometric determination of Na was 1.03 meq g^{-1}.

Fractionation

An attempt to fractionate the alkali lignin dissolved in the buffer by gradual decrease of pH with HCl failed. Most of the lignin precipitated sharply at pH 4.4 and could not be separated into fractions. The precipitated lignin could be redissolved and reprecipitated with an increase and decrease in pH respectively.

The lignin was then fractionated by adding non-solvents such as acetone, dioxane, or ethyl alcohol to aqueous solutions of the alkali lignin. A 2% solution of alkali lignin (batch 1, Table I) in the $NaHCO_3$–NaOH buffer was thermostated at 25° C. Fractions were obtained by progressive addition of the non-solvents and centrifuging the lignin off at 2000 r.p.m. for 30 minutes. The last fraction was recovered by evaporating the mother liquor under vacuum at 40° C. The fractions were redissolved in water, purified by ion-exchange (Dowex 1X-8 and 50X-8), neutralized to pH 7.0, freeze-dried, and desiccated over magnesium perchlorate. The data on fractionation with acetone and dioxane are given in Tables II and III respectively.

[b]D-3 was obtained by extracting D-1 and D-2 with dilute NaOH solution.

Invariably, the fractions initially precipitated by addition of non-solvents could not be redissolved in water or dilute NaOH. Fractionations with ethanol, similar to those in Tables II and III, produced insoluble initial fractions. Many variations of the procedure were tried. These include (*a*) addition of excess salt, (*b*) addition of diatomaceous earth to prevent aggregate formation, (*c*) decrease or increase pH, and (*d*) rigorous exclusion of oxygen. In all cases, part of the lignin was rendered insoluble by the fractionation procedure.

It was then found that fractionation by addition of barium chloride was possible and that the initial fractions were no longer insoluble. The barium chloride fractionation was carried out at 25° C on 11 g of alkali lignin (batch 2, Table I) dissolved in 500 ml of 0.02 *N* sodium hydroxide solution and centrifuged at 40×10^3 g for 20 minutes. *N*/10 $BaCl_2$ was then slowly added to the continuously stirred solution until a turbidity developed. The mixture was stirred for 30 minutes after which the precipitate was separated by ultracentrifugation and dissolved in 0.1 *N* sodium hydroxide solution. A series of such fractions was obtained by progressive addition of barium chloride solution. The last fraction B-9 was obtained by evaporating the mother liquor. The fractions in solution were converted into neutral freeze-dried powders as described earlier. The data are given in Table IV.

[a]Obtained by prolonged ultracentrifugation (2 hours at 150,000 *g*) of fraction B-4.

Finally, a series of fractions was made from the fractions shown in Tables IV and V. Low molecular weight material was removed by dialysis through cellophane tubing against successive changes of buffer and distilled water. Very high molecular weight material was eliminated by prolonged ultracentrifugation. In some cases fractions were blended to give enough material for study. The fractions thus obtained were designated the F-series and are shown in Table VI. Fractions F-1, F-2, and F-9 were prepared

TABLE VI

Fractions obtained by ultracentrifugal purification and dialysis

directly from the unfractionated material; F-2 and F-1 were obtained by two consecutive extractions with buffer of the sediment produced by ultracentrifugation at 150×10^3 g for 1 hour of a solution which had been centrifuged at 40×10^3 g for 1 hour; PF-2 was obtained on subsequent purification of F-2 by centrifugation and dialysis; F-9 was recovered from the dialyzate of the unfractionated material. In all cases (except F-1, F-2, and PF-2) fractions were neutralized and freeze-dried to give soluble powders. The purpose of more rigorous purification of the F-series was to prepare a series of fractions for light-scattering measurements to be described in a subsequent paper (26).

Viscosity

Intrinsic viscosity determinations were made in the $NaHCO_3$–NaOH buffer at $25\pm0.01°$ C with Ubbelohde-type viscometers as described by Craig and Henderson (31). The precision of the data is illustrated by the graphs of η_{sp}/c vs. c for the B-series shown in Fig. 1. From the "least square", lines $[\eta]$ and the Huggins' slope constant k' were

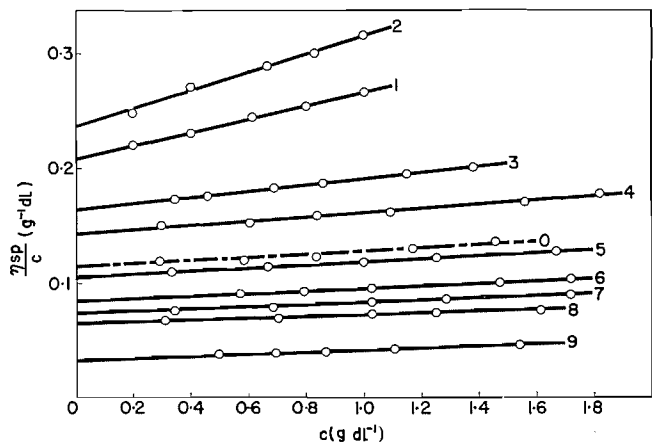

FIG. 1. η_{sp}/c vs. c in the $NaHCO_3$–NaOH buffer ($\Gamma/2 = 0.1$: pH = 9.65) for fractions of B-series.

obtained. Values of $[\eta]$ and k' for the various fractions are given in Tables III, IV, and VI. The intrinsic viscosity is given here as a convenient method of characterizing the fractions. Detailed interpretation of $[\eta]$ and k' is reserved for a later paper (26).

Although no barium could be detected in the purified fractions, it was considered possible that minute residual quantities of Ba^{++} might cause an anomalous increase in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

[η] by promoting aggregation. Accordingly the intrinsic viscosity of B-0 was redetermined in buffer with a small amount of $BaCl_2$ added. Instead of an increase, [η] was reduced by 13% in the presence of barium probably because of the increased cationic strength of the buffer. This proved that if traces of Ba^{++} were present they would not cause erroneously high values of [η].

Polyelectrolyte Behavior

Reduced viscosities were considerably increased with decrease in ionic strength and the characteristic polyelectrolyte upsweep of η_{sp}/c at low concentration was found for fractions dissolved in buffer of ionic strength 10^{-5} (Fig. 2). However, the effect was

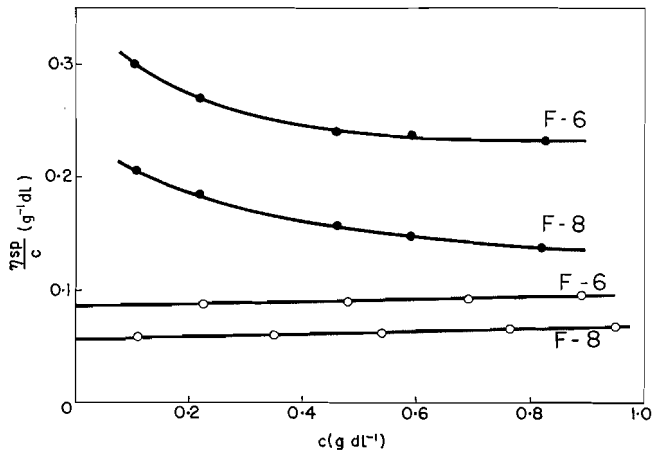

FIG. 2. η_{sp}/c vs. c in $NaHCO_3$–NaOH buffer at ionic strengths of 0.1 (open circles) and 10^{-5} (closed circles).

less than that found with lignin sulphonates by Rezanowich and Goring (32). Therefore the use of $\Gamma/2 = 0.1$ buffer was considered appropriate to depress the polyelectrolyte behavior, but a further small decrease in η_{sp}/c would be likely if the ionic strength was further increased.

Methoxyl, Neutralization Equivalent, and Light Absorption

Methoxyl estimations were made by Tappi Standard Method 2M43.

The neutralization equivalent was calculated from the sulphated ash obtained by igniting the samples with sulphuric acid at 750° C.

Optical densities were measured with a Beckman DU spectrophotometer as previously described (21). Measurements were made at wavelengths of 5460 Å and 2800 Å using concentrations of 0.2 and 0.002 g dl^{-1} respectively. The solvent was the $NaHCO_3$–NaOH buffer. Absorption was expressed in terms of the coefficient, ϵ, given by

$$\epsilon = D/cd \qquad [1]$$

where D is the optical density, c the concentration, and d the cell length. Values of ϵ together with methoxyl content and neutralization equivalent are given in Table VII.

Electrophoresis

Moving boundary electrophoresis was carried out in a Spinco Tiselius apparatus as previously described (22). The temperature of the bath was 0.8° C. Lignin fractions were dissolved directly in the $NaHCO_3$–NaOH buffer. The electrical conductivity of the

calculated in the usual manner (33) are shown in the diagram near the appropriate peaks.

X-Ray Analysis

It was possible that the insolubility of initially precipitated fractions could be ascribed to the development of crystallinity by polymerization (34). This would be revealed by X-ray diffraction, as more ordered patterns would be expected in the insoluble fractions.

X-Ray measurements were made using the technique described by Kouris, Ruck, and Mason (35). Exposures were of 4-hour duration with Cu K_α radiation. Broad diffuse rings, indicating an amorphous structure, were obtained and there was no difference in the diagram for the soluble and insoluble fractions. Therefore, the insolubility could not be associated with the development of crystallinity.

Partial Specific Volume

The classical pycnometer method (36) was used to determine the partial specific volume, $\bar{v}$, of the lignin fractions B-1 and B-6 in the buffer. A 5-ml Lipkin pycnometer (37) gave reproducible results with the usual precautions (38). Values of $\bar{v}$ for B-1 and B-6 were 0.63 and 0.68 g^{-1} ml respectively. The reported values of $\bar{v}$ range from 0.61 to 0.74 g^{-1} ml (5, 39, 40).

DISCUSSION

The fact that the alkali lignin could be fractionated into a series of fractions with progressively decreasing viscosity demonstrates its polydisperse macromolecular character. The intrinsic viscosities range from 0.027 to 0.585 g^{-1} dl. Such high $[\eta]$ values have not been reported earlier for alkali lignin. Recently, Goring and Rezanowich (21) obtained a similar range of $[\eta]$ for lignin sulphonates prepared by fractional solution under relatively mild cooking conditions. It is very interesting that two entirely different processes for making the lignin soluble yield macromolecular solutes similar as to particle size. This would support the concept that lignin exists as a three-dimensional network structure (41, 42) which, when made soluble by a comparatively mild treatment, yields a wide range of molecular weights.

The fractions were quite similar with regard to methoxyl content 13.1 ($\pm$0.3)% excluding B-9 and F-9. Constancy of methoxyl content has also been noted by Goring and Rezanowich (21), McCarthy and co-workers for non-dialyzable lignin sulphonates (24), and by Hess for fractionated native lignins (43). Values of methoxyl reported in the present work are higher as compared to lignin sulphonates but similar to native lignins. Gardon and Mason (12) reported low methoxyl contents in low molecular weight lignin sulphonates but further work showed that this was due to the presence of a small quantity of non-lignin organic impurity. The low values of 11.3% and 11.0% in B-9 and F-9 respectively may have been due to this effect. In agreement with results for other series of lignins (4, 6, 21, 23) the U.V. absorption was also constant. Though there was a greater variation in visible light absorption from fraction to fraction, no clear maximum was found as in the case of lignin sulphonates (21). The average value of ϵ_{2800} was 18.1 ($\pm$0.6) cm^{-1} l. g^{-1} which is considerably greater than the corresponding value of 13.8 cm^{-1} l. g^{-1} for the sulphonates (21) and nearly equal to the absorption noted by Hess for fractionated native black spruce lignin (43). These results suggest that the quick alkali treatment did not destroy the essential structure of the lignin. The high U.V. absorption seems also to have some bearing on the question of degradation of the lignin by the periodate treatment. In the oxidation by periodate some methoxyl is lost (27). As suggested by Adler (44), if this is accompanied by opening of the aromatic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

ring, then the proportion of aromatic to aliphatic carbon in the molecule will decrease, thereby altering the U.V. absorption. The good agreement of ϵ_{2800} with the values for spruce native lignin indicates that periodate degradation of the aromatic portion of the molecule must be small.

With one minor exception, single electrophoretic peaks were obtained (Fig. 3) similar to those for lignin sulphonate from a mild cook (21). Schubert *et al.* (45) found the native and enzymatically liberated lignins from oak, maple, and cork electrophoretically homogeneous while Scots pine lignin showed only small secondary components. This is in contrast to the marked electrophoretic heterogeneity of lignin sulphonates degraded by prolonged cooking (21). Similarly, McCarthy and co-workers (46) have found several electrophoretically distinguishable components in the alkali degradation products of lignin sulphonates. Evidently, separation into electrophoretically distinct components is characteristic of degraded lignins and the homogeneity found in the present work is a further support for the relatively undegraded character of the fractions studied.

The electrophoretic mobilities of the fractions studied were fairly constant. Migration was anodic and the mean U for the ascending and descending peaks were -12.8 (± 0.4) $\times 10^{-5}$ and -12.4 (± 0.3) $\times 10^{-5}$ cm^2 v^{-1} sec^{-1} respectively. Constant mobilities have also been observed by Goring *et al.* (22) for lignin sulphonates with a wide range of intrinsic viscosities. In a later report (26) it is demonstrated that the alkali lignin macromolecule is compact and not free-draining. Thus the ionizing charge groups which produce electrophoresis are probably near the surface of the macromolecule. Consistency of mobility suggests, therefore, identical surface charge densities, in spite of a large variation in size of the macromolecule. A fairly uniform charge distribution is indicated also by the failure to fractionate the lignin by addition of acid. A gradual decrease of pH caused most of the lignin to precipitate sharply at pH 4.4. This was probably due to the association of acidic groups on the molecule eliminating formal charges, the hydrophilic nature of which made the molecule soluble. The sharpness of the effect indicated that the ionizing groups were all of the same type and were probably —COO^- since the pK values of many carboxylic acids lie around pH 4–5. The charged nature of the molecule was verified also by its polyelectrolyte behavior although the effect was less than that produced by —SO_3^- groups in lignin sulphonate (32).

Fractional precipitation with non-solvents was intriguing as the initial few fractions became partially or completely insoluble. With acetone and dioxane about 45% and 27% respectively of the lignin was rendered insoluble. The later soluble fractions appeared to be effectively differentiated with respect to molecular weights because [η] decreased in the usual manner. Thus the material which became insoluble was probably of a higher molecular weight. Schuerch (13) has found in ethanol lignin that the initial fraction (supposedly the highest molecular weight fraction), when precipitated from chloroform–ethanol mixture on adding aqueous ethanolic alkali, gave an insoluble product. A higher dilution and a better aqueous solvent system was suggested by him for the partitioning of higher molecular weight fractions in order to avoid insolubilization.

In the present study an irreversible aggregation was considered as a possible cause for the insolubility of the initial fractions. To eliminate this, several variations of the technique were tried but without success. The precipitation was carried out in the presence of materials with large surface area such as diatomaceous earth, anion exchange resin (Dowex 1X-8; 200–400 mesh), or ball-milled glass. The idea was to provide nuclei for the precipitating lignin and decrease lignin–lignin contacts supposedly responsible for the aggregation. Diatomaceous earth absorbed lignin completely. Initially precipi-

For personal use only.

tated lignin still became insoluble in the presence of the powdered glass or resin. It was also considered possible that some oxidation (18) would occur during fractionation in alkaline medium rendering part of the lignin insoluble. Insoluble fractions still resulted when the lignin solution was deaerated and fractionation was carried out under a nitrogen atmosphere. Anyway, polymerization would not be likely in the mild alkaline conditions of the experiments as the sample had already been subjected to strong alkali at 162° C during its preparation from periodate lignin.

During the non-solvent fractionations it was noted that if the freshly precipitated lignin was removed immediately from the solution, it was still soluble. When the fractionation was carried out allowing time for equilibrium, the initially precipitated lignin was rendered insoluble. This result suggested that under the dehydrating conditions producing precipitation, irreversible lignin–lignin bonding developed with time in the high molecular weight material. Such an effect did not occur with the low molecular weight fractions even though the environment contained a greater proportion of non-solvent in the solution. X-Ray analysis revealed no greater order in the insoluble material, which showed that the insolubility was not associated with any tendency to crystallinity.

Whatever the cause of this interesting effect, it is quite evident that, under certain conditions, alkali lignin tends to adhere to itself. Also the material which behaves in this way is the high molecular fraction which, analogous to the sulphonates (21), is probably extracted at the final stage of cooking. Partial delignification of wood with alkali would therefore be expected to leave some of this "sticky" lignin on the cellulose which may effect considerably the subsequent bonding properties of the fiber.

Fractionation with Ba^{++} as precipitant was comparatively successful as the initially precipitated lignin was no longer rendered insoluble and there was a regular decrease in viscosity of the fractions. Fischer and co-workers (18) while studying alkaline oxidation of lignin were able to precipitate lignin with barium and separated it into readily soluble and slightly soluble fractions. Fractionation with Ba^{++} is not particularly selective and the fractions had a wide polydispersity as discussed in the following paper of the present series (25). Perhaps the polydispersity contributes to the solubility of the initial high molecular weight fractions with Ba^{++} as precipitant, assuming that the low molecular weight molecules peptize or disperse the high molecular weight material.

Finally, it is worth while to consider how representative the fractions were of the lignin in the wood. The periodate lignin was 64% of the Klason lignin content of the white spruce used (21). However, the lignin lost in the periodate preparation was mostly colloidal material which should be representative of the protolignin. With careful recovery on a small scale, Purves and co-workers (27) have obtained a 97% yield based on Klason lignin. From the data in Table I, it is evident that the material fractionated comprised about 65% of the periodate lignin. After the lignin was cooked with sodium hydroxide about 20% remained insoluble and about 15% could not be precipitated at the low pH. The latter would probably have a low intrinsic viscosity, while the insoluble portion if dissolved by longer digestion may have a somewhat higher $[\eta]$ than the values reported in this paper. The fractions used, therefore, corresponded to about 42% of the Klason lignin of the original wood and probably represented a "middle cut" with respect to molecular weight produced in the cooking process.

ACKNOWLEDGMENTS

PHYSICOCHEMICAL STUDIES OF ALKALI LIGNINS

II. ULTRACENTRIFUGAL SEDIMENTATION ANALYSIS[1]

P. R. GUPTA,[2] R. F. ROBERTSON, AND D. A. I. GORING

ABSTRACT

Ultracentrifugal sedimentation of alkali lignin fractions revealed marked boundary spreading at low and high centrifugal fields. An analysis of the gradient diagrams indicated a wide distribution of sedimentation coefficients ranging from 0.5 to over 400×10^{-13} second. There was only a small decrease in the polydispersity on subfractionation. The distributions were continuous with a single peak and positive skewness. A linear relationship was found between the intrinsic viscosity and the standard deviation of the weight-average sedimentation coefficient. The sedimentation coefficient based on the movement of the maximum ordinate at a field of 11.5×10^3 *g* was several times greater than the corresponding coefficient for the same fraction at 200×10^3 *g*. A qualitative interpretation of this phenomenon is given in terms of the Faxen and the Archibald solution to the Lamm equation.

INTRODUCTION

To interpret the physicochemical behavior of a macromolecule, a knowledge of the molecular weight distribution is a prerequisite. Theoretically, the sedimentation velocity method offers a direct measure of size distribution without recourse to fractionation. In practice, the technique is often unsatisfactory because marked concentration dependence in the sedimentation coefficient, *s*, masks the boundary spreading due to distribution in *s*. However in certain biological systems, e.g., enzymatically degraded glycogen (1, 2), there is only a small dependence of *s* on concentration and boundary spreading experiments can yield useful data on the molecular size distribution of a given sample. The present investigation deals with such an ultracentrifugal analysis of the fractionated alkali lignins described in the preceding paper of the present series (3).

We could find only one previous report on the sedimentation of lignins and this was by Gralen (4). Diffuse single peaks were obtained for thio- and hypo-bromide lignins. Sedimentation coefficients calculated from the movement of the maximum ordinate were from 1.0 to 3.0×10^{-13} second for the various fractions. The sedimentation diagrams were not analyzed for distribution of *s*, but Gralen noted that the fractions were polydisperse because the peak spreading in sedimentation was greater than observed in diffusion.

Recently, several workers (5–11) have reported wide polydispersity in lignin sulphonates fractionated by a variety of methods, and molecular weights as high as 138,000 were found. In contrast, the reported molecular weights of alkali lignin and other lignin derivatives are relatively low, i.e., up to 11,000 (12). Anticipating low molecular weights, the use of Archibald's (13) modification of Svedberg's (14) sedimentation equilibrium method was explored initially. To examine the applicability of this procedure, preliminary ultracentrifugal experiments were made at the lowest available rotor speed. It was found that even in this low field, sharp peak formation occurred indicating the presence of high molecular weight material. At centrifugal speeds, commonly used in velocity sedimentation experiments, a more diffuse peak was formed. A comparison of the movement of the peaks at the two speeds revealed an interesting discrepancy. Sedimentation coefficients based on the velocity of the maximum ordinate differed widely for the same

fraction at two speeds. A technique was then developed in which the same solution was run successively at two speeds thereby providing a more complete picture of the distribution of sedimentation coefficients.

The calculation of sedimentation coefficient distribution is an extremely laborious operation and the amount of labor depends on the degree of refinement used in the computations. The present study is the first of its kind to be made on any type of lignin. Therefore, it was decided to adopt certain approximations to permit the analysis of as many fractions as possible in the time available. The simplifying assumptions necessary for this are reported and discussed in the following sections.

EXPERIMENTAL AND RESULTS

The preparation and properties of the fractions studied are described in the first paper of the present series (3). Sedimentation measurements were made with Spinco Model E ultracentrifuge. The temperature was 26 (±0.5)° C. A double sector cell was used. One sector contained the solution while the other contained buffer which provided an accurate base line. A small quantity of methyl blue was added to the buffer to make its transmission at 5460 Å equal to that of the lignin solution. Phase plate optics were used and the schlieren angle was 45°. Unless otherwise stated, fractions were run at a concentration of 0.5 (±0.02) g dl^{-1} in $NaHCO_3$–NaOH buffer (pH = 9.65: $\Gamma/2 = 0.1$).

Measurements were made at 12,600 and 52,600 r.p.m. corresponding to 11.5×10^3 *g* and 200×10^3 *g* respectively. To allow for sedimentation during acceleration, one-third the acceleration time (15) was added to the time at the selected r.p.m. It was found possible to make the low and high speed measurements successively without stopping the ultracentrifuge. Usually six exposures at 4- or 8-minute intervals were taken at 12,600 r.p.m. The rotor was then accelerated to 52,600 r.p.m. and six more pictures at 8-minute intervals were recorded. Sedimentation diagrams obtained in this manner at the high speed were identical with diagrams at the equivalent time based on uninterrupted acceleration from 0 to 52,600 r.p.m.

Examples of sedimentation boundary gradient curves are shown in Fig. 1. The sedimentation coefficient, s_m, defined by the velocity of the maximum ordinate, was obtained

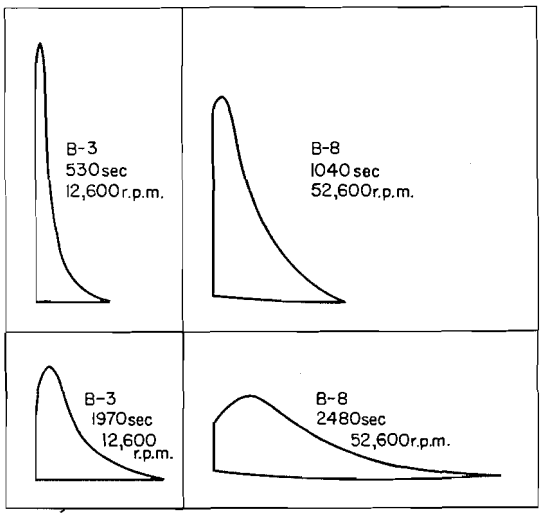

FIG. 1. Examples of sedimentation boundary gradient curves for fractions B-3 and B-8. The solvent was $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$).

from linear plots of $\log_{10} x_m$ vs. t (Fig. 2) where x_m is the distance of the maximum ordinate from the center of the rotor and t is the time. The origin was not used as a

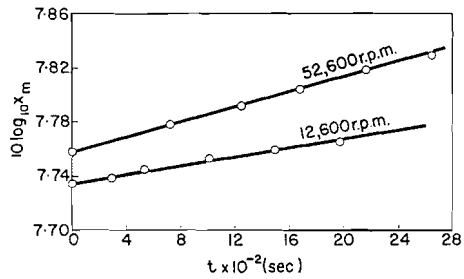

FIG. 2. Plot of log x_m vs. time for fraction B-3.

point in order to eliminate the error due to the interval of time at which the peak remains at the meniscus (16). The small correction required to normalize s_m to the viscosity and density of pure water at 25° C was neglected. Sedimentation coefficients, s_{m1} and s_{m2}, corresponding respectively to 12,600 r.p.m. and 52,600 r.p.m. are given in Table I.

The concentration dependence of sedimentation coefficients measured in a few selected fractions is shown in Fig. 3. It is evident that for the high speed runs, s_m is independent of concentration, c, within the experimental error imposed by the diffuse shape of the peaks. At the low speed, some dependence exists, partially due to the changing viscosity of the solution (of the low molecular weight material) through which the heavier particles sediment. In B-5 and F-3, the least square lines were given by the empirical relationship (17–20).

$$1/s = (1/s_m)_{c=0}(1+k_s c)$$

where the constant k_s was 0.53 and 1.61 g^{-1} dl respectively. If s_m is corrected for the viscosity of the solution, these values of k_s change to 0.37 and 1.21 g^{-1} dl. No correction was made for the concentration dependence of s in the low speed experiments, an approximation justified by the small ratio (15% on the average) of the material sedimenting at 12,600 r.p.m. to that sedimenting at the higher speed.

Distribution of Sedimentation Coefficients

The distribution of sedimentation coefficients was determined by the method of Williams and others (17, 18, 21–26), from the progressive spreading of the boundary with time. The distribution function $g(s)$ was obtained as a quantity such that the weight fraction of the material with sedimentation coefficients between s and $(s+ds)$ was given by $g(s)ds$. An apparent distribution function $g^*(s)$, corresponding to discrete

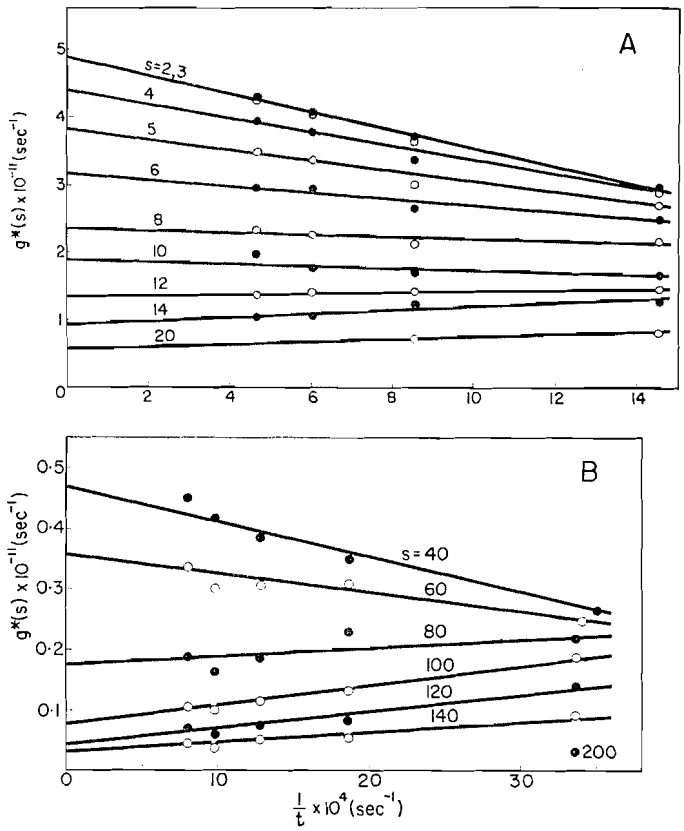

FIG. 4. Extrapolation of $g^*(s)$ to infinite time for fraction B-1 at 52,600 r.p.m. (A) and at 12,600 r.p.m. (B).

values of x, was computed from (27)

[1] $$g^*(s) = (dc/dx)(\omega^2 t x^3)(c_0^{-1} x_0^{-2})$$

where x, x_0, ω, and c_0 are respectively the distance from the center of rotor, the position of the meniscus, the angular velocity, and the initial concentration. Each value of x corresponds to a definite sedimentation coefficient, s, given by

[2] $$s - s_m = 2(x - x_m)/\omega^2 t(x + x_m).$$

In eq. [1], dc/dx and c_0 were replaced respectively by the refractive index gradient, dn/dx, and Δn, the difference in refractive index between solution and solvent.

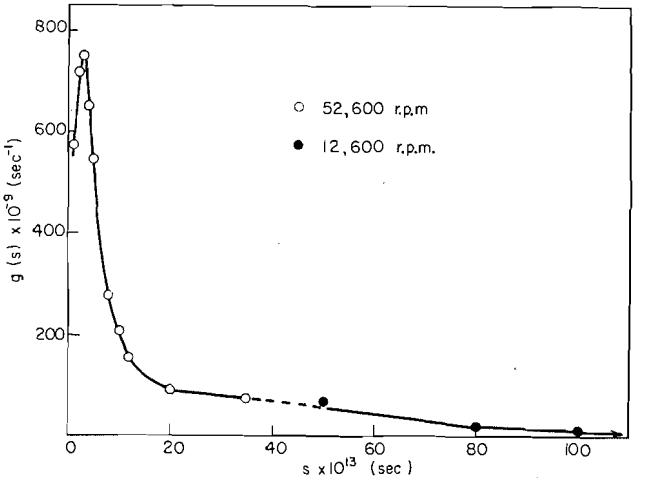

FIG. 5. Combination of distributions at 52,600 r.p.m. and 12,600 r.p.m. to give a single distribution curve for B-5.

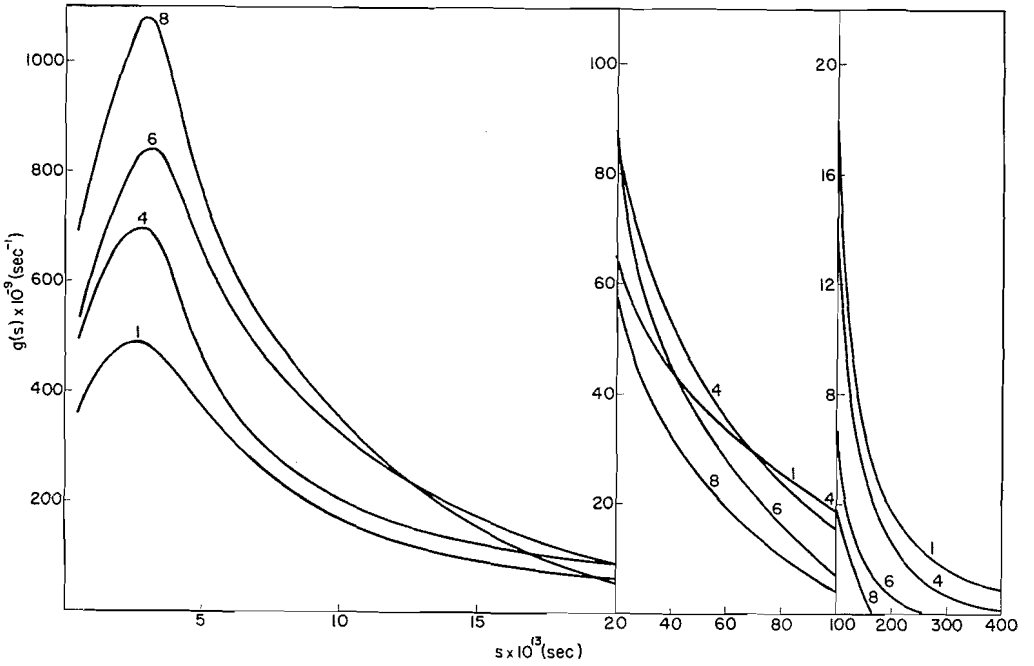

FIG. 6. Distribution of sedimentation coefficients for fractions B-1, B-4, B-6, and B-8 respectively (bottom to top). The solvent was $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2$ = 0.1).

In the initial experiments, the effect of diffusion was eliminated by plotting $g^*(s)$ (derived for discrete values of s) against $1/t$ as shown in Fig. 4. Such graphs were extrapolated as being linear (1) and from the intercepts at $1/t = 0$, values of $g(s)$ (i.e., $g^*(s)_{t=\infty}$) were obtained (21, 22).

From the data at the two speeds, two separate distributions of sedimentation coefficients were found. These did not overlap, which suggested that the material sedimenting at the low speed was spun quickly to the bottom of the cell in the 16 times stronger field at the high speed. The two graphs of $g(s)$ vs. s could, therefore, be combined to give single smooth curves shown in Fig. 5 for fraction B-5.

The distributions were all of the same type as shown in Fig. 6. They were characterized by a single maximum with positive skewness and varying proportions of heavy material in a wide range of s values. Curves were analyzed with an Amsler integrator (28). The null axis parallel to the ordinate gave the weight-average sedimentation coefficient, s_w; the square root, σ, of the second moment about the null axis was taken as a measure of the polydispersity (23).

As noted by others (1, 2, 29, 30), the procedure of computing the distribution in s is very time-consuming. Even with the use of an electronic computer, about 40 man-hours were required to process the data at two speeds for one sample. In order to simplify the procedure, extrapolation to infinite time was abandoned. Instead an analysis was done on a single sedimentation diagram at each speed. The second or third picture at the slow speed and the final picture at the high speed were found most suitable. The distribution for the two pictures were combined and analyzed as described above. The two methods were compared for several fractions and except for fractions heavier than B-3, the distributions obtained by the simplified method were nearly identical with those obtained by the detailed extrapolation method. The good agreement between s_w and σ obtained by the two methods for five fractions is given in Table II. A fivefold reduction in time was achieved by this method.

TABLE II

Comparison of s_w and σ computed by the detailed and simplified methods

	$s_w \times 10^{13}$ (sec)		$\sigma \times 10^{13}$ (sec)	
Fraction	Detailed	Simplified	Detailed	Simplified
B-4	53	68	60	60
B-5	32	28	43	42
B-6	20	21	29	27
B-7	15	15	22	22
B-8	14	14	21	17

In Table III, the value of σ, s_w, and $[\eta]$ are given for the fractions studied. Included is the most probable value of the sedimentation coefficient, s_p, corresponding to $g(s_p)$, the maximum value of $g(s)$ in the distribution curve. Fractions B-5-II and B-5-III (obtained by subfractionation of B-5) and F-3 to F-8 were analyzed by the simplified method.

With the exception of fractions B-1 to B-3, the integral $\int_0^\infty g(s)ds$ as measured by the area under a distribution curve was approximately unity. This represents a confirmation of the somewhat empirical technique of combining the distributions since the concentration term used in eq. [1] was not based on the sedimentation diagram but on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

known refractive index difference between solution and solvent. In the heavier fractions, the integral was less than unity, probably because even at the low speed some material sedimented quickly to the base of the cell.

TABLE III

Values of σ, s_w, s_p, $g(s_p)$ and $[\eta]$ for the fractions at 0.5 ($\pm$0.02) g dl^{-1}

Fraction	$\sigma\times10^{13}$ (sec)	$s_w\times10^{13}$ (sec)	$s_p\times10^{13}$ (sec)	$g(s_p)\times10^{-10}$	$[\eta]$ (g^{-1} dl)
B-1	59	46	2.5	50	0.208
B-2[a]	59	46	2.5	50	0.234

F-7	28	17	2.8	112	0.071
F-8	17	11	2.8	112	0.060

[a]The sedimentation diagrams of B-2 were identical with those of B-1. No analysis was made of B-2 and the values of σ, s_w, s_p, and $g(s_p)$ were assumed to be equal in the two fractions.

To avoid excessive computation, the distributions were not corrected for the concentration dependence of s or the related Johnston–Ogston effect (31). The error caused by such an approximation would be expected to be relatively small because of the small dependence of s on c quoted earlier. This point was further tested by measuring distributions on B-5 at four concentrations between 0.3 and 0.7 g dl^{-1}. The results in Table IV

TABLE IV

Concentration dependence of s_w and σ for fraction B-5

Concentration (g dl^{-1})	$s_w\times10^{13}$ (sec)	$\sigma\times10^{13}$ (sec)
0.65	23	30
0.50	32	42
0.41	25	44
0.30	32	48

show no clear trend in s_w and the mean deviation is $\pm$14%. This large error is probably due to the fact that s_w is a weight average and the difficultly measurable values of $g(s)$ at large s_w affect the result considerably. An increase in σ with decrease in c is noted but the effect is small for the three low concentrations. The results confirm that the change in s_w and σ between concentrations of 0.5 g dl^{-1} and zero is not gross and legitimate comparison can be made in data for different fractions obtained at the same concentration of 0.5 g dl^{-1}.

DISCUSSION

The results indicate that the alkali lignins prepared in the present study had an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

exceptionally wide range of particle size. Sedimentation coefficients from 0.5 to over 400×10^{-13} second were recorded. Polydispersity was not unexpected since other lignin preparations (4–12) have been shown to be polydisperse. But such a wide range as indicated by the sedimentation data has not previously been reported. Probably the extremely high molecular weight species were obtained as a result of the mild method of preparation. However, strikingly similar results have been obtained in degradation studies of glycogen (1, 2, 30), amylopectin (30), and dextran (32–35). It has been shown by a number of workers (34, 36–39) that a random degradation of a branched or cross-linked network will produce a broad size distribution in the degradation products. Thus the data support the concept that lignin exists in wood as an extensive three-dimensional structure which undergoes random scission during the process of delignification.

The data in Table III show that the B-series with barium ion as precipitant had a gradation in s_w as in $[\eta]$. In this respect the fractionation was successful. Fractions were highly polydisperse although there was no indication of a discontinuous distribution in any of the fractions. It is further interesting that not only was the form of the distribution the same in all the fractions but s_p was approximately constant at $2.9\ (\pm0.5)\times10^{-13}$ second. In contrast the value of $g(s_p)$ decreased in the heavier fractions and empirically $1/g(s_p)$ vs. $[\eta]$ gave a roughly linear graph (Fig. 7). This result suggested that the low

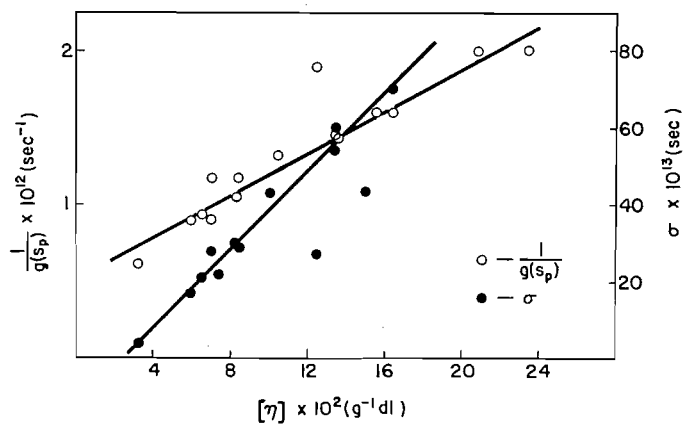

FIG. 7. Graphs of $1/\{g(s_p)\}$ vs. $[\eta]$ and σ vs. $[\eta]$ for fractions shown in Table III.

molecular weight, more soluble material was distributed relatively closely about a sedimentation coefficient of 2.9×10^{-13} second. In contrast, the high molecular weight, less soluble particles existed in an extreme range of size. Fractional precipitation produced successive fractions with decreasing amount of the heavy material. Therefore, in addition to a gradation in $[\eta]$, the initial fractions were more polydisperse as illustrated in Fig. 7 (except for B-1, B-2, and B-3) where σ shows a regular increase with an increase in $[\eta]$. In the case of B-1, B-2, and B-3 $\int_0^\infty g(s)\,ds$ was significantly less than unity which indicated that about 15% (on the average) of the material sedimented quickly to the bottom of the cell and did not contribute to the sedimentation diagrams. This may explain the reversal of the trend of increasing s and σ with $[\eta]$ for B-1, B-2, and B-3 (Table III). If an approximate correction is made based on the assumption that the proportion lost by rapid sedimentation had s values equal to the highest recorded in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

distributions, σ increases to 105, 105,[3] and 92×10^{-13} second and s_w increases to 133, 133,[3] and 133×10^{-13} second for B-1, B-2,[3] and B-3 respectively.

There was a small decrease in polydispersity on subfractionation as shown by the lower values of σ for F-4 and F-5 (Table III and Fig. 7) which were the subfractions of B-4 and B-5 respectively. It seems that fractionation with barium is not particularly selective as to particle size. Moreover, the initial heterogeneity of the material is so great that extensive refractionation may be needed to give homogeneous fractions. It is interesting that similar results, as to wide polydispersity and limited subfractionation, have been reported for glycogen by Bryce and co-workers (2, 30) and Stetten *et al.* (35). Purification of fractions B-6 to B-9 by dialysis and ultracentrifugation did not decrease the polydispersity significantly. Such treatment was, however, essential in order to prepare fractions for the light-scattering experiments (40) described in the following paper of the present series (41).

The values of s_m (Table I) obtained at the two centrifugal fields used differed by an order of magnitude. As far as is known this behavior has not yet been reported in any other system. It is probably not specifically associated with the lignin molecule but is a general phenomenon to be found in any widely polydisperse system in which the sedimentation rate is not dependent on the concentration. Roughly, one may say that at low speed, the high molecular weight material sediments through a constant concentration of the low molecular weight component. At the higher speed, the heavy particles sediment rapidly to the cell bottom and the moving boundary is made up of smaller molecules. The foregoing analysis of the data is based on such a picture. More correctly, the phenomenon is probably due to the simultaneous presence of particles, some of which are large enough to obey the Faxen (42) solution to the Lamm (43) sedimentation equation while the others are smaller and are more appropriately described by Archibald's solution (13). The resulting gradient pattern will then be a combination of the classical sedimentation equilibrium distribution in which the gradient decreases from the meniscus and the sedimentation velocity distribution in which a Gaussian peak moves down the cell. High speed will favor peak formation of smaller molecules and thus yield the smaller values of s_{m2}.

The wide difference in s_{m1} and s_{m2} at the two speeds is in marked contrast to the sedimentation behavior in certain other systems. In the case of naturally occurring polyelectrolytes such as sodium desoxyribonucleate, sodium alginate, and sodium carrageenate, Goring and Chepeswick (44) found sedimentation coefficients constant to $\pm1\%$ for changes in the field from 44×10^3 *g* to 260×10^3 *g*. Similarly, Huque (45) noted no change in the sedimentation coefficient of cellulose trinitrate for a change in field from 39×10^3 *g* to 260×10^3 *g*. The above examples are those of linear extended macromolecules which show a considerable concentration dependence. Thus the peak spreading due to diffusion and polydispersity necessary to produce the effect would be masked by the familiar peak sharpening (46) due to concentration dependence of *s*. It is probable that the difference between s_{m1} and s_{m2} would be found in systems such as the glycogens in which the concentration dependence of *s* is small. A more detailed study of this effect will be reported in a later publication in which changes of s_m with rotor speed are compared with similar data for a macromolecule known to be monodisperse.

Finally, it is worth while to consider the limitations in the present method of obtaining the distribution in *s*. Although used by others on similar systems (1, 2, 30), it is questionable whether the Singer–Gross relationship (eq. [1]) can be applied under the conditions

[3]*See Table III.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

described above. An analysis based on an exact theoretical treatment would be preferable. Such a treatment has never been presented and is beyond the scope of the present investigation. The approximate correctness of the results obtained by the present method is supported by the following:

(1) The agreement between the results obtained by extrapolation to infinite time (detailed procedure) and the simplified method.

(2) The fact that the slow and fast speed distributions did not overlap.

(3) The value of unity found for the integral $\int_0^\infty g(s)\,ds$ after use of the refractive index differences corresponding to gravimetric concentration in eq. [1].

Further confirmation of the method was obtained by comparing the distribution of s for the original alkali lignin, B-0, with a combined distribution of all the B-series. As shown in Fig. 8, the agreement was reasonable in spite of losses during fractionation and purification.

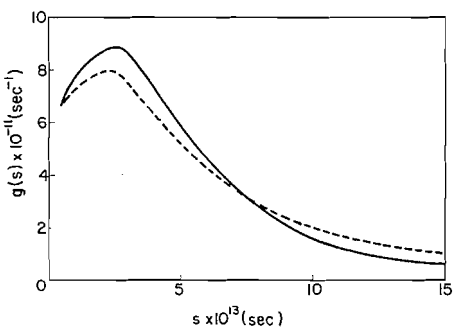

FIG. 8. Comparison of the distribution obtained by summation of $g(s)$ values of B-series fractions (dotted curve) with the distribution of the unfractionated lignin, B-0 (solid curve).

From the above, it is clear that future work in this field should include measurements with the synthetic boundary cell (47). Complications at the meniscus would be avoided and theoretical treatment of the boundary spreading would then be simplified. Also, values of s_m could be measured more accurately because of the initial sharp boundary.

Discussion of the relationship between s_w and $[\eta]$ is included in the following paper of the present series (41).

ACKNOWLEDGMENTS

The authors wish to thank Mr. Rankowicz for his extremely efficient operation of the ultracentrifuge.

PHYSICOCHEMICAL STUDIES OF ALKALI LIGNINS

III. SIZE AND SHAPE OF THE MACROMOLECULE[1]

P. R. GUPTA[2] AND D. A. I. GORING

ABSTRACT

Light-scattering measurements were made on the alkali lignin fractions described in a previous paper. The range of molecular weights found was from 50,000 to 48×10^6. The usual logarithmic graph of intrinsic viscosity and molecular weight was linear and gave a value of 0.32 for the exponent. From the logarithmic sedimentation coefficient – molecular weight relationship, the exponent was found as 0.52. Flory's hydrodynamic parameter Φ^1P^{-1} was 2.3×10^6. These results suggested that the configuration of the alkali lignin macromolecule conformed to a structure between that of a random coil and an Einstein's sphere impenetrable to solvent. The branching parameter, g, introduced by Zimm and Stockmayer, decreased with an increase in molecular weight as expected. Most of the values of Huggins' constant, k,' were between 1 and 2 which indicated a compact particle. A marked increase in k' was noted for fractions of low or very high molecular weight. The significance of the data is discussed and a model tentatively suggested for the macromolecule.

INTRODUCTION

Molecular weights of lignin derivatives reported in the early literature are usually between 250 and 11,000 (1, 2, 3). In contrast, McCarthy and co-workers (4) have recently obtained molecular weights as high as 138,000 in a light-scattering study of fractionated lignin sulphonates. Similarly, Gardon and Mason (5) reported M values as high as 58,000 in lignin sulphonates fractionated by ultrafiltration and dialysis. In another study, Gralen (6) found molecular weights up to 34,000 for thioglycolic acid lignins by sedimentation and diffusion. In considering the discrepancy it must be noted that the low molecular weights were all obtained by one or other of the number-average methods. In addition to this, the earlier investigators used highly degraded lignin samples.

The present paper deals with the light-scattering determination of molecular weights of alkali lignin fractions. As described in an earlier paper of the current series (7), the alkali lignin was prepared from a periodate lignin of white spruce by a relatively mild treatment and its properties may be regarded as being fairly close to those of the protolignin in the wood. Fractionation was achieved by precipitation with $BaCl_2$.

Several proposals exist as to the chemical structure of lignin, but little information is available about its configurational behavior in solution. Recently, McCarthy *et al.* (4) and Gardon and Mason (5) both tentatively suggested a random coil for the lignin sulphonates. On the other hand, lignin in wood has been regarded (but not proved) to be a three-dimensional network structure. In the present investigation the relationships between the molecular weight, intrinsic viscosity (7), and weight-average sedimentation coefficient (8) are analyzed and a possible configuration for the alkali lignin macromolecule is proposed. Certain hydrodynamic parameters are also derived and correlated with the size and shape of the macromolecule.

EXPERIMENTAL AND RESULTS

The alkali lignin fractions (except PB-0) investigated here are fully described in the first paper of the present series (7). Fraction PB-0 represented the remainder of un-

For personal use only.

fractionated lignin, B-0, from which the large and small molecular weight material was removed by ultracentrifugation (2 hours at 150,000 *g*) and dialysis respectively.

Light-scattering measurements were made with a Brice–Phoenix (9) photometer as modified by Huque *et al.* (10). Fractions were dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$) and a series of five concentrations was obtained by diluting aliquot portions. Solutions were spun in the light-scattering cells in the SW 25.1 swinging bucket rotor of a Spinco Model L ultracentrifuge. The centrifugation times were from 30 to 60 minutes at 2000 to 35,000 *g*. After light-scattering measurements, concentrations were measured spectrophotometrically. Usually there was no appreciable change from the initial gravimetric concentration except in F-3, F-4, and F-5 where there was a decrease of nearly 10%. The spectrophotometric concentration was used in light scattering.

The photometer was calibrated with Ludox colloidal silica taking the precautions described in an earlier paper (11). The calibration was checked by a measurement of the molecular weight of bovine serum albumin (Armour Lot No. S 68004) in 0.1 *N* sodium chloride. A value of 68,500 was obtained which was in good agreement with published data (12–15).

The refractive index increment, dn/dc, of the alkali lignin fractions was measured with a Brice–Phoenix differential refractometer for $\lambda = 5460$ Å at 25° C. The instrument was calibrated with sucrose solutions using sodium light ($\lambda = 5890$ Å). The calibration was checked and found correct with an aqueous potassium chloride solution. The data on dn/dc are given in Table I. For the nine fractions studied dn/dc is fairly constant with a mean value of 0.218 (± 0.004) g^{-1} ml. In calculating the molecular weight of F-1, F-2, PF-2, and PB-0, the mean value of dn/dc was used.

TABLE I

Light scattering and viscometric data for the fractions of alkali lignin dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$)

Fraction	$M_w \times 10^{-3}$	$[z]$ $(i_{45}/i_{135})_{c=0}$	$\bar{s}$ (Å)	$[\eta]$ (g^{-1} dl)	dn/dc (g^{-1} ml)
F-1	48,000[a]	3.5	1700[a]	0.585	—
F-2	47,000[a]	3.4	2600[a]	0.294	—

B-9	50	1.8	500	0.033	0.215
PB-0	450	1.6	440	—	—

[a]These were calculated from Zimm plots and therefore $\bar{s}$ is the *Z*-average radius of gyration. For fractions F-1, F-2, and PF-2, values of $\bar{s}$ computed from dissymmetry for a spherical model are 700 Å, 700 Å, and 590 Å respectively.

For most fractions molecular weights were determined by using Debye's equation (16)

$$[1] \qquad Hc/\tau = 1/M_w + 2A_2c$$

where $H = 32\pi^3n^2(dn/dc)^2/3N\lambda^4$ and the symbols have their usual significance. The turbidity was evaluated from 90° scattering measurements by means of a calibration factor. Linear plots of Hc/τ vs. c were extrapolated to zero concentration as shown for

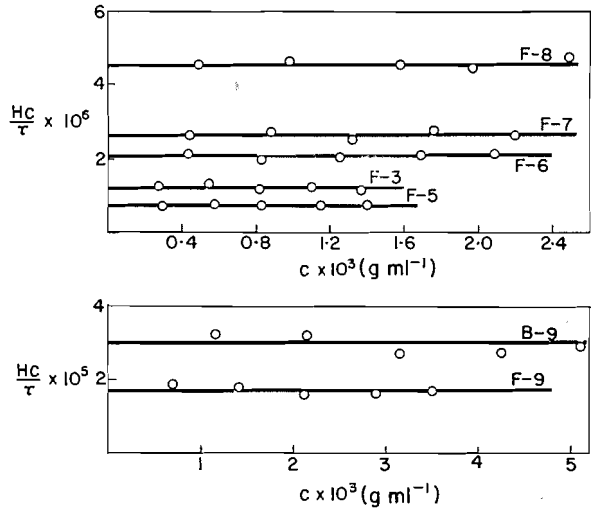

FIG. 1. Hc/τ vs. c for fractions of alkali lignin dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$). The abscissa scale for B-9 is shown ×5.

some of the fractions in Fig. 1. The dissymmetry, z, was also measured at each concentration and extrapolation to zero concentration gave the intrinsic dissymmetry, $[z]$. The reciprocal of $(Hc/\tau)_{c=0}$ gave the weight-average molecular weight, M_w, which was then corrected for dissymmetry assuming a spherical model. For dissymmetries of about 1.9 or less the choice of model does not alter the correction factor by more than 10% (17). Data on M_w, $[z]$, and the radius of gyration, $\bar{s}$, computed from $[z]$ for a spherical molecule are given in Table I.

The dissymmetry was large in the case of fractions F-1, F-2, and PF-2. Zimm plots, an example of which is shown in Fig. 2, were obtained for these fractions by plotting Kc/R_θ vs. $\sin^2\theta/2+kc$, where $K = 2\pi^2n^2(dn/dc)^2/N\lambda^4$ and the symbols have their usual meanings. The molecular weight was then obtained from the reciprocal of $(Kc/R_\theta)_{c,\theta=0}$. From the slope and intercept of the extrapolated zero concentration line, the radius of gyration, $\bar{s}$,

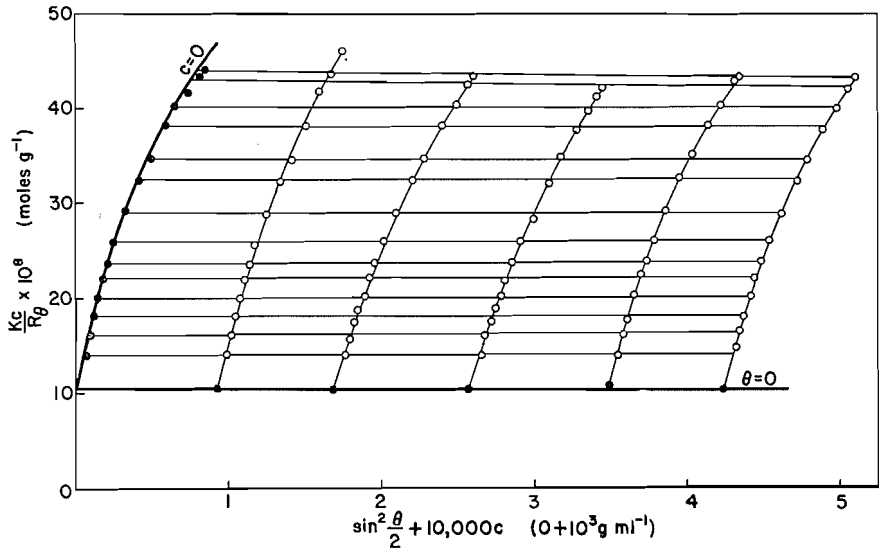

FIG. 2. Light-scattering Zimm plot for fraction PF-2 dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$).

For personal use only.

was calculated to give the values included in Table I. In all cases, either from the Zimm graphs or the turbidity plots, the second virial coefficient, A_2, was zero within the limits of experimental accuracy.

Also included in Table I are the intrinsic viscosities of the various fractions as reported in the first paper of the present series (7).

Absorption, Fluorescence, and Depolarization

The alkali lignin solutions were all amber colored because of strong absorption of visible light. Correction for absorption was not required; attenuation of transmitted and scattered beams were equal because of the symmetry of the cell.

The solutions were found to show considerable fluorescence which in some cases amounted to 20% of the emitted light. A high degree of fluorescence has also been noted for lignin sulphonates by McCarthy and collaborators (4) and Goring *et al.* (18). Rather than adopt the lengthy procedure described by Brice *et al.* (19) a filter was sought which would eliminate from the emitted beam the longer wavelength component due to fluorescence. The most suitable was a combination of blue-green (Corning No. 4305; C.S. 4-71) and didynium (Corning No. 5120; C.S. 1-60), called henceforth the blue–didynium filter. This filter combination was found to transmit 26.5% of the 5460 Å light and only 0.8% of the fluorescence. All light-scattering measurements were made with the blue–didynium filter in the analyzing nosepiece of the photometer. The proportion of 90° scattering due to fluorescent light was thus reduced to less than 1%. No correction was made for this effect.

Measurements were also made with the red filter (Corning No. 2424; C.S. 2-63, supplied with the instrument) which passes only fluorescent light. The galvanometer deflection, G_f, due to fluorescence alone is given by $G_f = G_r/T_r$ where G_r is the galvanometer reading with the red filter in the nosepiece of the phototube and T_r is the transmission of the red filter to fluorescent light. T_r was determined at the 90° position with a polaroid horizontal in the nosepiece, by the ratio of the galvanometer deflections with and without the red filter. From G_f and the calibration factor, a "turbidity", τ_f, equivalent to the fluorescent emission was computed. Therefore, τ_f may be regarded as a measure of the fluorescent intensity of a particular solution and τ_f/c becomes the fluorescence per gram of a given fraction. In Table II, values of τ_f/c for several of the fractions are compared with τ/c due only to scattering. Since the fractions were of different molecular weights, there is a considerable spread in τ/c. This is in contrast to τ_f/c which was relatively constant with a mean value of 5.2 ± 0.9.

TABLE II

Comparison of scattered and fluorescent light for alkali lignin fractions dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2 = 0.1$)

Fraction	$M_w \times 10^{-3}$	τ/c (g^{-1} ml cm^{-1})	τ_f/c (g^{-1} ml cm^{-1})
F-3	1200	52.7	3.7
F-4	1800	102.6	6.0
F-5	1860	90.9	7.4
F-6	610	33.5	5.5
F-7	550	26.3	4.9
F-8	290	15.2	4.1
PB-0	450	23.8	5.0

Depolarization of scattered light was small and no correction was made for this effect (20).

DISCUSSION

In most of the early work (1, 2), soluble lignins have been regarded as low molecular weight compounds with M values lying between 250 and 11,000. The weight-average molecular weights given in Table I show that the above concept is quite inaccurate. Values of M_w ranged from 50,000 to 48×10^6 proving that the alkali lignin of this investigation is definitely a macromolecule. There are two main reasons for this discrepancy. In the present study emphasis was placed on milder conditions of lignin solubilization whereas previous investigators used highly degraded samples. Perhaps the more important reason lies in the wide polydispersity of the fractions as shown by the spread in sedimentation coefficients (8). As many of the earlier workers computed the molecular weights by number-average methods, their values would be lower than the weight averages obtained by light scattering, particularly in highly polydisperse preparations. In amylopectin and glycogen where a wide polydispersity similar to the alkali lignins is common, Erlander and French showed theoretically that the ratio M_w/M_n may easily be as high as 100 and this has been verified experimentally (21).

Although no measurements similar to the present work have been reported for alkali lignins, support for their high molecular weight is to be found in several recent papers on the lignin sulphonates. Gardon and Mason (5) have reported number-average molecular weights up to 58,000 while McCarthy *et al.* (4) found light-scattering molecular weights as high as 138,000 for lignin sulphonates obtained by the usual acid sulphite procedure. Goring and Rezanowich (22) made soluble sulphonates by fractional solution of periodate lignin. The intrinsic viscosity of these fractions ranged from 0.035 to 0.34 g^{-1} dl (22), and light-scattering molecular weights of over 1×10^6 were found (18). It appears, therefore, that alkali lignins as well as lignin sulphonates can be very high molecular weight substances.

An important question concerns the origin of these soluble macromolecules. Does the lignin *in situ* exist as a high molecular weight network structure which gives soluble macromolecules on random degradation (2, 23, 24), or are the macromolecules produced by polymerization of relatively low molecular weight lignin during isolation (5)? The fact that the alkali lignins and the sulphonates both possess high molecular weights supports the concept of an infinite network broken down by alkali or acid treatment. It seems unlikely that an initial polymerization could occur in both the alkaline and acidic conditions of lignin solubilization. The network structure of protolignin would explain its well-recognized insolubility and difficulty of separation from the carbohydrate moiety. Wardrop has shown that lignification takes place at a comparatively late stage in the development of the cell wall (25). If the protolignin is laid down as a three-dimensional network, part of this material is likely to grow around individual carbohydrate molecules. The resulting entanglement of molecular chains could make separation difficult or impossible as in the case of the synthetic "snake cage" polymer mixtures (26). Thus it is not necessary to postulate chemical linkages between lignin and carbohydrate to explain their difficulty of separation (24).

At this stage a reservation should be made because of the nature of the starting material in the present investigation. This was periodate lignin. It is possible that the periodate oxidation polymerizes the lignin during its isolation although all the properties of periodate lignin suggest that this is not the case. For example, Purves *et al.* (2) showed that periodate lignin was chemically similar to protolignin in respect of ethanolysis, hydrogenation, and nitrobenzene oxidation. It is also sulphonatable under the conditions of a standard bisulphite treatment (22). Moreover, in the present study 80% of the lignin was

made soluble in 15 minutes, which is a considerably shorter time than usually used in commercial delignification of wood under comparable conditions. If the lignin was polymerized by the periodate treatment, the reverse would have been expected. However, it is recognized that the present work should be supplemented with a similar study on lignin made soluble directly from wood to settle this point.

The fluorescence measurements, as far as is known, are the first reported for a soluble lignin derivative. Fluorescence of organic compounds is a fundamental property, determined by the presence and configuration of π-electrons in the molecule (27). In lignosulphonic acid, Hägglund (1) proposed that fluorescence may be due to a carbonyl group. However, if the lignin fractions form a polymeric series, the fluorescence being an intrinsic property should be identical from fraction to fraction per unit weight of the material. The data in Table II roughly support this concept where τ_f/c over a wide range of molecular weight is constant within $\pm 17\%$. The variation could be due to experimental error introduced in measuring the small galvanometer deflections involved.

The refractive index increment also has a similar characteristic value for a series of fractions. As shown in Table I, dn/dc was essentially constant for the nine fractions studied. This may be compared with the previously obtained constancy of methoxyl content and U.V. absorption (7) and is a further proof of the chemical homogeneity of the fractions. It is interesting to note that the mean value of 0.218 g^{-1} ml was higher than the usual values (28) for proteins ($\simeq$ 0.19 g^{-1} ml) or polysaccharides ($\simeq$ 0.11 g^{-1} ml) but similar to polystyrene (0.22 g^{-1} ml). According to Freudenberg (1, 29), this may be due to the high proportion of aromatic nuclei in the alkali lignin.

We may now consider a somewhat detailed interpretation of the quantitative relationships obtainable from the present data. The customary double logarithmic plot of intrinsic viscosity versus molecular weight is shown in Fig. 3. The graph is roughly linear with no

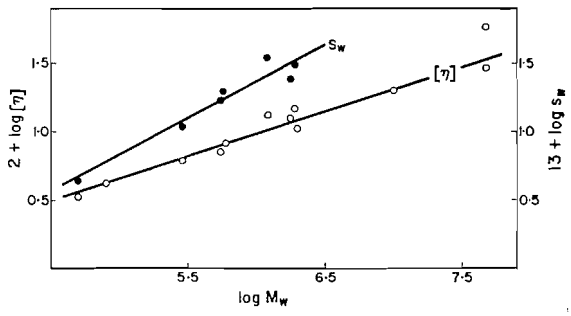

FIG. 3. Double logarithmic plot of intrinsic viscosity and weight-average sedimentation coefficient versus molecular weight.

indication of regions of different slope. Also plotted logarithmically against the molecular weight is the weight-average sedimentation coefficient, s_w, described in the preceding paper of the present series (8). From the two least square lines in Fig. 3

$$[\eta] = 1.16\times10^{-3}\, M_w^{0.32} \qquad [2]$$

$$s_w = 1.63\times10^{-15}\, M_w^{0.52}. \qquad [3]$$

The compact nature of the alkali lignin macromolecule may be inferred directly from eq. [2]. For a molecular weight of 10^6, $[\eta]$ = 0.1 g^{-1} dl, which is small compared with the approximate values of 20 and 2 g^{-1} dl respectively for nitrocellulose and polystyrene fractions of similar molecular weight. In eq. [2] the theoretical value of the exponent for linear coiled molecules is somewhat greater than 0.5 (30) while for Einstein spheres it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

zero (31). Similarly in eq. [3], the exponents expected for spheres (32) and random coils (33) are 0.66 and 0.44 respectively. In the present study it is clear that in both sedimentation and viscosity, the hydrodynamic properties of the fractions fall between those of a random coil and a rigid sphere. This point may be further illustrated by computing the combined hydrodynamic parameter $\Phi^{\frac{1}{3}}P^{-1}$ of Flory *et al.* (30) which is given by

$$[4] \qquad \Phi^{\frac{1}{3}}P^{-1} = s_w[\eta]^{\frac{1}{3}}N\,\eta_0/M_w^{\frac{2}{3}}\,(1-\bar{v}\rho_0)$$

in which the symbols have their usual significance. There was some spread in the data corresponding to individual fractions. If smoothed values for $[\eta]$, s_w, and M_w from Fig. 3 are substituted in eq. [4], $\Phi^{\frac{1}{3}}P^{-1}$ is found to be independent of molecular weight and equal to 2.3×10^6 which lies between 2.1×10^6 and 2.6×10^6, these being the expected values for sphere and Gaussian coil respectively.

The results described above may profitably be compared with similar data for systems which would be expected to be analogous to alkali lignin. For example, Granath (34) has found in a highly branched dextran, an exponent of 0.34 in the viscosity – molecular weight relationship which suggests a compact type of molecule. Bryce *et al.* (35) obtained an exponent of 0.63 in eq. [3] and concluded that glycogen molecules were essentially spherical. Further, they observed only a very small increase in viscosity with a large increase in molecular weight, thus giving additional confirmation of the compact nature of the particles. In an earlier investigation on lignin sulphonates, Gardon and Mason (5) found an exponent of 0.47 in eq. [2]. Interestingly, the point for their highest molecular weight fraction was considerably below the log–log line of 0.47 slope and indicated a lower exponent for the higher molecular weights. These fractions were prepared from a commercially spray-dried waste sulphite liquor and were of fairly low molecular weight compared with the fractions in the present study.

The intrinsic viscosity and molecular weight data may also be analyzed in terms of the branching parameter, g, introduced by Zimm and Stockmayer (36). This factor represents the ratio of the squares of the unperturbed radii of gyration of branched and unbranched molecules having the same molecular weight and is given by

$$[5] \qquad [\eta] = K^*g^{3/2}M^{\frac{1}{2}}\alpha^3$$

where α is the expansion factor arising from the polymer–solvent interaction and K^* is a constant for a given polymer series. Equation [5] is theoretically valid when the solution obeys van't Hoff's law, i.e., when $\alpha = 1$ (37). Such conditions of ideality hold at the θ-temperature or when the second virial coefficient, A_2, is independent of concentration in light scattering. In the present work, A_2 was zero for all the fractions studied. Thus the expansion factor is unity and g may be computed from eq. [5] if K^* is known. To

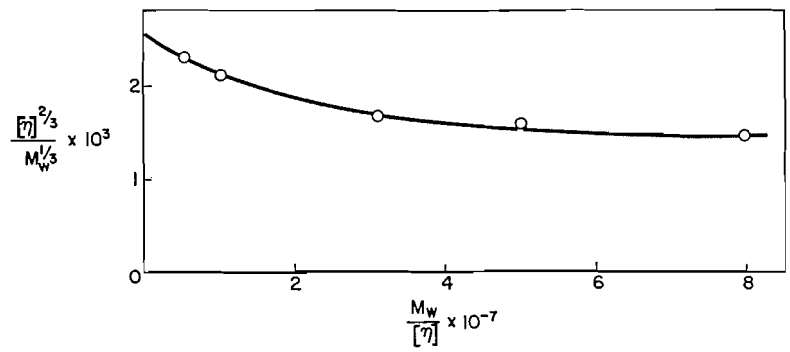

FIG. 4. Graph of $[\eta]^{\frac{1}{3}}/M_w^{\frac{1}{3}}$ vs. $M_w/[\eta]$ using smoothed values of intrinsic viscosity and molecular weight.

derive K^*, a plot of $[\eta]^{\frac{1}{3}}/M^{\frac{1}{3}}$ vs. $M/[\eta]$ was made as suggested by Wales *et al.* (38). Figure 4 shows such a plot with the present data. In the limit $M/[\eta] \rightarrow 0$, g becomes unity and $[\eta]^{\frac{1}{3}}/M^{\frac{1}{3}}$ approaches $K^{*\frac{1}{3}}$. From the intercept, K^* was found to be 1.25×10^{-4} and values of g computed for smoothed values of $[\eta]$ and M_w are given in Table III. The factor g is seen to decrease with increase of molecular weight as anticipated for a branched polymer (37).

TABLE III

Values of g computed from smoothed $[\eta]$ and M_w data

$[\eta]$ (g^{-1} dl)	$M_w \times 10^{-3}$	g
0.251	20,000	0.59
0.20	10,000	0.64
0.145	4,500	0.67
0.096	1,000	0.85
0.066	360	0.92

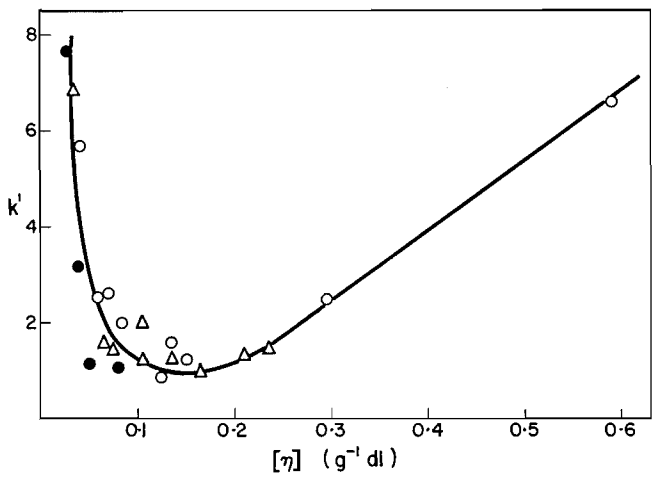

FIG. 5. Variation of Huggins' constant k' with intrinsic viscosity for alkali lignin fractions dissolved in $NaHCO_3$–NaOH buffer (pH = 9.65; $\Gamma/2$ = 0.1). The fractions are described in detail in the initial paper of the present series (7).

The variation of viscosity with concentration as expressed by the Huggins' coefficient k' (39) has been used as an indication of branching in a macromolecule (40–42) though recently some doubt has been expressed as to the validity of this interpretation (43). However, because of its widespread use, it may be worth while to consider the changes in k'. The values of k' (cf. Tables III, IV, and VI in the first paper of the present series (7)) are plotted against $[\eta]$ in Fig. 5 for 22 fractions of alkali lignin. For most of the fractions, k' lies between 1 and 2. According to Eirich and Riseman (44), such values of k' would suggest a compact structure for the lignin macromolecule. Recently Arlt and Schuerch (45) suggested branching in ethanol lignins based on k' values.

As shown in Fig. 5, considerably higher k' values were found for the lowest and the highest molecular weight fractions. It is interesting that a similar minimum in k' was obtained by Senti *et al.* (46) with acid-hydrolyzed dextran but no explanation was given. The increase at different ends of the molecular weight range is probably due to different phenomena. According to Cragg and Manson (47), for the fractions of a given polymer sample containing cross-linked species, cross-linking should be most intensive in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

fractions of highest intrinsic viscosity and k' should be highest when $[\eta]$ is highest. On the other hand, an increase in k' for very low molecular weight can be attributed to the transition from a random coil to the rigid linear form (48, 49). It may be noted, in passing, that for a polyelectrolyte, k' is a function of the ionic strength of the solution. Goring and Rezanowich (50) have found k' for a lignin sulphonate to increase from 1 to 400 for change in the ionic strength of 1 M to 2×10^{-5} M. In the present investigation, $\Gamma/2$ was maintained constant at 0.1, an ionic strength which would suppress the polyelectrolyte effect almost completely. Therefore the changes in Huggins' coefficient k' are probably related to change in the configuration or rigidity of the alkali lignin macromolecule at the extremes of molecular weight.

The radii of gyration (Table I) show that some of the fractions contained particles of appreciable size. There appeared to be no regular trend of $\bar{s}$ with molecular weight. Similar observations have been reported for glycogen by Stetten *et al.* (51). A probable reason for this is that the Z-average dimension obtained by light scattering is sensitive to the wide polydispersity of the fractions. Therefore the values of $\bar{s}$ in Table I are to be regarded as giving only an approximate measure of the dimension of the macromolecule. A more detailed consideration of the size must await data obtained for sharper fractions.

The alkali lignin molecule, thus, emerges as a polydisperse entity with the hydrodynamic behavior between that of a solid sphere and a Gaussian coil. These molecules are probably formed by random degradation of a three-dimensional network, i.e., protolignin. If the network is cross-linked, protolignin can then be regarded as a gel. Solubilization consists of breaking down the gel by hydrolytic degradation into microgel particles and at the same time producing hydrophilic groups on the gel. In the case of alkali lignin, these may be carboxylic or phenolic groups while in lignin sulphonate, the sulphonic acid group would supply a hydrophilic character. According to this picture, lignin derivatives made soluble by a mild procedure consist of particles of microgel, some of which would be large enough to correspond to the high molecular weights noted. In the loosening of a particular piece of gel from the mother matrix, links between the chains near the edge may be broken and the chains frayed apart. These loose chains would also bear most of the hydrophilic groups of the molecule. The microgel particle would be surrounded by a layer of loosely coiling chains which would be free to move about in the liquid. This halo of randomly coiling material would impart to the molecule a partly Gaussian character. It would also permit a certain degree of polyelectrolyte expansion as noted both in the alkali lignin (7) and the lignin sulphonates (18).

It must be emphasized that the results described above do not define the system unambiguously. The model proposed is therefore only tentative. It is possible that changes in axial ratio occur, particularly at the extremes of molecular weight. Here, an electron micrograph study of the high molecular weight material might be useful. Such a study is planned. It should also be pointed out that the variation of the sedimentation constant and the intrinsic viscosity with the molecular weight can be affected by the polydispersity of the fractions. However, M_w and s_w are both weight averages while the viscosity average is usually regarded as being equivalent to weight average. Thus the conclusions based on a comparison of these quantities are probably qualitatively valid although any further detailed interpretation must be postponed until more critical fractionation procedures have been developed.

STRUCTURE OF AN ARABOGALACTAN FROM TAMARACK (LARIX LARICINA)[1, 2]

G. A. ADAMS

ABSTRACT

A water-soluble polysaccharide containing L-arabinose and D-galactose in a molar ratio 1:3.8 was isolated from tamarack. Fractionation with ethanol from aqueous solution yielded one main component which was judged to be homogeneous on the basis of electrophoresis and sedimentation data. Hydrolysis of the fully methylated polysaccharide yielded, 2,3,5-tri-*O*-methyl-L-arabinose (2 moles); 2,3,4,6-tetra-*O*-methyl-D-galactose (16 moles); 2,5-di-*O*-methyl-L-arabinose (5 moles); 2,3,4-tri-*O*-methyl-L-arabinose (5.5 moles); 2,3,4-tri-*O*-methyl-D-galactose (11 moles); 2,4,6-tri-*O*-methyl-D-galactose (3 moles); 2,6-di-*O*-methyl-D-galactose (1 mole); 2,4-di-*O*-methyl-D-galactose (20 moles); 2-*O*-methyl-D-galactose (3 moles).

Possible structures for the arabogalactan are proposed and discussed on the basis of these results.

Complex polysaccharides composed of galactose and arabinose units occur abundantly in the larches (1–6) and to a lesser extent in several other coniferous trees (7–11). Among those occurring in larches the structure of the arabogalactan of the western larch (*Larix occidentalis*) has been studied by White (5, 12–14) and that of the ϵ-galactan of European larch (*Larix decidua*) by Campbell *et al.* (15) and Aspinall *et al.* (16). Arabogalactans from the coniferous trees Jeffrey pine (*Pinus jeffreyi*), jack pine (*Pinus banksiana*), and white spruce (*Picea glauca*) have been studied by Wadman *et al.* (9), Bishop (10), and Adams (11) respectively.

Structural studies, to be meaningful, require a homogeneous polysaccharide, and the problem of isolating such a material and establishing its homogeneity is a difficult one. The heterogeneity of the arabogalactan from western larch was demonstrated by Peterson *et al.* (17), and the ϵ-galactan of European larch was shown to be heterogeneous by Campbell *et al.* (15). White made a detailed structural study of the arabogalactan of western larch and regarded his material as homogeneous (5). However, Campbell *et al.* claim that the data could be interpreted as indicating heterogeneity of the original polysaccharide (15). On the other hand, the arabogalactans isolated from Jeffrey pine (9), jack pine (10), and white spruce (11) were shown to be homogeneous by all acceptable criteria.

This investigation was concerned with the isolation and structural features of an arabogalactan isolated from tamarack (*Larix laricina* (Du Roi) Koch).

The crude polysaccharide was extracted from extractive-free tamarack wood in 5.6% yield with water at room temperature. Purification was achieved by fractional precipitation from aqueous solutions with ethanol. The results were plotted graphically and the curve obtained is shown in Fig. 1. The shape of the curve is indicative of a single main component which was precipitated when the solution had attained an ethanol concentration of 50–60%. Further evidence of the homogeneity of the polysaccharide was provided by electrophoretic and sedimentation patterns shown in Fig. 2. Single, relatively sharp peaks in both the electrophoresis and sedimentation curves are indicative of a single homogeneous component.

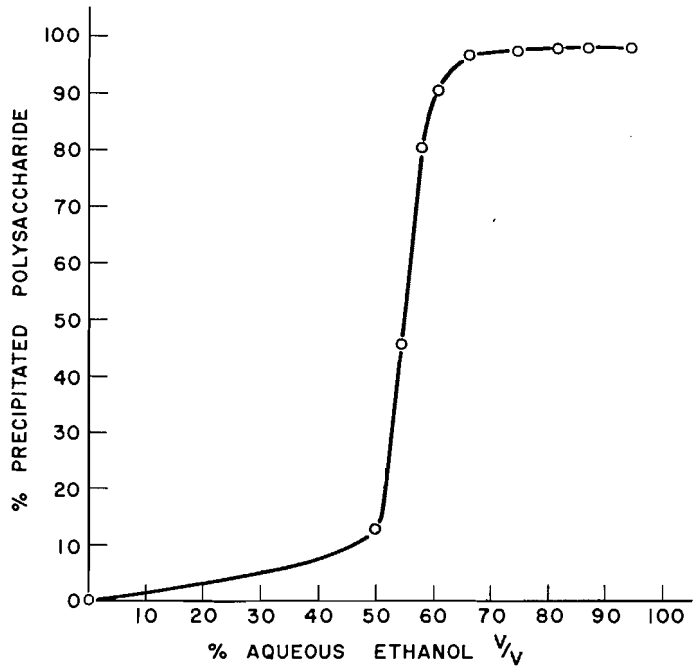

FIG. 1. Ethanol fractionation of water-soluble polysaccharide from tamarack.

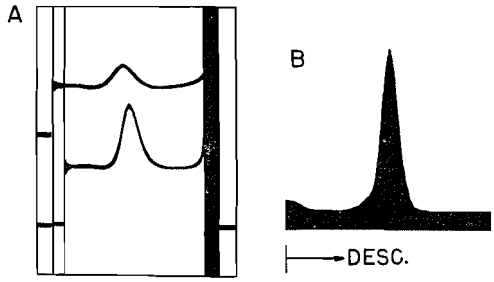

FIG. 2. (A) Sedimentation diagram of tamarack arabogalactan. Upper curve 0.5% solution (borate buffer 0.05 *M*), lower curve 1.0% solution, rotor speed 59,780 r.p.m., photograph taken 83 minutes after attaining full speed, direction of sedimentation left to right.
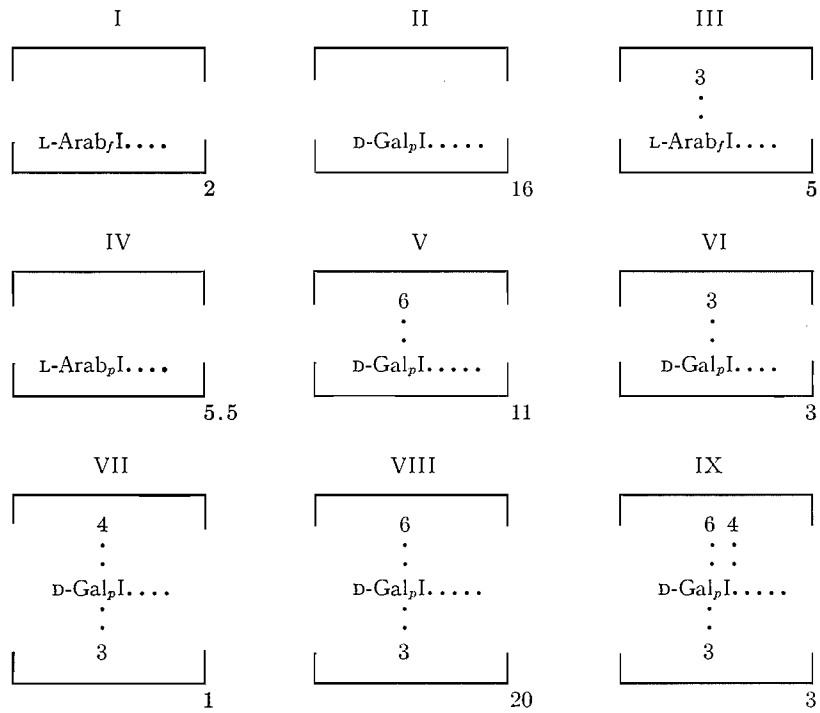
(B) Electrophoresis diagram of tamarack arabogalactan. Polysaccharide solution, 1.0% in 0.05 *M* borate buffer. Photograph taken 67 minutes after appearance of initial boundary.

The purified polysaccharide comprised 84% of the crude polysaccharide and contained arabinose and galactose in a molar ratio of 1:3.8. The specific rotation $[\alpha]_D^{25}$ +11° corresponded closely to those reported for larch arabogalactan $[\alpha]_D^{20}$ +11° to +15° (17). However, the molar ratio of the two component sugars is considerably different from the 1:6 L-arabinose to D-galactose ratio reported for the arabogalactans from larches (2, 14, 16, 17).



Sedimentation data as determined in the ultracentrifuge gave an approximate molecular weight of 50,000. Reported molecular weight values by Mosiman and Svedberg (18) on the component polysaccharides of ϵ-galactan showed that two polysaccharides were present having approximate molecular weights of 16,000 and 100,000 respectively. Examination of ϵ-galactan in the ultracentrifuge by Aspinall *et al.* (16) showed only one

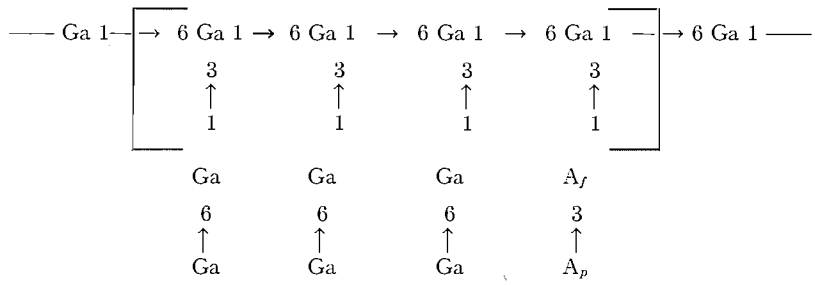
molecular species but no molecular weight estimations were made. The molecular weight of the arabogalactan of Jeffrey pine was approximately 100,000 and the polysaccharide was markedly polydisperse as determined from sedimentation data (9). It seems clear that considerable variation occurs in the molecular dimensions of arabogalactans from different species of wood.

The tamarack arabogalactan was methylated and the methyl ether was subjected to methanolysis and hydrolysis. The methylated sugars were separated chromatographically on a Celite column (19). Fractions that were still mixtures were refractionated by repeated column and paper chromatography. The purified methylated sugars were characterized by their physical properties and preparation of characteristic crystalline derivatives. The amounts and molar ratios of the various methylated sugar components are given in Table III. Comparison of the ratio of methylated arabinose to methylated galactose (1:4.5) with that of the arabinose to galactose ratio (1:3.8) in the original polysaccharide showed that some galactose units were lost during methylation and hydrolysis



On the basis of the methylation studies, the arabogalactan must contain the following units:

There are a number of ways in which these units may be joined together and no unique structural formula can be deduced from these data. However, certain constitutional features become evident, and on the basis of these some possible structures are proposed.

The large proportion of VIII showed that there was a predominance of 1→3 and 1→6 linkages between the galactose units of the molecule. It is possible to envisage repeating units composed of 1→6 linked units or 1→3 linked units or a combination of both. Possible structures involving the main components are shown in A, B, and C. Structure A would have a predicted periodate consumption of 1.17 moles, and a formic acid production

STRUCTURE B.

of 0.6 mole per anhydrohexose unit. These values are in close agreement with the experimental values of 1.16 moles of periodate and 0.51 mole of formic acid. However, the amount of 2,3,4-tri-*O*-methyl-D-galactose produced on hydrolysis of the fully methylated polysaccharide would be 50% greater than the amount found by experiment. Structure B, which is based on a main core of 1→3 linked D-galactose units, has the same objections as that of Structure A. Structure C, which combines 1→3 and 1→6 linked D-galactose units in the same chain, also gives values for calculated periodate consumption and formic acid production which agree closely with the experiment values. In addition, the proportions of methylated sugars are in reasonably good agreement with those found experimentally. It seems likely that the repeating units of the polysaccharide have a generalized structure similar to that of C. More details will have to await the results of fragmentation studies now in progress.

STRUCTURE C.

Branching occurs in the 1→3 linked D-galactopyranose units also at $C_{(4)}$ (as shown by the presence of 2,6-di-*O*-methyl-D-galactose), although with a frequency of 1 in 20 compared with the branching through $C_{(6)}$. In addition, a small number of 1→3 linked D-galactose units are unbranched as shown by the presence of a small proportion of 2,4,6-tri-*O*-methyl-D-galactose. The presence of 2-*O*-methyl-D-galactose showed the presence of triply branched D-galactose units IX. Although incomplete methylation of the polysaccharide and demethylation on hydrolysis may contribute to the presence of a monomethyl galactose, the presence of a relatively large amount suggests that it has a structural significance and actually originated from triply branched galactose units in the polysaccharide.

The number of units (27) forming branch points (VII, VIII, and IX) are in only fair agreement with the number of terminal units (23.5) (I, II, and IV) and indicate that some end group has been lost.

Jones (20) has identified the disaccharide 3-*O*-L-arabopyranosyl-L-arabinose as a product of partial hydrolysis of larch β-galactan. Although this disaccharide was not isolated from the partial hydrolyzate of tamarack arabogalactan, chromatographic examination showed a disaccharide containing arabinose units and having the same mobility on paper as that reported by Jones (20). It seems reasonable, therefore, that this unit is present in this arabogalactan and that it would give rise to approximately equimolar amounts of 2,3,4-tri-*O*-methyl-L-arabinose and 2,5-di-*O*-methyl-L-arabinose.

Single terminal arabofuranose units I attached to the galactose structure were released as free arabinose on acid hydrolysis and appeared as 2,3,5-tri-*O*-methyl-L-arabinose after methylation and hydrolysis of the polysaccharide.

Estimation of the periodate consumed and formic acid produced by the polysaccharide on the basis of the linkages found by methylation gave a value of 1.01 moles of the former and 0.49 mole of the latter per mole of anhydro-D-galactose residue. The experimental values (1.16 moles of periodate and 0.51 mole of formic acid) were somewhat higher than the calculated values and indicated that some end group or 1,6 linked D-galactose residues had been lost. Hydrolysis and chromatography of the periodate-oxidized polysaccharide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

showed that a large number of galactose units and some arabinose units had not been oxidized. Galactose units which were linked 1→3 and also 1→6 linked units which were branched at C_3 would account for the unoxidized galactose. The unoxidized arabinose units must have been those which gave rise to 2,5-di-*O*-methyl-L-arabinose after methylation and which presumably were substituted in the C_3 position by an arabopyranose unit in the polysaccharide.

The change in specific rotation on hydrolysis of the methylated polysaccharide from $[\alpha]_D^{25}$ −45° to +85° indicated that the glycoside bonds were mainly in the β configuration.

The tamarack arabogalactan has structural features that are very similar to those from other woods, particularly the other larches (5, 15, 16). The main characteristics are a high degree of branching through positions 3 and 6 of the anhydro-D-galactose units. The tamarack arabogalactan resembled most closely the ϵ-galactan of European larch (16) in which most of the arabinose units are in the pyranose form. The arabinose units in arabogalactan from western larch (13), jack pine (10), and white spruce (11) are all in the furanose form and are terminal in the molecule. Recently, however, the presence of 3-*O*-β-L-arabopyranosyl-L-arabinose has been reported in western larch arabogalactan (21).

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated, melting points are corrected, and all evaporations were done at 35° C or less.

Paper Chromatography

Chromatographic separations were carried out using the following solvent systems (v/v ratios): (*A*) pyridine:ethyl acetate:water (2:1:2); (*B*) methyl ethyl ketone:water (2:1); (*C*) ethanol:benzene:water (47:200:15); (*D*) *n*-butanol:ethanol:water (40:11:19); (*E*) ethyl acetate:acetic acid:formic acid:water (18.3:1:4); and (*F*) ethylacetate:acetic acid:water (3:1:3). Separations were made by the descending technique on Whatman No. 1 filter paper. Sugars were located on the paper by *p*-anisidine hydrochloride spray reagent (22).

Preparation of the Polysaccharide

A 47-year-old log of tamarack (*Larix laricina* (Du Roi) Koch) was stripped of its bark and planed into shavings which were passed through a Wiley mill. The milled wood was screened, and the fraction passing through 40 mesh and retained on 100 mesh was used. This material was exhaustively extracted with benzene:ethanol (2:1), then with ethanol, and was dried in air. The extracted wood meal (807 g) was added to water (14 liters) and stirred continuously for 24 hours at room temperature. At the end of the extraction period the wood residue was removed by filtration through fine filter cloth on a Buchner funnel and re-extracted twice more by the same procedure. Following the last extraction, the residue was washed with water. The aqueous extracts and washings were clarified by centrifuging in a Sharples supercentrifuge and were concentrated in a Majonnier evaporator at 26° C to about 1/16 of the original volume. The concentrated solution was dialyzed against distilled water for a period of 48 hours and the non-dialyzable portion was concentrated at 35°. Freeze drying yielded 45.5 g of polysaccharide (5.63% yield) sulphated ash, 0.55%, Klason lignin, 0.97%.

The polysaccharide dissolved in water to give a slightly opalescent solution, $[\alpha]_D^{25}$ +11, (*c*, 1% in water). Hydrolysis of a 10-mg sample by *N* sulphuric acid for 12 hours at 100° C and chromatographic examination of the sugars (solvents *A*, *D*, and *F*) showed the presence of arabinose and galactose. Quantitative estimation of the sugars was made by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

separating them from an acid hydrolyzate (200 mg) on a Celite column (19). The weights of arabinose and galactose were in a ratio of 1:4.6. Examination of the acid hydrolyzate by paper electrophoresis in 0.025 *N* sodium bicarbonate for 1 hour at 900 v showed no trace of sugar acid components.

Fractionation of the Polysaccharide

The crude polysaccharide (995 mg) was dissolved in water (100 ml) with stirring, and a small amount of insoluble material removed by centrifuging. The soluble polysaccharides were then fractionally precipitated from the aqueous solution by gradient addition of ethanol. The fractions were collected, washed, and dried by solvent exchange with ethanol and ether. Samples (10 mg) were hydrolyzed by acid and the resulting sugars were examined by paper chromatography (solvent *A*). The fractionation curve is shown in Fig. 1. The results indicated the presence of one main component, approximately 90% of the material being insoluble in 60% ethanol. There were small differences in the arabinose: galactose ratios, the first fractions being relatively richer in galactose than in the main fraction, while the later fractions were richer in arabinose. On the basis of this preliminary experiment a main lot of polysaccharide (16 g) was fractionated in the same way. The material precipitated by ethanol (53–63%) comprised 84% of the crude polysaccharide. The specific rotation $[\alpha]_D^{25}$ was +11 (*c*, 1.1% in water) and the weight ratio of arabinose:galactose was 1:4.6 (molar ratio, 1:3.8). All subsequent investigations were done on this fraction.

Graded Hydrolysis

Polysaccharide (27 mg) was heated in a boiling water bath for 5 hours with 5 ml of oxalic acid (0.025 *N*). Chromatography of the hydrolyzate showed arabinose and galactose in a ratio of 6:1. Degraded polysaccharide was recovered by precipitation with ethanol and washed thoroughly with methanol. The precipitate was hydrolyzed by *N* sulphuric acid and the sugars chromatographed in solvent *A*. Although the predominant sugar was galactose, some arabinose still remained. The precipitate was small (8 mg) and indicated that the galactan portion of the molecule was severely degraded. In another experiment, polysaccharide (100 mg) was heated on a boiling water bath in 10 ml of hydrochloric acid (0.01 *N*). Within 2 hours, galactose and arabinose were present in large amounts, and, in addition, four other spots were detected on the paper chromatogram having R_{xylose} values of 0.21, 0.40, 0.49, and 0.60 respectively in solvent *A*. The spot having R_{xylose} 0.60 increased in intensity up to 20 hours and then gradually disappeared. Chromatographic evidence indicated that it was a disaccharide of arabinose and was probably identical with 3-*O*-β-L-arabopyranosyl-L-arabinose ($R_{galactose}$ 0.70, solvent *E*) isolated by Jones (20) from larch ϵ-galactan. After about 10 hours heating the amount of galactose was almost equal to that of arabinose. The galactose continued to increase slowly throughout the experiment (53 hours). Precipitation of a small amount of degraded polysaccharide with ethanol after 53 hours heating and chromatographic examination of its acid hydrolyzate showed that the material was a galactan containing a trace of arabinose.

Periodate Oxidation

Duplicate samples of the polysaccharide (101.4, 101.3 mg) were dissolved in water (50 ml) and oxidized by 0.1 *M* sodium metaperiodate (50 ml) in the dark at 16° C. Appropriate blanks were prepared under the same conditions. At the intervals noted in the table below analyses were made for periodate consumption and formic acid production (23). The results given in moles per mole anhydro-D-galactose unit were as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Time (hours)	7	24	32	48	56
Periodate consumption	1.14	1.16	1.16	1.17	1.18
Formic acid production	0.45	0.46	0.47	0.49	0.51

In a separate experiment the polysaccharide (52 mg) was oxidized with periodate for 48 hours as described above. The excess periodate was destroyed by the addition of ethylene glycol and the solution was dialyzed. The non-dialyzable material was recovered by freeze-drying and hydrolyzed with *N* sulphuric acid. Chromatographic examination of the sugars showed galactose to be present in large amounts along with a small amount of arabinose.

Methylation

The polysaccharide (7.0 g) was dissolved in 20% sodium hydroxide (40 ml) and methylated by the dropwise addition of dimethyl sulphate (75 ml) and 45% sodium hydroxide (125 ml) with vigorous stirring. The reagent additions required a period of 4 hours and the solution was kept alkaline at all times. The addition of methylating reagents was repeated four more times. The methylation mixture was heated for 30 minutes at 80° C, then cooled and neutralized with sulphuric acid. The precipitated salts were dissolved in water, and the partly methylated polysaccharide was extracted continuously by chloroform for 48 hours. The recovered methylated polysaccharide (7.73 g) showed a definite hydroxyl band at 3500–3600 cm^{-1} in its infrared spectrum. The partially methylated polysaccharide was dissolved in methyl iodide (75 ml) and methylated on the addition of silver oxide (10 g) in portions of 2 g every hour. The solution was heated under reflux for 18 hours. The methylated product was recovered by extraction with acetone. Five additional methylations by this same procedure were required to yield a product having only a trace of hydroxyl band at 3500–3600 cm^{-1} in its infrared spectrum. The yield of methylated polysaccharide was 7.14 g, $[\alpha]_D^{25}$ −38.8° (*c*, 0.6% in chloroform), OMe 42.3% (theoretical value for the arabogalactan 43.0%).

Fractionation of Methylated Polysaccharide

The methylated polysaccharide (7.0 g) was fractionally extracted with various solvent mixtures of chloroform and petroleum ether (b.p. 30–60°). The solvents were removed and the residues dried to constant weight *in vacuo*. Specific rotation and methoxyl content

Hydrolysis of Methylated Polysaccharide

The methylated arabogalactan (5.17 g) was refluxed in 8% methanolic hydrogen chloride (60 ml) in a boiling water bath for 10 hours. The methanolic hydrogen chloride was then removed by a stream of air at room temperature and the residue was taken up in 0.5 *N* hydrochloric acid (35 ml) and refluxed for 10 hours. A small amount of insoluble precipitate was filtered off and the acidic solution was neutralized with Amberlite resin IR-45 (OH). The neutral solution was concentrated to a thin syrup, taken up in 50% aqueous ethanol, clarified with charcoal, and concentrated to a thick syrup. After drying *in vacuo* over calcium chloride the mixture of free methylated sugars weighed 5.07 g and had $[\alpha]_D^{25}$ +85° (*c*, 1.05% in water). Examination of the syrup by paper chromatography (solvent *D*) indicated the presence of the following methylated sugars:

2,3,5-tri-*O*-methyl-L-arabinose, (R_g 0.96);
2,3,4,6-tetra-*O*-methyl-D-galactose, (R_g 0.92);
2,3,4-tri-*O*-methyl-D-galactose, (R_g 0.76);
2,4-di-*O*-methyl-D-galactose, (R_g 0.58);
2,6-di-*O*-methyl-D-galactose, (R_g 0.62);
2,3,4-tri-*O*-methyl-L-arabinose, (R_g 0.83);
2,5-di-*O*-methyl-L-arabinose, (R_g 0.88); and monomethyl galactose (R_g 0.40).

(R_g, movement relative to that of 2,3,4,6-tetra-*O*-methyl-D-glucose).

Separation of Methylated Sugars

The mixture of methylated sugars (5.0 g) was separated on a Celite column using *n*-butanol saturated with water as the developing phase (19). The eluate was collected by an automatic fraction collector in 15-ml quantities. Chromatographic examination of every fifth tube on paper strips (solvent *D*) permitted grouping of fractions of similar composition. The combined samples were evaporated to dryness, taken up in water, filtered, and dried to constant weight. Results of the preliminary separation are given in Table II with the identification of the sugars being based tentatively on chromatographic evidence. The yields and molar ratio of the purified sugars are shown in Table III.

TABLE II

Chromatographic separation of methylated sugars

Fractions from column		Methylated sugar	Yield (mg)
1	(Tube 0–73)	2,3,5-Tri-*O*-methyl-L-arabinose	164
2	(Tube 74–123)	2,3,4,6-Tetra-*O*-methyl-galactose 2,5-Di-*O*-methyl-arabinose 2,3,4-Tri-*O*-methyl arabinose	1545

Identification of Methylated Sugars

Fraction 1

This methylated sugar was dissolved in water, clarified with charcoal, and dried to constant weight (130 mg). Chromatographic examination in solvents *B*, *C*, and *E* showed that the sugar had an identical rate of movement with 2,3,5-tri-*O*-methyl-L-arabinose. The specific rotation $[\alpha]_D^{25}$ was $-33°$ and the methoxyl content was 47.4% (calculated for $C_8H_{16}O_5$: OMe, 48.4%). A portion of the syrup (114 mg) was dissolved in water (3 ml) and oxidized with bromine (0.5 ml) for 72 hours. Bromine was removed by aeration and the acid solution was neutralized with silver carbonate. The filtrate was deionized with Amberlite IR-120 resin and evaporated to yield syrupy 2,3,5-tri-*O*-methyl-L-arabonic acid. The acid was lactonized by distillation (bath temp., 120–145° C at 0.025 mm), and the lactone was dissolved in methanol saturated with ammonia at 0° C. After 24 hours, the solvent was removed and the amide crystallized on nucleation. Recrystallization from methanol–ether solution yielded pure 2,3,5-tri-*O*-methyl-L-arabonamide, m.p. 136° C (undepressed with an authentic sample) and $[\alpha]_D^{25}$ $-18°$ (*c*, 1% in water), these values agree with those reported for this compound (24).

Fraction 2

Chromatographic examination of this syrup in solvents *C* and *D* showed a mixture of three sugars. The main component (R_g 0.92, solvent *D*) corresponded to 2,3,4,6-tetra-*O*-methyl-D-galactose, the next fastest moving component corresponded to 2,5-di-*O*-methyl-L-arabinose (R_g 0.88, solvent *D*), and the slowest moving component corresponded to 2,3,4-tri-*O*-methyl-L-arabinose (R_g 0.84, solvent *D*).

Fraction 3

Chromatographic examination in solvents *C* and *D* showed two components which corresponded to the tentatively identified 2,5-dimethyl arabinose and 2,3,4-trimethyl arabinose found in fraction 2.

Since fractions 2 and 3 were mixtures, they were fractionated chromatographically on a cellulose column using the solvent benzene:ethanol:water:ammonium hydroxide (200:47:14:1). The column was washed thoroughly first with the aqueous phase and then with the organic phase of the solvent and the separation was made by irrigating with the organic phase. Three separate sugars were recovered and corresponded chromatographically with those found in the original fractions.

2,3,4,6-Tetra-O-methyl-D-galactose

The sugar (1255 mg) had $[\alpha]_D^{25}$ $+118°$ (*c*, 1.12% in water) and MeO 52.3% (theoretical value for $C_{10}H_{20}O_6$, 52.5%). A portion of the syrup (110 mg) was refluxed with aniline

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

(49 mg) in ethanol (5 ml) for 3 hours. The solution was slowly evaporated in a desiccator leaving a crystalline residue which was recrystallized from ethanol to yield 72 mg of 2,3,4,6-tetra-*O*-methyl-N-phenyl-D-galactosylamine (25), m.p. and mixed m.p. 196–198° C, $[\alpha]_D^{25}$ −137° (*c*, 1.5% in pyridine).

2,5-Di-O-methyl-L-arabinose

The sugar (290 mg) had $[\alpha]_D^{25}$ −26° (*c*, 1% in water); OMe, 33.7% (calculated for $C_7H_{14}O_5$: OMe, 34.8%) and gave only one spot on chromatographic examination (R_g 0.88–0.89, solvent *D*). Demethylation by 47% hydrobromic acid yielded only one sugar which was identified as arabinose on paper chromatograms. Oxidation of the sugar (105 mg) with bromine for 72 hours at room temperature yielded the corresponding 2,5-di-*O*-methyl-L-arabonic acid (82 mg). Distillation of the acid (bath temp., 130–135° C, at 0.05 mm) yielded the lactone which crystallized on seeding with 2,5-di-*O*-methyl-L-arabonolactone, m.p. and mixed m.p. 60° C. To a portion of the lactone (28 mg) phenylhydrazine (20 mg) in methanol (5 ml) was added and the mixture was refluxed for 2 hours. On removal of the solvent the product crystallized (16 mg) and was recrystallized from ethanol:ether solution to give pure 2,5-di-*O*-methyl-L-arabonophenylhydrazide, m.p. and mixed m.p. 165–167° C.

2,3,4-Tri-O-methyl-L-arabinose

The syrup (362 mg) gave one spot on chromatographic examination (R_g 0.83–0.85, solvent *D*). Demethylation yielded only arabinose as detected on paper chromatograms. Specific rotation $[\alpha]_D^{25}$ was +120° (*c*, 1.2% in water) and the OMe 47.3% (calculated for $C_8H_{10}O_5$: OMe, 48.4%). A portion of the syrup (65 mg) was oxidized in aqueous solution (3 ml) with bromine (0.05 ml) for 50 hours at room temperature. The excess bromine was removed by aeration and the 2,3,4-tri-*O*-methyl-L-arabonic acid extracted with chloroform in a continuous extractor for 24 hours. The chloroform was evaporated and the acid lactonized by distilling (bath temp., 100–118° C, at 0.04–0.05 mm). The lactone (41 mg) was heated with phenylhydrazine (26 mg) in methanol (5 ml) for 3 hours. Removal of the solvent yielded 2,3,4-tri-*O*-methyl-L-arabonophenylhydrazide which crystallized on nucleation. Recrystallization from methanol–ether – petroleum ether yielded the pure product, m.p. and mixed m.p. 158° C. The reported value is 156° C (26).

Fraction 4

The syrup (973 mg) was chromatographically identical in solvents *B* and *D* with 2,3,4-tri-*O*-methyl-D-galactose, had $[\alpha]_D^{25}$ +114° (*c*, 0.79% in water) and OMe, 39.8% (calculated for $C_9H_{18}O_6H_{20}$: OMe, 38.7%). A portion of the fraction (118 mg) was refluxed with aniline (58 mg) in methanol (5 ml) for 2 hours. Evaporation of the solvent yielded crystals which on recrystallization from ethyl acetate proved to be 2,3,4-tri-*O*-methyl-N-phenyl-D-galactosylamine, m.p. and mixed m.p. 165–166° C and $[\alpha]_D^{25}$ +40° (*c*, 1.1% in methanol). Another portion of the syrup (125 mg) in water solution was oxidized with bromine (0.6 ml) for 72 hours at room temperature. Bromine was removed by aeration and the acid was neutralized with silver carbonate. The silver salts were filtered off and the excess silver ions were removed as sulphide. The 2,3,4-tri-*O*-methyl-D-galactonic acid was lactonized by distillation (bath temp., 150–160° C at 0.025 mm). Addition of methanolic ammonia and storage at 5° C for 24 hours yielded 2,3,4-tri-*O*-methyl-D-galactonamide, m.p. 166–167° C, and $[\alpha]_D^{25}$ +33 (*c*, 1% in water). These values are in good agreement with those previously reported (27).

Chromatographic examination of fraction 4 in solvent *C* showed a spot which was slightly slower in movement than 2,3,4-tri-*O*-methyl-D-galactose and which appeared to

be 2,4,6-tri-*O*-methyl-D-galactose. Separation of the two sugars was made according to the method described by White (13). A portion of fraction 4 (475 mg) was dissolved in pyridine (3 ml), triphenylchloromethane (654 mg) was added, and the reaction mixture was kept at room temperature for 2 days. A small amount of water was then added and the solution was poured into ice water. The insoluble trityl derivative precipitated as a gum and was removed by centrifugation. The solution and washings were neutralized with Amberlite IR-45, extracted with benzene to remove triphenylcarbinol, and the sugar was recovered as a yellow syrup (96 mg) OMe, 40.0% (calculated for $C_9H_{18}O_6$: OMe, 41.9%) and $[\alpha]$ +90 (*c*, 1.72 in water). The syrup (20 mg) was refluxed in methanol (5 ml) with aniline (10 mg) and yielded 2,4,6-tri-*O*-methyl-N-phenyl-D-galactosylamine, m.p. 176° (reported value 178°) (13). The amount of 2,4,6-tri-*O*-methyl galactose mixed with 2,3,4-tri-*O*-methyl galactose in the original fraction 4 was estimated to be 225 mg.

Fraction 5

This fraction (84 mg) was a mixture of two sugars which on paper chroamtograms in solvents *E* and *D* moved at the same rate as 2,3,4-tri-*O*-methyl-D-galactose (R_g 0.74–0.76, solvent *D*) and 2,6-di-*O*-methyl-D-galactose (R_g 0.59–0.60, solvent *D*). Separation on paper strips using solvent *E* yielded 2,6-di-*O*-methyl-D-galactose (64 mg). Oxidation of this sugar with bromine (0.3 ml) in water (5 ml) for 60 hours at room temperature yielded 2,6-di-*O*-methyl-D-galactonic acid. Distillation of the acid (bath temp., 100°–120° C/0.010 mm) yielded 2,6-di-*O*-methyl-D-galactonic acid lactone (15 mg). The lactone (15 mg) was refluxed with phenylhydrazine for 2 hours in methanol (5 ml) and yielded crystalline 2,6-di-*O*-methyl-D-galactonophenylhydrazide. Recrystallization from methanol–ether solution yielded a pure product, m.p. 144° C unchanged when admixed with an authentic sample.

Fraction 6

The syrup (280 mg) on chromatographic examination in solvent *D* showed a small amount of 2,3,4-tri-*O*-methyl-D-galactose (R_g 0.74–0.76) with the main component being 2,4-di-*O*-methyl-D-galactose (R_g 0.58). Separation of the two sugars was made chromatographically on paper sheets (Whatman No. 1) using solvent *D*. The yields were 2,3,4-tri-*O*-methyl-D-galactose (30 mg) and 2,4-di-*O*-methyl-D-galactose (230 mg).

Fraction 7

This fraction (1159 mg) crystallized spontaneously and was chromatographically identical in solvents *B* and *D* with 2,4-di-*O*-methyl-D-galactose. Recrystallization from ethyl ether yielded 2,4-di-*O*-methyl-D-galactose monohydrate m.p. 100–101° C with sintering at 73–76° C; $[\alpha]_D^{25}$ +125° (5 minutes) → 85° (18 hours) (*c*, 0.8% in water) and OMe 26.7% (theoretical value for $C_8H_{16}O_6.H_2O$: OMe, 27.4%). Dehydration of the monohydrate by heating at 55° C at 0.1 mm over phosphorus pentoxide for 18 hours yielded anhydrous 2,4-di-*O*-methyl-D-galactose, m.p. and mixed m.p. 103–104° C in good agreement with reported values (10). A portion of the pure sugar (85 mg) was refluxed with aniline (44 mg) in methanol (5 ml) for 3 hours. The solution was evaporated in a desiccator and the crystalline sugar was recrystallized from ethyl acetate yielding 2,4-di-*O*-methyl-N-phenyl-D-galactosylamine and having a m.p. and mixed m.p. 218–220° C and $[\alpha]_D^{25}$ −181 (*c*, 1.1% in pyridine).

Fraction 8

This fraction (204 mg) had an R_g of 0.40 (solvent *D*); $[\alpha]_D^{25}$ +88° (*c*, 1% in water) (reported value (29) for 2-*O*-methyl-D-galactose +86°); OMe 15.9%. The indication that the sugar was 2-*O*-methyl-D-galactose was confirmed by the preparation of its anilide by

the method already described. The product was crystalline, and on recrystallization from acetone solution yielded 2-*O*-methyl-N-phenyl-D-galactosylamine, m.p. 163° in good agreement with the reported value of 165° (25).

Fraction 9

This fraction (108 mg) on chromatographic examination (solvent *D*) showed two faint spots, one of which moved at a slower rate than 2-*O*-methyl galactose and the other, a bright red spot, was located near the starting line. The latter component appeared to be a methylated uronic acid although no uronic was detected in the hydrolyzate of the original polysaccharide. The components were separated on filter paper (solvent *D*) and the slower moving component recovered (60 mg), OMe 13.2% (calculated for $C_7H_{12}O_7$: OMe, 14.9%) and $[\alpha]_D^{25}$ +49°. In solvent *E*, the unknown had the same mobility as 4-*O*-methyl-D-glucuronic acid and on the basis of the foregoing properties was tentatively identified as 4-*O*-methyl-D-glucuronic acid.

Molecular Weight

Molecular weight was determined in the Spinco Model E ultracentrifuge by Archibald's method (30) as modified by Klainer and Kegeles (31). The methods of computation were those developed by Smith (32). The centrifuge was run at 8225 r.p.m., the temperature was controlled at 20° C, and a bar angle of 80° was used. A single run was made on a 1.0% arabogalactan solution in 0.05 *M* borate buffer. Measurements were made at the base and meniscus of five photographs taken over a period of 27 minutes to 51 minutes from the time of attaining full speed. A value of 0.60 for partial specific volume was used (9).

The weight average molecular weight measured at the meniscus was approximately 50,000 and at the base was approximately 67,000. These observations indicated a small degree of molecular weight heterogeneity.

Sedimentation Coefficient

Sedimentation coefficients were measured in a Spinco Model E ultracentrifuge at concentrations of 1.0, 0.75, 0.50, and 0.25% in 0.05 *M* borate buffer. The sedimentation coefficients ($S_{20,w}$) were calculated in the usual way and the results are:

Concn., %	$S_{20,w,10^{13}}$
1.0	4.87±.235
0.75	5.27±.193
0.50	4.73±.207
0.25	5.02±.256

There was no evidence of concentration dependence in the sedimentation rate. The absence of concentration dependence may be interpreted as indicating a relatively globular molecule and confirms the highly branched structure proposed on the basis of methylation data. Figure 1 shows the single peak obtained on ultracentrifugation and indicates that the arabogalactan was homogeneous.

Electrophoresis

Polysaccharide (151 mg) was dissolved in 0.05 *M* borate buffer (15 ml) and dialyzed against the buffer at 4° C for 24 hours. The electrophoretic separation was made in a Spinco apparatus Model H and the arabogalactan moved as a single peak with $\mu = 10.50 \times 10^{-5}$ cm^2/v^{-1}/sec^{-1}. The peak is shown in Fig. 1.

THE BIOGENESIS OF ALKALOIDS

XXIV. THE ROLE OF CITRIC ACID IN THE BIOGENESIS OF HYOSCYAMINE[1]

A. V. Robertson[2] and Léo Marion

ABSTRACT

It is known that ornithine is a precursor of the pyrrolidine ring present in hyoscyamine. It was assumed that citric acid might be the precursor of the remaining three carbons that complete the tropine ring structure. To test this assumption 3-^{14}C-citric acid was fed to *Datura stramonium* plants. The hyoscyamine isolated from these plants was radioactive, but the activity was very low. It must be concluded that citric acid, although it can be used to a small extent, is not the normal precursor of the chain of three carbons attached to the pyrrolidine ring in hyoscyamine.

Tracer work in these laboratories on the biosynthesis of the tropane alkaloids in mature *Datura stramonium* has shown that ornithine is an efficient precursor of the pyrrolidine ring in hyoscyamine and that the N-methyl group arises from methionine (1, 2). The radioactivity of labelled putrescine was not incorporated in hyoscyamine (3). Hyoscine in the above experiments was never radioactive, suggesting that this alkaloid was not being synthesized during the time the plants were in contact with the radiotracers. Derivation of the "acetone" fragment of tropine from acetone, acetoacetic acid, acetone dicarboxylic acid, or from citric acid in the presence of an oxidase has been suggested (e.g. Robinson (4), Birch (5)). Wenkert has emphasized that the direct intervention of acetone dicarboxylic acid is unlikely in biochemical processes (6), despite the very successful use of this compound in laboratory syntheses under "physiological conditions".

We have fed 3-^{14}C-citric acid to mature *D. stramonium* plants. Radioactivity in the nutrient solution decreased rapidly. The plants were harvested after 2 days to minimize randomization due to the various pathways available for citric acid metabolism. The alkaloids were isolated by established methods. Paper chromatographic assay of the crude basic fraction showed that neither hyoscyamine nor hyoscine had measurable radioactivity and that only a small proportion of the latter alkaloid was present. Separation of the bases by partition chromatography, usually employed, was therefore not undertaken. Instead the mixture was treated with gold chloride and the hyoscyamine aurichloride was purified by recrystallization and conversion to the picrate. Pure hyoscyamine picrate had an activity of 10 d.p.m./mg, unchanged by recrystallization. This measurement, just detectable with certainty, may represent a real though insignificant incorporation of radioactivity in the molecule. The activity was not sufficient to be detected at the concentrations used on paper chromatograms or to make degradations of the compound worth while. Hence citric acid is not a satisfactory "acetone equivalent" in *D. stramonium*. Feeding experiments with labelled acetoacetic acid are in progress.

Citric acid-1,5-^{14}C has been prepared by Rothchild and Fields (7), who improved the original synthesis of citric acid by Grimaux and Adam (8) which started from 1,3-dichloroacetone. 3-^{14}C-Citric acid required for the present experiment was obtained by synthesizing 2-^{14}C-1,3-dichloroacetone from 1-^{14}C-acetate and then following the method of Rothchild and Fields (7) except for the use of inactive cyanide in the last stage. The

dichloroacetone was prepared in good yield by the reaction sequence: acetic acid, chloroacetic acid, chloroacetyl chloride, 1,3-dichloroacetone. Of these steps only the last has not been described in the literature. Treatment of chloroacetyl chloride with diazomethane and hydrogen chloride gave an almost quantitative yield of dichloroacetone. The diazoketone was not isolated. Purity of intermediates at all stages was critical. The radioactive citric acid was purified by ion exchange chromatography (9) and via the trimethyl ester (7).

Feeding of 3-^{14}C-citric acid to *D. stramonium* was expected to give rise to hyoscyamine with the radioactivity located at carbon-3 of the tropine skeleton. The degradative scheme chosen to isolate this carbon atom in high yield was as follows. Tropine, obtained by alkaline hydrolysis of hyoscyamine, was oxidized to tropinone by the method of Willstätter (10). Interaction of tropinone with phenyl-lithium gave 3-phenyltropan-3-ol (10*a*) from which the required carbon atom was obtained by permanganate oxidation to benzoic acid.

Because of the low activity of the hyoscyamine isolated, however, the base was not degraded.

EXPERIMENTAL

Melting points are corrected. Radioactivities were determined with a Radiation Counters Laboratory "Nucleometer" counting 50% of disintegrations. Infrared spectra were measured in carbon disulphide solution on a Perkin–Elmer double beam spectrometer model 21B.

Synthesis of 3-^{14}C-*Citric Acid*

Sodium acetate-1-^{14}C (2 mc, 50 mg) was dissolved in acetic acid (3.25 g) and chlorinated using the method of Ostwald (11), yield of sublimed chloroacetic acid, 3.95 g (76%). Of the various methods available for preparing the acid chloride, the most readily adapted for small-scale work and ease of separation of product proved to be halide exchange with benzoyl chloride following the procedure of Brown (12), yield of distilled chloroacetyl chloride, 3.59 g (76%). This acyl chloride was added dropwise to an excess of a sodium-dried ethereal solution (200 ml) of diazomethane (prepared from 25 g of nitrosomethylurea). Thirty minutes later hydrogen chloride was passed through until the yellow color was discharged. The solution was concentrated *in vacuo* to 50 ml and washed with saturated aqueous sodium bicarbonate (2×5 ml). The residue obtained by evaporation of the ether was sublimed at 1 mm/50° onto a cold finger condenser containing dry ice and acetone; yield of white crystalline 2-^{14}C-1,3-dichloroacetone, 4.02 g (99%). The method of Rothchild and Fields (7) was followed for the rest of the synthesis. Failure to remove acid impurities in the dichloroacetone by washing with bicarbonate resulted in poor yields in the next step, presumably because of the influence of acid on the cyanohydrin equilibrium. Even so, small quantities of black oil or tar separated during the acid hydrolysis to bischloromethylglycollic acid. After reaction of potassium bischloromethylglycollate with radioinactive potassium cyanide and acid hydrolysis, the organic fraction in the dry residue was separated from inorganic material by several extractions with hot acetone. Most of the impurities in the crude citric acid were removed by ion exchange chromatography on Amberlite IRA-400 resin in the acetate form (9). Elution with 0.1 *N* hydrochloric acid and removal of solvent *in vacuo* at 30° gave a partly crystalline orange residue. The product was further purified through the trimethyl ester (7) which was crystallized from cyclohexane.

Administration of 3-^{14}C-Citric Acid and Isolation of Alkaloids

D. stramonium plants were grown from seed in soil for 8 weeks with transplantations as required. The almost mature plants were then transferred to a hydroponic setup (1). Nutrient solution as described by Leete (13) was used except for substituting ferrous ammonium sulphate (36 mg/l. of nutrient solution, added in dilute aqueous versenol) as the source of iron. Additional iron was added as required to suppress incipient chlorosis. The plants grew vigorously and in the 15th week 3-^{14}C-citric acid (434 mg, total activity 1.46×10^8 d.p.m.) in water (100 ml) was distributed evenly between 11 plants (total nutrient solution, 9 liters). Each plant had at least four seed pods, and several flowers and developing buds. Five per cent of the original activity remained in the nutrient solution after 1 day and less than 1% after 2 days, at which time the plants were harvested. After overnight drying at 110°, the entire plants were ground to 20 mesh, and the total activity, obtained by extracting a small sample with methanol, was 1.4×10^7 d.p.m. The ground material (234 g) was moistened overnight with water (150 ml) in a closed container and then triturated with powdered calcium hydroxide (50 g) after the method of Evans and Partridge (14). The mixture was extracted with water-saturated ether (1500 ml) by vigorous mechanical stirring (1 hour) in a beaker at room temperature. The extract was decanted and the process was repeated until no further radioactivity was removed (10 times). The combined ether extracts (total activity 1.14×10^6 d.p.m.) were evaporated to 200 ml and the basic material present was completely extracted into 2 *N* hydrochloric acid (5×20 ml). Separation of the emulsified phases was achieved by centrifugation. The crude alkaloids were obtained as a dark gum (237 mg, total activity 1.4×10^4 d.p.m.) by collection in ether after rendering the acid fraction alkaline with ammonia. Paper chromatography in butanol – concentrated hydrochloric acid (100:10) saturated with water (Bc 10 solvent of Munier and Macheboeuf (15)) showed the presence of hyoscyamine, R_F 0.90 and a comparatively smaller quantity of hyoscine, R_F 0.79. Neither spot had measureable radioactivity. The gum was treated with gold chloride (250 mg) in hot dilute hydrochloric acid. Hyoscyamine aurichloride (144 mg) crystallized on cooling of the solution, and after recrystallization had m.p. 163–165°, not depressed on admixture with an authentic specimen. The recrystallized sample had an activity of 16 d.p.m./mg. The aurichloride was decomposed with hydrogen sulphide and the free base (40 mg) which was isolated in the usual way was treated with picric acid (50 mg). The hyoscyamine picrate was crystallized from water and had m.p. 164–165° and radioactivity of 10 d.p.m./mg, unchanged by further recrystallization.

Degradation to Isolate Carbon-3 of Tropine

Tropinone, obtained by chromic acid oxidation of tropine (10), was purified via the picrate. Tropinone (565 mg) in ether (2 ml) was added dropwise to a solution of phenyllithium (2 mole equiv.) in refluxing ether (10 ml) under nitrogen. Five minutes later the reaction was cooled in ice and stirred magnetically while *N* hydrochloric acid (10 ml) was slowly added. The separated acid layer was washed with a little ether and basified with sodium hydroxide. Ether extraction of the alkaline solution gave 3-phenyltropan-3-ol (720 mg, 82%) which crystallized from hexane in rosettes of spears having m.p. 162–163° and infrared absorption at 3570 cm^{-1} (hydroxyl), 752 and 693 cm^{-1} (monosubstituted benzene), and having no absorption in the carbonyl region. Found: C, 77.3; H, 8.6; N, 6.5. $C_{14}H_{14}NO$ requires: C, 77.4; H, 8.8; N, 6.5%.

3-Phenyltropan-3-ol (200 mg), suspended in water (20 ml), was treated with potassium permanganate (2 g) and the mixture was refluxed (1 hour). Precipitated manganese

dioxide was dissolved by passage of sulphur dioxide and the solution was acidified with hydrochloric acid and extracted with ether. The acid fraction in the ether was separated from neutral material in the usual way, giving benzoic acid (102 mg, 91%) which had m.p. and mixed m.p. 121–122° after recrystallization from water. The infrared spectrum was indistinguishable from that of authentic benzoic acid.

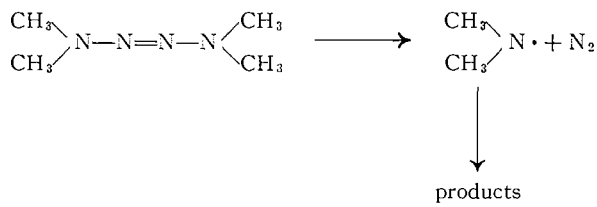
KINETICS OF THE THERMAL DECOMPOSITION OF TETRAMETHYLTETRAZEN[1]



J. S. WATSON AND A. J. WARING[2]

ABSTRACT

The kinetics of the thermal decomposition of tetramethyltetrazen (T.M.T.) have been studied in a static system at pressures up to 1.8×10^{-2} mm and temperatures between 125.5 and 147.5° C by measuring the rate of production of nitrogen. The results show that the decomposition is first order in T.M.T. at the pressures used and give approximate values for the Arrhenius parameters.

The present study of the kinetics of the thermal decomposition of tetramethyltetrazen was undertaken as a continuation of the work published previously by one of the authors (1). It was also intended to supplement the kinetic measurements by detailed analysis of the reaction products but, because of the death of Dr. J. S. Watson during the early stages of the experiments, the product analyses were not performed. Since this project is now terminated as a result of Dr. Watson's death, it is considered worth while to report briefly the results of the kinetic study.

The previous work (1) shows that thermal decomposition of tetramethyltetrazen proceeds by a radical mechanism involving $(CH_3)_2N\cdot$ radicals which react further. Thus, following the reaction by pressure change is inaccurate and the most satisfactory method seems to be by measurement of the nitrogen produced.

The previous work also shows that no H_2 is produced, so all products apart from the nitrogen can be trapped by liquid N_2.

Tetramethyltetrazen was prepared by Renouf's method (2) from 1,1-dimethyl hydrazine, the procedure being identical with that used previously (1). The apparatus used for pyrolysis consisted of a removable glass reaction vessel (volume approximately 100 ml) fitted with a teflon seat valve, attached to a vacuum system with Toepler pump, and calibrated gas burette with a mercury-sealed, one-way valve. The sample was introduced by micro syringe and frozen into the reaction vessel. Then the whole apparatus was evacuated to better than 10^{-3} mm and the teflon seat valve closed. Heating was carried out in an oil bath, the temperature of which was controlled by a Canlab magnetic control-type, mercury-metal thermoregulator. After the required time, the reaction was quenched with iced water and the products completely transferred, by the Toepler pump, through a liquid nitrogen trap into the gas burette where the nitrogen was measured.

[1]*Manuscript received October 23, 1959.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5494.
[2]*National Research Council exchange summer student, 1959. Present address: Department of Organic and Inorganic Chemistry, Cambridge University, Cambridge, England.*

Fifty-four runs were carried out at six different temperatures. Typical set of values is:

Temp., 147.5° C. Start with 75×10^{-5} mole T.M.T.

Time (minutes)	5	10	15	20	$24\frac{3}{4}$	$32\frac{1}{2}$
Moles N_2 produced $\times10^5$	0.68	1.64	2.39	2.86	4.14	5.30

Plots were made of $-\log_{10}$ (moles unchanged T.M.T.) against the time of heating. The values of the first order rate constants K_1 derived from the graphs were:

Temp., ° C	125.5	132.5	136.0	141	145	147.5
$K_1\times10^6$ (sec^{-1})	0.91	1.35	2.43	3.15	4.49	7.33
Error $\times10^6$ (sec^{-1})	0.02	0.09	0.08	0.28	0.33	0.07

Plot of $-\log_{10} K_1$ against the reciprocal absolute temperature is shown in the figure. It gives the following Arrhenius parameters:

$$E = (31.9\pm3.0) \text{ kcal/mole}, \qquad \log_{10} A = 11.4\pm1.65$$

i.e.

$$\log_{10} K_1 = (11.4\pm1.65) - \frac{(31.9\pm3.0)1000}{2.303\,RT} \qquad (K_1 \text{ in sec}^{-1}).$$

Within the experimental uncertainty the value of the pre-exponential factor is normal for a unimolecular reaction.

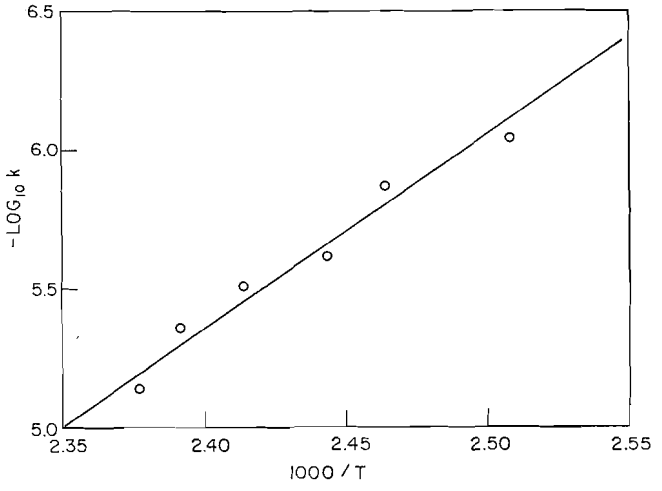


FIG. 1.

CHEMICAL SHIFTS IN THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF MOLECULES CONTAINING POLAR GROUPS[1]

A. D. BUCKINGHAM[2]

ABSTRACT

It is shown that the electric field at a particular nucleus arising from polar groups in other parts of a molecule can lead to chemical shifts proportional to the first power of the field strength. The change $\Delta\sigma$ in the proton screening constant of an X—H bond when it is subjected to an electric field E is approximately given by

$$\Delta\sigma = -2\times10^{-12}E_z - 10^{-18}E^2$$

where E_z is the component of E in the bond direction. A field along the X—H bond draws the electrons in the enriched region between the nuclei away from the proton, thereby causing its resonance to occur at lower magnetic field strengths, while a field in the H—X direction leads to resonance at higher fields. The electric field produced by the polarization of neighboring solvent molecules may also be important and lead to a solvent shift related to the dielectric constant of the solvent. The direction of the internal field, and that due to the solvent, can easily be estimated when the molecule is rigid, so that the model can be useful in assigning spectra. It gives a simple and reasonably accurate account of the observed spectra of substituted benzenes and of some solvent effects on the proton resonances of *cis*- and *trans*-1,2-dichloroethene.

INTRODUCTION

In nuclear magnetic resonance experiments, nuclei with magnetic moments are effectively used as probes to measure the actual magnetic field, H_{local}, at the nucleus.

[1] $$H_{\text{local}} = (1-\sigma)H$$

where H is the applied magnetic field strength and σ is the *screening constant*. Owing to rapid molecular motion in gases and liquids, the observed screening constant corresponds to an average for all molecular orientations. The molecules which are far removed from the one with the resonant nucleus interact with it as if they formed a continuum having the bulk properties of the fluid, and they may contribute to σ a term proportional to the volume susceptibility; this term depends on the sample shape, and vanishes for a spherical specimen. The screening constants quoted in this paper have all been "corrected" so as to remove this bulk susceptibility effect.

Progress in understanding observed screening constants has largely been based on models in which σ is split up into atomic contributions (see Pople, Schneider, and Bernstein (1) and Saika and Slichter (2)). Thus,

[2] $$\sigma = \sigma_d+\sigma_p+\sigma_o+\sigma_c$$

where σ_d and σ_p are the dia- and para-magnetic shielding of the nucleus whose total screening constant is σ; σ_d is proportional to the magnetic field produced at the nucleus by the moment induced through the rotation of the electrons about the nucleus with the Larmor precessional frequency $eH/2mc$. The paramagnetic shielding σ_p arises from the hindrance to the Larmor precession produced by the lack of axial symmetry about the field H; in a linear molecule, σ_p is zero when H is along the molecular axis, but in general it is non-zero for an atom in a molecule. σ_o is the shielding constant proportional to the field produced by the magnetic moments induced in other atoms, and σ_c is the contribution

from interatomic currents (3); σ_o is zero in a tumbling molecule if the other atoms have isotropic susceptibilities.

A uniform electric field E_z distorts an atom in an S-state, and this distortion affects σ_d and σ_p. σ_d is diminished in both the z and x (or y) directions, the diminution being greater in the z-direction; σ_p is zero in the z-direction, but is negative in the x- and y-directions. The change in σ due to E_z is proportional to E_z^2, for the symmetry of the atom requires the shielding to be unaffected by a reversal of E_z. For a hydrogen atom in its ground state, Marshall and Pople (4) showed that, neglecting the effect of electron spin,

$$\sigma_{zz} = \frac{e^2}{3mc^2a}\left\{1-\frac{439}{40}\frac{a^4E_z^2}{e^2}\right\}$$

[3]

$$\sigma_{xx} = \sigma_{yy} = \frac{e^2}{3mc^2a}\left\{1-\frac{193}{15}\frac{a^4E_z^2}{e^2}\right\}$$

for weak electric fields ($E_z \ll e/a^2$), where e is the protonic charge (4.803×10^{-10} e.s.u.) and a the Bohr radius (0.5292 Å).

If the resonant nucleus is not at a molecular center of inversion, the screening for a fixed orientation of the molecule may be affected by a reversal of E_z, so that in weak fields σ may be proportional to E_z, rather than E_z^2. If E_z is a fixed external field, the shielding proportional to E_z averages to zero in a gas or liquid, but if E_z arises from a polar group within the molecule itself, or from neighboring solvent molecules polarized by the solute, then the mean value of E_z at a particular nucleus may be non-zero. A screening constant proportional to E_z, in addition to one proportional to E_z^2, is therefore possible. Thus in an X—H bond, σ for the proton will be proportional to the first power of the component of the field along the bond, and to the second power of the field perpendicular to it.

The purpose of this paper is to investigate the influence of this "internal field" effect on proton screening constants in gaseous molecules, and to discuss changes in σ arising from fields due to the presence of a solvent; the latter part extends Stephen's approach (5) to the problem of solvent effects.

GENERAL THEORY

In the presence of a primary uniform magnetic field **H**, there will be, at a particular nucleus, an induced secondary magnetic field **H′**, and the screening constant tensor $\sigma_{\alpha\beta}$ for this nucleus is defined by

$$H'_\alpha = -\sigma_{\alpha\beta}H_\beta \qquad [4]$$

where the Greek subscripts denote tensor components (α and β can be x, y, or z, and repeated subscripts indicate a summation over x, y, and z components; thus $\sigma_{\alpha\beta}H_\beta = \sigma_{\alpha x}H_x+\sigma_{\alpha y}H_y+\sigma_{\alpha z}H_z$). It is supposed that if the molecule is in a uniform electric field **E**, the screening is affected in such a way that σ can be expanded as a power series in E

$$\sigma_{\alpha\beta} = \sigma^{(0)}_{\alpha\beta}+\sigma^{(1)}_{\alpha\beta\gamma}E_\gamma+\tfrac{1}{2}\sigma^{(2)}_{\alpha\beta\gamma\delta}E_\gamma E_\delta+\ldots \qquad [5]$$

If the molecule is symmetric in x (that is, if $\sigma_{\alpha\beta}$ is unaffected by an inversion in the yz plane), then $\sigma^{(1)}_{\alpha\beta x} = 0$. Thus $\sigma^{(1)} = 0$ for an atom; for a molecule which is symmetrical about the z-axis (an X—H bond is usually approximately symmetric about the bond direction) $\sigma^{(1)}_{\alpha\beta x} = \sigma^{(1)}_{\alpha\beta y} = 0$. The observed screening constant σ for a molecule in a gas or liquid corresponds to an average of $\sigma_{\alpha\beta}$ over all orientations. Averaging over all molecular

orientations is equivalent to fixing the molecule (and in this case the electric field) and averaging over all directions of the magnetic field. Thus,

$$[6] \qquad \sigma = \frac{1}{H^2}\sigma_{\alpha\beta}\overline{H_\alpha H_\beta} = \tfrac{1}{3}\sigma_{\alpha\alpha} = \tfrac{1}{3}\{\sigma^{(0)}_{\alpha\alpha}+\sigma^{(1)}_{\alpha\alpha\gamma}E + \tfrac{1}{2}\sigma^{(2)}_{\alpha\alpha\gamma\delta}E_\gamma E_\delta + \ldots\}.$$

For an atom in an S-state $\sigma^{(1)} = 0$ and there are two independent $\sigma^{(2)}$ tensor components. For a hydrogen atom in a uniform field E_z, [5] yields

$$\sigma_{zz} = \sigma^{(0)}+\tfrac{1}{2}\sigma^{(2)}_{zzzz}E_z{}^2+\ldots$$
$$\sigma_{xx} = \sigma^{(0)}+\tfrac{1}{2}\sigma^{(2)}_{xxzz}E_z{}^2+\ldots$$

whence, from [3],

$$[7] \qquad \sigma^{(0)} = \frac{e^2}{3mc^2a}; \qquad \sigma^{(2)}_{zzzz} = \sigma^{(2)}_{||} = -\frac{439}{60}\frac{a^3}{mc^2}$$
$$\sigma^{(2)}_{xxzz} = \sigma^{(2)}_{\perp} = -\frac{386}{45}\frac{a^3}{mc^2}.$$

The $\sigma^{(2)}$ tensor is given by

$$[8] \qquad \sigma^{(2)}_{\alpha\beta\gamma\delta} = \sigma^{(2)}_{\perp}\delta_{\alpha\beta}\delta_{\gamma\delta}+\tfrac{1}{2}(\sigma^{(2)}_{||}-\sigma^{(2)}_{\perp})(\delta_{\alpha\gamma}\delta_{\beta\delta}+\delta_{\alpha\delta}\delta_{\beta\gamma})$$

where $\delta_{\alpha\beta}$ is the substitution tensor ($= 1$ if $\alpha = \beta$, $= 0$ if $\alpha \neq \beta$).

In an axially symmetric X—H bond there can be no screening proportional to the first power of the field at right angles to the bond. Thus $\sigma^{(1)}_{\alpha\beta x} = \sigma^{(1)}_{\alpha\beta y} = 0$, and there are two independent $\sigma^{(1)}$ tensors, $\sigma^{(1)}_{zzz} = \sigma^{(1)}_{||}$ and $\sigma^{(1)}_{xxz} = \sigma^{(1)}_{yyz} = \sigma^{(1)}_{\perp}$. From [6] and [8]

$$[9] \qquad \sigma = \sigma^{(0)}+\sigma^{(1)}E_z+\tfrac{1}{2}\sigma^{(2)}E^2+\ldots$$

where

$$\sigma^{(0)} = \tfrac{1}{3}(\sigma^{(0)}_{||}+2\sigma^{(0)}_{\perp}) \qquad \text{and} \qquad \sigma^{(1)} = \tfrac{1}{3}(\sigma^{(1)}_{||}+2\sigma^{(1)}_{\perp}).$$

To estimate the importance of the proton shielding proportional to E and to E^2 in an X—H bond, use can be made of the results of Marshall and Pople (4) for the E^2 effect on an H-atom. Consider a model in which an H-atom is at a distance R from a point charge λ. In the presence of a uniform electric field **E**, the total electric field **F** acting on the atom is

$$[10] \qquad \mathbf{F} = \{E_x, E_y, E_z+(\lambda/R^2)\}$$

and hence an effect proportional to F^2 will involve terms of the first and second order in E. The screening constant for the proton in this "molecule" is given by [5] and [8] and is

$$[11] \qquad \sigma_{\alpha\beta} = \frac{e^2}{3mc^2a}\delta_{\alpha\beta}-\frac{193}{45}\frac{a^3F^2}{mc^2}\delta_{\alpha\beta}+\frac{227}{360}\frac{a^3}{mc^2}F_\alpha F_\beta.$$

Because of the form of F (see [10]), [11] leads to screening proportional to E_z and to E^2, and it can be shown that

$$\sigma^{(1)}_{||} = \frac{\lambda}{R^2}\sigma^{(2)}_{||} \qquad \text{and} \qquad \sigma^{(1)}_{\perp} = \frac{\lambda}{R^2}\sigma^{(2)}_{\perp}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Thus [9] becomes

$$\sigma = \frac{e^2}{3mc^2a} - \frac{881}{108}\frac{a^3}{mc^2}\frac{\lambda}{R^2}E_z - \frac{881}{216}\frac{a^3}{mc^2}E^2 - \ldots$$

$$[12] \qquad = \sigma^{(0)} + \sigma^{(2)}\left\{\frac{\lambda}{R^2}E_z + \tfrac{1}{2}E^2\right\} + \ldots$$

where

$$\sigma^{(2)} = \tfrac{1}{3}(\sigma_{||}^{(2)} + 2\sigma_{\perp}^{(2)}).$$

From [7], $\sigma^{(0)} = 17.8\times10^{-6}$, $\sigma^{(2)} = -1.5\times10^{-18}$ e.s.u., $\lambda = 10^{-10}$ e.s.u., and typical parameters are $R = 10^{-8}$ cm, whence

$$[13] \qquad \sigma = 2\times10^{-5} - 2\times10^{-12}E_z - 10^{-18}E^2 - \ldots$$

Thus for $E = 10^5$ e.s.u. (the field 7 Å from a proton), the shielding proportional to E is $\sim$0.2 p.p.m., and is $\sim$20 times that proportional to E^2.

The sign of $\sigma^{(1)}$ is opposite to that of λ. However, in most X—H bonds, it is reasonable to assume that there is an increased electronic charge between the nuclei (as for a positive λ), so that an electric field in the X—H direction will tend to draw this excess charge further away from the proton, thereby decreasing its shielding constant. Equation [13] indicates that the change in σ arising from the action of an electric field on an XH bond is approximately $-2\times10^{-12}E_z - 10^{-18}E^2$, and the measurements discussed later in this paper confirm this result in the case of CH bonds.

SOLVENT EFFECTS

When a polar molecule is dissolved, it polarizes the surrounding medium, and this polarization leads to an electric field—the "reaction field"—at the solute. If the molecule is sufficiently symmetrical, the mean reaction field is parallel and proportional to its dipole moment. For the Onsager model (6), in which the solute molecule is represented by a sphere of radius r containing a point dipole of moment μ at its center, and the solvent by a continuum of dielectric constant ϵ, the reaction field $\mathbf{R}$ is

$$[14] \qquad \mathbf{R} = \frac{2(\epsilon-1)}{2\epsilon+1}\frac{\mathbf{m}}{r^3} = \frac{2(\epsilon-1)(n^2-1)}{3(2\epsilon+n^2)}\frac{\mathbf{\mu}}{\alpha}$$

where $\mathbf{m} = \mathbf{\mu} + \alpha\mathbf{R}$ is the total dipole moment of the solute in the medium, $\alpha = \frac{n^2-1}{n^2+2}r^3$ being the polarizability of the sphere, and n the refractive index of the pure solute (as a liquid or solid). Thus $n^2 \sim 2.5$, and

$$[15] \qquad \mathbf{R} = \frac{\epsilon-1}{2\epsilon+2.5}\frac{\mathbf{\mu}}{\alpha}.$$

Protons are normally on the "surface" of a molecule and are therefore exposed to direct contact with the surrounding molecules, so that the Onsager field [14] is probably frequently a poor approximation to the actual reaction field acting on a proton, although it might adequately describe the field at a nucleus in the interior of a molecule. (Thus the C^{13} screening constants in substituted methanes $C^{13}X_nY_{4-n}$ should be approximately linearly dependent on $(\epsilon-1)/(2\epsilon+2.5)$.) Local solvent effects due to polar groups near a proton are probably important; thus in the non-dipolar molecule 1,4-dinitrobenzene, fields arising from the induced charges on the solvent molecules near the highly polar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

nitro groups probably lead to electric fields at the protons, even though $\mu = 0$. The reaction field gradient R' for a model similar to Onsager's is (7)

$$R' = \frac{6(\epsilon-1)}{3\epsilon+2}\frac{\Theta}{r^5} \qquad [16]$$

where Θ is the molecular quadrupole moment; for a molecule with two opposed dipolar groups of moment μ separated by a distance d, $\Theta = 2\,\mu d$. Figure 1 shows the probable

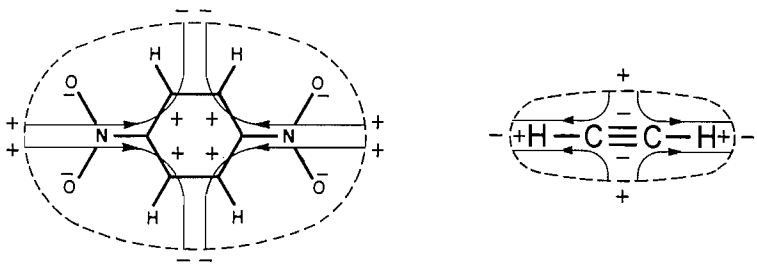

FIG. 1. Quadrupolar reaction fields in 1,4-dinitrobenzene and in acetylene.

form of the reaction field in 1,4-dinitrobenzene and in acetylene. If one of the protons in acetylene were replaced by an electronegative group (e.g., F, Cl, CN) a larger solvent shift would be expected, for in this case the shifts due to R and to R' are both to lower magnetic field strengths. When both R and R' are important, [15] and [16] indicate that σ should be approximately linearly dependent on $(\epsilon-1)/(\epsilon+1)$.

DISCUSSION

Although the well-known inductive and mesomeric effects undoubtedly play an important part in determining charge distributions in substituted aromatic molecules, the protons are isolated from the ring by sigma bonds, making it dangerous to try to correlate proton signals with pi-electron densities on the associated carbon atoms, or with Hammett acidity functions. In fact, it is shown in this section that the general pattern of proton screening constants in mono- and poly-substituted benzenes can be largely explained in terms of [13] and "internal" and "reaction" fields.

Consider a substituted benzene C_6H_5X, in which there is a "bond-dipole" μ as shown. If μ is situated at a point distant half-way along the X—C bond, and if the benzene ring is a regular hexagon, then the electric fields at the five protons, in the directions of the various CH bonds, are (if μ is the only significant contributor to the field)

$$E_{CH_2} = E_{CH_6} = \frac{4\mu\{10l_{CC}^2-8l_{CH}^2-2l_{CX}^2+10l_{CC}l_{CH}+5l_{CC}l_{CX}+13l_{CH}l_{CX}\}}{\{4l_{CC}^2+4l_{CH}^2+l_{CX}^2+4l_{CC}l_{CH}+2l_{CC}l_{CX}-2l_{CH}l_{CX}\}^{5/2}}$$

$$E_{CH_3} = E_{CH_5} = \frac{4\mu\{42l_{CC}^2+8l_{CH}^2+2l_{CX}^2+42l_{CC}l_{CH}+21l_{CC}l_{CX}+13l_{CH}l_{CX}\}}{\{12l_{CC}^2+4l_{CH}^2+l_{CX}^2+12l_{CC}l_{CH}+6l_{CC}l_{CX}+2l_{CH}l_{CX}\}^{5/2}} \qquad [17]$$

$$E_{CH_4} = \frac{16\mu}{\{4l_{CC}+2l_{CH}+l_{CX}\}^3}$$

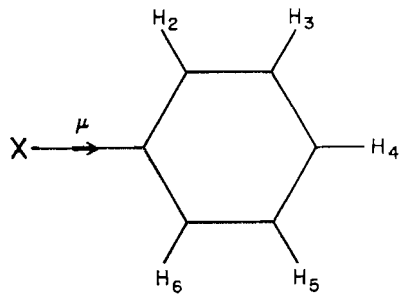
where l_{AB} is the length of the A—B bond. For $l_{CC} = 1.39$ Å, $l_{CH} = 1.07$ Å, $l_{CX} = 2.0$ Å

$$\begin{aligned} E_{CH_2} &= 8.74\times10^{22}\,\mu; & E_2^2 &= 82.8\times10^{44}\,\mu^2, \\ E_{CH_3} &= 2.32\times10^{22}\,\mu; & E_3^2 &= 5.88\times10^{44}\,\mu^2, \\ E_{CH_4} &= 1.75\times10^{22}\,\mu; & E_4^2 &= 3.07\times10^{44}\,\mu^2. \end{aligned} \qquad [18]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Thus for an isolated nitrobenzene molecule, $\mu \sim 4\times10^{-18}$ e.s.u., so that [13] leads to the following contributions to σ arising from E_z and E^2

$$\begin{aligned}\sigma_{H_2} = \sigma_{H_6} &= -0.70\times10^{-6}-0.13\times10^{-6},\\ \sigma_{H_3} = \sigma_{H_5} &= -0.19\times10^{-6}-0.01\times10^{-6},\\ \sigma_{H_4} &= -0.14\times10^{-6}-0.005\times10^{-6}.\end{aligned} \qquad [19]$$



From [19], it is clear that the approximately isotropic E^2 effect is of secondary importance, and is negligible except where the "source" of the electric field is close to the proton (as, for example, in hydrogen bonds (8)). If the electric field effects are the only significant contributors to the relative chemical shifts, [19] indicates that in gaseous nitrobenzene, for example, the *o*-protons should have the largest shift to low field (relative to benzene itself), followed by the *m*- and *p*-hydrogens. Unfortunately, there are no data on gaseous substituted benzenes, but in solution in cyclohexane (9) the *o*-proton in $C_6H_5NO_2$ is shifted by -0.97, the *m*, -0.30, and the *p*, -0.42 p.p.m. relative to benzene in the same solvent.

The reaction field R of [15] tends to shift the H_3 and H_4 signals to low field (H_3 being influenced less than H_4) and H_2 to high field. These data (9) were obtained in a solvent which was a mixture of equal volumes of cyclohexane and nitrobenzene, for which $\epsilon = 16$, so that for $\mu/\alpha = 4.0\times10^5$, $R = 1.7\times10^5$ e.s.u. When E_z in [13] is put equal to $R\cos\phi$, where ϕ is the angle between **R** and a C—H axis, the following solvent shifts are obtained:

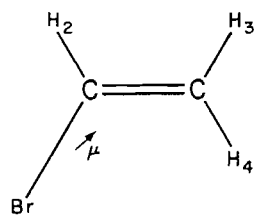
$$(\sigma_{H_2})_s = 0.14\times10^{-6},\quad (\sigma_{H_3})_s = -0.20\times10^{-6},\quad (\sigma_{H_4})_s = -0.37\times10^{-6}. \qquad [20]$$

Combining [19] and [20], it is found that the *o*-, *m*-, and *p*-protons should be shifted by -0.69, -0.40, and -0.51 p.p.m. relative to benzene, in qualitative agreement with the above facts. If this is a valid interpretation of the $C_6H_5NO_2$ spectrum, polar aliphatic solvents (e.g., acetone, acetonitrile) should increase the separation between the *m*- and *p*-proton signals, and bring the *o*-peak closer to the *p*-one (relative to the situation in a non-polar solvent like CCl_4).

If the sign of μ is changed (as, for example, in $C_6H_5NH_2$) E is reversed and shifts to higher field are expected. Also, since the E and E^2 effects now act in opposite directions, the *o*-signal should be closer to the *m*- and *p*-ones. These expectations are in accord with the facts (10).

The proton resonance spectrum of di- and tri-substituted benzenes should be interpretable in terms of the model. Thus in 1,2-dichlorobenzene, the difference between the electric fields acting along the CH_3 and CH_4 axes is (from [18]) $6.99\times10^{22}\,\mu$, and for a C—Cl bond dipole moment of 1.7×10^{-18} e.s.u., [13] leads to a difference in the resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.



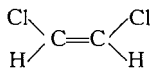
frequencies of the H_3 and H_4 protons of -0.24 p.p.m. The observed value is -0.25 p.p.m. for a solution in CCl_4 (11). The model predicts that increasing the polarity of the solvent will not affect H_3, but will shift the H_4 signal to lower field. Similarly, in 1,2,3-trichlorobenzene in CCl_4, the signal from H_4 and H_6 should be shifted -0.22 p.p.m. relative to that from H_5, but this difference should decrease as the polarity of the solvent increases. The observed shift in CCl_4 is -0.23 p.p.m. (11).

The effects of solvents on the chemical shifts of the protons in the 2- and 3-positions in some 1,4-disubstituted benzenes have been investigated by Schaefer and Schneider (12). They found that in *p*-methyl nitrobenzene the *m*-proton screening constant is shifted by -0.29 p.p.m. on changing the solvent from *n*-hexane to acetone. The corresponding shift for the *o*-proton is -0.06 p.p.m. Thus, although the *o*-proton is closer to the polar NO_2 group, its solvent shift is smaller. Our model is capable of explaining this, for the reaction field **R** is parallel to the 1-4 axis and therefore leads to a *m*-proton screening constant of $\frac{1}{2}\sigma^{(1)}R$ (that is, a shift to lower field, for $\sigma^{(1)}$ is negative) and an ortho shift of the same magnitude to higher field. (The small observed negative solvent shift (-0.06 p.p.m.) for the *o*-proton is partly due to an R^2 effect (this leads to a relative shift of -0.02 p.p.m.) but chiefly to the inadequacy of [15] for describing the reaction field in the immediate neighborhood of a highly polar group.) The difference between the *o*- and *m*-proton shifts in changing the solvent from *n*-hexane to acetone (-0.23×10^{-6}) should be approximately given by

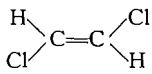
$$\left\{\left(\frac{\epsilon-1}{2\epsilon+2.5}\right)_{\text{acetone}}-\left(\frac{\epsilon-1}{2\epsilon+2.5}\right)_{\text{hexane}}\right\}\frac{\mu}{\alpha}\sigma^{(1)}.$$

Taking $\mu/\alpha = 3.3\times10^5$ e.s.u., this leads to $\sigma^{(1)} = -2.6\times10^{-12}$ (confirming the order of magnitude of the estimate in [13]). However, our model cannot explain the large positive shift of the *m*-proton relative to the *o*-proton on changing the solvent from *n*-hexane to benzene. It is clear that some other type of interaction between *p*-methyl nitrobenzene and benzene must exist; Schaefer and Schneider (12) postulated hydrogen bonding between the *m*-proton and the π-electrons of the neighboring benzene molecule.

The model should sometimes be helpful in assigning observed peaks to particular protons. Thus in vinyl bromide, the direction of the "bond" dipole moment is probably approximately along the line joining the bromine nucleus to the mid-point of the C=C bond. The reaction field is therefore approximately parallel to the CH_3 and



perpendicular to the CH_4 bonds. Hence, it can be anticipated that the H_3 resonance signal will be shifted more (to low field) than that of H_4 on increasing the dielectric constant of the aliphatic solvent.



In *cis*- and *trans*-1,2-dichloroethene (I and II) "local" effects are probably approximately the same for all protons, whereas only I has an effect due to a dipolar reaction field. Thus the protons in I should have a larger low-field shift on changing the solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

from hexane to acetone; since μ/α for I is 2.3×10^5, the expected difference is -0.07 p.p.m.; the experimental value is -0.08 p.p.m. (13).

I

II

Equation [16] for the quadrupolar reaction field implies that appreciable solvent shifts will occur in non-dipolar molecules like 1,4-dinitrobenzene, for which $\Theta \sim -20\times10^{-26}$ e.s.u. The four protons will experience a reaction field $R = -(R'r \cos 30°)/2$ along the C—H bonds, and this should lead to a shift of -0.15 p.p.m. on changing the solvent from *n*-hexane to acetone. In NNN′N′-tetramethyl *p*-phenylene diamine Θ will be positive, so the corresponding shift should be positive. For acetylene, $\Theta \sim 3\times10^{-26}$ e.s.u. and $R = R'r$, so that the corresponding shift in the proton signals should be -0.19 p.p.m. Thus protons near polar groups experience "local" solvent electric fields which may be comparable to those due to the reaction fields of polar molecules. Fortunately both are approximately proportional to $(\epsilon-1)/(\epsilon+1)$, so that if other solvent influences (such as shape effects coupled with diamagnetic anisotropy, as in benzene or diacetylene, or strong van der Waals forces, as in CH_2I_2, or strong specific interactions, as in hydrogen bonded substances (14)) are absent σ should vary approximately linearly with this solvent parameter.

ACKNOWLEDGMENTS

The author is grateful to Dr. W. G. Schneider for a number of very helpful discussions and for inviting him to spend the summer of 1959 in Ottawa, and to Dr. T. Schaefer for communicating experimental results to him.

NOTES

THE REACTION OF SODIUM METAPERIODATE WITH SOME NITROGEN DERIVATIVES OF CARBOHYDRATES

M. J. Abercrombie and J. K. N. Jones

Methods which might be used in the chemical degradation of carbon-14-labelled carbohydrates required an investigation of the reaction of sodium metaperiodate with certain nitrogen-containing carbohydrate derivatives. The aim of these experiments was to convert specific carbon atoms of the carbohydrates to formic acid, which could then be oxidized to carbon dioxide with mercuric acetate. The carbon dioxide was then converted to barium carbonate and its activity determined.

The oxidation of phenylosazones (1) and phenylosotriazoles (2) by sodium metaperiodate resulted in the rapid consumption of the theoretical quantity of metaperiodate. This was followed, in the case of the phenylosazones, by a slow overoxidation by the metaperiodate. Recently the metaperiodate oxidation of some phenylhydrazones has been reported by O'Donnel and Percival (3), who found that the consumption of oxidant corresponded to the amount required for an acyclic structure. They did not determine the quantities of formaldehyde and formic acid produced during the oxidation.

D-Mannose phenylhydrazone and D-xylose 2,4-dinitro-phenylhydrazone have been oxidized with sodium metaperiodate in aqueous ethanol; the metaperiodate consumed, the formic acid and formaldehyde produced were then measured.

The experimental and theoretical results, for an acyclic structure are shown in Table I (mole/mole).

TABLE I

	Theoretical			Experimental		
	IO_4	HCHO	HCOOH	IO_4	HCHO	HCOOH
D-Mannose phenylhydrazone	4.00	1.00	3.00	4.05	1.05	2.96
D-Xylose 2,4-dinitro-phenylhydrazone	3.00	1.00	2.00	3.02	1.01	2.06

These phenylhydrazones probably exist in solution as cyclic structures. On oxidation they form unstable intermediates which break down further.

The metaperiodate uptake and the formic acid released were determined using the procedure quoted by Hough (1). The formaldehyde was determined by the method of Perry and Pietak (4). The experimental results show that both of the compounds are oxidized in the open chain form by metaperiodate.

The metaperiodate oxidation of two other nitrogen derivatives was studied; these were 6-*O*-toluene-*p*-sulphonyl-(tosyl)-D-glucose phenylosotriazole and 6-*O*-benzoyl-D-glucose phenylosotriazole. The metaperiodate uptake and formaldehyde produced were determined as described above. Table II shows the theoretical and experimental results.

The experimental results show that only the hydroxyl group on position 6 has been substituted thus the periodate oxidation releases carbon 4 as formic acid. This carbon atom of D-mannose is difficult to isolate by standard procedure.

TABLE II

	Theoretical		Experimental	
	IO_4	HCHO	IO_4	HCHO
6-*O*-Tosyl-D-glucose phenylosotriazole	2.00	0.00	2.05	0.07
6-*O*-Benzoyl-D-glucose phenylosotriazole	2.00	0.00	1.98	0.00

EXPERIMENTAL

The 2,4-dinitro-phenylhydrazone of D-xylose was prepared by the method of Lloyd (5) and the mannose phenylhydrazone by the standard method (6).

6-O-Toluene-p-sulphonyl-D-glucose Phenylosotriazole

D-Glucose phenylosotriazole was prepared by the method of Hudson (2). To 0.5 g of the D-glucose phenylosotriazole dissolved in 15 ml of pyridine was added 0.39 g of toluene-*p*-sulphonyl chloride (1:1.2 mole). The solution was kept overnight at room temperature and was then added to 50 ml of crushed ice. The white precipitate thus produced was collected and the product washed with dilute acetic acid, water, and ethanol. The product was crystallized from ethanol (yield 0.52 g, 70%), m.p. 149–150°. Calc. for $C_{19}H_{21}O_6N_3S$: C, 54.50%; H, 5.10%. Found: C, 54.54%; H, 5.17%.

6-O-Benzoyl-D-glucose Phenylosotriazole

This was prepared in a manner similar to that of the previous compound. The product was recrystallized from ethanol by the addition of water until the solution became turbid. When the solution was left standing, long, white, needle-shaped crystals were obtained (yield 45%), m.p. 166–167°. Calc. for $C_{19}H_{19}O_5N_3$: C, 61.70%; H, 5.15%. Found: C, 61.95%; H, 5.39%.

marines show electron spin resonance absorption with a g-value of 2.029. On the basis of the similarity of the g-value of the radicals in ultramarine, in liquid sulphur 2.024 (2), and in the blue solution of sulphur in oleum 2.016 and 2.026 (3), they have suggested that the paramagnetism of ultramarine arises from some type of sulphur radical. Previously we have observed that the color, the intensity, and the g-value of resonance absorption of ultramarine change almost reversibly with the replacement of sodium ion by silver ion and vice versa (4). This observation can be explained by the assumption that unpaired electrons are associated with polysulphide ions and can interact with each other through cations. Here we wish to present further results which support this view.

It has been known that the fusion of borax, boric acid, and sodium sulphite gives a stable blue product (5). The presence of alkali and excess of boric acid is required to produce blue color. Sulphite can be replaced by sulphur or polysulphides. This system seemed to be more easily controllable than ordinary ultramarine, therefore we examined the electron spin resonance absorption of this so-called boro-ultramarine. The mixture of borax, boric acid, and sodium sulphite was heated to 750° C in an electric furnace. At this temperature sodium sulphite decomposes to sulphate and sulphide (6).

The electron spin resonance absorption spectrum of boro-ultramarine is not simple and seems to consist of three peaks, namely a main peak with a g-value of 2.209 and shoulders at both sides as shown in Fig. 1. This pattern does not depend on the composition of the starting mixture. The g-value of the main absorption is in good agreement with that

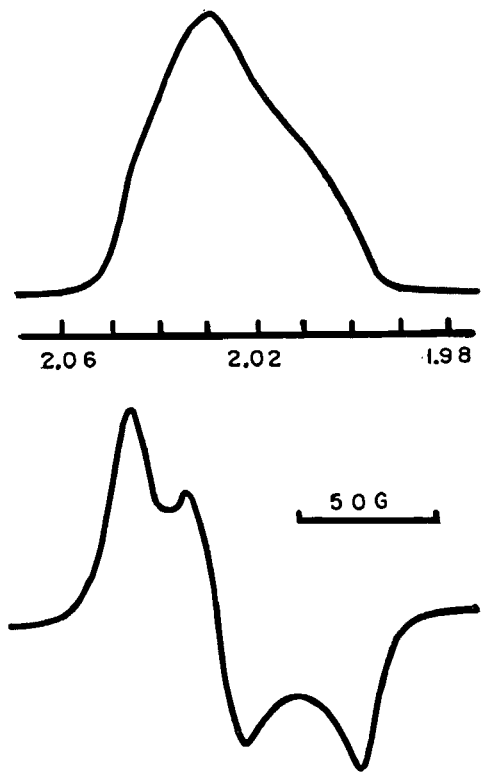

FIG. 1. Electron spin resonance absorption of boro-ultramarine at 9 kMc/s and at room temperature. Lower curve is derivative as recorded and upper curve is the integrated one.

of ordinary blue alkali-ultramarine. Ingram and Symons (7, 8) studied in more detail the resonance absorption of the sulphur–oleum system and postulated that the resonance absorption with a high *g*-value is caused by brown polymeric sulphur radicals similar to those in liquid sulphur. The difference of color and *g*-value of these sulphur radicals can be attributed to the effect of the medium as seen in the case of substituted ultramarines. Therefore, we may conclude that the blue color and the unpaired electrons in ordinary and boro-ultramarines arise from polysulphide sulphur in coexistence with alkali ions. The shoulder with a *g*-value of about 2.01 may correspond to the blue radical in the sulphur–oleum system. The latter was assigned to monomeric sulphur sesquioxide by Symons (8). The formation of the same compound at high temperature in our borax – boric oxide system containing sulphate and sulphide seems to be likely. The other shoulder has a *g*-value of about 2.04. The nature of this radical is not clear and such a high *g*-value has not been found in the other radicals containing sulphur.

We also examined the boro-ultramarine containing selenium instead of sulphur, but no electron spin resonance absorption was detected with the red product.

Thanks are due to Professor C. A. McDowell for his interest and encouragement throughout this work. The research was supported by grants from the National Research Council of Canada, and thanks are due to that body for its generosity.

A CHEMICAL SYNTHESIS OF 4-*O*-METHYL-D-GLUCURONIC ACID

W. D. S. Bowering and T. E. Timell

A chemical synthesis of 4-*O*-methyl-D-glucuronic acid has so far not been reported (1), although the compound has been obtained from numerous polysaccharides and a method for its large-scale preparation has been developed (2). This note is concerned with the synthesis of 4-*O*-methyl-D-glucuronic acid from methyl α-D-glucopyranoside.

Methyl 4-*O*-methyl-α-D-glucoside was prepared from methyl α-D-glucopyranoside in a yield of 18.5%, essentially according to the method of McGilvray (3, 4). Contrary to all expectations, oxidation of the 2,3-di-*O*-benzyl derivative of this compound with permanganate (5) failed to produce the expected uronic acid, nor was it possible to introduce a carboxyl group at C_6 in the methyl 4-*O*-methyl-α-D-glucoside by oxidation with air or oxygen in the presence of a platinum catalyst (6, 7). Oxidation of the glucoside with sodium nitrite in phosphoric acid (8), followed by hydrolysis, yielded a mixture of sugars, the acid portion of which was resolved on an anion exchange resin, resulting in the isolation of chromatographically pure 4-*O*-methyl-D-glucuronic acid in a yield of 1–2%. The compound was identified by reduction of its methyl ester – methyl glycoside, followed

A CHEMICAL SYNTHESIS OF 4-*O*-METHYL-D-GLUCURONIC ACID

W. D. S. Bowering and T. E. Timell

A chemical synthesis of 4-*O*-methyl-D-glucuronic acid has so far not been reported (1), although the compound has been obtained from numerous polysaccharides and a method for its large-scale preparation has been developed (2). This note is concerned with the synthesis of 4-*O*-methyl-D-glucuronic acid from methyl α-D-glucopyranoside.

Methyl 4-*O*-methyl-α-D-glucoside was prepared from methyl α-D-glucopyranoside in a yield of 18.5%, essentially according to the method of McGilvray (3, 4). Contrary to all expectations, oxidation of the 2,3-di-*O*-benzyl derivative of this compound with permanganate (5) failed to produce the expected uronic acid, nor was it possible to introduce a carboxyl group at C_6 in the methyl 4-*O*-methyl-α-D-glucoside by oxidation with air or oxygen in the presence of a platinum catalyst (6, 7). Oxidation of the glucoside with sodium nitrite in phosphoric acid (8), followed by hydrolysis, yielded a mixture of sugars, the acid portion of which was resolved on an anion exchange resin, resulting in the isolation of chromatographically pure 4-*O*-methyl-D-glucuronic acid in a yield of 1–2%. The compound was identified by reduction of its methyl ester – methyl glycoside, followed

For personal use only.

by hydrolysis, when there was obtained 4-*O*-methyl-D-glucose, characterized through its crystalline phenylosazone derivative (9).

EXPERIMENTAL

Preparation of Methyl 4-O-Methyl-α-D-glucoside

Methyl 2,3-di-*O*-benzyl-6-*O*-trityl-α-D-glycopyranoside (3, 4), $[\alpha]_D^{21}$ +14° (*c*, 4.6 in chloroform), was converted to methyl 2,3-di-*O*-benzyl-4-*O*-methyl-6-*O*-trityl-α-D-glucoside in an almost quantitative yield by one methylation according to Kuhn *et al.* (10). Anal. calc. for $C_{41}H_{42}O_6$:OCH_3, 9.8%. Found: OCH_3, 10.4%; $[\alpha]_D^{20}$ +30° (*c*, 1.6 in chloroform). Detritylation with aqueous acetic acid, followed by reductive debenzylation (3, 11), gave sirupy methyl 4-*O*-methyl-α-D-glucoside, which, after distillation *in vacuo*, was obtained in an over-all yield of 18.5%. Anal. calc. for $C_8H_{16}O_6$:OCH_3, 29.8%. Found: OCH_3, 28.6%; $[\alpha]_D^{20}$ +145° (*c*, 4.2 in ethanol). Hydrolysis gave 4-*O*-methyl-D-glucose, $[\alpha]_D^{22}$ +51° (*c*, 3.0 in water). Anal. calc. for $C_7H_{14}O_6$:OCH_3, 16.0%. Found: OCH_3, 15.5%. The osazone derivative had m.p. and mixed m.p. 159–160° (corr.).

Oxidation of Methyl 4-O-Methyl-α-D-glucoside

Methyl 4-*O*-methyl-α-D-glucoside (8.7 g) was dissolved in 85% phosphoric acid (200 ml) containing sodium nitrite (10 g) (8). After 17 hours at room temperature, water was added (25 ml) and the sirup obtained on evaporation was boiled under reflux for 5 hours in 0.5 *N* sulphuric acid (100 ml). The sirup obtained after neutralization (barium carbonate) contained approximately equal quantities of 4-*O*-methylglucuronic acid, glucuronic acid, 4-*O*-methylglucose, and glucose. The sugar mixture was resolved on a column of Dowex 1X4 (acetate form) anion exchange resin by elution with water, followed by 2 *N* acetic acid. The fractions containing 4-*O*-methylglucuronic acid only were concentrated to a sirup (0.12 g, 1.3%), $[\alpha]_D^{18}$ +35° (*c*, 1.3 in water). Anal. calc. for $C_7H_{12}O_7$:OCH_3, 14.9%. Found: OCH_3, 14.6%.

Characterization of 4-O-Methyl-D-glucuronic Acid

Chromatographically pure 4-*O*-methyl-D-glucuronic acid (73 mg) was converted to the methyl ester – methyl glycoside which was reduced with lithium aluminum hydride (0.5 g) in anhydrous tetrahydrofuran (30 ml). The sirup obtained after hydrolysis (40 mg) was chromatographically identical with 4-*O*-methyl-D-glucose, $[\alpha]_D^{19}$ +50° (*c*, 1.2 in water). Anal. Calc. for $C_7H_{14}O_6$:OCH_3, 16.0%. Found: OCH_3, 15.7%. The phenylosazone derivative had m.p. and mixed m.p. 158–159° C and gave an infrared spectrum indistinguishable from that of an authentic specimen.

ARSENIDES OF THE TRANSITION METALS
III. A NOTE ON THE HIGHER ARSENIDES OF IRON, COBALT, AND NICKEL*

R. D. Heyding and L. D. Calvert

The metal-rich binary compounds formed by arsenic and the transition metals, iron, cobalt, and nickel, have been discussed in the first two papers of this series (1, 2). In continuation of these studies, the arsenic-rich regions of the binary phase diagrams have been investigated, and the compounds observed are described in this note.

The materials and experimental methods employed were similar to those recorded in the earlier papers. The alloys were prepared by direct combination of metal sponge containing less than 10 p.p.m. total impurities, and metallic arsenic containing less than 0.01% antimony. The latter was obtained by reduction of reagent grade arsenic trioxide with sugar charcoal and subsequent double or triple vacuum sublimation.

In general, the alloys formed readily at moderate temperatures. Since the decomposition pressures of the higher arsenides are appreciable, annealing temperatures were not allowed to exceed 900° C, consequently only the nickel alloys were fused. The quantities of arsenic which separated on quenching from temperatures above 700° C were prohibitive except for the cobalt alloys. Again, because of the high arsenic vapor pressures, no attempts were made to study these systems in the high temperature diffraction camera. Room temperature diffraction patterns were obtained in 11.46-cm Norelco Debye–Scherrer cameras using copper K_α (λ = 1.5405 Å) and cobalt K_α (λ = 1.7889 Å) radiation.

Synthesis of the minerals skutterudite ($CoAs_3$), loellingite ($FeAs_2$), rammelsbergite and pararammelsbergite ($NiAs_2$) has been reported by Holmes (3, 4). We have confirmed the appearance of these compounds in the binary phase systems; we were able to detect only one other compound, $CoAs_2$. There is no evidence to support the formation of the compound Co_2As_3 discussed in the literature (5), nor of any of the higher arsenides previously supposed to exist.

The Iron/Arsenic System

One arsenic-rich compound, $Fe(Fe_xAs_{2-x})$, is formed in this system. The terminal composition determined by sublimation of excess arsenic from an alloy/arsenic mixture in a small temperature gradient at 400° C corresponded to an As/Fe ratio of 1.93. No variation in interplanar spacing with alloy composition was observed, and we conclude that the homogeneity range is narrow. The compound is isostructural with loellingite (orthorhombic V_h^{12}, *Pmnn* (6, 7)), with unit cell dimensions a_0 = 2.882, b_0 = 5.300, c_0 = 5.982 Å. The dimensions reported for the mineral are a = 2.85, b = 5.25, c = 5.92 Å. The observed density of the terminal alloy was 7.35 g/cc; the crystallographic densities for $Fe_2As_{3.86}$, $Fe_2(Fe_{0.08}As_{3.92})$, and $Fe_{2.08}As_4$ would be 7.28, 7.44, and 7.55 g/cc, respectively. It appears most probable that the unit cell contains $2(Fe(Fe_xAs_{2-x}))$, x = 0.04, and that some iron atoms occupy arsenic lattice positions, which is the arrangement proposed for the mineral itself (7).

The Cobalt/Arsenic System

In this system two compounds, $CoAs_2$ and $CoAs_3$, are formed. The latter is isostructural with skutterudite (cubic T_h^5, *Im*3, Z = 8 (8)) with a unit cell edge of 8.206±0.002 Å; D_m = 6.71, D_x = 6.79 g/cc. This cell edge is somewhat greater than Holmes' value of

Issued as N.R.C. No. 5496.

8.187 Å for synthetic skutterudite (4). The unit cell of the mineral varies from 8.187 Å to 8.311 Å, depending on the extent of substitution of other transition metals for cobalt in the lattice.

The low order diffraction pattern of the compound $CoAs_2$ is recorded in Table I. This pattern is unaltered by any heat treatment below 900° C, and is unchanged in the presence of CoAs or $CoAs_3$.

TABLE I

Low order diffraction pattern of $CoAs_2$

Fe-filtered Co radiation, $\lambda = 1.7889$ Å; camera diameter, 11.46 cm; cutoff, 20 Å; temperature, 24° C.
Tentative orthorhombic cell: $a_0 = 5.87$, $b_0 = 6.22$, $c_0 = 10.01$ Å; $D_{obs} = 7.56$; $Z = 8$.

In view of the similarity of the other compounds in these binary systems to those found in mineral systems, one might expect $CoAs_2$ and the corresponding mineral, safflorite, to be isostructural. Although there is some confusion in the literature with respect to the diffraction pattern of safflorite, it is shown quite clearly in Fig. 1 that the pattern of $CoAs_2$ is unlike any safflorite pattern. Moreover, safflorite invariably contains considerable quantities of iron, and is more accurately represented by the formula $(Fe,Co)As_2$. According to Peacock (7), the safflorite structure is similar to, but not isostructural with, the loellingite structure due to non-equivalence of Fe and Co positions. Accepting Peacock's crystal structure as the definition of the mineral, the synthetic counterpart of safflorite will be found only in the ternary Fe/Co/As system as $Fe_{1-x}Co_xAs_2$, in which the range of homogeneity may commence at $x = 0$, but will not extend to $x = 1$.

The orthorhombic unit cell proposed for $CoAs_2$ in Table I is offered only as a tentative solution obtained by the usual trial and error methods applied to powder diffraction patterns. Although de Jong's study (9) of the mineral diarsenides has been largely discredited, and although there is little apparent similarity in the pattern of $CoAs_2$ and de Jong's safflorite pattern (Fig. 1), our unit cell dimensions and those proposed by de Jong appear to be related by the transformation 001/100/020.

The Nickel/Arsenic System

One higher arsenide, $NiAs_2$, is formed in this system. It is dimorphic; the low temperature modification, α-$NiAs_2$, is isostructural with pararammelsbergite, while the high temperature modification, β-$NiAs_2$, is isostructural with rammelsbergite.

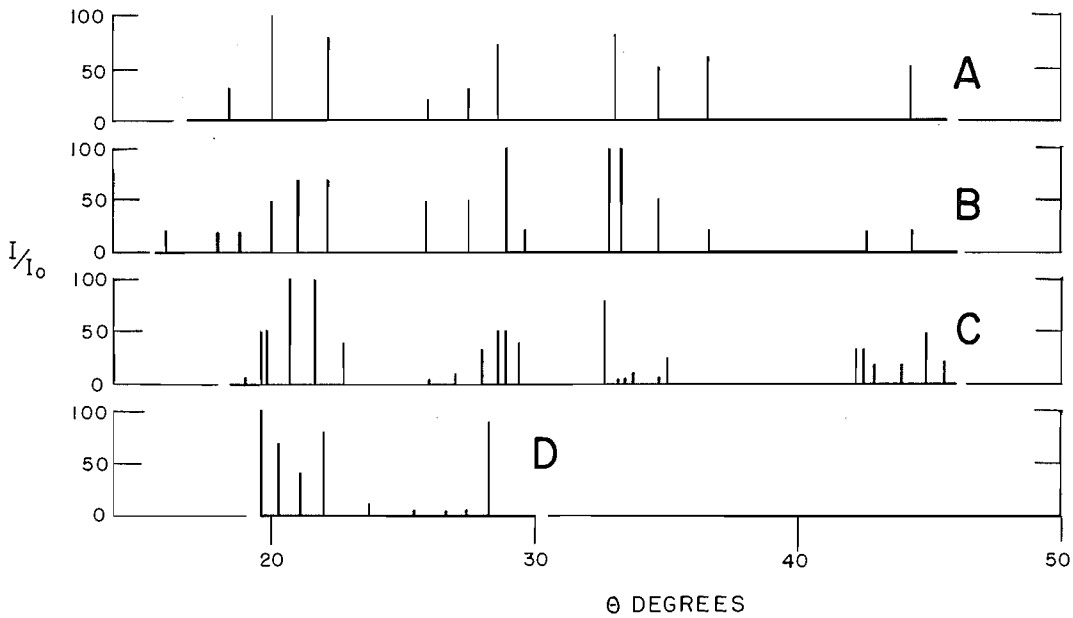

FIG. 1. Comparison of the low order diffraction patterns of safflorite and $CoAs_2$. (A) Safflorite; X-ray Powder Data File, card 2-0986. (B) Safflorite; X-ray Powder Data File, card 2-1317. (C) $CoAs_2$; this work. (D) Safflorite; de Jong (9).

Above 600° C nickel and arsenic in the proper proportions react to form β-$NiAs_2$. Unfortunately, the decomposition pressure is very appreciable, and we were unable to avoid disproportionation on cooling. However, small single crystals were recovered from the surface of several melts, and the patterns were identical with that of rammelsbergite (orthorhombic V_h^{12}, *Pmnn* (9, 10)). The unit cell dimensions are $a_0 = 3.54$, $b_0 = 4.76$, $c_0 = 5.79$ Å, in good agreement with Peacock's values of 3.53, 4.78, and 5.78 kX for the mineral. Terminal composition and density could not be determined. No variation in interplanar spacings with over-all sample composition could be detected.

Of all the compounds formed in these binary systems, α-$NiAs_2$ was the most difficult to obtain, and in fact was never obtained pure. Arsenic and nickel react rapidly to form NiAs even at an ambient temperature of 350° C, the heat of formation being sufficient to fuse the specimen. The subsequent attack of NiAs by excess arsenic is exceedingly slow below 500° C. The pattern of the product obtained by repeated grinding and reheating was identical with that of pararammelsbergite (10, 11, 12) in the presence of NiAs and As. Similarly, the transformation of β-$NiAs_2$ to α-$NiAs_2$ is exceptionally slow. In 6 weeks at 450° C the transformation was less than 20% complete judging from the relative intensities of the two patterns. The transformation of the α form to the β form occurs rapidly at 600° C.

Alloys containing As/Ni atomic ratios greater than two, when heated at 700° C and annealed at 450° C, exhibited only patterns of α- and β-$NiAs_2$ and arsenic, while alloys with As/Ni ratios less than two showed only the patterns of α- and β-$NiAs_2$ and NiAs. Consequently, although the precise constitution of the compound cannot be given, it cannot lie far from the simple 1:2 stoichiometric ratio. The orthorhombic unit cell dimensions are essentially identical with those proposed by Thompson (13) for pararammelsbergite: $a_0 = 5.75$, $b_0 = 5.82$, $c_0 = 11.43$ Å.

THE PENTITOL PENTANITRATES*

I. G. WRIGHT AND L. D. HAYWARD

In connection with a study of the selective denitration of polynitrate esters (1, 2, 3) we have prepared and characterized the crystalline, fully nitrated derivatives of the three isomeric pentitols, xylitol (I), ribitol (adonitol) (II), and L-(−)-arabinitol (III). The only previous references to the pentitol nitrates in the literature dated from the end of the last century and described xylitol pentanitrate (4) and the pentanitrate of D-(+)-arabinitol (IV) (5) as explosive, non-crystallizable sirups.

In the present work the stable, crystalline form of xylitol (I) was synthesized in 62% yield by the sodium borohydride reduction of D-xylose and was further identified through conversion to the known penta-*O*-acetyl derivative (6). The other two pentitols (II and III) were commercially available in crystalline form.†

Direct nitration of the pure pentitols in a mixture of fuming nitric acid and acetic anhydride at 0° C (7) gave the crystalline pentanitrate esters in excellent yield (Table I).

Presented in part at the Symposium on the Chemistry, Technology, and Pharmacology of Nitric Acid Esters, 132nd meeting, American Chemical Society, New York, September 8–13, 1957.

The structure and configuration of these high-explosive compounds were established through their nitrogen contents (Table I) and infrared spectra and by nearly quantitative conversion to the parent alcohols on catalytic hydrogenation (Table II).

TABLE I

The pentitol pentanitrates

Pentanitrate	Yield (%)	m.p. (° C)	Nitrogen content (%)[a]
Ribitol	90.2	33.5–34.0	18.2[b]
Xylitol	95.6	37–40	17.8[c]
L-(−)-Arabinitol	97.5	26.5–27.5	18.0[c]

[a]Theoretical value = 18.6%.

% Yield	97.5	95.5	97.5
M.p., ° C	99–101	92–94[a]	101–103
Mixed m.p., ° C	99–102	92.0–94.5	101–103
Reported m.p., ° C	102	93.0–94.5	102
Reference	(9)	(8)	(9)

[a]Stable modification.

The infrared spectra of the pentanitrates of ribitol and xylitol in nujol mull and the spectrum of L-arabinitol pentanitrate as a liquid film showed closely similar peaks near 1650, 1265, and 750 cm^{-1}. The very strong peaks at 1650 and 1265 cm^{-1} were characteristic of covalent nitrate groups (14) and this was probably also true of the medium-to-weak peak near 750 cm^{-1} which has also been observed in a series of other nitrate esters in this laboratory (15). No peaks occurred in the frequency ranges for hydroxyl and carbonyl stretching in saturated acyclic compounds. A strong peak at 2910 cm^{-1} in the spectrum of L-arabinitol pentanitrate was attributed to the methylene group and was not observed in the other spectra since they were compensated with nujol.

The three pentitol pentanitrates reacted with dry pyridine at 20–24° C in much the same manner as D-mannitol hexanitrate (1, 2). The xylitol derivative evolved more gas and the pyridine solution became darker in color than with the arabinitol and ribitol compounds. Partially nitrated sirups were recovered in good yield from the pyridine solutions on dilution with water. The nitrogen contents, solubility, and infrared spectra of these products indicated that they were probably partially nitrated anhydropentitols. Further study of their constitution is in progress.

EXPERIMENTAL

Xylitol

A solution of D-xylose (66.0 g, m.p. 145–6° C, $[\alpha]_D^{22.5}$ +18.9±0.2°) in 400 ml of water was cooled in an ice bath, and a solution of 16.5 g of sodium borohydride in 100 ml of water was added dropwise. The temperature of the mixture rose to 45° C during the addition, the rate of evolution of hydrogen slowly decreased, and the solution became alkaline (pH 9). After the mixture had been standing for 1.5 hours at room temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

reduction was complete as shown by Fehling's test. Excess borohydride was destroyed with 6 *N* acetic acid and the solution was deionized and concentrated to a sirup under reduced pressure. The sirupy xylitol was freed of boric acid by repeated evaporations with methanol and crystallized after seeding with a sample obtained through the courtesy of Dr. M. L. Wolfrom, Ohio State University. After recrystallization from ethanol the xylitol (41.3 g, 61.5%) melted correctly at 93.0–94.5° C (8).

Acetylation of 3.8 g of the xylitol with acetic anhydride and sodium acetate yielded 3.7 g of pure xylitol pentaacetate melting at 62.0–63.5° C after recrystallization from methanol (6).

Nitration of the Pentitols

A suspension of the pentitol (1.0 g) in acetic anhydride (4 ml) was cooled in an ice–salt bath and a cooled solution of fuming nitric acid (5 ml) in acetic anhydride (5 ml) was added slowly with stirring. After 1 hour the reaction mixture was allowed to warm to room temperature during 30 minutes by which time all of the pentitol had dissolved. The mixture was then poured into ice water and the colorless, semisolid product was separated and dried *in vacuo* at 0° C for several days. The pentitol pentanitrate was recrystallized from five parts of dry toluene at about −40° C and was recovered on a glass funnel jacketed with melting chlorobenzene (m.p. −45° C) and fitted with a drying tube. Yields and melting points of the pentitol pentanitrates are shown in Table I together with the nitrogen analyses. The nitrates detonated under the hammer and were not decomposed after they were stored in a desiccator at 0–5° C for 3 years.

Hydrogenation of the Pentitol Pentanitrates

The pentitol pentanitrate (0.5 g) was dissolved in 95% ethanol (100 ml) and hydrogenated over palladium-on-charcoal catalyst (0.5–1.0 g) as previously described (1, 13). The yields, melting points, and mixed melting points of the recovered pentitols are shown in Table II.

The Action of Pyridine on the Pentitol Pentanitrates

The pentitol pentanitrate (100 mg) dissolved readily at 20° C in pyridine (6.2 ml) freshly distilled from barium oxide (b.p. 114.5–116.0° C). Within 2 minutes the initially colorless solution became yellow and evolved a colorless gas while the temperature increased to 24° C. After 6 hours at 20° C the solution was warmed to 50° C for 30 minutes which caused no apparent change in color or rate of gas evolution. The reaction mixture was then diluted with water (8 ml) and extracted with ether. Evaporation of the washed and dried ether extract yielded 50 to 65 mg of a colorless, viscous sirup.

The nitrogen contents of the thoroughly dried products from ribitol, xylitol, and arabinitol pentanitrates were 15.0, 14.5, and 12.5% respectively. These products were insoluble in water, *n*-hexane, and carbon tetrachloride and readily soluble in ethyl acetate, ether, and acetone. The infrared spectra (potassium bromide windows) showed the presence of covalent nitrate groups (1635–1650 cm^{-1} and 1273–1287 cm^{-1} and 747–750 cm^{-1}) and no carbonyl groups. An hydroxyl stretching frequency (3420 cm^{-1}) appeared only in the spectrum of the product from L-arabinitol pentanitrate.

We thank Mr. I. G. Csizmadia for nitrogen analyses and the Defence Research Board of Canada for funds in support of this research.

A TEST OF TRANSITION STATE THEORY

G. O. PRITCHARD,* H. O. PRITCHARD,† G. H. MILLER,* AND J. R. DACEY‡

The transition state theory of the radical combination reactions $CX_3 + CX_3 \rightarrow C_2X_6$ has not yet been satisfactorily formulated because the concept of the transition state itself in the reactions is so indeterminate. Nor is the situation made any easier by the lack of good data on the frequency factors of such combination reactions and of the reverse decompositions. It has, however, been assumed that whatever the transition state may be, there must be free rotation of the CX_3 groups about the incipient C—C bond (1). A further difficulty arises in the calculation of frequency factors because the major contribution to the entropy of activation is dependent on the unknown pressure of the free radicals, since there is a change in the number of species in these reactions (2). Recently, Pritchard and Dacey (3) have obtained a ratio of frequency factors for CX_3 radical combination reactions which can be used as a test of transition state theory because the uncertainties in the formulation of the respective transition states cancel out.

Pritchard and Dacey studied the competition of the three reactions

$$CH_3 + CH_3 \xrightarrow{k_{11}} C_2H_6$$
$$CH_3 + CF_3 \xrightarrow{k_{12}} CH_3CF_3$$
$$CF_3 + CF_3 \xrightarrow{k_{22}} C_2F_6$$

by photolyzing mixtures of CH_3COCH_3 and CF_3COCF_3, and found that the ratio $k_{12}/(k_{11}k_{22})^{\frac{1}{2}} = 0.52 \pm 0.06 \exp[(1070 \pm 100)/RT]$ at pressures where three body restrictions were absent.

Considering the scheme

A TEST OF TRANSITION STATE THEORY

G. O. PRITCHARD,* H. O. PRITCHARD,† G. H. MILLER,* AND J. R. DACEY‡

The transition state theory of the radical combination reactions $CX_3 + CX_3 \rightarrow C_2X_6$ has not yet been satisfactorily formulated because the concept of the transition state itself in the reactions is so indeterminate. Nor is the situation made any easier by the lack of good data on the frequency factors of such combination reactions and of the reverse decompositions. It has, however, been assumed that whatever the transition state may be, there must be free rotation of the CX_3 groups about the incipient C—C bond (1). A further difficulty arises in the calculation of frequency factors because the major contribution to the entropy of activation is dependent on the unknown pressure of the free radicals, since there is a change in the number of species in these reactions (2). Recently, Pritchard and Dacey (3) have obtained a ratio of frequency factors for CX_3 radical combination reactions which can be used as a test of transition state theory because the uncertainties in the formulation of the respective transition states cancel out.

Pritchard and Dacey studied the competition of the three reactions

$$CH_3 + CH_3 \xrightarrow{k_{11}} C_2H_6$$
$$CH_3 + CF_3 \xrightarrow{k_{12}} CH_3CF_3$$
$$CF_3 + CF_3 \xrightarrow{k_{22}} C_2F_6$$

by photolyzing mixtures of CH_3COCH_3 and CF_3COCF_3, and found that the ratio $k_{12}/(k_{11}k_{22})^{\frac{1}{2}} = 0.52 \pm 0.06 \exp[(1070 \pm 100)/RT]$ at pressures where three body restrictions were absent.

Considering the scheme

$$2 \text{ radicals} \xrightarrow{\Delta S^*} \text{transition state} \xleftarrow{\Delta S'} \text{ethane},$$

where ΔS^* and $\Delta S'$ are the entropies of activation in the senses indicated, we may express the observed frequency factor ratio of $A^*_{12}/(A^*_{11}\,A^*_{22})^{\frac{1}{2}} = 0.52\pm0.06$ in the form

$$\Delta S^*_{12}-\tfrac{1}{2}(\Delta S^*_{11}+\Delta S^*_{22}) = -1.30\pm0.2 \text{ e.u.}$$

Rewriting this in terms of the absolute entropies S^*_{11}, S^*_{22}, and S^*_{12} of the activated complexes, we have

$$S^*_{12}-\tfrac{1}{2}(S^*_{11}+S^*_{22}) = -1.30\pm0.2 \text{ e.u.},$$

the absolute entropies of the free radicals having cancelled out.

This entropy difference expression can also be written in terms of the absolute entropies, S_{11}, S_{22}, and S_{12}, of the three ethanes, i.e.,

$$S^*_{12}-\tfrac{1}{2}(S^*_{11}+S^*_{22}) = [S_{12}-\tfrac{1}{2}(S_{11}+S_{22})]+[\Delta S'_{12}-\tfrac{1}{2}(\Delta S'_{11}+\Delta S'_{22})]$$

making, of course, the tacit assumption that the transition states for the forward and reverse reactions are identical.

At 298.15° K and 1 atmosphere, the absolute entropy of ethane is $S_{11} = 54.85$ e.u. (4), that of trifluoroethane is $S_{12} = 66.87$ e.u. (5), and that of hexafluoroethane can be calculated from the data of Pace and Aston (6) to be $S_{22} = 81.85$ e.u. Thus the first bracket becomes -1.48 e.u. In the evaluation of the second bracket we are not critically dependent on an exact formulation of the transition state. We infer that the restricted rotation which exists in each molecule must be freed (1), and that there will be some change in the nature of the vibrations in each ethane, principally associated with the stretching of the C—C bond. The changes in vibrational entropy in the three cases must be so similar as to cancel out when substituted in the second bracket, so that the only significant terms will be changes in entropy associated with the freeing of the restricted rotations. These changes were calculated using the tables of Pitzer (7) and the following experimental data (4, 5, and 6).

	C_2H_6	CH_3CF_3	C_2F_6	
Barrier height	2850	3450	4350	cal/mole
Reduced moment of inertia	2.65×10^{-40}	5.12×10^{-40}	76.7×10^{-40}	g cm^2

They are $(S_t-S_{rr})_{11} = 1.22$ e.u., $(S_t-S_{rr})_{12} = 1.50$ e.u., and $(S_t-S_{rr})_{22} = 1.92$ e.u. and the second bracket becomes -0.07 e.u. We therefore have to compare the experimental data for $[S^*_{12}-\tfrac{1}{2}(S^*_{11}+S^*_{22})]$ of -1.30 ± 0.2 e.u. with the calculated value of -1.55 e.u. (with a possible error at least as large as the experimental one).

The agreement between the two figures is well within the limits of error and provides an excellent over-all test of transition state theory as applied to these combination reactions. Because of the smallness of the rotational term we are unable to discriminate between a transition state with or without free rotation, and can say little more about the frequency factors for the ethane decompositions, other than to note that A'_{12} will be approximately the geometric mean of A'_{11} and A_{22}'.

MAGNETIC PROPERTIES OF MESONAPHTHODIANTHRENE[1]

YOSHIO MATSUNAGA[2]

ABSTRACT

Electron spin resonance absorption was detected in mesonaphthodianthrene and mesonaphthodianthrone. The spectra of both of these compounds consist of, at least, seven lines with a separation of 4.4 oersteds and the central line has a *g*-value of 2.0024±0.0002. The growth of the central line by admission of air was observed in the case of the hydrocarbon. Some suggestions are presented as to the nature of the unpaired electrons in these compounds. The magnitude of the molar diamagnetic susceptibility of mesonaphthodianthrene, after correction for the paramagnetic contribution from the unpaired electrons, is discussed in relation to the molecular structure.

INTRODUCTION

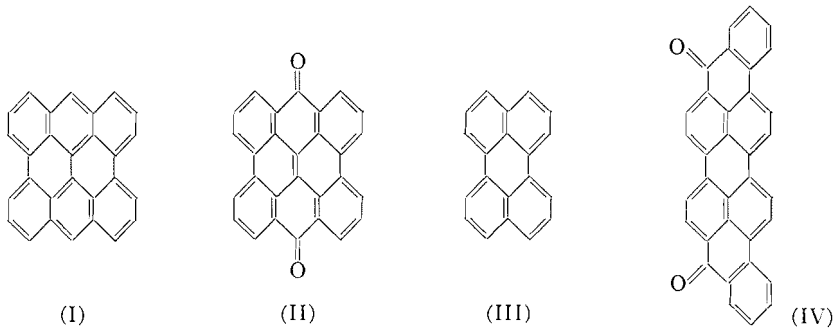
The appearance of unpaired electrons has been reported in crystals of some highly conjugated molecules, namely metal-free phthalocyanine (1, 2), violanthrone (3, 4), violanthrene (3, 4), and binaphthoquinones (5). Here we wish to present the results of a study of mesonaphthodianthrene (I) and mesonaphthodianthrone (II) by the electron spin resonance method. The hydrocarbons studied are compounds which have anomalously small values of diamagnetic susceptibility (6). This anomaly was found to be characteristic of perylene (III) and its analogues. In the sense of the valence-bond theory the central single bonds in perylene, violanthrone (IV), and mesonaphthodianthrene can be doubled only in the excited states.

EXPERIMENTAL

Mesonaphthodianthrone was prepared by photodehydrogenation of bianthraquinone dissolved in pyridine (7). The hydrocarbon was obtained by the zinc-dust fusion of the quinone (8). The latter was found to be reactive towards oxygen, therefore our sample was stored in an evacuated tube after repeated sublimation in high vacuum.

The electron spin resonance was examined at a frequency of 9 kMc/s at room temperature, and at 77° K.

RESULTS



Unlike the spectra of the other paramagnetic polycyclic aromatic compounds, the spectra of mesonaphthodianthrene and its quinone show some structure and this can be modified by admission of air. The spectra of these two compounds consist of at least seven lines with a separation of 4.4 oersteds and spread over 50 oersteds as shown in Fig. 1. The *g*-value of the central peak, estimated by comparison with D.P.P.H. (2.0036), was found to be 2.0024±0.0002. The spin concentration was about 3×10^{21} per mole

[1]*Manuscript received October 16, 1959.*

[2]*N.R.C. Postdoctoral Fellow 1957–59. On leave of absence from Department of Chemistry, University of Tokyo, Tokyo, Japan.*

in the hydrocarbon. This value was not affected by further sublimation nor by cooling to liquid-nitrogen temperature. The spin concentration in the quinone was about one-third of that of the hydrocarbon.

In contact with air the central peak in the spectrum of mesonaphthodianthrene grew slowly. After a few days the intensity of this sharp absorption reached its maximum. The line width of the signal from this oxygen-containing radical was about one oersted at half height. In Fig. 2, a higher magnetic-field modulation was used to detect the broad main absorption, so the central line is artificially broadened. The ratio of the number of unpaired electrons contributing to the sharp absorption to that contributing to the broad one was estimated as about one-tenth at its maximum. By evacuation for a few minutes the intensity of this sharp absorption was decreased considerably; however, only a slow decrease was observed by further prolonged evacuation at room temperature.

No electron spin resonance absorption was detected in bianthraquinone. However, samples heated to 194° C or higher show resonance absorption (9). No structure was observed and the line width at a half height was about twelve oersteds.

(I) (II) (III) (IV)

DISCUSSION

The nature of the broad absorption found in the hydrocarbon and quinone seems not to be simple. Winslow *et al.* (2) suggested that enough thermal energy is absorbed at room temperature to produce unpaired electrons in crystals of highly conjugated, metal-free phthalocyanine. Although the electron spin resonance absorption of naphthalene in a triplet state is too broad to be observed in a randomly orientated system (10), the dipolar interaction, which contributes to line broadening, is proportional to the inverse cube of the electron–electron distance, therefore the resonance absorption of the unpaired electrons in excited states might be detectable in large aromatic molecules like the present hydrocarbon. However, the spin concentration in our samples was found to be independent of temperature as in violanthrone (4).

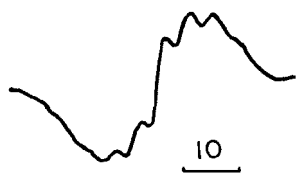

FIG. 1. Derivative of electron spin resonance absorption of mesonaphthodianthrene in vacuum.

Polycyclic aromatic compounds have been known as intrinsic semiconductors and the activation energy for semiconduction was considered as the energy gap between the full

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

band and the empty band (11, 12, 13). Consequently the unpaired electrons in the present compounds cannot be considered charge carriers and must be trapped somewhere. It has been shown that crystals of highly conjugated aromatic molecules contain the imperfections which can behave as traps for charge carriers. Although the nature of the imperfections in molecular crystals is not well known, this term includes not only chemical impurities but also some kinds of lattice defects (14, 15). Because our hydrocarbon and quinone give the same hyperfine structure in resonance absorption, the unpaired electrons must be in a common situation in these compounds. The presence of hyperfine structure can be attributed to the dipolar interaction between an unpaired electron and several ring protons. The line splitting can be given approximately by $28/r^3$ where r is the electron–proton distance (16). The presence of seven or more lines with a separation of 4.4 oersteds suggests that the unpaired electron is surrounded by six or more protons at a distance of about 1.8 Å.

It seems highly likely that the unpaired electrons in our compounds are associated with some common impurity. If the impurity molecule has originally an unpaired electron, this free-radical molecule must be extraordinarily stable and survive through the processes of zinc-dust fusion and repeated vacuum sublimations. Besides, it seems to be unlikely that such a free-radical molecule, which must be formed in the process of photodehydrogenation of bianthraquinone, has six nearly equivalent protons at a distance of about 1.8 Å from the unpaired electron. It is more probable that the impurity molecules which have originally no unpaired electrons can create favorable sites to trap electrons by interaction with the semiconductive host lattice. In this case an unpaired electron may be shared by neighboring molecules and find six or more nearly equivalent protons at a distance as small as 1.8 Å. This situation may be similar to that in aromatic hydrocarbon – iodine complexes which show strong resonance absorption. Therefore, we extended our low-temperature measurements to molecular complexes. For example, perylene–iodine (2 : 3) complex gives a resonance absorption with a g-value of 2.0033. At room temperature the line width at a half power was about eight oersteds and the ratio of the number of unpaired electrons to that of perylene molecules was about 0.07 (17). On cooling to 77° K the line width decreases to about 2.5 oersteds and the spin concentration is estimated as 0.06. Similar decreases of line width were observed in pyranthrene– and violanthrene–iodine complexes. The spin concentration in the latter two is also found to be independent of temperature within the limit of experimental error. If unpaired electrons in these highly conductive molecular complexes are charge carriers, the spin concentration must be decreased by a factor of hundreds by cooling to liquid-nitrogen temperature (18). The appearance of unpaired electrons in hydrocarbon–iodine complexes is apparently related to the complex formation by strong intermolecular charge-transfer forces. However, the whole mechanism is not yet clear.

It is interesting to point out that if we compare the spin concentrations in violanthrone and its hydrocarbon (3, 4) and mesonaphthodianthrene and its quinone, in each pair the member which is of perylene type shows stronger resonance absorption than the other. This fact suggests the importance of the role of the host molecules in the appearance of unpaired electrons. Therefore, it might be possible that without impurity molecules the host molecules associated with some kind of lattice defects can form traps for unpaired electrons; however, at present we have no detailed knowledge of such lattice defects in molecular crystals.

The nature of the unpaired electrons in the other polycyclic aromatic compounds may be similar to those in the present hydrocarbon and quinone. We can hope to resolve

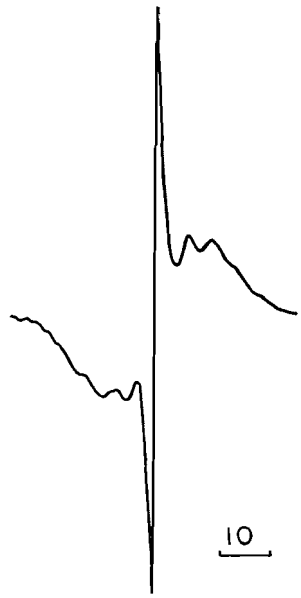

FIG. 2. Derivative of electron spin resonance absorption of mesonaphthodianthrene in air.

broad component lines from dipolar interaction in a randomly orientated solid sample only when the interaction is with equivalent protons. The absence of hyperfine structure in resonance absorption in the other cases may be due to non-equivalence of the interacting protons.

Oxygen molecules, which contribute to the appearance of a sharp line, seem to be combined loosely on the surface of crystals of the hydrocarbon, but the presence of slow diffusion in the formation and dissociation of this free radical is likely. Absence of detectable asymmetry in the sharp absorption line suggests that the new free radical has no axial symmetry; therefore the formation of a peroxide radical is not probable. The effect of oxygen on electron spin resonance absorption has been observed in a number of organic free radicals and carbonaceous materials; however, the effect in most cases is line broadening or disappearance. Similar appearance of a symmetric absorption by admission of air or oxygen has been reported only in the case of tri-*p*-nitrophenylmethyl where the *g*-value is as high as 2.006 (19). Therefore, the present case seems to be an entirely new kind of oxygen effect. Our oxygen-containing free radical, which gives a sharp line with a *g*-value as low as 2.0024, may be some kind of molecular complex formed by interaction between oxygen and the hydrocarbon molecule.

The effect of oxygen on the semiconductivity and the photoconductivity of some highly conjugated aromatic compounds is known (20, 21). Therefore, a study of the effect on the electrical properties of mesonaphthodianthrene might be fruitful in order to elucidate the nature of the oxygen-containing free radical. The semiconductivity of the present hydrocarbon was studied by Inokuchi but the oxygen effect was not considered (12).

Using London's molecular orbital theory for diamagnetic anisotropy of aromatic molecules, Hazato predicted that the conjugation between two naphthalene nuclei in a perylene molecule brings about a decrease of diamagnetic anisotropy from twice that of naphthalene (22). This prediction is qualitatively in agreement with the experimental results. We shall examine here whether or not the same relation is valid for mesonaph-

For personal use only.

thodianthrene and violanthrone after the correction for the paramagnetic contribution from the unpaired electrons. The diamagnetic anisotropy ΔK is defined by the following equation,

$$\Delta K = 3(\chi_m - K_I),$$

where χ_m is the mean molar susceptibility and K_I is the isotropic part of molar susceptibility. The latter can be estimated by empirical rules (23, 24). Following our previous paper (6), the isotropic part will be estimated by

$$K_I \times 10^6 = -3.36 \times N_C - 2.93 \times N_H + 1.73 \times N_O,$$

where N_C, N_H, N_O are the numbers of aromatic carbon atoms, hydrogen atoms, and quinone oxygen atoms in a molecule. The results are summarized in Table I. All the

TABLE I

Diamagnetic susceptibilities and anisotropies of mesonaphthodianthrene and related compounds

Compound	Molar susceptibility (multiplied by 10^6)				
	Total by static method	Paramagnetic part by ESR	Diamagnetic part	Isotropic part	Anisotropy
Naphthalene	−91.9	0	−91.9	−57.0	−105
Perylene	−166.8	0	−166.8	−102.4	−193
Anthracene	−129.4	0	−129.4	−76.3	−159
Mesonaphthodianthrene	−214.6	+6	−220.6	−135.1	−257
Benzanthrone	−142.9	0	−142.9	−84.7	−175

*See reference 4.

necessary values of susceptibility were taken from our previous paper. Although there is uncertainty in the values of the total molar susceptibility and the paramagnetic part because different preparations were used for the measurements with a Gouy balance and with an electron spin resonance spectrometer, it appears that the diamagnetic anisotropy of mesonaphthodianthrene is far less than twice that of anthracene even after the correction for the paramagnetic contribution from the unpaired electrons. A similar relation was found in violanthrone. The large difference between the anisotropy of mesonaphthodianthrene and twice that of anthracene suggests the presence of strong conjugation between two anthracene nuclei in a mesonaphthodianthrene molecule. This conclusion is in accordance with the fact that the difference between the calculated π-electron energy for mesonaphthodianthrene and twice that for anthracene is nearly twice as large as the similar difference for perylene and naphthalene as cited in Table II (25).

TABLE II

Total π-electron energies and average radii of π-electron orbitals in mesonaphthodianthrene and related compounds

Compound	Total π-electron energy by LCAO*	Average radius of π-electron orbital (Å)
Naphthalene	3.68 β	1.57
Perylene	8.24 β	1.51
Anthracene	5.31 β	1.64

The diamagnetic anisotropy is correlated with the average radius of the π-electron orbital $\sqrt{\bar{r}^2}$ by the two-dimensional Langevin's equation,

$$\Delta K = -(Ne^2/4mc^2) \sum \bar{r}^2 = -4.248\times10^{10}\, p\bar{r}^2,$$

where p is the number of π-electrons in a molecule and the other symbols have the usual physical meanings (26). Therefore, as shown in Table II, we must conclude that, on the average, the π-electrons in the mesonaphthodianthrene molecule are less mobile than those in the anthracene molecule.

ACKNOWLEDGMENTS

The author would like to thank Professor C. A. McDowell for his interest and guidance throughout the course of this research. This work was supported by grants from the National Research Council of Canada, and we wish to thank that body for its generosity.

THE REACTIONS OF ACTIVE NITROGEN WITH CYANOGEN AND CN RADICALS[1]

CATHERINE HAGGART[2] AND C. A. WINKLER

ABSTRACT

Cyanogen is destroyed by active nitrogen at temperatures of 80° to 400° C, and nitrogen pressures of 0.34 to 3.1 mm, with the formation of polymer. At 400° C and sufficiently high flow rates of cyanogen, a constant amount is destroyed, which apparently corresponds to practically complete consumption of the available nitrogen atoms.

The formation of CN radicals in the reaction of cyanogen with active nitrogen was established by the production of HCN and CH_3CN when hydrogen or methane was added to the reaction mixture. The rate of destruction of cyanide radicals, when they were transported through a reaction vessel, was determined by introducing hydrogen below the site of reaction, and found to follow first order kinetics.

INTRODUCTION

The reactions of active nitrogen with saturated and unsaturated hydrocarbons have been studied and found generally to produce small amounts of cyanogen in addition to hydrogen cyanide as the main product. The behavior of cyanogen with active nitrogen has therefore been investigated, to assess, if possible, the significance of its presence in the reaction products, in relation to the mechanism of formation of hydrogen cyanide in the hydrocarbon – active nitrogen systems.

EXPERIMENTAL

The apparatus used in this investigation was similar to those described in previous papers from this laboratory (1, 2). A spherical reaction vessel was employed in preliminary experiments to study the reactions of CN radicals, but subsequently a cylindrical vessel made of 28-mm O.D. pyrex tubing was used. Since the results were essentially similar, regardless of the reaction vessel employed, only those results obtained with the cylindrical vessel are reported in detail.

Three nitrogen flow rates were used, 14, 130, and 315 μmoles per second, corresponding to nitrogen pressures of 0.34, 1.4, and 3.1 mm in the reaction vessel. In the experiments in which the nitrogen flow rate was 14 μmoles per second, the total pressure in the reaction vessel was maintained constant at 1.43 mm, by the addition of argon to the nitrogen prior to its introduction into the discharge tube.

As in previous studies, the active nitrogen concentration in the system (assumed to be nitrogen atoms) was estimated from the maximum amount of HCN produced in the ethylene – active nitrogen reaction at 300° C (3).

Cyanogen was analyzed by hydrolysis followed by estimation of the cyanide thus formed. Since the hydrolysis proceeds slowly in water but rapidly and almost quantitatively in sodium hydroxide (4) to produce sodium cyanide and sodium cyanate, the unreacted cyanogen was collected in 10 to 20 ml 10% NaOH and the cyanide was then analyzed by the Liebig–Dénigès method (5).

When methane was added to the cyanogen – active nitrogen reaction mixture, the

[2]*Holder of a C.I.L. Fellowship 1958–59.*

HCN and CH_3CN formed, as well as the unreacted cyanogen, were collected in a known volume of 10% NaOH which was then separated into three equal portions. The cyanide content of the first portion, consisting of HCN and the cyanide from the hydrolysis of cyanogen, was determined by the Liebig–Dénigès method. To the second portion, dilute sulphuric acid was added to expel the HCN, and after this solution was heated for 2 hours, the nitrogen content was determined by a Kjeldahl distillation (5). The value so obtained corresponded to the amount of cyanate present in the original solution due to the hydrolysis of the cyanogen. The difference between the amounts of cyanide and cyanate was equal to the HCN present in the original solution. Since Ouillemard (6) reported that methyl cyanide was quantitatively hydrolyzed by the action of concentrated sulphuric acid to form ammonia and acetic acid, concentrated sulphuric acid was carefully added to the third portion, which had been previously frozen in liquid air, and then the solution was digested at 150° C for 8 hours. After the digestion, the total nitrogen content of the solution was determined by a Kjeldahl distillation. The difference between the total nitrogen content of this last solution and the total cyanide content of the first portion of the original solution provided a measure of the methyl cyanide formed in the reaction.

In the experiments in which hydrogen was added as a second reactant, HCN and cyanogen were present in the reaction products and were separated and analyzed by the method described by Wallis (7) and Rhodes (8). Since HCN, but not cyanogen, reacts with acidified silver nitrate solution, both products were collected in a known volume of standard silver nitrate solution to which a few drops of dilute nitric acid had been added. Cyanogen was quantitatively recovered from the mixture by bubbling nitrogen through the absorber and then into three scrubbers (Wallis bubblers), one containing acidified silver nitrate and two containing 10% sodium hydroxide solution. The excess silver nitrate was titrated with potassium thiocyanate using ferrous ammonium sulphate indicator (5) and the amount of cyanide in the last two bubblers was estimated by the Liebig–Dénigès method (5).

RESULTS AND DISCUSSION

The introduction of even small amounts of cyanogen into the stream of yellow active nitrogen immediately quenched the afterglow and caused the emission of a bright red reaction flame accompanied by the accumulation of a black polymer.

The extent to which cyanogen was destroyed by active nitrogen was determined under various conditions of temperature and pressure and over a wide range of cyanogen flow rates, Fig. 1. At 100° C, and a nitrogen pressure of 1.4 mm, with an active nitrogen concentration of 19.5 μmoles per second, the amount of cyanogen destroyed increased slowly to a constant or plateau value of about 9.5 μmoles per second when the cyanogen flow rate was 90 μmoles per second. Although an increase of temperature to 400° C increased somewhat the rate of destruction of cyanogen, the plateau value, which approximated one-half the nitrogen atom concentration, still was reached only at cyanogen flow rates greater than 85 μmoles per second.

To substantiate these observations, the nitrogen pressure was decreased to 0.34 mm and 7.6 μmoles per second respectively, with the total pressure in the system maintained at 1.4 mm by the addition of argon to the nitrogen prior to its introduction into the discharge tube. The results obtained were similar to those outlined previously, i.e. the amount of cyanogen destroyed increased slowly as the cyanogen flow rate was increased and at 400° C the plateau value for the amount of cyanogen destroyed corresponded to one-half the nitrogen atom concentration.

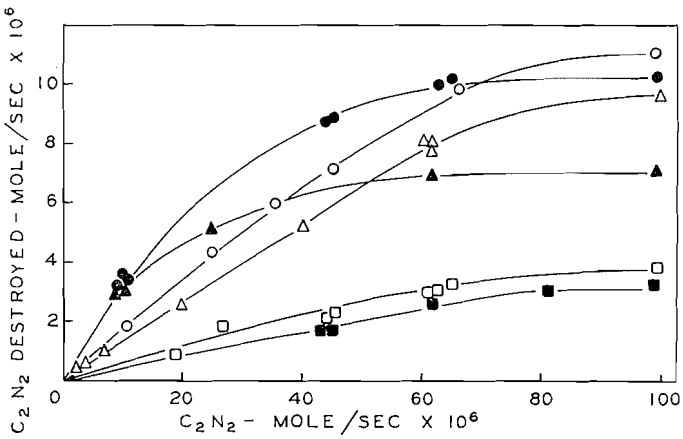

FIG. 1. Relation between amount of cyanogen destroyed by active nitrogen and the cyanogen flow rate. ○ P_{N_2} = 1.4 mm; T = 405° C. ● P_{N_2} = 3.1 mm; T = 410° C. △ P_{N_2} = 1.4 mm; T = 100° C. ▲ P_{N_2} = 3.1 mm; T = 115° C. □ P_{N_2} = 0.34 mm; T = 395° C. ■ P_{N_2} = 0.34 mm; T = 80° C.

The results obtained under the various experimental conditions suggested that NC radicals were formed in the cyanogen – active nitrogen reaction mixture. Since the NC radical, but not cyanogen itself, apparently reacts with hydrogen to produce HCN (9), while hydrogen does not react appreciably with active nitrogen, it seemed that the presence of CN radicals might be detected by the addition of hydrogen to the reaction mixture. Similarly, the addition of methane, which also reacts to a negligible extent with active nitrogen at lower temperatures, might be expected to cause reaction with CN radicals to produce HCN and CH_3CN.

A constant flow rate of hydrogen, 10 μmoles per second, was added to cyanogen prior to its introduction into the stream of active nitrogen. HCN was isolated from the reaction products in amounts which increased with increase of temperature. At flow rates of cyanogen below 6 μmoles per second, all the CN radicals produced in the cyanogen – active nitrogen mixture reacted with hydrogen to form HCN, and polymer formation was virtually eliminated. There was no evidence of a chain reaction, since the amount of HCN isolated was never greater than the amount of CN radicals formed, assuming that two CN radicals were produced for each cyanogen molecule destroyed. As the flow rate of cyanogen was increased, the presence of hydrogen was no longer able to eliminate the formation of polymer at either 124° or 440° C and the yield of HCN reached a plateau value, corresponding to about 30% reaction of the CN radicals with hydrogen.

To determine the amount of hydrogen necessary to react completely with all the CN radicals formed, experiments were made in which the cyanogen flow rate was maintained constant and the flow rate of hydrogen was varied. In this way it was found that at least 90% of the CN radicals produced could be isolated at 100° C as HCN when the hydrogen flow rate was some twenty-five times that of the flow rate of CN radicals, while at 400° C the hydrogen flow rate had to be about fifteen times that of the CN radicals for their complete conversion to HCN.

As an alternative to the large amounts of hydrogen necessary to react effectively with all the CN radicals formed, the use of methane as addend was investigated, since the abstraction of a hydrogen atom by a CN radical would result in the formation of a CH_3 radical which might be expected to combine easily with a second CN radical. When a constant flow rate of 40 μmoles per second of methane was added to the cyanogen at room

For personal use only.

temperature, prior to its introduction into the reaction vessel, both HCN and CH_3CN were isolated from the reaction products. Both products attained plateau values at sufficiently high flow rates of cyanogen when about 60% of the CN radicals were consumed by methane. Unfortunately, the reaction of CN radicals with methane was limited to lower temperatures since the reaction of methane with active nitrogen becomes significant at temperatures above about 250° C.

Since the use of hydrogen permitted a measure of the CN radicals present in the cyanogen – active nitrogen mixture, it was possible to study the rate at which CN radicals were lost in being transported through the reaction vessel. A cylindrical reaction vessel was used so that cyanogen could be introduced into the active nitrogen stream through one inlet and hydrogen through other inlets placed at various distances, 3.1, 7.3, 11.3, and 26.6 cm, below the cyanogen inlet.

When 90 μmoles per second of hydrogen was added to the active nitrogen – cyanogen mixture through the second inlet, it was found that, at low flow rates of cyanogen, the majority of the CN radicals formed reacted with hydrogen to produce HCN. Hence, this amount of hydrogen was introduced through the third, fourth, and fifth inlets and the amount of HCN produced was determined to follow the destruction of CN radicals as they were transported through the reaction vessel.

The rate of destruction of CN radicals appears to follow first order kinetics, Table I. The rate constant at 95° C was 220 ± 10 sec^{-1} and at 400° C 125 ± 10 sec^{-1}. On this basis,

TABLE I

Rate of destruction of CN radicals

N_2 pressure (mm)	T (° C)	Flow rate (μmoles/sec)					
		C_2N_2	CN produced	HCN produced (inlet) 1	2	3	4
1.4	100	2.0	0.8	0.8	0.25	0.09	Nil

		11.5	4.6	4.4		1.3	0.2
0.34	400	44.1	4.4	4.3		2.2	0.68
		45.0	4.3	4.3		2.2	0.7
3.1	410	9.0	6.4	4.5		1.0	Nil

$k_{av} = 220\pm10$ sec^{-1} at low temperature. $k_{av} = 125\pm10$ sec^{-1} at 400° C.

the process responsible for the destruction of CN radicals would have a negative activation energy of roughly -1.5 kcal and might be assumed to involve a wall reaction.

Since small amounts of cyanogen were sufficient to quench the active nitrogen afterglow, it was of interest to determine, if possible, the extent to which nitrogen atoms were destroyed in the process. Since ethylene is known to react rapidly with active nitrogen (3) to produce HCN, the introduction of ethylene into the reaction vessel below the site of the cyanogen – active nitrogen reaction should produce substantial amounts of HCN if relatively little destruction of nitrogen atoms by cyanogen occurred, whereas the formation of relatively small amounts of HCN should indicate that practically all the nitrogen atoms were destroyed by cyanogen. Cyanogen at the rate of 10 μmoles per second was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

admitted into the reaction vessel and the amount of ethylene was varied from 20 to 50 μmoles per second. HCN was formed but the amount isolated was always less than the amount of CN radicals produced, corresponding to reaction of not more than 5% of the nitrogen atoms with ethylene.

Some, at least, of this HCN might have been formed by reaction of CN radicals with ethylene, since a small amount of liquid, possibly acrylonitrile, was formed during the reaction, perhaps by abstraction of a hydrogen atom from ethylene by CN radicals. It may therefore be assumed that at least 95% of the nitrogen atoms were destroyed by small amounts of cyanogen, even though only about 10% of the cyanogen was destroyed in the reaction.

The following series of reaction can account for the observed behavior of the cyanogen – active nitrogen reactions.

$$C_2N_2 + N \rightarrow [C_2N_2 . N] \rightarrow CN + CN_2 \quad (I)$$

$$CN_2 + N \rightarrow CN + N_2 \quad (II)$$

$$2[C_2N_2 . N] \rightarrow 2CN + C_2N_2 + N_2 \quad (III)$$

in competition with the catalytic recombination of nitrogen atoms

$$[C_2N_2 . N] + N \rightarrow C_2N_2 + N_2 \quad (IV)$$

The competition between reactions (I), (II), and (IV) can account for the slow rate at which cyanogen is destroyed by active nitrogen. At high temperatures, the rates of reactions (I) and (II) would be expected to increase, thus using more nitrogen atoms at the expense of reaction (IV), and the concentration of CN radicals would then approach the nitrogen atom concentration.

If only reactions (I), (II), and (IV) are considered, an increase in nitrogen pressure, up to 3.1 mm, would be expected to result in an increase in the rates of all three reactions and no difference should be noted in the rate at which cyanogen was destroyed (Fig. 1). However, it was found that an increase in pressure effected a more rapid rate of destruction of cyanogen and it is then necessary to include reaction (III) which would be expected to occur more readily as the total pressure in the reaction vessel was increased.

It may be noted that the present study does not support the view that the formation of HCN in the reactions of active nitrogen with hydrocarbons involves the initial formation of CN radicals, since such relatively large amounts of hydrogen or hydrocarbon are required to react with one cyanide radical. Furthermore, the results when methane was added indicate that, since hydrocarbon free radicals are presumably formed in the active nitrogen – hydrocarbon reactions, the formation of nitriles would be expected if CN radicals were present in significant amounts, and this behavior is not noted experimentally.

THE REACTIONS OF ACTIVE NITROGEN WITH HYDROGEN SULPHIDE AND CARBON DISULPHIDE[1]

R. A. WESTBURY[2] AND C. A. WINKLER

ABSTRACT

The destruction of either hydrogen sulphide or carbon disulphide by active nitrogen appears to be minimal at some temperature in the range 200–250° C. Both reactions yield large amounts of polymer.

It is postulated that the main reactions involve destruction of the reactant as it acts as a third body for recombination of nitrogen atoms. As the temperature is increased, dissociation of the nitrogen atom – reactant complex apparently increases. To account for the observed temperature effects, it is assumed that reactions also occur to regenerate reactant.

INTRODUCTION

In his pioneering work with active nitrogen, Strutt (1) found it to react with both hydrogen sulphide and carbon disulphide and suggested that the respective reactions were

$$N + H_2S \rightarrow NS + H_2$$

and

$$N + CS_2 \rightarrow NS + CS$$

with subsequent polymerization of the NS and CS radicals. The N–H_2S reaction yielded a light yellow deposit, which was suggested to consist, "at all events in part", of nitrogen sulphide. Two separate polymers were produced in the N–CS_2 reaction. A blue deposit, which formed on the wall of the reaction vessel, was attributed to polymerized NS radicals. A brown-colored deposit, which appeared on the chilled surface of a liquid-air trap, was thought to be the polymeric carbon monosulphide described previously by Dewar and Jones (2).

The reactions have been studied spectroscopically by Strutt and Fowler (3) and by Fowler and Vaidya (4). A banded deep blue reaction flame was observed in both reactions, and Christy and Naude have shown (5) that this spectrum is derived from an allowed transition of the sulphur molecule, corresponding to the Schumann–Runge bands of oxygen. In the N–CS_2 reaction the only evidence for the presence of carbon was afforded by a weak band of the CN radical at λ 3883 Å.

EXPERIMENTAL

The apparatus used in the present study was of the fast-flow type described previously (6, 7).

Hydrogen sulphide (98.5% pure, Matheson) was twice partially fractionated, the first and last portions being rejected each time. This was followed by three complete cycles of thawing, freezing, and pumping to remove residual air, which was followed in turn by distillation from a bath at −78° C, (acetone – dry ice slurry). The gas finally obtained was sufficiently dry that it gave no indication of reaction with a clean mercury surface, while titration with standard alkali showed that, within experimental error, the gas was free of ammonia.

[1]*Manuscript received November 10, 1959.*
Contribution from the Upper Atmosphere Chemistry Research Group, the Physical Chemistry Laboratory, McGill University, with financial assistance from the National Research Council of Canada, Ottawa.
[2]*Holder of research grants, 1956–58, from the Scientific Research Bureau, Province of Quebec, Quebec.*

Ethylene (99%, Ohio Chemical Co.) was also given two bulb-to-bulb fractionations, followed by distillation from a bath at −78° C.

Carbon disulphide (reagent grade, Merck) was cycled four times through a treatment which consisted of cooling it to −78° C, followed by partial evacuation (10 minutes) and warming (to room temperature) to remove air and other possible volatile impurities. It was then dried by passage as a vapor through a column of activated alumina.

In the temperature range −23° C to +6° C, the purified carbon disulphide had a vapor pressure that agreed, within experimental error, with published data (8). To prevent its attack upon stopcock grease when experiments were not in progress, the purified carbon disulphide was stored at liquid-air temperature.

Unreacted hydrogen sulphide, after being absorbed into 15% NaOH solution, was analyzed by acidifying the solution, adding excess standard iodine solution, and then back-titrating with standard thiosulphate solution (9). Blank experiments showed that this scheme of analysis was quite satisfactory.

Ammonia, produced in the N–H_2S reaction, was absorbed in standard acid, which was then back-titrated with standard alkali after the acid solution had been heated to drive off residual hydrogen sulphide.

Hydrogen cyanide, produced in the high-temperature active nitrogen – ethylene reaction as a measure of nitrogen atom concentration, was titrated according to the Liebig–Dénigès method (10).

Unreacted carbon disulphide was estimated by distillation into a small glass bulb, which could then be weighed on an analytical balance. A graph was established to relate the amount of CS_2 to its pressure in a standard volume at room temperature, in order that reactant flow rates might be calculated from pressure–volume measurements.

RESULTS

The N–H_2S *Reaction*

The only reaction flame observed in the reaction was a deep blue glow that appeared to fill the entire upper half of the reaction vessel. This flame was almost invisible under normal artificial illumination, but could be seen clearly in a darkened room.

In conformity with the early qualitative studies of Strutt, a good deal of dark brown polymer was found to result from this reaction. Much of this polymer deposited on the wall of the reaction vessel when the reaction vessel was not heated externally, although a small amount was carried along in the gas stream, and deposited on the connecting tube to the cold trap. When the reaction vessel was heated externally, polymer was not deposited on the wall but on the cooler connecting tube, which gradually became quite black.

A reaction vessel in which polymer had been deposited at lower temperatures could be cleaned by heating it for 2 to 3 hours at 350° C.

The polymer that deposited on the wall of the reaction vessel was not stable. While it deposited as an unbroken layer, it began to evolve gas almost immediately, and after the polymer had been standing under vacuum for 4–5 days a number of "gas pockets", ranging in size from 5 mm to 20 mm, tended to force the polymer layer off the wall. Several attempts were made to remove the polymer layer intact for analysis, but all were unsuccessful. A dilute solution of ammonia, presumably because of its ability to attack the underlying phosphoric acid wall poison, quickly separated the polymer from the wall, while the solution itself became a deep violet color. However, the brown flakes and shreds almost as quickly hydrolyzed to sulphur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Several attempts to remove the polymer layer from the reaction vessel by organic solvents, of which CS_2 appeared to be the most promising, gave unsatisfactory results. Only a small amount of material was ever recovered, much less than by using aqueous ammonia solution. The product obtained upon solvent evaporation was usually a reddish-brown sticky substance, which dried to a hard mass. Attempts to fractionate this substance yielded only oils, but qualitative tests showed it to contain both nitrogen and free sulphur.

When present on the wall of the reaction vessel, the polymer markedly affected the decay of the active nitrogen. It appeared to act as a more efficient poison than the 2% metaphosphoric acid normally used, since the nitrogen afterglow was perceptibly brighter after some polymer had been deposited on the wall. It might be noted that Strutt found hydrogen sulphide to be the most effective of a number of substances that he introduced with the nitrogen to poison the walls of the discharge tube and reaction vessel (11).

Special precautions, which need not be detailed here, were taken to ensure that this poisoning effect did not vitiate the experimental results (12).

The amounts of H_2S destroyed at different flow rates, over a range of temperatures,

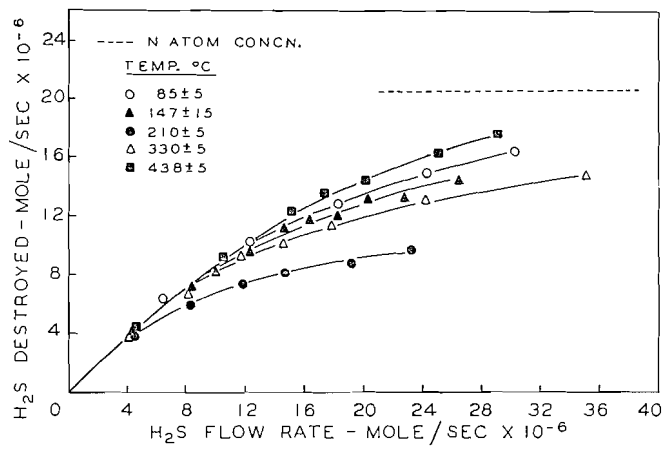

FIG. 1. Relation between H_2S flow rate and amount of H_2S destroyed by active nitrogen at different temperatures.

are shown in Fig. 1. Further experiments using a new discharge tube showed that the reaction was quite reproducible in its behavior with increase in temperature. The amount of ammonia recovered as a product of the reaction was virtually independent of temperature, and accounted for only about 3% of the nitrogen atom concentration, as estimated from the maximum HCN production in the active nitrogen – ethylene reaction.

The N–CS_2 *Reaction*

In this reaction, a pale blue flame was observed to fill the entire reaction vessel at high reactant flow rates, and continue some distance along the connecting tube to the pump. Examination with a small spectroscope (1-in. prism) showed this flame to be a continuum (within the resolution of the instrument) with its limits lying roughly between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

λ 4200 Å and λ 6400 Å. At very low flow rates of CS_2, however, this apparent continuum disappeared, to be replaced by what appeared to be the red and violet band systems of the CN radical.

Preliminary work showed that the reaction deposited a good deal of brown polymer on the wall of an unheated reaction vessel. This polymer was similar in appearance to that produced in the N–H_2S reaction, and it, too, slowly evolved gas upon standing. Most, but not all, of this polymer could be removed from the wall of the reaction vessel by heating it strongly. No analysis of the polymer was attempted, owing to the difficulty of removing it and its ease of hydrolysis, in which respects it resembled the polymer from the N–H_2S reaction.

The reaction was complicated by the appearance of a second polymer, of brownish-black color, which spread as a thin dark film on the tube connecting the reaction vessel to the pump, but deposited mainly on the wall of the first trap cooled with liquid air. This second polymer would seem to be the polymeric carbon monosulphide first described by Dewar and Jones (2), since its deposition, if continued long enough (50–100 seconds, depending upon the flow rate of CS_2) almost invariably resulted in an explosion in the trap.

It was quickly realized that the N–CS_2 reaction could be studied successfully only if the explosions could be prevented. This was necessary, since the reaction was followed by recovery and estimation of the unreacted CS_2 at various reactant flow rates, and it was obvious that the explosions might vitiate the results, apart from possible damage to the apparatus. (On several occasions, at the conclusion of an experiment, a vacuum could not be attained prior to distillation of the trapped CS_2, because the explosion had cracked the wall of the trap).

There are a number of references in the literature to this polymerized carbon monosulphide, but no information was available on possible methods of moderating or eliminating the explosions. Experiments showed that coolants at −112° C or −130° C were only partially successful, in that they did not prevent entirely the explosions that occurred in a following trap cooled with liquid air. However, a slurry of isopentane (approximately −160° C) was completely successful in allowing the reaction products to be condensed without subsequent explosion, and as a consequence a slurry of isopentane was usually used to trap excess CS_2 from the flowing gas stream. No explosion was ever observed with such trapping conditions, and blank experiments showed that CS_2 vapor was trapped quantitatively.

The actual character of the explosions is difficult to describe. During an experiment there would be a sudden sharp "click", a flash of light from the tube, and the liquid-air coolant would bubble vigorously for several seconds, indicative of a quite exothermic reaction. On several occasions the discharge faltered for a few tenths of a second, as if there had been a sudden rise of pressure within the discharge tube. Occasionally, the expected explosion did not occur during the deposition of the CS radical, but did take place 1 to 2 minutes after an experiment had been completed, with the discharge shut off, and no gas flowing through the system.

Analysis of the black polymer deposited at −160° C showed it to be a mixture of paracyanogen and $(CS)x$.

In Fig. 2 are shown the relations between the CS_2 flow rates and the amounts of CS_2 destroyed at different temperatures. These data were quite reproducible. The "Prussian blue" test gave no qualitative indication of cyanogen in the condensible products at any of the three reaction temperatures used.

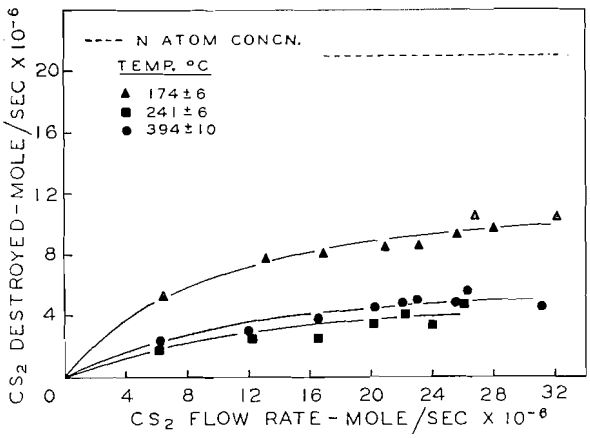

FIG. 2. Relation between CS_2 flow rate and amount of CS_2 destroyed by active nitrogen at different temperatures.

DISCUSSION

It is readily apparent from Figs. 1 and 2 that in both the N–H_2S and N–CS_2 reactions the amount of reactant destroyed passes through a minimum as the temperature is raised. It is tempting to explain this behavior in a similar manner for the two substances, and it will be seen that the proposed mechanisms do have a good deal in common.

The N–H_2S *Reaction*

The initial step involved in this reaction must certainly be the formation of a transition complex

$$N + H_2S \rightarrow N.H_2S. \qquad [1]$$

Decomposition of the complex by the reaction

$$N.H_2S \rightarrow NH + HS \qquad [2]$$

would seem to be improbable, not only because hydrogenation of the imino radical might be expected to yield ammonia in rather larger quantities than those found, but the fast reaction observed does not seem compatible with an activation energy of at least 7 kcal/mole for reaction [2].[3]

The complex might well decompose in the manner suggested by Strutt, i.e.

$$N.H_2S \rightarrow NS(^2\Pi) + H_2 \text{ (see footnote 4)} \qquad [3]$$

since the over-all change represented by reactions [1] and [3] is exothermic to the extent of 44 kcal/mole. However, it does not seem possible to account for the experimental results solely by these reactions.

Decomposition of the $N.H_2S$ complex by reaction [3] involves a change of spin, as well as the splitting of two bonds, and, as such, is likely to require a significant activation energy (13). It is suggested, therefore, that at lower temperatures this complex will have

a lifetime long enough that it might suffer a collision with a second nitrogen atom at low flow rates, or with another $N.H_2S$ complex, at higher flow rates of H_2S, to induce catalytic recombination of nitrogen atoms, with concomitant dissociation of the H_2S molecule. This may be represented at low flow rates of H_2S by

$$N + N.H_2S \rightarrow N_2 + H + HS + 133 \text{ kcal} \quad [4]$$

$$\rightarrow N_2 + 2H + S + 51 \text{ kcal} \quad [5]$$

and at higher flow rates by

$$N.H_2S + N.H_2S \rightarrow N_2 + H_2S + H + HS + 133 \text{ kcal} \quad [6]$$

$$\rightarrow N_2 + H_2S + 2H + S + 51 \text{ kcal} \quad [7]$$

$$\rightarrow N_2 + 2H + 2HS + 41 \text{ kcal.} \quad [8]$$

The hydrogen atoms formed in reactions [4] to [8] should destroy H_2S by the fast reaction

$$H + H_2S \rightarrow H_2 + HS + 11 \text{ kcal} \quad [9]$$

while the HS radicals probably interact by

$$2HS \rightarrow H_2S + S + 10 \text{ kcal} \quad [10]$$

$$\rightarrow H_2 + S_2 + 40 \text{ kcal.} \quad [11]$$

Darwent and Roberts (14) have found, by a steady-state approximation, that at room temperature 87% of the effective collisions of two HS radicals result in reaction [10], and the remaining 13% in reaction [11]. These authors concluded that reactions [10] and [11] occurred rapidly, and without appreciable activation energy. Some, though probably slight, regeneration of H_2S at 35° C might also result from hydrogen atom reaction with sulphur, since experiments showed that hydrogen atoms removed sulphur from the wall of the reaction vessel at room temperature.

The decrease in destruction of H_2S as the temperature is increased to 210° C may now be attributed to the increased recombination of hydrogen atoms at the higher temperature, together with increased regeneration of H_2S from attack of hydrogen atoms on sulphur, perhaps in the gas phase, or as a wall reaction. The apparent increase in destruction of H_2S at still higher temperatures may be explained by assuming that at these higher temperatures, decomposition of the $N.H_2S$ complex by reaction [3] becomes predominant. This follows from the earlier suggestion that this reaction probably has an appreciable activation energy. Decomposition of the $N.H_2S$ complex by reaction [3] would immediately result in a decrease in the production of H atoms and HS radicals, and this in turn should accentuate the decrease in the back reaction [10].

The small amounts of ammonia recovered probably had their origin in the known reaction of nitrogen atoms with hydrogen atoms (15), followed by hydrogenation of the NH radical.

The appearance of polymer is readily understood by polymerization of the NS radical. The monomer might also be produced, particularly at low flow rates of H_2S, by additional reactions such as

$$N + HS \rightarrow NS + H + 33 \text{ kcal,} \quad [12]$$

$$N + S_2 \rightarrow NS + S + 14 \text{ kcal,} \quad [13]$$

[4]*The ground state of the* NS *radical is* $^2\Pi$; *cf. R. F. Barrow, G. Drummond, and P. B. Zeeman. Proc. Phys. Soc. (London), A,* **67**, *365 (1954).*

For personal use only.

and

$$N + S + M \rightarrow NS + M + 115 \text{ kcal.} \quad [14]$$

In addition to a number of nitrogen sulphides in various degrees of polymerization, free sulphur might also be expected to deposit, as observed, on the wall of the reaction vessel or on the connecting tubing.

The N–CS_2 *Reaction*

As for the N–H_2S reaction, it is suggested that the initial step by which carbon disulphide is destroyed by active nitrogen is formation of a complex

$$N + CS_2 \rightarrow N.CS_2 \quad [15]$$

which might be expected to decompose according to

$$N.CS_2 \rightarrow NS(^2\Pi) + CS. \quad [16]$$

Reactions [15] and [16], considered as a whole, are of course equivalent to the over-all reaction suggested by Strutt,

$$N + CS_2 \rightarrow NS + CS.$$

However, this reaction involves a change of spin if, as seems probable from its relatively long lifetime, the CS radical is formed in the singlet state. This relatively long lifetime is clearly indicated since about 0.3 second was required for the CS radical to pass from the reaction vessel to the trap where explosions occurred. Moreover, Parker has found (16) by flash photolysis of CS_2, that the half life of the reaction

$$n\text{CS} \rightarrow (\text{CS})_n \quad [17]$$

was 60 seconds, and he concluded that a half life of this magnitude implied that the CS radical was in the singlet state. Dyne and Ramsay (17) have concluded that, in the gas phase, CS shows the chemical stability of a normal molecule, and this again is consistent only with the singlet state of the radical.

By analogy, then, with H_2S, it is suggested that the destruction of the $N.CS_2$ complex by reaction [16] requires an activation energy, so that, at lower temperatures, the complex may have sufficient lifetime to suffer collision with a further nitrogen atom, at low flow rates of CS_2, or with another complex, at higher reactant flow rates. At low reactant flow rates, the reaction would be

$$N + N.CS_2 \rightarrow N_2 + CS + S + 135 \text{ kcal} \quad [18]$$

while at higher flow rates it would be

$$N.CS_2 + N.CS_2 \rightarrow N_2 + CS_2 + CS + S + 135 \text{ kcal} \quad [19]$$

$$\rightarrow N_2 + 2CS + 2S + 45 \text{ kcal.} \quad [20]$$

It will be noted that the similarity to the mechanism suggested for the N–H_2S reaction is not complete, because there is not enough energy available to break both bonds in the CS_2 molecule.

Again, the results indicate that a reaction to regenerate the parent sulphur compound is an important factor in the mechanism. It might also be inferred from Fig. 2 that this regeneration reaction requires some activation energy, since otherwise more regeneration of CS_2, hence less apparent destruction of it, might have been expected than was actually found at 174° C.

The regeneration step might well be

$$CS + S \rightarrow CS_2^* \rightarrow CS_2 + h\nu \quad [21]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

in which the collision complex is probably in a triplet state to conserve spin. This is by analogy with the reactions

$$CO + O \rightarrow CO_2^* \rightarrow CO_2 + h\nu \text{ (continuous spectrum)} \quad [22]$$

and

$$CO + O + M \rightarrow CO_2^{**} + M \quad [23]$$

followed by

$$CO_2^{**} \rightarrow CO_2 + h\nu \text{ (band spectrum)} \quad [24]$$

by which the CO flame spectrum may be interpreted (18).

Broida and Gaydon (19) have recently concluded, from studies of the oxygen atom – carbon monoxide reaction, that reaction [22] has an appreciable activation energy, while [23] followed by [24], which occurred rapidly at room temperature, was suggested to require little or no activation energy. It is quite possible that reaction [21] might require rather less activation energy than [22], since the CS radical is probably more reactive than CO.

The analogue of reaction [23] is also possible as a regenerative reaction i.e.

$$CS + S + M \rightarrow CS_2^{**} + M \quad [25]$$

followed of course by

$$CS_2^{**} \rightarrow CS_2 + h\nu \quad [26]$$

and by reasoning similar to the above, reaction [25] should have virtually no activation energy.

Choice between [21] and [25] as the main reaction for regeneration of CS_2 probably can be made only on the basis of spectroscopic data, and a spectroscope of sufficient resolution was not available. As indicated earlier, examination of the N–CS_2 flame with a small glass spectroscope revealed the spectrum to be a continuum, but this is scarcely an adequate basis on which to distinguish between the two reactions.

It is apparent that reactions [18] to [21], the last with a small but significant activation energy, are able to explain both the high rate of destruction of CS_2 by active nitrogen at 174° C, and the apparent decrease in the amount of CS_2 destroyed as the temperature is raised. The increase destruction of CS_2 at 394° C relative to that at 241° C can be explained by assuming that, at the higher temperature, the rate of destruction of CS_2 by reaction [16] becomes important relative to its destruction by reactions [18] to [20] and its regeneration by reaction [21]. This explanation is similar to that suggested for the corresponding behavior of the N–H_2S reaction at high temperatures.

The suggestion that reaction [21] has an activation energy raises a question concerning those sulphur atoms and CS radicals, produced at 174° C, that do not react further by [21]. The fate of these entities must be to deposit eventually on the wall of the reaction vessel, although they may also react by reactions [11] and [12], or by

$$N + CS \rightarrow CN + S + 4 \text{ kcal} \quad [27]$$

followed by

$$2CN + M \rightarrow (CN)_2 + M. \quad [28]$$

Reactions [27] and [28] are consistent both with the small amount of paracyanogen present in the CS matrix, and with the appearance of CN bands in the N–CS_2 reaction flame at very low CS_2 flow rates.

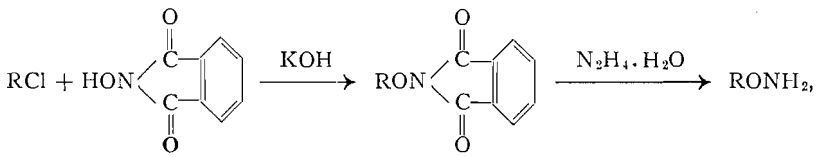
BACTERIOSTATS

III. OXYAMINES AND THEIR DERIVATIVES[1]



A. F. McKay, D. L. Garmaise, G. Y. Paris, and S. Gelblum

ABSTRACT

A number of benzyloxyamines were prepared for conversion into urea and thiourea derivatives. The benzyloxyamine hydrochlorides on treatment with phosgene gave a mixture of the corresponding benzyl 4-(benzyloxy)-allophanate and benzyloxycarbamyl chloride. Triethylamine converted the benzyloxycarbamyl chlorides into the corresponding 1,3,5-tri-(benzyloxy)-isocyanuric acids. The reactions of the allophanates with amines and sodium hydroxide are described.

A series of oxyamine derivatives has been examined for bacteriostatic activity. These O-substituted oxyamines were prepared by one of the following three routes;

$$RCl + HONHCOOC_2H_5 \xrightarrow{KOH} RONHCOOC_2H_5 \xrightarrow[H_2O]{KOH} RONH_2, \qquad [1]$$

[2]

$$RCl + HON(SO_3K)_2 \xrightarrow{KOH} RON(SO_3K)_2 \xrightarrow[H_2O]{H_2SO_4} RONH_2. \qquad [3]$$

The majority of the urea and thiourea derivatives listed in Table I were obtained by the addition of isocyanates or isothiocyanates to a solution of the oxyamine in an inert solvent such as ether or benzene. 1-(β-Hydroxyethyl)-2-(2,4-dichlorobenzyloxyamino)-2-imidazoline was formed by the reaction of 2,4-dichlorobenzyloxyamine with 1-(β-hydroxyethyl)-2-methylmercapto-2-imidazolinium chloride. β-Aminoethylamine dihydrochloride, γ-aminopropyloxyamine, N-(α-naphthylmethyloxy)-urethane, and N,N′-dicarbethoxy-α,α′-di-(aminoöxy)-p-xylene also were prepared during this investigation.

All of the oxythiourea derivatives were unstable. The white crystalline products, after standing at room temperature for several weeks, changed into a mixture of crystals and red, viscous oil. The product from 1-(3,4-dichlorobenzyloxy)-3-(3,4-dichlorobenzyl)-thiourea was separated into free sulphur, 1,3,5-tri-(3,4-dichlorobenzyl)-isomelamine, and unchanged thiourea. In 1891 Voltmer found that heating 1-ethoxy-3-phenyl-thiourea in solution split it into sulphur, ethanol, and phenylcyanamide according to the following equation

$$C_6H_5NHC(S)NHOCH_3 \rightarrow C_6H_5NHCN + S + C_2H_5OH.$$

The scission of crystalline oxythioureas undoubtedly follows a similar course but in this case the generated 3,4-dichlorobenzylcyanamide trimerized to 1,3,5-tri-(3,4-dichlorobenzyl)-isomelamine (m.p. 171–172° C). N^2,N^4,N^6-Tri-(3,4-dichlorobenzyl)-melamine

(m.p. 217–218° C) was prepared from the reaction of cyanuric chloride with 3,4-dichlorobenzylamine for comparison with the isomelamine derivative.

Earlier attempts (2, 3, 4) to prepare esters or salts of the hypothetical acid HONCO have been described in the literature. We also were unsuccessful in preparing the monomeric esters but the corresponding allophanates III and trimers IV were isolated. Phosgene combined with the substituted oxyamines to give the corresponding crude oxycarbamyl chlorides (II).

R = $C_6H_5CH_2$; 4-$ClC_6H_4CH_2$; 4-$NO_2C_6H_4CH_2$; 2,4-$Cl_2C_6H_3CH_2$; 3,4-$Cl_2C_6H_3CH_2$.
R′ = 3,4-$Cl_2C_6H_3$; 4-$ClC_6H_4CH_2$.

4-Chlorobenzyloxycarbamyl chloride (II, R = 4-$ClC_6H_4CH_2$—) on treatment with 2 equivalents of 3,4-dichloroaniline gave the calculated yield of 3,4-dichloroaniline hydrochloride and a 51% yield of 1-(4-chlorobenzyloxy)-3-(3,4-dichlorophenyl)-urea (V, R = 4-$ClC_6H_4CH_2$, R′ = 3,4-$Cl_2C_6H_3$). When 4-chlorobenzylamine was added to crude 4-chlorobenzyloxycarbamyl chloride (II, R = 4-$ClC_6H_4CH_2$) in ether, small amounts of 1,5-di-(4-chlorobenzyl)- and 1-(4-chlorobenzyloxy)-5-(4-chlorobenzyl)-biurets were obtained together with the expected 1-(4-chlorobenzyloxy)-3-(4-chlorobenzyl)-urea (V, R and R′ = 4-$ClC_6H_4CH_2$). This indicates that part of the oxycarbamyl chloride and/or the oxyamine hydrochloride is converted into carbamyl chloride and the corresponding benzyl alcohol under the conditions of the phosgene reaction. The benzyl alcohol could be expected to combine with phosgene or carbamyl chloride to yield 4-chlorobenzyl chloroformate or 4-chlorobenzyl carbamate. These products and the unchanged oxycarbamyl chloride supply the components required in the formation of the allophanates (III). The allophanates in turn combine with amines to give derivatives of biuret (5, 6, 7). When non-anhydrous chlorobenzene was used as a solvent in the reaction of phosgene with 4-chlorobenzyloxyamine hydrochloride, a low yield (11.5%) of 4-chlorobenzyl 4-(4-chlorobenzyloxycarbamyl)-allophanate (VI) was

VI

isolated.

If the oxyamine hydrochlorides (I) are heated to 120–125° in anhydrous chlorobenzene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

during the reaction with phosgene, they are converted mainly into the corresponding benzyl 4-(benzyloxy)-allophanates (III). When benzyloxyamine hydrochloride was treated with phosgene under these conditions, the benzyl group was chlorinated and 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate (III, R = 4-$ClC_6H_4CH_2$) was obtained. Some unchanged oxycarbamyl chlorides remained in solution after the allophanates were recovered by precipitation with ether. The ether solutions on treatment with triethylamine yielded the corresponding 1,3,5-tribenzyloxy-isocyanuric acids (IV). Several of the oxyurea derivatives (V) described in Table I(*A*) were obtained by heating the aralkyl 4-aralkyloxy-allophanates (III) with amines in chlorobenzene under reflux. The main product from the reaction of 4-chlorobenzylamine with 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate was 1-(4-chlorobenzyloxy)-3-(4-chlorobenzyl)-urea (88% yield) but small quantities of *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime and 1,5-di-(4-chlorobenzyl)-biuret also were isolated.

The products from the treatment of 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate (III, R = 4-$ClC_6H_4CH_2$) with alkali indicate that a rather complex series of reactions occur. The allophanate splits partly into 4-chlorobenzyl alcohol, 4-chlorobenzyloxyamine, 4-chlorobenzaldehyde, and 1-(4-chlorobenzyloxy)-urea. Then 4-chlorobenzyloxyamine condenses with the original allophanate to give 1,5-di-(4-chlorobenzyloxy)-biuret. It also could be considered to combine with 4-chlorobenzaldehyde to produce the isolated *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime. When 3,4-dichlorobenzyl 4-(3,4-dichlorobenzyloxy)-allophanate was treated with methanolic sodium hydroxide solution, 3,4-dichlorobenzaldehyde was isolated from the products as its 2,4-dinitrophenylhydrazone. The other product, which was isolated from this reaction, was 1,5-di-(3,4-dichlorobenzyloxy)-biuret.

Absorption Spectra

The infrared absorption bands associated with the N—H and C=O groups are given in Table II. The infrared absorption bands assigned to the C=O stretching modes in the oxyurea derivatives agree with those assigned in the urea series (8). When an aryl group is attached directly to a nitrogen atom of the urea then the absorption band of the C=O group shifts from 1642–1653 cm^{-1} to 1666–1678 cm^{-1}. In the carbamates, the C=O absorption band occurs between the frequencies associated with the ester and amide C=O group (9). Allophanates display two absorption peaks between 1700 and 1718 cm^{-1} which would be expected from the two C=O groups existing in different environments. The biuret derivatives also give two distinct absorption bands at ca. 1703–1710 cm^{-1} and 1672–1687 cm^{-1}. 4-Chlorobenzyl 4-(4-chlorobenzyloxycarbamyl)-allophanate, which contains three C=O groups, displays three strong absorption peaks at 1788, 1760, and 1735 cm^{-1} and another peak at 1688 cm^{-1} on the shoulder of the 1735 cm^{-1} band. In the cyclic isocyanuric acid derivatives three absorption peaks are also discernible. These absorption bands occur at 1794, 1750, and 1738 cm^{-1} with 1,3,5-tri-(4-chlorobenzyloxy)-isocyanuric acid but in the other isocyanuric acids the latter two bands are not resolved distinctly.

Bacteriostatic Activities

None of the compounds listed in Table I(*A*) nor the allophanates displayed strong bacteriostatic activity. The most active compound of this series, i.e., 1-(3,4-dichlorobenzyloxy)-3-(2,5-dichlorophenyl)-urea, inhibited the growth of the following organisms at the minimal inhibitory concentrations given in parentheses; *M. pyogenes* var. *aureus* (Penicillin sensitive) (1:80,000), *Sarcina lutea* (1:80,000), *Streptococcus faecalis* (1:40,000),

1,3,5-Tri-(benzyloxy)-isocyanuric acid		1796(w), 1730[c]	

(w) indicates weak absorption bands. The remainder are strong absorption bands. [a]NO_2 group asymmetric and symmetric absorption bands at 1520 cm^{-1} and 1348 cm^{-1}. [b]Strong absorption band at 1610 cm^{-1} which could be a combination of N—H bending and aryl absorption bands. [c]Doublets. [d]NO_2 group absorption bands at 1530 cm^{-1} and 1350 cm^{-1}.

E. coli No. 198 (1:20,000), *A. aerogenes* (1:20,000), *S. pullorum* (1:20,000), *P. aeruginosa* (1:40,000), and *P. vulgaris* (1:20,000).

EXPERIMENTAL[2]

Benzyl Isothiocyanates

The preparation and properties of the benzyl isothiocyanates, which were used in the preparation of the thiourea derivatives listed in Table I(*A*), have been described (10).

Hydroxyurethan

Hydroxyurethan was prepared in 77% yield by the method of Fuller and King (11).

N,N′-*Dicarbethoxy-α,α′-di-(aminoöxy)-p-xylene*

α,α'-Dichloro-*p*-xylene (8.75 g, 0.05 mole), hydroxyurethan (21.2 g, 0.2 mole), and 85% potassium hydroxide (8.05 g) in absolute ethanol (300 ml) were refluxed for 4.5 hours. The precipitated potassium chloride was removed by filtration and the clear filtrate was neutralized with concentrated hydrochloric acid. Evaporation of the filtrate gave 24.2 g of residue. This residue on treatment with ether – petroleum ether solution gave 13.7 g (71.5%) of solid melting at 90–94°. Several crystallizations from the same solution raised the melting point to 103–104°. Anal. Calc. for $C_{14}H_{20}N_2O_6$: C, 53.84; H, 6.45; N, 8.97. Found: C, 53.92; H, 6.41; N, 8.73.

[2]*All melting points are uncorrected. Microanalyses were determined by Micro-Tech Laboratories, Skokie, Ill. and Schwarzkopf Microanalytical Laboratory, Woodside, New York.*

α-Chloromethylnaphthalene

α-Chloromethylnaphthalene (n_D^{25} 1.63827) was prepared in 44.5% yield by the method of Cambron (12).

α-Naphthylmethyloxyurethan

An absolute ethanol (100 ml) solution of α-chloromethylnaphthalene (27.7 g, 0.16 mole), hydroxyurethan (10.5 g, 0.1 mole), and potassium hydroxide (6.6 g, 85% pure) was refluxed for 4.5 hours. After removal of the potassium chloride (7.7 g) the filtrate was evaporated to dryness, yield 27.7 g. The residue was dissolved in ether (50 ml) and a solid (m.p. 90–92°) was precipitated by the addition of petroleum ether (50 ml), yield 12.58 g, (51.2%). Crystallization from petroleum ether raised the melting point to 93–94°. Anal. Calc. for $C_{14}H_{15}NO_3$: C, 68.54; H, 6.61; N, 5.71. Found: C, 68.60; H, 5.84; N, 5.83.

2-Bromoethylurethan

2-Bromoethylurethan (b.p. 90°/0.6 mm) was prepared in 80% yield by the method of Katchalski and Ishai (13).

2-(N-Carbethoxyamino)-ethyloxyurethan

A solution of β-bromoethylurethan (9.8 g, 0.05 mole), hydroxyurethan (5.8 g, 0.05 mole), and potassium hydroxide (2.8 g, 0.05 mole) in methanol (50 ml) was refluxed for 15 minutes. The precipitate (5.38 g, 90.4%) of potassium bromide was removed and the filtrate was evaporated to dryness. The residue (9.38 g) was distilled *in vacuo*. The second fraction (b.p. 133°/0.18 mm; n_D^{25} 1.45459, d_4^{26} 1.137) weighed 5.23 g (56.8%). Anal. Calc. for $C_8H_{16}N_2O_5$: C, 43.62; H, 7.33; N, 12.73. Found: C, 43.61; H, 7.20; N, 12.88.

2-Aminoethyloxyamine

2-(N-Carbethoxyamino)-ethyloxyurethan (4.4 g, 0.02 mole) and barium hydroxide (10.29 g, 0.06 mole) in water (250 ml) were heated under reflux for 1 hour. The cooled solution was saturated with carbon dioxide and the precipitated barium carbonate was removed by filtration through Celite. The filtrate was acidified with hydrochloric acid and taken to dryness *in vacuo*. The residue (m.p. 165–169° decomp.) on crystallization from methanol–ether solution gave 1.54 g (51.7%) of crystalline hydrochloride melting at 187° with decomposition.

A large-scale preparation gave a 58.6% yield of the dihydrochloride of 2-aminoethyloxyamine melting at 189° C (decomp.). Anal. Calc. for $C_2H_{10}Cl_2N_2O$: C, 16.11; H, 6.77; Cl, 47.58; N, 18.80. Found: C, 16.38; H, 6.87; Cl, 47.53; N, 18.74.

4-Chlorobenzyloxyurethan

A solution of hydroxyurethan (14.2 g, 0.135 mole) and potassium hydroxide (85% grade) (8.9 g, 0.135 mole) in isopropanol (140 ml) was treated with 4-chlorobenzyl chloride (21.6 g, 0.135 mole) in isopropanol (10 ml). After the solution was refluxed for 4.5 hours, the precipitated potassium chloride was removed by filtration and the filtrate was evaporated to dryness. The yield of crude 4-chlorobenzyloxyurethan (m.p. 73–78°) was 21.6 g (69.7%). Crystallization from petroleum ether (b.p. 65–110°) raised the melting point to 85–86°. Anal. Calc. for $C_{10}H_{12}ClNO_3$: C, 52.27; H, 5.27; Cl, 15.44; N, 6.10. Found: C, 52.46; H, 5.26; Cl, 15.75; N, 6.34.

3,4-Dichlorobenzyloxyurethan

Hydroxyurethan (15.4 g, 0.146 mole), 3,4-dichlorobenzyl chloride (28.7 g, 0.146 mole), and potassium hydroxide (9.6 g) in absolute ethanol (150 ml) were refluxed for 4.5 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The potassium chloride was removed by filtration and the filtrate on evaporation gave 35.5 g (91.5%) of white solid (m.p. 57–62° C). Two crystallizations from petroleum ether (b.p. 65–110° C) raised the melting point to 82–83° C. Anal. Calc. for $C_{10}H_{11}Cl_2NO_3$: C, 45.46; H, 4.20; Cl, 27.85; N, 5.30. Found: C, 45.69; H, 4.21; Cl, 27.67; N, 5.58.

N-*Hydroxyphthalimide*

N-Hydroxyphthalimide (m.p. 220–225° C) was prepared in 83% yield by the method of Orndorff and Pratt (14). These authors report a melting point of 220–226° C.

3-N-*Phthalimidopropyloxy*-N-*phthalimide*

A stirred solution of γ-bromopropylphthalimide (150 g, 0.56 mole), N-hydroxyphthalimide (91.7 g, 0.56 mole), and triethylamine (121 g, 1.2 mole) in dimethylformamide (700 ml) was gradually heated to 90° C over a period of 1 hour and maintained at this temperature for another 30 minutes. The cooled reaction mixture was diluted with water (2 l.) and the precipitate (m.p. 177–179° C) was removed by filtration, yield 176 g (89.3%). Two crystallizations from glacial acetic acid (8 ml/g) raised the melting point to 178–180° C. Anal. Calc. for $C_{19}H_{14}N_2O_5$: C, 65.32; H, 4.03; N, 7.99. Found: C, 64.98; H, 4.20; N, 7.96.

3-Aminopropyloxyamine

Hydrazine hydrate (20 g, 0.4 mole) was added to a solution of 3-N-phthalimidopropyloxy-N-phthalimide (35.0 g, 0.1 mole) in dimethylformamide (200 ml) at 70° C. This solution was allowed to cool over a period of 1 hour after which it was diluted with water (300 ml) and the pH was lowered to 3 with hydrochloric acid. The phthalylhydrazide was removed and the filtrate was evaporated *in vacuo* at 40–50°. The residue was dissolved in methanol (1 l.) and the solution was passed through a column of IRA 400 resin (1 l. in OH form previously treated with methanol). The column was washed with methanol (1.5 l.) and the combined eluates were evaporated. Distillation of the residue gave 3.0 g (45%) of product (b.p. 110–115°/3 mm). Redistillation gave pure material (b.p. 99°/40 mm, n_D^{25} 1.4614; d_4^{25} 0.999), yield 2.06 g. Anal. Calc. for $C_3H_{10}N_2O$: C, 39.97; H, 11.19; N, 31.09; M_R 24.75. Found: C, 39.86; H, 11.11; N, 30.83; M_R 24.58.

A portion (0.32 g) of 3-aminopropyloxyamine in methanol was neutralized with dry hydrogen chloride. Ether was added to the mixture and the precipitated dihydrochloride (m.p. 207–208° decomp.) was recovered by filtration, yield 0.46 g (71.2%). One crystallization from methanol–ether solution raised the melting point to 208–209° with decomposition. Anal. Calc. for $C_3H_{12}Cl_2N_2O$: C, 22.10; H, 7.42; Cl, 43.48; N, 17.19. Found: C, 22.25; H, 7.39; Cl, 43.71; N, 16.85.

The dipicrate (m.p. 208–209° decomp.) was formed in the usual manner from aqueous solution. Anal. Calc. for $C_{15}H_{16}N_8O_{15}\cdot H_2O$: C, 31.79; H, 3.20; N, 19.77. Found: C, 32.00; H, 3.73; N, 20.04.

N-(*4-Chlorobenzyloxy*)-*phthalimide*

A methanolic solution of potassium hydroxide (20.2 ml of 4.95 *N* KOH) was added dropwise to a solution of N-hydroxyphthalimide (16.3 g, 0.1 mole) and 4-chlorobenzyl chloride (16.1 g, 0.1 mole) in dimethylformamide (300 ml) at 65° over a period of 1 hour. When the addition was complete, the solution was cooled and diluted with water (1 l.). The precipitate (m.p. 125–130°) was removed by filtration, yield 20.4 g (70.8%). Crystallization from ethanol (60 ml) raised the melting point to 137–138° C. Anal. Calc. for $C_{15}H_{10}ClNO_3$: C, 62.62; H, 3.50; Cl, 12.33; N, 4.87. Found: C, 62.60; H, 3.37; Cl, 12.68; N, 4.76.

N-(3,4-Dichlorobenzyloxy)-phthalimide

N-Hydroxyphthalimide (90.0 g, 0.05 mole) was added portionwise to a stirred solution of 3,4-dichlorobenzyl chloride (108 g, 0.55 mole) and triethylamine (120 g, 1.19 mole) in dimethylformamide (500 ml) at 70° C. When one-half of the N-hydroxyphthalimide was added, a massive precipitate prevented further stirring. The remainder of the phthalimide was added in one portion and the precipitate dissolved while the product separated from solution. The stirring was continued at 70° C for 2 hours. The cooled solution on dilution with water (3 l.) yielded crude N-(3,4-dichlorobenzyloxy)-phthalimide (m.p. 167–171° C), yield 133 g, (74.7%). Recrystallization from methanol raised the melting point to 182–183° C. Anal. Calc. for $C_{15}H_9Cl_2NO_3$: C, 55.92; H, 2.82; Cl, 22.02; N, 4.35. Found: C, 55.97; H, 2.97; Cl, 22.12; N, 4.30.

Dipotassium Hydroxylamine Disulphonate

Solid dipotassium hydroxylamine disulphonate was prepared in 77% yield by the method of Rollefson and Oldershaw (15).

4-Chlorobenzyloxyamine

Method A

A solution of dipotassium hydroxylamine disulphonate (300 g, 0.985 mole) in potassium hydroxide solution (83.7 g, in 560 ml water) was treated with 4-chlorobenzyl chloride (161 g, 1 mole). The stirred mixture was heated on a steam bath for 1.75 hours. After cooling the solid was removed and then refluxed in 1.5 *N* sulphuric acid solution (1000 ml) for 3 hours. The mixture was cooled and made strongly alkaline with 15% sodium hydroxide solution. The mixture was extracted with ether and the dried ethereal extract was taken to dryness. The solid residue (m.p. 35–38°) weighed 80 g (51.5%). Schroeter and Peschkes (16) reported a melting point of 38°. The solid in ether (1 l.) was treated with anhydrous hydrogen chloride and the precipitated 4-chlorobenzyloxyamine hydrochloride (m.p. 243–244° decomp.) was removed by filtration, yield 59 g (60%).

Method B

Potassium hydroxide (10.7 g, 0.19 mole) in water (25 ml) was added to 4-chlorobenzyloxyurethan (10.95 g, 0.098 mole) in isopropanol (60 ml) and this solution was refluxed for 1 hour. Additional water (50 ml) was added and the oily layer was extracted with ether (70 ml). Evaporation of the ether gave 6.5 g (84.2%) of an oil. Fractional distillation *in vacuo* gave 5.53 g (71.6%) of 4-chlorobenzyloxyamine (b.p. 100°/1 mm; m.p. 32–38°) and a second fraction of 1 g (b.p. 150°/1 mm; m.p. 66–71°). The second fraction, after two crystallizations from ethanol (10 ml), melted at 113–114°, yield 0.13 g. The analytical values of this by-product agreed with those calculated for *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime. Anal. Calc. for $C_{14}H_{11}Cl_2NO$: C, 60.00; H, 3.93; Cl, 25.36; N, 5.00. Found: C, 59.81; H, 3.92; Cl, 25.71; N, 5.11. Schroeter and Peschkes (16) reported a melting point of 114° for *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime.

Method C

N-(4-chlorobenzyloxy)-phthalimide (16 g, 0.056 mole) was dissolved in a solution of dimethylformamide (30 ml) in methanol (300 ml). Hydrazine hydrate (6.1 g, 0.123 mole) was added to the solution at 60° and the whole was allowed to stand for 3 hours. The suspension was acidified to pH 2 with 2 *N* hydrochloric acid and the phthalylhydrazide was removed by filtration. The filtrate was taken to dryness and 2 *N* sodium hydroxide solution (75 ml) was added to the residue. This suspension was extracted with ether

(2×40 ml) and the ether extract was distilled to give 3.8 g (57.6%) of 4-chlorobenzyloxyamine (b.p. 95–100°/2 mm; m.p. 38°).

3,4-Dichlorobenzyloxyamine

3,4-Dichlorobenzyloxyamine (b.p. 95–105°/1 mm) was prepared in 88% yield from 3,4-dichlorobenzyloxyurethan by method B described above for the preparation of 4-chlorobenzyloxyamine. A portion (b.p. 121°/3.6 mm; n_D^{25} 1.57140), which had been redistilled in a collar flask, was submitted for analysis. Anal. Calc. for $C_7H_7Cl_2NO$: C, 43.78; H, 3.67; Cl, 36.93; N, 7.29. Found: C, 43.87; H, 3.73; Cl, 36.70; N, 7.55.

A sample of 3,4-dichlorobenzyloxyamine was converted into its picrate in 45.5% yield by treatment with a saturated ether solution of picric acid. Two crystallizations from absolute ethanol – petroleum ether (1:5) solution raised the melting point from 173–175° to 175–176°. Anal. Calc. for $C_{13}H_{10}Cl_2N_4O_8$: C, 37.08; H, 2.39; Cl, 16.84; N, 13.30. Found: C, 37.26; H, 2.48; Cl, 16.96; N, 13.62.

3,4-Dichlorobenzyloxyamine also was prepared in 52% yield from N-(3,4-dichlorobenzyloxy)-phthalimide (method C).

3,4-Dichlorobenzyloxyamine Hydrochloride

3,4-Dichlorobenzyl chloride (190 g, 0.965 mole), dipotassium hydroxylamine disulphonate (303 g, 0.995 mole), and potassium hydroxide (83.7 g) in water (560 ml) were heated on a steam bath for 5 hours. The solid was removed from the cooled solution by filtration, washed with ethanol, and then refluxed in 1.5 *N* sulphuric acid solution (1 l.) for 3 hours. The mixture was made alkaline with 15% sodium hydroxide solution after which it was extracted with ether. Anhydrous hydrogen chloride was bubbled into the dried ether solution and the precipitated 3,4-dichlorobenzyloxyamine hydrochloride was recovered by filtration, yield 58 g (25.4%). Four crystallizations from ethanol raised the melting point from 195–198° C (decomp.) to 200° C (decomp.). Anal. Calc. for $C_7H_8Cl_3NO$: C, 36.78; H, 3.58; Cl, 46.54; N, 6.13. Found: C, 37.00; H, 3.66; Cl, 46.44; N, 6.16.

The hydrochlorides of benzyloxyamine (17), 4-chlorobenzyloxyamine (16), 4-nitrobenzyloxyamine (18), and 2,4-dichlorobenzyloxyamine were prepared similarly in yields of 34.5, 31, 39.5, and 16.5% respectively.

2,4-Dichlorobenzyloxyamine hydrochloride was converted into its free base by treatment with 10% sodium hydroxide. The oil was extracted with ether and distilled *in vacuo* in a collar flask. A sample of the 2,4-dichlorobenzyloxyamine (b.p. 120–121° C/4.6 mm; n_D^{25} 1.57168) was submitted for analysis. Anal. Calc. for $C_7H_7Cl_2NO$: C, 43.78; H, 3.67; Cl, 36.93; N, 7.29. Found: C, 43.91; H, 3.63; Cl, 36.60; N, 7.56.

The picrate formed in 50% yield in the usual manner from ether solution melted at 176–182°. Anal. Calc. for $C_{13}H_{10}Cl_2N_4O_8$: C, 37.08; H, 2.39; Cl, 16.84; N, 13.30. Found: C, 37.10; H, 2.70; Cl, 16.82; N, 13.28.

Reaction of 4-Chlorobenzyloxyamine Hydrochloride with Phosgene

4-Chlorobenzyloxyamine hydrochloride (5.82 g, 0.03 mole) in anhydrous chlorobenzene (60 ml) was saturated with phosgene at room temperature. Phosgene was bubbled through the reaction mixture while the temperature was increased to 95–100° and maintained at this level for 1 hour. Then the excess phosgene was removed by bubbling nitrogen through the reaction mixture and the chlorobenzene was removed *in vacuo*. An oil remained which was considered to be N-(4-chlorobenzyloxy)-carbamyl chloride, yield 6.6 g (100%). Anal. Calc. for $C_8H_7Cl_2NO_2$: N, 6.37; Cl, 32.23. Found: N, 6.98; Cl, 29.87.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The analysis indicated that the oil was not pure. However a part (2.58 g, 0.011 mole) of the oil in ether (100 ml) was treated with 3,4-dichloroaniline (3.80 g, 0.023 mole). The solid 3,4-dichloroaniline hydrochloride was removed by filtration, yield 2.36 g (50% based on added 3,4-dichloroaniline). The filtrate was evaporated to dryness and the residue was crystallized from ethanol, yield 2.07 g (51.2%). One crystallization from ethyl acetate – petroleum ether solution raised the melting point of the 1-(4-chlorobenzyloxy)-3-(3,4-dichlorophenyl)-urea from 135–140° to 150–151°. Anal. Calc. for $C_{14}H_{11}Cl_3N_2O_2$: C, 48.61; H, 3.21; Cl, 30.78; N, 8.11. Found: C, 48.68; H, 3.28; Cl, 30.71; N, 8.48.

4-Chlorobenzyl 4-(4-Chlorobenzyloxy)-allophanate and 1,3,5-Tri-(4-chlorobenzyloxy)-isocyanuric Acid

A suspension of 4-chlorobenzyloxyamine hydrochloride (50 g, 0.257 mole) in chlorobenzene (300 ml) was saturated with phosgene. This reaction mixture was heated at 120–125° for 3.5 hours (until the suspended solid dissolved) while phosgene was bubbled through the reaction mixture. Removal of the chlorobenzene *in vacuo* left a mixed solid and oil residue which was extracted with ether (150 ml). The ether-insoluble 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate (m.p. 147–149° C decomp.) was recovered by filtration, yield 19.55 g (41%). Crystallization from glacial acetic acid raised the melting point to 148–149° with decomposition. Anal. Calc. for $C_{16}H_{14}Cl_2N_2O_4$: C, 52.05; H, 3.82; Cl, 19.21; N, 7.59; mol. wt., 369.20. Found: C, 52.49; H, 3.63; Cl, 19.55; N, 7.90; mol. wt., 398 (Rast).

The ether solution was made alkaline with triethylamine at room temperature. The precipitated solid (m.p. 225–235° decomp.) was removed by filtration and washed with water until the filtrate gave a negative chloride ion test, yield 6 g (12.7%). The melting point of this crude 1,3,5-tri-(4-chlorobenzyloxy)-isocyanuric acid was raised to 248–249° with decomposition by crystallizing from glacial acetic acid. Anal. Calc. for $C_{24}H_{18}Cl_3N_3O_6$: C, 52.34; H, 3.29; Cl, 19.31; N, 7.63; mol. wt., 550.77. Found: C, 52.41; H, 3.22; Cl, 19.20; N, 7.71; mol. wt., 575 (Rast).

When benzyloxyamine hydrochloride was heated with phosgene under the above conditions a 68% yield of 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate (m.p. 148–149° decomp.) and a 4.8% yield of 1,3,5-tri-(4-chlorobenzyloxy)-isocyanuric acid (m.p. 248–249°) were obtained. These compounds were identified by mixed melting point determinations.

In another experiment a suspension of 4-chlorobenzyloxyamine hydrochloride (23.29 g, 0.12 mole) in commercial chlorobenzene (180 ml), which was not dried, was saturated with phosgene at room temperature. Phosgene was bubbled in while the reaction mixture was heated at 95–100° for 1.5 hours and 108–110° for 3 hours. Evaporation of the solution *in vacuo* left a semisolid residue which was triturated with ether (200 ml). The ether-insoluble 4-chlorobenzyl 4-(4-chlorobenzyloxycarbamyl)-allophanate, m.p. 230–260°, was recovered by filtration, yield 2.53 g (11.5% from 2 moles of 4-chlorobenzyloxyamine hydrochloride). Repeated recrystallization from methanol raised the melting point to 271–272°. Anal. Calc. for $C_{17}H_{15}Cl_2N_3O_5$: C, 49.54; H, 3.67; Cl, 17.20; N, 10.20. Found: C, 49.76; H, 3.47; Cl, 17.10; N, 10.50.

Reaction of 4-Chlorobenzylamine with Crude 4-Chlorobenzyloxycarbamyl Chloride

A solution of 4-chlorobenzylamine (11.0 g, 0.078 mole) in ether (50 ml) was added to crude 4-chlorobenzyloxycarbamyl chloride (8.35 g, 0.039 mole) at room temperature. The precipitate of 4-chlorobenzylamine hydrochloride was removed by filtration, yield 5.19 g (75.0%). The filtrate was evaporated and the residue was crystallized from ether, giving

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

a precipitate of 5.10 g, m.p. 113–115°. Recrystallization from chloroform and from ethanol gave 1-(4-chlorobenzyloxy)-3-(4-chlorobenzyl)-urea, m.p. 123–124°, yield 4.34 g, 24.3%. Elementary analysis of this product is given in Table I(*A*). The mother liquors from this crystallization were evaporated (0.65 g, m.p. 130–140° C) and the residue was recrystallized twice from ethanol, giving 1,5-di-(4-chlorobenzyl)-biuret (m.p. 177–178°), yield 0.043 g (0.3%). Anal. Calc. for $C_{16}H_{15}Cl_2N_3O_2$: C, 54.57; H, 4.29; Cl, 20.14; N, 11.93. Found: C, 54.64; H, 4.54; Cl, 19.91; N, 11.64.

The combined mother liquors were evaporated to dryness and dissolved in ether. Anhydrous hydrogen chloride was passed through the ether solution, causing the separation of additional 4-chlorobenzylamine hydrochloride, yield 2.20 g (31.8%). The total recovery of 4-chlorobenzylamine hydrochloride was 53.4% (based on added 4-chlorobenzylamine).

The filtrate was evaporated to dryness and the residue (5.81 g), in benzene, was chromatographed on alumina (240 g). The fraction eluted by ether (1.79 g) was recrystallized from ethanol – petroleum ether. The crystals melted at 84–85°, yield 0.25 g. The analytical values agree with the calculated for ethyl 4-chlorobenzyloxycarbamate. This apparently arose from presence of ethanol in the ether used as solvent. Anal. Calc. for $C_{10}H_{12}ClNO_3$: C, 52.29; H, 5.27; Cl, 15.44; N, 6.10. Found: C, 52.21; H, 5.02; Cl, 15.34; N, 6.14.

A 2% solution of methanol in absolute ether removed a fraction (1.79 g, m.p. 100–110°) from the column which was recrystallized from ethanol to give additional 1-(4-chlorobenzyloxy)-3-(4-chlorobenzyl)-urea, m.p. 123–124°, yield 0.72 g, 5.7%. The total yield of pure urea was 30.0%.

The fraction eluted by 4% methanol in ether consisted of crude 1-(4-chlorobenzyl)-5-(4-chlorobenzyloxy)-biuret (m.p. 140–145°), yield 0.59 g (0.52%). Crystallization from ethanol raised the melting point to 149–150°. Anal. Calc. for $C_{16}H_{15}Cl_2N_3O_3$: C, 52.20; H, 4.11; Cl, 19.26; N, 11.42. Found: C, 52.14; H, 4.22; Cl, 19.35; N, 11.91.

Reactions of 4-Chlorobenzyl 4-(4-Chlorobenzyloxy)-allophanate

A. Alkaline Hydrolysis

A solution of the allophanate (3.69 g, 0.01 mole) in 1,2-dimethoxyethane (100 ml) was added to sodium hydroxide (0.40 g, 0.01 mole) in water (10 ml). After standing at room temperature for 18 hours, the solution was neutralized with hydrochloric acid and evaporated almost to dryness. The residue was diluted with water (30 ml) and extracted with chloroform (2×100 ml). Evaporation of the dried chloroform extract yielded an oily residue (3.4 g) which on crystallization from chloroform gave 1,5-di-(4-chlorobenzyloxy)-biuret (m.p. 173–175°), yield 0.60 g (31.3%). Crystallizations from chloroform and ethyl acetate raised the melting point to 174.5–175.5°. Anal. Calc. for $C_{16}H_{15}Cl_2N_3O_4$: C, 50.02; H, 3.94; Cl, 18.46; N, 10.94. Found: C, 50.02; H, 4.10; Cl, 18.46; N, 11.04.

Repeated recrystallization of the mother liquors from ether yielded a small quantity (0.07 g) of unchanged allophanate (m.p. 148–149°).

Alumina chromatography of the combined mother liquors gave, in the petroleum ether:benzene (1:1) eluate, *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime (108 mg, 7.8% yield) melting at 113–114°. A mixed melting point determination with a known sample of *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime gave no depression. 4-Chlorobenzyl alcohol, melting point and mixed melting point 71–72°, was isolated from the ether:benzene (1:1) eluate, yield 0.238 g (16.7%).

A 10% methanol in ether solution removed 4-chlorobenzyloxyurea from the column.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

This urea melted at 165–166° after recrystallization from ethanol and petroleum ether, yield 0.255 g (12.8%). This product was identified by a mixed melting point determination with a known sample which was prepared as follows: A solution of 4-chlorobenzyloxyamine hydrochloride (1.0 g, 0.0051 mole) and potassium cyanate (0.42 g, 0.0051 mole) in water (25 ml) was refluxed for 5 hours. 4-Chlorobenzyloxyurea (m.p. 163–165°), separated from the cooled solution, yield 0.82 g (86.3%). Crystallization from ethanol – petroleum ether solution raised the melting point to 165–166°. Anal. Calc. for $C_8H_9ClN_2O_2$: C, 47.82; H, 4.52; Cl, 17.65; N, 13.95. Found: C, 47.96; H, 4.52; Cl, 17.93; N, 14.16.

B. Reaction with 4-Chlorobenzylamine

A solution of the allophanate (1.93 g, 0.0052 mole) and 4-chlorobenzylamine (1.47 g, 0.0104 mole) in chlorobenzene (20 ml) was refluxed for 90 minutes. The solution was evaporated to dryness and the residue was crystallized from chloroform, giving 1-(4-chlorobenzyl)-3-(4-chlorobenzyloxy)-urea (m.p. 123–124°), yield 1.51 g, (88.5%). The urea was identified by a mixed melting point determination.

The mother liquors were combined and evaporated to dryness, and the residue on crystallization from petroleum ether weighed 0.55 g (2.1%). It did not depress the melting point of a known sample of 1,5-di-(4-chlorobenzyl)-biuret (m.p. 177–178°).

Chromatography of the remaining mother liquors gave crystals of *O*-(4-chlorobenzyl)-4-chlorobenzaldoxime (m.p. 113–114°), yield 0.073 g (10.0%), and a very small quantity of a substance which sublimed readily to give crystals melting at 90–91°. The aldoxime was identified by a mixed melting point determination.

The other allophanates described in this paper were treated with 4-chlorobenzylamine in the same way. The resulting unsymmetrical ureas are described in Table I(*A*).

4-Chlorobenzyl Chloroformate

4-Chlorobenzyl alcohol (21.4 g, 0.15 mole) and quinoline (19.4 g, 0.15 mole) were added to a stirred solution of phosgene (61 g, 0.165 mole) in toluene (75 ml), and the mixture was allowed to stand for 36 hours. The quinoline hydrochloride was removed by filtration, and the filtrate was evaporated to dryness at 40–45°. An attempt to distill the crude chloroformate resulted in the isolation of 4-chlorobenzyl chloride, b.p. 72–74° (1.4 mm) (hexamethylenetetramine salt, melting point and mixed melting point 200° decomp). The undistilled chloroformate (2.05 g, 0.01 mole) in ether (50 ml) was added to 3,4-dichlorobenzylamine (3.52 g, 0.02 mole) in ether (50 ml) at room temperature. The precipitated 3,4-dichlorobenzylamine hydrochloride (1.10 g, 52%) was filtered, and the filtrate was concentrated to 10 ml. Addition of petroleum ether caused the separation of 4-chlorobenzyl N-3,4-dichlorobenzylcarbamate (m.p. 94–96°), yield 1.55 g, (45%).

Recrystallization from ethanol – petroleum ether raised the melting point to 95–96°. Anal. Calc. for $C_{15}H_{12}Cl_3NO_2$: C, 52.28; H, 3.51; Cl, 30.87; N, 4.06. Found: C, 52.16; H, 3.80; Cl, 30.68; N, 3.95.

The reaction of 4-chlorobenzyl chloroformate with potassium cyanate and potassium thiocyanate did not yield any identifiable products.

1,3-Di-(4-chlorobenzyloxy)-urea

A solution of phosgene (0.2 g, 0.002 mole) in toluene (7.5 ml) was added to a stirred and cooled solution of 4-chlorobenzyloxyamine (1.1 g, 0.007 mole) in benzene (25 ml). The precipitate of 4-chlorobenzyloxyamine hydrochloride was removed by filtration and the filtrate was evaporated to dryness. 1,3-Di-(4-chlorobenzyloxy)-urea (m.p. 116–118°) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

obtained from a solution of the residue in chloroform by addition of petroleum ether, yield 0.418 g (68%). One crystallization from ethanol raised the melting point to 117–118°. Anal. Calc. for $C_{15}H_{14}Cl_2N_2O_3$: C, 52.80; H, 4.14; Cl, 20.78; N, 8.21. Found: C, 52.74; H, 4.11; Cl, 20.68; N, 8.21.

4-Chlorobenzylcarbamate

A mixture of 4-chlorobenzyl alcohol (2.84 g, 0.02 mole), urea (0.60 g, 0.01 mole), and stannic chloride (0.04 g, 0.00015 mole) was stirred at 150° for 8 hours. The cooled reaction mixture was triturated with ether, giving 4-chlorobenzyl carbamate (m.p. 134–137°), yield 1.03 g (55.6%). Crystallization from ethanol raised the melting point to 136.5–137.5°. Anal. Calc. for $C_8H_8ClNO_2$: C, 51.76; H, 4.34; Cl, 19.11; N, 7.55. Found: C, 51.62; H, 4.37; Cl, 19.09; N, 7.25.

3,4-Dichlorobenzyl 4-(3,4-Dichlorobenzyloxy)-allophanate and its Treatment with Methanolic Sodium Hydroxide

3,4-Dichlorobenzyloxyamine hydrochloride was treated with phosgene in anhydrous chlorobenzene at 120–125° as described above in the preparation of 4-chlorobenzyl 4-(4-chlorobenzyloxy)-allophanate. 3,4-Dichlorobenzyl 4-(3,4-dichlorobenzyloxy)-allophanate (m.p. 121–123°) was obtained in 75.5% yield. Crystallization from glacial acetic acid raised the melting point to 125–126° (decomp.). Anal. Calc. for $C_{16}H_{12}Cl_4N_2O_4$: C, 43.87; H, 2.76; Cl, 32.38; N, 6.32; mol. wt., 438.11. Found: C, 44.19; H, 2.61; Cl, 32.67; N, 6.65; mol. wt., 430 (Rast).

A solution of the allophanate (2.19 g, 0.005 mole) and sodium hydroxide (0.2 g, 0.005 mole) in methanol (250 ml) was heated to boiling and then allowed to stand for 3 days. The solution was concentrated almost to dryness and then diluted with water. It gave an oily solid which was filtered and washed with ether. The crystalline residue of 1,5-di-(3,4-dichlorobenzyloxy)-biuret, melted at 156–158°, yield 0.83 g (57%). Crystallization from methanol raised the melting point to 157–158°. Anal. Calc. for $C_{16}H_{13}Cl_4N_3O_4$: C, 42.42; H, 2.89; Cl, 31.31; N, 9.28. Found: C, 42.30; H, 3.09; Cl, 31.36; N, 9.04.

The ether washings were evaporated and the residue was treated with an excess of 2,4-dinitrophenylhydrazine in ethanol. The 2,4-dinitrophenylhydrazone of 3,4-dichlorobenzaldehyde, (m.p. 308–309°) was recovered by filtration, yield 0.45 g (25%). It was identified by a mixed melting point determination with a known sample of the 2,4-dinitrophenylhydrazone of 3,4-dichlorobenzaldehyde.

4-Nitrobenzyl 4-(4-Nitrobenzyloxy)-allophanate and 1,3,5-Tri-(4-nitrobenzyloxy)-isocyanuric Acid

4-Nitrobenzyloxyamine hydrochloride on treatment with phosgene under the conditions described above for 4-chlorobenzyloxyamine hydrochloride gave an 81% yield of 4-nitrobenzyl 4-(4-nitrobenzyloxy)-allophanate (m.p. 183–185° decomp.). Crystallization from glacial acetic acid raised the melting point to 184–185° (decomp.). Anal. Calc. for $C_{16}H_{12}N_4O_8$: C, 49.01; H, 3. 61; N, 14.36; mol. wt., 390.30. Found: C, 49.18; H, 3.62; N, 14.60; mol. wt., 395 (Rast).

Treatment of the ether extract with triethylamine gave a 2.9% yield of 1,3,5-tri-(4-nitrobenzyloxy)-isocyanuric acid (m.p. 183–220° decomp.). The melting point was raised to 251–252° (decomp.) by crystallization from glacial acetic acid, yield 0.8%. Anal. Calc. for $C_{24}H_{18}N_6O_{12}$: C, 49.49; H, 3.12; N, 14.43. Found: C, 49.75; H, 3.04; N, 14.15.

2,4-Dichlorobenzyl 4-(2,4-Dichlorobenzyloxy)-allophanate and 1,3,5-Tri-(2,4-dichlorobenzyloxy)-isocyanuric Acid

When 2,4-dichlorobenzyloxyamine hydrochloride was treated with phosgene under the same conditions, a 34.5% yield of 2,4-dichlorobenzyl 4-(2,4-dichlorobenzyloxy)-allophanate (m.p. 95–98° decomp.) was obtained. Crystallization from glacial acetic acid raised the melting point to 97–98° (decomp.). Anal. Calc. for $C_{16}H_{10}Cl_4N_2O_4$: C, 43.87; H, 2.76; Cl, 32.38; N, 6.32; mol. wt., 438.11. Found: C, 44.28; H, 2.50; Cl, 32.62; N, 6.38; mol. wt., 438 (Rast).

The ether extract on addition of triethylamine gave 0.5% yield of 1,3,5-tri-(2,4-dichlorobenzyloxy)-isocyanuric acid (m.p. 198–200° decomp.). It melted at 201–202° (decomp.) after crystallization from glacial acetic acid. Anal. Calc. for $C_{24}H_{15}Cl_3N_3O_6$: C, 44.07; H, 2.31; Cl, 32.53; N, 6.43. Found: C, 44.25; H, 2.37; Cl, 32.41; N, 6.27.

1,3,5-Tribenzyloxy-isocyanuric Acid

A suspension of benzyloxyamine hydrochloride (9.57 g, 0.060 mole) in chlorobenzene (81 ml) was saturated with phosgene at room temperature. The flow of phosgene was continued while the reaction mixture was heated at 105–110° for 2 hours. The clear solution was evaporated *in vacuo* and the residual oil was dissolved in ether (40 ml). This solution was made basic with triethylamine and the precipitate was filtered and washed with water, yield 4.6 g (51.5%). The melting point was raised from 225–235° (decomp.) to 239–241° (decomp.) by crystallization from glacial acetic acid. Anal. Calc. for $C_{24}H_{21}N_3O_6$: C, 64.29; H, 4.73; N, 9.39; mol. wt., 447.42. Found: C, 64.45; H, 4.61; N, 9.59; mol. wt., 449 (Rast).

Urea and Thiourea Derivatives

The urea and thiourea derivatives prepared by the reaction of isocyanates and isothiocyanates with substituted oxyamines are described in Table I. The following procedure was used in the preparation of all of these derivatives.

4-Chlorobenzyl isothiocyanate (0.82 g, 0.004 mole) in ether (5 ml) was added to 4-chlorobenzyloxyamine (0.71 g, 0.004 mole). The ether on evaporation gave a crystalline residue (m.p. 107–111°), yield 1.51 g (99%). Crystallization from absolute ethanol raised the melting point to 115–116° C.

1-(β-Hydroxyethyl)-2-methylmercapto-2-imidazolinium Chloride

A mixture of 1-(β-hydroxyethyl)-2-imidazolidinethione (19) (612 g, 4.3 moles), methyl chloride (660 g, 13 moles), and isopropanol (1450 ml) was heated at 55–60° C under 30–70 p.s.i. in an autoclave with stirring for 6 hours. A quantitative gravimetric estimation of chloride ion at the end of the reaction period indicated a 92% conversion of the cyclic thiourea to 1-(β-hydroxyethyl)-2-methylmercapto-2-imidazolinium chloride. The autoclave was emptied and washed with isopropanol (2×200 ml). The combined washings and reaction mixture on cooling at 0° C for several hours deposited crystals. These crystals (m.p. 104–106° C) were recovered by filtration, yield 394 g (48%). The remainder of the product was obtained by evaporation of the filtrate *in vacuo*. Crystallization of the crude product from isopropanol raised the melting point to 105–106° C. Anal. Calc. for $C_6H_{13}ClN_2OS$: C, 36.63; H, 6.66; Cl, 18.02; N, 14.24; S, 16.29. Found: C, 37.02; H, 6.95; Cl, 17.92; N, 14.10; S, 15.91.

1-(β-Hydroxyethyl)-2-(2,4-dichlorobenzyloxyamine)-2-imidazoline

1-(β-Hydroxyethyl)-2-methylmercapto-2-imidazolinium chloride (19.67 g, 0.1 mole) and 2,4-dichlorobenzyloxyamine (19.20 g, 0.1 mole) in isopropanol (100 ml) were heated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

under reflux for 2 hours. Methyl mercaptan was evolved during the reaction. After the solution stood at 25° C overnight some solid (m.p. 124–125° C), precipitated, yield 2.09 g (11.9%). The melting point was raised to 125–126° C by crystallization from isopropanol. The analyses agree with the calculated values for *O*-(2,4-dichlorobenzyl)-2,4-dichlorobenzaldoxime. Anal. Calc. for $C_{14}H_9Cl_4NO$: C, 48.18; H, 2.60; Cl, 40.64; N, 4.01. Found: C, 48.37; H, 2.61; Cl, 40.46; N, 4.03.

The residue obtained on evaporation of the filtrate to dryness was treated with excess sodium hydroxide solution and the basic solution was extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulphate. Evaporation of the ether gave a solid melting at 103–105°, yield 18.04 g (59.2%). Crystallization from absolute ethanol – petroleum ether solution raised the melting point to 109–110°. Anal. Calc. for $C_{12}H_{15}Cl_2N_2O_2$: C, 47.37; H, 4.97; Cl, 23.31; N, 13.81. Found: C, 47.67; H, 5.11; Cl, 23.60; N, 14.05.

Isolation of 1,3,5-Tri-(3,4-dichlorobenzyl)-isomelamine

An analytical sample of 1-(3,4-dichlorobenzyloxy)-3-(3,4-dichlorobenzyl)-thiourea (m.p. 107–108°) on standing at room temperature for 2 weeks changed into a mixture of red oil and crystals. A portion (3.95 g) of this mixture was triturated with ether (50 ml) and the insoluble material (m.p. 151–156°) recovered. The solid was taken up in acetone (30 ml) and the insoluble free sulphur (0.11 g, m.p. 116°) was removed by filtration. The filtrate on dilution with water gave 0.72 g of product melting at 168–170°. Two crystallizations from acetone–water solution raised the melting point to 171–172°. Anal. Calc. for $C_{24}H_{18}Cl_6N_6$: C, 47.78; H, 3.01; Cl, 35.27; N, 13.93; mol. wt., 603.18. Found: C, 47.78; H, 3.19; Cl, 35.90; N, 13.82; mol. wt., 580 (Rast).

N^2,N^4,N^6-*Tri-(3,4-dichlorobenzyl)-melamine*

3,4-Dichlorobenzylamine hydrochloride (12.66 g, 0.06 mole) was treated with an excess of 25% sodium hydroxide solution and the free amine was extracted with ether (100 ml). The dried ether solution was treated with cyanuric chloride (1.84 g, 0.01 mole). An exothermic reaction occurred and the ether solution began to reflux. The ether was replaced with *o*-xylene and the mixture was refluxed for 4 hours. The solvent was removed *in vacuo* and the semisolid residue was triturated with acetone (50 ml). The insoluble material (m.p. 210–215°) was removed by filtration, yield 7 g. One crystallization from water raised the melting point to 244°. This solid was identified as 3,4-dichlorobenzylamine hydrochloride by a mixed melting point determination.

The acetone filtrate on dilution with petroleum ether (50 ml) gave crystals which melted at 203–214°, yield 1.84 g (20.9%). Crystallization from absolute ethanol raised the melting point to 217–218°. Anal. Calc. for $C_{24}H_{18}Cl_6N_6$: C, 47.78; H, 3.01; Cl, 35.27; N, 13.93; mol. wt., 603. Found: C, 47.66; H, 3.39; Cl, 35.77; N, 14.11; mol. wt., 643 (Rast).

ACKNOWLEDGMENTS

The bacteriostatic activities reported in this paper were determined by Dr. H. A. Baker of Ayerst, McKenna and Harrison Limited, Montreal, Quebec. The infrared spectra were run by Dr. C. Sandorfy of the University of Montreal, Montreal, Quebec.

PROTON MAGNETIC RESONANCE ABSORPTION IN THE C-FORM OF STEARIC ACID[1]

R. F. GRANT[2] AND B. A. DUNELL

ABSTRACT

The proton magnetic resonance absorption in the C-form of stearic acid has been measured over a temperature range from −78° C to the melting point. The results suggest that the methyl end groups may be free to rotate about their triad axes throughout this temperature range, and that premelting becomes significant above 40° C.

INTRODUCTION

Proton magnetic resonance absorption measurements are sometimes useful for determining the nature and extent of molecular motion in solid organic compounds. This method has been successfully employed in the study of several long chain hydrocarbon compounds. For instance, it has been shown that the methyl groups at the ends of *n*-pentane and *n*-hexane molecules may undergo reorientation about their triad axes at temperatures well below the melting points of these compounds (1). Moreover, considerable reorientation of whole molecules has been reported in the high temperature phases of solid octacosane, *n*-dotriacontane, and lauryl alcohol (2). With the onset of molecular motion, there is a decrease of the proton magnetic resonance line width, if the rate of molecular reorientation is comparable to or greater than the line width expressed in frequency units. The extent of the narrowing will depend upon the rate and nature of the reorientation. Rapid reorientation of the whole molecule about many axes, which may occur in liquids, leads to very narrow line widths.

No extensive motion of stearic acid molecules in the solid has been reported. However, stearic acid exhibits a large, anomalous increase in volume between 60° C and the melting point, 69.6° C (3). Such behavior in long chain hydrocarbon compounds has sometimes been attributed to premelting (4). The following is an investigation of this possibility.

EXPERIMENTAL

The stearic acid used in this investigation was Eastman Kodak white label grade with a freezing point of 68.1° C. The stearic acid was purified by numerous crystallizations at −20° C from freshly distilled acetone, after the method outlined by Brown and Kolb (5). The freezing point of the purified stearic acid was 69.3° C obtained from the plateau of a time – temperature cooling curve run on a 6-g sample of the purified acid using a calibrated thermometer. This value agrees very well with the best setting points (s.p.) obtained by Francis and his co-workers (6, 7), viz., 69.35 and 69.32° C for stearic acid, and indicates that at most a very small amount of impurity was present in our sample. Indeed, Francis, Collins, and Piper found that 1% of palmitic acid impurity added to pure stearic acid (s.p. 69.32° C) lowered the setting point to 69.08° (7).

Narrow proton magnetic resonance line widths from molten stearic acid were recorded with a Varian V-4300 high resolution spectrometer operating at 40 Mc/sec. The broad line widths from solid stearic acid were measured with an oscillating detector spectrometer of conventional design (8), operating at 28 Mc/sec. A Varian electromagnet with

6-in. pole faces and a 1.75-in. gap supplied the magnetic field, which was swept linearly in time and modulated at 27 c/sec.

The samples were placed in 10-mm O.D. Pyrex test tubes. These were maintained at the higher temperatures by arranging the sample container in a glass tube through which hot air was passed from an external heater. Low temperatures were obtained by immersing the sample container in a mixture of dry ice and acetone in a narrow glass dewar. The temperature was measured with a copper–constantan thermocouple placed directly in the sample. The temperature variation during the recording of a magnetic resonance signal was about $\pm 0.5°$ C. The widths of the proton magnetic resonance absorption lines were taken as the separation in gauss of the points of maximum and minimum slope, which are the maximum and minimum of the recorded derivative signal. The second moments of the resonance absorption lines (9) were obtained from the experimental derivative curves by numerical integration (10) and were corrected for the broadening effects of modulation (11).

RESULTS

Although the proton magnetic resonance signal of stearic acid showed no fine structure from $-77°$ C to about room temperature, at about 24° C the derivative absorption line began to show a narrow peak along with the usual broad peak expected for a solid paraffin. Above 24° C this narrow peak became more and more prominent until finally the broad peak almost disappeared. The selection of first derivative lines in Fig. 1 serves to illustrate this behavior. The variation of line width with temperature for the broad peak of the resonance curve from the purified stearic acid is given by Fig. 2. Over the temperature range from $-77°$ C to 66° C, the line width remains approximately constant with values ranging from 14.0 gauss to 14.6 gauss. At 67° C the broad component of the resonance curve is so weak that its width is difficult to measure accurately. A trace of the broad component remains, however, until 69° C.

The true width of the narrow component of the resonance line was not obtained directly. The line width of 0.1 gauss obtained with the broad line spectrometer was

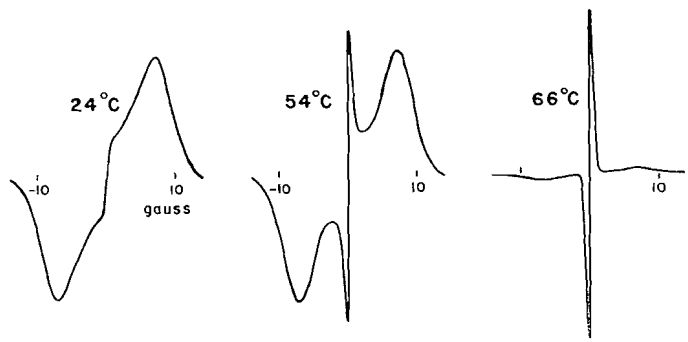

FIG. 1. Examples of derivative absorption curves showing growth of narrow component.

considered to be due to the inhomogeneity of the magnetic field over the sample and to modulation broadening. High resolution spectra from stearic acid were therefore obtained as the molten acid slowly solidified. No proton magnetic resonance absorption could be observed below the freezing point with the high resolution spectrometer, but just before freezing the line width was 0.01 gauss. The true widths of the narrow peaks of the resonance lines are, then, somewhere between 0.1 and 0.01 gauss.

The second moments of the proton magnetic resonance absorption lines decreased as the temperature approached the melting point if one took the second moment of the total curve, including the narrow peak. However, when the narrow peaks on the broad resonance lines were removed by a procedure first employed by Wilson and Pake (12), the second moment values remained almost constant throughout the whole temperature range. These second moment results from stearic acid are given as a function of temperature in Fig. 2.

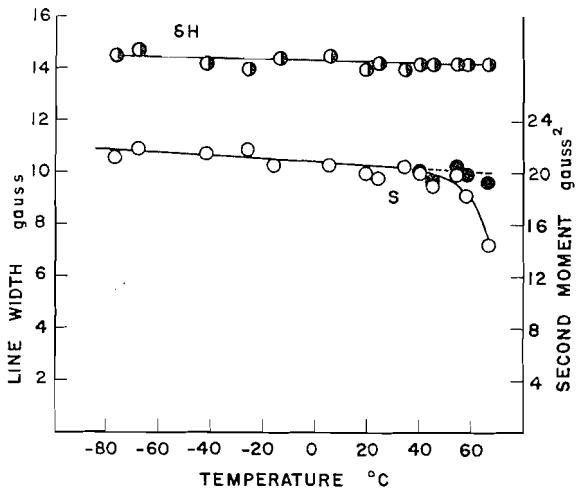

FIG. 2. Line width of broad portion of signal and second moment of stearic acid as functions of temperature. Half-filled circles, line width; open circle, second moment of the entire resonance line; filled circle, second moment calculated after the narrow component of the resonance line has been removed.

DISCUSSION

The second moment of the proton magnetic resonance of stearic acid can be calculated from structural parameters by means of Van Vleck's formula (9). For a polycrystalline sample the second moment, S, of an assembly of protons is

$$S = \frac{716}{N} \sum_{j>k} r_{jk}^{-6}$$

where N is the number of protons whose interactions are considered and r_{jk} is the distance in Å between any two protons j and k (1). We have assumed in using this formula that the crystal lattice is rigid, which in this case means that molecular reorientation occurs at a rate less than about 60 kc/sec, the low temperature experimental line width, expressed as a frequency. We have also assumed that nuclei with non-zero magnetic moments, other than protons, are absent. This is not exactly so, for C^{13} and O^{17} will be present in natural abundance. Their concentrations, however, are too small to have a significant effect on the proton second moment. The calculation of the rigid lattice second moment requires in principle a knowledge of the interproton distances throughout the crystal lattice, but because their contribution to the second moment is very small proton pairs whose separation r_{jk} is greater than 6 Å have been included in the second moment calculation by integration. The distances between pairs can be considered in two categories, namely, the intramolecular and intermolecular distances, which for convenience have been treated separately.

The intramolecular distances have been taken from the model of a long hydrocarbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

chain described by Müller (13). This model represents the molecules as planar zigzag chains of carbon atoms with tetrahedral angles of 109°28′ between the bonds. The C—H bond lengths have been taken as 1.094 Å and the C—C bond distances as 1.54 Å (14). With those parameters, the intramolecular second moment was found to be 18.4 gauss^2. The dimensions of the monoclinic unit cell used to calculate the intermolecular distances in the C-form of stearic acid are from the X-ray diffraction results of Abrahamsson and von Sydow (15). The tilt of the hydrocarbon chains has been assumed to be the same as that of lauric acid, 54°52′ to the basal (001) plane containing the carboxyl groups (16). The packing of the hydrocarbon chains is such that there are two acid dimers per unit cell. The arrangement of these carboxyl dimers has also been assumed to be the same as in lauric acid (16). The O—H bond length of the carboxyl group has been taken as 1.04 Å (17) and hence the interproton distance in the carboxyl dimer as 2.40 Å. The hydrocarbon chains are arranged end-to-end such that the distance between the planes passing through the carbon atoms of opposing methyl end groups is about 2.18 Å. From these data, the intermolecular second moment was found to be 6.0 gauss^2. The total rigid lattice second moment is therefore 24.4 gauss^2.

Since this calculated rigid lattice second moment is 3 gauss^2 larger than the mean experimental value of 21.5 gauss^2 found below −30° C, some molecular motion must be present below −30° C. It has already been mentioned that the methyl end groups might be free to reorient about their triad axes in the solid, even at low temperatures. Moreover, the low moment of inertia of the methyl group makes a tunnelling mechanism quite probable (18). If the methyl end groups reorient freely about their triad axes, the reduction in the theoretical second moment can be calculated following Gutowsky and Pake (19). The intramolecular contribution decreases by 1.92 gauss^2, and if we assume the intermolecular contribution changes proportionately (2), the total decrease is 2.6 gauss^2 and the theoretical second moment of stearic acid with rotating methyl groups is 21.8 gauss^2. This new value agrees within experimental error with the results obtained below −20° C. It is possible, therefore, that the broad portion of the resonance curve represents an almost rigid lattice and that the existing molecular motion probably concerns only the methyl-group ends of the molecules.

On the other hand, there is the possibility that the 3-gauss^2 difference between the experimental second moment below −30° C and the calculated rigid lattice value may be largely due to zero-point vibrational motions of the protons.* A detailed calculation of the importance of this effect would be difficult, but we may obtain an indication of its significance from the following considerations. An analysis of the reduction of the second moment resulting from zero-point motions has been made for ammonium halides and hydrazine fluoride (20–23). Gutowsky, Pake, and Bersohn found that the intramolecular contribution to the second moment of the ammonium ion was reduced by its zero-point torsional oscillations by a factor

$$1-\epsilon \cong \left(\left\langle 1-\frac{3}{2}\theta^2 \right\rangle\right)^2 \qquad [1]$$

where θ is the angle of torsional oscillation (20). If we consider that the significant motions in stearic acid are CH_2 twisting and rocking modes, we might use equations [34] and [35] of Ibers and Stevenson (23) to obtain

$$\theta^2 = (h/8\pi^2 c)\left(\frac{1}{I_1\nu_1}+\frac{1}{I_2\nu_2}\right) \qquad [2]$$

We are indebted to the referee for raising this question.

where ν and I are the torsional frequency and moment of inertia for each mode. Taking $\nu_1 = 720$ cm^{-1} for the rocking mode (24) and I_1 as the moment of inertia of both CH_2 protons about a fixed carbon, and $\nu_2 = 1200$ cm^{-1} for the twisting mode (24) and I_2 as the moment of inertia of both CH_2 protons about the center of the line joining them, one obtains $1-\epsilon = 0.946$ from equations [1] and [2]. This value will apply to the reduction of the second moment contribution of the methylene groups. If we now assume that the whole second moment is reduced by a similar factor we find a reduction of 1.3 gauss^2. The uncertainties involved in this estimation are very large. Ibers and Stevenson (23) suggest that the reduction of the intermolecular contribution may be larger than the reduction of the intramolecular contribution (in this case the CH_2 contribution). On the other hand, we have used the smallest possible values of moments of inertia, and if the methylene carbon is involved in the 720 cm^{-1} rocking mode or the 1180–1350 cm^{-1} band progression assigned to the wagging and twisting modes, the larger moments of inertia which would be appropriate would bring $1-\epsilon$ closer to unity. That these modes do involve the carbon atom is suggested by the fact that the 720 cm^{-1} band appears only in chains —$(CH_2)_n$— where $n \geqq 4$ (25), and that the 1180 cm^{-1} band progression exists only in the solid state and depends on chain length (26). There is, then, doubt as to whether the end methyl groups rotate. However, lack of an obvious reason for difference between the behavior of the methyl end groups in the fatty acid and in *n*-pentane and *n*-hexane studied by Rushworth (1), together with the uncertainties of the zero-point motional corrections, suggest to us that rotation of the methyl groups is the more probable explanation.

As we have reported above, the narrow component of the proton magnetic resonance line, which exists above about 20° C, does not correspond to a liquid condition, for which a line width of about 10^{-4} gauss might be expected. The observed line width of between 0.1 and 0.01 gauss does suggest, however, rapid molecular motion about several axes. The over-all line shape is similar to the proton magnetic resonance lines obtained from some high polymers for which the narrow component represents an amorphous phase and the broad component a crystalline one (10). In an important respect, however, the comparison with polymer systems breaks down. In polymers, the width of the narrow line is temperature dependent, being comparable to the width of the broad component at low temperatures (12, 27). In stearic acid the width of the narrow line is less than 0.1 gauss regardless of temperature, the change with temperature being in the amplitude of the narrow line. This increasing amplitude suggests that more and more molecules begin to move rapidly as the temperature rises. Since the percentage area under the narrow component corresponds approximately to the percentage of the hydrogen nuclei that are in rapid motion, a comparison of the integrated areas under the broad and narrow components of some of the proton resonance lines has been given in Table I. Although

TABLE I

Fraction of the protons involved in rapid motion

parts of molecules rather than entire molecules might be in rapid motion at temperatures above 20° C, it is unlikely that if 27% of each molecule is in rapid motion at 66° C, the remaining portion of each molecule would be rigidly constrained in the lattice as the high second moment of the broad component suggests. It seems more likely that solid stearic acid is present in two phases. One phase, as we have shown, has a rigid, ordered structure, possibly with only end methyl groups rotating and the other has a rather flexible and disordered structure. The amount of disordered phase increases as the temperature rises. This increase in the disordered phase below the melting point could account for the anomalous volume increase in stearic acid between 60° and 69° C (3).

Premelting in some cases has been thought to be due to rotation of molecules below the melting point. It might also be a co-operative increase in the number of holes and interstitial molecules in the solid which leads to the break up of long-range order at the melting point (28). It has been reported that the number of holes in equilibrium with the lattice is abnormally large near the melting points in some long chain hydrocarbons (29). These results suggest that such a process occurs in stearic acid. Lattice defects due to dislocations and impurities in the crystal might allow a few stearic acid molecules to flex and rotate. This could correspond to motion about many axes and lead to the observed narrow component of the proton magnetic resonance line. As the temperature rises these zones of motion and disorder grow in size at the expense of the surrounding ordered structure, until just below the melting point the entire crystal structure is completely disordered or amorphous.

ACKNOWLEDGMENTS

The authors are indebted to Dr. T. M. Connor for the high resolution measurements and to Professor C. A. McDowell for his interest in this problem. We thank the National Research Council for a studentship awarded to one of us (R.F.G.) and for a grant-in-aid of the research.

ELECTRONIC POTENTIAL SURFACES OF ACETYLENE IN LCAO/MO APPROXIMATION[1]

G. W. KING

ABSTRACT

A digital computer has been programmed to carry out 6-electron LCAO/ASMO calculations for linear and *trans*-bent acetylene, with the following input variables; coefficients of the LCAO/MOs, carbon–carbon bond length, and effective nuclear charge on the carbon atoms. The effect of varying these parameters upon the calculated electronic energy levels is discussed, and approximations to "best" MOs are obtained for various states of the molecule, leading to values of hybridization parameters for the carbon atoms. Certain assumptions enable the electronic energies to be related to the C—C—H bending angle; from this it is concluded the ground state is linear and the lowest A_u excited state is bent, in accordance with experiment. Values are given for electronic transition energies and hydrogen-bending force constants.

INTRODUCTION

In the LCAO/MO method for calculating the electronic energies of molecules, an orthogonal set of single-electron molecular orbitals[2] ϕ_i are formed by linear combination of n atomic orbitals χ_n:

$$\phi_i = \sum_n c_{in}\,\chi_n. \qquad [1]$$

These are combined in determinantal form to give ASMO wave functions:

$$\Phi_p = (N!)^{-\frac{1}{2}}|\phi_0(q_0)\ \phi_1(q_1)\ \ldots\ldots\ \phi_N(q_N)|. \qquad [2]$$

In general, the eigenvalues of the system have the expectation value

$$\int {\Psi_k}^{S*} H\, {\Psi_k}^{S}\, d\tau \qquad [3]$$

where the ${\Psi_k}^S$ are linear combinations of the ASMO functions:

$${\Psi_k}^S = \sum_p d_{kp}\,\Phi_p. \qquad [4]$$

If a large number of suitable Φ_p are taken in each such linear combination [4] (i.e., allowed to interact configurationally), and the stationary states of the system are found by solving the corresponding secular determinantal equations of high order, then the forms of the ϕ_i in [1] are of secondary importance. But if only a few Φ_p are taken in [4], it is necessary that the ϕ_i resemble the "best" MOs for a given electronic state as closely as possible, that is, the eigenfunctions of the Hartree–Fock operator for that state. The variational way to achieve this is an iterative one that becomes extremely complex for configurations comprising partly filled molecular orbitals, in which Ψ_k must be constructed from at least two suitably chosen Φ_p in order to be in accord with the Pauli principle.

For simple and highly symmetric molecules, the ϕ_i in [1] are usually chosen to transform like irreducible representations of the appropriate symmetry point group. This

[1]*Manuscript received November 9, 1959.*

[2]*The notation follows that of Howard and King, reference 1.*

often fixes values for certain of the c_{in}, and some of the remaining coefficients in [1] may be interrelated by orthogonality requirements between the MOs, leaving only a small number of coefficients c_j as independent parameters defining the whole set. Instead of attempting to find the best values of these by a cyclic self-consistent procedure, a more direct approach is used here in evaluating [3] for a wide range of values of the parameters c_j and locating the position of minimum energy for a given electronic state graphically, by plotting electronic energy [3] as a function of these parameters. This method is well suited to computer calculation, since a basic program can be written to evaluate concurrently the energies of different electronic states, with the c_j as the variable input parameters. Furthermore, it can be applied to configurations with partly filled orbitals.

It must be noted, however, that the various configurational wave functions for states of the same symmetry class are not necessarily orthogonal in the approximation used below. The only orthogonality present is due to differences in symmetry class, and a configuration interaction treatment would improve the values obtained for the energies.

APPLICATION TO ACETYLENE

The electronic states of *trans*-acetylene are considered here as a 6-electron problem, in LCAO/MO approximation. This example has certain disadvantages owing to the approximations it is necessary to make, especially those concerning the carbon–hydrogen bonds. On the other hand, there is considerable spectroscopic data available for the linear ground Σ_g^+ state (2) and for the lowest excited A_u *trans*-bent state (3, 4), which differ widely in geometry. LCAO/MO/CI calculations have been carried out by Ross (5) for the linear states with $r_{CC} = 1.203$ Å, corresponding to the observed ground state value, and by Howard and King (1) for bent states with $r_{CC} = 1.383$ Å and $\angle CCH = 120°$, corresponding to the observed values for the A_u state. The computer program closely followed the procedures used by Howard and King to obtain the diagonal elements E' of their equation [7], except that the coefficients listed in their paper[3] for the hybrid AOs χ_1–χ_8 were replaced by the general forms given below. Orthogonality was maintained between MOs of the same symmetry class.[4]

Let Cartesian axes be attached to each carbon atom with the z-axes pointing towards each other and with parallel y-axes in the molecular plane. Then the hybrid AOs on the carbon nuclei a and b may be written:

$$\chi_1 = t^{-1}(\lambda \cos\theta . a_s + r . a_z) \qquad \chi_2 = t^{-1}(\lambda \cos\theta . b_s + r . b_z)$$
$$\chi_3 = a_x \qquad \chi_4 = b_x$$
$$\chi_5 = t^{-1}(r\lambda \sin\theta . a_s - 2^{-1}\lambda^2 \sin 2\theta . a_z + t^2 . a_y)$$
$$\chi_6 = t^{-1}(r\lambda \sin\theta . b_s - 2^{-1}\lambda^2 \sin 2\theta . b_z - t^2 . b_y)$$
$$\chi_7 = r . a_s - \lambda \cos\theta . a_z - \lambda \sin\theta . a_y \qquad \chi_8 = r . b_s - \lambda \cos\theta . b_z + \lambda \sin\theta . b_y$$

where $t = (1-\lambda^2 \sin^2\theta)^{\frac{1}{2}}$ and $r = (1-\lambda^2)^{\frac{1}{2}}$, $0 < \theta < 90°$.

All the coefficients are expressed here in terms of two independent parameters, θ and λ. θ is the acute angle between the orbitals χ_7 or χ_8 and a line through the carbon nuclei,

[3]*See ref. 1, p. 703.*

[4]*Strictly, the electronic energies would be independent of the actual forms chosen for such* MOs *only if they were exact solutions of the Hartree-Fock equations. We note that in the calculations both of Ross and of Howard and King, the introduction of* CI *had only a small effect on the energies of many of the electronic states, indicating that the* MOs *they used were reasonably good approximations for these states.*

and λ is the amount of p character in each of these orbitals when they are written in the vectorial form

$$\chi_{7,8} = \eta s + \lambda p, \qquad 0 < \lambda < 1.$$

In previous calculations (1, 5), the hydrogen atoms were formally attached to χ_7 and χ_8 respectively, making θ the complement of the C—C—H bond angle. The validity of this assumption is discussed in a later section. Inserting $\theta = 60°$ and $\lambda = (2/3)^{\frac{1}{2}}$, we obtain the AOs used by Howard and King in which three equivalent sp^2 hybrids are centered on each carbon atom; $\theta = 0$ and $\lambda = 2^{-\frac{1}{2}}$ gives the sp hybrid AOs used by Ross for the linear molecule. Situations such as $\theta = 0$, $\lambda = 0$, for example, in which the H atoms are bound by pure $2s$ carbon orbitals are highly improbable, and the calculations show that very high energies are associated with such states. In general, one would not expect the C—H bond to have less p character than it does in the linear state, and it will be seen that the minima of potential surfaces fall within the anticipated range of values for λ.

χ_3 and χ_4 are pure p orbitals above and below the molecular plane, and remain unchanged as θ is varied. This is similar to the qualitative approach used by Walsh (6).

A Bendix D-15G computer, using the "Intercom 1000 Double Precision" interpretative subroutine was programmed to calculate energies of all the low-lying electronic states of *trans*-acetylene over all permissible (θ,λ) values at intervals of (10°, 0.1). The E' for each (θ,λ) value was computed in 12 minutes. These are simply the values of the diagonal elements of the secular determinants: limitations in the storage capacity of the computer prevented evaluation of the off-diagonal elements and the calculation of configuration interaction between states of the same symmetry. However, the program included interpolation in the tables of molecular integrals of Kotani (7), enabling the effective nuclear charge for $n = 2$ and also the separation of the carbon atoms to be included as additional variable parameters. The effective nuclear charge for $1s$ carbon atomic orbitals, to which the $2s$ orbitals were made orthogonal, was kept at 5.70.

The program was readily checked by comparison at different stages with results obtained by Ross and by Howard and King, using the appropriate (θ,λ) values. Excellent agreement was obtained.

Once a potential minimum for a given state had been located approximately, its position was accurately fixed by a "fine" scan over the region at (1°, 0.01) intervals.

RESULTS

Figure 1 shows energy contours, relative to the minimum value, for the lowest A_g state of acetylene, with $r_{CC} = 1.203$ Å. The contours were obtained by graphical interpolation of the computer results. This A_g state correlates with the ground Σ_g^+ state of the linear molecule. The potential minimum occurs at (0°, 0.643), λ having a slightly lower value than that of 0.707 for simple sp-type hybridization. Thus the C—H bond has slightly more, and the C—C bond slightly less, $2s$ character than is commonly supposed. Moffitt (8), on the basis of fairly general arguments, has predicted slight effects in the opposite direction.

Figure 2 is a similar diagram for the lowest A_u state, calculated for $r_{CC} = 1.383$ Å. This is the spectroscopically observed state. The potential minimum, indicated by a cross, is at the point (44°, 0.81). λ is fairly close to the value for ordinary sp^2-type

hybridization; this agrees with the observation (3) that the molecule in this state resembles ethylene with two *trans*-hydrogen atoms missing.

In these two figures, the effective nuclear charge Z_{eff} on the carbon atoms for $n = 2$ in the Slater AOs, is 3.18. In Fig. 3, the calculations of Fig. 2 have been repeated with

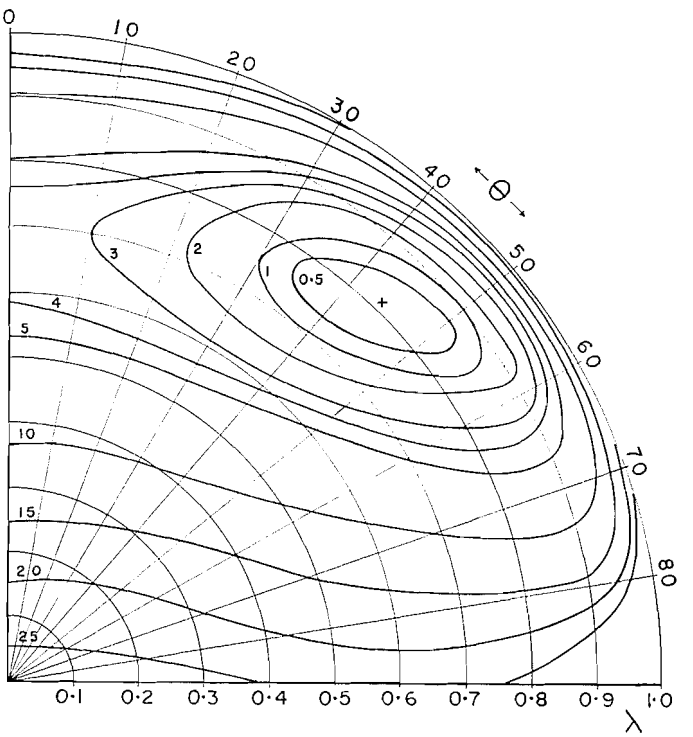

FIG. 3. Energy contours in ev for lowest A_u electronic state of *trans*-acetylene. $r_{CC} = 1.383$ Å, $Z_{eff} = 3.50$.

$Z_{eff} = 3.50$. Only small differences in the position of the energy minimum (44°, 0.82) and in the shapes of the energy contours are observed. This was found to be true generally for similar calculations with Z_{eff} ranging down to a 2.80. The relative energy levels for a given (θ,λ) in the region of minimum energy only changed slightly on varying Z_{eff}. Shull and Ellison (9) found this to hold also for benzene. Consequently, in subsequent calculations reported here, Z_{eff} was fixed at the free atom value of 3.18. Minimization of all potential energies with respect to Z_{eff} would have represented an unjustifiably large increase in the amount of computation.

TABLE I

Positions of electronic energy minima for the lowest A_u state for various C—C distances to nearest (1°, 0.01) intervals of (θ,λ)

r_{CC} (Å)	1.34	1.36	1.383	1.40	1.42
θ	44	44	44	45	45
λ	0.81	0.81	0.81	0.82	0.82

TABLE II

Positions of electronic energy minima for the ground Σ_g^+ state for various C—C distances, to nearest 0.001 intervals of λ, $\theta = 0°$

r_{CC} (Å)	1.18	1.203	1.22
λ	0.638	0.643	0.647

Tables I and II show the positions of potential minima for the A_u and A_g states respectively for different values of r_{CC}. Very little change occurs in each case. Table II indicates a slight increase in p character of the σ-type C—C bond as r_{CC} decreases.

In order to minimize the energy with respect to r_{CC}, and also to calculate the energy of the A_u–Σ_g^+ transition, it is necessary to evaluate energies of repulsion between the carbon nuclei. These have a magnitude of several hundred ev, and are very sensitive to small changes in the value for the nuclear charge, which depends on the extent of electron screening. In addition, variation of r_{CC} will affect electrostatic contributions to the energy due to any polarity in the C—H bonds, which is an unknown factor. In the circumstances, we merely report the value of 2.5 ev for transition between the potential minima of the two states, assuming a carbon nuclear charge of +4. The experimental value is 5.24 ev. The agreement is not as good as that obtained by Howard and King. It must, however, be remembered that the calculated figure is a difference between two quantities each of magnitude of some 250 ev.

The positions of minimum energy for the lowest states of the four symmetry classes of point group C_{2h} are summarized in Table III. These are all values for $r_{CC} = 1.383$ Å.

TABLE III

Electronic configurations and positions of minimum energy for lowest states of each symmetry class

State	Configuration	(θ,λ)
A_g	$(a_g\sigma_g 2sp^2)^2(a_u\pi_u 2p)^2(b_u 2sp^2)^2$	(0, 0.67)
A_u	$(a_g\sigma_g 2sp^2)^2(a_u\pi_u 2p)(b_u 2sp^2)^2(a_g 2sp^2)$	(44, 0.81)
B_g	$(a_g\sigma_g 2sp^2)^2(a_u\pi_u 2p)(b_u 2sp^2)(a_g 2sp^2)^2$	(50, 0.8)
B_u	$(a_g\sigma_g 2sp^2)^2(a_u\pi_u 2p)^2(b_u 2sp^2)(a_g 2sp^2)$	(0, 0.65)

The B_g state has $\theta > 0$. The B_u state is apparently linear, but this conclusion is invalid for the following reason. Certain of the lower excited states of bent acetylene correlate with degenerate species of the linear molecule; thus, $A_u + B_u \rightarrow \Delta_u$ (see ref. 3, Part III, Table 7). However, the calculated energies of such states do not converge in pairs upon the corresponding degenerate linear states as $\theta \rightarrow 0$; on the contrary, for example, the lowest pair of A_u states converge on each other, as do the lowest pair of B_u states, and each species would require a proper CI treatment to sort them in accordance with correlation relationships. Thus energy values for $\theta = 0$ for such states as calculated here are in error, which decreases as θ increases and states of the same symmetry move apart in energy. This does not apply to the lowest A_g state, which correlates with a single Σ_g^+ state; the next A_g state lies some 18 ev higher in the linear molecule for $\lambda = 0.643$, but this separation does decrease somewhat as θ increases to 90°.

THE CARBON-HYDROGEN BONDS

Two assumptions are made here: that the potentials of the hydrogen atoms can be neglected, and that they can be regarded as attached to orbitals χ_7 and χ_8 respectively,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

with complete localization of the C—H bond electrons. A refined calculation would include these in MOs extending over all four atoms of the molecule; and the coefficients of the carbon AOs in the "best" MOs, in the Hartree–Fock sense, need not bear a simple relationship to the C—C—H bond angles (although a suitable unitary transformation could be made to localize charge in the C—H bond directions).

On the other hand, it may be argued that for linear and moderately bent models, there is quite a small overlap between symmetry MOs formed purely from the well-separated C—H bond orbitals and the MOs of the C—C bond, and hence little interaction between them. There will also be a very small charge concentration of C—C bond electrons in the neighborhood of the hydrogen nuclei. The overlap would be greater if the C—H symmetry MOs contained several modes, but states in which such MOs are occupied will be high in energy and unlikely to affect the energies of low-lying electronic states. Hence in a first approximation θ can be correlated with the C—C—H angle; this becomes increasingly in error both as $\theta \rightarrow 90°$ and as $\lambda \rightarrow 0$, as interactions between C—C and C—H bond electrons increase. Since in general such interactions will lower the energies of our electronic states, it follows that the values calculated here are too high for small λ and large θ values; the necessary correction would shift the positions of the potential minima for bent states in the direction of these, and thus, for example, improve agreement with the observed 120° bending angle in the A_u state.

Ellison and Shull (10) have obtained SCF/MOs for the water molecule at different bond angles, and converted these by unitary transformations into equivalent orbitals directed towards the hydrogen atoms. They found that localization of electrons in O—H bond equivalent orbitals was not a justifiable assumption, as had been supposed by Pople (11) in his original treatment. Similar conclusions follow from the calculations of Higuchi (12) on the NH_2 radical. In these molecules, however, one would expect large interactions between electrons in any orbital representations directed along the X—H axes, owing to their proximity. This is not the case in acetylene.

If θ is identified with the acute C—C—H angle, some interesting conclusions emerge. The A_g (Σ_g^+) state in Fig. 1 is predicted to be linear and the A_u state in Fig. 2 to be *trans*-bent, in accordance with observation. The lowest B_u state is also expected to be bent.

Bending force constants can be derived for the C—H bonds. The two hydrogen atoms are approximated by a point executing small harmonic oscillations about the potential minimum at constant λ. This gives a bending constant of 0.24×10^{-11} erg/radian^2 for the A_g state, identical with the value derived from the known vibrational frequencies (13). The value for the A_u state is 4×10^{-11} erg/radian^2, which is much larger than would be expected; for example, the force constant for the comparable hydrogen-bending motion in benzene (3) is 0.8×10^{-11} erg/radian^2. The potential well for the A_u state is, however, very anharmonic, and the assumption of constant λ for this motion is somewhat provisional.

It would be helpful if λ could be related to r_{CH} and some estimate obtained for C—H stretching force constants. Various empirical expressions for the dependence of r_{CH} on degree of hybridization at a carbon atom are to be found in the literature (14, 15, 16). It was found that stretching constants several hundred times too large were obtained if any of these were used. Apart from the fact that none of them provides a good fit to experimental data, and that those methods based on addition of covalent bond radii are open to criticism (17), such expressions are derived using series of molecules in which both θ and λ vary with carbon atom hybridization, and cannot be readily employed here.

For personal use only.

In conclusion, a 6-electron, two-center approximation seems to give a better picture of the linear ground state of acetylene than of the bent excited states. The assumptions inherent in the treatment give only a qualitative significance to the results, but nevertheless avoid the troublesome calculation of three- and four-center integrals that would be entailed in more precise calculations.

TRITIUM EXCHANGE BETWEEN CELLULOSE AND WATER: ACCESSIBILITY MEASUREMENTS AND EFFECTS OF CYCLIC DRYING[1]

A. R. G. LANG[2] AND S. G. MASON

ABSTRACT

Tritium exchange between cellulose and water vapor was used to measure the accessibilities of amylopectin, amylose, regenerated cellulose, wood pulp, bacterial and Valonia cellulose, and cellulose trinitrate using both gas counting and solid counting techniques. The results compare satisfactorily with other accessibility and crystallinity measurements.

The incomplete reversibility of the exchange reaction was used to study directly changes in the accessibility of regenerated cellulose which occurred during repeated wetting and drying from water. The results indicated that a partial interchange of accessible and inaccessible regions occurs during wetting and drying.

INTRODUCTION

This paper describes preliminary experiments which use the exchange reaction of tritium between cellulose and water to study the "accessibility" of cellulose to water vapor, and to measure directly the formation of new inaccessible regions in cellulose during successive wetting and drying cycles.

Deuterium has been used extensively as a tracer in the exchange of hydrogen isotopes between cellulose and water (1–11), but only the more recent studies of Frilette, Hanle, and Mark (3), Almin (5), and Mann and Marrinan (8–11) are of value in accessibility studies. The exchange reaction, which was almost complete in 1 hour, was attributed to exchange with the hydroxyl hydrogens of the cellulose units in the amorphous regions and on the faces of the crystallites. The ratio of the cellulose participating in the reaction to the total, calculated by assuming that 3 hydroxyl groups reacted per anhydroglucose unit, was taken as a quantitative measure of the accessibility. These accessibilities were in good agreement with other accessibility and crystallinity measurements.

In the present work tritium (H^3), which, being radioactive, has the advantage that it may be easily, accurately, and sensitively determined, was introduced as a tracer in the exchange reaction

$$R.OH + HTO \rightleftharpoons R.OT + H_2O \qquad [1]$$

where R.OH is a carbohydrate containing accessible hydroxyls. The extent of this reaction was used to determine the accessibility of the carbohydrate. Measurements were made on a variety of samples in two ways.

1. By a gas counting technique in which cellulose and tritiated water vapor were reacted together, and the adsorbed and vapor-phase water removed and analyzed by gas counting. The extent of the reaction was calculated from the stoichiometry of the system and the dilution of the tritium in the water.

2. A radioactivity counting method for solid samples was used in which cellulose was exchanged with tritiated water vapor, the water removed, and the tritium in the cellulose measured by counting the solid sample. This method required a special apparatus, the Vacuum Transfer Counter (VTC), described elsewhere (12).

The gas counting method was used chiefly for calibration and corroboration of the solid counting method.

Confirming the observations of Mann and Marrinan (9) with deuterated water, it was found that the exchange of the accessible regions was not completely reversible; cellulose dried from tritiated water contained some tritium which could not be removed by soaking in water, i.e. some of the cellulose was rendered inaccessible by the wetting and drying. This newly formed inaccessibility is believed to be due to the formation of new interchain bonds during drying.

A number of additional experiments were conducted in which this newly created inaccessibility was used to study changes in cellulose caused by alternate wetting and drying. Two quantities were measured.

1. The amount of inaccessible material, $\delta\omega_n$, formed during the nth cycle, was determined by alternately wetting and drying the cellulose from ordinary water $(n-1)$ times, followed by a single wetting and drying from tritiated water for the nth cycle. The labile tritium was removed by soaking in ordinary water, and the amount of inaccessible cellulose formed in the nth cycle determined by counting the solid cellulose sample in the VTC. This quantity is analogous to the "resistant OD groups" of Mann and Marrinan (9).

2. The net inaccessible cellulose, W_n, formed during n cycles was determined by wetting and drying cellulose from tritiated water (n) times. The labile tritium was removed and the sample counted as before.

Both $\delta\omega_n$ and W_n were expressed as percentages of the total cellulose.

EXPERIMENTAL PART

Samples

(*a*) Amylopectin (Ramelin-G from Stein Hall and Co., Inc.) was dissolved in cold water and evaporated on a mercury surface to form a film with a superficial density of about 3 mg per sq. cm.

(*b*) Amylose (Superlose from Stein Hall) was dissolved in water at 160° C. A film (about 3 mg per sq. cm) was formed by evaporation of the solution on a mirror-finished stainless steel plate.

(*c*) Air-dried cellulose film (Dupont of Canada Ltd.) made from viscose was used, having a superficial density of 3.0 mg per sq. cm (about 23 μ thick). It had been neither plasticized nor coated.

(*d*) Acetate-grade softwood dissolving pulp having an α-cellulose (Tappi method) content of 96% was formed into sheets of superficial density 7.8 and 3 mg per sq. cm on a British sheet machine, pressed, and air-dried against a glazing plate.

(*e*) Bacterial cellulose grown from *Acetobacter xylinum* (kindly supplied by Dr. J. R. Colvin, National Research Council) was made into a sheet of superficial density 3 mg per sq. cm on a British sheet machine, pressed, and air-dried against a glazing plate.

(*f*) Valonia cellulose, obtained in a water–formaldehyde mixture from the General Biological Supply House, was purified by the method of Ranby (13), i.e. refluxed in 1.0% sodium hydroxide for 6 hours with a solvent change after 3 hours, then washed in dilute acetic acid and water.

(*g*) Ramie cellulose trinitrate (N content 13.80% corresponding to 97.7% complete nitration) was cast into a film (3 mg per sq. cm) from ethyl acetate on a mirror-finished stainless steel sheet.

Accessibility by Gas Counting

A dry sample containing exchangeable hydrogens was reacted with tritiated water and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

then all the water was recovered by distillation. The accessibility of the sample was calculated from the resultant dilution of the radioactivity in the water and the stoichiometry of the system.

The apparatus used is shown in Fig. 1. The reaction vessel (C), which has a removable top (B) sealed with an O-ring, was fitted with a Pirani gauge (Edwards MA-5) (A), a

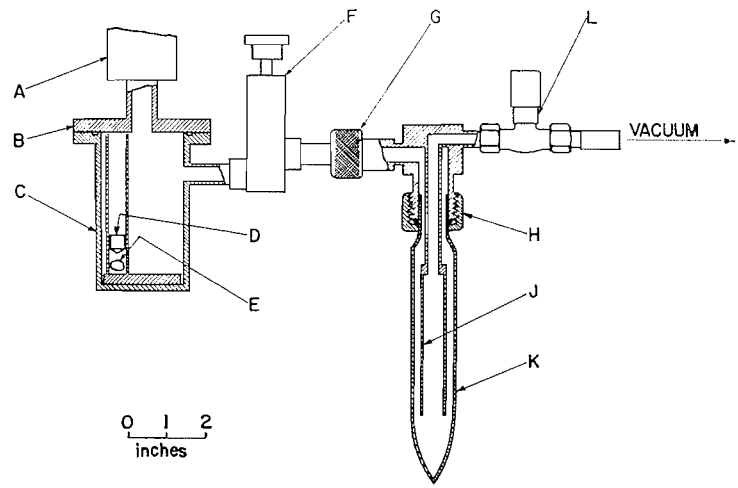

FIG. 1. Gas counting method apparatus. A, Pirani gauge; B, reaction vessel top; C, reaction vessel; D, ampoule breaker; E, ampoule; F, vacuum valve; G and H, vacuum couplings; J, trap inner tube; K, trap jacket; L, vacuum valve.

special ampoule breaker (D), and a Veeco high vacuum valve (L38S) (F). It could either be joined directly to the high vacuum system consisting of a liquid air trap, a two-stage oil diffusion pump, and a mechanical pump, or to the trap (K) by a Veeco quick coupling (G). The trap, which accommodated a special syringe (not shown) within the inner tube (J), could be dismantled by loosening another quick coupling (H) and was connected through a Hoke bellows seal-valve (L) to the vacuum system. The apparatus was, except for the Pyrex glass jacket of the trap (K), made of copper and brass, with connections either soldered or sealed with rubber O-rings. The metal and glass syringe with Teflon gaskets was made as described by Robinson (14).

About 0.4 ml of tritiated water with an activity of 0.5 microcurie (μc) per g was syringed into a weighed, thin-walled, Pyrex ampoule; freed of air by freezing, evacuating, and melting several times; then sealed and reweighed. Cellulose samples *a*, *c*, and *d* were used, of superficial densities 3, 3, and 7.8 mg per sq. cm, respectively. The ampoule, and a 2-g sample cut into strips about 7.5 cm wide and folded to expose as much surface as possible, were placed into the reaction vessel (C). This was sealed, and then evacuated for at least 11 hours at 70° C or for 43 hours at room temperature, and then isolated by closing valve F. The reaction was started by shaking until the ampoule was broken by the plunger (D) and continued at room temperature for an arbitrary period of 7 hours for amylopectin, and 1 hour for all other samples since this period was found adequate by other workers (3, 9).

Meanwhile the trap was assembled with the syringe, set to contain 0.2 ml, inside the central tube (J) so that the needle rested in the bottom of the jacket (K), and the isolated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

reaction vessel was coupled to the trap, which was then evacuated. After the reaction the water was recovered by cooling the trap with liquid air, closing valve L and opening valve F during the first rapid distillation, then opening valve L to the vacuum and heating the reaction vessel to 70° C for 4 to 46 hours. Valves F and L were closed, the water in the trap was melted and collected in the bottom of the jacket (K); then air, let in through valve L, forced the water into the still-evacuated syringe. This procedure prevented dilution of the radioactivity in the water by exposure to the water vapor in the atmosphere. Table I lists the experimental details.

The water in the syringe was analyzed for tritium by the method of Robinson (15), i.e. by reacting it with methyl grignard in butyl ether to form radioactive methane under carefully controlled conditions, fractionating the methane, metering it into a gas counting tube, and measuring the radioactivity with a suitable scaler. Several improvements or modifications were made to the apparatus described by Robinson.

1. A Kjeldahl flask was used for the reaction.
2. The burner heating the water bath was replaced by an annular electrical heater to ensure temperature uniformity.
3. Commercial glass, gas counting tubes patterned on those of Bernstein and Ballentine (16) replaced the metal gas counters.

The method of assay was found to be very satisfactory.

Accessibility by Solid Counting

A variety of samples (*b*, *c*, *d*, *e*, *f*, and *g*) were measured using the Vacuum Transfer Counter (VTC) and following procedures described earlier (12). Briefly stated, the sample was mounted on a suitable holder, evacuated in the VTC, treated with tritiated water vapor at a relative humidity of 79 to 97% at about 25° C for 1 hour, evacuated again, transferred while under vacuum to a counter, and the radioactivity of the sample measured. Corrections were made for contamination of the counter and absorption of radiation by the counter window.

It was shown (12) that a 1-hour reaction was sufficient for replication of results, and that the time for completion of the reaction probably depended upon the establishment of isotopic equilibrium throughout the apparatus after the dilution of activity by the cellulose; therefore, the mass of sample was kept constant by using a superficial density of 3 mg per sq. cm. The only exception was Valonia (1.1 mg per sq. cm) since there was insufficient material.

All samples were "infinitely" thick; i.e. their thicknesses exceeded the range of tritium β-particles (1 mg per sq. cm) (17, 18).

Amylopectin films could not be measured because they buckled and broke when exposed to the water vapor.

Cyclic Drying Experiments

Gel cellulose of the same stock as sample *c*, but which had never been dried, was used in all of these experiments.

(*i*) *Determination of* $\delta\omega$

Samples were placed in a vacuum desiccator containing anhydrous magnesium perchlorate or deaerated saturated sodium chloride solution to provide relative humidities of 0 and 75% respectively, evacuated for about 10 minutes, then isolated. After the 23 hours required for moisture equilibrium (19), the desiccator was opened and a sample removed. The remainder was soaked for 1 hour in distilled water at about 25° C, then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

replaced in the desiccator. Each drying and wetting cycle was repeated to 30 and 56 times for the 0 and 75% r.h. experiments respectively, with periodic removal of samples. The dried samples together with a piece of the original undried sample were mixed for 7 hours in a 50-ml flask with at least 1 ml tritiated water (about 8 μc per mg) per 80 mg of sample. Then the water was poured into a trap and the remaining water removed by vacuum distillation and collected in the same trap cooled with liquid air. Samples cycled at 0% r.h. were dried as quickly as possible with the flask surrounded by a water bath at 25° C; the 75% r.h. samples were distilled at a vapor pressure equivalent to 75% r.h. as measured with a mercury manometer, by throttling the vapor flow to the trap. Distillations at 0% r.h. were made in 3 batches and at 75% in 2 batches. The water removed from the samples was assayed for tritium by the gas counting method already described.

Labile tritium was removed from the cellulose by soaking in distilled water for at least 2 days with four changes of water. The wet sample was mounted on a holder (ref. 12, Fig. 4) dried in the air for 1 hour, evacuated in the VTC for 1 hour, then counted. The background determined immediately before counting was subtracted directly from the observed count rate, which was then corrected for window absorption (12).

(*ii*) *Determination of W*

An inverted U-tube of 15-mm o.d. Pyrex glass tubing with sealed arms 20 cm and 14 cm long was used in each experiment. One milliliter of tritiated water (about 8 μc per mg) was added to a sheet of undried gel cellulose (2.5×5 cm) held in the 20-cm arm by glass fingers. The tube, after being evacuated through a 5-mm o.d. side arm for 15 seconds so that water vapor purged the air from the apparatus, was sealed off with a torch. The sample and liquid water were mixed by shaking the tube and equilibrated for 7 hours, then the free water was poured from the sample into the 14-cm arm. The arm containing the cellulose was put in a water bath at 25.0±0.1° C and the other arm either in dry ice – acetone mixture or a water bath at 20.0±0.2° C for distillations at 0 and 75% r.h. respectively. After 23 hours the U-tube was removed from the baths, and the water poured back onto the cellulose for 1 hour, then the drying cycle repeated. The number of cycles was varied up to 28 corresponding to 0% r.h. and 57 to 75% r.h. Finally the U-tube was broken open, the water assayed for tritium, the labile tritium was removed from the sample by soaking in water, and the sample counted as before.

(*iii*) *Control Experiments*

Gel cellulose samples were soaked in tritiated water (6.5 μc per mg) for 1 hour, 12 hours, and 31 days, then, without drying, soaked in distilled water to remove the labile tritium and counted as before.

RESULTS AND DISCUSSION

Accessibility by Gas Counting

The results are summarized in Table I.

The per cent accessibility, A'_g, was calculated from the relation

$$[2] \qquad A'_g = 600\,\frac{m}{M}\left(\frac{N_0}{N_\tau}-1\right)$$

where m is the mass of water in the ampoule (g), M is the mass of the sample on an over-dry (105° C) basis (g), N_0 and N_τ are the original and final activities in the water in the same units; the factor 600 converts the masses m and M to molecular equivalents and the results to a percentage. This expression assumes that:

$$\frac{m}{M} = \frac{\text{mass of water in ampoule}}{\text{mass of dry cellulose}}.$$

1. There are three exchangeable hydrogens per anhydroglucose unit.

2. There is no adsorbed water on the cellulose prior to the reaction. Work described elsewhere (20) showed that under the conditions of the experiment the residual adsorbed water was generally zero and always less than 4 mg per g, corresponding to an apparent accessibility of 2.4%.

3. There is no isotope effect in eq. [1]; i.e.

$$[3] \qquad k_1 = \frac{\text{T/H in accessible part of carbohydrate}}{\text{T/H in adsorbed water}} = 1.$$

4. There is no change in the tritium concentration in the carbohydrate during the recovery of adsorbed water.

Equation [2] is equally applicable to linear and branched chain molecules of anhydroglucose units, provided that the D.P. is sufficiently high that the additional exchangeable end group per molecule may be neglected, since with branched chains the loss of one hydroxyl at the branch is exactly balanced by the gain in the additional end unit.

Since amylopectin, the highly branched fraction of starch, has been shown (21) to have a completely amorphous X-ray diffraction pattern (an observation which we have confirmed) all its hydroxyl hydrogens should be accessible to exchange with water. However, A_g' (expts. 8 and 9, Table I) exceeded the expected value of 100%. This suggested that some of the C—H linked hydrogens in addition to the hydroxyls were participating in the exchange. However, infrared measurements on cellulose (8) and the accessibility measurements on cellulose nitrate described later showed that no exchange occurred between hydrocarbon hydrogens of cellulose and water. It was concluded that the abnor-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

mally high A'_g was due to two isotope effects, one in the exchange reaction (eq. [1]) and the other in the recovery of tritiated water.

The reported values of the isotope distribution factor k_1 (eq. [3]) for the exchange equilibria between alcohols and deuterated water vary from 0.96 to 1.25 (22–28); of these the value of Hobden *et al.* (27) of 1.09 is probably the best. Although no data are available it is probable that similar effects exist for alcohols and tritiated water.

An isotope effect probably occurred in the recovery of the tritiated water from the sample because the equilibrium vapor pressure of HTO is lower than H_2O. From direct measurements of liquid/vapor equilibria, Price (29) has reported ratios of the vapor pressures of HTO and H_2O which may be expressed by the separation factor

$$\alpha = \frac{\text{T/H in liquid}}{\text{T/H in vapor}}. \qquad [4]$$

At 26° C, $\alpha = 1.29$. Therefore during a simple distillation, the distillate is deficient in HTO, while the water being distilled is correspondingly enriched. When all the water is distilled it has, of course, the same average composition as the original liquid; all distillations were, therefore, taken to completion. However, a complication probably occurred during the distillations from solids containing exchangeable hydrogens: as the tritium concentration in the adsorbed water increased, the equilibrium in eq. [1] was probably driven to the right, so that more tritium became attached to the hydroxyl oxygens to cause an additional decrease of tritium in the distillate. This would cause the accessibility calculated by eq. [2] to be high.

The possible magnitude of such an effect is indicated by first considering the equilibrium distillation of a mixture of H_2O and HTO. At low concentrations of tritium the molecular species T_2O may be neglected, so that the problem becomes the simple distillation of a mixture of two volatile components HTO and H_2O, and the expression

$$\log_e \frac{L_1}{L_2} = \frac{1}{k-1} \log_e \frac{x_1}{x_2} \qquad [5]$$

derived by Perry (30) is applicable, where L_1 is the number of moles of original water, L_2 is moles of residual water, x_1 and x_2 are the mole fractions of HTO in the original water and the residual water respectively, and

$$k = \frac{\text{mole fraction HTO in vapor}}{\text{mole fraction HTO in liquid}} \text{ at equilibrium.}$$

Note that the original derivation was made in terms of the more volatile component, but eq. [5] is equally applicable to the less volatile component, i.e., HTO.

When the concentration of T $\ll$ H, as in the conditions studied,

$$k \simeq \frac{\text{HTO/H}_2\text{O in vapor}}{\text{HTO/H}_2\text{O in liquid}} \simeq \frac{1}{\alpha} \qquad [6]$$

and

$$\frac{x_1}{x_2} \simeq \frac{\text{T/H in original water}}{\text{T/H in residual water}} = \frac{t_0}{t} \qquad [7]$$

i.e., replacing the mole fraction of HTO by the atom fraction of T. Using eqs. [6] and [7], the approximate value of $\alpha = 1.3$, and putting $L_1/L_2 = 1/m$, where m is the fraction of original liquid which has not been distilled, eq. [5] becomes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

[8] $$\log_e m = \frac{1.3}{0.3} \log_e \frac{t_0}{t}.$$

This expression gives the ratio of the atom fractions of tritium in the original to the residual water at any stage during the distillation.

By making a material balance this can be re-expressed to give the ratio F of the atom fraction in the original liquid to the average atom fraction in the distillate at any stage

[9] $$F = (1-m^{1/1.3})/(1-m).$$

If equilibrium is maintained between amylopectin and tritiated water at all times, the complete distillation of water from amylopectin may be considered as a partial liquid distillation in which the amylopectin corresponds to the residual liquid. Thus assuming that $k_1 = 1$ (eq. [3]), the value of m corresponding to 2 g amylopectin and 0.4 g water is 0.453, and by substitution in eq. [8], $F = 0.834$. If the correction for such a fractionation were neglected the accessibility, A'_g, calculated from eq. [2] would be 142%. While this value represents an upper limit, it serves to show the importance of this isotope effect.

The isotope effects in this exchange reaction are of some interest and will be discussed in a subsequent paper. For the present work the values in Table I were used as reference values for the accessibility of cellulose films which were subsequently measured in the solid counter (VTC). The measured accessibility values, A'_g, in Table I were corrected by multiplying by the factor 100/123 on the assumptions that amylopectin was 100% accessible and the correction for the isotope effect was given by a single factor which was the same for all samples, and hence cancelled out of the calculations.

Table II shows that this method of obtaining the corrected values, A_g, gave good agreement with comparable values obtained by other methods (3, 9–11, 31, 32).

TABLE II

Accessibility of samples by solid counting and comparison of data

†Values of Hermans (31) except for underlined value (32).

The advantages of the gas counting method are good reproducibility, relatively simple apparatus, and the fact that the surface roughness of the sample does not affect the results. The principal disadvantage is the uncertain magnitude of the isotope effects; these must be known in order to yield absolute values of the accessibilities.

Accessibility by Solid Counting

Table II contains a summary of the results obtained in the VTC. The percentage accessibility, A_s, of a sample was calculated from the relation

$$[10] \qquad A_s = \frac{\text{count rate of sample}}{\text{count rate of cellulose film}} \times 71$$

where 71 is the accessibility (A_g) of the cellulose film determined by the gas counting method. As in the gas counting method it is probable that isotope effects occurred in the exchange reaction and during the removal of water. It is assumed that the correction for the isotope effects was given by a single factor, which was the same for all the samples and hence cancelled out of eq. [10].

In this calculation no consideration has been given to differences in relative humidity during the reactions in the gas counting and solid counting methods. In the gas counting method the relative humidity for sample *c* was estimated from the sorption isotherm for viscose rayon given in the literature (33) as about 80%, while the measured relative humidity for the solid counting method ranged from 79 to 97%. The effect of relative humidity on the accessibility has not been studied, but it is believed that at high relative humidities it is not great.

Since radioactive water remaining adsorbed on the cellulose would contribute to the count rate, it was necessary to estimate the amount adsorbed under the experimental conditions. Separate experiments using oxygen isotope exchange between water vapor and cellulose sample *c*, which are described elsewhere (20), showed that the adsorbed water remaining on cellulose under the conditions of the present experiment, i.e. after 23 hours evacuation, was 6.5 mg per g, equivalent to an accessibility of 4%. Although a different apparatus was used, the value should be approximately the same for the VTC. However, the amount of adsorbed water in the other samples was roughly proportional to the accessibility (34), so that the total activity from the sample, arising from exchanged hydroxyls in the accessible regions and the small contribution from adsorbed water, remained proportional to the accessibility of the sample. Since only relative total activities are used to calculate A_s, the actual error introduced by the adsorbed water was less than 4%.

The amount of water which passed from the sample in the VTC into the vapor phase between isolation of the sample and the completion of counting (30 minutes) was calculated to be 0.016 μg from the pressure rise in separate adsorption experiments (20), and by making allowance for the much smaller sample in the VTC. This amount of water corresponded to 44 counts per minute which was negligible. Therefore, any errors caused by extraneous water were well within the experimental accuracy and may be neglected.

Table II shows that the accessibility values agreed reasonably with the D_2O vapor accessibilities of Mann and Marrinan (9–11). Although accessibilities and amorphous cellulose determined by X-ray diffraction and density methods measured different quantities, both methods graded the samples in the same order, except for bacterial cellulose. The X-ray values for bacterial cellulose were respectively twice and one and one-half times as high as the accessibility values of Mann and Marrinan and those of the present work. In making the comparisons the difference in the samples as well as the experimental methods should be borne in mind.

Amylose sheets have given an indication of an oriented X-ray diffraction pattern (35); however, the 100% accessibility of amylose (Table II) showed that the crystalline fraction was very small, or that the crystallites were unstable in the presence of water vapor. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

100±2% value also gave excellent confirmation of the self-consistency of the solid counting method. The 98% nitrated cellulose had the expected accessibility of zero since practically all its hydroxyl groups were replaced, and showed convincingly that only hydroxyl hydrogens take part in the exchange.

Because of the short range of tritium β-particles (about 6 μ in cellulose) and the difficulty of preparing reproducible samples (18, 36), it was expected that surface roughness might have a large effect on the accuracy of the measurements with the VTC, and so normally only smooth-surfaced samples were used. However, a sheet of acetate grade dissolving pulp having a fluffy surface, gave an accessibility only 6% higher than the value by the gas counting method, which is independent of surface roughness. This indicated that the VTC may also be used to compare paper samples with similar surfaces.

These results show that the solid counting method, once calibrated, provides reliable accessibilities for starch and cellulosic samples. It is believed that the simplicity of the method will make it useful for characterizing various kinds of cellulose and other substances.

Cyclic Drying Experiments

The results of these experiments are plotted in Figs. 2 and 3. The percentage of in-

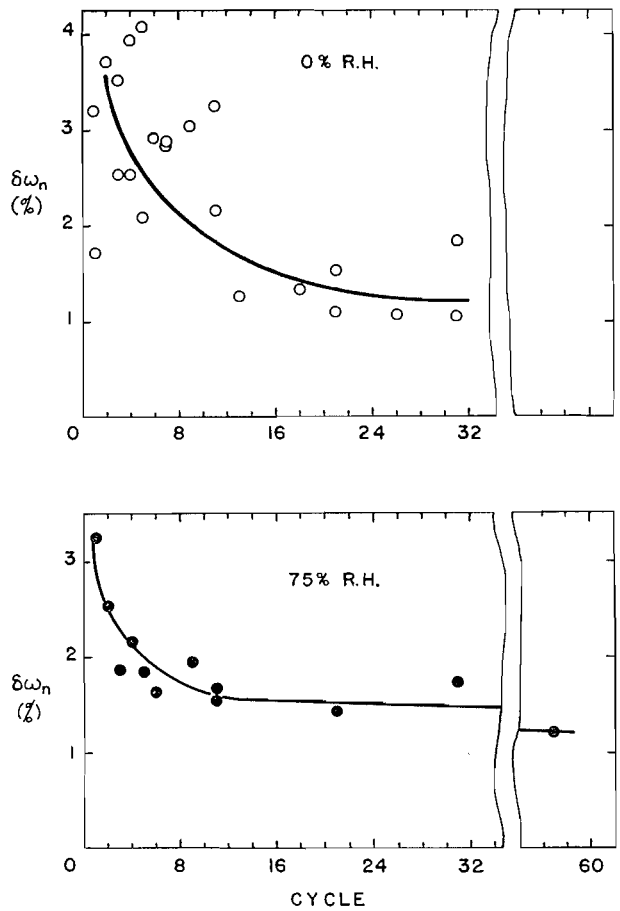

FIG. 2. Inaccessible cellulose formed during each wetting and drying cycle ($\delta\omega_n$). Top graph, 0% relative humidity. Bottom graph, 75% relative humidity.

For personal use only.

accessible cellulose, $\delta\omega_n$ or W_n, formed by drying tritiated water was calculated from the equation

$$[11] \qquad \delta\omega_n \quad \text{or} \quad W_n = \frac{N}{13{,}200} \times \frac{1.20}{S} \times 100$$

where N is the corrected counts per minute from the cycled sample, 13,200 the counts per minute for a completely exchanged sample calculated from the observed count rate of cellulose film (9400 per minute) and its known accessibility (71%), and 1.20 and S are the specific activities in μc per mg of the tritiated water used in the accessibility measurements and the cyclic experiments respectively. Each point on Fig. 2 was obtained from a separate piece of cellulose, but some of the pieces had common distillation steps from tritiated water. Because of the possibility of irregular temperature variations from one distillation to another, particularly at 0% r.h., the experimental points cannot strictly be considered as representing completely separate experiments. On the other hand, each point on Fig. 3 was obtained from a completely independent experiment. The newly formed inaccessibilities of the control samples soaked in tritiated water, but not dried, were only 0.2, 0, and 2.3% for the 1-hour, 12-hour, and 31-day soakings respectively, showing that only changes occurring during the wetting and drying need be considered for the interpretation of the values of $\delta\omega_n$ or W_n.

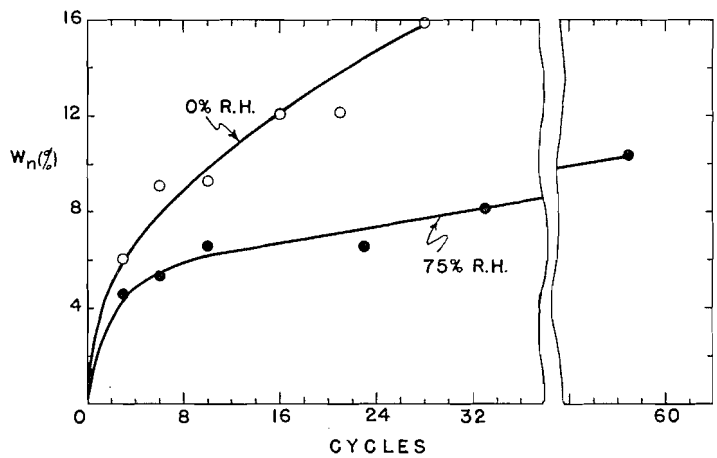

FIG. 3. Net inaccessibility formed during a number of wetting and drying cycles (W_n). At 0% and 75% relative humidity.

The values of $\delta\omega_n$ at both 0% and 75% r.h. decreased to a limiting value of 1.3% with increasing number of cycles. The corresponding W_n (Fig. 3) showed an initial rapid increase followed by a slower rise, but there was no indication of a limiting value at either 0% or 75% r.h. up to 28 and 57 cycles respectively. Somewhat unexpectedly the values of W_n for 0% r.h. were always greater than those at 75% r.h., since previous values of the liquid water permeability (19) and dimensional swelling (37) of cellulose cyclically dried at different relative humidities were interpreted to mean that more cross-linking occurred on drying at higher humidities. However, in the present experiments at 0% r.h. the temperature decreased during the rapid removal of water from the cellulose, and the influence of temperature on the processes is at present unknown. No difference was definable for the values of $\delta\omega_n$ at 0% and 75% r.h., possibly because of the scatter of the 0% r.h. results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The value of $\delta\omega_n$ is the inaccessibility to liquid water caused by the nth cycle alone, and that of W_n the net inaccessibility resulting from n cycles. Therefore, if the inaccessible material is formed irreversibly it follows that

$$[12] \qquad \sum_{1}^{n} \delta\omega_n = W_n.$$

Figure 4 shows that this is not so, but that $\sum\delta\omega_n$ at 75% r.h. increasingly exceeded W_n. Some of the newly formed inaccessible cellulose represented by $\delta\omega_n$ must therefore have become accessible during subsequent wettings and dryings. Furthermore, W_n at 10 and 28 cycles at 0% r.h. and 10 and 33 cycles at 75% r.h. decreased by 1.6, 4.5, 2.2, and 1.6 respectively when the samples were cycled four more times using ordinary water and drying at the relative humidity of their preparation.

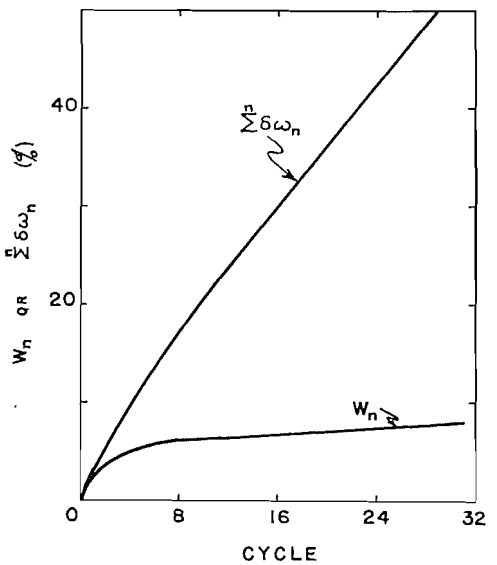

FIG. 4. Comparison of $\Sigma\delta\omega_n$ and W_n at 75% relative humidity.

It is believed that these experiments give the first direct evidence of the conversion of inaccessible to accessible cellulose by wetting and drying. In view of this it should be noted that all measurements were made after the samples had an additional wetting and drying cycle using ordinary water to remove labile tritium and to mount the sample on the holder. It is interesting to note that decreases of 0.5 to 1 in $\delta\omega_n$ and W_n occurred immediately after removal from the VTC, presumably by exchange between the atmospheric water and the inaccessible cellulose rendered accessible by the drying in the VTC. However, since exactly the same techniques of soaking, mounting, and drying were carefully followed in the measurements of $\delta\omega_n$ and W_n, the preceding observation does not affect the comparison made in Fig. 4.

After the initial small loss of activity immediately after removal from the VTC, the sample was stable for weeks, showing that the anhydroglucose units in the inaccessible part of the dried cellulose did not become accessible; otherwise the tritium would have exchanged with the atmospheric water (5).

The results discussed so far have shown that part of the newly formed inaccessible cellulose becomes once again accessible after further wetting and drying, but they give

no direct information about the stability of the inaccessible cellulose present in the original wet sample either while standing in water or on wetting and drying. However, the small inaccessibilities formed in the control experiments mentioned previously showed quantitatively that in the swollen state any formation of inaccessible cellulose was very slow. Nevertheless the 2.3% value showed that, in time, changes do occur which may be caused by (*a*) an increase in the total accessibility (which is, however, unlikely since the accessibility probably reached a constant value during the 6 months of soaking which preceded the experiment), (*b*) by penetration of tritiated water into the crystallites, or (*c*) by a slow process of interconversion of accessible and inaccessible regions. Thus there is the possibility that the inaccessible regions in the original undried gel may not be stable to prolonged soaking in water.

If the original inaccessible cellulose becomes accessible during the cyclic treatment then W_n should be greater than the decrease in accessibility caused by the corresponding number of cycles. The increase of W_n during 28 cycles at 0% r.h. and 57 cycles at 75% r.h. was not reflected by a decrease in the accessibility, A_s, between 1 and 56 cycles at 75% r.h. (Table II). However Mann and Marrinan (10, 11) reported a decrease of 3% and 5% in accessibility during the second wetting and drying of viscose film. D_2O accessibility measurements by Brickman *et al.* (6) of cyclically dried samples gave erratic results.

A net decrease in accessibility of cellulose on wetting and drying is consistent with many of the published experimental values which are believed to be related to the extent of the cross-bonding in cellulose. Thus irreversible decreases occurred in the dimensional swelling (37), permeability of water (19), moisture regain (6, 31), and heat of wetting (6). On the other hand, the X-ray crystallinity of cellulose was almost constant during drying from the gel state (38) and on cyclically drying (39). However, the experimental difficulties of the X-ray measurements and the relative small changes occurring in the cyclic experiments may account for these conflicting results. Under some experimental conditions the accessibility of cellulose to nitration (6, 40) and hydrolysis (41) showed a small but definite increase with successive wetting and drying; this appears to be at variance with the notion of lower accessibility after wetting and drying. It was not possible to decide definitely from this partly conflicting data whether or not inaccessible regions in the original cellulose are rendered accessible by wetting and drying.

CONCLUDING REMARKS

The unexpected difference between $\sum\delta\omega_n$ and W_n may be explained by the following hypothesis.

1. Cellulose chain molecules are continually moving, particularly when wet, and undergo segmental jumping, as shown by dielectric measurements (42). Thus an arrangement of chains, once formed, does not necessarily remain unchanged. The stability of a particular molecular configuration depends upon the attraction between chains resulting from van der Waals' forces and, more important, hydrogen bonding. For example in a crystalline configuration, which requires the greatest energies to separate the chains and is thus the most stable, there are one or two interchain hydrogen bonds per anhydroglucose unit (43, 44). Less regular arrangements having fewer interchain bonds are less stable, so that a spectrum of stabilities exists.

2. A configuration may be disrupted by (*i*) the formation of hydrogen bonds between cellulose and water at the expense of cellulose–cellulose interchain bonds, (*ii*) mechanical stresses resulting from the effort of neighboring molecules to arrange themselves into more stable configurations, and (*iii*) segmental thermal motion. In a very stable arrangement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

of cellulose chains such as in the crystalline regions, weakening of interchain bonds by water molecules alone is energetically unfavorable: the water molecule forms hydrogen bonds with the cellulose which may be equal in energy to those which are replaced; but the chains have to separate to accommodate the water molecule which stretches and weakens the neighboring interchain bonds, so that an increase in energy is required. However a stable configuration may be rendered less stable if the competition of water molecules for interchain hydrogen bond positions occurs simultaneously with the disruptive action of a number of mechanical stresses which act by chance in co-operation.

3. When cellulose is very wet, the water forms hydrogen bonds with all hydroxyl groups attached to *mobile* chains and the formation of new more stable configurations from these mobile chains is almost completely prevented. Furthermore, under these conditions no mechanical stresses arise to disrupt existing stable configurations. At the other extreme, in dry cellulose the mobility of the chains is decreased by the greater number of interchain bonds, so that rearrangement into new stabler configurations almost ceases. Therefore, new stable configurations do not form in very wet or very dry cellulose, but only at some intermediate, possibly narrow, range of moisture content. At this critical moisture content some of the stable regions are being continually disrupted while new stable configurations are being formed.

4. From simple statistical considerations, the rate of formation of the stabler configurations will decrease, and the rate of destruction increase, as the quantity of cellulose in stable configurations becomes larger. Thus, at the critical moisture content, the amount of cellulose in the stable configurations slowly increases with time until an equilibrium value is reached.

The mechanical stresses mentioned above are believed to be identical with those which cause cellulose to shrink when it is dried.

The hypothesis is now considered in terms of wetting and drying. Stable configurations which form and are not broken by the next wetting and drying cycle are measured as newly formed inaccessible regions by the cyclic drying experiments. Note that the critical moisture content which is favorable to the formation of stable configurations is traversed once on wetting and once on drying, so that inaccessible regions should form twice during a cycle but not necessarily in identical amounts.

The only reliable data which do not appear to be consistent with this hypothesis are the nitration of cyclically dried cellulose (6, 40), and the hydrolysis of dried cellulose (41). No reasons can be cited, but it may be significant that the hydrolysis measurements were made on samples dried from ethanol instead of water.

The hypothesis also explains the formation of "resistant OD groups" in the experiments of Mann and Marrinan (9), which are closely analogous to the $\delta\omega$ values. A careful study of their results showed that a necessary, and, except for one experiment involving a rapid treatment of a cyclically dried sample, a sufficient condition for the formation of resistant OD groups is that the cellulose be passed through the intermediate moisture range in the presence of D_2O, either by being wet or dried. Similarly their "deuteration of crystalline regions" (11), in which a higher accessibility was found with liquid D_2O than with the vapor, can be attributed to the deuteration by the liquid of cellulose which was accessible at any stage during the wetting and drying cycle, i.e. the cellulose originally available to the vapor, as well as the inaccessible cellulose which was rendered accessible during the wetting and drying processes. It follows also that the difference between this quantity (8% of the total viscose film) and the decrease in accessibility (3%) measured by their D_2O vapor method (11) after wetting and drying should be comparable with $\delta\omega_n$ for the

second cycle. The actual difference of about 5% is, considering the differences in technique, in very good agreement with the direct measurement of 2.5% in the present experiments.

The new feature of this hypothesis is the reversible interconversion of accessible (and possibly amorphous) and inaccessible (and possibly crystalline) regions on repeated wetting and drying. Thus it may be possible to completely deuterate the hydroxyl groups of cellulose by using a sufficient number of wetting and drying cycles with liquid D_2O.

It is proposed to continue these experiments.

SEPARATION OF CARBOHYDRATE DERIVATIVES BY GAS–LIQUID PARTITION CHROMATOGRAPHY[1]

C. T. Bishop and F. P. Cooper

ABSTRACT

Gas–liquid partition chromatography has been used to separate all of the possible tetra- and tri-*O*-methyl ethers of methyl α- and β-D-glucopyranoside. Anomeric methyl glycosides of each isomer were well separated except those of 3,4,6-tri-*O*-methyl-D-glucose. The six di-*O*-methyl-D-glucopyranoses were partially resolved as their methyl glycosides. The four possible mono-*O*-methyl-D-glucopyranoses were completely resolved after conversion to the corresponding mono-*O*-methyl-penta-*O*-acetyl-D-glucitols, a series of compounds which, except for the 6-*O*-methyl isomer, have not been reported previously. Quantitative estimations of mixtures containing varying amounts of methyl-2,3,4-tri-*O*-methyl-β-D-xylopyranoside and methyl-2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside showed that molar ratios of components in a mixture could be determined with a mean deviation of ±0.5 in 100.

Since its development by James and Martin (1) in 1952, gas–liquid partition chromatography has been used to separate a wide variety of volatile organic compounds. The first report of its application to carbohydrates dealt with the separation of fully methylated methyl glycosides of some monosaccharides (2). Good separations were obtained and it was also established that the compounds were stable under the conditions used because they could be recovered unchanged from the effluent gas stream. These results encouraged further investigation to see if gas–liquid partition chromatography could be extended to more general use in carbohydrate chemistry. This paper describes the separation of methyl ethers of glucose and also deals with the accuracy of gas–liquid partition chromatography in quantitative estimations of carbohydrate derivatives.

All separations shown in the figures were obtained on an apparatus employing an ionization detector (3). The high sensitivity of this detector permitted the use of small samples (2–4 γ) and this resulted in a considerable increase in resolution of components over that obtained in the apparatus previously described (2), which contained a thermal conductivity cell as a detector. However, the latter apparatus was used when it was necessary to collect samples from the effluent gas stream.

Retention volumes of the compounds used were dependent on the composition of the stationary liquid phase. It was advantageous to use two columns, one containing a polar liquid phase, the other a non-polar, because separations of some isomeric methyl ethers could be obtained on one and not on the other. Butanediol succinate polyester and Apiezon M were used as the polar and non-polar stationary liquid phases respectively. A number of other liquid phases were tried in preliminary work including Dow Corning silicone grease, carbowax 4000, zinc stearate, D-mannitol, partially benzylated raffinose, methyl cellulose (methoxyl, 27.9%), and mannitol hexastearate. The silicone gave separations comparable with those obtained on Apiezon M but was less convenient to use because a solvent extraction was required to remove low molecular weight material from the liquid phase. Most separations on carbowax were similar to those obtained on butanediol succinate polyester but the carbowax was not as suitable for general use. Mannitol, mannitol hexastearate, and zinc stearate gave columns having poor resolving power. The benzylated raffinose was unstable and the columns bled excessively at operating tempera-

Issued as N.R.C. No. 5522.

tures of 150–200° C; the methyl cellulose was not liquid at these temperatures. The carbohydrate derivatives mentioned were tested as liquid phases because their structural similarities to the components to be separated might be expected to give enhanced separations. Although none of the carbohydrate derivatives tested here were useful as liquid phases, Kircher (4) has reported recently the separation of fully methylated methyl glycosides of monosaccharides by gas–liquid partition chromatography using fully methylated hydroxyethyl cellulose as the liquid phase.

Alkali-washed Celite 545 was chosen as the inert support for the liquid phase because the alkali washing decreased the tendency of those compounds which passed easily through the column to give asymmetrical peaks (due to adsorption). However, the number of derivatives that could be eluted from the columns was reduced considerably by the use of alkali-washed Celite because of increased adsorption of sugars in which the anomeric hydroxyl group was free or substituted by an acetyl group and in which there were a large number of free hydroxyls. These derivatives which were adsorbed by alkali-washed Celite could be eluted, but with poor resolution, from columns in which the inert support was acid-washed Celite, firebrick, powdered glass, or sodium chloride. The alkali-washed Celite was sieved to give narrow screen fractions which facilitated even packing of the columns but the particle size appeared to have little effect on resolving power.

Because 1-*O*-acetyl- and free reducing sugars were adsorbed by alkali-washed Celite it was necessary to block the reducing group by formation of methyl glycosides. The diethyl mercaptals and *N*-phenyl glycosylamines were also tested but these derivatives, even when formed from fully methylated sugars, were not sufficiently volatile. The first publication (2) concerning this work reported that the anomeric methyl glycosides of 2,3,4-tri-*O*-methyl-L-arabinose and of 2,3,4,6-tetra-*O*-methyl-D-galactose were not separated under the conditions used. However, this was either a property of the particular conformations of these sugars or was caused by the lower resolving power of the instrument used in that work because it has now been found that anomeric methyl glycosides of methyl ethers of glucose can be separated.

The largest number of possible methyl ethers of glucose was best obtained by partial methylation and, because anomers were separable, methyl-α-D-glucopyranoside and methyl-β-D-glucopyranoside were partially methylated separately. Figure 1 shows the separation of the tetra- and tri-*O*-methyl ethers that resulted from these partial methylations. Identities were assigned to these peaks as described in the experimental section. All of the anomeric methyl-D-glucopyranosides were separated except those of 3,4,6-tri-*O*-methyl-D-glucose; isomers within an anomeric series were clearly distinguishable except for the methyl 2,3,6- and 2,4,6-tri-*O*-methyl-α-D-glucopyranosides which were both under peak 4, line A, in Fig. 1. This peak was collected from the effluent gas stream and rechromatographed on the non-polar Apiezon M column. As shown by Fig. 2 the two components were separated completely and it was possible therefore, by using the polar and non-polar liquid phases, to separate all of the isomeric tri-*O*-methyl-D-glucopyranosides. Table I gives the retention volumes of each of these components relative to that of methyl-2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside as a standard. An empirical observation based on these results is that in the glucose series the α-methyl glycosides, in which the anomeric methoxyl occupies the axial position, always had higher retention volumes than the corresponding β-methyl glycosides where the anomeric methoxyl is equatorial; this indicated a greater solubility of the axially oriented anomers in both the polar and non-polar phases. These relative retention volumes are much more reproducible than *R* values in paper chromatography and, although not obviating the necessity for preparing crystalline derivatives, constitute a much more sensitive and reliable criterion of purity and identification than any other chromatographic method.

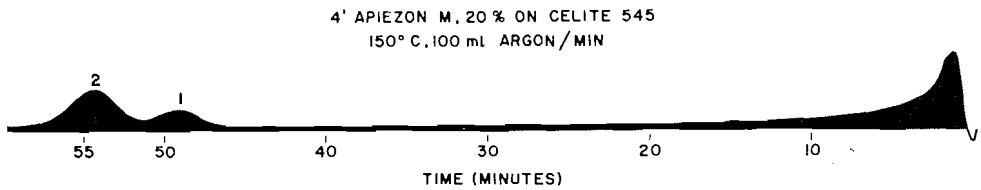

FIG. 2. Separation of methyl 2,3,6- and 2,4,6-tri-*O*-methyl-α-D-glucopyranosides. α-Methyl glycosides of: (1) 2,3,6-Tri-*O*-methyl-D-glucose. (2) 2,4,6-Tri-*O*-methyl-D-glucose.

The di-*O*-methyl ethers of glucose were not resolved as well as the tri-*O*-methyl ethers. Figure 3 shows a separation of the products from partial methylation of methyl-β-D-glucopyranoside and presumably all six of the di-*O*-methyl isomers should be present. Crystalline methyl-2,4-di-*O*-methyl-β-D-glucopyranoside was isolated from peak 4 but a

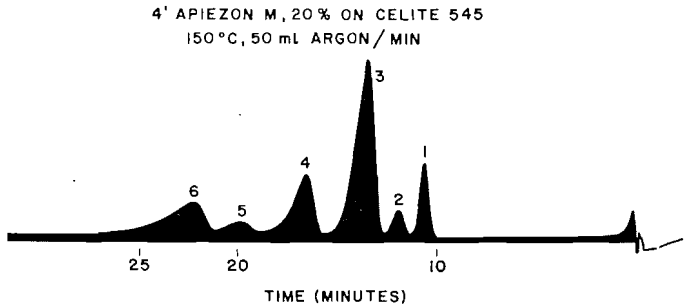

FIG. 3. Separation showing methyl di-*O*-methyl-β-D-glucopyranosides. β-Methyl glycosides of: (1) 2,3,4,6-Tetra-*O*-methyl-D-glucose. (2) 2,3,4-Tri-*O*-methyl-D-glucose. (3) Tri-*O*-methyl-D-glucoses (mainly 2,4,6-). (4), (5), and (6) Di-*O*-methyl-D-glucoses.

lack of standards has prevented assignments to the other peaks. Under the conditions used in this work it was found that skewed peaks invariably indicated heterogeneity and it is therefore almost certain that peaks 4, 5, and 6 in Fig. 3 each represent more than one component. This separation was done on Apiezon M in which the methyl-di-*O*-methyl α- and β-D-glucopyranosides moved quite rapidly but were not resolved sufficiently. On the butanediol succinate polyester column these compounds were retarded considerably because of the extra polar hydroxyl group and a useful separation was not feasible. A more selective liquid phase, or possibly one that is intermediate in polarity between those used here, is obviously needed to achieve a complete separation of all the possible methyl-di-*O*-methyl α- and β-glucopyranosides. However, Fig. 3 shows that the methyl glycosides of di-*O*-methyl hexoses are sufficiently volatile to be analyzed by gas–liquid partition chromatography. It should be mentioned that on freshly prepared columns, using alkali-washed Celite 545, the first few samples of methyl-di-*O*-methyl hexosides were irreversibly adsorbed. The columns were conditioned by running a few samples which presumably covered the active sites and no further adsorption of these compounds was encountered. There was no evidence of exchange or displacement of the samples used to condition the columns. Practically, the lack of complete separation of as complex a mixture of di-*O*-methyl hexoses as just described is not too serious because methanolysis of a methylated polysaccharide seldom yields more than three di-*O*-methyl hexoses. Work to be published on application of this technique to the structural investigation of polysaccharides has shown that the di-*O*-methyl hexoses in these less complex mixtures can be separated and identified easily (5).

The methyl mono-*O*-methyl-D-glucopyranosides were not sufficiently volatile to be separated by gas–liquid partition chromatography. Methyl mono-*O*-methyl hexopyranosides, and indeed methyl hexopyranosides, passed through columns that were conditioned as described for the methyl-di-*O*-methyl glucopyranosides. However, their retention volumes were so great that resolution of a mixture was not possible. The following sequence of reactions was therefore applied to the mono-*O*-methyl-D-glucose to give derivatives that were sufficiently volatile to be separated by gas–liquid partition chromatography. The mono-*O*-methyl-D-glucoses were reduced to the corresponding mono-*O*-methyl-D-

For personal use only.

glucitols which were then acetylated. The resolution of these mono-*O*-methyl-penta-*O*-acetyl-D-glucitols is shown in Fig. 4. It appears that the only one of these isomeric compounds to be reported previously was the 1,2,3,4,5-penta-*O*-acetyl-6-*O*-methyl-D-glucitol (6). Because anomeric methyl glycosides were separable by gas–liquid partition chromatography it appeared that this procedure of reduction and acetylation was a good way to

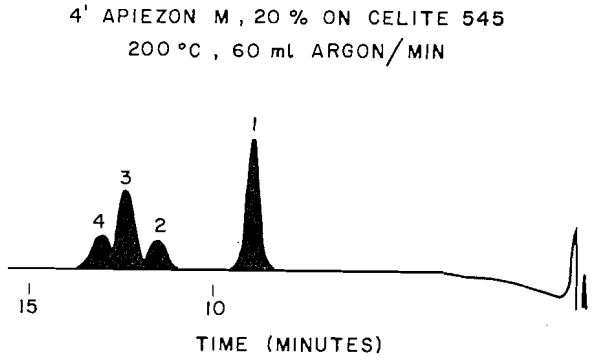

FIG. 4. Separation of mono-*O*-methyl-penta-*O*-acetyl-D-glucitols. (1) 6-*O*-methyl-D-sorbitol pentaacetate. (2) 2-*O*-Methyl-D-sorbitol pentaacetate. (3) 3-*O*-Methyl-D-sorbitol pentaacetate. (4) 4-*O*-Methyl-D-sorbitol pentaacetate.

avoid the complex mixture of anomers that might be expected in the methanolysis products from a methylated polysaccharide. However, there could be difficulty in deciding on the location of a methyl group in the original sugar when the resulting sugar alcohol was symmetrical and, in practice, it was found that methanolysis of methylated polysaccharides did not yield as complex mixtures as had been anticipated.

Gas–liquid partition chromatography affords a quick and accurate means of estimating the relative amounts of individual components in a mixture of methylated sugars. Table II gives the results from estimations of various molar ratios of two components and the mean deviation in the estimation was ±0.5 in 100. The argon ionization detector used in the

present work was developed by Lovelock (3) and shown to respond on a molar basis. It was therefore possible to obtain a molar ratio of components in a mixture directly from the separation curve simply by measuring the areas under the peaks. The method can also be used for measuring absolute quantities provided that a known percentage of an internal standard can be added to the mixture. The technique has proved extremely

useful in examining the methanolysis products of methylated polysaccharides. Although methyl mono-*O*-methyl hexosides and methyl hexosides are not sufficiently volatile to permit the separation of individual isomers, it is possible to obtain an estimate of these components, as one peak, relative to the more highly methylated products. Ratios of isomers within that one peak can then be determined by the procedure described for the mono-*O*-methyl glucoses. Other methods for estimating relative amounts of methylated sugars in a mixture depend on separation of the components by paper chromatography, elution from the paper, and estimation of the individual components by stoichiometric reaction of the reducing groups (e.g., 7) or spectrophotometric measurement of the color produced with specific reagents (e.g., 8, 9). Accuracies in these methods ranged from $\pm 0.8\%$ to $\pm 10\%$ and are, of course, influenced by impurities eluted from the paper; spectrophotometric methods require standard absorption curves for each component. Gas–liquid partition chromatography is therefore at least as accurate, much faster, and more convenient than any of those methods for estimating methylated sugars in a mixture. Each separation of the two components given in Table II required about 10 minutes and for quantitative estimation the peaks were simply cut from the chart and weighed.

EXPERIMENTAL

Apparatus

The apparatus with ionization detector was a "Pye Argon Chromatograph"* and some of its pertinent characteristics are listed below.

Column size, 4 ft, 5 mm I.D.
Detector, ionization (80 μc radium D).
Carrier gas, argon.
Sample size, 2–4 γ.
Resolution, up to 1000 theoretical plates/ft.
Limit of detection, 0.01 γ.
Temperatures used, 150° C and 200° C.

Column Packing

Celite 545 was screened to remove fines and material retained on the 100-mesh sieve was stirred with 5% methanolic potassium hydroxide for 2 hours. The solid was filtered and dried, first by air sucked through the filter and finally in an oven at 100° C. This dried material was used to prepare the columns described below.

Apiezon M vacuum grease (2 g/8 g Celite) was dissolved in petroleum ether (30–60° C) and added to the Celite in an open beaker. Sufficient solvent was used to give a mobile slurry, which was stirred during evaporation of the solvent at room temperature by a stream of air. Last traces of solvent were removed in an oven at 100° C, the mixture being stirred intermittently during this process. The dried material was then used to pack the columns and any traces of volatile material remaining were removed by equilibration of the column under operating conditions for 6–7 hours.

The butanediol succinate polyester was prepared (10) from succinic acid (50 g) and 1,4-butanediol (50 g) using zinc chloride (0.1 g) as catalyst. The mixture was stirred and heated for 3 hours at 160° C then for 2 hours at 190° C. The water formed during esterification was removed through an air condenser by a stream of nitrogen. Heating was continued for another 2 hours during which 1,4-butanediol was removed *in vacuo*. The mixture was then cooled to room temperature to give a white, crystalline solid which softened at 90° C and was completely melted at 96° C. To remove catalyst the mixture

**Obtained from Technical Service Laboratories, Toronto, Ont.*

was dissolved in chloroform and poured through a short column of Amberlite IR-120 ion exchange resin. Columns containing this liquid phase were prepared as described for those containing Apiezon M, except that chloroform was used as solvent instead of petroleum ether.

Partial Methylation

Methyl-α-D-glucopyranoside and methyl-β-D-glucopyranoside were methylated separately with 30% sodium hydroxide and dimethyl sulphate using one-third of the amount of dimethyl sulphate theoretically required for complete methylation. The reactions were stirred for 6 hours after the dropwise addition of dimethyl sulphate had been completed and the products were then isolated by extraction with chloroform.

Identification of Components

To assign identities to the peaks on the separation curves authentic samples of the various glucose methyl ethers were converted individually into glucosides by refluxing with 2% methanolic hydrogen chloride. These derivatives were then separated by gas chromatography each one giving two peaks, one of which coincided with the peak of that particular isomer in the α-series, the other with a peak in the β-series. It was not possible to establish the separations reported in this paper by using only authentic samples of glucose methyl ethers because, after methyl glycoside formation, each sample gave two peaks and it could not be proved which one was the α-anomer and which the β-. This could only be done by preparing the methyl ethers of each anomeric methyl glycoside as just described.

Mono-O-methyl-penta-O-acetyl-D-glucitols

Authentic samples of 2-, 3-, 4-, and 6-*O*-methyl-D-glucose were reduced separately with an equal weight of potassium borohydride in aqueous solutions. To assure complete reduction the reactions were allowed to stand at room temperature for 24 hours. Amberlite IR-120 ion exchange resin was then added until gas evolution ceased. The resin was then filtered, washed with methanol, and the combined filtrates and washings were evaporated under diminished pressure at 35° C. Repeated evaporation from methanol removed borate and the sirupy mono-*O*-methyl-D-glucitols were acetylated with acetic anhydride and sulphuric acid. The acetylation reactions were added directly to silica gel columns and the products were eluted with chloroform. Evaporation of the chloroform eluates left the isomeric mono-*O*-methyl-penta-*O*-acetyl-D-glucitols; the 6-*O*-methyl isomer crystallized on evaporation of the solvent and the 2-*O*-methyl isomer crystallized after being stored for 1 week in an evacuated desiccator over sodium hydroxide. The 3- and 4-*O*-methyl isomers have not crystallized. Anal. Calc. for $C_{17}H_{26}O_{11}$: C, 50.24%; H, 6.45%; acetyl, 52.9%. Found:

(*a*) 2-*O*-methyl-1,3,4,5,6-penta-*O*-acetyl-D-glucitol; m.p. 53–54° C (recrystallized from ether:hexane), $[\alpha]_D^{24} = +24° \pm 1°$ (*c*, 1.6% in chloroform). C, 50.15%; H, 6.64%; acetyl, 52.8%.

(*b*) 3-*O*-methyl-1,2,4,5,6-penta-*O*-acetyl-D-glucitol; $[\alpha]_D^{24} = +3° \pm 1°$ (*c*, 1.85% in chloroform). C, 50.52%; H, 6.75%; acetyl, 53.04%.

(*c*) 4-*O*-methyl-1,2,3,5,6-penta-*O*-acetyl-D-glucitol; $[\alpha]_D^{24} = +5° \pm 1°$ (*c*, 1.5% in chloroform). C, 49.92%; H, 6.71%; acetyl, 52.5%.

(*d*) 6-*O*-methyl-1,2,3,4,5-penta-*O*-acetyl-D-glucitol; m.p. 109–110° C (recrystallized from methanol:water), $[\alpha]_D^{24} = +6° \pm 1°$ (*c*, 1.71% in chloroform). C, 50.21%; H, 6.49%; acetyl, 53.07%. Vargha and Puskas (6) reported m.p. 105° C and $[\alpha]_D^{20} = +7.6°$ (*c*, 2.624% in chloroform) for this compound.

Quantitative Estimations

Solutions of known concentration were made up in methanol of methyl-2,3,4-tri-*O*-methyl-β-D-xylopyranoside and methyl-2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside. Samples were pipetted accurately from these standard solutions and mixed to give the molar mixtures listed in Table II. Aliquots from these mixtures were then analyzed by gas–liquid partition chromatography and the peaks on the separation curve were cut out and weighed giving the results shown in Table II.

ACKNOWLEDGMENTS

The authors wish to thank Mr. A. G. McInnes for many valuable discussions about this work. We would also like to thank Dr. B. M. Craig for making available detailed directions for preparing the butanediol succinate polyester prior to publication. A generous donation of many of the authentic samples of glucose methyl ethers by Dr. T. E. Timell is gratefully acknowledged, and our thanks are due to Dr. A. Wickstrom for a sample of 3,4,6-tri-*O*-methyl-D-glucose. Microanalyses were done by Mr. A. E. Castagne.

THE BIOGENESIS OF ALKALOIDS

XXV. THE ROLE OF HYGRIC ACID IN THE BIOGENESIS OF STACHYDRINE[1]

A. V. ROBERTSON[2] AND LÉO MARION

ABSTRACT

In alfalfa 2–3 weeks old neither labelled ornithine nor labelled proline act as precursors of stachydrine. It has been shown, however, that the methyl group of methionine becomes incorporated into the alkaloid so that the biogenesis appears to occur at that time of growth. It is now shown that hygric acid (N-methylproline) is a precursor of stachydrine. The implications of the results obtained are discussed.

It has been shown previously that in alfalfa seedlings, the activity of administered proline labelled with ^{14}C in the carboxyl group or at position 2 is not incorporated in the stachydrine subsequently isolated (1–4). Nevertheless, radioactive stachydrine is produced at the same plant age by feeding Me-^{14}C-methionine (4). The implications of these results have been discussed and several alternatives were suggested to circumvent the most obvious conclusion that proline is not a precursor of stachydrine (4). One of these hypotheses was that only processes involving the formation of the second N-methyl group of stachydrine were taking place in alfalfa 2–3 weeks old, the heterocyclic ring having been formed from proline at some other time. For example, the final step in the biosynthesis of stachydrine might be a methylation of already preformed hygric acid (N-methylproline). Possibly one of the methyl groups of stachydrine is dynamically involved in alfalfa transmethylation reactions, in which case the methylation of hygric acid to stachydrine would be reversible. Leete and Bell (5) have shown that the methyl group of nicotine is in equilibrium with methyl acceptors in tobacco plants.

Information has now been obtained about the role of hygric acid in stachydrine biosynthesis from experiments in which carboxyl-^{14}C-hygric acid was fed to alfalfa seedlings 17 days old. The plants were harvested 4 days later at which time most of the radioactivity in the nutrient solution had disappeared. The alkaloids were isolated by established methods (6), and the crystalline mixture of pure stachydrine and homostachydrine hydrochlorides obtained was highly radioactive. Paper chromatographic assay showed that there was no contamination due to hygric acid, and that all of the activity was present in the stachydrine. Although homostachydrine has been obtained pure from the mixture of betaine hydrochlorides (7), it has not yet proved possible to separate pure stachydrine on a preparative scale. Decarboxylation to isolate the radioactive carbon as barium carbonate was therefore performed on the mixture. Appropriate corrections were made for the relative proportions of the compounds in the mixture, and for the yields of barium carbonate obtained from either component in separate experiments with inactive material. Within the limits of experimental error, all of the activity in the stachydrine was present in the carboxyl group. Therefore hygric acid serves as an efficient precursor for the heterocyclic ring of this alkaloid.

All attempts so far to show the role of ornithine or proline in the biogenesis of stachydrine have failed (1–4), and the only definite precursor of the alkaloid that has been found is hygric acid. It is conceivable that the formation of proline and its conversion to hygric acid take place at an earlier stage of growth of the plant, but since some of the

[1]*Manuscript received November 9, 1959.*

Issued as N.R.C. No. 5532.
[2]*National Research Council of Canada Postdoctoral Fellow, 1957–59.*

experiments previously reported were done after only 12 days of growth this does not seem too probable. Further, since ornithine can be converted to proline in the plant in the presence of pyridoxal (2), it also seems improbable that the failure of proline to give rise to stachydrine at the same period of growth could be attributable to the possibility that the proline might not get to the site of synthesis. The observation of Abelson and Vogel (8) concerning the difference in behavior between exogenous and endogenous ornithine in *Neurospora crassa*, however, supports such a possibility. If hygric acid were formed from proline one would have to conclude that proline was synthesized in two different sites, and that neither the ornithine nor proline from one site could find its way to the other site. The concept of multiple sites is not in itself reluctant, but it is difficult to accept that the required precursors existing in one part of the plant could not be translocated to the site where they are needed when hygric acid is. Although the suggestion is made with hesitancy, the results obtained so far could best be explained if hygric acid were synthesized not from proline, but directly from smaller fragments. Further work will be necessary to prove or disprove such a suggestion, but it becomes impossible to ignore the repeated failures to implicate ornithine or proline in the pathway to stachydrine.

EXPERIMENTAL

Synthesis of Carboxyl-^{14}C-DL-*hygric Acid*

Carboxyl-^{14}C-DL-proline (0.1 mc, sp. act. 2.7 mc/mmole) was diluted with DL-proline (44 mg) and monomethylated by the method of Ingram (9) (see also Bowman and Stroud (10)). The product was sublimed at 140°/1 mm giving a quantitative yield of pure hygric acid.

Feeding Experiment and Extraction of Alkaloids

Alfalfa seed (240 g) was grown in 8 trays as previously described (6) and on the 18th day, carboxyl-^{14}C-DL-hygric acid (54 mg, total activity 1.8×10^8 d.p.m.) in water (80 ml) was divided evenly among the trays. The radioactivity in the nutrient solution decreased as follows: 9% remained after 1 day, 4% after 2 days, 3% after 3 days, less than 2% after 4 days. The plants were harvested on the 22nd day and the alkaloids were isolated by the usual extraction procedure (6). In this experiment the crude betaine hydrochlorides obtained by ion exchange of the reineckates were discolored and oily. The oil was removed by ether extraction of an aqueous acid solution of the hydrochlorides before purification through the mercuric chloride complex. The crystalline mixture of pure homostachydrine and stachydrine hydrochlorides had an activity of 2.82×10^3 d.p.m./mg. Paper chromatography in 95% ethanol – concentrated aqueous ammonia (95:5) showed that all of the activity was confined to the stachydrine spot, R_F 0.45, and that homostachydrine, R_F 0.54, was the only other component. Hygric acid had R_F 0.51 on the same paper. Hygric acid does not give a satisfactory reaction with Dragendorff's reagent or iodine vapor, so the orcinol – sulphuric acid method of Ingram (9) was used. The betaines are also developed by this reagent. The mixture was estimated by the intensity of spots on paper chromatograms (developed with Dragendorff's reagent) to contain 60 ± 5% (w/w) of stachydrine hydrochloride. The activity of the stachydrine hydrochloride is therefore 4.7×10^3 d.p.m./mg and sp. act. 8.4×10^5 d.p.m./mmole.

Degradation to Isolate Radioactivity

Fifty milligrams of the mixture of betaine hydrochlorides in quinoline (2 ml) was heated with copper powder (100 mg) and the temperature was gradually raised from 210–250° (1 hour). A slow stream of purified nitrogen was passed through the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

flask and the nitrogen and evolved gases were bubbled through barium hydroxide solution. The precipitated barium carbonate (42 mg) had an activity of 2.70×10^3 d.p.m./mg. In separate experiments with inactive stachydrine hydrochloride, homostachydrine hydrochloride, and mixtures of the two compounds, the weight of barium carbonate obtained under the above conditions was $86\pm2\%$ of the weight of starting material. Hence the ratio of the weights of barium carbonate arising from stachydrine to that from homostachydrine is equal (within $\pm2\%$) to the ratio of stachydrine to homostachydrine (w/w) in the mixture which was decarboxylated. The weight of barium carbonate arising from stachydrine is thus 60% of the total weight of the radioactive barium carbonate sample. Therefore barium carbonate formed by decarboxylation of radioactive stachydrine has an activity of 4.5×10^3 d.p.m./mg and sp. act. 8.9×10^5 d.p.m./mmole.

THE ACIDITY OF SOME AROMATIC FLUORO ALCOHOLS AND KETONES[1]

ROSS STEWART AND R. VAN DER LINDEN[2]

ABSTRACT

A series of five trifluoroacetophenones and five phenyl trifluoromethyl carbinols have been synthesized and their ionization constants in water measured. They are the unsubstituted, *p*-methoxy, *p*-methyl, *m*-bromo, and *m*-nitro compounds. The ketones exist as hydrates in aqueous solution and each is about two pK units stronger than the corresponding alcohol. The acidities of both series are correlated by the Hammett relation with ρ values of 1.11 and 1.01 for the ketone hydrates and alcohols respectively. The acid strengths vary from a pK_a of 9.18 for *m*-nitro-α,α,α-trifluoroacetophenone to 12.24 for *p*-methoxyphenyl trifluoromethyl carbinol.

In connection with an investigation of the mechanism of the permanganate oxidation of alcohols (1) we have examined a series of trifluoromethyl carbinols (2). These were chosen because their enhanced acidity permitted measurements to be made of the concentration of the alkoxide ion believed to be the intermediate in the oxidation mechanism. The trifluoromethyl carbinols and the ketones from which they are prepared are interesting compounds in their own right because of their acidities, the hydrates of the latter being of similar strength to phenols. We would like to report herein the synthesis of a series of substituted phenyl trifluoromethyl alcohols and ketones and the determination of their acidities.

EXPERIMENTAL

Reagents

α,α,α-Trifluoroacetophenone was obtained from Columbia Organic Chemicals and was fractionally distilled before use. All other reagents used were of reagent grade.

p-Methyl-α,α,α-trifluoroacetophenone

p-Tolylmagnesium bromide was prepared in the usual way from *p*-bromotoluene (34.7 g, 0.203 mole) and an equivalent amount of magnesium. Trifluoroacetic acid (7.5 g, 0.066 mole) dissolved in ether was added dropwise with vigorous stirring over a period of 2 hours at room temperature. After refluxing for 1 hour the reaction mixture was poured onto a 10% sulphuric acid – ice mixture and extracted several times with ether. The ether extracts were dried and distilled and a clear fraction boiling at 69° at 13 mm was obtained; yield, 30–50%, $n_D^{25} = 1.4710$ (lit., $n_D^{20} = 1.4693$ (3)); 2,4-dinitrophenylhydrazone, m.p. 133–136°. Calc. for $C_9H_7OF_3$: C, 57.4; H, 3.7; F, 30.3. Found: C, 57.8; H, 3.9; F, 26.8. This compound has been synthesized previously using a different procedure (3).

m-Bromo-α,α,α-trifluoroacetophenone

To a Carius tube of approximately 100 ml volume was added α,α,α-trifluoroacetophenone (20 g, 0.115 mole), anhydrous ferric chloride (0.1 g), and bromine (9 ml, 0.168 mole). The mixture was cooled in liquid nitrogen, the tube was sealed and then heated in a furnace for 6 days at 130°.

After reaction the liquid was extracted with aqueous sodium bromide and then fractionally distilled giving a small amount of unreacted ketone, a solid residue, and a clear liquid, b.p. 83.5° at 12 mm, $n_D^{24} = 1.5030$; yield, 50%. Calc. for $C_8H_4OF_3Br$: C, 38.0; H, 1.5; F, 22.5. Found: C, 38.2; H, 1.6; F, 20.6. 2,4-Dinitrophenylhydrazone, m.p.

[1]*Manuscript received November 18, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C.
[2]*Present address: Imperial Oil Limited, Sarnia, Ontario.*

121.5–123°. Calc. for $C_{14}H_8O_4N_4F_3Br$: C, 38.6; H, 1.9; N, 12.9; F, 13.2. Found: C, 38.8; H, 2.5; N, 12.0; F, 12.0.

As a check on the identity of this compound a sample was hydrolyzed with aqueous base and gave *m*-bromobenzoic acid, identical with an authentic sample.

m-Nitro-α,α,α-trifluoroacetophenone

Sixty milliliters of concentrated sulphuric acid was added slowly with stirring to trifluoroacetophenone (27.2 ml, 0.2 mole) with the temperature kept at 0° or below. A nitrating mixture (made up from 12 ml concentrated nitric acid, 4 ml fuming nitric acid, and 24 ml concentrated sulphuric acid) was added dropwise with cooling to keep the temperature from rising above 0°. A yellow solid began to precipitate after part of the nitrating mixture had been added. The mixture was poured onto crushed ice and extracted with ether. The latter was dried and on removal of the ether gave a yellow oil which on fractional distillation gave a pale yellow, low melting solid, b.p. 113° at 12 mm; yield, 75%. Calc. for $C_8H_4O_3F_3N$: C, 43.8; H, 1.8; F, 26.0; N, 6.4. Found: C, 43.4; H, 1.9; F, 24.3; N, 6.6. 2,4-Dinitrophenylhydrazone, m.p. 128–132°. Calc. for $C_{14}H_8O_5N_5F_3$: C, 42.2; H, 2.0; N, 17.6; F, 14.3. Found: C, 43.1; H, 2.8; N, 17.0; F, 13.4.

Alkaline hydrolysis of the ketone gave *m*-nitrobenzoic acid, identical with an authentic sample.

p-Methoxy-α,α,α-trifluoroacetophenone

This compound was prepared by the Grignard procedure essentially as described for *p*-methyl-α,α,α-trifluoroacetophenone. B.p. 64° at 0.5 mm; $n_D^{23} = 1.5051$. Calc. for $C_9H_7F_3O_2$: C, 52.9; H, 3.5. Found: C, 51.9; H, 3.6. 2,4-Dinitrophenylhydrazone, m.p. 104–105° (decomp.).

Phenyl Trifluoromethyl Carbinols

The unsubstituted, *m*-bromo, and *p*-methyl compounds were prepared by a lithium aluminum hydride reduction of the corresponding ketones by a standard method. Data are listed in Table I. The yields of crude product before purification were of the order of 80–90%.

m-Nitrophenyl Trifluoromethyl Carbinol

m-Nitro-α,α,α-trifluoroacetophenone (10 g, 0.045 mole) and aluminum isopropoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

(8.2 g, 0.04 mole) dissolved in 40 ml of dry isopropyl alcohol were distilled slowly for 2 hours with the alcohol being replaced as it distilled. The mixture was poured onto a 3 *M* HCl–ice mixture and extracted with ether. Distillation yielded a viscous oil, b.p. 106° at 2 mm, which crystallized on standing. Recrystallization from benzene – petroleum ether gave pale yellow needles, m.p. 47–48°.

p-Methoxyphenyl Trifluoromethyl Carbinol

This compound was prepared by essentially the method described for *m*-nitrophenyl trifluoromethyl carbinol. See Table I for physical constants.

pK_a *Measurements*

Stock solutions of the alcohols and ketones of appropriate concentration were prepared by weighing out the pure liquids (purified in most cases by gas chromatography), and dissolving them with shaking in distilled water. Usually 10 ml of these solutions and 10 ml of phosphate buffer were added to a 25-ml volumetric flask which was then made up to volume with distilled water. The buffer consisted of 0.02 *M* Na_2HPO_4 solution to which 1 *N* NaOH or 1 *N* H_2SO_4 was added to produce approximately the desired pH. Solutions more basic than pH 13 were obtained by using NaOH directly rather than the buffer. The pH of these solutions was obtained directly from the concentration of NaOH present. The optical density of a few milliliters of the buffered ketone or alcohol solution was then measured using a Beckman DU spectrophotometer at a suitable wavelength. The latter was located by measuring the entire spectrum of the ketone or alcohol in neutral and basic solution (usually pH 4.0 and 13.6) using a Cary model 14 recording spectrophotometer. The absorption maxima are listed in Tables I and II. The cell compartment of the DU spectrophotometer was kept at 25° by means of thermospacers.

buffer at pH 7.00 and 10.00. It has been reported (4) that trifluoroacetophenones are decomposed by alkali to CHF_3 and the corresponding benzoic acid. The alkaline solutions we used were stable during the time of the measurements but it was noted that decomposition was occurring in some cases after a few hours.

Calculations

For all the compounds studied a plot of optical density against pH gave a typical titration curve. The ionization constants were calculated using the equation,

$$pK_a = pH \pm \log [(D - D_{A^-})/(D_{HA} - D)]$$

where D is the optical density of the solution at the selected wavelength, D_{A^-} that at complete ionization obtained by measuring the optical density of a 0.6 N NaOH solution of the compound (corrected in the case of the alcohols for incomplete ionization), and D_{HA} that of the completely unionized form obtained by a measurement at pH 4. A minimum of three values in the vicinity of half ionization was obtained for each compound and these values averaged to obtain the values listed in Table III. The probable error varies from compound to compound because of the differences in spectra but is generally of the order of ± 0.06 pK units.

The wavelengths in millimicrons used for the pK measurements were as follows, with the alcohol listed first and the ketone second: H (260, 260); p-CH_3O (280, 276); p-CH_3 (269, 260); m-Br (274, 274.5 and 267.5); m-NO_2 (330, 320).

RESULTS

Polyfluorinated ketones exist in the hydrated form in aqueous solution (5, 6) presumably because of the strongly electron-withdrawing group which raises the energy of the dipolar canonical structure and shifts the following equilibrium to the right.

The trifluoroacetophenones reported herein are all hydrated in aqueous solution as can be seen from an examination of their ultraviolet spectra. Table II which lists the absorption maxima of the ketones in cyclohexane and in water and Fig. 1 which shows the spectrum of *m*-bromo-α,α,α-trifluoroacetophenone in water reveal the absence of the usual phenyl ketone absorption in aqueous solution. The latter spectrum appears when these compounds are dissolved in cyclohexane. (The absorption of the *p*-methoxy ketone

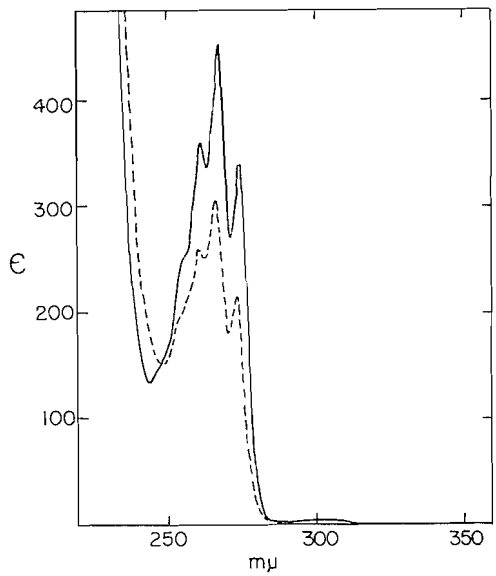

FIG. 1. The ultraviolet spectrum of *m*-bromo-α,α,α-trifluoroacetophenone in water: solid line, pH 4; broken line, pH 13.

at 300 mμ is probably due to the presence of some unhydrated ketone since this ketone is the one expected to be least hydrated in water.) When trifluoroacetophenone is dissolved in ethanol the characteristic phenyl ketone absorption at 253 mμ rapidly decays until the spectrum resembles that in aqueous solution.

The ultraviolet spectrum of the hydrate of trifluoroacetophenone is essentially a benzene spectrum modified by the side chain. When one of the hydroxyls in the side chain is ionized in basic solution the spectrum is sufficiently altered to enable measurements of the concentrations of the two forms to be made (Fig. 1).

The same applies to the alcohols, and in fact the spectra of the ketone hydrates and their anions were found to be very similar to those of the corresponding alcohols and their anions. Tables II and III reveal the close similarity in the wavelength maxima in the two series. The extinction coefficients are, however, somewhat larger for the ketone hydrates than for the alcohols.

Comparison of Acidities in the Two Series

The ionization constants of the alcohols and ketone hydrates are listed in Table IV; Fig. 2 shows the pK values plotted against σ, the Hammett substituent constant (7, 8). A satisfactory linear relation is obtained for both series. It can be seen that the ketone hydrates are about 2 pK units more acidic than the alcohols. This 100-fold increase in

ionization constant (50-fold if a statistical correction is made for the extra ionizable proton in the ketone hydrate) is due entirely to the electronegative nature of the additional oxygen atom in the former.

In these two systems resonance effects on the ionization are completely absent and it is worth comparing the effect of the additional oxygen atom on the acidity of the hydroxyl group with that in analogous cases. Table V shows that the addition of an oxygen atom

TABLE V
Effect of oxidation on acidities

Acid	K_I	Acid	K_{II}	K_{II}/K_I	Reference
$C_6H_5C(OH)(H)CF_3$	1.2×10^{-12}	$C_6H_5C(OH)(OH)CF_3$	1.0×10^{-10}	80	Herein

$HP(OH)_2$	1×10^{-2}	$HOP(OH)_2$	1.6×10^{-2}	1.6	(10)
$C_6H_5C(OH)H$	1.2×10^{7}	$C_6H_5C(OH)_2$	1.8×10^{7}	1.5†	(11, 12)

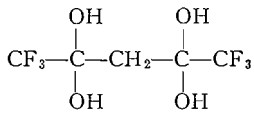
*Corrected for incomplete hydration of CO_2.

†This ratio varies with the substituent in the ring. The p-CH_3O substituent reduces the importance of resonance *within* the carbonyl group and raises this ratio to a value of 13.

to formic acid, hypophosphorous acid, and benzaldehyde conjugate acid produces much smaller charges in acidity than the addition of an oxygen atom to phenyl trifluoromethyl carbinol. In the former cases the electron-withdrawing inductive effect of oxygen is largely cancelled by its electron-donating resonance effect, assuming in the case of phosphorous acid that resonance occurs with the expanded valence shell of phosphorus. Resonance involving the oxygen atoms is not possible in the case of the ketone hydrates.

The Reaction Constant

The values of the reaction constant, ρ (the slopes in Fig. 2) (7, 8), are 1.01 for the alcohols and 1.11 for the ketone hydrates. Values close to 1.0 are expected for ionizations in which the proton is removed from the second atom of the side chain (13) as in both the present cases.*



Rate of Ionization of the Fluoroketones

When the fluoroketones reported herein are dissolved in water they react rapidly to form the hydrates since the spectrum taken immediately after solution is effected is identical with that taken after long standing. The ionization of these weak acids is essentially instantaneous as expected for hydroxylic compounds. This rather obvious point is referred to here because certain fluorinated ketone hydrates have been shown to ionize only slowly with base. Thus hexafluoroacetylacetone which exists in solution as

*NOTE ADDED IN PROOF: *Since there is no conjugation between the sidechain and the substituents in these series one should obtain a better correlation with the recently derived σ^0 values (R. W. Taft, Jr., S. Ehrenson, I. C. Lewis, and R. Glick. J. Am. Chem. Soc. **81**, 5352 (1959)) than with the standard sigma values. Even though σ and σ^0 are not greatly different for the substituents studied in this work it does appear that the correlation is slightly better for σ^0 than for σ.*

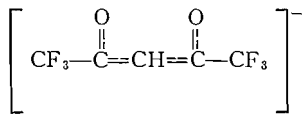
the dihydrate, I,



I

although a much stronger acid ($pK = 4.35$) than trifluoroacetophenone hydrate ($pK = 10.0$) ionizes at a relatively slow rate requiring over 3 hours for neutralization with 1 *M* NaOH (14, 15). A similar situation exists with thenoyltrifluoroacetone (14). The reason for the apparent discrepancy is the following. The stable anion of I is undoubtedly not ion II, but ion III.

II

III

The slow neutralization by base is due to ion II, which is almost certainly formed immediately by the action of strong base, having to revert to the unhydrated form and then eliminate a proton from the central carbon to form the more stable ion III. Such an enolate anion is, of course, not possible with aromatic ketones so that the further, slow, ionization does not take place.

THE IONIZATION AND DISSOCIATION OF SOME HALOGEN MOLECULES BY ELECTRON IMPACT[1]

D. C. Frost and C. A. McDowell

ABSTRACT

The ionization and dissociation of chlorine, bromine, iodine, iodine monochloride, and iodine monobromide by electron impact have been studied in a mass spectrometer which uses a monoenergetic electron source. Many ionization potentials have been observed for these molecules which, of course, refer to the formation of the parent molecular ions in different excited states. These experimental results are discussed in terms of simple molecular orbital theories of the electronic structures of the different halogen molecules.

Electron-induced dissociative ionization processes for the different substances have also been studied. Where possible, appearance potentials of both the positive and negative ions have been determined. These results have been used to construct potential energy diagrams illustrating the origin of some of the negative ion and dissociation processes observed.

INTRODUCTION

Modern electron impact methods (1, 2, 5, 6) which use monoenergetic electron sources can provide much information concerning the excited states of molecular ions. The data so obtained are of importance in understanding the electronic structure of the molecules studied. They also can be used to provide means of assessing quantum mechanical calculations. Frequently these data are the only source of information about the energy levels and excited states of the molecular ions of quite common molecules. This is so because in many cases little or nothing is known about the spectra of the molecular ions concerned.

In this paper we present the results of a detailed study of the ionization and dissociation of some halogen molecules. We have used the retarding potential difference (R.P.D.) method to obtain essentially monoenergetic electrons. The molecules studied are chlorine, bromine, iodine, iodine monochloride, and iodine monobromide.

EXPERIMENTAL

The mass spectrometer used was that described in our earlier publications (2, 3). Krypton was used as a calibrating gas for the measurements on positive ions; its ionization potential is 112,914.5 cm^{-1} (7) or 13.997 ev. For negative ions, the appearance potential of SF_6^- from sulphur hexafluoride at 0.03 ev (9) and the appearance potentials of O^- from oxygen at 4.53 ev (4) and 17.26 ev (8) were taken as standards.

In the sections dealing with resonance capture processes allowance has been made for the electron energy distribution (see reference 10) in the quoted capture energies.

Where ICl and IBr are concerned, we present results on the parent ions only, since the dissociative ionization was complicated through large contributions to the fragment ion currents from I_2 and Cl_2 or Br_2 impurities which could not be completely eliminated. Owing to the corrosive nature of the vapors studied, it was frequently necessary to remove the ion source for cleaning to retain an electron energy bandwidth of less than 0.2 ev.

RESULTS AND DISCUSSION

(A) The Ionization of Chlorine, Bromine, and Iodine

(i) Chlorine

The electronic structure of Cl_2, Br_2, and I_2 may be represented (11) by the formula:

$$[1] \qquad \text{-----}\,(\sigma_g ns)^2(\sigma_u ns)^2(\sigma_g np)^2(\pi_u np)^4(\pi_g np)^4,\ {}^1\Sigma_g^+$$

where $n = 3$, 4, or 5 for Cl_2, Br_2, and I_2 respectively. The inner electrons are omitted and the orbitals are written in order of decreasing binding energy.

The outer $(\pi_g np)^4$ and $(\pi_u np)^4$ orbitals are mainly atomic in character, and the energies necessary to remove an electron from either of them would not be expected to be too different. The ion formed by the removal of an electron from one of these π orbitals would be expected to have the configuration $\text{-----}(\pi_u)^4(\pi_g)^3$, $^2\Pi_g$, or at a higher energy, $\text{-----}(\pi_u)^3(\pi_g)^4$, $^2\Pi_u$, and each of these $^2\Pi$ states would be a doublet ($^2\Pi_{3/2}$, $^2\Pi_{1/2}$) with an energy separation somewhat less than that existing in the relevant halogen atom ion ground state. The energy separations for the doublet ground states of the halogen atoms are 0.11 ev for Cl, 0.46 ev for Br, and about 0.7 ev for I. The actual energy difference between the $^2\Pi_u$ and $^2\Pi_g$ states will depend on the overlap between the wave functions for the $(np\pi)^4$ and $(np\pi)^3$ atomic groups. Mulliken (11) predicted that the overlap should be quite small, perhaps small enough to give the order of ionic electronic states as:

$$^2\Pi_{3/2,\,g};\ ^2\Pi_{3/2,\,u};\ ^2\Pi_{1/2,\,g};\ ^2\Pi_{1/2,\,u}.$$

We will now consider the case of chlorine. Watanabe (12), using a photoionization technique, measured the first Cl_2 ionization potential to be 11.48 ± 0.01 ev. Morrison and Nicholson (13) and Thorburn (14) found a value of 11.8 ev by electron impact. The value obtained in our work is 11.63 ± 0.04 (standard deviation) ev. It will be noted that the electron impact figures are considerably higher than Watanabe's, and this is no doubt due to a low ionization cross section at the threshold. The Cl_2^+ ground state potential energy curve will be displaced in equilibrium internuclear distance from the $Cl_2(^1\Sigma^+)$ since primary ionization involves the removal of an antibonding electron.

The only spectroscopic observations on the chlorine molecular ion Cl_2^+ have been of the high frequency emission spectrum. This consists of ultraviolet continua and red-degraded bands from 3400 to at least 5500 Å. Ota and Uchida (15) arranged these bands into three systems, and later Elliott and Cameron (16) remeasured them and were unable to accept the former workers' analysis. Elliott and Cameron in 1938 (17) further analyzed the rotational structure of 18 bands and concluded that they belonged to $^2\Pi$–$^2\Pi$ transitions with system origins at approximately 20,800 and 20,600 cm^{-1}. This placed the $^2\Pi$ states about 2.55 ev apart.

Howell (18) disagreed with Elliott and Cameron's interpretation of their analysis, and put forward strong arguments in favor of assigning the bands to transitions with a common lower state deriving from $^2\Pi$, and the upper state from separate $^2\Sigma$ type levels. It will be shown later that this most recent interpretation fits in with our new electron impact data.

In the present work, there appear to be several ionic energy levels within about 0.6 ev of the ionization threshold (Fig. 1), and it seems very probable that within this energy range the Cl_2^+ ion is being formed in its $^2\Pi_g$ and $^2\Pi_u$ electronic states, each with an expected doublet separation of about 0.1 ev. This would explain the inability of the instrument to resolve any breaks in this neighborhood. Furthermore, since the curvature extends over

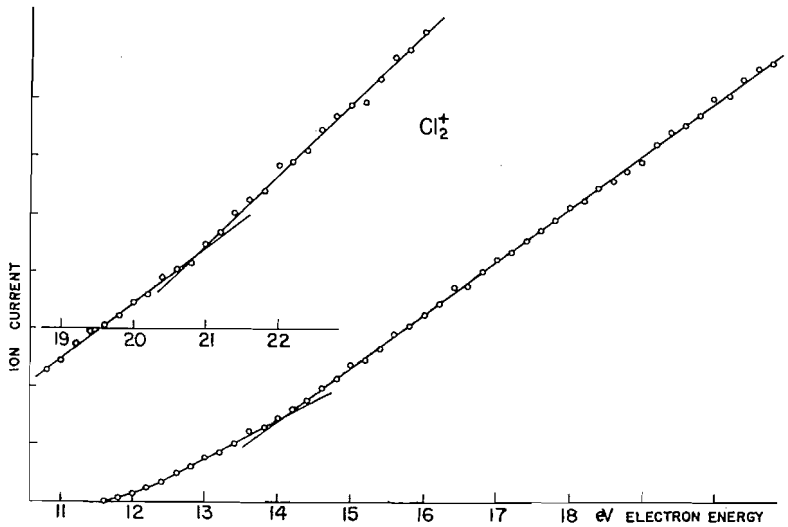

FIG. 1. The ionization efficiency curve for the formation of Cl_2^+ from chlorine by electron impact.

as great an energy as 0.6 ev, it appears probable that the $^2\Pi$ doublets do not overlap. The order of the $^2\Pi$ states would then be

$$^2\Pi_{3/2,\,g};\ ^2\Pi_{1/2,\,g};\ ^2\Pi_{3/2,\,u};\ ^2\Pi_{1/2,\,u}$$

in order of increasing energy. If the $^2\Pi_{3/2,\,u}$ did overlap the $^2\Pi_{1/2,\,g}$ level then the curvature in the ionization efficiency curve tail would be unlikely to spread over more than 0.3 or 0.4 ev.

The next inner ionization potential would be expected to refer to the removal of an electron from the strongly bonding $(\sigma_g 3p)^2$ orbital to leave the ion with the configuration;

[2] $$KKLL\ (\sigma_g 3s)^2(\sigma_u 3s)^2(\sigma_g 3p)(\pi_u 3p)^4(\pi_g 3p)^4,\ ^2\Sigma_g^+.$$

The $^2\Sigma_g^+$ ion formed by this process would therefore be expected to have a dissociation energy much less and an equilibrium internuclear distance greater than the Cl_2 molecule in the ground state.

The lowest Cl_2^+ dissociation limit, at 15.434 ev where $Cl^+(^3P)$ and $Cl(^2P)$ are the products, correlates with the molecular states Σ^+, Σ^- (2), Π (2), and Δ as doublets and quartets. These include the observed $^2\Pi_u$ and $^2\Pi_g$ and also a $^2\Sigma^+$. The next highest dissociation limit for Cl_2^+ occurs at 24.35 ev (giving at infinite separation $Cl^+(^4P) + Cl(^3P)$) and it is most unlikely that this limit is associated with the $^2\Sigma_g^+$ state of expression [2] since the corresponding ionization potential would be of the order of 22 ev. The energy required for the removal of a $Cl_2(\sigma_g 3p)$ electron would be expected to be much less than this.

It is fairly certain, then, that the Cl_2^+ ion represented by configuration [2] will have 15.434 ev as the dissociation limit; and for the following reasons it is proposed to assign the electron impact ionization potential at 14.09 ev to the process giving rise to this ion species. First, having assumed that ionization from the chlorine $(\pi_u)^4$ and $(\pi_g)^4$ orbitals takes place near the threshold, one would expect from expression [2] the first break in the curve (above the commencement of linearity) to refer to the removal of a $(\sigma_g 3p)$ electron. Secondly, Howell's (18) interpretation of the available spectroscopic data places

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

the $^2\Sigma_g^+$ state 2.55 ev above the $^2\Pi$, and this is in good agreement with the electron impact separation of 2.46 ev between the first ionization potential at 11.63 ev and the one at 14.09 ev. Thirdly, the vertical ionization potential at 14.09 ev infers that the ionic state has a dissociation energy of about 1 ev less than that for $Cl_2(^1\Sigma_g^+)$ (2.475 ev). This means the ionic state arises through the removal of a bonding electron. Lastly, Cl^+ fragment ions are observed to be formed at 15.51 ev (see below), this is strong evidence that at this energy vertical transitions are taking place to an upper stable state of Cl_2^+, having an internuclear distance r_e greater than that for $Cl_2(^1\Sigma_g^+)$, and to a region on the ionic potential energy curve opposite to the dissociation limit of 15.434 ev. It is fairly reasonable then to conclude that the electron impact ionization potential at 14.09 ev refers to the removal of a $(\sigma_g 3p)$ bonding electron to leave the ion with the configuration [2].

The next inner ionization potential would be expected to refer to the removal of a $(\sigma_u 3s)$ electron. This orbital is likely to have a somewhat antibonding nature, and so the energy necessary to remove an electron from it would be less than 24.46 ev, the binding energy of a Cl $3s$ electron. It seems reasonable to assign the electron impact ionization potential at 20.51 ev to a process which leaves the Cl_2^+ ion with the configuration

[3] $$KKLL\ (\sigma_g 3s)^2(\sigma_u 3s)(\sigma_g 3p)^2(\pi_u 3p)^4(\pi_g 3p)^4,\ ^2\Sigma_g^+.$$

(ii) Iodine

For iodine, five distinct processes leading to ion formation were observed, and they were found to occur at 9.35±0.03 ev, 9.97±0.02 ev, 10.91±0.04 ev, 11.72±0.04 ev, and 13.64±0.06 ev, quoted with standard deviations. Watanabe found the first ionization potential to be 9.28 ev (12).

A typical ion efficiency curve for the I_2^+ ion is shown in Fig. 2. The electronic structure of the iodine molecule may be written in a similar way to that for chlorine:

[4] $$KKLLMM(N)(N)(\sigma_g 5s)^2(\sigma_u 5s)^2(\sigma_g 5p)^2(\pi_u 5p)^4(\pi_g 5p)^4,\ ^1\Sigma_g^+.$$

The outer two π orbitals will be largely atomic iodine $5p$, and the main bonding orbital is the $(\sigma_g 5p)^2$. As with chlorine, each of the ionic states formed when an electron is removed from either of the two outer orbitals will be split into two owing to spin–orbit interaction.

The magnitude of the splitting is expected to be somewhat less than 0.7 ev. That is just what is found in our work. The first two ionization potentials at 9.35 and 9.97 ev are 0.62 ev apart, and the second two at 10.91 and 11.72 ev are 0.81 ev apart.

The ionization potentials at 9.35 and 9.97 ev therefore refer to the removal of an electron from the outer $(\pi_g 5p)^4$ orbital to form the I_2^+ ion with the electronic configuration

[5] $$\text{-----}\ (\sigma_g 5p)^2(\pi_u 5p)^4(\pi_g 5p)^3,\ ^2\Pi_{g;\ 3/2,\ 1/2}$$

and the third and fourth ionization potentials will refer to ionization from the $(\pi_u 5p)^4$ orbital to form the I_2^+ ion in the $^2\Pi_{u,\ 3/2}$ and $^2\Pi_{u,\ 1/2}$ states.

A fifth ionization potential is observed at 13.64 ev, and from the molecular orbital formula for I_2 this should be the energy necessary to ionize from the bonding $(\sigma_g 5p)^2$ orbital to leave the I_2^+ ion in the $^2\Sigma_g^+$ electronic state. It would be expected that the $(\sigma_g 5p)^2$ iodine ionization potential is less than that of the chlorine $(\sigma_g 3p)^2$, previously found to be 14.09±0.03 ev, since $D(I_2) < D(Cl_2)$. It is therefore reasonable to assume that the 13.64 ev ionization potential arises through the removal of a $(\sigma_g 5p)$ electron to leave the ionic configuration:

[6] $$\text{-----}\ (\sigma_g 5p)(\pi_u 5p)^4(\pi_g 5p)^4,\ ^2\Sigma_g^+.$$

(iii) Bromine

In the case of bromine we find that there are five distinct processes giving rise to ion formation within the energy range used. They occur at 10.69±0.03, 11.05±0.05, 11.97±0.03, 12.36±0.04, and 13.72±0.04 ev. An ion efficiency curve for the Br_2^+ ion is shown in Fig. 3.

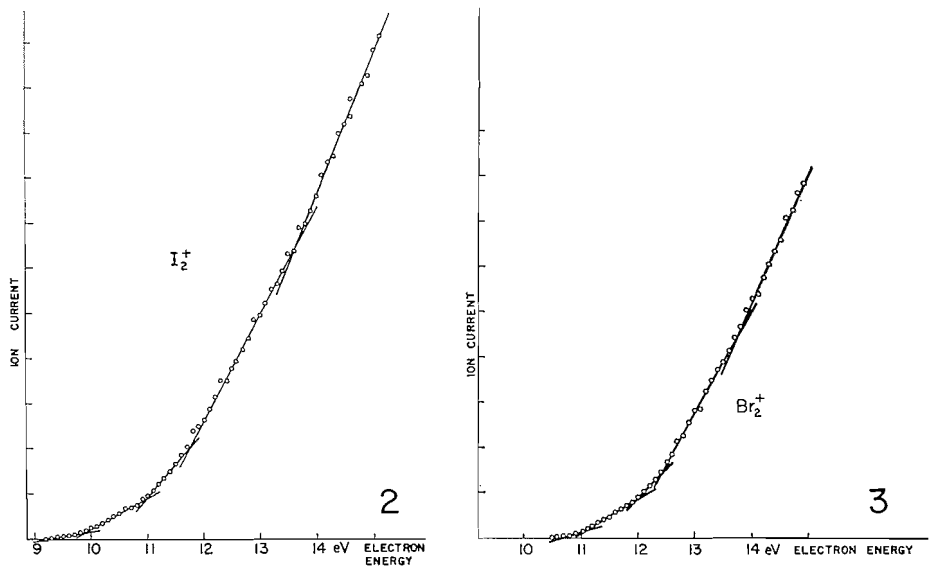

FIG. 2. The ionization efficiency curve for the formation of I_2^+ from iodine by electron impact.
FIG. 3. The ionization efficiency curve for the formation of Br_2^+ from bromine by electron impact.

Previous determinations of the first ionization potential of Br_2 have been made by Watanabe (12) (10.55 ev) and Morrison and Nicholson (13) (10.92 ev). The figure of 10.69 ev we obtain may be due to a low ionization cross section near the threshold as with chlorine.

As with iodine and chlorine, we expect four ionization potentials to lie near the ionization threshold, but here the separation of the components of each set of two is expected to be somewhat less than 0.45 ev. The first four experimental ionization potentials for bromine, quoted above, bear out this expectation. The components of each set are about 0.4 ev apart, and so we infer that at the energies of the first four processes Br_2^+ are being formed in the $^2\Pi_{g,\,3/2}$, $^2\Pi_{g,\,1/2}$, $^2\Pi_{u,\,3/2}$, and $^2\Pi_{u,\,1/2}$ electronic states. From expression [1], the next inner ionization potential would be expected to arise through the removal of one of the main bonding $(\sigma_g 4p)$ electrons. It has been shown above that similar processes in Cl_2 and I_2 require 14.09 and 13.64 ev respectively. Since $D(I_2) < D(Br_2) < D(Cl_2)$, the bromine (σ_g) ionization potential should lie between the chlorine and iodine (σ_g) values, i.e. 14.09 and 13.64 ev. The next innermost bromine ionization potential does lie between these values, at 13.72 ev, and will therefore refer to the formation of Br_2^+ with the structure

$$[7] \qquad \text{-----}(\sigma_g 4p)(\pi_u 4p)^4(\pi_g 4p)^4,\ ^2\Sigma_g^+.$$

(B) The Ionization of Iodine Monochloride and Monobromide

Figures 4 and 5 show the ion efficiency curves for ICl^+ and IBr^+ respectively, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

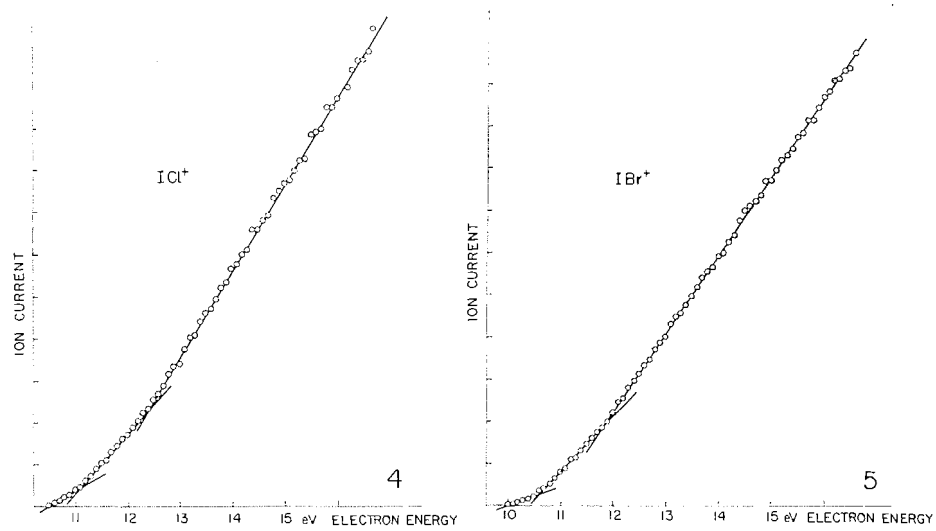

FIG. 4. The ionization efficiency curve for the formation of ICl^+ from iodine monochloride by electron impact.

FIG. 5. The ionization efficiency curve for the formation of IBr^+ from iodine monobromide by electron impact.

clearly they both exhibit three ionization processes. They occur, for ICl at 10.31 ± 0.02, 10.79 ± 0.03, and 12.13 ± 0.04 ev and for IBr at 9.98 ± 0.03, 10.49 ± 0.03, and 11.59 ± 0.05 ev.

The electronic configuration of ICl and IBr may be written, in order of decreasing binding energy (see reference 11)

[8] $$\text{-----}\,(np\sigma_X+5p\sigma_I,\,\sigma)^2(np\pi_X)^4(5p\pi_I)4,\ ^1\Sigma^+$$

where X refers to either Cl or Br. The outer two orbitals are mainly atomic X (X = Cl, or Br) and I π-type, whilst the $(\sigma+\sigma,\,\sigma)$ is mainly bonding. The first ionization potential should therefore correspond to the removal of a $(5p\pi_I)$ electron leaving the ionic structure

[9] $$\text{-----}\,(np\sigma_X+5p\sigma_I,\,\sigma)^2(np\pi_X)^4(5p\pi_I)^3,\ ^2\Pi_{3/2,\,1/2}.$$

The $^2\Pi$ states should be inverted, with a doublet separation mainly determined by the $(5p\pi_I)^3$ group and therefore similar to the spin–orbit splitting of the I^+ ground state. This splitting is about 0.7 ev, however the $^2\Pi$ splitting in ICl^+ and IBr^+ is expected to be less than this. The difference will depend on the degree of mixing of the outer (π_X) and (π_I) orbitals, and how much of the initial ionization occurs at the expense of the X atom. The evidence of this work is that for both ICl and IBr the splitting is less than the estimated value by about 0.2 ev (see Table I).

TABLE I

Electron impact ionization potentials of Cl_2, Br_2, I_2, ICl, and IBr

Proposed electronic state of ion	Ionization potentials, ev				
	Cl_2	Br_2	I_2	ICl	IBr
$^2\Pi_{g,\,3/2}$	$11.48\pm.01$	$10.69\pm.03$	$9.35\pm.03$	$10.31\pm.02$	$9.98\pm.03$
$^2\Pi_{g,\,1/2}$	~11.6	$11.05\pm.05$	$9.97\pm.02$	$10.79\pm.03$	$10.49\pm.03$
$^2\Pi_{u,\,3/2}$	~11.8	$11.97\pm.03$	$10.91\pm.04$	$12.13\pm.04$	$11.59\pm.05$
$^2\Pi_{u,\,1/2}$	~11.9	$12.36\pm.04$	$11.72\pm.04$	~12.2	~11.7
$^2\Sigma_g^+$	$14.09\pm.03$	$13.72\pm.04$	$13.64\pm.06$	—	—
$^2\Sigma_u^+$	$20.61\pm.06$	—	—	—	—

The first ionization potential of iodine monochloride is found to be 10.31 ev, and the second at 10.79 ev. Since these are 0.48 ev apart, i.e. less than 0.7 ev, we can reasonably assume that they refer to the formation of ICl^+ in the $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ states respectively.

Similar processes would seem to be responsible for the first two IBr ionization potentials we observe at 9.98 and 10.49 ev. The splitting here is 0.51 ev. We observe one additional increase in ion efficiency for each species, at 12.13 ev for ICl and at 11.59 ev for IBr. From expression [8] we would expect these ionization potentials to refer to the removal of, in each case, an $(np\pi_X)$ electron to leave the electronic configuration

[10] $$\text{-----}\ (np\sigma_X+5p\sigma_I,\ \sigma)^2(np\pi_X)^3(5p\pi_I)^4,\ ^2\Pi_{3/2,\ 1/2}.$$

The $^2\Pi$ splitting is expected to be 0.08 ev for ICl or 0.35 ev for IBr. It is clear, however, from Figs. 4 and 5 that we have been unable to resolve these doublets.

No further breaks are observed in the ion efficiency curves up to an electron energy of 18 ev, which infers that the cross sections for formation of ICl^+ and IBr^+ in their $^2\Sigma^+$ states through ionization from the σ bond are too small to be detected here. Probably the ion with the structure $\text{-----}\ (\sigma+\sigma,\ \sigma)(\pi)^4(\pi)^4$ immediately dissociates.

(C) The Dissociative Ionization of Chlorine, Bromine, and Iodine

(i) Chlorine

The Cl^- resonance capture peak is observed to have an onset energy of 1.60 ± 0.05 ev, a peak maximum at 2.4 ± 0.1 ev, and an over-all width of 1.6 ± 0.2 ev. It is most probable that the Cl^- ions are being produced by transitions to a repulsive Cl_2^- state, of dissociation limit equal to $D(Cl_2)-EA(Cl)$, or -1.055 ev with respect to the Cl_2 ground state. The process occurring is clearly

[11] $$Cl_2+e \rightarrow Cl^-+Cl+K+E$$

where K and E are respectively the total kinetic and excitation energies of the fragments.

The potential energy diagram illustrating the formation of Cl^- by process [11] is sketched in Fig. 7, and a typical Cl^- capture peak with a SF_6^- calibration peak is shown in Fig. 6.

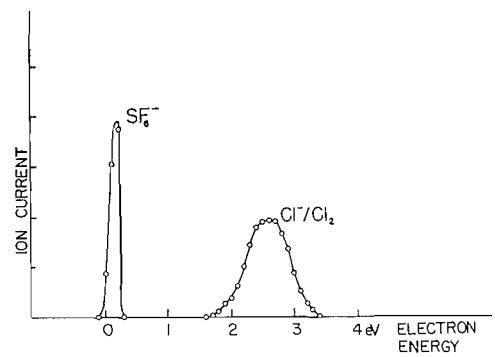

FIG. 6. The resonance capture peak for the formation of Cl^- from chlorine by electron impact.

Figure 8 shows the ion efficiency curve for Cl^+ from Cl_2. There are clearly only two processes here, and their onset energies are 11.86 ± 0.04 ev and 15.51 ± 0.03 ev. The former is identified with an ion pair process since Cl^- is observed to appear at the similar energy of 11.93 ± 0.06 ev (Fig. 9).

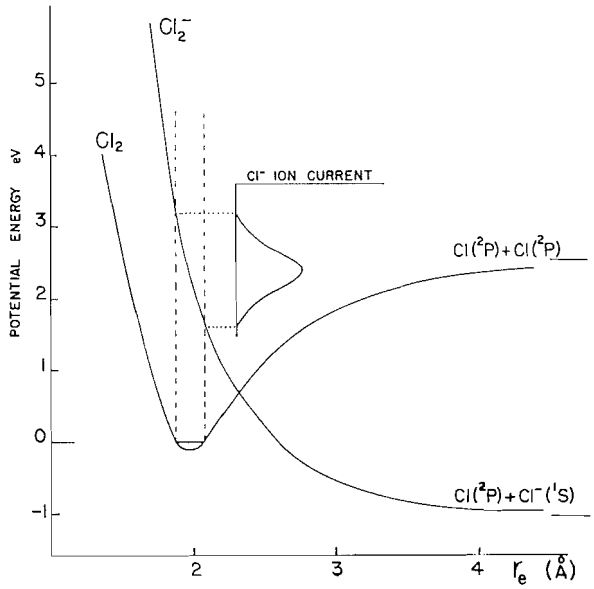

FIG. 7. Potential energy diagram to illustrate the formation of Cl^- from chlorine by a resonance capture process.

The lowest dissociation limit involving a Cl^+ and Cl^- ion pair is at 11.96 ev, assuming $EA(Cl) = 3.53$ ev (19), $D(Cl_2) = 2.48$ ev (20), and $I(Cl) = 13.01$ ev (21). The observed appearance potentials are very close to this limit, and so it is most probable that transitions are occurring from $Cl_2(^1\Sigma_g^+)$ to a stable excited state of Cl_2 having its dissociation limit at 11.96 ev.

The only other Cl^+ appearance potential detected below 23 ev is at 15.51 ev, and this clearly refers to vertical transitions from $Cl_2(^1\Sigma_g^+)$ to $Cl_2^+(^2\Sigma_g^+)$. Transitions to the ionic state will be likely to occur near the energy of the dissociation limit since the internuclear distance, r_e, for the $^2\Sigma_g^+$ is expected to be appreciably greater than r_e for the Cl_2 ground state.

These results on Cl^+ and Cl^- are in good agreement with Thorburn's (14) except that we do not detect the process producing Cl^- ions which he observed to occur at 4.4 ev.

(ii) Bromine

At low electron energies Br^- is observed to be formed with maximum probability at 0.03 ± 0.03 ev, and the ion current rapidly decreases to zero at 0.72 ± 0.05 ev. The process occurring is obviously

$$[12] \qquad Br_2+e \rightarrow Br^-+Br+K+E.$$

Assuming the fragments to be formed in their ground states, Fig. 10 shows the form of the potential energy curves involved here. The Br^- and SF_6^- resonance capture peaks are shown in Fig. 11.

Figure 12 shows an ion efficiency curve for Br^+ formation from Br_2. Several of the breaks are shallow, but repeated observations indicate that processes occur at energies of 10.38 ± 0.05, 12.30 ± 0.06, 14.31 ± 0.03, 15.88 ± 0.04, 17.06 ± 0.04, 17.97 ± 0.06, and 19.98 ± 0.06 ev.

Figure 13 concerns Br^- formation through processes other than resonance capture.

For personal use only.

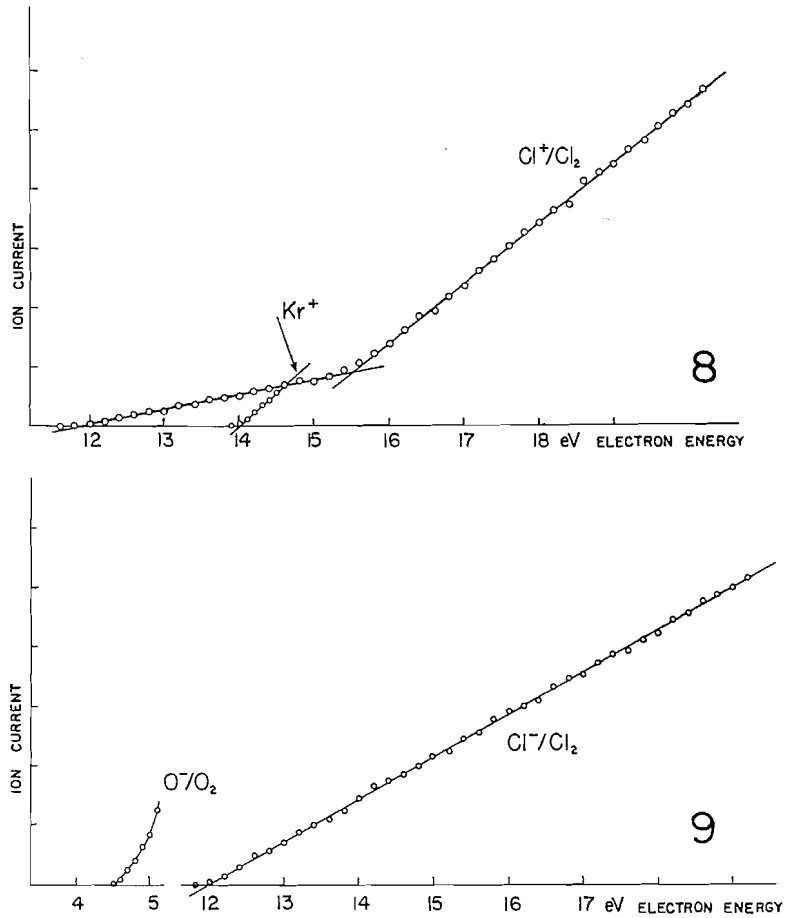

FIG. 8. The ionization efficiency curve for the formation of Cl^+ from chlorine by electron impact.
FIG. 9. The ionization efficiency curve for the formation of Cl^- from chlorine by an ion pair process as the result of electron impact.

There are two, and they occur at 10.34±0.04 and 12.27±0.05 ev. The first two appearance potentials for Br^- agree closely with the first two for Br^+, and so it is probable that these result from ion pair processes:

$$[13] \qquad Br_2 + e \rightarrow Br^+ + Br^- + K + E + e.$$

The average observed Br^+ and Br^- appearance potentials are 10.36 and 12.28 ev. Assuming $EA(Br) = 3.49$ ev (21), $D(Br_2) = 1.97$ ev (20), and $I(Br) = 11.80$ ev (21), the energy necessary to form Br^+ and Br^- in their ground states from $Br_2(^1\Sigma^+)$ is 10.28 ev. The ion pair process at 10.36 ev would therefore seem to be occurring through transitions to the potential curve of an excited Br_2 state at points opposite to the dissociation limit to give $Br^+(^2P_{3/2}) + Br^-(^1S)$. A repulsive Br_2 excited state is unlikely to be involved here as the observed appearance potential is very close to the dissociation limit energy.

The first excited state of the Br atom is the $^2P_{1/2}$ state, 0.457 ev above the ground $^2P_{3/2}$ state, and there is the possibility of a dissociation limit 10.74 ev above the ground $Br_2(^1\Sigma^+)$ state. The second ion pair process at 12.28 ev could therefore be occurring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

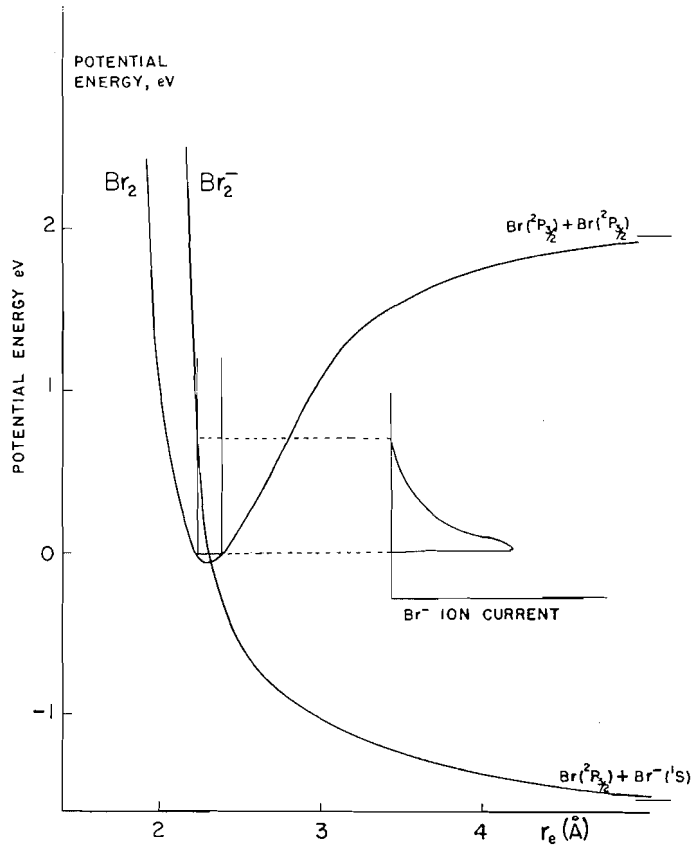

FIG. 10. Potential energy diagram to illustrate the formation of Br^- from bromine by a resonance capture process.

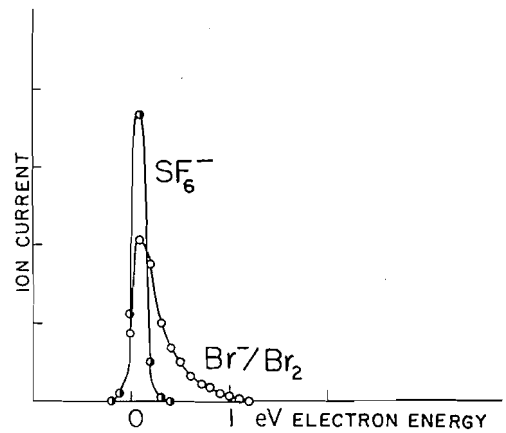

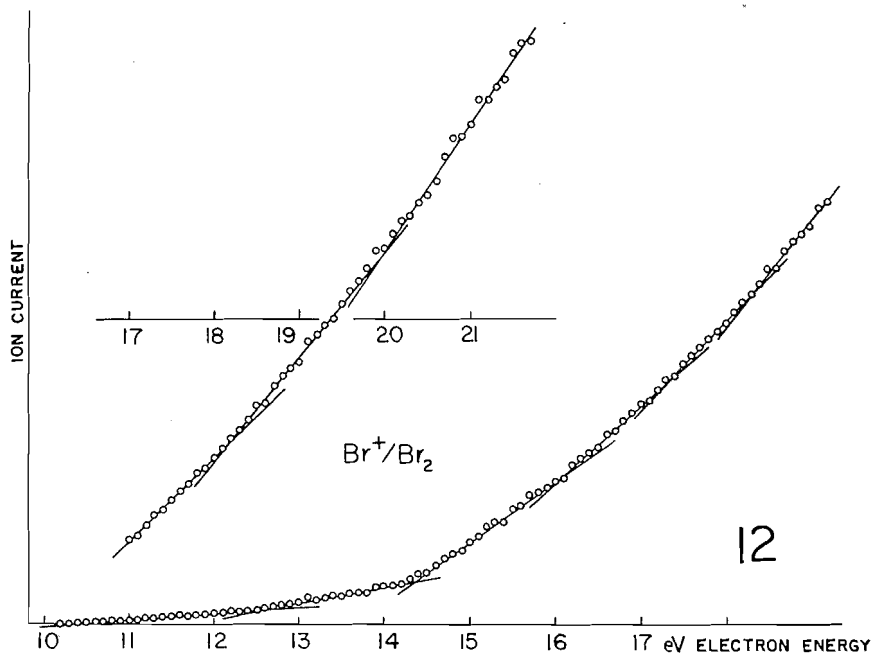

FIG. 11. The resonance capture peak for the formation of Br^- from bromine by electron impact.

through transitions to an excited unstable Br_2 state having a dissociation limit at 10.28 ev or at 10.74 ev. No further breaks in the Br^- ion efficiency curve were observed up to 18 ev.

The Br^+ ion is next formed at 14.31 ev, and from Fig. 12 it is evident that this process is easily the most important for Br^+ production. There are dissociation limits for Br_2^+ at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

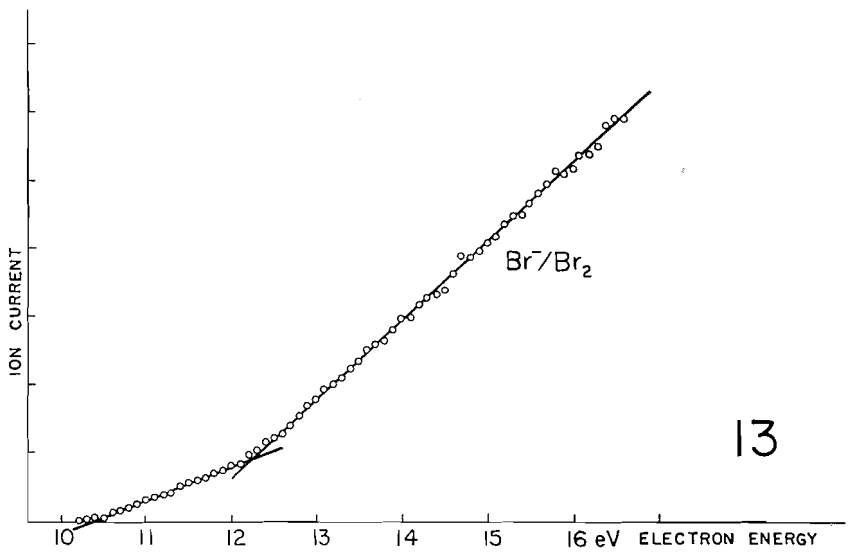

FIG. 12. The ionization efficiency curve for the formation of Br^+ from bromine by electron impact.
FIG. 13. The ionization efficiency curve for the formation of Br^- from bromine by ion pair processes as the result of electron impact.

13.77 and 14.23 ev, and we have observed a stable state (probably $^2\Sigma^+$) of Br_2^+ at 13.72 ev which probably dissociates into normal fragments at 13.77 ev. The $^2\Sigma^+$ state could, however, dissociate to $Br^+(^5S)+Br(^2P_{1/2})$ at 14.23 ev, and if this is so then the Br^+ ion group at 14.31 ev could be formed by transitions to the $^2\Sigma_g^+$ state just above the dissociation limit—a possibility since the internuclear distance, r_e, for this state is likely to be appreciably greater than that for $Br_2(^1\Sigma_g^+)$. Otherwise, the Br^+ ion formation here must result from transitions to a repulsive Br_2^+ state associated with the 13.77 ev dissociation limit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Br^+ ions are next observed to appear at 15.88 ev, and must be formed through transitions to a repulsive Br_2^+ state associated with the fragments $Br^+(^5S)+Br(^2P_{3/2})$ or $+Br(^2P_{1/2})$ mentioned above, or with a $Br(^2P)+Br^+(^5D)$ limit a few hundredths of a volt above the $Br^+(^5S)$ one.

At 17.06, 17.97, and 19.98 ev Br^+ ions are formed, and it is possible to write down the many possible processes in each case. However, little is to be gained by this since the kinetic energy with which the fragments are endowed upon formation is unknown and therefore it is not possible to make other than tentative suggestions regarding the processes occurring.

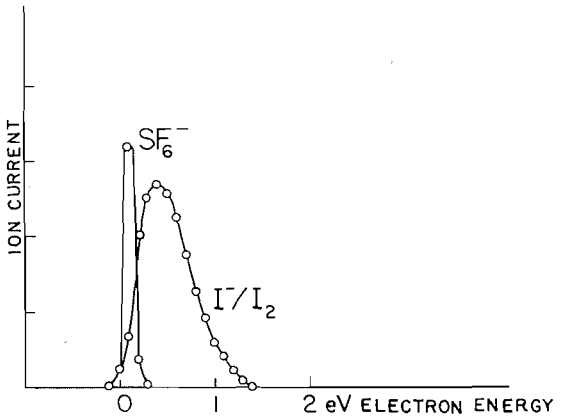

FIG. 14. The resonance capture peak for the formation of I^- from iodine by electron impact.

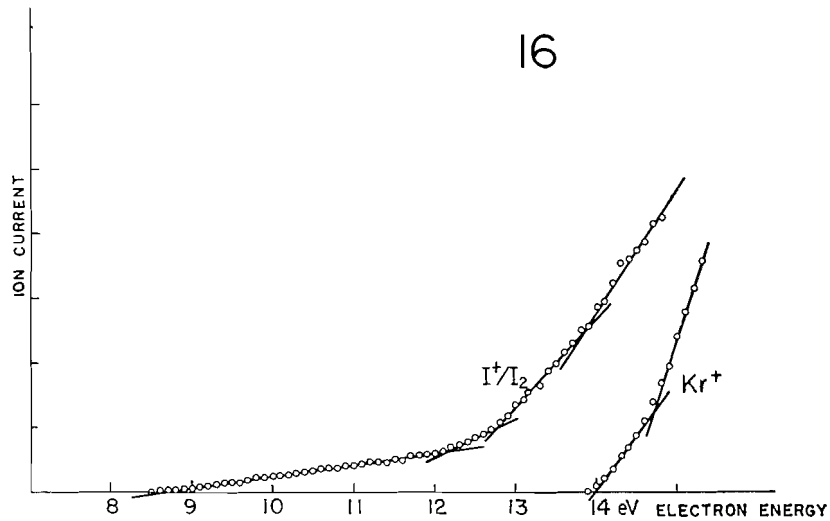
(iii) Iodine



We find the I^- resonance capture process onset energy to be 0.03 ± 0.03 ev, the upper energy limit to be 1.08 ± 0.04 ev, and the energy for maximum capture cross section to be 0.34 ± 0.07 ev. A typical I^- capture peak, with the one for SF_6^-, is shown in Fig. 14.

The process responsible for I^- formation here will be

$$I_2+e \rightarrow I^-+I+K+E \qquad [14]$$

and is illustrated in Fig. 15 where the relevant potential curves are sketched. We have described the formation of I^- from I_2 by resonance capture in more detail elsewhere (10).

Figure 16 shows the ion efficiency curve for I^+ from I_2 at electron energies between 8 and 17 ev. There are clearly four different processes possible for I^+ formation that have been resolved, and these are found to occur at 8.62 ± 0.06, 12.02 ± 0.04, 12.72 ± 0.04, and

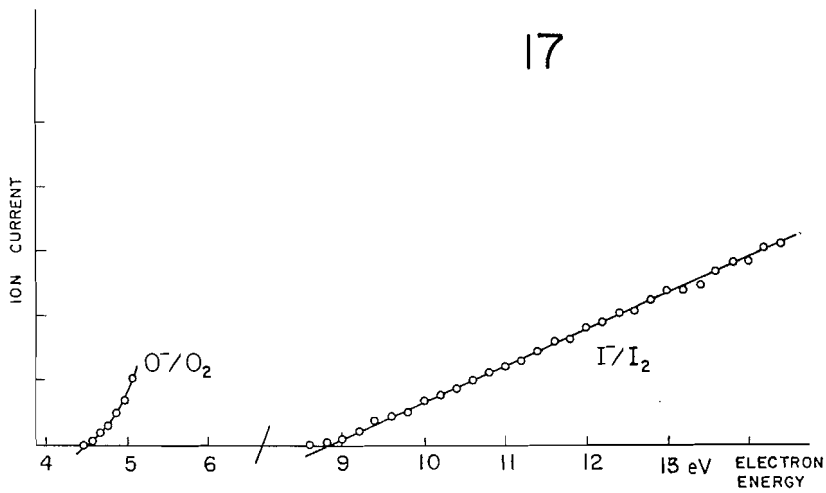


FIG. 16. The ionization efficiency curve for the formation of I^+ from iodine by electron impact.
FIG. 17. The ionization efficiency curve for the formation of I^- from iodine by ion pair processes as the result of electron impact.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

13.71 ± 0.06 ev. A typical ion efficiency curve for I^- is shown in Fig. 17, and there is evidence for only one process—found to occur at 8.68 ± 0.07 ev.

The first appearance potentials for I^+ and I^- are very close together and we assume that the ion pair process

$$[15] \qquad I_2 + e \rightarrow I^+(^3P_2) + I^-(^1S) + K + E + e$$

is responsible for their formation. Assuming no kinetic energy to be involved the minimum appearance potential for the pair would be 8.84 ev, since $EA(I) = 3.14$ ev (22), $I(I) = 10.44$ ev (21), and $D(I_2) = 1.542$ ev (20).

The excited I_2 upper state involved here must be stable because if it were not then the I^+ and I^- appearance potentials would be expected to considerably exceed the minimum energy required for their formation.

The second I^+ appearance potential occurs at 12.02 ev, and the upper state involved is almost certainly the $I_2^+(^2\Pi_u)$—of r_e greater than r_e of $I_2(^1\Sigma_g^+)$ and shown above to have components at 10.91 and 11.72 ev above the $I_2(^1\Sigma_g^+)$. This $^2\Pi_u$ state should dissociate to normal $I^+(^3P_2) + I(^2P_{3/2})$ at 11.98 ev.

I^+ ions are next formed at 12.72 ev, probably through transitions to a repulsive I_2^+ state associated with the dissociation limit just mentioned at 11.98 ev.

At 13.71 ev a further process giving rise to I^+ ions occurs, and it is probable that the $I_2^+(^2\Sigma_g^+)$ state is concerned here. We have deduced this state to lie 13.64 ev above the I_2 ground state, and it is likely to have an internuclear distance r_e much greater than r_e of the $I_2(^1\Sigma_g^+)$ since it arises through the removal of a strongly bonding σ electron. The I_2^+ ion in the $^2\Sigma_g^+$ state will therefore have a much lower dissociation energy than $I_2(^1\Sigma_g^+)$, and could dissociate to $I^+(^1D_2) + I(^2P_{3/2})$ at 13.68 ev. In this case, vertical transitions to $I_2^+(^2\Sigma_g^+)$ would be expected to produce not only I_2^+ but also I^+ ions, and this process is suggested to account for the I^+ observed to occur at 13.71 ev.

ABSOLUTE THERMAL NEUTRON FISSION YIELDS OF U^{233} [1]

D. C. SANTRY[2] AND L. YAFFE

ABSTRACT

The absolute fission yields of 22 nuclides formed in the thermal neutron fission of U^{233} have been measured radiochemically. Disintegration rates were measured by 4π β-proportional counting techniques. The identity of each nuclide was established by chemical separations and decay characteristics as determined by 4π β-counting and γ-ray scintillation spectrometry. The reaction $Co^{59}(n,\gamma)Co^{60}$ was used as a neutron flux monitor. Yields were calculated on the basis of $\sigma_f^{U^{233}}/\sigma_c^{Co^{59}} = 524/36.3$.

INTRODUCTION

Although the thermal neutron fission yields for U^{235} have been investigated extensively, yields reported for the fission products of U^{233} are few and inconsistent. Relative radiochemical yields for U^{233} fission have been measured by Grummitt and Wilkinson (1), and Steinberg *et al.* (2, 3). The yields given by the latter groups were determined relative to their absolute yield value of 6.0% for Ba^{140} which had been measured by direct fission counting (2). The uncertainty in the application of correction factors to observed counting rates of fission products in order to obtain disintegration rates accounted for most of the large errors (10% to 20%) associated with radiochemical yields.

In applying the mass-spectrometric method to isotope abundance measurements of U^{233} fission products, Steinberg *et al.* (4), Fleming *et al.* (5), and Melaika *et al.* (6) were able to measure relative yields believed reliable to 3% to 5%. These relative yields were often normalized with the aid of radiochemical yields (7, 8). Such mass-spectrometric data were then no more accurate on an absolute basis than the yields to which they were normalized.

Isotope dilution techniques have more recently been used in mass spectrometry by Anikina *et al.* (9), Kukavadze *et al.* (10), and Ivanov *et al.* (11) to measure the absolute yields of some stable and long-lived fission products in U^{233} fission. These investigators determined the number of fission events which occurred by measuring the depletion of U^{233} in a heavily irradiated sample. The errors associated with these measurements range from 2% to 15%.

Thus all fission yields for the thermal neutron fission of U^{233} previously measured possess rather large experimental errors. Such errors obscure the presence or absence of fine structure in the fission product, mass distribution curve.

The purpose of this work was to establish, radiochemically, accurate yields for various nuclides along the yield–mass curve. It was felt that by using 4π β-counting techniques, and by determining absolute rather than relative yields, the errors associated with radiochemical yields could be greatly reduced.

The $Co^{59}(n,\gamma)Co^{60}$ reaction was used to measure the neutron flux. Absolute yields could then be expressed in terms of the known values for the thermal neutron capture and fission cross sections for Co^{59} and U^{233} respectively.

It can be shown that, if U_0 atoms of U^{233} were irradiated in a thermal flux I of a nuclear

[1]*Manuscript received in original form April 27, 1959, and, as revised, December 9, 1959.*

[2]*Holder of a National Research Council Studentship, 1956–57. Present address: Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.*

reactor for a time T, then at some time t, after removal from the reactor, the following equation would apply:

$$[1] \qquad N\lambda = U_0 I\sigma_f Y_f(1-e^{-\lambda T})e^{-\lambda t}.$$

In the above equation λ is the disintegration constant of the fission product being studied and N is the number of atoms of that nuclide present at time t. Thus $N\lambda$ is the disintegration rate. The fission cross section of U^{233} is represented by σ_f, and Y_f is the probability of formation, or the fission yield of the nuclide under study.

If some cobalt were irradiated simultaneously with and under the same conditions as the U^{233}, then the following equation would obtain:

$$[2] \qquad N_1\lambda_1 = N_{Co} I\sigma_c(1-e^{-\lambda_1 T})e^{-\lambda_1 t}.$$

As before, $N_1\lambda_1$ would be the disintegration rate of Co^{60}, N_{Co} the number of cobalt atoms placed in the reactor, and σ_c the thermal neutron cross section for the reaction $Co^{59}(n,\gamma)Co^{60}$.

If equations [1] and [2] are now divided, the term I cancels, all other quantities are easily measurable, and Y_f, the fission yield, can be determined in terms of σ_f/σ_c.

EXPERIMENTAL AND RESULTS

(a) Irradiation

Accurately weighed amounts (2.30 to 6.18 mg) of uranium oxide (U_3O_8) were sealed into thin quartz tubes. Isotopic analysis of the uranium used indicated 97.746% U^{233},* the remainder being U^{238}. A spectrographic analysis showed that the level of impurities was too low to form any of the fission products by (n,γ) reactions. Into similar tubes were sealed weighed amounts (1.00 to 1.50 mg) of "spec-pure" cobalt wire (0.005-in. diameter). The tubes containing the fissile uranium and the cobalt wire were irradiated together in a "self-serve" position of the NRX reactor at Chalk River for a period of 24 hours. The position chosen was one where the neutron spectrum was predominantly thermal.

(b) Disintegration Rate Determinations

All disintegration rates were determined with good precision, using the 4π β-counters described by Pate and Yaffe (12–16). Sources were deposited on calibrated gold-plated VYNS films (10–19 $\mu g/cm^2$). Pretreatment of the films with a 5% insulin solution ensured an even deposition of the source over a known area. Sources were dried under infrared radiation.

Corrections for loss of the radiation in the exceedingly thin source-mount were obtained from the data of Pate and Yaffe (14) and were very small. Self-absorption losses were determined by combining the results of Pate and Yaffe (15) with those of Fishman and Yaffe (17) into a plot of self-absorption as a function of β-end-point energy and source thickness. The sources were all of high specific activity, so that the correction factors were usually small and accurately known.

(c) Treatment of Flux Monitor

The irradiated cobalt wire was removed from its quartz capsule, dissolved in nitric acid, and made up to a known volume. The fraction of Co^{60} activity lost by recoil into the quartz vial was measured on a γ-ray scintillation counter and found to be 0.31%.

Aliquots of the master solution were removed for disintegration rate determination.

*We wish to acknowledge with thanks the fact that this material was obtained on loan from A.E.C.L., Chalk River, Ontario.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The source superficial density was always less than 10 $\mu g/cm^2$. The self-absorption correction was 0.6% while that for source-mount absorption was 0.1%.

The neutron attenuation in the sample was calculated, using the formula

$$I = I_0 e^{-N\sigma\rho d/A}$$

where I and I_0 are the final and initial fluxes, N is Avogadro's number, σ is the total cross section of the sample for neutrons, ρ is the density of the sample, A the atomic weight, and d the thickness.

The attenuation factor was found to be 0.979* for a wire of 0.0064-cm radius.

The cobalt thermal neutron capture cross section and the half-life used were 36.3 barns (18, 19) and 5.24 years (20) respectively.

The epi-thermal contribution in the irradiation position used was determined by shielding the cobalt wire during one irradiation with $\frac{1}{2}$-mm cadmium. The epi-cadmium contribution was determined to be 1.76%.

(d) Treatment of U^{233}

The fissile sample was dissolved by crushing the irradiated vial under a warm nitric acid solution. To reduce the loss of activities by adsorption effects, 1 mg each of appropriate inactive ions (Cs^+, Ba^{++}, La^{+++}, and I^-) had been added to the nitric acid solution as "carriers". The dissolved uranium and fission products were transferred to a volumetric flask. The finely crushed remains of the vial were washed several times with small portions of nitric acid to recover fission products imbedded in the quartz. Measured aliquots of the fission product stock solution were removed and added to known amounts (10 to 20 mg) of inactive carriers of the elements to be separated. Standard methods (21, 22, 23) were used for the separation of fission product elements. In many cases slight modifications to reported procedures were used to ensure radiochemical purity. After decontamination, the element of interest was precipitated in a suitable chemical form, dissolved, and made up to a known volume. Aliquots of the solution were removed periodically for activity measurements and later for the determination of chemical recovery, using standard analytical techniques.

After the chemical separation, the radiochemical purity and identity of each nuclide was confirmed by the presence or absence of γ-radiation. A sodium iodide crystal spectrometer was used to measure gamma energies and half-lives.

The very high stability of the 4π β-counting equipment enabled the accurate measurement of both half-lives and disintegration rates.

The amount of Ba^{140} and Sr^{89} formed in cadmium-covered and -uncovered samples, irradiated under otherwise identical conditions, was measured. The epi-cadmium contribution was found to be 2.10%.

The neutron attenuation in the uranium oxide was calculated for all samples. The values ranged from 0.975 for the heaviest sample to 0.997 for the lightest.

Data given for the various nuclides include the half-life and other factors involving time. This was done so that corrections could be made later by others should more accurate nuclear constants be obtained.

(e) Individual Elements

(1) Bromine

The method of Glendenin *et al.* (24) was used to separate bromine. The activity of the

**This is in excellent agreement with that determined experimentally by Dr. R. E. Jervis, A.E.C.L., Chalk River, and we are grateful to him for making available to us the results of his determination.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

sample was measured for 100 hours and showed a pure 34.5-hour half-life corresponding to Br^{82}. Since the extraction was carried out 40 hours after the end of the irradiation, one would not expect to find any 2.3-hour Br^{83}.

Br^{82} is a shielded nuclide produced only by direct formation, so that measurement of its fission yield constitutes an independent yield determination. The relevant data are given in Table I.

TABLE I

Fission yield data for 36-hour Br^{82}

Time in reactor	24 hours
Time after irradiation	40.6 hours
Activity at saturation	1.694×10^{5} disintegrations/sec
Fission rate	2.270×10^{10} fissions/sec
Fission yield	$(7.46\pm0.17)\times10^{-4}\%$

(2) Strontium

A slight modification to the method of Glendenin (25) was used for this separation. Strontium and barium carriers were added and precipitated with fuming nitric acid. Further purifications were effected by scavenging with ferric hydroxide. Barium was removed by a chromate precipitation in a buffered solution. Strontium was precipitated as the oxalate, dissolved in nitric acid, and reprecipitated with fuming nitric. The nitrate precipitate was washed with ethanol before being dissolved in water and made up to volume.

Isotopes of strontium likely to be detected in this work are Sr^{89}, Sr^{90}, and Sr^{91}.

Each strontium separation showed the presence of a 50.0- to 50.5-day activity corresponding to Sr^{89} and a long-lived component. One separation performed shortly after the end of the irradiation exhibited the 9.7-hour Sr^{91} activity in addition to these. No γ-photopeaks were observed on the scintillation spectrometer except when the 9.7-hour activity was present. A plot of γ-counting rate vs. time showed that the 750- and 1020-kev peaks decayed with a 9.7-hour half-life. The initial growth and decay of the 550-kev peak indicated the formation of the 51-minute Y^{91m} daughter of Sr^{91}. The apparent purity of the sample was indicated by the absence of other γ-rays and the consistent half-lives obtained from the β- and γ-ray measurements allowed the assignment of the long-lived component to Sr^{90} (27.7 years).

When in equilibrium, the disintegration rates of Sr^{90} and Y^{90} are equal. Therefore one-half of the observed residual counting rate, after applying absorption corrections, could be attributed to the Sr^{90}. On this basis, the fission yield of Sr^{90} was calculated. As a further check on this yield, a separated strontium sample was allowed to decay and the yttrium which formed was separated and counted. The fission yield of Sr^{90}, calculated in this way from the Y^{90} daughter, agreed well with that in which the Sr^{90} was counted directly.

The counting rate of 50-day Sr^{89} was determined in the usual way by subtracting the amount of long-lived activity observed.

It is not possible to obtain the amount of Sr^{91} activity by direct analysis of the gross decay curve owing to the formation of Y^{91}. However, from the following considerations, it is possible to determine the amount of Sr^{89} and Sr^{91} present. At the end of the strontium separation there is no yttrium, therefore the total observed activity (N_T^0) is

$$N_T^0 = Sr^{89^0}+Sr^{91^0}+Sr^{90}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

At a time later when the Sr^{91} has completely decayed to form Y^{91}, the total observed counting rate (N_T^1) is

$$N_T^1 = Sr^{89^0}\exp(-\lambda_1 T)+\frac{\lambda_3}{\lambda_2-\lambda_3}Sr^{91^0}\exp(-\lambda_3 t)+(Sr^{90}+Y^{90^1})$$

where λ_1, λ_2, and λ_3 are the decay constants for Sr^{89}, Sr^{91}, and Y^{91} respectively, and t is the time from the end of separation until the time when N_T^1 is measured. Since N_T^0, N_T^1, $(Sr^{90}+Y^{90^1})$ can be measured, it is possible to solve for Sr^{89^0} and Sr^{91^0}. Since the decay of Sr^{91} involves delayed γ-emission, i.e. γ-emission from the Y^{91m} state, it is necessary to know the efficiency of the counting unit for the detection of Y^{91m} disintegrations. The important factors involved are: (*i*) the γ-detection efficiency, (*ii*) the amount of internal conversion, and (*iii*) the efficiency for detection of internal conversion electrons. By means of growth and decay equations and starting with pure Sr^{91}, the relative counting rates for Sr^{91}, Y^{91}, and Y^{91m} were calculated for various decay times. The calculated rates were then compared to the observed relative counting rates at the same decay times. The observed relative counting rates were obtained by dividing the observed counting rate at time t by the counting rate obtained by extrapolating the initial portion of the strontium decay curve to the time at which the separation had ended. This extrapolation procedure is justified if counting had begun soon after the separation, before Y^{91m} reached equilibrium with Sr^{91}. The observed relative counting rate agreed very well with that calculated for Sr^{91} plus Y^{91}, indicating that the efficiency for counting Y^{91m} in the 4π-proportional counter is very low.

The relevant data for the fission yields of the strontium isotopes are given in Tables II, III, and IV.

Fission rate	2.269×10^{10} f/s	2.885×10^{10} f/s
Fission yield	$(3.48\pm0.18)\%$	$(3.60\pm0.11)\%$

(4) Zirconium

The separation used was essentially a combination of procedures given by Hume (27) and Moore (23). The zirconium was extracted with 2-thenoyl-trifluoroacetone (TTA) and back-extracted from the organic phase with a nitric – hydrofluoric acid mixture. The zirconium was precipitated as barium zirconyl fluoride, dissolved in a boric acid – nitric acid mixture and passed through a Dowex-1 anion exchanger to remove borate and fluoride ions. The zirconium was precipitated with ammonia, dissolved in nitric acid, and made to volume.

The measurements in the 4π β-proportional counter indicated an initial growth and subsequent decay with a 65-day half-life. A 740-kev γ-photopeak, observed on the scintillation spectrometer, was a combination of the 722- and 754-kev γ-rays emitted by Zr^{95}. This peak also showed an initial increase and tailed off with a half-life of 65 days. The growth of this peak was due to the formation of the 770-kev γ-emitter Nb^{95} which is a daughter of Zr^{95}.

The counting rate for Zr^{95} was obtained by measuring sources immediately after the separation and by making a short extrapolation back to the end of separation where no niobium activity was present. A correct counting rate for Zr^{95} in the presence of niobium activities was not obtained due to incomplete knowledge of the decay schemes involved and the detection efficiency of radiations emitted. The fission yield data for Zr^{95} are given in Table VI.

TABLE VI

(5) Niobium

The separation of niobium from other fission products was based on the specific precipitation of Nb_2O_5 from an oxalate solution with chloric acid (28).

Sources of the niobium activity were counted in the 4π-proportional counter. All sources which had been separated at least 33 days after the end of the irradiation were followed for at least 200 days and decayed with a half-life of 35 days. A sample of the niobium when analyzed on the scintillation spectrometer indicated the presence of a nuclide emitting a 770-kev γ-ray with a half-life of about 35 days. No 90-hour Nb^{95m} could be detected, indicating that the amount of this isomer formed from the decay of Zr^{95} must indeed be small as is indicated by the decay scheme.

The β-end-point energy for Nb^{95} is 0.160 Mev. The calculation of a disintegration rate for this nuclide involves rather large self-absorption corrections ($\sim$25%). To keep the niobium in solution, it was necessary to add an excess of oxalic acid which increased the superficial density of the source. The total source thickness was determined by weighing an aliquot of the sample which had been evaporated on a known area.

The data for the fission yield of Nb^{95} are given in Table VII.

TABLE VII

Fission yield	(4.94 ± 0.29)%	(6.03 ± 0.99)%

(6) Ruthenium

Carriers of ruthenium (Ru^{+3}), iodide, and bromide were added to an aliquot of the fission product stock solution. After an oxidation with sodium bismuthate and perchloric acid, ruthenium was separated from the other fission products by distilling the volatile RuO_4 into a sodium hydroxide solution (29). Ruthenium oxide was precipitated several times in the presence of sodium hydroxide by reduction with ethanol. The final oxide separated was dissolved in 6 *M* hydrochloric acid, and made up to volume.

The decay of ruthenium was measured in the 4π-proportional counter. A drop of dilute lithium hydroxide was added to the active sources on VYNS films to aid in drying. A 40-day activity and a longer-lived component ($\sim$1 year) were observed. A γ-spectrum was obtained showing the presence of a 500-kev γ-ray which decayed with a half-life of 40 days. The 40-day activity could then be conclusively attributed to Ru^{103}.

The residual activity with a half-life of about 1 year was assigned to Ru^{106}, a known fission product with a half-life of 1.02 years (30) and a β-end-point energy of 39.2 kev (31).

The measurement of a disintegration rate for both Ru^{103} and Ru^{106} is difficult due to the low energy of the radiation and the presence of short-lived daughter activities.

For Ru^{103} it was necessary to consider the effects of the delayed γ-emitter Rh^{103m}. The total internal conversion coefficient (α_T) for the 40.2-kev γ-ray is about 484 (32). From this value can be calculated N_{e^-}, the number of conversion electrons emitted.

$$N_{e^-} = \alpha_T/(1+\alpha_T) = 0.998.$$

Therefore, 99.8% of Rh^{103m} disintegrations involve conversion electron emission. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

energies of these electrons are low enough so that only 5% are not absorbed in the source and source-mount and are detected by the counter.

The observed 1-year activity represents an equilibrium counting rate for Ru^{106} and Rh^{106}. Absorption losses are to be expected for the Ru^{106} radiation but not for Rh^{106} since the latter has maximum β-energies of 3.5 (82%) and 2.3 (18%) Mev (33).

Fission yield data are presented for Ru^{103} and Ru^{106} in Tables VIII and IX respectively.

(7) Rhodium

The separation of rhodium was based on its extraction into pyridine from a strongly alkaline solution (34).

Sources, when counted in the 4π-proportional counter, were observed to give a 36-hour decay curve, and the presence of a 320-kev photopeak in the γ-spectrum for this activity helped establish its identity as Rh^{105}.

The fission yield data for Rh^{105} are given in Table X.

(8) Silver

Silver was separated from other fission products by precipitating silver chloride. Additional decontamination was achieved, as suggested by Glendenin (35), by alternative ferric hydroxide scavengings and silver sulphide precipitations from an ammoniacal solution.

The silver decay curves were obtained with the 4π β-proportional counter. The length of time from the end of the irradiation to the silver separation was such that any Ag^{112}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

present had been formed from the decay of the parent Pd^{112}. Because of this, the Ag^{112} data have been presented in Table XIII with the fission yield data for Pd^{112}. The fission yield calculated for Ag^{111} is given in Table XI.

TABLE XI

(9) Palladium

The separation of palladium from other fission products was accomplished by the precipitation of palladium dimethylglyoxime from an acid solution. Scavenging with ferric hydroxide and silver iodide was performed for additional purification. Palladium was finally precipitated with dimethylglyoxime, dissolved in hot concentrated nitric acid and made up to volume.

The decay curves for palladium were measured on the 4π-proportional counter. They were found to contain a 65-day (probably Zr^{95}) and a 9-day impurity. A 21-hour activity was resolved by analyzing the initial portion of the gross decay curve. This activity was taken as Pd^{112} (36) and a fission yield was calculated (Table XII). The peaks observed on the scintillation spectrometer were not sufficiently resolved to permit an identification of nuclides present. If the 65-day activity represented Zr^{95}, then 17-hour Zr^{97} might also be present and add to the counting rate of Pd^{112}. As a further check on the Pd^{112} yield, the daughter activity Ag^{112} was counted and from its measurements the yield for Pd^{112} was indirectly determined (Table XIII). The values obtained for the yield of Pd^{112} by both methods agreed favorably.

(10) Antimony

The method of Boldridge and Hume (37) was used to separate antimony from other fission products. The decay of antimony activities, as measured by the 4π-proportional counter, yielded half-lives of 3.79 days and 75 days. An intense 245-kev γ-photopeak was observed on the scintillation spectrometer which also decayed with a 3.6-day half-life. Two less-defined γ-peaks were observed at 740 and 480 kev. These peaks appeared to be associated with the 75-day activity. The shorter-lived activity was assigned to Sb^{127}. Half-lives reported recently for this nuclide are 88 hours (38) and 93 hours (39). The value used in this work was the observed 91 hours. The γ-peaks at 480 and 740 kev appeared to correspond to the reported 463- and 772-kev energies of Sb^{127} but decayed with a 75-day half-life. No observed 75-day antimony activity has been reported in fission. The only antimony nuclide positively identified in this work is that of mass number 127 and the data for this are given in Table XIV. A fission yield was calculated for the observed longer-lived antimony activity, using a half-life of 75 days, and the data are shown in Table XV.

(11) Tellurium

A direct separation of radiochemically pure tellurium was obtained by using a method reported by Glendenin (40).

The decay of tellurium was measured in the 4π-proportional counter. The curve could be resolved into activities with half-lives of 3.2 days, 37 days, and 105 days corresponding to Te^{132}, Te^{129m}, and Te^{127m} respectively. A freshly separated tellurium sample analyzed on the scintillation spectrometer at first showed only a 220-kev γ-photopeak corresponding to Te^{132}. Then the 670- and 780-kev γ-peaks of the I^{132} daughter grew in and later decayed. In equilibrium, all three peaks decayed with a half-life of 3.2 days.

The data involved in the calculation of a fission yield for Te^{132} are given in Table XVI. An additional yield measurement for Te^{132} was obtained by separating and measuring 2.3-hour I^{132}. Data for the latter measurements are listed in Table XVII.

(12) Iodine

A rapid solvent extraction method for the separation of iodine has been reported by Glendenin and Metcalf (41) and has been used in this work. To the final iodine, separated

*Determined from the daughter 2.3-hour I^{132}.

in the form of iodide, was added a small amount of lithium hydroxide and the solution was diluted to volume.

The method used for source preparation was that suggested by Bartholomew *et al.* (42), in which the iodide solution was added to a drop of very dilute silver nitrate already present on the prepared VYNS film. The purpose of the silver is to prevent the oxidation and subsequent volatilization of iodine. Prior to each measurement, each iodine source was heated for 15 minutes under an infrared lamp. This technique was used to remove xenon decay products formed from iodine. The half-lives observed by 4π-counting were 2.3-hour I^{132}, 20.9-hour I^{133}, and 8.0-day I^{131}. All γ-photopeaks observed on the scintillation spectrometer decayed with similar half-lives. Peaks at 670, 780, 980, and 1400 kev decayed with a half-life of 2.2 hours. The 520-kev peak decayed with a half-life of 20.3 hours and the 360- and 640-kev peaks with a half-life of 8.4 days. No attempt was made to remove xenon decay products from the sources used on the scintillation spectrometer.

Iodine separations were performed at a time after the irradiation when any independently formed I^{132} had completely decayed. The observed I^{132} activity resulted from the decay of Te^{132} and consequently its disintegration rate was used to calculate the yield of Te^{132} (Table XVII). The fission yields of I^{131} and I^{132} are given in Tables XVIII and XIX.

An activity of 13 days was found attributable to Cs^{136}. This is a shielded nuclide and is therefore produced directly in fission as a primary fragment. After 80 days of counting, the cesium activity remained constant at a value well above the background counting rate for the counter due to the presence of long-lived Cs^{137}. The data for the independent fission yield of Cs^{136} are given in Table XX. By assuming that the residual cesium activity was due to Cs^{137}, calculations were made for the fission yield of this nuclide.

In the decay, 95% of the transitions go to the 2.6-minute Ba^{137m} state. Corrections for the contribution to the 4π β-counting rate were made, using the following data:

$$\alpha_K = 0.097$$

$$K/L = 4.9.$$

Therefore

$$\alpha_L = .02.$$

Assume

$$\alpha_M+\alpha_N+\ldots = 0.004.$$

Therefore

$$\alpha_T = .121.$$

The efficiency of the 661-kev γ-ray in our counter has been found to be 0.45%.

The total number of conversion electrons

$$N_e = \alpha_T/(1+\alpha_T)\ \text{(total } \gamma\text{-transitions)}.$$

The number of unconverted γ's

$$N = 1/(1+\alpha_T)\ \text{(total } \gamma\text{-transitions)}.$$

Therefore counts registered equal

$$\frac{\alpha_T}{1+\alpha_T}(0.95)n+0.0045\,\frac{1}{1+\alpha_T}(0.95)n+n$$

where n = true disintegration rate. Therefore counts registered = $1.106\,n$. The counting rate registered was divided by this number.

The half-life of Cs^{137} has recently been reported as 30.0 years (44) and 26.6 years (45). The fission yield for Cs^{137} is given in Table XXI using both half-lives.

(14) Barium

After the separation of barium from the strontium by a chromate precipitation, as described previously, the barium was dissolved and reprecipitated twice by means of a

cold hydrochloric acid – ether mixture. The final barium chloride precipitate was dissolved in water and made to volume.

Barium sources were mounted and counted as soon after the end of a separation as possible. The counting rate, as measured by the 4π-proportional counter, increased with time reaching a maximum value at about 4 days, and then decreased with a half-life of 12.8 days. For the first few hours after a barium separation the growth of La^{140} is linear with respect to time. Therefore a plot of the total counting rate vs. time can be accurately extrapolated back to the time at which barium was separated. By using growth and decay equations, it is also possible to calculate the amount of Ba present initially from a measured Ba plus La counting rate at a known time after the separation. The calculated values agreed with those obtained by back-extrapolating the initial portions of the growth and decay curves.

Barium sources counted were about 30 $\mu g/cm^2$ thick. A decrease in the thickness by a factor of 100 showed no change in the source specific activity. This observation, together with the agreement between calculated and observed growth and decay curves, indicated that absorption effects, as described by Grummitt *et al.* (46), were not significant in this work.

Each barium separation was analyzed on the scintillation spectrometer. No extraneous γ-peaks were observed. A plot of peak heights against time produced a curve similar to the net growth and decay as obtained in the 4π β-counter. The fission yield data for Ba^{140} are given in Table XXII.

(15) Cerium

Two procedures were used for the separation of cerium activity. The first was similar to that used for the separation of yttrium (26). After Ce, Y, and the rare earths were isolated from other fission products, cerium was oxidized and precipitated twice as the iodate. The precipitate was dissolved in a nitric acid – hydrogen peroxide mixture and further purified by zirconium iodate scavenging. Precipitations of ceric hydroxide, cerous hydroxide, and cerous oxalate produced radiochemically pure cerium. The final precipitate was washed with water, dissolved in a minimum of nitric acid, and made up to a known volume.

The second method used for the separation of cerium was described by Glendenin *et al.* (22). Cerium carrier and sodium bromate were added to an aliquot of the fission product stock solution. Cerium was extracted into methylisobutyl ketone. The organic layer was separated and washed with dilute nitric acid containing sodium bromate. Cerium was back-extracted into water containing a little 30% hydrogen peroxide. An oxalate precipitation was used to recover cerium from the aqueous layer. The cerium was then dissolved in dilute nitric acid, diluted, and reprecipitated with oxalic acid. The final oxalate precipitate was dissolved and made up to volume.

Cerium activities detected in this work were 33-day Ce^{141}, 33-hour Ce^{143}, and 285-day Ce^{144}. A 290-kev photopeak, attributed to Ce^{143}, was observed on the scintillation spectrometer to decay with a 33-hour half-life.

The data, for which the fission yields for Ce^{141}, Ce^{143}, and Ce^{144} were calculated, are given in Tables XXIII, XXIV, and XXV respectively.

The errors in these experiments are as follows:

(*a*) Systematic errors. These, such as weighing, dilutions, pipetting, were less than 0.5% due to the use of a sensitive microbalance, calibrated glassware, etc. The major error lies in the chemical yield determinations. In order to minimize source self-absorption corrections, minimal amounts of carriers were used. This made chemical yield determinations difficult, and this is reflected in the limits placed on the determinations.

(*b*) The fast fission correction was small ($\sim$2%) and the error in correcting for this is $\pm$0.2%.

(*c*) Loss of activity by fission recoil $\pm$0.2%.

(*d*) Source-mount absorption $\pm$0.2%.

(*e*) Self-absorption in the sample, 0.1 $\rightarrow$ 2%, depending on the energy of the β-emitter and sample thickness.

(*f*) Saturation activity calculations. The pile power was constant during all but one irradiation. In this latter irradiation, the saturation factor was obtained by use of an analogue computer.*

(*g*) External errors. Errors in reported decay schemes and decay constants may greatly influence the results. Each fission yield is given in terms of the half-life as observed and the decay schemes as discussed.

All yields were calculated relative to σ_t/σ_{Co} and can be renormalized should the necessity arise.

When several determinations were made for one nuclide, an average fission yield was calculated by weighing each individual value according to the reciprocal of its own experimental error. The error quoted finally is the root-mean-square deviation.

DISCUSSION

The absolute yields obtained are presented in Table XXVI. Included in this table are values measured by other investigators. Those listed in column 3 do not necessarily represent total chain yields, but merely refer to the cumulative yield for the nuclide given. No attempt was made to correct any of the values for delayed neutron emission, and no corrections were required for loss or gain due to neutron capture among the

*Most recent values by Anikina *et al.* (48) published after this work was complete.

†Most recent values by Ivanov *et al.* (49) published after this work was complete.

All other values are as listed by Katcoff (7).

The relative yields of Bartholomew *et al.* (50) were published after this paper had been compiled. A renormalization of their yields to our value of 5.21% for Ba^{140} gives Sr^{89} = 5.46, Sr^{91} = 5.22, Ba^{139} = 5.20, and La^{141} = 5.74%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

fission products themselves. The same fast fission factor has been applied to all values determined. This correction will certainly apply to values on or near the peaks of the yield–mass curve. The effect on the mass distribution of increasing the neutron energy above the thermal region is to increase the probability of symmetric fission. For this reason the yields of nuclides in the trough of the curve (Ag^{111} and Pd^{112}) are to be considered maximum values. However, the position of the sample inside the reactor was such that the epi-cadmium neutrons detected could not have possessed high energy. Recent investigations on the fission of U^{235} with energies as high as 9.5 ev show no significant change in the trough yields from that produced by thermal neutrons (47), so that little change in the trough yields is to be expected.

In the last column are estimated mass yields for the chains studied. These were calculated by determining the most probable nuclear charge of a particular mass number from the curves given by Katcoff (51). A chain correction factor is then obtained for a value of the displacement from the most probable charge. The cumulative yield can then be estimated from the product of the actual measured fission yield and its cumulative fractional chain yield.

The agreement between yields measured in this work and other absolute yields determined mass spectrometrically is good. However, yields which were determined earlier either radiochemically or normalized to radiochemical values are generally higher.

There appears to be a discrepancy between the observed yields of 4.82% for Sr^{91} and 3.55% for Y^{91}. A decrease in cumulative yield along a chain is not to be expected. Such a difference might well be due to an incomplete knowledge of the mass 91 chain. Other investigators have also reported irregularities in this chain (52, 53). The low yield of I^{133} obtained appeared real since I^{131} and Te^{132} yields, calculated on the same samples, gave normal results. The high yield at mass 143 was based on one measurement and has not been confirmed. The absolute yield measured mass spectrometrically does not agree with this value. However, the mass 141 yield, determined on the same sample, seems to give a reasonable result.

Absolute yields for Sr^{90} on the light mass peak and Ce^{140} on the heavy mass peak, which were reported by Anikina and Ershler (9) and Kukavadze *et al.* (10), respectively, were not dependent on cross-section values. The agreement with this work indicated that the value of σ_t/σ_c used appears correct.

The yield values in Table XXVI are plotted in Fig. 1. The curve drawn is that suggested by Katcoff (7) for the thermal neutron fission of U^{233} and is such that the sum of the yields is the required 200%. The measured independent yields of Br^{82} and Cs^{136} have been corrected to chain yields as indicated by the broken arrows.

PERFLUOROALKYL ARSENICALS

PART I. THE PREPARATION OF ALKYL PERFLUOROALKYL ARSENICALS[1]

W. R. CULLEN

ABSTRACT

The reaction of tetramethyldiarsine with trifluoroiodomethane gives dimethyltrifluoromethylarsine. Trifluoroiodomethane and iodomethane similarly react with the compounds $(CF_3)_2M—M(CF_3)_2$ to give the compounds $(CF_3)_3M$ and $(CF_3)_2MCH_3$ respectively (M = As or P). Trifluoroiodomethane reacts with iododimethylarsine and diiodomethylarsine in the presence of mercury to give dimethyltrifluoromethylarsine and methylbistrifluoromethylarsine respectively. Heptafluoropropyldimethylarsine can be isolated from a similar reaction using heptafluoroiodopropane.

INTRODUCTION

Trifluoromethyl derivatives of phosphorus and arsenic are prepared by the action of trifluoroiodomethane on the elements, a mixture of products being obtained (1, 2).

$$M + CF_3I \rightarrow (CF_3)_3M + (CF_3)_2MI + CF_3MI_2 + MI_3 \qquad (M = As \text{ or } P)$$

Alkyl-trifluoromethyl-arsines and -phosphines can be obtained from Grignard reactions using trifluoromethyl-iodo-arsines (3, 4) and from exchange reactions using the compounds $(CF_3)_3M$ and $(CH_3)_3M$ (4, 5, 6).

$$(CF_3)_3M + CH_3I \rightarrow (CH_3)_2MCH_3 + CF_3I$$

$$2(CH_3)_3M + CF_3I \rightarrow (CH_3)_2MCF_3 + (CH_3)_4MI$$

In this paper new methods of preparing alkyl-perfluoroalkyl-arsines and -phosphines are described.

DISCUSSION AND RESULTS

Organometallic compounds containing metal—metal bonds are known to be highly reactive. Tetramethyldiarsine spontaneously inflames in air and the As—As bond is readily split by halogens (7) or alkyl halides (8). The tin—tin bond is similarly reactive (9) and hexamethylditin has been recently found to react at 80° with trifluoroiodomethane to give trimethyltrifluoromethyltin (10).

$$(CH_3)_3Sn—Sn(CH_3)_3 + CF_3I \rightarrow (CH_3)_3SnCF_3 + (CH_3)_3SnI$$

It has now been found that tetramethyldiarsine reacts at room temperature with trifluoroiodomethane to give dimethyltrifluoromethylarsine.

$$(CH_3)_2As—As(CH_3)_2 + CF_3I \rightarrow (CH_3)_2AsCF_3 + (CH_3)_2AsI$$

When excess trifluoroiodomethane is used the reaction appears to be complete. Trifluoroiodomethane reacts less readily with tetrakistrifluoromethyldiarsine to give tristrifluoromethylarsine and iodobistrifluoromethylarsine.

$$(CF_3)_2As—As(CF_3)_2 + CF_3I \rightarrow (CF_3)_3As + (CF_3)_2AsI$$

At 75° with excess trifluoroiodomethane the reaction is 60% complete after 14 hours and could probably be brought to completion if the conditions were adjusted appropriately. Tetrakistrifluoromethyldiarsine reacts also with iodomethane to give methylbistrifluoromethylarsine and iodobistrifluoromethylarsine.

$$(CF_3)_2As—As(CF_3)_2 + CH_3I \rightarrow (CF_3)_2AsCH_3 + (CF_3)_2AsI$$

[1]*Manuscript received October 5, 1959.*
Contribution from the Chemistry Department, University of British Columbia, Vancouver, B.C.

The reaction in this case seems to be slower, as at 75° with excess diarsine very little reaction takes place and even after 14 hours at 105° the reaction is only 10% complete.

Tetrakistrifluoromethyldiphosphine reacts similarly with both trifluoroiodomethane and iodomethane. After 20 hours at 70° the reaction with excess trifluoroiodomethane is 60% complete. However the diphosphine, like the diarsine, reacts more slowly with iodomethane and after 20 hours at 70°, using excess diphosphine, only a trace of methylbistrifluoromethylphosphine is formed, and at 105° there is little reaction after 18 hours. At 150° the reaction goes further, resulting in the conversion of up to 76% of the iodomethane after 48 hours.

It has also been found that perfluoroalkyl iodides will react at room temperature with a mixture of alkyl-iodo-arsines and mercury to give perfluoroalkyl-alkyl-arsines. Thus dimethyltrifluoromethylarsine and heptafluoropropyldimethylarsine are obtained from iododimethylarsine, and methylbistrifluoromethylarsine is obtained from diiodomethylarsine.

$$(CH_3)_2AsI + Hg + IR \rightarrow (CH_3)_2AsR + HgI_2 \qquad (R = CF_3 \text{ or } C_3F_7)$$

$$CH_3AsI_2 + 2Hg + 2CF_3I \rightarrow CH_3As(CF_3)_2 + 2HgI_2$$

The reaction of iododimethylarsine with trifluoroiodomethane is much faster than the reaction of the arsine with heptafluoroiodopropane Similarly the reaction of trifluoroiodomethane with iododimethylarsine is much faster than with the diiodo-arsine. The reaction of trifluoroiodomethane with chlorodimethylarsine in the presence of mercury is very slow.

Further work is in progress in an attempt to elucidate the exact nature of these reactions in view of their great synthetic potential.

Heptafluoropropyldimethylarsine is the first compound to be isolated with the As—C_3F_7 link. The reaction of heptafluoroiodopropane with arsenic appears to produce heptafluoropropyl arsenicals but these cannot be separated from by-products (11). As would be expected this new arsenical is similar to dimethyltrifluoromethylarsine in being unattacked by water and in being difficult to hydrolyze with base (5, 6). It is only 26% hydrolyzed by 10% sodium hydroxide solution after 3 days at 100°. Methylbistrifluoromethylarsine is only 9% hydrolyzed by 20% aqueous sodium hydroxide after 3 days at room temperature, whereas tristrifluoromethylarsine is completely hydrolyzed in less than 24 hours under the same conditions (6).

EXPERIMENTAL

Apparatus and Technique

Conventional vacuum techniques were used for the manipulation of reactants and products out of contact with moisture and oxygen. Molecular weights were determined by Regnault's method. Reactions were carried out in sealed Pyrex tubes in the absence of air and light. The infrared spectra of the trifluoromethyl derivatives of phosphorus and arsenic were used extensively for the identification of pure compounds and the constituents of mixtures impossible to separate by trap-to-trap distillation. These spectra have been reported previously (1, 3, 4, 12) and the very strong C—F stretching bands in the region 1050–1250 cm^{-1} together with the C—F deformation bands at ca. 700 cm^{-1} enabled ready characterization. The spectra were measured in the gas phase on a Perkin–Elmer Model 21 double-beam instrument with rock-salt optics.

Reaction of Tetramethyldiarsine with Trifluoroiodomethane

Tetramethyldiarsine was prepared by the reaction of chlorodimethylarsine with zinc

For personal use only.

dust at 100° (13). The diarsine (1.627 g) and trifluoroiodomethane (5.359 g) were mixed in a sealed tube (100 ml). A yellow solid was produced which was soluble in the trifluoroiodomethane giving a green solution. The tube was opened after 28 days at room temperature. All the products were volatile and trap-to-trap distillation gave unchanged trifluoroiodomethane (3.866 g) identified spectroscopically and by its molecular weight (mol. wt.: found 197, calc. 196), a fraction condensing at −98° (1.198 g, 88%) identified spectroscopically as dimethyltrifluoromethylarsine, and a fraction condensing at −64° (1.435 g). This fraction was a relatively involatile red liquid which did not react with excess iodomethane at room temperature indicating that no unreacted diarsine was present (8). With iodomethane at 105° for 1 hour in a sealed tube (5 ml) crystals of tetramethylarsonium triiodide were obtained (m.p.: found 133°, lit. value 133° (8)). This identified the fraction as iododimethylarsine (8) (80% yield).

Reaction of Tetrakistrifluoromethyldiarsine with Trifluoroiodomethane

Tetrakistrifluoromethyldiarsine was obtained from the reaction of iodobistrifluoromethylarsine with mercury (4). The diarsine (1.125 g) and trifluoroiodomethane (1.991 g) in a sealed tube (30 ml) were heated to 75° for 14 hours. All the products were volatile and trap-to-trap distillation gave unreacted trifluoroiodomethane (1.681 g; mol. wt.: found 197, calc. 196), a fraction condensing at −98° which was identified spectroscopically and by molecular weight determination as nearly pure tristrifluoromethylarsine (0.475 g; mol. wt.: found 284, calc. 282; 61% yield based on the diarsine), and a fraction condensing at −64° (0.950 g). This fraction was shown by spectroscopic examination to be a mixture of iodobistrifluoromethylarsine and tetrakistrifluoromethyldiarsine. After the fraction was shaken with mercury at room temperature for 24 hours in a sealed tube (20 ml) spectroscopic examination showed it then contained only tetrakistrifluoromethyldiarsine. The loss of weight was 0.212 g corresponding to the formation of iodobistrifluoromethylarsine in 63% yield (based on the diarsine).

Reaction of Tetrakistrifluoromethyldiarsine with Iodomethane

The diarsine (0.975 g) and iodomethane (0.280 g) in a sealed tube (20 ml) were heated to 75° for 24 hours after which spectroscopic examination of the contents of the tube showed that only a very small amount of methylbistrifluoromethylarsine had been produced. The reaction mixture was then heated in a sealed tube (20 ml) for 14 hours at 105°. Trap-to-trap distillation and spectroscopic examination of the fractions showed that only a little more methylbistrifluoromethylarsine had been produced. All the fractions were combined and shaken with excess mercury in a sealed tube (20 ml) for 24 hours at room temperature to convert the iodobistrifluoromethylarsine to tetrakistrifluoromethyldiarsine. The loss of weight was 0.026 g corresponding to reaction of 10% of the iodomethane.

Reaction of Tetrakistrifluoromethyldiphosphine with Trifluoroiodomethane

Tetrakistrifluoromethyldiphosphine was prepared by the reaction of iodobistrifluoromethylphosphine with mercury (1). The diphosphine (0.848 g) and trifluoroiodomethane (3.072 g) in a sealed tube (20 ml) were heated to 70° for 20 hours. All the products were volatile and trap-to-trap distillation gave unreacted trifluoroiodomethane (2.800 g; mol. wt.: found 195, calc. 196), a fraction condensing at −112° which was identified spectroscopically and by molecular weight determination as nearly pure tristrifluoromethylphosphine (0.363 g; mol. wt.: found 236, calc. 238; 61% yield based on the diphosphine), and a fraction condensing at −78° (0.761 g). This fraction was shaken with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

excess mercury in a sealed tube (20 ml) at room temperature for 3 days, to convert the iodobistrifluoromethylphosphine to tetrakistrifluoromethyldiphosphine. The loss of weight was 0.217 g corresponding to the formation of the iodo-phosphine in 58% yield (based on the diphosphine).

Reaction of Tetrakistrifluoromethyldiphosphine with Iodomethane

The diphosphine (1.516 g) and iodomethane (0.452 g) in a sealed tube (30 ml) were heated to 70° for 20 hours after which spectroscopic examination of the contents of the tube showed that only a trace of methylbistrifluoromethylphosphine had been produced. The reaction mixture was next heated to 105° for 18 hours. Spectroscopic examination then showed that more methylbistrifluorophosphine had been formed; iodobistrifluoromethylphosphine was also present. The reaction mixture was shaken with mercury for 3 days in a sealed tube (30 ml) to convert the iodobistrifluoromethylphosphine to the diphosphine. The loss of weight was 0.084 g corresponding to reaction of not more than 2% of the iodomethane. The recovered reactants and products were finally heated to 150° for 48 hours. All the products were volatile and trap-to-trap distillation combined with spectroscopic examination of the fractions showed that a considerable quantity of methylbistrifluoromethylphosphine was present; tristrifluoromethylphosphine was also found but only a trace of unreacted iodomethane remained. The loss of weight on shaking the combined fractions with excess mercury for 3 days at room temperature was 0.308 g corresponding to an over-all reaction up to 76% of the iodomethane.

There is much uncertainty in estimating the extent of the reactions of the diphosphine, especially at higher temperatures, owing to the tendency of the iodo-phosphines to disproportionate (1).

$$2(CF_3)_2PI \leftrightarrow (CF_3)_3P + CF_3PI_2$$

Reactions of this kind would then increase the expected yield of tristrifluoromethylphosphine. The presence of tristrifluoromethylphosphine in the products of the reaction of the diphosphine with iodomethane indicates such disproportionation has taken place as it is unlikely that methylbistrifluoromethylphosphine would disproportionate within the temperature range used for the reactions (6). Similarly estimating the extent of the reactions by loss of weight of iodine can at best be only approximate as the reaction of iodobistrifluoromethylphosphine with mercury is not quantitative (1), and the reaction of diiodotrifluoromethylphosphine with mercury gives involatile polymers, $(CF_3P)_x$, as well as mercuric iodide (14) resulting in a greater loss of weight than would occur if only the mercuric iodide remained in the reaction tube.

Reaction of Iododimethylarsine with Trifluoroiodomethane in the Presence of Mercury

Iododimethylarsine was prepared by the reduction of a solution of cacodylic acid in hydrochloric acid with sulphur dioxide, in the presence of potassium iodide (15). The iodo-arsine (15 g), trifluoroiodomethane (37.99 g), and mercury (200 g) in a sealed tube (150 ml) were shaken for 3 days at room temperature. Trap-to-trap distillation of the volatile contents of the tube gave unreacted trifluoroiodomethane (28.35 g) and a fraction condensing at −98°. This fraction was distilled in a nitrogen atmosphere at 760 mm in a low temperature still to give dimethyltrifluoromethylarsine (4.52 g, 40%; b.p.: found 58°, lit. value 58° (5)).

Reaction of Diiodomethylarsine with Trifluoroiodomethane in the Presence of Mercury

Diiodomethylarsine was prepared by the reduction of a solution of methylarsonic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

in hydrochloric acid with sulphur dioxide, in the presence of potassium iodide (16). The iodo-arsine (38.9 g), trifluoroiodomethane (81.7 g), and mercury (300 g) in a sealed tube (150 ml) were shaken for 1 week at room temperature. Trap-to-trap distillation of the volatile products gave methylbistrifluoromethylarsine (3.689 g, 14%) which was identified spectroscopically and by molecular weight determination (mol. wt.: found 224, calc. 228).

Reaction of Chlorodimethylarsine with Trifluoroiodomethane in the Presence of Mercury

Chlorodimethylarsine was prepared by the reduction of a solution of cacodylic acid in hydrochloric acid with hypophosphorous acid (17). The arsine (7.2 g), trifluoroiodomethane (23.32 g), and mercury (150 g) in a sealed tube (150 ml) were shaken for 3 days at room temperature. Spectroscopic examination of the various fractions isolated by trap-to-trap distillation showed that only a trace of dimethyltrifluoromethylarsine had been produced. The recovery of trifluoroiodomethane was almost quantitative (23.19 g).

Reaction of Iododimethylarsine with Heptafluoroiodopropane in the Presence of Mercury

The iodo-arsine (8.2 g), heptafluoroiodopropane (33.5 g), and mercury (250 g) in a sealed tube (150 ml) were shaken at room temperature for 5 days. Fractionation of the volatile products gave unreacted heptafluoroiodopropane (19.9 g) and a fraction condensing at −64°. This fraction was distilled in a nitrogen atmosphere to give a further 11.1 g of heptafluoroiodopropane (b.p. 42°) and heptafluoropropyldimethylarsine (b.p. 93°) (1.6 g, 16%). Anal. calc. for $C_5H_6AsF_7$: C, 21.9; H, 2.19; As, 27.4; F, 48.5%; mol. wt., 274. Found: C, 22.2; H, 2.42; As, 27.5; F, 47.2%; mol. wt., 271.

The infrared spectrum showed the following absorption bands: vapor phase: 3010(vw), 2930(w), 2830(vw), 1427(w), 1345(vs), 1232(vs), 1224(vs), 1180(vs), 1157(s), 1129(vs), 1114(vs), 1070(m), 1042(s), 905(m), 882(m), 855(s), 822(s), 737(vs), 670(s).

Hydrolysis of Heptafluoropropyldimethylarsine

The arsine (0.168 g) and water (10 ml) were immiscible in a sealed tube (40 ml). Fractionation of the contents of the tube after 11 days at room temperature showed that no heptafluoropropane had been produced. The arsine (0.246 g) and 10% sodium hydroxide solution (10 ml) in a sealed tube (40 ml) were heated to 100° for 3 days. Fractionation of the contents of the tube gave heptafluoropropane (0.040 g, 26%) which was identified spectroscopically.

PERFLUOROALKYL ARSENICALS

PART II. THE PREPARATION AND PROPERTIES OF ARYL PERFLUOROALKYL ARSENICALS[1]

W. R. CULLEN

ABSTRACT

The reaction of iododiphenylarsine with trifluoroiodomethane in the presence of mercury produces diphenyltrifluoromethylarsine. Phenylbistrifluoromethylarsine and methylphenyltrifluoromethylarsine are prepared from similar reactions using diiodophenylarsine and iodomethylphenylarsine respectively. The properties of these new trifluoromethyl arsenicals are compared with those of related compounds.

DISCUSSION AND RESULTS

Although alkyl-trifluoromethyl-arsines have been known for some time (1, 2) no method of preparing aryl-trifluoromethyl-arsines was available. The reaction of trifluoroiodomethane with methyl-iodo-arsines in the presence of mercury has been recently found to yield methyl-trifluoromethyl-arsines (3) and by extending this reaction it has now been found that aryl-trifluoromethyl-arsines can be similarly prepared from aryl-iodo-arsines. Thus diphenyltrifluoromethylarsine is prepared by the reaction of trifluoroiodomethane with iododimethylarsine in the presence of mercury, phenylbistrifluoromethylarsine is prepared from diiodophenylarsine, and methylphenyltrifluoromethylarsine from iodomethylphenylarsine.

$$(C_6H_5)RAsI + Hg + ICF_3 \rightarrow (C_6H_5)RAsCF_3 + HgI_2 \qquad R = C_6H_5 \text{ or } CH_3$$

$$C_6H_5AsI_2 + 2Hg + 2ICF_3 \rightarrow C_6H_5As(CF_3)_2 + 2HgI_2.$$

The aryl-trifluoromethyl-arsines are involatile, colorless liquids of faint odor; they are stable to oxygen and moisture at ordinary temperatures. Table I gives their boiling points and those of related compounds, and it is apparent that the usual increase in volatility found on replacing all the hydrogens of methyl groups by fluorine is shown by these new compounds.

TABLE I

Compound	B.p.	Compound	B.p.
$(C_6H_5)_3As$	>360°	$C_6H_5As(CH_3)_2$	193–200°
$(C_6H_5)_2AsCH_3$	100–101 (10^{-3} mm)	$C_6H_5As(CF_3)_2$	160
$(C_6H_5)_2AsCF_3$	86–88 (10^{-3} mm)	$C_6H_5(CH_3)AsCF_3$	186

Diphenyltrifluoromethylarsine is less stable thermally than triphenylarsine, being decomposed slowly at 250° and at a much faster rate at 300°. The main volatile decomposition products are fluoroform and benzene. Triphenylarsine is stable above 360° and tristrifluoromethylarsine is unstable at 350° (4).

Diphenyltrifluoromethylarsine is stable to concentrated hydrochloric acid at 85° and is only slowly hydrolyzed to fluoroform by 10% aqueous sodium hydroxide at the same temperature. It is, however, unstable to alcoholic potassium hydroxide at 85°. The rate of hydrolysis of the aryl-trifluoromethyl-arsines increases as the number of trifluoromethyl groups is increased. A similar trend is shown by the rates of hydrolysis of the compounds $(CF_3)_nM(CH_3)_{3-n}$ (M = P, As, or Sb) (2). Methylphenyltrifluoromethylarsine is

[1]*Manuscript received November 23, 1959.*
Contribution from the Chemistry Department, University of British Columbia, Vancouver, B.C.

hydrolyzed much faster than is diphenyltrifluoromethylarsine indicating that alkyl-trifluoromethyl-arsines would be hydrolyzed more easily than the aryl-trifluoromethyl-arsines. When liquid ammonia is the solvolytic agent both diphenyltrifluoromethyl- and methylphenyltrifluoromethyl-arsine are only slowly attacked. The ammonolysis of phenylbistrifluoromethylarsine is faster as would be expected since ammonolysis of trifluoromethyl compounds parallels hydrolysis (5).

Diphenyltrifluoromethylarsine reacts with bromine in carbon tetrachloride solution to give diphenyltrifluoromethylarsenic dibromide. This compound, m.p. 110° (decomp.), is unstable to moisture and is easily hydrolyzed by aqueous sodium hydroxide to fluoroform (cf. the stability of diphenyltrifluoromethylarsine). In this case the fluoroform could easily be produced by elimination from an initially formed hydroxybromide. At 120° it decomposes to bromotrifluoromethane and bromodiphenylarsine. Bromination of methylphenyltrifluoromethylarsine under similar conditions appears to produce the pentavalent dibromide but this is unstable and decomposes to give mainly bromomethane, together with bromotrifluoromethane.The involatile liquid produced by the reaction is probably mainly bromophenyltrifluoromethylarsine. Although phenylbistrifluoromethyl-arsine was decomposed by bromine no evidence was obtained for the intermediate formation of a pentavalent dibromide; at 20° no decolorization of the bromine solution took place on addition to a solution of the arsine and no solid was obtained from the reaction. Tristrifluoromethylarsine is also decomposed by bromine without the formation of a pentavalent compound (6). Tertiary arsine dihalides containing both aromatic and alkyl groups decompose on heating to an alkyl halide and a secondary halogenated arsine (7).

$$RR_2'AsX_2 \rightarrow R_2'AsX + RX \qquad R = \text{alkyl group}$$
$$R_2R'AsX_2 \rightarrow RR'AsX + RX \qquad R' = \text{aryl group}$$

Thus the ease of loss of groups from the pentavalent dibromides seems to be in the order $C_6H_5 < CF_3 < CH_3$.

The aryl-trifluoromethyl-arsines do not easily form -onium compounds with iodomethane. No reaction occurs when ether solutions of the arsines and iodomethane are mixed and the reaction of diphenyltrifluoromethylarsine with excess iodomethane at 150° produces trifluoroiodomethane and fluoroform. Both tristrifluoromethylarsine and methyl-bistrifluoromethylarsine behave similarly (6, 2), but dimethyltrifluoromethylarsine reacts directly with iodomethane to give trimethyltrifluoromethylarsonium iodide (1). Dimethyl-trifluoromethylarsine is also the only arsine containing trifluoromethyl groups which is known to form a complex with mercuric chloride (8) since the aryl-trifluoromethyl-arsines failed to react on mixing solutions of mercuric chloride with solutions of the arsines.

The infrared spectra of the aryl trifluoromethyl arsenicals show the usual strong C—F stretching bands in the region 1050–1250 cm^{-1}. The compounds with only one trifluoromethyl group in the molecule show only two bands in this region, a feature which has been observed for other trifluoromethyl compounds (9, 10). The bands associated with the phenyl groups show little variation in intensity or position from compound to compound. The ultraviolet spectra of these and related compounds have been studied and the results will be published later.

Radical exchange reactions have previously been used to prepare alkyl-trifluoromethyl-arsines, as follows (1, 2, 6):

$$2(CH_3)_3As + CF_3I \rightarrow (CH_3)_2AsCF_3 + (CH_3)_4AsI,$$
$$(CF_3)_3As + CH_3I \rightarrow (CF_3)_2AsCH_3 + CF_3I.$$

For personal use only.

In the present work it was found that analogous reactions do not produce aryl-trifluoromethyl-arsines. There is no reaction between tristrifluoromethylarsine and iodobenzene at 240°, and the reaction of trifluoroiodomethane with triphenylarsine at 210° gives a mixture of products including fluoroform, benzotrifluoride, benzene, and arsenic triodide. Neither phenylbistrifluoromethyl- nor diphenyltrifluoromethyl-arsine is produced.

EXPERIMENTAL

Apparatus and Technique

Conventional vacuum techniques were used for the manipulation of volatile reactants and products out of contact with moisture and oxygen. Reactions were carried out in sealed Pyrex tubes in the absence of air and light. Gas phase molecular weights were determined by Regnault's method. Infrared spectra were measured on a Perkin–Elmer Model 21 double-beam instrument with rock-salt optics.

Reaction of Iododiphenylarsine with Trifluoroiodomethane in the Presence of Mercury

Iododiphenylarsine was prepared by the action of hydriodic acid on bis-diphenylarsenic oxide (11). The oxide was prepared from phenylmagnesium bromide and arsenious oxide (12). The iodo-arsine (19.5 g), trifluoroiodomethane (41.2 g), and mercury (200 g) in a sealed tube (150 ml) were shaken at 20° for 3 days. Trap-to-trap distillation of the volatile contents of the tube gave only trifluoroiodomethane (30.6 g). The remaining contents of the tube were extracted with benzene which was then removed by distillation at 760 mm in a nitrogen atmosphere leaving a colorless involatile liquid. The liquid was distilled at 10^{-3} mm and the fraction boiling at 86–88° collected. This fraction (12.4 g) was identified as *diphenyltrifluoromethylarsine* (76% yield). Anal. calc. for $C_{13}H_{10}AsF_3$: C, 52.4; H, 3.4; As, 25.2; F, 19.1%; mol. wt., 298. Found: C, 52.3; H, 3.5; As, 25.4; F, 19.4%; mol. wt., 286. The infrared spectrum showed the following absorption bands: liquid film: 3075(m), 2220(w), 1963(w), 1882(w), 1813(w), 1755(w), 1650(w), 1584(w), 1490(m), 1443(m), 1387(w), 1340(w), 1311(w), 1272(w), 1257(w), 1190(w), 1137(vs), 1105(vs), 1028(m), 1003(m), 974(w), 916(w), 848(w), 738(s), 726(m), 696(s) cm^{-1}.

Reaction of Diiodophenylarsine with Trifluoroiodomethane in the Presence of Mercury

Diiodophenylarsine was prepared from phenylarsineoxide and hydriodic acid (13). The iodo-arsine (41.7 g) trifluoroiodomethane (80 g), and mercury (350 g) in a sealed tube (150 ml) were shaken for 7 days at 20°. The excess trifluoroiodomethane was removed by trap-to-trap distillation and the remaining contents of the tube were extracted with benzene. Distillation of the benzene extracts at 760 mm in an atmosphere of nitrogen gave *phenylbistrifluoromethylarsine*, b.p. 160° (2.9 g, 10% yield). Anal. calc. for $C_8H_5AsF_6$: C, 33.1; H, 1.7; As, 25.8; F, 39.3%; mol. wt., 290. Found: C, 33.2; H, 1.7; As, 26.3; F, 39.0%; mol. wt., 276. A small amount of an unidentified substance which boiled at 90–95° (10^{-3} mm) was also isolated. Qualitative tests showed that this substance did not contain any As—I bonds. The infrared spectrum of phenylbistrifluoromethylarsine showed the following absorption bands: liquid film: 3085(w), 2220(w), 1970(w), 1908(w), 1889(w), 1833(w), 1815(w), 1759(w), 1658(w), 1584(w), 1492(m), 1447(m), 1390(w), 1342(w), 1264(w), 1168(vs), 1126(vs), 1100(vs), 1064(m), 1051(m), 1030(m), 1005(m), 975(w), 922(w), 850(w), 828(w), 792(m), 765(m), 742(s), 733(s), 695(s).

Reaction of Iodomethylphenylarsine with Trifluoroiodomethane in the Presence of Mercury

Iodomethylphenylarsine was prepared by the reduction of a hydrochloric acid solution of methylphenylarsinic acid with sulphur dioxide in the presence of potassium iodide. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

arsinic acid was prepared from iodomethane and phenylarsenoxide (14). The iodo-arsine (11 g), trifluoroiodomethane (40 g), and mercury (200 g) in a sealed tube (150 ml) were shaken for 5 days at 20°. The contents of the tube were worked up in the same manner as described for the preparation of phenylbistrifluoromethylarsine and *methylphenyltrifluoromethylarsine*, b.p. 186° (760 mm), was isolated in 67% yield. Anal. calc. for $C_8H_8AsF_3$: C, 40.7; H, 3.4; F, 24.2%; mol. wt., 236. Found: C, 41.0; H, 3.6; F, 24.5%; mol. wt., 235. The infrared spectrum showed the following absorption bands: liquid film: 3080(w), 3025(w), 2925(w), 2240(w), 1985(w), 1965(w), 1900(w), 1879(w), 1810(w), 1753(w), 1648(w), 1585(w), 1490(m), 1443(m), 1423(m), 1388(w), 1337(w), 1309(w), 1264(w), 1252(w), 1189(w), 1141(vs), 1098(vs), 1073(s), 1027(m), 1003(m), 971(w), 913(w), 891(w), 852(m), 815(w), 740(s), 725(m), 696(s).

Solvolysis of the Aryl Trifluoromethyl Arsenicals

The results of a number of solvolysis experiments which were carried out in sealed tubes (40 ml) are given below. The identity and purity of the fluoroform isolated by trap-to-trap distillation from these reactions was checked spectroscopically and, where possible, by molecular weight measurement. Fluoride ion was not detected as a product from any of the reactions.

TABLE II

Compound	mmoles	Solvolysis reagent	Time	Temp.	Yield of fluoroform
$(C_6H_5)_2AsCF_3$	1.12	10% aqueous NaOH (5 ml)	5 days	85°	11.5%
$(C_6H_5)_2AsCF_3$	1.37	Liquid NH_3 (3.59 g)	5 days	20°	Trace[a]
$(C_6H_5)_2AsCF_3$	1.03	Conc. HCl (10 ml)	2 days	85°	None
$(C_6H_5)_2AsCF_3$	1.52	10% ethanolic KOH (5 ml)	3 hours	85°	94.5%
$C_6H_5As(CF_3)_2$	0.641	10% aqueous NaOH (5 ml)	5 days	85°	98%
$C_6H_5As(CF_3)_2$	0.934	Liquid NH_3 (3.51 g)	10 days	20°	56.5%[b]
$C_6H_5As(CF_3)CH_3$	0.779	10% aqueous NaOH (5 ml)	5 days	85°	60%
$C_6H_5As(CF_3)CH_3$	0.943	Liquid NH_3 (3.96 g)	10 days	20°	Trace[c]
$(C_6H_5)_2CF_3AsBr_2$	0.146	10% aqueous NaOH (5 ml)	4 days	20°	94%

[a]Recovered 1.36 mmoles of $(C_6H_5)_2AsCF_3$.

[b]A white hygroscopic crystalline solid, soluble in ammonia but insoluble in ether was left in the tube after the volatile contents had been removed. The solubility in ether precludes the possibility that the compound was $C_6H_5As{=}NH$ (15). The infrared spectrum of the solid suggested that it was $(C_6H_5AsCF_3)_2NH$ since only one N—H stretching band and only two C—F stretching bands were present (9, 10).

[c]No solid was produced and the involatile liquid remaining in the reaction tube after removal of the more volatile NH_3 and CF_3H was identified spectroscopically as unchanged $(C_6H_5)CH_3AsCF_3$.

Reactions of Diphenyltrifluoromethylarsine

(a) Preparation of Diphenyltrifluoromethylarsenic Dibromide

A solution of bromine (1 g, 6.24 mmoles) in carbon tetrachloride (5 ml) was slowly added to a solution of diphenyltrifluoromethylarsine (1.174 g, 3.94 mmoles) in the same solvent (5 ml). The bromine was decolorized until excess was present. The solvent and excess bromine were removed *in vacuo* at 20° to give a pale yellow solid (1.836 g), the increase in weight corresponding to the addition of bromine to the arsine in the mole ratio of 1.05 to 1. The solid was recrystallized from ether to give colorless, hygroscopic rhombohedrons which melted at 110° with decomposition. Analysis identified the solid as *diphenyltrifluoromethylarsenic dibromide*. Anal. calc. for $C_{13}H_{10}AsBr_2F_3$: Br, 34.9%. Found: Br, 35.1%. The infrared spectrum showed the following absorption bands: Nujol mull and KBr disk: 3395(w), 2330(w), 1570(w), 1559(w), 1480(m), 1460(w), 1442(m), 1380(w), 1330(w), 1304(w), 1273(w), 1187(s), 1171(s), 1158(s), 1082(s), 1019(w), 966(w), 828(w),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

744(s), 736(s), 681(s). The dibromide (0.065 g) in a sealed tube (5 ml) was heated to 120° for 18 hours. Trap-to-trap distillation of the volatile products together with spectroscopic examination and molecular weight determination showed that only bromotrifluoromethane had been produced (0.0204 g, 97%; mol. wt.: found 153, calc. 149). A white solid which remained in the tube was identified as impure bromodiphenylarsine (m.p.: found 48–50°, lit. value 54–56° (11)).

(b) Thermal Decomposition of Diphenyltrifluoromethylarsine

The arsine (0.121 g) in a sealed tube (5 ml) was heated to 247° for 20 hours. Trap-to-trap distillation and spectroscopic examination of the very small amount of volatile product (1 mg) showed that this was mainly fluoroform. The liquid which remained in the reaction tube when examined spectroscopically was found to be mainly unchanged arsine. The arsine (0.113 g) in a sealed tube (5 ml) was heated to 302° for 48 hours. A black solid was deposited on the tube walls and no liquid remained. Trap-to-trap distillation of the volatile products gave a fraction which condensed at −196° (0.026 g) which was identified spectroscopically as a mixture of fluoroform, silicon tetrafluoride, and carbon dioxide, and a fraction which condensed at −98° (0.035 g) which was identified spectroscopically as benzene.

(c) Reaction with Methyl Iodide

The arsine (0.229 g) in ether solution (3 ml) was mixed with a solution of methyl iodide (1 g) in ether (5 ml). No precipitate was formed and after removal of the volatile materials the arsine (0.229 g) was recovered. The arsine (0.276 g) and methyl iodide (2.27 g) in a sealed tube (10 ml) were heated to 112° for 12 days; a very small amount of solid was formed. The tube was then left at 150° for a further 10 days. Trap-to-trap distillation of the volatile products gave a fraction condensing at −196° (0.019 g) which was identified spectroscopically as a mixture of fluoroform and trifluoroiodomethane, and a fraction condensing at −132° (0.099 g) which was shown spectroscopically and by molecular weight measurement to be slightly impure trifluoroiodomethane (mol. wt.: found 190, calc. 196). The remaining volatile fractions and the tarry material remaining in the reaction tube were not further investigated.

(d) Reaction with Mercuric Chloride and Cadmium Chloride

The arsine failed to give a complex with mercuric chloride when alcohol or ether solutions of the two reactants were mixed. Similarly, no complex was obtained from alcohol or ether solutions of the arsine and cadmium chloride.

Reaction of Methylphenyltrifluoromethylarsine with Bromine

A solution of bromine (1 g) in carbon tetrachloride (5 ml) was added to a solution of the arsine (0.721 g) in the same solvent (3 ml). The bromine was decolorized until excess was present. The volatile materials were removed *in vacuo* at 20° and a pale yellow solid remained which on standing for 2 hours at 20° decomposed to a colorless liquid (0.240 g). Spectroscopic examination of this liquid showed that trifluoromethyl and phenyl groups were still present and that no bromobenzene had been produced. The volatile products of the reaction were shaken with mercury in a sealed tube to remove the excess bromine. Trap-to-trap distillation of the contents of the tube gave a fraction (0.377 g), which had a molecular weight of 107, and which was found spectroscopically to be a mixture of bromomethane and bromotrifluoromethane. On the basis of the molecular weight this corresponds to loss of up to 100% of the methyl groups and loss of ca. 19% of the trifluoromethyl groups from the starting material. Thus the liquid formed in the initial reaction was probably mainly bromophenyltrifluoromethylarsine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Reactions of Phenylbistrifluoromethylarsine

(a) Reaction with Bromine

A solution of bromine (0.7 g) in carbon tetrachloride (25 ml) was added to a solution of the arsine (0.652 g) in the same solvent; the bromine was not decolorized. The reaction mixture was left for 30 minutes at 20° after which the volatile materials were removed *in vacuo* at 20°. No solid was formed and an involatile liquid (0.374 g) was left in the reaction vessel. Qualitative tests showed that the liquid contained bromine and spectroscopic examination showed that the material contained no bromobenzene and was probably mainly bromophenyltrifluoromethylarsine.

(b) Reactions with Iodomethane and Mercuric Chloride

When ether solutions of iodomethane and the arsine were mixed no precipitate was obtained and after removal of the volatile materials the arsine was recovered. No precipitate was obtained on mixing ethanol solutions of the arsine and mercuric chloride.

Reaction of Tristrifluoromethylarsine with Iodobenzene

Tristrifluoromethylarsine was obtained from the reaction of trifluoroiodomethane with arsenic (6). The arsine (0.989 g) and iodobenzene (2.654 g) in a sealed tube (20 ml) were heated to 220° for 36 hours. Spectroscopic examination of the products of the reaction showed that no fluoroform or trifluoroiodomethane had been formed. The tristrifluoromethylarsine was recovered quantitatively (0.982 g; mol. wt: found 281, calc. 282).

Reaction of Triphenylarsine with Trifluoroiodomethane

The arsine (3.81 g) and trifluoroiodomethane (26.02 g) in a sealed tube (100 ml) were left at 20°. The arsine was completely soluble and there was no sign of reaction. After 7 days trifluoroiodomethane (25.89 g) was recovered unchanged. Similarly, there was no reaction between the arsine (2.05 g) and trifluoroiodomethane (4.932 g) after 4 days at 85°. The arsine (4.5 g) and trifluoroiodomethane (10.15 g) in a sealed tube (150 ml) were heated to 210° for 12 hours. Trap-to-trap distillation of the volatile products gave impure trifluoroiodomethane (4.62 g) which spectroscopic examination showed to contain fluoroform and a fraction condensing at −98° (2.69 g) which was identified spectroscopically as a mixture of benzene and benzotrifluoride. A yellow involatile liquid and a yellow solid remained in the tube. The liquid was extracted from the tube with ether which was then removed by distillation in a nitrogen atmosphere. Spectroscopic examination of the involatile residue showed the absence of either phenylbistrifluoromethylarsine or diphenyltrifluoromethylarsine. The solid (1.7 g) was identified as arsenic triiodide (m.p.: found 145°, lit. value 146°).

STEROIDS AND RELATED PRODUCTS

XIII. THE SYNTHESIS OF 6α-FLUORO-17α-BROMOPROGESTERONE[1, 2]

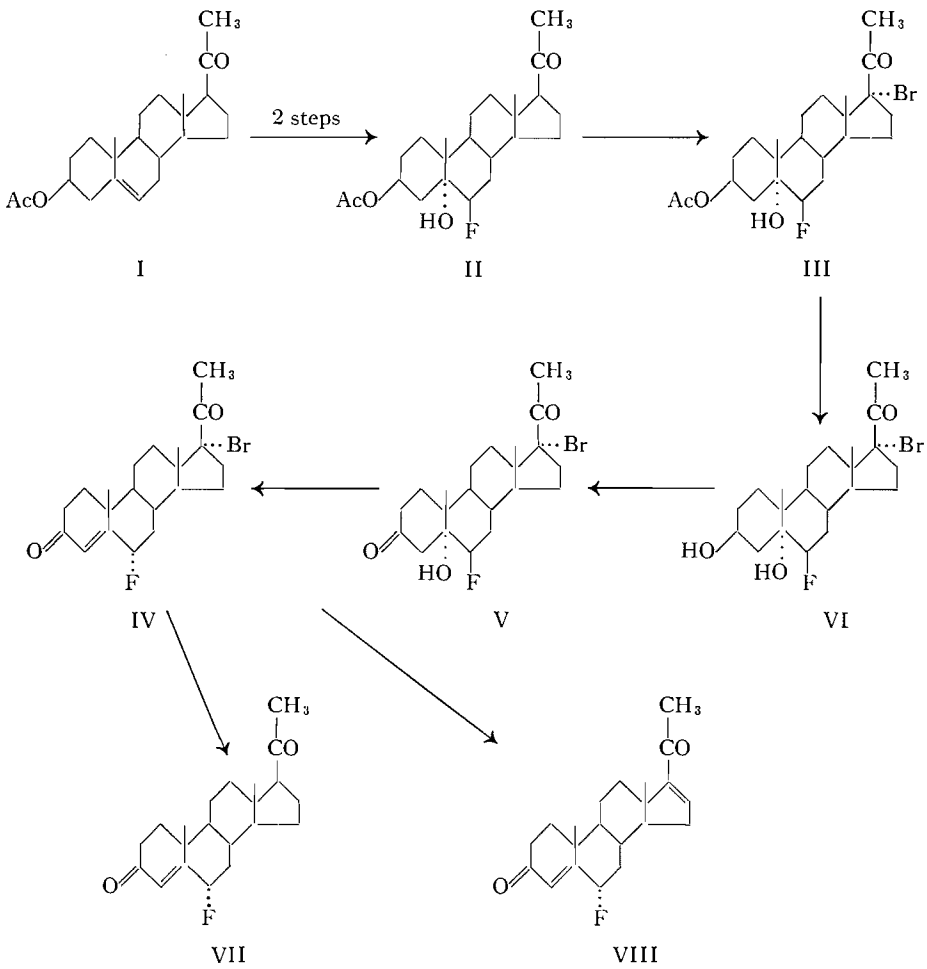
CH. R. ENGEL AND R. DEGHENGHI

ABSTRACT

The synthesis of 6α-fluoro-17α-bromoprogesterone, a new potent gestogen, from pregnenolone acetate, is reported.

In a previous publication of this series (2) our group reported the synthesis and marked progestational activity of 17α-bromoprogesterone. Revesz *et al.* (3) further investigated the biological properties of this compound and established *inter alia* that unlike progesterone, 11-dehydroprogesterone, and 17α-methylprogesterone, it exhibited oral luteoid activity and that it showed no oestrogenic or androgenic side effects. Recently, a number of laboratories reported that certain substitutions in position 6α of the steroid nucleus markedly increased the progestational effect, especially the oral activity, of the parent compound (4–14, compare also 15). Among the biologically most interesting substances of this kind were 6α-halogenated steroids (compare 9, 10, 14, and 15).

It seemed attractive to combine the work in these two fields by preparing 6-substituted 17-halogenated progesterone derivatives, since, in addition to producing compounds of potential biological interest, this would allow us to broaden our investigation of the influence of 17-substituents, especially of a large size, on the progestational activity. It was hoped that this study would ultimately lead to a better understanding of the mechanism by which such groups exert their activity-enhancing action.



In the present paper we report the synthesis of 6α-fluoro-17α-bromoprogesterone (IV), the first 6,17-dihalogenated progesterone derivative.

Pregnenolone acetate (I) served as starting material. We transformed it, according to the procedure of Bowers and Ringold (16) [compare also the article by Henbest and Wrigley (17)], via the 5α,6α-epoxide, to 6β-fluoro-3β-acetoxy-5α-hydroxy-20-oxopregnane (II) which, upon treatment with N-bromosuccinimide under illumination (compare 18), gave in 80–85% yield the corresponding 17α-bromide III. The assignment of location of the bromine substituent to position 17α is in accord with analogous brominations (1, 18, 19) and was confirmed by the conversion of the derivative IV to the 16-unsaturated diketone VIII (*vide infra*). The typical levorotatory shift produced by bromination of 20-ketones in 17α (1, 2, 21) was observed.

Hydrolysis with perchloric acid in methanol (2, 20) gave in high yield the 3-hydroxy derivative VI which was oxidized with chromic acid and sulphuric acid in acetone (compare 16, 22, 23) to 6β-fluoro-17α-bromo-5α-hydroxy-3,20-dioxopregnane (V) in 60–70% yield. Dehydration with concomitant epimerization in 6 by treatment with hydrogen chloride in acetic acid (compare 16) gave the desired 6α-fluoro-17α-bromoprogesterone (IV) in approximately 70% yield.

The configuration of the 6-fluoro substituent was ascertained by the comparison of its molecular rotation (+50°) with the calculated value. Indeed, if, in accordance with the results in the 6-unsubstituted series (2), one assumes that the decrement of molecular rotation upon bromination in position 17α is −560°, one obtains from the rotations of the

6α- and 6β-fluoroprogesterones reported in the literature (10, 16) the values for the 6α- and 6β-fluoro-17α-bromoprogesterones, given in Table I. It can be clearly seen that the configuration of the 6-substituent of our 6,17-dihalogenated progesterone must be α. Comparable results are obtained when the decrements of molecular rotation, obtained upon bromination in 17α, are chosen from other series of experiments (compare i.e. 1, 21).

TABLE I

Molecular rotations of 6α- and 6β-fluoro-17α-bromoprogesterones[a]

Compound	$[M]_D$ calc.	$[M]_D$ found
6α-Fluoro-17α-bromoprogesterone	+35°[b] +75°[c]	+50°
6β-Fluoro-17α-bromoprogesterone	−290°[b] −215°[c]	

[a]The molecular rotations were calculated to the nearest 5°.

[b]Calculated from the values of the 17-unsubstituted products reported by Hogg *et al.* (10).

[c]Calculated from the values of the 17-unsubstituted products reported by Bowers and Ringold (16).

The structure of the new progesterone derivative IV was confirmed both by reduction with hydriodic acid (under the reaction conditions described by Zimmerman and Wen-Hsuan Cheng (24)), to 6α-fluoroprogesterone (VII) (10, 16) and by elimination of hydrogen bromide with dimethylformamide and lithium chloride (compare 25), leading to 16-dehydro-6α-fluoroprogesterone (VIII), which showed the typical spectral characteristics of the Δ^4-3-keto and Δ^{16}-20-keto moieties.

According to preliminary biological assays, for which we are indebted to Drs. M. Eisler and P. Perlman, 6α-fluoro-17α-bromoprogesterone (IV) exhibits marked progestational activity. A detailed account of the biological results will be published elsewhere.*

EXPERIMENTAL [3, 4, 5]

6β-Fluoro-17α-bromo-3β-acetoxy-5α-hydroxy-20-oxopregnane (III)

Following the procedure of Bowers and Ringold (16), pregnenolone acetate (I) was converted, via the 5α,6α-epoxide, to *6β-fluoro-3β-acetoxy-5α-hydroxy-20-oxopregnane* (II). The product crystallized from acetone–hexane in two modifications, one in leaflets melting at 186.5–187°, the other in prisms melting at 214–216°;[6] $[\alpha]_D^{22}$ +36° (*c*, 1.17 in $CHCl_3$); ν_{max}^{KBr} 1255 and 1730 cm^{-1} (acetate), 1692 cm^{-1} (20-ketone), 3360 cm^{-1} (hydroxy). Anal. Calc. for $C_{23}H_{35}O_4F$: C, 70.02; H, 8.94; F, 4.82. Found: C, 70.10; H, 9.00; F, 5.00.

To a solution of 1.082 g of 6β-fluoro-3β-acetoxy-5α-hydroxy-20-oxopregnane (II), m.p. 210–214°, in 18 cc of dichloromethane, 620 mg of N-bromosuccinimide and, subsequently, 36 cc of carbon tetrachloride were added. The solution was refluxed over a photoflood lamp for 10 minutes, cooled to room temperature, diluted with further quantities of dichloromethane, and washed with a cold 10% sodium bisulphite solution. The solution was dried with sodium sulphate, the solvent was removed *in vacuo*, and the residue (1.549 g) was crystallized from acetone to give 680 mg of bromoketone III, m.p. 159–160° decomp. The mother liquors were chromatographed on 30 g of silica gel. Benzene, containing 4% of ethyl acetate, eluted 401 mg of pure III, m.p. 168° decomp. (total yield 83%). A sample was recrystallized from methylene chloride – ether for analysis; colorless needles, m.p. 165° decomp., $[\alpha]_D^{24}$ −60.2° (*c*, 0.85 in $CHCl_3$); ν_{max}^{KBr} 1250 and 1720 cm^{-1} (acetate), 1692 cm^{-1} (20-ketone), 3400 cm^{-1} (5α-hydroxy). Anal. Calc. for $C_{23}H_{34}O_4FBr$: C, 58.35; H, 7.24; F, 3.92; Br, 16.88. Found: C, 58.06; H, 7.15; F, 4.22; Br, 16.79.

6β-Fluoro-17α-bromo-3β,5α-dihydroxy-20-oxopregnane (VI)

To a solution of 680 mg of 6β-fluoro-17α-bromo-3β-acetoxy-5α-hydroxy-20-oxopregnane (III), m.p. 159–160° decomp., in 90 cc of methanol was added, at room temperature, 4.5 cc of 70% aqueous perchloric acid. The solution was stored for 22 hours at 25° and was subsequently poured into iced dilute sodium bicarbonate solution. The precipitate was extracted with dichloromethane and the organic solution was washed with water, and was dried over sodium sulphate. Evaporation of the solvent *in vacuo* gave 670 mg of a foamy residue which, upon crystallization from acetone–hexane, afforded 530 mg (85% yield) of

[3] *The melting points were taken in evacuated capillaries and the temperatures were corrected.*

[4] *The microanalyses were performed by Dr. O. Schwarzkopf and his associates, New York, N.Y., to whom we express our sincere appreciation.*

[5] *For chromatography, Davison's silica gel No. 923 and non-alkaline aluminum oxide Woelm, activity II–III, were used.*

[6] *Bowers and Ringold (16) reported only the higher melting modification.*

*NOTE ADDED IN PROOF. — *Dr. R. Gaudry, Ayerst, McKenna & Harrison, Ltd., Montreal, informed us that his group also synthesized 6α-fluoro-17α-bromoprogesterone and that he intends to publish the results of his team shortly.*

crystalline hydroxy ketone VI, m.p. 156–158° decomp. A sample was recrystallized from acetone–hexane for analysis; needles, m.p. 165° decomp., $[\alpha]_D^{26}$ −66.6° (*c*, 1.05 in $CHCl_3$); ν_{max}^{KBr} 1695 cm^{-1} (20-ketone), 3380 cm^{-1} (5α-hydroxy), 3500 cm^{-1} (3β-hydroxy). Anal. Calc. for $C_{21}H_{32}O_3FBr$: C, 58.47; H, 7.47; F, 4.41; Br, 18.52. Found: C, 58.57; H, 7.25; F, 3.91; Br, 18.42.

6β-Fluoro-17α-bromo-5α-hydroxy-3,20-dioxopregnane (V)

To a solution of 608 mg of 6β-fluoro-17α-bromo-3β,5α-dihydroxy-20-oxopregnane (VI), m.p. 156–158° decomp., in 50 cc of absolute acetone, was added dropwise and with stirring, at 0–5°, 1 cc of an 8 *N* solution of chromic acid. The stirring was continued for 2.5 minutes and subsequently the mixture was poured into ice water and the colorless precipitate was filtered, washed to neutral, and dried. There was obtained 590 mg of a white solid which, upon crystallization from acetone–ether, gave 400 mg (65% yield) of V, m.p. 171° decomp. A sample was recrystallized from acetone–ether for analysis; prisms, m.p. 160° decomp., $[\alpha]_D^{24}$ −34.4° (*c*, 0.758 in $CHCl_3$); ν_{max}^{KBr} 1690 cm^{-1} (20-ketone), 1705 cm^{-1} (3-ketone), 3380 cm^{-1} (5α-hydroxy). Anal. Calc. for $C_{21}H_{30}O_3BrF$: C, 58.74; H, 7.04; F, 4.42; Br, 18.61. Found: C, 58.48; H, 7.10; F, 4.24; Br, 18.80.

Δ⁴-6α-Fluoro-17α-bromo-3,20-dioxopregnene (6α-Fluoro-17α-bromopregesterone) (IV)

At 10°, a stream of dry hydrogen chloride was passed for a period of 2 hours through a stirred solution of 470 mg of 6β-fluoro-17α-bromo-5α-hydroxy-3,20-dioxopregnane (V), in 47 cc of acetic acid. The solution was kept for 19 hours at 5–10° and was subsequently poured into ice water. The precipitate was filtered, washed to neutral, and dried. The resulting product (406 mg) was chromatographed on 45 g of silica gel. Benzene – ethyl acetate (97:3) eluted 312 mg (69% yield) of crystalline Δ⁴-6α-fluoro-17α-bromo-3,20-dioxopregnene (6α-fluoro-17α-bromoprogesterone) (IV), m.p. 157° decomp. A sample was recrystallized from acetone–hexane for analysis; fine needles, m.p. 169–170° decomp., $[\alpha]_D^{24}$ +12.1° (*c*, 2.46 in $CHCl_3$); λ_{max}^{EtOH} 236–237 mμ (log ε 4.2), ν_{max}^{KBr} 1621 and 1680 cm^{-1} (Δ⁴-3-ketone doublet), 1704 cm^{-1} (20-ketone). Anal. Calc. for $C_{21}H_{28}O_2FBr$: C, 61.31; H, 6.86; F, 4.62; Br, 19.43. Found: C, 61.33; H, 6.98; F, 4.40; Br, 19.63.

Reduction [6α-Fluoroprogesterone (VII)]

To a solution of 200 mg of 6α-fluoro-17α-bromoprogesterone (IV), m.p. 169–170° decomp., in 8 cc of absolute acetone was added, dropwise and with stirring, within 1.5 minutes, a solution of 1 cc of 55% hydriodic acid in 5 cc of absolute acetone. The mixture was poured into iced dilute sodium bisulphite solution, and the precipitate was extracted with dichloromethane. The organic solution was washed with dilute sodium bicarbonate solution and with water and was dried over sodium sulphate. Upon removal of the solvent there was obtained 150 mg of an oil, which crystallized from acetone–hexane to give colorless needles, m.p. 135–139°. A sample was recrystallized twice for analysis; long, silky needles, m.p. 143°, $[\alpha]_D^{26}$ +175° (*c*, 0.8 in $CHCl_3$); ν_{max}^{KBr} 1620 and 1680 cm^{-1} (Δ⁴-3-keto doublet), 1701 cm^{-1} (20-ketone); λ_{max}^{EtOH} 236 mμ (log ε 4.1). Anal. Calc. for $C_{21}H_{29}O_2F$: C, 75.87; H, 8.79; F, 5.71. Found: C, 76.16; H, 8.91; F, 5.63.

Dehydrobromination [6α-Fluoro-16-dehydroprogesterone (VIII)]

A solution of 144 mg of 6α-fluoro-17α-bromoprogesterone (IV), m.p. 162–164° decomp., in 25 cc of dimethylformamide was refluxed with 25 mg of lithium chloride for 1 hour. The cooled mixture was extracted with ether, the ethereal solution was washed with dilute hydrochloric acid, sodium bicarbonate solution, and water and dried over sodium sulphate. Removal of the solvent gave 108 mg of yellowish crystals, m.p. 142–146°. The product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

was dissolved in benzene – ethyl acetate (97:3) and filtered through 4 g of silica gel. The colorless crystalline fractions (70 mg) were recrystallized twice from ether to afford pure $\Delta^{4,16}$-6α-fluoro-3,20-dioxopregnadiene (VIII), m.p. 162–163°, $[\alpha]_D^{26}$ +158.4° (*c*, 0.5 in $CHCl_3$), λ_{max}^{EtOH} 238 mμ (log ϵ 4.34); ν_{max}^{KBr} 1592 and 1662 cm^{-1} (Δ^{16}-20-ketone doublet), 1628 and 1678 cm^{-1} (Δ^4-3-ketone doublet). Anal. Calc. for $C_{21}H_{27}O_2F$: C, 76.33; H, 8.24; F, 5.75. Found: C, 76.22; H, 8.34; F, 5.61.

ACKNOWLEDGMENTS

We express our sincere thanks to Mr. D. Capitaine and Mrs. J. Capitaine for their devoted assistance in these experiments and to Drs. M. Eisler and P. Perlman, Bloomfield, New Jersey, for the preliminary biological tests. We are greatly indebted to the National Research Council of Canada, the Schering Corporation, Bloomfield, New Jersey, and the Schering Corporation Ltd., Montreal, for financial support of this project.

REACTION OF *syn*-BENZALDOXIME WITH CARBON MONOXIDE AND HYDROGEN TO YIELD SUBSTITUTED UREAS

A. ROSENTHAL AND J. P. O'DONNELL

Our previous successful application of a modified oxo reaction to aromatic ketoximes (1) led us to subject an aromatic aldoxime to the action of carbon monoxide and hydrogen in the presence of preformed dicobalt octacarbonyl. Although *syn*-benzaldoxime is generally known to be resistant to dehydration, there is mention in the recent literature (2) that this isomer, when subjected to a pressure of 38,400 atm at a temperature of 200°, underwent an explosive decomposition to ammonia and a carbonaceous material.

When a benzene solution of *syn*-benzaldoxime was subjected to a mixture of carbon monoxide and hydrogen (98.5:1.5) at 300 atm and at about 220° in the presence of a high concentration of preformed dicobalt octacarbonyl, *sym*-dibenzylurea and monobenzylurea were formed. The ureas were accompanied by a small amount of benzaldehyde, as well as two crystalline compounds (A and B) which possessed no carbonyl (by infrared analyses).

$$\mathrm{Ph{-}C(=N{-}OH){-}H} \xrightarrow{CO + H_2} \underset{(C)\ 35\%}{\mathrm{PhCH_2NHCONHCH_2Ph}} + \underset{(D)\ 10\%}{\mathrm{PhCH_2NHCONH_2}} + \underset{3\%}{\mathrm{PhCHO}} + \mathrm{A} + \mathrm{B}$$

The reaction mixture was separated chromatographically on alumina. Gas-chromatographic fractionation of the gaseous product of the reaction showed that all of the hydrogen had been consumed, and only unused carbon monoxide was present.

By analogy with our previously described work (1), phthalimidine could be expected as a product of this reaction. That this was not realized is further proof that aromatic aldoximes are more unstable than aromatic ketoximes. The presence of benzaldehyde in the product implies that some hydrolysis might have taken place, though it does not preclude the possibility that a complex formed by the reaction of *syn*-benzaldoxime with dicobalt octacarbonyl might have decomposed to yield benzaldehyde. In support of this speculation, it is to be noted that Greenfield and co-workers (3) have found that diphenylacetylene formed an unstable complex with dicobalt octacarbonyl, which decomposed at room temperature to yield benzil. Unfortunately, our attempts to form a complex of the aldoxime and the catalyst in open systems at moderate temperatures were fruitless. An unstable cobalt-containing material was isolated chromatographically from the original reaction mixture.

Monobenzyl and *sym*-dibenzylurea were identified by mixed melting point using authentic samples (4). These compounds also possessed infrared spectra identical with those of the authentic samples. *sym*-Dibenzylurea was also characterized by oxidation with sodium dichromate in glacial acetic acid to yield *sym*-dibenzoylurea.

The only tentative mechanism which the authors are able to advance in order to explain the formation of dibenzylurea is one deduced from the work of Natta and co-workers (5). When styrene, aniline, and carbon monoxide were reacted, the latter authors reported the presence of an abnormally high amount of diphenylurea and the reduction of styrene to ethylbenzene.

It was suggested that the cobalt carbonyl acted as a hydrogen-transfer agent by formation and decomposition of the hydrocarbonyl. Such a hypothesis might also apply to our reaction. Part of the *syn*-benzaldoxime might be expected to be reduced to benzylamine by the hydrogen present in the original gaseous reactants. The latter primary amine might then react with carbon monoxide and unreacted oxime in some type of hydrogen-transfer process to yield dibenzylurea.

$$PhCH{=}NOH + H_2 \rightarrow PhCH_2NH_2 + H_2O$$

$$2PhCH_2NH_2 + CO + PhCH{=}NOH \rightarrow PhCH_2NHCONHCH_2Ph + PhCH_2NH_2 + H_2O$$

EXPERIMENTAL

General Considerations

The equipment was described previously (1).

Reaction of syn-Benzaldoxime with Carbon Monoxide and Hydrogen

A mixture of 6.5 g (0.054 mole) of *syn*-benzaldoxime (6), 85 ml of catalyst solution containing 0.02 mole of dicobalt octacarbonyl in benzene and carbon monoxide containing 1.5% by volume of hydrogen (2300 p.s.i. at 11°) was placed in the high pressure bomb. The reactants were heated with rocking at 190–220° for 40 minutes. An observed pressure drop of 210 p.s.i. at 11° (2.1 moles per mole of substrate) was obtained. Vapor phase chromatography of the product gases showed carbon monoxide only to be present. After decomposition of the catalyst and removal of the benzene under vacuum, the residue was dissolved in 51 ml of benzene. A 3-ml aliquot of this solution was placed on an alumina column (125×30 mm diameter) for chromatography. The following mixtures of developer were then added consecutively.

(1) 125 ml of benzene gave 0.040 g of crystalline A which was recrystallized from light petroleum ether, m.p. 239–242°. Infrared (KBr): 3050 (w), 1589 (w), 1523 (s).

(2) 50 ml of benzene yielded nothing.

(3) 150 ml of benzene eluted 0.040 g of crystalline B which after two recrystallizations from light petroleum ether melted at 280–282°. Infrared (KBr): 3055 (w), 1601 (w), 1579 (w), 1507 (w).

(4) 450 ml of benzene removed no material.

(5) 300 ml of benzene–ethanol (99:1) yielded 0.120 g of compound C.

(6) 150 ml of benzene–ethanol (98:2) eluted no material.

(7) 50 ml of benzene–ethanol (98:2) gave 0.027 g of compound D.

Chromatography of an aliquot of the original reaction mixture on alumina using benzene eluted a red zone (not dicobalt octacarbonyl) which decomposed rapidly on standing. Addition of light petroleum ether to the red material produced a benzene-insoluble brown substance.

All attempts to form a complex between *syn*-benzaldoxime and preformed dicobalt octacarbonyl in benzene in open systems at different temperatures from 20° to 45° were fruitless.

Extraction of Benzaldehyde from the Reaction Mixture

After evaporation of the benzene from the reaction mixture under reduced pressure at 40°, the residue was extracted with light petroleum ether. Removal of the petroleum ether yielded impure benzaldehyde which was purified by conversion to the bisulphite salt. Reaction of the purified benzaldehyde with 2,4-dinitrophenylhydrazine gave the hydrazone (0.54 g), m.p. 235–237°, undepressed on admixture with an authentic sample of benzaldehyde 2,4-dinitrophenylhydrazone.

For personal use only.

Characterization of Compound C (*sym-Dibenzylurea*)

Compound C was twice recrystallized from benzene – light petroleum ether, m.p. 168–169°. The mixed melting point of compound C and an authentic sample of *sym*-dibenzylurea (4) was 167–169°. The infrared spectra of both compounds were identical. Anal. Found: C, 74.87; H, 6.79; N, 11.91; mol. wt. (Rast), 263. Calc. for $C_{15}H_{16}N_2O$: C, 75.00; H, 6.67; N, 11.67; mol. wt., 240. Infrared of C (KBr): 3337 (s), 3043 (w), 2922 (w), 1625 (s), 1591 (s), 1575 (s), 1497 (w).

Oxidation of sym-Dibenzylurea (Compound C*) to sym-Dibenzoylurea*

Compound C (63 mg) was dissolved in 25 ml of glacial acetic acid, and sodium dichromate (0.3 g) was added to the solution. After the solution was refluxed for 4 hours, the reaction mixture was poured into 50 ml of water. Extraction of the aqueous solution with chloroform gave on evaporation 42 mg of product. Recrystallization of the latter from ethanol yielded *sym*-dibenzoylurea, m.p. 202–203°. The literature (7) melting point of *sym*-dibenzoylurea is 203°. Infrared spectrum (KBr): 3240 (w), 1753 (s), 1670 (s), 1603 (w), 1577 (w), 1534 (m), 1506 (m), 1480 (m), 1288 (m), 1266 (s), 1200 (m).

Characterization of Compound D *(Monobenzylurea)*

Several recrystallizations of compound D from benzene – light petroleum ether gave pure monobenzylurea, m.p. 147–149°. The mixed melting point of an authentic sample of monobenzylurea (4) and compound D was 147–149°. The infrared spectrum of compound D was identical with that of the authentic sample. Infrared of D (KBr): 3440 (s), 3328 (s), 3035 (w), 2922 (w), 1651 (s), 1601 (s), 1564 (s), 1499 (w), 1471 (m), 1458 (m).

Characterization of Compound C (*sym-Dibenzylurea*)

Compound C was twice recrystallized from benzene – light petroleum ether, m.p. 168–169°. The mixed melting point of compound C and an authentic sample of *sym*-dibenzylurea (4) was 167–169°. The infrared spectra of both compounds were identical. Anal. Found: C, 74.87; H, 6.79; N, 11.91; mol. wt. (Rast), 263. Calc. for $C_{15}H_{16}N_2O$: C, 75.00; H, 6.67; N, 11.67; mol. wt., 240. Infrared of C (KBr): 3337 (s), 3043 (w), 2922 (w), 1625 (s), 1591 (s), 1575 (s), 1497 (w).

Oxidation of sym-Dibenzylurea (Compound C*) to sym-Dibenzoylurea*

Compound C (63 mg) was dissolved in 25 ml of glacial acetic acid, and sodium dichromate (0.3 g) was added to the solution. After the solution was refluxed for 4 hours, the reaction mixture was poured into 50 ml of water. Extraction of the aqueous solution with chloroform gave on evaporation 42 mg of product. Recrystallization of the latter from ethanol yielded *sym*-dibenzoylurea, m.p. 202–203°. The literature (7) melting point of *sym*-dibenzoylurea is 203°. Infrared spectrum (KBr): 3240 (w), 1753 (s), 1670 (s), 1603 (w), 1577 (w), 1534 (m), 1506 (m), 1480 (m), 1288 (m), 1266 (s), 1200 (m).

Characterization of Compound D *(Monobenzylurea)*

Several recrystallizations of compound D from benzene – light petroleum ether gave pure monobenzylurea, m.p. 147–149°. The mixed melting point of an authentic sample of monobenzylurea (4) and compound D was 147–149°. The infrared spectrum of compound D was identical with that of the authentic sample. Infrared of D (KBr): 3440 (s), 3328 (s), 3035 (w), 2922 (w), 1651 (s), 1601 (s), 1564 (s), 1499 (w), 1471 (m), 1458 (m).

SEPARATION OF SOME HEAVY METALS BY SOLVENT EXTRACTION AND BY PAPER CHROMATOGRAPHY

Gerhard Weidmann*

The partition of the chlorides of Fe, Co, and Cu between tri-*n*-butyl phosphate and an aqueous HCl solution of different concentrations was determined. Tri-*n*-butyl phosphate

**Present address: Coburg, Kanonenweg 33, West Germany.*

For personal use only.

was also used as an extraction agent to separate the chlorides of Fe, Ni, and Co or Fe, Ni, and Cu. The R_F values of Mn, Fe, Co, Ni, and Cu were determined using as a solvent tri-*n*-butyl phosphate adjusted with HCl of different concentrations.

Tri-*n*-butyl phosphate (TBP) is well known as an extraction agent for uranium, plutonium, and some other actinides from nitrate solutions (1, 2).

Other authors have investigated the extraction of zirconium (3), copper, and cobalt (4) from concentrated chloride or aqueous solutions using TBP. McKay and Hesford (5) and Healy and Kennedy (6) reported the extraction of nitrates of metals. Peppard and co-workers (7, 8) first showed that a feasible extraction of actinides, lanthanides, scandium, and zirconium from HCl solutions is possible using TBP and TBP – dibutyl ether mixtures and aqueous solutions of different HCl concentration.

In this work we have investigated the dependence of the partition of $FeCl_3$, $CoCl_2$, and $CuCl_2$ between pure TBP and aqueous HCl solutions as a function of HCl concentration. Referring to the obtained distribution coefficients and the fact that Ni is not extracted by pure TBP, a separation of Ni, Fe, and Co or Ni, Fe, and Cu can be realized. TBP was also used as a solvent in paper chromatography to separate a mixture of $MnCl_2$, $FeCl_3$, $CoCl_2$, $NiCl_2$, and $CuCl_2$.

Determination of the Distribution Coefficients of Fe, Co, Cu

Commercially available TBP was purified by washing with a 5% sodium carbonate solution and then by distillation at about 178° C, 25 mm Hg. All other reagents were of analytical grade.

Previous qualitative tests have shown that the chlorides of Fe, Co, Cu are extracted by TBP from an aqueous HCl solution, while Ni is not extracted.

EXPERIMENTAL

Before determination of the distribution coefficients the organic solvent was saturated with water. After separation 200-ml portions of the organic phase were shaken at 20° C with the following molarities of HCl: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11. Each portion was shaken so often with quantities of the corresponding HCl molarity that finally the HCl concentration in the aqueous phase remained constant. For this reason the distribution coefficients and R_F values in the following figures and tables are plotted as a function not of the actual HCl concentration in TBP but of the HCl concentration in the aqueous solution.

The chlorides corresponding to about 100 mg of each element were separately dissolved in 50 ml HCl of different molarity and shaken with an equal volume of TBP adjusted with HCl of the corresponding molarity. After the separation of the two phases, aliquots were taken and analyzed. Before analysis, the metals dissolved in the TBP phase were re-extracted completely by water. Concentrations higher than about 10 mg per 100 ml water of Co and Cu were transformed into sulphates and were determined by electrolysis. Fe was determined by redox titrations. Lower concentrations of Fe, Co, and Cu were determined colorimetrically using sulphosalicylate ($5HO \cdot C_6H_3 \cdot (COOH)SO_3H$) for Fe, ammonium thiocyanate for Co, and tetramine copper-II-chloride for Cu (10). Measurements were made with an ELKO Photo II colorimeter.*

Figure 1 shows the distribution coefficients (D) of $FeCl_3$, $CoCl_2$, and $CuCl_2$ and Fig. 2

shows the per cent of metal extracted ($\%E$) as a function of the molarity of aqueous HCl. $\%E$ is related to D by the following equation:

$$\%E = \frac{100D}{D+(V_{aq}/V_{TBP})},$$

where V_{TBP} and V_{aq} represent respectively the volumes of the organic and the aqueous phases.

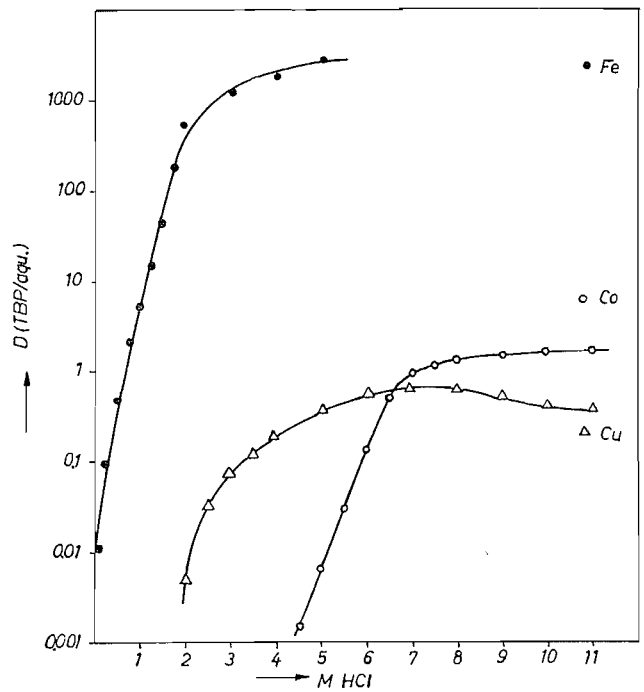

FIG. 1. Distribution of $FeCl_3$, $CoCl_2$, and $CuCl_2$ into TBP using HCl solutions of different molarity.

Separation of Ni, Fe, *and* Co *or* Ni, Fe, *and* Cu *Using* TBP *as an Extraction Agent*

As seen from Figs. 1 and 2 Fe can be easily separated from Co and Cu at about 2 *M* HCl, while a separation of Co and Cu is possible in the range from 2 to 4, 5 *M* HCl at a distribution coefficient$_{max}$ of Cu 0.288. The distribution coefficients of Co and Cu are greatest at high acid concentrations.

Procedure

The chlorides of Ni, Fe, and Co or Ni, Fe, and Cu each in portions of about 100 mg metal were dissolved in 2 *M* HCl. Fe was extracted quantitatively by adding TBP adjusted with 2 *M* HCl as described before, whereas Co(Cu), under these conditions, remains in the aqueous phase. After the acidity of the aqueous solution was increased to 10 *M* HCl for Co, or 8 *M* HCl for Cu, Co(Cu) was separated from Ni in stages by adding 30-ml portions of TBP. As mentioned before, Ni remains nearly completely in the aqueous phase. The chlorides of the metals in the TBP were re-extracted by water and were determined as described before. The procedure was repeated with four single samples and averages of the four results obtained for each element are recorded in Table I for Ni, Fe, Co and for Ni, Fe, Cu in Table II.

PLATE I

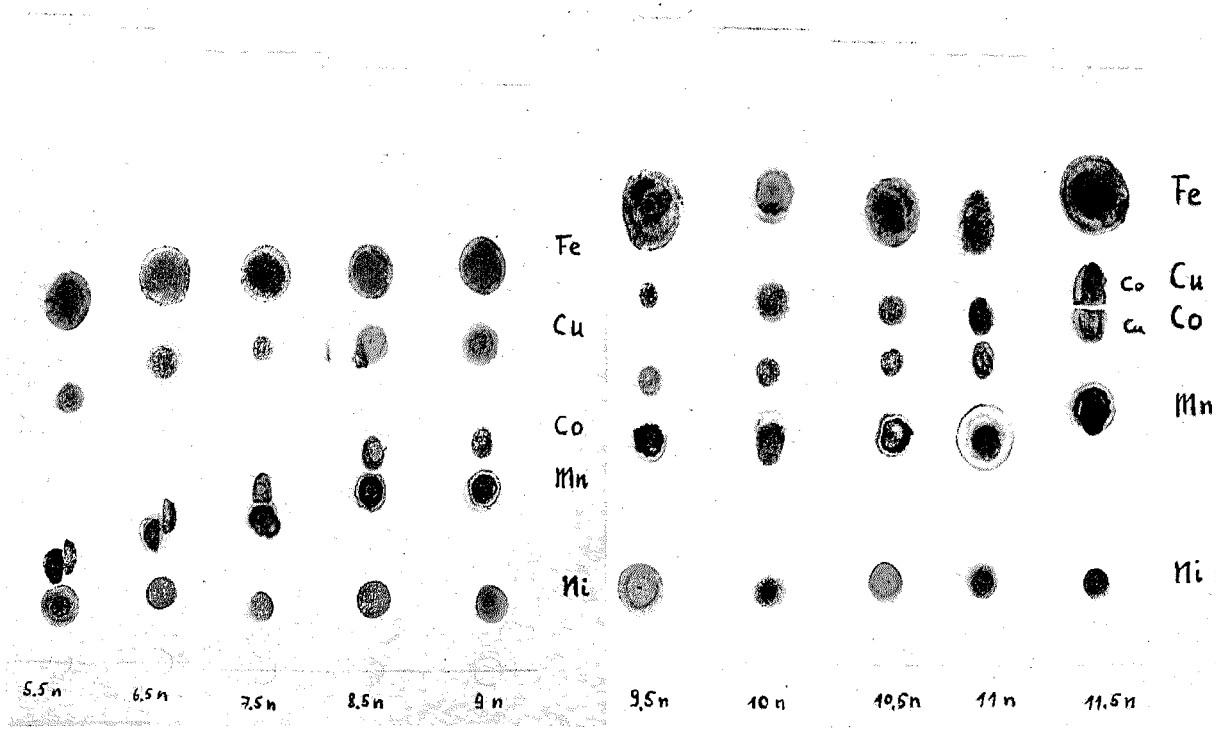

FIG. 3. Flow of Mn, Fe, Co, Ni, and Cu using a TBP/methanol mixture in the ratio 2:1 as a solvent.

The efficiency of TBP proved to be at least equal to that of other agents in the separation of Mn, Fe, Co, Ni, and Cu (12, 13, 14).

TABLE II

Separation of Ni, Fe, Cu using TBP as an extraction agent

Solution of chlorides	Micrograms applied	Metal found	Recovery (%)
Ni	100.0	98.9	98.9
Fe	99.5	98.6	99.0
Cu	101.2	100.1	98.9

Before use TBP was purified and then adjusted with HCl of different molarity as described above. The organic phase was separated and mixed with methanol (reagent grade) in the ratio of two volumes of TBP to one volume of methanol.

Procedure

The chromatograms were developed by ascending chromatography. The paper used was Schleicher and Schüll No. 4023*b* (Whatmann No. 1). Solutions of Mn-, Fe-, Ni-, Co-, and Cu-chlorides each in quantities of about 10 γ per 1 mm^3 were put on the paper. The process took 4 hours at a temperature of 22° C. Fe and Cu were easily identified by their yellow color and Co by its blue color.

In Fig. 3, Fe was marked with $K_4Fe(CN)_6$, Cu with an acetic acid – α-benzoinoxime solution, and Co with α-nitroso-β-naphthol. Ni was identified with an alcoholic solution of dimethyl glyoxime; Mn was first oxidized with sodium peroxide then marked with an acetic acid – benzidine solution (15).

RESULTS

The R_F values of Co, Mn, and Cu recorded in Table III show a significant dependence on the concentration of HCl used to equilibrate TBP. Increasing the concentration of HCl reduces the distance of Co, Mn, and Cu from the liquid front, i.e. the R_F values increase.

TABLE III

R_F values of Mn, Co, and Cu using TBP/methanol mixtures in the ratio 2:1

		TBP adjusted with HCl (molarity)									
		5.5	6.5	7.5	8.5	9.0	9.5	10.0	10.5	11.0	11.5
R_F	Mn	0.15	0.20	0.24	0.30	0.31	0.34	0.35	0.36	0.38	0.42
R_F	Co	0.16	0.23	0.28	0.35	0.38	0.43	0.46	0.48	0.51	0.61
R_F	Cu	0.42	0.48	0.52	0.54	0.56	0.57	0.57	0.57	0.58	0.59

At low concentrations of HCl similar R_F values are obtained for Co and Mn. However, this is optimum for the separation of Cu from Co and Mn. Increasing the concentration of HCl reduces the distance of Co from Cu and at a concentration of 11.5 *M* HCl the R_F value of Co is a little higher than the R_F of Cu.

The flow rates of Ni and Fe are independent of the HCl concentration and roughly proportional to the quantity of methanol present. Fe is always next to the liquid front (see Fig. 3).

SUMMARY

The chlorides of Fe, Co, and Cu were extracted by TBP from an aqueous HCl solution, while Ni was not extracted. Because of the different distribution coefficients of Fe, Co, and Cu, a separation of Ni, Fe, and Co or Ni, Fe, and Cu was possible. Fe can be easily separated from Ni, Co, and Cu at about 2 *M* HCl. After the acidity of the aqueous solution is increased to 10 *M* HCl for Co or 8 *M* HCl for Cu, Co or Cu can be separated from Ni.

TBP also served in paper chromatography as a solvent. Sharp chromatographic separations of the chlorides of Mn, Fe, Co, Ni, and Cu can be obtained using HCl-adjusted TBP. It is recommended that TBP is to be treated with 9 to 10 *M* HCl and mixed with methanol in the proportion 2:1.

THE YIELD OF Ba^{140} IN THE THERMAL NEUTRON FISSION OF U^{235} *

D. C. SANTRY† AND L. YAFFE

The fission product Ba^{140} has often been used as a standard in fission yield determinations. These determinations were usually subject to a large error due to uncertainties in the measurement of the various disintegration rates. In 1954, Yaffe *et al.* (1), using 4π β-counting methods, reported a value of $(6.32\pm0.24)\%$ for the yield of Ba^{140} in the thermal neutron fission of U^{235}.

The measurement consisted of a simultaneous, long-term irradiation of natural uranium and boron trifluoride. The Ba^{140} was estimated radiochemically and the depletion in the B^{10} content of the boron was determined mass spectrometrically. The Ba^{140} yield was estimated relative to a value of $\sigma_f/\sigma_B = 0.1456$ where σ_f is the fission cross section of U^{235} and σ_B is the cross section for the reaction $B^{10}(n,\alpha)Li^7$.

THE YIELD OF Ba^{140} IN THE THERMAL NEUTRON FISSION OF U^{235} *

D. C. SANTRY† AND L. YAFFE

The fission product Ba^{140} has often been used as a standard in fission yield determinations. These determinations were usually subject to a large error due to uncertainties in the measurement of the various disintegration rates. In 1954, Yaffe *et al.* (1), using 4π β-counting methods, reported a value of $(6.32\pm0.24)\%$ for the yield of Ba^{140} in the thermal neutron fission of U^{235}.

The measurement consisted of a simultaneous, long-term irradiation of natural uranium and boron trifluoride. The Ba^{140} was estimated radiochemically and the depletion in the B^{10} content of the boron was determined mass spectrometrically. The Ba^{140} yield was estimated relative to a value of $\sigma_f/\sigma_B = 0.1456$ where σ_f is the fission cross section of U^{235} and σ_B is the cross section for the reaction $B^{10}(n,\alpha)Li^7$.

Petruska *et al.* (2) introduced an additional self-shielding correction to the above value which they suggested should raise the value of the Ba^{140} yield to 6.55%. The uranium in the above-mentioned irradiation was in fairly massive form. This, coupled with the unpredictable nature of the geometrical arrangement, suggested to the present authors that the experiment be repeated under more favorable circumstances.

Accordingly, an irradiation was performed in a No. 1 self-serve position in the NRX Chalk River nuclear reactor. The uranium trioxide (63.67 mg) was placed in a quartz vial. Into similar tubes were sealed weighed amounts (1.348 and 1.174 mg) of "spec-pure" cobalt wire (0.005-in. diameter) which acted as flux monitors. The material was irradiated for 2.247 days. The neutron attenuations in the uranium and cobalt samples were calculated to be 1.0 and 2.1% respectively. The latter agreed with a similar value which R. E. Jervis of A.E.C.L., Chalk River, was kind enough to give to us for the same type of wire.

On removal from the reactor, the cobalt wires were dissolved and made up to a known volume. Measurements of the quartz vials after the removal of the cobalt wire indicated that the loss by recoil was negligible. A small aliquot of the cobalt solution was placed on a VYNS film and the Co^{60} disintegration rate determined in a 4π β-counter (3). Very small corrections were necessary for absorption in the very thin source and thin VYNS film. A thermal neutron flux value of 9.42×10^{11} n/cm^2 sec was obtained using 36.3 barns (4, 5) for the cross section of the reaction $Co^{59}(n,\gamma)Co^{60}$. Auxiliary measurements showed that the contribution by epicadmium neutrons in this irradiation position to the production of both Co^{60} and Ba^{140} was less than $\frac{1}{2}$%. The fission rate was then determined to be 5.220×10^8 fissions per second using σ_f equal to 571 barns (6). The reactor power was constant during this irradiation, so the normal saturation correction could be used.

The uranium trioxide was dissolved in dilute nitric acid and Ba^{140} was separated using standard methods. Agreement between theoretical and experimental growth and decay curves attested to the fact that both Ba^{140} with its soft β-component and La^{140}, the daughter with its hard β-component, were being measured with equal efficiency.

It can be shown that, if U_0 atoms of U^{235} were irradiated in a thermal flux I of a nuclear reactor for a time T, then at some time t, after removal from the reactor, the following equation would apply:

$$[1] \qquad N\lambda = U_0 I\sigma_f Y_f(1-e^{-\lambda T})e^{-\lambda t}.$$

In the above equation λ is the disintegration constant of the fission product being studied and N is the number of atoms of that nuclide present at time t. Thus $N\lambda$ is the disintegration rate. The fission cross section of U^{235} is represented by σ_f, and Y_f is the probability of formation, or the fission yield of the nuclide under study.

If some cobalt were irradiated simultaneously with and under the same conditions as the U^{235}, then the following equation would obtain:

$$[2] \qquad N_1\lambda_1 = N_{Co} I\sigma_c(1-e^{-\lambda_1 T})e^{-\lambda_1 t}.$$

As before, $N_1\lambda_1$ would be the disintegration rate of Co^{60}, N_{Co} the number of cobalt atoms placed in the reactor, and σ_c the thermal neutron cross section for the reaction $Co^{59}(n,\gamma)Co^{60}$.

If equations [1] and [2] are now divided, the term I cancels, all other quantities are easily measurable, and Y_f, the fission yield, can be determined in terms of σ_f/σ_c.

The fission yield of Ba^{140} was calculated in this manner and found to be (6.36 ± 0.12)%, in excellent agreement with that obtained earlier (1).

THE PRIMARY PROCESS IN THE MERCURY-6($^3P_1$)-PHOTOSENSITIZED POLYMERIZATION OF ACETYLENE

ALDEN G. SHERWOOD AND HARRY E. GUNNING

In the reaction of Hg 6($^3P_1$) atoms with acetylene, LeRoy and Steacie (1) have suggested the following possible primary processes:

$$\text{Hg } 6(^3P_1) + C_2H_2 \rightarrow \text{Hg } 6(^1S_0) + H + C_2H \quad [1]$$

$$\rightarrow HgH + C_2H \quad [2]$$

$$\rightarrow HgC_2H + H. \quad [3]$$

An excited molecule mechanism has also been recently suggested (2). However such a sequence could not explain the observed consumption of mercury during the reaction. In the present study, the technique of monoisotopic mercury photosensitization in natural mercury vapor (3, 4, 5, 6, 7, 8) has been employed to determine the extent to which mercury consumption occurs in the primary reaction.

The apparatus used for the investigation was similar to that described in reference 5. The mercury in the electrodeless discharge source contained 95.0% ^{202}Hg. All runs were made at an acetylene pressure of 6.7 mm of Hg. The solid product of the reaction was a yellow deposit which formed on the walls of the spiral quartz reaction cell. The yellow product was treated in separate runs with a variety of reagents to convert the chemically combined mercury to a solution of mercuric ion, from which the mercury was extracted, after neutralization, by electrodeposition. Isotopic analysis of the mercury was carried out on a Metropolitan–Vickers, type MS-2, mass spectrometer. The results are summarized below:

Run No.	Treatment of product	% ^{202}Hg in recovered mercury
A	Solution in hot HNO_3–H_2SO_4	39.3
B	Solution in hot, conc. HCl	33.8
C	Solution in 0.1 *N* HCl	64.0
D	Solution in boiling water	62.7
E	Evacuation for 8 hours followed by solution in hot HNO_3–H_2SO_4	63.0
F	Solution in 2 *N* KI, 0.1 *N* in $Na_2S_2O_3$	32.4
	Natural abundance	29.8

The results show conclusively that there is a primary process involving the formation of a mercury compound. The effects of the various methods of product treatment on the ^{202}Hg-content of the recovered mercury is instructive. In run A the hot HNO_3–H_2SO_4 reagent dissolved both the mercury compound and the cuprene polymer, together with any adsorbed natural mercury. The enrichment in ^{202}Hg was 32%. In run E the system, after reaction, was evacuated for 8 hours to pump off adsorbed natural mercury. The mercury recovered from this run, using the same reagent as in run A, was found to be enriched by 111% in ^{202}Hg. Previous experience has shown that it is very unlikely that all of the adsorbed natural mercury could be removed by this simple evacuation technique. The isotope-diluting effect of adsorbed natural mercury is also shown in run B. The hot, concentrated HCl reagent dissolved only the mercury compound and the adsorbed natural mercury. The cuprene was found to be insoluble under these conditions. The highest ^{202}Hg-enrichment was obtained by treating the product with dilute HCl as in run C. It is likely, however, that exchange reactions are occurring to some extent between dissolved natural mercury and $^{202}Hg^{+2}$ ions in the treatment with dilute HCl in run C and with boiling water in run D. The isotope-diluting effect of adsorbed natural mercury is obviously very extensive in the KI reagent used in run F.

The fact that mercury can be recovered from solution of the mercury product in boiling water would suggest that the primary product is readily hydrolyzed by water. This behavior is in consonance with the primary formation of a mercury carbide, as proposed in step [3].

As a result of this preliminary study it can be said that a mercury compound, probably a mercury carbide, is formed in the primary reaction between Hg $6(^3P_1)$ atoms and acetylene. A detailed investigation is currently underway in this laboratory to determine the specific primary processes operative in the acetylene reaction, and their relative importance.

SENSITIVE FREQUENCIES. V. THE SENSITIVE AMMINE FREQUENCIES AND ELECTRONEGATIVITIES OF COMPLEX TRANSITION METAL ION RADICALS

J. K. Wilmshurst

The internal vibrational frequencies of the methyl group in the CH_3X derivatives are known to vary (1, 2, 3, 4) with the nature of the substituent X and as these variations are greater than those due to mass effects alone (5), they can be considered to reflect

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

changes in the potential energy of the system. However, of the eight internal methyl group modes only three, the symmetrical deformation and the rocking modes, vary by a sufficiently large factor with changing X to make any empirical correlations meaningful and it has been shown in a previous publication (4) that the squares of these "sensitive" frequencies depend linearly on the electronegativity of X. Similar results would be expected for other series of the type MH_3X and, in fact, have been observed for the silyl (SiH_3X) derivatives (4).

In the present paper empirical plots of the squares of the symmetrical deformation and rocking frequencies in the ammine series (NH_3X) have been obtained against the electronegativity of X. The sensitive frequencies in the complex transition metal ammine ions have been fitted to these plots and estimates made for the electronegativity of the transition metal in its particular environment. A number of internal and external frequency relations in the MH_3X series are discussed and two are illustrated.

The Electronegativity Relation

In the ammine series, just as in the methyl and silyl series, only the symmetrical deformation (ν_d) and rocking frequency (ν_r) vary by a sufficiently large factor to warrant any reliable empirical correlation to be made. Only two simple NH_3—X molecules, in which the electronegativity of X is known (6) and for which the vibrational spectrum has been completely analyzed (7), are known, $[NH_3 \cdot OH]Cl$ and $[NH_3 \cdot NH_2]Cl$. If the assumption is made that the electronegativity of the mercury atom in $[Hg(NH_3)_2]Cl_2$ is

the same as that in $Hg(CH_3)_2$, then the infrared spectral data for $[Hg(NH_3)_2]Cl_2$, which have been analyzed (8), can also be used. One further point at zero electronegativity is available if the effect of decreasing electronegativity (χ_x) of X on the rocking frequency in NH_3—X is considered. As $\chi_x \rightarrow 0$ the N—X bond strength must go to zero, the molecule falling apart and the rocking frequency going over into a pure rotation. The corresponding deformation frequency is just that for the ammonia molecule (9). The sensitive frequencies, ν_d, ν_r, for these molecules are given in Table I, together with the electronegativity, χ_x, of X.

As discussed elsewhere (4), the pair of lines ν_d^2 versus χ_x and ν_r^2 versus χ_x should be parallel and they are fitted to the four sets of points above* under this condition, the resulting plots being shown in Fig. 1. The analytical expressions for the pair of lines are

$$\nu_d^2 = 3.66\chi + 8.12$$

$$\nu_r^2 = 3.66\chi - 0.78$$

and these can be compared with the expressions for the corresponding lines obtained in the methyl (4), silyl (4), and germanyl† series:

$$CH_3X\begin{cases}\nu_d^2 = 4.21\chi+5.72\\ \nu_r^2 = 4.05\chi-1.78\end{cases}$$

$$SiH_3X\begin{cases}\nu_d^2 = 1.41\chi+4.83\\ \nu_r^2 = 1.40\chi+0.20\end{cases}$$

$$GeH_3X\begin{cases}\nu_d^2 = 1.22\chi+3.54\\ \nu_r^2 = 1.22\chi.\end{cases}$$

If the sensitive ammine frequencies observed (10) in the complex transition metal ions (Table I) are plotted on Fig. 1 in such a way that the deviation of ν_d^2 and ν_r^2 from their respective lines is equal for any molecule, estimates of the electronegativity of the transition metal ion in that configuration can be obtained‡ and these are given in Table I. Of interest is the fact that the electronegativity of the transition metal ion increases with increasing charge, e.g. cobalt and platinum, and that in the series $[Co(NH_3)_n(NO_2)_{6-n}]$ the electronegativity of the cobalt ion increases smoothly as n increases. Electronegativities of the transition metals and ions are only poorly known at present (11) and the method of calculating electronegativities for these elements from a consideration of the nuclear charge at the covalent boundary (12) is not applicable without some modification. Likewise, the method of calculation of group electronegativities (6) would not be applicable to the complex transition metal radicals without modification.

The scatter of the experimental points about the two lines in Fig. 1 is greater than that observed (4) in the methyl and silyl series. However, it must be remembered that in the latter two cases all compounds discussed were in the gaseous state whereas here all the ammines are solid. Thus, in the present case, the sensitive frequencies do not depend on electronegativity alone, but will also depend, though to a much lesser extent, on the type

*For molecules of symmetry C_{3v} the rocking modes are degenerate. For molecules of lower symmetry the average of the squares of the two rocking frequencies is plotted.

†The pair of lines for the germanyl series was obtained from the data of R. C. Lord and C.M. Steese (J. Chem. Phys. **22**, 542 (1954)) for GeH_3Cl with the consideration that in GeH_3^- ($\chi_x = 0$) the rocking frequency is zero. The line for ν_d^2 versus χ_x was drawn parallel to that for ν_r^2 versus χ_x and gave a deformation frequency for GeH_3^- of 595 cm^{-1}.

‡The meaning of such group electronegativities is, of course, dependent upon the reality of the empirical correlation (but see reference 5 for a more complete discussion).

of inter- and intra-molecular bonding occurring. As this bonding will not, in general, be the same in every system the agreement obtained in Fig. 1 is considered reasonable.*

Frequency–Frequency Relations

It was illustrated in the methyl series that since both ν_d^2 and ν_r^2 depended linearly on electronegativity they would be linearly related to each other. Similar relations must hold between ν_r^2 and ν_d^2 in other MH_3X series.

Since the H—X stretching frequency depends (13) on the electronegativity of X, it would be expected that external relationships exist between it and the internal frequencies of the MH_3-group in the MH_3X series and this has been shown to hold true for the eight internal methyl group frequencies in the CH_3X series (1). Similar relationships would also be expected for the silyl, germanyl, and ammine series. Again, of course, since all the internal frequencies in the MH_3-groups are related to electronegativity, relations must exist between the internal frequencies of one MH_3-group with those of any other and this is illustrated in Fig. 2 for the symmetrical deformation and rocking frequencies.

It can be appreciated that the frequency–frequency relations suggested here are of use to the spectroscopist enabling him to predict the internal vibrational frequencies of any MH_3-group in MH_3X if the internal frequencies of the YH_3-group in YH_3X are known, or even more simply, if the HX stretching frequency is known.

DECARBOXYLATION OF DIMETHYLTRIFLUOROACETOXYARSINE

W. R. Cullen and L. G. Walker

This paper includes the preparation of the new compound dimethyltrifluoroacetoxyarsine and the characterization of fluorodimethylarsine. These compounds are best obtained as follows:

$$(CH_3)_2AsCl + AgOOCCF_3 \rightarrow (CH_3)_2AsOOCCF_3 + AgCl,$$

$$(CH_3)_2AsI + AgF \rightarrow (CH_3)_2AsF + AgI.$$

**Further, some coupling might be expected between the rocking modes when more than one ammine group is attached to the same metal atom, although this would, in general, be slight for the rather large central metal atoms experienced here.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

of inter- and intra-molecular bonding occurring. As this bonding will not, in general, be the same in every system the agreement obtained in Fig. 1 is considered reasonable.*

Frequency–Frequency Relations

It was illustrated in the methyl series that since both ν_d^2 and ν_r^2 depended linearly on electronegativity they would be linearly related to each other. Similar relations must hold between ν_r^2 and ν_d^2 in other MH_3X series.

Since the H—X stretching frequency depends (13) on the electronegativity of X, it would be expected that external relationships exist between it and the internal frequencies of the MH_3-group in the MH_3X series and this has been shown to hold true for the eight internal methyl group frequencies in the CH_3X series (1). Similar relationships would also be expected for the silyl, germanyl, and ammine series. Again, of course, since all the internal frequencies in the MH_3-groups are related to electronegativity, relations must exist between the internal frequencies of one MH_3-group with those of any other and this is illustrated in Fig. 2 for the symmetrical deformation and rocking frequencies.

It can be appreciated that the frequency–frequency relations suggested here are of use to the spectroscopist enabling him to predict the internal vibrational frequencies of any MH_3-group in MH_3X if the internal frequencies of the YH_3-group in YH_3X are known, or even more simply, if the HX stretching frequency is known.

DECARBOXYLATION OF DIMETHYLTRIFLUOROACETOXYARSINE

W. R. Cullen and L. G. Walker

This paper includes the preparation of the new compound dimethyltrifluoroacetoxyarsine and the characterization of fluorodimethylarsine. These compounds are best obtained as follows:

$$(CH_3)_2AsCl + AgOOCCF_3 \rightarrow (CH_3)_2AsOOCCF_3 + AgCl,$$

$$(CH_3)_2AsI + AgF \rightarrow (CH_3)_2AsF + AgI.$$

**Further, some coupling might be expected between the rocking modes when more than one ammine group is attached to the same metal atom, although this would, in general, be slight for the rather large central metal atoms experienced here.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Dimethyltrifluoroacetoxyarsine is a colorless mobile liquid stable in nitrogen at its boiling point of 136 to 137°. It is moderately stable in the absence of air at 150° but decomposes at 205° to give, among other products, the known compound dimethyltrifluoromethylarsine (1) and carbon dioxide.

$$(CH_3)_2AsOOCCF_3 \rightarrow (CH_3)_2AsCF_3 + CO_2$$

Organometallic haloacetates have been prepared by this method previously (2, 3) and the trifluoroacetates are unusually stable in comparison with other haloacetates (3, 4), probably because of the stability of the C—F bond. The actual mode of decomposition of the haloacetates has been incompletely studied and such decarboxylation reactions may be useful in synthesizing other perfluoroalkyl derivatives of the metals and metalloids. This is now being investigated.

Fluorodimethylarsine is a very reactive liquid isolated by Bunsen (5) but not characterized. The fluorodimethylarsine attacks glass very readily and is unstable to oxygen and moisture. It boils in a nitrogen atmosphere at 75°, a value in good agreement with the estimated 72° (6). The yield of the fluorodimethylarsine from silver fluoride and chlorodimethylarsine is very low. The reaction of iododimethylarsine with the appropriate silver salt gives good yields of dimethylchloro-, dimethylbromo-, and dimethylcyanoarsine. The bromide is not obtainable from the chloride by this method. Similar reactions are known in the bis(trifluoromethyl)arsine series (6) and previous workers have obtained cyanodimethylarsine from chlorodimethylarsine and silver cyanide in benzene solution (7).

A reinvestigation of the reaction between chlorodimethylarsine and dimethylamine has led to the characterization of dimethylaminodimethylarsine, first isolated by Cullen and Emeléus (8).

$$(CH_3)_2AsCl + 2HN(CH_3)_2 \rightarrow (CH_3)_2As—N(CH_3)_2 + (CH_3)_2NH_2Cl$$

The amino compound boils at 112° and is unstable to oxygen and moisture. The compounds $(CH_3)_2P—N(CH_3)_2$ and $(CF_3)_2M—N(CH_3)_2$ (M = As or P) are obtained by similar reactions (8, 9, 10).

EXPERIMENTAL

Apparatus and Technique

Conventional vacuum techniques were used for the manipulation of volatile reactants and products out of contact with moisture and oxygen. Reactions were carried out in sealed Pyrex tubes (50-ml capacity) in the absence of air and light. Infrared spectra were measured on a Perkin–Elmer Model 21 double-beam instrument with rock-salt optics.

Dimethyltrifluoroacetoxyarsine

Chlorodimethylarsine (10.5 g) and silver trifluoroacetate (22 g) were heated to 60° for 15 hours. Trap-to-trap distillation of the volatile products followed by distillation of the least volatile fraction in a nitrogen atmosphere at 760 mm gave dimethyltrifluoroacetoxyarsine, b.p. 136–137° (4.5 g, 32% yield). Anal. calc. for $C_4H_6AsF_3O_2$: As, 34.3%. Found: As, 33.7%.

Decarboxylation of Dimethyltrifluoroacetoxyarsine

The arsine (1.919 g) was heated to 150° for 17 hours and little decomposition was detected. When the same sample was heated to 205° a black solid was slowly deposited, and after 17 hours at this temperature trap-to-trap distillation of the volatile products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

gave a fraction condensing at −196° (0.194 g), a fraction condensing at −98° (0.354 g), and a fraction condensing at −64°. Spectroscopic examination showed the most volatile fraction to be mainly carbon dioxide together with traces of silicon tetrafluoride and fluoroform, and the least volatile fraction to contain no unchanged dimethyltrifluoroacetoxyarsine. The middle fraction was dimethyltrifluoromethylarsine (23% yield). Anal. found: mol. wt., 173. Calc.: mol. wt., 174. The infrared spectrum was identical with that of the pure compound (11, 12).

Preparation of Fluorodimethylarsine

Iododimethylarsine (12.5 g) and silver fluoride (12 g) were left at 20° for 48 hours. Distillation of the volatile products in a nitrogen atmosphere at 760 mm gave a 1-g (15% yield) fraction, b.p. 75°, identified as fluorodimethylarsine. Anal. calc. for C_2H_6AsF: As, 60.6%. Found: As, 61.2%.

Reaction of Iododimethylarsine with Silver Chloride

The arsine (8.5 g) and silver chloride (28 g) were heated to 60° for 14 hours. The volatile products were distilled in a nitrogen atmosphere to give 4.5 g (90% yield) of chlorodimethylarsine, b.p. 107° (published b.p. 106.5–107° (13)).

Reaction of Iododimethylarsine with Silver Bromide

The arsine (9.0 g) and silver bromide (38 g) were heated to 60° for 14 hours. The contents of the tube gave in the usual manner 6.0 g (81% yield) of bromodimethylarsine, b.p. 129° (published b.p. 128–129° (13)).

Reaction of Iododimethylarsine with Silver Cyanide

The arsine (12 g) and silver cyanide (13 g) were left at 20° for 48 hours. The solid cyanodimethylarsine (5 g, 76% yield) was sublimed *in vacuo* from the reaction tube. On distillation in a nitrogen atmosphere, the cyanodimethylarsine boiled at 162° (770 mm) (published b.p. 158–160° (730 mm) (7)).

Reaction of Chlorodimethylarsine with Dimethylamine

The arsine (4.8 g) and anhydrous dimethylamine (5.6 g) were left at 20° for 7 days. After removal of the excess dimethylamine by trap-to-trap distillation the least volatile fraction was distilled at 760 mm in a nitrogen atmosphere at 112°, with a middle cut of 2.1 g. This 2.1-g fraction on redistillation again boiled at 112° and was dimethylaminodimethylarsine. Anal. calc. for $C_4H_{12}AsN$: As, 50.3%. Found: As, 50.8%. The infrared spectrum showed the following absorption bands: liquid film: 2980(s), 2890(s), 2860(s), 2820(s), 2780(s), 2480(w), 1453(s), 1423(s), 1259(m), 1237(m), 1177(vs), 1140(m), 1095(w), 1054(s), 946(vs), 880(s), 813(s), 805(m), 775(w), 735(m) cm^{-1}.

AMINO ACID DISTRIBUTION IN BIOLOGICALLY ACTIVE PEPTIDES[1]

SAUL B. NEEDLEMAN,[2] R. QUENTIN BLACKWELL, AND LEONARD S. FOSDICK

ABSTRACT

A group of biologically active peptides were examined for possible favored chain positions exhibited by some of the 21 constituent amino acids as well as for the unusual occurrence of specific peptide linkages. High levels of significance were revealed for certain amino acid couplets when they were subjected to chi-square analyses.

The work of Scheraga (1), Koshland (2), and others dealing with the spatial orientation and sequential arrangement of amino acids has engendered much speculation as to the nature of the active sites of biologically significant peptides. The extremely detailed study of Sorm *et al.* (3) represents one novel approach to the study of amino acid sequences.

The present work deals with a statistical evaluation of peptide structure in which a group of peptides with totally established amino acid sequences were examined for the occurrence of relative chain position preferences of the individual constituent amino acids and for statistically significant repeating amino acid sequences (4).

A list of all of the dipeptide couplets which appear in the peptides included in this analysis was prepared by recording each succeeding pair of amino acid residues beginning at the N-terminus and proceeding along the chain, one residue at a time.

RESULTS

In the primary peptides, 21 different amino acids occurred a total of 184 times. The combined amino acid percentage composition of the group of peptides is not strikingly different from that of numerous general proteins. Although the study was restricted to biologically active peptides because of the availability of complete sequence analyses, there is no reason to believe that these data would differ significantly from that which will be found when the sequence of many "structural" as well as "biologically active" proteins are known (3). There is no unusual concentration of one or more specific amino acids to be noted in the individual peptides. In general, it would appear that the amino acid content of these peptides being studied does not account for their special biological action. The only point of difference distinguishing these peptides from numerous proteins, so far as amino acid composition is concerned, is the occurrence of certain D-configuration amino acids in bacitracin A and of ornithine only in some antibiotics.

A principal concern of the present study is the relative position in the peptide chain occupied by the individual amino acids. Examination of the amino acid distribution in the peptides investigated for this study reveals an interesting tendency towards adventi-

tious positional concentrations. By plotting each amino acid in terms of its numerical position within the peptide chain as well as according to its fractional distance from the amino end, it was possible to draw certain conclusions. Figure 1 depicts the relative or

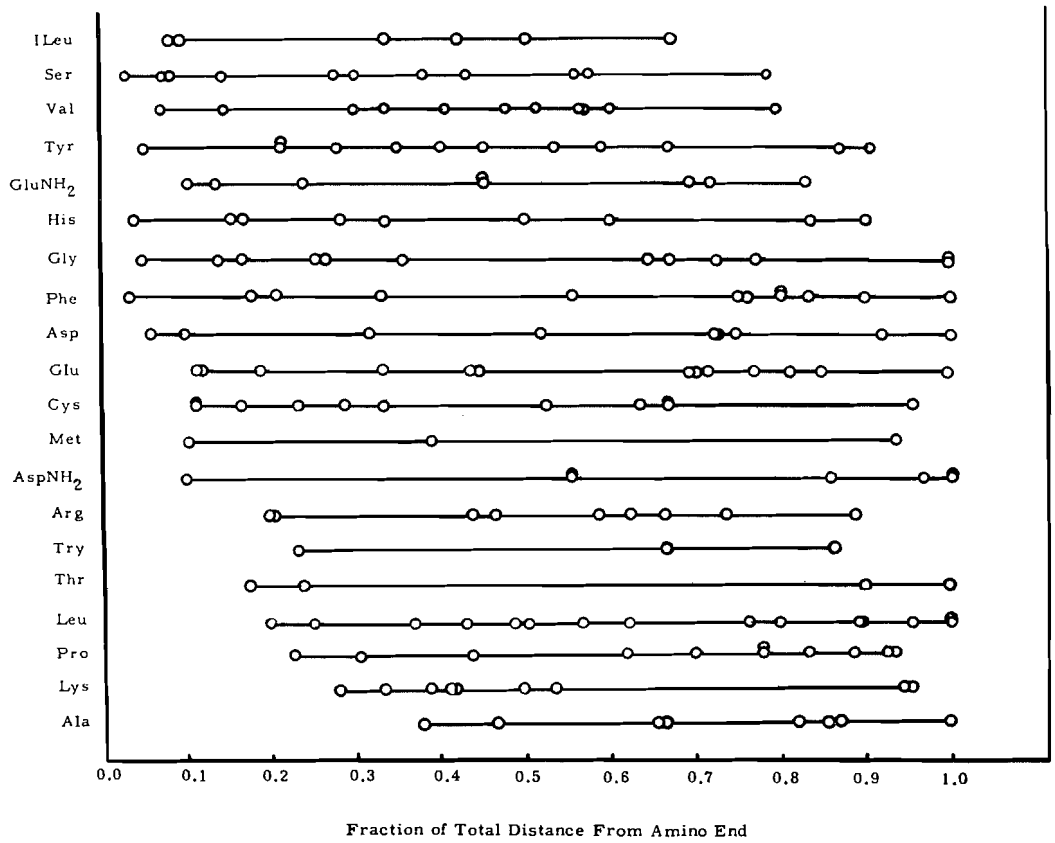

FIG. 1.

fractional distance of the individual amino acid moiety along the peptide chain. Our data show that certain acids, including glycine, glutamic acid, phenylalanine, and aspartic acid, are widely distributed from N- to C-terminal moieties. A few amino acids appear mainly in the interior: glutamine, methionine, tryptophan, and lysine. Cysteine predominates near the ends of the peptide chains. Others are found to tend toward one end of the molecule. For example, isoleucine, serine, valine, and histidine are associated more with the N-terminus while alanine, leucine, threonine, and proline are closer to the C-terminus. The remainder of the amino acids present do not fit well into any of the above groupings.

Some of the relationships may be seen best in terms of actual numerical positions within the peptide. For example, isoleucine does not appear in any of the peptides beyond the 8th moiety from the N-terminus, histidine not beyond the 10th, serine not beyond the 16th, although all of them occur in longer peptides and thus, presumably have the opportunity to occupy more distant positions. In the same way alanine is not found more than 14 positions from the C-terminus and leucine not more than 17. With two exceptions, all of the lysine moieties were clumped near the second quadrant of the peptide chains.

For personal use only.

Of the total of 11 prolines present in the peptides, 4 were located in the third position from the C-terminus and 3 more were in the fourth position. Proline also was found to exhibit a periodicity of 12 in the corticotropins and the β–MSH hormones. It appears, at least, at the 12, 24, and 36 positions from the N-terminus of the three corticotropins (A, α, β); in the β–MSH molecules it appears at the 4 and 16 positions.

For the analysis of terminal amino acids a number of proteins and peptides were added to the peptides used in the remainder of the study. Sixteen of the 21 amino acids found to be present are found as N-terminal groups and 11 are found one or more times as the C-terminal groups. A total of 17 different amino acids are found at one or the other end; only methionine, tryptophan, ornithine, and glutamine were absent from terminal positions.

Another object of the present study was to compare the significance of occurrence of a number of dipeptide couplets making up the structure of a select group of peptides and proteins. It was desirable to determine whether a dipeptide sequence occurred more frequently or less frequently than could be predicted purely by chance based on the quantity of each of the amino acids making up the pool. The concept of chi-squares which considers the theoretical as well as the actual occurrence of each dipeptide moiety was used to compare the significance of uniquely occurring entities.

The dipeptide structures arise by removal from the metabolic pool of those amino acids necessary to synthesize the total host peptide. The metabolic pool may be different in different tissues. For the purpose of the present study, the metabolic pool arbitrarily was taken to consist of all the amino acids present in the peptides examined, in concentrations determined by the numbers present in each of these peptides. Although the resulting pool is derived from heterogeneous peptides, valid conclusions can be made from the corresponding chi-square values. That the pool bears no necessary relationship to its derivative peptides can be seen in the work of Ramachandran and Winnick (5), whose analysis of the very short peptides of the pituitary metabolic pool showed no sequential correlation to the peptide hormones derived from the pituitary.

For significance at the 10% level and for one degree of freedom, the chi-square for a dipeptide moiety should exceed a value of 2.706 (6). Table I lists all of the dipeptide couplets which were found to have significant chi-square values. Only four of the 122 couplets which occurred only once had a chi-square exceeding the requisite statistical limit; the occurrence ratio also indicated a much greater than expected existence. Two of these couplets make up one tripeptide fraction, –AspNH_2–Met–Met–, found in the protein, ribonuclease. Another dipeptide, –Orn–Ileu–, appears in bacitracin and closely resembles the related –Orn–Leu– occurring in other peptide antibiotics. The fourth couplet, –Try-D-Phe–, is in the tyrothricin B sequence but is in part of the peptide which differs from tyrothricin A.

For dipeptide couplets occurring more than once there was an expected increase in statistical significance. Thus, for couplets appearing twice, more than one-fifth (10 of 49) had significant chi-squares. In a few cases, the dipeptide occurred twice within the same protein molecule. Such moieties generally contained amino acids rich in functional groups rather than simple aliphatic types.

Since a total of 294 dipeptides form all the compounds included in this communication and since these are made up of 202 different types, it is evident that almost all dipeptide couplets as well as their parent peptides are unique structures.

It is evident that the mere occurrence of a particular combination of amino acid residues, even those having significant chi-square values, does not confirm a strict functional

Arg	3.090	2.804			

*The expected "chance" frequency, C, may be calculated for the dipeptide couplet $X-Y$ from $(X/T) \times (Y/T-1)$, where X is the number of residues of the first amino acid comprising the couplet and Y is the number of units of the second amino acid. T represents the total of all amino acid units in the system.

The "actual" frequency, A, is found from the number of occurrences of $X-Y$ divided by the total number of dipeptide couplets.

The occurrence ratio is A/C.

†The chi-square value is calculated from the formula, $X^2 = (A-C)^2/C$, where A is the "actual" occurrence of a particular dipeptide unit and C is the "chance" occurrence of that couplet.

requirement for that combination of amino acids. Nevertheless, although couplets involved in other than activity functions may have chi-squares of significance, the technique may nevertheless be helpful for purposes of sequence characterization.

The existence of a number of significant chi-square values for certain couplets led to the reconstruction of the "characteristic" segments of some physiologically active peptide sequences. These sequences vary in length from five residues in the corticotropins to dipeptide couplets. In glucagon, in a span of nine residues, there are six hydroxyl-containing moieties. At least part of this unit is markedly characteristic through the –Thr–Ser– and –Tyr–Ser– couplets (Table I). Only one-third of the insulin A molecule, the portion at the N-terminus, showed non-random linkage frequencies by our test, while in the B chain, there was a continuous sequence of 12 residues, at the C-terminus, for which the chi-squares were not significant.

An interesting example which supports the possible usefulness of statistical evaluation of the dipeptide units can be noted from the specific biological activity of a synthetic peptide made up of the N-terminal portion of oxytocin and the C-terminus of vasopressin (7). This artificial hormone has a degree of activity of both natural peptides and contains only the statistically characteristic couplets of each.

Of the 441 unique dipeptidic arrangements which are possible for 21 different amino acids, 202 appeared in those compounds examined. Even under the best arrangements, it was not possible to find all 441 moieties since only a total of 294 dipeptide sequences comprised the pool. Assuming that naturally occurring proteins arise from metabolic pools similar to those yielding the peptides of this study, it would be reasonable to expect that certain of the missing couplets will yet appear as the sequence of additional proteins are unravelled. However, as has already been suggested in the work of Sorm (3), 897 couplets were examined and found to contain only 247 unique moieties. That is, by introducing an additional 603-couplet arrangement only 45 new and different dipeptide sequences were gained. One may further conclude that a natural barrier appears to exist for the occurrence of certain amino acid sequences in peptides. One might agree with Fox (8), who suggests that formation of peptides takes place by self-selection of the amino acid sequences, perhaps by a process akin to Darwinian selection which directs the synthesis of more adapted protein molecules from those of less value to the organism.

The authors are deeply indebted to Dr. Felix Haurowitz for his aid and helpful comments in the preparation of this manuscript.

SURFACE EFFECTS IN BUTANE OXIDATION[1]

M. Cherneskey and J. Bardwell

ABSTRACT

The oxidation of butane is considerably affected by the nature of the vessel surface. With a silica vessel, vigorous combustion accompanied by multiple cool flames occurs between 280° C and 320° C. These reactions are strongly inhibited when the vessel walls are coated with metal oxides or metal halides. Higher pressures are required for ignition at all temperatures. Of the compounds studied, lead monoxide is the most effective inhibitor. The results suggest that in the antiknock action of lead tetraethyl the true inhibitor is lead monoxide.

INTRODUCTION

There is considerable evidence that the oxidation of hydrocarbons is subject to surface effects. Kinetic experiments have revealed a dependence of rate on vessel diameter (1, 2) and on the previous treatment of the vessel walls (3, 4, 5). Although systematic investigations of surface effects have been made with hydrogen (6, 7, 8) and methane (4, 9) there is a lack of information about the role of the surface in the oxidation of the higher hydrocarbons, where mechanisms not found with methane come into play (10, 11). A better understanding of the part played by the surface in these reactions is desirable for several reasons: it would clarify some of the puzzling anomalies in the reaction kinetics (12, 13); it might suggest improvements in petrochemical processes; finally, it might help reveal the mechanism of "knock" and antiknock action in engines.

Although knock and its suppression have been subjected to much investigation (14, 15, 16) there is still considerable disagreement about the nature of the process. The work of King and co-workers (17, 18, 19) and of Walsh and co-workers (20, 21, 22) may be cited as illustrating both the lack of agreement on mechanism and the possible importance of heterogeneous processes.

King (17, 18) ascribes the action of antiknock agents such as iron carbonyl or lead tetraethyl to deposition of metals or metal oxides which are believed to promote the formation of steam and oxides of carbon; these gases may then dilute the combustible mixture and reduce its inflammability. Walsh and co-workers (20, 21, 22) ascribe the antiknock action of lead tetraethyl to the formation of a colloidal smoke of lead monoxide, which is assumed to inhibit the knocking reaction by virtue of a surface destruction of free radical chains. Each group of investigators claims supporting evidence from combustion experiments. The positive-catalyst theory favored by King is said to be supported by the results of flow experiments with fuels such as pentane and hydrogen (18, 19). The negative-catalyst theory favored by Walsh finds support from static experiments with fuels such as methane and ethers (21, 22).

The question of antiknock action has continued to be a contentious one (16, 23, 24). It appeared desirable to establish empirically the effects of various inorganic compounds on the combustion behavior of a typical hydrocarbon. For this investigation the fuel chosen was *n*-butane, which oxidizes at convenient rates between 250° C and 500° C. This compound's oxidation is accompanied by cool flames, two-stage ignition, and other phenomena associated with the low-temperature combustion of paraffin hydrocarbons and related substances (11, 25).

EXPERIMENTAL

Apparatus

The apparatus used was a conventional one, consisting of a reaction vessel heated in a well-lagged furnace and connected to a manometer, a pumping system, and storage vessels for the reactants. The *n*-butane and oxygen were admitted separately to the vessel and the progress of reaction was followed by pressure measurements and by observation through a window. The reaction vessel was of clear silica, and was cylindrical in shape, 6 cm in diameter and 9 cm long. It was fitted with a capillary inlet tube and a ground joint.

Procedure for Modifying the Surface

Deposition of Soluble Salts

Sufficient salt solution (20% by weight) was transferred to the clean vessel, to leave, on drying, a salt coating of 2.5 mg per sq. cm. The vessel was heated to about 80° C by immersion in a water bath, and then connected to an aspirator for evaporation of solvent. During solvent evaporation, the vessel was continuously rotated in such a way as to bring the solution in contact with all parts of the inner surface.

Deposition of Insoluble Powders

The powder was screened and the portion that passed a 200-mesh screen was used. The fine powder was suspended in a small volume of water and transferred to the vessel. The water was evaporated as described above. Deposits amounting to 0.9 mg per sq. cm were used in most experiments; observations with other amounts are described below. It was found that the technique described yielded deposits that were reasonably uniform and that remained in place after numerous combustion experiments.

Cleaning the Vessel

On completion of combustion experiments with a given surface coating, the vessel was detached, washed with water and then with dilute nitric acid or other suitable solvent. For removal of possible contamination by organic matter, the vessel was left in contact for 1 hour with a freshly prepared mixture of concentrated nitric acid and concentrated sulphuric acid held at about 100° C. The vessel was then thoroughly rinsed with hot distilled water and dried. The vessel so treated will henceforth be referred to as "acid-cleaned".

When combustion experiments were done with the acid-cleaned vessel the rates found at first were similar to those with the new untreated vessel. These rates differed slightly, however, from those obtained subsequently with the same vessel. It is therefore necessary to distinguish two types of "clean" surface, the freshly acid-cleaned vessel and the "aged" vessel. The aged vessel showed slightly higher rates and improved reproducibility. Similar "aging" effects have been reported by other investigators (2, 4, 12) but their cause remains obscure.

Comparison of Results with Different Surfaces

It has been shown that with hydrocarbons such as propane and *n*-butane the pressure changes that accompany oxidation run roughly parallel with the consumption of reactants and the appearance of products (25, 26, 27). With *n*-butane the pressure–time curves show the usual shape: at first there is an induction period, ranging in duration from seconds to hours; at the beginning of the induction period the rate of pressure change is often immeasurably small, but it usually increases in an approximately exponential way, culminating in a period of more rapid reaction. During the latter period there may occur

pressure surges, which accompany luminescence in the vessel and indicate the occurrence of cool flames or ignition. Of the various criteria of reaction rate that may be used to evaluate the influence of the surface, the following will be employed in this paper:

(*a*) the length of the induction period which, for this purpose, will be defined as the time elapsing between the admission of the reactants to the vessel and the attainment of maximum reaction rate (or the passing of a cool flame);

(*b*) the magnitude of the maximum rate of pressure change for a given reaction mixture and vessel temperature;

(*c*) the pressure–temperature limits for the onset of ignition;

(*d*) the range of occurrence of cool flames.

RESULTS

Effect of Surface on Induction Period and on Maximum Rate

Table I illustrates the large differences in reaction rate encountered with different surface materials, under otherwise identical experimental conditions.

TABLE I

Induction period and maximum rate of pressure change in the oxidation of *n*-butane under different surface conditions

Surface treatment	Induction period, minutes	Maximum rate, mm/min
Clean silica (aged)	0.3	Ignition
KI coated	2	7
PbO coated	27	0.24

NOTE: Initial pressure of *n*-butane, 150 mm; initial pressure of oxygen, 150 mm; temperature of vessel, 292° C.

On the basis of these results, which are typical of many, the aged silica surface may be designated as "active", the KI-treated surface as "moderately inhibiting", and the PbO-treated surface as "strongly inhibiting".

Effect of Surface on Ignition Limits

The pressure–temperature limits for ignition of equimolar mixtures of *n*-butane and oxygen under different conditions of surface are shown in Fig. 1. The adverse effect of a

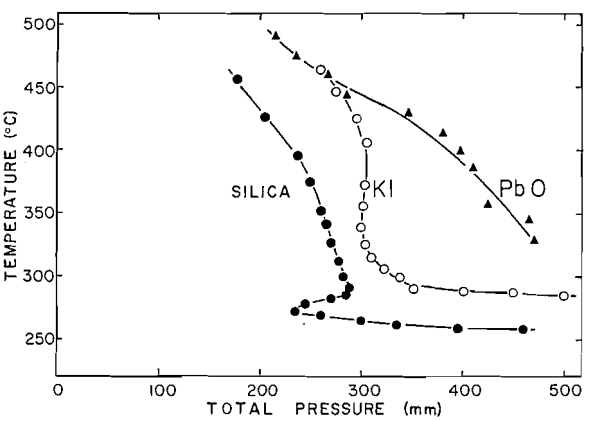

FIG. 1. Ignition limits for equimolar *n*-butane – oxygen mixtures with a silica vessel, untreated, and coated with KI and with PbO.

coating of KI or PbO on reaction rate is here revealed by an increase in the pressure required for ignition. Again it is clear that PbO is the more effective inhibitor, at least in the low-temperature region.

The results in Table I and Fig. 1 illustrate the difficulty of arriving at a satisfactory quantitative criterion of inhibition with a branching-chain reaction. The ratio of induction periods in Table I indicates that at 292° C reaction proceeds about 90 times faster in the aged vessel than in the PbO-coated vessel. On the other hand, the minimum pressures for ignition, in the low-temperature region, differ by a factor of a little less than two. This apparent discrepancy is believed to be related to the fact that reaction rate is strongly dependent on reactant pressure (1, 28, 29).

In subsequent sections of this paper, changes in ignition limits and cool flame limits will be used for assessing the magnitude of surface effects. It should be remembered that these limits are in general much less sensitive measures of inhibition than others that might have been employed, such as induction period or maximum rate. General use of the latter is made difficult or impossible by the marked changes in the nature of the reaction resulting from surface changes.

Ignition Diagram with an Active Surface

With *n*-butane, as with most hydrocarbons, intense reaction is frequently found even though the pressure is insufficient for ignition. Figure 2 shows, in a pressure–temperature

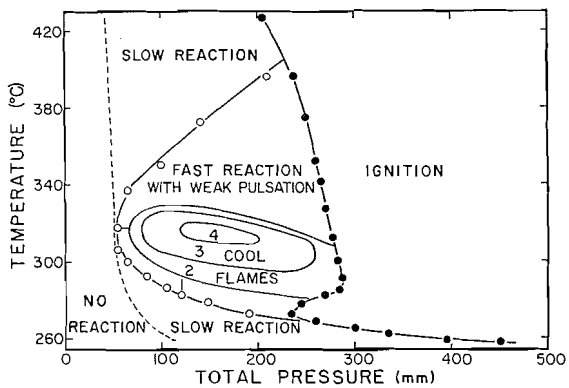

FIG. 2. Range of occurrence of combustion phenomena with equimolar *n*-butane – oxygen mixtures in a silica vessel, 6 cm in diameter. The numbers shown indicate the numbers of cool flames observed.

diagram, the range of occurrence of the various phenomena encountered when equimolar *n*-butane – oxygen mixtures were admitted to an aged silica vessel in the temperature range 250° C to 430° C. The phenomena include:

(*a*) No reaction: here the induction period is of infinite duration (28, 29).

(*b*) Slow reaction: the oxidation is accompanied by little if any luminescence, and the pressure increases without any surges or pulsations. This type of reaction occurs both at low temperatures and at high temperatures; for example, with a total pressure of 80 mm the maximum rate has a value of 10 mm/min at 287° C, at 380° C, and at 452° C (29).

(*c*) Single cool flame: the self-acceleration of the reaction is interrupted by a moderate pressure surge during which a bluish flame is seen in the vessel.

(*d*) Multiple cool flames: here a definite periodicity is present, the flames being separated by intervals of up to 100 seconds. The pressure–time record for this type of reaction is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

illustrated in Fig. 3 (curve for 284° C). The passing of each flame brings about a marked deceleration of the reaction.

(*e*) Fast reaction with weak pulsation: As the vessel temperature is increased beyond about 320° C the periodic nature of the reaction becomes much less pronounced. The initial acceleration of the reaction is rapid, but the pressure surge is relatively weak and it is not followed by a substantial deceleration; instead reaction continues at a rapid rate. Figure 3 (curve for 360° C) illustrates the pressure–time record for this type of reaction and shows the contrast with the multiple cool flames that occur at lower temperatures.

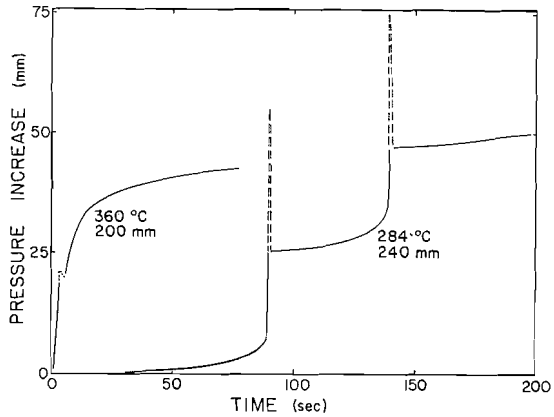

FIG. 3. Typical pressure–time record for double cool flame and for fast reaction with weak pulsation.

(*f*) Ignition: a bright blue or yellow flame traverses the reaction vessel and is associated with a large pressure increase. Below about 400° C, the ignition is a two-stage process, a cool flame preceding the hot flame. Many investigators have commented on the similarity of such ignition and the phenomenon of knock in engines (10, 11, 16).

The main features of the diagram in Fig. 2 are similar to those found by other investigators (using glass or silica vessels) with propane (26, 30), *n*-pentane (5), and butanone (31). As with these compounds the ignition limit is L-shaped with a peninsula at about 275° C.

As mentioned earlier, experiments with the acid-cleaned vessel gave somewhat slower reaction than those with the aged vessel. Examples are shown in Table II where some of the pressure–temperature limits are given. The differences, although appreciable, are evidently much smaller than those found between limits for the clean and the treated surfaces.

Ignition Diagram with a Moderately Inhibiting Surface

Typical results with a moderately inhibiting surface are shown in Fig. 4 which gives the ignition diagram for a NiO-coated surface. Comparison with Fig. 2 shows the following evidence of inhibition:

(*a*) A much larger region of no reaction.

(*b*) Elimination of multiple cool flames. The pressure–temperature conditions that usually give rise to these with the active surface, i.e., moderate pressures and temperatures in the range 280° C to 320° C now lead to either slow reaction or no reaction at all.

(*c*) Significantly higher ignition limits.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

The ignition diagram in the low-temperature region was also determined with the surface coated in turn with the following metal oxides: Cu_2O, Fe_2O_3, Pb_3O_4, and PbO. The results are summarized in Table II. It is seen that Cu_2O, Fe_2O_3, and Pb_3O_4 give limits very similar to those for NiO. Furthermore, the ignition diagrams showed the same general features as found in Fig. 4, namely an L-shaped ignition boundary and a large area where the pressure–time record was similar to that in Fig. 3 (360° curve). In no case was the pressure–time record similar to the 284° C curve in Fig. 3, i.e., clearly marked multiple cool flames were not observed. The exceptionally strong inhibition found with PbO will be discussed below.

Table II also summarizes the results for the vessel coated with the following metal halides: $MnCl_2$, $NiCl_2$, $CuCl_2$, $PbCl_2$, KCl, and KI. With the exception of KCl, which appears to be a rather ineffective inhibitor, these metal halides also give limits that differ little from those for a NiO coating. The ignition diagrams again were found to resemble

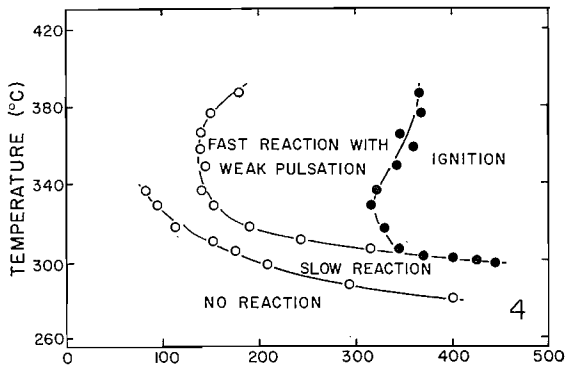
TABLE II

Pressure–temperature limits for various surface treatments

Surface treatment	Minimum ignition temperature at 400 mm pressure, °C	Minimum temperature for pulsating reaction at 300 mm pressure, °C	Minimum pressure for pulsating reaction at 335° C	Minimum pressure for ignition at 335° C
Aged silica	259	265	65	267
Acid-cleaned silica	262	268	75	270
NiO	301	306	150	320
Cu_2O	296	302	140	315
Fe_2O_3	293	300	140	315
Pb_3O_4	303	308	125	295
$MnCl_2$	296	300	135	305
$NiCl_2$	295	302	130	300
$CuCl_2$	295	303	150	310
$PbCl_2$	305	312	130	295
KI	288	293	150	300
KCl	282	287	120	279
PbO	395	344	195	465

that in Fig. 4; the ignition boundary was L-shaped, no multiple cool flames were found, but fast reaction with weak pulsation took place above about 310° C.

Ignition Diagram with a Strongly Inhibiting Surface



The exceptionally potent inhibition brought about by a PbO coating will now be presented in greater detail. Figure 5 shows the ignition behavior between 250° C and 435° C. The diagram is evidently much altered from that with the active surface (Fig. 2). Particularly noteworthy is the persistence of slow reaction in regions of pressure and temperature, e.g., 400 mm and 350° C, that lead to vigorous explosion with all the other surface treatments used.

Effect of Differences in Amount of Deposit

Some experiments were done to find out to what extent the inhibiting effect of PbO depends on the amount of it, present on the surface. Coatings amounting to 0.1, 0.9, and 2.2 mg per sq. cm were used.

The limit chosen for the comparison was the position of the upper boundary of the slow reaction zone, at 300 mm pressure, i.e., the temperature marking the transition from

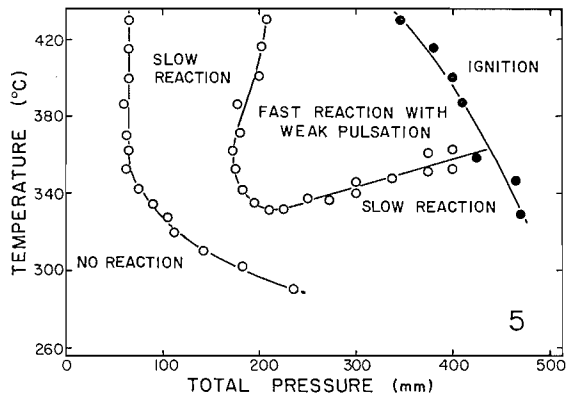

FIG. 4. Range of occurrence of combustion phenomena with equimolar *n*-butane – oxygen mixtures in a silica vessel coated with NiO.

FIG. 5. Range of occurrence of combustion phenomena with equimolar *n*-butane – oxygen mixtures in a silica vessel coated with PbO.

TABLE III

Effect of amount of PbO used on the degree of inhibition

Amount of PbO deposited, mg per sq. cm	Upper limit of slow reaction zone at 300 mm pressure, °C
0	268
0.1	321
0.9	344
2.2	343

non-pulsating reaction to reaction with pulsation. Table III shows that, by this criterion, the extent of inhibition increases sharply with the first addition of PbO (0.1 mg per sq. cm). When the coating is increased from 0.1 to 0.9 mg per sq. cm, there is some further inhibition, but increase beyond 0.9 mg per sq. cm is without effect.

Inert Gas Effects

The response of a free radical reaction to inert gas additions can provide a clue to the role of the surface. Attention will be confined to experimental conditions where the reaction proceeds without appreciable self-heating, since otherwise complications arise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

because of heat capacity effects (25). The effects of inert gas additions on the slow development of the reaction in the induction period will therefore be considered.

With the aged silica vessel the rate of development of the reaction was found to be unaffected by inert gas additions. Measurements in the slow combustion region (270° C, 160 mm pressure) and in the cool flame region (284° C, 240 mm) showed that nitrogen additions of 200 mm had no effect on the length of the induction period. Additions of argon and of water vapor were also found to be without effect.

A different result was obtained when an acid-cleaned vessel was used. Inert gas additions at 300° C now had a moderate accelerating effect. For example, with a total reactant pressure of 160 mm, addition of 200 mm of nitrogen shortened the induction period from 130 seconds to 60 seconds. It is of interest that with the aged vessel under the same experimental conditions (300° C, 160 mm pressure, no inert gas) the induction period was only 24 seconds. On the basis of these results it might be anticipated that the differences in induction period between the acid-cleaned vessel and the aged vessel would disappear if experiments were done in the presence of sufficient inert gas.

Still greater effects were found with a PbO-coated vessel. Measurements were made in the slow combustion zone (312° C, 150 mm pressure). Addition of only 108 mm of nitrogen shortened the induction period from 20 minutes to only 2 minutes and increased the maximum rate from 0.34 mm/min to 1.0 mm/min.

DISCUSSION

There seems little reason to doubt that the large effects of the different surface materials on the rate have their origin in different efficiencies of these substances in destroying intermediates, probably free radicals. The chain-breaking efficiency of the aged silica vessel appears to be relatively low. This conclusion is supported by the observations that with this surface, lively reaction develops over a wide range of experimental conditions (Figs. 2 and 3), and its rate of development is not accelerated by inert gas additions. The latter observation shows that, under typical experimental conditions, there is no serious depletion of radicals by diffusion to the walls. Such depletion does apparently become significant, however, when the pressure is sufficiently reduced, as there is complete suppression of the reaction at pressures below about 50 mm (Fig. 2).

The acid-cleaned surface is evidently somewhat more efficient in breaking chains than is the aged surface; this is indicated by the longer induction period, the acceleration by inert gas, and the slightly higher pressure–temperature limits for cool flames and ignition (Table II).

Of the 11 inorganic compounds used as surface coatings, all but KCl and PbO lead to approximately the same degree of inhibition. For example, Table II shows that at 400 mm pressure the ignition temperatures show a range of 136° when all the surfaces are considered; these nine compounds, however, show a range of only 17°. It is interesting that KCl, which has frequently been used to provide an inhibiting surface in oxidation experiments (2, 3, 8), appears, from this investigation, to be the least effective of all the compounds tested.

It seems difficult to avoid the conclusion that PbO is an exceptionally efficient chain-breaking agent. Evidence of unusually strong inhibition by this substance has been presented in Tables I and II and in Fig. 5. Corroboration may be found in a comparison of the data in Tables II and III. It is seen that even a light coating of PbO (0.1 mg/sq. cm) leads to greater inhibition than the normal coating (0.9 mg/sq. cm) of the other metal oxides or even the heavy coating (2.5 mg/sq. cm) of the metal halides. The latter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

comparison makes it unlikely that the observed difference between the results with PbO and with the other compounds is due to some unsuspected experimental factor such as differences in particle size distribution of the powders.

A complete discussion of surface effects would include identification of the radicals that suffer destruction at the walls. From indirect evidence Walsh and co-workers have suggested that the radical HO_2 plays such a role in the oxidation of methane at about 500° C (20, 22). In the oxidation of higher paraffins at low temperatures, many other radicals have been postulated as participating in the reaction mechanism (10, 27, 32). It is unlikely that some of the more complex of these radicals, e.g., C_4H_9OO, participate appreciably in wall reactions since there is evidence that they undergo rapid pyrolysis or isomerization reactions in the gas phase (27, 33). An additional possibility in the low-temperature range is the occurrence of heterogeneous side-reactions of intermediate molecules such as peroxides or aldehydes, whose normal reactions are believed responsible for chain-branching (12, 28).

Relation to Other Investigations

Although there appears to be no previous investigation of surface effects in the oxidation of *n*-butane, some information is available for propane and ethers. Day and Pease (30) determined cool flame limits and ignition limits for propane using three different surface treatments—cleaning with hot HNO_3, etching with HF, and rinsing with a KCl solution which was then drained out of the vessel. They found only small differences in the various limits and concluded that "the nature of the surface has no great effect on the cool flame and ignition characteristics of the reaction". In view of the results given above for *n*-butane and the general similarity of combustion behavior of propane and *n*-butane (25, 26), this generalization appears to be premature. A repetition of the work of Day and Pease, with thicker deposits and other compounds, would be desirable.

Chamberlain and Walsh (21) measured the ignition limits of diethyl ether using a silica vessel, with and without a coating of PbO. The PbO coating was found to raise the ignition pressure by 11% at 400° C and by 14% at 210° C. These results may be compared with those given above for *n*-butane, namely an increase of about 65% at 400° C and a slightly larger effect at lower temperatures, e.g., 75% at 330° C (Fig. 1). The lack of quantitative agreement is not surprising since ethers and hydrocarbons show other differences in their oxidation behavior (10, 33). There may also be a difference in amount of deposit used.

Relation to the Mechanism of Antiknock Action

The results given in this paper suggest that PbO may well be the true inhibitor when lead tetraethyl acts as an antiknock agent. It is worth while to compare the inhibition of the oxidation of *n*-butane by PbO with the known behavior of lead tetraethyl. As shown above in Tables I and II and in Figs. 1 and 5, the inhibition by PbO is pervasive; this substance greatly lengthens the induction period, it suppresses the phenomenon of multiple cool flames, and it raises ignition pressures by about 70%. Lead tetraethyl, on the other hand, has been found to have little effect on the induction period both with *n*-heptane (10, 16, 35) and with diethyl ether (34); its inhibiting effect apparently comes into play only at later stages of the reaction. The extent of inhibition by lead tetraethyl may be estimated from its effect on ignition pressures. Townend and Mandlekar found that this additive, when used in amounts similar to those required for satisfactory antiknock action (0.1%), brought about an increase in ignition pressure of about 5% with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

n-butane and *n*-pentane (11, 36). It is interesting that, with some fuels, lead tetraethyl fails to give any antiknock effect and may even act as a proknock agent (10).

The complicated behavior of lead tetraethyl becomes more understandable if the true inhibitor is in fact PbO. The observation that the early stages of the reaction proceed at about the same rate whether lead tetraethyl is present or not (10, 16, 34) is explained if there is a delay in the formation of PbO; such a delay is to be expected if both chemical transformation of lead tetraethyl into PbO vapor and physical condensation of PbO vapor to solid particles are required. Furthermore, the chemical transformation is likely to release ethyl radicals into the combustion mixture and so cause some promoting action. An explanation is then available for the observation that lead tetraethyl has a net promoting effect under certain experimental conditions, for example, at very high temperatures (17) or with fuels that are believed to oxidize via very short chains (10, 20).

It has been suggested by Norrish and co-workers that in the inhibition of combustion reactions by lead compounds the processes are probably homogeneous and depend on vapor molecules, possibly including PbO vapor at very high temperatures (23, 24). The results reported in this paper, however, leave little doubt that heterogeneous processes are predominant in the temperature range considered here. The large influence of added inert gas on reaction rate points to surface breaking of chains. Furthermore, if vapor molecules were responsible for the inhibition, one would expect that the effect would be roughly proportional to the vapor pressure of PbO and so would increase markedly with increase of vessel temperature and would be independent of the amount of solid PbO on the surface. Figure 1 and Table III show that these expectations are not fulfilled.

While heterogeneous chain breaking at the vessel surface appears to be the predominant process responsible for the inhibition described in this paper, somewhat different mechanisms may be important under the higher pressure conditions found in engines when lead compounds exert an antiknock effect. The suggestion of Chamberlain and Walsh (21) that lead tetraethyl reacts with oxygen to form a colloidal smoke of PbO particles appears to be a plausible one. This mechanism makes possible heterogeneous chain breaking without, however, necessitating a long diffusion path.

REMOVAL OF OXYGEN FROM METHANE AND THE USE OF NUCLEAR SPIN RELAXATION TO MEASURE OXYGEN CONCENTRATION[1]

H. S. SANDHU, J. LEES, AND M. BLOOM

ABSTRACT

Nuclear spin relaxation measurements are used to measure quantitatively the amount of oxygen present in methane. An upper limit of $2.5\times10^{-4}\%$ is placed on the amount of oxygen present in methane after treatment with a getter made of misch metal.

The proton spin relaxation time, T_1, in liquid and solid CH_4 has been found by us to be very sensitive to small amounts of oxygen in the sample, because of the fact that the O_2 molecule is paramagnetic. The effect of paramagnetic impurities on nuclear spin relaxation in diamagnetic liquids has long been known (1), and precautions must usually be taken to eliminate such impurities if one is interested in studying T_1 of the pure liquid (2). In our first measurements of T_1 in liquid CH_4 (3), T_1 was found to depend on the sample, the longest T_1 obtained being about 0.6 second while some "chemically pure" samples gave us T_1 values as low as 10^{-2} seconds. All samples used were obtained commercially, the purest samples being supplied by Phillips Petroleum Co.

Since the vapor pressure readings for such samples also disagreed with those published for pure CH_4 (4), it was considered necessary to find a reliable method of purifying our samples. Different techniques were used to remove oxygen. It may be noted that we plan to study T_1 in deuterated samples of methane, so that it is of importance that the purification method does not require very large quantities of the sample.

An attempt was first made to use the fact that the normal boiling point of oxygen (90° K) is lower than that of methane (112° K). The liquid was maintained at a temperature (106° K) such that most of the oxygen might boil off. The vapors were then pumped off. This process was repeated a number of times. Each time we pumped off the vapors and measured T_1 in the liquid, we obtained a longer relaxation time. Although T_1 values as long as 10 seconds were obtained, this technique for purification was finally dropped because T_1 values so obtained were not reproducible and the method was very wasteful of methane.

The second technique employed was to circulate methane over heated copper. This method was not satisfactory because the gas decomposed during the process.

The technique found to be most suitable for our purposes involved the use of a getter, misch metal, which consists of rare earths derived from monazite and alloyed with iron. This metal was selected because it was found by Ehrke and Slack (5) in their study of the gettering power of various metals like aluminum, magnesium, barium, and misch metal that misch metal is the most effective for removal of oxygen. As described in the following paragraph, our procedure is a slightly simplified version of that described by Ehrke and Slack (5).

A $\frac{1}{2}$-liter flask drawn into a long tube on one side is used as shown in Fig. 1. The end of the tube fits into an NMR probe to make T_1 measurements. A tungsten coil of five or six turns of 0.01-in. diameter, with two or three small pieces of misch metal in the coil, is sealed into the flask. The flask is then connected to a diffusion pump through a trap and evacuated to a pressure of the order of 10^{-6} cm. The flask is baked by flaming

Contribution from the Department of Physics, University of British Columbia, Vancouver, British Columbia.

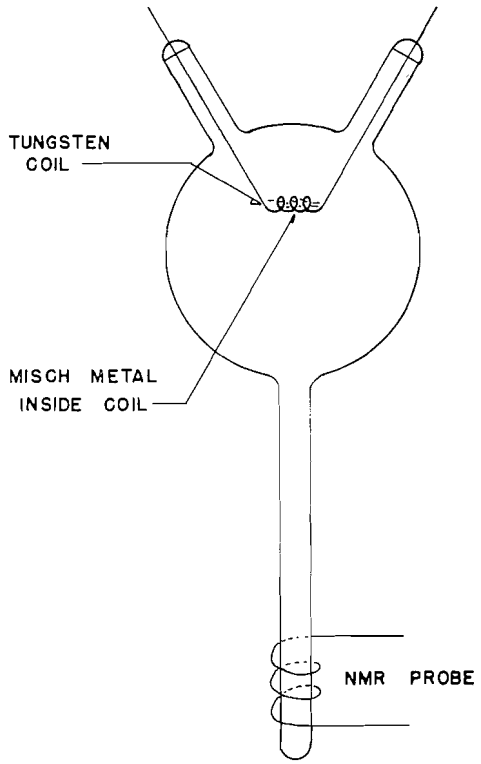

FIG. 1. Schematic drawing of the sample container.

several times during pumping to get rid of oxygen adsorbed on the walls. The tungsten coil is also degassed during pumping. When the flask has been thoroughly baked and pumped, it is filled with argon to a pressure of 1 to 2 mm. The getter is then flashed by passing current through the tungsten coil using a Variac to control the current, until a characteristic diffused layer of the deposit is produced. The presence of argon is necessary to produce a diffused deposit the gettering power of which is much higher than the bright shiny type (5). The argon is then pumped off, leaving an uncontaminated getter layer of high activity. Methane at 1-atmosphere pressure is introduced into the flask which is then sealed off from the system.

When this procedure was followed, T_1 was always found to increase to 14 seconds at 108° K, this value being reproduced whether the measurements were done on different samples or the same sample at different times during a period of several days. One of the samples studied had had approximately 0.5% oxygen purposely added as an impurity. The addition of nitrogen to the samples did not affect T_1.

In order to make quantitative measurements on the contribution of oxygen to T_1, a sample of CH_4 was prepared with approximately 1% oxygen. Mass spectrometer measurements performed at the Department of Chemistry, University of Washington, showed that the sample contained about 1.08% oxygen. T_1 was measured as a function of temperature and will be reported for this sample and other similarly prepared samples in a future publication. For purposes of using T_1 as a method of analyzing the oxygen concentration quantitatively, we give here only values of T_1 in CH_4 liquid under its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

own vapor pressure at 108° K. The measurements were made using pulse techniques (3) and were accurate to about 5%.

For 1.08% O_2, we obtained $T_1 = 34\times10^{-3}$ sec. It is expected that $1/T_1^0 \propto f$ where T_1^0 is the contribution to T_1 due to the oxygen, and f is the percentage of oxygen molecules. This was borne out by studying a sample containing 2.54% oxygen, as measured by the mass spectrometer, which gave $T_1 = 15\times10^{-3}$ sec at 108° K.

Because of the oxygen background in the mass spectrometer, it was impossible to analyze the oxygen concentration with it in a region where T_1 measurements indicated that f was less than about 0.1%. Therefore, our T_1 measurements represent a more sensitive means of detecting oxygen than a mass spectrometer unless special steps are taken to cut down the oxygen background in the mass spectrometer.

If T_1^n represents the natural relaxation time of pure CH_4, we can write

$$\frac{1}{T_1} = \frac{1}{T_1^n} + \frac{1}{T_1^0}.$$

Our measurements indicate that $T_1^n = 14$ seconds at 108° K, since our measurements were reproducible from day to day and we would have been able to detect a change of less than 10% in T_1. If T_1^0 were about 14 seconds at 108° K, this would correspond to $f = 2.5\times10^{-3}$%. On the basis of the reproducibility of T_1 with time and in different samples, we are probably justified in saying that our purification procedure resulted in $f \lesssim 2.5\times10^{-4}$ %.

It would seem that the technique described here would be well suited to removal of oxygen from other hydrocarbons and this is being planned in connection with future measurements of T_1 of higher hydrocarbons in this laboratory.

This research was supported by a Research Grant from the National Research Council of Canada. We wish to thank Dr. L. Reeves for valuable suggestions and the mass spectrometer group at University of Washington for analyzing our samples.

THE ACTION OF PYRIDINE ON THE DINITRATE ESTERS OF 1,4;3,6-DIANHYDROHEXITOLS[1]

M. JACKSON AND L. D. HAYWARD

ABSTRACT

In contrast to the rapid and selective replacement of a secondary *O*-nitro group by hydrogen in the hexitol hexanitrates at 25–50° C, the dinitrate esters of the 1,4;3,6-dianhydrides of D-mannitol, D-glucitol, and L-iditol (*cis*-isohexides) reacted slowly in anhydrous pyridine at 87–115° C. The chief products were a polymer, nitrogen oxides, and pyridinium nitrate; the yield of mononitrates did not exceed 10% and none of the parent diols were formed.

The relative rates of the first-order decomposition of the nitroxy groups in the isomeric dinitrates were in reverse order to that for S_N2 reaction at carbon in these compounds. Activation energies and frequency factors were determined and water was shown to have a retarding effect.

Thermal decomposition of the dinitrates in solution in nitrobenzene, *m*-xylene, or *sym*-tetrachloroethane was much slower than the pyridine reaction at the same temperature and was independent of the polarity of the solvent and the conformation of the ester.

INTRODUCTION

Dulcitol and D-mannitol hexanitrates have been shown to react selectively with pyridine to yield the corresponding 1,2,4,5,6-pentanitrates (1, 2). The rate of reaction was different for the two hexitol derivatives and the resulting pentanitrates were essentially stable to pyridine under the same conditions. Sorbitol hexanitrate reacted similarly with pyridine but the pentanitrate was not fully characterized (3). The reaction was inconveniently fast for kinetic studies even at 25° C and the multiplicity of nitroxy groups and molecular conformations further complicated the problem of sorting out the reaction mechanism.

The three known isomeric 1,4;3,6-dianhydrohexitols (the *cis*-isohexides) and their derivatives have been shown to behave characteristically in certain types of reactions due to differences in their restricted conformations (4, 5). In an attempt to determine the mechanism of the pyridine – nitrate ester reaction the dinitrates of the isohexides (I–III, Fig. 1) were selected for study since observation of similar steric effects in their reactions with pyridine would aid in diagnosis of the type of mechanism involved. The presence of only two, non-vicinal, secondary, nitroxy groups in these isomers was also expected to simplify analysis of the results.

RESULTS AND DISCUSSION

The three isohexide dinitrates (Fig. 1) were prepared in crystalline form and characterized through their nitrogen contents, infrared spectra, and nearly quantitative conversion to the parent diols. The physical constants and nitrogen contents of the isomers are shown in Table I. The dinitrates dissolved readily in pyridine and the colorless solutions were stable over several weeks at room temperature. No vigorous reaction occurred on heating under reflux; however, slow decomposition, accompanied by a red coloration of the solution and evolution of oxides of nitrogen, began at temperatures above 50° C.

At 115° C 0.424 *M* solutions of the isohexide dinitrates in anhydrous pyridine decomposed according to an apparent first-order rate law for loss of nitroxy groups (Fig. 2). Since pyridine, as solvent, was present in constant excess, it was likely that the reaction actually involved a second-order process which appeared to be first order because of this

TABLE II

Rates of decomposition of the isohexide dinitrates in pyridine

Conditions		Rate constants, $sec^{-1} \times 10^{-6}$		
Temperature, ° C	Moles water per mole nitroxy group	Isoidide dinitrate	Isosorbide dinitrate	Isomannide dinitrate
87	0	3.20	1.15	0.13
100	0	8.58	2.29	0.74
115	0	25.4	15.2	8.07
115	0.5	18.8	12.7	3.3
115	1.0	13.5	10.0	3.6
115	2.0	10.3	7.9	3.1

(Table II). From these results Arrhenius activation energies of 21, 24, and 41 kcal and log frequency factors of 7.6, 8.9, and 18.3 were found for isoidide, isosorbide, and isomannide dinitrates respectively.

None of the parent diols could be detected in the reaction products by chromatography. Isohexide mononitrates were isolated and characterized but accounted for a maximum of 10% of the decomposed dinitrate in runs with aqueous pyridine; with anhydrous pyridine only traces of mononitrate could be detected. Most of the weight of the reaction products was brown-black, polymeric material. In addition to pyridinium nitrate a small amount of an unidentified, optically active oil was also isolated.

For comparison with the pyridine reaction the rate of thermal decomposition of the dinitrates was determined in four solvents with boiling points above 115° C and dipole moments ranging from 0.37 to 3.98 Debye units. The slow decomposition of isosorbide dinitrate at 100° and 115° C in these solvents is shown in Table III. The other two

TABLE III

Thermal decomposition of isosorbide dinitrate in various solvents

		Decomposition, %			
		100° C		115° C

Diethylcarbinol	1.64	29	40	45	53

isomers decomposed at the same rate in *sym*-tetrachloroethane but were not tested in the other solvents.

The rates of decomposition of the nitroxy groups were very similar in nitrobenzene, *m*-xylene, and *sym*-tetrachloroethane with first-order rate constants of 0.41×10^{-6} and 2.7×10^{-6} sec^{-1} at 100° C and 115° C respectively. The more rapid reaction in diethylcarbinol was probably due to incursion of a transnitration reaction:

$$RONO_2 + R'OH \rightleftharpoons ROH + R'ONO_2.$$

It is well established that the first and rate-determining step in the thermal decomposition of nitrate esters in the gaseous state is the fission of the oxygen–nitrogen bond, generating a free alkoxyl radical (10, 11). A similar mechanism for the first-order thermal

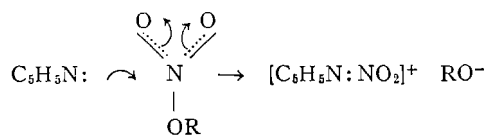
decomposition of the esters in the condensed state seems probable (12). Thermal decomposition of the esters in solution, however, has not been previously investigated.

For the first-order decomposition of the isohexide nitrates in the non-hydroxylic solvents the activation energy of 37 kcal/mole and log frequency factor of 15 calculated from the data of Table III were in good agreement with the values quoted for gaseous and condensed nitrate esters (10, 11, 12). This suggested a free radical mechanism for this case also. Additional evidence of a free radical mechanism was the fact that the rates were independent of the polarity of the solvent (9). Since the rate of the thermal reaction was exceeded by a factor of 5.6 in the pyridine reaction with isosorbide dinitrate at both temperatures it was concluded that thermal decomposition did not play a major part in the pyridine reaction.



It was noted that the decomposition went faster with well-dried pyridine. To test the effect of water on the rate a series of runs was made with increasing amounts of water present. There was appreciable decrease in rate with increase in water content (Table II) but the nature of the products was not altered substantially. The rate law,

$$\text{rate} = \frac{k_1\,[\text{nitrate ester}]}{1+k_2[H_2O]},$$

was followed where k_1 was 2.54×10^{-5} and k_2 1.70 for isoidide dinitrate.

The S_N2 reactions at carbon of isohexide *O*-derivatives, such as the replacement of sulphonoxy group by iodine, had a characteristic order of rates due to steric hindrance at one face of the molecule (5). The *endo* group (as in isomannide) reacted several times faster than the *exo* group (as in isoidide). The order of the rates of the pyridine – nitrate ester reaction, however, was exactly the reverse and hence ruled out this mechanism.

On the other hand these results were consistent with nucleophilic attack by pyridine at the nitrogen of the nitroxy group resulting in heterolytic cleavage of the low energy O—NO_2 bond.

The approach of the bulky pyridine molecule to the *exo*-nitroxy group would be least hindered by the isohexide skeleton in this case. The unstable *N*-nitrated pyridine intermediate was recently synthesized by Oláh and co-workers by direct nitration of pyridine with nitronium tetrafluoroborate (13). This mechanism also agrees with retention of configuration at asymmetric carbons actually found with the hexitol hexanitrates. The subsequent reaction of the alkoxide ion led to polymer formation in the isohexide case. The failure to detect the parent diols was not due to their decomposition since they could be added to the reaction mixture and recovered quantitatively.

The nitroxy groups in the isohexide isomers were well separated on the carbon chain, and, except in the case of isomannide dinitrate (Fig. 1), were also well separated in space. These isolated groups reacted only slowly with pyridine. In the hexitol hexanitrates the secondary nitroxy groups were contiguous and closely packed; steric compression in the initial state was clearly indicated by the molecular models. The proximity of the α-nitroxy groups must therefore be of considerable importance in the activation of the center groups and in the lifetime of the alkoxide ion.

EXPERIMENTAL

1,4;3,6-Dianhydrohexitols (cis-Isohexides)

Isomannide and isosorbide were prepared from D-mannitol and sorbitol respectively by the method of Wiggins (14). Isoidide was most conveniently prepared, together with isosorbide, through hydrogenation of L-sorbose followed by dehydration.

L-Sorbose (50 g) in water (200 ml) was hydrogenated at 55 p.s.i. and 80° C for 4 hours with Raney nickel catalyst (from 10 ml of the alcoholic sludge). The catalyst and solvent were removed and the residue was dissolved in concentrated hydrochloric acid (300 ml). The solution was saturated with hydrogen chloride and refluxed for 24 hours. Hydrogen chloride was removed by repeated evaporation under reduced pressure alternated with addition of water, and the residual sirup was fractionally distilled under reduced pressure: fraction 1, b.p. 135–140° C at 0.18–0.20 mm, 8 g, crystallized (isosorbide); fraction 2, b.p. 140–143° C at 0.20–0.22 mm, 5 g, sirup (mixture); fraction 3, b.p. 143–155° C at 0.22–0.25 mm, 12 g, crystallized (isoidide). Fraction 3 after recrystallization from ethyl acetate had m.p. 44–46° C and specific rotation in water $[\alpha]_D^{23}$ +21.0° (*c*, 1.1). Cope and Shen (4) reported m.p. 43–45.5° C, $[\alpha]_D^{25}$ +18.7° (*c*, 2; water) for isoidide.

1,4;3,6-Dianhydrohexitol Dinitrates (I–III)

The nitrate esters were prepared from the isohexides by the method of Forman *et al.* (6) in a yield of about 50%; the yield was increased to 85–90% by nitration in acetic anhydride – nitric acid – acetic acid mixture.

Fuming nitric acid (sp. gr. 1.45, 5 ml) was slowly added to acetic acid – acetic anhydride (1:1, 15 ml) maintained at −2 to 5° C. The mixture was added dropwise, with stirring, to the isohexide (2 g) in acetic acid – acetic anhydride (2:1, 15 ml) maintained at 0° C. After standing for 2 hours at 5° C the mixture was poured into ice water (400 ml). Part of the nitrate ester (2.2 g) crystallized out on standing for 18 hours at 20° C and a further amount (0.6 g) was recovered by ether extraction of the mother liquor. The esters were recrystallized from methanol and analyzed for nitrate-nitrogen (Table I). The infrared spectra of the isomers (potassium bromide window) showed covalent nitrate group absorption at 1650, 1265, and 750 cm^{-1} and no hydroxyl or carbonyl peaks.

Hydrogenation of the nitrates in alcohol solution over palladium–charcoal (1) gave the parent diols in 90–98% yield.

Decomposition of Isohexide Dinitrates in Solution

(a) Solvents

Reagent grade pyridine was distilled and the middle fraction of 80% was collected and dried over calcium hydride for 48 hours, decanted, and redistilled immediately before use. Reagent grade nitrobenzene was dried over calcium chloride, distilled, redried over phosphorus pentoxide, and redistilled under reduced pressure. *m*-Xylene and *sym*-tetrachloroethane were dried over calcium chloride and distilled. Technical grade diethylcarbinol was dried over anhydrous sodium sulphate and distilled and the middle fraction was used.

(b) Decomposition in Pyridine

The reactions were conducted in glass bulbs (2.5-cm diameter) with long stems (30 cm) fitted with water jackets and closed by drying tubes containing Drierite. An initial concentration of 0.100 g of isohexide dinitrate in 2 ml pyridine was used (0.424 mole nitroxy group per liter). The bulbs were heated in an oil bath for reactions at 115° C (reflux temperature), in the vapor of boiling water (100° C), or in the vapor of a boiling two-layer mixture of 2-butanol and water (87° C).

Aliquots of the reaction mixture (0.100 or 0.200 ml) were removed at intervals, distilled water (2 ml) was added, and the mixture was extracted three times with 1-ml portions of ether. Tests with added amounts of the dinitrates showed that extraction was then complete. The combined ether extracts were made up to 10 ml and 1-ml samples were taken for colorimetric determination of nitrate ester (15, 16).

The nitrate sample, containing 10–80 μg nitrogen, was added to 15 ml of 70% (v/v) sulphuric acid in a 250-ml flask and 1 ml of a 1% solution of 3,4-dimethylphenol was added. After being mixed, the solution was let stand for 30–60 minutes at 30° C. Water (150 ml) was then added, boiling stones introduced, and the flask fitted with a U-shaped distilling tube leading into a 25-ml volumetric flask containing 2% sodium hydroxide solution (2.5 ml). Distillation was carried out with the volumetric flask cooled in ice water and 20 ml of distillate was collected. The distillate was made up to 25 ml and brought to 24.0±0.5° C before colorimetric estimation at 435 mμ in a Bausch and Lomb Spectronic 20 colorimeter. The nitrate–nitrogen content of the sample was given by O.D.×103 = μg nitrogen.

(c) Thermal Decomposition in Solution

The nitrate ester (50 mg) and solvent (1 ml) were placed in a reaction bulb as used in the pyridine studies and heated in the vapor of boiling diethylcarbinol (114–115° C). After the reaction period the contents of the bulb were transferred with ether to a 7.5 mm ×20 cm column of alumina (Alcoa Grade F-20, acid-washed, activated at 400° C for 4 hours). The column was eluated with ether followed by ether – ethyl acetate (9:1). Fractions of the eluate containing nitrate (diphenylamine test) were pooled and evaporated under reduced pressure. The residual sirupy dinitrates crystallized on seeding and were identified by their melting and mixed melting points.

(d) Reaction Products

Isohexide dinitrate (5 g) in pyridine (50 ml) was refluxed under anhydrous conditions until 50–90% decomposed. The mixture was poured into water (500 ml), extracted with ether (600 ml), and the solutions were filtered. The precipitate was a brown-black amorphous solid (product A, 0.5–1.5 g).

The ether solution was evaporated to dryness *in vacuo* to remove traces of pyridine and yielded a pale brown sirup (0.5–2.5 g). Samples of this sirup were chromatographed on paper in hexane–methanol solvent (17). Unreacted isohexide dinitrate and a faint nitrate-containing spot with lower R_f value were detected in the products from each reaction. Quantitative separation was obtained by chromatography on alumina columns developed with ether – ethyl acetate (9:1) followed by acetone–methanol (1:1). The ether – ethyl acetate fractions yielded unreacted isohexide dinitrate which was recrystallized and characterized by mixed melting point determinations.

The acetone–methanol fractions yielded a small amount of sirup which had R_f 0.05 on papergrams developed with hexane–methanol. The nitrate–nitrogen content was 5.6% (required for isohexide mononitrate, 7.3%). Complete nitration of the sirup gave a spot running parallel to isohexide dinitrate on papergrams.

The aqueous solution was evaporated *in vacuo* to a dark red sirup (0.5–1.5 g). Extraction of the sirup with hot ethanol (50 ml) left a brown, amorphous solid (product B, 0.5–1.0 g). A red-brown sirup (0.5–1.5 g) was recovered on evaporation of the ethanol solution. Celite column chromatography with 1-butanol – water as solvent (18) showed that this sirup contained no isohexide since the fractions had zero optical rotation. Isohexide added to the initial reaction mixture in some runs was recovered quantitatively from the Celite column by this technique.

For personal use only.

The alcohol extract was subjected to ion-exchange and charcoal chromatography and pyridinium nitrate (0.2–0.8 g) was isolated together with a trace of an acidic, optically active oil.

Products A and B burned slowly in a Bunsen flame and were insoluble in organic solvents and water. Product A partially dissolved in 3 *N* sodium hydroxide solution and product B was soluble in aqueous pyridine and in 0.1 *N* sodium hydroxide solution. A brown-black solid was precipitated from the latter solution on acidification or addition of alcohol. Infrared spectra of the solid fractions thus obtained were very similar to each other and no functional groups could be identified. It was concluded that products A and B were polymers differing mainly in molecular weight.

THE ELECTRON SPIN RESONANCE SPECTRA OF THE POSITIVE AND NEGATIVE IONS OF DIPHENYLENE[1]

C. A. McDowell and J. R. Rowlands

ABSTRACT

The electron spin resonance spectra of the positive and negative ions of diphenylene have been measured. It has been found that these spectra consist of five lines showing that the observed hyperfine interaction is caused by four equivalent protons. The over-all extent of the positive ion spectrum is 18 gauss compared with that of 12.9 gauss for the negative ion. The hyperfine splittings observed are 4.0 gauss and 2.75 gauss respectively.

INTRODUCTION

The electron spin resonance spectra (e.s.r.) of both positive and negative ions of a number of alternant hydrocarbons have been measured in recent years (1). It has been shown that the qualitative features of the experimental spectra can be interpreted by use of unpaired electron spin densities calculated from the simple Hückel molecular orbital theory. The hyperfine interactions found in the e.s.r. spectra of these aromatic hydrocarbon ions are attributed to interactions between the odd electron spin and the nuclear spins of the protons attached to the carbon atoms. It has been shown that the hyperfine splitting produced by a proton attached to a given carbon atom is linearly proportional to the unpaired electron density on that carbon atom (2), i.e.,

$$\Delta H = Q\rho_\mu, \qquad [1]$$

where ΔH is the hyperfine splitting observed, and ρ_μ is the odd electron spin density on carbon atom μ.

From the properties of even alternant hydrocarbons it is evident that the odd electron spin densities on carbon atom μ, of an electron moving in a molecular orbital ϕ_i, are given by the equation

$$\rho_\mu = c_{i\mu}^2. \qquad [2]$$

It has been shown (3) that the atomic orbital coefficients $c_{i\mu}$ in paired orbitals are equal in magnitude, i.e. if orbitals ϕ_i and ϕ_j are paired in energy, then

$$c_{i\mu} = \pm c_{j\mu}. \qquad [3]$$

We can, therefore, expect that if ΔH^+ is the hyperfine splitting found in the monopositive ion, and ΔH^- that of the mononegative ion of a particular alternant hydrocarbon, and if Q is the same for both species, then

$$\Delta H^+ = \Delta H^-. \qquad [4]$$

It has been found experimentally for alternant hydrocarbons that although both species give the same number of components of hyperfine interaction, the over-all width of the monopositive ion spectra is in general about 4 gauss greater than the corresponding mononegative ions (1). The complexity of the spectra has made the determination of hyperfine splitting constants difficult. Where an analysis of the experimental spectra is possible, we have a choice of (*i*) assuming that the unpaired spin densities in both positive and negative ions are equal and are predicted accurately by the Hückel theory, and determining suitable values of the proportionality constant Q for the two species, or (*ii*)

[1]*Manuscript received December 22, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C.

assuming that this proportionality constant Q is the same for the two species, and is in fact constant for all even alternant hydrocarbons, and comparing the experimentally determined spin densities with those predicted from the Hückel molecular orbital theory.

In this paper on the ions of diphenylene the latter procedure has been followed.

EXPERIMENTAL

The mononegative ion of diphenylene was prepared by distilling dry tetrahydrofuran under vacuum into a bulb containing a freshly prepared sodium film. Attached to the bulb via a side arm was a narrow tube which held the diphenylene. The bulb was sealed off from the solvent source by freezing both sides with liquid nitrogen, pumping off any unfrozen tetrahydrofuran, and then sealing off at a constriction just above the neck of the bulb. When the solvent in the bulb was at room temperature the diphenylene was dissolved in it by shaking. The diphenylene then immediately reacted with the sodium to give a solution of the mononegative ion. Measurements of the e.s.r. spectra were then made by tipping the solution into the narrow tube, which was then placed in the cavity of the spectrometer operating in a TE012 mode. All the spectra were recorded on a high-resolution electron spin resonance spectrometer operating at 9000 Mc/sec. The magnetic field of approximately 3300 gauss was supplied by a Varian 6-in. magnet with shimmed pole faces. A modulating frequency of 10 kc/sec was used and the derivation of the spectra recorded on a Leeds & Northrup recorder as phase-sensitive detection was used. The monopositive ion of diphenylene was prepared by dissolving the hydrocarbon in concentrated sulphuric acid. Calibrations of all runs were made, by determining with the e.s.r. spectrum of Fremi's salt under identical sweep conditions.

RESULTS

The spectra of the negative and positive ions of diphenylene are shown in Figs. 1 and 2, together with the integrated absorption curves for each case. Each ion gives a spectrum containing five completely resolved lines with approximate intensity ratios of 1:4:6:4:1. No further hyperfine splitting could be detected for either ion, although the spectra were

measured over a range of concentrations. Figure 3 is the theoretical spectrum built up using the calculated Hückel spin densities, assuming that all Coulomb integrals for the carbon atoms are the same and that all resonance integrals for the C—C bonds are also equal. The theoretical spectra of both positive and negative ions are of course identical on this picture.

DISCUSSION

It can be seen from Figs. 1 and 2 that the observed spectra consist of five lines. These lines are well resolved and there is no trace of any other fine structure on the spectra of either the positive or negative ion even when spectra have been taken with extreme care and very high resolution. The theoretical spectrum calculated from the Hückel electron densities indicates that there are 25 lines to be expected (see Fig. 3). Our observed spectra must, therefore, be interpreted on the assumption that there are only four equivalent protons contributing to the hyperfine splitting. These can be taken to be the protons attached to carbon atoms 2, 3, 6, and 7, which of the two sets of carbon atoms with protons

attached are those having the highest electron density on the Hückel theory. Carbon atoms 9, 10, 11, and 12 have no protons attached and for this reason the e.s.r. spectra of the ions of diphenylene extend only over about half the range observed for the ions of other alternant hydrocarbons. Thus the spectrum of the positive ion of diphenylene extends over only 18 gauss compared with about 33 gauss for the anthracene positive ion. The spin densities on carbon atoms 9, 10, 11, and 12 total about 54% of the total spin densities at all the carbon atoms in diphenylene; hence we would expect the e.s.r. spectrum of this substance to extend only over about half the range of spectrum of say the anthracene positive ion. This is in agreement with our observations.

Although the intensity distribution of the experimental spectra of the two ions is the same, there is a marked difference in the magnitude of the hyperfine interaction. The overall width of the positive ion spectrum is 18 gauss, with a splitting constant of 4.0 gauss. The corresponding figures for the negative ion are 12.9 gauss and 2.75 gauss respectively.

If we take the value of the proportionality constant Q to be the same for the two species, then there is a difference in the odd electron distribution in the two ions. In Table I we have listed the experimental spin densities for the two ions, obtained by using a value of Q derived from the benzene negative ion spectrum, which is the only alternant hydrocarbon

TABLE I

Electron spin densities for the mononegative and monopositive ions of diphenylene

		Expt.	Calc., Hückel theory	Calc., assuming $\alpha_{C_9} = \alpha_C + 1/5\beta$
Diphenylene$^+$ ion				
	ρ_1		0.0269	0.0179
	ρ_2	0.1739	0.0873	0.0906
	ρ_9	0.0000	0.1360	0.1414
Diphenylene$^-$ ion				
	ρ_1		0.0269	0.0372
	ρ_2	0.1195	0.0873	0.0853
	ρ_9	0.0000	0.1360	0.1274

for which accurate spin densities are known. Column 2 of Table I lists the spin densities calculated from the Hückel theory, with the assumption of equal Coulomb integrals for the carbon atoms. In column 3 of the table we have included spin densities obtained by assigning the four central carbon atoms with a Coulomb integral equal to the normal carbon Coulomb integral *plus one-fifth* the carbon–carbon resonance integral. It may be seen from the table that this makes the calculated spin densities of the positive ion different from those of the negative ion. Since in diphenylene we are studying a derivative of cyclobutadiene, it is quite plausible that we should treat it as containing two different types of carbon atom. It is quite obvious from the lack of agreement between experiment and theory that the simple Hückel molecular orbitals obtained by the assumption of equal Coulomb and resonance integrals are inadequate. It must, however, be recalled that other workers have previously noted that exact agreement between the electron densities calculated from the simple Hückel molecular orbital theory and the experimental values

is lacking. Further it has also been observed that in other alternant hydrocarbon systems there are significant differences between the positive and negative ion spectra which cannot be explained on the basis of the simple Hückel molecular orbital theory.

ACKNOWLEDGMENTS

We wish to thank the National Research Council and the Defence Research Board of Canada for grants-in-aid of this work. Our thanks are due to Drs. V. Rogers and J. F. McOmie for the gift of diphenylene.

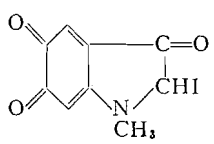
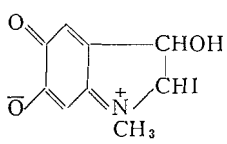
THE CHEMISTRY OF THE "AMINOCHROMES"



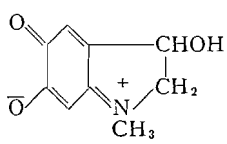
PART III. ON THE STRUCTURES OF "IODOÖXOADRENOCHROME" AND IODOEPINOCHROME[1,2]

R. A. HEACOCK AND B. D. SCOTT



ABSTRACT

A substance prepared by the oxidation of adrenaline with iodic acid and described in the literature as 2-idoöxoadrenochrome appears, after consideration of a number of its physical and chemical properties to be identical with 2-iodoadrenochrome. The iodine atom in iodoepinochrome, obtained by the oxidation of epinine with potassium iodate, has been shown to be in the 2-position of the heterocyclic ring in the molecule.



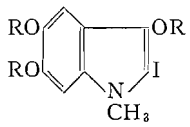
During the course of a study of the infrared spectra of the aminochromes and related compounds (1) it was observed that the spectrum of a substance described by Macciotta as 2-iodoöxoadrenochrome (formulated as I) (2) was identical with those obtained from

I

II

III

specimens of 2-iodoadrenochrome (usually formulated as II) prepared by the methods described in the literature (3, 4, 5, 6). The general form of the spectrum was more in keeping with a structure of type II than with one of type I. A definite hydrogen-bonded O—H stretching band was observed at 3410 cm^{-1} (microanalysis indicated that the compounds were anhydrous and therefore this peak could not have arisen from water of crystallization in I, and the "carbonyl" region was very similar to that of adrenochrome, usually formulated as III (cf. 7). It occurred to the authors that the possibility that Macciotta's compound was, in fact, merely 2-iodoadrenochrome (II) should be investigated, especially since no other "oxoaminochromes" have been isolated. The preparation, in solution, of "oxoadrenochrome" was reported (8), but this claim has since been disputed (9).



These compounds, which are very dark violet-brown in color, decompose on heating without melting and consequently melting point and mixed melting point determinations gave only inconclusive results. The analytical values obtained for carbon, hydrogen, and nitrogen were in good agreement in both cases with those calculated for II, although it must be admitted that only the hydrogen values are sufficiently different in the two cases to warrant drawing any conclusions. The ultraviolet and visible absorption spectra of I and II were identical and very similar to those of 2-iodoaminochromes in general (cf. 3). If I had the structure assigned to it by Macciotta it would contain a different chromophoric system to the 2-iodoaminochromes and would be expected to exhibit a different absorption spectrum.

Macciotta reported that reduction of I with sodium hydrosulphite gave 3,5,6-

trihydroxy-2-iodoindole (IV: R = H), m.p. 116°, which gave a triacetyl derivative (IV: R = CH_3CO), m.p. 140°. In the hands of the authors the sodium hydrosulphite

IV

V

reduction products of I and II were identical. This was demonstrated by paper chromatography of the crude reaction mixtures and by the physical and chemical properties of the crystalline compounds isolated in each case. The infrared spectra of these products were much more consistent with their being 5,6-dihydroxy- rather than 3,5,6-trihydroxyindoles. In the latter case the product would be an indoxyl which would exist in the keto form in the solid state and consequently its infrared spectrum should show the indoxyl carbonyl peak (7, 10). However there are no peaks in the "carbonyl" region of the spectra of either of these substances. Their ultraviolet absorption spectra resemble that of 5,6-dihydroxy-*N*-methylindole more closely than that of adrenolutin, the corresponding 3,5,6-trihydroxy derivative. These products are considered by the present authors to be 5,6-dihydroxy-2-iodo-*N*-methylindole (V: R = H). The diacetyl derivatives of both reduction products were also identical; the m.p.'s of 151.5–152.5° and 152° (derived from I and II respectively) obtained by the authors for these products are very similar to the value quoted by Bergel and Morrison (153–155°) for a substance described as 5,6-diacetoxy-2-iodo-*N*-methylindole (V: R = CH_3CO) obtained by the direct acetylation of the crude sodium hydrosulphite reduction products of 2-iodoadrenochrome (11).

The reaction mixtures obtained from the reduction of I and II with several reducing agents including sodium hydrosulphite, sodium bisulphite, sodium borohydride, zinc and 2% acetic acid, ascorbic acid, B.A.L. (2,3-dimercapto-1-propanol), and glutathione were studied paper chromatographically (cf. 12). It can easily be seen by inspection of Table I that the chromatographic patterns obtained from I and II with each reducing agent were virtually identical. The main reduction product in all but two cases was 5,6-dihydroxy-2-iodo-*N*-methylindole (R_f ca. 0.20). (The standard R_f value for this substance was obtained from a specimen of the pure crystalline material isolated from the sodium hydrosulphite reduction products.) It was also noticed that with most of the reagents studied, greater or lesser amounts of 5,6-dihydroxy-*N*-methylindole ($R_f = 0.44 \pm 0.02$) were produced presumably by the elimination of the iodine atom during the process of reduction; when reduction was effected with zinc and dilute acetic acid, total deiodination occurred and no 5,6-dihydroxy-2-iodo-*N*-methylindole was detected among the products. The reduction of the aminochromes will be discussed in more detail in a later paper in this series (13); the results of the chromatographic studies are merely presented here to support the author's thesis of the similarity of I and II.

3,5,6-Triacetoxy-2-iodo-*N*-methylindole (IV: R = CH_3CO) was obtained from the action of acetic anhydride in pyridine on II (4), and an identical triacetyl derivative was prepared from I by the same experimental procedure.

The oxidation of epinine (3,4-dihydroxyphenylethylmethylamine) with potassium iodate in aqueous solution gives iodoepinochrome, a violet-brown crystalline solid (3, 14). There has been some disagreement in the literature as to the position of the iodine atom; Sobotka and Austin suggested the 2-position (3), whilst Bu'Lock and Harley-Mason proposed that the iodine atom was present in the 3-position (14), since the 5,6-diacetoxy-

iodo-*N*-methylindole obtained from the action of acetic anhydride and pyridine on iodoepinochrome had m.p. 146–147°, whereas the 5,6-diacetoxy-iodo-*N*-methylindole obtained from 2-iodoadrenochrome by Bergel and Morrison (11) had m.p. 153–155°. We have repeated the preparation of these two 5,6-diacetoxy-iodo-*N*-methylindoles from iodoepinochrome and iodoadrenochrome and obtained m.p.'s of 148–150° and 152° respectively; a mixed melting point showed no depression. The infrared spectra ("NUJOL" mulls and chloroform solutions), and the ultraviolet absorption spectra of the two 5,6-diacetoxy-iodo-*N*-methylindoles were identical, indicating that the iodine atom was in the same position in the heterocyclic ring in both cases; Harley-Mason is now also of this opinion (15). Preliminary paper chromatographic examination of the products obtained from the treatment of iodoepinochrome with a number of reducing agents indicated that a complex mixture of products was usually obtained, but that the internal rearrangement product,

For personal use only.

i.e. 5,6-dihydroxy-2-iodo-*N*-methylindole ($R_f = 0.2$), was invariably detected among the products.

In conclusion it may be stated that: (*a*) the oxidation of adrenaline with iodic acid, carried out under the conditions described by Macciotta, gave, in the hands of the authors, a product that behaved identically to 2-iodoadrenochrome and did not exhibit the properties that would be expected for an oxoaminochrome; (*b*) the oxidation of epinine with potassium iodate gave an iodoepinochrome with the iodine atom in the 2-position in the nucleus (i.e. VI).

VI

EXPERIMENTAL

Oxidation of Adrenaline with Iodic Acid

Adrenaline (1.0 g) was oxidized with iodic acid according to the procedure of Macciotta (2). A brownish-violet crystalline solid (I) (1.1 g) was obtained (this was described as 2-iodoöxoadrenochrome by Macciotta). Found: C, 35.26; H, 2.62; N, 4.70. $C_9H_8NO_3I$ requires C, 35.43; H, 2.64; N, 4.59% (i.e. 2-iodoadrenochrome). $C_9H_6NO_3I$ requires C, 35.66; H, 1.99; N, 4.62% (i.e. 2-iodoöxoadrenochrome).

Oxidation of Adrenaline with Potassium Iodate

Adrenaline (1.0 g) was oxidized with potassium iodate according to the method of Sobotka and Austin (3) and 2-iodoadrenochrome (II) (1.5 g) was obtained in brownish-violet needles. Found: C, 35.11; H, 2.61; N, 4.76. $C_9H_8NO_3I$ requires C, 35.43; H, 2.64; N, 4.59%.

Reduction of I *and* II *with Sodium Hydrosulphite* (cf. Macciotta (2))

(*a*) A suspension of sodium hydrosulphite (2.0 g) in water (5 ml) was added to a suspension of freshly prepared I (1.0 g) in water (40 ml) and the reaction mixture stirred vigorously. The dark-violet solid dissolved with the formation of a cloudy yellow solution, from which a pale yellow flocculent precipitate separated, m.p. 96–97.5° (with decomposition), which gave pale yellow needles (product A, 0.22 g), m.p. 105–106° (with decomposition), on recrystallization from benzene – light petroleum (b.p. 80–100°).

(*b*) II (1.0 g) was reduced in the manner described above; the crude product, m.p. 94–95.5° (with decomposition), was recrystallized from benzene – light petroleum (b.p. 80–100°) and pale yellow needles (product B, 0.27 g), m.p. 105° (with decomposition), were obtained. A mixed melting point between the products A and B showed no depression (i.e. 105°, with decomposition). Found: product A: C, 37.66; H, 2.92%; product B: C, 37.63; H, 2.98%. $C_9H_8NO_2I$ requires C, 37.39; H, 2.79%. Macciotta, who considered product A to be 3,5,6-trihydroxy-2-iodo-*N*-methylindole ($C_9H_8NO_3I$ requires C, 35.43; H, 2.64), recorded a m.p. of 116°. However, consideration of the above analytical results, and those of the acetyl derivatives described below, together with the ultraviolet and infrared spectroscopic data strongly suggest that these substances are, in fact, 5,6-dihydroxy-2-iodo-*N*-methylindole.

Acetylation of Products A and B

The dihydroxy compound (i.e. product A or B) (0.2 g) was dissolved in acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

anhydride (5 ml) and dry pyridine (5 ml); after standing overnight at room temperature the reaction mixture was poured into ice water and a white solid was obtained. The diacetyl derivatives were purified by recrystallization from benzene – light petroleum (b.p. 80–100°) and obtained as very pale yellow plates. Melting points: from A, 151–152.5°; from B, 152°; mixed m.p. (A+B), 151.5–152.5°. Found: C, 41.79; H, 3.30; N, 3.84; I, 33.91. $C_{13}H_{12}NO_4I$ requires C, 41.84; H, 3.24; N, 3.75; I, 34.01%. Macciotta obtained a substance, m.p. 140° (found: C, 41.52; H, 3.41; N, 3.30%), from the acetylation of the product he obtained by the reduction of I with sodium hydrosulphite which he erroneously considered to be 3,5,6-triacetoxy-2-iodo-*N*-methylindole. Bergel and Morrison obtained a substance, m.p. 153–155° (found: I, 33.9%), which they described as 5,6-diacetoxy-2-iodo-*N*-methylindole, from the acetylation of the crude sodium hydrosulphite reduction products of II (11). The substances obtained by the present authors by the acetylation of products A and B are in all probability both 5,6-diacetoxy-2-iodo-*N*-methylindole.

Paper Chromatographic Study of the Reduction Products of I *and* II

The method used was essentially the same as that employed by the authors for preliminary studies on the reduction of adrenochrome (12). I (or II) (0.01 g) was suspended in water (1.0 ml) and treated with a slight excess of the reducing agent at room temperature until no dark particles of the starting material remained in suspension, and the product filtered to obtain a clear solution. Spots, consisting of ca. 30 μl of the reaction mixture, were examined on Whatman No. 1 paper (previously washed for 48 hours with 2% acetic acid) using 2% acetic acid as running solvent. After drying, the developed chromatograms were examined for fluorescence in ultraviolet light and sprayed with Ehrlich's reagent, Gibb's reagent, diazotized *p*-nitroaniline, and Folin and Ciocalteu's reagent.

The results obtained with seven reducing agents, i.e. sodium hydrosulphite, sodium bisulphite, sodium borohydride, zinc and dilute acetic acid, ascorbic acid, B.A.L., and glutathione are given in Table I. It can be seen from the table the same reduction products are obtained from I and II in each case.

The Action of Acetic Anhydride in Pyridine on I *and* II

A solution of I (or II) (0.5 g) in a mixture of acetic anhydride (10 ml) and dry pyridine (10 ml) was allowed to stand overnight at room temperature. The reaction mixture was then poured into ice water and the white solid, which separated, recrystallized from light petroleum (b.p. 100–120°); the triacetyl derivatives were obtained in colorless prisms. Melting points: product from I, 150.5°; product from II, 148–149°; mixed m.p. 148.5–150.5°. (Found: C, 41.75; H, 3.30; N, 3.33; I, 29.42. $C_{15}H_{14}NO_6I$ requires C, 41.78; H, 3.27; N, 3.25; I, 29.44%.) In both cases the substance was 3,5,6-triacetoxy-2-iodo-*N*-methylindole. This substance had previously been obtained by Bu'Lock and Harley-Mason by the above procedure (m.p. 150°) (4).

The Action of Acetic Anhydride in Pyridine on Iodoepinochrome

Iodoepinochrome (0.4 g), prepared by the method of Sobotka and Austin (3), was dissolved in a mixture of acetic anhydride (10 ml) and dry pyridine (10 ml) and the solution allowed to stand at room temperature for 24 hours. The reaction mixture was then poured into ice water; a white solid separated, which gave 5,6-diacetoxy-2-iodo-*N*-methylindole as pale yellow prisms on recrystallization from benzene – light petroleum (b.p. 80–100°), m.p. 148–150°, undepressed on admixture with a sample prepared from 2-iodoadrenochrome by the method described above. Bu'Lock and Harley-Mason obtained a substance, m.p. 146–147°, from iodoepinochrome by the above procedure

For personal use only.

which they considered to be 5,6-diacetoxy-3-iodo-*N*-methylindole (14), since its melting point differed from that (153–155°) previously reported by Bergel and Morrison for the corresponding 2-iodo compound (11).

Spectroscopic Studies

(a) Ultraviolet and Visible

The ultraviolet and visible absorption spectra of I and II, their sodium hydrosulphite reduction products (i.e. products A and B), the acetyl derivatives of A and B, the direct acetylation products of I, II, and iodoepinochrome were measured on a Warren Spectracord instrument. The results are given in Table II and it can easily be seen that

TABLE II

Ultraviolet and visible absorption spectra

Substance*	Solvent	Absorption maxima, mμ	Absorption minima, mμ
(1) "2-Iodoöxoadrenochrome" (I)	W	233; 303; 535	268; 385
(2) 2-Iodoadrenochrome (II)	W	233; 304; 535	268; 385
(3) Product A (from I)	M	282; 303; (313)†	256; 297
(4) Product B (from II)	M	282; 303; (313)	256; 296
(5) Diacetyl derivative of A	M	231; (280); 294; (303)	255
(6) Diacetyl derivative of B	M	231; (280); 293; (303)	255
(7) Product from direct acetylation of I	M	233; 302	263
(8) Product from direct acetylation of II	M	233; 301	263
(9) Product from direct acetylation of iodoepinochrome	M	231; (280); 293; (303)	254

NOTE: W = water; M = methanol.

*The above descriptions of the substances are given to indicate how each compound was obtained. In fact, (1) and (2) are both 2-iodoadrenochrome; (3) and (4) are both 5,6-dihydroxy-2-iodo-*N*-methylindole; (5), (6), and (9) are all 5,6-diacetoxy-2-iodo-*N*-methylindole; (7) and (8) are both 3,5,6-triacetoxy-2-iodo-*N*-methylindole.

†Figures in parentheses represent shoulders on the main peak.

the positions of the absorption maxima and minima are identical for corresponding pairs in the two series of compounds from I and II. It can also be seen that the absorption curve of the direct acetylation product of iodoepinochrome is the same as those of the diacetyl derivatives of products A and B.

(b) Infrared

The spectra were recorded on a Perkin–Elmer Infracord spectrophotometer. The spectra of I and II were obtained as "NUJOL" mulls and those of the various 5,6-dihydroxy- and 5,6-diacetoxy-indoles (i.e. compounds 3–9 in Table II) were obtained both as "NUJOL" mulls and in chloroform solution. The spectra of the corresponding pairs of substances in the two series of compounds from I and II were identical and that of the direct acetylation product of iodoepinochrome was the same as those of the diacetyl derivatives of the reduction products of I and II. The curves obtained from these last three substances together with those obtained from I and II are shown in Fig. 1.

Some of the more salient features of the infrared spectra are as follows. The products A and B (i.e. 5,6-dihydroxy-2-iodo-*N*-methylindole) showed a hydrogen-bonded O—H stretching band at 3240 cm^{-1} (in "NUJOL"). The ester carbonyl peak of the 5,6-diacetyl derivatives of A and B was observed at 1765 cm^{-1} (both in "NUJOL" and in chloroform). In the spectra of the direct acetylation products of I and II (i.e. 3,5,6-triacetoxy-2-iodo-*N*-methylindole), the main carbonyl absorption occurred at 1770 cm^{-1} in chloroform solution; in "NUJOL" the main peak was observed at 1757 cm^{-1} with a well-defined shoulder at ca. 1786 cm^{-1}.

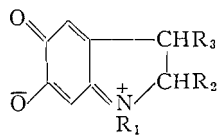
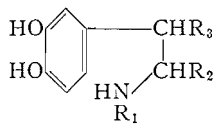
THE CHEMISTRY OF THE "AMINOCHROMES"



PART IV. SOME NEW AMINOCHROMES AND THEIR DERIVATIVES[1,2]

R. A. Heacock and B. D. Scott



ABSTRACT

N-Ethylnoradrenochrome, *N*-isopropylnoradrenochrome, adrenochrome methyl ether, adrenochrome ethyl ether, and their 2-iodo derivatives have been prepared in crystalline form. The action of acetic anhydride in pyridine on these aminochromes has been studied; acetylated rearrangement products were obtained in each case. *N*-Ethylnoradrenochrome monosemicarbazone, *N*-ethylnoradrenolutin, 5,6-diacetoxy-*N*-ethyl-2-iodoindole, and 5,6-diacetoxy-2-iodo-*N*-isopropylindole have been prepared. The ultraviolet and visible absorption spectra of the aminochromes described above and several 5,6-diacetoxy- and 3,5,6-triacetoxy-*N*-alkylindoles have been measured and the paper chromatographic behavior of the unhalogenated aminochromes studied.

Adrenochrome (I: $R_1 = CH_3$; $R_2 = H$; $R_3 = OH$) (see 1 for list of references) and epinochrome (I: $R_1 = CH_3$; $R_2 = R_3 = H$) (2) are the only unhalogenated aminochromes

I

II

that have, so far, been fully characterized in the solid state. Noradrenochrome (I: $R_1 = R_2 = H$; $R_3 = OH$) has been described as "red rings on the side of the flask" (3) and *N*-isopropylnoradrenochrome (I: $R_1 = i\text{-}C_3H_7$; $R_2 = H$; $R_3 = OH$) is referred to in the patent literature as a purplish-red crystalline solid (4). A preliminary report on the isolation of solid adrenochrome methyl ether (I: $R_1 = CH_3$; $R_2 = H$; $R_3 = OCH_3$) has appeared recently (5). Adrenochrome is usually prepared by the oxidation of adrenaline (II: $R_1 = CH_3$; $R_2 = H$; $R_3 = OH$) in methanol with silver oxide. It has recently been demonstrated that contamination of the product with residual silver (colloidal and/or ionic) derived from the oxidizing agent was minimized by passage of the reaction mixture through a Dowex-1 (Cl^-) resin bed prior to crystallization (6); in this way a stable crystalline product was obtained. The apparent instability of some of the earlier preparations of adrenochrome may have been due to contamination with silver. This general technique has now been successfully utilized for the preparation of crystalline *N*-ethylnoradrenochrome (I: $R_1 = C_2H_5$; $R_2 = H$; $R_3 = OH$) from *N*-ethylnoradrenaline (II: $R_1 = C_2H_5$; $R_2 = H$; $R_3 = OH$) and *N*-isopropylnoradrenochrome (I: $R_1 = i\text{-}C_3H_7$; $R_2 = H$; $R_3 = OH$) from *N*-isopropylnoradrenaline (II: $R_1 = i\text{-}C_3H_7$; $R_2 = H$; $R_3 = OH$); these two aminochromes were obtained in somewhat higher yield than the corresponding yield of adrenochrome from adrenaline. *N*-Ethylnoradrenochrome has also been obtained in crystalline form by the oxidation of *N*-ethylnoradrenaline in 90% methanol with the calculated quantity of iodic acid (cf. preparation of adrenochrome by Macciotta (7)); the *N*-isopropyl analogue has been obtained in the solid state by oxidation of a suspension of *N*-isopropylnoradrenaline hydrochloride in dry acetonitrile with silver

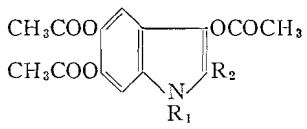
oxide. These compounds are stable dark red-violet crystalline solids, decomposing without melting and exhibiting very similar physical and chemical properties to adrenochrome. The monosemicarbazone of *N*-ethylnoradrenochrome was obtained by a standard method for the preparation of semicarbazones; *N*-isopropylnoradrenochrome monosemicarbazone has previously been described (8); both are bright orange crystalline solids.

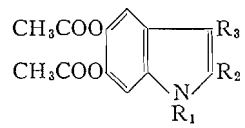


Although oxidation of the adrenaline ethers (II: $R_1 = CH_3$; $R_2 = H$; $R_3 = OCH_3$ or OC_2H_5) with silver oxide in methanol gave red solutions (from which the monosemicarbazones of the adrenochrome ethers have been isolated (9)) no solid could be isolated after cooling the solutions to $-20°$ (even after the addition of dry ether). However, oxidation of a suspension of adrenaline methyl ether hydrochloride in dry acetonitrile with silver oxide proceeded readily and crystalline adrenochrome methyl ether (I: $R_1 = CH_3$; $R_2 = H$; $R_3 = OCH_3$) could be obtained as a dark red solid on concentration of the solution (cf. 5). Adrenochrome ethyl ether (I: $R_1 = CH_3$; $R_2 = H$; $R_3 = OC_2H_5$) was prepared similarly.

When the oxidation of catecholamines is carried out with potassium iodate in aqueous solution (under acid conditions and with excess iodate) iodine-substituted aminochromes (e.g. 2-iodoadrenochrome, I: $R_1 = CH_3$; $R_2 = I$; $R_3 = OH$) are obtained (see 1 for references). *N*-Ethyl-2-iodonoradrenochrome (I: $R_1 = C_2H_5$; $R_2 = I$; $R_3 = OH$) and 2-iodo-*N*-isopropylnoradrenochrome (I: $R_1 = i\text{-}C_3H_7$; $R_2 = I$; $R_3 = OH$) have been obtained in good yield by the oxidation of *N*-ethylnoradrenaline and *N*-isopropylnoradrenaline respectively with potassium iodate, by an adaptation of the procedure described by Sobotka and Austin for the preparation of 2-iodoadrenochrome (2). The isopropyl derivative was obtained previously in lower yield by a slightly different procedure, the oxidation being carried out in more concentrated solution (8). The oxidation of adrenaline methyl and ethyl ethers with potassium iodate by the dilute solution technique (cf. 2) gave deep violet solutions but no precipitation of the iodoaminochrome occurred; however, when the reaction was carried out in more concentrated solution (cf. Bu'Lock and Harley-Mason's general procedure for the preparation of iodoaminochromes (8)) 2-iodoadrenochrome methyl ether (I: $R_1 = CH_3$; $R_2 = I$; $R_3 = OCH_3$) and 2-iodoadrenochrome ethyl ether (I: $R_1 = CH_3$; $R_2 = I$; $R_3 = OC_2H_5$) were obtained as brownish-purple crystalline solids.

The well-known hydroxyl ion catalyzed rearrangement of aminochromes to 5,6-dihydroxyindoles or 5,6-dihydroxyindoxyls (see 1 for references) has been extended to the preparation of *N*-ethyl-5,6-dihydroxyindoxyl (i.e. "*N*-ethylnoradrenolutin" (III)); the

III



IV

N-isopropyl analogue has previously been described (8). Aqueous solutions of *N*-ethyl-5,6-dihydroxyindoxyl resemble those of the corresponding *N*-methyl and *N*-isopropyl compounds in exhibiting a very strong apple-green fluorescence, and also in being unstable in air, rapidly undergoing a destructive oxidation resulting in the disappearance of the fluorescence followed by the formation of a black melanitic precipitate. The treatment of an aminochrome with acetic anhydride in the presence of pyridine leads to the formation of acetylated rearrangement products (8, 10, 11) (e.g. adrenochrome gives 3,5,6-triacetoxy-*N*-methylindole (IV: $R_1 = CH_3$; $R_2 = H$)). 3,5,6-Triacetoxy-*N*-ethylindole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

(IV: $R_1 = C_2H_5$; $R_2 = H$), 3,5,6-triacetoxy-*N*-isopropylindole (IV: $R_1 = i\text{-}C_3H_7$; $R_2 = H$), and 3,5,6-triacetoxy-*N*-ethyl-2-iodoindole (IV: $R_1 = C_2H_5$; $R_2 = I$) have been obtained in this manner from the corresponding aminochromes. Adrenochrome methyl and ethyl ethers and their 2-iodo derivatives appeared to behave similarly on treatment with acetic anhydride and pyridine. The products obtained analyzing well for 5,6-diacetoxy-3-methoxy-*N*-methylindole (V: $R_1 = CH_3$; $R_2 = H$; $R_3 = OCH_3$), 5,6-diacetoxy-3-ethoxy-*N*-methylindole (V: $R_1 = CH_3$; $R_2 = H$; $R_3 = OC_2H_5$), 5,6-diacetoxy-2-iodo-3-methoxy-*N*-methylindole (V: $R_1 = CH_3$; $R_2 = I$; $R_3 = OCH_3$), and 5,6-diacetoxy-3-ethoxy-2-iodo-*N*-methylindole (V: $R_1 = CH_3$; $R_2 = I$; $R_3 = OC_2H_5$)

V

respectively. The infrared spectra ("NUJOL" mulls) of the acetylated rearrangement products from adrenochrome methyl and ethyl ethers and from 2-iodoadrenochrome methyl ether exhibited a double ester "carbonyl" peak (e.g. the product from the methyl ether had two distinct peaks at 1770 and 1752 cm^{-1}). This behavior was in contrast to that observed in the spectra of several other 5,6-diacetoxy-*N*-alkylindoles available to the authors, which show only a single peak in the carbonyl region (e.g. 5,6-diacetoxy-2-iodo-*N*-methylindole has a single peak at 1765 cm^{-1}, cf. 12) and the product obtained from 2-iodoadrenochrome ethyl ether also showed only a single peak in this region at 1761 cm^{-1}.

5,6-Diacetoxy-2-iodo-*N*-methylindole (V: $R_1 = CH_3$; $R_2 = I$; $R_3 = H$) was obtained by Bergel and Morrison by the acetylation of the crude sodium hydrosulphite reduction products of 2-iodoadrenochrome (13); recently the intermediate 5,6-dihydroxy-2-iodo-*N*-methylindole has been isolated in crystalline form, and gave the same product (i.e. V: $R_1 = CH_3$; $R_2 = I$; $R_3 = H$) on acetylation (12). By an extension of this procedure 5,6-diacetoxy-*N*-ethyl-2-iodoindole (V: $R_1 = C_2H_5$; $R_2 = I$; $R_3 = H$) and 5,6-diacetoxy-2-iodo-*N*-isopropylindole (V: $R_1 = i\text{-}C_3H_7$; $R_2 = I$; $R_3 = H$) have been prepared by acetylation of the reduction products (obtained with sodium hydrosulphite or sodium borohydride) of *N*-ethyl-2-iodonoradrenochrome or 2-iodo-*N*-isopropylnoradrenochrome respectively.

It was reported in an earlier paper in this series that the paper chromatography of adrenochrome could be carried out satisfactorily on acid-washed paper using water or 2% acetic acid/water as running solvents, but that the employment of other common solvent systems usually resulted in decomposition of the adrenochrome (6). In the course of a chromatographic study of the reduction products of the aminochromes derived from "dopa" (3,4-dihydroxyphenylalanine, II: $R_1 = R_3 = H$; $R_2 = COOH$), dopamine (3,4-dihydroxyphenylethylamine, II: $R_1 = R_2 = R_3 = H$) and noradrenaline (II: $R_1 = R_2 = H$; $R_3 = OH$), Bouchilloux and Kodja reported the R_f's of dopachrome (I: $R_1 = R_3 = H$; $R_2 = COOH$), norepinochrome (I: $R_1 = R_2 = R_3 = H$), and noradrenochrome (I: $R_1 = R_2 = H$; $R_3 = OH$) as 0.92, 0.70, and 0.75 respectively on prewashed Whatman No. 1 paper with water as the running solvent (14). These authors also stated that the quinonoid pigments were unstable in butanol/acetic acid/water mixtures. Recently Bouchilloux has stressed the need to work with well-washed papers when studying the paper chromatography of the aminochromes, since traces of residual bisulphites in the paper combine with the aminochromes with great avidity to form

stable addition compounds (15). These products, which form bright yellow fluorescent spots, have high R_f's in water and 2% acetic acid/water, and low R_f's in butanol/aqueous acetic acid (cf. 16, 17). *N*-Ethylnoradrenochrome, *N*-isopropylnoradrenochrome, adrenochrome methyl ether, and adrenochrome ethyl ether behave similarly to adrenochrome and can be satisfactorily chromatographed on acid-washed paper with 10% acetic acid/water as running solvent; their R_f's were found to be: 0.79, 0.77, 0.81, and 0.82 respectively. The spots, being red in color, are self-indicating; however, the red color of the spots fades when the developed chromatograms are dried (cf. 6). The aminochrome spots give violet colors with Ehrlich's reagent. The aminochrome ethers are readily distinguished from aminochromes without the 3-alkoxy group by spraying the chromatograms with 10% zinc acetate solution, the "ethers" gave non-fluorescent dark blue spots and not the yellow "lutin" spots exhibiting the vivid apple-green fluorescence given by aminochromes with a 3-OH group. All attempts to chromatograph epinochrome solutions (in 2% acetic acid/water) gave in addition to the epinochrome spot (R_f ca. 0.8) an intense spot due to 5,6-dihydroxy-*N*-methylindole (the rearrangement product (cf. 11)) at $R_f = 0.44$ (cf. 17) and a spot due to an unknown substance (R_f = ca. 0.25) giving a violet color with Ehrlich's reagent. When the chromatograms were sprayed with 2% zinc acetate solution the red epinochrome spot was converted into a colorless spot, exhibiting a weak blue fluorescence, probably due to the formation of 5,6-dihydroxy-*N*-methylindole.

The ultraviolet and visible absorption spectra of adrenochrome and a few simple aminochromes have been reported in aqueous and alcoholic solutions (see 1, 18 for references). In general, with the unhalogenated aminochromes maxima occur at ca. 205–215, 300, and 470–500 mμ; with the iodoaminochromes the short wavelength maximum was observed at ca. 230 mμ, and the long wavelength maximum shifted to ca. 520–535 mμ; however, the position of the third peak remained unchanged in the region of 300 mμ (cf. 1, 2, 18). The spectra of the new aminochromes described in this paper have been measured in aqueous or methanolic solution, and in general the absorption maxima and minima occur at the wavelengths expected for this class of compounds. In all cases but one (2-iodoadrenochrome ethyl ether) the visible absorption peak was observed at a somewhat longer wavelength in water than in methanol; the same was true, to a lesser extent, of the peak near to 300 mμ. In the series adrenochrome, *N*-ethylnoradrenochrome, *N*-isopropylnoradrenochrome, there was a progressive small shift of the visible absorption peak towards lower frequencies with the increase in size of the alkyl group (i.e. 486, 490, 495 mμ, in water, respectively). This phenomenon was not observed in the case of their 2-iodo derivatives, the visible absorption peak in aqueous solution was observed at 535 mμ in each case. Adrenochrome methyl and ethyl ethers gave absorption curves similar to adrenochrome whilst that from 2-iodoadrenochrome methyl ether was very similar to that obtained from 2-iodoadrenochrome. 2-Iodoadrenochrome ethyl ether appeared to behave somewhat anomalously, the expected maximum was observed at 300 mμ but the high-frequency peak occurred at ca. 222 mμ and the long wavelength maximum was observed at 508 mμ in methanol and 505 mμ in water. In this case the wavelengths of these absorption maxima are about 10–20 mμ less than those usually observed for the iodoaminochromes. The ultraviolet spectra of several 5,6-diacetoxy- and 3,5,6-triacetoxy-*N*-alkylindoles have been measured in methanol solution; they all show the general form expected for a compound containing the indole chromophore. 5,6-Diacetoxy-*N*-methylindole and the *N*-ethyl and *N*-isopropyl analogues have maxima at 225 and 287–288 mμ ("shoulders" are present on the latter peak at 280 and 296 mμ). Iodination of these compounds in the 2-position results in a small shift (ca. 6 mμ) in the

position of all the peaks towards longer wavelengths. The 3,5,6-triacetoxy-*N*-alkylindoles show two main maxima, one in the region 225–229 mμ and the other at 292 mμ. Once again, the introduction of an iodine atom in the 2-position results in a slight shift in position of these maxima (i.e. to 233 and 301 mμ respectively).

EXPERIMENTAL

N-Ethylnoradrenochrome (cf. Preparation of Adrenochrome (*a*) by Heacock, Nerenberg, and Payza (6) and (*b*) by Macciotta (7))

(*a*) DL-*N*-Ethylnoradrenaline (5.0 g) was suspended in absolute methanol (150 ml) and 98% formic acid added dropwise, with stirring, until a clear solution was obtained. Freshly prepared silver oxide (20.0 g) was added portionwise to the well-stirred solution and the agitation continued for a further 3 minutes. The temperature of the reaction mixture was not allowed to exceed 25° during the oxidation. The product was filtered (with suction) through a Dowex-1 (Cl^-) resin bed (diam. = 6.5 cm; height = 1.8 cm),* and on cooling the deep red filtrate at −20° for 6 hours *N*-ethylnoradrenochrome separated in very dark red-violet (almost black) prisms (1.83 g) (decomposes without melting at 115°)†. Found: C, 62.24; H, 5.61; N, 7.20. $C_{10}H_{11}NO_3$ requires C, 62.16; H, 5.70; N, 7.31%. Dry ether (100 ml) was added to the filtrate and after cooling overnight at −20° a second crop of crystalline *N*-ethylnoradrenochrome (0.23 g) was obtained.

(*b*) DL-*N*-Ethylnoradrenaline (1.08 g) was suspended in methanol (50 ml) and just enough glacial acetic acid added to clarify the solution. A solution of iodic acid (0.5 g) in water (5 ml) was added and the solution, which rapidly became deep red in color, cooled to −20° for 6 hours; *N*-ethylnoradrenochrome (0.15 g) was obtained in dark red-violet prisms. A satisfactory second crop of crystalline material could not be obtained by the addition of dry ether and further cooling of the solution; only a black amorphous powder was obtained.

N-Ethylnoradrenochrome Monosemicarbazone

DL-*N*-Ethylnoradrenaline (1.05 g) was suspended in methanol (16.5 ml) and 98% formic acid added dropwise until a clear solution was obtained. Freshly prepared silver oxide (4.2 g) was added to the stirred solution and after the addition was complete, stirring was continued for 3 minutes. The reaction mixture was filtered through a Dowex-1 (Cl^-) resin bed (diam. = 2.5 cm; height = 1 cm) directly into a solution of semicarbazide hydrochloride (0.5 g) and sodium acetate (1 g) in water (6.5 ml). After standing at 0° for 4 hours bright orange-red needles of *N*-ethylnoradrenochrome monosemicarbazone (0.48 g) were obtained, m.p. 215° (with decomposition). Found: C, 52.67; H, 5.58; N, 22.32. $C_{11}H_{14}N_4O_3$ requires C, 52.80; H, 5.64; N, 22.40%. The ultraviolet and visible absorption spectra were measured in aqueous solution (λ_{max}: 354 with a shoulder at 435 mμ).

N-Isopropylnoradrenochrome

(*a*): (*i*) DL-*N*-Isopropylnoradrenaline (10.0 g) was suspended in absolute methanol (250 ml) and 98% formic acid added dropwise with stirring until a clear solution was obtained. Freshly prepared silver oxide (40.0 g) was added portionwise to the stirred solution and the stirring continued for a further 3 minutes. The reaction temperature was

**Unless otherwise stated the resin (200/400 mesh size) used in all the preparations described in this paper was prepared by extensive washing with: (1) 3 N hydrochloric acid, (2) with water until neutral to litmus, and (3) finally with dry methanol.*

†The decomposition points of all the aminochromes described in this paper were measured on a Leitz hot-stage instrument.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

not allowed to rise above 25° during the oxidation. The product was filtered (with suction) through a Dowex-1 (Cl^-) resin bed (diam. = 6.5 cm; height = 3.5 cm) and the deep red filtrate allowed to crystallize slowly for 6 hours at −20°; *N*-isopropylnoradrenochrome was obtained in deep red-violet needles (2.0 g) (decomposes without melting at 123°). Found: C, 63.40; H, 6.36; N, 6.74. $C_{11}H_{13}NO_3$ requires C, 63.74; H, 6.32; N, 6.76%. Dry ether (150 ml) was added to the filtrate and after standing overnight at −20° a second crop (1.4 g) of *N*-isopropylnoradrenochrome was obtained.

(*a*): (*ii*) The above oxidation procedure was repeated except that DL-*N*-isopropylnoradrenaline hydrochloride (10 g), which was freely soluble in dry methanol (250 ml), was used in place of the free base and therefore in this instance the addition of formic acid was not required. A slightly better yield of crystalline *N*-isopropylnoradrenochrome (1st crop, 3.5 g; 2nd crop, 1.32 g) was obtained in this case.

(*b*) Freshly prepared silver oxide (4.0 g) was added to a well-stirred suspension of *N*-isopropylnoradrenaline hydrochloride (1.0 g) in dry acetonitrile (25 ml). An exothermic reaction ensued (the temperature rose to ca. 35–40°) and the red suspension was stirred for a further 5 minutes; the reaction mixture was filtered and after standing at −20° overnight the filtrate deposited deep red-violet needles of *N*-isopropylnoradrenochrome (0.20 g).

Like adrenochrome, when pure, these substances appear to be quite stable when kept in the dry state. They are readily soluble in water and other polar solvents to give deep red solutions, but are virtually insoluble in non-polar solvents. Similarly to adrenochrome, they form bright yellow solutions in concentrated sulphuric acid.

N-Ethyl-2-iodonoradrenochrome (cf. Preparation of 2-Iodoadrenochrome by Sobotka and Austin (2))

N-Ethylnoradrenaline (4.3 g) was suspended in water (3000 ml) and concentrated hydrochloric acid added, dropwise with stirring, until a clear solution was obtained. Potassium iodate (6.9 g) was added and the stirring continued until all the potassium iodate was in solution. After standing at room temperature for 4 hours *N*-ethyl-2-iodonoradrenochrome (5.9 g) was obtained as deep violet rods (decomposed without melting at 134.5°). Found: C, 37.73; H, 3.23; N, 4.37. $C_{10}H_{10}NO_3I$ requires C, 37.63; H, 3.16; N, 4.39%.

2-Iodo-N-isopropylnoradrenochrome (cf. Preparation of *N*-ethyl-2-iodonoradrenochrome (Above))

Potassium iodate (3.3 g) was added to a solution of *N*-isopropylnoradrenaline hydrochloride (2 g) in water (1600 ml); the solution was stirred until all the iodate was in solution. After standing at room temperature for 4 hours 2-iodo-*N*-isopropylnoradrenochrome (1.63 g) was obtained as deep violet-brown needles (completely decomposes without melting at 105.5°). Found: C, 39.68; H, 3.80; I, 38.21. $C_{11}H_{12}NO_3I$ requires C, 39.66; H, 3.63; I, 38.12%. (This substance had previously been obtained, in a lower yield, by Bu'Lock and Harley-Mason as the hemihydrate (8), who carried out the reaction in more concentrated solutions.)

Adrenochrome Methyl Ether

(*a*) Adrenaline methyl ether hydrochloride (1.0 g, prepared by the method of Hukki and Seppäläinen (9)) was dissolved in dry methanol (30 ml) and freshly prepared silver oxide (4.0 g) added. After standing for 5 minutes the bright red solution was filtered through a Dowex-1 (Cl^-) resin bed (diam. = 2.5 cm; height = 1 cm). No crystallization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

occurred after allowing the solution to stand at −20° overnight and no solid product was obtained after the addition of dry ether (30 ml) and further cooling at −20°.

(*b*) Freshly prepared silver oxide (4.0 g) was added to a well-stirred suspension of adrenaline methyl ether hydrochloride (1 g) in dry acetonitrile (20 ml). The suspension rapidly developed a deep red color and the temperature rose to ca. 35–40°; the stirring was continued for 5 minutes. After filtration, the deep red filtrate was concentrated, *in vacuo* (with a nitrogen "leak"), below 35° to small bulk, dry ether (10 ml) was added and after cooling to −20°, adrenochrome methyl ether (0.46 g) was obtained as a deep red microcrystalline solid, m.p. 83° (with decomposition).* Found: C, 61.83; H, 5.61; N, 7.63. $C_{10}H_{11}NO_3$ required C, 62.16; H, 5.70; N, 7.31%.

Adrenochrome Ethyl Ether

Adrenaline ethyl ether hydrochloride (1.0 g, prepared by the method of Hukki and Seppäläinen (9)) was oxidized as described in section (*b*) above; adrenochrome ethyl ether (0.55 g) was obtained as a deep red microcrystalline powder, m.p. 70–72° (with decomposition).* Found: C, 63.25; H, 6.29. $C_{11}H_{13}NO_3$ requires C, 63.74; H, 6.32%.

The adrenochrome ethers were readily soluble in polar solvents to give deep red solutions; their solubility in non-polar solvents (e.g. chloroform), whilst being low, was considerably higher than that of adrenochrome. In this respect these compounds show a stronger resemblance to rubreserine than to adrenochrome.

2-Iodoadrenochrome Methyl Ether (cf. Preparation of Iodoaminochromes by Bu'Lock and Harley-Mason (8))

A solution of adrenaline methyl ether hydrochloride (2.0 g) in water (70 ml) was treated at 0° with a solution of potassium iodate (2.2 g) in water (70 ml). A dark violet tarry precipitate soon began to separate out and was removed by filtration after standing at 0° for 30 minutes and a further quantity of tar was filtered off after 1 hour; at this stage a crystalline precipitate began to form and after standing overnight at 0°, 2-iodoadrenochrome methyl ether (1.05 g) was obtained in violet-brown needles (completely decomposes without melting at 85°). Found: C, 38.07; H, 3.11; N, 4.15; I, 39.60. $C_{10}H_{10}NO_3I$ requires C, 37.63; H, 3.16; N, 4.39; I, 39.78%.

2-Iodoadrenochrome Ethyl Ether (cf. Preparation of Methyl Ether (Above))

A solution of adrenaline ethyl ether hydrochloride (2.0 g) in water (70 ml) was treated at 0° with potassium iodate (2.2 g) in water (70 ml). After filtration of the black tarry precipitates that formed during the first hour, a crystalline precipitate began to separate out and after standing overnight at 0°, 2-iodoadrenochrome ethyl ether (0.71 g) was obtained in violet-brown needles (decomposes without melting at 88°). Found: C, 39.92; H, 3.76. $C_{11}H_{12}NO_3I$ requires C, 39.66; H, 3.63%. These iodoadrenochrome ethers appear to be more soluble in water than 2-iodoadrenochrome and when the oxidation was carried out under more dilute conditions (cf. 2) deep violet solutions were obtained but no precipitation occurred even after standing at 0° for 24 hours.

N-Ethyl-5,6-dihydroxyindoxyl (*i.e. N-Ethylnoradrenolutin*) (cf. Preparation of Adrenolutin by Heacock and Mahon (20))

N-Ethylnoradrenaline (5 g) was suspended in water (150 ml) and concentrated hydrochloric acid was added dropwise until a clear solution was obtained. Freshly prepared silver oxide (20.0 g) was added to the well-stirred solution and the stirring continued for

**In contrast to the aminochromes without the 3-alkoxy group which decompose without melting, these substances appeared to actually form a liquid phase before decomposing.*

a further 3 minutes. The reaction mixture was then filtered through a Dowex-1 (Cl^-) resin bed (diam. = 6.5 cm; height = 1.5 cm)* and the filtrate cooled in ice. A stream of nitrogen was passed through the cooled filtrate, and 10% sodium hydroxide solution (50 ml) added. The brownish-green solution, which exhibited a typical "lutin" fluorescence was stirred and acidified by the dropwise addition of glacial acetic acid. *N*-Ethylnoradrenolutin (1.52 g) separated out as a bright yellow crystalline precipitate which was filtered off, washed with a little water, and rapidly dried *in vacuo* at room temperature. The product was obtained in very small yellow-orange prisms (m.p. indefinite, decomposes without melting at ca. 170°) on recrystallization from water (containing a little sodium hydrosulphite to prevent oxidation). In contrast to adrenolutin this product did not contain water of crystallization. Found: C, 62.01; H, 5.87; N, 7.21. $C_{10}H_{11}NO_3$ requires C, 62.16; H, 5.70; N, 7.31%. Although the crystalline material as prepared above tended to darken in color on keeping, a sample (decomposes without melting at 174–175°) which was purified by vacuum sublimation (190–200°/0.2 mm) and obtained in very small bright yellow rods showed no tendency to lose its bright yellow color. The ultraviolet and visible absorption spectra were measured in methanol solution (λ_{max}: 224, 259, 288 (with a shoulder at 308), 415 mμ; λ_{min}: 239, 274, 335 mμ).

The Action of Acetic Anhydride and Pyridine on the Aminochromes Described Above (cf. Bu'Lock and Harley-Mason (8))

The aminochrome (1.0 g) was dissolved in a mixture of acetic anhydride (15 ml) and dry pyridine (15 ml) and the solution allowed to stand at room temperature for 36 hours, after which time it was poured, with stirring, into ice water, when either an amorphous solid or an oil separated. If solid, the crude product was removed by filtration; if oily, it was extracted with peroxide-free ether (4×100 ml) (the ethereal extract washed with 5% sodium bicarbonate solution (4×100 ml) and with water (100 ml)) and concentration of the dried (Na_2SO_4) extract gave the crude product, usually as a greenish-yellow gum. In some instances it was possible to purify the product directly by recrystallization, but where this was not possible, chromatographic purification on silica gel columns was carried out.

N-Ethylnoradrenochrome gave 3,5,6-triacetoxy-*N*-ethylindole (0.61 g), m.p. 84.5–85.5°, in pale yellow prisms after chromatographic purification on silica gel using benzene as eluent and recrystallization from benzene – light petroleum (b.p. 80–100°). Found: C, 60.19; H, 5.41; N, 4.41. $C_{16}H_{17}NO_6$ requires C, 60.17; H, 5.37; N, 4.39%.

N-Isopropylnoradrenochrome gave 3,5,6-triacetoxy-*N*-isopropylindole (0.25 g), m.p. 85.5–87.5°, after chromatographic purification on silica gel using benzene as eluent. The product was initially obtained as a gum and only crystallized with difficulty after seeding with an authentic specimen. This compound had previously been prepared by Bu'Lock and Harley-Mason by the deiodination of 3,5,6-triacetoxy-2-iodo-*N*-isopropylindole (8), who reported a melting point of 87°. The product obtained by the authors did not depress the melting point of a sample prepared by Bu'Lock and Harley-Mason's method.

N-Ethyl-2-Iodonoradrenochrome gave 3,5,6-triacetoxy-*N*-ethyl-2-iodoindole (1.2 g) in pale yellow plates, m.p. 142–143.5°, after recrystallization from benzene – light petroleum (b.p. 80–100°). Found: C, 43.09; H, 3.45; I, 28.50. $C_{16}H_{16}NO_6I$ requires C, 43.15; H, 3.62; I, 28.51%.

Adrenochrome methyl ether gave 5,6-diacetoxy-3-methoxy-*N*-methylindole (0.4 g) in pale yellow prisms, m.p. 140–141°, after chromatographic purification on silica gel using

**This resin bed was prepared as previously described, except that the final washing with methanol was omitted.*

benzene as eluent and three recrystallizations from benzene – light petroleum (b.p. 80–100°). Found: C, 60.62; H, 5.41; N, 5.12; O—$COCH_3$, 31.5%; mol. wt., 311. $C_{14}H_{15}NO_5$ requires C, 60.64; H, 5.45; N, 5.05; O—$COCH_3$, 31.04%; mol. wt., 277. The peaks in the "carbonyl" region of the infrared spectrum* occur at 1770 and 1752 cm^{-1}.

Adrenochrome ethyl ether gave 5,6-diacetoxy-3-ethoxy-*N*-methylindole (0.47 g) in pale yellow-green elongated prisms, m.p. 84.5–85.5°, after chromatographic purification on silica gel using benzene as eluent and two recrystallizations from benzene – light petroleum (b.p. 80–100°). Found: C, 61.39; H, 5.86; N, 4.81%; mol. wt., 272. $C_{15}H_{17}NO_5$ requires C, 61.84; H, 5.88; N, 4.81%; mol. wt., 291. The peaks in the "carbonyl" region of the infrared spectrum occur at 1776 and 1755 cm^{-1}.

2-Iodoadrenochrome methyl ether gave 5,6-diacetoxy-2-iodo-3-methoxy-*N*-methylindole (0.57 g) in pale yellow plates, m.p. 191–192°, on recrystallization from benzene – light petroleum (b.p. 80–100°). Found: C, 41.88; H, 3.53; N, 3.20; I, 32.00; O—$COCH_3$, 21.66%; mol. wt., 406. $C_{14}H_{14}NO_5I$ requires C, 41.70; H, 3.49; N, 3.47; I, 31.48; O—$COCH_3$, 21.35%; mol. wt., 403. The peaks in the "carbonyl" region of the infrared spectrum occur at 1779 and 1767 cm^{-1}.

2-Iodoadrenochrome ethyl ether gave 5,6-diacetoxy-3-ethoxy-2-iodo-*N*-methylindole (0.61 g) in pale yellow prisms, m.p. 149.5°, on recrystallization from benzene – light petroleum (b.p. 80–100°). Found: C, 43.45; H, 3.86; N, 3.54; I, 30.29%; mol. wt., 400. $C_{15}H_{16}NO_5I$ requires C, 43.17; H, 3.86; N, 3.36; I, 30.42%; mol. wt., 417. There is apparently only one peak in the "carbonyl" region of the infrared spectrum of this compound occurring at 1761 cm^{-1}.

5,6-Diacetoxy-N-ethyl-2-iodoindole

A suspension of sodium hydrosulphite (2.0 g) in water (5 ml) was added to a stirred suspension of *N*-ethyl-2-iodonoradrenochrome (1.0 g) in water (40 ml). After being stirred at room temperature for 1 hour the reaction mixture was extracted with peroxide-free ether (6×50 ml). Concentration of the combined dried (Na_2SO_4) extracts in vacuum (nitrogen "leak"), below 35°, gave a greenish gum which was dissolved in a mixture of acetic anhydride (10 ml) and dry pyridine (10 ml). After standing overnight at room temperature the reaction mixture was poured into ice water; a pale yellow solid separated which afforded 5,6-diacetoxy-*N*-ethyl-2-iodoindole (0.5 g), m.p. 157.5–158.5°, in pale yellow small plates on recrystallization from benzene – light petroleum (b.p. 80–100°). Found: C, 43.00; H, 3.66; I, 32.30. $C_{14}H_{14}NO_4I$ requires C, 43.43; H, 3.65; I, 32.79%.

5,6-Diacetoxy-2-iodo-N-isopropylindole

(*a*) 2-Iodo-*N*-isopropylnoradrenochrome (1.0 g) was reduced with sodium hydrosulphite as described above for the *N*-ethyl analogue and gave 5,6-diacetoxy-2-iodo-*N*-isopropylindole (0.38 g), m.p. 111–112.5°, in white prisms after chromatographic purification on silica gel using benzene as eluent and recrystallization from light petroleum (b.p. 80–100°). Found: C, 45.04; H, 4.17; I, 31.60. $C_{15}H_{16}NO_4I$ requires C, 44.91; H, 4.02; I, 31.64%.

(*b*) 2-Iodo-*N*-isopropylnoradrenochrome (1.0 g) was suspended in water (25 ml) and solid sodium borohydride added very slowly to the stirred suspension until a clear yellow solution was obtained. After decomposition of the excess reducing agent by the cautious dropwise addition of 2 *N* sulphuric acid, the reaction mixture was immediately extracted with peroxide-free ether (4×100 ml). The combined dried (Na_2SO_4) extracts were

**The infrared spectra were recorded as "NUJOL" mulls on a Perkin–Elmer Infracord spectrophotometer using a sodium chloride prism.*

concentrated to dryness *in vacuo* (nitrogen "leak"), below 35°, and the residue dissolved in a mixture of acetic anhydride (10 ml) and dry pyridine (10 ml). After standing overnight at room temperature the acetylation mixture was poured into ice water and a yellow oil separated, which was extracted with peroxide-free ether (4×100 ml). After washing the combined ethereal extracts with 5% aqueous sodium bicarbonate (2×50 ml) and water (100 ml), the dried (Na_2SO_4) extract gave, on concentration, a yellowish-green gum which was purified chromatographically on a silica gel column using benzene as

TABLE I

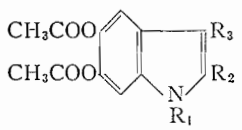
eluent; 5,6-diacetoxy-2-iodo-*N*-isopropylindole (0.67 g), m.p. 111–113°, was obtained in white prisms after recrystallization of the product from light petroleum (b.p. 80–100°).

Paper Chromatography



Whatman No. 1 paper was washed with (*a*) 2% acetic acid for 24 hours, and (*b*) water for 12 hours, and dried prior to use. The descending method of chromatography was employed in all cases and 2% acetic acid/water was used as the running solvent. The solvent was allowed to descend ca. 15 inches; this required about 2.5 to 3 hours running time. The R_f's (under these conditions) of *N*-ethylnoradrenochrome, *N*-isopropylnoradrenochrome, adrenochrome methyl ether, and adrenochrome ethyl ether were determined, ca. 20 μg of the compound being applied to the paper in each case. (The results are given in Table I). All four compounds are colored and therefore are self-indicating and location of the spots with spray reagents is not necessary; however, the colors developed by the aminochrome spots with a number of reagents are given in Table I.

Absorption Spectra

(*a*) The ultraviolet and visible absorption spectra of a number of aminochromes were measured in freshly prepared aqueous or methanol solutions of the pure crystalline aminochrome at a concentration of 1–2 mg/100 ml, using a Warren Spectracord instrument. The results are given in Table II.

TABLE III

Ultraviolet absorption spectra of some 5,6-diacetoxy- and 3,5,6-triacetoxy-*N*-alkylindoles (in methanol)

(*b*) The ultraviolet absorption spectra of a number of 5,6-diacetoxy- and 3,5,6-triacetoxy-*N*-alkylindoles were measured in methanol at a concentration of 1–2 mg/100ml, using the apparatus described above. The results are given in Table III.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Burroughs–Wellcome and Co. (Canada) Ltd. and Winthrop Laboratories of Canada Ltd. for generous gifts of chemicals, and to Dr. J. Harley-Mason of Cambridge University for kindly supplying an authentic sample of 3,5,6-triacetoxy-*N*-isopropylindole. Thanks are also accorded to Mr. W. Irwin, who recorded the ultraviolet spectra.

LYCOPODIUM ALKALOIDS

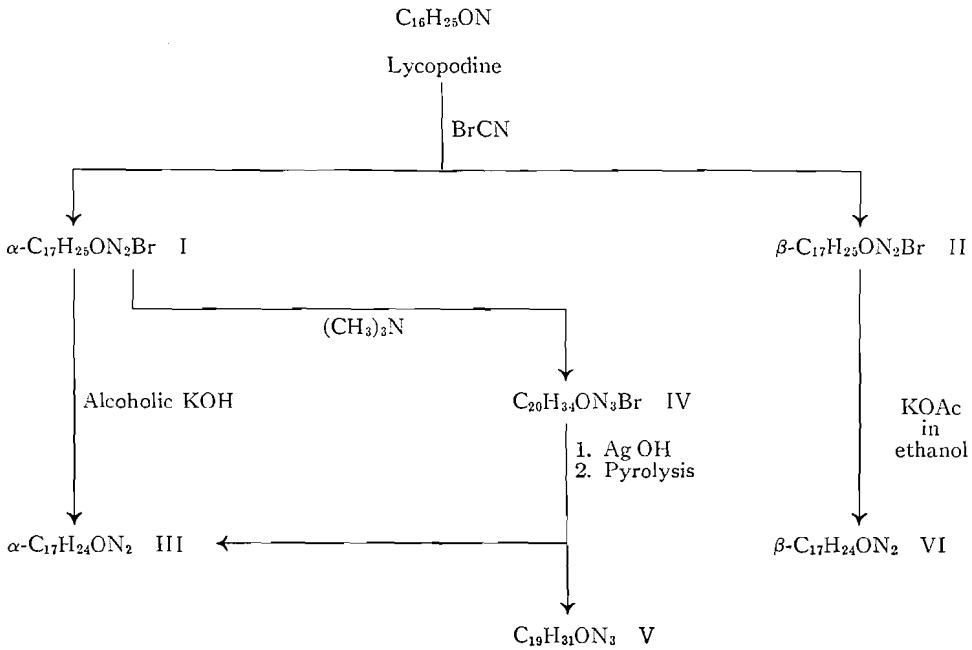
IX. CYCLIZED PRODUCTS FROM α- AND β-CYANOBROMOLYCOPODINE[1]

D. B. MacLean, Won-Ryul Song, and W. A. Harrison[2]

ABSTRACT

A study has been made of the products formed on treatment of α- and β-cyanobromolycopodine with potassium hydroxide in methanol and potassium acetate in ethanol, respectively. The product derived from the α-isomer is apparently formed in a cyclization reaction taking place alpha to the carbonyl group while that formed from the β-isomer may be an enol ether. The olefin expected from a normal dehydrobromination of α-cyanobromolycopodine has been prepared by an indirect method. Attempts to prepare the analogous olefin in the β-series led to the formation of a saturated cyclic ether. The hydrogenolysis product of β-cyanobromolycopodine has been prepared.

The reaction of lycopodine, $C_{16}H_{25}ON$, with cyanogen bromide to yield two isomeric bromocyanamides was first reported by MacLean, Manske, and Marion (1). A number of reactions of the bromocyanamides were reported at the same time. The study of their reactions has since been extended by Barclay and MacLean (2) and by MacLean and Harrison (3), and it is now known that both bromides are primary.



Among the reactions reported in the initial study were those leading to the formation of two isomeric compounds of the formula $C_{17}H_{24}ON_2$ from α-cyanobromolycopodine I, $C_{17}H_{25}ON_2Br$, and β-cyanobromolycopodine II, $C_{17}H_{25}ON_2Br$. Both isomers were formed in an elimination reaction with loss of hydrogen bromide. The α-isomer III was the product of the reaction of I with boiling methanolic potassium hydroxide. It also formed, along with a product of demethylation V, when α-cyanotrimethylaminolycopodine bromide IV was converted to the quaternary base and pyrolyzed. The β-isomer VI was obtained by the action of boiling ethanolic potassium acetate on the β-bromide II. Since neither compound displayed any evidence of unsaturation, it was suggested that III and VI were formed in cyclization reactions. This work is summarized below.

A more detailed study of the two compounds III and VI has now been undertaken and is reported here.

The product III, $C_{17}H_{24}ON_2$, was prepared from α-cyanobromolycopodine according to the method of MacLean, Manske, and Marion (1) and was examined by infrared and ultraviolet spectroscopy. The infrared spectrum of III showed a strong band at 1700 cm^{-1} in the carbonyl region but there was no absorption characteristic of an olefin linkage. The ultraviolet spectrum did not reveal the presence of a conjugated system in the molecule. The presence of the carbonyl group in III was confirmed chemically for it readily underwent reduction to the alcohol VII, $C_{17}H_{26}ON_2$, on treatment with sodium borohydride. Compound VII was in turn converted to III by oxidation with chromic acid.

Indirect evidence that a cyclization reaction had occurred adjacent to the carbonyl group came from the following observations. Compound III failed to react with benzaldehyde when it was treated under the same conditions that led to reaction with α-cyanolycopodine VIII (in α-cyanolycopodine the bromine atom of I has been replaced by hydrogen) (1, 2). When III was hydrolyzed to the secondary base and methylated

Contribution from the Burke Chemical Laboratories, Hamilton College, McMaster University, Hamilton, Ontario. Parts of this work were taken from theses submitted by W. R. Song in May, 1958, and W. A. Harrison in May, 1957, to the Faculty of Graduate Studies in partial fulfillment of the degree M.Sc.
[2]*Holder of National Research Council Studentship 1956–57, 1957–58, and 1958–59.*

to the tertiary base, the latter failed to react with phenyl lithium. The first observation suggests that the methylene group, which has been shown to be present in VIII (2), is absent or more hindered in III. The failure of III to form a benzylidene derivative cannot be taken as conclusive evidence for the absence of a methylene group for it has been reported that lycopodine, which must contain the methylene group found in α-cyanolycopodine, does not react with benzaldehyde (4). The second observation indicates that the carbonyl group in III is more hindered than in lycopodine, which reacts readily with phenyl lithium (1). Both observations lend support to a cyclization alpha to the carbonyl function. It has also been shown in the sequence outlined below, in which the olefin expected from a normal dehydrobromination of I has been prepared by an indirect method, that in the absence of the carbonyl group cyclization does not occur. One may conclude therefore that III is formed in a cyclization reaction and that, if cyclization is to occur, the carbonyl function must be present.

In the preparation of the olefin derived from compound I the following procedure was followed. The bromide I was treated with dimethylamine and yielded the dimethylamino compound V. Treatment of V with sodium borohydride yielded the dimethylamino alcohol IX, $C_{19}H_{33}ON_3$, which was in turn converted to its methiodide X. The Hofmann decomposition of X with potassium tertiary butoxide in boiling tertiary butanol proved the most satisfactory of a number of methods investigated. The product of this reaction was separated into a neutral and a basic fraction. The basic fraction was a mixture of V and IX which was separated by chromatography on alumina. The neutral fraction yielded two olefinic products XI, $C_{17}H_{24}ON_2$, and XII, $C_{17}H_{26}ON_2$. The olefin XI had absorption in the carbonyl region at 1700 cm^{-1} and in the olefin region at 1640 cm^{-1}, while the olefin XII showed no carbonyl absorption but had hydroxyl and olefin absorption. Both compounds had cyanamide absorption at 2200 cm^{-1}. The presence of the ketonic products

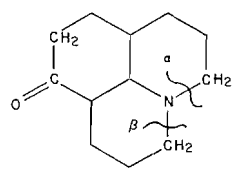
V and XI in this reaction is probably the result of oxidation catalyzed by potassium tertiary butoxide.

Compound XI was readily converted into XII on treatment with sodium borohydride. Treatment of XI with hydrogen over a platinum catalyst yielded α-cyanolycopodine VIII, indicating that rearrangement of the carbon skeleton had not occurred in the reaction. Ozonolysis of XII yielded formaldehyde, thus establishing the terminal character of the olefin linkage.

Compound VI, $C_{17}H_{24}ON_2$, was prepared originally by MacLean, Manske, and Marion (1) by treatment of β-cyanobromolycopodine II with potassium acetate in boiling ethanol. MacLean and Harrison (3) have found that it is also the main product formed on treatment of II with silver acetate in boiling benzene. In this laboratory it has been found that VI forms readily in a variety of basic media. For instance, it is the sole product formed on treatment of II with boiling methanolic potassium hydroxide. It is also formed when β-cyanobromolycopodine is treated with a solution of dimethylamine in methanol (5) and when a solution of II in ethanol is added to an excess of sodium borohydride in ethanol (6). In the latter case it is possible to induce the reaction to follow a different course and this is described in detail later.

Like its α-isomer, compound VI has been examined by infrared and ultraviolet spectroscopy. The infrared spectrum of VI has an absorption band at 1675 cm^{-1} which is less intense than that of the carbonyl absorption of lycopodine or of its α-isomer III and is shifted by about 25 cm^{-1}. There is no absorption in the 1600–1650 cm^{-1} region which might be expected of a compound with a terminal vinyl linkage. The ultraviolet spectrum is lacking in any absorption characteristic of a conjugated system. Chemically, the compound has proved to be peculiarly inert. It has been recovered unchanged after treatment with sodium borohydride under conditions which readily reduced its α-isomer III. Lithium aluminum hydride in boiling tetrahydrofuran converted VI into the secondary base XIII, $C_{16}H_{25}ON$, an oil which would not crystallize, and which was converted to its N-methyl base XIV, $C_{17}H_{27}ON$, which readily formed a crystalline perchlorate. Both XIII and XIV retained the characteristic absorption at 1675 cm^{-1} exhibited by VI. The N-methyl base XIV was recovered unchanged after treatment with phenyl lithium or further treatment with sodium borohydride or lithium aluminum hydride. This lack of reactivity toward hydride reducing agents makes it unlikely that there is a carbonyl function in VI, and accordingly, non-ketonic structures were considered.

The most reasonable alternative to a ketonic structure is one in which the oxygen is present in a cyclic enol ether linkage. This is compatible with the infrared spectrum of VI since some cyclic enol ethers have a strong band near 1675 cm^{-1} (7). The enol ether structure explains the inertness of XIV to hydrides and phenyl lithium, but inertness of this system to the addition of hydrogen as reported previously (1) and confirmed by us is not to be expected. Furthermore, an enol ether might be expected to cleave readily on treatment with acids, but the base XIV proved to be relatively stable under acidic conditions. It is true that treatment over prolonged periods with strong mineral acids yielded unidentified products which showed absorption in the carbonyl region at 1700 cm^{-1} and in the hydroxyl region. The fact that we were able to isolate the secondary base XIII by acid hydrolysis of VI is ample indication of the stability of the unsaturated function of VI, XIII, and XIV in an acidic medium.

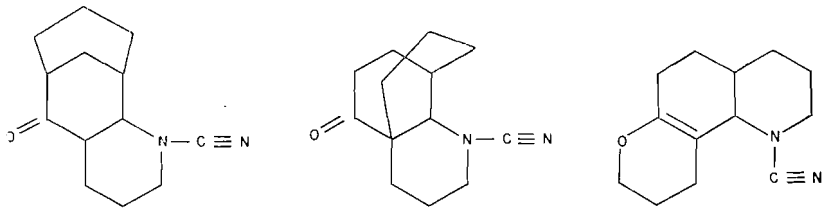


An attempt to form the normal product of dehydrobromination of β-cyanobromo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

lycopodine led instead to the formation of a cyclic saturated ether. A procedure analogous to that used in the preparation of the olefin XI in the α-series was employed. Although Barclay (6) has reported that compound VI is formed when β-cyanobromolycopodine is treated with an excess of sodium borohydride, we have been able to alter the reaction conditions so that the reaction follows a different course. When II was dissolved in ethanol, cooled to 0°, and treated with an ethanolic solution of sodium borohydride, the main reaction product was the hydroxybromide XV, $C_{17}H_{27}ON_2Br$. The hydroxybromide XV was readily converted to the quaternary salt XVI, $C_{20}H_{36}ON_3Br$, on treatment with trimethylamine. When the quaternary salt XVI was decomposed with potassium tertiary butoxide in boiling tertiary butanol, trimethylamine was liberated and a new compound XVII, $C_{17}H_{26}ON_2$, was isolated. This compound showed no hydroxyl or olefin absorption in its infrared spectrum and it can be concluded that an ether linkage formed in the reaction. This is substantiated by the appearance of a strong band in its infrared spectrum in the region characteristic of ethers. This is the third instance in which a cyclization involving the oxygen function has been observed in the β-series. Two of these have been discussed in this paper while the third was the formation of the lactone reported by MacLean and Harrison (3).

The ease with which the compound VI formed in a variety of basic media led us to investigate again the hydrogenolysis of the β-bromide II reported by MacLean, Manske, and Marion (1). We have found that under their conditions at least 90% of the reaction product was compound VI and not the expected hydrogenolysis product as they reported. If, however, the hydrogenolysis was carried out at dry ice temperature, and in the absence of a large excess of alkali, a normal reaction course was followed. The product of this reaction contained none of the cyclized compound VI but, instead, a new compound XVIII, $C_{17}H_{26}ON_2$, which had a normal carbonyl absorption in its infrared spectrum near 1700 cm^{-1}. Compound XVIII, designated β-cyanolycopodine, has also been prepared indirectly in the following manner. The hydroxybromide XV, $C_{17}H_{27}ON_2Br$, was treated with hydrogen over a palladium catalyst and underwent hydrogenolysis in a normal manner to give the compound XIX, $C_{17}H_{28}ON_2$, and that in turn was oxidized by the Oppenauer method to β-cyanolycopodine, identical in all respects with the compound prepared directly from II.



The reactions which have been discussed here can be accommodated by the partial formula A below which was recently proposed by MacLean and Harrison (3).

A

Compound III would form in a displacement reaction by the enolate ion involving C-alkylation to yield either structure B or C while compound VI would form in a displacement reaction by the enolate ion involving O-alkylation to give structure D. Partial structures of other compounds mentioned in the text can be deduced in a logical fashion from structure A.

For personal use only.

B C D

The evidence in support of the cyclization reaction adjacent to the carbonyl group in the α-series is substantial, but we have been unable to differentiate between structures B and C. Support for structure D is meager but it appears to be the only plausible formulation for this peculiarly unreactive compound. The double bond has been assigned the position shown, rather than the alternative position, since this compound shows no =C—H stretching absorption in the region 3000–3120 cm^{-1} in its infrared spectrum.

EXPERIMENTAL

Treatment of α-Cyanobromolycopodine with Potassium Hydroxide in Methanol

The reaction was carried out and the product isolated according to the procedure of MacLean, Manske, and Marion (1). The infrared spectrum* of this product showed strong absorption at 1700 cm^{-1} in the carbonyl region and cyanamide absorption at 2200 cm^{-1}. The ultraviolet spectrum had no peaks characteristic of a conjugated system. This compound, III, would not form a benzylidene derivative under conditions which were successful with α-cyanolycopodine (2).

Reduction of III, $C_{17}H_{24}ON_2$, *with Sodium Borohydride*

Compound III (1.7 g) was added to a solution of 3.5 g of sodium borohydride in 80 ml of 95% ethanol and the solution was stirred for 3 hours and then allowed to stand overnight. The excess borohydride was destroyed with formaldehyde and the solution was made nearly neutral by the addition of mineral acid. The solvent was evaporated, water was added to the residue, and the resulting mixture was extracted with chloroform. The chloroform extract was evaporated to yield a residue which was purified by chromatography on alumina using chloroform as eluant. There was recovered 1.5 g of product VII which crystallized from ether and melted at 219°. Calc. for $C_{17}H_{26}ON_2$: C, 74.4; H, 9.55; N, 10.2%. Found: C, 74.5; H, 9.48; N, 10.0%.

The infrared spectrum had strong hydroxyl and cyanamide absorption but no absorption in the carbonyl region. The compound was converted to III upon treatment with chromic acid in pyridine.

Hydrolysis and Methylation of III, $C_{17}H_{24}ON_2$

Compound III (3.3 g) was dissolved in a mixture of 100 ml of 95% ethanol and 15 ml of 12 *M* hydrochloric acid. The solution was heated under reflux on a steam bath for 30 hours and then evaporated to dryness. The residue was dissolved in water, filtered, made basic with ammonia, and extracted with chloroform. The crude reaction product (2.3 g) was dissolved in acetone and acidified with perchloric acid. A crystalline perchlorate

**Infrared spectra were run in Nujol mull using a sodium chloride prism unless otherwise stated.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

separated which, after recrystallization from acetone, melted at 300°. Calc. for $C_{16}H_{25}ON.HClO_4$: C, 55.2; H, 7.53; N, 4.0%. Found: C, 55.3; H, 7.39; N, 4.1%.

The free base was liberated from the perchlorate and crystallized from petroleum ether. It melted at 105–106°. Calc. for $C_{16}H_{25}ON$: C, 77.7; H, 10.12; N, 5.7%. Found: C, 77.4; H, 9.97; N, 5.6%.

The infrared spectrum of the base had a sharp peak at 3330 cm^{-1} in the =NH region and a carbonyl peak at 1695 cm^{-1}.

The secondary base (2.0 g) obtained above was dissolved in a mixture of 40% formaldehyde (2.4 ml) and 90% formic acid (0.8 ml) and refluxed for a period of 33 hours. The mixture was quenched in water, made basic with ammonia, and extracted with ether. From the ether extract a residue was obtained on evaporation which was purified by chromatography on alumina using chloroform as eluant. There was obtained 1.6 g of tertiary base which was converted to its perchlorate in acetone solution. The crystalline perchlorate which separated was recrystallized from acetone and melted at 249–250°. Calc. for $C_{17}H_{27}ON.HClO_4$: C, 56.4; H, 7.80; N, 3.8%. Found: C, 56.6; H, 7.77; N, 3.9%.

The free base, regenerated from the perchlorate, crystallized in the absence of solvent and melted at 87–88°. Calc. for $C_{17}H_{27}ON$: C, 78.2; H, 10.33; N, 5.4%. Found: C, 78.0; H, 10.30; N, 5.4%.

This base was recovered unchanged after treatment with phenyl lithium under the same conditions which gave a successful reaction with lycopodine (1).

α-Cyanodimethylaminolycopodine V

This compound was prepared by the reaction of α-cyanobromolycopodine I with a saturated solution of dimethylamine in methanol. After removal of methanol the residue was dissolved in water, made basic with ammonia, and extracted with chloroform. Evaporation of the chloroform yielded the free base which was dissolved in acetone and treated with perchloric acid. A crystalline perchlorate separated which was recrystallized from boiling acetone. This compound proved to be identical with the compound isolated by MacLean, Manske, and Marion (1) from the pyrolysis of the quaternary base derived from the quaternary bromide IV. The melting point of a mixture of the two samples was not depressed and their infrared spectra were identical. The yield was virtually quantitative.

Reduction of V *with Sodium Borohydride*

α-Cyanodimethylaminolycopodine (1.90 g) was added to a solution of 0.95 g of sodium borohydride in 200 ml of 95% ethanol and the mixture was stirred for 3 hours. After standing overnight at room temperature the mixture was worked up in the manner previously described to yield 1.80 g of the reduced compound IX, which melted at 190–191° after recrystallization from acetone. Calc. for $C_{19}H_{33}ON_3$: C, 71.5; H, 10.34; N, 13.2%. Found: C, 71.2; H, 9.85; N, 13.0%.

Conversion of the Base IX *to its Methiodide* X

A solution of 0.43 g of IX in 10 ml of acetone was treated with methyl iodide and set aside in the refrigerator. A fine, crystalline precipitate, which was collected and recrystallized from acetone, separated after a few hours. It melted at 231–232°. Calc. for $C_{20}H_{36}ON_3I.H_2O$: C, 50.1; H, 7.52; N, 9.0%. Found: C, 50.6; H, 7.67; N, 9.0%.

Decomposition of the Quaternary Salt X *with Potassium Tertiary Butoxide*

Metallic potassium (7.4 g) was added in pieces over a period of 1 hour to 160 ml of dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

tertiary butyl alcohol. The methiodide X (6.7 g) was added to the above solution and the mixture was refluxed for 42 hours. The reaction mixture was taken to dryness under vacuum and the residue mixed with water and extracted with ether. From the ether extract 2.0 g of a basic fraction and 2.2 g of neutral fraction were obtained. The basic fraction proved to be a mixture of V and IX, in which the latter predominated. The neutral fraction was separated into two fractions by chromatography on alumina using chloroform as eluant. The first fraction eluted was recovered from the chloroform and purified by crystallization from ether. It melted at 112–113°. Calc. for $C_{17}H_{24}ON_2$: C, 75.0; H, 8.82; N, 10.3%. Found: C, 74.9; H, 8.84; N, 10.3%.

The infrared spectrum of compound XI had a strong carbonyl absorption at 1700 cm^{-1}, double-bond absorption at 3070, 1640, and 910 cm^{-1}, but no absorption in the hydroxyl region. The ultraviolet absorption spectrum showed no evidence of conjugation.

The more strongly adsorbed fraction was recovered from the chloroform and recrystallized from ether. It melted at 201–202°. Calc. for $C_{17}H_{26}ON_2$: C, 74.4; H, 9.55; N, 10.2%. Found: C, 74.6; H, 9.25; N, 10.5%.

The infrared spectrum of this compound showed olefin absorption at 3070 and 1640 cm^{-1} and hydroxyl absorption at 3400 cm^{-1}. Both compounds had the usual cyanamide absorption at 2200 cm^{-1}.

The keto-olefin XI was converted to the hydroxyolefin XII by reduction with sodium borohydride in 95% ethanol. Hydrogenation of the keto-olefin yielded α-cyanolycopodine (1) identified by a mixed melting point determination and by comparison of its infrared spectrum with an authentic sample.

Ozonolysis of the Hydroxyolefin XII

The hydroxyolefin XII (0.30 g) was dissolved in a solution of 10 ml of anhydrous ethyl acetate and 1 ml of glacial acetic acid and cooled to 20°. A stream of ozone-containing oxygen was passed through the mixture until absorption of ozone no longer occurred. The solution was then transferred to a 50-ml flask, 10 ml of glacial acetic acid and 0.4 g of zinc dust were added, and the mixture was heated under reflux for 5 minutes. The apparatus was then arranged for distillation and the mixture was distilled until the vapor temperature reached 97°. The distillate was collected in an ethanolic solution of 0.28 g of dimedone containing a drop of piperidine and the resulting mixture was allowed to stand for 1 hour. The solvent was then evaporated and the residue was allowed to crystallize from aqueous alcohol. There was obtained 0.13 g of white crystalline solid which melted at 189°, and which did not depress the melting point of an authentic sample of the dimedone derivative of formaldehyde.

Reaction of β-Cyanobromolycopodine II *with Potassium Hydroxide in Methanol*

A sample of II (0.5 g) was heated at reflux temperature with a mixture of 1 g of potassium hydroxide in 40 ml of methanol for 12 minutes. The solution was made slightly acid and evaporated to dryness under vacuum. The residue was treated with water and extracted with chloroform. Evaporation of the chloroform extract yielded 0.38 g of crystalline product which, when recrystallized from petroleum ether, melted at 98–100°. This compound, VI, proved to be identical with the product which MacLean, Manske, and Marion (1) obtained by treatment of II with ethanolic potassium acetate. The infrared spectrum of a solution of the compound in carbon tetrachloride had a strong absorption band at 1675 cm^{-1}, while the band at 1700 cm^{-1} in the starting compound had completely disappeared. The spectrum of crystalline VI in Nujol mull showed a slight shift of the band to 1680 cm^{-1}. The determination of the spectrum of VI in carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

tetrachloride solution was repeated with a calcium fluoride prism in the spectrophotometer. No bands or inflections were detected in the region 3000–3120 cm^{-1} characteristic of the =C—H stretching absorption. The ultraviolet absorption spectrum showed no evidence of conjugation.

Acid Hydrolysis of Compound VI

A sample of the cyclized compound VI (0.60 g) was dissolved in a mixture of 6 ml of 1-propanol and 30 ml of 2 *M* hydrochloric acid. The mixture was heated for 20 hours on the steam bath and then evaporated to dryness under vacuum. The residue was partitioned between ether and dilute hydrochloric acid solution. The acid solution was then made basic with ammonia and extracted with ether to yield 0.33 g of acid-soluble material. This base was adsorbed on alumina and the column was eluted with chloroform. A fraction (0.24 g) was obtained which had strong infrared absorption at 1675 cm^{-1} and no cyanamide absorption. This semicrystalline fraction was converted to the hydrochloride in acetone solution. Recrystallization of the salt from acetone–ether yielded a sample which melted at 256–257°.

Reduction of Compound VI *with Lithium Aluminum Hydride*

A solution of VI (0.60 g) in anhydrous tetrahydrofuran was added to lithium aluminum hydride (1 g) in tetrahydrofuran (25 ml). The mixture was heated under reflux for 4 hours and then allowed to stand overnight. The excess hydride was destroyed with wet tetrahydrofuran and the tetrahydrofuran solution was filtered from inorganic residue. The precipitated hydroxides were washed well with warm chloroform and the combined filtrates were evaporated to dryness. The residue yielded 0.21 g of basic material which was dissolved in acetone and converted to the hydrochloride. The hydrochloride was identical with that obtained from the hydrolysis of VI in acid solution.

Methylation of the Secondary Base XIII

The secondary base XIII (0.2 g), derived from the hydrochloride above, was treated with a solution of 0.08 ml of 98% formic acid and 0.24 ml of formalin. The mixture was heated on the steam bath for 4 hours and allowed to stand overnight. The resulting solution was treated with dilute hydrochloric acid, filtered, made alkaline with ammonia, and extracted with ether. The dried ether extract yielded an oily residue (0.2 g) which was dissolved in acetone and treated with perchloric acid. The crystalline perchlorate, which separated, melted at 232° after recrystallization from acetone. Calc. for $C_{17}H_{27}ON.HClO_4$: C, 56.4; H, 7.80; N, 3.8%. Found: C, 56.5; H, 7.64; N, 3.7%.

Reduction of β-Cyanobromolycopodine II *with Sodium Borohydride*

A solution of 0.45 g of sodium borohydride in 95% ethanol was added dropwise over ½ hour to a stirred, ice-cooled solution of 0.50 g of β-cyanobromolycopodine in 95% ethanol. The reaction mixture was stirred for 7 hours at 0°, then made slightly acid with dilute hydrochloric acid and evaporated to dryness under reduced pressure. Water was added to the residue and the mixture extracted with ether. The ether extract was washed with dilute hydrochloric acid and with water, and dried over anhydrous sodium sulphate. Evaporation of the ether solution yielded a crystalline residue whose infrared spectrum exhibited strong hydroxyl and cyanamide absorption and very weak absorption in the carbonyl region. The presence of only a very small peak at 1675 cm^{-1} showed that little cyclization to form compound VI had taken place. Recrystallization of the product from ether gave 0.25 g of a compound, XV, which melted at 139–141° with decomposition. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

compound gave a positive Beilstein test for halogen. Calc. for $C_{17}H_{27}ON_2Br$: C, 57.5; H, 7.66; N, 7.9%. Found: C, 57.5; H, 7.66; N, 8.0%.

Preparation of the Quaternary Salt XVI

An ice-cold methanolic solution of 200 mg of the hydroxybromide XV was treated with an excess of a methanolic solution of trimethylamine. The solution was left overnight in the refrigerator. The solvent and excess amine were removed by evaporation under reduced pressure and the crystalline residue was washed with warm ether and then dissolved in acetone. Concentration of the acetone solution yielded a crop of crystals (135 mg) which melted at 271–272° with decomposition. The infrared spectrum exhibited strong cyanamide absorption at 2200 cm^{-1}, a band of medium strength at 1640 cm^{-1}, and three bands in the hydroxyl region: a strong band at 3315 cm^{-1} and medium bands at 3490 and 3550 cm^{-1}. When the sample was dried under vacuum at 56° for 4 hours a loss of weight of about 8% was observed, which corresponds to a loss of 2 moles of water. On exposure to the atmosphere the sample recovered about half of the weight loss in less than 5 minutes, but further gain in weight took place very much more slowly. The infrared spectrum of the material which had been dried and then exposed to the air showed cyanamide absorption as before, but only two bands in the hydroxyl region: a strong one at 3370 cm^{-1} and a very weak one at 3600 cm^{-1}. The band at 1640 cm^{-1} was no longer present but several very weak peaks were observed in the region 1600–1660 cm^{-1}. The analytical sample, which melted with decomposition at 271–272°, was taken from material which had been dried and then exposed to the atmosphere. Calc. for $C_{20}H_{36}ON_3Br.H_2O$: C, 55.5; H, 8.86; N, 9.7%. Found: C, 55.6; H, 8.62; N, 9.5%.

Decomposition of the Quaternary Salt XVI *with Potassium Tertiary Butoxide*

A solution of potassium tertiary butoxide was prepared by dissolving 0.35 g of potassium metal in 10 ml of tertiary butanol. To this solution was added 75 mg of the quaternary salt XVI. The reaction mixture was heated under reflux for 3 hours, then the solvent was removed under vacuum. The residue was treated with water and extracted with ether. The ether solution was washed with dilute hydrochloric acid and dried over anhydrous sodium sulphate. Evaporation of the ether yielded a crystalline residue (48 mg) which, after recrystallization from petroleum ether and a second recrystallization from ether, melted at 130–136°. An analytical sample, m.p. 135.5–137.5°, was prepared by sublimation of this material at a pressure of about 0.05 mm of mercury and at 75–110°. Calc. for $C_{17}H_{26}ON_2$: C, 74.4; H, 9.55%. Found: C, 74.1; H, 9.47%.

The infrared spectrum of the product showed strong cyanamide absorption, but no hydroxyl or olefin absorption. A strong band was observed at 1070 cm^{-1}, which is in the region where the ether C—O stretching absorption has been found to occur.

Reduction of the Hydroxybromide XV *with Hydrogen in an Alkaline Medium*

A pellet (ca. 50 mg) of potassium hydroxide and 30 mg of 2% palladium – calcium carbonate catalyst were added to a hydrogenation bottle containing a methanolic solution of 30 mg of the hydroxybromide. The mixture was shaken under hydrogen at a pressure of 24 lb/sq. in. for 4.5 hours, then filtered and the filtrate evaporated. The residue was treated with water and extracted several times with ether. The ether solution was dried over anhydrous sodium sulphate and filtered. Removal of the solvent by evaporation yielded a crystalline product, which melted at 183–185.5° after recrystallization from ether. The product XIX gave a negative Beilstein halogen test. Calc. for $C_{17}H_{28}ON_2$: C, 73.9; H, 10.21; N, 10.1%. Found: C, 73.9; H, 10.36; N, 9.8%.

Oppenauer Oxidation of β-Cyanodihydrolycopodine XIX

To a solution of 0.20 g of β-cyanodihydrolycopodine in 25 ml of anhydrous benzene were added 2.5 ml of acetone and 0.50 g of aluminum isopropoxide. The mixture was refluxed for 24 hours, then poured into water and the benzene layer separated and dried over anhydrous sodium sulphate. Evaporation of the benzene solution yielded a residue (0.20 g) which partially crystallized on standing. Recrystallization from ether – petroleum ether yielded 54 mg of unreacted XIX. The material recovered from evaporation of the mother liquor was dissolved in benzene and chromatographed on an alumina column using benzene as the eluant. The first fractions yielded 84 mg of crystalline material whose infrared spectrum showed carbonyl and cyanamide absorption at 1705 and 2210 cm^{-1}, respectively, and no hydroxyl absorption. Recrystallization from ether – petroleum ether yielded an analytical sample, m.p. 82.5–84°. Calc. for $C_{17}H_{26}ON_2$: C, 74.4; H, 9.55; N, 10.2%. Found: C, 74.6; H, 9.60; N, 10.5%.

After the band containing the oxidation product, designated β-cyanolycopodine XVIII, had been collected, elution of the column was continued with 99:1 benzene–methanol and a fraction yielding a further 40 mg of starting material was obtained.

Treatment of β-Cyanobromolycopodine II *with Hydrogen in Alkaline Medium*

β-Cyanobromolycopodine II (0.2 g) was dissolved in 25 ml of methanol containing 1 g of potassium hydroxide and 0.2 g of 2% palladium – calcium carbonate catalyst. The mixture was shaken with hydrogen at 40 lb/sq. in. for 6 hours and then worked up in the manner described in the account of the hydrogenolysis of the hydroxybromide XV. The reaction conditions are those which are given by MacLean, Manske, and Marion (1). The crude crystalline product gave a negative Beilstein test for halogen. The infrared spectrum of the product had a strong absorption band at 1675 cm^{-1} and only weak absorption at 1700 cm^{-1}. After recrystallization from petroleum ether the product melted at 98–100° and proved to be identical with that obtained by treatment of β-cyanobromolycopodine with methanolic potassium hydroxide. No β-cyanolycopodine XVIII was isolated.

The reaction was repeated under the same conditions and this time the crude product was treated with sodium borohydride in order to reduce any β-cyanolycopodine present to β-cyanodihydrolycopodine and thus facilitate chromatographic separation. The hydride reduction mixture was worked up in the usual way and the crude product was adsorbed on alumina and eluted with benzene–methanol. After the cyclized compound had passed through the column a fraction was collected which contained 15 mg of material whose infrared spectrum had absorption in the hydroxyl region and at 1630–1650 cm^{-1}. It could not be ascertained whether or not β-cyanodihydrolycopodine was present in this fraction. Further elution of the column failed to yield any more material.

A methanol solution of 0.25 g of β-cyanobromolycopodine was poured into a hydrogenation bottle containing a solution of 0.05 g of potassium hydroxide in methanol which had been cooled to about −60° by fitting the bottle with a jacket packed with dry ice. Palladium – calcium carbonate catalyst (0.2 g) was added to the solution and the mixture was shaken under hydrogen at 40 lb/sq. in. for 6 hours. During the first 1–2 hours of shaking, a low temperature was maintained by keeping the jacket filled with dry ice, but after this period the mixture was allowed to come to room temperature. The mixture was worked up by the usual procedure. The infrared spectrum of the crude product showed strong cyanamide absorption at 2210 cm^{-1} and a strong band at 1705 cm^{-1} in the carbonyl region. The 1675 cm^{-1} absorption characteristic of the cyclized compound was absent. The material was purified by chromatography on alumina using benzene–methanol as

For personal use only.

eluant. The product (0.15 g) melted at 82–84° after recrystallization from ether – petroleum ether and was found to be identical with β-cyanolycopodine XVIII prepared by Oppenauer oxidation of compound XIX.

RADIATION CHEMISTRY OF CYCLOHEXANE

I. ISOTOPIC COMPOSITION OF HYDROGEN EVOLVED FROM MIXTURES OF C_6D_{12} AND C_6H_{12}[1]

P. J. Dyne and W. M. Jenkinson

ABSTRACT

The yield of D_2 formed by a unimolecular process in the γ-ray irradiation of cyclohexane-d_{12} has been deduced from the isotopic composition of hydrogen evolved from C_6H_{12}–C_6D_{12} mixtures. A value of 0.25 molecule/100 ev is found for this "molecular" yield. This yield is only slightly reduced by iodine but is considerably reduced in the presence of biphenyl.

Hydrogen is the principal gaseous product formed in the fast-electron irradiation of cyclohexane, its initial yield being 5.5–5.8 molecules/100 ev. This yield is quite sharply reduced by small additions of solutes. Solutions containing $\sim 5 \times 10^{-3}$ moles/liter iodine, for instance, have $G(H_2) \sim 4.0$ (1); solutions of cyclohexane with benzene (1, 2), biphenyl, and terphenyls (3, 4) show a similar behavior. From a study of curves of $G(H_2)$ vs. iodine concentration, Burton *et al.* (1) conclude that hydrogen is produced by two mechanisms each with a yield of 2 to 3 molecules/100 ev, one of which is more rapidly suppressed by iodine than the other. Studies of $G(H_2)$ in biphenyl solutions lead to a similar conclusion (3, 4).

The two mechanisms could be (*a*) a bimolecular mechanism involving hydrogen-atom abstraction from the parent molecule and (*b*) a unimolecular mechanism in which molecular hydrogen is split off in one step from an excited parent molecule. These two types of mechanisms are sometimes referred to as "radical and molecular" or "intermolecular and intramolecular".

The existence of two such processes has been demonstrated by Dewhurst (5) in the radiolytic decomposition of *n*-hexane. The high probability of "molecular" processes in organic molecules is shown by Dorfman's work on the gas-phase radiolysis of ethane (6) where it was shown that 66% of the molecular hydrogen is formed by a molecular detachment process not involving free hydrogen atoms.

By examining the variation of the D_2 yield in C_6D_{12}–C_6H_{12} mixtures we have determined the value of the 'unimolecular' yield of D_2 from C_6D_{12}. Its value is low, $G(D_2)$ (unimolecular) being 0.25 molecule/100 ev.

THE METHOD OF SEPARATING UNIMOLECULAR AND BIMOLECULAR YIELDS

In a mixture of C_6H_{12}, (C_H), and C_6D_{12}, (C_D), the amount of D_2 produced by a unimolecular process will have a first-order dependence on the concentration of C_D and the amount produced by a bimolecular process will have a second-order dependence on C_D. For a precise development of the relation between the yield of D_2 and the relative amounts of C_H and C_D we symbolize the reactive intermediates in the bimolecular process as X_H and X_D and all other products by P. The symbols X_H and X_D are used for the reactive intermediates to stress the generality of the reasoning. The argument is independent of the identity of the intermediates. The unimolecular process is

$$C_H \rightsquigarrow H_2 + P \qquad \text{yield } G_1(H).$$

[1]*Manuscript received November 24, 1959.*
Contribution from Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 973.

The bimolecular process consists of two steps. The first

$$C_H \rightsquigarrow X_H + P$$

has a yield $G_2(H)$ and is followed by

$$X_H + C_H \rightarrow H_2 + P$$

which has a specific rate constant k_1.

In mixtures of C_6H_{12} and C_6D_{12} the following additional reactions will occur:

$C_D \rightsquigarrow D_2 + P$	yield	$G_1(D)$
$C_D \rightsquigarrow X_D + P$	yield	$G_2(D)$
$X_D + C_H \rightarrow HD + P$	rate constant	k_2
$X_H + C_D \rightarrow HD + P$	rate constant	k_3
$X_D + C_D \rightarrow D_2 + P$	rate constant	k_4

In a mixture containing C_H and C_D gram-molecules of the two components the fraction of ionization energy absorbed by each species is proportional to the mole fractions $C_H/(C_H + C_D)$ and $C_D/(C_H + C_D)$. The number of species X_D formed on the absorption of 100 I ev is $I.G_2(D).C_D/(C_H + C_D)$. The fraction of these species which react to give D_2 is $k_4C_D/(k_2C_H + k_4C_D)$. The number of molecules of D_2 formed by the bimolecular process is therefore

$$\frac{I.G_2(D).k_4C_D^2}{(C_D+C_H)(k_2C_H+k_4C_D)}$$

which reduces to $I.G_2(D)\ (k_4/k_2)F^2$ where $F = C_D/C_H$ for mixtures in which $C_H \gg C_D$.

Similarly the number of molecules of D_2 formed by the unimolecular process is $IG_1(D).C_D/(C_D + C_H)$ which reduces to $I.G_1(D).F$ for mixtures in which $C_H \gg C_D$.

For these dilute solutions therefore we find that the yield of deuterium $G(D_2)$ based on the amount of energy absorbed in the mixture is given by

[1] $$G(D_2) = G_2(D).(k_4/k_2)F^2 + G_1(D)F$$

or

$$G(D_2)/F = G_2(D).(k_4/k_2)F + G_1(D).$$

A plot of the left side of equation 1 against F should give a straight line with an intercept of $G_1(D)$, the unimolecular yield.

The tacit assumption has been made that products P do not react with the intermediates X to any extent. This will only be generally true at low conversions.

EXPERIMENTAL

Cyclohexane-d_{12} was obtained from Merck and Co. The analysis given by the manufacturers was 94.8 mole % cyclohexane-d_{12}, 5.2 mole % cyclohexane-d_{11}, and 0.4% benzene-d_6 corresponding to an isotopic purity of 99.6%. Dilution of C_6D_{12} with C_6H_{12} was done in two stages. First, an accurate dilution by weighing was made to give a solution containing about 40% C_6D_{12}. Small amounts of this mixture (100–500λ) were added to 2-ml samples of light cyclohexane to give solutions containing up to 7% C_6D_{12}. These 2-ml samples were degassed by freezing, pumping, and thawing five times and were irradiated at room temperature under vacuum for 16 hours in glass vessels in a Co^{60} source at a dose rate of 8.5×10^{21} ev/lt hr. The residual vacuum above the frozen sample

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

was <0.1 micron before irradiation. Dosimetry is based on the Fricke dosimeter $G(Fe^{3+}) = 15.5$. The gas was pumped off, the amount measured in a conventional gas-analysis line and analyzed on a Consolidated 21-610 mass spectrometer. The mass spectrometer was calibrated against synthetic mixtures of H_2, HD, and D_2.

In blank experiments solutions of D_2 in C_6H_{12} were irradiated. No significant radiation-induced exchange was observed. This is to be expected when it is noted that the parent hydrocarbon, which can react with H atoms, is present in a very much higher concentration than the D_2.

THE YIELDS OF HD AND D_2

Results on mixtures of C_6D_{12} and C_6H_{12} are shown in Table I. They are plotted in the form required by equation 1 in Fig. 1. The experimental points extrapolate to give a value of $G_1(D)$, the unimolecular yield of 0.25 molecule/100 ev.

TABLE I

Results on mixtures of C_6D_{12} and C_6H_{12} with added iodine or biphenyl are given in Table II and Table III and are also plotted in Fig. 1. The value of $G_1(D)$ in the presence of iodine is 0.22, approximately 10% lower than in the absence of iodine. The value of $G_1(D)$ is much more strongly reduced by biphenyl, the intercept being 0.12.

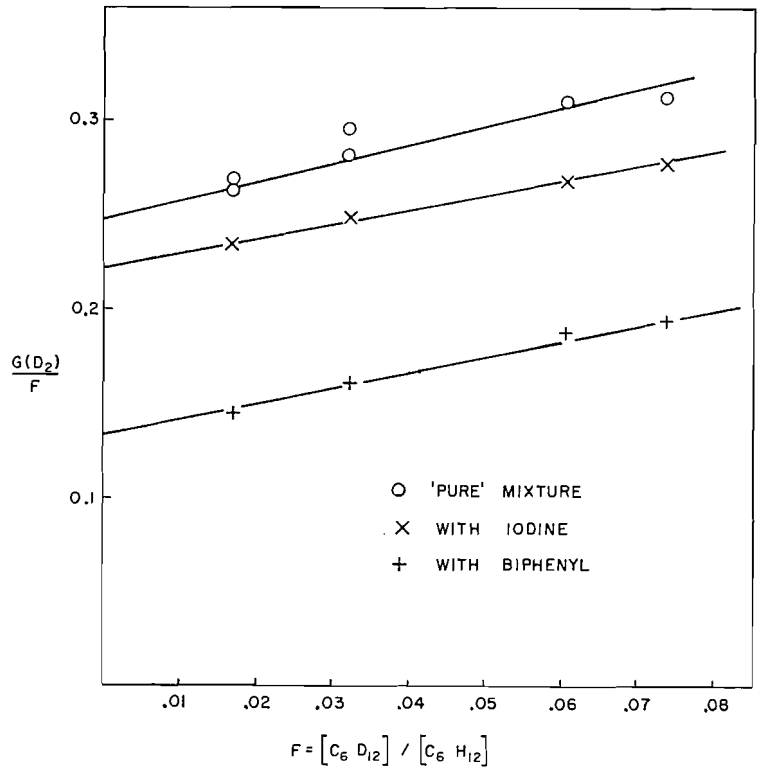

FIG. 1. The experimental results plotted in the form required by eq. 1. The intercept when $F = 0$ is the value of the "molecular" yield of D_2 from C_6D_{12} and from C_6D_{12} containing iodine and biphenyl.

DISCUSSION

The value of 0.25 for the unimolecular yield is for D_2 from C_6D_{12}. The corresponding yield for H_2 from C_6H_{12} will, in all probability, be considerably larger. This general prediction is borne out by Gordon and Burton's (7) measurements of $H_2(D_2)$ yields from benzene and benzene-d_6 and by Boyd's measurements of $H_2(D_2)$ and "polymer" yields from deuterated biphenyl and terphenyl (8). A value between 0.5 and 1.0 for $G_1(H)$ is reasonable. This estimate is in agreement with the limiting yield of cyclohexene observed by Dewhurst (9) in the presence of dissolved oxygen. A constant yield of 0.7 molecule C_6H_{10}/100 ev was observed which was assigned to the yield of the unimolecular process which would not be reduced by radical scavengers such as oxygen.

The small effect of iodine on the unimolecular yield in our experiments is consistent with our interpretation. The difference in the intercepts, which is of the order of 10%, may not be experimentally significant. While the isotopic measurements have a high degree of internal consistency the principal parameter determining the intercept is the total hydrogen yield. These experiments were not suited to the measurements of hydrogen yield to the highest accuracy and the values of $G(H_2) = 3.2$ are lower than the values we obtained for larger samples of cyclohexane and iodine, viz. 3.5.

The 50% reduction of the unimolecular yield by 10^{-1} M biphenyl is significant. If the mechanism of the "unimolecular" yield is

$$C_6H_{12} \rightsquigarrow C_6H_{12}^*$$

$$C_6H_{12}^* \rightsquigarrow C_6H_{10} + H_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

where $C_6H_{12}^*$ represents an excited intermediate state, then the reduction of the yield can only be due to quenching of the $C_6H_{12}^*$ by the biphenyl. This is an example of the energy-transfer process postulated by Manion and Burton (2).

The main conclusion to be drawn from these results is that the yield of "molecular" hydrogen from C_6H_{12} is a small fraction, 10–20%, of the total. If the balance of the hydrogen yield comes from two processes each with yields of between 2 and 3 molecules/100 ev as suggested in reference 1 it follows that both these processes are bimolecular.

A similar measurement of $G_1(H)$ using solutions of C_6H_{12} in C_6D_{12} was attempted. The isotopic purity of the C_6D_{12}, now the major constituent of the mixture, was not, however, sufficient to allow the application of the simple interpretation given above.

FREE RADICALS BY MASS SPECTROMETRY

XIX. PRIMARY STEPS IN THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF FORMALDEHYDE[1]

A. G. HARRISON[2] AND F. P. LOSSING

ABSTRACT

In the Hg^3P, photosensitized decomposition of formaldehyde, evidence from deuterium labelling shows that 40% of the primary dissociation proceeds by way of an intramolecular elimination of H_2. The remainder dissociates by formation of H and HCO, or of 2H and CO. A clear distinction between these latter two processes cannot be made under the reaction conditions employed.

INTRODUCTION

Although the direct photolysis of formaldehyde has been rather extensively studied by a number of authors, no investigation of the mercury-photosensitized decomposition appears to have been made. One question of particular interest is whether the relative probability of occurrence of free radical and intramolecular rearrangement processes is dependent on the means of activation. If one uses the symbol HCHO* to designate a formaldehyde molecule which has been excited by a quantum, either by direct absorption or by collision with an excited mercury atom, the two primary dissociation processes of interest are

$$HCHO^* \rightarrow H + HCO, \quad [1]$$

$$\rightarrow H_2 + CO. \quad [2]$$

At wavelengths shorter than 2700 Å, a third reaction becomes energetically possible:

$$HCHO^* \rightarrow 2H + CO. \quad [3]$$

In this wavelength region reaction [1] might become indistinguishable from reaction [3] if the lifetime of the HCO radical were sufficiently shortened by energy carried over from the primary dissociation step.

Information as to the relative importance of these three primary steps in the direct photolysis at various wavelengths is rather ambiguous. Gorin (1) investigated the photolysis at 2537 Å, 3130 Å, and 3650 Å, using iodine as a radical trap. He concluded that at 2537 Å and 3130 Å reaction [1] is essentially the only process. Although reaction [3] is energetically possible at 2537 Å, he assigned an upper limit of 0.1 to its occurrence. He concluded that reaction [1] was still the major primary process at 3650 Å, although reaction [2] occurred to the extent of 0.3. These findings have been questioned by Steacie (2) in view of later work on the interfering effect of iodine in aldehyde photolyses.

Using the Paneth technique, Volman *et al.* (3) showed, by the removal of tellurium mirrors, that H atoms or HCO radicals must be formed in the photolysis at 2750 Å.

Calvert and Steacie (4) examined the photolysis at 3130 Å in some detail and found the mechanism to be consistent with the occurrence of reaction [1]. The extent to which reaction [2] occurred could not be determined from their results, however.

Klein and Schoen (5) photolysed mixtures of H_2CO and D_2CO at wavelengths from 3130 Å to 3750 Å. They found that at 3650 Å reaction [1] occurred, but to a smaller

[1]*Manuscript received December 17, 1959.*

Issued as N.R.C. No. 5586.
[2]*National Research Council of Canada Postdoctorate Fellow, 1957–59.*

extent than reported by Gorin (1), and they concluded that reaction [2] was the major process. The occurrence of reaction [1] at this wavelength requires that D(H—CHO) be less than 78 kcal/mole, and consequently that D(H—CO) in formyl must be greater than 27 kcal/mole. This conclusion has been questioned by Calvert (6) on the grounds that the observed rate of reaction [1] at 3650 Å could result from absorption by vibrationally excited formaldehyde molecules. The interpretation of these results and their bearing on the bond dissociation energy in HCHO and HCO is still controversial (7, 8). For the present purpose, however, a significant finding of Klein and Schoen was that reactions [1] and [2] both occurred at 3130 Å, the latter with a greater probability. Concerning the occurrence of reaction [2] at 2537 Å, on the other hand, there seems to be no unambiguous evidence either for or against.

It was thought that a measurement of the relative probabilities of reactions [1] and [2] in the mercury-photosensitized reaction at 2537 Å would be of interest for comparison with the direct photolytic experiments at longer wavelengths. A similar investigation of the mercury-photosensitized decomposition of acetaldehyde (9) showed that the corresponding intramolecular reaction to form CH_4 and CO did not occur to any appreciable extent, although there is evidence in the literature for its participation in the direct photolytic decomposition.

EXPERIMENTAL

The mercury-photosensitized reaction was carried out at 55° C in a fast-flow reaction system coupled to a mass spectrometer (10). A portion of the stream of reaction products from the illuminated zone was allowed to flow directly into the ionization chamber. A modification to the original apparatus has been described recently (11), together with some considerations regarding the experimental conditions in the reactor. The partial pressure of formaldehyde was in the region of 1–6 microns, carried in a stream of helium at 8–10 mm. Addition of formaldehyde to the helium stream was controlled by means of metal needle valves leading to samples of liquid formaldehyde maintained at −78° C.

The sample of D_2CO, prepared for us through the kindness of Dr. L. C. Leitch, had an isotopic purity of about 99%.

RESULTS AND DISCUSSION

In preliminary experiments formaldehyde was found to have a relatively large cross section for reaction with Hg^3P_1 atoms. In a contact time of 0.001 second formaldehyde at a partial pressure of 6.0 microns was decomposed to the extent of 24.4%. At the same pressure and contact time acetone was decomposed to the extent of 21.9%. The yield of CO was found to be essentially quantitative (97%); consequently the polymerization of formaldehyde vapor was negligible. Using electrons of low energy, no increase in the mass 29 peak attributable to the HCO radical could be observed. Earlier experiments have indicated, however, that the sensitivity for detection of HCO radical in this instrument is quite low (9), presumably as a result of the dissociation of HCO on surfaces in the ionization chamber. No formation of the dimer, glyoxal, was observed.

The participation of reaction [2] was demonstrated using H_2CO–D_2CO mixtures in a manner similar to that previously employed for acetaldehyde (9). The results are given in Table I. In experiments using H_2CO alone, the yield of H_2 per H_2CO decomposed was 0.96 to 0.98, and independent of the partial pressure of H_2CO over the range 1.84–5.63 microns. When D_2CO was added to the reaction stream containing H_2CO, the yield of H_2 per H_2CO decomposed decreased progressively as the mole fraction of D_2CO was

increased. In these mixtures HD and D_2 were formed. It is evident that, as the ratio D_2CO/H_2CO is made very large, any H atoms produced in the primary dissociation step must result in the formation of HD rather than H_2. In this respect it makes no difference whether the H atoms are removed by any or all of the three possible reactions:

$$H + D\,(+ M) \rightarrow HD\,(+ M), \qquad [4]$$

$$H + DCO \rightarrow HD + CO, \qquad [5]$$

$$H + D_2CO \rightarrow HD + DCO. \qquad [6]$$

Any H_2 produced in mixtures containing a very large excess of D_2CO must therefore have been formed by the intramolecular process [2]. The yield of H_2 as a function of the mole fraction of H_2CO in the mixture, shown graphically in Fig. 1, was an approximately straight line. An extrapolation of the line to infinite dilution of H_2CO by D_2CO indicates that about 40% of the H_2CO must decompose to give H_2 in one step. One can therefore assign the relative probability of 0.40 ± 0.05 to reaction [2], leaving 0.6 ± 0.05 to be divided between reactions [1] and [3].

The relative probability of reaction [2] can also be calculated independently from HD production in mixtures of H_2CO and D_2CO. With the approximately equimolar mixture given in the last line of Table I, the partial pressure of HD formed was 0.660 micron. Neglecting possible interference from a very small amount of HDCO (see below), we may assume that all the HD was formed by reactions [4] and [5] and the isotopic equivalent of [5]:

$$D + HCO \rightarrow HD + CO. \qquad [7]$$

The amount of HD formed by reaction [6] is extremely small. That this reaction is negligibly slow under the reaction conditions employed is shown by the fact that the percentage of formaldehyde decomposed showed no increase with increasing partial pressure. With the further assumption that the fraction of formaldehyde dissociating by reaction [2] is the same for both isotopic species, and that consequently in this experiment [H] ≈ [D] and [HCO] ≈ [DCO], the amounts of H_2, HD, and D_2 formed by reactions [4], [5], and [6] and their isotopic equivalents would be in the ratio 1:2:1. The total amount of isotopic hydrogens formed as a consequence of the primary reactions [1] and [3] will then be twice the amount of HD observed, i.e. 1.32 microns. Since the total amount of formaldehyde decomposed was $1.059+1.045 = 2.104$ microns, reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

[1] and [3] must account for 1.32/2.104 or 0.63 of the total reaction. The remainder, 0.37, is the relative probability of reaction [2]. This result agrees closely with the extrapolation in Fig. 1.

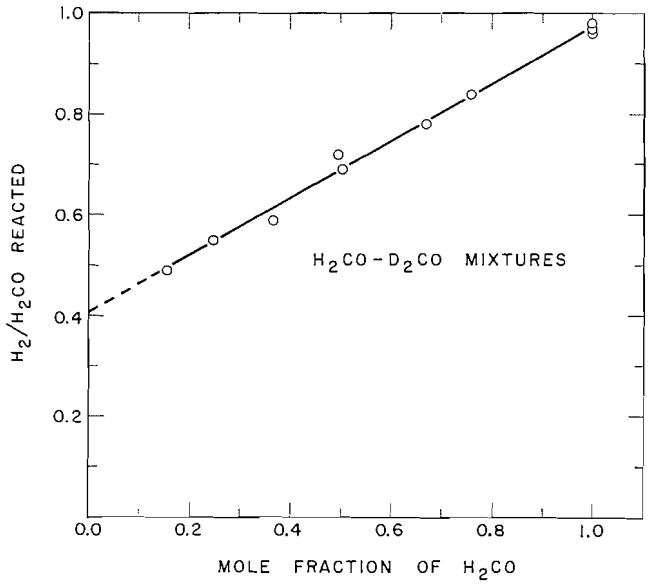

FIG. 1.

Although the data given above provide good evidence that about 40% of the total reaction goes by way of reaction [2], there remains the question as to whether the remainder of the reaction is better described by reaction [1] or reaction [3]. The energy available from $^3P_1$ mercury atoms, 112 kcal/mole, is more than sufficient to bring about reaction [3], for which the energy requirement is 105 kcal/mole. It is evident therefore that HCO radicals formed in reaction [1] would have sufficient excitation to dissociate spontaneously. Unless some effective means of deactivation is available, reactions [1] and [3] would consequently be indistinguishable. In the present experiments conditions would appear to be quite unfavorable for rapid deactivation, since helium at 8 mm pressure would be quite ineffective in this respect, and the partial pressure of formaldehyde was only a few microns. Nevertheless, some evidence for the presence of an appreciable concentration of formyl radicals in the reactor was obtained. It was observed that when mixtures of H_2CO and D_2CO were decomposed, a significant amount of the mixed aldehyde HDCO was formed. Possible modes of formation of HDCO are the following:

$$HCO + DCO \rightarrow HDCO + CO, \quad [8]$$

$$H + DCO \rightarrow HDCO, \quad [9]$$

$$H + D_2CO \rightarrow HDCO + D. \quad [10]$$

In a separate experiment in which the photosensitized decomposition of a mixture of H_2 and D_2CO in the reactor was carried out, no HDCO was formed. The formation of HD in this reaction showed, however, that H atoms were present either as a result of quenching of Hg^3P_1 atoms by H_2, or by exchange of D atoms with H_2. Since no HDCO

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

was formed, even though an appreciable quantity of H atoms was present, it may be concluded that reactions [9] and [10] are negligibly slow under the present reaction conditions. It would appear, then, that in mixtures of H_2CO and D_2CO, reaction [8] is the most probable source of the observed HDCO. In one such experiment, in which the amounts of H_2CO and D_2CO decomposed were 1.20 and 1.29 microns respectively, the partial pressure of HDCO formed was estimated to be 0.06 micron. (For this calculation the mass spectral sensitivity for HDCO at mass 31 was assumed to be the mean of the parent ion sensitivities for H_2CO and D_2CO.) If, as seems probable, the concentrations of HCO and DCO were not greatly different, the amounts of isotopic formaldehydes formed by disproportionation would be in the ratio 1:2:1. The total formaldehydes resulting from reaction [8] would then be 0.12 micron, and the total of formyl radicals involved equal to 0.24 micron. This amount corresponds to a lower limit of about 0.1 for reaction [1]. The fraction of primary reaction yielding such "stable" formyls is undoubtedly much greater than this, since formyls will be destroyed by other reactions. By analogy with the reaction of CH_3 with HCO (9), the abstraction reaction

$$H + HCO \rightarrow H_2 + CO \qquad [11]$$

is probably quite rapid. Some formyls may also be decomposed by reaction with a second excited mercury atom:

$$HCO + Hg^3P_1 \rightarrow H + CO + Hg^1S_0. \qquad [12]$$

From the present experiments, therefore, a lower limit for the occurrence of reaction [3] cannot be set. It might be expected that at higher pressures, where the possibility for deactivation of HCO radicals formed in [1] is increased, reaction [1] would be favored over reaction [3]. In the present reactor the effect of pressure could not be examined over a range wide enough to be significant.

In view of the large excess of energy available at 2537 Å, it is surprising that such a large part of the primary reaction proceeds by the almost thermoneutral formation of H_2 and CO rather than by rupture of a C—H bond. The substitution of CH_3 for H, as in acetaldehyde, is sufficient to reduce the similar intramolecular processes

$$CH_3CHO + Hg^3P_1 \rightarrow CH_4 + CO + Hg^1S_0 \qquad [13]$$

$$\rightarrow H_2 + CH_2 = CO \qquad [14]$$

to negligible proportions (9).

LONG-RANGE COUPLING CONSTANTS IN THE N.M.R. SPECTRA OF OLEFINES[1]

ROBERT R. FRASER

ABSTRACT

The spectra of tiglic and angelic acids and their methyl esters have been determined and analyzed by first-order perturbation theory. The magnitudes of the long-range coupling constants were found to be greater in each instance for *trans* oriented hydrogens than for *cis* hydrogens. All long-range coupling constants already reported have been examined and found to be consistent with the proposal that *trans* coupling constants are larger than *cis* coupling constants for hydrogens separated by more than three bonds.

Thus far, N.M.R. spectroscopy has been utilized in two ways to assign configuration to a pair of isomeric olefines. The magnitude of the coupling constant between the hydrogens attached to opposite ends of the double bond of a disubstituted olefine has been observed consistently to be larger for *trans* hydrogens than for *cis* hydrogens (1). These observations are in agreement with the theoretical calculation of coupling constants for olefines which were recently reported by Karplus (2). In symmetrically substituted olefines where coupling is not observable due to identical chemical shifts for the two protons on the double bond, the constant has been determined by examination of the peaks produced by interaction of the ethylenic hydrogens with the C^{13} nuclei present in natural abundance (3). The second method, proposed by Jackman and Wiley (4), assigns configuration to olefines on the basis of observations that a substituent β to a methoxycarbonyl group (each attached to one end of a double bond) will appear at a lower field strength when oriented *cis* to the ester group. A third method may be applicable by determination of the relative magnitude of long-range coupling constants between hydrogens *cis* or *trans* to each other.

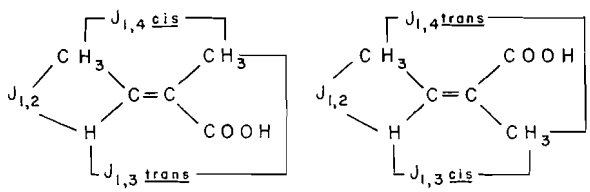

FIG. 1. Coupling constant nomenclature for tiglic (left) and angelic (right) acids.

Although the magnitude of spin–spin coupling decreases rapidly with increasing distance between the nuclei, the decrease is not so large when one of the intervening bonds possesses unsaturation. In olefines the size of the coupling constant between hydrogens separated by four bonds, hereafter called $J_{1,3}$, generally varies from 0.4 to 2.0 cycles per second (see Fig. 1 for nomenclature). Surprisingly we have observed equally large coupling constants between hydrogens separated by five bonds ($J_{1,4}$) as well. An examination of the literature revealed only relatively few cases where the spectra of a pair of *cis* and *trans* olefines are reported, including the $J_{1,3}$ values. We have measured the spectra of tiglic and angelic acids, and their methyl esters, to determine whether or not a simple relationship exists between the relative magnitude of 1,3 coupling constants and the geometrical relationship of the interacting nuclei. Should such a relationship obtain,

[1]*Manuscript received November 23, 1959.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

assignment of configuration to trisubstituted olefines on this basis would be possible. Furthermore, as Muller and Pritchard have pointed out (5) such distant interaction indicates appreciable contribution of hitherto neglected structures to the ground-state wave function of the molecule. Thus the data obtained should be of use in estimating such contributions as was the case for ethylene (2).

		1.2	(11)

**cis* and *trans* refer to the orientation of the two chlorine atoms on the double bond.

†*cis* and *trans* refer to the orientation of the two chlorine-containing groups.

The values of 1,3 coupling constants reported in the literature are given in Table I. At first glance no clear-cut relationship is obvious. Each set of values, however, must be critically appraised. The constants reported by Alexander (6) were obtained after a complete analysis of the spin wave functions for a system of five nuclei. The purpose of his analysis was to determine the relative signs of $J_{1,2}$ and $J_{1,3}$ and he found by testing various values for nine adjustable parameters that the best fit with the observed spectrum was obtained with the indicated values. An inversion of the magnitudes of $J_{1,3}$ *cis* and $J_{1,3}$ *trans* was not tested for comparison with the observed spectrum and could well be as acceptable. The relative magnitude of the coupling constants listed for α-methylstyrene depends on the assignment of peaks to the two ethylenic hydrogens. Pople, Bernstein, and Schneider (7) have only tentatively assigned the peak at high field to the hydrogen *cis* to the methyl group. The opposite assignment, perhaps even more acceptable,* would reverse the values for $J_{1,3}$ *trans* and $J_{1,3}$ *cis*. The results for the isomeric propenyl benzenes are more difficult to assess as details of the analysis of the *cis* isomer have not been reported. Should the values listed for the first three systems prove erroneous then the general rule $J_{trans} > J_{cis}$ would be obeyed.

Similar uncertainties exist in the remaining reported values in Table I with the exception of the trichloropropenes, which gave a simple spectrum. The most reliable values can only be obtained from spectra which can be analyzed by first-order perturbation theory. Such spectra have been obtained for tiglic and angelic acids and their methyl esters. The

**The effect of the benzene ring on its cis hydrogen can be either diamagnetic or paramagnetic depending on its orientation with respect to the rest of the molecule (12). The ultraviolet spectrum of α-methylstyrene shows a K-band maximum at lower wavelength with diminished intensity compared with that of styrene (13). Such a shift is most likely attributed to deviation of the aromatic ring from coplanarity with the ethylene system, the amount of which determines the strength of the paramagnetic effect.*

spectra for tiglic acid and methyl tiglate were first measured in carbon tetrachloride and showed complications in structure due to lack of a difference in chemical shift between the two methyl groups. When the spectra were measured on 10% solutions in benzene, solute–solvent interactions caused a preferential shift of the β-methyl group by 20 cycles/sec to high field thus allowing first-order analysis to be applied. Figure 2 shows the

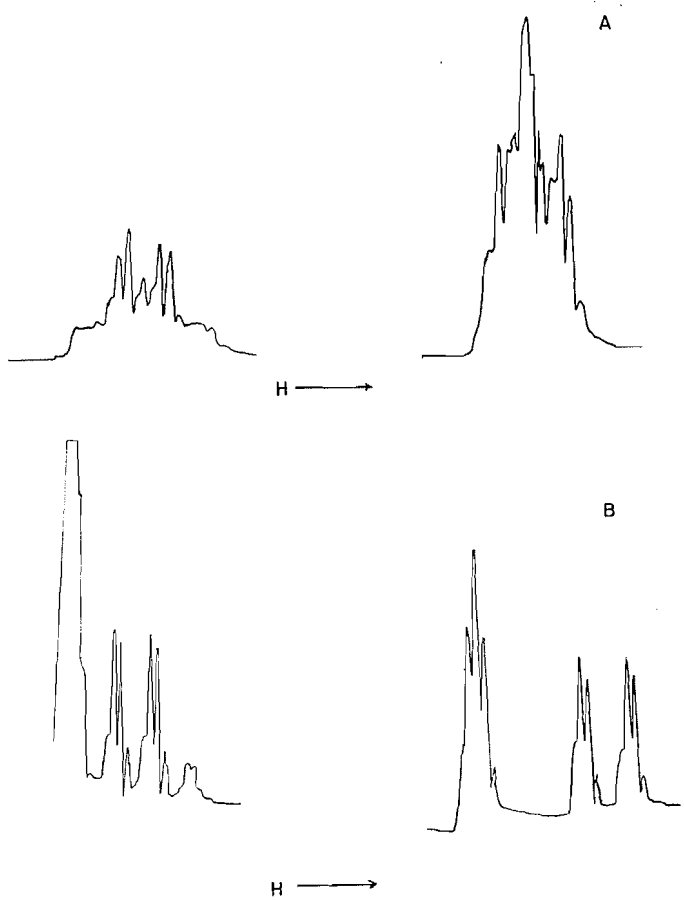

FIG. 2. Spectra due to ethylenic hydrogen (low-field peak) and methyl groups of tiglic acid. (A) 10% solution in carbon tetrachloride; (B) 10% solution in 93% deuterated benzene. (The 7% of benzene protons obscures the first quartet of the ethylenic absorption.)

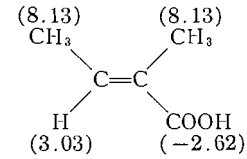

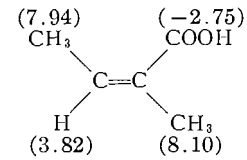

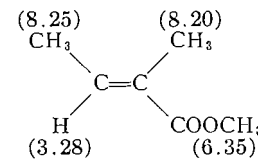

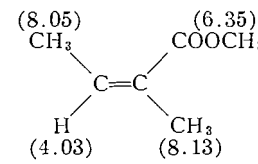

absorption peaks for the ethylenic hydrogen and the two methyl groups of tiglic acid in carbon tetrachloride and deuterobenzene solutions. Assignment of the two quartets at highest field to the β-methyl group is made on the basis of the assumption that the larger CH_3—C—H coupling will occur between hydrogens on adjacent carbon atoms. Exceptions to this assumption are known but are not likely here. The reverse assignment for the two methyl groups would require $J_{1,3}$ to be 7.11 cycles/sec and $J_{1,2}$ to be 1.43 cycles/sec, a highly improbable situation. Any doubt as to the structures of tiglic and angelic acids has recently been removed by the irrefutable evidence of X-ray analysis (14).

The measured values for the chemical shifts and coupling constants are given in Table II. The results obtained show $J_{1,3}$ *trans* > $J_{1,3}$ *cis* in both pairs of isomers. In addition $J_{1,4}$ *trans* > $J_{1,4}$ *cis*. The only other pair of geometrical isomers whose $J_{1,4}$ values have been

†In units of cycles per second.

determined are the butene-2 isomers. There, too, $J_{1,4}$ *trans* was found to be greater than $J_{1,4}$ *cis* (15). Demonstration that such a general relationship is true for long-range coupling constants in all olefines must await the accumulation of sufficient empirical and theoretical evidence. Work is continuing in this direction. Finally, it is interesting to note that our chemical shift data agree with the findings of Jackman and Wiley (4).

EXPERIMENTAL

The spectra were measured with a Varian V-4302 high resolution N.M.R. spectrometer. Peak separations in each multiplet were measured by the side band technique (16) employing a Hewlett–Packard wide-range oscillator. The accuracy of the oscillator was checked with a Hewlett–Packard standardized frequency counter and the error was found to be less than 0.5% in the range employed for coupling constant determinations and less than 0.75% when used for determination of chemical shifts. Each coupling constant is reported as the average of at least four determinations and the standard deviation is reported with each value. The spectrum of angelic acid was measured on a 10% solution in carbon tetrachloride. Those for tiglic acid and its methyl ester were obtained from 10% solutions in deuterobenzene and benzene respectively. Methyl angelate was run as the pure liquid. All chemical shifts were measured from 10% solutions in carbon tetrachloride containing 1% of tetramethylsilane as internal standard (17).

Tiglic Acid

This compound was prepared by the oxidation of tiglaldehyde by a modification of the method of Goldberg and Lindstead (18). A mixture of 52 g (0.6 mole) of tiglaldehyde, b.p. 114–115°, and 260 g (1.6 mole) of silver nitrate in 840 ml of 28% ethanol in a 3-l. flask was stirred for 4 hours. After standing for 12 hours the mixture was filtered. The filtrate was acidified and treated with 34 g (0.3 mole) of calcium chloride in 75 ml of water. The precipitated calcium salt was filtered off, and converted to the sodium salt by boiling with an excess of 10% sodium carbonate. The solution of the sodium salt was acidified, extracted with ether, and the dried extracts upon evaporation gave 32.5 g (53%) of tiglic acid, m.p. 64–65° (literature m.p. 64° (19)).

Methyl Tiglate

The methyl ester was obtained by esterification according to the method of Buckles and Mock (20). Methyl tiglate, b.p. 133–135°, n_D^{24} 1.4360 was obtained in 91% yield (literature b.p. 137.5–139°, n_D^{20} 1.4371 (20)).

Angelic Acid

Tiglic acid was converted to angelic acid by the procedure of Buckles and Mock (20). The over-all yield of angelic acid, m.p. 42–44°, was 39% (literature m.p. 44–45.2° (21)).

Methyl Angelate

Angelic acid was esterified by the procedure of Buckles and Mock (20). From 2.5 g of acid was obtained 1.5 g (52%) of methyl angelate, b.p. 125–126°, n_D^{24} 1.4307 (literature b.p. 127.2–128°, n_D^{20} 1.4330 (20)).

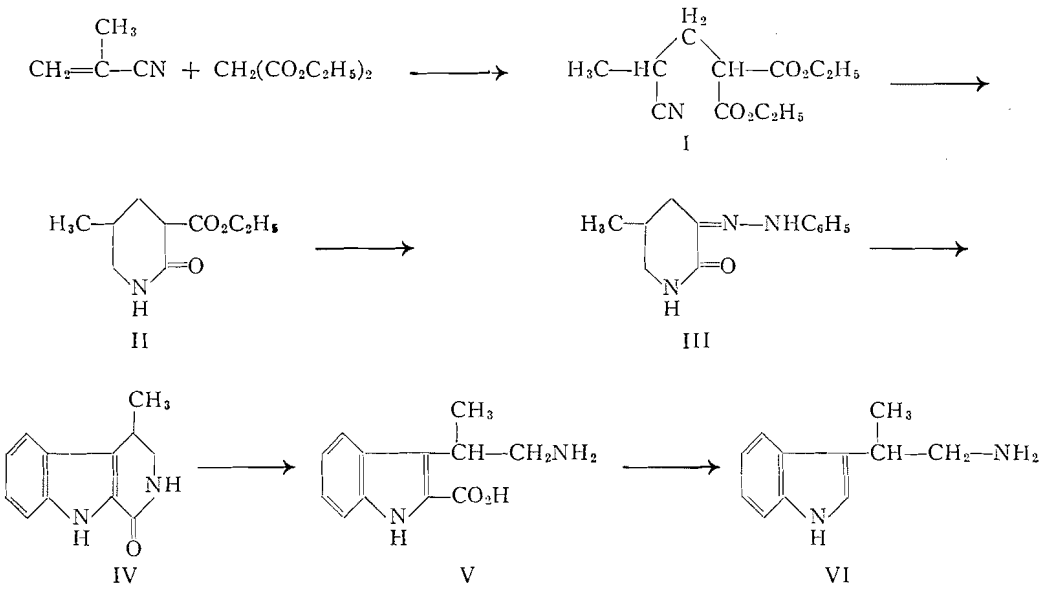
TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS

PART V. 3-(α-ALKYL-β-AMINOETHYL)INDOLES[1,2]



R. A. ABRAMOVITCH AND J. M. MUCHOWSKI

ABSTRACT

The scope of the tryptamine synthesis via 1-oxo-1,2,3,4-tetrahydro-β-carbolines has been extended to tryptamines bearing a side-chain α-alkyl group. The preparation of 3-(2-amino-1-methylethyl)indole by this procedure is described.

In a previous paper (1) an attempt was made to extend the method of synthesis of tryptamines via 1-oxo-1,2,3,4-tetrahydro-β-carbolines (2, 3) to the elaboration of the physostigmine ring system. The intermediate 4-methyl-2,3-dioxopiperidine 3-phenylhydrazone did not, however, undergo Fischer cyclization but instead rearranged to the geometrically isomeric phenylhydrazone. In order to examine the scope of this method of tryptamine synthesis the cyclization of 5-alkyl-substituted 2,3-dioxopiperidine 3-phenylhydrazones was examined, in particular that of 5-methyl-2,3-dioxopiperidine 3-phenylhydrazone (III). This reaction sequence should eventually lead to 3-(2-amino-1-methylethyl)indole (VI). This type of compound may be of physiological interest since Velluz (4) has shown that when a methyl substituent is introduced into the corresponding position in reserpine a more physiologically active compound is obtained.

The synthesis of the required indole was uneventful and followed the path described in the previous examples (2, 3):

Ethyl malonate was condensed with methacrylonitrile in the presence of sodium ethoxide giving diethyl 2-cyanopropylmalonate (I), which was hydrogenated to 3-ethoxycarbonyl-5-methyl-2-oxopiperidine (II). This underwent a Japp–Klingemann

[1]*Manuscript received December 14, 1959.*
Contribution from the Chemistry Department, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*Part IV: Can J. Chem.* **36**, *354 (1958).*

reaction with benzenediazonium chloride at pH 5 to give 5-methyl-2,3-dioxopiperidine 3-phenylhydrazone (III) which, unlike the corresponding 4-methyl-derivative, was cyclized quite smoothly to 4-methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (IV). Hydrolysis gave the amino acid (V). Decarboxylation of this acid takes place less readily than in the case of the unsubstituted tryptamine-2-carboxylic acid itself. Thus, whereas the latter yielded tryptamine in 75% yield after it was boiled for 1 hour with 10% hydrochloric acid, the methyl substituted acid only gave a 49% yield of 3-(2-amino-1-methylethyl)indole (VI) after it was boiled with 10% hydrochloric acid for 2 hours. In the latter case, an appreciable amount (44%) of unchanged acid is recovered. The methyltryptamine so obtained was identical with the product described by Noland and Lange (5) which these authors prepared from indole and 1-nitro-1-propene.

The method described above should be amenable to extension to the introduction of other alkyl groups, besides methyl, into the α-position of the tryptamine side chain, as well as to the preparation of such tryptamines bearing substituents in the benzene ring or on the nitrogen atoms (3).

EXPERIMENTAL

Melting points and boiling points are uncorrected. Infrared spectra were measured on a Perkin–Elmer Model 21 double-beam instrument using sodium chloride optics.

Diethyl 2-Cyanopropylmalonate (I)

To a cold solution of sodium (0.1 g) in absolute ethanol (10 ml) was added freshly distilled ethyl malonate (9.3 g). Methacrylonitrile (1.8 g) was added dropwise to the solution at such a rate that the temperature did not exceed 35°. The mixture was then stirred for 5 hours at room temperature, treated with acetic acid (0.3 g), diluted with water (15 ml), and extracted with ether (3×15 ml). The dried ($MgSO_4$) ether extract was evaporated and the residue distilled, ethyl malonate and any other low boiling products being collected below 130°. Vacuum distillation of the residual oil gave diethyl 2-cyanopropylmalonate (5.0 g, 84%) as a colorless liquid, b.p. 101–105°/0.23 mm. Calc. for $C_{10}H_{15}O_4N$: C, 58.16; H, 7.55. Found: C, 58.14; H, 7.79. Infrared spectrum (liquid film) (main bands only): 2240 (w), 1743 (s), 1728 cm^{-1} (s).

3-Ethoxycarbonyl-5-methyl-2-oxopiperidine (II)

Diethyl 2-cyanopropylmalonate (5.5 g) in absolute alcohol (100 ml) was hydrogenated over Raney nickel (0.2 g) at 80° and 1200 p.s.i. for 6 hours. The cooled solution was then filtered, evaporated on a steam bath, and the residue poured into 100 ml of light petroleum (b.p. 60–80°). The product crystallized immediately as a colorless solid (2.7 g, 60.2%). Recrystallization from light petroleum (b.p. 60–80°) containing a small amount of benzene gave colorless needles, m.p. 100–101°. Calc. for $C_9H_{15}O_3N$: C, 58.36; H, 8.16. Found: C, 58.47; H, 8.06. Infrared spectrum (Nujol mull) (main peaks only): 3196 (w), 1728 (s), 1674 (s), 1658 cm^{-1} (s).

5-Methyl-2,3-dioxopiperidine 3-Phenylhydrazone (III)

3-Ethoxycarbonyl-5-methyl-2-oxopiperidine (2.1 g) in water (25 ml) containing potassium hydroxide (0.7 g) was kept at room temperature overnight. The solution was cooled in an ice bath, stirred, and treated with a solution of benzenediazonium chloride (30 ml) (prepared from aniline (1.2 g), sodium nitrite (1.0 g), and concentrated hydrochloric acid (3 ml)). The mixture was immediately adjusted to pH 5 by the addition of cold 45% aqueous sodium acetate (25 ml). Stirring was continued at 0–10° for 4 hours, after which time the orange solid was filtered and dried, to give the phenylhydrazone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

(2.0 g, 81.2%). Recrystallization from dilute alcohol gave light yellow needles, m.p. 238–239°. Calc. for $C_{12}H_{15}ON_3$: C, 66.34; H, 6.96. Found: C, 66.35; H, 7.05. Infrared spectrum (Nujol mull) (main peaks only): 3174 (m) (br), 1660 (s), 1603 (m), 1564 (s), 753 (m), 693 cm^{-1} (m).

4-Methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (IV)

The phenylhydrazone (2.2 g) was boiled under reflux with 90% formic acid (10 ml) for 1 hour, the hot solution diluted with water, and the brown oil which separated just brought into solution with hot absolute alcohol. The hot solution, on cooling, gave the oxocarboline (1.6 g, 80%) which, on recrystallization from absolute alcohol, gave white plates, m.p. 204–206°. Calc. for $C_{12}H_{12}ON_2$: C, 71.98; H, 6.04. Found: C, 71.58; H, 6.17. Infrared spectrum (Nujol mull)(main peaks only): 3195 (m) (br), 1649 (s), 1620 (m), 747 cm^{-1} (s). The picrate separated from alcohol as deep red rectangular rods, m.p. 185–187°.

3-(2-Amino-1-methylethyl)indole-2-carboxylic Acid (V)

4-Methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (0.45 g) in 50% aqueous ethanol (10 ml) containing potassium hydroxide (1.1 g) was boiled under reflux for 6 hours. The solvent was evaporated down to 5 ml, water (5 ml) was added, and the cooled solution filtered and acidified with acetic acid giving the amino acid (0.48 g, 96.8%). Recrystallization from dilute ethanol gave lustrous white plates, m.p. 242–243° (decomp.). Calc. for $C_{12}H_{14}O_2N_2$: C, 66.03; H, 6.47. Found: C, 65.65; H, 6.86. Infrared spectrum (Nujol mull) (main peaks only): 3420 (w), 2121 (w), 1642 (w) (br), 1624 (m), 1563 (m), 1544 (m) (br), 755 cm^{-1} (s).

3-(2-Amino-1-methylethyl)indole (VI)

3-(2-Amino-1-methylethyl)indole-2-carboxylic acid (0.30 g) was boiled under reflux with 10% hydrochloric acid (10 ml) for 2 hours. The cooled solution was made alkaline with dilute sodium hydroxide, extracted with ether, the ether layer dried ($MgSO_4$), and evaporated leaving the tryptamine (0.117 g, 48.8%) as a light brown oil. Neutralization of the aqueous layer with dilute hydrochloric acid resulted in the recovery of unreacted amino acid (0.133 g). The indole was converted to the picrate (from ether). Recrystallization from water gave the picrate as deep orange plates, m.p. 224–226° (decomp.). Noland and Lange (5) report m.p. 224–226° for this picrate. Calc. for $C_{11}H_{14}N_2$, $C_6H_3O_7N_3$: C, 50.62; H, 4.25. Found: C, 50.18; H, 3.90.

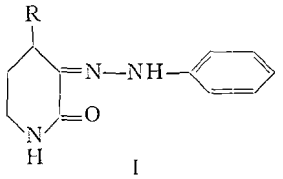
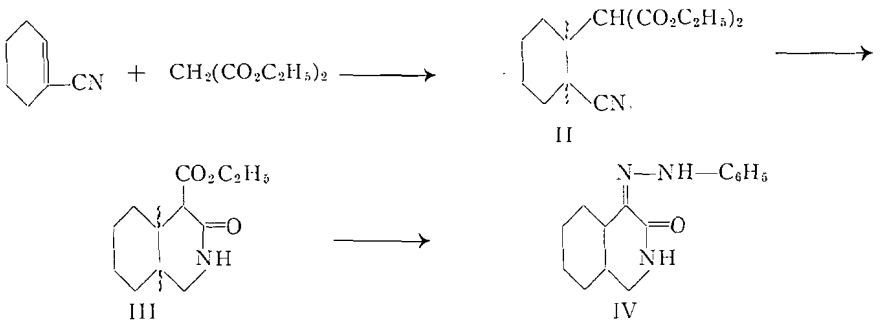
TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS



PART VI. STEREOCHEMISTRY OF THE MICHAEL ADDITION OF ETHYL MALONATE TO 1-CYCLOHEXENE CYANIDE[1,2]

R. A. ABRAMOVITCH AND J. M. MUCHOWSKI

ABSTRACT



The Michael addition of diethyl malonate to 1-cyclohexene cyanide has been shown to give a mixture of the *cis*- and *trans*-diethyl 2-cyanocyclohexylmalonates in 72% and 28% yields respectively. The stereochemistry of the products was established by their unambiguous conversion to the respective *cis*- and *trans*-decahydroisoquinolines. Hydrogenation of a cyclohexane cyanide to the corresponding aminomethyl derivative takes place with retention of configuration. A number of substituted decahydroisoquinolines of known stereochemistry have been prepared. Decahydro-3,4-dioxoisoquinoline-4-phenylhydrazone underwent Fischer cyclization to a product assumed to be 2-oxo-octahydroindolo[2,3-d]isoquinoline indicating that the observation that 4-methyl-2,3-dioxopiperidine-3-phenylhydrazone did not undergo cyclization is not general for such 4-substituted piperidones.

It was shown in Part IV (1) that 4-methyl-2,3-dioxopiperidine-3-phenylhydrazone (I:R = CH_3) did not undergo Fischer cyclization to the indolenine but instead was rearranged to a geometrically isomeric phenylhydrazone. On the other hand, 5-methyl-2,3-dioxopiperidine-3-phenylhydrazone underwent smooth cyclization to the oxocarboline (2). It was, therefore, of interest to establish whether this limitation in what appears to be a widely applicable method of preparation of tryptamines was general for 2,3-dioxopiperidine-3-phenylhydrazones (I) having alkyl substituents at the 4-position. To this end it was decided to study the cyclization of decahydro-3,4-dioxoisoquinoline-4-phenylhydrazone (IV). The choice of that particular compound was of twofold interest:

I

(*i*) the generality of the limitation mentioned above could be tested, and (*ii*) little is definitely known concerning the steric route of nucleophilic additions of the Michael type to cyclohexene derivatives, and the preparation of the required phenylhydrazone would involve a study of the addition of ethyl malonate to 1-cyclohexene cyanide, as shown in the following scheme:

The work described in this paper involves mainly a study of the stereochemistry of the above Michael addition and eventually of the cyclization of the phenylhydrazone (IV).

Previous work in this field may be summarized briefly. Kon and Qudrat-I-Khuda (3) could only isolate *cis*-decahydro-4-carbethoxy-1,3-dioxonaphthalene from the condensation of 1-cyclohexenylmethyl ketone with ethyl malonate, whereas Ruzicka, Koolhaas, and Wind (4) and also Chuang and Tien (5) reported getting a mixture of the *cis*- and *trans*-isomers in this reaction. Boorman and Linstead (6) reported that 1-carbethoxycyclohexene yielded a triester of unspecified orientation on condensation with ethyl malonate. This ester, on hydrolysis with concentrated hydrochloric acid, yielded solely *trans*-hexahydrohomophthalic acid. Wohl and Losanitsch (7) carried out a similar reaction between ethyl malonate and 3-cyano-1,2,5,6-tetrahydropyridine and obtained a mixture of the *cis*- and *trans*-diethyl (3-cyano-4-piperidyl)malonates. Mixtures of stereoisomers were also obtained in the condensation of the sodio-derivative of 6-methoxy-1-tetralone with 1-acetylcyclopentene (8) and in the self-condensation of 1-acetylcyclohexene in the presence of sodamide (9, 10). On the other hand, Ginsburg and Pappo (11) condensed diethyl malonate with 2-phenyl-2-cyclohexenone; the orientation of the resulting malonate was not established, but after hydrolysis and decarboxylation to the acetic acid followed by Clemmensen reduction, *trans*-2-phenylcyclohexylacetic acid was obtained exclusively. As the authors rightly point out, isomerization to the more stable form may take place (particularly in the keto-malonate) so that the more stable form would be isolated after the sequence of reactions described. No conclusion can, therefore, be drawn concerning the steric mechanism of the addition reaction. The same comments would apply to the reactions studied by Bergmann and Szmuszkovicz (12). The above results do not provide conclusive evidence for the stereochemical course of addition. If, as seems likely, *trans*-addition predominates then the *cis*-isomer should be the one preferentially formed.

Addition of diethyl malonate to 1-cyanocyclohexene gave a mixture of the *cis*- and *trans*-diethyl 2-cyanocyclohexylmalonates (II). These could not be separated by fractional distillation so that a number of methods were explored to try and determine the relative proportions of the isomers. The mixture of cyano-esters was hydrolyzed to the corresponding mixture of hexahydrohomophthalic acids with boiling hydrochloric acid; it was hoped to separate these by fractional crystallization. This method of quantitative analysis of the cyano-esters was abandoned, however, when it was realized that the *cis*-acid may be converted to the more stable *trans*-form under the conditions used for the hydrolysis (13, 14). It is, therefore, not possible to assign any specific configuration to the triester obtained by Boorman and Linstead (6) which these authors hydrolyzed to *trans*-hexahydrohomophthalic acid using the above procedure.

The mixture of the stereoisomeric esters was hydrogenated to *cis*- and *trans*-decahydro-4-ethoxycarbonyl-3-oxoisoquinolines (V) which could be separated by chromatography on alumina into the two individual isomers: *cis*-68%, *trans*-32%. The configuration of each one of the isomers was established by converting it into the corresponding decahydroisoquinoline (VIII) of known geometry (15) by a series of reactions which could not effect inversion of configuration at the ring junctions. The method used is illustrated by the following equations:

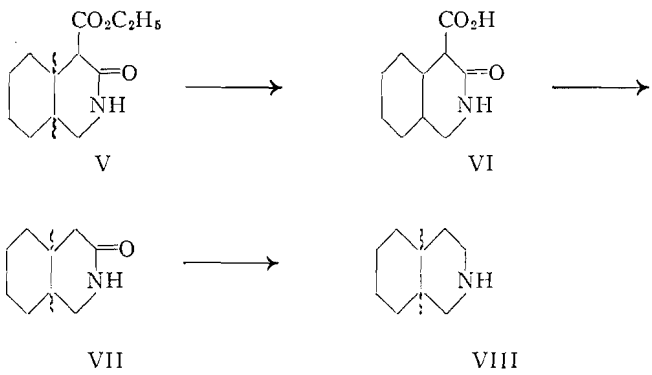

CHART I.

The pure amido-ester was saponified at room temperature to the decahydro-3-oxo-isoquinoline-4-carboxylic acid (VI) which, on being heated to its melting point, underwent decarboxylation to the decahydro-3-oxoisoquinoline (VII). This was reduced with lithium aluminum hydride to the known *cis-* or *trans*-decahydroisoquinoline thus establishing the conformation of the amido-ester. The same series of reactions was carried out on the mixture of *cis-* and *trans-* (V) before chromatography, final separation of the isomers being effected by fractional crystallization of the picrates of the secondary amines (VIII). This method gave the values *cis*-66%, *trans*-34%, which, though undoubtedly less reliable than the estimation by chromatographic separation, is in close agreement with it.

It should be emphasized at this stage that the stereospecificity of the reduction of a nitrile such as (II) to a cyclic amide via the primary amine seems to have had, up to this time, no experimental backing in the literature, and could therefore not be assumed. Unless such a reduction was stereospecific the quantitative data for the ratio of *cis*-to-*trans* amido-esters (V) could not be assumed to hold for the cyano-esters (II). It is theoretically possible that on hydrogenation the cyano-esters could pass through an intermediate such as (IX), and if one assumes, as is likely, that the larger malonate group is equatorial (16) in both cases, this intermediate will be the same for both geometrical isomers. Such being the case one would expect to get either the *same* geometrical isomer starting from the *cis-* or the *trans*-cyanide or the same mixture of geometrical isomers from each on hydrogenation of the cyano group. The absence of such an effect could be taken as evidence that an intermediate of the type IX was not involved and that reduction was indeed stereospecific.

At that stage two rather fortunate observations were made. A number of unsuccessful attempts had been made to resolve the mixture of cyano-esters by vapor phase chromatography using a variety of columns such as silicone on firebrick and polyesters on celite. It was now found that the geometrical isomers could be easily separated and estimated quantitatively using an Apiezon "M" column operated at 160°. The ratio of the two isomers was 72% to 28% as determined by this method. There was, however, no way of knowing which was which until it was observed that a sample of the mixed cyano-esters which had been standing for a few months deposited crystals of one of the isomers. These were filtered off and, after further recrystallization, shown to consist of a single isomer by vapor phase chromatography. The residual oil, on repeated distillation, gave a pure sample of the other geometrical isomer. Each one of these isomers was now catalytically

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

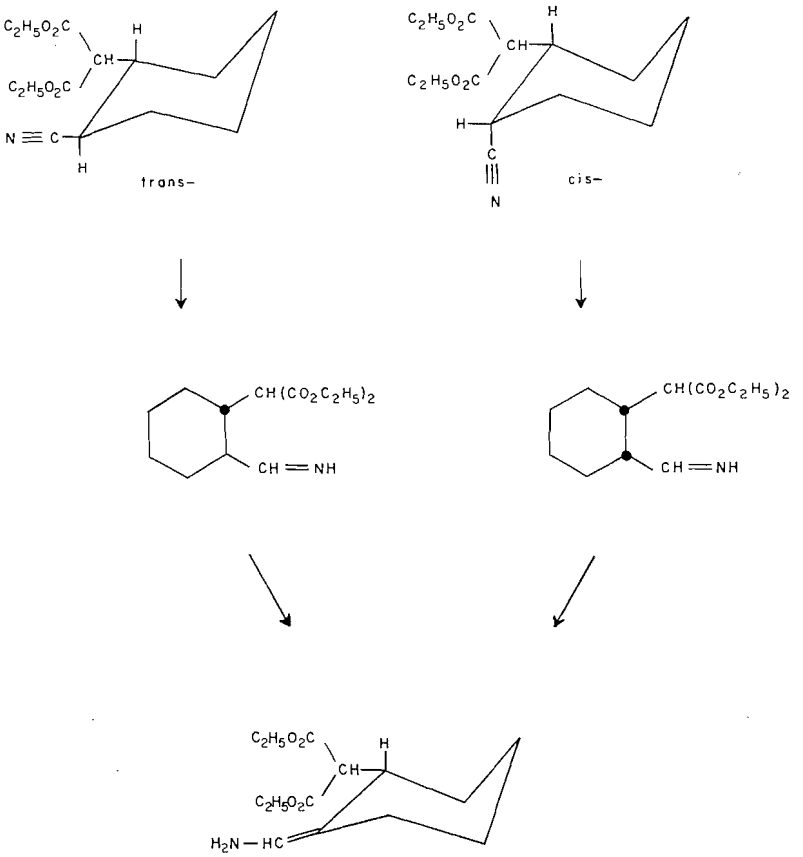

CHART II.

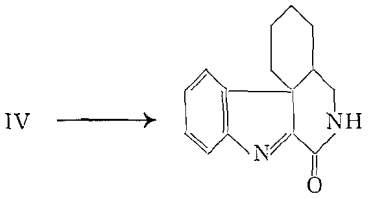
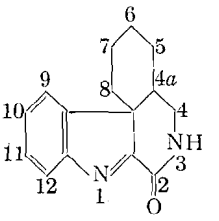


reduced individually and each one gave a single geometrical isomer of the corresponding amido-esters: the *trans*-form from the crystalline cyano-ester, and the *cis*-form from the liquid one. From the considerations outlined above it may be concluded that the catalytic reduction of the nitriles did not involve a change in the configuration so that the ratio of isomers obtained from the Michael addition is *cis*-72%, *trans*-28%. These figures are in close agreement with those obtained from the chromatography of the amido-esters on alumina, and it is felt that the difference between them falls within the experimental error expected for this type of estimation.

The results indicate that, as anticipated, the addition of diethyl malonate to 1-cyanocyclohexene gives predominently the *cis*-isomer, but that the *trans*-isomer is also formed in appreciable quantity. It should be emphasized that these results give the postequilibrium ratio of isomers. Work is at present under way to determine whether they apply also to pre-equilibrium conditions. If so, the mechanistic conclusion could be drawn that the Michael reaction proceeded, in this case, predominently by *trans*-addition. The equilibration of each of the cyano-esters is also being examined. The hydrogenation results indicate, however, that probably no equilibration of the cyano-esters takes place under vigorous treatment in the presence of base (the secondary amine is formed as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

by-product) so that predominent *trans*-addition might be tentatively assumed. As a by-product of the reactions a number of substituted decahydroisoquinolines (V, VI, VII) of known geometry have been obtained.



The mixture of amido-esters (V) was saponified and treated with benzenediazonium chloride to give a low yield of a single decahydro-3,4-dioxoisoquinoline-4-phenylhydrazone (IV). Since equilibration is possible at this stage one would expect the more stable of the two isomers, probably the *trans*-, to be formed. The geometry of the product was not determined though it is proposed to do so later. A red, tarry substance, assumed to be the phenylazo-derivative on the basis of its infrared spectrum, was also isolated but was not investigated further at this stage. When the phenylhydrazone was boiled with 90% formic acid a base was obtained which is tentatively assigned the structure 2-oxo-2,3,4,4*a*, 5,6,7,8-octahydroindolo[2,3-d]isoquinoline (X).* The evidence in support of this assign-

X

ment is based on the ultraviolet (see Fig. 1) and infrared spectra and on microanalytical data. The latter were not too good since, though the expected values were obtained in one instance, a somewhat lower value for carbon was obtained on a repeat analysis of a different sample. The nitrogen analysis also gave low values but indicated quite definitely that one nitrogen atom had been lost during the cyclization. There was not sufficient material on hand to repeat the purification of this compound, but this will be done as soon as possible. An interesting feature of the infrared spectrum of the cyclized product was the presence of *two* peaks in the 800–680 cm^{-1} region (765 and 685 cm^{-1}). This is unexpected, and might be due to some contamination which could perhaps be giving rise to the 685 cm^{-1} band, though the intensity of the latter seems to render this rather doubtful. The compound also exhibits two melting points, melting at 150°, resolidifying above that temperature, and melting again at 186–187°. After heating above 150°, the solid product only exhibited a *single* infrared peak in the aromatic C—H out-of-plane deformation region, at 758 cm^{-1}. Attempted hydrolysis of the amide (X) to an amino acid with ethanolic alkali gave rise instead to an isomeric product, m.p. 240–242°. The analysis of this substance agrees with the formula $C_{15}H_{16}ON_2$ but its infrared spectrum and particularly its ultraviolet absorption spectrum differ from those of X. The structure of this compound is presently under investigation.

**Proposed numbering for this ring system:*

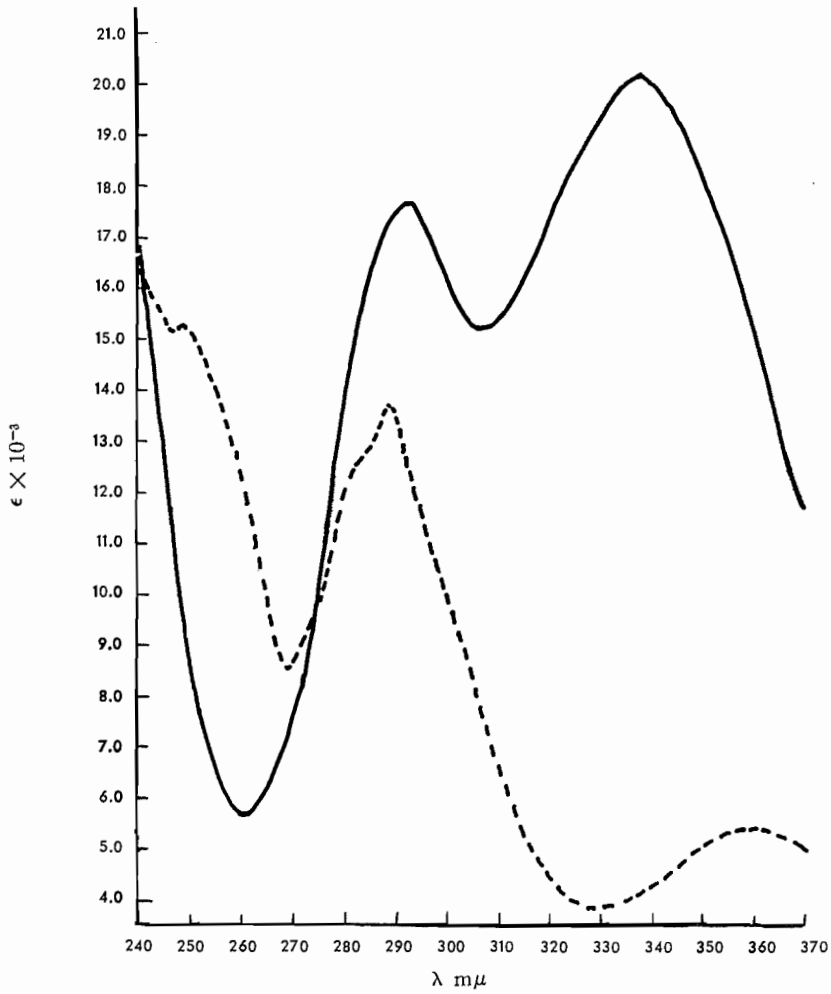

FIG. 1. —— Decahydro-3,4-dioxoisoquinoline-4-phenylhydrazone.
– – – 2-Oxo-2,3,4,4*a*,5,6,7,8-octahydroindolo[2,3-b]isoquinoline.

The results of the acid treatment of the phenylhydrazone (IV) indicate at least that the limitation reported (1) in the attempted cyclization of (I: R = CH_3) is not a general one for 4-substituted 2,3-dioxopiperidine-3-phenylhydrazones, since cyclization of some sort has occurred in the present case. Clearly, further work is necessary to clarify the identity of the cyclized product and of the isomeric amide it gives on prolonged alkali treatment. This will be reported on at a later date.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrometer using sodium chloride optics. Ultraviolet absorption spectra were recorded on a Beckman DK2 spectrophotomer.

Diethyl 2-cyanocyclohexylmalonate

To a stirred solution of sodium ethoxide (from 16.9 g of sodium in 300 ml of absolute alcohol) was added freshly distilled diethyl malonate (170.5 g). To this solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

added 1-cyclohexene cyanide (29.8 g), prepared by the procedure of McElvain and Starn (17) and the solution boiled under reflux for 24 hours when the initially colorless solution turned yellow. The solution was cooled, treated with glacial acetic acid (46.0 g), extracted with water (3×100 ml), and the aqueous solution extracted with ether (3×50 ml). The ether extract and the organic layer were combined, dried ($MgSO_4$), and the solvent removed. The residue was distilled up to 130° (bath temp.)/15 mm to remove excess diethyl malonate and any other low-boiling material and the residue distilled *in vacuo*, the fraction boiling at 125–135°/0.34 mm (53.0 g, 71% yield) being collected as the mixture of geometrically isomeric cyano-esters. This on redistillation had b.p. 119–125°/0.28 mm. Calc. for $C_{14}H_{21}O_4N$: C, 62.90; H, 7.92. Found: C, 62.35; H, 7.61.

Separation and Quantitative Analysis of the cis- and trans-Diethyl 2-Cyanocyclohexylmalonates by Vapor Phase Chromatography

A Beckman vapor phase chromatograph (Model GC-2) was used with a 4-ft Apiezon "M" on firebrick column operated at 160° and a helium inlet pressure of 20 p.s.i. The mixture (0.005 ml) was chromatographed and the areas under the curves for each isomer measured. The pure *trans*-isomer (0.005 ml) was then chromatographed and the area under the curve also measured.

% *trans*-diethyl 2-cyanocyclohexylmalonate: 27.6,

% *cis*-diethyl 2-cyanocyclohexylmalonate: 72.4 (by difference).

trans-Diethyl 2-Cyanocyclohexylmalonate

After standing for some months, *trans*-diethyl 2-cyanocyclohexylmalonate crystallized from the mixture as colorless needles. It was filtered and recrystallized from light petroleum (b.p. 60–80°) to give large, colorless, rectangular rods, m.p. 50–52°. Calc. for $C_{14}H_{21}O_4N$: C, 62.90: H, 7.92. Found: C, 63.26; H, 7.86. Infrared spectrum (liquid film) (main peaks only): 2242 (w), 1747 (s), 1732 cm^{-1} (s).

cis-Diethyl 2-Cyanocyclohexylmalonate

After removal of the *trans*-isomer by filtration from the above mixture the filtrate consisted almost entirely of *cis*-diethyl 2-cyanocyclohexylmalonate (as shown by vapor phase chromatography). Distillation under reduced pressure gave the pure *cis*-isomer, entirely free of the *trans*-form as far as could be detected by vapor phase chromatography, as a colorless mobile liquid, b.p. 118–120°/0.28 mm. Found: C, 62.56; H, 7.83. Infrared spectrum (liquid film) (main peaks only): 2242 (w), 1746(s), 1731 cm^{-1} (s).

cis- and trans-Hexahydrohomophthalic acid

The mixed diethyl 2-cyanocyclohexylmalonates (1.0 g) were boiled under reflux with 10% hydrochloric acid (30 ml) for 4 hours. The solvent was evaporated giving a brown oil (0.65 g, 93.2%) which solidified on cooling. Recrystallization of the product from water gave white rosettes of the mixture of the two isomeric acids, m.p. 90–130°. Infrared spectrum (Nujol mull) (main peaks only): 2645 (m)(br), 1705 (s), 1689 cm^{-1} (s). Windaus, Hückel, and Reverey (13) report m.p. 146° for *cis*- and m.p. 157° for *trans*-hexahydrohomophthalic acid respectively.

cis- and trans-Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline

The mixture of stereoisomeric diethyl 2-cyanocyclohexylmalonates (5.5 g) in commercial absolute alcohol (50 ml) was hydrogenated over Raney nickel (0.2 g) at 110–120° and 1200 p.s.i. for 9 hours. The solution was filtered, the ethanol removed on a steam bath, and the residue distilled under reduced pressure to give the mixture of amido-esters as a very viscous liquid (3.1 g, 66.8%), b.p. 160–185°/0.4 mm. Calc. for $C_{12}H_{14}O_3N$: C, 63.97;

H, 8.50. Found: C, 63.74; H, 8.55. The mixture of esters (1.269 g) was chromatographed on a column of neutral alumina (3/4 in.×12 in.). Elution with ether–ethanol (200 ml) (20:1 v/v) gave the *trans*-isomer (0.406 g, 32.5%) identical with the product obtained as described below. Elution with hot alcohol (500 ml) gave the *cis*-isomer (0.843 g, 67.5%) identical with the product described below.

trans-Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline

trans-Diethyl 2-cyanocyclohexylmalonate (3.0 g) was hydrogenated as described for the mixture of cyanides to give the pure *trans*-β-amido-ester (1.6 g, 63.3%) as a colorless, viscous liquid, b.p. 160–170°/0.04 mm, which slowly solidified. Crystallization from light petroleum (b.p. 60–80°) gave colorless needles, m.p. 114–115°. Calc. for $C_{12}H_{14}O_3N$: C, 63.97; H, 8.50. Found: C, 64.58; H, 7.95. Infrared spectrum (Nujol mull) (main peaks only): 3208 (w)(br), 1729 (s), 1673 cm^{-1} (s).

cis-Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline

cis-Diethyl 2-cyanocyclohexylmalonate (4.8 g) treated in a manner analogous to the *trans*-compound yielded the *cis*-amido-ester (2.4 g, 59.4%) as a colorless viscous liquid, b.p. 136–140°/0.022 mm. Found: C, 64.25; H, 8.51. Infrared spectrum (liquid film) (main peaks only): 3187 (m)(br), 1724 (s), 1656 cm^{-1} (s).

trans-Decahydro-3-oxoisoquinoline-4-carboxylic Acid

trans-Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline (0.62 g) in water (10 ml) containing potassium hydroxide (0.3 g) was shaken mechanically at room temperature for 12 hours, the solution filtered, acidified with concentrated hydrochloric acid, and set aside. After 2 hours the β-amido-acid had separated out (0.54 g, 100%) as short, colorless needles which on recrystallization from water had m.p. 113–115° (decomp.). Calc. for $C_{10}H_{15}O_3N$: C, 60.89; H, 7.67. Found: C, 60.37; H, 7.31. Infrared spectrum (Nujol mull) (main peaks only): 3297 (w)(sh), 3194 (m), 2590 (m)(br), 1735 (s), 1645 cm^{-1} (s).

trans-Decahydro-3-oxoisoquinoline

trans-Decahydro-3-oxoisoquinoline-4-carboxylic acid (0.180 g) was heated in an oil bath at 110–120° until effervescence ceased. The viscous oil remaining was sublimed at 110–120°/20 mm giving the colorless amide (0.060 g, 42.8%) which was recrystallized from light petroleum (b.p. 60–80°) containing a small amount of benzene and had m.p. 165–167°. Calc. for $C_9H_{15}ON$: C, 70.55; H, 9.87. Found: C, 70.61; H, 9.75. Infrared spectrum (Nujol mull) (main peaks only): 3216 (m), 3042 (m)(sh), 1654 cm^{-1} (s).

trans-Decahydroisoquinoline

trans-Decahydro-3-oxoisoquinoline (0.200 g) in dry dioxan (5 ml) was added to a suspension of lithium aluminum hydride (0.200 g) in dry ether (25 ml) at such a rate as to keep the ether boiling. When the addition was complete the mixture was boiled under reflux in an atmosphere of nitrogen for 5 hours. The suspension was cooled, the excess metal hydride decomposed by the careful addition of water, and the product extracted with ether (3×25 ml) and dried ($MgSO_4$). The solvent was evaporated, eventually under vacuum, to give the base (0.130 g, 71.4%) as a colorless oil. The amine was converted to its picrate (from ethanol); this, on recrystallization from methanol, gave *trans*-decahydroisoquinoline picrate, m.p. 172–174°. Gray and Heitmeier (18) report m.p. 173–174° for this picrate.

cis-Decahydro-3-oxoisoquinoline

cis-Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline (2.83 g) in water (25 ml) containing potassium hydroxide (1.0 g) was mechanically shaken at room temperature for 12 hours.

The solution was filtered, acidified with concentrated hydrochloric acid, and kept in the refrigerator. After 24 hours a few crystals of the acid had separated as fine colorless needles. No attempt was made to purify this acid. The acidic solution was evaporated to dryness, the solid residue extracted with absolute alcohol (3×10 ml), the alcohol solution filtered and evaporated, and the residue heated in an oil bath at 100–110°. When effervescence had ceased the viscous oil obtained was sublimed at 100–110°/20 mm to give the *cis*-amide (1.05 g, 59.4%); this, on recrystallization from light petroleum (b.p. 60–80°), gave colorless flakes, m.p. 149–151°. Calc. for $C_9H_{15}ON$: C, 70.55; H, 9.87. Found: C, 70.60; H, 9.85. Infrared spectrum (Nujol mull) (main peaks only): 3214 (w), 3044 (w)(sh), 1654 cm^{-1} (s).

cis-Decahydroisoquinoline

The above amide (0.30 g) was treated with lithium aluminum hydride as described for the *trans*-amide to give the *cis*-base (0.20 g, 73.3%). The picrate, on recrystallization from methanol, gave pale yellow plates, m.p. 150–152°. Witkop (15) reported m.p. 150° for *cis*-decahydroisoquinoline picrate.

cis- and trans-Decahydro-3-oxoisoquinoline

The mixed decahydro-4-ethoxycarbonyl-3-oxoisoquinolines (0.219 g) were hydrolyzed and decarboxylated as described in the preparation of pure *cis*-decahydro-3-oxoisoquinoline. The mixture of amides (0.105 g, 70.5%), after sublimation at 100–110°/20 mm, had m.p. 65–95°.

cis- and trans-Decahydroisoquinoline

The mixture of *cis*- and *trans*-decahydro-3-oxoisoquinolines (0.585 g) in dry dioxan (10 ml) was reduced with lithium aluminum hydride (0.750 g) in dry ether (50 ml) as described for the preparation of *trans*-decahydroisoquinoline to give the mixture of bases (0.449 g, 84.5%) as a colorless oil. The picrates were prepared and fractionally crystallized as follows: The dried picrates (0.400 g) were washed five times with 1-ml portions of cold methanol. This removed mainly the *trans*-decahydroisoquinoline picrate. Recrystallization of the residue from methanol gave the *cis*-picrate (0.260 g, 66.2%), m.p. 150–152°. The combined cooled methanol extracts were slowly evaporated to give the *trans*-picrate as large, yellow, rectangular prisms which could easily be separated mechanically from some *cis*-picrate. After two recrystallizations from methanol the *trans*-picrate (0.133 g, 33.8%) had m.p. 172–174°.

Decahydro-3,4-dioxoisoquinoline-4-phenylhydrazone

Decahydro-4-ethoxycarbonyl-3-oxoisoquinoline (10.1 g, *cis* and *trans*) in water (50 ml) containing potassium hydroxide (2.6 g) was shaken mechanically at room temperature for 12 hours. The solution was cooled to 0° and adjusted to pH 5 with glacial acetic acid. To the stirred solution was added a solution of benzenediazonium chloride (70 ml) (prepared from 4.3 g of aniline, 3.4 g of sodium nitrite, and concentrated hydrochloric acid (7.0 ml)). The mixture was immediately adjusted to pH 5 by the addition of cold, 45% aqueous sodium acetate. Stirring was continued at 0–10° for 10 hours after which the suspension was kept in a refrigerator for 12 hours. The yellow brown solid (6.5 g) was filtered, dried, and extracted with benzene leaving behind the phenylhydrazone as a pale yellow solid (2.6 g, 22.6%). Recrystallization from dilute ethanol gave pale yellow needles, m.p. 214.5–215.5°. Calc. for $C_{15}H_{19}ON_3$: C, 70.00; H, 7.44. Found: C, 69.69; H, 7.68. Infrared spectrum (Nujol mull) (main peaks only): 3163 (w)(br), 1660 (s), 1602 (m), 1564 (m), 750 (m), 694 cm^{-1} (m). Ultraviolet absorption spectrum (in absolute ethanol), λ_{max}293, 338 mμ. $\epsilon \times 10^{-3}$ 17.67, 20.16.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

Evaporation of the benzene washings above gave a red, tarry substance, assumed to be the phenylazo-derivative, which was not investigated further at this stage. Infrared spectrum (liquid film) (main peaks only): 3140 (s)(br), 1714 (m)(sh), 1639 (s), 1604 (s), 1547 (s), 752 (s), 692 cm^{-1} (s).

*2-Oxo-2,3,4,4a,5,6,7,8-octahydroindolo[2,3-*d*]isoquinoline*

The phenylhydrazone (0.993 g) was boiled under reflux with 90% formic acid (8 ml) for 1/2 hour, the solution cooled and filtered. The filtrate was made slightly alkaline (pH 8) with dilute sodium hydroxide, and the solid which separated (0.424 g, 45.7%) filtered and recrystallized from benzene, to give colorless needles, melting completely and sharply at 150°, resolidifying above that temperature, and melting again at 186–187°. Calc. for $C_{15}H_{16}ON_2$: C, 74.70; H, 6.72. Found: C, 74.97; H, 6.72. Infrared spectrum (Nujol mull) (main peaks only): 3192 (w)(br), 1672 (s), 1640 (m)(sh), 1599 (m), 765 (s), 685 cm^{-1} (m). Ultraviolet absorption spectrum (in absolute ethanol): λ_{max} 248 (infl.), 289, 360 mμ. $\epsilon \times 10^{-3}$ 15.27, 13.69, 5.4. After being heated to 150° and cooled again the compound exhibited the following peaks in the infrared: 3330 (w)(br), 1680 (s), 1602 (m), 758 cm^{-1} (m).

*Alkali Isomerization of 2-Oxo-2,3,4,4a,5,6,7,8-octahydroindolo[2,3-*d*]isoquinoline*

The indolenine (0.070 g) in 50% aqueous ethanol (5 ml) containing potassium hydroxide (0.5 g) was boiled under reflux for 6½ hours. The hot solution was filtered and gave, on cooling, a white crystalline solid (0.035 g). Acidification of the mother liquors with acetic acid did not give any of the expected amino acid. The solid obtained above was recrystallized from benzene to give colorless needles, m.p. 240–242° (decomp.). Calc. for $C_{15}H_{16}ON_2$: C, 74.97; H, 6.72. Found: C, 74.61; H, 7.21. Infrared spectrum (Nujol mull) (main peaks only): 3365 (m), 3182 (w)(br), 1667 (s), 1608 (m), 740 cm^{-1} (s). Ultraviolet absorption spectrum (in absolute ethanol): λ_{max} 235, 236 (infl.), 243, 248, 254, 260 mμ. $\epsilon \times 10^{-3}$ 13.66, 13.45, 12.79, 11.97, 11.20, 9.47.

THE KINETICS OF THE FORMATION OF THE MONO-FLUORO COMPLEX OF IRON (III) IN AQUEOUS SOLUTION[1]

D. POULI[2] AND W. MACF. SMITH[3]

ABSTRACT

The kinetics of the reactions involved in the formation of the mono-fluoro complex of iron (III) in aqueous solutions have been examined spectrophotometrically at ionic strength 0.5 and over the temperature interval 0.1 to 12.1° C. The results are interpretable on the assumption that the following two reactions contribute significantly to the rate $Fe^{+++} + F^- = FeF^{++}$ and $Fe^{+++} + HF = FeF^{++} + H^+$, the former having a heat of activation of 22.8 ± 2.5 kcal mole^{-1} and an entropy of activation of 35 ± 9 cal deg^{-1} mole^{-1}, the latter having a heat of activation of 8.7 ± 0.7 kcal mole^{-1} and an entropy of activation of -24.5 ± 3 cal deg^{-1} mole^{-1}.

INTRODUCTION

Reactions involving association of cations and anions may be considered displacement reactions in which the ligand displaced from the cation is a solvent molecule, e.g. $M(H_2O)_n^+ + X^- \rightarrow M(H_2O)_{n-1}X + H_2O$. Kinetic aspects of such reactions will reflect the nature of the path by which reaction occurs. The transition state associated with the prevailing path may involve loss of solvent molecules from the inner solvation spheres of the interacting ions (1) as well as reorganization of more distant solvent. It is also possible that protolytic changes in the co-ordinated solvent may be involved in some of the alternative mechanisms by which the net reactions may occur (2, 3, 4).

Although these so-called association reactions are among the simplest of those occurring in solution, experimental data relating to their kinetics are restricted. Eigen (5) is contributing valuable data about very fast reactions through his technique of relaxation spectrometry. The slow associations of chromic and thiocyanate have been studied by Postmus and King (2), of chromic and oxalate by Hamm and Davis (3). Below, Connick, and Coppel have recently published work on the ferric-thiocyanate association (4). Smith found that ferric and fluoride associates at a rate measurable with stop watch timing (6).

This paper deals with an extension of Smith's work to a wider range of acidities (and of necessity to a higher ionic strength) and to a range of temperatures. A spectrophotometric rather than the redox method used in the preliminary work has been used to follow the reaction, but the conditions studied have been restricted to those yielding rates measurable with stop watch timing.

EXPERIMENTAL

The course of the reaction was followed spectrophotometrically at 260 mμ using Beckman quartz cells of 1 cm path length as reaction vessels. At this wavelength there is a substantial increase in transmission accompanying the association reaction, ranging from about 25 to 300% under the range of conditions studied. The segment of a Beckman DU spectrophotometer normally housing the cell holder was replaced by an extended segment which housed a specially constructed holder for two quartz cells. This holder was machined from a brass block so that it had channels to carry thermostating water and demisting tubes which directed thermostated dry gas against the windows of the cells.

During a kinetic run 2 ml of a solution containing ferric perchlorate, perchloric acid, and sodium perchlorate, previously brought close to reaction temperature in a thermostat bath, was pipetted into the reaction cell and also into a reference cell in the cell holder. The solution containing fluoride was added to the solution in the reaction vessel from a fine polythene tube connected to a 5-ml glass syringe. Prior to addition, the small volume (about 0.03 ml) of solution containing hydrogen fluoride, sodium perchlorate, and perchloric acid was in a length of the polythene tubing within the quartz cell. Pushing the plunger of the syringe introduced the solution of fluoride followed by a stream of gas which ensured mixing. The volume of solution introduced was reproducible to $\pm 2\%$. A small length of gas in the tubing between the fluoride solution and the exit of the tubing prevented loss of fluoride to the ferric solution prior to the pressing of the syringe.

Adequacy of mixing involved in this procedure was examined by adding acidified ferric perchlorate solution to dilute perchloric acid in the reaction vessel, using the same volumes as those involved during addition of fluoride, and noting the time required for attainment of a steady value for the transmission. It was found that a steady reading was attained within the time required to deliver the gas from a regular 5- or 10-ml syringe which was about three seconds. It should be noted that the values of the rate constant determined as indicated below are not dependent on knowledge of the exact time of mixing or the exact amount of reaction occurring during the mixing period and that some variability in the amount of reaction during the mixing procedure would not introduce an error in the rate constant. Trial kinetic runs carried out using various slit widths and wavelength settings of 240 mμ and 250 mμ as well as 260 mμ indicated no significant dependence between apparent reaction rate and slit width or wave length. The removal of fluoride by reaction with the wall of the reaction vessel was examined by gently agitating the equilibrium mixture containing ferric and fluoride for about thirty minutes (a period much in excess of that of a kinetic run) and noting the dependence of transmission on time. Four quartz vessels were examined and one only yielded a change of transmission with time. This vessel also gave irreproducible kinetic results. It was not used in further kinetic measurements and the data obtained during its use are not included in the results given below.

Initial and final transmittance readings were made on both reaction and reference cells but no attempt was made to correct the transmittance readings obtained with the reaction cell during the main course of the association which occupied periods ranging from about 150 down to 60 seconds after addition of fluoride.

All solutions were prepared from triply distilled water, the second distillation being from alkaline permanganate solution. Sodium perchlorate (anhydrous), perchlorate acid (70%), and ferric perchlorate were reagent grade chemicals obtained from G. Frederick Smith Chemical Company. The 50% hydrofluoric acid was Fisher reagent. The stock solutions of hydrofluoric acid were stored and manipulated in polythene ware and the concentrations of the diluted solutions which served as stocks were estimated by adding slight excess of sodium hydroxide and back titrating with hydrochloric acid using phenolphthalein as indicator. The stock solutions of sodium perchlorate were prepared from sodium perchlorate which had been heated for about two hours at 140° C prior to weighing. The stock solution of ferric perchlorate was prepared by dissolving the reagent in approximately 1 molar perchloric acid. Iron content of this solution was determined by redox titration (7) and gravimetry (8). Total acid plus iron (precipitated as $Fe(OH)_3$) was determined by titration with sodium hydroxide to phenolphthalein end point.

TREATMENT OF THE DATA

The data involving transmission were interpreted using the relation

$$[1] \qquad \frac{x}{c_e} = \frac{\log T_t - \log T_0}{\log T_\infty - \log T_0}$$

where x is the concentration of FeF^{++} at time t, c_e is that at equilibrium, and T_0, T_t, and T_∞ represent transmittance readings before association, at time t, and at equilibrium. In the lower range of acidities used in this work hydrolysis of ferric ion is appreciable and $FeOH^{++}$ as well as Fe^{+++} and FeF^{++} will contribute to the effective extinction coefficient. However, as the hydrogen ion concentration remained substantially constant during a single run, so will the ratio $[Fe^{+++}]/[FeOH^{++}]$ and consequently a single effective extinction coefficient may be associated with all Fe (III) in the forms Fe^{+++} and $FeOH^{++}$ at a given acidity and temperature, and the change in optical density will be proportional to concentration of FeF^{++} as long as the production of FeF_2^+ is negligible.

To estimate the value of x from the primary experimental data it was necessary to know the value of c_e for a given set of conditions. This may be calculated using the relationship

$$[2] \qquad \frac{c_e}{rs(m-c_e)(n-c_e)} = K_e$$

where $m = [Fe^{+++}]+[FeOH^{++}]+[FeF^{++}]$ = total iron (III) concentration,

$n = [F^-]+[HF]+[FeF^{++}]$ = total fluoride concentration,

$$r = \frac{[Fe^{+++}]}{[Fe^{+++}]+[FeOH^{++}]} = \frac{[H^+]}{K_h+[H^+]},$$

$$s = \frac{[F^-]}{[F^-]+[HF]} = \frac{K_a}{K_a+[H^+]}.$$

K_e is the association quotient for the reaction $Fe^{+++} + F^- \rightleftharpoons FeF^{++}$, e.g., K_e is the equilibrium value of $[FeF^{++}]/[Fe^{+++}][F^-]$ where [ ] signifies concentration in moles/per liter,

K_h is the hydrolysis quotient for the reaction $Fe^{+++} + H_2O \rightleftharpoons FeOH^{++} + H^+$;

K_a is the ionization quotient for the reaction $HF \rightleftharpoons H^+ + F^-$.

Our measurements were made at ionic strength 0.50 with sodium perchlorate the main contributor and consequently the equilibrium quotient for any one of these three reactions should have a unique value at one temperature.

The values of the various equilibrium quotients used in reducing our data are given in Table I. They were obtained by extrapolation of log K–$(1/T)$ plots of the values for

TABLE I

Equilibrium quotients used in reduction of kinetic data

Temperature (° C)	Ionic strength	$K_a \times 10^3$ (mole liter^{-1})	$K_h \times 10^4$	$K_e \times 10^{-5}$ (mole^{-1} liter)
0.11	0.50	1.96	5.02	1.07

12.10	0.50	1.52	10.1	1.28

K_a, K_e, and K_h for ionic strength 0.5 and temperatures 15°, 25°, and 35° C given by Connick and co-workers (9).

Substitution of the value of c_e appropriate to a given set of conditions along with values of transmittance readings obtained during a kinetic run in equation 1 allowed values of x at various times during approach to equilibrium to be estimated. These were interpreted to yield rate constants by the method described below.

It was initially assumed that the sole reaction involved in the formation of FeF^{++} was a second-order association opposed by a first-order dissociation as summarized by

$$Fe^{+++} + F^- \underset{k_{-I}}{\overset{k_I}{\rightleftharpoons}} FeF^{++}. \qquad (I)$$

To interpret the data obtained over a range of acid concentrations, it was necessary to assume that the second-order reactions

$$Fe + {}^{+++}HF \underset{k_{-II}}{\overset{k_{II}}{\rightleftharpoons}} FeF^{++} + H^+ \qquad (II)$$

are also contributing substantially at higher acidities. Since [HF] is proportional to $[H^+][F^-]$, kinetic data will not distinguish between II and a hydrogen ion catalyzed association.

If I is the sole set of reactions involved, then

$$[3] \qquad \frac{d}{dt}[FeF^{++}] = k_I[Fe^{+++}][F^-] - \frac{k_I}{K_e}[FeF^{++}]$$

or

$$\frac{dx}{dt} = k_I\left\{rs(m-x)(n-x) - \frac{1}{K_e}x\right\}$$

if the rates of ionization of hydrogen fluoride and of hydrolysis of ferric ion are relatively fast.

If reactions II are also involved,

$$\frac{d[FeF^{++}]}{dt} = k_I[Fe^{+++}][F^-] + k_{II}[Fe^{+++}][HF] - \frac{k_I}{K_e}[FeF^{++}] - \frac{k_{II}}{K_eK_a}[FeF^{++}][H^+].$$

This may be rewritten as

$$[4] \qquad \frac{dx}{dt} = \left(k_I + \frac{1-s}{s}k_{II}\right)\left\{rs(m-x)(n-x) - \frac{1}{K_e}x\right\}$$
$$= k'\left\{rs(m-x)(n-x) - \frac{1}{K_e}x\right\}.$$

The solution of [3] is

$$[5] \qquad \frac{1}{rs}\frac{1}{\sqrt{q}}\log\frac{2ax+b-\sqrt{q}}{2ax+b+\sqrt{q}} = k_It + \text{constant}$$

where

$$a = 1,$$
$$b = -m-n-\frac{1}{K_ers},$$
$$c = mn,$$
$$q = b^2-4ac.$$

The solution of [4] is the same except that k_I of [5] is replaced by k' where $k' = k_I + \{(1/s)-1\}k_{II}$.

If the above-mentioned assumptions are correct a plot of the values of the expression on the left of equation 5 against time should lie in a straight line. If reactions I are the sole contributors, the slope will be independent of $[H^+]$ and equal to k_I. If reactions II are also contributing then the slope will be dependent on $[H^+]$ and equal to k' $(= k_I + \{(1/s)-1\}\, k_{II})$. In the latter event a plot of k' against $1/s-1$ should yield a straight line with intercept at $1/s-1 = 0$ equal to k_I and slope equal to k_{II}.

EXPERIMENTAL RESULTS

Most of our measurements have been carried out at ionic strength 0.50, with acid concentrations ranging from 0.02 to 0.40 molar and the maximum Fe (III) concentration about 10^{-3} molar. The highest concentrations of Fe (III) which could be conveniently studied in the 1-cm cells were limited by the very high molecular extinction coefficient of ferric ion at 260 mμ (10) and also at lower acidities by complications which would be introduced due to the formation of condensed species such as $Fe_2(OH)_2^{4+}$ (10, 11). In all determinations the concentration of total fluoride was less than that of total ion, a condition particularly important at higher concentrations in maintaining a low value for the ratio $[FeF_2^+]/[FeF^{++}]$. We estimate, using values for the first and second association quotients derived from Connick's values (9), that the maximum equilibrium value for this ratio under any of our experimental conditions was less than 0.03.

The data obtained under each set of conditions which we examined were interpreted as indicated above and the quantity on the left of equation 5 when plotted against time yielded quite good straight lines regardless of the conditions. Figure 1 shows a plot of

have a moderate scatter there is no significant dependence on the total concentration of iron (III) or of fluoride. However, there is a positive and significant dependence on the hydrogen ion concentration (which we take as identical with the concentration of perchloric acid). A 20-fold increase in hydrogen ion concentration leads to a 3-fold increase in the apparent rate constant on 0.1° C.

The values of k' plotted against $1/s-1$ ($= \{[H^+]/K_a\}$) for each of the three temperatures investigated (0.11, 7.16, and 12.10° C) are shown in Fig. 2. There appears to be the

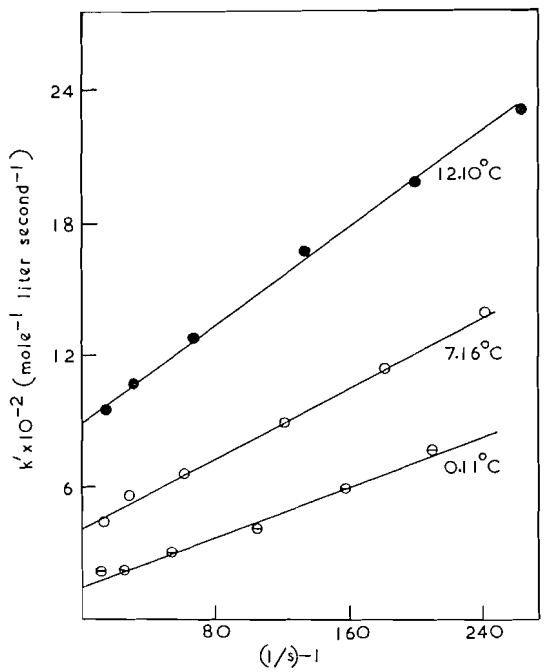

FIG. 2. Variation of effective rate constant k' with $1/s-1(= [H^+]/K_a)$.

linear relationship between k' and $\{(1/s)-1\}$ which would be expected if reactions I and II are involved. If a reaction involving $FeOH^{++}$ and fluoride ion were contributing appreciably to the rate, then the values of k' applying to the lower range of acidities should be greater than those indicated by the linear extrapolations of the points applying to the higher acidities. The data for 0.11° C may be consistent with a slight trend of this sort, but there is no evidence for such a trend at the higher temperatures.*

Values of k_I and k_{II} have been estimated from the intercepts and slopes of the lines of regression in Fig. 2 and are given in Table III. As can be seen from inspection of Fig. 2 the

**We have made measurements at 0.1° C, at ionic strength 0.05, and perchloric acid concentrations down to 0.01 molar and find that the apparent rate constant at this acidity is not significantly different from that at acid concentration 0.045 molar. Smith's preliminary measurements suggested such a lack of dependence of rate on acidity over this range, but the values he found were about 30% lower than ours. The interpretation of the spectrophotometric measurements for lower acidities may be complicated by the formation of FeF_2^+ and $Fe_2(OH)_4^{4+}$ but this apparent lack of dependence of rate constant on acidity suggests that a significant contribution to the rate at acid concentration 0.01 by a reaction involving $FeOH^{++}$ cannot be definitely ruled out.*

uncertainties associated with the values of k_I are considerable and the third figure recorded in Table III for each value is of doubtful significance.

Plots of log (k_I/T) against $(1/T)$ and of log (k_{II}/T) against $(1/T)$ are given in Fig. 3. Heats and entropies of activation for the two reactions estimated from these plots are as follows:

For the reaction $Fe^{+++} + F^- \rightarrow FeF^{++}$

$$\Delta H_I^{\ddagger} = 22.8 \pm 2.5 \text{ kcal mole}^{-1} \text{ and } \Delta S_I^{\ddagger} = 35 \pm 9 \text{ cal deg}^{-1} \text{ mole}^{-1}.$$

For the reaction $Fe^{+++} + HF \rightarrow FeF^{++} + H^+$

$$\Delta H_{II}^{\ddagger} = 8.7 \pm 0.7 \text{ kcal mole}^{-1} \text{ and } \Delta S_{II}^{\ddagger} = -24 \pm 3 \text{ cal deg}^{-1} \text{ mole}^{-1}.$$

DISCUSSION

Below, Connick, and Coppel carried out their investigations of the ferric–thiocyanate association (4) at ionic strength 0.4 and obtained for the purely ionic association $Fe^{+++} + SCN^- \rightarrow Fe(SCN)^{++}$ a heat of activation of 13.0 ± 1.4 kcal per mole and an entropy of activation of -5 ± 5 cal deg^{-1} mole^{-1}. They did not detect any reaction catalyzed by hydrogen ions or involving any species protonated beyond that of triply charged ferric ion or singly charged thiocyanate, but they did find an increase of rate with decrease in acidity which they attributed to the reaction involving $Fe(OH)(H_2O)_5^{++}$ and the anion. The effect on the heat of activation or the entropy of activation of changing the ionic strength from 0.4 to 0.5 is small (12) and our values and those of Below, Connick, and Coppel may be considered comparable.

The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ which we estimate for the forward reaction I are decidedly larger than those found for the ferric–thiocyanate association. This is possibly due to fluoride ion being much more firmly solvated than thiocyanate. If the attainment of the transition state involves marked desolvation of the anion then the reaction involving fluoride may be more demanding energetically and have a higher heat of activation. Likewise as has been pointed out by Below *et al.* (4) the entropy increase accompanying liberation of water from the anions will be more marked for fluoride than for thiocyanate.

Connick and co-workers have estimated the entropies of reaction for these two associations at ionic strength 0.4 and at 25° C. For the thiocyanate association $\Delta S°$ was given as 4.6 cal deg^{-1} mole^{-1} (4), and for the fluoride association as 30 cal deg^{-1} mole^{-1} (9). A moderate parallelism between the entropy of activation and the entropy of reaction for each of these reactions is apparent. The entropies of activation and reaction for the fluoride association are close in magnitude and positive. This supports the view that the organization of solvent in the transition state approaches that of the final state, even though the states are quite different energetically, and that the fluoride is actively involved in the transition state (i.e. the mechanism is S_N2). The entropies of activation and reaction for the thiocyanate association are both small and it appears that the entropy of activation is significantly more negative. However, in view of the weak solvation of thiocyanate ion and the lack of marked dependence of entropy change on the involvement or non-involvement of thiocyanate it is difficult to interpret these data as supporting either an S_N2 or an S_N1 mechanism.

The increase in apparent rate constant with acidity which we find could be attributed to either a hydrogen ion catalyzed reaction or to one involving HF. We favor the latter because it is difficult to envisage a likely mechanism for hydrogen ion catalysis, but possible to envisage a process where the reaction involving HF has a lower heat activation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

than the mechanism involving fluoride. We consider that, relative to the conditions obtaining in the mechanism involving fluoride ion, the weaker solvation of HF may contribute more to the reduction of the heat of activation than does the reduced electrostatic interaction between ferric ion and hydrogen fluoride (relative to that between ferric and fluoride ions) contribute to its increase.

The values discussed above for the heats and entropies of activation for the reactions involving fluoride with ferric ions and thiocyanate with ferric ions were obtained from measurements made in solutions where the ionic strength was adjusted to 0.5 or 0.4 with sodium perchlorate and these values should be comparable. However, in view of the possibility of some association between ferric and perchlorate ions complicating the interpretation of the measurements at high ionic strength, it seems worth while to examine the kinetics of both the ferric–fluoride and ferric–thiocyanate associations over a wider range of ionic strengths and temperatures in an effort to obtain data applicable to limitingly low ionic strength and concentrations of competing ions.

THEORY OF THE POLARIZATION CURVE TECHNIQUE FOR STUDYING CORROSION AND ELECTROCHEMICAL PROTECTION[1]

W. A. MUELLER

ABSTRACT

This study of the analysis of polarization curves is based on the identification of the partial currents of the single electrochemical reactions involved. The relationship between the gradient of polarization curves and the corrosion rate in uninhibited corrosion processes is investigated. The analysis of polarization curves is explained and two methods of using polarization curves in corrosion studies are compared. The conditions for stability of the active and the passive states are specified for application in anodic and cathodic protection.

I. INTRODUCTION

In the course of studies of the corrosion of steel in the presence of hot alkaline solutions (as in the kraft process of pulping of wood), some basic features of the electrochemical theory of corrosion were defined, and two methods for recording polarization curves were developed (1). The theory and experimental methods are expected to apply generally to the electrochemical reactions of any metal with any electrolyte. In this paper the practical corrosion problem, as studied previously, is considered only as an example of the general application of the theory and methods.

The practical problem concerned carbon-steel digesters attacked by alkaline pulping liquors in kraft mills. The cooking liquors contain 40 to 75% mill white liquor, the remainder being black liquor. The constituents of white liquor are about 100 g/liter sodium hydroxide and 35 g/liter sodium sulphide and minor quantities of sodium thiosulphate and polysulphides. Black liquor is the product of the reaction between the liquor mixture and wood (2).

The initial laboratory studies measured corrosion rates as a function of the liquor composition. Ruus and Stockman (3) found by laboratory experiments that sodium hydroxide, sodium sulphide, and sodium thiosulphate are main factors determining the corrosion rate in cooking liquor. This finding was corroborated by a Canadian field study (4). The role of polysulphide, thiosulphate, and dimethyldisulphide as depolarizers has also been described (5, 6, 7). However, two independent studies (3, 8) reported that the corrosion rates were not always reproducible even under presumably identical conditions. For instance, in an extreme case negligibly small corrosion rates of 10 or 20 M.P.Y. (milli-inches per year) were found alternating with rates of 650 and 750 M.P.Y. It appeared that the conditions were close to the border line between the stable active and passive states. Several series of potential–time curves revealed that steel immersed in white liquor at room temperature assumes either the active state at a potential of about -1.05 volt or the passive state at about -0.7 to -0.8 volt in reference to a saturated calomel cell (1) depending only on minor differences in the pretreatment of the steel. Another problem was provided by the observation that, during the heating period of the cook, the corrosion rate is high and falls unexpectedly during the later phase of the cook (3).

These observations, together with the problems connected with applying anodic or cathodic protection to steel in contact with these solutions, indicated a need for a basic study of the processes. The search for a theory and for experimental methods capable of

[1]*Manuscript received November 25, 1959.*
Contribution from the Physical Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Que.

clarifying these problems was directed towards electrochemical methods for analyzing localized attack as well as general uniform corrosion. Electrochemical corrosion in the narrow meaning of the term requires that areas of anodic and cathodic reaction can be distinguished. The mechanism of extremely localized corrosion, characterized by complete separation of areas in which anodic or cathodic reactions occur, has been previously explained (9, 10) on this basis; but this principle does not apply in the case of general, uniform corrosion. However, a solution was found by assuming electrochemical reactions in the broad meaning of the term (11, 12, 13, 14, 15, 16) which implies the exchange of positive or negative electrical charges between metal and electrolyte, whereby anodic and cathodic reactions may occur on the same metal surfaces simultaneously. On this basis the general laws which govern the increase of corrosion resistance by means of alloying were examined by Tomashov (17).

Pourbaix (14) derived electrochemical equilibrium diagrams, which describe the effect of pH on electrochemical reactions at varied potentials. During recent years the "measurement of the corrosion rate of iron by the polarization curve techniques" has been studied by several workers (18, 19, 20) applying different principles. They showed empirically that the slope of the polarization curve of iron in certain solutions is related to the corrosion rate. This relationship was theoretically derived by Stern (21). It receives an improved and more detailed formulation in this paper on the basis of a different derivation.

However, the analysis of "current density – potential curves",* to determine their components, was considered to be an appropriate approach to the initially stated problem. This principle, introduced by Wagner and Traud (22) was applied by Bonhoeffer (23) to the analysis of the polarization curve of iron immersed in sulphuric acid. A very detailed account of the analysis was published by Schwarz (16). The analysis of polarization curves was recently discussed by Stern (15) and applied to criticize the "current–potential break" criterion as used in cathodic protection. The principle of the analysis has been extended, in an independent study (1), to cover both the active and passive states and particularly the potential range around the boundary between them. In this connection the studies of Edeleanu (24) are of particular interest.

This paper intends to clarify some basic problems of the polarization curve theory and its application in the study of corrosion problems. It shows how the polarization curve is combined from the waves of the single reactions (25) involved. Some new aspects are revealed of the relation between the corrosion rate, the slope of the polarization curve, and the diffusion conditions in the corrosive environment of the metal. Finally, the conditions of the stability of the active and passive states are explained.

II. ELECTROCHEMICAL ANALYSIS OF POLARIZATION CURVES

When the polarizing and the depolarizing reactions occur at separate electrodes, a cell is formed, causing corrosion of the anodic specimen (9) if it is in the active state. The corrosion rate is proportional to the strength of the current in agreement with Faraday's law. However, the total current is decreased when the partial reactions occur at the same electrode. When both reactions occur at equal rates all over the metal, there is no current flow, for as the partial currents are opposed, their sum is zero. The partial currents are governed by the same quantitative relationships, independently of the current distribution. An applied current causes a shift of the potential difference between metal and

*This term, which is normally used in continental Europe, implies that the potential is considered primarily as the independent variable, to be plotted on the abscissa, and the current or current density as the dependent variable, to be plotted on the ordinate. In this paper the expression polarization curve is used without discrimination and the potential is recorded on the abscissa as the independent variable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

electrolyte and this in turn causes an alteration of the partial currents. The potential shifts until the external current equals the sum of the partial currents (some of which may be negative). This quantitative relationship was experimentally proved by Bonhoeffer (23) for iron dissolving in sulphuric acid.

Identification of the single reactions is often possible when the current density is considered as the sum of partial currents, each of which is caused by one single reaction and represents an independent function of the potential difference between metal and electrolyte. The combination of single reactions with their respective reverse reaction has been discussed in another paper (25). This paper is concerned with polarization curves as combined from the single reactions which include their reverse reactions.

III. THE RELATIONSHIP BETWEEN THE POLARIZATION CURVE AND THE CORROSION RATE

In the introduction an empirical rule was mentioned which relates the corrosion rate to the slope of the polarization curve (20) and which can be formulated as:

$$[1] \qquad \frac{dE}{dI} = \frac{K}{-\left(\frac{dW}{dt}\right)^S}$$

where K = constant, $-dW/dt$ = corrosion rate, W = weight per unit area, S = exponent, $S > 1$. To avoid misunderstanding it may be pointed out that "the slope of the polarization curve" given by Skold and Larson (20) and by Stern (21) is defined as the reciprocal of the value used in this paper. The following derivation is based on the assumption that the partial currents are independent of one another. This implies that the corrosion rate is primarily related to the anodic dissolution current, but not to the polarization curve, which refers to the depolarization current in addition.

A method for determining corrosion rates from linear polarization data has been developed by Stern (21). In the following, a new derivation is given of this relation, and the deviations from Stern's equations are discussed. If the possible reverse reaction is included, the anodic dissolution current I_a on a metal surface free of a protective film can be formulated as a modified Tafel relation (25, 26)

$$[2] \qquad I_a = I_1 \exp \frac{a_a n_a F}{RT} (E - E_1)$$

where n_a = valency of ions formed in the dissolution process,

I_1 and E_1 are a couple of interconnected values of current density and potential,

a_a = apparent symmetry factor as defined and derived in a study of the transition from equilibrium conditions to single electrochemical reactions (25).

If I_a contains only the current caused by the forward reaction, a_a becomes identical with the symmetry factor α_a and eq. 2 becomes a conventional Tafel relation. If a reverse reaction is superposed on the forward reaction, the following relation is valid

$$[3] \qquad \alpha_a \leqq a_a \leqq 1$$

where $a_a = 1$ at equilibrium. Only in a limited potential range can "a" values be considered as constants. If "a_a" changes, I_1 and E_1 do so also.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

If I_a equals the absolute value of the depolarizing current of an oxidizing reagent I_{ox}, $I_a = -I_{ox} = I_{corr}$ and the slope of I_a becomes

$$[4] \qquad \left(\frac{dI_a}{dE}\right)_{I_a=I_{corr}} = I_{corr}\frac{a_a n_a F}{RT}$$

where I_{corr} = corrosion current.

The current–potential relation referring to the depolarizing reaction represents a typical redox wave, caused by the reaction of an oxidizing reagent, which might be counteracted by the produced reducing reagent (25). This relation can be formulated

$$[5] \qquad \ln\frac{I_d - I_{ox}}{I_{ox}} = a_{ox}\frac{n_{ox}F}{RT}(E - E_{\frac{1}{2}})$$

where I_{ox} = current density of the depolarizing reaction of the oxidizing reagent,
I_d = current density of the diffusion current (I_d and I_{ox} are negative),
n_{ox} = valency involved in the depolarizing reaction,
$E_{\frac{1}{2}}$ = half wave potential of the depolarizing reaction,
a_{ox} = apparent symmetry factor of the depolarizing reaction of the oxidizing reagent. For an oxidizing reaction without reverse reaction $a_{ox} = \alpha_{ox}$ which is the symmetry factor of the oxidizing reaction. At equilibrium $a_{ox} = 1$.

This eq. 5 is basically different from Stern's corresponding eq. 2

$$[6] \qquad E_{conc} = 2.3\frac{RT}{nF}\log\left(1 - \frac{I}{I_L}\right)$$

where E_{conc} = change of potential caused by concentration polarization,

I_L = I_d of this paper.

Equation 6 is valid with respect to a metal in equilibrium with its ions in solution (27) as it has been derived from

$$[7] \qquad E_{conc} = 2.3\frac{RT}{nF}\log\frac{c}{c_b}$$

where c = concentration of the metal ions at the interface,
c_b = bulk concentration.

This is the overpotential of a metal in contact with a solution of its ions close to equilibrium; it is not the overpotential caused by a depolarizing reaction.

Differentiation of eq. 5 with respect to E results in

$$[8] \qquad -\frac{dI_{ox}}{dE}\frac{1}{I_d - I_{ox}} - \frac{dI_{ox}}{dE}\frac{1}{I_{ox}} = \frac{a_{ox}nF}{RT}.$$

Accordingly the slope of the partial current density of the depolarizing reaction under steady-state conditions ($I_a = -I_{ox} = I_{corr}$) is

$$[9] \qquad \left(\frac{dI_{ox}}{dE}\right)_{(I_a=I_{corr})} = I_{corr}\frac{a_{ox}n_{ox}F}{RT}\frac{-I_d - I_{corr}}{-I_d}.$$

Hence the relation between the slope of the polarization curve $dI/dE = (dI_a/dE) + (dI_{ox}/dE)$ and the corrosion rate can be expressed

$$[10] \qquad \left(\frac{dI}{dE}\right)_{(I_a=-I_{ox}=I_{corr})} = I_{corr}\frac{F}{RT}\left(a_a n_a + a_{ox}n_{ox}\frac{-I_d - I_{corr}}{-I_d}\right).$$

To show the meaning of eq. 10, the anodic dissolution current (ADC) and three polarigraphic waves (W1, W2, and W3) of oxidizing reagents are plotted in Fig. 1 as a schematic

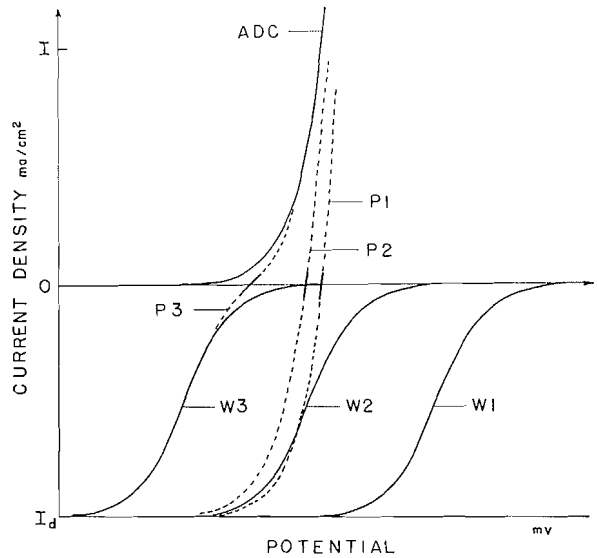

FIG. 1. Polarization curves and their slope combined from partial currents and the respective slopes.

demonstration. Three polarization curves (P1, P2, and P3) are derived from the combination of the anodic dissolution current with the waves. The slope of the diffusion controlled curve P1 is equal to the slope of the anodic dissolution current; the slopes of the curves Pa and P3 are combined from two partial slopes each.

When replacing I_{corr} by

$$\left(-\frac{dW}{dt}\right)\frac{Fn_a}{A\cdot 24\cdot 3600}$$

eq. 10 results in

$$[11] \qquad \frac{dI}{dE} = \left(-\frac{dW}{dt}\right)\frac{F^2 n_a}{RTA\cdot 24\cdot 3600}\left(a_a n_a + a_{ox} n_{ox}\frac{-I_d - I_{corr}}{-I_d}\right)$$

where A = atomic weight, W = weight per unit area, $(-dW/dt)$ = mg(dm)$^{-2}$(day)$^{-1}$ (corrosion rate).

In double logarithmic plotting the values of the corrosion current are located on or between two limiting lines (L1 and L2) which result from eqs. 10 and 11 when $(-I_d)_{ox} = I_{corr}$ (L1) and when $(-I_d)_{ox} \gg I_{corr}$ (L2).

These conditions may be illustrated by a comparison of the relation calculated on the arbitrary assumption $a_a = 1/4$, $n_a = 2$, $a_{ox} = 1/2$, and $n_{ox} = 4$ with the experimental values of Skold and Larson (20). Figure 2 shows that the measured values are close to, or between, the calculated lines. The position of the measured points indicates that the corrosion was controlled by diffusion mainly at high values of the gradients of the polarization curve as expected. The derivation suggests that the empirical relation (Le) is valid only between the calculated lines. For the exact calculation of the limiting lines the coefficients $a_a n_a$ and $a_{ox} n_{ox}$ have to be known.

A final comparison with Stern's equation (21) shows an agreement only of Stern's eq. 8

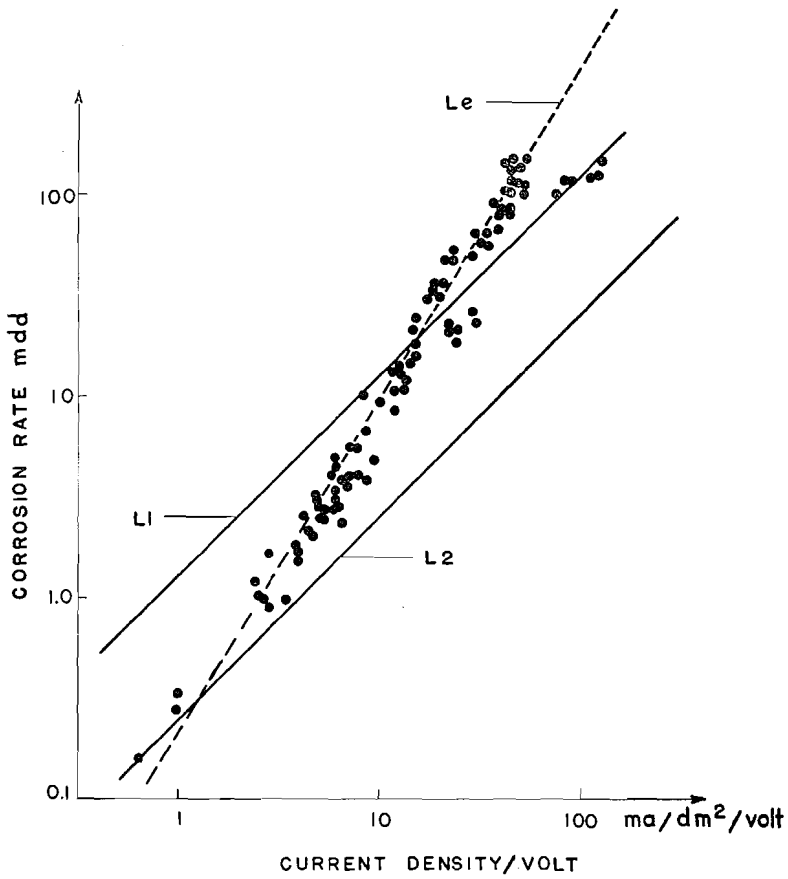

FIG. 2. Skold and Larson's (20) empirical relation between corrosion rate and the slope of the polarization curve (dotted line) in comparison with the calculated limiting condition (extended lines).

with eq. 10 of this paper if the redox reaction is completely controlled by concentration polarization and if Stern's $\beta = RT/a_a n_a F$. This is the well-known case derived from a Tafel reaction according to eq. 4. However, eqs. 10 and 11 are valid at any degree of concentration polarization. In addition to Stern's formulation eqs. 10 and 11 give an explicit relation to the valencies involved in the reaction and the relation to the diffusion current. Equations 10 and 11 reveal to which degree the corrosion under study is diffusion controlled when the "$a.n$" values are known, and they allow a close estimation of corrosion rates from the slope of the polarization curves even if only the metal and the depolarizer are known. The effect of possible reverse reactions such as electrodeposition of the dissolved metal and reducing redox reactions have also been included in these derivations.

The exact validity of the derived equations is limited to polarization curves composed of the partial currents of anodic dissolution of the metal (eq. 2) and of the depolarizing current (eq. 5). If other partial currents, such as listed in the following chapter, contribute to the polarization curve the above equations become inaccurate. Adsorption of anions can also change the basic equations of redox reactions (28).

IV. THE POLARIZATION CURVE COMBINED FROM PARTIAL CURRENTS

The polarization curve of a metal immersed in an electrolyte represents the dependence of the sum of well-defined partial currents on the potential, as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

1. In the active state the anodic dissolution current of the metal which can be characterized by the constants a_a, a_n, I_1, and E_1 (eq. 2). When passivation begins, a characteristic rapid decline of the current density occurs (24, 1, 29).

2. Anodic dissolution current of hydrogen contained in the metal.

3. The partial currents due to redox reactions the products of which are soluble in the oxidized and reduced state. These currents are characterized by n, a_{ox} or a_r, I_d, $E_{\frac{1}{2}}$, and $E°$ (eq. 5)

where a_r = apparent symmetry factor of the reaction of the reducing reagent (25),
$E°$ = standard redox potential.

4. The partial current of deposition of metals also characterized by a, n, I_d, $E_{\frac{1}{2}}$, and $E°$.

5. The partial current due to slow dissolution and rebuilding of the passive film (30), in the passive state.

The various partial currents combined result in the polarization curve. As an example, Fig. 3 shows the schematic construction of the polarization curve of iron in laboratory

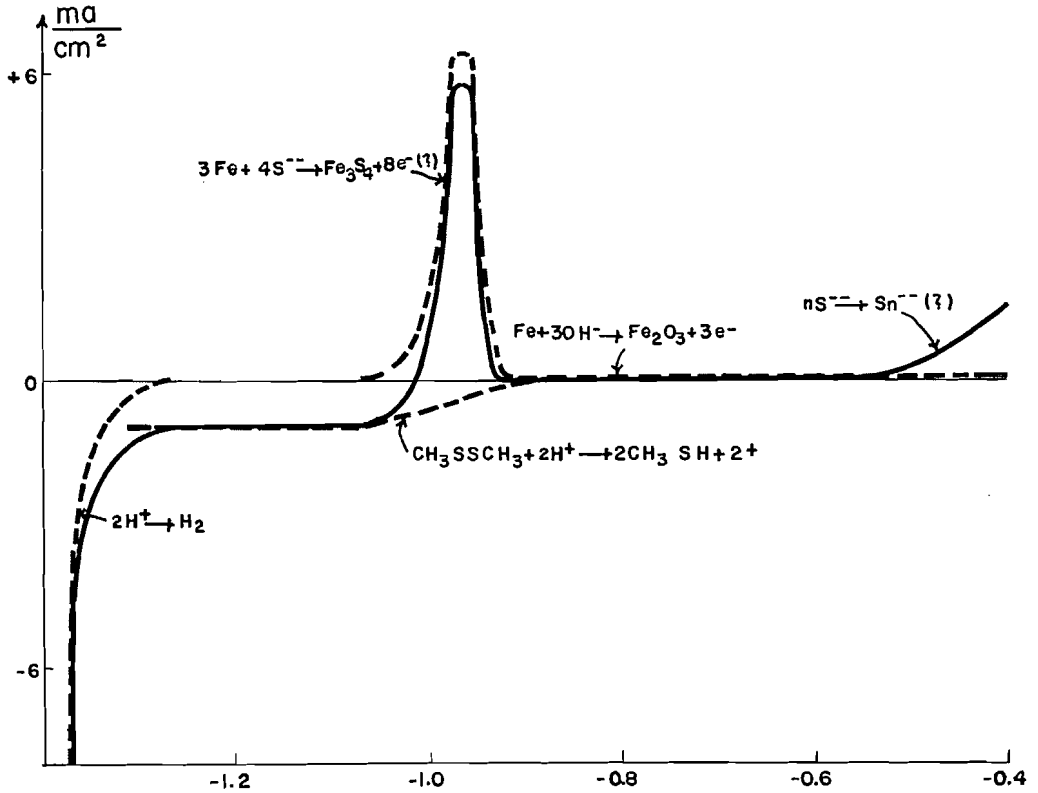

FIG. 3. Construction of the polarization curves of iron in alkaline pulping liquor from the partial currents involved.

white liquor containing 1 g/liter dimethyldisulphide. The partial currents are caused by the development of hydrogen, the redox reaction of dimethyldisulphide, the anodic dissolution current, the slow dissolution and rebuilding process of the passive film, and finally an anodic current probably due to formation of polysulphides from sulphides. The corrosion rate at a certain potential is proportional to the partial current of the anodic dissolution of the metal when in the active state or of the dissolution of the passive film when it is passive.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

When specimens of two different metals, in metallic contact, are immersed in the same electrolyte the respective anodic dissolution currents are different and so are the depolarization currents due to different overpotentials. The same is true with respect to identical specimens in metallic contact when immersed in electrolytes of different composition. The potentials approach one another more closely with improved conductivity of the circuit. The final values of the potentials are located between the potential values of disconnected specimens and they depend on the gradients of the polarization curves and the extent of the exposed areas, as explained before (9, 10).

These conditions can be calculated when currents, rather than current densities, are compared. The potentials E_A and E_C shift to values where

(*a*) the net anodic current of the specimen A equals the net cathodic current of the specimen C;

(*b*) the potential difference $E_A - E_C$ equals the product of the current and the resistance in the cell circuit.

For comparison these conditions are expressed by the diagram of Evans and Hoar (10) in Fig. 4(*a*), and according to Schwarz (16) in Fig. 4(*b*), with reference to two connected

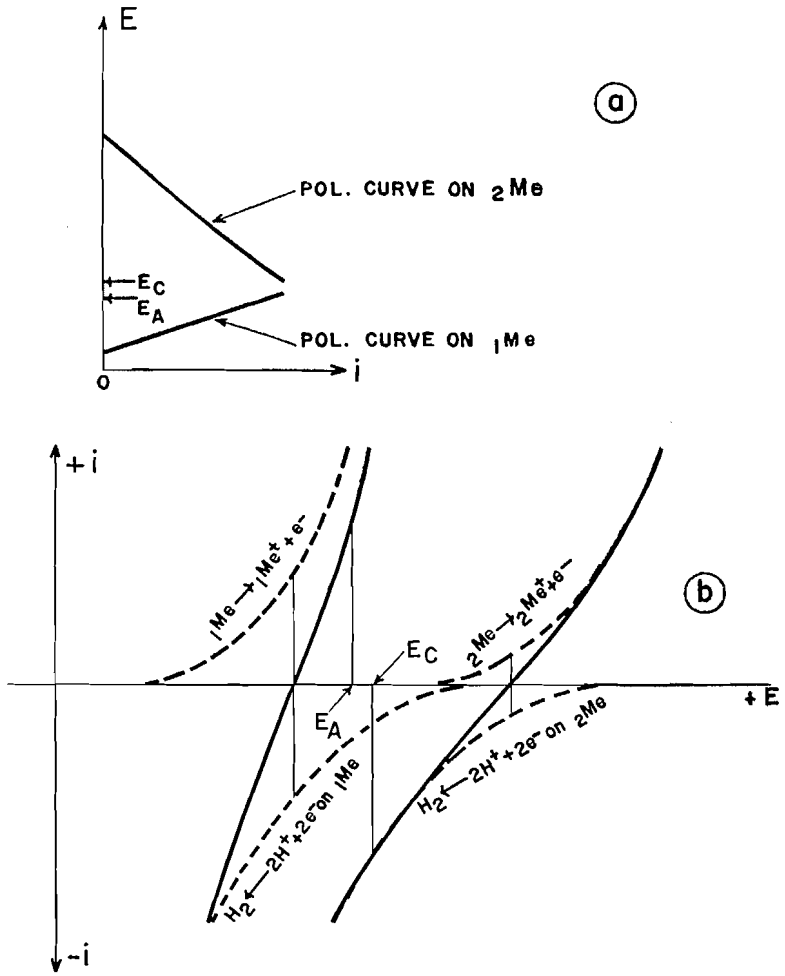

FIG. 4. The electrochemical behavior of a bimetallic system: (*a*) as plotted by Evans, (*b*) as plotted by Schwarz.

For personal use only.

metals immersed in an acidic solution. Anodic and cathodic currents in Fig. 4(*a*) are plotted on the abscissa and the potentials on the ordinate. The corrosion rate is proportional to the current. The figure below (Fig. 4(*b*)) shows the same conditions plotted similarly to the other polarization curves in this paper. The clear distinction between anodic and cathodic currents and the clarification of the sources of these currents are assumed to be advantages of the way of plotting used in Fig. 4(*b*). This advantage becomes evident as soon as at least one of the compared currents results from more than one partial current. Only the method of Fig. 4(*b*) indicates the rate of anodic dissolution, i.e., the corrosion rate, reliably.

V. STABILITY OF THE ACTIVE AND THE PASSIVE STATES AND APPLICABILITY OF ANODIC PROTECTION

The stability of the passive state is of basic importance when it forms the basis of corrosion protection. Two types of stability have to be distinguished with respect to passivity. This paper is not concerned with instability phenomena (31), which cause rhythmic behavior or propagation of activating and passivating waves, nor with the irreversible behavior exhibited by a potential jump which is connected with the change from active to passive states (32). In this paper stability for instance of the passive state means that the passivity is maintained without supply of anodic current. The instability or low degree of stability of the active and passive states of steel in contact with alkaline cooking liquors points to the necessity for clarifying these conditions.

These conditions of stability have been discussed before by Vetter (33) and Edeleanu (24) on the basis of single electrochemical reactions and, in complete agreement with these derivations, by Mueller (1) on the basis of combined polarization curves. The experience gathered during the application of anodic protection of alkaline pulping digesters (34) may justify another discussion, which is mainly concerned with the practical application. Single reactions explain the mechanism of the electrochemical reactions involved. But combined polarization curves are usually measured and they give the information that is practically required, even if none of the single reactions is known; hence they have been chosen for this discussion.

The conditions of electrochemical equilibrium can be expressed by analogy to the definition of a mechanical equilibrium as follows: An equilibrium potential is reached if the potential is constant at zero current density. The equilibrium is stable if the potential, after receiving a small displacement, tends to return to its original values. The criterion of a stable equilibrium (S, Fig. 5) is a positive value of the gradient of the current density versus potential at a zero current density. Stability means that a current which restores the original potential is produced when the potential is changed. The criterion of unstable equilibrium (UE) is a negative gradient of the polarization curve when passing through zero current density. The presence of two stable potentials (Fig. 5(*b*)) requires a positive maximum of the polarization curve in the active state and a negative minimum in the passive state.

If there is no negative minimum of the current density in the passive state (Fig. 5(*a*)) the positive current, which leaves the metal, removes positive charges from the metal thus causing a shift of the potentials to the more negative values in the active state, i.e., the passive state is unstable; and so is the active state (Fig. 5(*c*)) if there is no positive maximum of the current density in the active range. The degree of the stability of the active state is proportional to the value of the positive maximum of current density; and the degree of the stability of the passive state is proportional to the value of the negative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

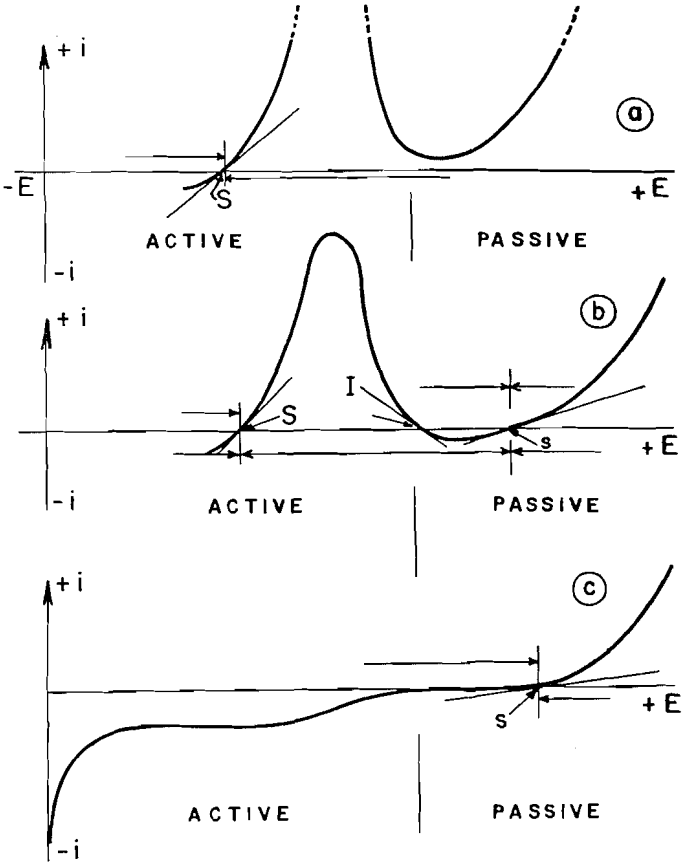

FIG. 5. Stability and instability of the electrochemical equilibrium in the active and passive states: (*a*) only active state stable, (*b*) active and passive states stable, (*c*) only passive state stable.

minimum of the current density. For establishing a stable passivity it is important to know how the partial currents depend on the composition of the electrolyte and on the diffusion conditions.

The three cases of electrochemical stability are demonstrated by potential time curves recorded at alkaline pulping digesters during application of anodic protection (34). The shift of the potential to the active range, when no current is supplied at the beginning of each cook (Fig. 6), shows that only the active state is then stable. Without application of anodic protection the digester remains in the active state for about two hours. However, when applying anodic protection for about one hour the digester apparently has then reached a stable passive state because the potential does not shift back when the current supply is shut off. At the end of the cook only the passive state is stable as the potential shifts to the passive range even without current supply. Thus the three mentioned cases of electrochemical stability are passed in succession during a cook in an alkaline pulping digester. Polarization curves recorded under these conditions corroborated this conclusion.

As another example, this principle gives a new explanation to the result of the study of Brauns and Pier (35) on the intercrystalline corrosion of stainless steel in boiling 5% sulphuric acid. In the case of a properly heat-treated specimen, which is free of intercrystalline corrosion and displays a stable passivity, the minimum of the current density

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

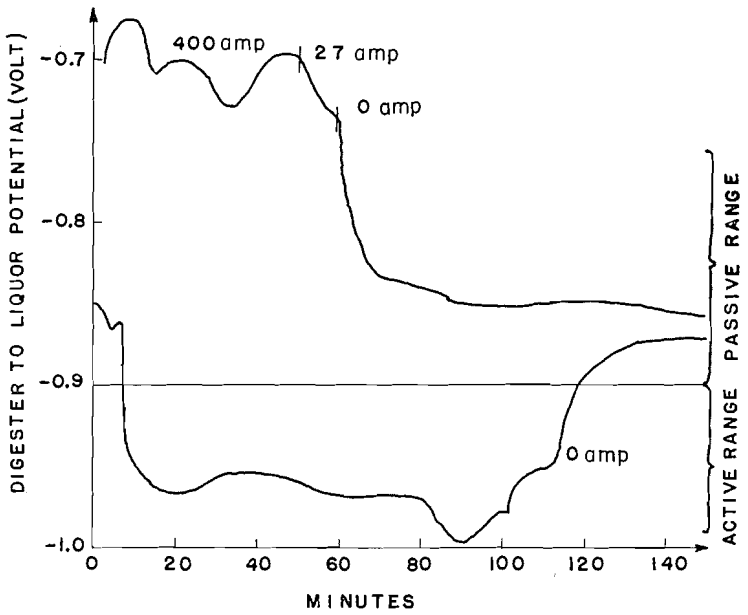

FIG. 6. Potential time curves recorded by varying the current during directly steamed cooks of alkaline pulping digesters.

in the passive state is negative. However, with increasing instability to intercrystalline attack, the minimum shifts to increasingly positive values of the current density.

The known effect of depolarizers, such as oxygen or other oxidizing substances, of stabilizing the passive state consists in the formation of a cathodic partial current which must be sufficiently high to make the minimum current density of the polarization curve in the passive range cathodic. This effect was observed with different concentrations of dimethyl disulphide, which is one of the main depolarizers in oxidized black liquor.

For the passivation of a metal which is in the active state, a high initial current is required to shift the potential past the maximum in the polarization curve in the active state. This current can be reduced by passivating different areas in succession. After reaching stable passivity (stable equilibrium in the passive state) the current can be switched off without causing re-activation. However, if there is no stable equilibrium in the passive state, a current has to be maintained at a level higher than the minimum current indicated by the polarization curve in the passive range. Insufficient supply of current or of depolarizers does not passivate or protect the electrode; on the contrary, it increases the corrosion rate.

The danger of corrosion caused by reaching the transpassive state has also to be taken into consideration for the application of anodic protection. Evidently a shift to extreme anodic potentials may be caused by some changes during long time operation, for instance, when scale is formed on an increasing ratio of the surface. A potential shift to the transpassive range is easily prevented if the polarization curve shows high current densities in the passive range, before reaching transpassivity. If this is not the case potentiostatic control of the applied current is required to prevent a shift of the potential to the transpassive potential range. Figure 3 demonstrates a system in which corrosion by shifting to the transpassive state is not very likely because in the extreme anodic range the anodic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

current density reaches high values when corrosion is still literally zero. Thus the field experiment with the application of anodic protection to alkaline pulping digesters (34) is the first practical application of these theories.

RATES OF ADSORPTION OF HYDROGEN ON PALLADIUM AND ON RHODIUM[1]

MANFRED J. D. LOW

ABSTRACT

A study of the effects of temperature and initial gas pressure on the kinetics of chemisorption of hydrogen on alumina-supported palladium and rhodium catalysts revealed, for both gas–solid systems, that the adsorption proceeded via three distinct and consecutive kinetic stages. Each stage could be described by the Elovich equation. The temporal range of existence of each kinetic stage was temperature- and pressure-sensitive, low initial pressures and high temperatures favoring early appearance of each stage. On increasing the temperatures from 0° to 400° C, the amounts of hydrogen adsorbed on both solids decrease. Over that temperature range the rates of adsorption on Pd decrease, while those on Rh increase, with increasing temperature. The general effect of increasing the initial gas pressure over the range 10–60 mm Hg is to increase both rates and extents of adsorption.

INTRODUCTION

The rates of chemisorption in many gas–solid systems have been shown (1) to obey the Elovich equation,

$$\frac{dq}{dt} = ae^{-\alpha q},$$

where q is the amount of gas taken up at time t, and a and α are constants. The q–t relation can be expressed by an integrated form of the Elovich equation as

$$q = \frac{2.3}{\alpha}\log_{10}(t+k) + \text{constant},$$

where k is a constant, so that a plot of q versus $\log_{10}(t+k)$ is linear. In certain systems isothermal discontinuities (1), or breaks, have been reported, in that abrupt changes in slope occurred in the $q - \log_{10}(t+k)$ plots, and such behavior was ascribed to adsorption on different sites (1). The change in slope corresponded to relatively increased or to decreased rates of adsorption, changes in both directions sometimes occurring within the same gas–solid system (2). Preliminary experiments had shown that such breaks occurred in the system H_2–Pd and H_2–Rh, and suggested more extensive work.

EXPERIMENTAL DETAILS

The uptake of gas by the solids was followed by measuring decreases in pressure with time in systems of constant volume, using previously described techniques (2–6). The adsorbents were: 20.46-g sample of 0.5% Pd supported on the exterior of 3×5 mm γ-Al_2O_3 pellets; 15.85-g sample of 0.5% Pd on exterior of 1×3 mm γ-Al_2O_3 extrudates. The unreduced commercial catalysts were black in color. On heating of the catalysts to 500° C *in vacuo* a copious evolution of gas occurred. A part of the gas was condensible and probably water. After pumping overnight at 500° C a pressure $\leqslant 10^{-6}$ mm Hg was attained, the original black coloration being retained. On exposure to H_2 the catalysts turned gray. A test was made for efficiency of reduction by (*a*) reducing the catalysts at 500° for a specific time with H_2 at 20 l. N.T.P./hour, (*b*) degassing at 500° overnight, (*c*) measuring H_2 uptake on the degassed surface. No significant change in adsorption

[1]*Manuscript received October 13, 1959.*
Contribution from Texas Research Center, Beacon, New York.

occurred on increasing the reduction period from 10 minutes to 48 hours. Identical results were obtained by three alternate steps of exposures to H_2 (at 1 atm for 1 hour at 500°) and degassing at 500° for 30 minutes.

EXPERIMENTS, RESULTS, AND DISCUSSION

The General Nature of the Adsorption

For both gas–solid systems, most plots of q versus log t show the previously described breaks. For all plots k was indistinguishable from zero. Five general types of plots were obtained, shown schematically in Fig. 1. A few linear plots, such as plot 4, were obtained.

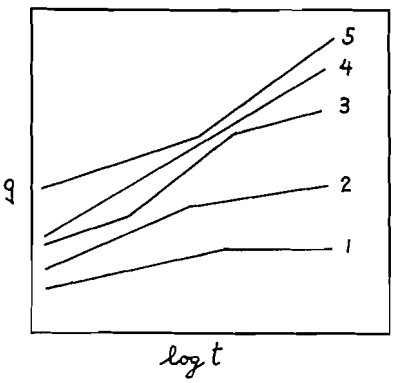

FIG. 1. Types of plots.

For most runs the $q - \log t$ plots were discontinuous, and the rate of adsorption, proportional to the slope of the $q - \log t$ line and hence to the constant $1/\alpha$, became relatively faster (as in plot 5) or relatively slower (as in plot 2).

Inspection of the plots of all data revealed certain consistent features in the occurrence of the various types of plots of Fig. 1. In comparing rate curves of experiments performed at different initial gas pressures and at different temperatures it became apparent that comparisons of kinetic stages, i.e. linear portions of $q - \log t$ plots, on the basis of their temporal order of appearance resulted in misleading correlation and interpretation. If stages were compared on the basis of the relative magnitude of the constant α of the following kinetic stage, using the scheme depicted in Fig. 2, then correlation of the rate

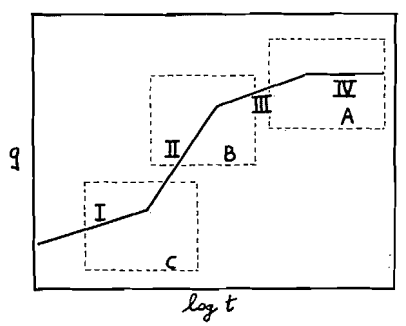

FIG. 2. Composite of multiple kinetic stages.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12

parameters of individual stages with temperature and pressure became possible. In Fig. 2 the different kinetic stages are arbitrarily termed I, II, III, and IV, the last representing completion of adsorption.

It is probable that all stages are present in any one run but, because of limitations imposed by the technique and by the experimental variables of temperature and pressure, not all stages necessarily are detected during the course of a single experiment.

Effects of Temperature and Pressure on Kinetic Stages

The plots 1 to 5 of Fig. 1 represent in general fashion the order of appearance of the various types of plots with increasing initial pressure, P_s. For the adsorption of H_2 on Pd and on Rh at pressures of about 10 to 20 cm DBP (dibutylphthalate) several runs were obtained which had the appearance of the schematic plot 1 of Fig. 1. For such runs the $q - \log t$ plots are equivalent to the region A enclosed by dotted lines of Fig. 2. According to the scheme of that figure the segments of the $q - \log t$ plots showing positive slope correspond to stage III, while the portions parallel to the abscissa correspond to stage IV. For such cases the preceding stages I and II are assumed to have appeared before the time of the first measurement.

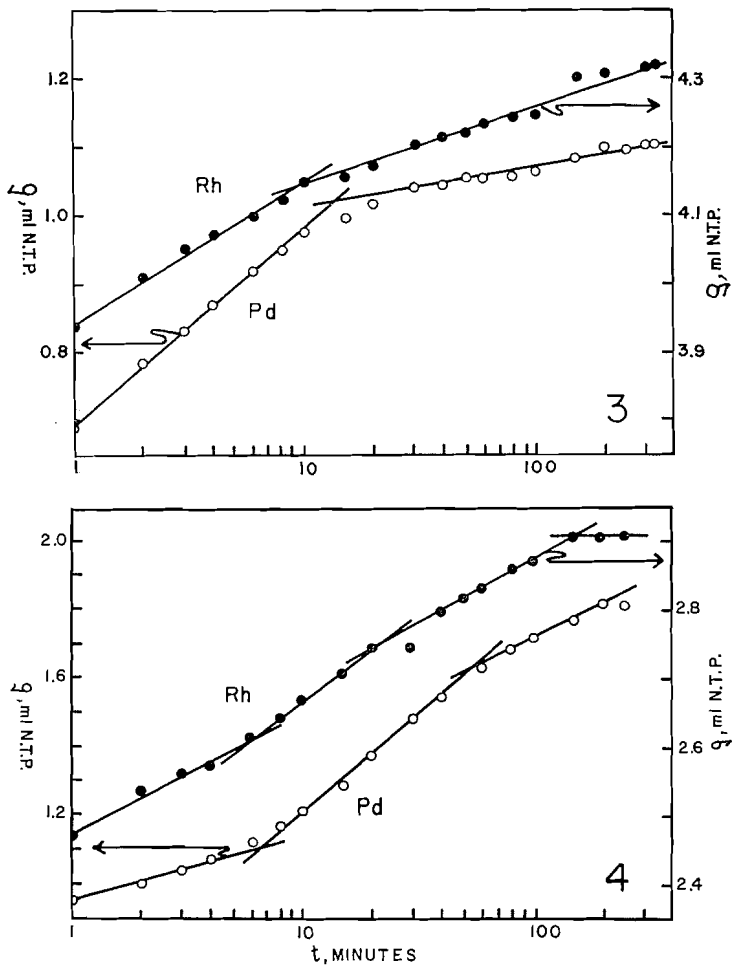

FIG. 3. Typical runs. Rh: run D65, 56° C, 50.5 cm DBP; Pd: run E57, 200° C, 44.2 cm DBP.
FIG. 4. Typical runs. Rh: run D66, 257° C, 51.7 cm DBP; Pd: run E74, 56° C, 50.88 cm DBP.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

At intermediate pressures of about 20 to 50 cm DBP, stages II and III generally appear. The experimental plots have the appearance of the schematic plot 2 of Fig. 1, and correspond to the region B of Fig. 2. Examples of such data are shown by the plots of Fig. 3. For such cases the preceding stage I is assumed to have appeared before the time of the first measurement. Stage IV, the termination of the adsorption, must appear at higher t values.

At intermediate pressures some plots showed the presence of stages I, II, and III, having an appearance like the schematic plot 3 of Fig. 1. This corresponds to a combination of the regions B and C of Fig. 2. Such data is illustrated by the plots of Fig. 4. Such three-stage plots were found frequently with the H_2–Pd system.

Also, at intermediate pressures, several plots were obtained which were linear throughout, like the schematic curve 4 of Fig. 1. Such plots were assigned stage II connotation because the value of the corresponding α corresponds very closely to stage II α values to be expected from a knowledge of α values of stage II of other runs.

At P_s from about 40 to 70 cm DBP, the $q - \log t$ plots had the appearance of the schematic curve 5 of Fig. 1. This implies the appearance of stages I and II. Such plots correspond to the region C of Fig. 2. Examples of such data are shown by the plots of Fig. 5. For these

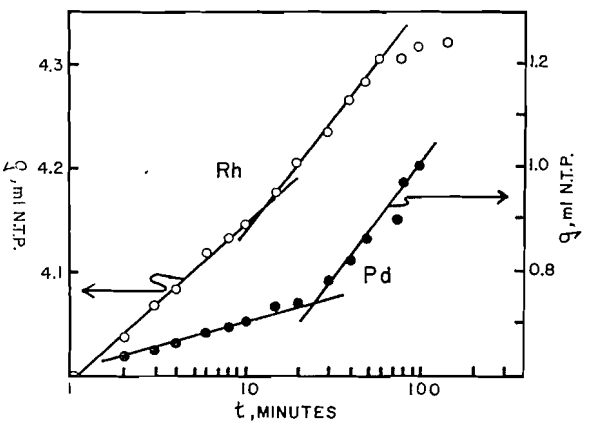

FIG. 5. Typical runs. Rh: run D40, 100° C, 51.3 cm DBP; Pd: run E36, 100° C, 51.7 cm DBP.

cases, stages III and IV would appear if the adsorption could be followed for a sufficiently long period of time. In practice this is frequently not possible because the rate of adsorption at long times becomes so slow that the precision of measurements is poor and hence continuation of the experiment is useless.

The kinetic multiplicity is further complicated by effects of P_s and temperature on the α and a values of individual kinetic stages. Changes in the slopes of the $q - \log t$ plots with changing temperature or pressure are reflected as changes in the co-ordinates of the intersections of two kinetic stages. Such effects are illustrated by the plots of Figs. 6, 7, and 8. In Fig. 6 the q-co-ordinate of the intersection of stages I and II, q_{bI}, is seen to decrease with increasing temperatures. Increase in P_s causes increase in q_{bI} and in q_{bII}, the latter being the co-ordinate of intersection of stages II and III. The corresponding t-co-ordinates, t_{bI} and t_{bII}, decline with increasing P_s, as illustrated by Fig. 8. The t_b-temperature relations are not clear.

The appearance of three consecutive stages in some plots, such as those of Fig. 4, as well as the consistent changes in α values of corresponding stages with changing

temperature or pressure, suggest that the composite structure of Fig. 2 is consistent with the data. Similar changes to both relatively faster and slower rates, apparently occurring haphazardly, have been found previously in the system H_2–$ZnO \cdot Cr_2O_3$ (2, 7), and in the system H_2–Ir–Al_2O_3 (4), while in the system H_2–ZnO (8) breaks towards a relatively faster rate were consistently obtained. It appears probable that in those systems a similar succession of kinetic stages exists.

The Effects of P_s and Temperature

At 100°, 200°, and 257° C a series of runs were made at random at different P_s, permitting some observations to be made on the effects of P_s and temperature on the constants a and α. If the scheme of Fig. 2 is adopted then a consistent correlation between values of the parameter a or α for any one stage and P_s and temperature is possible. In this fashion values of α for stage II lines (α_2), for example, are compared with other α_2 values, and the temporal order of appearance of the lines on $q - \log t$ plots is disregarded.

The effects found are less clearcut than those of previous studies because (*a*) different kinetic stages appeared under different conditions of temperature and P_s, in a manner discussed above, so that over some P_s regions not enough data are available for correlation, and (*b*) scatter of parameter values with changing P_s was encountered, this being particularly noticeable in the highly sensitive a values. The correlations between parameters and P_s and temperature were similar to those obtained previously (2–6), roughly linear changes being obtained, so that the following statements, illustrated by the plots of Figs. 9 and 10, suffice to describe the data. (*a*) Multiple kinetic stages exist, as described above. (*b*) For both adsorption systems, an increase in temperature decreases the amounts of gas adsorbed over the range 56°–400° C. This is shown by the plots of Fig. 9, which are

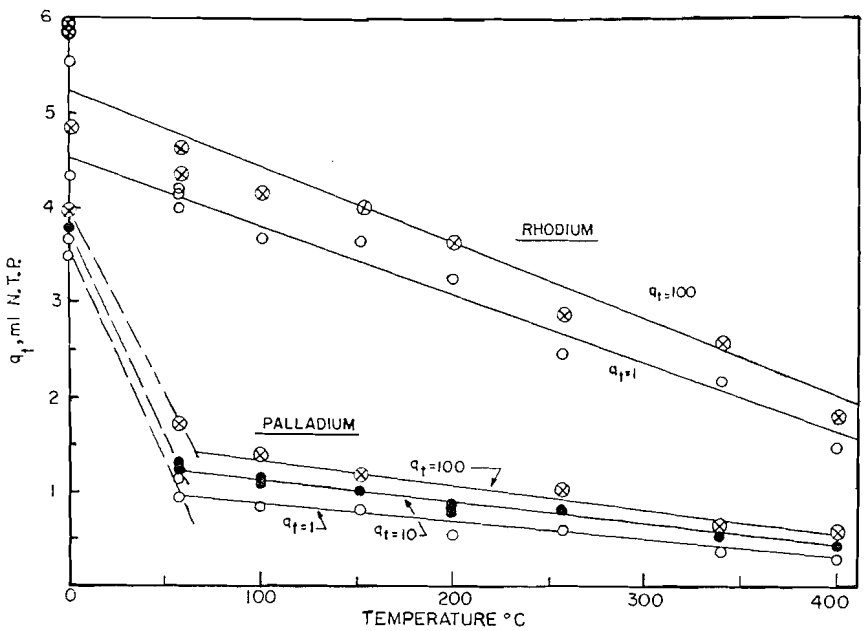

FIG. 9. The effect of temperature on adsorption. q_t is the amount adsorbed after t minutes.

essentially isobars at P_s = 51 cm DBP. (*c*) For the H_2–Rh system, momentary rates of adsorption ($\propto 1/\alpha$) are increased, but values of a are decreased with increasing temperature. (*d*) For the H_2–Pd system, momentary rates of adsorption are decreased with increasing temperatures, and initial rates similarly decrease slightly or remain constant.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

(*e*) For both adsorption systems the general effect of increasing initial gas pressure is to increase adsorption rates, but in discontinuous fashion. At pressures below about 30 cm DBP the effects of increasing P_s on parameter values are larger than those above that pressure. Such discontinuity is illustrated by the α–P_s plots of Fig. 10.

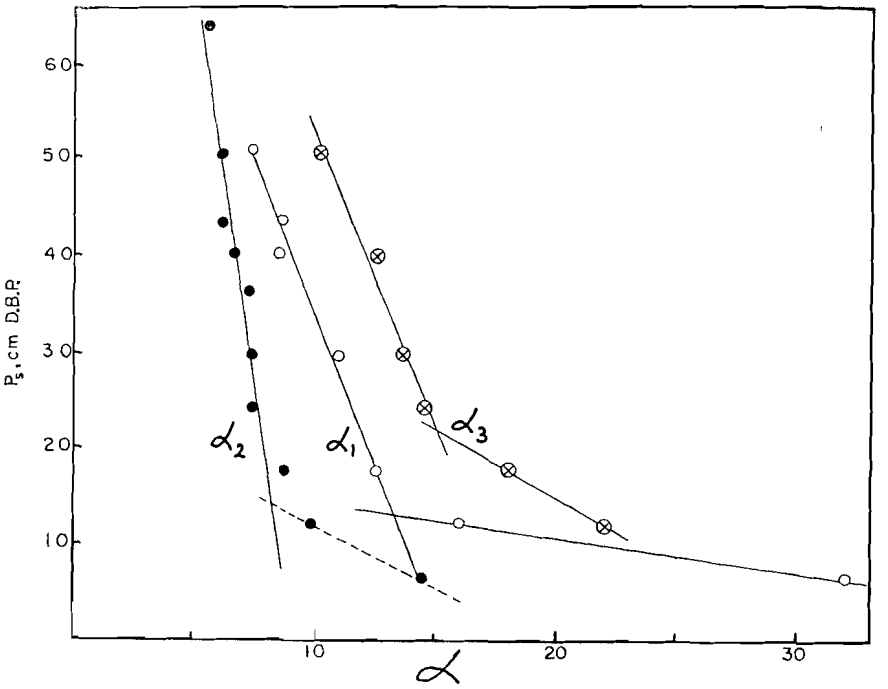

FIG. 10. The effect of P_s on α values. H_2 adsorption on Pd at 100° C.

A complete, physical explanation for the observed multiple stages has not been devised. It is possible that they may result from surface contamination, a suggestion supported by such observations as: originally (3) linear $q - \log t$ plots were found with the system H_2–Ru, while in a later study (5) breaks occurred; with CO adsorption on clean Ru (5) the rate declined monotonically whereas it was discontinuous when H_2 was preadsorbed on the solid; for the H_2–Ni–SiO_2 system (9) on rigorous reduction a fast adsorption was increased in magnitude at the expense of a slow adsorption; under conditions of preadsorption of CO on Ru, two kinetic processes of H_2 adsorption exist (5), the region of discontinuity of rates being approximately linearly dependent on the amount of preadsorbed CO. However, the rigorous reduction conditions, the apparent stability of the adsorbent surfaces, and the dependence of kinetic stages on temperature and pressure suggest that a simple poisoning phenomenon is unlikely to account for the present observations. Rather, some model of a surface is required which changes its character drastically by the very act of adsorption. The present results are reminiscent of the observations of Becker (10) on the change of sticking coefficient with coverage of several molecules on W ribbons, which led to the suggestion that the adsorption properties of a metal surface change rather abruptly when adsorbed species make the first set of valence bonds with every surface metal atom and again when they make second valence bonds. The observed temperature and pressure dependencies of the kinetic stages, however,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

require a different model, such as that suggested by Taylor and Thon (1), according to which the discontinuities would represent change-over of the adsorption process from one kind of site to another before coverage is complete. With homotatic surfaces such as those presented by the probably polycrystalline Ru and Pd adsorbents, such a mechanism is not implausible.

DECOMPOSITION OF ZINC OXIDE[1]

E. A. SECCO

ABSTRACT

Experimental results on the loss in weight of zinc oxide in a closed vessel under varying conditions of temperature, initial zinc pressure, oxygen pressure, and vacuum are reported. The data show more consistency interpreted in terms of dissociation rather than sublimation of the oxide. Plots of $\log_{10} K_p$ versus $1/T$ and $\log_{10} P_{ZnO}$ versus $1/T$ yield slopes corresponding to 24.0±2.0 kcal and 43.0±5.0 kcal, respectively. These results cannot be explained on the basis of available thermodynamic data. Interpretations of these results in terms of an unstable suboxide and non-equilibrium are discussed.

INTRODUCTION

It was observed in 1954 during a study (1) on the exchange between zinc vapor and single crystals of zinc oxide that there occurred appreciable losses from a bucket carrying the oxide in a closed quartz vessel at 1025° C. The oxide losses from the bucket were much greater at low zinc pressures. It was further confirmed that considerable oxide was lost from the bucket in a vacuum, i.e., 5×10^{-4} mm Hg. These observations could not be explained by a decomposition reaction on the basis of the standard free energy for the reaction

$$ZnO_{(c)} = Zn_{(g)} + \tfrac{1}{2}O_{2(g)}$$

that is, $\Delta G^\circ = -114{,}640+51.65\ T$ cal/mole (2). The equilibrium pressures of zinc and oxygen from the above reaction as estimated from the equilibrium constant $K_p = P_{Zn}P_{O_2}^{\frac{1}{2}}$ are many orders of magnitude below the experimental pressures.

A recent study (3) involving zinc oxide at low pressures and lower temperatures has shown a recurrence of appreciable losses of the oxide. This report contains experimental data pertaining to loss in weight of zinc oxide under varying conditions of temperature, initial zinc pressure, oxygen pressure, and vacuum.

EXPERIMENTAL

The polycrystalline ZnO used in this work was the Fisher Certified Reagent Grade with a certified purity of 99.98%. The zinc oxide was stated to be a product of the Dry Process. The oxide powder was dried in an oven at 150° C for at least 10 hours before using. The surface area of the oxide powder was found to be 3.39 m^2/g as determined by krypton adsorption measurements. The particle size is calculated to be ca. 3×10^{-5} cm.

These experiments were carried out in a static system with the use of quartz vessels which has already been described (1). All weighings were done on a single pan, constant load, Gram-atic Balance (E. Mettler, Zürich, Switzerland) and the weights were obtained to 0.05 mg. The weighed bucket bearing the zinc oxide was suspended at the center in the quartz vessel. The vessel was connected to a vacuum system, evacuated for 1 hour at 200° C, sealed, and placed in the furnace. The furnace with its temperature regulation and the timing of the anneal was already described (3). After the anneal the vessel was withdrawn, allowed to cool to room temperature, and opened. The bucket was withdrawn and reweighed. The difference in weighings represented the loss in weight of the oxide.

RESULTS

In Table I are given the losses in weight of zinc oxide at different temperatures while maintaining a constant initial zinc pressure, calculated from the ideal gas equation, i.e.,

13	1253	6.0	77.7	3.2×10^{-2}	1.6×10^{-2}	3.6×10^{-2}
14	1273	13.0	85.0	7.0×10^{-2}	3.5×10^{-2}	6.0×10^{-2}

$PV = nRT$, and constant mole fraction of zinc in the solid oxide, s. The volume of the vessel, V, was 0.24 liter. Included in this table are the observed losses in terms of the pressure of zinc oxide vapor, P_{ZnO}, if the loss was due to evaporation of the oxide and the oxygen pressure, P_{O_2}, if dissociation occurred. The terminal column contains the values of the equilibrium constant, $K_p = P_{Zn}P_{O_2}^{\frac{1}{2}}$, for the dissociation reaction.

Table II contains the loss in weight as a function of initial zinc pressure at constant temperature and constant s. The weight losses are given in terms of P_{ZnO}, P_{O_2}, and K_p as in Table I. The average values of P_{ZnO} and K_p are shown on the bottom of their respective columns. On withdrawal of the vessel from the furnace after the anneal it was invariably observed for experiments involving an initial zinc pressure that the zinc oxide was dark gray or black. The color of the oxide transformed to pale cream within 1 minute after withdrawal, indicating that the adsorbed zinc on the oxide condensed on the cooler walls of the vessel. In experiments 27 and 29 of Table II metallic zinc deposits were observed

oxide pressure, P_{ZnO}, against the reciprocal of the absolute temperature with the slope of the best straight line corresponding to an energy of 43.0±5 kcal/mole. The values of P_{ZnO} and K_p plotted in Figs. 1 and 2 include all values from all tables; where two or more experiments were carried out at constant temperature, the average values of P_{ZnO} and K_p were plotted. The average values plotted are given on the bottom of their respective columns in each table. It is noteworthy that the K_p values corresponding to the weight losses observed for single crystals, experiments 51, 52, 55–57, are in agreement with the values obtained in this work.

DISCUSSION

The results reported herein defy explanation by simple conventional equilibria, i.e.,

[1] $$ZnO_{(s)} = Zn_{(g)} + \tfrac{1}{2}O_{2(g)}$$

and

[2] $$ZnO_{(s)} = ZnO_{(g)}$$

where the heat of sublimation of [2] is 10.1 kcal/mole (4). Since it has been established (5) that ZnO sublimes only by dissociation into $Zn_{(g)}$ and $O_{2(g)}$, reaction [2] is disregarded in favor of reaction [1] in this discussion. There has been passing reference (6, 7) to the fact that there is an apparent oxygen dissociation pressure of zinc oxide, which is many orders of magnitude greater than that deduced theoretically from the thermodynamic data. More recently Moore and Williams (8) reported some data on dissociation of zinc oxide by zinc vapor. According to their data the rate of evaporation of ZnO in zinc vapor is ca. 10^9 times the equilibrium value as calculated from the standard free energy data. Moore and Williams' data are concordant with our results which indicate that our equilibrium dissociation constant is greater than that calculated from the standard free energy data by a factor of ca. 10^8.

How can ZnO decompose under conditions deemed thermodynamically unfeasible? One *ad hoc* possibility is the existence of an unstable superficial suboxide such as Zn_2O or Zn_4O_3. If the surface of the ZnO becomes covered with an impervious layer of the suboxide so as to isolate the oxide, the dissociation reaction is essentially that of the solid suboxide. This possibility is supported by the observation that the oxide is completely covered with zinc during the anneal. Further evidence for a zinc-rich film on the oxide surface was obtained during sintering studies at 500° C and at oxygen pressure at 10 mm when the oxide became gray and exhibited a positive temperature coefficient of resistance and very high conductivity (7). The formation of the zinc-rich surface on zinc oxide in the latter case has been explained in terms of Schottky disorder where zinc leaves its normal lattice site and takes up normal positions on the surface of the oxide.

Appreciable dissociation of ZnO may be the result of a highly defective surface zone (9) which is without the limits of thermodynamics. Although it is not certain what is defined by this defective surface zone it must be recognized that some surface variable exists which could play an important role in the dissociation reaction. It is of significance that heat treatment and adsorbed gases can affect the activity and hence the defect constitution of the surface. In this regard, experiment 54 shows negligible loss with ca. 1-atm argon as contrasted to experiment 57 without argon. Furthermore, widely divergent weight losses were observed in experiments 27–29 following an identical procedure. In experiment 48, when zinc oxide was exposed to the atmosphere in an open vessel no loss was observed. It is quite reasonable therefore to believe that a non-equilibrium condition exists where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

the decomposition is determined by rate processes, such as diffusion of defects to surfaces and interface reactions. This problem of oxide decomposition at temperatures much lower than those predicted from thermodynamic data is not restricted to ZnO. The decomposition of NiO and alumina have already been reported (10, 11). Very little is known about the detailed mechanisms of such a reaction as decomposition of an oxide at the crystal–gas interface, but the present observations, if extended, may show that such reactions proceed through more complex mechanisms than have been hitherto suspected.

THE ACIDITY FUNCTIONS H_0 AND $J_0(H_R)$ FOR THE SYSTEM FORMIC ACID – WATER[1]

ROSS STEWART AND TREVOR MATHEWS

ABSTRACT

The acidity functions H_0 and $J_0(H_R)$ have been measured for the whole range of the formic acid – water system. The large negative J_0 values for the more concentrated solutions fail to correlate with the functions derived by Gold on the basis of certain assumptions regarding the activity coefficients of the species involved. The cause of this deviation is discussed. The term log $[R^+]/[ROH]$ for the ionization of triphenylcarbinols in formic acid has been found to vary linearly with $1/T$.

The Hammett acidity function, H_0, which measures the tendency of a solvent to transfer a proton to a neutral base has found wide application in two important fields, viz. the determination of the strengths of very weak bases and the study of acid-catalyzed reaction mechanisms in strongly acid media. It describes the simple ionization

$$B + H^+ \rightleftharpoons BH^+ \qquad [1]$$

and H_0 values, defined by the equation

$$H_0 \equiv pK_{BH^+} - \log [BH^+]/[B], \qquad [2]$$

have been determined for solutions of several strong acids in water and other solvents (1, 2). The values of pK_{BH^+} for the various indicators used to establish the H_0 scale must be obtained by a stepwise operation starting from a dilute aqueous solution of the acid where the activities of the various species involved in the equilibrium are assumed to be the same as in pure water.

A different acidity function governs the ionization of secondary bases, i.e. those compounds which ionize as follows:

$$ROH + H^+ \rightleftharpoons R^+ + H_2O. \qquad [3]$$

Lowen, Murray, and Williams examined such a system and used the term H_R to describe the acidity function governing the ionization (3). Gold and Hawes (4) soon after used the symbol J_0 for this function which is defined as follows:

$$J_0 \equiv pK_{R^+} - \log [R^+]/[ROH]. \qquad [4]$$

K_{R^+} is the ionization constant which governs reaction 3 and is defined as

$$K_{R^+} = \frac{a_{ROH} \cdot a_{H^+}}{a_{R^+} \cdot a_{H_2O}}. \qquad [5]$$

(Throughout this paper "a" stands for activity, "f" for activity coefficient, [ ] for molar concentration, and $[\ ]_N$ for concentration in units of mole fraction). Here again a stepwise operation is required to find the values of pK_{R^+} for the indicators used to establish the J_0 scale for concentrated acid solutions.

It can be shown that

$$H_0 = -\log (a_{H^+} \cdot f_B/f_{BH^+}) \qquad [6]$$

$$J_0 = -\log \left(a_{H^+} \cdot f_{ROH}/f_{R^+} \cdot \frac{1}{a_{H_2O}} \right) \qquad [7]$$

and Gold and Hawes (4) suggested that $J_0 = H_0 + \log a_{H_2O}$ (equation 7) which is based

[1]*Manuscript received November 2, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, British Columbia.

on the assumption—a reasonable one in view of earlier work—that $f_B/f_{ROH} = f_{BH^+}/f_{R^+}$ (equation 8) where ROH is a secondary base, such as triphenylcarbinol, and where B is a base of the ammonia type used to establish the H_0 scale. Cryoscopic measurements show clearly that triphenylcarbinol is ionized by sulphuric acid as follows (5, 6):

$$(C_6H_5)_3COH + 2H_2SO_4 \rightleftharpoons (C_6H_5)_3C^+ + H_3O^+ + 2HSO_4^- . \quad [8]$$

Gold and Hawes used vapor pressure data to obtain the acitivity of water in sulphuric acid solutions and thus calculated J_0 values for sulphuric acid solutions of from 5% to 95% composition by means of equation 7. Since at that time values of pK_{R^+} had not been established for any secondary bases, the only test of equation 7 and the principles used in its derivation was to plot values of log $[R^+]/[ROH]$ for a secondary base dissolved in sulphuric acid against values of J_0 calculated using equation 7. Equation 4 shows that a straight line of unit slope should result. When data for 4,4′,4″-trinitrotriphenylcarbinol was plotted in this way, a straight line of slope 1.16 was obtained in fairly close agreement with theory.

In 1955 Deno, Jaruzelski, and Schriesheim (7), starting with dilute aqueous solution, used the stepwise technique to determine values of pK_{R^+} for a series of substituted triphenylcarbinols and also values of the acidity function for secondary bases in sulphuric acid from 0–98% concentration. They observed that the acidity function departed very seriously from the values of J_0 obtained from equation 7 and suggested the symbol C_0 for the function defined by equation 4. They showed that this function correlated the change in rate with change in sulphuric acid concentration of several chemical reactions which were believed to proceed via the ionization reactions shown in equation 3.

At about the same time, Gold (8) derived two additional equations similar in form to equation 7 based on certain assumptions regarding the behavior of the various activity coefficients. These functions were designated J_0'' and J_0''' and the function defined by equation 7 as J_0'. Thus the true acidity function for secondary bases defined by equation 4 is referred to by Gold as J_0, and by Deno *et al.* first as C_0 (7) and subsequently as H_R (9). The function defined by equation 7 is now referred to by Gold as J_0' and by Deno *et al.* as J_0. Paul and Long in their review article (1) use J_0 as the symbol for the experimentally determined acidity function for secondary bases. However, since then Deno *et al.* (9) have abandoned C_0 in favor of Williams original symbol, H_R, and it would seem that both J_0 and H_R will continue to appear in the literature for some time. We have accordingly used both symbols throughout this paper to refer to the experimental acidity function and primed J_0 symbols for the derived functions.

Previous work by Stewart (10) and by Evans *et al.* (11) has shown that formic acid reduces the triphenylcarbinol to triphenylmethane probably via hydride transfer from formate ion to the carbonium ion. Formic acid is a medium which facilitates reduction of tertiary carbinols by this mechanism. It is sufficiently acidic to ionize triphenylcarbinols and some olefins to carbonium ions; it has a high dielectric constant (58.5 at 16°) and a high degree of autoprotolysis producing a reasonable concentration of formate ion, the reductant; and its oxidation product, carbon dioxide, is of low energy.

The purpose of this work, then, was to determine the values of the acidity functions, H_0 and $J_0(H_R)$, for formic acid solutions primarily for future use in kinetic studies, but in addition as a test of the validity of Gold's derived functions, J_0', J_0'', and J_0''', as approximations to the experimentally determined function J_0 in a solvent other than sulphuric acid. Bascombe and Bell have recently reported a careful investigation of acidity functions of some aqueous acids but did not list H_0 values for formic acid because of apparent discrepancies between values obtained with different indicators (12).

EXPERIMENTAL

Indicators

Triphenylcarbinol and *o*- and *p*-nitroaniline were reagent grade chemicals which were crystallized repeatedly to constant melting point. *p*-Nitrodiphenylamine was prepared from *p*-nitroaniline and bromobenzene by the method of Goldberg and Sissoeff (13). 4-Methoxytriphenylcarbinol was prepared by the Grignard synthesis using phenylmagnesium bromide and ethyl anisate after the method of Brand (14). 4,4′,4″-Trimethoxytriphenylcarbinol was also prepared by this method using 4,4′-dimethoxybenzophenone and *p*-bromoanisole.

Formic Acid

Reagent grade 88–90% formic acid, Baker and Adamson (4 l.), was distilled at reduced pressure and middle cuts of 1600 and 1200 ml were used as stock solutions. Titrations with standard base showed the formic acid content to be 94.5% and 87.4% respectively.

Anhydrous formic acid was prepared by zone freezing, as previously described (10), one liter of formic acid taken from the middle cut of two liters of Baker and Adamson 98–100% formic acid which had been distilled *in vacuo*. After three zone freezings the melting point of the residue (about 400 ml) was found to be 8.4° (15). Titration with standard base gave the formic acid content as 99.9%.

Measurement of H_0

H_0 values were calculated using equation 4 and the revised pK_{BH^+} values of Paul and Long (1). Measurements of the $[BH^+]/[B]$ ratio were made by adding 0.1 ml of a solution of the particular indicator dissolved in acetone to a 1-cm absorption cell fitted with a ground-glass neck and stopper. The acetone was evaporated, 3 ml of formic acid of known composition was added, and the optical density of the resulting solution which was generally of the order of 10^{-4} *M* in indicator was determined at λ_{max} using a Beckman DU spectrophotometer. Then 0.1 ml of the same indicator solution was dissolved in a known volume of water and the light absorption measured as before. The temperature was controlled to $25° \pm 0.5°$ by means of thermospacers. Each of the indicators was colorless in the ionized form but absorbed strongly in the visible or near ultraviolet in the unionized form. It was observed that a slow reaction occurred between the nitroanilines and the formic acid since the spectrum of the solution changed on long standing to resemble that of the corresponding formanilide (16). Extrapolations to zero time were made wherever the reaction was appreciable. Beer's law was checked for each indicator under conditions where $[BH^+]$ is negligible and each indicator was checked to ensure that no shift in λ_{max} occurred in going from water to formic acid solutions. It was observed, however, that values of $[BH^+]/[B]$ were not independent of the concentration of the base. Plots of the ratio against concentration of the base produced approximately straight lines which were extrapolated to zero concentration to determine the ratio used in the calculation.

Measurement of $J_0(H_R)$

$J_0(H_R)$ values were calculated using equation 4 and the pK_{R^+} values of Deno, Jaruzelski, and Schriesheim (7). The method of determining $[R^+]/[ROH]$ was similar to that used in determining $[BH^+]/[B]$ except that ROH was determined by addition of 0.1 ml of the carbinol solution to a known volume of formic acid of such concentration as to completely ionize the carbinol. For these compounds, of course, the colored species is the ion. The solutions were of the order of 10^{-4} to 10^{-5} *M*. The assumption that no change in extinction coefficient occurs with changing formic acid concentration was tested by measuring the optical density of the methoxy-substituted carbinols at λ_{max} for a range of 25% formic

acid above that at which the alcohol was effectively completely ionized to the carbonium ion. In these cases no change in extinction coefficient was observed.

As in the H_0 measurements the values of $[R^+]/[ROH]$ were found to be not independent of the concentration of the carbinol. Deno *et al.* (7) observed this phenomenon in sulphuric acid but found that at extremely low concentrations of carbinol using long path cells the ratio did become independent of concentration. In this work a linear extrapolation was used to find the limiting value of the ratio. This value may be very slightly in error in the light of the work of Deno *et al.*, but, if so, the error is small.

Since reduction of the carbinol can occur (10) in formic acid a plot of optical density against time was made for each carbinol solution in which appreciable fading of the carbonium ion occurred. This plot was extrapolated back to zero time in order to obtain $[R^+]$.

RESULTS AND DISCUSSION

Table I and Fig. 1 show the values of H_0 as a function of formic acid concentration.

◐ 4,4′,4″-Trimethoxytriphenylcarbinol.
× *o*-Nitroaniline. ● *p*-Nitroaniline.

There appears to be satisfactory overlap in H_0 values for the indicators used, indicating that H_0 is independent of the base used for the determination. It should be pointed out, however, that less satisfactory agreement is obtained with our data using the indicator pK values of Bascombe and Bell (12) and that there is a variation in indicator ratio with indicator concentration, as described in the experimental section. This may account for our not observing the discrepancies noted by them. We can only report that for the indicators used in the present work a fair correlation was obtained indicating that H_0 is an approximately valid function in formic acid. In dilute solution the values of H_0 approach pH as required. The pH of 0.22 M formic acid in water should be 2.18; H_0 for this solution is 2.00.

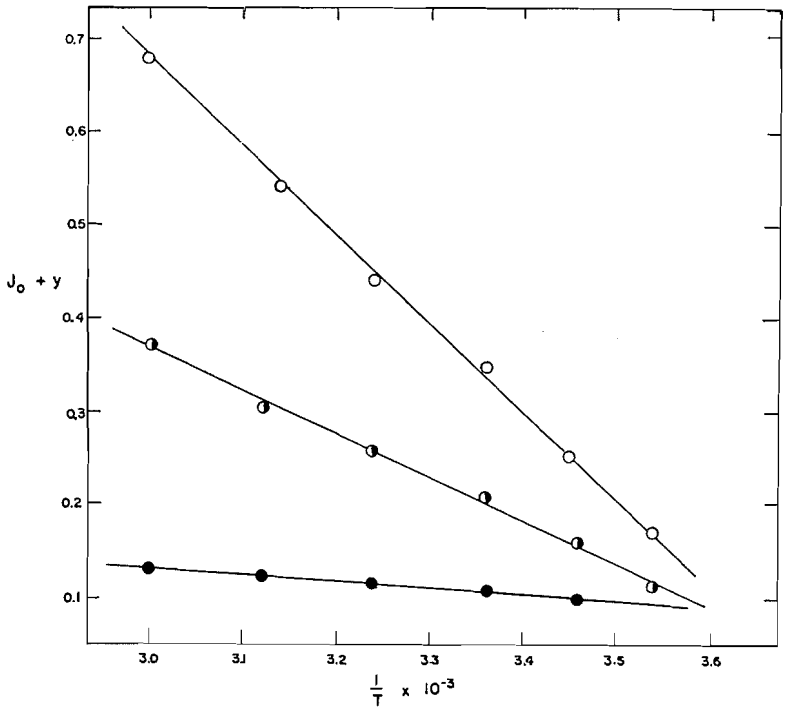

FIG. 2. Variation of apparent $J_0(H_R)$ with absolute temperature.
○ Triphenylcarbinol, $Y = 5.9$. ◑ 4-Methoxytriphenylcarbinol, $Y = 3.8$.
● 4,4′,4″-Trimethoxytriphenylcarbinol, $Y = 1.5$.

Table II and Fig. 1 show $J_0(H_R)$ as a function of formic acid concentration. There is reasonable overlap between triphenylcarbinol and 4-methoxytriphenylcarbinol. Although there is no overlap between 4-methoxytriphenylcarbinol and 4,4′,4″-trimethoxytriphenylcarbinol $dJ_0/d\%$ formic acid is the same for the lower region of the former curve and the upper region of the latter, a sufficient substitute for overlap. The $J_0(H_R)$ function therefore appears to be a valid acidity function in formic acid. As required, the values of $J_0(H_R)$ approach H_0 and pH in dilute formic acid.

Turning to Gold's derived quantities J_0', J_0'', and J_0''' we find them deviating rather widely from the experimental function $J_0(H_R)$. J_0' is defined by equation 9

$$[9] \qquad J_0' = H_0 + \log a_{H_2O}.$$

Values for the activity of water in formic acid solutions were calculated using the vapor pressure data of Takagi (17) and the equation $a_{H_2O} = p_{H_2O}/p^0_{H_2O}$ where $p^0_{H_2O}$ is the vapor pressure of pure water at the same temperature. A slight extrapolation was required to obtain the partial pressures of water at 25° in these solutions but any errors involved in the calculations are small compared with the difference between $J_0(H_R)$ and J_0' as shown in Fig. 1.

J_0'' is defined by equation 10,

$$[10] \qquad J_0'' = 2H_0 + \log [H_3O^+]_N + 1.74.$$

11.2	0.36	+1.27
4.4	0.14	+1.67

[a] These values must be regarded as approximations only since $[R^+]$ is calculated using the extinction coefficient of the carbonium ion in sulphuric acid.

Information does not appear to be available in the literature for the hydronium ion concentration but it can be shown that, at least for concentrated formic acid solution, rather unlikely values of the hydronium ion concentration would be required to make $J_0(H_R)$ and J_0'' coincide. Thus in 90% to 95% formic acid an hydronium ion concentration of the order of 10^{-4} molar must be assumed decreasing for 99% formic acid to a value closer to 10^{-5} molar. This compares with a known hydronium ion concentration of the order of 10^{-2} molar in 0.1 *M* formic acid and at the other end of the scale a known con-

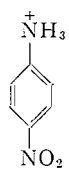
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

centration of $HCO_2H_2^+$ of about 10^{-3} molar in 100% formic acid (6). The H_3O^+ concentration in the 90–99% range must therefore be considerably greater than this.

J_0''' is defined by the equation

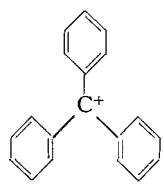
$$[11] \qquad J_0''' = H_0 + \log [H_2O]_N.$$

Gold found that for sulphuric acid solutions this was the least satisfactory of the three functions as approximations to $J_0(H_R)$. In agreement with this we find that J_0''' lies between J_0' and H_0 for formic acid solutions. If the data of Gold (8) and Deno *et al.* (7) for sulphuric acid are combined it can be shown that the derived functions all fall between the experimental ones H_0 and $J_0(H_R)$ with J_0'' being the only one of the three which is closer to $J_0(H_R)$ than to H_0.



Thus both in sulphuric acid and in formic acid, secondary bases such as triphenylcarbinol ionize to a much greater extent than would be expected from a consideration of equations 9–11. Consider equation 12, which is obtained by the combination of equations 5 and 6; all activity coefficients refer to dilute aqueous solution as the standard state.

$$[12] \qquad J_0(H_R) = H_0 + \log a_{H_2O} + \log \frac{f_B \cdot f_{R^+}}{f_{BH^+} \cdot f_{ROH}}.$$



It can be seen from Fig. 1 that the final term in the above equation must make a considerable contribution to $-J_0(H_R)$ and it is worth while speculating on the reason for this since for two bases of the ammonia type, B_1 and B_2, the value of $\log f_{B_1} f_{B_2H^+} / f_{B_1H^+} f_{B_2}$ is effectively zero (1).

Since solvation effects are usually more important for ions than for neutral molecules, we might assume that the principal change in activity due to solvation in going from water to sulphuric or formic acid solution is for the species BH^+ and R^+. In this connection Briegleb (18) has calculated the heat of hydration of typical amines to be 10–12 kcal $mole^{-1}$ while that of the ammonium ions is 83–85 kcal $mole^{-1}$. Cations are solvated best by basic molecules, i.e. those with available pairs of electrons and one would expect water to perform this function better than either sulphuric or formic acid. Thus in going to the latter solutions from water the activity of the cations should increase.

The greatly increased solubility of some weak bases in sulphuric acid of strength below that required to cause appreciable ionization of the base shows that the term f_B can decrease markedly in going from water to sulphuric acid (19, 20). Thus a considerable change in the activity coefficients of the neutral species B and ROH may also occur but it is not obvious why this effect should be greatly different for B than for ROH. A principal difference between the ions BH^+, typified by the nitroanilinium ion (used to determine the H_0 scale), and the carbonium ions (used to determine the $J_0(H_R)$ scale) is the fact that in the former the charge is localized on the nitrogen atom as in I whereas in the carbonium ion (II) the charge is spread by resonance to a very considerable extent into the three rings.

Thus solvation is less important to the carbonium ion and when it is transferred to a sulphuric or formic acid solution, the increase in its activity due to the decreased solvation should be less than that for the anilinium ion. This argument is, at least, in qualitative agreement with the experimental fact that the ratio $f_B f_{R^+}/f_{BH^+} f_{ROH}$ does decrease greatly in going from water to sulphuric and formic acid. Deno and Perrizolo (20) have recently determined the ratios of the activity coefficients of several ions in sulphuric acid – water mixtures. Comparing a small unshielded ion like K^+ with a large shielded ion like $(C_4H_9)_4N^+$ they found, in fact, that $d(f_{K^+}/f_{(C_4H_9)_4N^+})/d\%$ H_2SO_4 underwent a 25-fold increase on going from 0% to 70% sulphuric acid. Deno *et al.* found, however, that the concentration of the ion, NO^+, formed by the ionization of HNO_2, follows the acidity function $H_R(J_0)$ in sulphuric acid (9). Since this is a small ion in which extensive charge delocalization is not possible they have suggested that the group of cations which follows this acidity function (carbonium ions and the NO^+ ion) do so because of the presence of an empty available orbital (open sextet) in the ions. They propose that the weak bonding resulting from overlap of the cation's empty orbital and the solvent oxygen's orbitals is a different function of acidity from the usual cation–solvent interaction. It is difficult to reconcile this similarity in behavior of NO^+ and arylcarbonium ions with the charge delocalization concept which we have advanced herein to explain the difference between the experimental acidity function, $J_0(H_R)$, and the calculated values of Gold. Both factors referred to above may be important. It is worth pointing out here that the position of equilibrium between a charge localized ion and its tautomeric delocalized form has been shown in at least two cases (protonated Michler's ketone and Michler's hydrol) to be strongly affected by the nature of the solvent (21).

Variation of $J_0(H_R)$ with Temperature

The effect of a temperature change on $J_0(H_R)$ was determined for three different concentrations of formic acid. Although H_0 is altered only slightly by temperature change, it was found that the ionization of the carbinols studied increased with increasing temperature, the increase being small in dilute formic acid but much larger in concentrated solution. Plots of apparent $J_0(H_R)$, calculated by assuming pK_{R^+} to be constant, against $1/T$ gave straight lines as can be seen in Fig. 2. The significance of this result must await a determination of the effect of temperature on pK_{R^+}. (7).

SOLVENT EXTRACTION OF MINERAL ACIDS

PART III. SOLUTE–SOLVENT INTERACTION IN THE SYSTEM HYDROBROMIC ACID – WATER – TRI-*n*-BUTYL PHOSPHATE[1]

A. S. KERTES AND V. KERTES

ABSTRACT

Evidence, based on physical–chemical measurements of the organic layers, has been presented to show that tributyl phosphate extracts hydrobromic acid as its disolvate in medium acid concentrations, and probably as monosolvate in high concentrations. The determination of water in the tributyl phosphate phases indicates that at low and medium acid concentrations the acid is extracted as its tetrahydrate, and at high concentrations as an unhydrated species. From these results, the formation of $[(TBP)_2.HBr.(H_2O)_6]$ and $[TBP.HBr.(H_2O)_3]$ could be deduced.

Compared with the extensive literature on the extraction of inorganic nitrates from aqueous nitric acid solutions by tributyl phosphate, relatively few investigations have dealt with tributyl phosphate extraction of inorganic halides from aqueous solutions of the corresponding hydrohalic acid. The reactions between metal salts or ions and tributyl phosphate can only be correctly understood if the very pronounced tendency of this basic extractant to react with the acid present in such systems is taken into account. It was therefore considered necessary to investigate more thoroughly the solute–solvent interactions involved in the heterogeneous equilibria existing in systems of hydrohalic acid – water – tributyl phosphate. Our earlier research determined the species formed as a result of solute–solvent interaction in the system $HCl–H_2O–TBP$ (1). The second paper in this series dealt with the hydration phenomena of tributyl phosphate – hydrochloric acid complexes existing in the organic layer (2). In the continuation of this research we made a similar investigation of the system $HBr–H_2O–TBP$.

On the experimental side, the present research is an extension of that carried out recently by Baldwin, Higgins, and Soldano (3), in which the distribution coefficient of hydrobromic acid, and its hydration number, were investigated. These authors found that HBr is more effectively extracted than HCl into TBP, and that at low acid concentrations the halogen acids carried water along into the TBP, at the rate of approximately $4H_2O$ per HX. At high acid concentrations it seemed to these authors that water was again forced from the tributyl phosphate. It was also indicated (4) that hydrobromic acid entered the organic phase along with the four water molecules at low acid concentrations. No other studies have been published in the open literature dealing with tributyl phosphate extraction of HBr.

The results reported here reveal the certain existence of a well-defined compound among hydrobromic acid, tributyl phosphate, and water, and indicate the existence of another. The mechanism of extraction of the compounds is suggested.

EXPERIMENTAL

Reagents

B. D. H. Analar grade colorless hydrobromic acid was standardized against standard carbonate-free sodium hydroxide solution. Calculated amounts were taken for 13 stock

[1]*Manuscript received November 16, 1959.*
Contribution from the Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel.

solutions of various concentrations as listed in Table I. Tri-*n*-butyl phosphate was treated as reported previously.

Procedure

The procedure for the distribution experiments consisted of equilibrating 5 ml of pure undiluted TBP with 5 ml of initial aqueous acid solution of various concentrations. The changes in volume, the density, viscosity, and conductivity of the organic layers were measured as described in the previous paper (1). The acid and water determinations followed the methods outlined in Part I. All the measurements were performed at room temperature of 20°±1° C and where necessary in a thermostatic water bath at 20°± 0.1° C.

RESULTS AND DISCUSSION

Partition and Ionization of the Acid

Column 2 of Table I shows the molarity of hydrobromic acid in the initial aqueous solutions, and columns 3 and 4 the molarity in the equilibrium aqueous and organic phases respectively. The concentration and mass distribution coefficients, as previously

defined (1), are compiled in columns 6 and 7 respectively. Figure 1 represents the graph of the acid molarity in the equilibrium phases. The non-uniform shape of the curve indicates that the species of HBr extracted from aqueous solutions of hydrobromic acid of initial concentrations up to about 1 *M* differ from those extracted from more concentrated solutions. Furthermore, when the TBP phase is equilibrated with aqueous solutions of initial concentrations as above, the decrease in the values of the equivalent conductance (column 5 of Table II, and Fig. 5) suggests that from these dilute aqueous acid solutions the acid passes into the organic phase to a large extent in ionized form. Increase in the acid concentration of the initial aqueous solutions promotes ion-pair formation and causes an increase in the acid content of the organic layer. It should be noted that this interpretation does not agree with the values of the degree of ionization estimated by means of Walden's rule, $\lambda\eta/60$, shown in column 6 of Table II.

Solvation of the Acid

The solvation number of hydrobromic acid in the extractant, i.e. the composition of the compound formed between the acid and the extractant as a result of their interaction, was determined by physical–chemical measurements of the organic layer.

On equilibrating 5 ml of pure TBP (18.35 mmoles) with an equal volume of aqueous acid solution, the volume of the organic phase increases. In Fig. 2 the changes in volume of the organic layer, shown in column 5 of Table I, are plotted against the acid content of this layer. It is clear that there are three different interactions, occurring in low, medium, and high acid concentrations respectively. For acid concentrations up to 1 M, the increase in volume of the organic phase is equal to the increase caused by pure water. For concentrations between 1 M and $\sim$5.5 M there is a greater increase in volume, and

a break occurs in the curve when the ratio TBP:HBr reaches two. The third type of interaction occurs when the acid concentration exceeds $\sim 5.5\ M$.

When the densities and viscosities (Table II) are plotted against the acid content of the equilibrium organic layers, the curves shown in Figs. 3 and 4 are obtained. When the

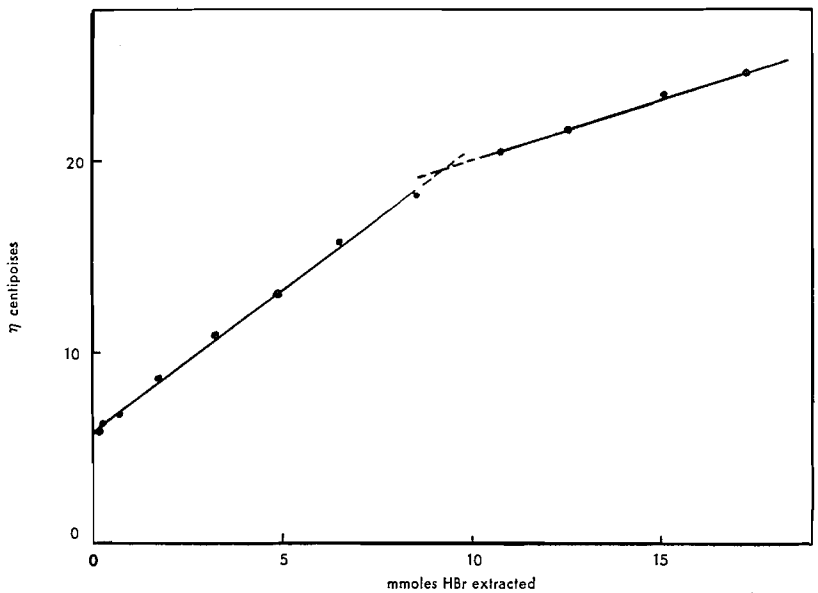

Fig. 4. The plot of viscosity of the equilibrium organic phases versus mmoles of HBr extracted.

TBP phase is equilibrated with aqueous solutions of concentrations up to ~1 *M* HBr, only very slow changes, if any, are observed in these physical data. The interaction in medium acid concentrations is demonstrated by a break in both curves, at a point when the organic layer contains 9.2 mmoles of hydrobromic acid and 18.35 mmoles of tributyl phosphate, i.e. a TBP:HBr ratio of two.

The results of conductivity measurements of the organic phase are given in columns 4 and 5 of Table II. Figure 5 shows the equivalent conductance values, plotted against the

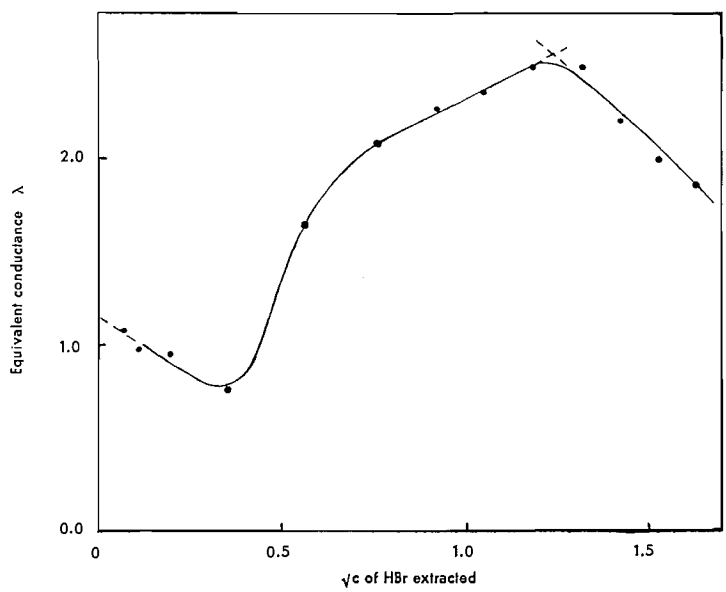

FIG. 5. The plot of equivalent conductance of the equilibrium organic phases versus the square root of the HBr concentration in the organic phase.

square root of the acid concentration, $\sqrt{c}$. It has already been noted that the appearance of a conductance minimum is very probably associated with the end of an ionization region (maximum concentration of the acid in the organic layers of this region being 0.1 M), and it is characteristic of polar compounds dissolved in media of low dielectric constant. Higher values can be explained by the increased extraction of HBr into the TBP due to ion-pair formation (5, 6). The curve, in addition, shows an interception, on extension over a flat maximum, between the medium and high acid concentration regions. This break corresponds to a TBP:HBr ratio of two, evidence for the formation of $(TBP)_2.HBr$.

The solvation number of inorganic species in organic solvents under conditions of liquid–liquid extraction have so far been deduced from partition data, using undiluted (7) and diluted extractants (8). By the methods employed in this study, the physical–chemical behavior of the tributyl phosphate extractant (in equilibrium with aqueous hydrobromic acid of various concentrations) has revealed that the extracted hydrobromic acid species contains two tributyl phosphate molecules per acid molecule. It was further shown that the solvation number is to a large extent dependent on the acid concentration. In high concentrations the solvation of the extracted acid species is determined by an interaction leading to the formation of a compound which probably contains a TBP:HBr ratio of unity. Although the formulation of this compound cannot be considered as established, the great change in the nature of the organic layers, when using high acid concentrations, seems to indicate results comparable with those of the similar system containing hydrochloric instead of hydrobromic acid (1).

With the exception of our study (1), there seem to be no examples of mineral acids being extracted with two tributyl phosphate molecules. In fact, the solvation numbers of nitric and perchloric acids extracted into TBP appear to be one. This was also found to be true for hydrochloric, and very probably hydrobromic, acids, but only in high acid concentrations. It has now been shown that for medium acid concentrations the main solute–solvent interaction leads to the formation of hydrobromic acid disolvate, analogous to hydrochloric acid disolvate.

Hydration of the Acid

The water content of the organic layer in millimoles, and the corresponding water:extractant ratios, are compiled in the last two columns of Table I. Figure 6 shows the curve obtained by plotting the water content against the acid content of the tributyl phosphate layer. The curve shows the water content of the organic phase in two stages. The points corresponding to tributyl phosphate phases with very low acid content (up to $\sim$0.1 M, that is up to about 0.5 mmole) could not be integrated into these stages, and so at these low acid concentrations nothing could be stated about the hydration mechanism of the acid. For medium acid concentrations (initial acid concentration between $\sim$1 and $\sim$5.5 M), the graph shows a straight line, of slope four, indicating that each acid molecule passing from the aqueous into the organic layer is associated with four water molecules. This relationship holds until the acid content of the tributyl phosphate layer is 9.2 mmoles, when the TBP:HBr ratio is two. After this, the water content no longer changes with increase in the acid content of the organic phase. For these high acid concentrations the H_2O:TBP ratio remains practically constant, and equal to three approximately.

The above results of the acid hydration are completely analogous to those obtained in the system with hydrochloric acid, as is also the stability of hydration (2) of the extracted species.

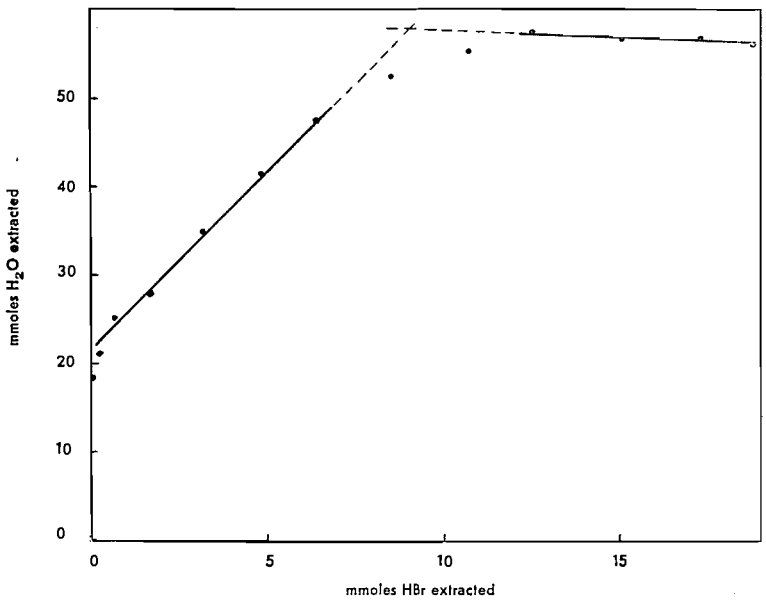

FIG. 6. The plot of mmoles of H_2O versus mmoles of HBr both in the equilibrium organic phases.

CONCLUSIONS

The acid passing into the tributyl phosphate phase from dilute aqueous hydrobromic acid is probably ionized. For these low acid concentrations, the main reaction involved is that between water and the extractant, resulting in the formation of the stable tributyl phosphate monohydrate. For medium acid concentrations, ion-pair formation becomes significant, and each acid molecule is extracted together with four water molecules. The acid–ester interaction leads to the formation of a compound with a TBP:HBr ratio of two, and H_2O:TBP ratio of three. These reactions could be formulated as follows:

$$TBP_{org} + H_2O_{aqu} \rightarrow [TBP.H_2O]_{org}, \quad [1]$$

$$2[TBP.H_2O]_{org} + H^+(H_2O)_{4\,aqu} + Br^-_{aqu} \rightarrow [(TBP)_2.HBr.(H_2O)_6]_{org}. \quad [2]$$

Both these reactions are analogous to those previously found in systems containing hydrochloric acid.

Under the experimental conditions of this investigation, it was found impossible to equilibrate the tributyl phosphate phase so that the acid content corresponded to a TBP:HBr ratio of unity. Therefore for high acid concentrations this system is not completely analogous to that containing HCl. Nevertheless, following the analogy between the two systems, it can be presumed that for high acid concentrations, when the extracted acid is unhydrated, the H_2O:TBP ratio is constant and practically equal to three, and as the TBP:HBr ratio decreases and approaches unity, a further reaction probably takes place. This reaction should be analogous to that in the HCl system at these high acid concentrations, and should be formulated as follows:

$$[(TBP)_2.HBr.(H_2O)_6]_{org} + H^+_{aqu} + Br^-_{aqu} \rightarrow 2[TBP.HBr.(H_2O)_3]_{org}. \quad [3]$$

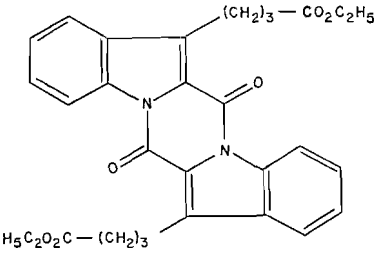
1,6-BIS(γ-CARBETHOXYPROPYL)-2,3,7,8-DIBENZOPYROCOLL. A BY-PRODUCT IN THE PREPARATION OF γ-(3-INDOLYL)BUTYRIC ACID

RICHARD H. MANSKE AND WALTER R. BOOS



During the preparation of γ-(3-indolyl)butyric acid a by-product was obtained when the phenylhydrazone of the half ester of α-ketopimelic acid (I) was subjected to the Fischer indole synthesis and esterified to ethyl γ-(2-carbethoxy-3-indolyl)butyrate (II). The compound was identified as 1,6-bis(γ-carbethoxypropyl)-2,3,7,8-dibenzopyrocoll (III) by hydrolytic ring fission to γ-(2-carboxy-3-indolyl)butyric acid.

(I)

(II)

(III)

EXPERIMENTAL

1,6-Bis(γ-Carbethoxypropyl)-2,3,7,8-dibenzopyrocoll (III)

A 5-liter round-bottom flask equipped with a reflux condenser was charged with 1052 g of the half ethyl ester of the phenylhydrazone of α-ketopimelic acid (I), 3 liters of 99% ethanol, and 270 ml of sulphuric acid (density = 1.84). The mixture was boiled for 20 hours under reflux on a steam bath. Subsequently the ethanol was distilled off and the remaining liquid was taken up in 1 liter of benzene, washed well with water, then with 5% aqueous sodium bicarbonate solution, and again with water. The benzene was distilled from the extract and an attempt to distill the residue at a pressure of 0.1 mm failed due to partial decomposition. On cooling crystals were obtained, and these were taken

up in 1.5 liters of 99% ethanol. The yellow crystalline material which then separated was removed by filtration; yield was 180 g. (The filtrate was stripped of ethanol and distilled at 0.1 mm and 210° C and yielded 506 g of ethyl γ-(2-carbethoxy-3-indolyl)butyrate (II).) The precipitate was recrystallized twice from benzene and yielded pale yellow plates, m.p. 214.5–215° C. Calc. for $C_{30}H_{30}N_2O_6$: C, 70.02; H, 5.88; N, 5.44; mol. wt., 514. Found: C, 70.06; H, 5.81; N, 5.80; mol. wt., 548 (Rast).

Hydrolytic Degradation of III *to the Diacid of* II

Three grams of the pyrocoll (III) was hydrolyzed by refluxing for 1 hour in 70 ml of propanol together with 5 g of potassium hydroxide. On cooling a colorless precipitate was obtained which was filtered off, washed with propanol, and dissolved in 60 ml of distilled water. Addition of dilute hydrochloric acid yielded a colorless precipitate which was washed with distilled water and recrystallized from 20 ml of a 1:1 mixture of methanol and benzene: yield 2.3 g of colorless plates; m.p. 210° with loss of carbon dioxide. Calc. for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30. Found: C, 62.82; H, 5.26. Decarboxylation at 220 to 230° in a nitrogen atmosphere readily yielded γ-(3-indolyl)butyric acid melting at 124° either alone or in admixture with an authentic specimen (1).

MAGNETIC MOMENT OF Ni^{2+} ION IN $(Ph_3P)_2NiBr_2(PhBr)_2$

Yoshio Matsunaga

Recently Gill, Nyholm, and Pauling (1) have suggested that a regular tetrahedral arrangement of four-covalent spin-free Ni^{2+} complexes is much less probable than a distorted one. If distortion from a regular tetrahedron is small, the magnetic moment of Ni^{2+} ion should be larger than the spin-only value of 2.8 B.M. They have observed the magnetic moment of the Ni^{2+} ion in $(Et_4N)_2(NiCl_4)$ and $(Et_4N)_2(NiBr_4)$ being in the range of 3.8 to 3.9 B.M. Similar high moments have been found in the following cases: the Ni^{2+} ion in the tetrahedral hole of glass, 3.6 B.M. (2), the Ni^{2+} ion in the tetrahedral site of spinel, about 3.6 B.M. (3), and the Ni^{2+} ion in $[(Ph_3PO)_4Ni](ClO_4)_2$, 3.51 B.M. (4). In all of the above-mentioned cases, Ni^{2+} ion is surrounded by four equivalent ions or atoms. Venanzi (5) has found that complexes of the type $(Ph_3P)_2NiX_2$ show the magnetic moments which are only a little higher than the spin-only value and are monomeric in benzene solution. It has been shown by X-ray studies that the Ni^{2+} ion is located at the center of a distorted tetrahedron (6). Here we wish to report the increase of the magnetic moment of the Ni^{2+} ion in $(Ph_3P)_2NiBr_2$ by addition of crystalline solvent.

A number of compounds of the types $(Ph_3P)_2NiX_2Y$ and $(Ph_3P)_2NiX_2Y_2$, where Y is alkyl or phenyl halide, have been described by Reppe and Schweckendiek (7) and by Yamamoto (8). Among them we examined the compounds $(Ph_3P)_2NiBr_2$, $(Ph_3P)_2NiBr_2$ *tert.* BuBr, and $(Ph_3P)_2NiBr_2(PhBr)_2$, which are intense green, green, and grayish blue, respectively. The following values of specific magnetic susceptibility at room temperature and effective magnetic moment of Ni^{2+} ion were obtained: $(Ph_3P)_2NiBr_2$,

5.64×10^{-6} c.g.s.-e.m.u., 3.2 B.M.; $(Ph_3P)_2NiBr_2$ *tert.* BuBr, 5.37×10^{-6}, 3.4 B.M.; and $(Ph_3P)_2NiBr_2(PhBr)_2$, 5.59×10^{-6}, 3.8 B.M. The high magnetic moment of the Ni^{2+} ion in the latter two suggests that distortion from a regular tetrahedral arrangement can be decreased by the presence of crystalline solvent. The distortion in the compounds $(Ph_3P)_2NiX_2$ (X = Cl, Br, I, and NO_3) seems to be partially due to the steric requirement by the size difference between triphenylphosphine and halide ion. To compensate for such a steric effect in $(Ph_3P)_2NiBr_2$ two molecules of bromobenzene may be more suitable than one molecule of tert.butyl bromide. The appearance of blue tint in many cases of compounds of the types $(Ph_3P)_2NiX_2Y$ and $(Ph_3P)_2NiX_2Y_2$ may have some correlation with rather small distortion from a regular tetrahedral arrangement.

CRYSTALLINE GLYOXYLIC ACID AND ITS SODIUM–CALCIUM SALT

A. A. Eisenbraun* and C. B. Purves

Early researches on the preparation and properties of glyoxylic acid were extensively reviewed by Debus (1) and by Hendricks (2), who noted that the substance occasionally yielded ill-defined rhombic crystals of a monohydrate when stored over a drying agent. In 1925, Hatcher and Holden (3) used the electrochemical method to reduce oxalic acid, isolated barium glyoxylate, decomposed the latter with sulphuric acid, and prepared anhydrous glyoxylic acid for the first time as monoclinic crystals melting at 98°. This result was questioned by Hendricks (2) because oxalic acid monohydrate, a probable impurity, melted at 99° and occurred as monoclinic crystals, and also because his attempts to repeat the crystallization of glyoxylic acid failed. Later workers oxidized tartaric acid or its esters with a glycol-cleaving agent, periodic acid or a periodate (4, 5, 6), lead tetraacetate (7), or sodium perbismuthate (8, 9), but apparently restricted their interest to the preparation of various esters and metallic salts of glyoxylic acid.

In the present work, tartaric acid was oxidized with aqueous periodic acid, by-product iodic acid was removed as the insoluble lead salt, and, after neutralization with barium hydroxide, crystalline barium glyoxylate dihydrate was recovered in high yield. An ion-exchange resin eliminated the cations from an aqueous solution of this salt, and evaporation of the effluent left glyoxylic acid as a clear syrup which eventually crystallized. The melting point was 104–107°, with softening at 94°. The replacement of periodic acid by sodium metaperiodate in the above oxidation, followed by the removal of iodate ion, left

a solution which was mixed with an equimolar amount of aqueous calcium acetate. A white, crystalline, sodium–calcium salt, $CaNa_2(C_2HO_3)_4.4H_2O$, promptly separated. This salt was thought to be new.

EXPERIMENTAL

Glyoxylic Acid

An aqueous solution, 300 ml, containing 15 g (0.1 mole) of L-tartaric acid and 25.1 g (0.11 mole) of paraperiodic acid (H_5IO_6) was kept at 23° in the dark for 10 hours, when a titration by the sodium arsenite – iodine method showed that all of the periodic acid had been reduced. The addition of 110 ml of 0.52 *M* lead acetate (0.114 equivalent) caused the nearly quantitative separation of lead iodate, which was removed by filtration. After residual lead ions were removed as lead sulphide, the clarified liquor was evaporated *in vacuo* to a syrup, by-product acetic and formic acids being incidentally eliminated. The acidity of the syrup was cautiously reduced to pH 8 by the addition of cold 0.3 *N* barium hydroxide, and partial evaporation of the liquor caused the crystallization of 27.8 g (86.8%) of barium glyoxylate dihydrate. Although the solubility of the salt in water was reported (3) as only 0.005% at 18° and 0.08% at 68°, the present sample could be readily recrystallized from hot water. This recrystallization did not significantly change the composition. Calc. for $Ba(C_2HO_3)_2.2H_2O$: Ba, 43.0%. Found: Ba, 42.8, 43.0%. Samples, 0.2580 g and 0.2577 g, reduced 32.5, 32.5 ml, respectively, of 0.104 *N* potassium permanganate (3), the calculated amount being 30.9 ml.

An aqueous solution of 8.0 g of the above salt was freed of barium ions by passage through a column of Amberlite IR-120 cation-exchange resin, and the effluent was evaporated *in vacuo* to a thick syrup. This syrup was dried to nearly constant weight by storage over phosphorus pentoxide in an evacuated desiccator at room temperature. After several months the colorless product, 3.68 g or 99% yield, crystallized solidly. The melting point was 104–107°, with softening at 94°. No solvent suitable for recrystallizing the glyoxylic acid was found.

Sodium – Calcium Glyoxylate Tetrahydrate

Fifteen grams (0.1 mole) of L-tartaric acid dissolved in 300 ml of water was mixed with 200 ml of 0.515 *M* sodium metaperiodate (0.103 mole). The reduction of the latter was complete after the mixture had been kept in the dark and at room temperature for 36 hours. After iodate ion was removed as the lead salt, the filtrate was evaporated *in vacuo* to 50 ml, and was adjusted to pH 8 with 2 *N* sodium hydroxide. A concentrated aqueous solution of 17 g (0.1 mole) of calcium acetate monohydrate was then added, and 19.6 g (87.1%) of the sodium–calcium salt separated as white crystals. Calc. for $Na_2Ca(C_2HO_3)_4.4H_2O$: Na, 10.2; Ca, 8.3%. Found: Na, 9.65, 9.58; Ca, 9.27, 9.21%. Samples, 0.1338 g, 0.2038 g, and 0.1024 g, reduced 24.6 ml, 37.7 ml, and 19.0 ml of 0.101 *N* potassium permanganate (3), the calculated volumes being 23.6 ml, 35.9 ml, and 18.1 ml, respectively.

Two recrystallizations from hot water reduced the over-all yield to about 75% but failed to alter the composition significantly. A 0.0365-g sample of the salt when treated with 2,4-dinitrophenylhydrazine yielded 0.0658 g (79%) of crystalline glyoxylic acid 2,4-dinitrophenylhydrazone with the correct (10) melting point of 191–191.5°.

DIFFERENTIATION BETWEEN SOME 2,3- AND 2,5-DISUBSTITUTED PYRIDINE DERIVATIVES BY INFRARED SPECTROSCOPY

R. A. ABRAMOVITCH, GIAM CHOO SENG, AND A. D. NOTATION

In connection with studies of the orientation in the nucleophilic addition of phenyllithium to 3-substituted pyridines (1, 2) it became necessary to find a simple method of determining whether the attacking phenyl group had entered into the 2- or the 6-position of the pyridine ring, i.e. of distinguishing between 2- and 6-phenyl-3-substituted pyridines. This could be done by examining the N.M.R. spectrum of the compounds (1, 3) but was limited in that these determinations could not be carried out in our own laboratories. We therefore turned to infrared spectroscopy for such a method.

In theory, it should be quite simple to differentiate between 2,3- and 2,5-disubstituted pyridines by an examination of the aromatic C—H out-of-plane deformation region between 830 and 700 cm^{-1}. Infrared spectra – structure correlations have been found for the alkylbenzenes in the 11–15 μ region which are characteristic of the substitution positions in the benzene ring (4, 5). If one then considers that the pyridine ring corresponds to a monosubstituted benzene as far as the aromatic C—H out-of-plane bendings are concerned then a 2,3-disubstituted pyridine derivative should be equivalent to a 1,2,3-trisubstituted benzene whereas a 2,5-disubstituted pyridine derivative should correspond to a 1,2,4-trisubstituted benzene. The 1,2,3-trisubstituted benzenes show absorption in the 810–750 cm^{-1} range with a second band of medium intensity in the 726–680 cm^{-1} region, whereas 1,2,4-trisubstituted benzenes give rise to a strong band in the range 860–800 cm^{-1} (6). A number of 2,3- and 2,5-disubstituted pyridine derivatives have recently been shown to fall in nicely with this pattern (7, 8, 9). In particular, Podall (7) has studied the problem systematically and shown that 2-methyl-5-alkylpyridines exhibited two bands at 828–813 cm^{-1} and 735–724 cm^{-1}, whereas 2-methyl-3-alkylpyridines (1,2,3-trisubstitution) showed two bands at 813–769 cm^{-1} and 752–725 cm^{-1}.

A number of minor discrepancies in the band pattern in this region were observed in the present work. 2-Phenylnicotine exhibited a band at 805 cm^{-1}, quinoline a band at 805 cm^{-1}, and 5,6,7,8-tetrahydroquinoline a band at 827 cm^{-1} (see also (8)). On the other hand, 2-phenyl-3-alkyl- and 2-phenyl-5-alkyl-pyridines exhibited the expected absorptions though the presence of the monosubstituted phenyl-group obscured the assignment of the higher wavelength band. All that could be said was that most 2-phenyl-5-substituted pyridines exhibited a band of medium intensity between 850 and 800 cm^{-1} whereas most 2-phenyl-3-substituted pyridines did not.

A new and quite useful empirical correlation has now been observed in the C=C and

DIFFERENTIATION BETWEEN SOME 2,3- AND 2,5-DISUBSTITUTED PYRIDINE DERIVATIVES BY INFRARED SPECTROSCOPY

R. A. ABRAMOVITCH, GIAM CHOO SENG, AND A. D. NOTATION

In connection with studies of the orientation in the nucleophilic addition of phenyllithium to 3-substituted pyridines (1, 2) it became necessary to find a simple method of determining whether the attacking phenyl group had entered into the 2- or the 6-position of the pyridine ring, i.e. of distinguishing between 2- and 6-phenyl-3-substituted pyridines. This could be done by examining the N.M.R. spectrum of the compounds (1, 3) but was limited in that these determinations could not be carried out in our own laboratories. We therefore turned to infrared spectroscopy for such a method.

In theory, it should be quite simple to differentiate between 2,3- and 2,5-disubstituted pyridines by an examination of the aromatic C—H out-of-plane deformation region between 830 and 700 cm^{-1}. Infrared spectra – structure correlations have been found for the alkylbenzenes in the 11–15 μ region which are characteristic of the substitution positions in the benzene ring (4, 5). If one then considers that the pyridine ring corresponds to a monosubstituted benzene as far as the aromatic C—H out-of-plane bendings are concerned then a 2,3-disubstituted pyridine derivative should be equivalent to a 1,2,3-trisubstituted benzene whereas a 2,5-disubstituted pyridine derivative should correspond to a 1,2,4-trisubstituted benzene. The 1,2,3-trisubstituted benzenes show absorption in the 810–750 cm^{-1} range with a second band of medium intensity in the 726–680 cm^{-1} region, whereas 1,2,4-trisubstituted benzenes give rise to a strong band in the range 860–800 cm^{-1} (6). A number of 2,3- and 2,5-disubstituted pyridine derivatives have recently been shown to fall in nicely with this pattern (7, 8, 9). In particular, Podall (7) has studied the problem systematically and shown that 2-methyl-5-alkylpyridines exhibited two bands at 828–813 cm^{-1} and 735–724 cm^{-1}, whereas 2-methyl-3-alkylpyridines (1,2,3-trisubstitution) showed two bands at 813–769 cm^{-1} and 752–725 cm^{-1}.

A number of minor discrepancies in the band pattern in this region were observed in the present work. 2-Phenylnicotine exhibited a band at 805 cm^{-1}, quinoline a band at 805 cm^{-1}, and 5,6,7,8-tetrahydroquinoline a band at 827 cm^{-1} (see also (8)). On the other hand, 2-phenyl-3-alkyl- and 2-phenyl-5-alkyl-pyridines exhibited the expected absorptions though the presence of the monosubstituted phenyl-group obscured the assignment of the higher wavelength band. All that could be said was that most 2-phenyl-5-substituted pyridines exhibited a band of medium intensity between 850 and 800 cm^{-1} whereas most 2-phenyl-3-substituted pyridines did not.

A new and quite useful empirical correlation has now been observed in the C=C and

C=N stretching vibration region, which seems to apply provided no substituents which absorb in this region (—NH_2, —CO—, —NO_2, etc. . . .) are present. Table I summarizes the results obtained; the compounds are divided into two groups according to whether they are classed as corresponding to 1,2,3-trisubstituted or to 1,2,4-trisubstituted benzenes. 1,2,3-Trisubstituted compounds exhibit a band in the range 1578–1588 cm^{-1} whereas 1,2,4-trisubstituted derivatives give a band in the 1599–1605 cm^{-1} range. A second band at a somewhat higher wavelength is also generally observed but does not seem to be too characteristic. The orientation of the two isomeric phenylnicotines obtained by the action of phenyllithium on nicotine (1) was first assigned on the basis of the infrared bands in this region and later confirmed both by chemical means and also through a comparison of the N.M.R. spectra of the two isomers. The isomeric ethylphenylpyridines were also so oriented and the structure then proved unambiguously by degradative experiments. It is important to emphasize that this new correlation is only useful in determining the orientation of disubstituted pyridines provided one is sure that only these are present. Some trisubstituted pyridines have no bands in this region above 1590 cm^{-1} (e.g. 3,4,5-collidine and 2,3,4-collidine (9)), whereas others have. It is, therefore, not applicable to the possible determination of the number of substitutents present in the pyridine ring as the correlation of the bands due to the aromatic C—H out-of-plane deformation frequencies potentially is.

EXPERIMENTAL

The infrared spectra were measured on a Perkin–Elmer Model 21 recording spectrometer using sodium chloride optics. All the spectra were measured on liquid films and the positions of the bands calibrated by comparison with a polystyrene-film spectrum. All the samples were freshly distilled before use. We wish to express our gratitude to Dr. Hardegger (Zürich) for samples of 3-butyl-4-methylpyridine picrate, 5-butyl-2-

AN N.M.R. STUDY OF ELECTRON RELEASE BY ALKYL AND ALKOXY GROUPS IN VARIOUS SOLVENTS

R. B. MOODIE*, T. M. CONNOR,† AND ROSS STEWART

Recently dipole moment studies (1) and measurements of substrate activity (2) have shown the importance of solvent effect on molecules in their ground state. We have used N.M.R. to measure the chemical shifts of aromatic protons in alkyl and alkoxy benzenes in various solvents. Table I gives the chemical shifts in cycles per second relative to benzene at the same concentration in the same solvent.

TABLE I

Chemical shifts from benzene for the aromatic protons, in cycles/sec

Compound	Solvent			
	C_6H_{12}	$(CH_3)_3N$	CH_3OH	CH_3NO_2
Toluene	5.9	6.2	6.4	6.8
Ethylbenzene	4.4	5.1	5.2	5.3
Isopropylbenzene	3.8	4.1	4.6	4.7
tert-Butylbenzene	1.1*	1.2*	0.9*	1.2*

*These measurements are not to a single peak (see discussion) and are therefore less accurate. Probable error ±0.5 cycle/sec.

AN N.M.R. STUDY OF ELECTRON RELEASE BY ALKYL AND ALKOXY GROUPS IN VARIOUS SOLVENTS

R. B. MOODIE*, T. M. CONNOR,† AND ROSS STEWART

Recently dipole moment studies (1) and measurements of substrate activity (2) have shown the importance of solvent effect on molecules in their ground state. We have used N.M.R. to measure the chemical shifts of aromatic protons in alkyl and alkoxy benzenes in various solvents. Table I gives the chemical shifts in cycles per second relative to benzene at the same concentration in the same solvent.

TABLE I

Chemical shifts from benzene for the aromatic protons, in cycles/sec

Compound	Solvent			
	C_6H_{12}	$(CH_3)_3N$	CH_3OH	CH_3NO_2
Toluene	5.9	6.2	6.4	6.8
Ethylbenzene	4.4	5.1	5.2	5.3
Isopropylbenzene	3.8	4.1	4.6	4.7
tert-Butylbenzene	1.1*	1.2*	0.9*	1.2*

*These measurements are not to a single peak (see discussion) and are therefore less accurate. Probable error ±0.5 cycle/sec.

Shifts were measured on a 40-Mc Model 4300 Varian N.M.R. spectrometer by graphical interpolation between two side bands from the solvent resonances, set as near as possible on either side of the aromatic protons. The side bands were measured with a Hewlett–Packard frequency counter. Samples were 5% solutions sealed *in vacuo*. Six determinations of the cyclohexane–toluene shift by this technique gave a mean-square deviation of ±0.13 cycle/sec. An additional small error may be present in all these measurements

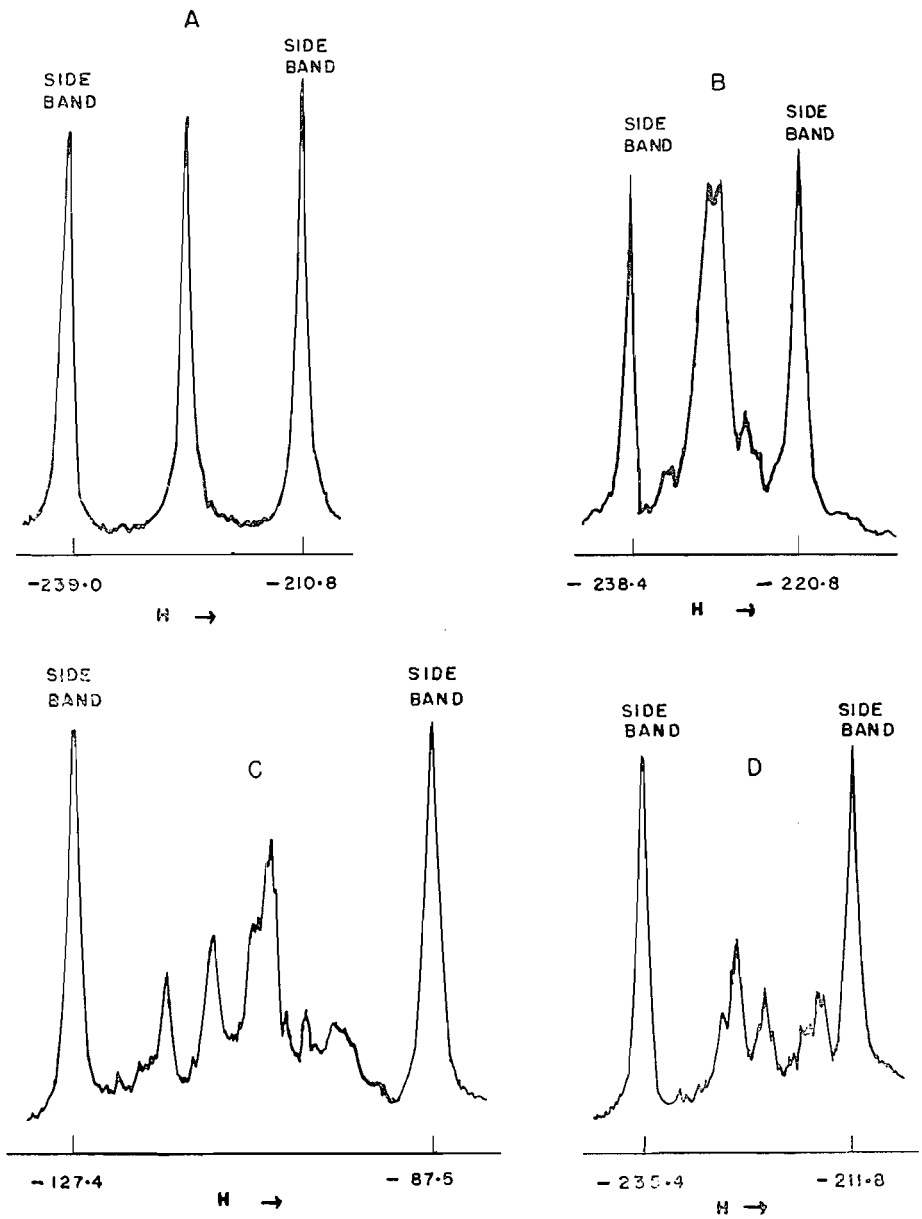

FIG. 1. Spectrum of aromatic protons with side band shifts in cycles per second from the solvent resonance: (A) toluene, (B) *tert*-butylbenzene in cyclohexane, (C) isopropyl phenyl ether in nitromethane, and (D) isopropyl phenyl ether in cyclohexane.

due to dilution effects, since these figures do not represent extrapolation to infinite dilution (3).

In so far as the shifts reflect the average electron density around the aromatic protons in the substituted compounds, the shifts of the alkylbenzenes indicate that the Baker–Nathan order prevails, even in cyclohexane, in contrast to the evidence of dipole moments (1). Since *tert*-butylbenzene shows a well-resolved fine structure but the other alkylbenzenes do not (Fig. 1), the conclusions for this compound are less valid. (Shifts are for the approximate "center of gravity" of the aromatic proton resonances for this compound.) In the comparison of *p*-bromo-*tert*-butylbenzene and *p*-bromotoluene this objection is removed since measurements on the quartet (which show further fine structure due to cross ring coupling) enable calculations of the chemical shifts of ortho and meta protons (4, 5). These values are given in Table II. (It is assumed that the protons ortho to the alkyl group are responsible for the high field doublet of the quartet.) These show

TABLE II

Ortho coupling constants and chemical shifts from benzene for the aromatic protons in *p*-bromo-alkylbenzenes

	p-Bromotoluene in:		*p*-Bromo-*tert*-butylbenzene in:	
	Solvent C_6H_{12}	Solvent CH_3NO_2	Solvent C_6H_{12}	Solvent CH_3NO_2
Coupling constant in cycles/sec	8.7	8.8	8.6	—[b]
Chemical shift of ortho protons[a]	12.0	10.0	1.5	(−0.4)[b]
Chemical shift of meta protons[a]	−2.0	−0.9	−3.0	(−0.4)[b]

[a]The positions are relative to the alkyl group.

[b]Only a single peak was observed for the aromatic protons of *p*-bromo-*tert*-butylbenzene in nitromethane.

that the ortho and meta protons are more shielded in the methyl than the *tert*-butyl-substituted compound, in agreement with the evidence above. As might be expected, more polar solvents increase the degree of electron release of the alkyl groups in the alkylbenzenes. The benzene–toluene shift in a particular solvent may constitute a useful measure of solvent polarity, if the accuracy of the shift measurements can be improved (by, for example, using a 60-Mc spectrometer and taking the mean of a number of determinations). The solvent effect may be more marked in toluene, ethylbenzene, and isopropyl benzene than in *tert*-butylbenzene (6) but the effect is at present of the same order as the experimental error.

The alkoxy benzenes, anisole, phenetole, isopropyl phenyl ether, and *tert*-butyl phenyl ether, show a more complicated aromatic proton spectrum. Assignment of ortho, meta, and para proton resonances is not possible, and this precludes any precise determination of solvent and substituent effects. Two interesting observations may, however, be made. Firstly, in all four solvents, the aromatic proton resonances of *tert*-butyl phenyl ether are at lower field and show a much less well-defined fine structure than those of the other three ethers. This is due to steric hindrance to conjugation between the oxygen atom and the aromatic π electrons, an effect previously shown to exist from ultraviolet spectral data and from rates of bromination (7). Secondly, there is a sharp contrast between the spectra of anisole, phenetole, and isopropyl phenyl ether in cyclohexane and their spectra

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

in the other three solvents. Typical spectra of the two types are shown in Figs. 1C and 1D. This suggests that differential electron release to ortho, meta, and para positions varies with the solvent. A similar effect has been observed in the solvent dependence of the ortho/para ratio in the nitration of phenol (8).

By studying suitably substituted ethers it may be possible to eliminate the uncertainty due to spin–spin splitting of non-equivalent proton resonances.

THE SEPARATION OF SOME TERPENOID COMPOUNDS BY GAS–LIQUID CHROMATOGRAPHY[1]

E. VON RUDLOFF

ABSTRACT

A study has been made of the degree of separation of mixtures of some terpene hydrocarbons, some of their oxygenated derivatives, two sesquiterpene alcohols, and three monophenols on a variety of columns. Temperature and sample size affected the degree of separation and the solid support Chromosorb W, a calcined diatomaceous earth, was found to combine the advantages of Celite and C-22 firebrick without causing decomposition of the sample at higher temperatures. When Craig polyesters were used as liquid phases, separations equal to those obtained on polyethylene glycol were realized with the added advantage that these produced columns which are stable at 190 to 220° C. Consequently, sesquiterpene alcohols and monophenols were also separated successfully. Another useful liquid phase for both low and high temperatures was found in a meta-linked polyphenyl ether. Squalene was found to be an efficient liquid phase for the separation of terpene hydrocarbons at 130° C and lower. The possible application of the present findings for preparative work is discussed.

INTRODUCTION

A general method for the separation of small amounts of closely related terpene hydrocarbons, some of their oxygenated derivatives as well as some higher boiling sesquiterpene alcohols and monophenols, was required in this laboratory. Such mixtures often have a narrow range of boiling points and separation by fractional distillation not only requires large amounts, but frequently fails to produce pure components. Gas–liquid chromatography (GLC) offers considerable advantages over fractional distillation when quantities of 0.01 to 0.1 g are required, and has in several instances been extended to the gram scale. This technique was, therefore, studied in some detail to find suitable conditions for complete separation of such terpenoid mixtures on a 0.1- to 1-g scale. The experiments were carried out with a Beckman GC-2 chromatograph, using helium as carrier gas, a thermal conductivity cell as detector, and 6-foot columns of 6-mm inner diameter.

Successful separations of terpenoid compounds by GLC have been described in the literature. Bernhard (1) separated five monoterpene hydrocarbons on 20-foot polyethylene glycol and *n*-octyl phthalate columns, but obtained poor results when silicone fluid, Apiezon L, or high vacuum grease was used as liquid phase. Bayer *et al.* (2) used hydrogen as carrier gas and obtained a fair degree of separation for a large variety of terpenoid compounds on columns containing silicone vacuum grease to which alkali capronates had been added. Cvrkal and Janák (3), also using hydrogen, obtained good results for

Issued as N.R.C. No. 5605.

terpene hydrocarbons on dimethylsiloxane and proposed glycerol for oxygenated compounds. The use of hydrogen as carrier gas for mixtures containing unsaturated compounds may create difficulties, since activated centers of the solid support could catalyze phases for the separation of many terpene hydrocarbons, but their retention times of 80 minutes and more are rather high. These authors discuss some of the difficulties encountered in the analysis of essential oils and point out the need for polar liquid phases which can be used at 150° C or higher to fractionate oxygenated derivatives. This has been found in the present study in adipate polyethylene glycol, succinate ethylene glycol, and phthalate ethylene glycol polyesters (Craig polyesters) and in a *m*-linked polyphenyl hydrogenation. Liberti and Cartoni (4) used silicone and tricresyl phosphate as liquid ether. Columns with polyethylene glycol were also used by Stanley (5) and Eglington *et al.* (6) and recently Westaway and Williams (7) have separated almost completely α- and β-pinene, α- and γ-terpinene, and limonene on a 6-foot Apiezon M column with nitrogen as carrier gas.

From the data contained in the above communications and in the monograph by Keulemans (8) it was concluded that silicone-type columns could be used for a wide range of compounds at lower and higher temperatures with a fair degree of separation. Far better separation could be expected with polyethylene glycols but the temperature limit of 100 to 130° C (8) would limit its application. These two types of liquid phases were, therefore, used to study the effect of the various physical factors involved and to compare the degree of separation obtained with polyethylene, squalene, Apiezon M, polystyrene, a polyphenyl ether, polyesters of adipic, succinic, and phthalic acids (Craig polyesters), a polyamide, and diglycerol as liquid phases. *d*-Limonene, the mixture of *p*-menthadienes produced by dehydration of α-terpineol with oxalic acid as catalyst (9), and a synthetic mixture containing *d*-limonene, 1,8-cineole, fenchone, citronellal, camphor, α-terpineol, citronellol, and bornyl acetate were used as test compounds. The sesquiterpene alcohols, occidentalol and eudesmol, and the monophenols, anethole, eugenol, and isoeugenol, were used for the chromatographic studies at higher temperatures.

Initial experiments in the present study showed that a number of factors influencing the separation of terpenoid compounds have not been described fully in the literature. Also, most of the liquid phases used to date for this purpose, except the rather inefficient silicone type, cannot be used above 100 to 130° C for any length of time. Furthermore, the above communications are mainly concerned with qualitative determinations and do not give the most favorable conditions for preparative separations. The present investigation was therefore extended to cover the effect of sample size, temperature, flow rate, nature of solid support, and the ratio of solid support to liquid phase, as well as a search for liquid phases which could be used successfully for the wide range required. The results obtained in this study show that sample size, temperature, and, to a lesser degree, the solid support can affect the degree of separation. Some of the liquid phases tested gave poor results when samples of 5 μl or more were used, yet gave excellent separation with 2 μl or less, making these columns useful for analytical work. Two types of liquid phases, Craig polyesters and a polyphenyl ether, could be used equally well at 190–220° C or at lower temperatures. An adipic acid – polyethylene glycol polyester was found to give separations equal to, or better than, those obtained on a polyethylene glycol (Carbowax 400), besides being suitable for high temperature separations, and proved to be the best general purpose column for up to 50 μl of terpenoid compounds investigated thus far.

EXPERIMENTAL

Apparatus

A Beckman GC-2 chromatograph equipped with a fraction collector (No. 92730) and a heated inlet (suitable for injection of up to 2 ml) was used in conjunction with a Bristol Dynamaster strip-chart recorder (0.05- to 1.05-mv scale). The chart speed was 0.5 inch per minute and the flow rate of helium carrier gas was measured at the exit by the soap bubble method. Samples were introduced with a Beckman liquid sampler (No. 224000) which allowed the accurate injection of 1.5 to 80 μl quantities. The column exhaust was at atmospheric pressure (710–715 mm Hg) whereas the pressure at the column inlet was varied to give the desired flow rates.

Solid Support and Chemicals

Celite 545 was water-washed to remove the fines, then acid-washed, neutralized with bicarbonate solution, washed with water, and dried. C-22 Firebrick (60–80 mesh) was prepared by wet milling, drying, and sifting of commercial firebrick. Chromosorb W, a flux-calcined diatomaceous earth, produced by Johns–Manville, was obtained commercially. Silicone high vacuum grease (Dow Corning), squalene (90%, Eastman Chemicals), Carbowax 400 (Carbide and Carbon Chem. Co.), the polyphenyl ether *m*-bis(*m*-phenoxyphenoxy)-benzene (Monsanto Corp.), Apiezon M (Metropolitan–Vickers Electrical Co.), and diglycerol (Colgate–Palmolive Co.) were also obtained from commercial sources. The Craig polyesters were kindly supplied by Dr. B. M. Craig and were prepared by reaction of adipic acid with polyethylene glycol (Carbowax 400) and 1% diglycerol as plasticizer and succinic or phthalic acid with ethylene glycol (10). The succinate polyester (SEG) was a solid having m.p. 96–100° C, whereas the adipic (APEG) and phthalate (PEG) polyester were viscous liquids.

Commercial samples of liquid terpenes and oxygenated derivatives were purified by fractional distillation and for critical work by GLC, using the Carbowax 400 or APEG polyester columns. Collection of the samples was carried out with the detector current reduced from 250 ma to 100 ma or completely turned off. The refractive indices of the samples thus obtained are shown in Table I.

TABLE I

Refractive indices of terpenoid compounds

	Boiling point (° C)	n_D^{20}	
		Purified by distillation	Purified by GLC

Bornyl acetate	223–224	1.4643	—

Eudesmol, m.p. 82–84° C, $[\alpha]_D$ +32°, was obtained by crystallization and sublimation of a commercial sample (Plaimar Ltd., Perth, Australia) which was obtained from

Callitropsis araucarioides Compt. Occidentalol, m.p. 95–96° C, $[\alpha]_D$ +363°, was obtained from the neutral extractives of the heartwood of *Thuja occidentalis* L. as described by Nakatsuka and Hirose (11).

The mixture of *p*-menthadienes obtained by dehydration of α-terpineol (9) was prepared by refluxing oxalic acid (120 g) in water (240 ml) with α-terpineol (40 g) for 6 hours. The mixture was steam-distilled, the distillate extracted with ether, and the ethereal solution was dried over calcium chloride. The mixture of terpene hydrocarbons was used as such after the solvent had been evaporated.

Packing of Columns

The liquid phase (2.5 g) was dissolved in a volume of low-boiling solvent (50 ml chloroform) which is equal to that of the solid support. This solution was placed into a high, narrow beaker or cylinder and the solid support (12.5 g) was added with stirring. Stirring was continued for 3 to 5 minutes after addition and the mixture was spread on a shallow stainless steel tray. After the solvent had evaporated, the residual material was dried *in vacuo* at 60–70° C for about 1 hour. The dried material was poured in small aliquots with tapping into 6-mm inner diameter copper tubing of 6-foot length, taking note of the weight of mixture added. The column was closed on each end with a small glass wool plug and coiled into a 5- to 7-in. diameter coil. It was allowed to equilibrate at the desired temperature and flow rate of helium gas (0.5 to 1.5 hours). Injection of samples was begun when the recorder maintained a steady base line.

When polyethylene (obtained by cutting polyethylene reagent bottles into small pieces) was used as liquid phase, it was dissolved by refluxing in a minimum volume of petrol (b.p. 154–202° C). The solid support was added to the hot solution as above and the drying time was extended to 5 hours.

RESULTS AND DISCUSSION

Initial Experiments

Optimum conditions for each type of column were obtained by trial and error. Columns having Celite 545 as solid support were found to require higher temperatures and inlet pressures than those with C-22 firebrick, but the latter caused decomposition of some compounds at higher temperatures, especially aldehydes and tertiary alcohols. Liberti and Cartoni (4) report that Stermachol, a material similar to C-22 firebrick, is not suitable for terpene alcohols, and used inactivated Celite instead. A more suitable solid support was found in Chromosorb W, which combined the advantages of firebrick without causing decomposition. This support was, therefore, used in all subsequent experiments.

For preparative work a high ratio of liquid phase to solid support is desirable (8, 12), but in the present study the degree of separation deteriorated when 20% or more liquid phase was used. A ratio of 1:6 was found to give consistently good results.

Polyethylene, Apiezon M, polystyrene, and a polyamide (Zytel) gave inferior results and these were not further studied. Solid compounds, such as the SEG polyester (m.p. 96–100° C), gave poor separations below their melting or softening point.

Effect of Physical Factors

The effect of temperature on the degree of separation of the mixture of *p*-menthadienes on the Carbowax column is shown in Fig. 1. Contrary to the report of Bernhard (1), the effect was found to be considerable. Keulemans (8), from theoretical considerations, also considers the effect to be important. The separation at 80° C, the lowest feasible tem-

For personal use only.

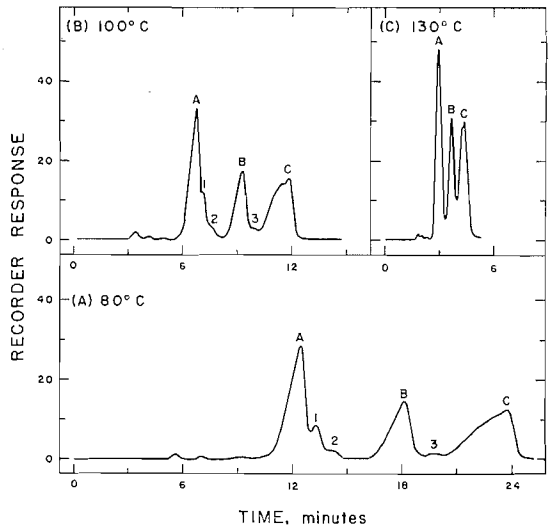

FIG. 1. Separation of the mixture of *p*-menthadienes on the Carbowax column at (A) 80° C and 43.5 ml helium per minute, (B) 100° C and 42.8 ml helium per minute, (C) 130° C and 41.9 ml helium per minute.

perature, was by far the best (Fig. 1(A)), even though the curves are skewed. From a preparative point of view skewing of curves is not detrimental, but is less satisfactory for quantitative calculation. The collection of fractions at the lowest possible temperature has the additional advantage of minimizing the danger of thermal decomposition or rearrangements.

Changes in the flow rate of the carrier gas over the practical range of about 10 to 400 ml (8) did not effect the degree of separation noticeably, which is in agreement with the considerations of Keulemans (8) and the findings of Bernhard (1). Thus, the flow rate was adjusted to give optimum separations at as low a temperature as possible.

The effect of sample size on the retention time of each component was found to be considerable. Table II shows the retention times obtained for *d*-limonene on various columns when samples of 1.5 to 50 μl were injected at optimum temperatures and flow rates. From these results it is evident that an increase in sample size above 1 to 3 μl

produces considerable delays in the emergence of a peak maximum, and this is accompanied by broadening of the peaks. This is in agreement with the findings of Bens and McBride (13), those obtained by Porter *et al.* (14) with gaseous samples, and those obtained by Bethea and Smutz (15) with aliphatic alcohols on a butyl phthalate column. The latter authors report the optimum sample size for 6-mm diameter columns to be from 4 to 12 μl and detected overloading above 20 μl. Thomas (16) found the optimum for liquid samples to be 30–70 μl. Table II shows that different types of columns have different capacities, silicone and APEG polyester allowing samples of up to 40 μl size, although skewing became noticeable with 10–20 μl samples. Diglycerol has too low a capacity to be attractive for preparative work, but the other liquid phases may be useful since they have a fair capacity and different separation properties.

The fact that larger samples cause a considerable delay of peak maxima has important consequences for both analytical and preparative work. In the former, an unknown peak is often identified by comparing its retention time with those of known compounds run under identical conditions (8). This is only permissible if the sample size of the unknown and known compounds are nearly the same. The technique of adding the known compound to the unknown (8) may be preferred, but actual isolation and comparison of physical constants (e.g., the infrared spectrum) would seem to be a more reliable means of identification. Another alternative is to make use of the fact that the initial emergence time of a peak remains practically constant with different sample sizes up to where the column becomes badly overloaded (14, Table II). However, this can be used only when all peaks are completely separated from one another.

From a preparative point of view the delay of the peak maximum and broadening of the peak caused by a larger sample is not detrimental, provided skewing or broadening does not cause an overlap with neighboring peaks. Even then, an overloaded column may still produce pure fractions if center cuts are collected. The use of columns having larger diameter (12, 17, 18, 19) did not give the same degree of separation as was obtained on the corresponding 6-mm columns when larger samples (50 μl or more) were used. Also, because of the higher flow rates required in larger diameter columns the consumption of helium gas was found to be considerable and it was found more advantageous to carry out repeated runs of 25 to 50 μl on the 6-mm diameter columns. Since most columns required only 15–30 minutes for each run, the collection of 0.1 to 0.5 g of a desired fraction was possible within half a day. When such fractions were collected with a normal detector current of 200 to 250 ma, these were yellowish and on rechromatographing the material, typical decomposition peaks were recorded besides the normal symmetrical peaks for the pure compounds. This difficulty was overcome in most instances by using a detector current of 100 ma, which was sufficient for samples of 20 μl or more. Only in exceptional cases, e.g. α-pinene or tertiary alcohols, was it necessary to carry out preparative runs without the detector, i.e. fractions were collected at times determined previously in a run of the same sample size with the detector current on. A possible means of overcoming the necessity of "blind" runs may be to construct a bypass system, similar to those used with detectors other than the thermal conductivity type.

Separation Obtained with Various Liquid Phases

Terpene hydrocarbons were separated most successfully on columns containing squalene, APEG polyester, and polyphenyl ether, separations being in the same order as those obtained on Carbowax 400 and superior to those obtained on silicone (see Table III). Each column appears to offer slight advantages for one or another compound, a finding which was especially apparent in runs with the complex *p*-menthadiene mixture

α-Terpinene	0.92	0.88	0.825	0.88	0.88

(Figs. 1 and 2). The squalene column is unstable at 130° C for prolonged periods of time, and an efficient aliphatic polyunsaturated liquid phase which is stable at 130° C or higher is still lacking.

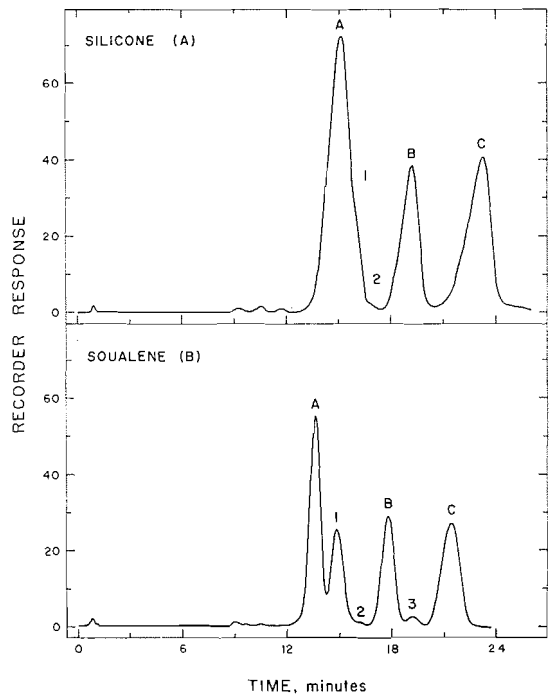

FIG. 2. Separation of the mixture of *p*-menthadienes on (A) silicone (at 100° C and 50.5 ml helium per minute), (B) squalene (at 100° C and 74.2 ml helium per minute).

Resolution of the mixture of *p*-menthadienes on the silicone column (cf. Fig. 2(A)) shows three major peaks A, B, and C, with an indication of further constituents at 1 and 2. The squalene (cf. Fig. 2(B)) and the Carbowax columns (cf. Fig. 1) clearly showed three additional components, 1, 2, and 3, and on the latter column peak C appears to be composed of two compounds in about equal amounts. A very similar separation was obtained with the APEG and SEG polyester columns, whereas the polyphenyl ether column gave the same resolution except that C appeared as a single peak. The best resolution of A, which corresponds to α-terpinene, was obtained on the squalene column, separation from impurity 1 being complete. From these results it follows that the com-

plex mixture of *p*-menthadienes obtained by dehydration of α-terpineol cannot be resolved by one column alone, but requires successive fractionation on the squalene and polyester columns. For analytical purposes longer columns or the very efficient Golay columns (20, 21) may have to be used. Peak C presents a problem and its composition, as well as the chemical identification of the other components will be the subject of another communication.

TABLE IV

Relative retention times (*d*-limonene = 1) of various monoterpenoid compounds

Column (liquid phase)	Silicone	Squalene	Carbowax	Polyphenyl ether	Polyesters		Diglycerol
					APEG	SEG	
Temperature (° C)	130	130	130	130	130	100	100
Flow rate (ml He/min)	30.0	74.2	42.0	53.6	41.6	26.3	20.0
Inlet pressure (mm Hg)	1531	2029	1531	1531	1531	1531	1014
Retention time of *d*-limonene	8.3	15.5	3.15	6.0	3.8	2.0	1.5
Specific retention volume V_g	19.1	27.2	19.1	23.0	15.9	9.0	8.9
1,8-Cineole (b.p. 174°)	1.1	0.95	1.25	1.2	1.25	1.05	1.5
Fenchone (b.p. 192°)	1.4	—	3.0	2.2	2.9	3.0	3.2
Citronellal (b.p. 205°)	2.0	—	3.8	3.0	3.65	4.2	3.25
Camphor (sublimes)	1.95	—	5.15	3.7	5.1	5.6	6.4
α-Terpineol (b.p. 220°)	2.45	—	11.6	4.7	10.95	11.5	6.6
Citronellol (b.p. 222°)	3.1	—	20.2	4.45	14.6	13.3	6.7
Bornyl acetate (b.p. 223°)	3.85	—	6.2	5.5	5.95	6.2	4.8

Table IV shows the relative retention volumes with respect to *d*-limonene of some oxygenated derivatives. The best degree of separation of these compounds was obtained on the Carbowax and APEG polyester column, and that of the former is compared in Fig. 3 with the separation obtained on silicone (Fig. 3(A)). Since Carbowax cannot be

used above 100° to 120° C for long periods (8), the use of APEG polyester is to be preferred, especially so, since the latter has also a higher capacity (cf. Table II) and can be used for high boiling sesquiterpene alcohols and monophenols (see below) as well. All columns, except squalene, eluted *d*-limonene (b.p. 177° C) ahead of 1,8-cineole (b.p. 174° C) and all, except silicone and polyphenyl ether, eluted the higher boiling bornyl acetate ahead of α-terpineol and citronellol. Bornyl acetate was eluted even ahead of camphor on the diglycerol column. Thus the use of different liquid phases can be used to differentiate between different functional groups (22). The sequence of separations on polyphenyl ether as compared with that obtained on the polyesters is noteworthy. From the present findings it is concluded that no single column will satisfy all requirements.

Silicone grease and the Craig polyesters (10) are known to be sufficiently stable at 160 to 220° C to allow the chromatography of compounds with higher boiling points than α-terpineol. In addition, the polyphenyl ether was found to be suitable for runs at higher temperatures, and Table V shows the degree of separation of the closely related

TABLE V

Relative retention times (α-terpineol = 1) of sesquiterpene alcohols

Column (liquid phase)	Silicone	Polyphenyl ether	Polyesters		
			APEG	SEG	PEG
Temperature (° C)	160	160	190	190	190
Flow rate (ml He/min)	99	120	41.6	39.4	62.5
Inlet pressure (mm Hg)	2546	2546	1531	2029	2029

*Broad, unresolved peak.

sesquiterpene alcohols, occidentalol ($C_{15}H_{24}O$) and eudesmol ($C_{15}H_{26}O$), as compared with α-terpineol obtained with these columns. Occidentalol differs structurally from eudesmol only by having one more double bond, yet it is completely separated from the latter even on the silicone column. This may, in part at least, be due to steric differences. The superior efficiency of the polyester columns is evident in that eudesmol is resolved partially into the α- and β-isomers.

Since essential oils sometimes contain phenolic compounds, the degree of separation of the monophenols, anethole, eugenol, and isoeugenol, was tested on the APEG polyester and the polyphenyl ether columns. The former, at 190° C and 83.5 ml helium per minute, gave retention times of 5.3, 14.7, and 25.4 minutes, whereas the latter, at 220° C and 70.5 ml helium per minute, gave 4.3, 6.45, and 10.4 minutes respectively. Both columns gave even peaks without any sign of decomposition taking place. The separation of other types of phenols has been described by Janák *et al.* (23, 24).

CONCLUSIONS

1. Monoterpene hydrocarbons are best separated on columns using squalene, Carbowax 400, Craig polyesters, and polyphenyl ether as liquid phase at temperatures of 130° C and lower. At higher temperatures the polyester and polyphenyl ether columns give best results, separating oxygenated terpenes, sesquiterpene alcohols, and monophenols satisfactorily. The adipate polyethylene glycol (APEG) polyester column is most suited for all compounds tested.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

2. The effect of temperature and sample size on the degree of separation is considerable, the lowest possible temperature giving best results from a qualitative and preparative point of view. With 6-mm diameter columns sample sizes above about 3 μl cause considerable delays in the retention time of peak maxima as well as a broadening of peaks. The initial emergence of a peak is practically constant up to sample sizes which cause overloading of the columns. For qualitative work actual isolation of each component and determination of its physical properties is to be preferred over comparison of the retention time (or volume) with those of known compounds.

3. Chromosorb W, a calcined diatomaceous earth, was found to be a better solid support for the separation of terpenoid compounds than either washed Celite 545 or C-22 firebrick.

4. In preparative work with instruments using a thermal conductivity cell as detector, pure samples cannot be obtained with normal detector currents, and collection of thermally labile terpenes must be carried out in "blind" runs.

HYDROGENOLYSIS OF CARBOHYDRATES

VIII. COMPARATIVE STUDIES ON METHYL GLYCOPYRANOSIDES[1]

P. A. J. GORIN

ABSTRACT

Several methyl glycopyranosides have been hydrogenated under pressure at 180° C with copper chromite catalyst in dioxane. Many glycosides underwent hydroxyl group inversion and another reaction observed consisted of hydrogenolytic removal of the methoxyl group coupled with reduction of a hydroxyl group to a methylene group. Other glycosides were stable under these conditions, and these included methyl β- and methyl α-D-glucopyranosides and unexpectedly methyl β-D-mannopyranoside and methyl α-D-talopyranoside. The data indicated that generally β-glycosides are more stable than their α-anomers in the hexopyranoside series and that the methyl hexopyranosides are more stable than the methyl pentopyranosides. Explanations have been made in the theoretical section in order to cover these observations. At 240° C, however, methyl α-D-glucopyranoside is hydrogenolyzed giving 11% of 1,5-anhydro-4-deoxy-hexitols. These polyols have been fractionated and the mixture shown to contain lyxo- and arabo-1,5-anhydro-4-deoxy-D-hexitols.

The earlier findings of von Rudloff, Bauer, and Stuetz (1) showed that the hydrogenolysis of methyl α-D-glucopyranoside yields 1,5-anhydro-4-deoxy-hexitol (11% yield) along with many other products. The hydrogenolytic procedure was vigorous, the experiments being carried out with Adkins' copper chromite catalyst (2) at 240° C using dioxane as solvent under a hydrogen pressure of 170 atmospheres. More recent investigations (3, 4, 5, 6, 7) have indicated that at lower temperatures (180–220° C) some inversion of the asymmetric centers occurs as well as hydrogenolysis. However, methyl α- and methyl β-D-glucopyranosides were found to be virtually unaffected at 180° C. Since the hydroxyl groups on methyl β-L-arabopyranoside are readily inverted by catalytic hydrogenation (3) the behavior of the methyl glucosides seemed anomalous. Therefore, another hexopyranoside methyl α-D-mannopyranoside was hydrogenated at 180° C and was found to yield a mixture of isomeric glycosides.* By fractionation, on a cellulose column (8), methyl α-D-talopyranoside has been isolated from the mixture† together with unchanged methyl α-D-mannopyranoside and a small amount of methyl α-D-glucopyranoside. As the hydroxyl configurations in the substrate appeared to play a role in determining its susceptibility to hydrogenation other methyl α-D-hexopyranosides were examined. Methyl α-D-galacto- and -altro-pyranosides were transformed by hydrogenation to other isomers, mainly methyl α-D-talopyranoside, which is a stable methyl glycoside under the conditions used (Table I). This was confirmed by synthesizing methyl α-D-talopyranoside, hydrogenating it, and isolating the unchanged glycoside.

As well as the α-glycosides, several methyl β-D-hexopyranosides were tested. These included methyl β-D-allo-, -altro-, -galacto-, -gluco-, and -manno-pyranosides (Table I) and as a group these compounds were more stable to hydrogenation than the α-glycosides, a greater percentage of substrate being recovered unchanged. This stability was most pronounced in methyl β-D-gluco- and -manno-pyranosides which were virtually unaffected and were found to be the main end products of hydrogenation of the other β-glycosides.

In contrast to the hexopyranosides the methyl pentopyranosides, as represented by

For personal use only.

chromatography indicated in each instance easy interconversion since two to four chemically different pentoses were present. Also, the pentopyranosides were hydrogenolyzed with greater ease to dihydroglycals (tetrahydropyrandiols) by reductive elimination of the methoxyl group coupled with reduction of a hydroxyl to a methylene group. The hydrogenation products of the methyl glycopyranosides are summarized in Tables I and II with the percentage of each compound contained in the reaction product as determined on column chromatographic separation.

It appears likely that resistance to catalytic hydroxyl inversion is affected by the shape of the substrate. For example, the 6-hydroxymethyl group seems to exert an influence in limiting hydroxyl group inversion and formation of compounds of the dihydroglycal type. The large substituent on C-5 would render the molecule more bulky and perhaps less flexible so that it could adopt fewer positions suited to reaction on the surface of the catalyst. Unfortunately too little is known about the surface properties of copper chromite to generalize on the probability of individual hydroxyls in the glycosides to invert. If, as has been assumed (7), inversion results from dehydrogenation followed by hydrogenation this ability would be concerned firstly, with the ease of dehydrogenation of the alcohol group to a ketone, and secondly with the specificity of reduction of the ketone to the two possible alcohols (Fig. 1). It has been shown that the rate of dehydrogenation

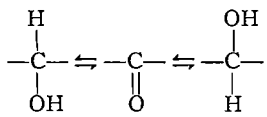

FIG. 1.

of a secondary alcohol with chromic acid in cyclohexane ring systems (9) to a ketone depends on the accessibility of the C-hydrogen atom (10) and not the rate of intermediate ester formation. The dehydrogenation rate was shown to be greater when the C-hydrogen atom was in the less sterically hindered equatorial position (9). However, this is in solution rather than on the surface of a catalyst. In order to explain the surprising observations that methyl β-D-mannopyranoside and methyl α-D-talopyranoside are virtually unaffected under hydrogenation conditions it must be assumed that the catalyst plays a role in limiting dehydrogenation. This may well be because the surface contours of the copper chromite prevent the C-hydrogen atoms, some of which are equatorial (11), from becoming available. On the other hand, methyl α- and β-D-glucopyranosides, which are also stable do not contain equatorial C-hydrogen atoms in their stable C-1 chair forms (11).

Since hydroxyl inversion readily occurs in polyhydroxyl compounds, even at temperatures as low as 180° C, it appeared likely that the syrupy 1,5-anhydro-4-deoxy-D-hexitol formed by hydrogenation of methyl α-D-glucopyranoside at 240° C (1) was a mixture of stereoisomers and accordingly, this product has been examined further. Cellulose column chromatography of the syrupy polyols derived by catalytic deacetylation of the fractionated acetate contained two main components which were distinguishable on paper chromatograms. The fraction which was slower on paper was syrupy but gave a crystalline tris-*p*-nitrobenzoate derivative from which a crystalline polyol (I) of R_{Rh} 1.1* was regenerated. The 1,5-anhydro-4-deoxy-hexitol structure for the substance was indicated by carbon and hydrogen composition and its consumption of 1.0 molar equivalent of sodium periodate. If it is assumed that no inversion at C-5 takes place and that the six-membered ring is not modified in the course of hydrogenolysis the only

**Throughout the text R_{Rh} denotes the distance moved by a spot on a paper chromatogram compared with rhamnose in the n-butanol – ethanol – water (40:11:19) v/v solvent.*

For personal use only.

alternative structure fitting the data is that of a dihydroglycal (IV). However, since periodic acid oxidation of I followed by sodium borohydride reduction gave an optically active triol (III) the dihydroglycal formula is invalidated since it would have given a triol (V) with no asymmetric centers (Fig. 2).

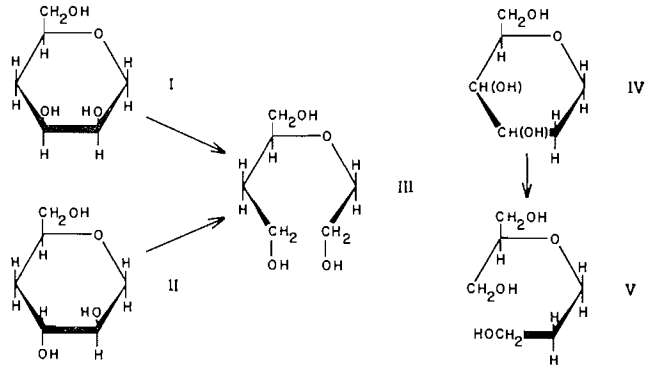

FIG. 2.

The other fraction having R_{Rh} 1.3, from the cellulose column, also gave a crystalline tris-*p*-nitrobenzoate, which on debenzoylation yielded a syrupy polyol (II) which consumed 1.0 molar equivalent of sodium periodate. Periodic acid oxidation and sodium borohydride reduction of the resulting dialdehyde formed the same compound as obtained from I. Their identity was confirmed by comparison of their crystalline tris-*p*-nitrobenzoates.

Comparison of the rates at which I and II consumed lead tetraacetate showed that the former was oxidized 4 times faster in the initial stages. This difference which is appreciable considering that the α-glycol groups are in a six-membered ring (4, 12, 13, 14) is interpreted as evidence that they are *cis* in I and *trans* in II. By consideration of the molecular rotations of various methyl hexopyranosides and 1,5-anhydro-hexitols theoretical values for the specific rotations of the four structural isomers of 1,5-anhydro-4-deoxy-D-hexitol can be calculated by use of Hudson's rules of optical superposition and isorotation (see Table III) (15). Since I has $[\alpha]_D$ $-50°$ it is probably lyxo-1,5-anhydro-4-deoxy-D-hexitol and II ($[\alpha]_D$ $+19°$) corresponds to arabo-1,5-anhydro-4-deoxy-D-hexitol. These compounds are different in hydroxyl configuration from methyl α-D-glucopyranoside and it is likely that the other two possible stereoisomers are present in the hydrogenolysis product, but were not isolated through the limitations of the fractionation procedures. Although the 1,5-anhydro-4-deoxy-hexitols are difficult to distinguish chromatographically from the dihydroglycals of the hexose series, shown to be formed by hydrogenolysis under milder conditions (4), it seems unlikely that they are present, because they are extensively degraded by hydrogenolysis at 220° C (26).

The readiness of methyl glycopyranosides to form polyols on hydrogenolysis parallels their tendency to undergo hydroxyl inversion in the hexose as well as pentose series (except that with the hexoses a higher temperature is generally needed to remove the methoxyl group). For instance, methyl β-D-galactopyranoside is much more reactive at 180° C than methyl α-D-glucopyranoside as far as hydroxyl group inversion is concerned. At 200° C the former is degraded to a mixture of dihydro-D-altral (12%), dihydro-D-glucal (31%), and dihydro-D-galactal (12%). But methyl α-D-glucopyranoside is relatively inert at this temperature and complete hydrogenolysis only takes place at 240° C,

arabo-1,5-Anhydro-4-deoxy-D-hexitol (II) +20°	Methyl α-D-altropyranoside (24) ($[M]_D$ +24,420°); Methyl β-D-idopyranoside (25) ($[M]_D$ −18,430°)

to form the more stable 1,5-anhydro-4-deoxy-hexitols and degradation products such as ethylene and propylene glycols. Much of these lower molecular weight materials may therefore have been formed through an unstable 1,2-dihydroglycal intermediate rather than 1,5-anhydro-4-deoxy-D-hexitol which does not contain the 1,3-dihydroxy grouping which is susceptible to hydrogenolysis (27).

EXPERIMENTAL

Optical rotations were measured at 25° C. Evaporations were carried out under reduced pressure. The solvent used for paper chromatographic separations was *n*-butanol – ethanol – water (40:11:19 v/v). Reducing sugars were detected with the *p*-anisidine hydrochloride spray (28) and non-reducing sugars with ammoniacal silver nitrate (29). Acid hydrolysis of glycosides was carried out with *N* H_2SO_4 at 100° C for 3 hours, the solutions neutralized with $BaCO_3$, filtered, and evaporated.

A. Preparation of Reference Compounds

Methyl β-D-Allopyranoside

D-Allose (500 mg), kindly supplied by Dr. A. C. Neish, was refluxed in 3% methanolic hydrogen chloride (20 ml) for 5 hours, and the solution neutralized, after it was cooled, with silver oxide which was then filtered off. The filtrate was evaporated to a syrup which crystallized and three recrystallizations from ethanol – ethyl acetate afforded material with m.p. 155–157° C and $[\alpha]_D$ −49° (*c*, 1.0, H_2O), yield 95 mg. Calculated for $C_7H_{14}O_6$: C, 43.3%; H, 7.3%. Found: C, 43.2%; H, 7.3%. The constants of the product agree with those given by Lindberg and Theander (30).

Methyl α-D-Talopyranoside and Derivative

Syrupy D-talose (1.26 g) was heated for 4 hours in refluxing 3% methanolic hydrogen chloride (40 ml), the acid was neutralized (Ag_2O), the solution filtered and evaporated to a syrup (1.17 g). Examination on a paper chromatogram indicated a main spot having R_{Rh} 1.4 with a minor component of R_{Rh} 1.1. The faster material was isolated by cellulose chromatography using benzene–ethanol–water (500:50:1 v/v) as the mobile phase. The product was a syrup (0.56 g) with $[\alpha]_D$ +105° (*c*, 1.0, H_2O). Calculated for $C_6H_{11}O_5 \cdot OCH_3$: OCH_3, 16.0%. Found: OCH_3, 16.0%. The glycoside was designated the α-configuration because of its strong dextrorotation.

The syrupy product (30 mg) was heated at 100° C for 2 hours in pyridine (0.5 ml) containing triphenylchloromethane (61 mg). After it was cooled, acetic anhydride (0.5 ml) was added and the solution left overnight. Then it was added to aqueous sodium bicarbonate and the insoluble material which formed was isolated and recrystallized twice from aqueous ethanol, then ethanol. The crystals (25 mg) had m.p. 177–178° C and $[\alpha]_D$ +21° (*c*, 1.3, pyridine) and analyzed for 2,3,4-tri-*O*-acetyl-6-*O*-triphenylmethyl methyl α-D-talopyranoside. Calculated for $C_{32}H_{34}O_9$: C, 68.3%; H, 6.1%. Found: C, 68.2%; H, 6.2%.

B. Hydrogenation of Methyl Glycopyranosides at 180° C

In hydrogenation of the following methyl hexopyranosides identical procedures were used. The glycoside was added to one-third its weight of copper chromite in 50 parts of dioxane (v/w). The mixture was shaken at 180° C for 6 hours at a hydrogen pressure of 600 p.s.i. and after it was cooled the solution was filtered and evaporated. An attempt was then made to crystallize any sugars from solution and the resulting syrup was chromatographed on a cellulose column. The solvents for cellulose chromatography were benzene–ethanol–water (500:50:1 v/v) to isolate materials moving faster than rhamnose on a paper chromatogram. For compounds moving slower than rhamnose *n*-butanol one-quarter saturated with water was used.

When methyl pentopyranosides were hydrogenated the procedure was the same as above except for the relative proportion of components in the reaction mixture. In this case the weight of catalyst was 30% that of the methyl pentoside and the solvent used was 45 times that of the pentoside on a volume per unit weight basis.

(*i*) *Methyl α-D-glucopyranoside.*—From the hydrogenation product of the glucoside (2.00 g) mainly unchanged material was recovered by crystallization from ethanol, m.p. and mixed m.p. 165–166° C. Column chromatography yielded only 42 mg of substance that ran at a different rate than methyl glucoside on a paper chromatogram.

(*ii*) *Methyl β-D-glucopyranoside.*—Using the same procedure as with the above α-anomer only 9 mg of material was obtained not corresponding to methyl β-D-glucopyranoside. From ethyl acetate – ethanol the crystals had m.p. and mixed m.p. 115–116° C.

(*iii*) *Methyl α-D-mannopyranoside.*—The mannoside (1.75 g) was hydrogenated and some unchanged glycoside (0.47 g) was recovered from the reaction mixture having m.p. and mixed m.p. 192–195° C. The remainder was fractionated on a cellulose column to give material containing methyl α-D-talopyranoside (0.47 g) with $[\alpha]_D$ +83° (*c*, 3.3, H_2O). Calculated for $C_6H_{11}O_5 \cdot OCH_3$: OCH_3, 16.0%. Found: OCH_3, 16.7%. Acid hydrolysis yielded a sugar which corresponded to talose and ran faster than galactose on a paper chromatogram, and which gave D-lyxohexose phenylosazone on treatment with aqueous phenylhydrazine acetate at 80° for 6 hours. The phenylosazone gave an X-ray diffraction pattern identical with authentic D-lyxohexose phenylosazone and different

from D-arabohexose, D-ribohexose, and L-xylohexose phenylosazones. The next fraction contained unchanged methyl α-D-mannopyranoside (63 mg), m.p. and mixed m.p. 192–194° C. A later fraction (46 mg) from the column crystallized and two recrystallizations from ethanol – ethyl acetate yielded methyl α-D-glucopyranoside, m.p. and mixed m.p. 167–168° C. Calculated for $C_7H_{14}O_6$: C, 43.3%; H, 7.3%. Found: C, 43.4%; H, 7.35%.

(*iv*) *Methyl β-D-mannopyranoside.*—Methyl β-D-mannopyranoside (1.16 g) on hydrogenation followed by acid hydrolysis yielded 137 mg of material from a cellulose column that did not correspond to mannose. In another experiment the unchanged glycoside was characterized as its tetraacetate, m.p. and mixed m.p. 161–163° C.

(*v*) *Methyl α-D-galactopyranoside.*—Methyl α-D-galactopyranoside (1.60 g) was hydrogenated and crystals were obtained from an ethanolic ethyl acetate solution of the product. The material (0.36 g) corresponded to methyl α-D-glucopyranoside since it had m.p. and mixed m.p. 163–165° C and $[\alpha]_D$ +161° (*c*, 3.5, H_2O). The mother liquor on cellulose chromatography gave three main fractions. These were a mixture (0.26 g) of polyols and methyl α-D-talopyranoside having OCH_3, 9.3%, and $[\alpha]_D$ +27° (*c*, 1.2, H_2O). The methoxyl content of the mixture corresponded to 58% of glycoside and it was acid hydrolyzed to give free aldose (R_F = talose) which was converted to D-lyxohexose phenylosazone by heating at 80° C for 6 hours with 4 moles of aqueous phenylhydrazine acetate. The identity of the phenylosazone was proved by its X-ray diffraction pattern, which was identical to that of an authentic specimen. The other two fractions which both crystallized from ethyl acetate – ethanol consisted of methyl α-D-glucopyranoside (0.16 g), m.p. and mixed m.p. 165–166° C, and methyl α-D-galactopyranoside (80 mg), m.p. and mixed m.p. 117–118° C.

(*vi*) *Methyl β-D-galactopyranoside.*—Hydrogenation of methyl β-D-galactopyranoside (2.0 g) gave a syrup from which methyl β-D-glucopyranoside (0.34 g), m.p. and mixed m.p. 116–117° C, was isolated. Cellulose chromatography gave as one of the main products a polyol fraction (0.32 g) and another contained glycosides (0.77 g) having R_{Rh} 0.7. The latter was fractionated by crystallization from ethyl acetate – ethanol to give methyl β-D-glucopyranoside (163 mg) as thick prisms with m.p. and mixed m.p. 116–117° C and $[\alpha]_D$ −37° (*c*, 1.0, H_2O) after two further recrystallizations. Calculated for $C_7H_{14}O_6$: C, 43.3%; H, 7.3%. Found: C, 43.2%; H, 7.5%. After the bulky prisms were removed a fluffy solid (62 mg) remained which on two recrystallizations from the same solvent yielded methyl β-D-allopyranoside with m.p. and mixed m.p. 157–158° C and $[\alpha]_D$ −52° (*c*, 1.6, H_2O). Calculated for $C_7H_{14}O_6$: C, 43.3%; H, 7.3%. Found: C, 43.25%; H, 7.4%. The last fraction from the column consisted of unchanged methyl β-D-galactopyranoside (0.35 g) with m.p. and mixed m.p. 179–180° C.
