The above methods have been used in studying the biosynthesis of the sugars found in the polysaccharides produced by *Cryptococcus laurentii*. Details of this work will be published shortly.

METHODS

The chromic acid reagent used for the complete combustion of organic samples was prepared according to the directions given by Van Slyke (21).

The mercuric acetate/acetic acid reagent used for the oxidation of formic acid to carbon dioxide was prepared by the method of Bernstein (7). These oxidations were carried out in an apparatus which is a slightly modified form of that described by Johansson *et al.* (22) for the determination of uronic acid.

The radioactive sugars used in the experiments described in this paper were purchased from Isbell (National Bureau of Standards, Washington).

The separation of glycerol and ethylene glycol was carried out on Whatman 3MM paper which had been washed with acid, water, and solvent. The following solvent system was used for the chromatographic separation: butanol–ethanol–water, 3:1:1. The glycols were detected on the chromatograms by spraying them with the metaperiodate / *p*-anisidine hydrochloride reagent described by Bragg *et al.* (23).

Measurement of C^{14} *in Barium Carbonate Samples*

The barium carbonate plates were prepared by the method of Calvin *et al.* (24) and each sample was plated in triplicate (ca. 10 mg barium carbonate on each plate).

The activity of the barium carbonate plates was measured in a proportional methane gas flow counter comprised of the following: the detector, model CFIS2, purchased from the Atomic Energy of Canada Limited and a preamplifier, scaler, and high-voltage assembly manufactured by the Atomic Instrument Co.

The background count was determined and a standard C^{14} plate was counted before and after each counting period. The barium carbonate plates were counted until 1000–1200 counts had accumulated; each plate was counted in triplicate. A correction factor for self-absorption of the barium carbonate was applied.

EXPERIMENTAL

Degradation of Glucose-1-C^{14} *(method A)*

The total activity (C 1–6) of the glucose sample was determined in the usual way by use of the Van Slyke reagent.

Metaperiodate Oxidation (C 1–5)

The glucose (6–7 mg) was dissolved in phosphate buffer solution pH 8.0 (*M*/20) and 2 ml of 0.3 *M* aqueous sodium metaperiodate was added. The oxidation was allowed to proceed in the dark for 2 hours. An excess (×10) of sodium borohydride was added to destroy the remaining metaperiodate; after 15 minutes 2 *N* sulphuric acid was added until the solution was acidic (pH 2.0). The formic acid was separated from the inorganic material by steam distillation (7), the mercuric acetate/acetic acid reagent (9 ml) was added to the distillate, and after the apparatus was flushed with nitrogen for 10 minutes the reaction mixture was boiled for 20 minutes with constant stirring. The barium carbonate was collected and prepared for counting as described above.

Reduction with Sodium Borohydride and Oxidation with Sodium Metaperiodate (C 2–5)

Glucose (7–8 mg) was dissolved in water (2 ml) and sodium borohydride (9 mg) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

added; the solution was allowed to stand for 12 hours. The excess sodium borohydride was destroyed by making the solution acidic (pH 2.0) with 2 *N* sulphuric acid. Sodium hydroxide (2 *N*) solution was added until the pH of the solution was ca. 7.0, 10 ml of phosphate buffer solution and 2 ml of 0.3 *M* aqueous sodium metaperiodate were added, and the solution was left in the dark for 2 hours. The metaperiodate was destroyed with excess sodium borohydride and the oxidation was continued as before.

Degradation of Glucose-1-C^{14}, -6-C^{14}, *and* -2-C^{14} *(method B)*

The total activity (C 1–6) of the glucose samples was determined as above.

Metaperiodate Oxidation (C 1–5)

The metaperiodate oxidation and addition of sodium borohydride was carried out as described in method A. The excess sodium borohydride was destroyed by the addition of 2 *N* sulphuric acid and the mercuric acetate/acetic reagent (10 ml) was added. A bright red precipitate of mercuric salts was formed, the apparatus was flushed out with nitrogen, and the oxidation continued as described above.

Reduction with Sodium Borohydride and Oxidation with Sodium Metaperiodate (C 2–5)

The reaction was carried out in a similar manner to that described above, i.e. without distillation of the formic acid.

Degradation of Glucuronolactone-6-C^{14}

The total activity (C 1–6) was determined as usual.

Metaperiodate Oxidation (C 1–5)

The glucuronolactone solution (7 mg in 3 ml of water) was titrated to neutrality with 0.01 *N* sodium hydroxide solution. The acetate buffer, pH 3.65 (10 ml), and 2 ml of 0.3 *M* aqueous sodium metaperiodate were added. The reaction mixture was kept in the dark for 6.5 hours, after which ethylene glycol was added to destroy the excess metaperiodate. After 10 minutes the acidic solution was gently boiled to drive off carbon dioxide (C-6) the solution was cooled and the mercuric acetate/acetic acid reagent (9 ml) was added. The oxidation was continued in the usual manner.

*Preparation of Methyl-α-*D*-glucopyranoside*

The methyl-α-D-glucopyranoside was prepared by the standard method (25). The product was recrystallized from a mixture of equal parts of ethanol and methanol until a constant melting point of 164–165° C was obtained.

*Periodic Acid Oxidation of Methyl-α-*D*-glucopyranosides*

A solution of methyl-α-D-glucopyranoside (194 mg) in water (3 ml) was treated with 0.4 *M* periodic acid (5.5 ml) at room temperature for 3 hours. The solution was then passed through a column of Duolite A-4 (OH) resin (1.9×6 cm). The column was washed with distilled water until the total volume of the eluate reached 110 ml. This eluate, which contained the dialdehyde (II) (Fig. 1), was concentrated to ca. 25 ml, sodium borohydride (60 mg) was added, and the reduction to the triol (III) (Fig. 1) was allowed to proceed overnight. The excess sodium borohydride was destroyed by making the solution acidic with 2 *N* hydrochloric acid. The triol was hydrolyzed to glycerol and glycolic aldehyde (IV) (Fig. 1) by adding 2 *N* hydrochloric acid (4 ml) and warming at 60° C for 20 minutes. After the solution was cooled 2 *N* sodium hydroxide solution was added until the pH of the solution was 6.0–6.5. Sodium borohydride (40 mg) was added to reduce the glycolic aldehyde to ethylene glycol (V) (Fig. 1); the reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was allowed to stand for 2 hours. The excess sodium borohydride was destroyed by making the solution acid with 2 *N* hydrochloric acid. The solution was brought to neutrality by the addition of 2 *N* sodium hydroxide solution and concentrated *in vacuo* to 15 ml.

Separation of Glycerol and Ethylene Glycol from the Inorganic Material

The glycerol and ethylene glycol were separated from the inorganic material by passing the solution through a Dowex 50W (8% D.V.B.) resin column (Ba^{++}) (20×115 cm) (20). The eluate was collected in the tubes of a fraction collector. The tubes containing the glycerol and ethylene glycol were combined and evaporated to dryness. Boric acid was still present in the fractions and was removed by codistillation with methanol (×2). A pale yellow syrup was obtained (146 mg). This syrup was passed through a short mixed resin column (Amberlite IR-120 (H) and Duolite-A-4 (OH)) and again evaporated to dryness. The colorless mobile syrup was taken up in methanol, filtered through a celite/charcoal pad, and again evaporated to dryness. A colorless, clear mobile syrup was obtained (134 mg, 100%). Chromatographic examination of an aliquot of this syrup showed spots which moved at rates corresponding to those of ethylene glycol and glycerol. A small quantity of a third material, which moved at a slower rate than glycerol, was detected. This material is probably a tetritol derived from the dimerization of glycolic aldehyde.

*Separation of Glycerol (*C-6, C-5, *and* C-4*) and Ethylene Glycol (*C-1 *and* C-2*)*

The syrup (134 mg) was fractionated by placing it on Whatman 3MM paper and by chromatography of the mixture with the neutral solvent. The appropriate portions of the paper containing the glycerol and ethylene glycol were eluted with water and evaporated to dryness. The syrups obtained were dissolved in water, deionized on mixed ion-exchange resin columns, and evaporated to dryness. These syrups were taken up in methanol (3 ml) filtered through small celite/charcoal pads, and evaporated to dryness. The fraction corresponding to glycerol weighed 92 mg (100%) and that corresponding to ethylene glycol 27 mg (65%). Both fractions were clear, colorless, mobile syrups. On chromatographic examination each showed a single spot which moved at a rate corresponding to either glycerol or ethylene glycol.

Identification of Glycerol and Ethylene Glycol

Each fraction was treated with a 50% molar excess of *p*-nitrobenzoylchloride (recrystallized) in pyridine (freshly dried and distilled) according to the method of Smith *et al.* (26). The glycerol fraction gave crystalline glycerol-tris-*p*-nitrobenzoate, m.p. 198–199° C; the ethylene glycol fraction gave crystalline ethylene glycol-bis-*p*-nitrobenzoate, m.p. 143–144° C. (Mixture melting points with authentic samples were not depressed.)

*Degradation of Methyl-α-*D*-glycopyranoside-*1-C^{14} *and* -6-C^{14}

Each sample (100 mg and 57 mg) was subjected to the degradation procedure described above and afforded 65 mg (95%) and 36 mg (100%) of the glycerol/ethylene glycol mixtures.

Determination of C^{14} *in* C-3 *(13)*

After removal of the dialdehyde, the resin column was washed with a further 50 ml of water and the washings were discarded. The formic acid was eluted from the column with 0.25 *N* barium hydroxide (20 ml) solution followed by water (30 ml). The alkaline

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

barium formate solution was acidified with 2 *N* sulphuric acid. The formic acid in the solution was then oxidized to carbon dioxide by refluxing it for 20 minutes with mercuric acetate. The barium carbonate was collected and assayed for C^{14} as described above.

Radiographic Examination of the Glycerol/Ethylene Glycol Mixtures

Each of the two samples was chromatographed on Whatman 3MM paper in the neutral solvent. An X-ray film was left in contact with the chromatogram for 4 weeks. On development the radiogram showed one band corresponding to the position of glycerol from the methyl-α-D-glycopyranoside-6-C^{14} and one band corresponding to the position of ethylene glycol from methyl-α-D-glucopyranoside-1-C^{14}, the latter also showed a weak band corresponding to the position of the tetritol discussed earlier. The positions of the non-radioactive samples of glycerol and ethylene glycol were determined in the usual manner. The appropriate sections of the paper were eluted and purified as described above.

The methyl-α-D-glucopyranoside-1-C^{14} yielded glycerol, 40 mg (84%), and the ethylene glycol, 10 mg (46%). The methyl-α-D-glucopyranoside-6-C^{14} yielded glycerol, 25 mg (92%), and ethylene glycol, 5 mg (40%).

Degradation of Glycerol and Ethylene Glycol

The samples of ethylene glycol (5 mg) were totally combusted in the normal manner. The total activities of the glycerol samples were determined in a similar fashion. The glycerol derived from the methyl-α-D-glucopyranoside-6-C^{14} was further degraded to determine the radioactivity in C-5. Glycerol (15 mg) was oxidized with aqueous 0.3 *M* metaperiodate in a similar manner to that described for the metaperiodate oxidation of glucose-1-C^{14} (method B).

ACKNOWLEDGMENTS

The authors are grateful to Dr. G. Krotkov of the Biology Department of Queen's University for making available the counting apparatus. We thank the National Research Council of Canada for financial assistance and (M. J. A.) thanks them for the award of a scholarship.

THE POLYSACCHARIDES OF CRYPTOCOCCUS LAURENTII (Y1401)

PART II. BIOSYNTHESIS OF THE CARBOHYDRATES FOUND IN THE ACIDIC POLYSACCHARIDE[1]

M. J. Abercrombie, J. K. N. Jones, and M. B. Perry

ABSTRACT

Cryptococcus laurentii was grown on media which contained D-glucose-1-C^{14}, D-glucose-6-C^{14}, D-mannose-1-C^{14}, D-galactose-1-C^{14}, D-xylose-1-C^{14}, and L-arabinose-1-C^{14}. The radioactive polysaccharides were isolated and hydrolyzed. The distribution of the radioactivity in D-mannose, D-xylose, and D-glucuronic acid isolated from the polysaccharides was determined.

The results show that (A) D-mannose and D-glucuronic acids are formed from the hexoses without any appreciable breakdown of the hexose skeleton; (B) D-xylose is formed from the hexoses mainly by a process involving loss of carbon-6; (C) D-xylose and L-arabinose are both converted to D-mannose, D-xylose, and D-glucuronic acid with rearrangement of the pentose skeleton that may involve the action of transaldolase and transketolase.

INTRODUCTION

In Part I of this series of papers (1) the growth, isolation, and preliminary structural investigation of the polysaccharides produced by *Cryptococcus laurentii* were reported. It was shown that two polysaccharides were present: an acidic polysaccharide containing D-mannose, D-xylose, and D-glucuronic acid and a neutral polysaccharide which consisted of D-glucose only.

In this paper the biosynthesis of the monosaccharides found in the acidic polysaccharide is discussed.

EXPERIMENTAL

Materials

D-Glucose-1-C^{14}, D-glucose-6-C^{14}, D-xylose-1-C^{14}, and L-arabinose-1-C^{14} were purchased from the National Bureau of Standards, Washington. D-Mannose-1-C^{14} and D-galactose-1-C^{14} were purchased from Merck & Co., Montreal. The uniformly labelled D-glucose-C^{14} was provided by Dr. G. Krotkov, Department of Biology, Queen's University, Kingston.

The purity of these compounds was checked by chromatographic and radioautographic examination.

Growth of Cryptococcus laurentii and Isolation of the Polysaccharide

The organism was grown on the media described in Part I (1). The aqueous solution containing the carbon-14 labelled sugar and the growth solution were steam sterilized in separate vessels. These solutions were combined in a sterile 250-ml, two-necked round-bottom flask. The final strength of the solution was $2\frac{1}{2}\%$ with respect to the sugar. A slow stream of sterilized, carbon dioxide free air was drawn through the solution; the carbon dioxide evolved was collected in a trap which contained 200 ml of 2 *N* sodium hydroxide solution. The media were inoculated from a freshly prepared slope on which the yeast organism was growing. The slope contained the same sugar as the growth media which were to be inoculated.

The growth of the organism was followed by sampling the carbon dioxide evolved. When the sodium carbonate content of the aqueous sodium hydroxide trap reached a constant value the growth was stopped. The conversion of carbohydrate to carbon dioxide

[1]*Manuscript received May 11, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario, Canada.

reached a constant value at about 55% of the theoretical assuming complete oxidation of carbohydrate to carbon dioxide (see Table I). The average growth time was 7 days.

The growth solution was diluted to 50 ml with water and the solution was shaken to wash the viscous material from the wall of the reaction vessel. The yeast cells were removed by centrifugation and the cells were washed with water (2×20 ml). The supernatant and the washings were combined and diluted to 100 ml.

A 5-ml sample of this solution was deionized by passing the solution through a small mixed bed ion-exchange resin column (Amberlite IR-120 (H)/Duolite-A-4 (OH)). The eluate was concentrated *in vacuo* to a small volume and was examined by chromatography and radioautography. In most experiments a spot moving at the same speed as the free sugar which formed part of the original substrate was the only compound detected by either method. In the other experiments no spots were observed (see Table I).

The remainder of the supernatant (95 ml) was dialyzed against distilled water (2 liters) in which was suspended mixed ion-exchange resins (as above) for 2 days. The dialyzed solution, which had become cloudy, was filtered through a small pad of "Celite" to give a clear filtrate. The pad of "Celite" was washed with a further 50 ml of water and the washings were combined with the filtrate. The solution was concentrated to about 10 ml; the polysaccharide was precipitated by addition of 75 ml of ice-cold ethanol which contained 1% of hydrochloric acid. The polysaccharide was collected by centrifugation, washed with ethanol, and dried *in vacuo*. The yields are recorded in Table I.

Hydrolysis of the Polysaccharides

The polysaccharides isolated from media which had contained D-xylose-1-C^{14} or L-arabinose-1-C^{14} were hydrolyzed for 24 hours with ca. 7 ml of *N* sulphuric acid in sealed glass tubes which were suspended in a boiling-water bath. The hydrolyzates were diluted to 50 ml with water, neutralized with barium carbonate, filtered through beds of "Celite", and deionized by passage through small columns of Amberlite IR-120 (H) ion-exchange resin. These solutions were made up to a known volume (100 ml). Aliquots of each solution were then dried on aluminum disks and counted. The total activity of the hydrolyzates and the radioactive yields are recorded in Table I. Since there appeared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to be a considerable loss of material due to degradation during hydrolysis the remaining samples of polysaccharides were hydrolyzed by the following procedure.

The polysaccharides were hydrolyzed with ca. 5 ml of 2% methanolic hydrogen chloride in sealed glass tubes in a boiling-water bath for 15 hours. After the tubes had cooled they were opened and the solutions were evaporated to dryness under a stream of air. To the residues 5 ml of *N* hydrochloric acid was added, the tubes were sealed, and the methyl glycosides were hydrolyzed in a boiling-water bath for 5 hours. After cooling, the hydrolyzates were diluted to 50 ml with water and silver carbonate was added to neutralize the hydrochloric acid. The insoluble salts were removed by filtration and the filtrates were deionized by passage through small Amberlite IR-120 (H) ion-exchange resin columns. The solutions were diluted to known volumes and counted as before. The results are collected in Table I.

The hydrolyzates of the polysaccharides produced from the media containing uniformly labelled glucose-1-C^{14} had recoveries of ca. 80% based on the dry weight of the polysaccharides. The recoveries from the polysaccharides derived from D-glucose-1-C^{14}, D-glucose-6-C^{14}, D-mannose-1-C^{14}, and D-galactose-1-C^{14} were rather less. This is attributed to the fact that when the hydrolyzates were fractionated by chromatography considerable quantities of methyl glycosides were detected and the fractions had to be eluted from the paper and rehydrolyzed with *N* hydrochloric acid.

Isolation of the Radioactive Carbohydrates

The 3MM Whatman paper on which the hydrolyzate mixtures were fractionated was washed with acid, water, and solvent before use. Chromatographic fractionations were carried out using the following solvent system (v/v) *n*-butanol:pyridine:benzene:water, 5:3:3:1. After the chromatograms had been developed for ca. 30 hours they were dried and placed in contact with X-ray films for 9 days. The bands corresponding to the portions of mannose, xylose, glucose, and uronic acids (present on the base line) were eluted and the eluates were diluted to known volumes. Aliquots of each solution were then dried on aluminum disks and counted. The solutions were concentrated *in vacuo* at 35° C to a small volume and applied to the base line on sheets of Whatman 3MM paper (treated as above). The chromatograms were developed in ethyl acetate : acetic acid : water, 9:2:2 (v/v). The chromatograms were radioautographed and the sugars eluted and counted as before. The results are collected in Table II. The solutions of the neutral radioactive carbohydrates were passed through small columns of mixed ion-exchange resins (as

*Analysis of mannose/xylose ratio by colorimetric method of Smith (5) gave 3.10/1.00.

above) to remove traces of ash which were present. The radioactive monosaccharides were diluted with the quantity of cold material required for the degradation procedures.

Degradation of the Sugars

The radioactive content of the carbon atoms of D-mannose and D-glucuronic acid and of the terminal carbon atoms of D-xylose were determined by methods described previously by the authors (2). The radioactive content of the carbon atoms 3 and 4 of D-xylose were determined by methods described in the literature (3, 4). The results are collected in Table III.

TABLE III

Distribution of C^{14} in D-mannose, D-xylose, and D-glucuronic acid isolated from the polysaccharide produced by *Cryptococcus laurentii*

		C^{14} as % total in monosaccharide					
Compound fed	Sugar isolated	Carbon-1	Carbon-2	Carbon-3	Carbon-4	Carbon-5	Carbon-6
D-Glucose-1-C^{14}	D-Mannose	83.8	←	5.8		→	10.4
	D-Xylose	93.6	←	4.7	→	1.7	—
	D-Glucuronic acid	86.6	←	7.4		→	7.0
D-Glucose-6-C^{14}	D-Mannose	6.3	←	2.5		→	91.2
	D-Xylose	37.0	←	21.0	→	42.0	—
	D-Glucuronic acid	2.6	←	2.0		→	95.6
D-Mannose-1-C^{14}	D-Mannose	81.7	←	3.3		→	15.0
	D-Xylose	85.6	←	5.4	→	9.0	—
	D-Glucuronic acid	26.3	←	26.3		→	47.2
D-Galactose-1-C^{14}	D-Mannose	76.8	←	7.2		→	16.0
	D-Xylose	93.7	←	4.1	→	2.8	—
	D-Glucuronic acid	55.0	←	24.0		→	21.0

	D-Xylose	56.9	2.6	30.0	9.0	1.5	—
	D-Glucuronic acid	53.0	←	38.5		→	8.5
L-Arabinose-1-C^{14}	D-Mannose	50.9	0.2	27.7	9.8	2.8	7.1
	D-Xylose	56.0	0.5	32.5	7.5	4.5	—
	D-Glucuronic acid	48.5	←	45.0		→	6.5

RESULTS

The percentage yields of polysaccharides shown in the fifth column of Table I indicate that D-glucose may be a more efficient precursor for polysaccharide formation than the other sugars; however, there is little to choose between them.

In the last column of Table II the ratio of D-mannose to D-xylose in the polysaccharides from the growths on uniformly labelled D-glucose is shown to be approximately 3:1 (w/w). This is in agreement with the value obtained from the colorimetric procedure (5) which was determined on the same sample of polysaccharide. Allowing for the difficulties encountered during the hydrolysis of the radioactive polysaccharides the ratios of D-mannose to D-xylose in the other experiments are in the region of 3:1 except for the polysaccharide grown from substrate containing D-glucose-6-C^{14} where the apparent ratio is 45:1. This result shows that the main pathway for the conversion of D-glucose (or hexose) to D-xylose is via a pathway which involves the loss of carbon-6. This is in agreement with the results of previous workers (9, 14).

Columns A and B (Table II) show the total activities of the uronic acid fraction from the hydrolyzate of the polysaccharides after the first and second fractionation by paper chromatography. Column A shows the total uronic acid residue content (mono-, di-, and tri-uronic acid residues) and column B shows the amount of D-glucuronic acid obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

from these fractions. The radioautograms showed that there was at least one aldobiouronic acid and one aldotriuronic acid plus other minor components. These figures show that in all cases the D-glucuronic acid content was 50% or less of the uronic acid containing fraction first isolated from the hydrolyzate.

Table III shows the distribution of C^{14} in D-mannose, D-xylose, and D-glucuronic acid.

The conversion of the hexoses to D-mannose is primarily a direct conversion with at least 76% retention of labelling in the original position. The bulk of the remainder of the labelling is in the other terminal carbon. This supports the conclusion of other workers (6–15, 26) that the Embden–Meyerhof glycolytic pathway is also utilized. It is interesting to note that the carbon-1 to carbon-6 rearrangement of the hexoses is greater for D-galactose and for D-mannose than for D-glucose. This is of special interest since it indicates that some of the D-mannose is not incorporated directly into the mannose-containing backbone of the polysaccharide via the mannosyl phosphate or guanosine diphosphate – mannose (16, 17) but that it is probably in equilibrium with D-fructose 1,6-diphosphate.

The distribution of C^{14} in the samples of D-xylose further supports the theory that D-xylose may arise from the hexoses via loss of carbon-6.

It has been postulated (18, 19) that uronic acids in pectin are derived from hexoses by direct oxidation of carbon-6 without significant breakdown of the carbon skeleton. The C^{14} labelling in D-glucuronic acid derived from D-glucose-1-C^{14} and D-glucose-6-C^{14} supports this theory. The D-glucuronic acid derived from D-mannose-1-C^{14} and D-galactose-1-C^{14} while retaining approximately 50% of the activity in carbon-1 also has a considerable distribution of activities in the other carbons. Thus in these cases there must be a significant amount of breakdown of the carbon skeleton to fragments followed by resynthesis.

L-Arabinose was not converted directly to D-xylose as was found by Neish (14). From the results it seems probable that L-arabinose is converted into a hexose which is the common precursor for the formation of D-mannose, D-glucuronic acid (via oxidation of carbon-6), and D-xylose via oxidation and decarboxylation of carbon-6. D-xylose follows a similar pathway to that of L-arabinose.

DISCUSSION

The topic *Biosynthesis of Monosaccharides* has been recently reviewed (20, 21, 22).

The results presented in this paper support the theory that hexoses are readily interconvertible with only a small amount of cleavage of the carbon skeleton occurring (6–15, 27). The probable intermediates for such conversions are shown in Fig. 1 (20).

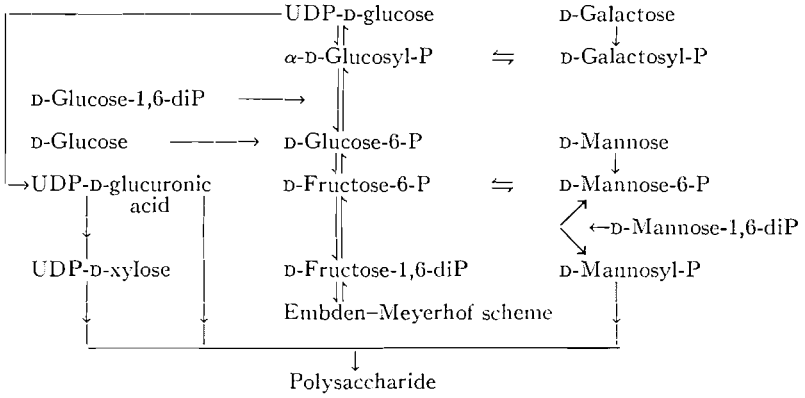

FIG. 1. The interconversion of hexoses. P = phosphate; UDP = uridine diphosphate.

The results show that the conversion of D-galactose to the D-glucose intermediate takes place without appreciable breakdown of the carbon skeleton, probably via a "galactowaldenase" enzyme system (23). The D-glucose intermediate is epimerized to D-mannose; the over-all retention of activity in carbon-1 for the conversion of D-galactose to D-mannose is 77%. The bulk of the remainder of the activity (16%) is present in carbon-6 as would be expected if the Embden–Meyerhof pathway was operative.

The formation of D-xylose from hexoses by loss of carbon-6 is apparent, since the D-xylose derived from D-glucose-6-C^{14} contains only 6.5% of the activity that it would have contained had it been derived from D-glucose-1-C^{14}. The D-xylose derived from D-glucose-1-C^{14}, D-mannose-1-C^{14}, and D-galactose-1-C^{14} retains 85–94% of its activity in carbon-1. Similar results were obtained by other workers (12, 14, 9).

It is possible that D-xylose and D-glucuronic acid derived from D-glucose-1-C^{14} and D-glucose-6-C^{14} had the same UDP-hexuronic acid precursor since the retention of activity in carbon-1 in the former is very high. In the latter the D-glucuronic acid had 4.4% of its activity in carbons 1–5 and the D-xylose contained 6.5% of activity in carbons 1–5 as mentioned above.

The D-xylose and D-glucuronic acid derived from D-mannose-1-C^{14} and D-galactose-1-C^{14} do not come from the same UDP-hexuronic acid precursor since the retention of activity in carbon-1 of the D-xylose is high (85–93%), but the activity in the D-glucuronic acid is much more widely distributed through the molecule.

The conversion of D-xylose-1-C^{14} and L-arabinose-1-C^{14} into the polysaccharide constituents takes place with much breakdown of the pentose carbon skeleton and resynthesis to pentose, hexose, and hexuronic acid. Gibbs and Horecker (24) showed that D-ribose-5-phosphate was converted to hexose monophosphate via a pathway involving transketolase and transaldolase (Fig. 2). The results collected in Table III show that the distribution of the activity in D-mannose, D-xylose, and probably D-glucuronic acid agree with the results expected from this pathway if it is assumed that D-xylose is derived from a hexose precursor by loss of carbon-6. Neish (12, 13) and Hassid *et al.* (9) found with wheat seedlings that D-xylose was metabolized by such a pathway but L-arabinose was not (14). It was proposed that UDP-L-arabinose was formed as an intermediate which could be converted to UDP-D-xylose which was incorporated directly into the xylan. Neish suggested that the enzyme systems for converting free D-xylose into UDP-D-xylose were not present in wheat seedlings and that it was metabolized by the following scheme:

$$\text{D-xylose} \xrightarrow[\text{transaldolase}]{\text{transketolase}} \text{hexose} \rightarrow \text{UDP-hexuronic acid} \rightarrow \text{UDP-D-xylose} \rightarrow \text{xylan.}$$

It is apparent that in the growth media of *Cryptococcus laurentii* although there is an enzyme system for converting D-galactose → D-glucose → D-mannose there is no such system for the similar L-arabinose → D-xylose conversion. The results in Table III indicate that L-arabinose and D-xylose are metabolized through the same intermediates. Recently Horecker *et al.* (25) have shown that D-ribose, D-xylose, and L-arabinose are interconvertible through the scheme showed in Fig. 3.

It is now recognized that D-threopentulose-5-phosphate, not D-erythropentulose-5-phosphate, is the substrate of transketolase in animals and microorganisms (22).

Since D-xylose and L-arabinose are metabolized by *Cryptococcus laurentii* via the same intermediates then it would be reasonable to propose that the enzyme systems responsible for the intermediates involved in Fig. 3 and Fig. 2 must be present.

PHASE EQUILIBRIUM RELATIONSHIPS IN THE BINARY SYSTEM METHYL ETHYL KETONE – WATER[1]

IRWIN SIEGELMAN[2] AND C. H. SORUM[3]

ABSTRACT

A complete investigation of the phase equilibrium relationships in the binary system of the partially miscible liquid pair methyl ethyl ketone – water is presented. The system shows a minimum azeotrope at 73.35±0.05° C with a composition of 88.45±0.15 wt.% ketone. The azeotrope falls outside of the miscibility gap for this system. The liquid–vapor curves intersect the miscibility gap at the temperature of 73.60±0.05° C at which two conjugate solutions of compositions 18.10±0.10 and 87.78±0.15 wt.% ketone, respectively, are in equilibrium with a vapor phase of composition 88.00±0.15 wt.% ketone. The partially miscible liquid pair shows an upper consolute temperature of 139±0.5° C at a composition of 44.9±0.2 wt.% ketone. The liquid–liquid curves intersect the solid–liquid curves at a temperature of −6.0±0.5° C at which two conjugate solutions of composition 40.0±0.2 and 78.0±0.2 wt.% ketone, respectively, are in equilibrium with ice. A binary eutectic exists at a temperature of −89.0±0.5° C with composition of the eutectic solid equal to 99.4±0.4 wt.% ketone. The freezing point of pure, dry methyl ethyl ketone is determined to be −83.5±0.5° C.

INTRODUCTION

Discrepancies in the literature data (1–8) on mutual solubility studies for the system methyl ethyl ketone – water, as shown in Fig. 1, and similar discrepancies in the literature

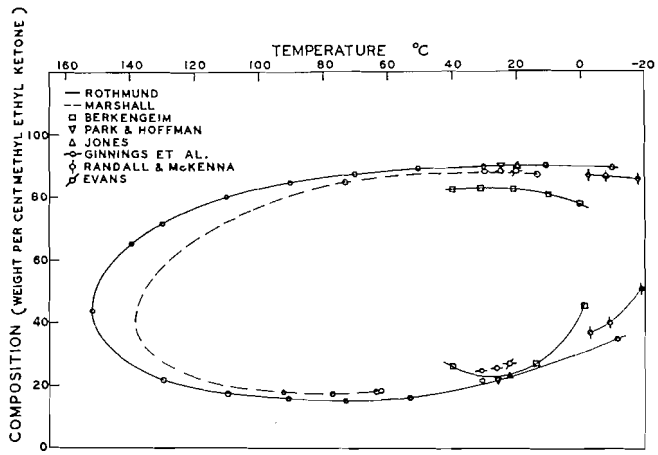

FIG. 1. Mutual solubility data as reported in the literature.

(9, 10, 11) on liquid–vapor studies of this system, as shown in Fig. 2, prompted this present work. This paper presents, then, the results of a reinvestigation of the mutual solubility and liquid–vapor relationships found in the system methyl ethyl ketone – water plus a study of the solid–liquid equilibria for a complete picture of the phase equilibrium relationships in this system.

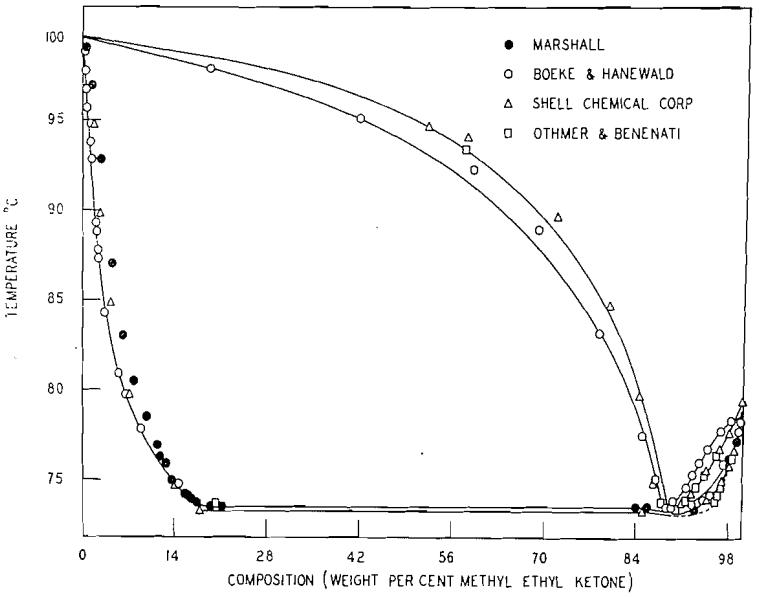

FIG. 2. Liquid–vapor data as reported in the literature.

EXPERIMENTAL

A. Materials

The water used in these studies was distilled water from the laboratory tap which was redistilled from alkaline permanganate solution. Constancy of freezing point was used as a criterion of purity.

Commercial methyl ethyl ketone (minimum purity 99.0% by weight, b.p. 79.0–81.0° C), a straw yellow in color, was dried following the technique found in Weissberger's standard work (12). Middle fractions of doubly distilled water-clear ketone (b.p. 79.60± 0.05° C) were collected and stored over anhydrous potassium carbonate in the dark. (Methyl ethyl ketone is subject to slow photolysis.) A combination of physical techniques and visual observation used indicated a ketone purity of not less than 99.6% and probably of the order of 99.9%. As will be noted below, in the section pertaining to solid–liquid studies, the freezing point of methyl ethyl ketone as prepared for this work is further evidence of its high purity and dryness.

B. Thermometers

Throughout these studies temperatures were measured by use of conventional liquid-in-glass thermometers. The mercury-in-glass instruments (Brooklyn Thermometer Company precision grade) used between 0° C and 140° C were calibrated against a National Bureau of Standards' certified platinum resistance thermometer. The petrolate-in-glass instruments (Brooklyn Thermometer Company) used between 0° C and −90° C were calibrated and certified by the National Bureau of Standards.

C. Determination of the Liquid–Vapor Curves

The Othmer equilibrium still (13) was used to determine the liquid–vapor curves for this system. In order to present data at 1 atmosphere it was necessary to use the still in conjunction with a simple pressure line capable of maintaining the pressure in the still at 760±1 mm. Compositional analyses of boiling liquids and their condensed vapors were made by measurement of their relative refractive indices which were then compared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to working curves of relative readings of refractive index versus percentage composition of known solutions. An interesting result obtained for refractive index of ketone-rich solutions at 25° C is that a maximum occurs in the curve in the vicinity of 90% ketone (Fig. 3). Data obtained by the Shell Chemical Company (14) do not show such a maximum.

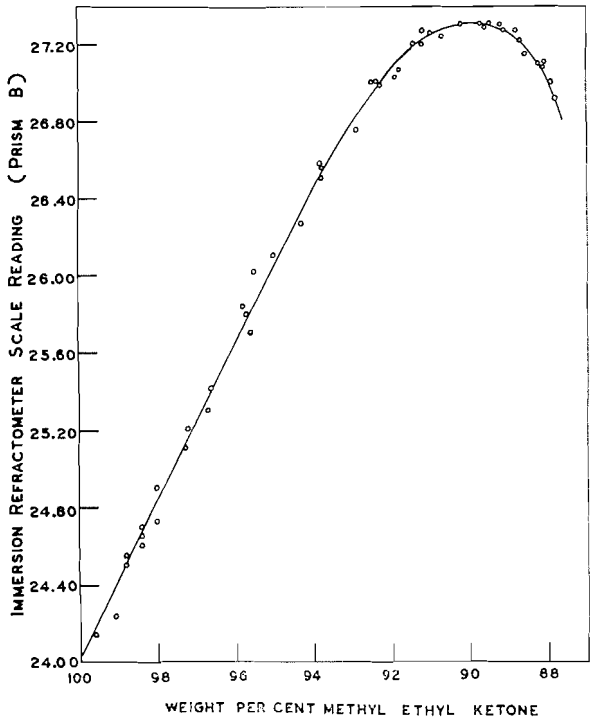

FIG. 3. Working curve of refractive index for ketone-rich solutions.

For most solutions tapped from the Othmer still no further treatment beyond cooling them to 25° C was necessary prior to relative refractive index measurement. In some cases, however, the condensed vapors were heterogeneous and had to be mechanically agitated until equilibrium was attained. In those cases also, known weights of water were added until a homogeneous solution prevailed and then relative refractive indices were taken. A simple back calculation gave the compositional analyses for the original heterogeneous samples.

The data found for the liquid–vapor curves in the system are presented in Table I and Fig. 4. The most interesting point on this aspect of the system is that the minimum azeotrope, which occurs at 73.35±0.05° C at a composition of 88.45±0.15 wt.% methyl ethyl ketone, falls just outside of the intersection of the miscibility gap and the boiling point curve. This intersection, an invariant point of the system, occurs at 73.60±0.05° C where conjugate solutions of compositions 18.10±0.10 and 87.78±0.15 wt.% ketone, respectively, are in equilibrium with a vapor of composition 88.00±0.15 wt.% ketone.

D. Determination of the Solid–Liquid Curves

The method of thermal analysis was used throughout the study of the solid–liquid equilibria. The freezing point cell was capped with a teflon stopper through which the low-temperature thermometer and all glass stirring rod were fitted. The latter was, in

turn, fitted with a semiball joint and spun in contact with the self-lubricating teflon stopper. This allowed for efficient mechanical agitation of the synthetic mixtures in the cell, particularly if they were heterogeneous, and at the same time provided a confined system, thereby preventing any loss of material through vaporization.

The temperature-controlling system employed was relatively crude. The cooling mixes

chosen were an ice slurry (for cooling to 0° C), a trichloroethylene – dry ice mix (for cooling in the range of 0° to −35° C), and liquid air (for cooling to very low temperatures). Manual raising and lowering of the cooling mix was chosen to establish a fairly well-regulated rate of cooling. Each synthetic mixture was thermally analyzed at least twice.

The data found for the solid–liquid curves in the system are presented in Table II

and Fig. 5. The first invariant point for the solid–liquid curves occurs at −6.0±0.5° C, at which a pair of conjugate solutions are in equilibrium with ice. The approximate compositions of the conjugate solutions were determined by extrapolation to be 36% and 80% by weight of methyl ethyl ketone, respectively. As a result of the liquid–liquid studies reported below, these compositions were determined with greater accuracy. The second invariant point for the solid–liquid curves occurs at −89.0±0.5° C, the eutectic point. It was impossible to determine the eutectic composition by any means other than extrapolation since this composition lies so close to that of pure ketone. Such extrapolation would indicate the eutectic composition to be 99.4±0.4% by weight methyl ethyl ketone. This piece of data would seem to account for the low freezing points of methyl ethyl ketone (−86° C to −86.9° C) as reported in standard reference tabulations (15, 16, 17). This work reports a freezing point for pure, *dry* methyl ethyl ketone of −83.5 ± 0.5° C.

E. Determination of the Liquid–Liquid Curves

The "thermostatic method" of Hill (18) was used primarily to determine the liquid–liquid curves. Two separate Hill method analyses were run. The results of those analyses are reported in Table III and Fig. 6. The Hill method allows for the calculation of the mean compositions of the conjugate liquid pair. Such calculations were made and plotted as a function of temperature. This was done in order to ascertain the general vicinity of the upper consolute temperature for the system. According to a variation of the law of Cailletet and Mathias (19) such calculations should lead to a straight line passing through the consolute point. The results of these calculations are also given in Table III and Fig. 6. From them the upper consolute temperature for this system appeared to be near 140° C at a composition of 40–45% by weight methyl ethyl ketone. In order to determine the upper consolute point more closely, several more points on the liquid–liquid curve

[c] First four figures are for experiment in which the two synthetic mixtures were composed of 7.1266 g ketone/8.2682 g water, and 6.9349 g ketone/9.3329 g water. All other figures are for sealed experiments in which the two synthetic mixtures were composed of 7.0760 g ketone/12.6050 g water, and 9.8135 g ketone/9.6782 g water.

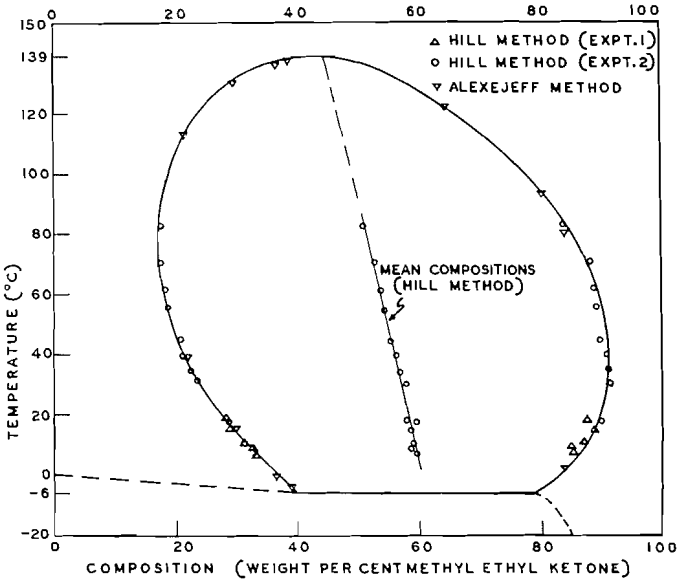

FIG. 6. Liquid–liquid phase equilibria.

were determined using the familiar "synthetic method" (cloud-clear points) of Alexejew (20). These results are given in Table IV and also shown on Fig. 6.

With the additional points obtained from the cloud-clear point analyses, the extrapolated Cailletet–Mathias plot indicates that the upper consolute temperature for this system occurs at 139.0±0.5° C at a composition of 44.9±0.2% by weight of methyl ethyl ketone.

[a]Average of two experiments.
[b]±0.5° C.
[c]Ice formed at −6.0±0.5° C.

It was indicated in the solid–liquid section of this paper (Section D) that the miscibility gap intersects the freezing point curves in the vicinity of 36% and 80% by weight methyl ethyl ketone, respectively. From the liquid–liquid work a very short extrapolation to the freezing point curves indicates that these invariant points have the more accurately determined values of 40.0±0.2% and 78.0±0.2% by weight methyl ethyl ketone, respectively, at the temperature of −6.0±0.5° C.

DISCUSSION

A summary of all the equilibrium phase relationships for the binary system, methyl ethyl ketone – water, as found in this study is given by a total phase diagram shown in Fig. 7.

From the liquid–vapor studies, the results of this work (Table I and Fig. 4) compare quite well with the data reported by the Shell Chemical Corporation (10) and, earlier, by Marshall (2). The minimum azeotrope found in this study, at a temperature of 73.35±0.05° C and a composition of 88.45±0.15% by weight methyl ethyl ketone, is consistent with their reported figures of 73.4° C and 73.6° C, and 88.7% and 88.62% by weight, respectively. Othmer and Benenati (11) report a higher composition, 89.1%, while Boeke and Hanewald (9) report a lower figure, 87.8%.

From the liquid–liquid studies given here (Tables III and IV and Fig. 4) agreement with Marshall's studies (2) from 20° C to approximately 100° C is found. However, the enhanced solubility of methyl ethyl ketone in water and vice versa at temperatures below 20° C found in this work are at variance with Marshall's data for the same temperature region, but are in close agreement with the solubilities found by Ginnings *et al.* (6). It appears probable that the results reported in other previous investigations (1, 3, 4, 5, 7, 8) are in error. The most recent investigation on this aspect of the system is that of Campbell *et al.* (21), which is less extensive than the present work. Their work agrees closely with the combined data of Marshall and Shell Chemical Corporation investigators (22) with which this work is in some slight disagreement at temperatures near the upper consolute point. In particular, the initial study on the mutual solubilities to be reported for this system by Rothmund (1) is further shown to be incorrect by consideration of the upper consolute point. The data of this study, 139.0±0.5° C and 44.9±0.2% by weight methyl ethyl ketone, and that of Campbell *et al.* (21) and the Shell Chemical Corporation (22), 143° C and 45% by weight ketone, would indicate that Rothmund's data of 151.8° C and 44.2% by weight ketone is probably in error.

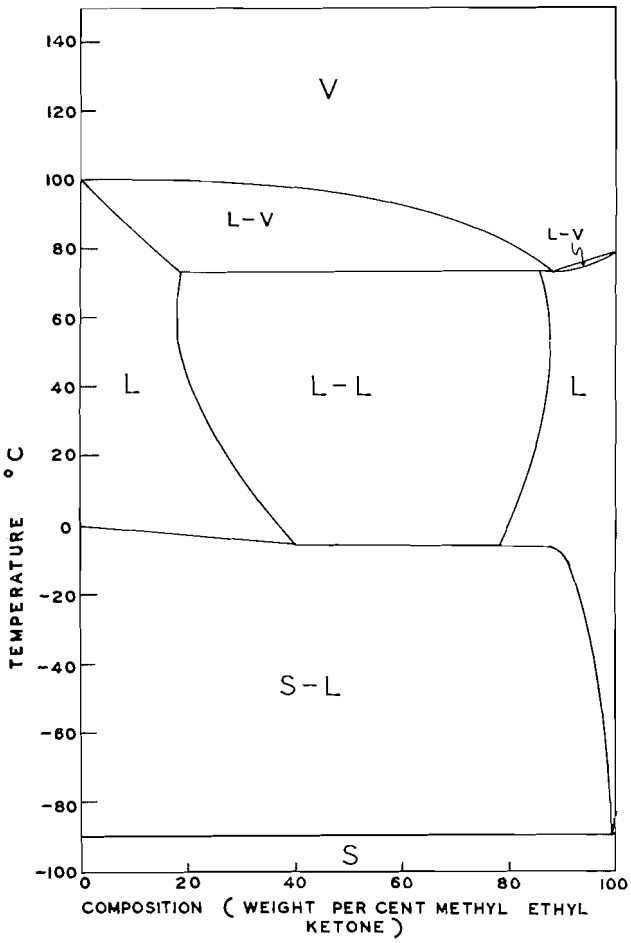

FIG. 7. Summary phase equilibria diagram.

The solid–liquid studies reported here (Table II and Fig. 5) are in good agreement with those of Randall and McKenna (7), who report the eutectic temperature to be $-88.88\pm0.01°$ C at a composition of 99.91% by weight methyl ethyl ketone, while this work reports values of $-89.0\pm0.5°$ C and $99.4\pm0.4\%$ by weight ketone.

ACKNOWLEDGMENTS

We wish to thank Dr. Charles C. Price, Chairman, and members of the Staff of the Department of Chemistry at the University of Pennsylvania for their encouragement and material aid which allowed this work to be completed.

NOTES

VAPOR/LIQUID PARTITION OF TRITIUM IN TRITIATED WATER

O. Sepall and S. G. Mason

INTRODUCTION

In a study of the exchange of tritium between cellulose and tritiated water, it was necessary to extend the published data on the ratio of isotopic concentrations $[H^3]/[H^1]$ in the saturated vapor and liquid phases of tritiated water so as to cover the temperature range 0° to 90° C.

METHOD

Isotopic concentrations in tritiated water were determined by the gas counting method of Robinson (3) in which the hydrogen in the water is converted to methane by reaction with methyl grignard. Vapor samples were obtained by an equilibrium distillation technique.

The distillations were carried out in the arrangement shown in Fig. 1. The tritiated

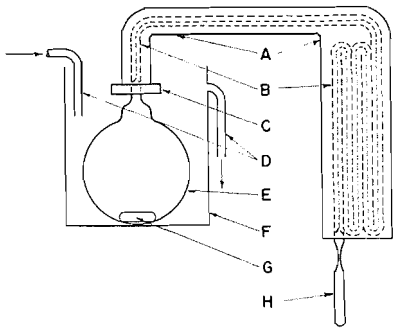

Fig. 1. Equilibrium distillation apparatus.

G. Magnetic stirrer.
H. Sample collecting tube.

water was contained in the flask E, immersed in a constant temperature bath. The vapor was distilled through the capillary tube B into a collecting tube H. The capillary served to restrict the distillation rate and to prevent diffusion back from the collecting tube to the flask. As the temperature was raised, the length of capillary was increased so as to ensure equilibrium distillation. The complete length of tubing was heated electrically by a resistance wire embedded in the asbestos covering to avoid condensation.

For a distillation, 50 ml of tritiated water (0.8 μcurie/g, $[H^3]/[H^1] = 10^{-10}$) were introduced into the flask. This quantity was large enough that concentration changes during distillation were negligible. The system was evacuated through the sampling tube until all air had been removed, and the sample tube was sealed off. The capillary heater was adjusted to give a temperature about 30° C higher than the saturation temperature for the experiment. A sample of 0.3 ml was then distilled over by immersing the collecting tube in liquid air. The length and size of the capillary had been selected so that

distillation time was at least 30 minutes. Longer times gave the same result. The sample was then isolated by sealing off the constriction in the tube.

RESULTS AND DISCUSSION

The measured ratios of isotopic concentrations in vapor and liquid are listed in Table I, and are seen to agree with the values of Brown (2). They are much higher than those of Price (1), which are concluded to be in error.

TABLE I

Isotopic ratios in tritiated water vapor and liquid

Temperature, °C	$\frac{[H^3]/[H^1]_{vapor}}{[H^3]/[H^1]_{liquid}}$	
	Present data	Brown (2)
0 ±0.5	0.86±0.005	
0.5		.88
14	0.90	
19.5		.91
20	0.91	
30	0.92	
50	0.94	
56.5		.945*
70	0.96	
90	0.97	

*From reference 4.

The accuracy of the data is limited by the gas-counting assay for tritium. The results of this analysis show a scatter with a standard deviation of 0.6%. The data reported here are averages of duplicate determinations and have been rounded off to the nearest 0.5%.

The procedure used in this work was found to be quite satisfactory. The results were reproducible for distillation times of 30 minutes or longer. For times as short as 5 minutes, the ratios tended to rise, indicating a non-equilibrium distillation.

This technique could readily be adapted for measurements above 100° C by making provision for the pressure developed.

THE REACTION OF THE *O*- AND *N*-METHYL DERIVATIVES OF AROMATIC KETOXIMES WITH CARBON MONOXIDE AND HYDROGEN

Alex Rosenthal

It has been previously shown that benzophenone oxime cyclizes with carbon monoxide containing about 1% hydrogen to yield 3-phenylphthalimidine in high yield (1). The

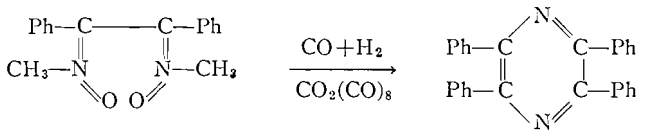
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

present work was initiated in an attempt to devise a method for obtaining *N*-hydroxyphthalimidines using similar high-pressure reactions described before (1). It was hoped that by blocking the labile hydroxyl group on the oxime with an *O*-methyl ether group concurrent or subsequent elimination of the former group would be prevented, without obstruction of the cyclization with carbon monoxide. Thus, reaction of *O*-methylbenzophenone oxime with carbon monoxide might be expected to yield *N*-methoxy-3-phenylphthalimidine (I) as shown below:



I II

Subsequent demethylation of the latter might produce *N*-hydroxy-3-phenylphthalimidine since the lactam ring is stable to acid hydrolysis.

When a benzene solution of *O*-methylbenzophenone oxime was reacted with a mixture of carbon monoxide and hydrogen (99:1) at about 300 atmospheres and at about 220° for 70 minutes in the presence of preformed dicobalt octacarbonyl the main product was 3-phenylphthalimidine (II). Compound II was characterized by direct comparison (mixed melting point and infrared) with an authentic sample (2). No attempt was made to determine whether the cleavage of the ether took place prior or subsequent to the cyclization with carbon monoxide.

As carbon monoxide cyclized readily with nitrogen (in the trivalent state) to the aromatic ring (1), it seemed of interest to determine if the nitrogen in the *N*-methyl ether might undergo a similar attachment to the aromatic ring. When α-benzildioxime *N*,*N*′-dimethyl ether was reacted with carbon monoxide and hydrogen at about 225° for 2 hours the main product was tetraphenylpyrazine (III) as shown below:

III

The structure of compound III was unequivocally established by direct comparison (mixed melting point and infrared) with an authentic sample (3).

Various analyses were carried out in an attempt to ascertain the mechanism of formation of the unexpected tetraphenylpyrazine. Three moles of gases per mole of substrate was consumed in the reaction. Reaction of the gases with dilute hydrochloric acid gave a trace amount of a crystalline salt melting at approximately the correct temperature for ammonium chloride. Treatment of the salt with sodium hydroxide produced a gas which turned red litmus blue. Gas chromatographic analyses of the liquid component of the reaction mixture showed only benzene to be present. The residual organic material remaining after extraction of tetraphenylpyrazine appeared to be polymeric in nature as evidenced by the fact that the residue was insoluble in organic solvents. Since none of these experiments shed any light on the mechanism, further work was abandoned.

EXPERIMENTAL

General Considerations

The equipment was described previously (1).

Reaction of O-Methylbenzophenone Oxime with Carbon Monoxide and Hydrogen

1. Preparation of O-Methylbenzophenone Oxime

Benzophenone (20 g) and *O*-methylhydroxylamine hydrochloride (14 g) were refluxed for 4 hours with 20 ml of pyridine and 200 ml of ethanol. The ethanol was then removed under reduced pressure. Slow addition of water with stirring caused the product to crystallize (87% yield). *O*-Methylbenzophenone oxime was twice recrystallized from acetone–methanol–water according to the method described by Hauser and Hoffenberg (4), m.p. 60–61°; reported m.p. 60–61° (4).

2. Carbonylation of O-Methylbenzophenone Oxime

To a solution of *O*-methylbenzophenone oxime (10.5 g, 0.05 mole) and dicobalt octacarbonyl (0.026 mole) in 50 ml of purified thiophene-free benzene contained in a glass liner in the bomb was added a mixture of carbon monoxide and hydrogen (99:1) at 2300 p.s.i. The bomb was rocked and heated at 220° for 70 minutes. The over-all pressure drop was 125 p.s.i. measured at 0° C (1.3 moles of gas per mole of substrate). After the dicobalt octacarbonyl was decomposed at 70–80°, the benzene was removed under reduced pressure. The solid residue was extracted with two 100-ml portions of ether. The remaining residue was extracted with hot chloroform. After the chloroform was evaporated the residue was recrystallized from ethanol to yield 3-phenylphthalimidine, m.p. 218–220°, mixed melting point with an authentic sample of 3-phenylphthalimidine (2), 218–220°.

After removal of the catalyst and solvent, a portion of the crude product (0.55 g) in 10 ml of benzene was added to the top of a glass column containing a 80×38 mm (diameter) adsorbent column of alumina. Elution of the column with 200 ml of benzene gave a trace of brown oil. An amount of 0.40 g (about 75%) of 3-phenylphthalimidine was eluted using benzene–ethanol (9:1) as developer.

When the reaction product (after removal from the bomb) was fractionated on alumina using benzene as developer, an unstable brown organo–cobalt complex was eluted which on being warmed in petroleum ether became insoluble. Attempts to characterize this material were unsuccessful.

Reaction of α-Benzildioxime N,N′-Dimethyl Ether with Carbon Monoxide and Hydrogen

In a similar way a mixture of 5.9 g of α-benzildioxime *N,N′*-dimethyl ether (5) in 60 ml benzene containing 2 g of dicobalt octacarbonyl as catalyst was reacted with 3800 p.s.i. of carbon monoxide and hydrogen (99:1), at 225–230° for about 2 hours. The over-all pressure drop was 130 p.s.i. measured at room temperature. The gaseous product was bubbled through dilute hydrochloric acid. Evaporation of the solvent left a few milligrams of a crystalline product which melted at 300–340°. Treatment of the salt with dilute sodium hydroxide evolved a gas which was basic to litmus paper.

An aliquot of the reaction mixture was allowed to stand at room temperature until the catalyst was decomposed. Vapor phase chromatography of the distillate showed benzene only to be present.

After the catalyst was decomposed, the crude product (0.75 g) was fractionated by chromatography on alumina (85×38 mm diameter) using benzene ethanol (99.5:0.5) as developer. Evaporation of the eluate from the main zone gave a faint yellow residue (0.28 g, about 55% yield) which after several recrystallizations from acetone yielded pure

For personal use only.

tetraphenylpyrazine (III), m.p. 252–253°. The mixed melting point of the main fraction and an authentic sample of tetraphenylpyrazine (3) was 252–253°. The infrared spectra of both compounds were identical. Anal. Found: C, 87.86; H, 5.29; N, 7.26. Calc. for $C_{28}H_{20}N_2$: C, 87.48; H, 5.24; N, 7.29. Infrared of II (KBr): 3040(m), 1625(w), 1580(w), 1448(s), 1393(s), 1215(m), 1160(m), 1107(s).

A second minor component could not be purified.

STOICHIOMETRY OF THE REACTION OF CHROMYL CHLORIDE WITH CYCLOHEXENE

R. A. STAIRS

In the reactions of chromyl chloride with hydrocarbons, brown precipitates of unknown structure, that have been formulated in most cases as $(HC).2CrO_2Cl_2$, are obtained (1). However, where the hydrocarbon is an olefin, analysis of the precipitate has led to very uncertain results. Cristol and Eilar have suggested (2) that only one molecule of chromyl chloride is essential. A simple experiment has been performed that strongly supports this suggestion, consisting of a calorimetric "titration" of cylohexene with chromyl chloride in carbon tetrachloride solution. The two solutions were mixed in various proportions in a crude calorimeter, the temperature rise was measured, and the quantity of heat liberated in the reaction was calculated and plotted against the logarithm of the molar ratio in each mixture. The result, shown in the figure, indicates a pronounced maximum. This was located at $\log_{10} R = 0 \pm .02$ by linear extrapolation of the two branches, corresponding to $R = 1.00 \pm 0.05$. This may be compared with results from analysis of precipitates, which yield values of r from 1.2 to 2.3 depending on the conditions, and on whether chlorine or chromium content is the basis of calculation (2).

In the figure the solid curves represent the theoretical effect of a heat of reaction of 50 kcal/mole. (The asymmetry arises from the inequality of the concentrations of the two reagent solutions.)

It is apparent that an additional heat effect is present when chromyl chloride is in excess. Comparison with the analyses suggests that further attack by chromyl chloride on the main product occurs, leading to chlorination, as all the results reported (2) are high in chlorine. To avoid this in preparative use of this reaction, it should be carried out at as low a temperature as possible and with the olefin always in excess.

A simple experiment has been performed that strongly supports this suggestion, consisting of a calorimetric "titration" of cylohexene with chromyl chloride in carbon tetrachloride solution. The two solutions were mixed in various proportions in a crude calorimeter, the temperature rise was measured, and the quantity of heat liberated in the reaction was calculated and plotted against the logarithm of the molar ratio in each mixture. The result, shown in the figure, indicates a pronounced maximum. This was located at $\log_{10} R = 0 \pm .02$ by linear extrapolation of the two branches, corresponding to $R = 1.00 \pm 0.05$. This may be compared with results from analysis of precipitates, which yield values of r from 1.2 to 2.3 depending on the conditions, and on whether chlorine or chromium content is the basis of calculation (2).

In the figure the solid curves represent the theoretical effect of a heat of reaction of 50 kcal/mole. (The asymmetry arises from the inequality of the concentrations of the two reagent solutions.)

It is apparent that an additional heat effect is present when chromyl chloride is in excess. Comparison with the analyses suggests that further attack by chromyl chloride on the main product occurs, leading to chlorination, as all the results reported (2) are high in chlorine. To avoid this in preparative use of this reaction, it should be carried out at as low a temperature as possible and with the olefin always in excess.

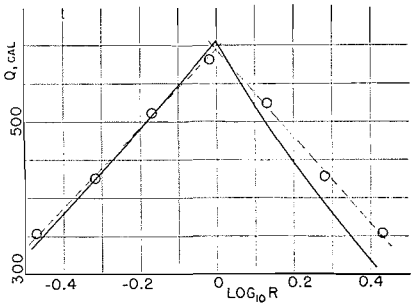

FIG. 1. Heat evolved on mixing vs. the logarithm of the molar ratio $R = (CrO_2Cl_2)/(C_6H_{10})$.

EXPERIMENTAL

Solutions were prepared as follows:

(A) Cyclohexene (Matheson, once distilled, b.p. 82.0–82.8° C, 755 mm) made up by direct weighing, 0.197±0.002 mole/l., and (B) chromyl chloride (prepared from CrO_3 and dry HCl, b.p. 115.5–117° C, 755 mm) standardized iodometrically, 0.134±0.001 mole/l., both in reagent CCl_4 dried over calcium sulphate.

A certain volume of solution B was measured into a Dewar flask (the calorimeter), and a volume of solution A to make the total 150 ml was measured into another Dewar vessel. In view of other inaccuracies in the method, and to avoid stopcock troubles and lessen troubles from evaporation these volumes were measured with graduated cylinders.

The temperature of each was read, A was poured into B, and the mixture was stirred. Temperature readings were taken about every half minute until successive readings agreed to 0.2° C (about 5 minutes). Temperature rises of 5 to 10 degrees were observed. No attempt was made to correct for the effects of stirring or of heat exchange with the room, since these systematic errors would not affect the conclusions respecting stoichiometry.

The approximate heat evolved, Q, was calculated by the formula

$$Q = K[t(V_A+V_B+C)-t_AV_A-t_B(V_B+C)],$$

where t_A and t_B, V_A and V_B are the initial temperatures and volumes of the solutions, C is the CCl_4 equivalent of the calorimeter (estimated to be 30±15 ml, from the water equivalent found by students in teaching laboratory), and K is the volume specific heat of carbon tetrachloride, about 0.32 cal ml^{-1} deg^{-1}.

3,5-DI-*O*-METHYL-D-GALACTOSE, A NEW METHYLATED SUGAR FROM A FULLY METHYLATED POLYSACCHARIDE OF GIBBERELLA FUJIKUROI (FUSARIUM MONILIFORME)*

I. R. SIDDIQUI AND G. A. ADAMS

During methylation studies of the extracellular acidic polysaccharide of *Gibberella fujikuroi* A.T.T.C. 10052 (*Fusarium moniliforme*), a di-*O*-methyl fraction was obtained

**Issued as N.R.C. No. 5911.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which gave, *inter alia*, a di-*O*-methyl sugar which has been identified as 3,5-di-*O*-methyl-D-galactose. This is a new sugar derivative and proof of its identification is provided by the following evidence.

The aforementioned di-*O*-methyl sugar showed $[\alpha]_D^{26}$ $-24.8°\pm0.5°$ in water and a methoxyl content of 28.7%; a di-*O*-methyl hexose requires OMe, 29.8%. On demethylation (1) it gave only galactose as the parent sugar. The di-*O*-methyl galactose moved as a single spot on paper electrophoresis (2) in borate buffer and on paper chromatograms in three different solvent systems.

In addition to indicating homogeneity the results of these experiments also suggested that the di-*O*-methyl galactose was in the furanose rather than in the pyranose ring form. None of the reported di-*O*-methyl-D-galactopyranoses show negative rotation (3). The di-*O*-methyl galactose gave a higher M_g value (0.66) on paper electrophoresis in borate (2) than is to be expected for a di-*O*-methyl hexopyranose (4). The R_g value (0.65) on paper chromatography in *n*-butanol:ether:water (5:1:4) was much higher than reported for the known di-*O*-methyl galactopyranoses (5).

Confirmation of the furanose structure was obtained by methylation and oxidation studies. Complete methylation by Purdie's method of the glycoside of the di-*O*-methyl galactose yielded the glycoside of 2,3,5,6-tetra-*O*-methyl-D-galactose as shown by gas–liquid partition chromatography (6, 7). Oxidation of the di-*O*-methyl galactose with bromine water afforded a crystalline lactone which showed the slow hydrolysis in water typical of γ-lactones (8). An additional piece of evidence in support of the γ-lactone structure was provided by the infrared spectrum of the compound. It showed a strong C=O stretching peak at 1786 cm^{-1}. For comparison the infrared spectra of 2,5-di-*O*-methyl-L-arabonolactone and gluconic acid δ-lactone were also examined. The former compound showed the C=O stretching peak at 1772 cm^{-1} while in the latter it occurred at 1720 cm^{-1}. These values are in agreement with those given by Bellamy (9) for γ- and δ-lactones respectively. Barker *et al.* have also pointed out that in the five-membered lactone rings the increase of strain results in an increase of the C=O stretching frequency from 1733 cm^{-1} in δ-hexanolactone to 1770 cm^{-1} in γ-butyrolactone (10). The γ-lactone was converted by methanolic ammonia into a crystalline amide which gave a positive Weerman test (11), thereby proving the presence of a free hydroxyl group at position 2.

Finally, reduction of the di-*O*-methyl-D-galactose by potassium borohydride (12) yielded a crystalline di-*O*-methyl hexitol having the same melting point and equal but opposite specific rotation as 2,4-di-*O*-methyl-D-galactitol (13). The infrared spectrum of this hexitol and authentic 2,4-di-*O*-methyl-D-galactitol were superimposable. These findings proved that the derived galactitol was 2,4-di-*O*-methyl-L-galactitol, which is the same as 3,5-di-*O*-methyl-D-galactitol. Hence the parent sugar was 3,5-di-*O*-methyl-D-galactose.

EXPERIMENTAL

The organic phases of the following solvents (v/v) were used for paper chromatographic separations: (A) *n*-butanol:ethanol:water (5:1:4); (B) benzene:ethanol:water:ammonia (200:47:14:1); (C) 2-butanone saturated with water containing 2% ammonia; (D) pyridine : ethyl acetate : water (1:2.5:2.5). Sugars were detected on chromatograms by spraying with *p*-anisidine hydrochloride spray reagent. Infrared spectra were measured using the Nujol mull technique and a microcell. Measurements were made in the frequency range 3800–600 cm^{-1}.

The di-*O*-methyl sugar under consideration was found as a product of hydrolysis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the methylated polysaccharide from *Gibberella fujikuroi*. It was separated from other di-*O*-methyl hexoses by preparative paper chromatography using solvent C.

*3,5-Di-O-methyl-*D*-galactose*

The syrupy di-*O*-methyl sugar showed $[\alpha]_D^{26}$ $-24.8°\pm0.5°$ (*c*, 1.935 in water) and a methoxyl content of 28.7%; a di-*O*-methyl hexose requires OMe, 29.8%. Paper chromatographic analysis of this sugar in solvents A, B, and C gave R_g values of 0.64, 0.23, and 0.41 respectively. Paper electrophoretic (2) examination of this sugar in borate buffer, pH 10, showed a single component (M_g, 0.66). A small quantity of the syrup (1–2 mg) was dissolved in dichloromethane (0.2 ml) and was demethylated (1) with boron trichloride (0.5 ml) at −70° C. Paper chromatographic analysis of the demethylated sugar in solvent D showed that only galactose was the parent sugar. The di-*O*-methyl sugar (ca. 1 mg) was heated in a sealed tube with 4% methanolic hydrogen chloride for 24 hours, neutralized with silver carbonate, filtered, evaporated, and methylated by Purdie's reagents (silver oxide ca. 20 mg + methyl iodide 2 ml). Examination of the fully methylated sugar by gas–liquid partition chromatography, using a 4-ft column of 20% Apiezon M on Celite 545 at 150° C and an argon flow rate of 150 ml/minute, showed that the relative retention time of the sample with respect to quinoline was 1.54. The authentic methyl glycoside of 2,3,5,6-tetra-*O*-methyl-D-galactose gave a retention time of 1.52 under the same conditions.

*3,5-Di-O-methyl-*D*-galactitol*

Di-*O*-methyl-D-galactose (35 mg) in water (2 ml) was mixed with a solution of potassium borohydride (12) (75 mg in 1 ml) and the solution was left overnight. Excess borohydride was destroyed with glacial acetic acid (few drops) and the solution was deionized with Amberlite resins IR-120 and IR-4B. The resulting hexitol crystallized when kept as a syrup overnight. It was recrystallized from ethyl acetate containing a little methanol. The crystals showed a melting point of 134–135° C, $[\alpha]_D^{26}$ $-23.7°\pm1°$ (*c*, 1.01 in methanol). Anal. Calc. for $C_8H_{18}O_6$: C, 45.71%; H, 8.63%. Found: C, 45.92%; H, 8.32%. Reported values for 2,4-di-*O*-methyl-D-galactitol are m.p. 134–135° C, $[\alpha]_D^{28}$ $+23.5°\pm0.5°$ (*c*, 2.04 in methanol) (13). The unknown hexitol and 2,4-di-*O*-methyl-D-galactitol showed superimposable infrared spectra.

*3,5-Di-O-methyl-*D*-galactonic Acid Lactone*

3,5-Di-*O*-methyl-D-galactose (180 mg) in water (4 ml) was oxidized with bromine (15 drops), in the presence of barium carbonate (100 mg), for 60 hours. Bromine was removed by aeration and the solution was extracted with chloroform for 3 days. The chloroform extract was dried with anhydrous sodium sulphate and concentrated to a syrup which was lactonized by distillation (bath temperature 130–160° C/0.02 mm). Crystallization of the syrup from ether : petroleum ether containing a few drops of methanol gave 3,5-di-*O*-methyl-D-galactonic acid-γ-lactone; m.p. 89.5–91° C; $[\alpha]_D^{26}$ $-72.9°\pm2° \rightarrow -49.2°\pm2°$, 18 days (incomplete) (*c*, 1.015 in water); ν_{max} 1786 cm^{-1}. Anal. Calc. for $C_8H_{14}O_6$: C, 46.60%; H, 6.84%. Found: C, 46.84%; H, 6.93%.

*3,5-Di-O-methyl-*D*-galactonamide*

3,5-Di-*O*-methyl-D-galactonic acid lactone (15 mg) was kept in methanol saturated with ammonia at 5° C for 24 hours. Removal of the solvent gave a syrup which crystallized when scratched. Recrystallization from ethanol:ether gave the amide, m.p. 131–133° C; $[\alpha]_D^{27}$ $+9.2°\pm2°$ (c, 0.87 in methanol). Anal. Calc. for $C_8H_{17}O_6N$: N, 6.27%. Found: N, 6.26%.

For personal use only.

A portion of the amide (ca. 4 mg) was oxidized with sodium hypochlorite and on addition of semicarbazide hydrochloride (14) gave a white precipitate of hydrazodicarbonamide.

NUCLEOPHILIC DISPLACEMENT OF METHYL SULPHONIC ESTERS BY HYDROXIDE ION IN WATER[1]

S. HARTMAN[2] AND R. E. ROBERTSON

ABSTRACT

Rate data for the reaction between OH^- and methyl benzenesulphonate, methyl methanesulphonate, and dimethyl sulphate in water are determined for a series of temperatures. The corresponding k_{OH^-}/k_{H_2O} ratio are found to be 3 to 6 times smaller than those values characterizing the reaction for the methyl halides, and the ratios in all cases are temperature dependent. While the stability of the initial state solvation shell undoubtedly contributes to the difference between the halides and sulphonates in these reactions, it is probable that differences in nucleophilic interaction between the oxygen of the water molecule and the partially empty p orbital of the methyl carbon is a more important factor in determining the characteristic difference.

In a recent paper (1) Fells and Moelwyn-Hughes suggested that the rough constancy of the k_{OH^-}/k_{H_2O} ratio of ~216 for the three methyl halides be taken as evidence for the similarity of the two reactions

$$R{-}X + H_2O = ROH + H^+ + X^-, \quad [1]$$

$$R{-}X + OH^- = ROH + X^-. \quad [2]$$

Extending this argument, the fact that the corresponding value for the above ratio for methyl benzenesulphonate was calculated to be 75 (2) would suggest some marked difference in mechanism between the methyl benzenesulphonate and the methyl halides in one or both of the above reactions. The aim of this work was to determine the rate of base-catalyzed hydrolysis for the methyl benzenesulphonate, methyl methanesulphonate, and dimethyl sulphate and to examine any differences in the k_{OH^-}/k_{H_2O} ratio between these values and the corresponding values reported by Moelwyn-Hughes for the methyl halides in terms of current mechanistic ideas.

EXPERIMENTAL METHOD

The experimental method adopted for the determination of the rate of bimolecular displacement of sulphonate ions from methyl esters by hydroxide was the classical one involving the use of ampoules containing a measured aliquot of the reaction mixture. Since the methyl sulphonic esters are relatively involatile at the temperatures studied, the presence of a small vapor space above the solution would not introduce the errors noted by Moelwyn-Hughes (3). There can be no doubt that there is a great need for the development of a method for obtaining bimolecular rate data such as sought here by some means which does not involve a sampling technique. However, the tube method

[1]*Manuscript received May 27, 1960.*

Issued as N.R.C. No. 5954.
[2]*Summer student, 1959. Present address: Queen's University, Kingston, Ontario.*

was used in this instance in spite of its shortcomings because the rate data so obtained would be accurate enough as a basis for our conclusions. The methyl benzenesulphonate, methyl methanesulphonate, and dimethyl sulphate were from the same samples as had been purified for detailed study of the temperature dependence of the rate of hydrolysis of these compounds (4, 5, 6) and were used without further purification. The reaction mixture was made up to 0.02 N in NaOH and 0.01 M with respect to ester. Aliquots of 5 cc$\pm$0.007 were added to ampoules with a semiautomatic tube filler, the filling temperature being held at approximately 0° C in the case of the dimethyl sulphate. Rates were determined by immersing the required number of tubes simultaneously in the bath, with shaking, and, after allowing sufficient time for temperature equilibrium, initial tubes were chilled and analyzed for residual base. A series of such analysis over a suitable range of time, combined with corresponding solvolytic rates, provided the necessary data for calculation of the bimolecular rate of reaction, according to the following equation (7):

$$k_2 = \frac{1}{(a-b)t} \ln \frac{b(a-x)}{a(b-x)} - \frac{k_1}{a-x}.$$

Typical data for the hydrolysis of methyl benzenesulphonate at 30.0° C are given in Table I.

RESULTS AND DISCUSSION

A summary of the rate data for the three compounds methyl methanesulphonate, methyl benzenesulphonate, and dimethyl sulphate is given in Table II for several temperatures. By combining these values with those for the hydrolytic process in the absence of base the corresponding k_{OH^-}/k_{H_2O} ratios may be calculated. In Table III these are compared with the corresponding values for the methyl halides from the work of Moelwyn-Hughes (7). The difference in the value of this ratio between the methyl halides and that for methyl benzenesulphonate from the early work of Praetorius (8) is seen to be confirmed and, if we may generalize from three examples, represents a general difference between the relative reactivity of the halides and sulphonates in respect to one or both reactions [1] and [2].

that of methyl chloride for the two types of reaction. For nucleophilic displacement by OH^-, individual differences as a consequence of differences in the C—X bond being broken are surprisingly small (column 1, Table III). The differences in relative reactivity for hydrolysis show a slightly greater range of values for hydrolysis through the three halides (column 2, Table III) but a 10-fold increase in reactivity between the halides and the sulphonates. Hence, assuming that the difference is quantitative rather than qualitative, the reduced value of the k_{OH^-}/k_{H_2O} ratio noted in Table IV is the consequence of the relatively greater increase in the reactivity of the sulphonic esters for hydrolysis, in the absence of strong base.

Since a value of the k_{OH^-}/k_{H_2O} ratio > 1 indicates (9) some degree of nucleophilic interaction in the activation process for hydrolysis, the reduced values of this term for the sulphonates (Table IV) would suggest that bond making is less advanced in the transition state for these compounds than for the halides. The inverse secondary deuterium isotope effect ($k_H/k_D < 1$) recently reported by Llewellyn, Robertson, and Scott (6) for the hydrolysis of the above compounds leads to the same conclusion. Thus, the sharing of the p orbital between the entering and leaving groups leads to crowding of the transition state which will vary with the degree of overlap required of the former in the transition state and so leads to a proportional increase in the C—H bending frequencies and corresponding changes in the zero-point energy terms. Gratifying confirmation of this interpretation is seen in the linear correlation between the k_H/k_D and k_{OH^-}/k_{H_2O} ratios for a series of methyl esters (Fig. 1).

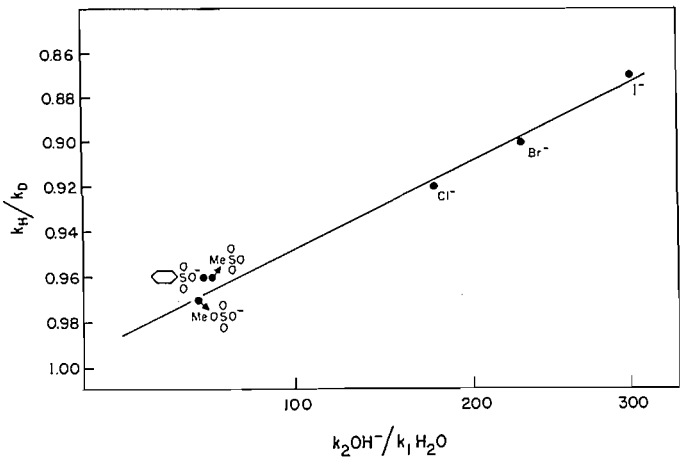

FIG. 1. A correlation of α-deuterium isotope effect with the k_{OH^-}/k_{H_2O} ratio.

The temperature dependence of the k_{OH^-}/k_{H_2O} ratio follows directly from the fact that reaction [1] is characterized by a large negative heat capacity of activation (6) while it would appear that this factor is small for reaction [2] (13).

Differences in the stability of the initial state solvation shell about the two types of esters will also contribute to the difference in reactivity but it is difficult to evaluate the relative importance of this factor. Thus the medium isotope effect which appears to depend on the relative stability of the initial state solvation shell in light and heavy water is, for the sulphonates, but one-half the average value for the halides (10, 11) and shows a much lower temperature dependence as would be expected (12). Evidence for

modification of the initial state solvation shell by the nature of the sulphonate grouping may be also obtained by considering the relative heat capacity changes ($\Delta C_p^{\ddagger}$) which characterize the hydrolysis of corresponding sulphonic and halide esters (4). The latter terms, which appear to be determined to an important degree by the temperature dependence of the stability of the initial state solvation shell, have less negative values for the sulphonic esters than for the halides, a result quite consistent with the indications of the medium isotope effect and supported by the value of $\delta_X \Delta H^{\ddagger}$ (below). Against such arguments favoring the importance of initial state solvation differences in determining differences in reactivity must be considered the position of methyl phosphate in such reactions. Thus judging from the medium isotope effect (k_{D_2O}/k_{H_2O}) the methyl phosphate would appear to have reduced the stability of the initial state solvation shell in a manner analogous to the sulphonates (11) (k_{D_2O}/k_{H_2O} for methyl methanesulphonate and methyl phosphate being identical, 0.94). The relative reactivity of the methyl phosphate, however, is but one-third that of methyl chloride in hydrolysis, while methyl methanesulphonate reacts 100 times faster (Table III).

While no particular significance can be attached to small differences in the values of the enthalpy and entropy corresponding to the reaction of the sulphonates and the halides with hydroxide (Table V), there is, approximately, a regular decrease in enthalpy

TABLE V

Thermodynamic parameters for the reaction of a series of methyl esters with OH^- and H_2O in water

with increasing reactivity in contrast to the 4–5 kcal difference ($\delta_X \Delta H^{\ddagger}$) between the values for the halides and the sulphonates in the hydrolysis reactions. With the exception of the iodide, the entropy change associated with the displacement by OH^- is 3–5 e.u. more positive than for the corresponding hydrolysis, as is required by the difference in the charge distribution in the initial and transition states.

ACKNOWLEDGMENT

The authors wish to acknowledge the technical assistance received from Mr. S. Sugamori during the initial stages of this investigation.

THE CHEMISTRY OF ETHYLENE OXIDE

VI. THE ACID-CATALYZED REACTION OF ETHYLENE OXIDE WITH ETHANOL–WATER MIXTURES[1]

R. K. Brown and A. M. Eastham

ABSTRACT

The rate of reaction of ethylene oxide with alcohol–water mixtures at 25° C has been determined. The ratio of glycol to ethoxyethanol in the product was determined for each mixture and found to be approximately equal to the molecular ratio of water to ethanol in the solvent.

Ethylene oxide reacts with water to form ethylene glycol and with ethanol to form 2-ethoxyethanol. The uncatalyzed and alkali-catalyzed reactions are very slow at ordinary temperatures but the acid-catalyzed reactions are rapid and suitable for kinetic measurements because they can be followed easily by the dilatometric method. Rate data are well established for the water reaction (1, 2, 3) but not for ethanol so this paper records the results of some measurements in ethanol and ethanol–water mixtures.

EXPERIMENTAL

Anhydrous ethanol was prepared from the commercial anhydrous material by distillation from sodium and ethyl phthalate (4). No aldehydes could be detected with Tollen's reagent.

Commercial ethylene oxide having a purity of over 99% was used as received.

Stock solutions of perchloric acid in alcohol were prepared from the 70% acid (perchloric acid dihydrate) and anhydrous ethanol and were found to be stable for several weeks. All titrations were made with a pH meter as most acid–base indicators give unsatisfactory end points.

Sodium perchlorate was dried by heating at 110° C for 24 hours, then over phosphorus pentoxide. It is sparingly soluble in dry ethanol so was used only with solutions containing at least 1% water.

Lithium perchlorate was dried under vacuum for 8 hours at 100° C, then was held for 10 hours at 160° C in a stream of thoroughly dry air. The product was immediately dissolved in dry ethanol and used as a solution.

For all reactions in aqueous ethanol the amount of glycol in the product was determined by the periodic acid – arsenite method (5). The remainder of the ethylene oxide was assumed to form ethoxyethanol.

For the rate measurements, acid and salt were dissolved in the appropriate alcohol–water mixture in a dry container attached to the dilatometer. A small glass vial containing a weighed quantity of ethylene oxide was introduced and the solution was then degassed by slight suction. The solution was brought to constant temperature (25.0° C) in a water bath, the vial of oxide was broken by means of a plunger, and the solution was then forced into the dilatometer by air pressure. The concentration of oxide in all experiments was between 0.01 and 0.06 M and its rate of disappearance showed excellent first-order dependence under all conditions. Rates were evaluated by the Guggenheim method (6).

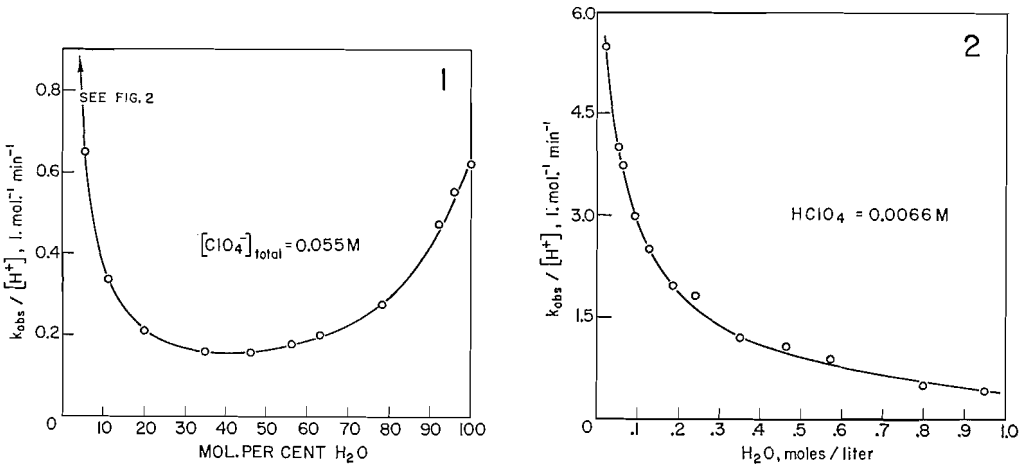
RESULTS

As the acid-catalyzed hydration of ethylene oxide shows a marked salt effect, it was desirable to evaluate this effect in ethanol so a series of runs were made with varying concentrations of lithium perchlorate and a constant acid concentration of 0.0034 *M*. The results were quite erratic possibly due to traces of water (see below), but indicated a strong positive salt effect. All points within the concentration range 0.005 *M* to 0.12 *M* of perchlorate ion were accounted for within ±3% by a rate constant having the value

$$k_{H^+} = 5.9+16.\,c \text{ liter mole}^{-1} \text{ min}^{-1},$$

where c is the total concentration of perchlorate ion. However, the data suggest that the salt effect may be even greater at lower salt concentration (compare the results for reaction of acetaldehyde in ethanol – hydrogen chloride solutions (7)).

The corresponding expression for the salt effect upon the hydration of ethylene oxide at 25° C was found to be (2)



$$k_{H^+} = 0.55+0.48\,c,$$

so the rate of reaction with ethanol is much faster than with water and shows a salt effect which is in the same direction but proportionately about three times as large as that in water. The subsequent runs in water–ethanol mixtures were conducted at a constant concentration of perchlorate ion (0.055 *M*) but the magnitude of the salt effect was not determined for each composition. It cannot be assumed that salt effects do not make at least a minor contribution to the shape of the curve in Fig. 1; presumably they make a larger contribution to the rate at the higher alcohol concentrations.

TABLE I
Composition of the product in alcohol–water mixtures

Molarity H_2O	Mole% H_2O	Mole% glycol in product
1	5.7	~8
2	11	13
4	20	26
8	35	37
12	46	47
16	56	51
20	63	60.5
30	78	70
43	92	86
49	96	92
52	98	95
—	100	101

The rates of reaction of ethylene oxide with water–ethanol mixtures containing up to 95 mole % of ethanol are shown in Fig. 1. Each point represents the average of several runs at acid concentrations varying from about 0.01 to 0.06 *M*. The rates decrease to a minimum at about 40 mole % (ca. 15 wt.%) of water from either pure water or pure ethanol. Throughout this range the ratio of glycol to ethoxyethanol is approximately equal to the molecular ratio of water to alcohol in the solvent (Table I), which might indicate a reaction independent of the concentration of nucleophilic reagent. In other studies of competition between reactants for ethylene oxide in acid solution, however, it was found that the rate was markedly dependent upon nucleophilicity (2), so one must conclude that water and ethanol are about equally reactive under the present conditions.

FIGS. 1 AND 2.

It follows that the shape of the curve in Fig. 1 must be determined primarily by medium effects and by variations in the acid–base equilibria due to changes in the ratio of the ions H_3O^+ and $C_2H_5OH_2^+$.

At water concentrations below about one molar, the rate increases very sharply with further reduction in the water concentration (Fig. 2). The extent of the increase cannot be estimated from the present data because solutions made up from 70% perchloric acid always contain small amounts of water, but it is at least 10-fold on reducing the water concentration from 1 *M* to about 0.015 *M*. Similar observations have been made by Deyrup (7) in studies of the acid-catalyzed reaction of acetaldehyde in ethanol solution and by Goldschmidt and his co-workers (8) in studies of acid-catalyzed esterifications in ethanol. The usual explanation is due to Goldschmidt and accounts for the decreasing rate with increasing water as due to the replacement of the ion $C_2H_5OH_2^+$ by the less acidic and therefore less catalytic ion, H_3O^+. So far as we are aware, however, this phenomenon has been observed only in ethanol; in the reaction of acetaldehyde with methanol the effect of small amounts of water ought to be very large if the above explanation is correct, because the rate in pure methanol is greater than that in water by a factor of 10^3 (9).

THE PREPARATION OF SUBSTITUTED THIONOCARBAMATES[1]

A. F. McKay, D. L. Garmaise, G. Y. Paris, S. Gelblum, and R. J. Ranz

ABSTRACT

The preparations and properties of a number of substituted thionocarbamates are described.

The thionocarbamate derivatives in Tables I–IV were prepared by one of the following three methods:

$$ROH + CSCl_2 \xrightarrow{-HCl} ROC(S)Cl + R'NH_2 \xrightarrow{-HCl} R'NHC(S)OR, \quad [1]$$

$$ROH + R'NCS \xrightarrow{(C_2H_5)_3N} R'NHC(S)OR, \quad [2]$$

$$ROH + R'NCS \xrightarrow{NaH} R'NHC(S)OR. \quad [3]$$

Route 1 was used to prepare both the aryl arylthionocarbamates and the aryl aralkylthionocarbamates. Procedure 2 gave good results with aralkyl isothiocyanates but triethylamine did not catalyze the addition of aryl isothiocyanates to phenols under the conditions employed in this study. All of the benzyl N-substituted thionocarbamates were prepared by procedure 3.

Harris and Fischback (1) reported the preparation of thionocarbamates by the reaction of amines with methyl xanthates. An attempt to prepare phenyl 3,4-dichlorobenzylthionocarbamate from S-methyl phenylxanthate by this procedure gave methyl 3,4-dichlorobenzyldithiocarbamate. Thus the phenoxy group was replaced more readily by 3,4-dichlorobenzylamine than the methylmercapto group. However, if 3,4-dichlorobenzylamine is added to S-methyl ethylxanthate the methylmercapto group is replaced and ethyl 3,4-dichlorobenzylthionocarbamate is formed. These reactions are represented by equations 4 and 5.

$$RNH_2 + \langle\bigcirc\rangle\!-\!OC(S)SCH_3 \longrightarrow RNHC(S)SCH_3 + \langle\bigcirc\rangle\!-\!OH \quad [4]$$

$$RNH_2 + C_2H_5OC(S)SCH_3 \longrightarrow RNHC(S)OC_2H_5 + CH_3SH \quad [5]$$

$R = 3,4\text{-}Cl_2C_6H_3CH_2-$

The thiolcarbamates in Table V were prepared by treating the corresponding phenyl chlorothiolformates with the appropriate amines. The phenyl chlorothiolformates were obtained by treating the lead salts of the thiophenols with phosgene by the method of Rivier (2).

An attempt to prepare phenyl 3,4-dichlorobenzylthionocarbamate by heating a methanolic solution of methyl 3,4-dichlorobenzyldithiocarbamate in the presence of Amberlite IRA-400 resin saturated with phenol gave methyl 3,4-dichlorobenzylthionocarbamate in 48% yield.

The aryl chlorothionoformates, which were isolated during these studies, are described in Table VI.

EXPERIMENTAL[2]

Di-3,4-dichlorobenzylamine

A mixture of 3,4-dichlorobenzyl chloride (9.75 g, 0.05 mole) and 3,4-dichlorobenzylamine (35.2 g, 0.20 mole) was heated on the steam bath for 2 hours. Ether (200 ml) and 10% sodium hydroxide solution (50 ml) were added, and the ether layer was washed with water and dried over anhydrous sodium sulphate. Fractionation of the ether extract yielded 15 g (85.2%) of unchanged 3,4-dichlorobenzylamine (b.p. 93–100°/1 mm) and di-3,4-dichlorobenzylamine (b.p. 175–180°/1 mm, n_D^{25} 1.60665, D_4^{27} 1.3690), yield 10 g (59.7%). Anal. Calc. for $C_{14}H_{11}Cl_4N$: C, 50.20; H, 3.31; Cl, 42.34; N, 4.18. Found: C, 50.68; H, 3.44; Cl, 42.00; N, 4.13.

A solution of the amine (0.61 g, 0.0018 mole) in absolute ethanol (30 ml) was acidified with hydrogen chloride. Di-3,4-dichlorobenzylamine hydrochloride (m.p. 228–229°) was recovered by filtration, yield 0.21 g (33%). Anal. Calc. for $C_{14}H_{12}Cl_5N$: C, 45.26; H, 3.26; Cl, 47.72; N, 3.77. Found: C, 45.17; H, 3.09; Cl, 47.80; N, 3.98. N-4-Chlorobenzylaniline (3) (b.p. 155°/0.5 mm) and di-4-chlorobenzylamine (m.p. 30–32°) were prepared in the same way in 62.8% and 60% yield respectively. A melting point of 31° has been reported (4) for di-4-chlorobenzylamine.

2-(3,4-Dichlorophenyl)-acetonitrile

A solution of 3,4-dichlorobenzyl chloride (48.87 g, 0.25 mole) in ethanol (50 ml) was added during 30 minutes to a stirred solution of potassium cyanide (19.50 g, 0.30 mole) in water (15 ml) at 60°. The mixture was refluxed for 4 hours, and then cooled and filtered. The filtrate was concentrated *in vacuo* and the residue was extracted with ether (100 ml). The ether solution was dried and evaporated, and the residue was distilled to give the product (b.p. 106–108°/0.1 mm; m.p. 35.5–38.5°), yield 37.6 g (81%). Recrystallization from ether – petroleum ether raised the melting point to 39.5–40.5°. Anal. Calc. for $C_8H_5Cl_2N$: C, 51.65; H, 2.71; Cl, 38.12; N, 7.53. Found: C, 51.81; H, 2.92; Cl, 38.14; N, 7.56.

2-(3,4-Dichlorophenyl)-ethylamine

Aluminum chloride (6.66 g, 0.05 mole) in ether (150 ml) was added to a suspension of lithium aluminum hydride (1.99 g, 0.05 mole) in ether (100 ml) maintained in a nitrogen atmosphere. A solution of 2-(3,4-dichlorophenyl)-acetonitrile (9.3 g, 0.05 mole) in ether (200 ml) was added dropwise to the stirred mixture, and the stirring was continued for 30 minutes. Water was added cautiously to destroy the excess lithium aluminum hydride and after further addition of water (total 140 ml) and 6 *N* sulphuric acid (140 ml), the aqueous layer was separated and washed with ether (100 ml). The aqueous layer was basified with 40% sodium hydroxide solution at 0°, and the free base was extracted with ether (3×150 ml). Fractionation of the dried ether extract yielded the product (b.p. 100–102°/0.12 mm), yield 6.75 g (71%). Anal. Calc. for $C_8H_9Cl_2N$: C, 50.56; H, 4.78; Cl, 37.32; N, 7.37. Found: C, 50.25; H, 4.92; Cl, 37.16; N, 7.22.

The amine in aqueous ethanol was converted into its picrate (m.p. 199–200°, decomp.) in the usual manner, yield 67.5%. Anal. Calc. for $C_{14}H_{12}Cl_2N_4O_7$: C, 40.12; H, 2.89; Cl, 16.92; N, 13.37. Found: C, 40.15; H, 3.14; Cl, 17.06; N, 13.50.

3-(3,4-Dichlorophenyl)-propionic Acid

3,4-Dichlorobenzaldehyde was converted to 3,4-dichlorocinnamic acid (m.p. 214–217° C) in 69.2% yield by the method of Walling and Wolfstirn (5).

[2]*All melting points are uncorrected. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois.*

3,4-Dichlorocinnamic acid (58.5 g, 0.27 mole) in glacial acetic acid (1500 ml) was hydrogenated at atmospheric pressure in the presence of 5% palladium on charcoal (5.8 g). The absorption of hydrogen ceased after 10.5 hours (6 liters). The solution was filtered and evaporated, and the residue was crystallized from water to give the product (m.p. 90–93°), yield 53.0 g (90%). Recrystallization from ethanol raised the melting point to 96–97°. Anal. Calc. for $C_9H_8Cl_2O_2$: C, 49.34; H, 3.68; Cl, 32.37. Found: C, 49.07; H, 3.68; Cl, 32.41.

3-(3,4-Dichlorophenyl)-propionamide

A solution of 3-(3,4-dichlorophenyl)-propionic acid (53.0 g, 0.24 mole) and thionyl chloride (119 g, 1.0 mole) in benzene (100 ml) was allowed to stand overnight, and was then evaporated to dryness. The oily residue was added in portions to 28% aqueous ammonia (270 ml) with stirring at 20–25° and the mixture was stirred for 4 hours. The product (m.p. 76–80°) was recovered by filtration, yield 45.5 g (86.3%). Recrystallization from benzene – petroleum ether raised the melting point to 80–81°. Anal. Calc. for $C_9H_9Cl_2NO$: C, 49.56; H, 4.16; Cl, 32.51; N, 6.42. Found: C, 49.78; H, 4.22; Cl, 32.67; N, 6.42.

3-(3,4-Dichlorophenyl)-propionitrile

A solution of the amide (37.9 g, 0.174 mole) and thionyl chloride (119 g, 1.0 mole) in benzene (200 ml) was refluxed for 5 hours, and the solution was then evaporated. Distillation of the residue yielded crude 3-(3,4-dichlorophenyl)-propionitrile (b.p. 140–158°/1 mm), yield 30.8 g (88%). Redistillation gave the pure product (b.p. 121°/0.4 mm, n_D^{25} 1.55403; d_{20} 1.2742). Anal. Calc. for $C_9H_7Cl_2N$: C, 54.02; H, 3.53; Cl, 35.44; N, 7.01. Found: C, 54.24; H, 3.66; Cl, 35.38; N, 7.03.

3-(3,4-Dichlorophenyl)-propylamine

3-(3,4-Dichlorophenyl)-propionitrile (18.0 g, 0.09 mole) was reduced by lithium aluminum hydride – aluminum chloride in ether exactly as described above for 2-(3,4-dichlorophenyl)-acetonitrile. The product (b.p. 120–125°/1 mm) was obtained in 17.3 g (95%) yield. A redistilled sample (b.p. 104°/0.4 mm, n_D^{27} 1.55487, d_{20} 1.2082) was submitted for analysis. Anal. Calc. for $C_9H_{11}Cl_2N$: C, 52.96; H, 5.43; Cl, 34.75; N, 6.87. Found: C, 53.08; H, 5.45; Cl, 34.73; N, 7.09.

The picrate of the amine, which was prepared in quantitative yield from water, melted at 150–151° after recrystallization from hot water. Anal. Calc. for $C_{15}H_{14}Cl_2N_2O_7$: C, 41.59; H, 3.26; Cl, 16.37; N, 12.93. Found: C, 41.69; H, 3.21; Cl, 16.53; N, 12.84.

Preparation of 4-n-Alkylphenols

A series of 4-*n*-alkylphenols, three of which are new, was prepared by the general method of Sandulesco and Girard (6).

4-n-Hexylphenol

4-*n*-Hexylphenol (b.p. 135–136°/0.4 mm) was prepared in 72.6% yield from *p*-caproylphenol. The reported (6) boiling point at 10 mm is 146–147°.

4-n-Decylphenol

Decanoyl chloride (69 g, 0.35 mole) was heated with phenol (32.9 g, 0.35 mole) at 120° for 1 hour. The crude phenyl decanoate was added during a 30-minute period to a suspension of anhydrous aluminum chloride (56 g, 0.42 mole) in carbon disulphide (100 ml). The reaction was exothermic and the solvent began to reflux during the addition. Refluxing was continued for 2 hours. The solution was then evaporated to dryness, and the residue was heated at 150° for 2 hours. Hydrochloric acid (200 ml of 18% HCl) was added cautiously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the mixture was diluted with water (150 ml). The oily product was extracted with chloroform (200 ml) and the chloroform solution was dried and evaporated. Fractionation of the residue yielded 2-decanoylphenol (b.p. 130–133°/0.25 mm), yield 42.8 g (49.4%), and 4-decanoylphenol (b.p. 194–195°/0.4 mm), yield 15 g (17.3%). The *p*-isomer (m.p. 59–60°) crystallized in the receiver. Anal. Calc. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found: C, 77.26; H, 9.79.

4-Decanoylphenol (10 g, 0.04 mole) in ethanol (50 ml) was added to a vigorously stirred suspension of amalgamated zinc (70 g) in 18% hydrochloric acid (140 ml) and the reaction mixture was refluxed for 2 hours. The mixture was extracted with toluene (100 ml) and the toluene solution was dried and evaporated. Fractionation of the residue gave 7.8 g (83%) of 4-*n*-decylphenol (b.p. 146–148°/0.75 mm). The product crystallized (m.p. 54–56°) on standing. Anal. Calc. for $C_{16}H_{26}O$: C, 82.00; H, 11.19. Found: C, 81.83; H, 11.01.

4-n-Dodecylphenol

Phenol was heated with dodecanoyl chloride under similar conditions to form phenyl dodecanoate, which was rearranged to yield 51% of 2-dodecanoylphenol (b.p. 140–165°/0.75 mm), and 29.5% of 4-dodecanoylphenol (b.p. 198°/0.25 mm). Reduction of 4-dodecanoylphenol with amalgamated zinc and hydrochloric acid gave 4-*n*-dodecylphenol (b.p. 154°/3 mm, m.p. 65–67°), yield 81%. Anal. Calc. for $C_{18}H_{30}O$: C, 82.38; H, 11.53. Found: C, 82.48; H, 11.58.

4-n-Octadecylphenol

A mixture of stearic acid (113 g, 0.4 mole) and thionyl chloride (143 g, 1.2 mole) was refluxed for 1 hour. The mixture was distilled to give octadecanoyl chloride (b.p. 159–162°/0.1 mm), yield 87.9 g (72.5%). The acid chloride was converted to phenyl *n*-octadecanoate, which was rearranged to 31.6% of 2-*n*-octadecanoylphenol (b.p. 164–182°/0.15 mm) and 28% of 4-*n*-octadecanoylphenol (b.p. 209–212°/0.15 mm). Reduction of the para-isomer gave 4-*n*-octadecylphenol (b.p. 182–187°/0.15 mm, m.p. 65–67°) in 83% yield. Anal. Calc. for $C_{24}H_{42}O$: C, 83.18; H, 12.22. Found: C, 83.10; H, 12.00.

Aryl Thionocarbamates

Method A: 4-n-Propylphenyl 3,4-Dichlorophenylthionocarbamate

4-*n*-Propylphenol (20.43 g, 0.15 mole) in 3% sodium hydroxide solution (200 ml) was added to a stirred solution of thiophosgene (17.25 g, 0.15 mole) in chloroform (200 ml) at 0–10° during a period of 30 minutes. The stirring was continued for 30 minutes and the chloroform layer was separated, dried, and evaporated. Distillation of the residue gave 4-*n*-propylphenyl chlorothionoformate (b.p. 101–102°/0.8 mm), yield 24 g (74.7%).

3,4-Dichloroaniline (16.2 g, 0.1 mole) in chloroform (150 ml) was added to a stirred solution of 4-*n*-propylphenyl chlorothionoformate (10.73 g, 0.05 mole) in chloroform (200 ml) at 25° during a period of 30 minutes. The stirring was continued for 1 hour, and the precipitated 3,4-dichloroaniline hydrochloride (9.6 g, 97%) was removed by filtration. The filtrate was concentrated to a volume of 200 ml and petroleum ether (300 ml) was added to give the product (m.p. 150–151°), yield 12.6 g (74%). Recrystallization from the same solvents did not raise the melting point. When the phenol was insoluble in dilute sodium hydroxide, the dried sodium phenoxide was reacted with thiophosgene in chloroform suspension.

The compounds listed in Tables I and III, and those compounds in Table II for which no other method is noted, were prepared by this general procedure.

[a]Crystallized from acetone–water. [b]Ethanol–water.

Method B: 4-Methylphenyl 3,4-Dichlorobenzylthionocarbamate

A mixture of 3,4-dichlorobenzyl isothiocyanate (4.36 g, 0.02 mole), *p*-cresol (2.16 g, 0.02 mole), and triethylamine (0.04 g, 0.0004 mole) was heated in a sealed tube at 80° for 4 hours. The reaction mixture was dissolved in ether (100 ml) and the ether solution was washed with 2% sodium hydroxide solution and with water. The residue obtained on evaporation of the ether solution (5.8 g, m.p. 92–96°) was recrystallized from petroleum ether (40 ml) to give the product melting at 115–117°, yield 4.4 g (67.5%). One crystallization from ether – petroleum ether solvent raised the melting point to 118–119°. This reaction was found to be generally applicable to the addition of phenols to aralkyl isothiocyanates. Compounds prepared by this method are included in Table II.

Aralkyl Thionocarbamates

3,4-Dichlorobenzyl 3,4-Dichlorobenzylthionocarbamate

Sodium hydride (0.48 g of a 50% dispersion, 0.01 mole) was added to 3,4-dichlorobenzyl alcohol (1.77 g, 0.01 mole) in benzene (30 ml). The mixture was stirred at room temperature until the evolution of hydrogen ceased, after which it was briefly heated to boiling. The cooled suspension of sodium 3,4-dichlorobenzyloxide was treated with 3,4-dichlorobenzyl isothiocyanate (2.18 g, 0.01 mole) in benzene (10 ml) and the mixture was stirred overnight. The precipitated sodio derivative (4.18 g) was dissolved in acetone and the solution was filtered clear of insoluble impurities (0.34 g). Acidification of the filtrate with aqueous acetic acid precipitated the product (m.p. 103–104°), yield 2.86 g (72.1%). Recrystallization from aqueous acetone raised the melting point to 104–105°.

All of the compounds listed in Table IV were prepared by this procedure.

1,4-Phenylene Di-(3,4-dichlorobenzylthionocarbamate)

A mixture of 3,4-dichlorobenzyl isothiocyanate (2.18 g, 0.01 mole), hydroquinone (1.10 g, 0.01 mole), and triethylamine (0.01 g, 0.0001 mole) was heated in a sealed tube at 144° for 3 hours. The crude product was triturated in ether (100 ml) to give 1.79 g (65.6%) of product (m.p. 165–170°). Recrystallization from aqueous acetone raised the melting point to 170–171°, yield 1.25 g (45.8%). Anal. Calc. for $C_{22}H_{16}Cl_4N_2O_2S_2$: C, 48.38; H, 2.95; Cl, 25.96; N, 5.13; S, 11.74. Found: C, 48.49; H, 3.13; Cl, 25.98; N, 5.27; S, 11.73.

1,4-Phenylene Di-(benzylthionocarbamate)

A mixture of benzyl isothiocyanate (3.83 g, 0.026 mole), hydroquinone (1.41 g, 0.013 mole), and triethylamine (0.023 g, 0.0023 mole) was heated in a sealed tube at 144° for 3 hours. The crude product was extracted with ether, and the residue was recrystallized from aqueous acetone to give crystals melting at 171–172°, yield 0.24 g (4.6%). Recrystallization from acetone raised the melting point to 178–179°. Anal. Calc. for $C_{22}H_{20}N_2O_2S_2$: C, 64.67; H, 4.94; N, 6.86; S, 15.70. Found: C, 64.93; H, 5.07; N, 6.67; S, 15.79.

Aryl Thiolcarbamates

Phenyl chlorothiolformate (b.p. 90–95°/13 mm) was prepared in 18% yield by the method of Rivier (2).

The chlorothiolformate (3.40 g, 0.02 mole) in chloroform (30 ml) was added dropwise to a stirred solution of 3,4-dichlorobenzylamine (4.30 g, 0.04 mole) in chloroform (10 ml) at 25°. The reaction mixture was allowed to stand overnight, and the precipitated 3,4-dichlorobenzylamine hydrochloride (2.87 g, 100%) was recovered by filtration. The residue obtained on evaporation of the filtrate was crystallized from benzene – petroleum ether to give crystals melting at 101–102°, yield 2.65 g (55%).

4-Chlorophenyl chlorothiolformate (b.p. 145–155°/30 mm) was prepared in 67.5% yield from lead 4-chlorophenylmercaptide and phosgene, according to Rivier's method (2). Condensation with the appropriate amine as described above yielded the other thiolcarbamates listed in Table V.

S-*Methyl Phenylxanthate*

The reaction between carbon disulphide and potassium phenolate in ethanol (7) was found to yield only potassium ethylxanthate. Replacement of the ethanol by dimethylformamide yielded the desired potassium phenylxanthate.

Carbon disulphide (6.09 g, 0.08 mole) was added during a 30-minute period to potassium phenolate (10.58 g, 0.08 mole) in dimethylformamide (80 ml) at 20°. Methyl chloride was bubbled through the reaction mixture for 30 minutes at 30°. Water (1500 ml) was added, and the mixture was extracted with ether (5×100 ml). The ether extracts were combined and washed with 5% sodium hydroxide solution, 5% hydrochloric acid, and water. Fractionation of the dried ether solution yielded S-methyl phenylxanthate (b.p. 82–84°/0.11 mm, n_D^{25} 1.62189), yield 6.0 g (41.8%). Anal. Calc. for $C_8H_8OS_2$: C, 52.15; H, 4.38; S, 34.80. Found: C, 52.15; H, 4.45; S, 34.19.

Methyl 3,4-Dichlorobenzyldithiocarbamate

Method A.—3,4-Dichlorobenzylamine (2.58 g, 0.146 mole) was added to S-methyl phenylxanthate (2.7 g, 0.0146 mole) at room temperature. The temperature rose to 42°, and the mixture gradually solidified. Crystallization from chloroform – petroleum ether yielded methyl 3,4-dichlorobenzyldithiocarbamate (m.p. 98–100°), yield 3.37 g (74.1%). Recrystallization from chloroform – petroleum ether gave the analytical sample melting at 100–101°. Anal. Calc. for $C_9H_9Cl_2NS_2$: C, 40.61; H, 3.41; Cl, 26.64; N, 5.26; S, 24.08. Found: C, 41.11; H, 3.44; Cl, 26.07; N, 5.42; S, 24.14.

Method B.—Carbon disulphide (16.75 g, 0.22 mole) was added to a stirred mixture of sodium hydroxide (8.8 g, 0.22 mole) in water (14 ml) and 3,4-dichlorobenzylamine (35.21 g, 0.20 mole) in ether (100 ml) at 0–5°. The mixture was stirred for 1 hour at room temperature, and the sodium 3,4-dichlorobenzyldithiocarbamate (40.7 g, 75%) was recovered by filtration. The sodium salt (13.71 g, 0.05 mole) was added to a solution of methyl iodide (7.10 g, 0.05 mole) in methanol (150 ml) and the mixture was allowed to stand for 1 hour. The solution was concentrated and diluted with water, giving methyl 3,4-dichlorobenzyldithiocarbamate (m.p. 95–100°). Recrystallization from benzene yielded the pure product (9.0 g, 71%), melting point and mixed melting point with the product described above in A was 100–101°.

Methyl 3,4-Dichlorobenzylthionocarbamate

A solution of methyl 3,4-dichlorobenzyldithiocarbamate (1.33 g, 0.005 mole) in methanol (50 ml) was refluxed for 1 hour in the presence of Amberlite IRA-400 resin (25 ml) which had been saturated with phenol. The solution was filtered and evaporated. Crystallization of the residue from chloroform – petroleum ether yielded methyl 3,4-dichlorobenzylthionocarbamate (m.p. 75–76°), yield 0.60 g (48%). Anal. Calc. for $C_9H_9Cl_2NOS$: C, 42.23; H, 3.63; Cl, 28.35; N, 5.60; S, 12.82. Found: C, 42.23; H, 3.90; Cl, 28.60; N, 5.39; S, 12.59.

Ethyl 3,4-Dichlorobenzylthionocarbamate

The procedure is essentially that of Harris and Fischback (1). Methyl chloride was passed through a solution of potassium ethylxanthate (0.20 mole) in ethanol (200 ml) for 1 hour at 25–30°. 3,4-Dichlorobenzylamine (35.2 g, 0.20 mole) was added and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution was maintained at 40° for 30 minutes. The solution was evaporated, and the residue was dissolved in chloroform (200 ml). The chloroform solution was extracted with 5% sodium hydroxide solution, 5% hydrochloric acid, and water. The chloroform solution was dried and evaporated to give ethyl 3,4-dichlorobenzylthionocarbamate (m.p. 55–58°), yield 16 g (30.3%). Anal. Calc. for $C_{10}H_{11}Cl_2NOS$: C, 45.46; H, 4.19; Cl, 26.84; N, 5.30; S, 12.14. Found: C, 45.39; H, 4.30; Cl, 27.00; N, 5.70; S, 12.10.

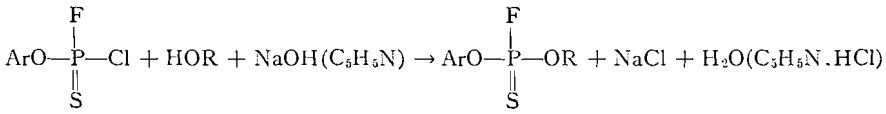
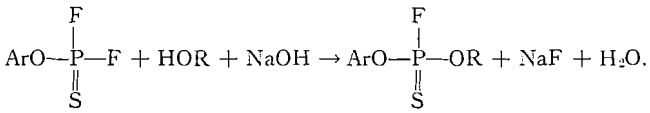
ORGANOPHOSPHORUS COMPOUNDS



VIII. O-ALKYL, O′-ARYL PHOSPHOROFLUORIDOTHIOATES AND O-ARYL N-ALKYL PHOSPHORAMIDOFLUORIDOTHIOATES[1, 2]

G. A. Olah and A. A. Oswald[3]

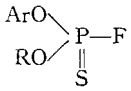


O-Alkyl, O′-aryl phosphorofluoridothioates and O-aryl N-alkyl phosphoramidofluoridothioates were prepared from the corresponding aryl phosphorochlorofluoridothioates and aryl phosphorodifluoridothioates.

In a previous paper (1) the preparation of aryl phosphorochlorofluoridothioates and aryl phosphorodifluoridothioates was described. Using these compounds as starting materials, it was now possible to prepare the previously unknown O-alkyl, O′-aryl phosphorofluoridothioates and O-aryl N-alkyl phosphoramidofluoridothioates.

O-Alkyl, O′-aryl phosphorofluoridothioates have been obtained in good yields by reacting aryl phosphorochlorofluoridothioates with sodium alcoholates, or with alcohols in the presence of NaOH or pyridine.

Aryl phosphorodifluoridothioates react in a similar manner:



The yields with this method, however, are in general slightly smaller than with aryl phosphorochlorofluoridothioates.

The following O-alkyl, O′-aryl phosphorofluoridothioates were prepared: O-ethyl, O′-phenyl-; O-methyl, O′-*p*-tolyl-; O-ethyl, O′-α-naphthyl-; and O-methyl, O′-*p*-chlorophenyl-phosphorofluoridothioates. Some physical properties and analytical data are shown in Table I.

TABLE I

Alkyl esters of phosphoramidofluoridic acid were prepared by Saunders (2), Schrader (3), and Sartori (4) to combine the rapid toxic action and miotic effect of the dialkyl phosphorofluoridates and of the high toxicity of some of the phosphorodiamidofluoridates. The synthesis started from phosphorus oxydichlorofluoride and was carried out without the isolation of the ethyl phosphorofluoridochloridate intermediate according to the following sequence of reactions (5):

$$POCl_2F + C_2H_5OH \rightarrow C_2H_5OPOClF + HCl \xrightarrow{3C_6H_5NH_2} \begin{matrix} C_2H_5O \\ C_6H_5NH \end{matrix}\!\!>\!POF + 2C_6H_5NH_2.HCl.$$

Similar reactions starting from phosphorus thiodichlorofluoride were used for the preparation of the alkyl esters of phosphoramidofluoridothioic acids as described in a previous paper of this series (6). No aryl esters of either phosphoramidofluoridic or phosphoramidofluoridothioic acid were reported.

In this work aryl esters of N-alkyl phosphoramidofluoridothioic acid were prepared by reacting aryl phosphorochlorofluoridothioates with a primary or secondary amine according to the following equation:

$$ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}Cl + 2HNR_2 \rightarrow ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}NR_2 + R_2NH.HCl.$$

Aryl phosphorodifluoridothioates react with amines in a similar manner to yield O-aryl N-alkyl phosphoroamidofluoridothioates and amine hydrofluorides:

$$ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}F + 2HNR_2 \rightarrow ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}NR_2 + R_2NH.HF.$$

Syntheses starting from aryl phosphorodifluoridothioates required somewhat higher reaction temperatures and gave slightly lower yields.

In the place of the second mole of amine, pyridine (or another organic base) can be used to bind the halogen hydrogen formed in the reaction

$$ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}Cl + H_2NR + C_5H_5N \rightarrow ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}NHR + C_5H_5N.HCl.$$

Yields and purity of compounds were equivalent to previous methods.

TABLE II

O-Aryl N-alkyl phosphoramidofluoridothioates

$$ArO{-}\overset{\overset{F}{|}}{\underset{\underset{S}{\|}}{P}}{-}N\begin{matrix}R_1\\R_2\end{matrix}$$

*Obtained by the reaction of aryl phosphorochlorofluoridothioates with amines.

The following O-aryl N-alkyl phosphoramidofluoridothioates were prepared: O-phenyl N,N-dimethyl-; O-*o*-tolyl N,N-dimethyl-; amido-, O-*o*-tolyl N-ethyl-; and O-phenyl N-*t*-butyl-phosphoramidofluoridothioates. The yields and some of the properties of the compounds prepared are shown in Table II.

All derivatives are colorless liquids. They are fairly resistant to hydrolysis. Therefore, they can be prepared also in water media in satisfactory yields.

EXPERIMENTAL

O-Alkyl, O'-Aryl Phosphorofluoridothioates

(A) From Aryl Phosphorochlorofluoridothioates with Alcoholates

Aryl- (phenyl-, *p*-tolyl-, α-naphthyl-, and *p*-chlorophenyl-) phosphorochlorofluoridothioate (0.1 mole) was dissolved in 100 ml of benzene (ether could be also used as an alternate solvent) and placed in a 500-ml three-necked flask equipped with a stirrer, dropping funnel, and thermometer. The other reagent, 0.1 mole of sodium alcoholate (methylate and ethylate), was dissolved in the corresponding alcohol. The sodium alcoholate solution was then added in small portions to the aryl phosphorochlorofluoridate while the reaction mixture was stirred and cooled in an ice bath. Sodium chloride precipitated instantly. After the reaction mixture was allowed to stand for 2 hours, it was washed with three volumes of water, then with 2.5% sodium carbonate solution, and then again with water. The mixture was dried over anhydrous sodium sulphate, and the solvent was removed by distillation at atmospheric pressure and then the remaining product was fractionated *in vacuo*. For yields, physical and analytical data see Table I.

(B) From Aryl Phosphorochlorofluoridothioates with Alcohols

A solution of 0.1 mole of aryl phosphorochlorofluoridothioate in 50 ml of the corresponding alcohol (methanol or ethanol in our experiments) was placed into a 200-ml flask equipped with a mechanical stirrer, dropping funnel, and thermometer. To the alcoholic solution, an aqueous solution of 4.0 g (0.1 mole) of sodium hydroxide (in 15 ml of water) was added dropwise, with effective stirring and ice-water cooling. After the addition, the reaction mixture was allowed to stand overnight at room temperature and then extracted with 150 ml of ether. The ether solution was washed with water, 1% aqueous sodium hydroxide solution, and then again with water. The ether solution was then dried over anhydrous sodium sulphate, the solvent was removed by distillation at atmospheric pressure, and the remaining raw O-alkyl, O'-aryl phosphorofluoridothioate was purified by fractionation *in vacuo*.

In the presence of pyridine.—To a solution of 0.1 mole of aryl phosphorochlorofluoridothioate in 50 ml of the corresponding alcohol, a solution of 0.1 mole of pyridine in 100 ml of ether was added slowly with shaking. After the addition, the reaction mixture was allowed to stand overnight, diluted with 200 ml of water and 100 ml of ether. The ether phase was washed successively with water, 5% aqueous sodium carbonate, and water and then dried over sodium sulphate. The solvent was removed by distillation, and the O-alkyl, O'-aryl phosphorofluoridothioate was obtained by fractionation *in vacuo*.

(C) From Aryl Phosphorodifluoridothioates

Aryl (α-naphthyl-, and *p*-chlorophenyl-) phosphorodifluoridothioate (0.1 mole) was dissolved in 100 ml of benzene and reacted with an alcoholic solution of 0.1 mole of sodium alcoholate (methylate and ethylate) as described under method (*A*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

O-Aryl N-Alkyl Phosphoramidofluoridothioates

(A) From Aryl Phosphorochlorofluoridothioates with Amines

To a solution of 0.1 mole of aryl- (phenyl-, *o*-tolyl-) phosphorochlorofluoridothioate in 100 ml of benzene (or toluene), 0.2 mole of the corresponding alkylamine (methyl, dimethyl, *t*-butyl) in 100 ml of benzene was added with cold water cooling and stirring. The amine hydrochloride precipitated instantly. The reaction mixture was allowed to reach room temperature and to stand overnight. The amine hydrochloride was then removed by filtration and washed with benzene. The combined filtrate was distilled; at first the benzene solvent was removed at atmospheric pressure and then the raw O-aryl N-alkyl phosphoramidofluoridothioate was fractionated *in vacuo*. Yields and physical and analytical data are shown in Table II.

(B) From Aryl Phosphorochlorofluoridothioates with Amines and Pyridine

To a solution of 0.1 mole of aryl phosphorochlorofluoridothioate in 150 ml of benzene, a mixture of 0.1 mole of alkylamine and 0.1 mole of pyridine was added dropwise with stirring. The reaction mixture was warmed to 50° C and kept at that temperature for an hour. Then the pyridine hydrochloride precipitate was removed by filtration and washed with benzene. The combined benzene filtrates were washed with water, dried over anhydrous sodium sulphate and distilled.

(C) From Aryl Phosphorodifluoridothioate

To a benzene solution of 0.1 mole of phenyl phosphorodifluoridothioate, 0.2 mole of alkylamine (dimethyl and *t*-butyl) in 100 ml of benzene was added with stirring. The reaction mixture was heated to 50° C and kept at that temperature for an hour. Then it was worked up as described under method (*A*).

THE DETERMINATION OF THE AREAS OF RESOLVED AND PARTIALLY RESOLVED CHROMATOGRAPHY PEAKS[1]

JOHN C. BARTLET AND D. MORISON SMITH

ABSTRACT

Gas chromatographic peaks were demonstrated to have the form of normal distribution curves. A mathematical treatment has been developed which permits the calculation of the areas of these curves from the statistical parameters, height of the mode (peak height), and standard deviation σ. The standard deviation equals the width of the peak at 0.882 of peak height. Methods given for the evaluation of the mutual effects of overlapping peaks have made it possible to obtain corrected peak heights. The standard deviation of the gas chromatography peak has been found to vary linearly with the retention time, thus permitting the graphical estimation of σ for use with corrected peak heights in the calculation of true areas for overlapping peaks. The method has also been extended to the treatment of skewed, overlapping peaks. The variation of σ with retention time, its constancy, and its relationship to the number of theoretical plates are discussed.

INTRODUCTION

In quantitative gas chromatography using a differential detector, the area under the peak corresponding to a compound is proportional to the amount of that compound present in the gas stream. Area measurements are therefore fundamental.

Various procedures have been proposed for the measurement of peak areas. The integrator built into the recorder is the least laborious, but suffers from obvious disadvantages if there is a base-line drift or if there are overlapping peaks. The triangulation procedure (1) gives a good first approximation. Another procedure which has been widely used is to cut out the peaks or a tracing of the peaks, and to weigh the cut paper. Planimeter tracing has also been used. With all these procedures, precision and accuracy suffer when the peaks are very narrow or if two or more peaks have a moderate overlap.

AREA OF SYMMETRICAL PEAKS

(a) Isolated Peaks

It has been pointed out and developed theoretically (2, 3, 4) that the peaks obtained with a well-designed chromatograph closely approximate a normal or Gaussian distribution curve as shown in Fig. 1. The equation for this type of curve is given by Goulden (5) as

$$Y = \frac{N}{\sigma\sqrt{2\pi}} \cdot e^{-\frac{1}{2}(x/\sigma)^2} \qquad [1]$$

where Y is the height of the curve measured at a distance x from the mean, N is the number of variates, which, for our purposes may be taken as the area, A, and σ is the standard deviation. At the mean or central peak of the curve, $x = 0$, $Y = h$ or peak height, and equation [1] becomes

$$h = \frac{A}{\sigma\sqrt{2\pi}} \qquad [2]$$

or

$$A = h\sigma\sqrt{2\pi} = 2.507h\sigma. \qquad [3]$$

[1]*Manuscript received June 30, 1960.*
Contribution from Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada. Presented in part at the Ottawa Meeting of the Chemical Institute of Canada, June 14, 1960.

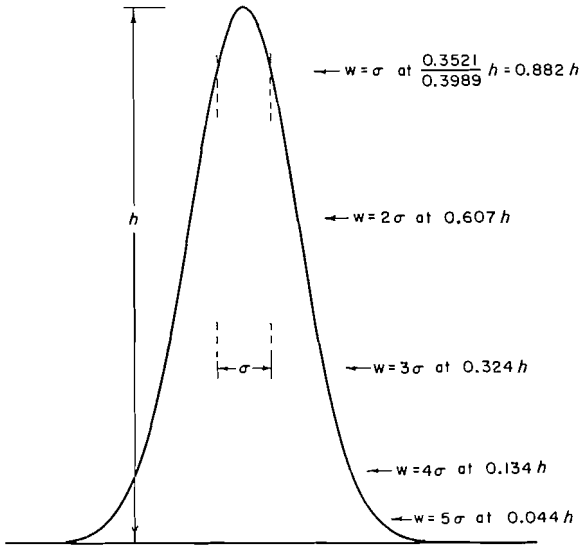

FIG. 1. The normal distribution curve.

For a normal distribution curve, σ may easily be determined, as shown in Fig. 1, by any one of the formulae which have been derived from Sheppard's tables of the Probability Integral (Biometrika Tables) (6). Thus, for an isolated peak, the area may be calculated, without construction, by simply measuring the peak height and the σ derived from the peak width at $0.607h$ or $0.324h$ and substituting in equation [3]. For accuracy, the peak width measurements for σ should be made using a magnifying viewer with reticle such as the Bausch and Lomb spectrum measuring magnifier No. 81-34-97-20.

The conformity of the peaks to the normal distribution curve can be tested by measuring the peak width of an isolated peak at the various heights listed in Fig. 1. The σ obtained should be constant or nearly constant to a peak width of 4σ.

Figure 2 gives a typical chromatogram for which the σ of the various peaks are indicated. Some of these values and others taken from other chromatograms using pure standard substances on the same column have been plotted against retention time in Fig. 3. As may be seen from the figure, the function is linear. In this way, the value for σ may be obtained from the graph for peaks which are insufficiently resolved for accurate measurement. These values of σ can be used directly in equation [3] for resolved peaks.

(b) Unresolved Peaks

If distances along the x axis are measured in terms of σ and the area is taken as 1 (i.e., a standardized normal distribution) then equation [2] becomes

$$h = \frac{1}{\sqrt{2\pi}} \qquad [4]$$

and the ordinate Y becomes Z (5). Then

$$Z = \frac{e^{-\frac{1}{2}(x/\sigma)^2}}{\sqrt{2\pi}}. \qquad [5]$$

Note that $Z = h = 1/\sqrt{2\pi}$ when $x = 0$.

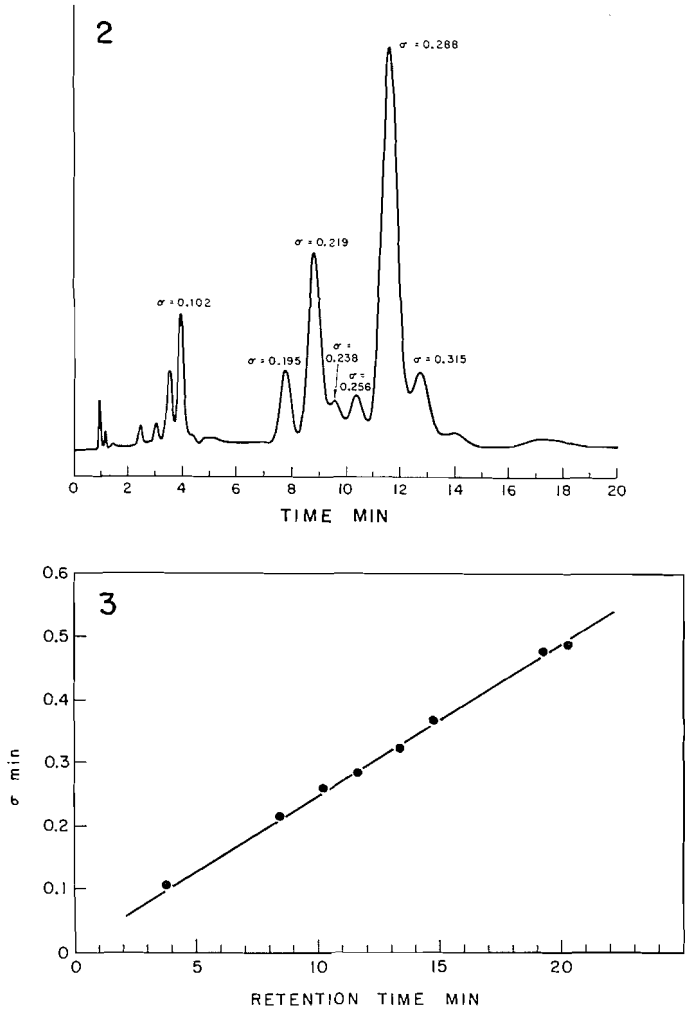

FIG. 2. Gas chromatogram of peppermint oil. Temperature of column, 170°; flow rate, 80 ml/minute of helium; packing, 20% SAIB on Chromosorb W, 2½ meters long.
FIG. 3. Relationship of σ, standard deviation, to retention time, t_r.

The values for Z may be found in Sheppard's table (5) for a standardized normal distribution curve. These values have been converted to percentage of peak height h at a distance x from the mean. Figure 4 gives these percentage corrections at separations, x, measured in units of the σ of the interfering peak.

When there are two incompletely resolved peaks as in Figs. 5 and 6, it is possible to calculate the height of the curve due to one component at the position of the other peak, and thus the contribution of one component to the observed peak height of the other.

For example, let us consider two peaks, a and b, of peak heights h_a and h_b separated by x (measured in units of σ_a and hence called x_a) as shown in Fig. 5. The ordinate Y of the curve of peak a at a distance x_a from the mean is given by substituting h_a for $N/\sigma\sqrt{2\pi}$ in equation [1].

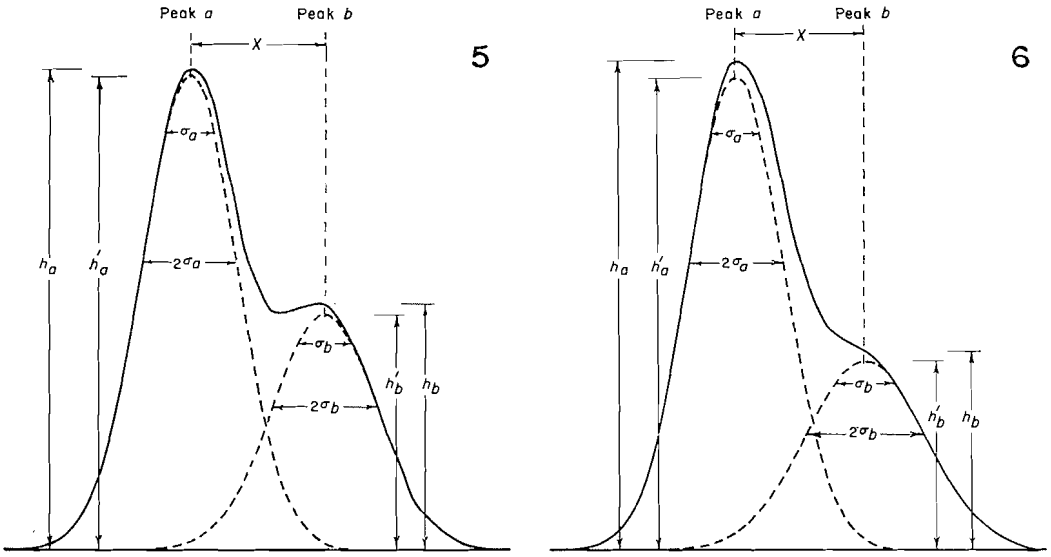

FIG. 5. Symmetrical peak with partially resolved side peak.
FIG. 6. Symmetrical peak with unresolved shoulder.

[6] $$Y = h_a e^{-\frac{1}{2}(x_a/\sigma_a)^2}$$

and the corrected height of peak b, h_b', becomes

[7] $$h_b' = h_b - h_a e^{-\frac{1}{2}(x_a/\sigma_a)^2}$$

and the area, A_b, becomes

[8] $$A_b = h_b' \sigma_b \sqrt{2\pi} = 2.507\, h_b' \sigma_b.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

This is obviously the first member of a series of iterative approximations, whose later members are usually too small to be considered. However, if both h_a and h_b are large and x is small, it may be necessary to carry through the corrections a second time using h_a' in place of h_a in equation [7] and h_b' in the corresponding correction for h_b.

To simplify the correction for peak height, Fig. 4 or Sheppard's table (6) may be used to obtain the percentage of the height of the interfering peak to be subtracted from the peak under consideration. If the separation is greater than 4σ, the correction is usually negligible even though the valley between the peaks does not return to the base line. In the above example h_a can similarly be corrected for the effect of peak b, using x measured in units of σ_b. Note that if peak b comes after peak a, σ_b will be greater than σ_a as shown in Figs. 5 and 6, x_b will be less than x_a, and the percentage of h_b to be subtracted from h_a will be greater than the percentage correction of h_a on h_b. In Fig. 6 the correction for h_b on h_a is actually larger even though the peak b is smaller.

Figure 5 shows two symmetrical peaks, which, although overlapping, are still well enough separated so that the peak positions can be determined.

Figure 6 shows an extreme case where peak b appears only as a shoulder. The corrections can still be applied provided the retention time of the second compound relative to the first is known from other data. This is necessary so that the distance x can be measured accurately.

Note that although in both Figs. 5 and 6 there is serious overlap, there is still only a relatively small correction on peak height. However, as may be seen from these figures a serious error would be introduced if the σ used in the calculations were taken from the curve. In the case of overlapping peaks the σ to be used must be derived from a graph of the type of Fig. 3 for accurate results.

ASYMMETRICAL PEAKS

A peak may be skewed and still have some of the properties of a normal distribution curve. Skewed peaks which will be considered in detail are of the type shown in Fig. 7

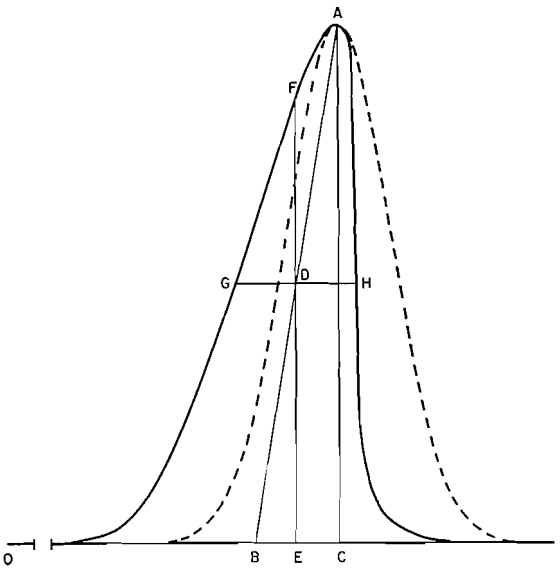

FIG. 7. Comparison of skewed and symmetrical distribution curves.

and have the following properties:

1. The asymmetry is such that the locus of the midpoint of the peak width at all heights is a straight line (AB in Fig. 7).
2. The peak width measured at the various heights listed on Fig. 1 shall yield a constant value for σ.

Skewness has been defined by Pearson (7) as (mean$-$mode)/σ where the mean is the value which vertically bisects the area and the mode is the position of peak height. Figure 7 shows a skewed curve of the type described, along with a symmetrical normal distribution curve with arbitrary origin at 0. Line AC gives peak height h and line AB is the locus of the midpoint between the ascending and descending portions of the curve. The mode is given by point C. To a first approximation the mean or vertical bisector EDF of the area can be obtained from the half height, GDH, at its intersection, D, of line AB, thus, an approximate skewness, Sk, is given by

$$[9] \qquad Sk = \frac{OE-OC}{\sigma} = \frac{EC}{\sigma} \quad \text{or} \quad \frac{\frac{1}{2}BC}{\sigma}.$$

If the distance BC is less than σ the error of this estimate of the mean is negligible.

The distance BC cannot exceed 1.66σ for any curve which satisfies the conditions of a straight line for the midpoint locus, AB, or a constant value for σ at various points on the curve. Thus, the skewness, Sk, which can be treated, will be -0.83 to $+0.83$ (using the approximate mean derived from the above construction).

(*a*) *Area of isolated asymmetrical peaks.*—As may be seen from Fig. 7, the areas of the symmetrical and the asymmetrical peaks are virtually identical. The area may therefore be calculated from equation [3] where $h = AC$ (Fig. 7).

(*b*) *Area of overlapping asymmetrical peaks.*—If two peaks, only one of which is skewed, overlap, the area of the asymmetrical peak can be calculated using the corrections for the contribution of the symmetrical peak to the peak height of the other as described in the previous section.

The correction for the contribution of an asymmetrical peak to the height of either a symmetrical or skewed peak is more complicated and requires a series of successive approximations. In the remainder of this section, points and lines referred to are taken from Fig. 7. The distance between the peaks is measured in terms of the σ of the asymmetrical peak from the midpoint of the base line (point B) rather than from the mode (point C) to the mode of the second peak. The ordinate, Y, of the curve at the distance x can be calculated in the same way as for a symmetrical peak. The intersection of this height Y with the midpoint locus (line AB) is determined, and a new value for the distance x is measured from this point to the mode of the second peak. The height, Y, is recalculated using the corrected distance, and the entire operation is repeated if necessary.

These corrections, after the successive approximations, are given in terms of percentage of the interfering peak for various values of skewness, Sk, in Table I. The distance x between peaks is given in terms of σ of the interfering peak measured from the midpoint locus intersection with the base line (point B) to the mode of the peak under consideration. The corrections to be applied for symmetrical peaks ($Sk = 0$) have also been plotted on probability paper in Fig. 4.

DISCUSSION

The calculation for area using this method eliminates the subjective errors of construction in the triangulation method or of cutting in the paper weighing method. It is a

reasonably rapid procedure for isolated peaks requiring only the measurement of peak height and the determination of σ, either from the chromatogram itself by direct measurement or from a graph similar to Fig. 3 constructed from such measurements. For overlapping peaks the area determination is much less subjective than by any other method, and can be done quickly after practice.

A probability treatment for gas chromatography has been worked out by Sen (8). The values of the position of the peak (here called t_r) and of σ, the standard deviation, are stated to "completely define the distribution curve or the macroscopic behaviour of the column". Difficulty is frequently encountered in repeating work on two different columns which apparently have been made up identically. The same conditions of flow rate and temperature do not produce the same results due to microscopic differences in packing, etc. With proper manipulation of the adjustable variables, it is possible to reproduce the probability and distribution of successes, that is, curves with the same t_r and σ. This should be aimed at, rather than duplication of flow rate, temperature, etc., since this also corresponds to duplication of the number of theoretical plates, r, for, as pointed out by Schmauch (9),

$$r = \left(\frac{t_r}{\sigma}\right)^2. \qquad [10]$$

Another way of presenting this data is in a plot of σ versus t_r (both in minutes) as given in Fig. 3. By reversing the criteria in the above paragraph, deterioration of the column packing can be detected. Thus, the constancy of the σ versus t_r plot obtained under fixed conditions will indicate that the column is still in its original state.

If a measured value of σ for a given peak falls off the plot of σ versus retention time, two or more compounds have emerged together. Figure 2 gives the plot for a single SAIB column (10) obtained from a large number of chromatograms of peppermint oil. The σ obtained for one peak was invariably well off the curve even though the peak was often reasonably symmetrical. Further investigation showed that two compounds with nearly identical retention volumes were responsible for the wider peak. By a series of successive approximations using equation [3], it was possible to make an estimate of the two areas.

For all calculations in this paper, it has been assumed that the normal distribution curve holds true. Factors affecting the peak shape such as detector volume and sample size have been discussed by Johnson and Stross (11) and others. If both are kept small the curves obtained are sufficiently close to the normal curve for the use of these calculations. The peaks often obtained from highly polar compounds such as water, ammonia, amines, alcohols, etc. are too badly skewed to treat by calculations in this paper.

Using these calculations it is possible to obtain a great deal of information from chromatograms with incompletely resolved peaks. Thus it may be unnecessary to use long columns, a variety of packings, or long elution times to complete a difficult analysis.

SYMBOLS USED

A = area.
h = peak height.
r = number of theoretical plates.
t_r = time between introduction of the sample and the peak emergence.
w = peak width at any specified height.
x = distance from a peak center measured in units of its σ.
Y = the ordinate of the curve at a distance x from peak center.
Z = the special case of Y when $A = 1$.
σ = standard deviation.

SOLVENT EFFECTS AS AN AID IN THE ANALYSIS OF THE PROTON MAGNETIC RESONANCE SPECTRUM OF VINYL BROMIDE[1]

T. SCHAEFER[2] AND W. G. SCHNEIDER

ABSTRACT

By making use of specific solvent effects it has been possible to vary the relative chemical shift between the *geminal* protons of vinyl bromide from about +10 cycles/sec to −4 cycles/sec (at 60 Mc/sec) and to study the resultant changes in the proton resonance spectrum in the limiting region of zero chemical shift. Of particular interest is the growth and displacement of the combination lines, which appear in the resonance signals of the proton bonded to the same carbon atom as the bromine. From the variation of the six possible lines in this region it was confirmed that the *cis* and *trans* proton coupling constants must have the same sign. The intensity distribution of the lines in the *geminal* proton region require the *geminal* coupling constant to be of opposite sign to the other two.

INTRODUCTION

Recent studies of specific solvent interactions (1) have shown that, within limits, it is possible to vary the relative chemical shifts of protons in certain molecules in a continuous and controlled manner by altering the solvent conditions. This provides a very useful aid in arriving at an assignment and analysis of the proton spectrum, as well as a convenient method of studying the pronounced changes of the spectrum in the limit as the relative chemical shift is progressively reduced to zero. Solvent-induced shifts of this kind are generally observed for unsaturated molecules containing a strongly electronegative or electropositive substituent (1). Vinyl bromide, CH_2:CHBr, chosen for the present work, fulfills these conditions. Its proton spectrum is typical of a three-spin system and has been discussed by several authors (2, 3, 4, 5). Depending on the relative proton chemical shifts such spectra may be classed as ABX, ABC, or AB_2 types and are observed in the resonance spectra of many common molecules (2, 4, 5, 6, 7). In general vinyl compounds belong to the type ABC when observed at a measuring frequency of 40 Mc/sec, and usually also at 60 Mc/sec, although a rough analysis is often possible on the basis of an ABX type (8).

Lately it has become a matter of theoretical interest to determine, if not the absolute sign, at least the relative signs of the three coupling constants involved (9, 10, 12). Theory indicates that if the coupling constant is small between protons it may be negative, whereas if it is large it is probably positive (12). The coupling constant between the *geminal* protons in vinyl compounds is small, about 0 to 2 cycles/sec. The *trans* coupling constant is over 10 cycles/sec and often over 15 cycles/sec as compared with about 5 to 10 cycles/sec for the *cis* coupling constant (8). An exact analysis of the proton spectrum involves a numerical solution of the case ABC. This has been done for a number of vinyl compounds by means of a computer (11, 12). In particular, the proton spectrum of vinyl bromide requires the *cis* and *trans* coupling constants to be of the same sign but of opposite sign to the *geminal* coupling constant, the latter being small and presumably negative.

It is the purpose of the present work to present an experimental method for the determination of the relative signs of the *cis* and *trans* coupling constants in vinyl

bromide and to illustrate the appearance and growth of the combination lines as the relative electronic screening of the protons is changed.

EXPERIMENTAL

Measurements of the proton resonance spectra of vinyl bromide in the pure state and at various concentrations in solvents were made at 60 Mc/sec on a Varian n.m.r. spectrometer. The vinyl bromide was distilled before use and the solvents used were acetone, hexane, and benzene. The concentrations in acetone and hexane were 5 mole% but the solutions in benzene were made up approximately by volume. Since vinyl bromide boils below room temperature the pure substance was contained in a sealed tube. The solutions could be measured in an open tube.

RESULTS AND DISCUSSION

(a) Pure Vinyl Bromide

The observed spectrum of pure vinyl bromide is shown in Fig. 1 together with the proton assignment and the spectrum calculated as an ABC case. The resultant chemical shifts and spin-coupling constants are compared with those derived by Sheppard (11) and by Karplus, Grant, and Gutowsky (12) in Table I. Chemical shifts have been converted to 60 Mc/sec. It should be noted that Sheppard's parameters apply to a 10% solution in carbon tetrachloride.

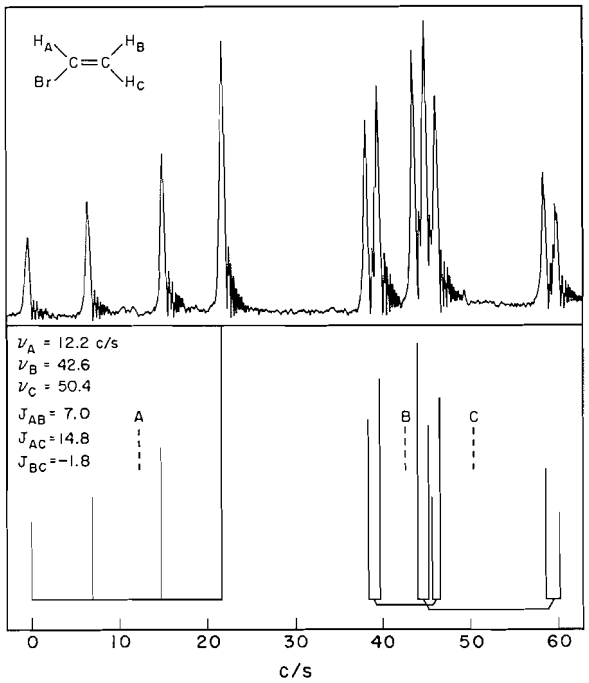

FIG. 1. Observed and calculated proton spectra of vinyl bromide at 60 Mc/sec. Increasing applied field is from left to right.

The opposite signs between J_{BC} and J_{AC} is not obvious from the spectrum at 60 Mc/sec because of the overlap of the two lines at about 45 cycles/sec in the observed spectrum. The relative positions of the lines can be fitted with all coupling constants of the same

†At 60 Mc/sec; notation of Fig. 1.

sign and with slight changes in the values of the parameters. However, at 40 Mc/sec there is no overlap and from the intensity distribution of the lines the other workers deduced the correct sign relationship. It is actually the pair of B lines at high field which decides the matter. In many of the spectra in Fig. 3 it is clear that in this pair the line at low field is much weaker than its neighbor. J_{BC} must be of opposite sign to J_{AC} and J_{AB} if this situation is to be met, together with the right intensities for the other lines arising from transitions of protons B and C.

(b) Relative Signs of J_{AB} and J_{AC}

Considerable labor is involved in the determination of the relative signs of the coupling constants even if a computer is available. It would be of value if there were a way of deciding, before the numerical work is begun, which of the coupling constants have the same sign. An examination of the spectra in Fig. 3 below suggests such a possibility. Note, first, that the most widely separated lines in the A region maintain a constant separation even though $\nu_C-\nu_B$ changes from positive to negative values. Then consider the line separations for the corresponding region for the case XBC given below in Part (*c*) (see also p. 134 of reference 7). One pair of lines (1 and 4 below) is separated by $|J_{AB}+J_{AC}|$ and since coupling constants are independent of chemical shift* this pair of lines should maintain a constant separation as $\nu_C-\nu_B$ is varied. If the line positions (as compared with the line intensities) of the vinyl bromide spectrum approximate sufficiently closely to an XBC spectrum, it follows that the pair of lines maintaining a constant separation in the A region of the observed spectra (X region in the case XBC) must be spaced by $|J_{AB}+J_{AC}|$. Evidently this is the case. In the seven spectra in Figs. 2 and 3 the two outside lines in the A region have a separation of between 21.7 and 22.2 cycles/sec (the variation can be attributed to experimental error and to the fact that we are really dealing with the case ABC). The other lines in the A region vary greatly in position as $\nu_C-\nu_B$ changes.

Hence $|J_{AB}+J_{AC}| \approx 22$ cycles/sec and if J_{AB} and J_{AC} are both less than 22 cycles/sec in magnitude, as seems clear, they must have the same sign. This fact reduces the four possible sign permutations in the three-spin system to two. If, in addition, the change in intensity distribution of the lines in the 40 cycles/sec region with change in $\nu_C-\nu_B$

It is, of course, well known that the chemical shift is directly proportional to the applied magnetic field while the coupling constants are independent of the latter. However, when the relative *electronic shielding of protons in a solute molecule is changed rather drastically by perturbations from solvent molecules, it is not inconceivable that the coupling constants will change somewhat because of a "selective perturbation" of the various bonds in the solute molecule. Experiments along these lines are being made.*

is taken into account, an a priori sign permutation can be arrived at by inspection of solvent effects on the spectrum.

(c) Combination Lines

The manner in which the relative chemical shifts of the protons in vinyl bromide are altered in different solvents is illustrated by the results shown in Table II. The

TABLE II

Proton chemical shifts of vinyl bromide in various solvents: concentration, 5 mole% (in cycles/sec at 60 Mc/sec, relative to external $CHCl_3$, and corrected for differences in bulk susceptibility)

Solvent	Chemical shift (cycles/sec)			
	Proton *A*	Proton *B*	Proton *C*	$\nu_C-\nu_B$
Benzene	114	149	145	−4
n-Hexane	62.5	96	100	+4
Acetone	48	82	91	+9

nature of these solvent effects has been discussed elsewhere (1, 14, 15). Figure 2 shows the proton resonance spectra of vinyl bromide in acetone and hexane solutions and Fig. 3 shows the corresponding spectra for different concentrations of vinyl bromide in benzene. The relative chemical shifts of protons H_B and H_C are roughly indicated. As $\nu_C-\nu_B$ becomes small enough, two extra lines appear in the A region (Fig. 3(*a*)). As $\nu_C-\nu_B$ is further decreased and made negative they approach one another in position, coalesce, and then separate again (Figs. 3(*b*)–3(*e*)). For purposes of discussion it is appropriate to consider this region of the spectrum as the X region of an XBC spectrum. The exact (ABC) calculation in Fig. 1 agrees well with the approximate XBC calculation

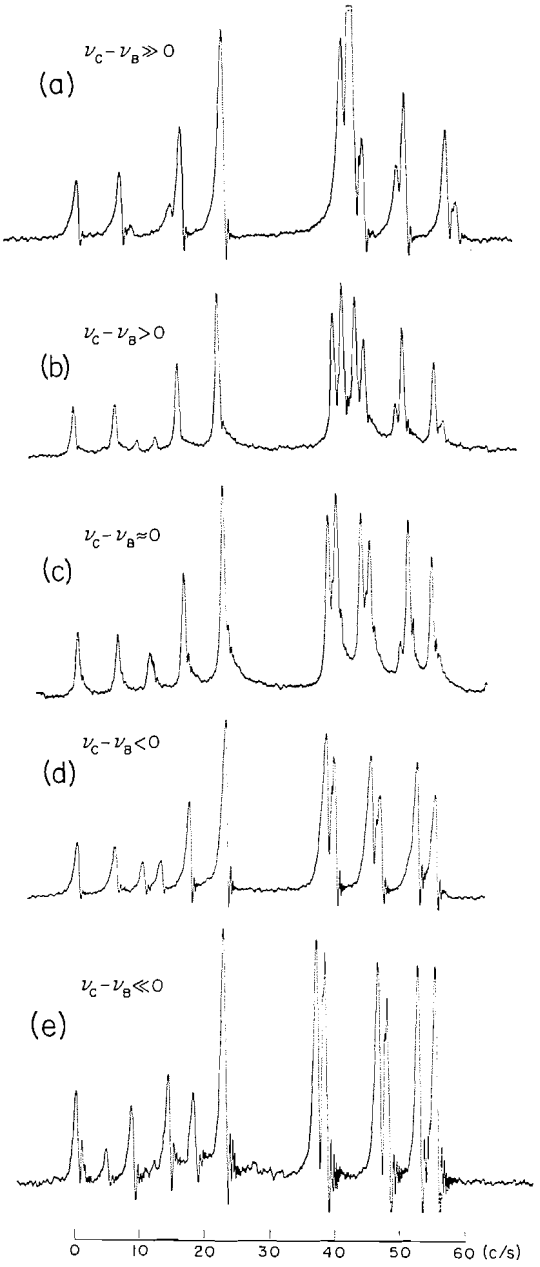

FIG. 3. Proton resonance spectrum of vinyl bromide at various concentrations in benzene. Approximate ratios (by volume) of vinyl bromide to benzene in the solutions are as follows: (*a*) 1:1, (*b*) ~2:3, (*c*) ~1:2, (*d*) ~1:3, (*e*) ~1:20.

in the prediction of the line *positions* in this region of the spectrum. The comparison in Fig. 5 between one of the observed spectra and the spectrum calculated using the parameters indicated is intended to show that the position of the predicted combination lines again agrees well with the *XBC* prediction. There is some disagreement in other

line positions but this only means that the chemical shifts employed in the calculated spectrum are not quite correct: the shift between protons B and C is no doubt not quite zero.

In the present notation the six transitions in the X (or A) region are then written relative to the origin of the lines as:

	Energy	Relative intensity
1.	$-\frac{1}{2}(J_{AB}+J_{AC})$	1
2.	D_+-D_-	$\cos^2(\phi_+-\phi_-)$
3.	$-D_++D_-$	$\cos^2(\phi_+-\phi_-)$
4.	$\frac{1}{2}(J_{AB}+J_{AC})$	1
5.	$-D_+-D_-$	$\sin^2(\phi_+-\phi_-)$
6.	D_++D_-	$\sin^2(\phi_+-\phi_-)$

The positive quantities D_+, D_- and angles ϕ_+, ϕ_- are defined by

$$D_+ \cos 2\phi_+ = \tfrac{1}{2}(\nu_C-\nu_B)+\tfrac{1}{4}(J_{AB}-J_{AC}),$$
$$D_+ \sin 2\phi_+ = \tfrac{1}{2}J_{BC},$$
$$D_- \cos 2\phi_- = \tfrac{1}{2}(\nu_C-\nu_B)-\tfrac{1}{4}(J_{AB}-J_{AC}),$$
$$D_- \sin 2\phi_- = \tfrac{1}{2}J_{BC}.$$

In these expressions $\nu_C-\nu_B$ has the same meaning as in the discussion above, namely, the relative chemical shift between protons C and B in cycles per second.

On this energy level scheme lines 1 and 4 are independent of $\nu_C-\nu_B$ and they are the lines at 0 and about 22 cycles/sec in the observed spectra. The predicted intensities are clearly wrong but they are much more sensitive to the correct wave functions than are the line positions and the main points of the discussion will still be valid.

Figure 4 gives a plot of the energy levels when $\nu_C-\nu_B$ is varied from 10 to 0 cycles/sec with J_{AB} = 7.0, J_{AC} = 14.8, J_{BC} = −1.8 cycles/sec. The plot as $\nu_C-\nu_B$ varies from 0 to −10 cycles/sec is the mirror image of Fig. 4. The combination lines 5 and 6 reach

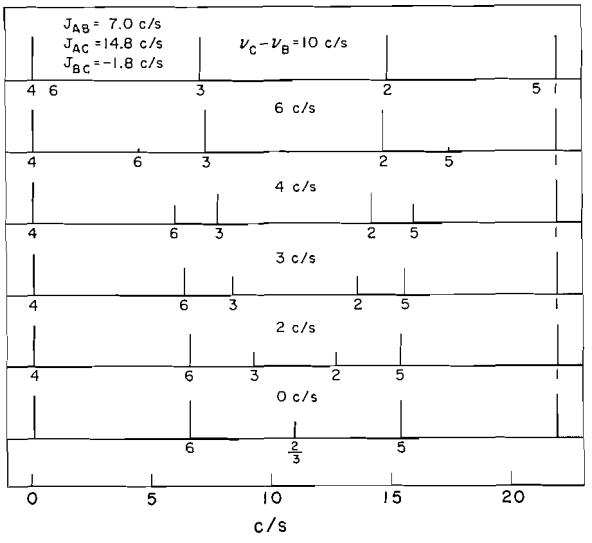

FIG. 4. The X part of an XBC spectrum calculated with the spin-coupling constants given and various values of the relative chemical shift $\nu_C-\nu_B$.

a measurable intensity for the given values of the coupling constants when $\nu_C - \nu_B$ is in the region of 5 cycles/sec. They derive this intensity at the expense of lines 2 and 3 (at about 7 and 15 cycles/sec in Fig. 1). When $\nu_C - \nu_B$ becomes less than 5 cycles/sec, lines 5 and 6 become effectively A lines. When $\nu_C - \nu_B = 0$, lines 2 and 3 coalesce, as is clear from the definitions of D_+ and D_-, and are in effect combination lines. When $\nu_C - \nu_B$ becomes less than zero, lines 2 and 3 separate and recede and eventually become A lines again, while 5 and 6 once more take on the role of combination lines. The sign of J_{BC} does not affect the predicted intensities.*

In the observed spectra this course of events is not followed exactly but is clearly similar. The combination lines arise at about the same value of $\nu_C - \nu_B$ (Fig. 3(a)) and coalesce when $\nu_C - \nu_B \approx 0$ (Fig. 3(c) and Fig. 5). The intensity distribution is, however,

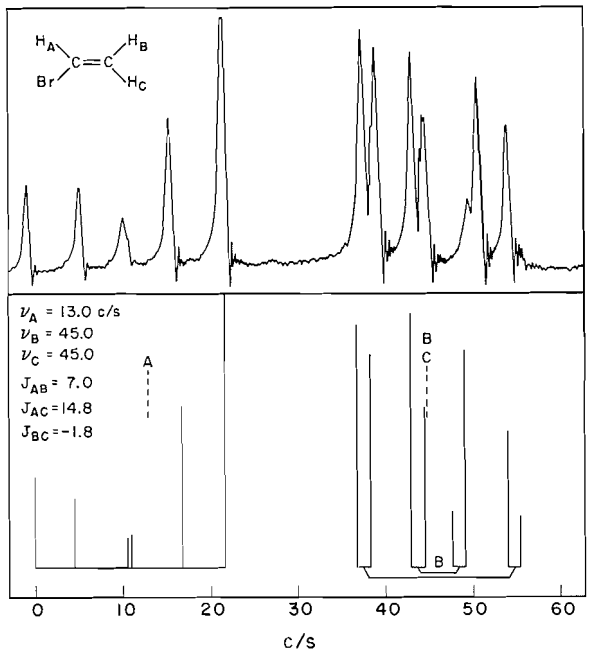

FIG. 5. The observed and calculated spectrum of vinyl bromide diluted in benzene. The spectrum was calculated as an XBC type with $\nu_C - \nu_B = 0$.

not in agreement with the XBC calculation. When $\nu_C - \nu_B$ becomes less than zero the effective combination lines are receding in the direction from which they appeared and have decreased in intensity.† The solvent effects are not large enough to eliminate them entirely.

**It should perhaps be noted that it is only when $\frac{1}{2}|J_{BC}| \approx \frac{1}{4}|J_{AB} - J_{AC}|$ that the combination lines have a large predicted intensity. This is immediately clear from the definitions and expressions for the intensities above. If, on the other hand, $|J_{BC}| \gg |J_{AB} - J_{AC}|$ the predicted spectrum would in effect be one of three equally spaced lines when $\nu_C - \nu_B = 0$. These lines would have the intensity ratio 1:2:1 and this could lead to a wrong determination of coupling constants. Such an effect has been discussed and illustrated with actual spectra for p-fluorotoluene (13).*

†In Fig. 3(e) the couplings between C^{13} and H^1 nuclei in the benzene solvent produce a "hump" in the 15–20 cycles/sec region of the spectrum and obscure the true intensity relations of the lines. This effect could be eliminated by using the expensive C_6D_6 as a solvent.

SOME FACTORS AFFECTING THE ZONE MOBILITY OF INORGANIC IONS DURING ELECTROMIGRATION IN PAPER[1]

R. A. BAILEY[2,3] AND L. YAFFE

ABSTRACT

A number of factors which affect the zone mobilities of inorganic ions were investigated. The influence of temperature was that expected from its effect on the conductance in free solution. The zone mobility tends to decrease, and the zone size to increase, with increasing migrant concentration. Excess foreign ions in the initial migrant zone can have a similar result. Experiments in the presence of the swelling agent thiourea indicate that swelling has at least a constant and perhaps a negligible influence on the obstructive factor. Finally, variation of the zone mobility with paper type was considered in relation to the ion-exchange capacity. Of the ions studied, only copper showed any correlation. Some observations were made using ion-exchange papers.

INTRODUCTION

The study of the electromigration of ions in moist paper has received considerable attention from the point of view of a separatory technique, but comparatively little has been done to try to understand the interactions between the ions and the porous supporting medium in this process. It is well known that many physical variables affect the zone mobility. However, very little work, aimed at investigating these variables thoroughly, has appeared. This paper will attempt to show quantitatively the effects of some of these variables with regard to inorganic ions.

The following are the factors which can have a direct influence on the zone mobility of an ion in paper.

1. Temperature

Since the conductance in free solution (and hence the mobility) of an ion increases with increasing temperature, a similar effect should be expected for the mobility in paper. This has been found by a few workers (1, 2, 3). Although the mobility values actually obtained may be questionable, the temperature coefficient seems to be similar in free solution and in paper, or about 2% per degree centigrade.

2. Absorbance

As the absorbance (the volume of liquid present per gram of paper) increases, so does the zone mobility. This factor was considered in a previous paper (4).

3. The Nature of the Supporting Medium

The zone mobility varies with the supporting medium, even when two papers are compared at corresponding values of absorbance. Although some effects might result from different fiber structure, this should be small, at least as long as only cellulose papers are considered. Most of the influence is more probably due to specific interactions of the ions with paper itself. This in turn could be different for various papers because of differences in the manufacturing process. In particular, the number of carboxyl groups which are present, and which can take part in ion-exchange reactions with the migrant ions, may differ from paper to paper. The fact that acid-washed paper yields larger

[1]*Manuscript received June 3, 1960.*

values of zone mobility than the same paper without acid washing (3, 5) has been interpreted as implying that exchange processes are important. Exchange presumably takes place more readily between the migrant cation and the metal cation impurity than between the migrant ion and the hydrogen ion which would be on the carboxyl group in the absence of impurities. Examples of the effect of ion-exchange capacity will be shown later.

4. The Concentration and Composition of the Migrant Solution

The concentration of the migrant solution itself can have an effect on the resulting migration, but most studies on this have taken place in complex-forming media. Miller (6), Sato (7), and Strain (8) claimed that if the migrant ion is not adsorbed, the zone mobility is independent of the concentration unless this is greater than that of the background electrolyte solution. When it is greater, the size of the spot increases markedly, and the zone mobility decreases. In cases where small amounts of the migrant are strongly adsorbed by the paper, an increase in migrant concentration may result in an increased over-all mobility because of the more rapid motion of the non-adsorbed part. Such cases usually exhibit trailing. The increase in size of the zone when the migrant concentration exceeds that of the background electrolyte has been noted many times, and has been predicted theoretically by Edward (9).

The actual composition of the migrant solution apart from its concentration may be important also, since interactions between the components may give rise to their anomalous behavior. This may be an effect of ionic strength, or a specific chemical interaction, but the latter need not concern us here.

5. The Background Electrolyte Solution

The ionic strength and viscosity of the background electrolyte solution can affect the mobility of an ion moving in it. This will occur in free solution as well as in paper, as was brought out in a previous communication (4) where the calculation of zone mobilities was discussed. A more important effect of the background solution lies in its ability to form complexes with the migrant ions. If complexing occurs, the mobility observed will depend on the stability of the complex formed, as well as on the mobility of the complexed and non-complexed species present. It can be calculated in principle.

Berbalk and Schier (10) showed that the zone mobility of a weakly dissociated substance such as a weak acid depends on its degree of dissociation b. The zone mobility is given by

$$U_z = b\rho U_F \qquad [1]$$

where ρ is a factor for the slowing of the ions by the paper, and U_F is the actual speed of the ion formed by dissociation. For a weak acid, for example, this could be determined from the limiting conductance of the anion. Equation [1] is equivalent to the statement that the zone mobility is given by the speed of the mobile form and the fraction of time which the migrant spends in that form.

We can extend this to complex-forming systems where a number of mobile species are present in a rapid dynamic equilibrium. In the simplest case, suppose the forms present are M_1 and M_2, and the fraction of the migrant present as M_1 is b_1, and as M_2 is $b_2 = 1-b_1$. If the mobilities in free solution are U_{F_1} and U_{F_2}, respectively, then

$$\begin{aligned} U_z &= \rho[b_1U_{F_1}+b_2U_{F_2}] \\ &= \rho[b_1(U_{F_1}-U_{F_2})+U_{F_2}] \end{aligned} \qquad [2]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

if we neglect specific adsorption effects. If n species are present,

$$[3] \qquad U_z = \rho\left[\sum_{i=1}^{n} b_i U_{F_1}\right].$$

This takes into account adsorbed and non-ionized forms, since for these $U_F = 0$.

In practice, values of b and the free solution mobility of complex species usually are not known, so that this equation cannot be used to estimate the zone mobility. However, if more were known about ρ, this treatment might provide a means of obtaining information about the stabilities of complexes.

Extraneous factors such as evaporation and flow of background electrolyte solution in the strip can affect the zone mobility very much. Unless such factors are eliminated or corrected for, the zone mobilities obtained have no meaning. The chief factors of this sort which may be encountered are electroosmotic flow of electrolyte solution, flow of electrolyte from the ends toward the center of the strip (due to either evaporation from the strip or initial unsaturation of it), changes in concentration of electrolyte in the strip due to evaporation and non-uniform absorbance. These are problems of experimental technique.

From a very simple model (11) it can be shown that the zone mobility U_z may be given by the expression

$$[4] \qquad U_z = \rho U_F$$

where U_F is the mobility in free solution, and ρ is the obstructive factor which accounts for the tortuous path followed by a particle migrating through a medium such as wet paper. If adsorption effects are neglected, a semiempirical expression can be deduced for the obstructive factor (4, 12). For fibers which do not swell in the presence of the solution, this is

$$[5] \qquad \rho = \alpha\left(\frac{a}{a+v_s}\right) = \alpha\epsilon$$

where a is the absorbance, v_s is the specific volume of the fibers, and ϵ is the void fraction or porosity. Here, α is a constant equal to 0.96. For fibers which do swell,

$$[6] \qquad \rho = \alpha\left(\frac{a-2v_sX}{a+v_s}\right)$$

where X is the fractional increase in volume on swelling. The latter expression would be expected to apply to cellulose papers in aqueous solution, but X is not known.

We may define an apparent obstructive factor

$$[7] \qquad \rho_{app} = \frac{U_z}{U_F}.$$

The term ρ_{app} includes all factors which tend to slow an ion moving through a porous medium—adsorption as well as mechanical obstruction. This gives a means of comparing the hindrance encountered by different ions moving under various conditions.

If r represents an adsorption or hindrance factor,

$$[8] \qquad \rho_{app} = r\rho$$

where ρ is the mechanical obstructive factor calculated from equation [5] or [6]. For a given paper, r may vary with the migrant and the background electrolyte. In effect, r represents the fraction of time during which the ion is free to move.

Attempts have been made to account for adsorption effects by means of the chromatographic R_f factor, which is defined as

$$R_f = \frac{\text{distance moved by zone of substance}}{\text{distance moved by advancing solvent front}}.$$

This was used by Yasunaga and Shimomura (13) and Pucar and Jakovac (14). Since the conditions in paper chromatography and electromigration are not the same, and since the R_f factor is notoriously variable with minor changes in experimental technique, this is not satisfactory. An approach by Maki (15) based on partition chromatography is of interest, but it has not been sufficiently tested. Thus, although there are available a few values of ρ_{app} obtained under conditions such that all of the variables concerned were fixed (4), there is as yet no independent means of obtaining a value for r even if ρ can be calculated.

EXPERIMENTAL

A closed strip technique was used in which the paper was placed between metal plates and kept at a constant temperature. The paper was moistened to the desired absorbance by means of a pipette. Electrodes were placed in direct contact with the paper, and the electrolytic products were prevented from entering the central part of the strip by having suitable buffer solutions at the ends. Normally, no motion of background electrolyte could be detected.

Radioactive migrants were detected by measuring 1-cm broad segments of the strip with a Geiger counter, while inactive migrants were located by suitable chemical means. The migrant concentrations were very low, and small volumes were used. With inactive materials, 10 microliters of 0.001 M solution were used. The concentrations of the radioactive solutions were much lower.

Complete details of the technique and apparatus are given in a previous publication (4).

RESULTS AND DISCUSSION

The variation of zone mobility with temperature in several systems is illustrated in Fig. 1. The effect is that expected from the variation of the conductance. The temperature coefficient over the range 25° C to 39° C is about 2% per degree centigrade in all cases except that of Cu(II) moving in an oxalic acid background electrolyte solution. Here, the copper is present as a negatively charged complex. The increase in zone mobility (expressed as a negative number since the motion is anionic) is only 1.6% per degree centigrade, appreciably less than in the other examples. This would be the expected behavior if the complex were less stable at higher temperatures. There seems to be no change in the interaction of the ions with the paper over this temperature range. In those cases for which U_F could be found, the value of ρ_{app} did not change with temperature. This is shown in Table I.

The effect of migrant concentration was studied for Na^+ in 2.36 M acetic acid. The results are shown in Figs. 2 and 3. The first of these shows that the zone mobility decreases with increasing migrant concentration. This decrease is linear with the square root of the concentration, at least as long as this is greater than the ionic strength of the background electrolyte. In Fig. 3, the size of the zone relative to that given by 'carrier-free' Na^+ also yields a plot which is linear with the square root of the Na^+ concentration in this region.

†Zone elongated with trailing.

zone is shown. The behavior can be due only to ionic strength effects here, since the moving zone of sodium is freed rapidly from excess H^+ and Cl^- ions. When the HCl concentration is increased to 0.12 *M*, the zone mobility decreases appreciably, while the zone itself becomes longer. Most of this effect is due to a low concentration tail from the main peak, which does not seem to be influenced very much.

Thiourea is a substance which, in aqueous solution, enhances the swelling of cellulose fibers. Determination of values of ρ_{app} in the presence of thiourea accordingly might give some information about the effect of swelling on a migrating ion. Values of ρ_{app} for Cs^+ and Na^+ in 1.18 *M* acetic acid are compared with those in 1.18 *M* acetic acid in 1 *M* thiourea in Table IV. As is evident, there is no increase in hindrance when

thiourea is present for any of the three papers used. There may even be a slight decrease in those which are not hardened. This may be interpreted as indicating that the swelling is accompanied by an increase in the fractional volume of the fibers now permeable to the ions (16, 17), or to reduced adsorption which counteracts the effects of swelling. However, these results are in agreement with those of Vacik *et al.* (18, 19) which indicate that there is no decrease in void fraction, and hence in ρ, with wet (swollen) paper.

The above authors have studied a number of chromatography papers, and for Whatman No. 52, that used for most of our experiments, they found that ϵ, the porosity or void fraction, of the wet paper was 0.74. The value of ϵ calculated from equation [5] is 0.77

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at the appropriate absorbance (2.05 ml/g). Although no value of X is known, any calculation using equation [6] would give a lower value for ρ. A value of X of 0.2, for instance, a reasonable estimate from previous work, would yield a result of 0.68. Values of X determined empirically (4) include adsorption effects as well as swelling. Moreover, the results of these workers indicate that the void fraction of wet paper is greater than that of dry paper, implying that, whatever swelling may occur, it does not decrease the void fraction on a molecular scale, and hence does not contribute to enhanced mechanical hindrance. This is in agreement with the values obtained for ρ_{app} in the presence of thiourea. These data indicate that the mechanical obstructive factor may be calculated reasonably well from equation [5], even for cellulose papers, and the specific effects of adsorption may be taken care of in the hindrance factor r. It remains possible that the fraction of the fibers, permeable to the migrant ions (16, 17), may show some specific nature.

For a given ion and background electrolyte, the zone mobility, and hence also ρ_{app}, may vary with the type of paper used, even if measurements are carried out at the same value of absorbance. Data on this are given in Table V. Of the properties of the

paper which may influence the mobility of an ion, adsorption by ion-exchange processes seems to be one of the most probable (15, 20). The values of the exchange capacity included in the table were determined by the method of Ultee (21); this is claimed to give a measure of the carboxyl content, and hence the ion-exchange capacity, of the paper. As is evident, the effects on ρ_{app} are very specific. There is no correlation between ρ_{app} and the exchange capacity except in the case of Cu(II). With this ion, ρ_{app} decreases roughly linearly as the exchange capacity increases (Fig. 4). Copper is more hindered than the other ions considered (ρ_{app} is smaller), indicating that more interaction is taking place. It appears that copper undergoes a different type of reaction with the paper and, although this seems to take place with the ion exchange sites, it may not be an ion-exchange process.

Jakovac and Lederer (22) have proposed from electromigration studies that copper, like a few other ions, forms complexes with cellulose. However, evidence indicates that these form with the hydroxyl groups on adjacent carbon atoms, rather than with carboxyl groups which are the chief ion-exchange sites.

Copper is also more hindered than zinc in Reeve Angel 934AH glass fiber filter paper. The zone mobilities and apparent obstructive factors of these ions in acetic acid are given in Table VI; the calculated obstructive factor is 0.86. This is considerably larger

NOTE: Absorbance 3.96 ml/g, 25±0.5° C.

than any value of ρ_{app} for these ions, and indicates a good deal of adsorption. However, in cellulose acetate paper,* zinc and copper have similar mobilities. Although accurate measurements could not be made because of electroosmosis and difficulties in establishing a known, uniform absorbance, ρ_{app} was fairly close to the calculated value of ρ for copper, zinc, and sodium in acetic acid background electrolyte.

Further experiments were carried out in paper loaded with Amberlite ion-exchange resins, and with cellulose ion-exchange papers. In Reeve Angel SA-2 papers which have strong cation exchange properties, cobalt, zinc, copper, and cesium all had very low mobilities in acetic acid. The mobilities in Reeve Angel WA-2 paper, a weakly acid exchanger, were higher under similar conditions, implying weaker adsorption. This is reasonable, since the carboxyl groups of this material are not strongly ionized in an acid solution. The bivalent ions showed similar behavior in Whatman P20 cellulose phosphate paper, and in Whatman CM50 carboxymethyl cellulose paper (strong and weak cation exchangers, respectively), but the univalent ions were comparatively faster. In the former, the zone mobility of Na^+ was about 10×10^{-5} cm^2 v^{-1} sec^{-1} in 2.36 M acetic acid at an absorbance of 0.98 ml/g. All mobilities in these materials were much lower than in ordinary papers, but this cannot be attributed completely to ion-exchange adsorption. In Whatman DE 20 diethylaminoethyl cellulose paper, an anion exchanger, the zone mobility of Na^+ was only 8.3×10^{-5}, and that of Zn^{++} and Cu^{++} about 3.7×10^{-5} and 1×10^{-5} cm^2 v^{-1} sec^{-1}, respectively, under similar conditions. These figures are not too significant because of factors such as electroosmosis, but they do show that even in this material copper is more hindered than zinc.

In anion-exchange resin loaded paper (Reeve Angel SB-2) the zone mobilities of cations are still much lower than in ordinary paper, although they are larger than in the cation-exchange papers. Jakubovic *et al.* (23) have reported some ionic mobilities in ion-exchange resins which indicate that bivalent ions in particular are hindered a great deal.

Most of the above work in ion-exchange papers, and in cellulose acetate, is only qualitative. Flow of background electrolyte is often different in these materials from that in ordinary paper; in some cases this was clearly evident from the visible distribution of liquid in the strip after electromigration. This was especially marked with cellulose acetate. Although in this instance the flow was measured with H_2O_2, uncertainties in corrections obtained from such measurements, and the non-uniform absorbance which was set up, make the figures obtained for U_z have little quantitative value. They do indicate, however, that this material offers less hindrance by non-mechanical effects (adsorption) than do the other materials studied. The zones, especially of sodium, were very sharp.

Ion-exchange papers may prove useful for separations, although the higher obstruction which they in general seem to possess is a disadvantage. A few preliminary experiments with cobalt and zinc in Reeve Angel SA-2, WA-2, and SB-2 papers showed that separations were possible in suitable complexing agents, but ordinary papers gave as good or better results.

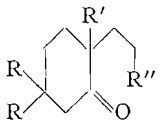
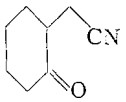
LA RÉACTION DE REFORMATSKY APPLIQUÉE À L'OXO-2 CYCLOHEXANE-PROPIONITRILE ET À DES CÉTO-NITRILES ANALOGUES[1]



F. BRUDERLEIN,[2] HÉLÈNE BRUDERLEIN,[3] H. FAVRE, R. LAPIERRE[3] ET Y. LEFEBVRE[4]



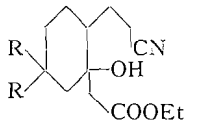
RÉSUMÉ

L'action du bromo-acétate d'éthyle et du zinc sur l'oxo-2 cyclohexane-propionitrile, le diméthyl-4,4 oxo-2 cyclohexane-propionitrile et l'oxo-2 cyclohexane-acétonitrile est discutée; en plus de l'hydroxy-ester-nitrile attendu, on obtient divers composés: lactones-esters et acides carboxyliques. Les acides méthylène-2 cyclohexane-propionique, diméthyl-4,4 méthylène-2 cyclohexane-propionique et méthylène-2 cyclohexane-acétique sont décrits.

Pour des fins de synthèse dans le domaine des terpènes nous avons examiné les produits résultant de l'action du bromo-acétate d'éthyle et du zinc sur quelques céto-nitriles: oxo-2 cyclohexane-propionitrile (I) (1), diméthyl-4,4 oxo-2 cyclohexane-propionitrile (II) et oxo-2 cyclohexane-acétonitrile (III) (2). Baumgarten et Eifert (3) ont rapporté que la réaction de Reformatsky appliquée à l'acétyl-4 valéronitrile conduisait au composé normalement attendu, l'ester éthylique de l'acide cyano-6 hydroxy-3 diméthyl-3,4 hexanoïque, avec un rendement de 35%.

Nous attribuons la constitution II au produit de monocyanoéthylation de la diméthyl-3,3 cyclohexanone selon la méthode de Stork (1), parce que l'hydrolyse de ce céto-nitrile conduit à l'acide cétonique IV, p.f. 61–62°, que l'on obtient également par hydrolyse du composé V, issu de la cyanoéthylation de l'ester éthylique de l'acide diméthyl-4,4 oxo-2 cyclohexane-carboxylique.[5] La constitution du composé V est établie par le fait que ce céto-ester ne donne plus de réaction colorée avec le chlorure ferrique alcoolique: il n'est donc plus énolisable (voir (6)).

III



I	R = R' = H	R'' = CN	
II	R = CH_3	R' = H	R'' = CN
IV	R = CH_3	R' = H	R'' = COOH
V	R = CH_3	R' = COOEt	R'' = CN

La réaction de Reformatsky, à partir des cétones cyanoéthylées I et II, conduit à trois types de composés facilement séparables les uns des autres: 1) les hydroxy-ester-nitriles VI et VII; malgré plusieurs tours de distillation ils n'ont pu être obtenus tout à fait purs, mais leurs spectres infrarouges montrent bien leurs bandes nitrile, hydroxyle et ester; 2) les lactone-esters IX et X, caractérisées par une bande unique dans la région carbonyle du spectre infrarouge (1730 cm^{-1}, ester et δ-lactone); 3) des acides carboxyliques:

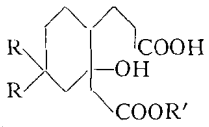
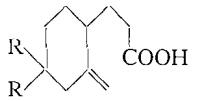
[4]*Boursier du Conseil National de Recherches du Canada 1953–1957. Adresse actuelle: Ayerst, McKenna & Harrison Ltd., Montréal, Qué.*
[5]*Pour la synthèse de ce céto-ester, voir (4, 5).*

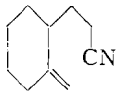
(*a*) dans la série diméthylée l'acide est solide, de formule $C_{13}H_{22}O_5$, p.f. 144.5–145.5°; nous lui attribuons la constitution XIII bien supportée par un spectre infrarouge; il se décompose par chauffage en acide diméthyl-4,4 méthylène-2 cyclohexane-propionique (XV), dont la constitution est discutée plus loin.



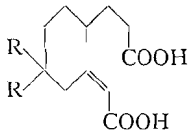
(*b*) dans la série non méthylée les acides par chauffage se décomposent soit en acide méthylène-2 cyclohexane-propionique (XIV) dont la constitution est prouvée plus loin, soit en (éthoxycarbonyl-méthyl)-8*a* oxo-2 perhydro-chromanne (IX), identique à celui obtenu plus haut en 2); comme ces acides sont des huiles qui résistent à toute tentative de cristallisation leur nature exacte n'a pu être déterminée. La fraction acide qui se décarboxyle en acide à double liaison semicyclique pourrait renfermer soit le diacide hydroxylé XI par analogie avec la série diméthylée, soit un diacide déshydraté (du type XVII avec double liaison sur le cycle), soit encore l'acide VIII; tous ces composés sont susceptibles d'engendrer par chauffage une double liaison semicyclique (7, 8, 9, 10, 11). L'acide qui engendre la lactone IX serait l'ester XII. Ces fractions acides sont certainement des mélanges des isomères cis et trans.



VI R = H
VII R = CH_3



VIII R = H R′ = H
IX R = H R′ = C_2H_5
X R = CH_3 R′ = C_2H_5



XI R = R′ = H
XII R = H R′ = C_2H_5
XIII R = CH_3 R′ = H

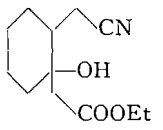
XIV R = H
XV R = CH_3

XVI

XVII R = H
XVIII R = CH_3

Les deux acides à insaturation semicyclique XIV et XV ont dans leurs spectres infrarouges les bandes caractéristiques, 1645 et 890 cm^{-1}, de la double liaison méthylénique, comme Stauffacher et Schinz (11) l'ont mentionné pour l'acide diméthyl-6,6 méthylène-2 cyclohexane-propionique. La formaldéhyde formée, selon le mode opératoire de Seidel, Schinz et Ruzicka (12), indique une teneur de 87% en liaison méthylénique chez l'acide XIV; cet acide fut obtenu également, avec un rendement global de 7–10%, en faisant réagir le méthylène-triphényl-phosphorane (13)[6] sur l'oxo-2 cyclohexane-propionitrile (I) et en saponifiant le nitrile méthylénique XVI brut.

L'hydrolyse (hydroxyde de potassium–méthanol) des lactone-esters IX et X conduit à des diacides que nous formulons comme XVII et XVIII rsepectivement, après examen de leurs spectres ultraviolets caractéristiques d'acides cyclohexylidène-acétiques (15) (XVII: λ_{max} 220.5 mμ, log ϵ = 4.11; XVIII: λ_{max} 221.5 mμ, log ϵ = 4.10) et de leurs spectres infrarouges montrant deux sortes de groupes carbonyles.



La saponification de l'hydroxy-ester-nitrile XI conduit à un acide brut, p.f. 124–137°, qui, traité par de l'acide chlorhydrique conduit à un carboxyméthyl-8*a* oxo-2 perhydro-chromanne (VIII), p.f. 150°; cette constitution est établie par spectroscopie infrarouge et par titrage alcalimétrique. Cet acide se décarboxyle difficilement par

[6]*Pour cette nomenclature, voir (14).*

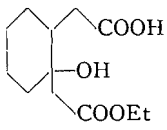
For personal use only.

chauffage en acide méthylène-2 cyclohexane-propionique (XIV) (rendement de 20%) et en divers autres composés que nous n'avons pas étudiés plus à fond. La pyrolyse de l'acide brut, p.f. 124–127°, mène à l'acide XIV avec un rendement voisin de 60%; il se forme également dans cette réaction des traces de γ-lactones et de δ-lactones, décelées par spectroscopie infrarouge.



À partir de l'oxo-2 cyclohexane-acétonitrile (III) la réaction de Reformatsky donne trois composés également: l'hydroxy-ester-nitrile XIX, dont le spectre infrarouge est typique pour ces groupes fonctionnels; l'ester lactonique XX, dont le spectre infrarouge présente les deux bandes caractéristiques de la γ-lactone et de l'ester; et une fraction acide, probablement XXI, qui donne XX par chauffage. L'hydrolyse de l'hydroxy-ester-nitrile XIX donne un mélange d'acides (diacide hydroxylé correspondant à XXI et acides non saturés XXII, selon le spectre infrarouge et le titrage alcalimétrique) qui se décarboxylent pour donner l'acide méthylène-2 cyclohexane-acétique (XXIII); cet acide a été caractérisé par son sel de benzyl-iso-thio-uronium; il est identique à celui que l'on obtient à partir du nitrile XXIV (préparé par la réaction de Wittig (13) au départ du céto-nitrile III). L'ozonolyse de cet acide XXIII confirme sa structure; le spectre infrarouge présente les bandes (1645 et 892 cm^{-1}) caractéristiques de la double liaison semi-cyclique.

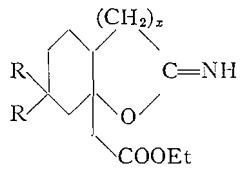
XXI

XXII



XXIII

XXIV

La façon dont les divers produits de réaction se forment doit être soulignée. Une fois la condensation terminée et le composé zincique décomposé par de l'acide sulfurique on ne retrouve dans la phase organique, lors des extractions usuelles, que l'hydroxy-ester-nitrile. L'ester-lactone et la fraction acide se séparent peu à peu de la phase aqueuse acide sous forme d'une huile rouge; il faut donc admettre que ces derniers composés, solubles dans les solvants organiques, n'existent pas comme tels au moment de la décomposition du composé zincique, sans quoi on les retrouverait dans la phase organique à côté de l'hydroxy-ester-nitrile; nous formulons un composé intermédiaire basique formé dans le milieu anhydre requis par la condensation, puis retenu dans les eaux acides sous forme de sel, s'hydrolysant enfin petit à petit en lactone-ester et en acides carboxyliques; ce composé basique est une imino-O-lactone du type:[7]

R = H ou CH_3

x = 1 ou 2

[7]*Les sels des imino-éthers s'hydrolysent en esters en milieu aqueux lorsque le catalyseur est un acide minéral fort (16, 17, 18, 19).*

PARTIE EXPÉRIMENTALE[8]

1. Diméthyl-4,4 oxo-2 cyclohexane-propionitrile (II)

1.1. La diméthyl-3,3 cyclohexanone est préparée d'après la méthode de Frank et Hall (20), selon le mode opératoire décrit en (21) pour la préparation de l'homocamphre.

1.2. Selon la technique de Cohen et Witkop (22) on prépare avec un rendement de 93.5% la N-(diméthyl-5,5 cyclohexényl-1) pyrrolidine, à partir de diméthyl-3,3 cyclohexanone et de pyrrolidine. C'est un liquide incolore, p. é. 125° sous 18 mm, brunissant très rapidement. Calculé pour $C_{12}H_{21}N$: C, 80.38; H, 11.81; N, 7.81%. Trouvé: C, 80.47; H, 11.55; N, 7.97%. Cette ène–amine est cyanoéthylée selon la technique décrite en (22). On obtient avec un rendement de 73% le *diméthyl-4,4 oxo-2 cyclohexane-propionitrile* qui, purifié par distillation, présente les constantes: p. é. 97–98° sous 0.55 mm, $n_D^{29} = 1.4640$. Calculé pour $C_{11}H_{17}NO$: C, 73.70; H, 9.56; N, 7.81%. Trouvé: C, 73.94; H, 9.47; N, 7.92%. Spectre infrarouge: —CN, 2250 cm^{-1}; =C=O, 1700 cm^{-1}. Dinitro-2,4 phénylhydrazone: aiguilles orangé, p.f. 148.5–149.5° (CH_3OH–$CHCl_3$). Calculé pour $C_{17}H_{21}N_5O_4$: C, 56.81; H, 5.89; N, 19.49%. Trouvé: C, 56.90; H, 5.93; N, 19.46%.

1.3. Le céto-nitrile précédent (1 g) est chauffé à reflux avec 625 mg d'hydroxyde de potassium dans 6.25 ml d'eau pendant 20 heures. Après refroidissement, on extrait par de l'éther pour éliminer les composés neutres, refroidit la solution aqueuse alcaline à 5°, ajoute lentement de l'acide chlorhydrique concentré refroidi à 5° jusqu'au virage bleu du rouge congo. On extrait l'acide libéré par de l'éther; on lave deux fois la solution éthérée avec de l'eau, sèche sur sulfate de sodium et distille l'éther; le résidu est recristallisé dans un mélange d'éther et d'éther de pétrole (p. é. 40–60°): on obtient 1 g d'acide diméthyl-4,4 oxo-2 cyclohexane propionique (IV), p.f. 61–62°, ne donnant pas de dépression avec l'acide préparé en 2.

2. Acide diméthyl-4,4 oxo-2 cyclohexane-propionique (IV)

On ajoute à 58 g de diméthyl-4,4 oxo-2 cyclohexane-carboxylate d'éthyle, dans 77 g de *tert*-butanol, 2 ml de Triton B (solution aqueuse d'hydroxyde de benzyl-triméthyl-ammonium à 40%), puis, goutte à goutte, en maintenant la température à 25°, 20 g d'acrylo-nitrile. Il y a précipitation abondante; on fait passer le précipité en solution par adjonction de 40 ml de benzène anhydre. Après 4 heures d'agitation le catalyseur est neutralisé par de l'acide chlorhydrique; la solution benzénique est lavée à neutralité. On distille le solvant et recristallise le résidu dans un mélange d'éther et d'éther de pétrole: 73 g (98% de rendement) d'éthoxycarbonyl-7 diméthyl-4,4 oxo-2 cyclohexane-propionitrile, p.f. 63°. Calculé pour $C_{14}H_{21}NO$: N, 5.57%. Trouvé: N, 5.62%. On hydrolyse le tout en chauffant à reflux avec 82.5 g d'hydroxyde de potassium dans 825 ml d'eau. Après 24 heures de chauffage on isole comme plus haut en 1.3, 55 g d'acide diméthyl-4,4 oxo-2 cyclohexane-propionique brut, p.f. 59°. On en prépare l'ester éthylique (méthode ordinaire à l'alcool éthylique et l'acide sulfurique) que l'on saponifie (méthode habituelle par KOH) et obtient ainsi l'acide plus pur, p.f. 62°; P.M. calculé 198.27; trouvé 197.3. Calculé pour $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. Trouvé: C, 66.43%; H, 9.05%.

[8]*Les points de fusion (p.f.) ont été déterminés en tubes capillaires, le thermomètre étant étalonné avec des substances de point de fusion connu (Bureau des Standards de Washington). Les spectres infrarouges ont été déterminés à l'aide d'un spectromètre Perkin–Elmer, modèle 21, optique* NaCl*; les liquides étaient sous forme de film, les solides en suspension dans le nujol; seules les bandes servant à l'identification des composés sont indiquées: les valeurs en cm^{-1} correspondent aux maxima d'absorption, sauf celles qui correspondent aux groupes* —OH *des acides carboxyliques et qui montrent la région entière de l'absorption. Les spectres ultraviolets ont été déterminés au moyen d'un spectromètre Beckman DK1, dans l'éthanol 95%. Les poids moléculaires (P.M.) des acides ont été déterminés par titrages alcalimétriques. Les analyses sont de Geller Laboratoires, Hackensack, N.J., et de W. Manser, Herrliberg, Suisse.*

Dinitro-2,4 phénylhydrazone de l'ester méthylique.—En traitant l'acide oxo-2 cyclohexane-propionique par une quantité équimoléculaire de dinitro-2,4 phénylhydrazine dans 20 fois son poids de méthanol contenant 4% d'acide chlorhydrique concentré on obtient la dinitro-2,4 phénylhydrazone de l'ester méthylique correspondant, aiguilles jaunes (MeOH), p.f. 110–111°. Calculé pour $C_{18}H_{24}N_4O_6$: C, 55.09; H, 6.16%. Trouvé: C, 55.15; H, 6.07%.

3. Action du bromo-acétate d'éthyle sur l'oxo-2 cyclohexane-propionitrile en présence de zinc

3.1. Dans un ballon rond à deux tubulures, surmonté d'un refrigérant et d'une ampoule à robinet, on introduit 33.3 g (0.510 mole) de zinc en fine grenaille, préalablement lavé avec de l'acide chlorhydrique à 5% et à l'eau et séché sous 12 mm à 100° en présence d'un petit cristal d'iode. On fait couler dans le ballon 40 ml du mélange: 70 g (0.463 mole) d'oxo-2 cyclohexane-propionitrile, 92.7 g (0.555 mole) de bromo-acétate d'éthyle, 140 ml de benzène et 93 ml de toluène anhydres. On amorce la réaction en chauffant légèrement et on fait couler, goutte à goutte, le reste du mélange, de façon à maintenir une douce ébullition. À la fin de l'addition on reprend le chauffage et maintient l'ébullition à reflux durant 2 heures 30 minutes. On abandonne ensuite la solution à 25° pendant 12 heures. On projette alors le tout sur 800 g de glace concassée et on ajoute 750 ml d'acide sulfurique 2 *N*. On obtient deux phases limpides que l'on agite vivement, sépare par décantation et examine séparément.

3.2. Examen de la phase organique.—Elle est lavée successivement par des solutions d'acide sulfurique à 5%, de carbonate de sodium à 10% et par de l'eau jusqu'à neutralité. Après séchage sur sulfate de sodium, on élimine les solvants par distillation et rectifie le résidu sous vide; fraction I: p. é. 96–149° sous 0.6 mm, 7 g, formée principalement par le céto-nitrile non entré en réaction; fraction II: p. é. 149–152° sous 0.6 mm, 21.9 g, constituée essentiellement de l'*ester éthylique de l'acide (cyano-2 éthyl)-2 hydroxy-1 cyclohexane-acétique* (VI), p. é. 128–130° sous 0.15 mm, n_D^{23} = 1.4782, après redistillation. Calculé pour $C_{13}H_{21}NO_3$: C, 65.24; H, 8.85; N, 5.85%. Trouvé: C, 65.92; H, 8.96; N, 5.04%. Spectre infrarouge: —OH (—COOH), 3400–2400 cm^{-1}; —OH (alcool), 3500 cm^{-1}; —CN, 2552 cm^{-1}; =CO ester, 1730 cm^{-1}.

3.3. Examen de la phase aqueuse.—Elle laisse déposer peu à peu une huile rouge, qui, après 8 heures, est extraite par de l'éther. La solution éthérée est lavée avec une solution d'hydroxyde de sodium à 10%, ce qui permet d'en extraire une fraction acide. Ce qui reste dans l'éther est isolé, après séchage de la solution et évaporation du solvant, et rectifié par distillation: l'*(éthoxycarbonyl-méthyl)-8a oxo-2 perhydro-chromanne* (IX) est un liquide incolore, p. é. 138° sous 0.4 mm, n_D^{27} = 1.4842. Calculé pour $C_{13}H_{20}O_4$: C, 64.97; H, 8.39. Trouvé: C, 64.82; H, 8.26%. Spectre infrarouge: =CO ester et δ-lactone, 1730 cm^{-1}.

La fraction acide est isolée en acidifiant les eaux alcalines et en extrayant l'huile formée par de l'éther. L'huile obtenue après distillation de l'éther ne cristallise pas. Par chauffage à 165°, sous vide de 0.1 mm, cette fraction acide se décompose en acide *méthylène-2 cyclohexane-propionique* (XIV) (voir plus loin en 5.2).

3.4. Au cours de certaines réactions de Reformatsky la fraction acide ne se décarboxyle pas en acide méthylène-2 cyclohexane-propionique, mais conduit à la lactone ester IX mentionnée en 3.3, p. é. 135° sous 0.3 mm, n_D^{26} = 1.4842 (identité prouvée par spectres infrarouges). Le spectre infrarouge de cette fraction acide montre une bande à 3520 cm^{-1} (—OH, alcool), une région d'absorption prononcée de 3400 à 2500 cm^{-1} (—OH, acide carboxylique), une bande large dans la région du groupe carbonyle, maximum à 1730 cm^{-1}, provenant des groupes —COOH et COOEt.

4. Carboxyméthyl-8a oxo-2 perhydro-chromanne (VIII)

On chauffe à l'ébullition à reflux durant 24 heures 5 g d'ester éthylique de l'acide (cyano-2 éthyl)-2 hydroxy-1 cyclohexane-acétique avec 5 g d'hydroxyde de potassium dans 50 ml d'eau. Après refroidissement on extrait par de l'éther pour éliminer les parties neutres; on acidifie par de l'acide chlorhydrique concentré la solution alcaline et on extrait les acides précipités par de l'éther; la solution éthérée est lavée à l'eau, séchée sur du sulfate de sodium et évaporée. Le résidu (4.18 g, 90%) se solidifie lentement. Après quatre cristallisations dans le mélange acétone – éther de pétrole le point de fusion s'étend de 124° à 137°. Le composé ainsi obtenu (14.2 g) est chauffé, 2 heures durant, sous un séparateur d'eau, dans 350 ml de benzène contenant 2 ml d'acide chlorhydrique concentré. Après distillation du benzène on recueille 14.0 g d'acide, p.f. brut 144–146°, montant à 150° après cristallisation dans le mélange acétone – éther de pétrole. P.M. trouvé 210.7; calculé 212.25. Calculé pour $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. Trouvé: C, 62.16; H, 7.68%. Spectre infrarouge: —OH (COOH), 3400–2400 cm^{-1}; bande forte à 1700 cm^{-1} (=C=O, acide) avec fort épaulement à 1730 cm^{-1} (δ-lactone).

5. Acide méthylène-2 cyclohexane-propionique (XIV)

5.1. Première méthode.—À une solution 14.3 g (0.170 mole) de phényl-lithium dans 150 ml d'éther on ajoute 61 g (0.170 mole) de bromure de méthyl-triphényl-phosphonium) puis on agite 1 heure à reflux sous atmosphère d'azote; à la solution rouge-brique refroidie à 0°, on ajoute goutte à goutte 25.7 g (0.170 mole) d'oxo-2 cyclohexane-acétonitrile; on chauffe à reflux pendant 3 heures, puis centrifuge et lave le précipité à l'éther. Les solutions éthérées réunies sont lavées à l'eau, séchées sur sulfate de sodium. Le résidu de la distillation de l'éther est distillé plusieurs fois pour fournir une fraction, p. é. 110–112° sous 0.5 mm, présentant des bandes à 2250 cm^{-1} (—CN) et 890 cm^{-1} (double liaison semicyclique), donc riche en méthylène-2 cyclohexane-propionitrile. Ce nitrile (3 g) est hydrolysé par chauffage avec 3 g d'hydroxyde de sodium dans 50 ml d'eau, pendant 24 heures. On isole à la manière habituelle 2.1 g d'acide; l'acide méthylène-2 cyclohexane-propionique pur présente les constantes suivantes: p. é. 108° sous 0.7 mm, $n_D^{25} = 1.4810$. Calculé pour $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%. Trouvé: C, 71.29; H, 9.59%. Spectre infrarouge: OH (—COOH), 3400–2400 cm^{-1}; =CO acide, 1715 cm^{-1}; insaturation semi-cyclique, 1650 et 890 cm^{-1}.

5.2. Deuxième méthode.—En la chauffant à 165° sous vide de 0.1 mm, dans un ballon de Claisen, la fraction acide décrite plus haut en 3.3 se décarboxyle pour donner l'acide méthylène-2 cyclohexane-propionique, p. é. 107–109° sous 0.7 mm, $n_D^{21} = 1.4838$.

5.3. Troisième méthode.—En le chauffant à 165° sous 0.1 mm dans un ballon de Claisen le carboxyméthyl-8*a* oxo-2 perhydro-chromanne brut décrit en 4, p.f. 124–137°, se décarboxyle pour donner l'acide méthylène-2 cyclohexane-propionique qui distille; acide purifié par distillation, p. é. 104–114° sous 1.0 mm, $n_D^{23.5} = 1.4840$. Rendement de l'opération: 61%. Le spectre infrarouge montre des épaulements, sur la bande à 1715 cm^{-1} vers 1735 (δ-lactone) et 1770 (γ-lactone). En pyrolysant le carboxyméthyl-8*a* oxo-2 perhydro-chromanne, p.f. 150° (décrit en 4), on obtient à côté de l'acide méthylène-2 cyclohexane-propionique, p. é. 102° sous 0.4 mm, $n_D^{25} = 1.4842$ (25%), une fraction huileuse importante, p. é. 185°, dont le spectre infrarouge montre des bandes à 1740 et 1770 cm^{-1} indiquant une forte teneur en δ- et γ-lactones.

5.4. Sel de benzyl-iso-thio-uronium.—Aiguilles (MeOH), p.f. 145–145.5°. Calculé pour $C_{18}H_{26}N_2O_3S$: C, 64.64; H, 7.84%. Trouvé: C, 64.73; H, 7.90%.

5.5. Ozonolyse.—En suivant fidèlement la technique et les proportions indiquées par

Stauffacher et Schinz (11) 250 mg d'acide méthylène-2 cyclohexane-propionique ont donné 130 mg du dérivé formaldéhyde-dimédon (soit une teneur de 87% en liaison méthylénique) et 40 mg d'acide oxo-2 cyclohexane-propionique, p.f. 62.5°, ne donnant pas de dépression de point fusion en mélange avec l'acide authentique, p.f. 64° (23).

6. Acide carboxyméthylène-2 cyclohexane-propionique (XVII)

On chauffe sur un bain-marie, durant 2 heures 1 g d'(éthoxycarbonyl-méthyl)-8*a* oxo-2 perhydro-chromanne (IX), 1 g d'hydroxyde de potassium dans 20 ml de méthanol. On distille le méthanol et projette le résidu sur 50 g de glace. On acidifie la solution par de l'acide chlorhydrique concentré, jusqu'au virage bleu du rouge congo. L'acide carboxyméthylène-2 cyclohexane-propionique qui précipite (918 mg) est cristallisé dans l'eau, p.f. 161–162°. P.M. trouvé 211.8; calculé 212.24. Spectre ultraviolet: λ_{max} 220.5 mμ, log ϵ = 4.11. Spectre infrarouge: —OH (—COOH) 3400–2400 cm^{-1}; 1714 cm^{-1}, =CO acide non conjugué; 1690 cm^{-1}, =CO acide conjugué; 1623 cm^{-1}, double liaison conjuguée. Calculé pour $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. Trouvé: C, 62.11; H, 7.59%.

7. Action du bromo-acétate d'éthyle sur le diméthyl-4,4 oxo-2 cyclohexane-propionitrile en présence de zinc

En procédant comme plus haut en 3, on ajoute à 18.3 g de zinc un mélange de 44.4 g de diméthyl-4,4 oxo-2 cyclohexane-propionitrile, 51.8 g de bromo-acétate d'éthyle, 100 ml de benzène et 66 ml de toluène anhydres. On recueille (*a*) dans la phase organique 17 g de céto-nitrile de départ, p. é. 104–118°, et 4.8 g d'un mélange riche en ester éthylique de l'*acide (cyano-2 éthyl)-2 hydroxy-1 diméthyl-5,5 cyclohexane-acétique* (VII), p. é. 140–150° sous 0.45 mm. Calculé pour $C_{15}H_{25}NO_3$: C, 67.38; H, 9.43; N, 5.24%. Trouvé: C, 68.70; H, 9.16; N, 4.05%. Spectre infrarouge: —OH, 3505 cm^{-1}; —CN, 2268 cm^{-1}; =CO ester non conjugué, 1729 cm^{-1}; on décèle également une bande faible à 1717 cm^{-1}. (*b*) Dans la phase aqueuse acide (séparation en composés acide et neutre comme en 3.3) on recueille: l'*acide carboxyméthyl-2 hydroxy-2 diméthyl-4,4 cyclohexane-propionique* (XIII), 8.5 g, p.f. 144.5–145.5°. Anal. Calculé pour $C_{13}H_{22}O_5$: C, 60.45; H, 8.58%. Trouvé: C, 60.55; H, 8.58%. Spectre infrarouge: —OH (—COOH), 3400–2400 cm^{-1}; —OH (hydroxyle), 3505 cm^{-1}; =CO acide, 1700 cm^{-1} et l'*(éthoxycarbonyl-méthyl)-8a diméthyl-7,7 oxo-2 perhydro-chromanne* (X), qui après redistillation présente les constantes suivantes: p. é. 137° sous 0.3 mm; n_D^{22} = 1.4847. Calculé pour $C_{15}H_{24}O_4$: C, 67.14; H, 9.01%. Trouvé: C, 66.91; H, 8.90%. Spectre infrarouge: =CO ester et δ-lactone, 1731 cm^{-1}.

8. Acide diméthyl-4,4 méthylène-2 cyclohexane-propionique (XV)

L'acide carboxyméthyl-2 hydroxy-2 diméthyl-4,4 cyclohexane-propionique (XIII) (8.5 g) est chauffé dans un ballon de Claisen jusqu'à 165° à pression atmosphérique, puis à 0.6 mm jusqu'à 220°. Le vide varie de 0.6 à 2.7 mm, puis revient à 2 mm. En même temps un liquide incolore distille, p. é. 117–124° (3 g ou 48% de rendement); l'acide diméthyl-4,4 méthylène-2 cyclohexane-propionique redistillé présente les constantes: p. é. 102–103° sous 0.2 mm, n_D^{25} = 1.4755. Calculé pour $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%. Trouvé: C, 73.35; H, 10.23%. Spectre infrarouge OH (acide) 3400–2400 cm^{-1}; =CO acide, 1706 cm^{-1}; double liaison semicyclique, 1647 et 894 cm^{-1}.

9. Acide carboxyméthylène-2 diméthyl-4,4 cyclohexane-propionique (XVIII)

Comme décrit en 6, la saponification de 11 g d'(éthoxycarbonyl-méthyl)-8*a* diméthyl-7,7 oxo-2 perhydro-chromanne (X) conduit à 9.2 g d'acide carboxyméthylène-2 diméthyl-4,4 cyclohexane-propionique. Le point de fusion brut 136–138° passe à 135–140° par

cristallisation dans un mélange d'acétone et d'éther de pétrole et à 137–140° par cristallisation dans l'eau. P.M. trouvé 246.2; calculé 240.30. Spectre ultraviolet: λ_{max} 221.5 mμ, log ϵ = 4.10. Spectre infrarouge: —OH (—COOH) 3400–2400 cm^{-1}; =CO acide conjugué, 1678 cm^{-1}; =CO acide non conjugué, 1707 cm^{-1}; double liaison conjuguée, 1629 cm^{-1}. Calculé pour $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%. Trouvé: C, 64.91; H, 8.42%.

10. Action du bromo-acétate d'éthyle sur l'oxo-2 cyclohexane-acétonitrile en présence de zinc

Selon la technique décrite en 3, on ajoute à 37.3 g de zinc un mélange de 71 g d'oxo-2 cyclohexane-acétonitrile, 104 g de bromo-acétate d'éthyle, 150 ml de benzène et 100 ml de toluène anhydres. On examine immédiatement la phase organique et au bout de 24 heures la phase aqueuse.

(*A*) La phase organique contient 23 g d'*ester éthylique de l'acide cyanométhyl-2 hydroxy-1 cyclohexane-acétique* (XIX) qui après distillation présente les constantes: p. é. 128° sous 0.3 mm, n_D^{24} = 1.4788. Calculé pour $C_{12}H_{19}NO_3$: C, 63.97; H, 8.50; N, 6.22%. Trouvé: C, 63.98; H, 8.47; N, 6.06%. Spectre infrarouge: —OH, 3500 cm^{-1}; —CN, 2260 cm^{-1}; =CO 1720 cm^{-1}.

(*B*) La phase aqueuse abandonne: (*a*) 54.5 g d'*(éthoxy-carbonyl-méthyl)-7a oxo-2 oxa-1 perhydro-indène* (XX), p. é. 132° sous 0.5 mm, n_D^{22} = 1.4788. Calculé pour $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%. Trouvé: C, 63.65; H, 7.94%. Spectre infrarouge: =CO (γ-lactone) 1780 cm^{-1}; =CO (ester) 1735 cm^{-1}. (*b*) 2.2 g d'acide qui par distillation donne 1.2 g d'un composé dont le spectre infrarouge est superposable à celui de l'(éthoxycarbonyl-méthyl)-7*a* oxo-2 oxa-1 perhydro-indène (XX).

11. Acide mthyélène-2 cyclohexane-acétique (XXIII)

11.1. Première méthode.—Selon le mode opératoire décrit en 5.1, on ajoute 15.4 g d'oxo-2 cyclohexane-acétonitrile dans 120 ml d'éther anhydre à une solution éthérée préparée à partir de 40.0 g de bromure de méthyl-triphényl-phosphonium, 2.4 g de lithium et 27 g de bromobenzène dans 106 ml d'éther. On chauffe à reflux, en atmosphère d'azote, pendant 3 heures. On obtient après extraction et distillation 2.2 g (15) d'un liquide incolore, jaunissant très rapidement, p. é. 95–105° sous 25 mm. Bande —CN à 2254 cm^{-1} et bandes à 1645 et 892 cm^{-1} (double liaison semicyclique) dans le spectre infrarouge. On hydrolyse immédiatement ce nitrile: 3 g sont chauffés à reflux durant 24 heures avec 3.8 g d'hydroxyde de potassium dans 10 ml d'eau. L'acide méthylène-2 cyclohexane-acétique, extrait à la manière habituelle, est un liquide, p. é. 139° sous 11 mm, n_D^{25} = 1.4814. P.M. trouvé 156.9; calculé 154.21. Calculé pour $C_9H_{14}O_2$: C, 70.10; H, 9.15%. Trouvé: C, 70.13; H, 9.16%. Spectre infrarouge: —OH (—COOH) 3400–2400 cm^{-1}; =CO acide, 1700 cm^{-1}; double liaison semicyclique, 1646 et 892 cm^{-1}.

11.2. Deuxième méthode.—Selon le mode opératoire décrit plus haut en 4, 20.8 g d'ester éthylique de l'acide cyanométhyl-2 hydroxy-1 cyclohexane-acétique (XIX) sont saponifiées par 20.8 g d'hydroxyde de potassium dans 200 ml d'eau. On obtient 17 g d'acides, cristallisant en partie dans le nitrométhane, p.f. 153.5–154.5°. P.M. trouvé: 208.8. Calculé pour l'acide hydroxy-1 cyclohexane diacétique-1,2, 216.24, et pour l'acide déshydraté correspondant XXII, 198.22. La littérature (24) donne pour un mélange des acides XXII isomères un point de fusion de 164–166°. En chauffant 125 g de l'acide, p.f. 153.5–154.5°, à 250° sous pression atmosphérique, puis sous 11 mm dans un ballon de Claisen, on recueille un distillat de 204 mg, p. é. 125–139°, n_D^{24} = 1.4795. On reprend cet acide par de l'éther; on lave la solution avec une solution aqueuse $NaHCO_3$ 10% refroidie à 5°; on libère l'acide méthylène-2 cyclohexane-acétique par HCl 10% (température 5°) que l'on isole à la manière habituelle par de l'éther. Le spectre infrarouge de cet acide est superposable à celui obtenu par la première méthode.

11.3. Sel de benzyl-iso-thio-uronium.—Après trois cristallisations dans l'acétone, aiguilles p.f. 159–160° (première méthode), 158–158.5° (deuxième méthode); pas de dépression en mélange. Calculé pour $C_{17}H_{24}N_2O_2S$: C, 63.72; H, 7.55; N, 8.74%. Trouvé: C, 63.71; H, 7.54; N, 8.69%.

11.4. Ozonolyse.—Selon le mode opératoire mis en œuvre en 5.5, 254 mg d'acide méthylène-2 cyclohexane-acétique donnent 150 mg de dérivé formaldéhyde-dimédon, p.f. 189–190°, soit un rendement de 34.2% correspondant à une teneur de 102.6% en insaturation semicyclique.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada de son aide financière (subvention de recherches (H.F.) et bourses d'études (F.B. et Y.L.)), ainsi que l'Office de Recherches Scientifiques de la Province de Québec pour des bourses d'études à H.B. et R.L. Nous remercions aussi M. le Professeur C. Sandorfy de son aide dans l'étude des spectres infrarouges.

SELECTIVE ENZYMOLYSIS OF POLY-β-D-GLUCANS, AND THE STRUCTURE OF THE POLYMERS[1]

F. W. PARRISH,[2] A. S. PERLIN, AND E. T. REESE[3]

ABSTRACT

The soluble poly-β-D-glucan from oats has been subjected to degradation by two different types of enzymes. "Cellulase" converts the polysaccharide to a trisaccharide, 4-*O*-β-D-laminaribiosyl-D-glucose, and two tetrasaccharides, 3′-*O*-β-D-cellobiosyl-D-cellobiose and 4′-*O*-β-D-laminaribiosyl-D-cellobiose.* Degradation by the second enzyme, "laminarinase", produces a trisaccharide, 3-*O*-β-D-cellobiosyl-D-glucose, and a tetrasaccharide, 3-*O*-β-D-cellotriosyl-D-glucose.† These products, which account for 75–85% of the polymer in each experiment, have been characterized by chemical methods. The data show that the glucan is composed almost entirely of two types of structural sequences: one is a tetrameric unit in which a single β-(1 → 3) linkage alternates with two β-(1 → 4) linkages, and the other, a pentameric unit in which a single β-(1 → 3) linkage alternates with three consecutive β-(1 → 4) linkages.

The soluble poly-β-D-glucan from barley has been shown by enzymolysis with the "cellulase" to be closely related in detailed structure to the oat polymer.

Steric aspects of the enzymic degradations are discussed.

The grains of oats and barley contain water-soluble polysaccharides which are composed of β-D-glucopyranosyl units (1, 2, 3, 4, 5). In barley, the polyglucan appears to be closely associated with the malting process, during which there occurs a large increase in the proportion of the water-soluble polymer. Results from several investigations (6, 7, 8, 9) have shown that these polysaccharides are linear and that the monomeric units are joined by either (1 → 3) or (1 → 4) β-D-glycosidic linkages. An examination by Peat, Whelan, and Roberts (9) of the products formed by partial acid hydrolysis of oat glucan, has demonstrated clearly that both types of linkage occur together in the same chain, and that a major proportion of the polymer may be represented by a tetrameric repeating unit (I) in which two (1 → 4) linkages and a (1 → 3) linkage alternate. Lichenin, a poly-β-D-glucan from Iceland moss, was found also by this approach to be constituted in a closely similar fashion (9).

In the current study, the β-D-glucans from oats and barley have been degraded selectively with two different enzymic preparations, a "cellulase" and a "laminarinase". From the identity of the products formed detailed information about the structure of the polysaccharides has been obtained. The basic type of formula (I) advanced by Peat, Whelan, and Roberts has been confirmed for the oat glucan, and shown to apply also for barley glucan, and additional data about the constitution of these polymers provided.

Enzymic Degradation by Cellulase

The glucans were found to be hydrolyzed rapidly and extensively by a cellulase isolated from *Streptomyces* sp. QM B814. This enzyme preparation hydrolyzes cellulose in high yield to cellobiose and cellotriose (10). Under conditions expected to minimize transglycosylation side-reactions, the products formed from both glucans were mainly one tri- and two tetra-saccharides, and only minor or trace proportions of higher oligosaccharides, disaccharides, and glucose were detected. The products (Table I) were isolated by preparative paper chromatography.

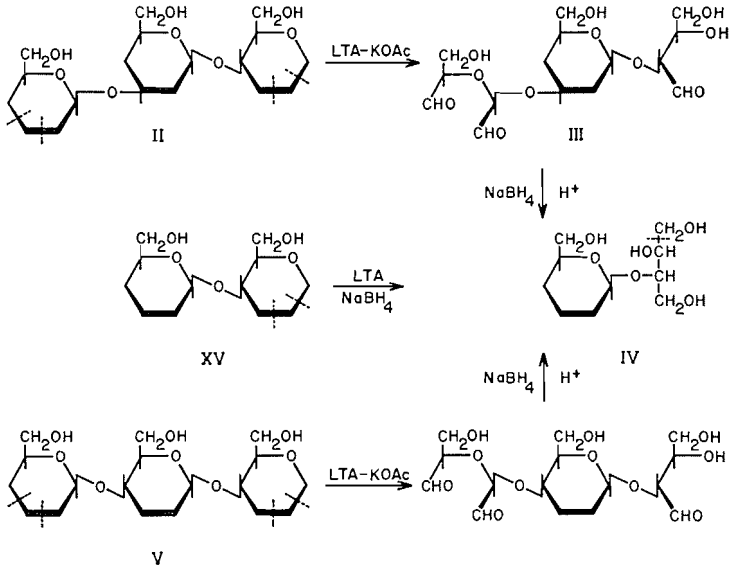

TABLE I

Yields of products from enzymolysis of poly-β-D-glucans*

	Cellulase		Laminarinase
Fraction	Barley glucan	Oat glucan	Oat glucan
Trisaccharide	628 } (2.7)	638 } (2.5)	520 } (2.3)

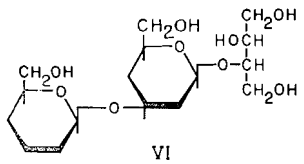
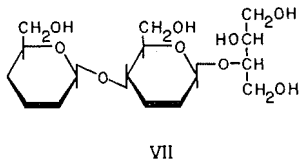
Unidentified†	93	67	—

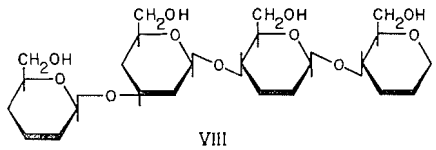


*Milligrams of crude product/1.0 g polyanhydroglucose. Figures in parentheses are moles trisaccharide : moles tetrasaccharide.
†Components remaining close to the origin on paper chromatograms.

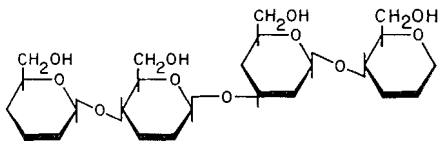
The major product obtained from each glucan (yield, about 60%) was an amorphous trisaccharide, which was purified by conversion to a crystalline acetate. The physical constants of the derived acetate corresponded to those reported for 4-*O*-β-D-laminaribiosyl-D-glucose undecaacetate (9), and the free trisaccharide was found to possess this structure (II)* in the following way. On treatment with lead tetraacetate in the presence of potassium acetate the compound produced formic acid at the same rate as cellotriose (11), and consumed 4 moles of oxidant, consistent with the formulation of a



**All hexopyranosyl units represented by these formulae possess the* D-*gluco-configuration.*



4-substituted reducing end-unit, and the production of III. The oxidation product was reduced with sodium borohydride (12), and selectively hydrolyzed with acid under the conditions recommended by Smith and co-workers (13), yielding 2-*O*-β-D-glucopyranosyl-D-erythritol (IV) (14). Hence the central unit of the original trisaccharide was attached to the reducing end-unit by a β-(1 → 4) linkage. The validity of this degradation procedure was checked with cellotriose (V), which also yielded IV since the central unit in this trisaccharide is resistant to lead tetraacetate oxidation under the conditions used (11). In the absence of potassium acetate, a relatively slow uptake of about 1.7 moles of lead tetraacetate was observed with II, characteristic of a 4-substituted D-glucose (14), and reduction of the product afforded 2-*O*-β-D-laminaribiosyl-D-erythritol (VI). Presence of the β-(1 → 3) linkage in II was confirmed by partial hydrolysis, which afforded laminaribiose, characterized as the octaacetate.



VI

VII

VIII

IX

The amorphous tetrasaccharide fraction obtained from the oat and barley glucans accounted for about 30% of the original polysaccharides. Oxidation of each fraction with lead tetraacetate – potassium acetate, followed by reduction of the oxidized tetramer with sodium borohydride and selective acid hydrolysis (13), yielded two products in a ratio of approximately 3 to 2. The major product was 2-*O*-β-D-cellobiosyl-D-erythritol (VII) and the other, 2-*O*-β-D-laminaribiosyl-D-erythritol (VI). Isolation of these two triitols showed that the tetrasaccharide fractions contained two components (not separable by paper chromatography), one containing a central β-(1 → 4) linkage and the other a central β-(1 → 3) linkage, and both having a β-(1 → 4) linkage adjacent to the reducing end-unit. One of these components was isolated by fractional crystallization,* and when degraded according to the reaction sequence described above afforded VII. Also, on reduction followed by partial acid hydrolysis, the crystalline tetrasaccharide gave laminaribiose, cellobiose, and trisaccharide (II). These properties therefore characterized the compound as 4′-*O*-β-D-laminaribiosyl-D-cellobiose (VIII). The second tetrasaccharide component was amorphous. However, it was shown to be 3′-*O*-β-D-cellobiosyl-D-cellobiose (IX), since it yielded VI on selective degradation (as above), and after reduction followed by partial hydrolysis it afforded cellobiose, laminaribiose, and trisaccharide (X).

A detailed structure for the major proportion (about 85%) of the oat and barley β-D-glucans may clearly be formulated from the identity of the three oligosaccharides obtained by enzymolysis. Since the molar ratio of trisaccharide to tetrasaccharide formed

**Two modifications of this tetrasaccharide were obtained, the α-anomer and a dihydrate of the β-anomer.*

For personal use only.

is about 2.5 to 1, and since (on the average) about seven glucose units are linked by (1 → 4) bonds and three by (1 → 3) bonds, a structural relationship between polymer and products may be depicted as in Fig. 1.* According to this scheme, the polymers

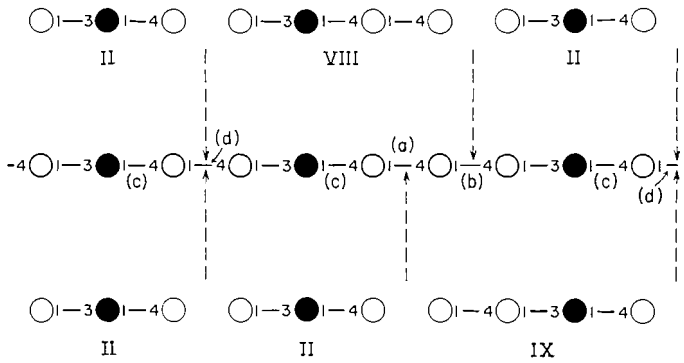

FIG. 1. Structural relationship between oat and barley poly-β-D-glucan (central row of circles) and oligosaccharides produced by the action of "cellulase". All circles represent β-D-glucopyranosyl units; those units which are bonded glycosidically through positions-1 and -3 are in black, for contrast.

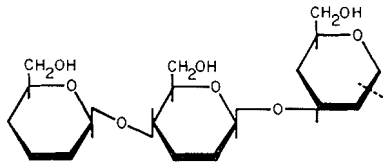
contain two types of repeating units represented by (*a*) a tetrameric unit (I, page 2094) in which a single β-(1 → 3) linkage alternates with two consecutive β-(1 → 4) linkages (9), and (*b*) a pentameric unit in which a single β-(1 → 3) linkage alternates with three consecutive β-(1 → 4) linkages. The (1 → 3) bonds occur solely in isolated positions, but there can be few, if any, isolated (1 → 4) bonds in the molecule.† Rather, the (1 → 4) linkages are found most frequently in pairs and less often as a sequence of three, but the available evidence suggests that there are never more than three (1 → 4) linkages in consecutive order along the polymer chain.

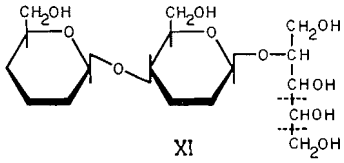
Formation by the cellulase of the two tetrasaccharides VIII and IX appears to involve cleavage of bond (*b*) or (*a*), respectively (Fig. 1), 2 moles of trisaccharide II being formed in either instance. Since more of VIII than IX is produced, bond (*a*) is the more easily cleaved although the difference is rather small (ratio of 3.5 to 2). However, it may be noted that bond (*c*) is *not* cleaved by the enzyme, although it is also of the β-(1 → 4) type usually associated with cellulase action. As noted elsewhere (15), the D-glucosyl unit to the left of bond (*c*) is substituted at position-3, rather than at position-4, making for a "(→ 3)-β-(1 → 4)" relationship. By contrast, linkages (*a*), (*b*), and (*d*), which possess a "(→ 4)-β-(1 → 4)" arrangement, all are cleaved by the cellulase.

Enzymic Degradation by Laminarinase



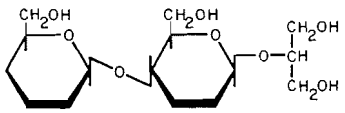
A second type of enzyme, classified as a "laminarinase" by Reese and Mandels (16) since it shows high specificity for laminarin, was also found capable of rapidly degrading the β-D-glucans. This glycosidase is an endo-enzyme produced by *Rhizopus arrhizus* QM 1032. Acting on laminarin, it yields laminaribiose and laminaritriose as the dominant products (16). With the oat polymer, a tri- and tetra-saccharide were detected in the hydrolyzate together with a small proportion of laminaribiose. The major product, which

**For simplicity, the ratio of tri- to tetra-saccharide in Fig. 1 is 2 to 1. However, closer agreement is obtained with the ratio found experimentally by considering a larger repeating structure (e.g., one containing 20–25 units). The molecular weight of the polysaccharides was not estimated, but the low yield of formic acid produced during periodate oxidation of the materials (experimental section) indicated a D.P. value of not less than 50–100 units.*

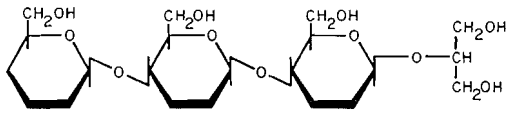


†Oligosaccharides having D.P. greater than 4, which were formed in low yield (Table I), were not examined and may represent minor structural sequences not accommodated by Fig. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



accounted for about 50% of the glucan, was an amorphous trisaccharide, characterized as the derived acetate. This trisaccharide was shown to be 3-*O*-β-D-cellobiosyl-D-glucose (X)* by the following reactions. It rapidly consumed 1 mole of lead tetraacetate per mole and yielded an equivalent of pentose showing that the reducing end-unit was substituted at position-3 (14). In agreement with this assignment the compound migrated on an electrophoretogram (18) at a rate close to that of laminaribiose. The oxidized trisaccharide was reduced to the corresponding glycitol (XI, not isolated) which was treated in turn with 2 moles of lead tetraacetate, followed by a second reduction. This degradation procedure had been used earlier to convert a 3-linked hexose disaccharide to a 2-*O*-glycosyl-glyceritol (19). Accordingly, the final product obtained was 2-*O*-β-D-cellobiosyl-glyceritol (XII).



X

XI

XII

XIII

The tetrasaccharide, which accounted for 30% of the polymer, was crystalline. Its behavior on oxidation with lead tetraacetate and ionophoresis paralleled that of the trisaccharide (X) (above), showing that this compound also possesses a 3-substituted reducing end-unit. By selectively degrading the reducing end-unit to a 2-substituted glyceritol unit (as for X to XI), 2-*O*-β-D-cellotriosyl-glyceritol (XIII) was obtained. Accordingly, the tetrasaccharide produced by laminarinase action is 3-*O*-β-D-cellotriosyl-D-glucose (XIV, Fig. 2).

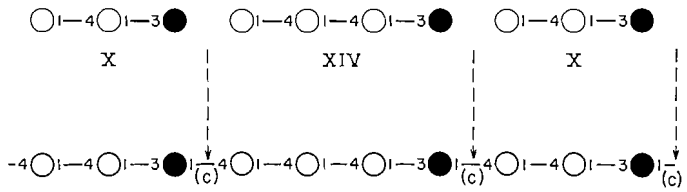


FIG. 2. Structural relationship between oat poly-β-D-glucan (lower row of circles) and oligosaccharides produced by the action of "laminarinase". All circles represent β-D-glucopyranosyl units; those units which are bonded glycosidically through positions-1 and -3 are in black, for contrast.

Together, the tri- and tetra-saccharide account for about 80% of the original oat β-D-glucan and are produced in a molar ratio of about 2.3 to 1. As shown in Fig. 2, formation of these products can readily be accommodated by the polymeric structure

Two sets of physical constants have been reported for the undecaacetate of this compound: m.p. 110° C, $[\alpha]_D$ −8° (9) and m.p. 183° C, $[\alpha]_D$ −22° (17). (The acetate obtained in the current study has the same properties as recorded in reference 9.) Consequently, a confirmation of the structure of X appeared necessary, and is reported herein.

already depicted in Fig. 1.* With laminarinase, cleavage was specific for linkage (*c*), i.e., one adjacent to a β-D-glucosyl unit *substituted at position-3*, rather than the β-(1 → 3) bond itself (15). Hence, in contrast to the action of cellulase, only one tetrasaccharide was obtained. These results, therefore, fully complement those obtained by enzymolysis of the β-D-glucans with cellulase, and show clearly that the major proportion of the polysaccharides is constituted as depicted in Figs. 1 and 2. It is possible that the glucans comprise a mixture of molecules, some of which contain only the tetrameric repeating unit and others only the pentameric unit. However, formation of the two tetrasaccharides by the "cellulase" is accommodated most readily by assuming that both types of repeating units occur interspersed within the same molecule. Of possible significance in this connection is the fact that fractional precipitation of barley glucan yielded several fractions, each of which was hydrolyzed to the same degree by cellulase and gave the same mixture of products.

EXPERIMENTAL

Paper chromatography was carried out with ethyl acetate:pyridine:water (10:4:3) as solvent (20); for preparative chromatography Whatman 3MM paper was used. Spray reagents used were aniline oxalate (21) and ammoniacal silver nitrate (22). R_G represents the rate of travel of a compound on a chromatogram relative to the rate for glucose.

Paper electrophoresis (18) was carried out using borate buffer (pH 9.2 (23)) at 10 volts per centimeter.

Copper-reducing power was measured by the method of Nelson (24).

Solutions were evaporated at 40–50° C, and optical rotations were measured at approximately 25° C. Melting points are corrected.

Oat flour was milled from Fortune oats grown at the University of Saskatchewan, and barley flour from husky six-rowed barley grown in the Saskatoon area.

Isolation of Polyglucans

A combination of the procedures described by Morris (2) and by Meredith, Watts, and Anderson (5) was used. Oat or barley flour (3 kg), previously heat-inactivated with boiling 80% ethanol, was extracted with water (24 liters) for 3 hours in the presence of papain (6 g). The digest was centrifuged and ammonium sulphate (2200 g) was added to the supernatant solution causing flocculation of the polyglucan. The latter was collected, washed with 50% ethanol until sulphate-free, then with acetone, and air-dried. The barley glucan (19.0 g) was a white powder, $[\alpha]_D^{22}$ −13.1° (*c*, 0.9, H_2O). Found: anhydroglucose (copper-reducing power after hydrolysis), 89.0%; N, 0.37%; ash, 0.81%; moisture, 12.4%. The oat glucan (26.0 g) was a white fibrous material, $[\alpha]_D^{27}$ −8.3° (*c*, 0.9, H_2O). Found: anhydroglucose, 86.9%; N, 0.36%; ash, 0.17%; moisture, 10.2%.

Periodate Oxidation of Polyglucans

By oxidation of the polyglucans with 2 molar equivalents of sodium metaperiodate at 20° C in the dark, the following results were obtained:

Periodate consumed by barley glucan (moles/mole (hours)): 0.72 (20), 0.73 (45), 0.79 (95), 0.81 (141). Formic acid production (moles/mole) at 20 and 141 hours was 0.005 and 0.055, respectively, giving a corrected value of about 0.75 mole periodate consumed per anhydroglucose unit at 141 hours.

Closely similar data were obtained with the oat glucan. Periodate consumption (moles/

*See footnote, p. 2097.

For personal use only.

mole (hours)): 0.65 (23), 0.76 (47), 0.77 (102), 0.80 (143). At 47 hours the yield of formic acid was 0.016 mole/mole.

Degradation of Barley Glucan Fractions with Cellulase

Ethanol was added dropwise to a vigorously stirred barley glucan solution (500 mg, 22.5 ml). Precipitates obtained (weights in parentheses) between zero and 17% ethanol (115 mg), 17–23% (276 mg), 23–31% (57 mg), 31–47% (21 mg), and 47–64% (5 mg) were collected and dried. The first four fractions (18 mg) were incubated in water (1.7 ml) at 48° C and pH 6 with cellulase (6 mg). No difference was observed between fractions in rate of hydrolysis (copper-reducing power). In addition, when the reducing power became constant (at glucose equivalent of 25%, 2 hours), paper chromatographic examination of the digests showed the presence in each of two main products, corresponding to a tri- and tetra-saccharide, respectively (R_G 0.45 and 0.22). Of the three minor products detected, two were indistinguishable from glucose and cellobiose, and the third had R_G 0.10.

Further experiments with the unfractionated glucan showed that the glucan:cellulase ratio could be increased to 8:1 with little effect on the degree of hydrolysis attained and the type of products formed.

Degradation of Oat and Barley Glucans with Cellulase

Oat or barley glucan (1.0 g) in water (100 ml) was incubated at 48° C with cellulase (0.12 g) for 5 hours. The enzyme was then inactivated by heating the digest for 10 minutes on the boiling-water bath, the digest was filtered, concentrated, and the syrup obtained was chromatographed on Whatman 3 MM paper sheets. After elution from the papers with water, the sugars were purified by use of mixed-bed ion-exchange resins. Yields of individual sugars are given in Table I.

Products from the Cellulase Degradation of Barley Glucan

4-O-β-D-Laminaribiosyl-D-glucose (II)

The trisaccharide fraction was chromatographically homogeneous containing neither laminaritriose nor cellotriose, $[\alpha]_D$ +11.6° (*c*, 1.3, H_2O). Partial hydrolysis of the material yielded cellobiose, laminaribiose, and glucose (paper chromatogram). On treatment with lead tetraacetate the rate of uptake of oxidant was closely similar to that of cellotriose and cellobiose (11, 14), and in the presence of potassium acetate the lead tetraacetate oxidation characteristics were those of a hexopyranosyl trisaccharide possessing a 4-linked reducing end-unit (11).

4-O-β-D-Laminaribiosyl-β-D-glucose Undecaacetate

A portion (53 mg) of II was heated at 100° C for 2 hours with acetic anhydride containing anhydrous sodium acetate. After evaporation of the acetic anhydride the product was isolated by extraction into chloroform and crystallized from ethanol (weight, 75 mg), m.p. 120–122° C and $[\alpha]_D$ −20.0° (*c*, 1.5, $CHCl_3$) (lit. (9) m.p. 121–123° C and $[\alpha]_D$ −22.2°). Calculated for $C_{40}H_{54}O_{27}$: C, 49.69%; H, 5.63%; acetyl, 48.98%. Found: C, 49.55%; H, 5.70%; acetyl, 49.10%.

Deacetylation of the material in the mother liquors, followed by paper chromatography, indicated the presence of II only.

Degradation of II *to 2-O-β-D-Glucopyranosyl-D-erythritol*

The amorphous material (149 mg) in water (1 ml) was taken up in acetic acid (9 ml) and treated with a solution of lead tetraacetate (660 mg, 5 molar proportions) and potassium acetate (400 mg) in acetic acid (27 ml). After 11 hours the excess tetravalent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

lead was reduced with a 10% solution of oxalic acid in acetic acid (0.2 ml), and the solution was treated with excess Amberlite IR-120 and concentrated. By repeated addition of ethanol and toluene to the residue, and evaporation, the last traces of acetic acid were removed. The final residue was dissolved in water (5 ml) and added slowly to a solution of sodium borohydride (150 mg) in ice water (5 ml). After 16 hours, sodium ions were removed with Amberlite IR-120 and borate as the volatile methyl ester, and the reduced product was treated with 0.1 *N* sulphuric acid at room temperature for 16 hours (13). The hydrolyzate was neutralized with Dowex-1 resin and concentrated, and was found by paper chromatographic examination to contain two main components indistinguishable from 2-*O*-β-D-glucosyl-D-erythritol and glycerol. This mixture (105 mg) was fractionated on a column of coconut charcoal (25) (5 g) by gradient elution with aqueous ethanol up to a concentration of 20% ethanol, affording 2-*O*-β-D-glucopyranosyl-D-erythritol (40 mg), m.p. 191–194° C and $[\alpha]_D$ −15.2° (*c*, 1.3, H_2O). The X-ray diffraction pattern of the compound was indistinguishable from that of an authentic sample (14). Calculated for $C_{10}H_{20}O_9$: C, 42.25%; H, 7.09%. Found: C, 42.42%; H, 7.39%.

Degradation of II *to Laminaribiose*

A portion (800 mg) of II was hydrolyzed with 0.33 *N* sulphuric acid (30 ml) for 1 hour at 100° C, the hydrolyzate was neutralized, concentrated, and fractionated on a cellulose column using butanol saturated with water as solvent. Laminaribiose (117 mg) was isolated and characterized by conversion to the β-octaacetate, m.p. 163–165° C and $[\alpha]_D$ −26.2° (*c*, 2, $CHCl_3$), which gave an X-ray powder diagram indistinguishable from that of an authentic specimen. Calculated for $C_{28}H_{38}O_{19}$: C, 49.56%; H, 5.65%. Found: C, 49.38%; H, 5.78%.

2-O-β-D-Laminaribiosyl-D-erythritol (VI)

4-*O*-β-D-Laminaribiosyl-D-glucose (II) (200 mg) in water (0.5 ml) was taken up in acetic acid (30 ml) and oxidized with lead tetraacetate (320 mg). After 5 hours excess tetravalent lead was reduced and divalent lead precipitated by addition of excess 10% oxalic acid in acetic acid. The product was reduced with sodium borohydride and crystallized from methanol–ethanol, m.p. 164–166° C and $[\alpha]_D$ −23.8° (*c*, 1.5, H_2O). Calculated for $C_{16}H_{30}O_{14}$: C, 43.05%; H, 6.77%. Found: C, 42.84%; H, 7.08%.

2-O-β-D-Cellobiosyl-D-erythritol (VII) *and 2-O-β-D-Laminaribiosyl-D-erythritol* (VI) *from the Tetrasaccharide Fraction*

The tetrasaccharide fraction appeared to be chromatographically homgeneous, $[\alpha]_D$ +9° (*c*, 3.1, H_2O). The copper-reducing power ratio before and after acid hydrolysis was 1:3.9 (requires 4.0).

A portion (229 mg) of the material was oxidized in 90% acetic acid with lead tetraacetate (916 mg, 6 molar proportions) in the presence of potassium acetate (440 mg) for 11.5 hours. By the procedure described above, the oxidation product was recovered, reduced with sodium borohydride, and partially hydrolyzed. Paper chromatographic examination of the hydrolyzate showed the presence of two triitol components which, after separation by preparative paper chromatography, were found to be:

(*a*) *2-O-β-D-Laminaribiosyl-D-erythritol* (VI) (29 mg).—Crystallized from methanol–ethanol, it had a melting point of 171–173° C and gave an X-ray powder diagram indistinguishable from that of the authentic material.

(*b*) *2-O-β-D-Cellobiosyl-D-erythritol* (VII) (65 mg)—which, after crystallization from aqueous methanol, had a melting point of 209–211° C, $[\alpha]_D$ −8.3° (*c*, 1.2, H_2O), and gave an X-ray powder diagram indistinguishable from that of a specimen prepared from

cellotriose* (27). Calculated for $C_{16}H_{30}O_{14}$: C, 43.05%; H, 6.77%. Found: C, 42.86%; H, 6.84%.

Isolation of these two products showed that the original fraction contained two tetrasaccharide components. The ratio of the triitols, estimated by the anthrone method (26) after elution of the products from paper chromatograms, was 1.8 to 1.

*4'-O-β-*D*-Laminaribiosyl-α-*D*-cellobiose* (VIII)

The tetrasaccharide fraction (243 mg) afforded crystalline material (120 mg) from solution in aqueous methanol, m.p. 221–224° C (decomp.), $[\alpha]_D$ +12.9° (2 minutes) → +10.6 (45 minutes, constant) (*c*, 3.6, H_2O). Calculated for $C_{24}H_{42}O_{21}$: C, 43.24%; H, 6.35%. Found: C, 43.16%; H, 6.67%.

Degraded by the procedure described in the previous section, the crystalline tetrasaccharide afforded 2-*O*-β-D-cellobiosyl-D-erythritol (VII), but no laminaribiosyl-erythritol. Reduction of the tetrasaccharide with sodium borohydride, followed by partial acid hydrolysis with 0.33 *N* sulphuric acid at 100° C for 1 hour, yielded glucose, laminaribiose, cellobiose, and 4-*O*-β-D-laminaribiosyl-D-glucose (II) (paper chromatographic and electrophoretic evidence).

*3'-O-β-*D*-Cellobiosyl-*D*-cellobiose* (IX)

After separation of the crystalline tetrasaccharide (VIII) a second crop of impure VIII was precipitated by addition of ethanol to the mother liquor. Concentration of the supernatant solution afforded an amorphous product (80 mg), $[\alpha]_D$ +19.8° (*c*, 1.6, 90% CH_3COOH). On oxidation with lead tetraacetate – potassium acetate followed by reduction and partial hydrolysis, this material was found chromatographically to account for the production of 2-*O*-β-D-laminaribiosyl-D-erythritol (VI) from the tetrasaccharide fraction; a minor proportion of the cellobiosyl-erythritol (VII) was also detected. The material was reduced with sodium borohydride, then hydrolyzed with hot 0.33 *N* sulphuric acid for 1 hour, yielding glucose, laminaribiose, cellobiose, and 3-*O*-β-D-cellobiosyl-D-glucose (X) (paper chromatographic and electrophoretic evidence).

Products from the Cellulase Degradation of Oat Glucan

*4-O-β-*D*-Laminaribiosyl-D-glucose* (II)

This product, which was chromatographically homogeneous, was characterized by conversion to the β-undecaacetate (540 mg from 310 mg of free sugar), m.p. 120–122° C and $[\alpha]_D$ −22.7° (*c*, 1.5, $CHCl_3$). Calculated for $C_{40}H_{54}O_{27}$: C, 49.69%; H, 5.63%; acetyl, 48.98%. Found: C, 49.77%; H, 5.55%; acetyl, 48.73%.

Tetrasaccharide Fraction

The amorphous product afforded crystalline material from aqueous methanol, m.p. 223–227° C (decomp.), indistinguishable from VIII by comparison of X-ray diffraction powder diagrams. Calculated for $C_{24}H_{42}O_{21}$: C, 43.24%; H, 6.35%. Found: C, 43.04%; H, 6.38%.

In one experiment, a second crystalline modification of this tetrasaccharide was obtained and found to be a dihydrate of the β-anomer, m.p. 180–181° C and $[\alpha]_D$ +7° (2 minutes) → +10° (constant) (*c*, 2, H_2O). Calculated for $C_{24}H_{42}O_{21}.2H_2O$: C, 41.02%; H, 6.60%. Found: C, 41.05%; H, 6.76%. By seeding, the higher-melting α-form (m.p. 221–223° C) of the tetrasaccharide obtained from barley glucan (above) was converted to this lower-melting modification.

By the degradative procedure described above the original, amorphous, tetrasaccharide

**2-O-β-D-Cellobiosyl-D-erythritol was prepared from cellotriose by oxidation with 1.8 molar proportions of lead tetraacetate followed by reduction with sodium borohydride, as in the conversion of cellobiose to 2-O-β-D-glucopyranosyl-D-erythritol (14).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fraction was shown (chromatographically) to yield both cellobiosyl-erythritol and laminaribiosyl-erythritol in a ratio of 1.7 to 1 (anthrone method (26)).

Enzymic Degradation of Oat Glucan with Laminarinase

Oat glucan (9.3 mg) in water (1.5 ml) was incubated at 40° C with laminarinase (1, 2 or 3 mg). At the two highest levels of enzyme concentration the copper-reducing power was virtually constant in 2 to 3 hours, when the apparent conversion to glucose was about 25%. A substantially slower reaction was observed at the substrate:enzyme ratio of 9:1. Examined by paper chromatography, all three digests were found to contain two major components which corresponded to a tri- and tetra-saccharide, respectively (R_G 0.47 and 0.22). Minor components detected were glucose, laminaribiose, and material having R_G 0.04.

Oat glucan (1.5 g) in water (100 ml) was incubated with laminarinase (0.25 g) for 2.5 hours. The digest was heated on the boiling-water bath for 7 minutes, filtered, and concentrated. The sugar mixture was fractionated by preparative paper chromatography; individual components were eluted and purified with mixed ion-exchange resins. Yields of the products are given in Table I.

3-O-β-D-Cellobiosyl-D-glucose (X)

The amorphous trisaccharide fraction was chromatographically and electrophoretically homogeneous, $[\alpha]_D$ +12.1° (*c*, 1.7, H_2O). On oxidation with lead tetraacetate in 97% acetic acid an uptake of 0.8 mole of oxidant per mole was found in 15–30 minutes and, in 90% acetic acid and in the presence of potassium acetate, the consumption of lead tetraacetate was 2.9 moles per mole. In both oxidations, approximately 1 mole of pentose (estimated colorimetrically (28)) was produced per mole of trisaccharide, the over-all data being consistent with presence of a 3-linked reducing end D-glucose unit.

Acetylation of the material (225 mg) with hot acetic anhydride – sodium acetate yielded a β-undecaacetate (340 mg), m.p. 104–105° C and $[\alpha]_D$ −9.7° (*c*, 1.6, $CHCl_3$). Calculated for $C_{40}H_{54}O_{27}$: C, 49.69%; H, 5.63%; acetyl, 48.98%. Found: C, 49.42%; H, 5.69%; acetyl, 49.37%.

2-O-β-D-Cellobiosyl-glyceritol (XII)

Trisaccharide X (264 mg) in water (1.5 ml) was taken up in acetic acid (50 ml) and treated with lead tetraacetate (232 mg, 1 molecular proportion) for 2 hours. Excess oxalic acid was added to precipitate the divalent lead, and the filtrate was concentrated. The residue in water (2 ml) was neutralized with sodium bicarbonate and the solution added dropwise to ice-cold sodium borohydride solution (264 mg, 12 ml). After 16 hours the reaction mixture was worked up, affording a solid product (227 mg), which was treated in 97% acetic acid (24 ml) with lead tetraacetate (424 mg, 2 molar proportions) for 16 hours. A second reduction with sodium borohydride followed, and the final product was crystallized from aqueous ethanol, m.p. 138–141° C and $[\alpha]_D$ −15.6° (*c*, 2.5, H_2O). The compound gave an X-ray diffraction pattern indistinguishable from that of an authentic sample* (27). Calculated for $C_{15}H_{28}O_{13}$: C, 43.27%; H, 6.78%. Found: C, 43.00%; H, 6.83%.

3-O-β-D-Cellotriosyl-α-D-glucose (XIV)

The tetrasaccharide fraction readily crystallized from solution in hot aqueous ethanol, m.p. 241–245° C (decomp.) and $[\alpha]_D$ +11.4° (5 minutes) → +8.4° (3 hours, constant)

**Prepared from 2-O-β-D-cellobiosyl-D-erythritol* (VII) *by oxidation with 1 molar proportion of lead tetraacetate followed by reduction with sodium borohydride, as in the degradation of 2-O-β-D-glucopyranosyl-D-erythritol to 2-O-β-D-glucopyranosyl-glyceritol (14).*

(*c*, 2.7, H_2O). Calculated for $C_{24}H_{42}O_{21}$: C, 43.24%; H, 6.35%. Found: C, 43.19%; H, 6.37%.

Treated in 97% acetic acid with 3 molar proportions of lead tetraacetate, the tetrasaccharide (20 mg) consumed 0.91, 0.96, and 0.99 mole of oxidant/mole at 5, 15, and 30 minutes, respectively, and yielded 1.0 mole of pentose/mole. Hydrolysis of the oxidation product with 0.33 *N* sulphuric acid at 100° C for 1 hour yielded arabinose, glucose, cellobiose, and cellotriose as well as two pentose-containing oligosaccharides (detected chromatographically).

*2-O-β-*D*-Cellotriosyl-glyceritol* (XIII)

Tetrasaccharide XIV (157 mg) was degraded as described above for the conversion of X to XI. The procedure involved, successively, oxidation with 1 molar proportion of lead tetraacetate, reduction with sodium borohydride, oxidation with 2 molar proportions of lead tetraacetate, and reduction with sodium borohydride. The final product was crystallized from aqueous ethanol (weight, 122 mg), m.p. 234–237° C; the X-ray powder diagram was indistinguishable from that of 2-*O*-β-D-cellotriosyl-glyceritol* (27), $[\alpha]_D$ −12.4° (*c*, 1.4, H_2O). Calculated for $C_{21}H_{38}O_{18}$: C, 43.60%; H, 6.62%. Found: C, 43.16%; H, 6.87% (hygroscopic material).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the technical assistance of Mr. J. W. L. C. Christ. Barley flour was kindly provided by Mr. R. Teed, University of Saskatchewan, and a sample of Fortune oats by Dr. D. Knott, University of Saskatchewan. Microanalyses were performed by M. Mazurek, and X-ray diffraction patterns prepared by Miss Inez Gaffney.

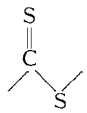
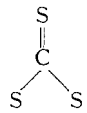
STRUCTURE OF BRIDGMAN'S BLACK CARBON DISULPHIDE[1]



E. WHALLEY

ABSTRACT



The infrared spectrum of black carbon disulphide dispersed in a potassium bromide disk has been examined. The blackness and the infrared spectrum are consistent with its being a linear polymer, $-(C{=}S.S)_n-$.

1. INTRODUCTION

Bridgman (1) found that carbon disulphide transformed slowly to a black solid at pressures of about 45 kilobars and temperatures over 175° C. When heated to about 200° C at normal pressure it decomposed to carbon and sulphur. It was denser than either graphite or sulphur, and it gave a broad, diffuse X-ray diffraction pattern. He suggested that the structure might be similar to that of silicon dioxide, i.e. a three-dimensional network of carbon and sulphur atoms linked by single bonds. It is difficult to see how a substance with this structure would be black. The blackness of black carbon disulphide demands a highly polarizable system, probably a conjugated one. The simplest that can be envisaged is a linear structure with the unit

repeated indefinitely. The group

is a strong chromophore (2, 3) and thiophene is an aromatic compound, so it seems very likely that the C—S—C group can conjugate with the C=S group. It is difficult to imagine any other structure which is conjugated and in which the atoms are not formally charged.

In order to test this structure, we have investigated the infrared spectrum of black carbon disulphide.

2. EXPERIMENTS AND RESULTS

A small amount of black carbon disulphide was made by subjecting carbon disulphide to a pressure of about 55 kilobars at 185° C in a simple squeezer (4). About 0.1 to 0.2 mg were incorporated into a disk with 400 mg of potassium bromide; more than this amount in the disk caused too much scattering. The spectra were recorded with a Perkin–Elmer Model 21 double-beam infrared spectrophotometer with a sodium chloride prism and with a Beckman IR-4 double-beam spectrophotometer with a cesium bromide prism. Many of the absorption bands observed were very weak and so a 10-times scale expansion was used, and the transmission of a disk containing the sample was divided

[1]*Manuscript received July 8, 1960.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 5946.

point by point by the transmission of a disk containing only potassium bromide. Calibration was conveniently done on the 10-times scale by using incompletely compensated atmosphere bands. The spectrum is shown in Fig. 1. A strong band of variable relative

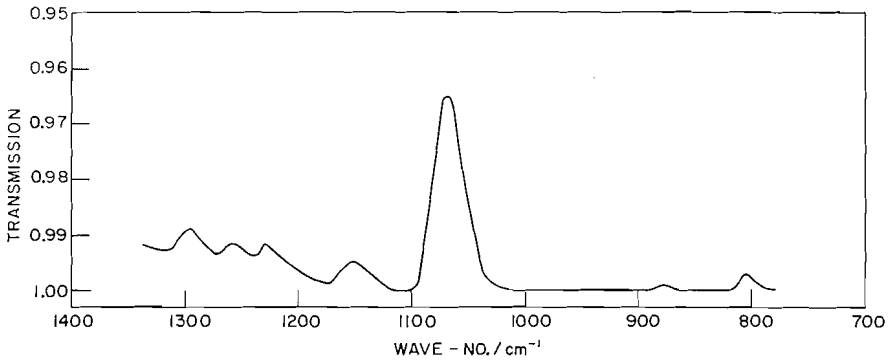


FIG. 1. Infrared spectrum of black carbon disulphide dispersed in a potassium bromide disk.

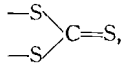
intensity was always present at $1502\pm\sim5\ cm^{-1}$. It could be removed by prolonged evacuation and gentle warming either before or after making the potassium bromide pellet, and it is attributed to unchanged carbon disulphide. The small shift from the vapor frequency, which is $1522\ cm^{-1}$, indicates that the carbon disulphide is not very strongly attached to the black carbon disulphide. The difficulty of removing it is therefore probably due to slow diffusion through the black carbon disulphide. The other bands were of constant relative intensity, and are listed in Table I.

TABLE I

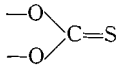


Infrared bands of black carbon disulphide

Frequency cm^{-1}	Rough relative intensity	Assignment
$1286\pm\sim5$	w	O—H bending, end group?
$1250\pm\sim5$	w	C—O stretching, end group, and bands due to imperfections in the chain?
$1220\pm\sim5$	w	
$1144\pm\sim5$	w	
$1063\pm\sim5$	vs	C═S stretching
$870\pm\sim10$	vw	C—S stretching
$806\pm\sim5$	m	

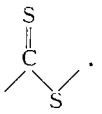
In order to avoid confusion with graphite, the spectrum of graphite was recorded in a similar manner; no bands were observed. The spectrum is discussed in another publication.

3. DISCUSSION



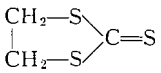
If black carbon disulphide has the structure suggested here then it should show a C═S stretching band. It is well established that compounds that contain the group

such as the trithiocarbonates (5, 6, 7), have a strong infrared band near $1060\ cm^{-1}$



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

which is due to the C═S stretching vibration. The strong band in the spectrum of black carbon disulphide at 1063 cm^{-1} is very strong evidence for the presence of this group, in agreement with our expectation. The decrease of frequency of the C═S stretching vibration from its value of about 1220 cm^{-1} in compounds (7) with the group



is consistent with a decrease of force constant due to conjugation with the singly bonded sulphur atoms.

If the chain of black carbon disulphide is mainly planar, as it probably is in order to facilitate conjugation, the repeating unit is

In an isolated chain, the only infrared-active vibrations are those that are in phase in each repeating unit, and so the factor group of the line group that describes the symmetry of the chain is appropriate for analyzing the spectrum. There are two parallel reflection planes, one through the S═C group and one through the singly bonded S atom, both perpendicular to the plane of the chain, and a reflection plane in the plane of the chain. There are, of course, twofold axes at the junctions of the planes. The corresponding point group is therefore C_{2v}. There are three atoms in the repeating unit and so there are $(3\times3-4) = 5$ fundamental vibrations that are potentially active. These can be described approximately as a C═S stretching vibration of species a_1, two C—S stretching vibrations of species a_1 and b_1, an S—C═S in-plane bending vibration of species b_1, and an S—C═S out-of-plane bending vibration of species b_2. All are active in infrared absorption.

It is likely that the medium band at 806 cm^{-1} is due to one of the C—S stretching vibrations, and perhaps the very weak band at 870 cm^{-1} is due to the other. There is almost no published information about similar vibrations in simple molecules. The only relevant spectra the author knows of is that of ethylene trithiocarbonate

which was deposited with the Chemical Society by Haszeldine and Kidd (5). There is a moderate band at about 870 cm^{-1} which may correspond to the C—S stretching vibration. The stretching frequency of an unconjugated C—S bond is usually between 700 and 600 cm^{-1} according to Bellamy (8), but conjugation with C═S will probably increase the force constant and so increase the frequency. Our assignment of the 806-cm^{-1} and perhaps the 870-cm^{-1} band to the C—S vibrations seems therefore to be reasonable. The bending vibrations are probably of lower frequency, and are probably weak. They are not observed.

The remaining bands, which are all very weak, cannot be certainly assigned, but plausible guesses can be made. Although it is possible that the chains end in free radicals, as presumably sometimes occurs with the sheets of graphite, it is also possible that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

chemically saturated end groups are present. A possible complete structure is

$$HO\left(\begin{matrix}S\\ \|\\ C-S\end{matrix}\right)_nH,$$

the end groups being derived from a molecule of water, in a similar manner to the polyaldehydes (9). The 1286-cm^{-1} band is perhaps an OH deformation and one of the bands at somewhat lower frequency (1144 cm^{-1}?) is perhaps a C—O stretching vibration. No OH stretching band was observed, though this is not surprising in view of the greater scattering in this region and the presence of adsorbed water. Some of the other bands could be due to imperfections in the chain such as a —C—S— group the wrong way round, but because there are few published spectra of model simple compounds detailed speculation is fruitless.

The author is indebted to Mr. A. Lavergne for help with the high-pressure experiments and to Mr. R. Ironside for taking the infrared spectra.

IONIZATION OF ORGANIC COMPOUNDS IN ACID

I. ALIPHATIC KETONES[1]

H. J. CAMPBELL[2] AND J. T. EDWARD

ABSTRACT

The changes in the ultraviolet absorption spectra of aliphatic ketones in aqueous sulphuric acid have been followed as the acid strength is increased from 0 to 98%. With increase in strength up to 65% the weak peak at about 270 mμ is shifted to shorter wavelengths by a medium effect. However, with further increase in acid strength the peak disappears altogether because of protonation of the carbonyl group. The pK_{BH^+} values of several ketones have been calculated from the spectrophotometric results to be about −7. The pK_{BH^+} values of cyclic ketones vary systematically with ring size. The significance of the present work to recent studies on the rate of enolization of acetone is discussed.

INTRODUCTION

In absolute sulphuric acid, aliphatic and aromatic ketones (B) are essentially completely protonated to form the conjugate acid (BH^+) (1). The extent of protonation of the ketone in a less concentrated acid solution may be determined by the ultraviolet absorption at a given wavelength, according to the equation

$$[1] \qquad [B]/[BH^+] = (\epsilon_{BH^+}-\epsilon)/(\epsilon-\epsilon_B)$$

where ϵ_B, ϵ_{BH^+}, and ϵ are the molecular extinction coefficients of the unprotonated ketone, the protonated ketone, and the ketone in the test solution, and the quantities in brackets represent concentrations (2, 3). From the variation of $[B]/[BH^+]$ with the acidity function H_0 (4, 5) of the acid solvent, the protonation constant (pK_{BH^+}) of BH^+, defined by

$$[2] \qquad pK_{BH^+} = H_0 - \log [B]/[BH^+],$$

may be determined. For acetophenone Hammett (2) found a pK_{BH^+} of −6.03, recalculated as −6.15 by use of a corrected acidity function scale (5). This value was confirmed recently by Stewart and Yates (6).

By analogy with the behavior of other aliphatic and aromatic oxygen bases, e.g. benzoic acid ($pK_{BH^+} = -7.38$) and acetic acid ($pK_{BH^+} = -6.2$ (5)), the pK_{BH^+} values of aliphatic ketones would also be expected to be about −6. This view finds support in measurements of the relative basicities of various ketones from their effect on the rate of the acid-catalyzed etherification of benzhydrol in refluxing benzene (7), which indicated cyclopentanone, cyclohexanone, and diethyl ketone to have about the same basicity as *p*-methylacetophenone ($pK_{BH^+} = -5.47$ (6)). Furthermore, Lemaire and Lucas (8) observed no measurable protonation of acetone, acetophenone, and benzophenone by small concentrations of perchloric acid in acetic acid, and concluded that these compounds must have pK_{BH^+} values below −4.5. On the other hand, Nagakura, Minegishi, and Stanfield (9) recently reported a spectrophotometric determination of a pK_{BH^+} of −1.58 for acetone. This unexpectedly high basicity has prompted our reinvestigation by spectrophotometry of the ionization of acetone and other aliphatic ketones. We have found that protonation of the ketones occurs only in much more concentrated acids than those investigated by Nagakura *et al.*, and that in fact most aliphatic ketones have pK_{BH^+} values of about −7.

EXPERIMENTAL

Materials

Chemically pure acetone and methyl ethyl ketone were purified by treatment with potassium permanganate according to Vogel (10), followed by fractionation through a 25×1 cm vacuum-jacketed column packed with glass helices, the middle fraction being taken. Cyclobutanone (Aldrich Chemical Co.) was distilled, and the middle fraction, b.p. 98–99° C at 759 mm, was used. Methyl isopropyl ketone, methyl *t*-butyl ketone, cyclopentanone, cyclohexanone, cycloheptanone (Aldrich), and cyclooctanone (Aldrich) were purified via their semicarbazones (11), which were recrystallized to constant melting point and then decomposed with 10% sulphuric acid. The ketones were removed by steam distillation, dried over magnesium sulphate, and then distilled as above.

The acid solutions were obtained by dilution of Nichols C.P. Reagent sulphuric acid (95.5–96.5%) and Baker and Adamson Reagent perchloric acid (70–72%), and the concentrations determined by titration with standard alkali. Sulphuric acid (98%) was prepared by adding 30% fuming sulphuric acid (Baker and Adamson Reagent) to 96% sulphuric acid. The corresponding H_0 values were read from large scale plots of H_0 against acid concentration, constructed from the data of Paul and Long (5).

Apparatus

Most measurements were made with a Beckmann Model DU spectrophotometer using quartz cells of 1 cm light path. The cell compartment was maintained at 25±0.1° C by thermospacers. With this instrument measurements could be taken down to a wavelength of about 220 mμ. For a few measurements down to wavelengths of about 185 mμ, a Unicam SP 500 spectrophotometer was used. There was no temperature control in the cell compartment of this instrument; the temperatures of the solutions in these cases were about 22±3° C.

Procedure

Solutions were made up by weighing the ketone (10–20 mg) directly into a 10-ml volumetric flask containing about 2 ml of the acid solution to be used as solvent, and swirling to mix the solution. In this manner weighing errors due to evaporation of the ketone were reduced. The solutions were made up to volume, mixed, and their extinction coefficients at various wavelengths measured. A solvent blank of acid of the same concentration as that containing the ketone was used.

RESULTS AND DISCUSSION

A selection of curves for the absorption above 220 mμ of acetone (Figs. 1A and 1B) and of cyclohexanone (Figs. 1C and 1D) in various strengths of sulphuric acid is shown. The family of curves over this range of wavelengths for methyl ethyl ketone in 0 to 65.3% acid resembled that of acetone; those for the other ketones resembled more that of cyclohexanone. The positions of the long wavelength peaks in water and in 65.3% sulphuric acid are given in Table I. The spectra of solutions of acetone in 0–66.6% perchloric acid varied with acid concentration in a fashion similar to that shown in Fig. 1A for solutions in sulphuric acid.

Extent of Condensation Reactions in Strong Acid Solution

Acetone in 96% sulphuric acid, when in fairly high concentration, is converted to mesityl oxide, phorone, and other compounds having strong ultraviolet absorption (9). However, it is believed that following the experimental procedure given above such condensation reactions are almost negligible, because of the great dilution almost

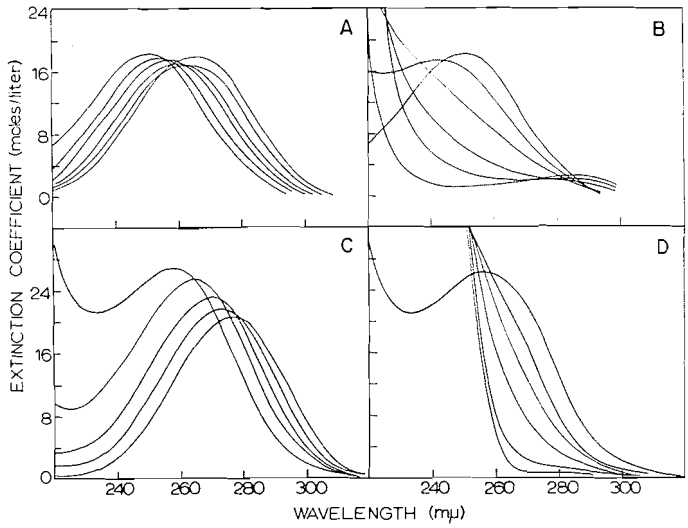

FIG. 1. Ultraviolet absorption curves of ketones in sulphuric acid solutions.

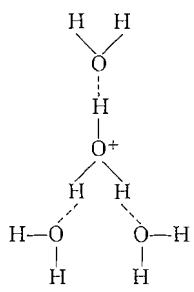
Cyclopentanone	300,[c] 299,[d] 295[b]	281	261
Cyclohexanone	285,[d] 288[b]	277	262
Cycloheptanone	281[e]	278	259
Cyclooctanone	290[c]	277	(<260)[f]

[a]In cyclohexane, ref. 21. [b]In ethylene dichloride, ref. 22. [c]In cyclohexane. [d]In hexane, ref. 11. [e]In hexane, ref. 23. [f]Submerged by edge of much more intense peak at ca. 185 mμ due to $\pi \rightarrow \pi^*$ transition.

instantaneously achieved by the ketone in the acid solutions. (The importance of the dilution effect has been emphasized by Grace and Symons (12).) Thus, when a solution of acetone in 98% sulphuric acid was diluted to give an acid concentration of 50%, the spectrum was practically identical with that of a solution prepared directly from 50% acid; the latter preparation would almost certainly be free from condensation products. However, it seems likely that the small peak found at about 280 mμ for solutions of acetone, methyl ethyl ketone, and cyclooctanone in the stronger acid solutions (see Fig. 1B for acetone) comes from condensation products. Mesityl oxide in concentrated sulphuric acid has λ_{max} at 284 mμ (9); the condensation to mesityl oxide of 0.03% of the acetone dissolved in 98.2% sulphuric acid would suffice to give the molecular extinction coefficient observed by us (Fig. 1B) at 284 mμ. This portion of the spectrum, further-

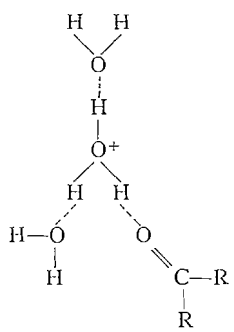
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

more, was found to have an optical density which increased very slowly with time; however, the portion from 220–260 mμ, which furnished the values of the extinction coefficient for the calculations mentioned below, did not change with time.



While we may conclude that the spectra obtained in the present instance are substantially those of the ketones themselves and not of condensation products, the reverse has been true for the spectra previously reported for aliphatic ketones in concentrated acid solution (13).

Gillespie, Hughes, and Ingold (14), in cryoscopic studies of very dilute solutions of acetone in absolute sulphuric acid, assumed that no destruction of the ketone was taking place, although the condensation of two molecules of acetone to form one molecule of mesityl oxide and one molecule of water would have led to no change in the cryoscopic behavior of the solution. However, the present work shows their assumption to have been justified.



Effect of Acid Strength on the $n \rightarrow \pi^*$ Transition of Ketones

The weak, long wavelength absorption of aliphatic ketones is ascribed to the excitation of an electron from a non-bonding (n) orbital of the oxygen to an antibonding (π^*) orbital of the carbonyl group (15). The absorption peak is shifted to shorter wavelengths (a "blue shift") with increasing polarity of the solvent, because of the preferential stabilization of the ground state of the carbonyl group by dipole–dipole interactions or by hydrogen-bonding with a solvent molecule (16, 17, 18, 19, 20). This effect accounts for the different wavelengths of the absorption peaks of the ketones in hydrocarbon or other inert solvents and in water (Table I).

It has long been known that the 265 mμ peak of acetone in water undergoes a further blue shift to 261 mμ in 5 *M* aqueous calcium chloride (24); we have found the peak also at 261 mμ in 15 *M* lithium bromide. In these concentrations of electrolyte a fair proportion of the water is bound in the primary or secondary hydration shells of the cations (25). The polarization of these water molecules, induced by the charge of the cation, should increase the strengths of the hydrogen bonds to the carbonyl oxygen (26). The progressive blue shifts produced by increasing hydronium ion concentration in going from 0 to 65.3% sulphuric acid (Table I and Figs. 1A and 1C) and from 0 to 66.6% perchloric acid are also best explained by a progressive increase in the strength of the hydrogen-bonding of solvent molecules to ketone. In dilute aqueous solution the hydronium ion exists as the relatively stable ion $H^+.4H_2O$ (I) (27, 28). However, in 65.3% sulphuric acid only 3 moles of water are present for each mole of acid, so that it is possible that in this strength of acid the ketone molecules are for the most part associated directly with hydronium ions as pictured in (II).

Nagakura, Minegishi, and Stanfield (9) have interpreted the blue shifts of acetone with increasing acid concentration as due to protonation of the ketone. However, their arguments for this interpretation are unsound for the following reasons:

1. They claim that a simple equilibrium between two species of molecules is shown by the presence of an isobestic point in the family of absorption curves. However, only the curves for acetone (Fig. 1A) and methyl ethyl ketone show an approximation to an isobestic point (cf. Fig. 1C).

2. They point out that the pK_B ($= -pK_{BH^+}$) values for acetone calculated from extinction coefficients at various wavelengths, and on both sides of the isobestic point, are approximately constant, varying from 1.39 to 1.72. However, they restricted their attention to solutions having $H_0 = -2.32$ or more. Over this limited range of acidities the absorption of acetone and methyl ethyl ketone (but *not* of the other ketones) does indeed change with H_0 according to equations 1 and 2. However, this correspondence of experimental results with those expected for a $pK_{BH^+} = -1.58$ for acetone is limited to the region above $H_0 = -2.3$, and is not found if one takes account of the absorption in more acidic solutions of $H_0 = -3$ to -5.

It seems more reasonable to associate protonation of the ketone with the disappearance of the long wavelength peak (16) as the sulphuric acid concentration is increased from 65% to 98% (Figs. 1B and 1D), a region of acid concentrations not investigated by Nagakura *et al.* This explanation is confirmed by the fact that in this region of acid concentrations the changes in absorption *for all ketones* follow approximately the changes in acidity function according to equations 1 and 2. This is shown in Figs. 2A and 2B

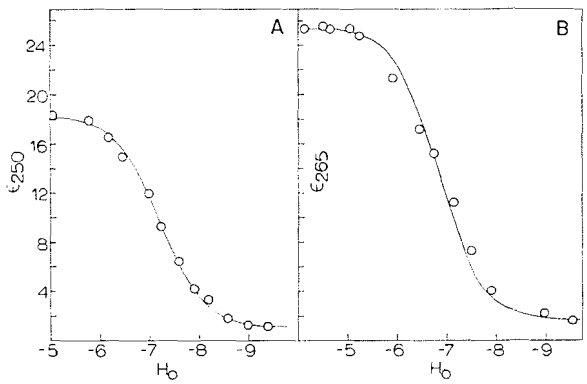

FIG. 2. (A) Ionization of acetone in H_2SO_4. Theoretical curve for equations 1 and 2, with $pK_{BH^+} = -7.2$.

for acetone and cyclohexanone, in which the molecular absorption coefficients at 250 mμ and 265 mμ, respectively, have been plotted against the values of the acidity function of the solutions. The experimental values fit reasonably well with the theoretical curve calculated from equations 1 and 2, using the values of ϵ_B and ϵ_{BH^+} recorded in Table II. Plots of ϵ at other wavelengths against H_0 indicated slightly different pK_{BH^+} values. Those for acetone (wavelengths given) were: -7.4 (245 mμ), -7.3 (248 mμ), -7.1 (252 mμ), -7.0 (255 mμ). However, the fit of the experimental points to the theoretical curve was less satisfactory than that found taking ϵ at 250 mμ. It was assumed that these deviations were caused by the medium effect (2), and the wavelength chosen (λ, Table II) was that which afforded the best fit of experimental points to the theoretical curve. However

TABLE II

Basicities of ketones

Ketone	λ (mμ)	ϵ_B	ϵ_{BH^+}	$-pK_{BH^+}$
Acetone	250	18.2	1.2	7.2
Methyl ethyl ketone	250	21.8	0.9	7.2
Methyl isopropyl ketone	260	34.0	3.2	7.1
Methyl *t*-butyl ketone	265	36.5	1.8	7.1
Cyclobutanone	260	33.0	3.0	9.5
Cyclopentanone	260	24.8	1.8	7.5
Cyclohexanone	265	25.4	1.8	6.8
Cycloheptanone	265	32.3	3.8	6.6
Cyclooctanone	270	24.5	6.4	6.2

it seems likely that because of the uncertainty in allowing for the medium effect the precision of the pK_{BH^+} values cannot be better than about ±0.2 unit. These values, listed in Table II, were all obtained by this graphical method. Graphical analysis of the absorption results by the slightly different method of Davis and Geissman (29) gave substantially the same pK_{BH^+} values.

It is apparent that unstrained cyclic and acyclic ketones all have pK_{BH^+} values of about −7. Contrary to the evidence of Pratt and Matsuda (7), the basicities of cyclopentanone and cyclohexanone differ considerably from that of *p*-methylacetophenone; however, it is not to be expected that exactly the same order of basicities will be shown in aqueous acids and in benzene.

In the series acetone, methyl ethyl ketone, methyl isopropyl ketone, and methyl *t*-butyl ketone, it is probable that the tendency for basicity to be increased by the inductive effect of an increasing number of alkyl groups on the α-carbon atom is offset by the effect of these groups in restricting the stabilization of the protonated ketone by solvation (30). The increase in basicity with ring size on going from cyclobutanone to cyclooctanone agrees with recent findings that the strengths of hydrogen bonds between these ketones and methanol or chloroform increase in the same order (31). These changes in basicity parallel changes in the infrared stretching frequency of the carbonyl group, as shown in Fig. 3. A similar change has been noted in both basicity and infrared frequency

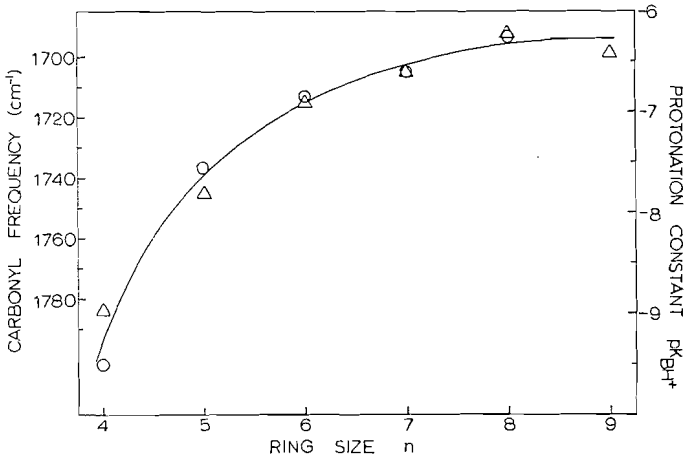

FIG. 3. Change of infrared stretching frequency (△) and pK_{BH^+} (○) with number of carbon atoms (*n*) in cyclic ketones.

of the carbonyl group of benzlactams with increasing ring size (32), while Stewart and Yates (6) have shown a linear relationship between the basicity and carbonyl frequency of *meta*- and *para*-substituted acetophenones.

The simple aliphatic ketones of Table II are much weaker bases than enolized β-diketones such as 5,5-dimethylcyclohexane-1,3-dione (pK_{BH^+} −0.8) and acetylacetone (pK_{BH^+} −3.7) (33); this is to be expected because of the resonance stabilization of the protonated forms of the latter compounds (e.g., V).

Va Vb

Effect of Acid on the $\pi \rightarrow \pi^*$ Transition of Aliphatic Ketones

Besides the $n \rightarrow \pi^*$ transition, ketones show a more intense absorption at shorter wavelengths due to a $\pi \rightarrow \pi^*$ transition. In the case of α,β-unsaturated ketones the change from an inert solvent to a hydrogen-bonding (17, 24, 34) or protonating solvent (9) causes a red shift in this peak, but acetone shows a blue shift on changing the solvent from isooctane (λ_{max} 187.6 mμ (34)) to water (34, 35). It has been claimed that this differing behavior is to be expected for two-center (36) and four-center (9) $\pi \rightarrow \pi^*$ transitions. However, the $\pi \rightarrow \pi^*$ peak for cyclohexanone showed a red shift on protonation (Table III). Unfortunately, with the spectrophotometers available it was not

TABLE III

Molecular extinction coefficients at 190 mμ of ketones in various solvents

Ketone	Solvent

possible to measure the absorption at low enough wavelengths to define this peak for the protonated forms of acetone and cyclooctanone. However, it seems likely, from the change in extinction coefficient at 190 mμ (Table III) that it undergoes a red shift on protonation in these cases also. The results in Table III indicate that the spectra of the non-protonated ketones vary with the solvent in an irregular fashion.

The Basicity and Rate of Enolization of Acetone

The enolization of ketones is known to involve the participation of one or more water molecules in addition to the protonated ketone molecule in the rate-determining step (37). However, Archer and Bell (38) recently showed that if a pK_{BH^+} of −1.58 were accepted for acetone, then its rate of enolization in 1–8 *M* hydrochloric acid is approximately proportional to the fraction of the compound protonated. According to the Hammett–Zucker hypothesis (39, 40), this would indicate that the reaction does *not*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

involve a water molecule in rate-determining step, and hence the results were interpreted as a disproof of the hypothesis. However, it seems likely that Archer and Bell's correlation is fortuitous because of the limited range of acid concentrations investigated by them. In fact, accepting a pK_{BH^+} of -7.2, a better correlation of their enolization rates with changing acidity is obtained by plotting $\log k_\psi + H_0$, where k_ψ is the experimental first-order rate constant based on the concentration of acetone, against $\log a_{H_2O}$, where a_{H_2O} is the activity of the water in the various concentrations of hydrochloric acid. The points fit closely to a straight line of slope 3.7. Bunnett (41) has recently shown that such a relation is more general than the Hammett–Zucker relations, and that the slope of the curve defines a hydration parameter w for the reaction, which is related to the number of water molecules in the transition state of the rate-determining step.

THE USE OF THE HELLMANN–FEYNMAN THEOREM TO CALCULATE MOLECULAR ENERGIES[1]

RICHARD F. W. BADER

ABSTRACT

The Hellmann–Feynman theorem has been employed to calculate the repulsion between two helium atoms and the molecular energies of H_2 and H_3. The method of molecular orbitals was used to determine the necessary expressions for the electron densities. The screening constants of the atomic orbitals comprising the molecular orbitals were treated as functions of the internuclear separation according to an empirical expression which duplicates very closely the "best" values for these parameters as determined by the variational method. The results of the calculations indicate that the present method is capable of yielding estimates of molecular energies which are comparable to those obtained by the more elaborate and time-consuming variational methods.

I. THE ELECTROSTATIC METHOD OF CALCULATING MOLECULAR ENERGIES

The Hellmann–Feynman theorem states that the x-component of the force acting on the αth nucleus, considered as occupying some fixed position in a molecule, is

$$[1] \qquad F_{\alpha x} = \frac{\partial}{\partial x_\alpha}\left(\sum_{\beta(\neq\alpha)} \frac{Z_\alpha Z_\beta e^2}{r_{\alpha\beta}}\right) - \int \rho \mathfrak{E}_{\alpha x}\, d\mathbf{r}$$

where Z_α is the nuclear charge of nucleus α, $r_{\alpha\beta}$ an internuclear separation, ρ is the electron density at the point (x, y, z), and $\mathfrak{E}_{\alpha x}$ is the electric field produced by the αth nucleus in the x-direction at the position of the ith electron (1). Equation [1] states that the force $F_{\alpha x}$ acting on a nucleus in any system of nuclei and electrons is simply the sum of the classical electrostatic forces due to the other nuclei and to the electron charge distribution. Thus, once the electronic charge density $\rho(x, y, z)$ has been determined by the methods of quantum mechanics, the forces acting on the nuclei are interpretable entirely in terms of classical electrostatics. The wave function for a molecule containing n electrons is a function of $3n$ space co-ordinates. However, due to the equivalence of all the electrons in a molecule, the electron density at any point is a three-dimensional quantity of physical significance. Because of this the formulation given by equation [1] of the forces which bind a molecule together is conceptually simpler than the more usual discussion in terms of the energies involved.

Hurley, in a series of papers (2, 3, 4, 5), has given a reformulation of the Hellmann–Feynman theorem together with a very thorough comparison of the electrostatic method of calculating molecular energies with the more usual method employing the Ritz variational procedure. Hurley has shown that if the exact wave function is used in equation [1] then the forces acting on the nucleus as calculated by the electrostatic method will agree precisely with those calculated from the results obtained by the variational procedure. However, when an approximation is made to the wave function, either in terms of molecular orbitals or Heitler–London functions, the two methods will not necessarily agree. Hurley has examined this question and has shown that when all of the variable parameters in the wave function, excluding the scale factor (the orbital exponent in hydrogen-like atomic orbitals), are determined by the variational procedure, the electrostatic and the conventional methods will lead to identical results. Variation of the scale factor as well insures that the results will be consistent with the virial theorem.

[1]*Manuscript received July 5, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

Although not always thought of as such, the internuclear distance is a variable parameter in a valence bond or molecular orbital wave function. Thus to insure agreement between the electrostatic and the variational methods it is necessary to employ so-called floating wave functions. These are wave functions which allow for the possibility of the electron charge detaching itself from the nucleus and taking up an optimum position along the internuclear axis, thus in effect making the internuclear separation a parameter to be varied in terms of the *electronic* co-ordinates.

There is no reason a priori to prefer the variational method to the electrostatic method in the calculation of molecular energies. One is forced to employ approximate wave functions in both methods and the ultimate test is the agreement with experiment. Thus there is no need to employ floating wave functions in electrostatic calculations in order to insure that the results of such a calculation will agree with those obtained from the conventional method.* In fact it is well known that a wave function based on the molecular orbital approximation leads to incorrect results at large internuclear distances when this wave function is employed in a variational type of calculation. If this same simple molecular orbital formulation is used to approximate the electron density for use in equation [1] this difficulty does not arise as the function leads to the correct expression for the electron density at infinite internuclear separation. Thus to employ a floating wave function in an electrostatic calculation would but reintroduce the errors of the conventional method when molecular orbitals were employed.

Hurley (2) has employed the simple molecular orbital approximation in the electrostatic calculations for the hydrogen molecule and for the repulsion between two helium atoms. The agreement of these calculations with the experimental results was fair. The great merit of the electrostatic calculations lies in their great simplicity and the case with which they may be carried out. It would be of great value, therefore, if they could be improved to the point where the accuracy of their results would justify their application to systems which at present are too complicated by the conventional methods. Such calculations would also be very useful for rapid estimates of the properties of transition-state molecules with reference to absolute rate theory and isotope effects.

It is the purpose of the present investigation to show that an improvement may be obtained in the calculation of molecular energies by the electrostatic method by employing molecular orbitals in which certain of the parameters are adjusted empirically so as to give a wave function which approximates very closely the one obtained by a variational calculation. The great beauty of the variational method whereby parameters may be varied to minimize the energy is of course not found in the electrostatic method. Instead some means must be devised to adjust the parameters in the wave function empirically. The most suitable parameters to vary in a simple molecular orbital function are the orbital exponents or screening constants. This is the procedure that has been adopted in the present calculations.

The expression for the electron density to be substituted into equation [1] was determined by the methods of molecular orbitals. The molecular orbitals were taken as linear combinations of Slater atomic orbitals. The screening constant $Z(R)$ in the atomic orbitals is treated as a parameter, a function of the internuclear separation, R. The empirical rule used to govern the variation of $Z(R)$ with R is

$$[2] \qquad Z(R) = Z_s - \Delta Z e^{-R}$$

**Shull and Ebbing (19) have in fact shown that much of the previously published numerical work involving floating wave functions is in error, and that very little improvement in energy results from allowing the orbitals to float.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where R is expressed in atomic units (a.u.). Z_s is the value of the screening constant for the separated atoms (when R equals infinity) and $\Delta Z = Z_s - Z_u$, Z_u being the screening constant for the united atom (when R equals zero). It is well known from variational calculations that the value of $Z(R)$ varies in a smooth fashion from the value for the separated atoms to that for the united atom. Equation [2] reproduces the values obtained for $Z(R)$ by the variational method in a very striking fashion. The merits of this function have been previously discussed by Musulin (6).

II. AN ELECTROSTATIC CALCULATION OF THE ENERGY OF THE HYDROGEN MOLECULE

The hydrogen molecule correlates with the ^1S state of the helium atom. Thus for this calculation $Z_s = 1$, $Z_u = 2$, and the expression for $Z(R)$ becomes

$$Z(R) = 1+e^{-R}.$$

If we let the atomic orbital centered on nucleus α be represented by ϕ_α and that on nucleus β by ϕ_β then the electron density for the hydrogen molecule, as given by the molecular orbital theory, is

[3] $$\rho = (1+s)^{-1}(\phi_\alpha^2+\phi_\beta^2+2\phi_\alpha\phi_\beta)$$

where s is the overlap integral between ϕ_α and ϕ_β. When this expression for the electron density is substituted into equation [1] the following expression is obtained for the force in atomic units acting on nucleus α in the line of the nuclei which is taken as the x-axis,

[4] $$F_{\alpha x} = \frac{1}{R^2} - (1-s)^{-1}[\langle\phi_\beta\phi_\beta|\cos\theta_{\alpha i}/r_{\alpha i}^2\rangle+2\langle\phi_\alpha\phi_\beta|\cos\theta_{\alpha i}/r_{\alpha i}^2\rangle],$$

where $\theta_{\alpha i}$ and $r_{\alpha i}$ are the polar co-ordinates of the ith electron with origin at nucleus α. All of the integrals occurring in equation [4] have been evaluated analytically by Coulson (7). Equation [4] together with equation [3] allows one to calculate the force acting on nucleus α for any value of R. The results of the calculation are shown in Fig. 1

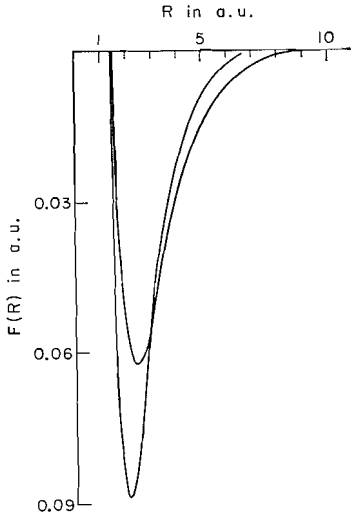

FIG. 1. Experimental (lowest curve at 2 a.u.) and calculated force curves for H_2.

together with the experimental curve obtained from the derivative of the Morse potential for the hydrogen molecule. It is seen that the force predicted by equation [4] is too large at large distances and not quite large enough at shorter distances. The agreement, however, is very good and represents a substantial improvement over the earlier electrostatic calculations and over the variational method. The energy of the hydrogen molecule as obtained from an integration of the calculated curve together with the equilibrium internuclear distance is compared in Table I with the experimental values and with those obtained by other methods as indicated.

III. AN ELECTROSTATIC CALCULATION OF THE REPULSION BETWEEN TWO HELIUM ATOMS

The approach of two normal helium atoms results in the molecular state $(\sigma_g 1s)^2\ (\sigma_u 1s)^2\ {}^1\Sigma_g^+$. For very small internuclear separations this state will correlate with the $1s\sigma^2 2p\sigma^2\ {}^1\Sigma_g^+$ state, which in the limit of the united atom reverts to the $1s^2 2p^2$ electronic configuration of the beryllium atom. However, the splitting of a beryllium atom with a $1s^2 2s^2$ electronic configuration will also give rise to a ${}^1\Sigma_g^+$ molecular state, which for small internuclear separations must lie lower than the state resulting from the $1s^2 2p^2$ configuration (9). This second ${}^1\Sigma_g^+$ state correlates with two separated helium atoms in ${}^3S$ states and thus for large internuclear separations it must possess a higher energy than the state resulting from the configuration $(\sigma_g 1s)^2\ (\sigma_u 1s)^2$. It is evident from these considerations that for large separations the molecular orbitals of the He_2 system are best considered as $\sigma_g 1s$ and $\sigma_u 1s$ while for very close approach of the two nuclei the system is more faithfully represented by an electronic configuration of the form $(\sigma_g 1s)^2\ (\sigma_g 2s)^2$.

Buckingham (20) and Wu (10) have pointed out that all of the quantum mechanical calculations performed so far for the He_2 system have used an upper molecular orbital of σ_u character. This, they feel, explains why all such calculations have been in serious error for small values of R. Much better results should be obtained if instead one employed an orbital with more $\sigma_g 2s$ character for small internuclear separations.

We have employed two wave functions in the electrostatic calculations for the He_2 system. The first is similar to that employed by Huzinaga (11) in the best variational treatment so far performed for He_2. It is derived from the electronic configuration $(\sigma_g 1s)^2\ (\sigma_u 1s)^2$. The second was used in calculations for very small values of R and thus employed the $\sigma_g 2s$ orbital in place of the $\sigma_u 1s$ orbital.

In this case it is necessary to employ two screening constants, one for the σ_g orbital and one for the σ_u orbital. The value of Z_s for the σ_g orbital is 1.70, the value of the screening constant for the helium atom. The screening constant for the united atom is taken equal to 4.00, the nuclear charge for the beryllium atom.* The expression for the screening constant for the σ_g orbital, $Z(R)_g$ is

$$Z(R)_g = 1.70 + 2.30e^{-R}.$$

The presence of the second electron in the orbital is not taken into account in determining the screening constant for the united atom. Thus Z_u in the case of H_2 was taken as 2.00, not as 1.70, and for the helium atoms, Z_u is given a value of 4.00, not 3.70. This procedure is followed simply because the values so obtained for the energies are in better agreement with the experimental ones and Z(R) is in any event an empirical parameter.

The screening constant for the σ_u orbital goes to the same limit for infinite internuclear separation as it does for the σ_g orbital, i.e., 1.70. However, the united atom limit for the σ_u orbital is a $2p$ atomic orbital of a beryllium atom, screened by two $1s$ electrons. Thus $Z_u = 2.30/2$. (The result is divided by 2, the principal quantum number, as required by the Slater recipe.) The screening constant for the σ_u orbital, $Z(R)_u$, is

$$Z(R)_u = 1.70 - 0.55e^{-R}.$$

There are thus two atomic orbital functions necessary for each helium atom. They are of the form

$$\phi_{\alpha g} = (Z(R)_g^3/\pi)^{1/2} \exp(-Z(R)_g r_\alpha),$$
$$\phi_{\alpha u} = (Z(R)_u^3/\pi)^{1/2} \exp(-Z(R)_u r_\alpha).$$

The wave function for a system of two helium atoms is

$$\Psi = (4!)^{-1/2} \sum (-1)^p P \sigma_g(1)\sigma_g(2)\sigma_u(3)\sigma_u(4)\alpha(1)\beta(2)\alpha(3)\beta(4)$$

where σ_g and σ_u are the orthonormal molecular orbitals

$$\sigma_g = (2+2s_g)^{-1/2}(\phi_{\alpha g} + \phi_{\beta g}); \qquad \sigma_u = (2-2s_u)^{-1/2}(\phi_{\alpha u} - \phi_{\beta u})$$

and s_g and s_u are the appropriate overlap integrals. The electron density resulting from this wave function is

$$\rho = (1+s_g)^{-1}(\phi_{\alpha g}^2 + \phi_{\beta g}^2 + 2\phi_{\alpha g}\phi_{\beta g}) + (1-s_u)^{-1}(\phi_{\alpha u}^2 + \phi_{\beta u}^2 - 2\phi_{\alpha u}\phi_{\beta u})$$

and thus the force exerted on nucleus α along the line of approach of the two atoms is

$$[5] \qquad F_{\alpha x}(R) = \frac{1}{R^2} - 2(1+s_g)^{-1}[\langle \phi_{\beta g}\phi_{\beta g} | \cos\theta_{\alpha i}/r_{\alpha i}^2\rangle + 2\langle \phi_{\alpha g}\phi_{\beta g} | \cos\theta_{\alpha i}/r_{\alpha i}^2\rangle]$$
$$- 2(1-s_u)^{-1}[\langle \phi_{\beta u}\phi_{\beta u} | \cos\theta_{\alpha i}/r_{\alpha i}^2\rangle - 2\langle \phi_{\alpha u}\phi_{\beta u} | \cos\theta_{\alpha i}/r_{\alpha i}^2\rangle]$$

where the symbols have the same significance as previously. Again, as in the case of the hydrogen molecule, only one- and two-center one-electron integrals arise which are easily evaluated. The results of the calculation are shown in Fig. 2 together with the best variational calculation that has so far been performed (11) and the experimental results of Amdur and Harkness (12). The electrostatic calculations in this case almost duplicate the variational treatment. It is evident that the repulsion predicted by the electrostatic and the variational calculations at small values of R is far too extreme. This is to be expected of a wave function with σ_u character in the light of the opening discussion on the He_2 system. If we assume that for small values of R we are justified in excluding all σ_u character and instead employ a wave function resulting from the electronic configuration $(\sigma_g 1s)^2 (\sigma_g 2s)^2$, then a separate electrostatic calculation may be performed. From this we may hope to determine whether or not the contribution from the $\sigma_g 2s$ orbital does improve the calculation to a point where it gives results of the right order of magnitude and at the same time gain some idea of where the transition from $\sigma_u 1s$ to $\sigma_g 2s$ character occurs. Both of these features would be of value in a more refined variational treatment which took account of the $\sigma_g 2s$ contribution.

We begin by assigning the four electrons to two orthogonal molecular orbitals

$$\Psi = (4!)^{-1/2} \sum (-1)^p P \sigma_g(1)\sigma_g(2)\sigma_{g0}(3)\sigma_{g0}(4)\alpha(1)\beta(2)\alpha(3)\beta(4)$$

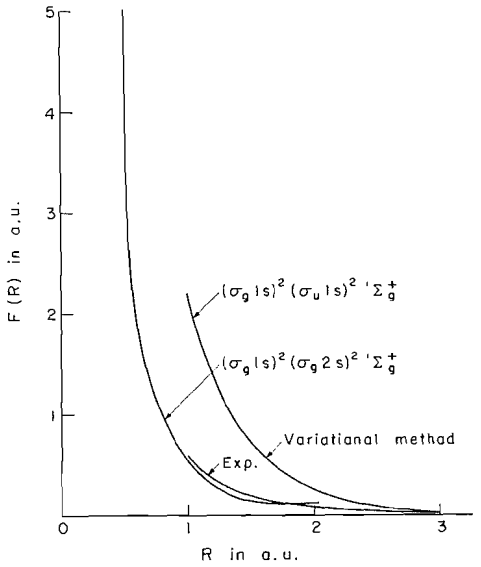

FIG. 2. Force curves for He_2. The curve of the results obtained by the variational method (3 a.u.→1 a.u.) is identical with that obtained by the indicated electrostatic method to the accuracy of this plot.

where σ_g is identical with the corresponding orbital employed above and σ_{g0} is given by

$$\sigma_{g0} = (\sigma_{g'} - s_{gg'}\sigma_g)(1-s_{gg'}^2)^{-1/2}.$$

The $\sigma_{g'}$ molecular orbital is composed of atomic $2s$ orbitals and is of the form

$$\sigma_{g'} = (2+2s_{g'})^{-1/2}(X_\alpha + X_\beta)$$

where

$$X_\alpha = (Z_{g'}^5/3\pi)r_\alpha \exp(-Z_{g'}r_\alpha).$$

The electron density for the system is then found to be

$$\rho = (\sigma_g^2 + \sigma_{g'}^2 - 2s_{gg'}\sigma_{g'}\sigma_g)(1-s_{gg'}^2)^{-1}.$$

The expression for the force on nucleus α is obtained in the same manner as previously, but due to the lack of orthogonality between the σ_g and $\sigma_{g'}$ orbitals is too cumbersome to be set down here. Since the Slater method of assigning screening constants does not differentiate between orbitals of the same principal quantum number, i.e., the $2s$ and $2p$ of the united atom beryllium, we have employed the same value for $Z_{g'}$ as was employed for Z_u.

The results of the calculations are given in Fig. 2. Obviously the answer to improving the calculations for He_2 does depend upon the inclusion of the $\sigma_g 2s$ orbital. The electrostatic calculations now predict a repulsion which is actually slightly less than that obtained experimentally for small values of R. It is only for values of R less than 3 a.u. that the function with σ_u character diverges seriously. Any contribution from this function must be small in the region of 1 a.u. A calculated point has been included for 0.5 a.u., a region which is not covered by experiment. The force of repulsion is seen to rise very steeply in this region to a value of 5.02 a.u.

IV. AN ELECTROSTATIC CALCULATION OF THE ENERGY OF THE H_3 MOLECULE

The electronic energy of a system of three hydrogen atoms has been the subject of many theoretical investigations. The most recent of these calculations was carried out by Boys and Shavitt (13), who employed the method of molecular orbitals with the superposition of configurations. This very extensive variational calculation demanded the use of an electronic computer. It is of interest to compare with their results those which can be obtained by an electrostatic calculation, a calculation which is easily carried out using a desk computer.

The three hydrogen atoms are arranged in a linear symmetric fashion as shown:

$$\underset{\alpha}{\cdot}\overset{\leftarrow R \rightarrow}{\text{———}}\underset{\beta}{\cdot}\text{———}\underset{\gamma}{\cdot}$$

The two internuclear distances $R_{\alpha\beta}$ and $R_{\beta\gamma}$ are maintained equal to each other ($= R$) and varied from infinity to the equilibrium value R_e. For any value of R the force exerted on nucleus α is equal and opposite to the force exerted on nucleus γ. There is no net force acting on nucleus β in the linear symmetrical configuration. The energy of H_3 in this configuration can thus be obtained by the integration of the force acting on nucleus α as the three atoms are brought together in the symmetric fashion from infinity to the equilibrium separation R_e.

The correlation diagram for the approach of three hydrogen atoms (the system at all times possessing $D_{\infty h}$ symmetry) is shown in Fig. 3. Two molecular orbitals will be

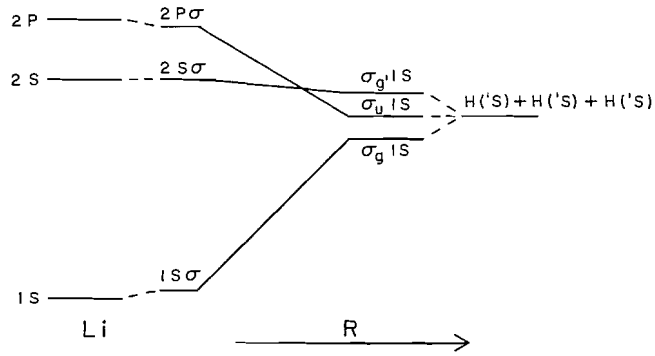

FIG. 3. Correlation diagram for H_3 in the $D_{\infty h}$ nuclear configuration.

occupied in the ground electronic configuration, a σ_g and a σ_u orbital. The value of Z_s for all three of the molecular orbitals will be unity and Z_u will equal 3.00 and 0.65 for the σ_g and σ_u orbitals, respectively. The screening constants for the two occupied orbitals are therefore,

$$Z(R)_g = 1+2e^{-R} \qquad \text{and} \qquad Z(R)_u + 1 - 0.35e^{-R}.$$

The forms of the three molecular orbitals which result from the linear combinations of the hydrogen 1s atomic orbitals are

$$\sigma_g = N_g(\phi_{\alpha g}+\lambda\phi_{\beta g}+\phi_{\gamma g})$$

$$\sigma_u = N_u(\phi_{\alpha u}-\phi_{\gamma u})$$

$$\sigma_{g'} = N_g'(\phi_{\alpha g}'-\lambda'\phi_{\beta g}'+\phi_{\gamma g}')$$

where the N_i are normalizing factors and the ϕ's are again normalized atomic orbitals of the Slater type. The ground state wave function for linear symmetric H_3 is

$$\Psi = (3!)^{-1/2}\sum (-1)^p P\sigma_g(1)\sigma_g(2)\sigma_u(3)\alpha(1)\beta(2)\alpha(3)$$

and this results in an electron density

$$\rho = 2[2+2S^g_{\alpha\gamma}+2\lambda(S^g_{\alpha\beta}+S^g_{\beta\gamma})]^{-1}[\phi_{\alpha g}{}^2+\lambda^2\phi_{\beta g}{}^2+\phi_{\gamma g}{}^2+2\lambda\phi_{\alpha g}\phi_{\beta g} + 2\lambda\phi_{\beta g}\phi_{\gamma g}+2\phi_{\alpha g}\phi_{\gamma g}]+[2-2S^u_{\alpha\gamma}]^{-1}[\phi_{\alpha u}{}^2+\phi_{\gamma u}{}^2-2\phi_{\alpha u}\phi_{\gamma u}].$$

The five necessary atomic orbitals will be of the forms

$$\phi_{\alpha g} = (Z(R)_g{}^3/\pi)^{1/2}\exp(-Z(R)_g r_\alpha) \qquad \text{for the } \sigma_g \text{ orbital,}$$

$$\phi_{\alpha u} = (Z(R)_u{}^3/\pi)^{1/2}\exp(-Z(\mathrm{R})_u r_\alpha) \qquad \text{for the } \sigma_u \text{ orbital.}$$

The application of the Hellmann–Feynman theorem gives the following expression for the force acting on nucleus α along the line of centers

$$F_{\alpha z}(R) = \frac{1.25}{R^2} - 2N_g^2\{\langle\phi_{\beta g}\phi_{\beta g}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle+\langle\phi_{\gamma g}\phi_{\gamma g}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle + 2\lambda\langle\phi_{\alpha g}\phi_{\beta g}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle+2\lambda\langle\phi_{\beta g}\phi_{\gamma g}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle + 2\langle\phi_{\alpha g}\phi_{\gamma g}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle\} - N_u^2\{\langle\phi_{\gamma u}\phi_{\gamma u}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle - 2\langle\phi_{\alpha u}\phi_{\gamma u}|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle\}.$$

All but one of the integrals occurring in equation [6] are similar to the ones previously encountered. The one new integral is

$$\langle\phi_\beta\phi_\gamma|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle.$$

This is a three-center one-electron integral and it possesses no analytical solution. The integral represents the interaction of an ideal dipole centered on nucleus α with the charge distribution arising from the overlap of the atomic orbitals on nuclei β and γ. The value of this integral can be approximated by a transformation to known integrals of the type $\langle\phi_\beta\phi_\beta|\cos\theta_{\alpha i}/r^2_{\alpha i}\rangle$ using an expansion first suggested by Mulliken (14) and later commented on and discussed by Rüdenberg (15) and Csavinszky (16). Both ϕ_β and ϕ_γ are expanded in terms of an orthonormal set of hydrogenic wave functions centered on the opposite atom, i.e.,

$$\phi_\beta = \sum_j S_{\beta\gamma(j)}\phi_{\gamma(j)} \qquad \text{and} \qquad \phi_\gamma = \sum_i S_{\gamma\beta(i)}\phi_{\beta(i)}$$

where the coefficients of the expansion, $S_{\beta\gamma(j)}$, are the corresponding overlap integrals

$$\langle\phi_\beta|\phi_{\gamma(j)}\rangle.$$

With this expansion $\phi_\beta\phi_\gamma$ becomes

$$\phi_\beta\phi_\gamma = 1/2S_{\beta\gamma(1)}(\phi_\beta\phi_{\beta(1)}+\phi_\gamma\phi_{\gamma(1)})+1/2S_{\beta\gamma(2)}(\phi_\beta\phi_{\beta(2)}+\phi_\gamma\phi_{\gamma(2)})+\ldots\ .$$

Rüdenberg has pointed out that this expansion is best for small values of R. Under these conditions the coefficients $S_{\beta\gamma(j)}$, $j \neq 1$ become vanishingly small because of their near orthogonality. As a guide to the approximation we have employed the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

expansion to approximate the known integral $\langle\phi_\alpha\phi_\beta|\cos\theta_\alpha/r_{\alpha i}^2\rangle$. Out to 4 a.u. the major portion is contributed by the leading term as is to be expected. Beyond 4 a.u. the contributions from terms of larger j values became increasingly important and made the approximation prohibitive. Instead, it was found that the known integral was very well approximated by the values of

$$R^{-1/2}S_{\alpha\beta}\langle\phi_\beta\phi_\beta|\cos\theta_{\alpha i}/r_{\alpha i}^2\rangle.$$

For values of $R > 4$ a.u. this same form was used to approximate the three-center integral as well.

The value which is to be given to the parameter λ, which occurs in the expression for the σ_g orbital, is yet to be determined. In variational calculations the energy is minimized with respect to λ and its optimum value is thus determined. The parameter λ possesses no optimum value in an electrostatic calculation, the force exerted on nucleus α by the electrons in the σ_g orbital increasing to a limiting value of $2\langle\phi_\beta\phi_\beta|\cos\theta_\alpha/r_\alpha^2\rangle$ as the value of λ is increased. However, a lower limit can be given to λ even in the electrostatic calculations. For large values of R, λ must approach the value $\sqrt{2}$ if the wave function is to give the correct electron density for large separations. Walsh and Matsen (17) have carried out a variational calculation for H_3 using the wave function employed in this investigation and have found the optimum value for λ to be 1.5 when the effective nuclear charges were simultaneously varied. It is to be expected that λ will have a value greater than $\sqrt{2}$ as charge is forced onto the central atom from the two neighboring atoms as the internuclear separation is decreased.*

TABLE II

	Present calc.		Simple M.O. (17)	M.O. with C.I. (13)	Expt. (13)
	$\lambda = \sqrt{2}$	$\lambda = 1.5$			
Binding energy (in a.u.)	0.1307	0.1482	0.0733	0.1278	0.1625
R_e (in a.u.)	1.66	1.61	1.82	1.779	—

The energy of H_3 has been determined for λ equal to $\sqrt{2}$ and to 1.5, that is, the lower limiting value and a higher one, consistent with that found from a variational calculation. The results of the calculations are given in Table II. The electrostatic calculation with $\lambda = \sqrt{2}$ (equivalent to treating λ as a constant in a variational calculation) is seen to far surpass the simple molecular orbital approach and to match the more elegant calculation of Boys and Shavitt which included the contributions from configurational interaction. When the value of λ is increased to 1.5, only a 9% error remains in the calculated energy, and of course this is a more realistic value of λ than is $\sqrt{2}$. The values of the frequencies for the symmetrical stretch ω_1 and the bending vibration ω_2 of the H_3 molecule are easily determined from the results of the electrostatic calculation. The value of the frequency for the antisymmetric stretching vibration cannot, unfortunately, be determined in these calculations unless some additional assumptions are made. The frequencies obtained, together with those determined by Boys and Shavitt (13) and by Weston (18) are given in Table III. The values reported by Weston were obtained by an application of Sato's method for determining potential energy surfaces, in this

*The parameter λ was not treated as a function of R in the electrostatic calculations. A variation of λ from 1.5 at $R = 2$ to $\lambda = \sqrt{2}$ at $R = \infty$ would not significantly change the result since the variation is slight and since the major change brought about by a change in λ is in the region of $R = 2$.

case applied to the H + H_2 reaction. The values for ω_1 are seen to be in fair agreement with the other calculations, while a higher value is predicted for the bending vibration.

V. DISCUSSION

The results of the present calculations indicate that the electrostatic method, when complemented with the empirical expression [2] for determining the screening constant, is capable of giving very reliable estimates of binding energies and force constants. Furthermore, these results may be obtained with relative ease and in a short period of time. This method should be of value in the calculation of the properties of transition states where calculations capable of giving reliable results would be of great help.

It should be pointed out that the use of equation [2] need not necessarily be considered an empirical correction. Since it reproduces the "best" wave functions as determined by the variational procedure to such a remarkable degree, it can be argued that its use is simply to provide the electrostatic method with the best possible wave function obtainable from the variational method.

THE REACTIONS OF PERFLUOROETHYL RADICALS WITH HYDROGEN AND METHANE[1]

S. J. W. PRICE[2] AND K. O. KUTSCHKE

ABSTRACT

The reactions of C_2F_5 radicals, produced by the photolysis of $(C_2F_5)_2CO$, with methane and hydrogen have been studied. Assuming zero activation energy for $2C_2F_5 \rightarrow C_4F_{10}$ the activation energies for $C_2F_5 + CH_4 \rightarrow C_2F_5H + CH_3$ and $C_2F_5 + H_2 \rightarrow C_2F_5H + H$ are 10.6 kcal/mole and 11.9 kcal/mole respectively. The present results have been correlated with data on the reactions of CF_3, C_3F_7, and CH_3 radicals with H_2, D_2, CH_4, and C_2H_6. Taking $E_{recombination} \approx 0$ in all cases and assuming the frequency factor for the recombination reaction varies little from radical to radical, the order of ease of hydrogen abstraction from a given substrate is $CF_3 > C_2F_5 > C_3F_7 > CH_3$. Similarly the ease of hydrogen abstraction from a substrate by a given fluorinated radical is $C_2H_6 > H_2 > CH_4 > D_2$. A calculation based on very limited data indicates the reaction $CH_3 + C_2F_5COC_2F_5 \rightarrow CH_3COC_2F_5 + C_2F_5$ may occur with an activation energy of approximately 7 kcal/mole.

INTRODUCTION

The availability of CF_3 and n-C_3F_7 radicals from the photolysis of the appropriate ketone (1, 2) has led to the study of the reactions of these radicals with simple hydrocarbons, hydrogen, and deuterium (3, 4, 5, 6). Recently C_2F_5 radicals have been obtained by the photolysis of $(C_2F_5)_2CO$ (7). In the present work the reactions of this radical with hydrogen and with methane have been studied.

As was the case in the study of n-C_3F_7 radical reactions the condensable product could not be separated quantitatively from the ketone by low-temperature distillation. A combination of gas phase adsorption chromatography and mass spectrometry has been used in an attempt to obtain complete analysis of the reaction products.

EXPERIMENTAL

Apparatus

The photolysis apparatus was similar to that employed in similar investigations in this laboratory (2, 5). The quartz reaction cell (optical path 10 cm, 190 cc) was mounted inside a hot box which could be controlled to $\pm 0.1°$ C. It was fully illuminated by a parallel beam of light in the 3130 Å region obtained via a standard set of filters (8) from a Hanovia S500 lamp operated on a regulated supply. The cell was connected to the vacuum system through a mercury cutoff mounted immediately below the hot box. The volume of the connecting tubing and a small Dewar sealed to the top of the reaction cell, both of which were outside the irradiated region, was approximately 20 cc thus giving a total volume of 210 cc for the reaction system.

Materials

The perfluorodiethyl ketone used in this work was supplied by Merck and Company of Canada. The ketone contained significant quantities of benzene and some unidentified bromine compound. These impurities were removed in the later stages of the work by a method described previously (7). Phillips Research Grade methane was used without further purification. Hydrogen was purified by passage through a palladium thimble.

C_2F_5H for calibration of the mass spectrometer and the chromatographic columns was prepared by photolysis of $(C_2F_5)_2CO$ (80 mm) with hydrogen (160 mm) at 250° C and low light intensity (approximately 0.8×10^{12} quanta/cc sec). The mass spectrum of C_2F_5H is given in Table I.

TABLE I

Mass spectrum of C_2F_5H*

Mass No.	Relative height	Probable positive ion
31	8.33	CF
32	2.68	CFH
44	3.80	C_2FH
50	2.88	CF_2
51	100.00	CF_2H
69	27.60	CF_3
100	2.16	C_2F_4
101	47.0	C_2F_4H
119	1.53	C_2F_5

*The isotope peaks are not recorded.

Procedure

Perfluorodiethyl ketone was admitted to the reaction zone and to connecting tubing of the mixing volume, and its pressure read on a mercury manometer. The ketone was condensed in a side arm of the mixing chamber which then was isolated from the measuring volume. Hydrogen or methane was admitted and measured in a similar manner. The ketone was warmed and transferred back to the measuring volume by means of a Toepler pump. After they were mixed 10 times by expansion into the Toepler pump the mixed gases were compressed to their original volume. The reaction zone was isolated by raising the mercury in the cutoff below the hot box and the experiment was started by removing a stop from the light beam. The experiments were allowed to proceed to 2.5% to 10% decomposition of the ketone, most experiments being in the region of 5% decomposition.

Analysis

(*i*) $(C_2F_5)_2CO + CH_4$

The products of the photolysis were passed through two traps at −120° C to remove the bulk of the ketone and then through a trap at −210° C to remove the remaining condensable materials. Carbon monoxide and methane were transferred to a copper oxide furnace at 300° C. After 2 hours, during which time the gases in the copper oxide furnace were mixed several times, the mixture in the furnace was condensed at −196° C and the methane pumped off. The CO_2 was measured in a gas burette.

Since C_4F_{10} and the ketone cannot be separated readily by low-temperature distillation, the entire mixture of condensable products was transferred to a gas chromatographic apparatus where it was analyzed using a 3-ft alumina column (4 mm I.D.) maintained at 25° C. Hydrogen was used as a carrier gas at a flow rate of approximately 60 cc per minute. Exact retention volumes or appearance times cannot be given as these varied considerably with the moisture content of the alumina and the age of the column. As far as could be ascertained the ketone is completely absorbed on the column. Because of this the columns have a useful life of approximately 15 analyses. During this time the sensitivity based on peak height increases by as much as a factor of two.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The elution times similarly decrease. However, for a given column at a fixed temperature and flow rate, the relative elution times remain constant as does the sensitivity based on peak area (this latter point was checked by running a standard C_4F_{10} sample immediately after each analysis). In all cases the products appeared in the order C_2H_6, C_4F_{10}, a peak initially unidentified which was later shown to be C_2F_5Br, and a peak consisting of a mixture of C_2F_5H and $C_2F_5CH_3$. Under the stated conditions the appearance time of C_4F_{10} varied from column to column and with column age over the approximate range 10 minutes to 30 minutes. When the appearance time for C_4F_{10} was about 10 minutes the following approximate appearance times were observed: C_2H_6, 1 minute; C_2F_5Br, 17 minutes; $C_2F_5H + C_2F_5CH_3$, 35 minutes.

The mass spectrum of accumulated C_2F_5Br peaks is shown in Table II.

TABLE II

Mass spectrum of C_2F_5Br

Mass No.	Relative peak height	Probable positive ion
31	20.0	CF
50	10.7	CF_2
69	44.9	CF_3
79	5.9	Br
81	6.1	Br
91	1.1	CBr
93	1.1	CBr
100	4.9	C_2F_4
110	2.0	CFBr
112	2.0	CFBr
119	100	C_2F_5
129	30.6	CF_2Br
131	30.0	CF_2Br
141	.05	C_2F_2Br
143	.05	C_2F_2Br
160	.17	C_2F_3Br
162	.17	C_2F_3Br
179	13.9	C_2F_4Br
181	13.5	C_2F_4Br
198	17.7	C_2F_5Br
200	19.0	C_2F_5Br

The mixture of C_2F_5H and $C_2F_5CH_3$ was collected as it was eluted from the column, its volume measured in a gas burette, and the mixture analyzed on a mass spectrometer using the mass 51 (CF_2H) and mass 101 (C_2F_4H) peaks for C_2F_5H and the mass 65 (CF_2CH_3) peak for $C_2F_5CH_3$. The mass spectrometer was calibrated using C_2F_5H. Hence C_2F_5H was determined directly and the $C_2F_5CH_3$ calculated by difference. In each case the relative sensitivity to C_2F_5H (based on mass 51) and $C_2F_5CH_3$ (based on mass 65) was 0.63:1.00. During the course of the work a new element was installed in the mass spectrometer. This changed the sensitivity to CH_4 (using mass 15) from approximately 7 cm peak height per micron to 24 cm peak height per micron but had no apparent effect on the relative sensitivity of C_2F_5H to $C_2F_5CH_3$ (as based on masses 51 and 65). The mass spectrum of $C_2F_5CH_3$ obtained by subtracting the C_2F_5H spectrum from that of a mixture of the compounds is given in Table III. Virtually the same $C_2F_5CH_3$ spectrum is obtained using any of the analyses carried out in the course of the work.

(*ii*) $(C_2F_5)_2CO + H_2$

The condensable products were trapped out as described in Section (*i*). Carbon monoxide and hydrogen were oxidized to carbon dioxide and water in a copper oxide furnace

TABLE III

Mass spectrum of $C_2F_5CH_3$ obtained by subtracting the C_2F_5H spectrum from the spectrum of a mixture of these compounds

Mass No.	Relative height	Probable positive ion
15	1.7	CH_3
31	1.9	CF
44	12.0	CFCH
45	15.5	$CFCH_2$
50	0.2	CF_2
64	5.6	CF_2CH_2
65	100.0	CF_2CH_3
69	13.0	CF_3
115	5.2	$C_2F_4CH_3$
119	10.0	C_2F_5
134	3.2	$C_2F_5CH_3$

and the CO_2 was estimated by transferring it to a gas burette. Several degassings of the water–CO_2 mixture were carried out to obtain as complete a separation as possible. During removal of CO_2 the CO_2–water mixture was kept at $-90°$ C. Since $C_2F_5CH_3$ is not formed in this photolysis complete analysis of the condensable products was carried out using the gas chromatographic system described in Section (*i*).

RESULTS

The observed products of the photolyses may be accounted for qualitatively by the following mechanisms:

(*a*) *Photolysis in the presence of methane.*—

$$C_2F_5COC_2F_5 + h\nu \rightarrow 2C_2F_5 + CO,$$

$$C_2F_5 + CH_4 \rightarrow C_2F_5H + CH_3, \quad [1]$$

$$2C_2F_5 \rightarrow C_4F_{10}, \quad [2]$$

$$C_2F_5 + CH_3 \rightarrow C_2F_5CH_3, \quad [4]$$

$$2CH_3 \rightarrow C_2H_6. \quad [5]$$

For the unpurified ketone two additional reactions are required:

$$C_2F_5 + \text{impurity} \rightarrow C_2F_5H + \text{radical}, \quad [6]$$

$$C_2F_5 + \text{impurity} \rightarrow C_2F_5Br + \text{radical}. \quad [7]$$

The impurities shown in equations [6] and [7] are not necessarily the same. The exact nature of the contaminants was not established; however, mass spectrometric analyses and infrared experiments suggest benzene as one possible impurity in which case the "radical" in equation [6] would be the phenyl radical, which would presumably either dimerize or abstract from methane regenerating benzene. The impurity containing bromine may possibly be present as bromobenzene in which case the radical in equation [7] would also be the phenyl radical. When impure ketone was used, the material balance was always low, i.e., less product was found than is compatible with the production of $2C_2F_5$ per CO. This fact also suggests an unsaturated impurity.

(*b*) *Photolysis in the presence of hydrogen.*—

$$C_2F_5COC_2F_5 + h\nu \rightarrow 2C_2F_5 + CO,$$

$$C_2F_5 + H_2 \rightarrow C_2F_5H + H, \quad [3]$$

$$H + C_2F_5 \rightarrow C_2F_5H, \quad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

plus reactions [2], [6], and [7]. It has been assumed that [10] is of negligible importance under the experimental conditions used (5).

$$H + H + M \rightarrow H_2 + M. \qquad [10]$$

If this reaction did contribute appreciably then all values reported for $k_3/k_2^{\frac{1}{2}}$ should be increased by a factor lying between one and two.

The results of the photolyses in the presence of methane are given in Table IV and those for the photolyses in the presence of hydrogen in Table V. Except as noted the

experiments were done using the slightly impure ketone. Since it had been found previously that the photolysis of the impure ketone gave C_2F_5H as a product (unpublished results of work carried out in connection with reference 7), a correction for this was made as follows.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$R_{C_2F_5H} = k_6[C_2F_5][\text{impurity}]+k_1[C_2F_5][CH_4]$$

$$R_{C_2F_5H}/R_{C_4F_{10}}^{\frac{1}{2}} = (k_6/k_2^{\frac{1}{2}})([\text{impurity}]/[\text{ketone}])[\text{ketone}]+(k_1/k_2^{\frac{1}{2}})[CH_4].$$

From experiments in the absence of CH_4

$$(k_6/k_2^{\frac{1}{2}})([\text{impurity}]/[\text{ketone}]) = \text{antilog}\ (\bar{3}.987+461/T)$$

(second-order rate constants are expressed in $(\text{mole/cm}^3)^{-1}\ \text{sec}^{-1}$). Hence values of $k_1/k_2^{\frac{1}{2}}$ could be calculated. As may be seen from Fig. 1, the ratios $k_1/k_2^{\frac{1}{2}}$ obtained in this manner are in excellent agreement with those calculated from data taken with the purified ketone. A similar correction was applied to the data from the hydrogen – impure ketone system; good agreement was also achieved with data obtained when purified ketone was used. In the hydrogen system

$$\tfrac{1}{2}R_{C_2F_5H}/R_{C_4F_{10}}^{\frac{1}{2}} = \tfrac{1}{2}(k_6/k_2^{\frac{1}{2}})([\text{impurity}]/[\text{ketone}])[\text{ketone}]+(k_3/k_2^{\frac{1}{2}})[H_2].$$

With a ketone concentration of approximately 1.45×10^{-6} mole/cc, varying the methane concentration from 0.80×10^{-6} to 3.24×10^{-6} mole/cc had no apparent effect on $k_1/k_2^{\frac{1}{2}}$ ($t = 212°$ C). Similarly with a ketone concentration of approximately 1.3×10^{-6} mole/cc, a variation in the hydrogen concentration from 0.40×10^{-6} to 4.28×10^{-6} mole/cc did not alter the value of $k_1/k_3^{\frac{1}{2}}$ ($t = 174°$ C).

DISCUSSION

The following values have been obtained from Fig. 1:

$$E_1-\tfrac{1}{2}E_2 = 10.62\ \text{kcal/mole};\qquad A_1/A_2^{\frac{1}{2}} = 4.17\times10^4\ (\text{mole/cm}^3)^{-\frac{1}{2}}\ \text{sec}^{-\frac{1}{2}};$$

$$E_3-\tfrac{1}{2}E_2 = 11.90\ \text{kcal/mole};\qquad A_3/A_2^{\frac{1}{2}} = 5.25\times10^5\ (\text{mole/cm}^3)^{-\frac{1}{2}}\ \text{sec}^{-\frac{1}{2}}.$$

By analogy with other simple radicals the activation energy for the recombination of two C_2F_5 radicals may be expected to be very small (9, 10, 11, 12, 13). Therefore the observed activation energies should be approximately those for the hydrogen abstraction reactions.

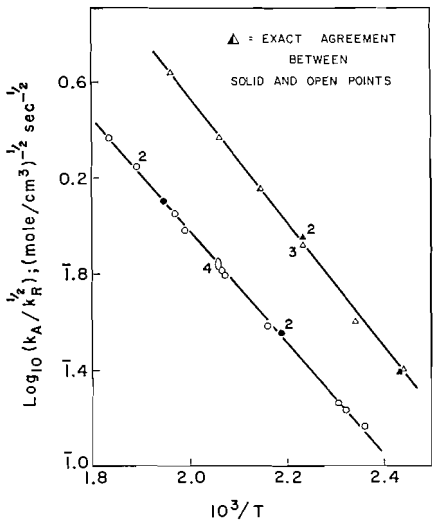

FIG. 1. Arrhenius plots for the reactions of C_2F_5 radicals with methane (○) and with hydrogen (△). Solid points refer to runs using the purified ketone. Subscripts refer to number of experiments averaged to obtain a point; the maximum and minimum values of each set lie within the point.

CH_4	13.0	4.41‡	.014	9.5	3.99††	0.41	10.6	4.62‡‡	0.55	10.3	4.99‡	1.74
D_2	12.2	4.71§	.068	13.8	5.78**	.107	—	—	—	9.70	4.77††	1.25

NOTE: In each case $E = E_1 - \frac{1}{2}E_2$, $\log A = A_1/(A_2)^{\frac{1}{2}}$, and $k = k_1/k_2^{\frac{1}{2}}$ where the subscript 1 refers to the abstraction reaction and the subscript 2 to the reaction $R + R \rightarrow R_2$. Units: E kcal/mole; A_1, A_2, k_1, and k_2 (moles $cm^{-3})^{-1}$ sec^{-1}; all k's refer to 200° C.

*Reference 14. These values actually refer to $CD_3 + C_2H_6$; however, the limited data available indicates that rates of abstraction by CH_3 and CD_3 do not differ greatly. †Reference 15. ‡Reference 3. §Reference 16. ‖Reference 4. **Reference 5. ††Reference 6. ‡‡Present work.

In Table VI the present results are compared with those obtained with similar radicals and substrates. As indicated in the footnotes of Table VI, the tabulated E values are $E_{\text{abstraction}} - \frac{1}{2}E_{\text{recombination}}$; however, in the ensuing discussion it will be assumed that $E_{\text{recombination}}$ is effectively zero in each case. The further assumption will be made that $A_{\text{recombination}}$ is approximately the same for the four radicals considered. This has been borne out by experiment for CH_3 and CF_3 (9, 10, 11); it might not be true for C_2F_5 and C_3F_7 recombinations but will serve as a basis for discussion, any errors thus introduced being remedied easily when experimental values become available. As may be seen from Table VI there is no consistent trend in either activation energies or frequency factors. However, there is a marked and in fact almost unique pattern in the values of k calculated at 200° C. In many of these investigations the exact slope of the Arrhenius curve is somewhat doubtful. Since the A factors are calculated using the experimental E, compensation between A and E must occur if E is incorrectly calculated. However, provided k values are calculated from these A and E values within or close to the experimental temperature range, much less relative error is to be expected in these than in A or E separately. Using k as a measure of the relative radical reactivity with respect to hydrogen abstraction, the following sequence is observed for all four substrates: $CF_3 > C_2F_5 > C_3F_7 > CH_3$. Although this order is obtained from k's at 200° C the convergence of values with temperature is so small that it apparently should hold over all readily accessible temperatures, except in the case of C_3F_7 and C_2F_5, which would apparently replace each other in the reactivity series below approximately 70° C. Similarly, for all three fluorinated radicals the ease of hydrogen abstraction from a given substrate is observed to be $C_2H_6 > H_2 > CH_4 > D_2$. It is assumed that the abstraction by C_2F_5 from C_2H_6 and from D_2 would follow this pattern although at present this is not known.

Although the data are extremely limited another point may be considered. In the photolysis of azomethane in the presence of hexafluoro-acetone, Pritchard and Steacie (17) found that the over-all reaction $CH_3 + CF_3COCF_3 \rightarrow CH_3COCF_3 + CF_3$ had an activation energy of approximately 6 kcal/mole. In the three runs with pure $C_2F_5COC_2F_5$ in the presence of methane the following material balance was expected:

$$(C_4F_{10} + \tfrac{1}{2}C_2F_5H + \tfrac{1}{2}C_2F_5CH_3)/CO = 1, \quad \text{(i)}$$

$$(2C_2H_6 + C_2F_5CH_3)/C_2F_5H = 1. \quad \text{(ii)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

However, it was observed that (i) exceeded unity and (ii) was much less than unity. The total radical balance

$$(C_4F_{10} + C_2F_5CH_3 + C_2H_6)/CO = 1 \qquad \text{(iii)}$$

was obeyed experimentally (1.002 ± 0.001). This suggests that [9] occurs. The reaction merely exchanges free radicals so that (iii) should be obeyed whereas (i) and (ii) should not.

$$CH_3 + C_2F_5COC_2F_5 \rightarrow C_2F_5 + CH_3COC_2F_5 \qquad [9]$$

The reaction might proceed via an addition complex but the lifetime of the complex must be sufficiently small that it will not scavenge free radicals to form an ether.

Considering reactions [9], [2], and [4]

$$(R_{C_4F_{10}} \cdot R_{exchange})/R_{C_2F_5CH_3} = \{(k_2^{\frac{1}{2}}k_9)/k_4\}[C_2F_5COC_2F_5]$$

and assuming k_2 and k_4 to be temperature independent, the value of E_9 is found to be 7 ± 1 kcal/mole where, noting that the result is based on only three experiments, the limits of error are rather arbitrary. In principle it would also be possible to use reactions [9] and [5] to calculate this quantity. However, the quantities of C_2H_6 are very small and the accuracy of their analysis is questionable. Therefore any calculations employing ethane yields would be of very doubtful value.

In the photolyses with H_2 it was expected that $(\frac{1}{2}C_2F_5H + C_4F_{10})/CO = 1$. This was indeed the case when purified ketone was used. Thus the analogue with H of reaction [9],

$$H + C_2F_5COC_2F_5 \rightarrow C_2F_5CHO + C_2F_5,$$

does not occur.

Consideration of reactions [2], [4], and [5] indicates that

$$R_{C_2F_5CH_3}/(R_{C_4F_{10}}R_{C_2H_6})^{\frac{1}{2}} = k_4/(k_2k_5)^{\frac{1}{2}},$$

which should be a constant equal to about 2.5 if $E_2 = E_4 = E_5 = 0$ and if the collision theory cross-sections are related by $\sigma_4 = (\sigma_2\sigma_5)^{\frac{1}{2}}$. The data for all the experiments, except that at the highest temperature, give values of the left side of this expression in the range 2 ± 1. A slight trend toward larger values at the higher temperatures was noted, but the lack of good precision in the ethane analysis, leading to considerable scatter, prevents the drawing of a definite conclusion in this regard.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Mrs. R. H. Riem for the mass spectrometric analyses and to Dr. R. N. Jones for infrared experiments on the impure ketone. We also wish to thank Dr. E. W. R. Steacie for many stimulating discussions during the course of this work.

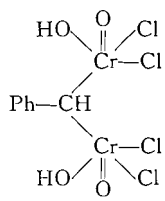
ÉTARD REACTION

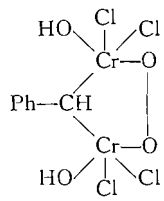
III. NATURE OF THE COMPLEX[1]

OWEN H. WHEELER



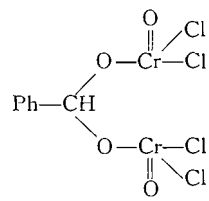
ABSTRACT

Magnetic susceptibility measurements have shown that the chromium atoms in the toluene – chromyl chloride complex are tetravalent. The structure of the complex and the reaction mechanism are discussed. Spectroscopic evidence has been found of the initial formation of a π-complex. The products of reaction of chromyl chloride and ethylbenzene, isopropylbenzene, tetralin, and indane have been determined.



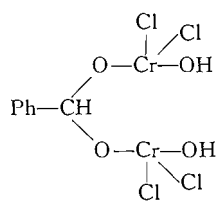
An insoluble dark-brown complex is formed as an intermediate in the Étard oxidation of toluenes with chromyl chloride (1, 2, 3), and although a number of structures have been suggested for the complex (3) no positive evidence has been published concerning its structure.

The analysis of the complex formed with toluene agrees with the empirical formula $C_7H_8.2CrO_2Cl_2$. The complexes are generally sparingly soluble in organic solvents and are decomposed by water to give benzaldehydes and to liberate chromium in a valence state of +4 or +5 (1). The chromium atoms in the complex must thus have some valency from four to the six of the original chromyl chloride.



Hartford and Darrin (3) have suggested structures involving hydrogen bonding between two hydrogen atoms of the methyl group of toluene and two chlorine or oxygen atoms of two molecules of chromyl chloride. Structure I, proposed by Rhode (4), also involves Cr^{VI} but with the rather improbable co-ordination number of 5.

I



II

III

Two structures (II and III) can be envisaged for pentavalent chromium. However, the former (II) again has a co-ordination number of 5. In structure III the Cr^{V} has a co-ordination number of 4, and, although the molecule lacks two hydrogen atoms, the formula could be accommodated by the analysis. Étard (5) and later Westheimer (6) proposed structure IV involving tetravalent and tetraco-ordinate chromium.

IV

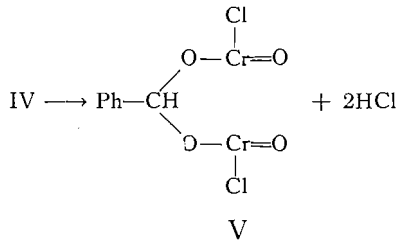
[1]*Manuscript received in original form October 13, 1959, and, as revised, May 30, 1960.*
Contribution from the Departments of Chemistry of Dalhousie University, Halifax, N.S., and the College of Agriculture and Mechanic Arts, University of Puerto Rico, Mayaguez, Puerto Rico. Presented in part at the VII Congreso Latinoamericano de Química, in Mexico City, March 1959. Part II: Can. J. Chem. **36**, *667 (1958).*

In order to determine the valency state of the chromium atoms the magnetic susceptibility (7) of the toluene complex was measured and it gave a value of 3.16 Bohr magnetons per chromium atom. This value (Table I) can only correspond to two unshared electrons

TABLE I

Magnetic susceptibilities of chromium*

	n†	μ_{calc}‡	μ_{obs}§
Cr^{VI}	0	0	0
Cr^{V}	1	1.73	1.7–1.8
Cr^{IV}	2	2.83	2.8–3.1
Cr^{III}	3	3.87	3.85–3.9



*Values for covalent atoms, from ref. 8. †Number of unshared electrons. ‡Magnetic moment calculated from $\mu = \sqrt{\{n(n+2)\}}$. §Magnetic moments observed in covalent bond complexes of Cr and other atoms with the same number of unshared electrons.

per atom. The fact that the value is a little higher than that usually found is probably due to the approximations involved in determining the susceptibility of a solid, or to interaction between the two chromium atoms in the same molecule. The chromium atoms must thus be tetravalent and the complex must have structure IV.

The infrared spectrum of the complex, either as a Nujol mull or as a potassium bromide disk, was rather ill-defined but showed evidence of the presence of a hydroxyl group (maxima at 2.35, 9.3, and 9.7 μ, which may be due to OH stretching and deformation vibrations).

It might be expected that the third hydrogen atom of toluene would be displaced, but the product of the Étard reaction is always a benzaldehyde and not a benzoic acid. The fact that the reaction terminates after displacing two hydrogen atoms probably has its origin in the low solubility of the complex formed with two molecules of chromyl chloride, although a more important factor is probably a steric one. The commonest stereochemical configuration of co-ordination number four is the square planar (dsp^2) form (8), and with two such planes joined to a carbon atom, together with the benzene ring in IV, the third hydrogen atom will be completely hindered to displacement by the bulky chromyl chloride molecule. In the alternative tetrahedral (d^3s) form of the complex the molecule would be even more crowded. It may be noted that ortho-substituted toluenes with large substituents, such as an iodo-atom or nitro-group, give much lower yields of benzaldehydes than their para isomers (1) and this is no doubt largely due to steric hindrance.

The structure IV is in accord with the reactions of the complex, since hydrolysis of the chromium–oxygen bonds will give benzaldehyde (initially as its hydrate). The loss of half the chlorine as hydrogen chloride on heating the complex (3) is also easily explained since a structure with tetravalent chromium atoms such as V could be readily formed.

V

As has been already suggested (1) the first stage in the reaction of chromyl chloride and a toluene will be the formation of a π-complex, the chromyl chloride acting as a Lewis acid and the aromatic ring as the corresponding base. The formation of such a π-complex accounts for the initial exothermic reaction observed (1, 3) and spectroscopic evidence for this complex has now been obtained (Fig. 1). A solution of chromyl chloride in carbon tetrachloride has maxima at 290 and 415 mμ (curve II), while a solution of toluene has no significant absorption above 270 mμ (curve I). On mixture of the two solutions, the intensity near 290 mμ increases while the intensity at 415 mμ decreases (curve III). This is consistent with the reaction of the chromyl chloride (decrease in intensity of visible band) with the toluene to form a π-complex with a maximum near 300 mμ. When the mixture is allowed to stand, a precipitate forms and the intensity of both bands decreases, although the greatest decrease is observed at 300 mμ (curve IV) since the π-complex is transformed into the insoluble reaction complex.

The oxidation of a methyl group to an aldehyde is not the only reaction which can take place between an aromatic compound and chromyl chloride. In a previous publication (2) it was shown that the methylene groups in 9,10-dihydroanthracene, phenanthrene, and fluorenene could be oxidized to quinones and that 9-methylanthracene was oxidized to anthraquinone. The products of the oxidation of ethylbenzene have been found to be acetophenone (oxidation of methylene group) and phenylacetaldehyde (oxidation of terminal methyl group) in about equal quantities. It has been reported (12) that benzaldehyde is also formed but this could not be detected in the infrared spectrum of the products. Isopropylbenzene similarly afforded acetophenone (displacement of a methyl group, cf. 9-methylanthracene) and α-phenyl propionaldehyde (oxidation of terminal methyl group) again in about equal amounts (cf. 13). Under the same conditions tert-butylbenzene was unaffected. It has also been found that the oxidation of tetralin gave about equal amounts of α- and β-tetralone. The formation of two products again illustrates the high reactivity of chromyl chloride since the chromic oxide oxidation of tetralin gives only α-tetralone (14). Indane similarly gave apparently a mixture of α- and β-indanone, although the yield was very low and a large amount of polymer was formed.

EXPERIMENTAL

Toluene Complex

Toluene (2.5 g, 0.027 mole) in carbon tetrachloride (20 ml) was treated dropwise with stirring with chromyl chloride (9) (7.75 g, 0.05 mole) in carbon tetrachloride (30 ml) during 1/2 hour, stirred for a further 2 hours, and allowed to stand at room temperature overnight. The suspension was filtered and the precipitate washed with carbon tetrachloride until the washings were colorless, and then dried in a vacuum (9.3 g). Analysis: found, Cl = 34.5, 34.8%; calc. for C_7H_8 $(Cr\ O_2Cl_2)_2$, Cl = 35.16%.

Reaction of benzene (3.9 g) in a like manner gave an oily precipitate (0.20 g) which fumed in air.

Similarly reaction of *tert*-butylbenzene (5.0 g) gave a dark-black precipitate (0.8 g) which decomposed on standing.

Magnetic Measurements

The magnetic susceptibility (χ) was determined by the method of Gouy (7). $X = (a+b\ \delta w)/W$ (10), where $a = k.v$ (k = volume susceptibility of air, v = volume of specimen) and $b = 2\ gv/AH^2$ (A = cross-sectional area and H = field strength). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

susceptibility (diamagnetic) of air is very small and the formula can be reduced to $X = b\ \delta w/W$. For two specimens occupying the same volume, this becomes

$$\chi_1/\chi_2 = \delta w_1 . W_2/\delta w_2 . W_1.$$

Ferrous ammonium sulphate ($\chi = 9500\times10^{-6}/(T+1)$ (11)) was used to calibrate the apparatus. The molecular susceptibility ($\chi_M = \chi \times$ mol. wt.) was corrected for the diamagnetic susceptibility of the other atoms using the values of Pascal (7) and the corrected value was halved to obtain the atomic susceptibility (χ_A) of each chromium atom. The atomic magnetic moment (μ_A) was then calculated using the Langevin formula,

$$\mu_A = \sqrt{(3\,RT\,\chi_A/N)}.$$

Spectroscopic Measurements

The ultraviolet and visible spectra (Fig. 1) were determined in stoppered Corex cells using carbon tetrachloride as solvent. Chromyl chloride had two maxima, at 290 mμ (ϵ = 3600) and 415 mμ (ϵ = 2900).

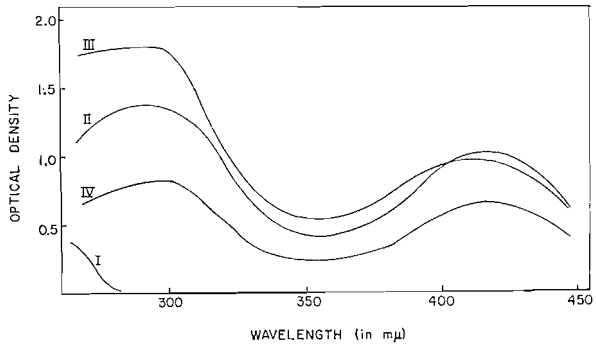

FIG. 1. Spectra of complex. (I) Toluene (1.3×10^{-3} M) in CCl_4. (II) CrO_2Cl_2 (4×10^{-4} M) in CCl_4. (III) Toluene (1.3×10^{-3} M) + CrO_2Cl_2 (4×10^{-4} M). (IV) Same after 24 hours.

The infrared spectrum of the toluene complex was determined in a Nujol mull and as a potassium bromide disk.

The principal maxima and their most probable assignments (values in microns and relative intensities in parenthesis) are:

Nujol mull	2.35 (m)	6.26 (m)	6.58 (m)	—	6.85 (s)
KBr disk	—	6.25 (s)	6.54 (s)	6.68 (m)	—
Assignment	OH?	Benzene	Benzene	Benzene	Nujol
Nujol mull	7.26 (s)	8.49 (w)	9.33 (w)	9.74 (w)	
KBr disk	—	8.47 (m)	9.29 (m)	9.74 (m)	
Assignment	Nujol	Mono-sub. benzene	OH?	OH?	

Reactions with Aromatic Hydrocarbons

(Ultraviolet spectra determined in ethanol solution and infrared spectra in carbon tetrachloride.)

Ethylbenzene

Ethylbenzene (21 g) in carbon tetrachloride (100 ml) was treated dropwise with stirring and cooling to 20–25° with chromyl chloride (60 g) in carbon tetrachloride (100 ml) during 1 hour, stirred for 2 hours more, and allowed to stand at room temperature overnight. The reaction mixture was decomposed by being poured into excess aqueous sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

bisulphite solution and the organic phase separated and dried. After removal of the solvent, the residue was distilled to give a product (10.5 g), b.p. 76–80° at 100 mm, with infrared maxima at 5.85 and 5.97 μ (acetophenone and benzaldehyde have bands at 5.97 and 5.75 μ, respectively). Ultraviolet absorption λ_{max} 242 mμ, ϵ = 7500 corresponding to 59% acetophenone (242 mμ, ϵ = 12,700). A small sample gave a precipitate with 2,4-dinitrophenylhydrazone sulphate solution, which was separated by chromatography on a long column of alumina and elution with benzene, into two fractions; one melting point 247° (from ethyl acetate) (mixed melting point with acetophenone derivative 246–247°) and a second melting point 108–110° (mixed melting point with phenyl acetaldehyde derivative 110–111°).

Isopropylbenzene

Isopropylbenzene (16 g) in carbon tetrachloride (40 ml) was treated dropwise with chromyl chloride (43 g) in carbon tetrachloride (50 ml) over 1 hour at 20–25°. The mixture was stirred for 2 hours, allowed to stand overnight, and worked up as usual, giving a fraction (5.5 g), b.p. 80–85° at 100 mm, having infrared bands at 5.85 and 5.98 μ. Ultraviolet absorption λ_{max} 242 mμ, ϵ = 5850 corresponding to 46% acetophenone. A small sample gave a mixture of 2,4-dinitrophenylhydrazones, separated by chromatography on alumina and elution with benzene into a fraction, m.p. 246° (from ethyl acetate) (no depression on admixture with authentic derivative of acetophenone), and another, m.p. 227–233° (mixed melting point with derivative of α-phenylpropionaldehyde (m.p. 238°) 235–237°).

tert-Butylbenzene

Reaction of *tert*-butylbenzene (20 g) in the same manner gave recovered material (18.5 g), b.p. 168–170°, which showed a very weak carbonyl infrared band, but gave no precipitate with 2,4-dinitrophenylhydrazine reagent.

Tetralin

Freshly distilled tetralin (10 g) in carbon tetrachloride (50 ml) was treated with chromyl chloride (25 g) in carbon tetrachloride (50 ml) at 0° during 2 hours and stirred at 0° for a further 5 hours. Decomposition of the complex in the usual manner gave unchanged tetralin (2 g) and a mixture of α- and β-tetralones (5.6 g), b.p. 112–124° at 10 mm, which had infrared bands at 5.85 and 5.97 μ (authentic α-tetralone had a band at 5.98 μ), and ultraviolet absorption of λ_{max} 242 mμ, ϵ = 5300 (α-tetralone showed λ_{max} 248 mμ, ϵ = 11,400). A small sample gave a 2,4-dinitrophenylhydrazone, m.p. 200–215°, separated as above, into a fraction, m.p. 272° (from ethyl acetate) (mixed melting point with the derivative of α-tetralone 270–271°) and another melting point, 250° (mixed melting point with the derivative of β-tetralone 251–252°).

The main portion (5.2 g) was shaken with an excess of 10% aqueous sodium bisulphite and allowed to stand overnight. The precipitate was filtered, washed with ether, and decomposed with acid, giving β-tetralone (2.5 g), b.p. 123° at 10 mm, 2,4-dinitrophenylhydrazone, melting point and mixed melting point 251°. The ether washings yielded α-tetralone (2.3 g), b.p. 120° at 10 mm, 2,4-dinitrophenylhydrazone melting point and mixed melting point 271°.

Indane

Indane (5.5 g) (prepared by Clemmensen reduction of α-indanone) in carbon tetrachloride (50 ml) was reacted, as above with chromyl chloride (17.0 g) in carbon tetrachloride (50 ml) giving a mixture of α- and β-indanones (0.8 g), b.p. 130–132° at 25 mm,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

having infrared maxima at 5.73 and 5.86 μ (α-indanone showed a band at 5.86 μ) and ultraviolet absorption λ_{max} 245 mμ, ϵ = 4100. The amount of product was insufficient to identify it completely. (α-Indanone showed λ_{max} 250 mμ, ϵ = 10,800.)

ACKNOWLEDGMENTS

The author is grateful to Dr. D. A. Ryan, Dalhousie University, for the loan of the Gouy balance and Dr. J. L. Mateos, University of Mexico, for determining the infrared spectra of the toluene complex.

THE SOLID–LIQUID EQUILIBRIUM BETWEEN ANHYDROUS MAGNESIUM CHLORIDE AND N,N-DIMETHYLFORMAMIDE[1]

DENYS COOK

ABSTRACT

The solid–liquid equilibrium between anhydrous magnesium chloride and N,N-dimethylformamide has been investigated between −58° and +97° C, and up to 25 mole% in magnesium chloride by the techniques of thermal analysis. The following compounds and their melting points have been noted: $MgCl_2.12DMF$, 8.7°; $MgCl_2.6DMF$, 35.0° (incongruent); $MgCl_2.5DMF$, 51.0°; $MgCl_2.4DMF$, 69.0° C. Infrared examination of some of the compounds suggests that co-ordination is through the carbonyl group.

INTRODUCTION

Anhydrous magnesium chloride is known to form complexes with a variety of molecules such as H_2O (1), NH_3 (2), etc. These are usually of the form $Mg6X.Cl_2$ where the cation is octahedrally surrounded by six equivalent donor molecules. These can be thermally degraded and lose some or all of the donor molecules. The thermodynamic properties of this process for the hexahydrate (1) and diammonate (2) have been known for some time.

Because of an interest in the remarkable solvent properties of N,N-dimethylformamide (DMF) it was decided to investigate the solid–liquid equilibrium of the $MgCl_2$–DMF system. It was hoped that specific information concerning the possible formation of an octahedral complex of DMF around Mg^{++} would result. This was of interest since the DMF molecule is a good deal larger than either H_2O or NH_3 mentioned previously, and steric factors could easily play a part in the equilibrium. It was also hoped to ascertain the site of the donor center in DMF.

EXPERIMENTAL

To establish the phase boundaries, the method of thermal analysis of cooling curves of mixtures of $MgCl_2$ and DMF was employed (3). A pyrex cooling cell was constructed, provided with an efficient, magnetically operated stirring system, and a thin-walled tube to accommodate a copper–constantan thermocouple. A Brown strip-chart recorder traced the temperature–time cooling curves.

A weighed amount of $MgCl_2$ was placed in the cell and the proper amount of DMF was added. These operations were performed in a dry box. This mixture was outgassed and then heated to dissolve the $MgCl_2$. A cooling curve was started when all the $MgCl_2$ was in solution. A jacket, which could be evacuated, was placed round the cell, and the appropriate refrigerant surrounded this. The melting point was always easily discernible, particularly as with many mixtures supercooling, occasionally up to 10° C, was observed. The eutectic points, however, were much more elusive and few were recorded with any confidence.

Originally, mixtures were made up by adding further DMF to a known mixture, but some irreproducibility seemed to be introduced by this technique, so subsequently mixtures were freshly and individually prepared.

Between three and five cooling curves were recorded for each mixture and the average

melting point taken. Temperatures could be read to about 0.5° C but points were reproducible to probably 1–2° C.

RESULTS

The results obtained are shown in Table I and are plotted in Fig. 1. Table II shows the melting points of compounds as determined by the dystectic points of the curves.

DISCUSSION

The appearance of a compound albeit of incongruent melting point at a molecular ratio of 1:6, i.e. $MgCl_2.6DMF$, indicates that even a relatively large molecule like DMF can co-ordinate, probably octahedrally, round the Mg^{++}. (A powder X-ray diffraction pattern of the 1:6 compound showed marked differences from those of anhydrous $MgCl_2$ or the hexahydrate.) The compounds with fewer DMF molecules are probably derived from this compound by successive loss of a DMF molecule from the co-ordination shell at higher temperatures. A 1:3 compound has been tentatively shown in Fig. 1. It probably exists but, in this temperature region, the reproducibility of the melting points was growing worse. There is a strong possibility that thermal decomposition may be a factor at these elevated temperatures.

For all these mixtures, in the crystallization period, especially if supercooling occurred, the first crystals observed were nearly transparent and had a cubic structure. Furthermore, when a mixture of approximately 14.28 mole% $MgCl_2$ was made up, heated to dissolve all the $MgCl_2$, and then cooled slowly, a mass of poorly shaped crystals grew. But by leaving them in a place exposed to weak sunlight, after a few days, a portion of a beautiful cubic crystal grew on top of the other crystals, with an edge of about 6 mm. This cubic structure could be consistent with octahedral co-ordination around the Mg^{++} ion.

Infrared examination of the 4:1 and 3:1 complexes showed a spectrum very similar to that of DMF except that its carbonyl frequency was displaced to lower frequencies by about 46 cm^{-1}. This phenomenon is well known to occur when there is an interaction with the carbonyl oxygen, as in hydrogen bond formation, or Lewis acid–base interaction (4). It is concluded, therefore, that the carbonyl group is the donor group in DMF in this case. Very similar results have been obtained recently for the DMF_2:$TiCl_4$ complex, in which the carbonyl frequency was some 30 cm^{-1} lower than in DMF (5).

The 1:12 compound was rather unexpected, although a compound of the same constitution is observed in the $MgCl_2$–H_2O system. On freezing the $MgCl_2.12DMF$ compound, a mass of small white crystals appeared with no supercooling so observation of their shape was difficult. Their appearance was different enough from the $MgCl_2.6DMF$, or lower compounds, to infer a difference in lattice type. While conjecture on the structure is quite speculative, it seems most unlikely that this could be a Mg^{++} with 12 DMF molecules co-ordinated around it. What is more likely is a six co-ordinated Mg^{++} with six further DMF molecules not interacting with the cation but incorporated in the lattice. Since this compound melted at 9° C it was not possible to take the infrared spectrum to see if two carbonyl bands were present due to two environmentally different DMF molecules.

Finally, a rough estimate of the stability of the 1:6 compound can be deduced from the following evidence. Treatment of a solution of $MgCl_2$ in DMF with NH_3 gave a slow-forming white precipitate, which settled very slowly. By contrast, a solution of $MgCl_2$ in water which is, in effect, $Mg(6H_2O)^{++}$, $2Cl^-$, when treated with NH_3 gave an immediate, copious white precipitate of $MgCl_2.6NH_3$, identified by its infrared spectrum. This is a rough indication that the stability of the $MgCl_2.6DMF$ is intermediate between $MgCl_2.6NH_3$ and $MgCl_2.6H_2O$.

ACKNOWLEDGMENT

The author is indebted to Miss C. D. Anderson for preparing the infrared spectra.

SEARCH FOR INDEPENDENT FORMATION OF Cs^{134m} IN FISSION[1]

A. P. Baerg,[2] R. M. Bartholomew, and R. H. Betts

ABSTRACT

The independent yield of Cs^{134m} in thermal neutron fission of U^{235} is less than 1.7×10^{-6} of the mass 134 chain yield and that of Cs^{136} was found to be $(0.94\pm0.04)\times10^{-3}$ of the mass 136 chain yield. The half-life for Cs^{134m} was measured as 2.91 ± 0.01 hours.

INTRODUCTION

The principal mode of formation of the shielded nuclide Cs^{134} in neutron-irradiated uranium is generally thought to be by neutron capture in Cs^{133}. This latter nuclide is a fission product of high yield which builds up in the uranium during a long irradiation. However, recent unpublished work (1) involving highly irradiated uranium dioxide has shown that, in some cases at least, the amount of Cs^{134} is apparently considerably larger than that expected from the 30-barn (2) neutron capture cross section of Cs^{133}. One explanation suggested to account for this anomaly was that the independent fission yield of Cs^{134} may be unexpectedly large; a value of about $7\times10^{-3}\%$ would account for the "excess" Cs^{134} found.

Although it would be very difficult in a short irradiation to detect independent formation of the order of $7\times10^{-3}\%$ yield for 2.2-year Cs^{134} in the presence of other fission product cesium isotopes, it would be readily observable as the high-spin Cs^{134m} isomer (3 hours half-life), if this were formed in amounts comparable with that of the 2.2-year ground state. Judging from the limited information available on isomer ratios of independently formed fission products (3, 4) this is not an unlikely situation. This paper reports on the results of a search which was made for Cs^{134m} formed directly in thermal neutron fission of U^{235}.

EXPERIMENTAL

The method consisted of extracting carrier-free fission product cesium from a sample of uranium which had been irradiated for a short time only to avoid production of Cs^{134m} through neutron capture in fission-produced Cs^{133}. Samples of the carrier-free material were counted in a 4π beta proportional counter to determine the Cs^{134m} relative to Cs^{136} and Cs^{137}. The counting efficiency for the low-energy electrons from the isomeric transition in Cs^{134m} was determined in separate experiments by a coincidence counting method, using Cs^{134m} produced by neutron capture in Cs^{133}.

Irradiation and Purification

Approximately 1 g samples of natural uranium, as UO_2, were sealed in quartz capsules and irradiated in a self-serve position of the Chalk River, NRX reactor. The neutron flux was about $10^{13}/cm^2$ sec and the irradiations were limited to 3 hours. The purification of the cesium, requiring about 3 hours, was delayed 12 hours to permit 32-minute Cs^{138} and 9-minute Cs^{139} to decay to negligible levels.

The irradiated UO_2 was dissolved in a solution 9 *N* in hydrochloric and 3 *N* in nitric

acid. This solution was evaporated and the residue taken up in 10 ml of 1 *M* sodium citrate buffer solution adjusted to pH 6 with nitric acid. The cesium was extracted, carrier-free, from this solution with an amyl acetate solution 0.05 *M* in sodium tetraphenyl boron (5). After scrubbing with water the cesium was backwashed with 3 *N* hydrochloric acid and the latter scrubbed with pure amyl acetate. This acid solution was again evaporated and the extraction procedure repeated three times.

It was found that carrier-free silver is also extracted very efficiently in this procedure and so an ion-exchange purification step was introduced. The cesium, in 0.1 *N* hydrochloric acid, was adsorbed on a 200–400 mesh Dowex-50 (8% cross-linked) cation resin column, 10 cm long and 3 mm in diameter. The column was washed, first with 3 ml of 0.1 *N* hydrochloric acid which removed all the silver.* This was followed by about 24 ml of 0.5 *N* hydrochloric acid and finally the cesium was collected in about 2 ml of this eluant. This cesium fraction was further purified by two more extractions with sodium tetraphenyl boron and another cation resin column elution. An additional check on the purity was made in each experiment by adding cesium carrier to a portion of the sample and precipitating cesium silicotungstate (6). These several samples always showed identical decay characteristics and gamma-ray spectra.

Samples of Cs^{134m} for determination of counting efficiency were prepared by irradiation of approximately 1 mg of "spec-pure" CsCl, sealed in a quartz ampoule. The irradiated cesium was purified by several elutions from a cation resin column (see above). Purity checks were made by precipitation of a portion of the cesium with silicotungstic acid and comparison of the decay characteristics.

Counting

Samples of the fission product cesium were prepared for 4π beta counting by evaporating aliquots onto VYNS films. These films were rendered conducting by evaporated gold (10 $\mu g/cm^2$) (7). The dried sources were covered with a similar film. Frequent counts were taken during the first day after the purification, accumulating a minimum of 10^6 counts in each measurement. Subsequently the decay was followed over a period of about 2 months to determine the relative amounts of Cs^{136} and Cs^{137}.

The 4π beta proportional counter-efficiency for the detection of Cs^{134m} was determined by a coincidence technique, using about 1 μg samples of irradiated Cs^{133} mounted in the same way as the fission product samples. Coincidence counting equipment similar to that described by Campion (8) was used. In Fig. 1 is given the decay scheme for Cs^{134m}

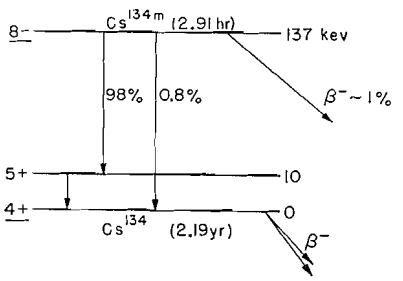

FIG. 1. Disintegration scheme of Cs^{134m}.

**The silver was found by gamma-energy analysis and half-life measurements to be of very high purity. Decay of the Ag^{111}, observed over a period of 60 days, yielded a half-life of 7.45±0.01 days. The purification described appears to be an excellent one for both carrier-free silver as well as for cesium.*

(9) showing 98% of the transitions going to the 10.5-kev level. The transitions from this level are essentially 100% converted in the L shell (10) giving rise to 4.5- to 6.2-kev electrons. The detection efficiency for these electrons was determined by counting in coincidence with the 127-kev gamma rays from those transitions to the 10.5-kev level which are not themselves converted. Provided these low-energy electrons are detected with good efficiency, it is reasonable to assume nearly 100% efficiency for the other conversion electrons which are of much higher energy.

Treatment of Data

The total disintegration rate of the fission product cesium samples at any time, t, following the irradiation is given by

$$[1] \qquad Cs_{total} = Cs_0^{137}e^{-\lambda_7 t} + Cs_0^{136}e^{-\lambda_6 t} + Cs_0^{134m}e^{-\lambda_4 t}$$

where the subscripts 0 denote initial disintegration rates and λ_7, λ_6, and λ_4 are the respective disintegration constants. No contribution from Cs^{138} and Cs^{139} is indicated in the equation because the purification was delayed long enough to allow these to decay. Since the irradiations were of short duration no significant amount of Cs^{134} would have been formed by neutron capture in fission-produced Cs^{133}. The contribution to the observed counting rate is also negligible from Cs^{135}, due to its long half-life (2×10^6 years).

In the long-term counting data there is no contribution from Cs^{134m} and equation [1] may be rearranged to

$$[2] \qquad Cs_{total}e^{\lambda_7 t} = Cs_0^{136}e^{(\lambda_7-\lambda_6)t} + Cs_0^{137}$$

so that if the total observed count, multiplied by $e^{\lambda_7 t}$, is plotted versus $e^{(\lambda_7-\lambda_6)t}$, a straight line should result having a slope equal to Cs_0^{136} and a zero intercept equal to Cs_0^{137}.

Having determined Cs_0^{136} and Cs_0^{137}, the initial counting rate of Cs^{134m} may be determined by rearrangement of equation [1] as follows,

$$[3] \qquad (Cs_{total} - Cs_0^{137}e^{-\lambda_7 t})e^{\lambda_6 t} = Cs_0^{136} + Cs_0^{134m}e^{(\lambda_6-\lambda_4)t},$$

and plotting the term on the left versus $e^{(\lambda_6-\lambda_4)t}$. The slope of the straight line then represents Cs_0^{134m} and the zero intercept represents Cs_0^{136}.

RESULTS AND DISCUSSION

Two measurements on the Cs^{134m} yield were made, treating in each case first the long-term counting data according to equation [2] to determine the Cs^{136} and Cs^{137} content of the samples. This treatment of the data is illustrated in Fig. 2. The values of Cs_0^{136} and Cs_0^{137} thus obtained were then used in equation [3] and the short-term counting data plotted as shown in Fig. 3. The errors indicate the standard deviation of the observed count. It is evident from this figure that the contribution of Cs^{134m} to the observed counting rate is very small indeed and that at best an upper limit may be set for the yield of this isomer. This limit is estimated to be $<1.3\times10^{-5}\%$. The parameters used in arriving at this value are given in Table I. The results of the counting data are summarized in Table II, together with the estimated limits. These limits will, however, depend on various factors including the Cs^{134m} counting efficiency, the accuracy of the Cs^{136} and Cs^{137} determinations, and the half-life values used in the calculations.

The detection efficiency of the 4π beta counter for the conversion electrons from the 10.5-kev transition in Cs^{134m} was found, in three separate experiments, to be $(86\pm2)\%$. In view of this fairly high efficiency the conversion electrons from the 127-kev transition

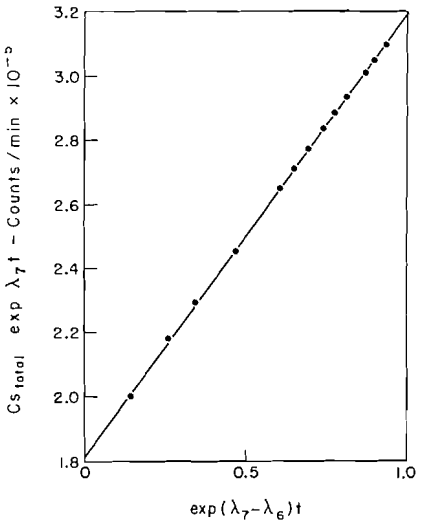

FIG. 2. Long-term decay of fission product cesium.

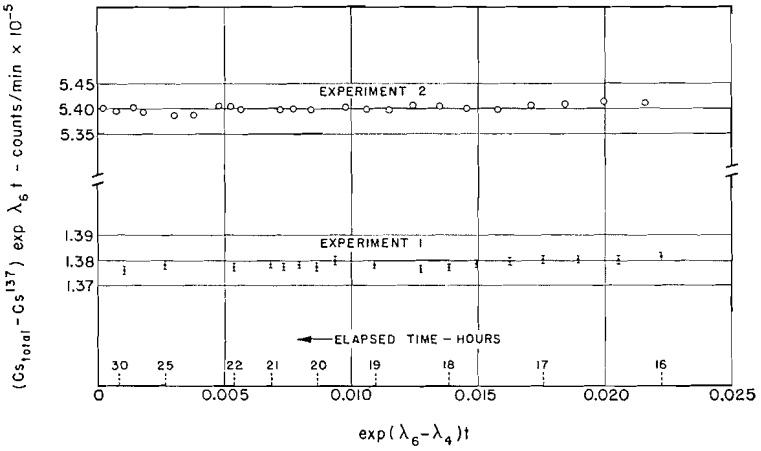

FIG. 3. Short-term decay of fission product cesium.

TABLE I

Values of parameters used to estimate the yield of Cs^{134m}

Irradiation time	3 hours
Half-life of Cs^{136}	12.9 days (11)
Half-life of Cs^{137}	30.0 years (12)
Correction to Cs^{137} activity	0.909 (12)
Half-life of Cs^{134m}	2.91 hours
Counting efficiency of Cs^{134m}	0.974

were assumed to be detected with 100% efficiency. These transitions are 86.9% converted in the K and L shells. The conversion coefficient for the 137-kev transition is not known. It constitutes only 0.8% of all transitions and was assumed not detected. The 1% abundant beta transition was taken to be detected with 100% efficiency. These considerations then lead to an over-all counting efficiency of 97.4% for the Cs^{134m}.

TABLE II

Experimental data and results

Experiment	Cs_0^{137}, counts/min	Cs_0^{136}, counts/min	Cs_0^{134m}, counts/min	Fission yield ratios	
				Cs^{136}/Cs^{137}	Cs^{134m}/Cs^{136}
1	1.81×10^5	1.38×10^5	$<0.2\times10^5$	0.99×10^{-3}	$<2\times10^{-3}$
2	7.12×10^5	5.40×10^5	$<0.9\times10^5$	0.98×10^{-3}	$<2.2\times10^{-3}$

	Fission yields*	
	% Yield	Fraction of mass chain
Cs^{136}	$(6.1\pm0.24)\times10^{-3}$	$(0.94\pm0.04)\times10^{-3}$
Cs^{134m}	$<1.3\times10^{-5}$	$<1.7\times10^{-6}$

*Taking the cumulative yields of Cs^{137}, mass 136, and mass 134 to be 6.15%, 6.44%, and 8.03% respectively (13).

The counting efficiency for Cs^{136} and Cs^{137} was taken to be 100%. This is believed not to be in error by more than 4% and it is expected that these nuclides were counted with equal efficiency within 1%. In the two measurements a value of 0.76 was obtained for the counting ratio Cs_0^{136}/Cs_0^{137}, with an estimated error of 4%. After a correction factor of 0.909 is applied to the counting rate of Cs^{137} for Ba^{137m} (12), the yield of Cs^{136} becomes $(0.94\pm.04)\times10^{-3}$ as the fraction of the mass 136 chain yield. This value agrees favorably with that of 1×10^{-3} given by Grummitt and Milton (14).

The decay of Cs^{134m}, obtained from the irradiated and purified Cs^{133}, was followed over at least eight half-lives in each of the three counting efficiency measurements. These data yielded a half-life of 2.91 ± 0.01 hours, the value that was used in the calculation. It is somewhat lower than the accepted one of 3.2 hours (9).

The largest error in estimating the Cs^{134m} arises from errors in the value of the term Cs_0^{136} and in the half-life of Cs^{136}. Neither of these is believed to be greater than 5%. It is estimated that even a 10% error in either Cs_0^{136} or its half-life would not change the present results for the Cs^{134m}/Cs^{136} yield ratio by more than a factor of two.

The upper limit for the yield of Cs^{134m} relative to the mass 134 cumulative yield becomes $<1.7\times10^{-6}$ taking the yields of masses 134, 136, and 137 as given in Table II. Extrapolation of existing correlations (14) for independent fission yields suggests a value for Cs^{134} of the order of 5×10^{-6}. The present results then do not indicate any unusual behavior in the independent formation of Cs^{134m} in fission.

TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS

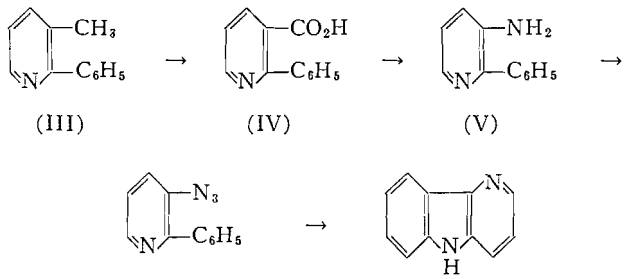
PART VIII. δ-CARBOLINE[1, 2]

R. A. Abramovitch, K. A. H. Adams, and A. D. Notation

ABSTRACT

The first unambiguous synthesis of δ-carboline has been achieved starting with 3-amino-2-phenylpyridine. This was converted to the azide which was thermally cyclized to δ-carboline. The carboline gave a *py*-*N*-methiodide which was converted to the anhydronium base. The pK_a of the anhydronium base was determined and its significance is discussed. The anhydronium base formed a methiodide which, on dry distillation, gave *ind*-*N*-methyl-δ-carboline. The spectral properties of the various derivatives of δ-carboline were examined and the bond structures of the anhydronium base and the methiodides are discussed.

Whereas the chemistry of α-, β-, and γ-carboline has been well studied and a number of unambiguous methods are available for the synthesis of these ring systems practically nothing is known concerning δ-carboline (I). There has appeared only one reference to the synthesis of the parent compound and that to the Graebe–Ullmann cyclization of 1-β-pyridylbenztriazole by Späth and Eiter (1), who obtained a mixture of β-carboline and what was tentatively identified as δ-carboline (since it was not identical with either α-, β-, or γ-carboline) in unspecified low yield. *N*-3-Pyridylaniline was also obtained in this reaction. Subsequently, Eiter (2) was unable to obtain any of the supposed δ-carboline by carrying out this reaction on a larger scale. A similar cyclization of 4-methyl-1-β-pyridylbenztriazole gave 5-methyl-β-carboline as the main product together with a small amount of a compound for which the structure 5-methyl-δ-carboline was suggested (3). Gulland, Robinson, Scott, and Thornley (4) were unable to degrade 3,4-methylenedioxyquindoline to δ-carboline. However, oxidation of this compound with nitric acid gave 7-nitro-δ-carboline-2-carboxylic acid in low yield.

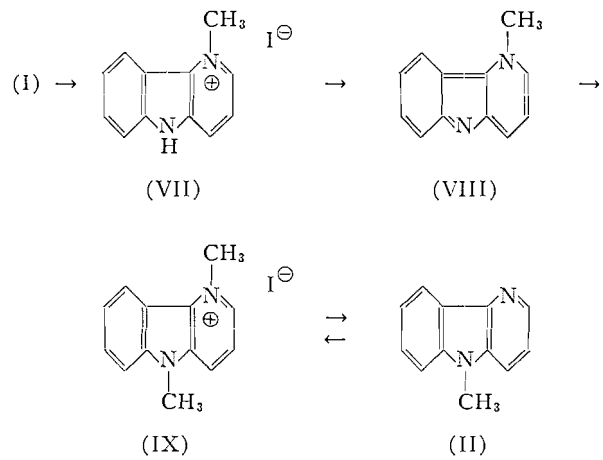


Apart from the fact that it is the only member of the carboline family whose chemistry has not been studied to any degree δ-carboline is interesting from a number of other points of view. It is present in the ring system of the alkaloid cryptolepine (5), which is noteworthy from a biogenetic point of view (6). Also, the relative basicities of α-, β-, and γ-carboline anhydronium bases have been measured by Gray (7), who proposed an explanation for the observed order of base strengths (β- > γ- > α-) and suggested, on the basis of considerations outlined below, that the δ-carboline anhydronium base should have a dissociation constant almost as high as that of the β-isomer. It was of interest to try and test this prediction experimentally.

Smith and Boyer (8) attempted to cyclize 2-*o*-azidophenylpyridine to δ-carboline but obtained instead 2-*o*-aminophenylpyridine.* When 2-*o*-nitrophenylpyridine was heated with ferrous oxalate, cyclization took place preferentially at the pyridine nitrogen atom to give pyrid[1,2-*b*]indazole (9). The Pschorr-type cyclization of 2-amino-*N*-methyl-*N*-3′-pyridylaniline gave a relatively good yield of *ind*-*N*-methyl-δ-carboline (II) (together with some *ind*-*N*-methyl-β-carboline) (10*a*) but attempted *N*-demethylation using a variety of procedures failed (10*b*).

δ-Carboline has now been synthesized unambiguously from 3-amino-2-phenylpyridine

[1]*Manuscript received June 6, 1960.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan. Presented at the 43rd Annual Meeting of the Chemical Institute of Canada in Ottawa, June 1960.
[2]*Part VII: Can. J. Chem.* **38**, *2273 (1960).*
**Our results in this reaction differ from those of Smith and Boyer and will be reported in a subsequent paper.*



(V). The amine was obtained from 2-phenyl-3-picoline (III), which was oxidized to the carboxylic acid (IV) (11); this was transformed into the amine (V) via the acid chloride and the Curtius reaction. It could also be obtained directly by the action of phenyllithium on 3-aminopyridine (12). It was diazotized and converted to 3-azido-2-phenylpyridine (VI), which on being heated in decalin, gave variable yields of δ-carboline (I).

(III) (IV) (V)

(VI) (I)

The base formed a yellow methiodide (VII) readily but resisted all attempts at *ind-N*-methylation. Treatment of the methiodide with alkali gave the orange anhydronium base (VIII); this gave a yellow methiodide (IX) identical with that obtained from *ind-N*-methyl-δ-carboline (II), thus establishing conclusively the structure which had been assigned (10*a*) to (II), as well as the fact that methylation of the anhydronium base occurs at the *ind-N*-atom. Finally, dry distillation of the methiodide (IX) gave *ind-N*-methyl-δ-carboline (II) identical with the sample obtained from the Pschorr reaction (10*a*).

(VII) (VIII)

(IX) (II)

Ultraviolet Absorption Spectra and pK_a

Gray (7) obtained the following values for the pK_a's of the carboline anhydronium bases: α-, 7.75; β-, 11.11; and γ-, 10.54. The greater basicity of the β-derivative was ascribed to a lower stabilization energy of the β-carboline anhydronium base indicated from a consideration of the relative contributions made by quinonoid canonical forms. The low basic strength of the α- as compared with the γ-derivative was interpreted on

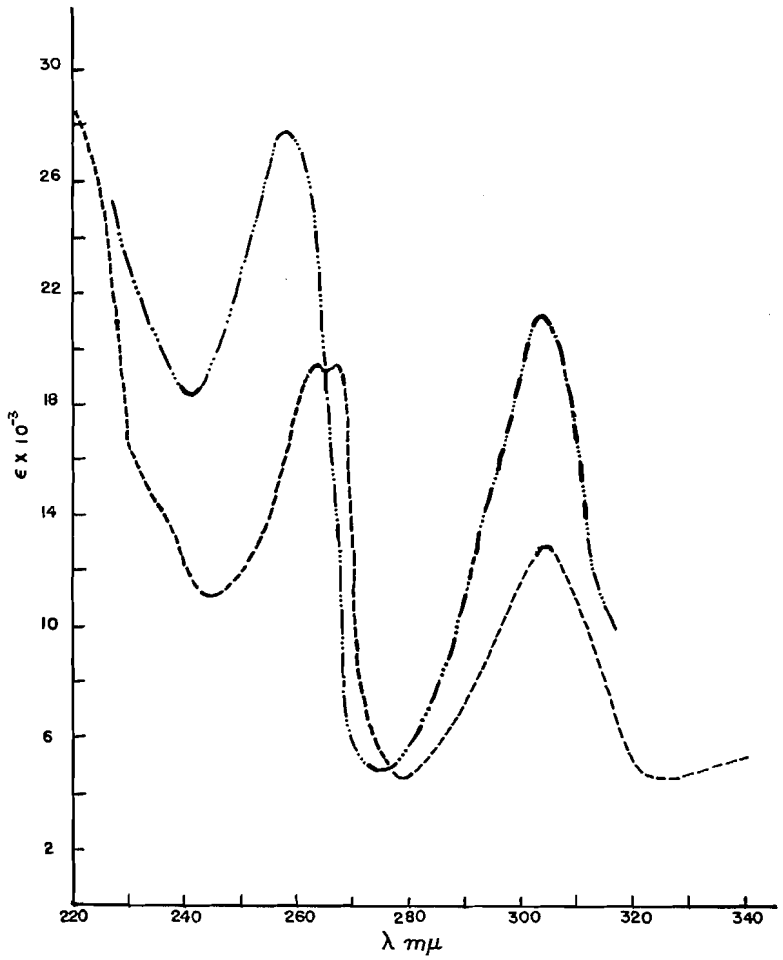
the basis of two complementary factors: (*a*) a much increased stability of the α-anhydronium base as a result of the juxtaposition of the oppositely charged centers; and (*b*) a reduced stability of the α-carboline salt owing to the inductive effect of the indole nitrogen attached to the same carbon as the positively charged pyridine nitrogen. Support for point (*a*) comes from the fact that pyrid[1,2-*b*]indazole, in which the charged centers are even closer together, is very reluctant to form a methiodide at all (9). A consideration of the basicities of the pyridonimines led Gray to suggest that there is some slight evidence that the aromatic charge-separated forms more nearly represent the properties of all three anhydronium bases. Additional support for this suggestion comes from the high dipole moment of sempervirine (13). Paoloni and Marini-Bettòlo (14) have argued that it is unnecessary to write a formula bearing separated charges for the β-carboline anhydronium base as suggested by Schwarz (15), and have carried out calculations using the LCAO method on 1-methyl-7-azaindole and on 7-methyl-7H-pyrrolo[2,3-*b*]pyridine, the results of which they say support their contention. It was hoped that the determination of the pK_a and spectral properties of the δ-carboline anhydronium base would shed some light on this problem and also verify or disprove Gray's suggestion concerning its base strength.



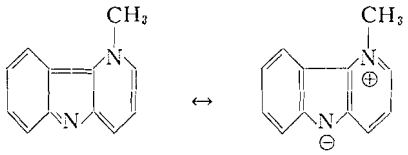


FIG. 1. —·—·— δ-Carboline in 95% ethanol. – – – *ind*-*N*-Methyl-δ-carboline in 95% ethanol.

A A′

The pK_a's of the anhydronium bases prepared from the methosalts of α-, β-, and δ-carboline were determined both spectroscopically and by potentiometric titration of the methiodides in 60% ethanol with 0.1 *N* sodium hydroxide, the pH at half neutralization being taken as the pK_a value, no correction for the ionic strength being applied. The average values of several determinations are given in Table I.

TABLE I

Anhydronium base	*py*-*N*-Methyl-α-carboline	*py*-*N*-Methyl-β-carboline*	*py*-*N*-Methyl-δ-carboline
pK_a	7.55	10.88	10.77

*Methiodide kindly supplied by Dr. I. D. Spenser, McMaster University, Hamilton, Ontario.

The values for the α- and β-bases are somewhat lower than those reported by Gray (7) but, as suggested by him, *py*-*N*-methyl-δ-carboline anhydro-base is almost as strong a base as its β-isomer. This result would seem to favor the quinonoid structure A as being an important contributor to the structure of the base, resulting in its having a lower stabilization energy as compared with its salt in which the benzenoid structure is preserved.* The infrared spectrum of *py*-*N*-methyl-δ-carboline anhydronium base afforded some slight tentative *negative* evidence in support of this suggestion. In the infrared spectra of two compounds, pyrid[1,2-*b*]indazole (9) and anthranil (16) in which the grouping $C_6H_4N^{\ominus}$ is known to make a strong, if not predominant contribution, bands have been observed at 1650 and 1642 cm^{-1}, respectively, which have been tentatively assumed to be characteristic of such a grouping. No such band was observed for the δ-carboline anhydronium base. A medium band at 1619 cm^{-1} might be ascribed to a highly conjugated C=N as would be present in A, or alternatively to an aromatic ring vibration as is present in A′. *py*-*N*-Methyl-α-carboline anhydronium base exhibits a band at 1630 cm^{-1} which is intermediate between the above values as might be expected from the suggested structure for this compound in which the benzenoid structure remains unchanged and in which the dipolar structure makes an important contribution. The evidence seems to indicate a mesomeric structure A ↔ A′ for the δ-anhydronium base with the quinonoid structure A making perhaps the weightier contribution to the ground state.

The analysis values of *py*-*N*-methyl-δ-carboline anhydronium base were unsatisfactory, but this seems to be characteristic of this type of compound (17). Its anhydro-base character was confirmed by its ultraviolet absorption spectrum (Fig. 2) compared with that of *py*-*N*-methyl-δ-carbolinium iodide; the bands for the anhydro-base exhibited the usual bathochromic shifts. The colors of the methiodides and anhydronium bases and of their solutions are of interest. Thus, both *py*-*N*-methyl-β- and -δ-carbolinium iodide are yellow in the solid state whereas the unmethylated bases are colorless and

**That disruption of the benzenoid structure is an important factor in the destabilization of the bases is shown by the recent work of Adler and Albert on the ionization constants of the diazaindenes (21) where this factor is not present and the order of base strengths is 1,5 > 1,6 > 1,4 > 1,7.*

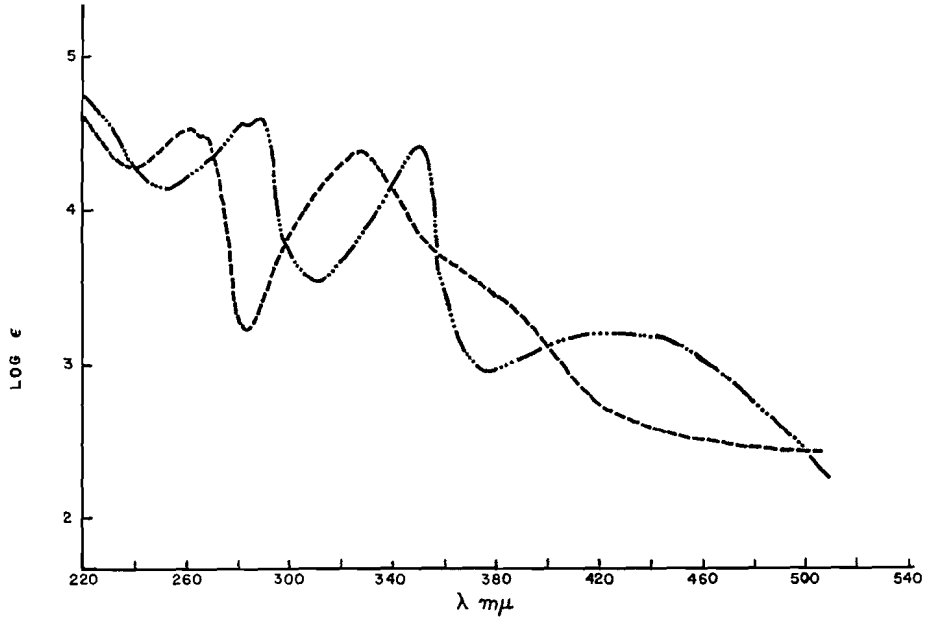

FIG. 2. *py-N*-Methyl-δ-carbolinium iodide. - - - In acidified 95% ethanol. —·· — In alkaline 95% ethanol.

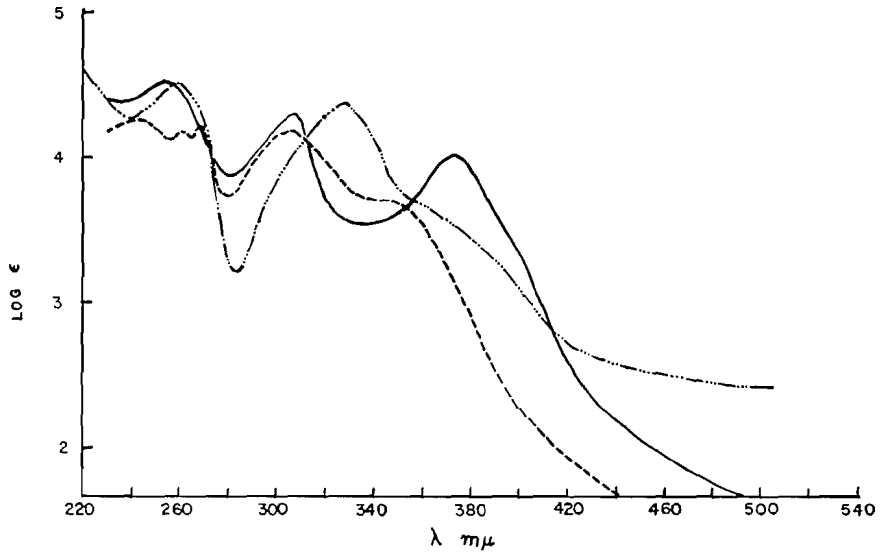

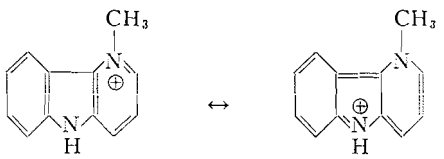

FIG. 3. - - - *py-N*-Methyl-α-carbolinium iodide (in 95% ethanol). ——— *py-N*-Methyl-β-carbolinium iodide (in 95% ethanol). —·· — *py-N*-Methyl-δ-carbolinium iodide (in 95% ethanol).

the α-methiodide is cream-colored (see Fig. 3). The anhydronium bases are all orange-colored and give yellow solutions in hydroxylic solvents. The ultraviolet spectra of *py-N*-methyl-δ-carbolinium iodide and of its anhydronium base in 95% ethanol are identical, indicating the ease with which the anhydronium base reverts to the more stable salt structure (compare the case of the β-carboline anhydro-base (18, and references

cited therein)). On the other hand, solutions of *py-N*-methyl-δ-carboline anhydronium base in non-polar solvents such as ether are darker in color than those in hydroxylic solvents and this is reflected in the ultraviolet absorption spectrum of an ethereal solution of this compound when the bands at 282, 289, 350, and 422 mμ (in alkaline 95% ethanol) are shifted to 289, doublet at 295 and 300, 362 and 464 mμ (in ether) respectively. This contrasts with the behavior of the β-carboline anhydro-base whose spectrum in alkaline ethanol is reported to be the same as that in ether solution despite the fact that the latter solution is darker than the former (18). For the δ-carboline anhydro-base the deepening of the yellow color on passing from aqueous ethanolic alkali to ether solution is undoubtedly due to the fact that the color is due to an $n \rightarrow \pi$ transition and that in aqueous ethanolic alkali the unshared electrons of the nitrogen atoms are stabilized in the ground state by hydrogen bonding. As regards the bands in the 282–350 mμ region the bathochromic shift is in the *opposite* direction to that expected for *K*-bands (19) which arise from $\pi \rightarrow \pi$ transitions. Such a blue shift on passing from a non-polar to a polar solvent might indicate an appreciable instantaneous change in polarity from the ground state to the excited state causing the solvating molecules of a polar solvent to be more disoriented than those of a non-polar one during such a transition. If this conclusion is valid it could be taken as providing some tenuous support for the suggestion that structure A is the more important of the two structures contributing to the resonance hybrid. Some comment may also be made concerning the yellow color of the δ-carboline methiodide as compared with the unmethylated base and the α-carboline methiodide. It seems likely that a structure such as (VII′) is contributing to the structure of the ground

VII ↔ VII′

state of the δ-carboline methiodide, the introduction of a positive charge on the *py-N*-atom producing a strong perturbation of the π-electron cloud. Similar comments will apply to the β-carboline methiodide. Due to the closeness of the two nitrogen atoms the perturbation in the α-carboline methiodide case is not as great (this is reflected in the lower pK_a of this compound).

In connection with the ultraviolet absorption spectra of the δ-carbolines it is of interest to note that Eiter and Nezval (3) claimed to have prepared 5-methyl-δ-carboline (no analysis given) and reported that this compound had two bands at 351 and 288 mμ in the ultraviolet. δ-Carboline itself has two bands at 303 and 258 mμ (Fig. 1); furthermore, the shape of the absorption curve given by Eiter and Nezval is quite different from that of δ-carboline reported here, but resembles that of 5-methyl-β-carboline (3). Horner compared the ultraviolet spectra of α- and β-carboline and found them to be similar (20). Both, however, are substantially different from the spectrum of δ-carboline. It seems unlikely therefore, that the compound isolated in very low yield by Eiter and Nezval was really 5-methyl-δ-carboline.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer

Model 21 spectrometer using sodium chloride optics. Ultraviolet absorption spectra were recorded on a Beckman DK2 spectrophotometer.

3-Amino-2-phenylpyridine

2-Phenylpyridine-3-carboxylic acid (11) (0.5 g) was kept at room temperature with thionyl chloride (3.5 ml) for ½ hour. The excess thionyl chloride was removed under vacuum, the residue dissolved in dry acetone, and the solvent evaporated leaving the acid chloride behind as a powder. This was dissolved in dry acetone (9 ml) and sodium azide (0.5 g) in water (1 ml) was stirred into the solution, the temperature being maintained below 20°. After 15 minutes, water (14 ml) was added and the mixture basified with 2 *N* sodium hydroxide. The mixture was heated on a steam bath for 3 hours, cooled, and extracted with ether. The combined extracts were dried (Na_2SO_4) and evaporated to give crude 3-amino-2-phenylpyridine (0.4 g; 92% yield) which was distilled under vacuum and had a boiling point of 119–121°/0.35 mm. The distillate solidified on cooling, and was recrystallized from benzene – light petroleum (b.p. 40–60°) to give colorless crystals, m.p. 62–64°, whose infrared spectrum was identical with that of a sample prepared from 3-aminopyridine and phenyllithium (12). The picrate, m.p. 204–206° (from ethanol), was identical (mixed melting point) with that of the specimen prepared by the 3-aminopyridine method (12).

δ-Carboline

3-Amino-2-phenylpyridine (1.0 g) was dissolved in concentrated hydrochloric acid (2.6 ml) and water (1 ml). A solution of sodium nitrite (0.41 g) in water (1 ml) was added with stirring and cooling on ice to the above solution at such a rate that the temperature remained below 3°. The excess nitrous acid was destroyed by the addition of urea and then a solution of sodium azide (0.45 g) in water (1.5 ml) was added below 3°. At the completion of this addition the solution gave a negative alkaline β-naphthol coupling test. The reaction mixture was allowed to stand at 0° for 1 hour, the solution was then made alkaline with cold sodium hydroxide solution (temperature kept below 5° at all times) and the aqueous solution was then extracted with ether repeatedly. Acidification of the aqueous layer caused the precipitation of 3-hydroxy-2-phenylpyridine (0.3 g; 33% yield), m.p. 206–207°, undepressed on admixture with an authentic specimen (12). The dried (Na_2SO_4) ether extract was evaporated to give the crude azide (0.67 g) as a reddish oil which could not be purified but was used as such in the next stage. Infrared spectrum (liquid film): 2120 (s) (azide), 1580 (m), 1285 (s) (broad), 1185 (m), 802 (m), 735 (s), 695 cm^{-1} (s).

The crude 3-azido-2-phenylpyridine (0.67 g) was dissolved in redistilled decalin (70 ml) and heated at 155–170° for 3 hours. Nitrogen was evolved smoothly at this temperature. On cooling of the reaction mixture, some crystals of δ-carboline separated. The whole mixture was extracted with dilute hydrochloric acid, the acid extracts made alkaline, and the solution extracted with ether. The dried (Na_2SO_4) ether extract was evaporated to give *δ-carboline* (0.44 g), which was recrystallized from benzene to give colorless needles, m.p. 216°. Calc. for $C_{11}H_8N_2$: C, 78.55; H, 4.79. Found: C, 78.15; H, 4.72. The *monopicrate* was recrystallized from ethanol and had a melting point of 277–279°. Calc. for $C_{11}H_8N_2$, $C_6H_3O_7N_3$: C, 51.39; H, 2.79. Found: C, 51.69; H, 2.78. The yields of δ-carboline obtained in several runs varied appreciably, the one reported above being the highest obtained. In some runs, some 3-amino-2-phenylpyridine, formed undoubtedly by hydrogen abstractions from the solvent, was isolated.

py-N-Methyl-δ-carbolinium Iodide (VII)

δ-Carboline (110 mg) in 95% ethanol (1 ml) was treated with an excess of methyl iodide (2 ml) and the solution kept overnight at room temperature. The precipitate (200 mg) was filtrated and recrystallized from methanol to give the *methiodide* as light yellow needles, m.p. 250–252°. Calc. for $C_{12}H_{11}N_2I$: C, 46.47; H, 3.57. Found: C, 46.27; H, 3.70. λ_{max} 262, 328 mμ; λ_{infl} 266, 348 mμ; log ε 4.53, 4.50, 4.35, 3.70 (in 95% ethanol).

py-N-Methyl-δ-carboline Anhydronium Base (VIII)

The above methiodide (50 mg) was dissolved in hot water (2 ml) and the solution treated with a warm 20% aqueous solution of sodium hydroxide (4 ml). The yellow precipitate (22.6 mg) which separated from the cooled suspension was filtered off and washed with a little cold water. The combined filtrates were extracted repeatedly with ether, the extracts dried (Na_2SO_4), and the ether evaporated to yield a further small quantity of base. The combined solids were recrystallized from anhydrous benzene to give the *anhydronium base* as orange-yellow plates which became almost black at ca. 200° and melted at 204–205°. The microanalytical values were unsatisfactory as is common for such substances (17). Calc. for $C_{12}H_{10}N_2$: C, 79.09; H, 5.53. Found (average of two determinations): C, 71.33; H, 6.00. Infrared spectrum (KBr disk) (main peaks only): 1619 (m), 1588 (m), 1335 (s), 797 (m), and 718 cm^{-1} (ms). λ_{max} 282, 290, 350, 422 mμ; log ε 4.56, 4.60, 4.38, 3.20 (in alkaline 95% ethanol).

ind-N-Methyl-δ-carboline py-N-Methiodide (IX)

A benzene solution of *py-N*-methyl-δ-carboline anhydronium base was treated with an excess of methyl iodide to give an immediate precipitate of the *methiodide* which was recrystallized from 95% ethanol and formed light yellow needles, m.p. 270.5–271.5°, identical with the authentic specimen obtained by treating *ind-N*-methyl-δ-carboline (10*a*) in 95% ethanol with methyl iodide and allowing the solution to stand at room temperature overnight. The melting points of the two specimens were undepressed on admixture and their infrared spectra were identical. Calc. for $C_{13}H_{13}N_2I$: C, 48.14; H, 4.01. Found: C, 48.08; H, 4.12.

ind-N-Methyl-δ-carboline (II)

The anhydro-base methiodide (IX) (13.7 mg) was heated at 300–310°/0.15 mm in a microsublimation apparatus. The methiodide decomposed smoothly and practically no residue was left. The condensate was washed off with ether and the ether evaporated to give the demethylated product (6.3 mg; 82% yield) as a colorless oil which crystallized on standing to a colorless solid, m.p. 77.5–78.5°, undepressed on admixture with an authentic specimen (10*a*). The two samples had identical infrared spectra.

pK_a *Determinations*

The titrimetric determinations were carried out by dissolving the methiodides (ca. 26 mg) in carbon-dioxide-free 60% aqueous ethanol (6 ml) and titrating with 0.998 *N* sodium hydroxide. The pH measurements were carried out with a Leeds–Northrup pH meter equipped with micro pH electrodes; the solution being titrated was stirred by means of a magnetic stirrer. The *py-N*-methyl-δ-carboline anhydronium base was similarly titrated with 0.989 *N* sulphuric acid.

The spectrophotometric determinations were carried out by measuring the extinction coefficients of acid, alkaline, and buffered (pH 10.61) solutions of the methiodides at two or more wavelengths.

THE PHOTOLYSIS OF DEUTERATED ACETONE AND OF DEUTERATED ACETONE–HYDROGEN MIXTURES[1]

J. F. HENDERSON[2] AND E. W. R. STEACIE

ABSTRACT

The photolyses of acetone, acetone-d_6, and acetone-d_6 – hydrogen mixtures were investigated at 471° K. The rates of formation of methane, ethane, and carbon monoxide and the ratio $R_{\text{methane}}/R_{\text{ethane}}^{\frac{1}{2}}$ were independent of the fractional amount of acetone which photolyzed, as measured by $100[CO]/[A]_0$, which was varied from <1% to 18%. When the acetone-d_6 – hydrogen mixtures were photolyzed, $R_{CD_4}/R_{C_2D_6}^{\frac{1}{2}}[A]_0$, $R_{CD_3H}/R_{C_2D_6}^{\frac{1}{2}}[H_2]_0$, and R_{CD_3H}/R_{CD_4} $[A]_0/[H_2]_0$ were observed to be functions of $[A]_0$ and $[H_2]_0$. It is postulated that some of the CD_4 and CD_3H was formed by a reaction between methyl radicals and an excited molecule which contained both C—D and C—H bonds.

INTRODUCTION

The results of many investigations indicate that, during the photolysis of acetone and acetone–hydrogen mixtures, methane and ethane are formed by the following reactions (1, 2, 3, 4, 5):

$$CD_3 + CD_3 \rightarrow C_2D_6, \qquad (a)$$

$$CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_2COCD_3, \qquad (b)$$

$$CD_3 + H_2 \rightarrow CD_3H + H. \qquad (c)$$

Hence

(i) $$R_{CD_4}/R_{C_2D_6}^{\frac{1}{2}}[A] = k_b/k_a^{\frac{1}{2}},$$

(ii) $$R_{CD_3H}/R_{C_2D_6}^{\frac{1}{2}}[H_2] = k_c/k_a^{\frac{1}{2}},$$

(iii) $$R_{CD_3H}/R_{CD_4}[A]/[H_2] = k_c/k_b.$$

It has been suggested by Long that, in addition to these reactions, methane is formed by reaction between methyl radicals and the ethane formed by step (*a*), and that this reaction is important even when the amount of acetone decomposed is small, e.g. <5% (6). Kutschke and Steacie have summarized evidence which indicates that reaction between methyl radicals and the product ethane is negligible under these conditions (7).

If Long's suggestion were correct, the rate constants calculated by equations (i), (ii), and (iii) would be functions of the length of photolysis. However, in none of the many investigations which have been made has this question been subjected to a detailed experimental test. Consequently, experiments have been carried out here to determine whether these rate constants vary with the extent of decomposition of the acetone.

EXPERIMENTAL

The apparatus and methods of analysis were similar to those described elsewhere (2). The cracking pattern for CD_3H suggested by McNesby and Gordon was used when determining the isotopic composition of the methane fractions mass spectrometrically (4).

The reaction cell, which was 10 cm in length and 5 cm in diameter (195 cc volume), was filled with a nearly parallel beam of light from B.T.H. ME/D 250-w mercury lamp. The light was filtered either by a Corning filter 9863 in combination with a solution of potassium chromate (filter A) or a Corning filter 7910 (filter B) (8). The light intensity was varied either by neutral density filters or wire gauzes and both gave similar results. In some experiments the light absorption was measured by a photocell placed at the rear of the cell.

Reagent grade acetone (Merck), deuterated acetone (Merck of Canada; 98.2% acetone-d_6 and 1.8% acetone-d_5), and the hydrogen were purified by methods described earlier (2). Perfluoro-*n*-butane (Minnesota Mining and Manufacturing Co.) was outgassed at $-160°$ C.

In a few experiments, the methyl ethyl ketone produced during the photolysis of acetone was analyzed by gas chromatography on a 30-ft column consisting of 30% dinonyl phthalate on firebrick held at 94° C.

The temperature of the reaction cell was controlled by a Fenwal 560 temperature regulator, and the experiments were done at $471 \pm 0.5°$ K.

RESULTS

Deuterated acetone was photolyzed at pressures of 50 mm and 100 mm Hg, and the results are shown in Table I. The extent of the decomposition of the acetone, measured by 100 $[CO]/[A]_0$, was varied over a considerable range, and $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$, R_M/R_E, and $(R_M+2R_E)/R_{CO}$ were independent of the conversion except at the very low conversions. It is interesting to note that at a given light intensity the rates of formation of methane, ethane, and carbon monoxide were independent of the length of photolysis. The light absorption, measured in a few experiments, was also independent of time for conversions up to 18%.

To determine more about the decrease in $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$ at very low conversions, light acetone at 100 mm Hg was photolyzed, and the results are shown in Fig. 1. When

the mixtures of methane, ethane, and carbon monoxide were analyzed by distillation, $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[A]_0$ decreased rapidly at low conversions, but this was not observed when these mixtures were analyzed by mass spectrometric analyses. It is concluded that a small but constant amount of methane was being occluded in the solid nitrogen trap

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

used to separate methane and carbon monoxide from ethane by distillation, and at low conversions this was appreciable relative to the total yields of methane and ethane. The amount of methane occluded varied with the temperature of the solid nitrogen. Recently similar observations were made elsewhere (9).

A few experiments were done in which the methyl ethyl ketone produced during the photolysis of acetone was determined, and the results (Table II) agree with those of Mandelcorn and Steacie (10).

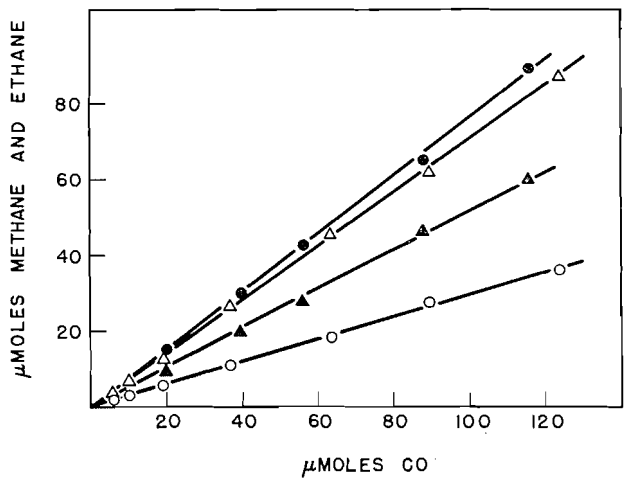
procedures called methods I and II for calculating $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$ are the same as those used by Whittle and Steacie (2). The formation of CD_3H was determined either by using results obtained when deuterated acetone was photolyzed alone (method I) or by mass spectrometric analyses of the methane fractions (method II). The CD_3H arising from the small amount of acetone-d_5 present in the deuterated acetone was evaluated by equation (iv) and subtracted from the total CD_3H formed

$$\text{(iv)} \qquad R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6} = 0.014[A]_0 \times 10^{-12}(\text{molecules/cc})^{\frac{1}{2}}\ \text{sec}^{-\frac{1}{2}}.$$

No CD_2H_2 could be detected.

The values of $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$, $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$, R_{CD_3H}/R_{CD_4}, R_M/R_E, and $(2R_E+R_M)/R_{CO}$ were independent of the fraction of the acetone that was photolyzed, and again the rates of formation of methane, ethane, and carbon monoxide were independent of conversion. The addition of hydrogen to deuterated acetone caused the ratio $R_{C_2D_5H}/R_{C_2D_6}$ to increase very slightly.

In both the presence and absence of hydrogen the formation of methane and ethane during the photolysis of deuterated acetone was linear in the carbon monoxide produced (Fig. 2).



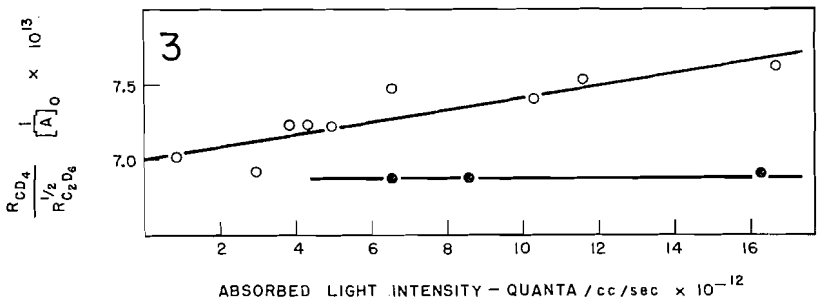


FIG. 2. Variation of the yields of methane and ethane with carbon monoxide.
○ CD_4 from 100 mm Hg *d*-acetone. △ C_2D_6 from 100 mm Hg *d*-acetone.
● Methane from 100 mm Hg *d*-acetone and 50 mm Hg hydrogen.
▲ Ethane from 100 mm Hg *d*-acetone and 50 mm Hg hydrogen.

It is interesting to note that in the presence of hydrogen $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$ and $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$ but not R_{CD_3H}/R_{CD_4} depended on the light intensity. Experiments were made to investigate this effect in more detail, and the results are shown in Figs. 3 and 4. At zero light intensity, differences between the results calculated by methods I and II became very small.

□ $(R_{CD_3H}/R_{CD_4})\,([A]_0/[H_2]_0)\times 6.83\times 10^{-13}$.

Some experiments were carried out to determine the variations, if any, of $(R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})(1/[A]_0)$, $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$, and $(R_{CD_3H}/R_{CD_4})\,([A]_0/[H_2]_0)$ with the pressures of deuterated acetone and hydrogen. The results, shown in Figs. 5, 6, and 7, are rather surprising. Although the photolysis of deuterated acetone alone was not affected by the addition of perfluoro-*n*-butane, both $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$ and $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$ were decreased when this substance was added to the deuterated acetone–hydrogen mixtures.

In one experiment, following the photolysis of deuterated acetone alone, about 50 mm Hg of hydrogen was added to the system, and it was shown that this had no effect on the analyses of the methane and ethane.

DISCUSSION

The object of this investigation, as mentioned earlier, was to determine the importance of the reaction between methyl radicals and the ethane produced during the photolysis of acetone or acetone–hydrogen mixtures.

If this reaction were important, then, $R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6}[A]_0$, $R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6}[H_2]_0$, R_M/R_E, and

R_{CD_3H}/R_{CD_4} in all probability would have been functions of the length of photolysis, but this was not observed. Furthermore, in the presence of hydrogen, a larger yield of C_2D_5H than was found would be expected due to the reaction of C_2D_5 radicals with hydrogen. Finally, the linear relations between both the methane and ethane and the carbon monoxide produced (Fig. 2) would not have been observed.

Both these observations and the evidence already summarized (7) make it apparent that this reaction of methyl radicals with the ethane, though possible under certain conditions, is negligible when the decomposition of the acetone is small.

It is difficult to discuss the observed independence of the absorbed light intensity and of the rates of formation of methane, ethane, and carbon monoxide with time as the length of photolysis was increased. Very many reactions become possible at the larger conversions due to the accumulation of products.

It is apparent that the results observed during the photolysis of the deuterated acetone–hydrogen mixtures are not predicted by reactions (*a*), (*b*), and (*c*) alone. The fact that the ratio (R_{CD_3H}/R_{CD_4}) $([A]_0/[H_2]_0)$ varies with $[H_2]_0$ and $[A]_0$ but is independent of conversion suggests that the anomalous behavior cannot be ascribed entirely to the production of ethane by a reaction other than (*a*) or by the consumption of ethane by radical attack. Consequently, it is postulated that appreciable amounts of methane were formed by reactions in addition to (*b*) and (*c*), and equations (i) and (ii) should be rewritten as follows:

$$(v) \qquad (R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})_{meas} = (k_b/k_a^{\frac{1}{2}})[A]_0 + (R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})_{excess},$$

$$(vi) \qquad (R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6})_{meas} = (k_c/k_a^{\frac{1}{2}})[H_2]_0 + (R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6})_{excess}.$$

Although neither $(R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})_{excess}$ nor $(R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6})_{excess}$ could be estimated with high

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

precision, they were found to be approximately equal in all the experiments and tended to zero at zero light intensity, zero hydrogen pressure, and infinite acetone pressure.

To account for these observations it is proposed that the excess methane was produced by reaction of methyl radicals with an activated molecule X* which was formed by a reaction involving hydrogen atoms, and this contained both C—H and C—D bonds.

$$CD_3 + X^* \rightarrow CD_4 + R \qquad (d)$$

$$\rightarrow CD_3H + R' \qquad (e)$$

$$X^* + M \rightarrow X + M \qquad (f)$$

If the reactivities of both hydrogen atoms and methyl radicals toward acetone are similar, some hydrogen atoms would be available for combination with methyl and acetonyl radicals to form CD_3H^* and $CD_3COCD_2H^*$. Very little quantitative information is available for the reaction between hydrogen atoms and acetone, but it can be shown that hydrogen atoms are about 10 times more reactive toward ethane at 471° K than are methyl radicals (11, 12). If CD_3H^* is unlikely because of the rapidity of

$$H + CD_3COCD_3 \rightarrow HD + CD_2COCD_3$$

then the formation of $CD_3COCD_2H^*$ must be rejected for a similar reason. On the other hand, if CD_3H^* and $CD_3COCD_2H^*$ are formed, it is likely that they would be partially stabilized very rapidly though it is possible that many collisions (10^6) may be required before they are deactivated to their ground vibrational states (13).

If X* represents an excited molecule of CD_3H, reaction (*d*) would give rise to CD_2H radicals, and some would undoubtedly combine with CD_3 radicals to form C_2D_5H. It was observed, however, that although $(R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})_{excess}$ was independent of the conversion and increased with increasing light intensity, the small yield of C_2D_5H increased with increasing conversion and decreased with increasing light intensity. Furthermore, due to reaction (*f*) the addition of a third body to the reaction mixture would cause the ratio $(R_{CD_3H}/R^{\frac{1}{2}}_{C_2D_6})_{excess}/(R_{CD_4}/R^{\frac{1}{2}}_{C_2D_6})_{excess}$ to increase and this was not observed.

On the other hand, if X* represents an excited molecule of $CD_3COCD_2H^*$ the observed kinetics are predicted. However, more direct evidence is required before it will be possible to identify the excited molecule X* with any degree of certainty.

The formation of some such excited molecule during the photolysis of acetone–hydrogen mixtures will account for the observations made here. It also suggests an explanation for the differing values obtained here, and earlier (1, 2), by methods I and II for the rate constant for the reaction of methyl radicals with hydrogen. Such an explanation could also account for the lowering of the apparent value of the activation energy of the reaction of methyl radicals with acetone as observed by Whittle and Steacie (2) for the two systems, acetone-d_6 – hydrogen and acetone–deuterium. It is possible that for the same reason the activation energies reported for the reaction of methyl radicals with hydrogen are slightly low, for example, by about 1 kcal/mole.

ACKNOWLEDGMENTS

We wish to thank Drs. K. O. Kutschke and K. J. Laidler for their interest in this work, Mrs. R. H. Riem for the mass spectrometric analyses, and Mr. R. Pilon for the gas chromatographic analyses.

SOME DEUTERIUM KINETIC ISOTOPE EFFECTS

IV. β-DEUTERIUM EFFECTS IN WATER SOLVOLYSIS OF ETHYL, ISOPROPYL, AND *tert*-BUTYL COMPOUNDS[1]

K. T. LEFFEK,[2] J. A. LLEWELLYN,[2] AND R. E. ROBERTSON

ABSTRACT

The secondary β-deuterium isotope effects have been measured in the water solvolytic reaction of alkyl halides and sulphonates for primary, secondary, and tertiary species. In every case the kinetic isotope effect was greater than unity ($k_H/k_D > 1$). This isotope effect may be associated with varying degrees of hyperconjugation or altered non-bonding intramolecular forces. The experiments make it difficult to decide which effect is most important.

As an extension of our work (1, 2, 3) on deuterium kinetic isotope effects we have measured the kinetic consequences of β-deuteration for a series of compounds solvolyzing in water,

$$RX + H_2O \rightarrow ROH + H^+ + X^- \qquad [1]$$

The kinetic effect produced by substituting deuterium for β-hydrogen in molecules undergoing solvolytic substitution has been studied by Shiner (4, 5, 6), Lewis *et al.* (7, 8, 9), Streitwieser *et al.* (10), and others (11, 12, 13). This paper presents a survey for a series of alkyl halides and sulphonates and the results of these measurements have been collected in Table I.

DISCUSSION

It will be noted that in all cases the deuterated compounds react more slowly than their protium analogues, the magnitude of the total isotope effect increasing both absolutely and relatively as the transition state becomes more ionic. Thus the effect of deuteration for a given alkyl group is greater in the sulphonates than for the halides and increases with increasing α-methylation. Since some of the compounds have been extensively deuterated, it will be necessary to consider as sources of the observed isotope effect not only those factors involved in the activation process contributing to changes in the zero-point energy such as changes in hyperconjugation and non-bonded interaction but also the consequence of mass increase. This factor has been discussed by us in an earlier paper as a "thermodynamic" effect involving changes in translational and rotational properties which affect the thermodynamic properties of the molecule independently of the zero-point energy shifts.

"Thermodynamic" Factors

Although a detailed evaluation of these elements is not yet possible, the relative values of k_H/k_D evident in Table I provide a basis for a semiquantitative discussion of the importance of possible contributors to the deuterium isotope effect.

Isopropyl iodide	3.125	2.380	60.00_3	1.31_3
t-Butyl chloride	9.860	3.840	2.07_0	2.56_8

In order to consider these effects, it is necessary to postulate models for initial and transition states of reaction. Obviously there is scope for considerable conjecture here, and it appears advisable to set limits where possible by oversimplification, and thereby obtain maximum values. For these reactions, the C—X bond (X represents the leaving group) is undoubtedly stretched almost to breaking; the number and role of the water molecules in the transition state form a field for speculation. Consider first translational changes: a simple ionization with no water involved and bond stretching in the transition state would have zero translational contribution to the isotope effect. For an extensively solvated transition state and an unsolvated initial state (almost as unrealistic a model as the first (14)), the translational differences will approximate to those in the initial state. This contribution will tend to slow the reaction for the heavy compound and a maximum value of about 86 cal/mole ($\Delta F_H^{\ddagger} - \Delta F_D^{\ddagger}$) can be calculated for *tert*-butyl chloride at 273° K. Initial-state solvation, which is undoubtedly important in these reactions, will serve to reduce this effect considerably. Rotational changes may be considered for similar models. Simple C—X extension if carried sufficiently far might produce an inverse effect ($k_H/k_D < 1$) by displacing the center of gravity in a direction away from the site of isotopic substitution. For more complicated models the expression for the rotational contribution (eq. 2) may be examined as follows in order to assess its maximum contribution

$$[2] \qquad k_H/k_D(\text{rotation}) = \left[\frac{\Pi I_D}{\Pi I_H}\frac{\Pi I_H^{\ddagger}}{\Pi I_D^{\ddagger}}\right]^{\frac{1}{2}}.$$

The maximum value for the second factor in the square bracket (referring to the transition state) is unity. Such a condition would exist for a massive, highly solvated transition state when deuteration made a negligible contribution to the mass. Thus the maximum value of the rotational contribution is now dependent on the ratio of the initial-state terms to the one-half power so that in case of a doubling of this inertial product by deuteration the maximum rotational isotope effect would be $k_H/k_D = \sqrt{2}$. Rough estimates for *t*-butyl and isopropyl halides indicate smaller effects which would again be further reduced by initial-state solvation. If rotational contributions were important, a decrease in isotope effect would be expected to follow substitution of toluenesulphonate for a halide as leaving group. Such changes do occur for the ethyl compounds, suggesting that inertial changes cannot be neglected. For the *n*-propyl series (3), and more particularly for higher members of the α-methylated series, such a change in the leaving group produces an increase in k_H/k_D, which becomes more marked as the transition state becomes more ionic indicating that other more powerful factors are determining the larger isotope effects.

For personal use only.

As usual we neglect the thermodynamic contribution from vibrations in comparison with the zero-point energy change coming from the same source.

Zero-Point Effects

The factors involved here may be conveniently considered in three groups.

Protium–Deuterium

(a) Inductive and Hyperconjugative Differences

Halevi and co-workers have focussed attention on the fact that the mean lengths of bonds to hydrogen and deuterium are different (15). This arises as a consequence of effect of a lower ground-state potential energy for the deuterium-containing molecule, allied with the asymmetry of the potential surface describing the energy of the molecule with respect to displacements of the atoms in bond-stretching and bond-shortening directions. Since the potential surface rises more steeply for bond shortening, the mean positions of atoms for a molecule in a given vibrational state will correspond to increasing bond distances as the energy of the state increases, so that the lower potential energy deuterium compound will have effectively shorter bonds than the protium compound. As a consequence of this altered bond length, dipolar and other interactions will be altered and the behavior of C—H bonds and C—D bonds with respect to inductive and hyperconjugative effects will be different, quite apart from the consequences of altered vibrations produced by the activation process.* From experiment (16, 17, 18, 19) Halevi deduces that hyperconjugative electron release is reduced in the CD_3 group, whereas inductive release is increased in the CD_3 group, compared with the CH_3 group. It might therefore be expected that these differences would be most marked where charge separations are greatest, and vice versa. Our experiments show that the magnitude of the isotope effect k_H/k_D increases in cases where the electron deficiency is expected to be greater and hyperconjugation more powerful.

(b) Non-bonding Interactions

As a consequence of the isotopic alteration in bond length there will be differences in non-bonding forces in the two species (20) but there are other larger changes which might produce zero-point variations (3). Almost all activation processes produce alterations in the molecular geometry and the hydrolyses which have been examined involve changes in the position of the leaving group, the possible insertion of the nucleophile, and the movement of three of the groups attached to the reaction-center carbon atom from tetrahedral positions to something approaching coplanarity. This latter movement will affect intramolecular non-bonded forces between β-hydrogen atoms. If we compare the geometry about the tertiary carbon atom in *tert*-butyl chloride (21, 22, 23) with that about the central carbon in a coplanar carbonium ion we find the methyl groups are about 12% farther apart (as measured by the separation of their respective carbon atoms) even when 0.05 Å is allowed for the bond contraction for C—C sp^3–sp^2 bonding (24) in the transition state. When the high inverse power expressions for non-bonding repulsions are applied to this change in separation, it is obvious that forces affecting vibrations may be considerably reduced. The magnitude of this reduction will depend on other modifying factors such as the proximity of the nucleophile and the leaving group and it is interesting to note the qualitative inverse relationship between the

This aspect of the secondary deuterium isotope effect has been criticized by Weston (Tetrahedron, **6, 31 (1959)), who showed that isotopic perturbation of the potential energy hypersurface is negligible. Since Halevi considers that these effects (difference in bond lengths) arise in the lowest vibrational state as a result of anharmonicity, the isotopic invariance of the potential energy hypersurface will still be consistent with his hypothesis.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

magnitude of k_H/k_D and the expected proximity of these groups, with k_H/k_D per D greatest for that system which of those examined best fits the S_NI case with decreasing values as this description becomes increasingly less apt and the transition state becomes more crowded.

(c) Hyperconjugative Effects

The work of Lewis and Shiner and their respective groups has established that substitution of D for H in hyperconjugative positions usually produces kinetic isotope effects. The weakening of the C—H link, which is represented in valence bond theory by the contribution of non-bonded structures to the hybrid, is thought to decrease zero-point energy by facilitating the vibrations which involve relative extensive movement of β-hydrogens. The isotope effects which we have observed are consistent with such a hypothesis. The direction of the effect and its order of magnitude are in agreement with previous work in other solvents, e.g. 2-pentyl-βd_5 bromide and *p*-toluenesulphonate solvolyzing in formic acid have isotope rate ratios k_H/k_D 1.39 and 1.69, respectively (7), which can be composed with our values for isopropyl-βd_6 bromide (k_H/k_D = 1.34) and *p*-toluenesulphonate (k_H/k_D = 1.54) solvolyzing in water. For tertiary compounds a comparison may be made between *t*-amyl-βd_8 chloride solvolyzing in 80% aqueous alcohol with a rate ratio k_H/k_D = 2.35 (4) and *t*-butyl-βd_9 chloride solvolyzing in water (k_H/k_D = 2.57). The larger β-deuterium isotope effects in formic acid are consistent with the expectation that ionization was more advanced at the transition state in formic acid than in H_2O where some degree of nucleophilic interaction between oxygen and the reactive carbon will be expected, even for the isopropyl compounds. Although water is a better ionizing medium than 80% ethanol it is not possible to decide whether the small increase in k_H/k_D observed by us is to be attributed to increased charge development in the transition state or some other solvation effect. Experimental temperature differences will also make a minor contribution.

The increase in the stability of carbonium ions along the series ethyl, isopropyl, *tert*-butyl is usually associated with an increase in both the inductive and hyperconjugative effects. The expected increase in the β-deuterium isotope effect from ethyl to *tert*-butyl as a consequence of the increase in hyperconjugation is exemplified by the k_H/k_D rate ratios for ethyl and isopropyl bromide and *tert*-butyl chloride, which are 1.03_3, 1.33_6, and 2.56_8 respectively. Differences in the rate ratios are also found when the ease of formation of the carbonium ion is altered by changing the anionic group. Thus, isopropyl methanesulphonate, which is considered to be more easily ionized than the bromide, has a rate ratio $k_H/k_D = 1.54_5$ compared with 1.33_6 for the bromide.

In a discussion of the β-deuterium isotope effect in solvolysis the possible occurrence of an olefin-forming elimination reaction accompanying substitution must be examined. Where the mechanism of the reaction is such that the formation of the olefin takes place after the transition state (e.g. *tert*-butyl chloride) olefin production will not affect the k_H/k_D ratio. However, for reactions where this is not so (E_2) the elimination reaction would exhibit a primary deuterium isotope effect with a rate ratio k_H/k_D of the order of 4 to 6, since an isotopically substituted β-C—H bond is breaking. This would affect the measured k_H/k_D ratio to an extent depending on what fraction of the total reaction was elimination. We have measured the percentage of elimination occurring in the solvolysis of the compounds studied. These results are shown in Table II.

Even in the case of the ethyl compounds where the β-deuterium isotope effects are small, the amount of elimination which takes place concurrently with substitution is insufficient to account for the observed k_H/k_D values.

The most commonly accepted theoretical mechanism for hyperconjugation is the treatment due to Mulliken *et al.* (25), although an alternative model has been set up by Kreevoy and Eyring (26) which these authors call α-hydrogen bonding. Application of this latter model to β-deuterium isotope effects would require an interaction between the β-hydrogen orbital and the developing p orbital on the electron deficient α-carbon atom. One advantage of this treatment is its ability to explain the greater effectiveness of hydrogen in hyperconjugation as compared with carbon–carbon hyperconjugation. With this model the reduction in β-hydrogen vibration frequencies on activation can occur for bending modes and is therefore in harmony with Streitwieser's treatment of β-deuterium isotope effects (10). Kreevoy and Eyring have pointed out (26) that their model for hyperconjugation is closely related to neighboring group participation as described by Winstein and co-workers (27). Neighboring hydrogen participation, however, only occurs in situations favoring skeletal rearrangement of the reacting molecule whereas α-hydrogen bonding is much more widespread, does not involve rearrangement, and gives smaller effects.

Thus, although it is not possible to choose between Mulliken's model for hyperconjugation and that of Kreevoy and Eyring from the measurement of β-deuterium isotope effects, the latter is attractive in that it is able to link qualitatively the two fields of hyperconjugative effects and neighboring group participations.

CONCLUSION

It appears that hyperconjugative and non-bonding interactions are the principal sources of these isotope effects, with small modifications arising from rotational–translational inertia changes. The role of non-bonding interactions ("intramolecular van der Waals forces" (2, 3)) has been discussed by Bartell (20) and he has shown that they can be sufficiently large to account for a major portion of the observed effects. As far as hyperconjugation is concerned the relationships are largely qualitative since no calculations appear to have been made which would even establish the order of magnitude of the consequences of hyperconjugation on isotope effects. Despite this the evidence is moderately convincing (29), isotope rate effects usually being observed for hyperconjugative sites of substitution with magnitudes varying in the way which would be expected from considerations of hyperconjugative change. The jump in isotope effect observed on passing from an isotopically substituted group on the para position of an aromatic ring to a site adjacent to the reaction center (5, 28) seems large even allowing for the damping action of the ring. This may represent the effect of changing non-bonded forces arising

For personal use only.

from the change from tetrahedral to trigonal configuration, which will be insignificant for the para position compared with that for the site adjacent to the reaction center. For the particular effects described in this paper it is difficult to decide which contribution is greater, hyperconjugation or intramolecular van der Waals forces, but undoubtedly both are present and make the major contribution to the isotopic rate change.

EXPERIMENTAL

Ethyl-βd_3 alcohol was prepared by a lithium aluminum hydride reduction of acetic-βd_3 acid (30). The redistilled product, boiling range 79.5–81.5° C, was converted to ethyl-βd_3 *p*-toluenesulphonate by reaction with *p*-toluenesulphonyl chloride in dry pyridine (31). The crude ester (m.p. 30.6° C) was purified by distillation under a vacuum. A comparison of the N.M.R. spectrum of this compound with that of an undeuterated sample indicated that the β-carbon atom was fully deuterated.

Ethyl-βd_2 iodide, bromide, and methanesulphonate were made from the *p*-toluenesulphonate by the methods previously described for the corresponding ethyl-αd_2 compounds (2).

Isopropyl-βd_6 alcohol was obtained by the reduction of acetone-βd_6 with lithium aluminum hydride (32). The crude product was redistilled, boiling range 83.5–84.5° C, and converted to the bromide by the phosphorus tribromide method. The N.M.R. spectrum of this compound showed that the β-carbon atom was fully deuterated.

Isopropyl-βd_6 methanesulphonate, *p*-toluenesulphonate, and iodide were prepared from the bromide by the methods used in the preparation of the deuterated ethyl compounds.

Tertiary butyl-βd_9 chloride (minimum isotopic purity 99%) was purchased from Merck and Co.

For all of the above deuterated compounds the protium analogues were prepared by parallel reactions and were used to check the rate constants which had been determined in the course of previous work under the same conditions (14). Excellent agreement was obtained in all cases.

The rate measurements were made conductometrically as described previously (3).

The following procedure was used for the olefin determinations. Water (75 ml) was placed in a 100-ml bulb fitted with a break-seal. Samples of 0.05 to 0.1 g of the sulphonate or halide were weighed in a weight pipette and introduced into the bulb. The system was then sealed and allowed to react. After reaction the break-seal side arm was fused to a distillation system consisting of a short column and condenser with an outlet passing under the absorbing solution of Byrne and Johnson (33). A slow stream of dry nitrogen was introduced through a mercury trap above the bulb. After opening the bulb, the reacted solution was boiled for 15 minutes. The amount of olefin was determined by back-titration with thiosulphate, suitable corrections being made for a blank in the presence of the alcohol produced and the original unreacted ester.

ACKNOWLEDGMENTS

Thanks are due to Dr. W. Raynes for the N.M.R. measurements, to Mr. S. Sugamori for the careful kinetic measurements, and to Mr. R. Maillet for the olefin determinations.

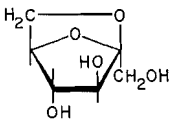
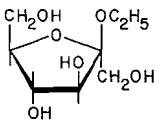
HYDROGENOLYSIS OF CARBOHYDRATES

IX. FORMATION OF 2,6-ANHYDRO-β-D-FRUCTOFURANOSE AND ETHYL α- AND β-D-FRUCTOFURANOSIDE FROM SUCROSE[1]



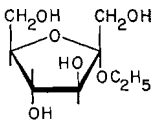
H. R. GOLDSCHMID[2] AND A. S. PERLIN

ABSTRACT



A compound formed during the hydrogenolysis of sucrose in ethanol or dioxane at 180° C, in the presence of copper chromium oxide catalyst, has been characterized as 2,6-anhydro-β-D-fructofuranose (2,5-anhydro-α-D-fructopyranose), a new type of anhydro-ketose. Ethyl α- and β-D-fructofuranosides are also produced when the hydrogenolysis reaction is carried out in ethanol, and various derivatives of these anomeric ketosides have been prepared.

Earlier papers of this series have described the hydrogenolysis of alkyl glycopyranosides in the presence of copper chromium oxide catalyst (1) at moderate temperature and pressure (2, 3, 4, 5, 6). A major effect observed in these reactions is the isomerization of carbinol groups but, particularly at temperatures above 180–200° C, glycosidic linkages also become unstable and extensive hydrogenolysis of hydroxyl groups occurs. Methyl β-L-arabopyranoside, for example, is isomerized to a mixture of methyl pentopyranosides at 180° C (4), whereas at 240° C it is converted in high yield to a mixture of 1,5-anhydro-2-deoxy-DL-pentitols (2, 5). In current studies the behavior of furanose glycosides towards these conditions of hydrogenolysis is being examined, and sucrose has been selected as a readily available substrate containing a furanosyl moiety.



In ethanol at 180° C,* sucrose readily afforded three derivatives of D-fructose, each in about 10% yield (based on the fructose unit of sucrose). Detected initially on paper chromatograms as compounds having high R_F values (relative to that of sucrose) and giving a typical ketohexose test with urea oxalate (7), these products have been isolated by column chromatography on charcoal (8) and cellulose (9) and characterized as 2,6-anhydro-β-D-fructofuranose (I) (2,5-anhydro-α-D-fructopyranose), and ethyl α- and β-D-fructofuranoside (III and II).

The anhydride, m.p. 118–119° C, was found by the isothermal distillation method (10) to be monomeric. It did not reduce hot Fehling's solution nor react with sodium borohydride and, since it was recovered unchanged after prolonged treatment with methanolic ammonia, did not appear to contain an epoxy group. At room temperature, it was easily hydrolyzed by 0.1 *N* sulphuric acid affording D-fructose as the sole product. Tritylation of the anhydride in pyridine proceeded very slowly at room temperature, and two crystalline derivatives were isolated in low yield, one being a monotrityl and the other a ditrityl ether. The compound was resistant also to tosylation but, on prolonged treatment with tosyl chloride in pyridine, yielded a syrupy diester which, however, did not react with sodium iodide. These properties suggested that only the relatively unreactive C-1-carbinol group and/or secondary hydroxyl groups of the anhydride were being substituted, and hence that the normally reactive 6-position was involved in ring formation.

Attempts to methylate the anhydride fully with dimethyl sulphate – sodium hydroxide or with methyl iodide – silver oxide were unsuccessful, but several treatments with potassium in liquid ammonia (11) followed with methyl iodide under reflux, yielded a syrupy trimethyl derivative. On acid hydrolysis this ether afforded crystalline 1,3,4-tri-*O*-methyl-D-fructose (12), showing that both the 5- and 6-hydroxyl groups of the anhydride are involved in ring formation, and hence that the anhydride is 2,6-anhydro-D-fructofuranose (2,5-anhydro-D-fructopyranose).

Since the specific rotation of the anhydride, $[\alpha]_D$ −107°, is more strongly levorotatory than D-fructose itself, the 2,6-oxygen bridge of the compound appears to possess the β-configuration. The β-assignment is strongly supported by an examination of molecular models, which shows also that the 2,6-anhydro ring assumes a boat conformation (as in IV). The eclipsing of bonds and distortion of bond angles in such a molecule could account for the observed ease of acid hydrolysis of the anhydride, as had been anticipated by Mills (13), which contrasts with the relatively high acid stability of other anhydro sugars (epoxides excepted). That the 2,6-pyranoid ring of the compound is much less stable than the five-membered 2,5-ring (see 14, 15) was indicated by the rapid formation of ethyl α- and β-D-fructofuranoside when the anhydride was treated with ethanolic hydrogen chloride at room temperature. Moreover, the α-D-anomer predominated initially, which was to be expected from scission of a β-D-anhydro ring (16), and the observed rate of formation of the mixture of furanosides (rate of rotational change) closely paralleled that found with ethyl β-D-fructofuranoside.

The anhydride consumed no periodate, although it possesses a free glycol group (the *trans*-3,4-diol group), and with lead tetraacetate in acetic acid only a slow uptake of oxidant was found, caused most probably by gradual opening of the anhydro ring. This behavior is in accord with the recent report by Angyal and Young (17) that the camphane-2,3-*trans*-diols are virtually unoxidized by glycol-cleaving agents since the structure of the anhydride is closely analogous to that of the camphane diols. Dimler (18) has suggested that the 2,3-*trans*-diol group of 1,6-anhydro β-D-gluco- and α-galactofuranose, situated on a fused bicyclic system, resists glycol scission most probably because it is fixed rigidly in an arrangement highly unfavorable for complexing by the oxidants. The *trans*-glycol groups of the camphane-*trans*-diols and the anhydrofructose appear to possess a similar spatial arrangement, and their unreactivity can therefore be interpreted in the same way.*

Recently it has been found (H. R. Goldschmid and A. S. Perlin. Can. J. Chem. **38, 2178 (1960)) that these compounds are cleaved oxidatively by lead tetraacetate using pyridine as solvent (27).*

It may be noted, however, that some *vic–trans*-diols which are not located on bicyclic ring compounds, i.e., the 2,3-*trans*-glycol groups on internal (1 → 4)-linked units of oligosaccharides, are also resistant to attack by lead tetraacetate (19).

Several dimeric anhydrides of D-fructose are known to be formed by acid hydrolysis of D-fructans (20) and a 2,3-anhydro monomeric derivative of D-fructofuranose, as well as dimeric anhydrides, has been found recently among the products of direct nitration of D-fructose (21). The compound described here is yet another type of D-fructose anhydride. Also, it represents a class of rare anhydro-sugars, namely, that having the 1,4(2,5)-1,5(2,6)-bridged system. One other member of this class, 1,5-anhydro-β-D-ribofuranose, has been synthesized recently by Vis and Fletcher (22), and also has been converted to the 2,3-*O*-isopropylidene derivative, which proved to be indistinguishable from a compound described several years earlier but only tentatively identified (23). Derivatives of three related glycosans have been reported but incompletely characterized (see 14); these are 1,5-anhydro-2,3,6-tri-*O*-methyl-β-D-glucofuranose (24) and -α-L-idofuranose (25), and 2,3-di-*O*-acetyl-1,5-anhydro-β-L-rhamnofuranose (26).

Although 2,6-anhydro-β-D-fructofuranose cannot be regarded as a *hydrogenolysis* product derived from sucrose, it was not obtained when the reaction was carried out in the presence of argon rather than hydrogen. Considerable charring occurred under these latter conditions, however, and ethyl β-D-fructopyranoside was isolated from the reaction mixture, the furanosides being relatively minor products. Hence the hydrogenolysis conditions used may prevent decomposition of labile compounds, rather than serve directly in promoting formation of the furanose products. The occurrence together of the anhydride and of the anomeric furanosides suggests the possibility that all three products are formed from a carbonium-ion intermediate of the type encountered in the acid-catalyzed solvolysis of glycosides (see 15). A protonated form such as V, by reaction with the solvent, could yield the anomeric furanosides (II and III), and through intramolecular attack by the C-6-carbinol group give the 2,6-anhydride. Formation of an acyclic carbonium-ion intermediate (15) appears less likely in these reactions, since ethyl pyranosides would then be expected to predominate among the products at the high temperatures used. That the anhydride may be derived directly from sucrose rather than from the glycosides was shown by its formation also when the hydrogenolysis reaction was carried out in dioxane as solvent in place of ethanol. The anhydride itself undergoes ethanolysis readily by heat in the absence of added acid catalyst to yield the anomeric furanosides. Hence, the glycosides isolated from the hydrogenolysis mixture may be produced by solvolysis of the anhydride, as well as via a carbonium-ion intermediate such as V.

The α- and β-anomers of ethyl D-fructofuranoside were isolated as analytically pure syrups,* the β-anomer being readily cleaved by invertase. On tosylation, the β-glycoside furnished a crystalline diester which was converted by treatment with sodium iodide in acetone to a syrupy, monoiodo monotosyl derivative. In pyridine solution (27) the ditosylate consumed 1 mole of lead tetraacetate, in agreement with the expectation that the ester groups were located at positions-1 and -6; presumably, that at position-1 is not readily replaceable by iodide ion (28, 29). The β-anomer also furnished a crystalline 1,6-di-*O*-trityl derivative, the terminal location of the ether groups being shown by the fact that the compound, in pyridine, consumed a mole of lead tetraacetate; the ditrityl ether was characterized further as a crystalline diacetate. Tritylation of the α-glycoside

**The α-anomer of methyl D-fructofuranoside has been obtained in crystalline form (30).*

followed by acetylation afforded a crystalline di-*O*-acetyl dityrityl ether. After deacetylation the dityrityl ether was shown, also by oxidation with lead tetraacetate in pyridine, to be the 1,6-derivative.

No ethyl D-glucosides were detected among the reaction products, in accord with the expectation that the D-fructofuranosyl linkage should be cleaved preferentially. Further, as shown by the formation of D-sorbitol, the D-glucosyl unit appeared to be converted mainly to the free sugar and then reduced. The presence of D-mannitol in the mixture suggested that some D-fructose also was formed during the reaction. In addition to these products, glycerol and a small proportion of erythritol were isolated, but the origin of these fragments was not determined.

In contrast to the behavior of sucrose, the derived octaacetate was completely stable to the hydrogenolysis conditions, even at 240° C. The (2 → 6)-linked poly-D-fructan, inulin, although converted in small proportion in ethanol to the furanosides, appeared to yield none of the anhydride.

EXPERIMENTAL

Paper chromatography was carried out with butan-1-ol:ethanol:water (40:11:19) as solvent, and with urea oxalate (7) and ammoniacal silver nitrate (31) as spray reagents.

Column chromatography on cellulose was carried out using benzene:ethanol:water (500:50:1), (500:100:1) and ethanol.

Evaporations were carried out at 40–50° C, and optical rotations were measured at approximately 25° C. Melting points are corrected, and boiling points recorded are air-bath temperatures.

Hydrogenolysis of Sucrose in Ethanol and Separation of the Products

Sucrose (20 g) in absolute ethanol (75 ml) was heated at 180° C and a pressure of 1100 p.s.i. of hydrogen in the presence of copper chromium oxide catalyst (2 g) for 6 hours. The catalyst was filtered off and the filtrate concentrated, yielding a colorless syrup. Paper chromatographic examination of the syrup indicated the presence of the following components: hydroxymethylfurfural; glycerol; erythritol; ketohexose derivatives at R_F 0.60, 0.48, and 0.35; fructose; mannitol; sorbitol; sucrose; and slower-moving materials streaking to the origin.

The syrupy reaction product was chromatographed on a column of coconut charcoal (32). The glycerol (0.35 g) and erythritol (0.25 g) (m.p. 120° C, undepressed) were eluted with water.

By adding 5% ethanol to the column and then fractionating the mixture of eluted products on a cellulose column, the following were obtained: component R_F 0.60 (0.85 g), fructose (0.5 g), glucose (2.0 g), and admixed D-mannitol and D-sorbitol (1.5 g). D-Mannitol (m.p. 166° C, undepressed) was isolated by fractional crystallization, and D-sorbitol was characterized as the hexaacetate (m.p. 99° C, undepressed).

The charcoal column was washed finally with 10% ethanol yielding a mixture of products. This mixture was resolved on a cellulose column, giving component R_F 0.48 (0.9 g), component R_F 0.35 (0.85 g), and unchanged sucrose (9.5 g).

*2,6-Anhydro-β-*D*-fructofuranose* (I)

The chromatographically pure syrup (component R_F 0.35) solidified on prolonged storage, and was recrystallized from acetone, m.p. 118–119° C and $[\alpha]_D$ −107° (*c*, 1, H_2O) (no mutarotation). Calculated for $C_6H_{10}O_5$: C, 44.44%; H, 6.22%; mol. wt., 162. Found:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

C, 44.49%; H, 6.37%; mol. wt., 157 (by isothermal distillation (10) in methanol at 50° C).

The compound did not reduce Fehling's solution, was unaffected by treatment under reflux for 6 hours with 1% methanolic ammonia, and also by treatment for 3 days at room temperature with aqueous sodium borohydride. With sodium metaperiodate no uptake of oxidant was found in 24 hours reaction time, and with lead tetraacetate in acetic acid the consumption of oxidant was 0.1 mole in 8 hours reaction time.

In 0.05 *N* sulphuric acid at 25° C the observed rotation of the anhydride solution (1.0%) decreased slightly from α_D −1.00° (3 minutes) → α_D −0.97° (5 hours, constant, 1 dcm tube). Paper chromatographic examination showed that most of the anhydride was hydrolyzed in 2 hours, and that conversion to fructose was complete within 5 hours; accordingly, the calculated $[\alpha]_D$ of the hydrolyzate was −89° (D-fructose shows $[\alpha]_D$ −92°). The product was characterized further by conversion to D-glucose phenylosazone, m.p. 209° C (decomp.), and indistinguishable from an authentic sample by X-ray diffraction.

The observed rotation of the anhydride in ethanolic hydrogen chloride (0.5%) at room temperature rose rapidly to $[\alpha]_D$ +0.44° (7 minutes), then decreased slowly to −0.09° (18 hours) (*c*, 1.2, 1 dcm tube). Paper chromatographic examination of the reaction mixture indicated that ethyl α-D-fructofuranoside was formed as the major product during the first 10 minutes reaction time. Under similar conditions, rotational changes shown by ethyl β-D-fructofuranoside were a rapid rise to $[\alpha]_D$ +0.32° (9 minutes), then dropping slowly to 0.03° (19 hours); ethyl α-D-fructofuranoside showed $[\alpha]_D$ +0.22° (2 minutes)→ −0.07° (20 hours), D-fructose, $[\alpha]_D$ +0.18° (14 minutes)→ −0.24° (18 hours). These values are similar to the data reported by Purves and Hudson (30, 33) for the methyl D-fructofuranosides and D-fructose.

Acetylation of the anhydride with acetic anhydride – pyridine at room temperature afforded a triacetate, b.p. 110–120° C at 0.05 mm, $[\alpha]_D$ −108° (*c*, 1.3, $CHCl_3$). Calculated for $C_{12}H_{16}O_8$: C, 50.00%; H, 5.60%; acetyl, 44.8%. Found: C, 50.17%; H, 5.79%; acetyl (sapon.), 44.4%.

Treated with benzoyl chloride and pyridine in cold chloroform, the anhydride yielded an amorphous tribenzoate, $[\alpha]_D$ −163° (*c*, 1.1, $CHCl_3$). Calculated for $C_{27}H_{22}O_8$: C, 68.35%; H, 4.67%. Found: C, 67.90%; H, 4.73%.

*1,3,4-Tri-O-methyl-*D*-fructose*

The anhydride (0.20 g) was dissolved in liquid ammonia (20 ml) and potassium was added portionwise until a stable blue color developed in the solution. After evaporation of the ammonia, methyl iodide (3 ml) was added and the solution heated under reflux for 3 hours and then stored at room temperature for 18 hours. The methyl iodide was evaporated off, the methylation procedure repeated twice, and the final reaction mixture was extracted with chloroform. The chloroform extract afforded a syrup which was distilled, b.p. 60–70° C at 0.05 mm. Paper chromatographic examination of the distillate showed the presence of a major component and a minor, slower-moving component which corresponded to 1,3,4-tri-*O*-methyl-D-fructose (below), indicative of partial hydrolysis. Calculated for $C_9H_{16}O_5$: methoxyl, 45.6%. Found: (two preparations) methoxyl, 42.9%, 41.7%.

The distillate (105 mg) was hydrolyzed with *N* sulphuric acid, the solution was neutralized with barium carbonate and extracted with chloroform. On evaporation, the aqueous layer yielded a syrup (99 mg) which consisted of a single component (paper chromatogram). Purified by distillation (b.p. 115–120° C at 0.05 mm) the product solidi-

For personal use only.

fied, and was recrystallized from carbon tetrachloride, m.p. 72–73° C and $[\alpha]_D$ −49.6° (*c*, 1.3, H_2O) (lit. (12), m.p. 73° C and $[\alpha]_D$ −51.8° (H_2O)). Calculated for $C_9H_{18}O_6$: C, 48.36%; H, 8.3%; methoxyl, 41.89%. Found: C, 48.34%; H, 8.17%; methoxyl, 41.79%.

In acetic acid, the trimethyl D-fructose consumed no lead tetracetate in 4 hours reaction time, showing the absence of a free *vic*-diol at the 2,3-position (34) and also at the 1,2-position (35). After reduction with sodium borohydride, 1 mole of formaldehyde was produced (chromotropic acid method (36)) in 1 hour reaction time. This behavior showed the absence of methoxyl groups at positions-2, -5, and -6, and hence confirmed that the product was the 1,3,4-tri-*O*-methyl derivative.

Tritylation of 2,6-Anhydro-β-D-fructofuranose

In a preliminary experiment, using 2.2 moles of trityl chloride per mole of anhydride in pyridine at room temperature, some unchanged anhydride was present in the reaction mixture after 1 week (paper chromatogram). The anhydride (162 mg) in pyridine (4 ml) was treated at room temperature for 10 days with triphenylchloromethane (615 mg). Ice water was added, the reaction mixture was extracted with benzene, and the extract washed successively with water, sodium bicarbonate solution, and water, then dried over sodium sulphate, and the benzene was evaporated off. The oily product (720 mg) was fractionated on a column of reagent silicic acid using chloroform as the solvent. After elution of triphenylcarbinol, a ditrityl derivative (85 mg) was isolated and recrystallized from ethanol, m.p. 224–226° C and $[\alpha]_D$ −38.5° (*c*, 0.8, $CHCl_3$). Calculated for $C_{44}H_{38}O_5$: C, 81.75%; H, 5.92%; mol. wt., 643. Found: C, 81.88%; H, 6.00%; mol. wt., 621 (melting point depression in camphor).

Continued washing of the column with chloroform eluted a monotrityl derivative (145 mg) which, after recrystallization from dichloromethane – *n*-hexane, had a melting point of 150–153° C, $[\alpha]_D$ −43.7° (*c*, 1.0, $CHCl_3$). Calculated for $C_{25}H_{24}O_5$: C, 74.24%; H, 5.98%. Found: C, 74.24%; H, 5.98%.

Di-O-tosyl-2,6-anhydro-β-D-fructofuranose

The anhydride (200 mg) in pyridine (5 ml) was treated with *p*-toluenesulphonyl chloride (500 mg) at room temperature for 18 hours. A few drops of water were added, and after 30 minutes the reaction mixture was poured into ice water and extracted with benzene. After successive washings with water, sodium bicarbonate solution, and water, the benzene extract was dried and concentrated affording a glass (139 mg). The product, treated in acetone with sodium iodide in a sealed tube at 100° C, yielded only a trace of sodium *p*-toluenesulphonate in 24 hours reaction time, $[\alpha]_D$ −29.1° (*c*, 1.4, $CHCl_3$). Calculated for $C_{20}H_{22}O_9S_2$: C, 51.04%; H, 4.71%; S, 13.62%. Found: C, 51.60%; H, 4.91%; S, 14.17%.

Ethyl β-D-Fructofuranoside (II)

The syrupy, chromatographically pure glycoside had $[\alpha]_D$ −36° (*c*, 1, H_2O), was readily degraded to fructose by treatment with invertase, and was hydrolyzed to fructose at room temperature within 2 days by 0.1 *N* sulphuric acid. It consumed 1.0 mole of sodium periodate per mole.

On acetylation with acetic anhydride in pyridine at room temperature, the glycoside (200 mg) afforded a tetraacetate (310 mg), b.p. about 150° C at 0.06 mm, $[\alpha]_D$ −25° (*c*, 1.1, $CHCl_3$). Calculated for $C_{16}H_{24}O_{10}$: C, 51.06%; H, 6.43%; acetyl, 45.8%. Found: C, 51.07%; H, 6.52%; acetyl (sapon.), 46.1%.

1,6-Di-O-trityl Ethyl β-D-Fructofuranoside

The glycoside II (200 mg) in pyridine (4 ml) was treated at room temperature with trityl chloride (600 mg) for 48 hours. Isolated after treatment with ice water and extraction into benzene, the product (490 mg) was crystallized from ethanol, m.p. 180–183° C and $[\alpha]_D$ −2.3° (*c*, 1.0, $CHCl_3$). Calculated for $C_{46}H_{44}O_6$: C, 79.74%; H, 6.40%. Found: C, 79.91%; H, 6.60%.

Treated with lead tetraacetate in pyridine (27) at 0° C the ditrityl derivative consumed 1 mole of oxidant per mole in 0.5 hour.

The ditrityl glycoside (100 mg) treated with acetic anhydride – pyridine afforded a diacetate (95 mg) which, after recrystallization from ethanol, had a melting point of 207–208° C, $[\alpha]_D$ +35.8° (*c*, 1.3, $CHCl_3$). Calculated for $C_{50}H_{48}O_8$: C, 77.30%; H, 6.23%. Found: C, 77.07%; H, 6.29%.

1,6-Di-O-tosyl Ethyl β-D-Fructofuranoside

To the glycoside II (400 mg) in pyridine (5 ml) at 0° C was added a solution of *p*-toluenesulphonyl chloride (750 mg) in chloroform (10 ml). After 2 hours at 0° C and 18 hours at 25° C the reaction mixture was diluted with chloroform (30 ml), treated with a few drops of water, and 30 minutes later was washed successively with ice water, copper sulphate, sodium bicarbonate, and water. The solution was dried over sodium sulphate and concentrated, yielding a crystalline product (230 mg) which was recrystallized from ethanol – *n*-hexane, m.p. 125–127° C (decomp.), $[\alpha]_D$ −12.8° (*c*, 1.0, $CHCl_3$). Calculated for $C_{22}H_{28}O_{10}S_2$: C, 51.15%; H, 5.46%; S, 12.41%. Found: C, 51.02%; H, 5.46%; S, 12.13%.

In pyridine, the ditosyl derivative consumed 1.0 mole of lead tetraacetate per mole in 1 hour reaction time.

The ditosylate (100 mg) was heated at 100° C with sodium iodide (75 mg) in acetone (6 ml) for 24 hours. Sodium *p*-toluenesulphonate (35 mg), which crystallized out on cooling, was filtered off. After evaporation of the acetone, the residue was taken up in chloroform, washed with water, and recovered as an oil (72 mg), $[\alpha]_D$ −22.5° (*c*, 1.0, $CHCl_3$). Calculated for $C_{15}H_{21}O_7SI$: S, 6.79%; I, 26.87%. Found: S, 6.68%; I, 25.94%.

Ethyl α-D-Fructofuranoside (III)

The syrupy, chromatographically pure material showed $[\alpha]_D$ +65° (*c*, 1, H_2O), was not attacked by invertase, and was hydrolyzed to D-fructose within 15 hours at room temperature by 0.1 *N* sulphuric acid. It consumed 1 mole of sodium periodate per mole. Calculated for $C_8H_{16}O_6$: C, 46.15%; H, 7.75%; ethoxyl, 21.6%. Found: C, 45.98%; H, 8.13%; ethoxyl, 21.1%.

Acetylated at 25° C with acetic anhydride – pyridine, the glycoside yielded a tetraacetate, b.p. about 135° C at 0.01 mm, $[\alpha]_D$ +76° (*c*, 1.4, $CHCl_3$). Calculated for $C_{16}H_{24}O_{10}$: C, 51.06%; H, 6.43%; acetyl, 45.8%. Found: C, 51.22%; H, 6.65%; acetyl (sapon.), 45.8%.

3,4-Di-O-acetyl-1,6-di-O-trityl Ethyl α-D-Fructofuranoside

The glycoside III (205 mg) was treated with trityl chloride (615 mg) in pyridine (4 ml) at room temperature for 7 days, and the reaction mixture was worked up as described previously. The syrupy product (722 mg) was fractionated on a silicic acid column using chloroform as solvent, affording a crystalline ditrityl ether (260 mg) and, by continued elution, an oily product which probably was a monotrityl derivative. Despite repeated recrystallization from ethanol the ditrityl ether had a broad melting point (about

140–150° C). On acetylation at 100° C with acetic anhydride – sodium acetate, a di-*O*-acetyl di-*O*-trityl derivative was obtained, m.p. 142–144° C and $[\alpha]_D$ +44.7° (*c*, 1.4, $CHCl_3$). Calculated for $C_{50}H_{48}O_8$: C, 77.30%; H, 6.23%. Found: C, 77.32%; H, 6.32%.

The product was deacetylated with sodium methoxide in chloroform–methanol, the solvent was evaporated, and the residue treated at 0° C with lead tetraacetate in pyridine. Found: 1.0 mole of oxidant consumed per mole in 0.5 hour.

Hydrogenolysis of Sucrose in Dioxane

Sucrose (5 g) and copper chromium oxide catalyst (0.5 g) in dioxane (75 ml) were heated for 6 hours at 180° C under hydrogen at 1100 p.s.i. An oil consisting mainly of unchanged sucrose separated out on cooling, and the dioxane solution was evaporated. The residue (2.9 g) showed heavy streaking on a paper chromatogram. By chromatography on a cellulose column, a fraction corresponding (paper chromatogram) to the anhydride (I) was isolated (167 mg). After recrystallization from acetone, the product had a melting point of 118–119° C, undepressed. The X-ray diffraction powder diagram of the product was indistinguishable from that of the anhydride (I).

Ethanolysis of Sucrose

Sucrose (10 g) in dry ethanol (75 ml) was heated for 6 hours at 180° C in an atmosphere of argon (10 p.s.i.). The resulting dark-brown solution was concentrated to a syrup which, from paper chromatographic examination, appeared to contain hydroxymethylfurfural, ethyl D-fructofuranosides (II and III), a trace of anhydride (I), fructose, and sucrose. By column chromatography on cellulose the glycoside mixture was found to contain ethyl β-D-fructopyranoside (105 mg), m.p. 150–151° C and $[\alpha]_D$ −160° (*c*, 1.0, H_2O). Calculated for $C_8H_{16}O_6$: C, 46.15%; H, 7.75%. Found: C, 46.21%; H, 7.86%. The derived tetraacetate had a melting point of 83–84° C and $[\alpha]_D$ −127° (*c*, 1.2 $CHCl_3$). Calculated for $C_{16}H_{24}O_{10}$: C, 51.06%; H, 6.43%. Found: C, 51.33%; H, 6.57%.

ACKNOWLEDGMENTS

REACTION OF OXYGEN ATOMS WITH BUTADIENE[1]

R. J. Cvetanović and L. C. Doyle

ABSTRACT

Reaction of oxygen atoms with 1,3-butadiene has been investigated at room temperature. It is found that it conforms to the general mechanism established previously for the analogous reactions of monoolefins. Only 1,2-addition occurs, and the addition products, butadiene monoxide and 3-butenal, possess excess energy when formed as a result of high heats of reaction. The pressure dependence of the formation of the addition products yields the values of the "lifetimes" of the initially produced "hot" molecules. The relative rate constants have been determined at 25 and 127° C and from these the relative values of the Arrhenius parameters have been calculated.

INTRODUCTION

The general mechanism of reaction of oxygen atoms with alkenes has recently been established in this laboratory (1) and the trends in the relative rate constants (2) demonstrated the electrophilic character of the ground-state oxygen atoms in these reactions. As an extension of this work the present study of the analogous reaction with 1,3-butadiene, as the simplest representative of conjugated diolefins was carried out.

The particular questions which the present investigation was hoped to answer are: first, whether conjugated diolefins in their reactions with oxygen atoms follow the general mechanism established for monoolefins; secondly, whether only 1,2- or also 1,4-addition products are formed; and lastly, whether the value of the rate constant of the reaction of oxygen atoms with 1,3-butadiene is such as might be expected in view of the trends and relations established in the case of monoolefins (2). Affirmative answers to these questions have been obtained and only the two 1, 2-addition products predicted on the basis of the rules formulated for the monolefins (1), butadiene monoxide and 3-butenal, the latter readily isomerizing to the more stable crotonaldehyde, have been observed. The 1,4-addition product, 2,5-dihydrofuran, is not formed.

The pronounced pressure effect observed in the present work illustrates particularly well initial formation of "hot" addition products and the consequent "pressure-dependent fragmentation" (1) in the reactions of oxygen atoms with olefins. As a result, in some of these reactions, including 1,3-butadiene itself, the addition products are essentially completely decomposed at pressures of a few millimeters and are then not observable experimentally. This feature and some other difficulties inherent in the electrical discharge method for production of oxygen atoms, as discussed recently elsewhere (3), are believed to be responsible for the entirely different conclusions from the present ones arrived at by Avramenko and Kolesnikova (4) in what seems to be the only other attempt reported in the literature to study the reaction of oxygen atoms with butadiene. These differences are of a general character and are not limited to the case of butadiene.

Oxygen atoms were generated by mercury-photosensitized decomposition of nitrous oxide, as described in the previous work (1, 2), and nitrogen liberated provided a quantitative measure of the oxygen atoms consumed in the reaction.

EXPERIMENTAL

The apparatus used in this work consisted of a cylindrical quartz reaction cell 5 cm in diameter and 10 cm long, connected in series with an all-glass vertical plunger-type

circulating pump. The circulating reaction system had a total volume of 415 ml. It was connected by means of mercury cutoffs to a constant volume burette for measuring the amounts of reactant hydrocarbons (butadiene, cyclopentene) to the analysis system and to the vacuum manifold. Nitrous oxide was measured manometrically on a volume of 1000 ml and then was frozen over into the reaction vessel.

The analysis system consisted of a Le Roy still (5), followed by a "pump-out" trap and then by a constant volume burette and outlets for transfer of samples to the gas–liquid chromatographic apparatus (GLC), mass spectrometer, and infrared spectrometer. The Le Roy still was used in particular for the separation of the more volatile fractions. The noncondensable gases, N_2, CO, CH_4, and H_2, were analyzed by the use of a copper oxide tube to oxidize CO and H_2. The CO_2 formed was measured manometrically and mass spectra were taken of the residual N_2 and CH_4. Hydrogen, the amount of which was determined by difference, was at best formed only in trace amounts in the present work. The "pump-out" trap ensured quantitative retention of C_2H_4 which, together with C_2H_6 and traces of CH_4 and N_2O, was eluted from the Le Roy still at $-180°$. This fraction was further analyzed mass spectrometrically. No appreciable amounts of methane, ethylene, or ethane were formed in the reaction of oxygen atoms with butadiene. Ethylene formed from cyclopentene served for the determination of the relative rate constants, as described before (2).

After removal of excess N_2O and a part of the butadiene, the remainder was run on a 4-ft GLC column consisting of about 4 weight per cent dimethyl sulpholane on glass beads (passing 270 mesh). Infrared and mass spectra of the major reaction products were taken after their elution from the GLC column.

An air-cooled low-pressure mercury lamp was used as source of the mercury resonance radiation. In most experiments the large excess of N_2O employed ensured only negligible quenching by butadiene and separate experiments showed that mercury-photosensitized decomposition of butadiene itself was not important under conditions of the present experiments. The reactants were of the best available grade and were degassed and bulb-to-bulb distilled *in vacuo* in the usual manner before use.

In the reaction of oxygen atoms with butadiene only two addition products were detected by GLC analysis (using dimethyl sulpholane column): butadiene monoxide and crotonaldehyde. They had GLC elution times, infrared spectra, and mass spectra identical with those of the respective commercial samples (a sample of butadiene monoxide was kindly supplied by Columbia-Southern Chemical Corp.). The GLC analysis of the condensable products showed also small amounts of what appeared to be three compounds eluting much faster than the two addition products. These were formed in too small amounts to be identified by the analytical techniques used but are believed to be the products of fragmentation of the "hot" addition products, as will be discussed in the following section. No 2,5-dihydrofuran, a potential 1,4-addition product, was detected.* The quantitative data on the products observed by GLC are based on calibrations made with butadiene monoxide and crotonaldehyde and with the assumption that the fragmentation products had equal response per unit area of the peaks to that of butadiene monoxide. Only the total sum of the fragmentation products observed by GLC is reported here since individually they were present in most cases in little more than trace amounts.

In the reaction of oxygen atoms with butadiene there was evidence for the formation

**The authors are very grateful to Dr. E. C. Horswill of these laboratories for synthesizing a sample of 2,5-dihydrofuran in order that its absence in the reaction products could be verified directly.*

of a deposit (referred to in the following as the "polymer") which was not removed, or was removed only extremely slowly, from the reaction vessel by evacuation or freezing out. No attempt was made to obtain qualitative and quantatitive information on this material.

RESULTS

The results of several experiments carried out at 25±2° at constant pressures of nitrous oxide and butadiene, 300 and 30 mm, respectively, but at varying exposure times are presented in Fig. 1. They show that within the investigated range the rates of formation of the products are independent of the reaction time.

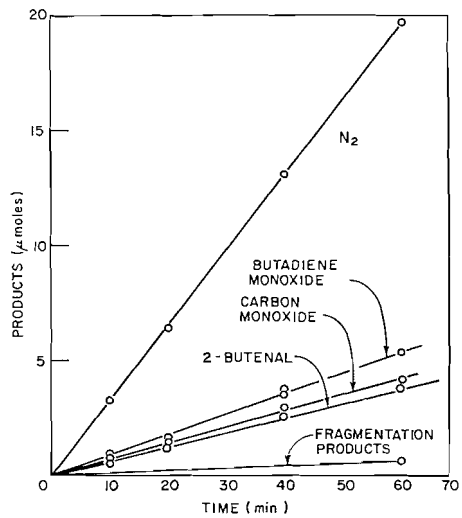

FIG. 1. Variation of the amounts of products formed with irradiation time. (Pressure of N_2O 299±2 mm, pressure of butadiene 31±2 mm, temperature 25±2° C. "Fragmentation products" refer to the unidentified condensable products of pressure-dependent fragmentation as observed by GLC.)

In the experiments shown in Fig. 1 exceptionally large amounts of butadiene were employed, about 10 times as large as in most of the other experiments. Even then no products other than those usually observed were detected. The only effect of variation in butadiene concentration reflected itself in a slight variation in the number of oxygen atoms generated (as measured by nitrogen formation) because of some competitive quenching by the diolefin. This is shown in Table I where more than fourfold increase

TABLE I

Dependence of the amounts of products formed on the initial concentration of butadiene

			Products				
Run	Butadiene, mm	Butadiene / N_2O	N_2, μmoles	CO / N_2	Epoxide / N_2	2-Butenal / N_2	Frag. products* / N_2

in butadiene concentration did not affect the rates of formation of the products per oxygen atom consumed (R/R_{N_2}) and only slightly decreased nitrogen production. This decrease is of correct magnitude to be entirely explainable as due to competitive quenching by butadiene. At the relatively high total pressures employed in the present work the energy transferred by quenching to butadiene is likely to be rapidly dissipated through collisional deactivation, as is usually the case with olefins, without causing any substantial decomposition of butadiene. Small amounts of a butadiene dimer, identified as such mass spectrometrically, were occasionally observed by GLC analysis of the products. This compound was found, however, to be present as a minor impurity in the butadiene used and was initially introduced together with the butadiene into the reaction system.

The effect of pressure on the products formed is very pronounced, as is shown in Fig. 2. In these experiments the pressure of butadiene was kept approximately constant

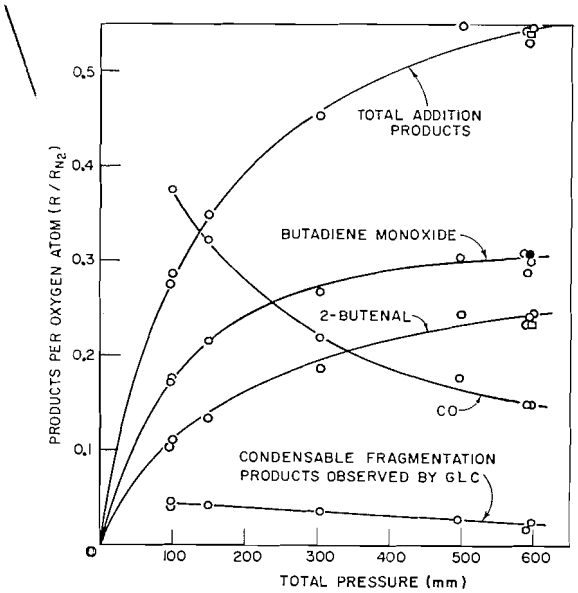

FIG. 2. Rates of product formation per oxygen atom consumed (R/R_{N_2}) at various total pressures. (Pressure of butadiene 3.0±0.5 mm, exposure 40 minutes, temperature 26±1° C. Filled circle and squares indicate initially added 3 mm of O_2.)

at about 3 mm, the exposure was 40 minutes so that between 11 and 13 μmoles of nitrogen were produced, and the temperature was 26±1°. The total pressure was varied by varying the partial pressure of nitrous oxide.

The general behavior in the case of butadiene is quite similar to that observed previously with propylene (1): with increasing pressure the amounts of the addition products, butadiene monoxide and crotonaldehyde, increase while at the same time those of the fragmentation products decrease. The reaction of oxygen atoms with butadiene provides therefore another good illustration of the pressure-dependent fragmentation in the reactions of oxygen atoms with olefins: at higher pressures greater number of the initially produced "hot" addition products is deactivated and less fragmentation of these products occurs.

An initial addition of 3 mm of molecular oxygen to 3 mm of butadiene and 587 mm

of nitrous oxide did not affect the formation of butadiene monoxide and crotonaldehyde, as shown by filled circle and squares in Fig. 2, and eliminated the condensable fragmentation products. No attempt was made to measure directly N_2 and CO in this case because of large excess of O_2 present. Nitrogen was estimated from comparable runs done in the absence of molecular oxygen.

The rate constants of the reaction of oxygen atoms with butadiene (k_B) were determined relative to those of cyclopentene (k_C) at 25.4±1° and 126.8±2° C. The experimental details and the results are given in Table II. The rate constants have been

calculated from the rates of ethylene production in the manner described previously (2). From the mean values of the relative rate constants at the two temperatures the relative values of the Arrhenius parameters are found to be $E_B - E_C = 0.20$ kcal/mole and $A_B/A_C = 1.14$.

DISCUSSION

The products formed in the reaction of oxygen atoms with butadiene indicate that this diolefin conforms to the general mechanism established before (1) for the reaction of oxygen atoms with monoolefins. In the case of butadiene this mechanism requires the formation of butadiene monoxide and 3-butenal as the initial addition products. Actually crotonaldehyde (2-butenal) was observed after elution from the dimethyl sulpholane GLC column instead of 3-butenal. However, infrared absorption spectra of the condensable products taken *before* passage through GLC show that crotonaldehyde is not the primary product of the reaction but is formed during passage through GLC by isomerization of an aldehyde which has the carbonyl stretching absorption band at about 1745 cm^{-1} instead of a doublet at about 1720 cm^{-1} present in crotonaldehyde. Both aldehydes have the C=C stretching absorption band at about 1650 cm^{-1}. *After* GLC the infrared spectra of the products show only the presence of butadiene monoxide and crotonaldehyde, the latter at the expense of the aldehyde initially present, from which it is apparently formed by isomerization. We believe that the initially formed aldehyde

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is 3-butenal. Some additional evidence for this was obtained by separating from a polypropylene glycol column a compound with an infrared spectrum similar to that of the initially formed aldehyde. This compound elutes much faster than crotonaldehyde but has a mass spectrum essentially the same as crotonaldehyde.

The isomerization of the initially produced aldehyde to crotonaldehyde apparently takes place quite readily on passage through GLC. Also there appeared to be as a rule slight and sometimes quite appreciable isomerization even in the course of the regular handling of the products in the vacuum apparatus before passage through GLC. While the information on 3-butenal available in the literature is somewhat limited, it would seem that an isomerization to the more stable 2-butenal under present conditions could readily take place.

A 1,4-addition of oxygen atoms to butadiene would produce 2,5-dihydrofuran. However, this compound is not observed so that 1,4-addition does not occur. The assumed primary intermediate in these reactions is a triplet biradical (1). There is evidence that this is extremely short-lived, since the distribution of the products differs somewhat between the two 2-butene isomers (1). Also, in view of the pronounced electronegativity of oxygen, the initial "biradical" is likely to have some zwitterion character. The formation of the 1,2- rather than 1,4-adduct with oxygen atoms in the case of 1,3-butadiene may then be understandable both on kinetic and energetic grounds.

The observed pressure effect in the reaction of oxygen atoms with 1,3-butadiene is very interesting and, together with the corresponding reaction of propylene (1), it illustrates well one of the fundamental features of these addition processes. As a result of high heats of reaction the products formed are "hot" to the extent of about 115 kcal/mole in the case of carbonyl compounds and probably about 80 to 90 kcal/mole in the case of the epoxides. Depending largely on the number of degrees of freedom available, various average time intervals will be required before sufficient excess energy is concentrated in a critical bond to break it. In the meantime the molecule will tend to become stabilized through collisional deactivation. In the case of ethylene, decomposition largely predominates at the usual pressures (6), while the products from the butenes are stabilized already at about 10 to 30 mm (7). Propylene exhibits an intermediate behavior and the same is now found to be true for 1,3-butadiene as well.

For a kinetic treatment of the observed pressure effect the following reaction scheme, based on the general mechanism of reaction of oxygen atoms with olefins, is considered.

$$N_2O + Hg(^3P_1) \rightarrow N_2 + O + Hg(^1S_0) \qquad (i)$$

$$CH_2{=}CH{-}CH{=}CH_2 + O \rightarrow (CH_2{=}CH{-}\dot{C}H{-}CH_2O\cdot) \rightarrow \alpha BO^* + \beta BA^* + X \qquad [1]$$

$$BO^* \rightarrow \gamma CO + \text{other decomposition products} \qquad [2]$$

$$BO^* + M \rightarrow BO + M \qquad [2a]$$

$$BA^* \rightarrow \delta CO + \text{other decomposition products} \qquad [3]$$

$$BA^* + M \rightarrow BA + M \qquad [3a]$$

where BO stands for butadiene monoxide, BA for butenal, X for any unknown products of reaction [1], and the asterisk indicates "hot" molecules. Steady-state treatment leads to the following expressions:

[1] $$\frac{R_{N_2}}{R_{BO}} = \frac{1}{\alpha}\left(1 + \frac{k_2}{k_{2a}(M)}\right),$$

[2] $$\frac{R_{N_2}}{R_{BA}} = \frac{1}{\beta}\left(1 + \frac{k_3}{k_{3a}(M)}\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and

$$[3] \qquad \frac{R_{CO}}{R_{N_2}} = \frac{\gamma\alpha}{1+k_{2a}(M)/k_2} + \frac{\delta\beta}{1+k_{3a}(M)/k_3}.$$

Plots of R_{N_2}/R_{BO} and R_{N_2}/R_{BA} against 1/(M) are given in Fig. 3. From these the

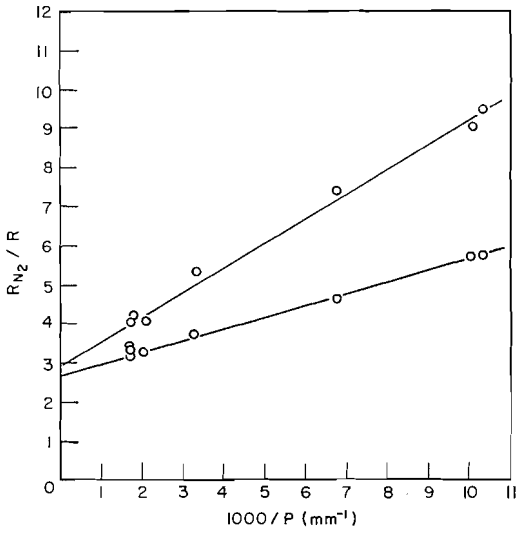

FIG. 3. Plots of R_{N_2}/R_{BO} and R_{N_2}/R_{BA} against reciprocal total pressure (equations [1] and [2]).

following values are obtained: $k_2/k_{2a} = 3.7\times10^{18}$ cc/molecule, $k_3/k_{3a} = 7.2\times10^{18}$ cc/molecule, $\alpha = 0.38$, $\beta = 0.34$.

In Fig. 4 R_{N_2}/R_{CO} is seen to be a linear function of (M) and this simple relation requires

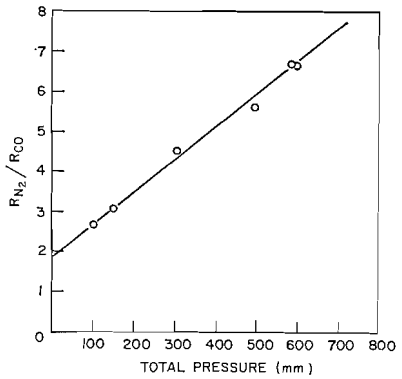

FIG. 4. Plot of R_{N_2}/R_{CO} against total pressure (equation [3a]).

simplification of equation [3]. The slope-to-intercept ratio of the plot in Fig. 4 indicates a k/k_a value of 7.3×10^{18} cc/molecule which is essentially the same as that obtained for k_3/k_{3a} from the plot in Fig. 3. In view of this it would appear that CO is produced by decomposition of "hot" butenal and not to any important extent from decomposition of "hot" butadiene monoxide, i.e., that in equation [3] $\gamma = 0$ and therefore

$$[3a] \qquad R_{CO}/R_{N_2} = \delta\beta/(1+k_{3a}(M)/k_3).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The plot in Fig. 4 is in agreement with equation [3*a*]. The intercept gives 0.54 for the value of $\delta\beta$, i.e. the value of R_{CO}/R_{N_2} as $P \rightarrow 0$. If CO is formed only from "hot" butenal such a high value of $\delta\beta$ is inconsistent with the value $\beta = 0.34$ from the plot in Fig. 3 since δ cannot be larger than unity. Additional CO is not produced in a pressure-independent fragmentation, as is evident from the alternative plot of equation [3*a*] in Fig. 5. The

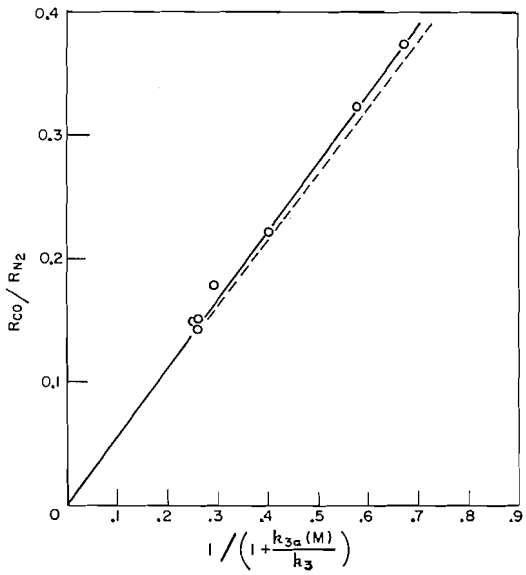

FIG. 5. Plot of R_{CO}/R_{N_2} against $1/(1+k_{3a}(M)/k_3)$ (rearranged equation [3*a*]).

values for k_3/k_{3a} have been taken as 7.2×10^{18} (broken line) as found above and 6.6×10^{18} cc/molecule (full line), the latter to show the relatively small effect of an appreciable variation in the value selected for k_3/k_{3a}. As $P \rightarrow \infty$ R_{CO}/R_{N_2} approaches zero or a value very close to it. The difficulty could be formally resolved by assuming that a constant fraction (37%) of the collisionally deactivated BA* molecules are not recovered as butenal but polymerize instead, either during the reaction or in subsequent handling of the products. This would also bring up the material balance of the oxygen atoms used in the reaction as $P \rightarrow \infty$ from about 70 to 75% to about 90 to 95%, which is satisfactory in view of the long extrapolations made to obtain the intercepts. In this connection it is of interest that Farberov and Ustavshchikov (8) have recently observed that 3-butenal resinifies rapidly on standing. However, it was not feasible in the present work to obtain quantitative estimates of the polymer formed and the suggested explanation must be regarded as only speculative.

Besides carbon monoxide only small amounts of other fragmentation products are observed. This is probably due to the scavenging action of butadiene for H atoms and free radicals with eventual formation of higher molecular weight compounds not directly observable by the analytical techniques used.

If it is assumed approximately that $k_{2a} = k_{3a} = 10^{-10}$ cc molecule^{-1} sec^{-1}, i.e. that deactivation occurs at approximately every collision, then the lifetimes of the "hot" butadiene monoxide and 3-butenal are calculated to be, respectively, $1/k_2 = 2.7\times10^{-9}$ and $1/k_3 = 1.4\times10^{-9}$ sec. From the plots in earlier work (1) the lifetime for the "hot" propanal is similarly found to be 8.0×10^{-9} and that of the "hot" propylene oxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

5.8×10^{-9} sec, although in this latter case on the basis of a very limited number of experiments the pressure dependence appeared to be more complex. For the hot addition products of the reaction of oxygen atoms with butene-1 and isobutene lifetimes an order of magnitude greater were indicated by the complete suppression of pressure-dependent fragmentation at pressures as low as 10 to 30 mm (7). The exceptionally short lifetimes of butadiene monoxide and in particular of 3-butenal considering the number of degrees of freedom available in these compounds are understandable since breakage of bonds may lead to the resonance stabilized allylic and substituted allylic radicals.

The rate constant of the reaction of oxygen atoms with butadiene is very close to that of isobutene and other two-substituted ethylene derivatives as may be expected in view of the electrophilic character of oxygen atoms in their reactions with olefins (2, 9). The temperature coefficient of the rate constant will be discussed elsewhere together with the data obtained for a number of monoolefins (10).

It is evident from the present work that at pressures as low as a fraction of a millimeter to several millimeters essentially complete decomposition of the "hot" addition products should occur and the primary step of the process, addition of oxygen atoms to the double bond, would no longer be directly observable. Under such conditions only fragmentation products would be produced and in particular their derivatives from secondary reactions with molecular oxygen, even when the latter is present only in small amounts, or with other active species which may be present. On this basis the entirely different results from the present ones obtained by Avramenko and Kolesnikova (4) are understandable, as well as the conclusions of these authors that oxygen atoms exhibit a versatility of behavior in their reactions with some organic compounds, and with olefins as well. These conclusions have not been born out by investigations in this laboratory, which show instead an electrophilic addition of the ground-state oxygen atoms to the double bond as the only primary reaction with olefins at room temperature.

DECOMPOSITION PRESSURES OF FERRIC SULPHATE AND ALUMINUM SULPHATE[1]

N. A. WARNER[2] AND T. R. INGRAHAM[3]

ABSTRACT

The gas pressures over samples of anhydrous ferric sulphate and anhydrous aluminum sulphate have been measured in a static system, using a mercury manometer in which the exposed surface was covered with a flexible Pyrex bellows. The calculated ΔH for the decomposition of $Fe_2(SO_4)_3$ was +135.4 kcal/mole. It was not possible to calculate the ΔH for the $Al_2(SO_4)_3$ decomposition, because a discrete aluminum oxide with singular thermodynamic properties was not obtained.

In the $Fe_2(SO_4)_3$ system, the fraction of SO_3 in the gas phase was found to be almost constant over the range of temperature and pressure changes used in the study.

At any given temperature, the decomposition pressure over a ferric sulphate sample is greater than that over an aluminum sulphate sample, thus indicating that preferential decomposition of ferric sulphate should be thermodynamically feasible in mixtures of ferric sulphate and aluminum sulphate.

INTRODUCTION

When metallic sulphates are heated *in vacuo* or in a neutral atmosphere, they can be decomposed to oxides, e.g.,

$$MSO_4 \rightleftharpoons MO + SO_3,$$

$$M_2(SO_4)_3 \rightleftharpoons M_2O_3 + 3SO_3.$$

The ease with which this decomposition can be brought about varies widely with the different metallic sulphates. This variation has been utilized commercially in the separation of some sulphates. For example, copper sulphate is more stable than ferric sulphate. Hence, when some ores which contain copper and iron compounds are roasted in controlled sulphating atmospheres, it is possible to prepare copper sulphate almost selectively, while the iron is retained as oxide. Simple leaching techniques effectively separate the soluble copper sulphate from the insoluble iron oxide. The same basic principle of selective sulphate formation or decomposition has been applied industrially for the separation of cadmium and zinc compounds when they occur together in smelting dusts (1).

One of the recently patented methods for separating the constituents of clays and shales (2) would seem to depend on the fact that aluminum sulphate is more stable than ferric sulphate. Since the problem of utilizing the constituents of shale is an important one, the literature was searched to determine whether this assumption were true. Very little information is available on the stability of either compound, and the published data (3) fail to satisfy the critical tests of Kelley (4). Hence, it seemed worth while to measure the decomposition pressures of both of these compounds to determine whether the separation would be thermodynamically possible.

APPARATUS AND PROCEDURE

Because of its simplicity, a static method was chosen for measuring the equilibrium dissociation pressures of the sulphates. The apparatus assembled for the measurements

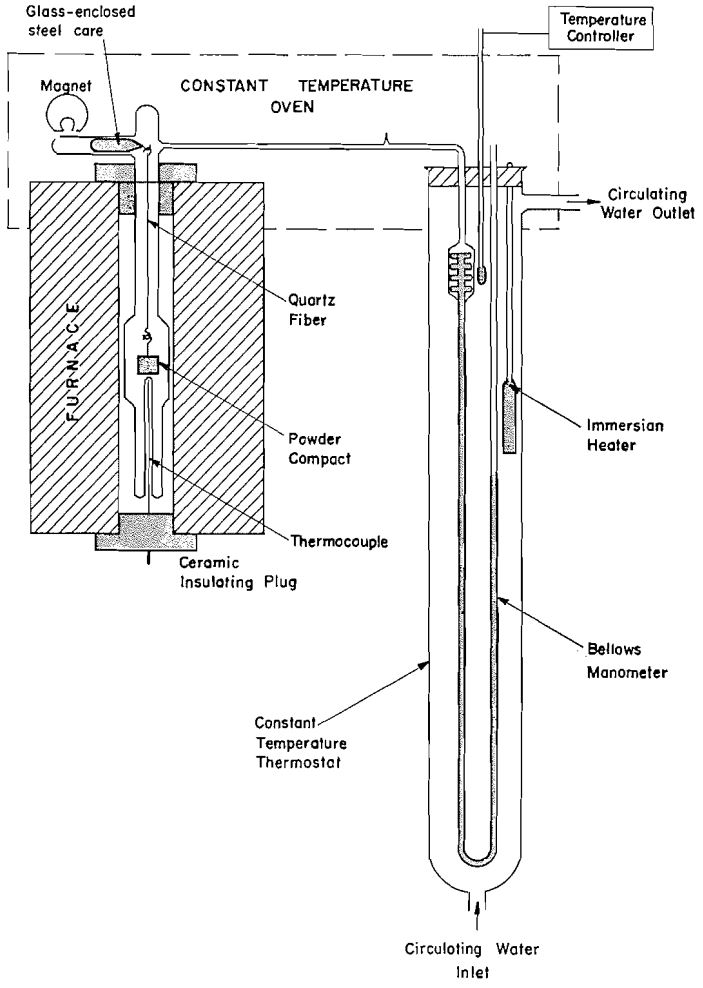

FIG. 1. Apparatus for measuring decomposition pressures of anhydrous sulphates.

is shown diagrammatically in Fig. 1. The most important feature of the apparatus is the glass-bellows mercury manometer. The design of the manometer is based on one originated by Spence (5). However, in the present version the mercury displacement has been modified from horizontal to vertical, and an appreciable increase in sensitivity has resulted (6).

The apparatus was constructed entirely from Pyrex and Vycor glass. The Vycor section extended out to the cool zone of the furnace, where it was joined through graded seals to the Pyrex part of the apparatus.

To avoid complications that might be introduced by the condensation of sulphur trioxide, the bellows manometer and the connecting tubing were thermostatically controlled at a temperature of 60° C.

For convenience in handling, powder compacts of anhydrous ferric sulphate and aluminum sulphate were pressed with a small platinum wire anchored in the pellet. The pellets were suspended by this platinum wire and a small quartz fiber which was attached

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to a magnetically moveable hook. The hook was made moveable to permit free access for installing and removing the pellet through the top of the furnace tube.

After installation of each pellet, the reaction tube was sealed and the apparatus was evacuated. During the period of evacuation the pellet was heated to a temperature of about 650° C to remove the last traces of moisture. After several hours at this temperature, the vacuum line was sealed and the temperature raised to the point at which displacement of the mercury column indicated that decomposition of the sulphate had begun. Readings of the pressure were made at 24-hour intervals in the study of the ferric sulphate system, and at 48-hour intervals in the study of the aluminum sulphate system. The experiment was continued until a steady state had been reached.

Displacement of the mercury column in the manometer was observed with a cathetometer, and was corrected for changes in barometric pressure. With small changes in pressure, some sticking of the mercury in the column was noted. Sticking was relieved by rapping the manometer sharply just before readings were made.

RESULTS AND DISCUSSION

The results obtained in experiments with ferric sulphate, with aluminum sulphate, and with 1:1 mole mixtures of aluminum sulphate with iron oxide are shown in Table I.

TABLE I

Decomposition pressures over ferric sulphate, aluminum sulphate, and an aluminum sulphate – iron oxide mixture

Ferric sulphate		Aluminum sulphate		Aluminum sulphate – ferric oxide (mole ratio 1:1)

Ferric Sulphate

When the results shown in Table I were plotted on a log p versus reciprocal of absolute temperature graph, Fig. 2 was obtained. It will be noted from Fig. 2 that the linearity

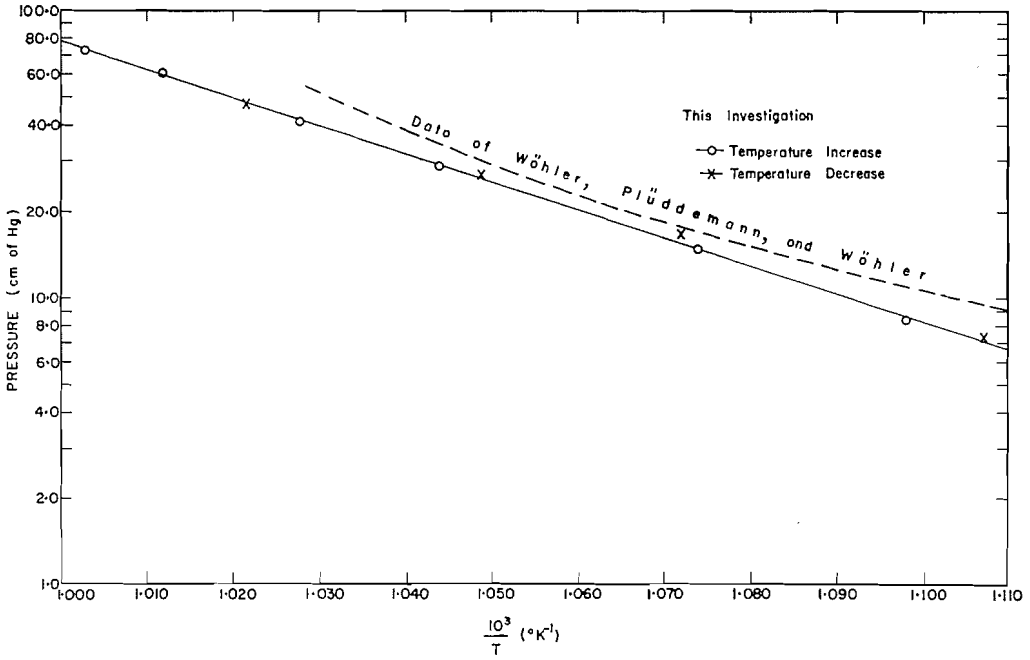

FIG. 2. Pressure vs. reciprocal temperature relationship for anhydrous ferric sulphate.

of the results is good, thus indicating that over the temperature range of the experiments there is not an appreciable change in the heat of the decomposition reaction. The linearity of the results and the demonstrated reversibility of the system indicate that true equilibrium had been reached in the experiments and that the gas phase probably contained only SO_2, SO_3, and O_2. It seems unlikely that polymers of SO_3 were present. The iron oxide product was identified as hematite.

When the static method of measuring the decomposition pressures was selected, the selection was made with some misgiving. From preliminary experiments it had been established that the dynamic method might be subject to substantial errors, because the rate of attainment of equilibrium decreases as equilibrium is approached, and it would be easy to assume that equilibrium had been reached, when in fact the reaction was still proceeding slowly.

Alternatively, the measurement of pressures in a static system containing a substantial temperature gradient and gases of different molecular weights is also subject to error. In this instance, due to thermal diffusion, the lighter molecules tend to congregate in the hotter zone. This means that the 2:1 molar ratio of SO_2:O_2, produced by the decomposition of SO_3, is reduced to somewhat less than 2:1 in the hot zone, and increased to somewhat more than 2:1 in the cold zone. This departure from exact stoichiometry can lead to errors in any quantities, e.g. degree of dissociation, etc., calculated on the basis of the 2:1 stoichiometry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The magnitude of the error caused by thermal diffusion is difficult to assess on a purely theoretical basis (7), but the linearity of the results shown in Fig. 2 would favor the conclusion that the error is small or at least comparable with the other errors of measurement. Recently a novel method of studying sulphate equilibria, through the measurement of only one gas pressure, was developed by Kellogg (8). It is expected that when similar systems have been examined by both methods, it may be possible to assess the magnitude of the thermal diffusion error.

Having measured the decomposition pressure exerted by the mixed gases SO_3, SO_2, and O_2, over a ferric sulphate sample, it was of interest to calculate the heat of the decomposition reaction

$$Fe_2(SO_4)_3 \rightleftharpoons Fe_2O_3 + 3SO_3 \qquad [1]$$

from the variation of the equilibrium constant of the reaction with temperature. For this calculation it was necessary to know p_{SO_3}, since $K'_p = p^3_{SO_3}$ for reaction 1. The magnitude of p_{SO_3} was calculated on the assumption that p_{SO_3} satisfied both equation 1 and the equation for the decomposition of SO_3,

$$2SO_3 \rightleftharpoons 2SO_2 + O_2. \qquad [2]$$

The calculation was made by obtaining the equilibrium constant K_p, for reaction 2, from the data of Evans and Wagman (9) and converting this K_p to K_x (the equilibrium constant in terms of mole fractions) by dividing by the total pressure at each of a series of temperatures. For convenience and to minimize errors, interpolated temperatures from Fig. 2 were used.

When K_x had been calculated, it was equated to the equilibrium constant which was set up in mole fraction form on the basis that α is the fraction of 1 mole of SO_3 dissociated at a given temperature. Thus, $\{2(1-\alpha)\}/\{(2+\alpha)\}$ represents the mole fractions of SO_3, and $K_x = 4\alpha^3/(4\alpha^3-12\alpha+8)$. It should be noted that in this calculation an exact SO_2:O_2 ratio of 2:1 is implicitly assumed.

When K_x was calculated, it was found to be almost constant, with an average deviation of 1% over the temperature range 920 to 1000° K. The average K_x was used in calculations, and $\alpha = 0.538$ and a mole fraction of $SO_3 = 0.364$ were obtained.

The implications of the constancy of the mole fraction of SO_3 are of interest. Once the value 0.364 is known, the pressure of SO_3 in a system can be set very conveniently by including an excess of ferric sulphate in the system and then heating the system until the total pressure, reduced by the factor 0.364, produces the required partial pressure of SO_3.

When $\log K'_p = p^3_{SO_3}$ was plotted against reciprocal absolute temperature, a linear relationship was obtained. The relationship can be described by the equation:

$$\log K'_p = 28.34-(29{,}600/T).$$

When this equation was used to calculate the heat of reaction for the dissociation of ferric sulphate, a ΔH of +135.4 kcal was obtained.

Aluminum Sulphate

The results obtained from a study of the decomposition of aluminum sulphate and 1:1 mole mixtures of aluminum sulphate with ferric oxide are shown in Table I and as a log P versus reciprocal temperature relationship in Fig. 3. The curvature of the relationship indicates that the type of treatment accorded the ferric sulphate results to obtain a heat of decomposition would not be valid for the aluminum sulphate systems. It would

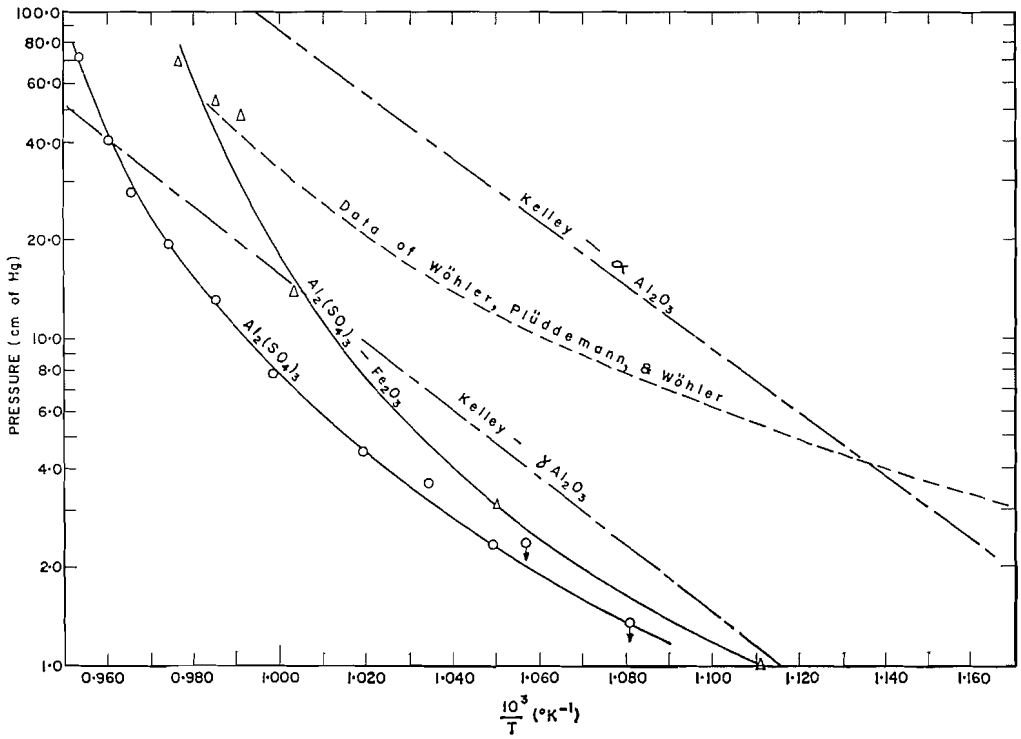

FIG. 3. Pressure vs. reciprocal temperature relationship for anhydrous aluminum sulphate and aluminum sulphate – iron oxide mixtures.

therefore seem sufficient to seek an explanation for the lack of linearity of the results, and to compare the pressures with the corresponding pressures for ferric sulphate, under similar conditions of temperature.

When the partly decomposed and completely decomposed pellets of aluminum sulphate were examined by X-ray diffraction, it was observed that gamma alumina was present. In one pellet which had been heated for a long time at a high temperature, alpha alumina was found. This is in general agreement with the observations of Kelley (10): "In actual decomposition of $Al_2(SO_4)_3$, there is not obtained Al_2O_3 (alpha) but a less stable variety usually designated Al_2O_3 (gamma). Unfortunately the latter appears not to have unique thermodynamic properties; available information indicates that there may be two varieties of Al_2O_3 (gamma) or at any rate that its properties depend upon the temperature to which it is heated and the time of heating." From the foregoing, it would seem possible that the results shown in Fig. 3 represent steady-state pressures over a metastable system of aluminum sulphate and some modification of gamma alumina. The curvature of the line in Fig. 3 could be interpreted as representing the presence of an increasingly stable modification of alumina, as the temperature of the experiments was increased. From a few experiments, there was an indication that the pressure measurements, although steady, were not readily reversible if the temperature of the specimen had previously been raised to appreciably above the temperature of the measurement. This would tend to confirm the presence of the more stable form of alumina at higher temperatures. Time did not permit a more extensive investigation of this point.

It is of interest to note, in Fig. 3, that the stable pressures over the aluminum sulphate –

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ferric oxide system are, at all temperatures, greater than those over pure aluminum sulphate. This has been resolved by considering that ferric oxide acts as a catalyst in promoting the formation of the more stable forms of alumina. Higher equilibrium pressures are to be expected over the more stable forms of alumina.

Finally, it is of interest to compare, in Table I, the steady-state pressures over the ferric sulphate and aluminum sulphate systems at various temperatures. The comparison shows clearly that at all temperatures the pressure at any given temperature is always greater over the ferric sulphate system than over an aluminum sulphate system.

TABLE II

980	0.1914	0.6650	0.288			1.418×10^{-2}
1000	0.3050	1.047	0.291			5.535×10^{-2}
			Average 0.287 ± 0.003			

CONCLUSIONS

From an examination of the steady-state gas pressures over ferric sulphate and aluminum sulphate samples heated in a closed system, it has been concluded that the pressure at any given temperature is always substantially greater over a ferric sulphate sample. Hence, it would seem thermodynamically feasible to separate aluminum sulphate from ferric sulphate by roasting the compounds under conditions selected to decompose the ferric sulphate only, and then leaching the water-soluble aluminum sulphate from the roasted mixture. The practical limitations affecting the application of this approach will be discussed in a later communication.

ACKNOWLEDGMENT

The authors wish to express their thanks to Mr. George Ensell, glassblower at the National Research Council of Canada, for the construction of the bellows manometer used in this project.

STUDIES ON IONIC SOLVATION

PART III. NEW THEORY FOR CALCULATING HEATS OF HYDRATION OF MONOVALENT IONS AT 25° C[1]

A. M. AZZAM

ABSTRACT

From Part I of this series, the structure of solution around a completely hydrated monovalent ion could be visualized. On the basis of this picture, the ionic heats of hydration is to be due to three terms. These three terms are critically discussed and evaluated for the case of alkali metals and halide ions.

The present theory shows that the Born–Bjerrum term contributes a significant part to the heat and that the ionic radius value included in this term must be dependent only on the charge and not on the ionic size. The most probable value is 2.4 Å for the positive ions and 2.9 Å for the negative ions.

The calculated ionic heats of hydration, which are in good agreement with the experimental values, are compared with those of previous theories.

1. INTRODUCTION

The heat of solvation of an ion, which does not combine chemically with the solvent, depends upon the difference in its potential energy in vacuum and in solution. Knowledge of values of ionic heats of solvation is of great importance in the calculation of several physical properties of ionic solutions (9, 12, 15, 37, 41, 42, 44).

Using experimental data on the heats of solution (13, 14, 31), together with the crystal lattice energy values (8, 9, 10, 11, 16), and following Born–Haber cycle, the heats of hydration of alkali halides (see Table I) had been calculated (5, 12). There is no simple

way of dividing these sums into the hydration energies of the separate ions. However, several attempts (3, 5, 6) have been made to deduce from these experimental values the corresponding ionic heats of solvation. None of these methods is completely satisfactory (12, 19, 20, 21).

Moreover, several workers (1, 2, 3, 4, 5, 6, 29, 33) have theoretically calculated the ionic heats of solvation with widely divergent results (see Table II). However, certain features of this work are not entirely satisfactory (7, 18, 19, 24, 46).

Recently, the present author (7, 36) suggested a new method for the calculation of ionic solvation number by applying statistical-mechanical analysis to a postulated structure of the solution around an ion. The good agreement between the calculated values and those obtained by several experimental methods is a strong evidence for the validity of the suggested physical approach of the molecular structure of the solvent (7, 36).

The present theory is an attempt to calculate the heats of hydration of alkali metals and halide ions at 25° C.

2. ORIENTATION OF A SOLVENT MOLECULE NEXT TO AN ION

It seems to be generally agreed (3, 4, 7, 46, 47, 49) that the orientation for a water molecule next to a positive ion is as shown in case I, Fig. 1. On the other hand, it has been assumed by previous theories (3, 4, 6, 47, 49) that the orientation for a water molecule next to a negative ion is as shown in case IV, Fig. 1. This configuration was criticized and critically discussed by the present author (7, 18). Accordingly, it was suggested that the most probable structure of the solvated negative ion is as shown in case III, Fig. 1.

A similar conclusion was reached recently by Buckingham (46). In conclusion, cases I and III are energetically more favorable. Less familiar orientations (6, 26, 34) have been already criticized (19, 24).

3. STRUCTURE OF SOLUTION AROUND AN ION

The most outstanding problem, which is connected with the calculation of ionic heats of hydration, lies in the need of definite quantitative knowledge of the structure of solution around an ion. A simple model for the structure of solution around an ion could

r_p = radius of the primary solvated ion,
r_s = radius of the completely solvated ion.

be visualized from the present author's statistical–mechanical analysis (7) for the distribution of solvent dipoles around an ion.

The model suggested by these results is shown diagrammatically in Fig. 2. The firmly bound water molecules will be those constituting the primary solvation sheath (the innermost region). Beyond this sheath, there is the secondary solvation sheath with less firmly bound water molecules and finally there is the main bulk of the solvent (for definition see 7, 36).

Frank and Evans, from a re-analysis of the entropy of hydration (43), have developed a fundamentally similar picture. These authors claim that the ion is surrounded by three

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

concentric regions which are: the immobilization of water molecules, the structure-breaking and the structurally "normal" water regions. These three zones seem very probable to correspond with the three layers of the preceding model (see Fig. 2).

4. NEW THEORY FOR CALCULATING HEATS OF HYDRATION

From the proposed structure of ionic solution, the ionic heat of hydration is represented essentially by the sum of three terms corresponding to the three zones around an ion (see Fig. 2). It follows that

$$[1] \qquad \Delta H = (\Delta H)_{I} + (\Delta H)_{II} + (\Delta H)_{III}$$

where $(\Delta H)_{I}$ represents the contribution of water dipoles in the primary solvation sheath to (ΔH),

$(\Delta H)_{II}$ represents the contribution of water dipoles in the secondary solvation sheath to (ΔH),

$(\Delta H)_{III}$ represents the contribution of water dipoles beyond the solvation sheaths to (ΔH). In other words, it is the contribution of transferring an ion from the gas phase into solution.

The magnitudes of various contributions to ΔH for alkali metals and halide ions are discussed in Section 5 of this paper.

Concerning the structure of the primary solvation shell, a very clear physical picture, which is suitable for our purpose, is known from the present author's previous results (7). This is discussed in Section 3 of this paper. Accordingly the most probable value of $(\Delta H)_{I}$ could be evaluated.

The secondary solvation layer (see Fig. 2) is the intermediate zone between the frozen water (7, 18, 19, 41, 43) region and the normal structure region. Calculation of the term $(\Delta H)_{II}$ requires definite and quantitative knowledge of the structure-breaking effect (43, 48). Such a knowledge is not available. Any attempt to estimate the numerical magnitude of this structure-breaking effect must be based on rather arbitrary assumptions for which in the first instance no strict justification can be given.

As long as we consider the alkali metals and halide ions, it is not known whether or not, and to what extent, this structure-breaking effect is important in the calculation of heats of hydration. It seems very probable that such an order–disorder phenomenon is of significant importance for the calculations of entropies but not for the calculation of heats (49).

In the present theory, we will follow the most physical approach which was adopted by Buckingham (46) and treat the solvent beyond the primary solvation shell as a continuous dielectric, that is, a dielectric constant which can vary with the electric field strength.

We do not know how much error is involved in this approximation, but the effect is in any case of insignificant magnitude and could be checked in the following way.

CsI is usually regarded as having the relatively most marked structure-breaking effect (43, 45). In this case, $(\Delta H)_{II}$ contributes 8.7% to the total (ΔH). Assuming, as the result of neglecting the structure-breaking effect, a maximum of 25% error in the value of $(\Delta H)_{II}$, this will give rise to a maximum error of about 2.2% in the value of $(\Delta H)_{total}$.

A serious difficulty in the previous theories (3, 4, 5, 6, 8) is the choice of dielectric model. This problem was treated to a first approximation on the basis that very near to the ion the dielectric constant is taken as 1 and for layers of water molecules outside the first

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

layer it is taken as 80. In the present theory a less approximate treatment of the dielectric constant difficulty has been attempted by the application of Webb's analysis (2). It must be pointed out here that the structure-breaking effect, which is neglected in the present theory, is either partially or completely covered on using Webb's values for the dielectric constant as a function of distance.

5. VARIOUS CONTRIBUTIONS TO (ΔH)

(a) Evaluation of the Term $(\Delta H)_{\mathrm{I}}$

Consider an element volume (dv) at a distance (r) from an ion in the primary solvation sheath. If $(ds)_r$ is the number of dipoles associated with the ion in this element volume and $(u)_r$ is the ion–dipole interaction, it follows that

$$d(\Delta H) = (ds)_r\, u_r. \qquad [2]$$

The present author's statistical–mechanical analysis (7) showed that the number of dipoles associated with the ion in a concentric shell at a uniform distance (r) from the ion and of thickness (dr) is given by

$$(ds)_r = 4\pi n_0\, e^{-\{(w_r - w_0)/kT\}} r^2\, dr \qquad [3]$$

where

n_0 is the number of water molecules per cubic centimeter in the bulk of solution,
w_0 is the potential of a water molecule in the bulk of solution,
w_r is the net potential energy of a solvent dipole at a distance (r) from the ion.

Taking into account the specific factors on which the solvation number depends (7, 18), together with the suggested structure of a solvated ion, the net interaction energy term (w_r) could be evaluated from the following equation.

$$w_r = (u_1 - u_2 - u_3)_r \qquad [4]$$

where

u_1 is the ion–dipole interaction energy,
u_2 is the electrostatic potential due to the presence of the two water molecules attached to the dipole which is associated with the ion (3, 4, 7, 36), and
u_3 is to allow for the mutual effect of the co-ordinated water molecules.

Substituting from [3] into [2]

$$d(\Delta H_{\mathrm{I}})_r = 4\pi n_0\, u_r\, e^{-\{(w_r - w_0)/kT\}} r^2\, dr. \qquad [5]$$

The contribution of water molecules in the primary solvation sheath could be evaluated by integrating equation [5] over the volume of the solvent that surrounds the ion from a_1 to r_{p} (limits of primary solvation (see Fig. 1)).

$$(\Delta H)_{\mathrm{I}} = 4\pi n_0 \int_{a_1}^{r_{\mathrm{p}}} u_r\, e^{-\{(w_r - w_0)/kT\}} r^2\, dr. \qquad [6]$$

(b) Evaluation of the Term $(\Delta H)_{\mathrm{II}}$

This term could be evaluated in a similar manner as in the case of $(\Delta H)_{\mathrm{I}}$. The main differences between the two cases lie in the values of the limits of integration and also in the expression of the term (w_r). A solvent molecule in the secondary solvation sheath is no longer associated with the ion (4, 7, 12, 19) but it is only under the influence of its field.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[7] $$d(\Delta H)_{II} = 4\pi n_0 u_r e^{-\{(u_r - w_0)/kT\}} r^2 dr.$$

The integration will be carried out over the volume of the solvent that surrounds the ion from the distance at which the primary solvation ceases (r_p) to the distance at which secondary solvation terminates (r_s).

From the above discussion, it follows that

[8] $$(\Delta H)_{II} = 4\pi n_0 \int_{r_p}^{r_s} u_r e^{-\{(u_r - w_0)/kT\}} r^2 dr.$$

(c) Evaluation of the Term $(\Delta H)_{III}$

Whenever an ion passes from the gas phase into solution, the free energy of this process is best given by Born expression (1),

[9] $$\Delta G = -\frac{N(Ze)^2}{2x}\left(1-\frac{1}{D}\right),$$

where N is the Avogadro's number,
Ze is the charge of the ion,
x is the radius of the ion,
D is the dielectric constant of the medium.

The corresponding heat of hydration (Q) is obtained from the Gibbs–Helmholtz equation as

[10] $$Q = -\frac{N(Ze)^2}{2x}\left\{1-\frac{1}{D}-\frac{T}{D^2}\left(\frac{\partial D}{\partial T}\right)_p\right\}$$

(Born–Bjerrum equation) (32).

The term $(\Delta H)_{III}$ of the present theory (see equation [1]) can be evaluated from equation [10] provided that the selected value of "x" will be taken as r_s (the termination of solvation). It follows that

[11] $$(\Delta H)_{III} = -\frac{N(Ze)^2}{2r_s}\left\{1-\frac{1}{D}-\frac{T}{D^2}\left(\frac{\partial D}{\partial T}\right)_p\right\}.$$

(d) Evaluation of the Ionic Heats of Hydration

On substituting from equations [6], [8], and [11] into (1), the total ionic heat of hydration is given by

[12] $$(\Delta H)_{total} = 4\pi n_0 \int_{a_1}^{r_p} u_r e^{-\{(w_r - w_0)kT\}} r^2 dr + 4n_0 \int_{r_p}^{r_s} u_r e^{-\{(u_r - w_0)kT\}} r^2 dr + \frac{N(Ze)^2}{2r_s}\left\{1-\frac{1}{D}-\frac{T}{D^2}\left(\frac{\partial D}{\partial T}\right)_p\right\}.$$

6. METHOD OF CALCULATION

Methods of evaluations of u_1, u_2, u_3, r_p, r_s, n_0, w_0, and w_r have already been critically discussed in a previous paper (7) by the present author. It must be pointed out that in these calculations, microscopic values of the dielectric constant (2, 7) of water at different distances from the ion are used.

The integration terms of equation [12] cannot be evaluated directly. However, these integrations were solved graphically.

7. DISCUSSION

The various theoretical calculations of ionic heats of solvation (3, 4, 5, 6, 29) do not give values which are in good agreement (see Table IV). However, some measure of agreement is obtained among the results if they are classified in such a way as to compare theories which are self-consistent. Accordingly, previous theories could be divided into two main groups:

group I: (1) Bernal and Fowler theory, (2) Eley and Evan theory;
group II: (1) Latimer *et al.* theory, (2) Verwey theory, (3) Miscenko theory.

A comparison between the results of the present theory and those of previous theories is of interest. The most important fact which arises from this analysis is that theories of group I give higher values for the positive ions, lower values for the negative ion while theories of group II show the reverse. It follows that the agreement of the present calculation with the average values of all previous theories is good (see Table II).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The numerically calculated values of ionic heats of hydration from the theories of group II (mainly that of Latimer *et al.*) disagree with those of the present theory. Their values for the positive ions are smaller by about 10–18 kg cal/g ion. On the other hand, their values for the negative ions are higher by about 10–18 kg cal/g ion. This is mainly due to an incorrect assumption in the method of calculation (19, 21). However, these authors claim that the validity of their theories rest upon the comparison of their values with experimental values which have been obtained by a procedure in which the validity of the theory under test is assumed (12, 18, 19, 20, 21, 23, 24). Moreover, their results disagree markedly with those of theories of group I which are apparently theoretically valid.

It is of interest to compare values obtained from the present theory with those from theories of group I. Table IV shows that all the group I values of the negative ions are lower by about 10–18 kg cal/g ion^{-1}. The fundamental reason for this difference is that the orientation of a water molecule near an anion, which is postulated in the present work, differs from that of authors of theories of group I (see Fig. 1) (7, 46). However, if the present author's model, which was successfully used in the calculation of ionic solvation number (7), is used in these authors procedures, values of the correct order could be obtained.

On the other hand, numerical values of Bernal and Fowler for the case of cations are in agreement with those of the present theory. The model of orientation of a water molecule near a cation is the same in both theories of Bernal and Fowler, and theories of the present author. This fact is a further supporting evidence for the explanation of the discrepancy found in the case of anions.

Using the same model as that of Bernal and Fowler, but subjecting the theory to a more vigorous treatment, Eley and Evans' calculated values show a better agreement with those of the present theory (see Table IV).

The small difference in the case of cations between the present theory and those of the theories of group I may be the consequence of the very approximate treatment given by these authors to the variation of dielectric constant with distance in which two zones were considered. The first layer near an ion is assumed to have $D = 1$ whereas the value $D = 80$ is used elsewhere. This picture is oversimplified (2, 7, 12, 18, 19, 27, 28, 35).

In conclusion, there is an essential agreement between the results of the present theory and those of the more reliable theories of group I.

It is to be stressed that some of the previous theories suffer from mixing of heat and free energy terms which may introduce an ambiguity of 3 to 30 kcal (19). However, this was avoided in the present theory (38).

The real test is to compare theoretically calculated and experimental values, but experimental values of ionic heats of hydration cannot be directly measured. The problem of evaluating individual heats of solvation depends on the assumption used in dividing up the experimental values. None of these methods can be considered as completely satisfactory (12, 19, 20, 21, 46). This difficulty hinders the checking of the theoretical values. However, the present theory can be verified by adding up the calculated ionic values to give values for the corresponding salts which can be then compared with the most reliable experimental results. This method of checking can only be applied to the present theory and to Eley and Evans' theory since all the other theories are semi-empirical ones (they depend on experimental values).

The good agreement which is shown in Table VI is a further indication of the validity of the present theory.

TABLE VI

Comparison between the theoretically calculated and experimentally determined values of heats of hydration of alkali halides

Salt	Results of experimental methods (mean of four sets (see Table I))	Theoretically calculated values	
		Azzam	Eley and Evans' theory (3)
LiF	244.4	245.7	224
LiCl	210.4	210.7	192
LiBr	200.5	207	185
LiI	190.8	202.7	178
NaF	215.4	214.6	206
NaCl	182.8	179.6	174
NaBr	175.9	175.9	167
NaI	166.3	171.6	160
KF	198.1	191.3	185
KCl	161.4	156.3	153

CsBr	139.7	143.1	125
CsI	132.0	138.8	118

8. "THE THIRD TERM OF EQUATION 12" BORN'S HEAT TERM

One of the most important conclusions arising from the present work is that the third term of equation [12] makes a significant contribution to the ionic heats of solvation (see Table V). Accordingly, a discussion of this term which has been used in all previous theories (1, 2, 3, 4, 5, 6) is of interest.

The main difficulty, which arises in the application of equations [9] and [10] in the calculation of ionic solvation energies, is the choice of the ionic radius (term x).

A list of the selected values of "x" in the different theories, which calculated the ionic solvation energies of alkali metal and halide ions, is as follows:

Theory	Selected value of x in Å	Remarks
Born (1)	a_i	Crystallographic radius
Latimer *et al.* (5)	$a_i+0.1$ (for anions) $a_i+0.85$ (for cations)	Assuming that $[\Delta G\ \alpha(1/r)]$
Eley and Evans (3)	$a_i+2r_{H_2O}$ ($2r_{H_2O} = 2.76$)	Arbitrary
Verwey (6)	$a_i+2r_{H_2O}$	Arbitrary
Bernal and Fowler (4)	2.9	Empirically
Azzam	2.4 (for cations) 2.8 (for anions)	Statistical–mechanical limit of solvation

With the exception of Bernal and Fowler and the present author's theories, the selected value of (x) is a function of the crystallographic ionic radii. Evidence given by these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

authors in support of their selections are not completely satisfactory and have been criticized (4, 12, 19, 21, 22).

Bernal and Fowler suggested that "x" should represent the radius of the saturation sphere around the ion and pointed out that it must be dependent only on the charge and not on the ionic size. A similar picture has been given by Passynaski (39).

Bernal and Fowler suggested the value of 2.9 Å as the radius of the saturation sphere. There is an essential agreement between Bernal and Fowler's value and those of the present theory. The small differences in these values may arise from the very approximate treatment given by Bernal and Fowler (7, 19). Furthermore, Bernal and Fowler have derived their value 2.9 Å empirically while the values given in the present theory (2.4 and 2.8 Å) were calculated statistically–mechanically. Moreover, Bernal and Fowler did not differentiate between the case of cations and anions as in the present theory. However, due to the difference in the mode of orientation of water dipoles in the case of cations and the case of anions we should expect different values of the radius of the saturation sphere.

9. GENERAL REMARKS

It must be pointed out that all calculations of this kind by the author and by previous workers are beset with inherent difficulties (46, 47). The most important ones are probably the ordered structure of water, the effect of ions on it, and the time factors involved in the movement of water molecules near an ion.

This is mainly due to our incomplete state of knowledge of polar dielectrics. However, with the aid of some reasonable assumptions, it has been found possible to make successful attempts. These limitations must be borne in mind in judging the quantitative conclusions for such calculations.

10. CONCLUSIONS

1. Three layers around an ion contribute to ionic heats of solvation. These layers are:
   - (*a*) primary solvation sheath with contribution = $(\Delta H)_{\mathrm{I}}$,
   - (*b*) secondary solvation sheath with contribution = $(\Delta H)_{\mathrm{II}}$,
   - (*c*) main body of water with contribution = $(\Delta H)_{\mathrm{III}}$.
2. The following critical conditions have been derived:

Conditions	Remarks	$(\Delta H)_{\text{total}}$
Monovalent cations with radius less than 1.7 Å Monovalent anions with radius less than 2.1 Å	Primary and secondary hydrated	$(\Delta H)_{\mathrm{I}}+(\Delta H)_{\mathrm{II}}+(\Delta H)_{\mathrm{III}}$
Monovalent cations with radius less than 2.4 and greater than 1.7 Å Monovalent anions with radius less than 2.8 and greater than 2.1 Å	Secondary hydrated	$(\Delta H)_{\mathrm{II}}+(\Delta H)_{\mathrm{III}}$
Monovalent ions with radius beyond the above-mentioned limits	Unhydrated	$(\Delta H)_{\mathrm{III}}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

3. Both $(\Delta H)_{I}$ and $(\Delta H)_{II}$ can be calculated by statistical-mechanical analysis, while $(\Delta H)_{III}$ is best obtained from the Born-Bjerrum equation.

4. The effective radius term of Born-Bjerrum term is theoretically found to be 2.4 Å for cations and 2.8 Å for anions.

5. Theoretically calculated ionic heats of solvation are in good agreement with experimental values.

6. This theory supports the suggested physical approach concerning the orientation of a water molecule next to an ion and the structure of ionic solutions.

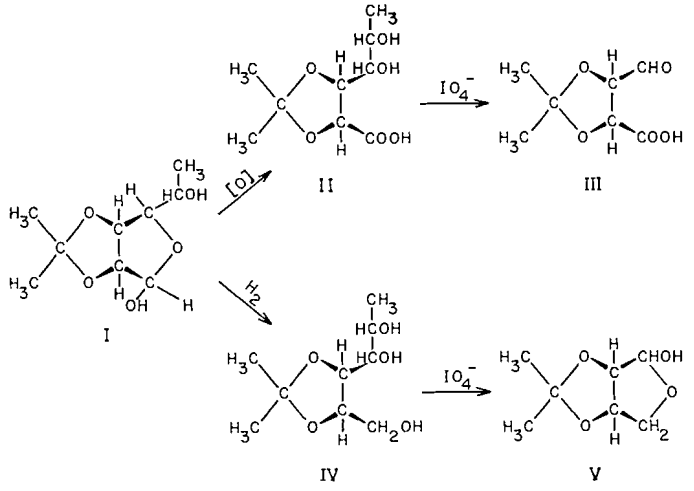
2,3-*O*-ISOPROPYLIDENE-L-ERYTHROTETRURONIC ACID AND -L-ERYTHROSE, AND THE METHYL D-ERYTHRO- AND D-THREO-TETROFURANOSIDES[1]

J. N. BAXTER[2] AND A. S. PERLIN

ABSTRACT

Oxidation of 2,3-*O*-isopropylidene-β-L-rhamnose (I) with hypoiodite, followed by periodate cleavage of the derived aldonic acid, affords 2,3-*O*-isopropylidene-L-*erythro*tetruronic acid. Reduction of I with sodium borohydride and periodate oxidation of the resulting glycitol gives 2,3-*O*-isopropylidene-L-erythrose. Both products have been obtained in high yield, and are readily hydrolyzed to L-*erythro*tetruronic acid and L-erythrose, respectively.

Methyl α- and β-D-*erythro*- and D-*threo*-tetrofuranosides have been prepared by the Fischer glycoside synthesis from D-erythrose- and D-threose-formates, respectively. A notable anomeric difference in the lead tetraacetate oxidation behavior of the methyl D-threosides has been observed, the β-anomer being more reactive than the α-anomer.



In continuing earlier studies in this laboratory on the chemistry of the tetrose sugars (1, 2, 3, 4) several new tetrose derivatives have been prepared and are described in the current paper.

Stepwise degradation of D-glucuronic and D-galacturonic acids to D-*erythro*- and D-*threo*-tetruronic acids, respectively, by lead tetraacetate oxidation has been described previously (3). Since the L-isomers of these hexuronic acids are rare compounds, they do not provide practical sources of the L-tetruronic acids. The L-*threo*-isomer has been prepared by selective reduction of 2,3-di-*O*-acetyl-L-tartaric anhydride (5) and by oxidative degradation of D-glucosaccharo-γ-lactone (6), but the L-*erythro*-acid does not appear to have been reported. In the current paper a method is described for preparing L-*erythro*tetruronic acid from readily available 2,3-*O*-isopropylidene-L-rhamnose (7) (I). The latter derivative also has been utilized to prepare L-erythrose in high yield.

Acetonation of L-rhamnose in the presence of hydrogen chloride (7) appears to yield the 2,3-*O*-isopropylidene derivative almost exclusively. Two crystalline forms of monoacetone L-rhamnose have been described (8, 9) but only the β-anomer (9) has been isolated in the present study. The isopropylidene derivative (I) was oxidized with hypoiodite (10) to the L-rhamnonate (II) and the latter, which was not isolated, was degraded by periodate cleavage. From the reaction mixture crystalline 2,3-*O*-isopropylidene-L-*erythro*tetruronic acid (III) was isolated in about 75% yield. Chromatographically pure L-*erythro*tetruronic acid was readily obtained by autohydrolysis of III in aqueous solution.

Reduction of isopropylidene-β-L-rhamnose (I) to the rhamnitol derivative (IV), followed by periodate oxidation, afforded crystalline 2,3-*O*-isopropylidene-L-erythrose (V) in about 80% yield. The L-glycitol derivative (IV) was obtained as a syrup by catalytic hydrogenation but, with sodium borohydride reduction, attempts to isolate it resulted in partial hydrolysis of the isopropylidene group. For preparation of V, however, it was most convenient to carry out the reduction with borohydride and, after neutralizing the reaction mixture, to continue directly with the periodate cleavage step. Such a procedure was used by Ballou (11) in converting 3,4-*O*-isopropylidene-D-arabinose to the D-isomer

[1]*Manuscript received June 23, 1960.*

of V. Ballou's method, it will be noted, can also readily furnish V itself by starting with L-arabinose, but the required isopropylidene-pentose derivative is less readily prepared than is the monoacetone-L-rhamnose used in the current study.

Hydrolysis of 2,3-*O*-isopropylidene-L-erythrose with dilute acid afforded chromatographically pure L-erythrose. The calculated $[\alpha]_D$ of the latter sugar was +39°, somewhat higher numerically than most values reported earlier for the D- or L-isomer (see ref. 1 and references cited therein), but close to the value of $[\alpha]_D$ −41° found by Schaffer for D-erythrose derived from crystalline 2,4-*O*-ethylidene-D-erythrose dimer (12). These higher values, together with rotational data obtained by hydrolysis of the methyl D-erythrosides (see below), indicate that the specific rotation of D- or L-erythrose is −38° or +38° (±3°).

The current procedure for preparing L-erythrose may be found more satisfactory than previous means for obtaining this tetrose. Of other methods available the sulphone degradation (13) of diethyl dithio-L-arabinose affords the highest over-all yield of chromatographically pure L-erythrose (13), although the low specific rotation ($[\alpha]_D$ +23°) recorded for the syrupy product (13) suggests the presence of an undetected impurity.

Hockett and Maynard (15) found that D-erythrose reacts with methanolic hydrogen chloride (16) to form a mixture of the α- and β-furanosides (VII and VIII) rather than the dimethyl acetal or dimeric products, in this respect resembling more closely the higher-order sugars rather than DL-glycerose (17). In the current study it was of interest to isolate the isomeric tetrosides, which represent the simplest of the true glycosides. Di-*O*-formyl-D-erythrose (1), in 1% methanolic hydrogen chloride at room temperature, was rapidly deacylated and converted to a mixture of the glycosides. The anomeric compounds were readily distinguished on paper chromatograms (which showed also that

VI $R_1 = OCH_3$, $R_2 = H$

VII $R_1 = H$, $R_2 = OCH_3$

VIII $R_1 = OCH_3$, $R_2 = H$

IX $R_1 = H$, $R_2 = OCH_3$

other products were produced in only minor proportions), and were separated by chromatography on a cellulose column. The ratio of α- to β-anomer formed was about 1 to 3, whereas Hockett and Maynard found the ratio to be about 4 to 5 (15) and, recently, Ballou (18) has reported that the β-anomer is produced almost exclusively. In all three instances the reaction conditions used appear to have been similar and no explanation is offered to account for these wide variations. It may be noted, however, that the *trans*-β-glycoside always predominates in the mixtures.

Both glycosides were isolated as analytically pure syrups and characterized by optical properties and glycol-cleavage oxidation. Methyl β-D-erythroside was smoothly converted to a 2,3-cyclic carbonate, and a di-*p*-nitrobenzoate of the α-anomer was prepared. On hydrolysis with dilute aqueous acid each glycoside afforded chromatographically pure D-erythrose, the calculated specific rotation of the latter being $[\alpha]_D$ $-36°$ to $-39°$.

For the preparation of methyl α- and β-D-*threo*-tetrofuranosides (IX and X), di-*O*-formyl-D-threose (2) was treated with methanolic hydrogen chloride as for the corresponding D-erythrose derivative. The specific rotation of the syrupy product and of the dialdehydes derived by periodate oxidation indicated that the α- and β-glycosides were formed in a ratio of about 3 to 2. The mixture was not well resolved on paper chromatograms and only a partial separation was effected on a cellulose column. Presence of two major components in the reaction mixture in the ratio given above was demonstrated more satisfactorily by gas–liquid chromatography* and small analytically pure samples of the α- and β-threosides were obtained by this chromatographic method. Methyl α-D-threoside was isolated also via the mixture of derived di-*p*-nitrobenzoates by fractional crystallization and deacylation.

The possibility of preparing methyl α-D-threoside by means of the Koenigs–Knorr reaction (20) was examined briefly. Extensive studies on the halides of *O*-acyl-pentofuranoses (21) have shown that the 1,2-*trans*-glycoside is generally formed starting with either the α- or β-halide. Applied to the D-*threo*furanose series, formation of the α-glycoside was to be expected. Tri-*O*-acetyl-D-threofuranose (22) was accordingly treated with hydrogen bromide in acetic acid, yielding an unstable syrupy product which appeared to contain both anomeric bromides. Reaction of this material with methanol, either in the presence or absence of silver oxide, led to formation of the mixed α- and β-glycosides, with the former predominating. Under the conditions used, therefore, the reaction was less stereospecific than usually encountered with the higher sugars and did not constitute a satisfactory preparative procedure.

The behavior of the various glycosides towards glycol scission by lead tetraacetate in acetic acid (23) was in general accord with the oxidation characteristics of related five-membered ring compounds. The steric arrangement of the *vic*-diol group of the D-erythrosides should correspond closely to that found in cyclopentane-*cis*-1,2-diol (24) and 1,4-anhydro erythritol (25) and, accordingly, these glycosides consumed oxidant extremely rapidly (Table I), as already shown for the mixed anomers (15). Similarly, as with cyclopentane-*trans*-1,2-diol (23) and 1,4-anhydro-L-threitol (26, 27), the D-threosides were attacked relatively slowly (Table I). The oxidation rates for the anomeric forms differed substantially, however, in contrast to the more uniform behavior of anomeric pyranose glycosides towards lead tetraacetate.†

**This technique has been shown to be highly effective for separating the anomeric forms of some methyl hexoside methyl ethers (19).*

†*A notable exception is the observation that the α-anomer of methyl 2-deoxy-D-erythropentopyranoside consumes lead tetraacetate almost twice as rapidly as does the β-anomer (28). In the periodate oxidation of* sterically rigid *bicyclic methyl glycosides, substantial anomeric differences have been observed (29).*

TABLE I

Properties of the methyl D-tetrofuranosides

Isomer	$[\alpha]_D^{25}$	$[\alpha]_D^{25}$ dialdehyde*	Oxidation rate (k)†
α-D-*Erythro*-(VII)	+133°	+121°	Fast (0°)‡
β-D-*Erythro*-(VIII)	−148°	−119°	Fast (0°)‡
α-D-*Threo*-(IX)	+97°	+113°	0.084 (25°)§
β-D-*Threo*-(X)	−193°	−116°	0.49 (25°)§

*D'- of L'-Methoxy-diglycolic aldehyde formed by periodate oxidation. Derived from crystalline methyl pentosides, these dialdehydes show $[\alpha]_D^{20}$ ±122–124° (37, 38).

†Rate of lead tetraacetate oxidation in mole^{-1} liter minute^{-1}. Cyclopentane-*trans*-1,2-diol gives $k_{20°}$ 12.8 (24).

‡One mole of oxidant per mole was consumed within 45 seconds.

§The compound was not hydrolyzed when kept in acetic acid at 25° C for 6 hours.

EXPERIMENTAL

Paper chromatography was carried out using as solvents (A) ethyl acetate – acetic acid – formic acid – water (18:3:1:4), (B) butan-1-ol – ethanol – water (40:11:19), and (C) ethyl acetate – pyridine – water (100:40:30).

Gas–liquid chromatography was carried out as described by Craig and Murty (30), using a succinate – ethylene glycol polyester on Chromosorb W at a column temperature of 205° and a helium flow of 60 ml/minute.

Solutions were concentrated *in vacuo* at 40° C. Melting points are corrected. Boiling points cited are air-bath temperatures. Optical rotations were measured at approximately 25°.

2,3-O-Isopropylidene-L-*rhamnose* (I)

A slight modification of the procedure of Fischer (16) was used. L-Rhamnose hydrate (30 g) was dehydrated by heating *in vacuo* at 100° C for 3 hours. Dry acetone (300 ml) was added, followed by a solution of acetone (20 ml) containing hydrogen chloride (1.5 g), and the mixture was shaken at room temperature until the solid dissolved (1–2 hours). Excess ammonia was bubbled into the solution, the ammonium chloride filtered off, and the filtrate concentrated. The syrupy residue was dissolved in water (50 ml), extracted twice with ethyl acetate (100 ml), and the extract was washed twice with water (25 ml), dried over sodium sulphate, and concentrated. Weight, 19.0 g, $[\alpha]_D$ +6° (c, 4.3, H_2O). Paper chromatographic examination of the syrupy product and of the aqueous fractions indicated that the former consisted almost exclusively of monoacetone L-rhamnose (R_F 0.9, solvent B) and the latter mainly of L-rhamnose. Five grams of 2,3-*O*-isopropylidene-β-L-rhamnose, m.p. 88–90° C, $[\alpha]_D$ +17° (equilibrium value) (c, 2, H_2O), was obtained from a solution of the syrup in ether–hexane, but prolonged storage of the mother liquor in the cold failed to yield additional crystalline material. (For further examination of the syrupy residue, see below.)

2,3-O-Isopropylidene-L-*erythruronic Acid* (III)

2,3-*O*-Isopropylidene-β-L-rhamnose (1.0 g) was dissolved in water (50 ml), 0.1 N iodine (110 ml containing 2.4 g of potassium iodide) was added, and the solution cooled in an ice bath. Sodium hydroxide (N, 17.0 ml) was added dropwise with good stirring during a period of 15 minutes. At 45 minutes, titration of a portion of the reaction mixture showed that the consumption of hypoiodite was 1.0 mole/mole. A few drops of 0.1 N thiosulphate was added to decolorize the solution, silver acetate (7.0 g) was added and the suspension stirred at room temperature for 15 minutes, and sodium chloride solution

For personal use only.

then added to remove excess silver ion. The suspension was filtered, the filtrate cooled to 5° C, and powdered sodium periodate (1.0 g) added. After 30 minutes, the oxidation mixture (which gave a faint test for excess periodate) was concentrated to a volume of 200 ml, acidified with Amberlite IR-120, and the solution and resin were extracted 5 times with ethyl acetate (50 ml). The combined extract was washed twice with water (25 ml) and dried over sodium sulphate. Evaporation of the solvent afforded a syrup which rapidly solidified (weight, 0.65 g), m.p. 92–98° C. (R_F 0.85, solvent A, yellow color with *p*-anisidine hydrochloride spray (31).) Recrystallized from ethyl acetate – hexane, the product had a melting point of 103–104° C, $[\alpha]_D$ +1.4° (*c*, 1.4, H_2O). Calculated for $C_7H_{10}O_5$: C, 48.27%; H, 5.79%. Found: C, 48.05%; H, 5.76%.

L-*Erythrotetruronic Acid*

Monoacetone L-erythruronic acid (28 mg) in water (2.0 ml) was heated on the steam bath: α_D +0.02° (1 dm, initial) → α_D −0.20° (60 minutes, constant); $[\alpha]_D$ −18° (calc.). (D-Erythruronic acid has $[\alpha]_D$ +18° (3).) Chromatographic examination of the hydrolyzate indicated the presence of one component travelling at the rate of D-*erythro*tetruronic acid (R_{gal} 1.4, solvent A) and giving an intense yellow color (which appears in the cold and intensifies on heating) with *p*-anisidine hydrochloride spray.

D-*Erythrono-γ-lactone*

Monoacetone L-erythruronic acid (0.3 g) was reduced with sodium borohydride (0.3 g) in water–methanol (2:1). The isopropylidene group of the syrupy product was hydrolyzed at 100° C in 80% acetic acid for 1.5 hours, affording D-erythrono-γ-lactone (0.1 g), which, recrystallized from ethanol, had a melting point of 100–102° C, undepressed, $[\alpha]_D$ −73° (*c*, 2.4, H_2O). (Lit. (1): m.p. 103–104° C; $[\alpha]_D$ −72°.) Calculated for $C_4H_6O_4$: C, 40.68%; H, 5.12%. Found: C, 40.69%; H, 5.16%.

2,3-O-Isopropylidene-L-*erythrose* (V)

2,3-*O*-Isopropylidene-L-rhamnose (2.0 g) in water (80 ml) was added dropwise to a well-stirred solution of sodium borohydride (0.8 g) in ice water (40 ml). After 4 hours at room temperature, acetic acid was added slowly to destroy excess borohydride and to adjust the pH to 6. The solution was cooled externally to 10° C, and powdered sodium periodate (2.2 g) was added portionwise over a period of 15 minutes. The reaction mixture was kept at 25° C for 3 hours (it then gave a faintly positive test for periodate), then concentrated to a volume of about 25 ml, and the slurry extracted 4 times with ethyl acetate (50 ml). After the extract was washed twice with water (15 ml) and dried over sodium sulphate, the solvent was evaporated off affording a clear, colorless syrup* (1.3 g) (R_F 0.8, solvent B) which solidified almost completely when stored overnight at 3° C. The crystalline material melted at 27–30° C. After distillation (60–70° C (bath) at 10 mm) the product still contained a small proportion of liquid, and the crystalline material melted at 29–31° C, $[\alpha]_D$ +72° (*c*, 2.4, CH_3OH) (no mutarotation observed). Calculated for $C_7H_{12}O_4$: C, 52.49%; H, 7.55%. Found: C, 52.53%; H, 7.56%.

2,3-O-Isopropylidene-L-*erythrose from Syrupy Monoacetone* L-*Rhamnose*

A sample (1.0 g) of the material remaining after crystallization of I (above) was treated with sodium borohydride followed by periodate oxidation, as in the preparation of V. The syrupy product (0.8 g) was distilled (50–70° C (bath) at 2 mm) affording a colorless syrup which solidified almost completely at 3° C. The melting point of the crystalline

**This product is moderately volatile, and hence should not be dried for a prolonged period in vacuo.*

material was 27–31° C. In addition to V, the product was found chromatographically to contain a minor component (R_F 0.9, solvent B) that was detected with aniline oxalate but did not give the tetrose color. Attempts to purify the monoacetone-L-erythrose by recrystallization from various solvent systems were unsuccessful.

L-Erythrose

2,3-*O*-Isopropylidene-L-erythrose (19.3 mg) in 0.1 *N* sulphuric acid (1 ml) was heated on the steam bath: α_D +1.22° (1 dm, initial) → +0.97° (30 minutes, constant); $[\alpha]_D$ +39° (calc.). After neutralization with Dowex-1 resin (bicarbonate form) the hydrolyzate was found chromatographically (solvent C) to contain a single component travelling at the rate of D-erythrose and giving the typical tetrose fluorescence under ultraviolet with aniline oxalate spray (32). The infrared absorption spectrum (potassium bromide disk) of the product was indistinguishable from that of D-erythrose. Reduction of the product with aqueous sodium borohydride yielded chromatographically pure erythritol, m.p. 118–120° C, undepressed. Calculated for $C_4H_{10}O_4$: C, 39.34%; H, 8.25%. Found: C, 39.43%; H, 8.30%.

2,3-O-Isopropylidene-L-rhamnitol

2,3-*O*-Isopropylidene-L-rhamnose (0.5 g) in absolute ethanol (10 ml) was heated at 100° C for 8 hours at a pressure of 1400 p.s.i. of hydrogen in the presence of Raney nickel catalyst (0.3 g). The catalyst was filtered off and the filtrate evaporated, affording a colorless syrup (0.5 g) which gave a single spot on a paper chromatogram (R_F 0.7, solvent B, ammoniacal silver nitrate spray (33)), $[\alpha]_D$ +5.5° (*c*, 4.1, CH_3OH). Presence of an isopropylidene group was indicated by the infrared absorption spectrum. The product consumed 1.0 mole of periodate per mole, affording 2,3-*O*-isopropylidene-L-erythrose. Acetylation and benzoylation gave amorphous products.

Reaction of Di-O-formyl-D-erythrose with Methanolic Hydrogen Chloride

Di-*O*-formyl-D-erythrose syrup (1) (3.2 g) in methanol (50 ml) (α_D +0.14°) was treated with 2.5% methanolic hydrogen chloride (35 ml) at 25° C, the observed rotation changing to α_D −1.65° (5 minutes, constant). Excess silver carbonate was added, the neutral filtrate was treated with hydrogen sulphide and again filtered, and the solution was concentrated to yield a colorless syrup (2.2 g), $[\alpha]_D$ −49° (*c*, 4.4, CH_3OH). Examined by paper chromatography (solvent B), the syrup was found to contain two main components (R_F 0.59 (major) and R_F 0.66), a small proportion of free erythrose, and two trace components (R_F 0.74 and R_F 0.79).

Methyl β-D-Erythrotetrofuranoside (II)

Methyl D-erythroside syrup (5.5 g) was chromatographed on a cellulose column using benzene–ethanol–water (500:50:1) as solvent. The component (R_F 0.59) was eluted from the column first and isolated as a colorless syrup (3.5 g), b.p. 80–90° C at 0.5 mm; n_D 1.4630, $[\alpha]_D$ −148° (*c*, 1.5, H_2O). (Ballou reports $[\alpha]_D$ −149° (*c*, 1, $CHCl_3$) (18).) Calculated for $C_5H_{10}O_4$: C, 44.77%; H, 7.52%. Found: C, 44.30%; H, 7.62%.

The glycoside was hydrolyzed with 0.1 *N* sulphuric acid at 100° C to constant rotation in 30 minutes. Calculated for chromatographically pure D-erythrose formed $[\alpha]_D$ −36° (in the acid solution, and after treatment with Dowex-1 resin (bicarbonate form)).

Oxidized with sodium periodate, the uptake by the glycoside was 1.0 mole/mole, and the observed rotation changed from α_D −2.55° (*c*, 1.75) to −2.06° (20 minutes, constant). Calculated for dialdehyde formed $[\alpha]_D$ −119°.

Methyl β-D-Erythrofuranoside-2,3-carbonate

Methyl β-D-erythroside (0.9 g) was dissolved in pyridine (30 ml) and to the stirred solution was added dropwise a solution of phosgene (0.75 g) in toluene (35 ml) (34). After 18 hours the solid pyridine hydrochloride was filtered off, the filtrate concentrated, and the residue taken up in chloroform. The chloroform solution was washed twice with copper sulphate solution, then with bicarbonate solution, twice with water, dried over sodium sulphate, and concentrated. The syrupy product (1.0 g) solidified, and recrystallization was effected from ethyl acetate – hexane, m.p. 73° and $[\alpha]_D$ −152° (*c*, 2.4, $CHCl_3$). Calculated for $C_6H_8O_5$: C, 45.00%; H, 5.01%. Found: C, 44.81%; H, 5.01%. The infrared absorption spectrum showed a major broad peak at 1790–1795 cm^{-1}, characteristic of a cyclic, rather than acyclic, carbonate group (35).

Methyl α-D-Erythrotetrofuranoside (I)

Following elution of the β-glycoside from the cellulose column, a fraction consisting mainly of the α-anomer was obtained (0.6 g), rechromatographed on the cellulose column, and distilled (b.p. 65–85° C at 0.2 mm); n_D 1.4665, $[\alpha]_D$ +133° (*c*, 1.2, H_2O). Calculated for $C_5H_{10}O_4$: methoxyl, 23.1%. Found: methoxyl, 22.8%.

On hydrolysis with 0.1 *N* sulphuric acid at 100° C to constant rotation, the observed value corresponded to $[\alpha]_D$ −37° for chromatographically pure D-erythrose formed; after neutralization with Dowex-1 (bicarbonate form), $[\alpha]_D$ −39°.

Treated with sodium periodate, the glycoside consumed 1.0 mole/mole, the observed rotation changing from α_D +1.71° → +1.48° (10 minutes, constant). Calculated for the dialdehyde formed, $[\alpha]_D$ +121°.

Methyl α-D-Erythrofuranoside Di-p-nitrobenzoate

Methyl α-D-erythroside (0.10 g) in pyridine (5 ml) was treated with *p*-nitrobenzoyl chloride (0.65 g) at 55° C for 4 hours. On addition of aqueous sodium bicarbonate, a solid product was obtained (0.30 g) and was recrystallized from ethyl acetate – hexane, m.p. 109–110° C and $[\alpha]_D$ −17.3° (*c*, 1.7, $CHCl_3$). Calculated for $C_{19}H_{16}O_{10}N_2$: C, 52.78%; H, 3.73%. Found: C, 52.84%; H, 3.60%.

Reaction of D-Threose Formate with Methanolic Hydrogen Chloride

D-Threose formate syrup (2) (4.5 g), treated with methanolic hydrogen chloride as described above, afforded a colorless syrup (2.6 g). Purified by distillation (b.p. 75–90° C at 0.2 mm) the product had $[\alpha]_D$ +7.9° (*c*, 2.4, H_2O) and, examined by paper chromatography (solvent B), was found to contain two major tetrose components (R_F 0.65 and 0.62; overlapping, with the former predominant) and a minor tetrose component (R_F 0.75). On treatment with periodate the mixture consumed 0.9 mole of oxidant per mole, the calculated value of $[\alpha]_D$ +33° for the dialdehydes formed corresponding to an α,β-mixture of about 3 to 2. Calculated for $C_5H_{10}O_4$: methoxyl, 23.1%. Found: methoxyl, 24.6%.

Methyl α- and β-D-Threotetrofuranosides

Vapor phase chromatography of the syrupy mixture of D-threosides readily separated the two major components from each other, and showed them to be present in a ratio of about 3 to 2 (α- to β-). On a preparative scale, 50–100 mg of each component was isolated by repeated chromatographic runs, and purified by distillation.

The first of the two components to emerge from the column was the *β-anomer* (R_F 0.62, b.p. 80–90°/0.2 mm), $[\alpha]_D$ −193° (*c*, 1.1, H_2O). The glycoside consumed 1.0 mole of

periodate per mole, affording a dialdehyde having $[\alpha]_D$ −116° (calculated). Calculated for $C_5H_{10}O_4$: C, 44.77%; H, 7.52%. Found: C, 44.60%; H, 7.48%.

The *α-anomer* (R_F 0.65, b.p. 85–100°/0.2 mm) had $[\alpha]_D$ +97° (*c*, 1.6, H_2O). It consumed 1.0 mole of periodate per mole, yielding a dialdehyde having $[\alpha]_D$ +113° (calculated). Calculated for $C_5H_{10}O_4$: C, 44.77%: H, 7.52%. Found: C, 44.73%; H, 7.31%.

Methyl α-D-Threofuranoside Di-p-nitrobenzoate and Methyl α-D-Threofuranoside

The mixture of α- and β-D-threosides (0.5 g) was treated with *p*-nitrobenzoyl chloride as described above, and the amorphous product (1.2 g) was taken up in ethyl acetate – hexane. Crystalline material (0.6 g) was deposited and recrystallized twice from the same solvent, m.p. 131–133° C and $[\alpha]_D$ −115° (*c*, 2.0, $CHCl_3$). Calculated for $C_{19}H_{16}O_{10}N_2$: C, 52.78%; H, 3.78%. Found: C, 52.80%; H, 3.65%.

The di-*p*-nitrobenzoate (0.3 g) suspended in methanol (20 ml) was treated under reflux with sodium methoxide (0.1 *N*, 2 ml). Acetic acid was added to neutrality, the methanol evaporated off, and the residue taken up in water and extracted three times with benzene. The aqueous layer was concentrated, and the product distilled, $[\alpha]_D$ +96° (*c*, 2.2, H_2O). The infrared absorption spectrum of the syrup was indistinguishable from that of methyl α-D-threoside and different from that of the β-glycoside.

Methyl β-D-Threofuranoside Di-p-nitrobenzoate

A syrup consisting mainly of methyl β-D-threofuranoside ($[\alpha]_D$ −165°) was obtained by partial separation of the mixed threosides on a cellulose column using benzene–ethanol–water (1000:15:0.5). Treatment with *p*-nitrobenzoyl chloride afforded a di-*p*-nitrobenzoate which, when crystallized from ethyl acetate – pentane, had a melting point of 55–57° C, $[\alpha]_D$ −213° (*c*, 1.6, $CHCl_3$). Calculated for $C_{19}H_{16}O_{10}N_2$ (containing a mole of ethyl acetate): C, 53.05%; H, 4.62%; N, 5.38%; acetyl, 8.27%. Found: C, 53.03%; H, 4.63%; N, 5.21%; acetyl, 7.81%.

Preparation of the Methyl D-Threosides via Acetobromo-D-threose

Tri-*O*-acetyl D-threose (22) (0.50 g) in chloroform (4 ml) ($[\alpha]_D$ +35°) was treated with hydrogen bromide (2 ml, 40% in acetic acid). Within 5 minutes the observed rotation was constant, giving a calculated value of $[\alpha]_D$ −10°. The solution was quickly concentrated, toluene being added 4 times in completing the evaporation of solvent, affording a pale yellow syrup (0.54 g). (Attempts to dry a portion thoroughly for analysis resulted in rapid darkening, and no crystalline product could be isolated from cold ether–hexane.)

The syrup (0.1 g) in methanol (5 ml) was shaken for 18 hours with silver oxide (0.3 g) and Drierite (0.7 g). Found: $[\alpha]_D$ −5° (calculated for methyl tetroside). In the absence of silver oxide and Drierite the observed rotation of the solution was constant in 10 minutes, $[\alpha]_D$ −6° (calculated for methyl tetroside). Both products were deacylated with sodium methoxide, and found by paper chromatography to contain mainly methyl threoside, $[\alpha]_D$ +25° (*c*, 1, H_2O). The infrared absorption spectra of the deacetylated products were closely similar to that of methyl α-D-threoside. Examined by vapor phase chromatography the α- and β-anomers were detected in the products in a ratio of about 3 to 1.

Lead Tetraacetate Oxidations

The methyl D-erythrosides (40 mg) in 5 ml of acetic–propionic acid mixture (75:25) (2) were each treated at 0° C with lead tetraacetate solution (50 mg in 4 ml of the same solvent). Oxidation of the methyl D-threosides was carried out in acetic acid at 25° C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

using the same concentration of reactants. Reaction rates were measured as described by Criegee (36).

ACKNOWLEDGMENTS

The authors are grateful to Dr. B. M. Craig for carrying out the vapor phase chromatographic separations reported, and to Mr. J. W. L. C. Christ for technical assistance. Microanalyses were carried out by Mr. M. Mazurek, and infrared absorption spectra were prepared by Miss Inez Gaffney.

CHEMICAL SHIFTS IN THE N.M.R. SPECTRA OF SUBSTITUTED XYLENES[1]

ROBERT R. FRASER

ABSTRACT

The complete results of analysis of the N.M.R. spectra of twelve 2,6-dimethyl-1-substituted benzenes are reported. The results are interpreted as evidence that the ability of the substituent to donate or withdraw electrons by resonance interaction with the benzene ring is a major factor in determining the position of absorption of the protons attached to the ring. The chemical shifts and coupling constants for nitroethylene are also reported.

The study of the effect of a substituent on the position of absorption in the N.M.R. spectra of protons attached to a benzene ring has been greatly hindered by the complexity of the spectra of monosubstituted benzenes. These spectra generally fall in the classification AB_2C_2 following the nomenclature of Bernstein, Pople, and Schneider (1). Analysis of such a five-spin system is extremely tedious even in the case of pyridine, which belongs to the slightly simpler AB_2X_2 system (2). For this reason little work has appeared in the literature on the correlation of chemical shifts of protons on a benzene ring with substituents since the first report by Corio and Dailey (3). These authors reported the values δ_o, δ_m, δ_p for the chemical shifts of the ortho, meta, and para protons in the N.M.R. spectra of 22 monosubstituted benzenes. Their analysis was of a qualitative nature on spectra whose resolution was limited by the use of a transmission frequency of 30.00 Mc/sec. Furthermore Bothner-By and Glick subsequently showed that solvent effects were responsible for inaccuracies of as much as 0.07 p.p.m. in the values for δ_p (4). Correlation of their δ values with Hammett's σ constants gave only rough agreement although Taft later showed that agreement to within 0.07 p.p.m. could be obtained employing the equation* $\delta_p = +0.40\sigma_I + 1.04\sigma_R^0 + 0.02$ (5). In this equation σ_I is the inductive substituent constant of Taft (6) and σ_R^0 is the resonance substituent constant corrected for isovalent conjugation (5). Taft has interpreted this agreement to be an indication that polarization effects in the transition state are sufficiently similar to those in the ground state to give the correlation between σ and δ_p (7).

An alternative theory of the origin of chemical shift differences in the ring protons of monosubstituted benzenes has been suggested in a recent article by Buckingham (8). He proposes that the screening constant for each proton is determined by the "internal electric field" of the molecule. In addition polarization of the surrounding solvent by the solute produces a "reaction field" whose effect combines with that of the electric field to give the total effect on the screening constants. He has derived expressions for these two fields in terms of the dipole moment of the solute, its refractive index, and the dielectric of the solution from which screening constants can be directly calculated. Calculations for nitrobenzene gave values of -0.69, -0.40, and -0.51 p.p.m. relative to benzene for the ortho, meta, and para protons in fair agreement with the values -0.97, -0.30, and -0.42 observed by Corio and Dailey. In order to provide data which might aid in the elucidation of the cause of chemical shift differences with different substituents, a series

[1]*Manuscript received June 29, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario. This paper was presented at the 43rd Annual Conference of the Chemical Institute of Canada, Ottawa, June 13–15, 1960.

**It should be noted that Corio and Dailey employ $\delta_p = 10^6\{(H_{ref}-H)/H_{ref}\}$, which causes negative signs to represent shifts to higher field.*

of 2,6-dimethyl-1-substituted-benzenes were synthesized and their spectra obtained with a Varian V-4302 spectrometer using a 60 Mc/sec r.f. unit. These xylene derivatives were selected for study since they provide spectra which can be accurately analyzed.

RESULTS AND DISCUSSION

The results of analysis of the spectra of 12 substituted xylenes are given in Table I.

TABLE I

Results of analysis of twelve 2,6-dimethyl-1-substituted benzenes (substituent σ values are also given)

Substituent	$\Delta\nu_m$*	$\Delta\nu_p$*	$\Delta\nu_m'$	σ_m	σ_p	σ_R	τ_{CH_3}†

NOTE: All the σ values for the first seven substituents are taken from R. W. Taft, Jr., N. C. Deno, and A. S. Skell. Ann. Rev. of Phys. Chem. **9**, 292 (1958). The σ_R values for the last five substituents are calculated from normal σ_R values by correcting for the percentage of steric inhibition of resonance. The percentage inhibition was taken from the following sources: R. W. Taft, Jr. and H. D. Evans. J. Chem. Phys. **27**, 1427 (1957), who reported NO_2 (67%), OCH_3 (59%), and $N(CH_3)_2$ (75%); B. M. Wepster. Rev. trav. chim. **76**, 335, 357 (1957), who found NO_2 (69%), $N(CH_3)_2$ (80%), and $NHCH_3$ (60%); A. Burawoy and J. T. Chamberlain. J. Chem. Soc. 2310 (1952), from whose results the value 62% is calculated for OCH_3; and G. M. Moser and A. I. Kohlenburg. J. Chem. Soc. 805 (1957), from whose data the value 50% is estimated for COOH. For a discussion of steric inhibition of resonance in these compounds see B. M. Wepster. Progress in stereochemistry. Vol. 2. *Edited by* W. Klyne and P. B. D. de la Mare. Butterworths Scientific Publications, London. 1958.

*$\Delta\nu_m$ and $\Delta\nu_p$ are the chemical shifts in cycles/sec at 60 Mc/sec relative to the internal reference benzene for the meta and para protons.

†τ_{CH_3} gives the chemical shift of the ortho methyls expressed as parts per million with tetramethylsilane assigned a value 10.00.

The protons attached to the aromatic ring appeared in all but three cases as an AB_2 pattern whose general solution has been reported in reference 1. The spectrum consists of eight transitions whose energies and intensities are dependent only on the ratio $J_{AB}/\Delta\nu_{AB}$.* In Fig. 1 the spectra of 2,6-dimethylphenol, 2,6-dimethylanisole, and N,N-dimethyl-2,6-dimethylaniline are shown. They illustrate cases where the ratio is less than one, about one, and much greater than one, respectively. In 2,6-dimethylphenol, as in all AB_2 systems, line 3 gives the position of chemical shift for the A nucleus, unmodified by spin coupling. The corresponding position for the B nuclei is the mean of transitions 5 and 7. Thus $\Delta\nu_{AB} = \Delta\nu_p - \Delta\nu_m$ can be obtained directly from the spectrum. In the spectrum of this compound transitions 5 and 6 could not be resolved. To insure accurate results, theoretical spectra were calculated for various ratios of $J/\Delta\nu_{AB}$ until agreement with the observed spectra to within 0.4 cycle/sec for each transition was obtained. In most spectra the agreement was within 0.2 cycle/sec for each transition. In all spectra J_{AB} was found to be 7.7 cycles/sec. The spectra of N,N-dimethyl-2,6-dimethylaniline and 2,6-dimethylbromobenzene showed only a single observable peak under high gain and it is estimated that the chemical shift of the meta and para protons in these two compounds is the same to within 3.0 cycles/sec.

**J_{AB} is the coupling constant between the para (A) and meta (B) protons. $\Delta\nu_{AB} = \nu_A - \nu_B$ represents the chemical shift between the meta and para protons. The symbol $\Delta\nu$ is used to denote chemical shifts in units of cycles per second as recommended by Pople, Schneider, and Bernstein (11).*

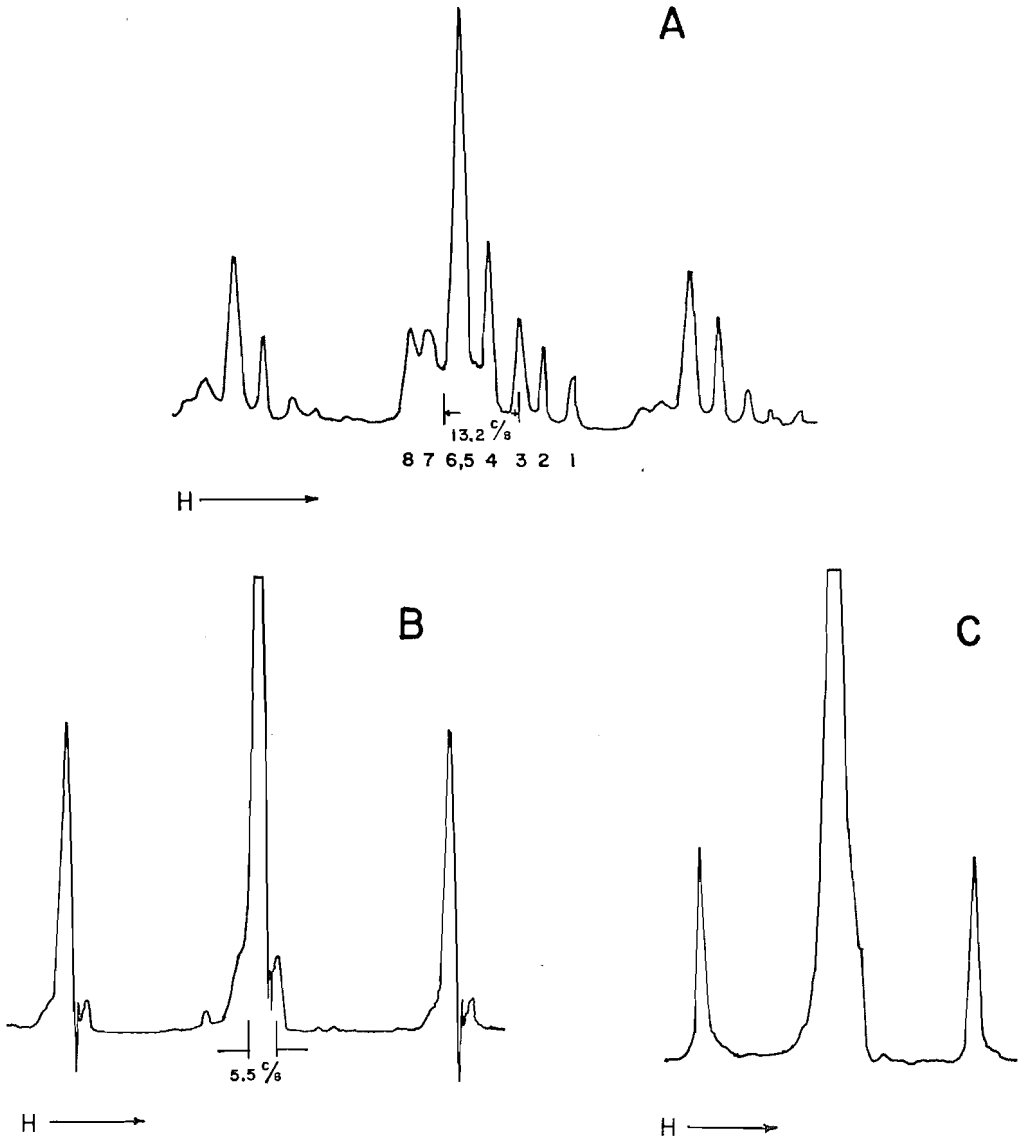

FIG. 1. (A) Aromatic proton absorption of 2,6-dimethylphenol (side bands at 40.0 cycles/sec) as a 10% solution in carbon tetrachloride. (B) Aromatic protons of 2,6-dimethylanisole (side bands at 35.1 cycles/sec) and (C) N,N-dimethyl-2,6-dimethylaniline (side bands at 25.0 cycles/sec) as 10% solutions in carbon tetrachloride.

In 2,6-dimethylfluorobenzene coupling of the fluorine atom with the meta and para protons resulted in the more complex spectrum shown in Fig. 2. By neglecting coupling of the methyl groups with the ring protons we can classify the aromatic protons and the fluorine nucleus as an AB_2X system. In order to simplify the calculations we have considered the aromatic proton spectrum as the sum of two AB_2 systems. This type of simplification has been employed previously by Anet in the analysis of the 2,3-dibromobutanes (9). When the X nucleus, fluorine, has a spin of $+1/2$ the aromatic protons will form one AB_2 system. When fluorine has a spin of $-1/2$ the aromatic protons comprise

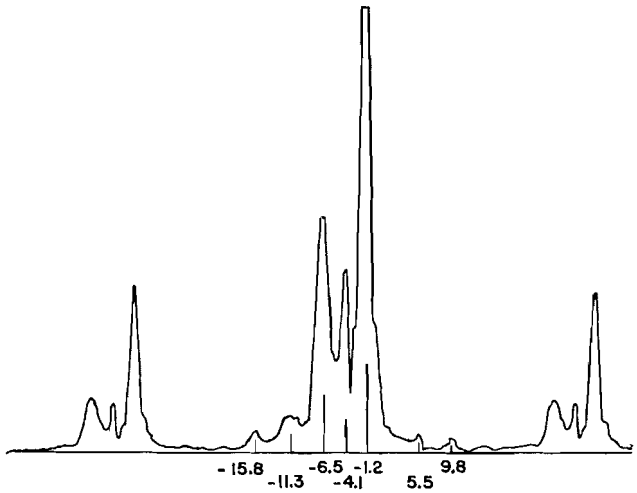

FIG. 2. Aromatic absorption of 2,6-dimethylfluorobenzene (side bands at 30.0 cycles/sec) as a 10% solution in carbon tetrachloride.

a second AB_2 system of equal total intensity. From the experimentally determined spectrum we found the chemical shift for the widely separated AB_2 system to be 8.6 cycles/sec. Using the values $J_{FH_B} = 7.0$ cycles/sec, $J_{FH_A} = \pm 2.2$ cycles/sec, and $J_{AB} = 7.7$ cycles/sec, it was then possible to calculate the complete spectrum for the aromatic protons. Two solutions were obtained, one for the case where the coupling constants between fluorine and the meta and para protons are of opposite sign (Fig. 3A) and one where the coupling constants are of the same sign (Fig. 3B). The numerical values for the fluorine–hydrogen coupling constants were chosen from the results of Gutowsky, Holm, Saika, and Williams, who observed the coupling between the ring protons and fluorine in fluoromesitylene to be 7.0 cycles/sec and the coupling between fluorine and a para proton to be 2.2 cycles/sec in several fluorinated benzenes (10). The line width of the strongest peak in the observed spectrum suggests that it is due to an AB_2 system having a very large ratio of $J/\Delta\nu_{AB}$ as depicted in Fig. 3A. In addition failure to observe the transition at $+2.2$ cycles/sec shown in Fig. 3B further indicates that the observed spectrum is due to a system in which the two fluorine–proton coupling constants are of opposite sign. Unfortunately an element of doubt remains as the differences between the two theoretical spectra are not large. The spectrum of 2,6-dimethylfluorobenzene was also measured in acetone, methylene iodide, dimethylsulphoxide, and aqueous methanol. Only in acetone was the spectrum altered significantly, $\Delta\nu_{AB}$ for the well-resolved AB_2 system being increased to 10.1 cycles/sec. Again better agreement between observed and calculated spectra was obtained assuming the fluorine–hydrogen coupling constants to be of opposite sign. With the values chosen in Fig. 3A, the chemical shift difference between the meta and para protons is found to be 4.0 cycles/sec with the para proton at higher field. The alternative assumption increases the difference to 6.2 cycles/sec. The methyl groups in 2,6-dimethylfluorobenzene appeared as a doublet of spacing 2.05 cycles/sec due to coupling with the fluorine nucleus.

Before the results are examined it is necessary to make a correction in the $\Delta\nu_m$ values. The spectrum of 2,6-dimethyldeuterobenzene shows that the meta protons are shifted 10.3 cycles/sec more to high field than the para ones by the methyl groups. Whatever

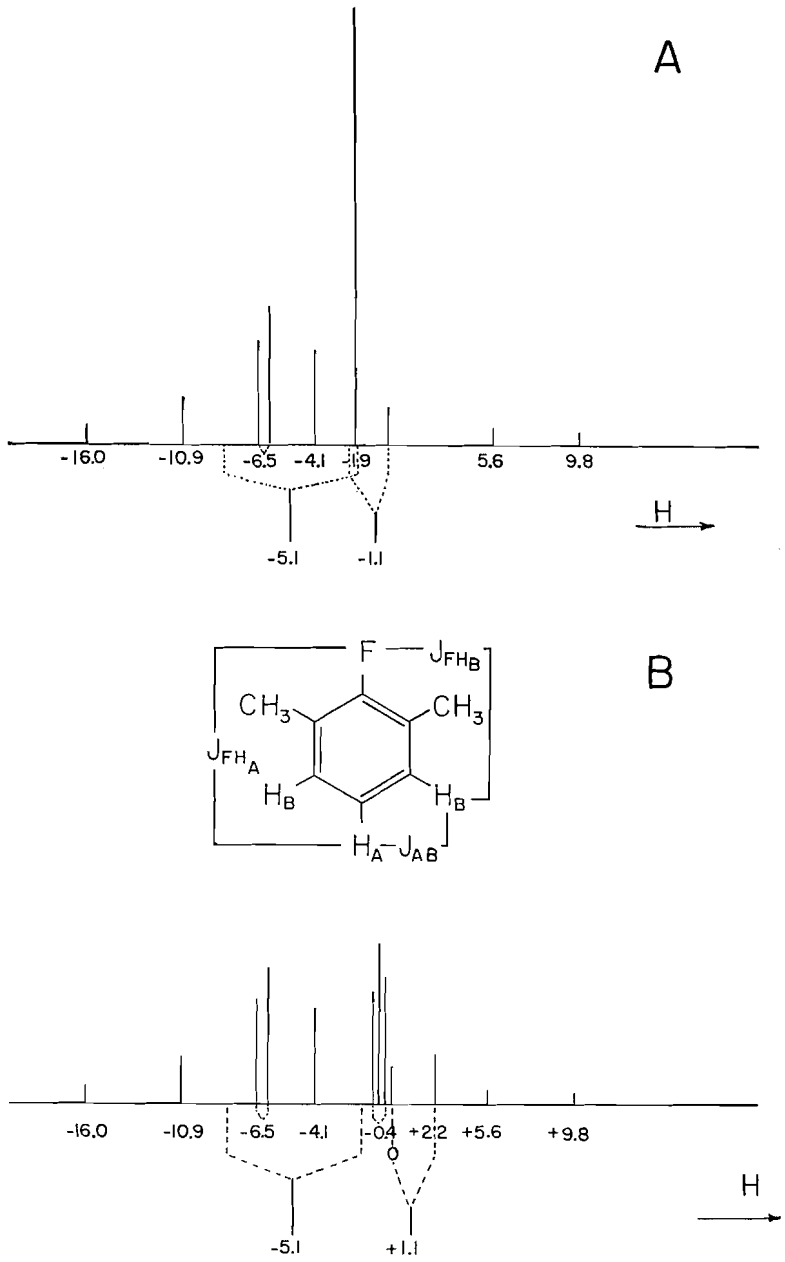

FIG. 3. Theoretical spectra of aromatic protons in 2,6-dimethylfluorobenzene.
(A) For $J_{AB} = 7.7$ cycles/sec, $J_{F-H_B} = 7.0$ cycles/sec, $J_{F-H_A} = -2.2$ cycles/sec, $\Delta\nu_{obs} = 8.6$ cycles/sec.
(B) For $J_{AB} = 7.7$ cycles/sec, $J_{F-H_B} = 7.0$ cycles/sec, $J_{F-H_A} = 2.2$ cycles/sec, $\Delta\nu_{obs} = 8.6$ cycles/sec.
In this diagram transitions of intensity less than 40% of band at +5.6 are not included. The positions of the A and B nuclei in the absence of coupling are shown below the abscissa.

the origin of this preferential shift, it is necessary to assume that it remains constant throughout the series of compounds measured. If this is true we can assign $\Delta\nu_m'$ values = $\Delta\nu - 10.3$ to the meta protons. Now the effect of the methyls is removed and the substituent

effect of a deuterium atom appears the same at the meta and para positions. The $\Delta\nu_m'$ values are also given in Table I. Let us now consider the chemical shifts observed in 2,6-dimethylaniline and its N,N-dimethyl derivative. The para proton in 2,6-dimethylaniline occurs at 47.2 cycles/sec relative to benzene, the meta proton at 29.0 cycles/sec relative to benzene. The value $\Delta\nu_p - \Delta\nu_m'$ shows that the amino substituent causes the para proton to be shifted 28.5 cycles/sec to higher field relative to the meta, which is corrected for the effect of the methyl group. On the other hand the dimethylamino substituent can be seen to cause only a 10.3 cycles/sec preferential shift of the para proton to higher field. It has been established by ultraviolet spectroscopy and by chemical reactivity (see references 1 and 2 in Table I) that two methyl groups ortho to a dimethylamino group greatly inhibit its resonance interaction with the benzene ring by preventing it from attaining coplanarity with the ring. The large difference in chemical shifts in 2,6-dimethylaniline can be explained by a resonance effect. That is to say the nitrogen atom donates its electrons to the para position more than to the meta position in the ground state and the increase in electron density results in a shift to higher field. The resonance interaction of the dimethylamino group with the ring is greatly decreased and so the effect on the shielding of the para and meta protons is also greatly diminished. The screening at the meta and para positions in the two compounds was calculated from the equations derived by Buckingham. The values 1.62 and 0.94, which Fischer found (12) for the dipole moments of 2,6-dimethylaniline and N,N-dimethyl-2,6-dimethylaniline, were used in the calculation. The dielectric constants for 5% solutions in carbon tetrachloride were estimated to be 2.5 and 2.4 respectively.

For 2,6-dimethylaniline the equations of Buckingham give values for $\Delta\nu_m'$ and $\Delta\nu_p$ of 6.4 cycles/sec and 7.2 cycles/sec. For the N,N-dimethyl derivative values of 3.7 and 4.1 cycles/sec were obtained. When these are compared with our experimental results it can be seen that the agreement is very poor.

A more obvious contradiction of the electric field effect is seen in the data for 2,6-dimethylfluorobenzene. Its dipole moment will most certainly be greater than zero with the negative end directed away from the ring.* Electric field theory then predicts that the para protons will be less screened than the meta when, in fact, the opposite situation has been found.

A plot of $\Delta\nu_m'$ and $\Delta\nu_p$ against the Hammett sigma constants for each substituent is shown in Fig. 4. No linear relationship is seen as the strongly electron-donating substituents appear at too high field. The same type of behavior was found for the F^{19} chemical shifts determined by Gutowsky (14). However, Taft later showed that the observed chemical shifts could be correlated with the inductive and resonance substituent constants σ_I and σ_R (7). The measured chemical shifts for the seven compounds whose substituents are free of steric inhibition of resonance were tested for correlation by the equation $\Delta\nu = \alpha\sigma_I + \beta\sigma_R + \gamma$ where α and β represent the susceptibility of the chemical shift to inductive and resonance effects of the substituent, respectively, and γ represents the constant methyl group effect. The chemical shifts for the meta protons are correlated by the equation $\Delta\nu_m' = 14.5 - 17\sigma_I - 10\sigma_R$, with the maximum error being 2.4 cycles/sec in the case of the bromo compound. The equation $\Delta\nu_p = 14.5 - 17\sigma_I - 46\sigma_R$ gives a better correlation, the maximum error being 1.7 cycles/sec in the iodo compound. As an illustration of the greater susceptibility of the para protons to σ_R, the value $\Delta\nu_p - \Delta\nu_m'$ for each

*The only available dipole moment data on fluorobenzenes is that of Everard, Kumar, and Sutton (13), who found the dipole moment of fluorobenzene to be 1.48 Debye units. The introduction of two methyl groups could lower the dipole moment by no more than 0.6 Debye unit which would lead to a minimum estimate of 0.88 Debye unit for 2,6-dimethylfluorobenzene.

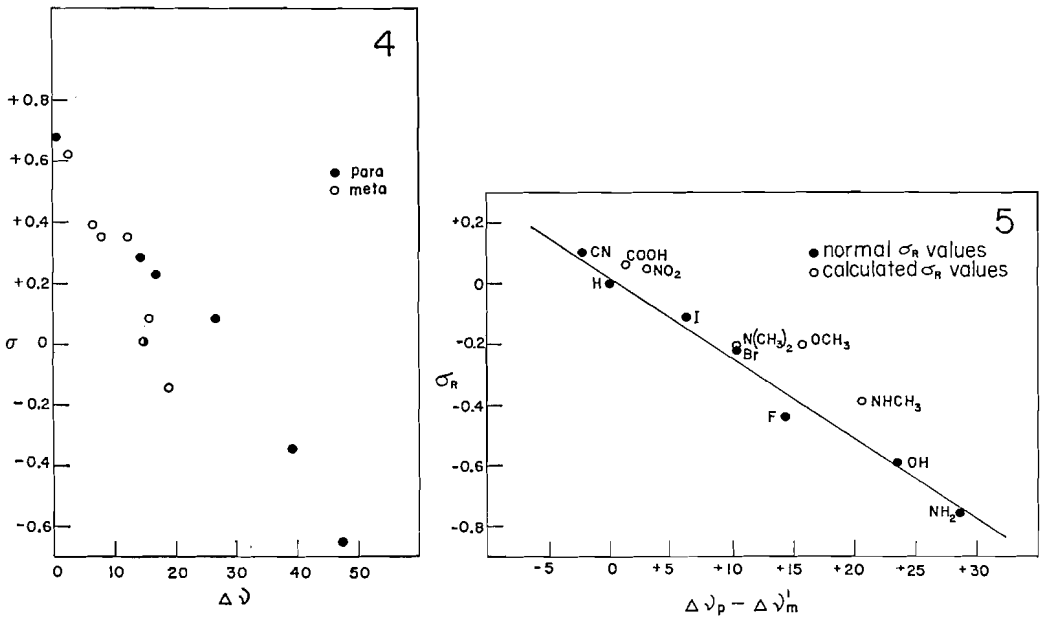

FIG. 4. Correlation of the shielding of the meta and para protons expressed in cycles per second at 60 Mc/sec from benzene by Hammett's σ's.
FIG. 5. Correlation of the separation in cycles per second at 60 Mc of the meta and para protons by Taft's σ_R.

compound is plotted against the σ_R value of the substituent in Fig. 5.* The linear relationship is obeyed to within 2.5 cycles/sec for those substituents free from resonance inhibition by the adjacent methyl groups. The substituents for which there is experimental evidence of steric inhibition of resonance are also plotted on the graph using σ_R values corrected for the percentage of inhibition as listed in Table I. The points for these substituents do not give a good linear plot, which might be interpreted as failure of the spectral and chemical methods to give a quantitative measure of the steric inhibition of resonance. Indeed the theoretical interpretation of the observed decrease in intensity of the ultraviolet absorption spectrum with increasing resonance inhibition, which was proposed by Braude, Sondheimer, and Forbes (15), has been invalidated by the recent work of Waight and Erskine (16). They observed no change in intensity of the ultraviolet spectra of a series of ortho-methylacetophenones with a 216° temperature change, a finding which contradicts Braude and co-worker's theory. It would be too presumptuous on the basis of our limited findings to propose corrected values for resonance inhibition by assuming the linear relationship to be valid for our compounds. It is sufficient to say that the deviation of these compounds from linearity does not refute the proposal that chemical shifts are determined by the inductive and resonance effects of the substituents.

Our findings can be compared with those of Corio and Dailey for the meta and para protons. The absence of ortho protons in our spectra is unimportant as Jackman has pointed out that the ortho shieldings are in many instances misleading (17). Jackman has found that each of the groups CN, Br, COOH, COCl, $COCH_3$, CHO in 2-substituted-1-propenes causes a shift of the proton cis to it to lower field relative to the trans proton.

*$If\ \Delta\nu_m' = \alpha\sigma_I+\beta\sigma_R+\gamma\ and\ \Delta\nu_p = \alpha\sigma_I+\beta'\sigma_R+\gamma\ then\ \Delta\nu_p-\Delta\nu_m' = (\beta'-\beta)\sigma_R\ and\ so\ a\ linear\ relationship\ between\ \Delta\nu_p-\Delta\nu_m'\ and\ \sigma_R\ should\ be\ found.$

The magnitude of the effect varies from 0.05 to 0.5 p.p.m. We have found that the nitro group has an even greater effect. Nitroethylene as a 10% solution in carbon tetrachloride gave a spectrum with well-separated absorption peaks. Assignments were made by assuming the coupling to be greater between protons trans to one another than cis and the results of analysis by first-order perturbation theory are given in Fig. 6. The

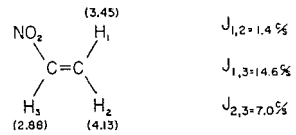

FIG. 6. Chemical shifts (τ values) and coupling constants for nitroethylene.

proton cis to the nitro group appears 0.68 p.p.m. to lower field than the proton trans to the nitro group. This effect of substituents will undoubtedly also be present in monosubstituted benzenes and will result in ortho protons appearing to lower field than in the absence of the effect. In instances where the effect is large, e.g. nitro, it could also be significant in the meta position even though it should fall off with the cube of the distance (11, p. 176). Our results are generally in agreement with those of Corio and Dailey although they show much greater sensitivity. For example, phenol showed no resolvable fine structure at 30 Mc/sec whereas 2,6-dimethylphenol showed signals for the meta and para protons separated by 13.2 cycles/sec. There is a discrepancy in the case of the iodo substituent. The values assigned to the para and meta protons in iodobenzene were +.10 and +.17 p.p.m. or 6.0 and 10.2 cycles/sec at 60 Mc/sec respectively. By subtracting the effect of the methyl groups our results for iodobenzene would be −0.1 and −6.4 cycles/sec respectively. Presumably, the discrepancy is due to those factors mentioned earlier, solvent effects and approximate analysis.

In conclusion it can be stated that our findings are not explainable by the Buckingham electric field theory. They are in agreement with the proposal of Taft that the observed shifts at the meta and para positions are determined by both the inductive and resonance effects of the substituent. The theoretical basis for such a relationship has been clearly discussed by Taft (7). In spite of our findings it should be emphasized that the quantitative value of the correlations is questionable. The meta protons are subject to only small shifts which could easily be overwhelmed by solvent or anisotropy effects. Indeed the recent work of Schneider (18) points out the need for caution. He found that the chemical shifts of the C^{13} nuclei in monosubstituted benzenes show appreciable variation due to resonance at the para position and even larger variation due to resonance and anisotropy effects at the ortho positions. At the meta position the variation in chemical shift was extremely small and not interpretable by resonance effects.

EXPERIMENTAL

The spectra were measured with a Varian V-4302 high-resolution N.M.R. spectrometer. Every result reported is the average of at least three determinations. Peak separations were determined by the side-band technique (11, p. 74) employing a Hewlett–Packard wide-range oscillator. The frequency of the side band was counted after each determination with a Hewlett–Packard 521C frequency counter with an accuracy of ±0.1 cycle/sec. If a broad peak was being measured the calibration was carried out by superposition of the reference signal on the desired peak. Alternatively, several of the spectra were calibrated by recording the spectrum of the reference and aromatic compound and their

side bands, then measuring the separation by interpolation. Both methods were used on 2,6-dimethylphenol and were found to agree to within 0.2 cycle/sec. All calibrations with respect to the internal reference were made employing 5% solutions of the aromatic compound in carbon tetrachloride containing 1% of benzene as internal reference. Measurements of the aromatic proton absorption of 2,6-dimethylanisole were made on 20%, 10%, and 5% solutions in carbon tetrachloride. From complete analysis of the multiplet system it was found that the chemical shift between the meta and para protons changed only 0.4 cycle/sec over the range studied. The check on effect of dilution was made since it was necessary to employ a concentration of 10% of some compounds in order to get reproducible measurements of the AB_2 system. For analysis of the deutero, dimethylamino, carboxyl, bromo, and methoxy compounds 5% solutions were employed. It is estimated from the average standard deviation for all compounds that the measured chemical shift between meta and para protons is accurate to within 0.4 cycle/sec and that the same accuracy was obtained for reference measurements. This would lead to a maximum possible error of ± 0.8 cycle/sec for the chemical shifts in Table I. The τ values for the methyl groups as listed in the table were obtained from measurements on 5% solutions in carbon tetrachloride containing 1% of tetramethylsilane. The nitroethylene spectrum was obtained from a 10% solution in carbon tetrachloride containing 1% of tetramethylsilane.

2,6-Dimethylaniline

Reagent grade 2,6-dimethylaniline (Eastman Kodak Co.) was freshly distilled from zinc dust to give a liquid, b.p. 79–80°, 6 mm, n_D^{25} 1.5588 (literature b.p. 216°, 747 mm, n_D^{20} 1.5602 (19)).

2,6-Dimethylnitrobenzene

Practical grade 2,6-dimethyl-1-nitrobenzene (Eastman Kodak Co.) was distilled before use to give a light yellow liquid, b.p. 81°, 7 mm, n_D^{25} 1.5203 (literature b.p. 225°, 744 mm (20, Vol. 3, p. 815)).

2,6-Dimethylphenol

Reagent grade 2,6-dimethylphenol (Eastman Kodak Co.) was twice sublimed before use to give white crystals, m.p. 43–44.5° (literature m.p. 49° (20, Vol. 4, p. 680)).

2,6-Dimethylanisole

Methylation of 2,6-dimethylphenol with dimethyl sulphate in alkali (21, p. 58) gave 69% of product from which a portion was redistilled to give a colorless liquid, b.p. 54°, 6 mm, n_D^{23} 1.5024 (literature b.p. 66–67°, 11 mm, n_D^{25} 1.5003 (22)).

N-*Methyl-2,6-dimethylaniline*

A mixture of 2.55 g (0.021 mole) of 2,6-dimethylaniline and 3.2 g (0.023 mole) of methyl iodide was heated under reflux for 30 minutes. The solid which formed was recrystallized from chloroform and acetone. The purified solid, 2.7 g, was then dissolved in 10% sodium bicarbonate and the solution extracted twice with ether. The ether extracts were dried over magnesium sulphate, then filtered, and the filtrate was distilled to remove the ether. The residue, 1.1 g (37%), was distilled through a Holtzmann column to give N-methyl-2,6-dimethylaniline, b.p. 73.5–74°, 6 mm, n_D^{25} 1.5347 (literature b.p. 87°, 13 mm (12)).

N,N-*Dimethyl-2,6-dimethylaniline*

Following the procedure of Brown and Grayson (19), N,N-dimethyl-2,6-dimethylaniline was prepared in 41% yield. The product distilled at 64–64.5°, 5 mm, n_D^{24} 1.5136 (literature b.p. 195°, 740 mm, n_D^{25} 1.5133 (19)).

2,6-Dimethylbenzonitrile

The nitrile was obtained in 37% yield from 2,6-dimethylaniline by diazotization and treatment with cuprous cyanide (21, p. 514). The product melted from 88–89.3° (literature m.p. 90–91° (23)).

2,6-Dimethylbenzoic Acid

The nitrile was converted to the amide by treatment with concentrated sulphuric acid and thence to the acid by heating with 100% phosphoric acid as described by Berger and Olivier (24). The acid after recrystallization from benzene melted from 115.5–116.5° (literature m.p. 115–116° (24)).

2,6-Dimethyliodobenzene

Following the procedure used for the preparation of iodobenzene (25, p. 351), 2,6-dimethylaniline was converted to the iodo compound in 14% yield. The product was a liquid, b.p. 98–99°, 9 mm (literature b.p. 228–230° (20, Vol. 3, p. 49)). Calc. for C_8H_9I: C, 41.4; H, 3.9. Found: C, 41.6; H, 3.7.

2,6-Dimethylbromobenzene

The procedure used for the conversion of *o*-toluene to *o*-bromotoluene (21, p. 135) was employed to convert 2,6-dimethylaniline into 2,6-dimethylbromobenzene in 15% yield. The product was a liquid, b.p. 74.5–75°, 7 mm, n_D^{25} 1.5532 (literature b.p. 206° (20, p. 379)). Calc. for C_8H_9Br: C, 51.8; H, 4.9. Found: C, 52.4, 51.9; H, 5.0, 5.0.

2,6-Dimethylfluorobenzene

This compound, although not previously prepared, was readily obtained from 2,6-dimethylaniline following exactly the procedure for the conversion of aniline to fluorobenzene (25, p. 295). The product was obtained in 40% yield as a liquid, b.p. 85°, 115 mm, n_D^{28} 1.4762. Calc. for C_8H_9F: C, 77.4; H, 7.3. Found: C, 77.6; H, 7.4.

2,6-Dimethylbenzene-1-d

The procedure for the preparation of this compound was kindly provided by Dr. L. C. Leitch (26). A mixture of 5 g of 2,6-dimethylaniline and 8 ml of heavy water (99.9%) containing a pellet of sodium hydroxide was stirred for 8 hours at 80°. The heavy water was separated in a separatory funnel and the exchange procedure was repeated twice more with fresh heavy water. The amine, 4.18 g (0.035 mole), was added to 12.1 ml of completely deuterated 50% hypophosphorous acid and 6.2 ml of heavy water and the mixture was cooled to −5° in an ice–salt bath. To this was added dropwise a solution of 2.38 g (0.035 mole) of sodium nitrite in 4.2 ml of heavy water keeping the temperature below 0°. The resultant solution was kept at 0° for 20 hours then extracted with ether. The extracts were dried over magnesium sulphate, filtered, and after removal of the ether under reduced pressure, distillation of the residue gave 0.7 g of colorless liquid, b.p. 65° (80 mm), whose N.M.R. spectrum gave no indication of contamination by other products.

Nitroethylene

This compound was prepared by the sequence recommended by Noland (27). The product was a lachrymatory yellow liquid, b.p. 43°, 90 mm, (literature b.p. 38–39°, 80 mm (28)).

ACKNOWLEDGMENTS

The author is grateful to Dr. W. G. Schneider for his helpful discussions. The author wishes to thank Dr. L. C. Leitch for providing the method of preparation of 2,6-dimethylbenzene-1-*d* and for a gift of deuterated hypophosphorous acid. The financial assistance

of the National Research Council of Canada is gratefully acknowledged. The author is also indebted to Mrs. V. Nicolson for technical assistance and to Miss E. Busk for the microanalyses.

THE MECHANISMS OF PERMANGANATE OXIDATION

VI. THE OXIDATION OF CYANIDE ION[1, 2]

ROSS STEWART AND R. VAN DER LINDEN[3]

ABSTRACT

Kinetic and oxygen-18 tracer experiments have been used in an attempt to elucidate the mechanism(s) of permanganate oxidation of cyanide. From pH 12 to 14.6 the oxidation is represented by the equation,

$$2MnO_4^- + CN^- + 2OH^- \rightarrow 2MnO_4^{=} + NCO^- + H_2O.$$

From pH 12 to 6 the reaction was found to be complex and unstoichiometric yielding cyanate, carbon dioxide, cyanide ion, and finally cyanogen at pH 9 to 6.

The rate of reduction of permanganate, as followed iodometrically and spectrophotometrically, is found to be markedly dependent on the pH of the medium and reactant concentration. The rate is negligible in acid solution but rapid in basic media.

At pH greater than 12 two parallel processes are indicated which have been designated as reaction A and reaction B. Reaction A appears at low reactant concentrations $<0.0004\ M$ cyanide and higher hydroxyl ion concentrations >pH 13 and is represented by the kinetic expression

$$\left(-\frac{d[MnO_4^-]}{dt}\right)_A = k_2[MnO_4^-][CN^-]$$

where k_2 is independent of hydroxyl ion concentration and is insensitive to the presence of manganate and barium ions. A positive salt effect is observed and labeling experiments using permanganate enriched in oxygen[18] showed that the oxygen introduced into the product cyanate comes mainly from the oxidant (70%–80% oxygen-18 transferred).

The existence of a second process reaction B was indicated by the changing kinetics at higher reactant concentrations and lower basicities, by the non-linear Arrhenius plots, and by the observation that only 15–25% oxygen-18 transfer from permanganate to substrate had occurred at pH 13. The rate of this latter process is approximately represented by the kinetic expression

$$\left(-\frac{d[MnO_4^-]}{dt}\right)_B = \frac{k_3[MnO_4^-][CN^-]^2}{[OH^-]}.$$

These reactions are discussed in terms of mechanism.

INTRODUCTION

The permanganate oxidation of cyanide ion in basic solution is known to be a quantitative reaction and has been used by Drummond and Waters (5) in their studies of the oxidation of organic compounds by various compounds of manganese. Little is known about the mechanism of this reaction, however. Preliminary work in these laboratories (6) indicated that a transfer of oxygen occurs since oxidation with permanganate enriched in oxygen-18 produced cyanate containing an excess of oxygen-18. The present work was undertaken to elucidate the mechanism of this reaction.

After this work was completed a report of a kinetic study of the permanganate–cyanide reaction by Freund appeared (7). He studied the reaction in the 0.035–0.18 M hydroxyl ion region and obtained the rate law

$$-d[MnO_4^-]/dt = k_2[MnO_4^-][CN^-]$$

with an energy of activation of 9.0 kcal/mole^{-1}.

EXPERIMENTAL

Product Analysis

1. Cyanogen

A method developed by Rhodes (8) for detecting cyanogen was used. Nitrogen gas was bubbled through the cooled, acidified reaction mixture after the oxidation displacing the gaseous cyanogen. This was washed free of hydrocyanic acid by passing the gas flow through two tubes containing acidified 10% silver nitrate solution, and then was passed into two tubes containing 0.5 *M* sodium hydroxide which can hydrolyze cyanogen quantitatively to cyanide and cyanate (9). Cyanide was then determined by a Liebig titration (10). Yields of cyanogen were much lower if the permanganate oxidation was carried out at room temperature or if the reaction mixture was allowed to stand for any length of time before acidification, owing mainly to extensive hydrolysis under these conditions. If the oxidation was carried out at pH 9 at room temperature no cyanogen was found nor was cyanogen found when freshly precipitated manganese dioxide was used as the oxidizing agent. Paracyanogen or cyanogen polymer could not be observed when the reaction mixture after oxidation was slightly acidified and the manganese dioxide reduced with sodium bisulphite to obtain a clear solution.

2. Cyanate

(*a*) Cyanic acid was converted quantitatively (11) to carbon dioxide and ammonia by acid hydrolysis and the latter was determined by the usual Kjeldahl method. Cyanogen was removed from the reaction solutions before carrying out the Kjeldahl analysis.

(*b*) A gravimetric method, found to be reliable, involved the precipitation of cyanate as the silver salt after neutralization of the alkaline reaction mixtures to pH 5. This method cannot be used when the oxidation is carried out below pH 11, since cyanide, recovered in the reaction mixture, is precipitated as silver cyanide.

3. Carbon Dioxide

The total CO_2 content of the reaction mixtures was determined by using the same technique as for the analysis of cyanogen. Nitrogen was bubbled through the acidified oxidation mixture in which the cyanate has been hydrolyzed to CO_2, then through an acidified 10% silver nitrate solution into two tubes containing standard barium hydroxide solution. The unneutralized barium hydroxide was then titrated with standard acid. The amount of carbon dioxide which is produced in the oxidation at a given pH is the total amount minus the amount produced by cyanate hydrolysis.

4. Cyanide

Cyanide was analyzed by the usual Liebig titration. Below pH 12, where a 2:3 molar ratio of permanganate–cyanide is used, the precipitated MnO_2 was first removed by filtration. Above pH 12, where a 2:1 molar ratio is used, barium nitrate was added initially to the reaction mixture to precipitate insoluble barium manganate, which was then removed by filtration.

Reagents

Reagent grade chemicals were used. Potassium permanganate–O^{18} was prepared as previously described (1).

Alkaline manganate solutions were prepared by the method of Pode and Waters (12). The oxidizing power and alkalinity of the solutions were determined by an iodometric and hydrochloric acid titration methods respectively. A small correction to the alkalinity is required due to disproportionation of manganate. When manganate solutions were diluted, the solution was not allowed to become less basic than 0.01 *M* sodium hydroxide.

Kinetic Methods

Iodometric and spectrophotometric methods were used to follow the rate of reduction of permanganate and an argentimetric method was used to follow the rate of oxidation of cyanide.

1. Iodometric Method

In a typical kinetic run 50-ml samples were pipetted into 125-ml glass-stoppered Erlenmeyers and the Erlenmeyers brought to a temperature of 25±0.05° in a constant temperature bath. After addition of the permanganate these aqueous solutions became 0.1 *M* in KOH, 0.00024 *M* in KCN, 0.0005 *M* in $KMnO_4$, and 0.0363 *M* in K_2SO_4 ($\mu = 0.2$).

The reaction was initiated by introducing 4.73 ml of 0.00574 *M* permanganate solution with manual stirring from a rapid delivery pipette. The reaction was quenched at a given time interval with an acidified potassium iodide solution and the liberated iodine was titrated immediately with thiosulphate solution. In most cases at least eight points were obtained for the kinetic plots. The procedure for following the rate of manganate oxidation of cyanide was similar except that equimolar concentrations of reactants were used.

2. Spectrophotometric Method

This was essentially the same as that previously described with light absorption measurements being made at 522 and 426 mμ (3).

3. Argentimetric Method

In a typical kinetic method for following the rate of oxidation of cyanide the solutions were made up as for the iodometric method. Then 4.92 ml of 0.0116 *M* permanganate solution was added to each solution to start the reaction. The reaction was timed and then quenched with 1 drop of 30% hydrogen peroxide and the manganese dioxide filtered off. The clear solution was then titrated for cyanide by the Liebig method using 0.05 *M* silver nitrate solution.

4. Fast Reaction Kinetics

For very fast reactions the disappearance of permanganate was followed with the aid of an automatic quenching and timing device like that described by Sheppard and Wahl (13).

Oxygen-18 Tracer Techniques

1. Oxidation of Cyanide with Permanganate–O^{18}

Procedure (a): Silver cyanate obtained under stoichiometric reaction conditions.—A typical experiment was performed as follows. Over-all conditions: volume of solution 55 ml; approximate alkalinity 4 *M*; $[CN^-]_0 = 0.0195$ *M*. To a 125-ml glass-stoppered Erlenmeyer was added 0.304 gram of potassium permanganate (0.00192 mole; 1.114% enriched in O^{18}) dissolved in 25 ml boiled distilled water, 10 ml of 0.2 *M* barium nitrate solution, and 14 ml of 15.8 *M* sodium hydroxide carbonate free solution. The solution was cooled and immediately 5.5 ml of 0.195 *M* (0.00107 mole) potassium cyanide solution was pipetted into the stirred alkaline permanganate solution. The reaction mixture was allowed to stand for approximately 5 minutes at room temperature. The solution was centrifuged and the supernatant liquid filtered through a sintered glass funnel to remove the remaining insoluble barium manganate. The clear alkaline solution was then neutralized to pH 5 with dropwise addition of 4 *M* nitric acid. The neutralizing mixture was cooled in an ice bath while the solution was vigorously stirred with a magnetic stirring arrangement. Four milliliters of 0.5 *M* silver nitrate solution was added, silver cyanate was allowed to

settle and filtered on a sintered glass funnel, washed, and then dried over P_2O_5 under vacuum.

Procedure (b): Silver cyanate obtained using a twofold excess permanganate-O^{18}.—When a twofold excess of labeled permanganate was used, the excess permanganate was reduced with a few drops of 30% hydrogen peroxide after the reaction mixture was allowed to stand for 2 minutes. After filtration and centrifugation of the managanese dioxide – barium manganate precipitate, the solution was neutralized and the silver cyanate precipitated as in the previous procedure.

Procedure (c): Silver cyanate obtained under dilute reaction conditions.—Over-all conditions: volume of solution 500 ml of water; alkalinity 0.2 M; $[CN^-]_0 = 2.2\times10^{-3}$ M; $[MnO_4^-]_0 = 2.27\times10^{-3}$ M. To a 1000-ml stoppered Erlenmeyer was added 0.172 (0.00109 mole) of labeled permanganate dissolved in 300 ml of water, 5.6 grams of barium nitrate dissolved in 150 ml of water, than 49 ml of 2.04 M sodium hydroxide solution. To the vigorously stirred mixture was added 10 ml of 0.1088 M (0.00109 mole) potassium cyanide solution. The reaction mixture was allowed to stand until the permanganate color had disappeared (approximately 15 minutes) and then the combined silver cyanide – silver cyanate precipitate was obtained as before.

2. Determination of Oxygen Exchange Between Cyanate and H_2O^{18}

A typical experiment was performed as follows: A sample of recrystallized potassium cyanate (0.092 gram, 0.00113 mole) was weighed into a 4-ml stoppered flask and dissolved with 2 ml of water (>1.4% enriched in O^{18}). The pH of the solution, as measured on a Beckman Model G pH meter, was varied by addition of concentrated sodium hydroxide or dilute nitric acid. The solution was allowed to stand in a constant temperature bath at 25° for 30 minutes. The acidified solution was transferred to a 5-ml centrifuge tube and the cyanate precipitated with silver nitrate solution. The precipitate was centrifuged, the liquid decanted, and the solid washed with water. The wet precipitate was transferred to a 5-ml beaker, dried over calcium chloride and then over P_2O_5 under vacuum.

3. O^{18} *Analysis of Silver Cyanate*

Two methods, sulphuric acid decomposition and pyrolysis, were found suitable for converting silver cyanate to carbon dioxide which could be conveniently analyzed for O^{18} content by mass spectrometric analysis.

Method (a).—The silver cyanate was dropped on to concentrated sulphuric acid and the evolved carbon dioxide was collected. This method is similar to that previously used (12) except that break seals were used to transfer the gas to the mass spectrometer. The amount of excess O^{18} found in the silver cyanate can be calculated using the following equation (1); natural abundance of O^{18} = 0.204%.

$$\%\ \text{O from permanganate} = \frac{2y-0.408}{x-0.204}\times 100,$$

where

$$2y = \frac{I_{\text{mass}}46}{I_{\text{mass}}44 + I_{\text{mass}}46},$$

$$x = \%\ O^{18}\ \text{in}\ KMnO_4 = 1.114.$$

Method (b).—The silver cyanate samples were decomposed under a low flame using the same apparatus as for the previous method. The carbon dioxide produced was collected and analyzed in a mass spectrometer. Other gases were produced in the decomposition as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

observed by scanning the mass spectrum of the gaseous material but unlabeled silver cyanate on decomposition gave the expected normal isotopic abundance for O^{18}. The amount of O^{18} found in the silver cyanate can be calculated using a similar equation except that now all the oxygen in the carbon dioxide comes from the silver cyanate.

$$\% \ O^{18} \text{ from permanganate} = \frac{y-0.204}{x-0.204} \times 100,$$

where

$$2y = \frac{I_{mass}46}{I_{mass}46 + I_{mass}44},$$

$$x = \% \ O^{18} \text{ in } KMnO_4 = 1.114.$$

Similar results were obtained when samples of silver cyanate were subjected to analysis by both methods.

RESULTS

Kinetic Results

The rate constants were calculated using the following equations (1). For the iodometric method

$$k_2 = \frac{1}{[CN^-]_0 \times t} \times \frac{V_0 - V_t}{V_t - 4/5 V_0}$$

where V is the volume of thiosulphate solution required in the titration. When $(V_0 - V_t)/(V_t - 4/5 V_0)$ was plotted against time, linear plots were obtained over a limited reactant and hydroxyl ion concentration range. Linear second-order rate plots were obtained in some cases to 70% completion of the reaction although most plots were taken to 50% completion. Second-order rate constants (k_2, liter mole^{-1} sec^{-1}) were calculated from the slopes.

For the spectrophotometric method the following equation was used, where D is optical density at the indicated wavelength (3):

$$[MnO_4^-] = \frac{D_{522} - 0.282 D_{426}}{2248}.$$

The usual integrated second-order rate expression was applied to the rate data.

Plots of reciprocal of the permanganate concentration versus time were found to be linear up to approximately 50% reaction (Fig. 1) and second-order rate constants were calculated. The plots become non-linear and variable if the reaction was taken beyond 50% completion of the reaction possibly from light scattering due to precipitation of manganese dioxide caused by disproportionation of manganate.

The rate expression

$$-\frac{d[MnO_4^-]}{dt} = k_2[CN^-]\,[MnO_4^-]$$

is in agreement with the observed kinetics over a limited reactant and hydroxyl ion concentration range. The second-order rate constants k_2, liter mole^{-1} sec^{-1}, obtained by both spectrophotometric and iodometric kinetic methods are in good agreement and indicate that the rate constants, calculated from the rate plots, are reliable (Table I).

For personal use only.

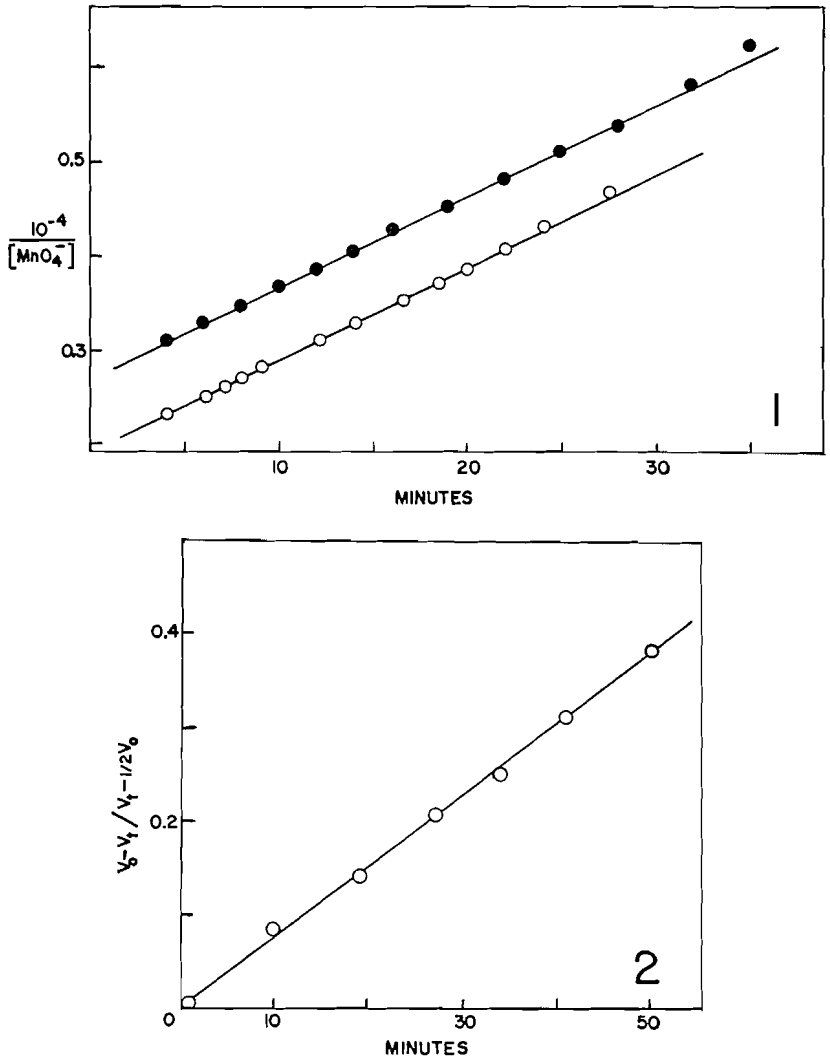

FIG. 1. Second-order rate plots for the permanganate–cyanide reaction by the spectrophotometric method.
$[OH^-] = 0.1\ M$, $T = 25°$, $k_2 = 3.20$ l. mole^{-1} sec^{-1}. ● $[MnO_4^-]_0 = 2[CN^-]_0 = 3.67\times10^{-4}$ mole/l.; ○ $[MnO_4^-]_0 = 2[CN^-]_0 = 5.13\times10^{-4}$ mole/l.

FIG. 2. Second-order rate plot for the manganate–cyanide reaction.
$[MnO_4^-]_0 = [CN^-]_0 = 3.27\times10^{-3}$ mole/l., $[OH^-] = 0.125\ M$, $T = 25°$, $k_2 = 0.039$ l. mole^{-1} sec^{-1}.

Observation of Table II with reference to Table I indicates that the second-order rate constants are relatively insensitive to additions of initial amounts of manganate ions and barium ions. Strontium nitrate was used to replace barium nitrate in one experiment in order to keep the ionic strength constant. Addition of initial amounts of manganate to the reaction mixture was possible since this species oxidizes cyanide 80 times slower than permanganate (Fig. 2).

Data from Table I and Table III indicate that the second-order reaction is independent of the hydroxyl ion concentration under constant ionic strength conditions. For example, a 25-fold change in hydroxyl ion concentration does not change k_2 appreciably.

If increasing amounts of an inert electrolyte (potassium sulphate or potassium nitrate) are added to the reaction mixtures an increase in rate is observed at 0.1 M potassium hydroxide (Table IV and Table III). A primary positive salt effect is observed when log k_2 is plotted against $\sqrt{\mu}$ giving a straight line of slope +1 (Fig. 3). This agreement with the value expected from the Brönsted–Debye–Hückel relationship is rather surprising since this is a region of high ionic strength.

In order to determine the activation parameters a temperature study was done at 0.1 M and 0.2 M potassium hydroxide (Fig. 4 and Table V). When Arrhenius-type plots were made, linear plots were not obtained indicating that a more complex process was taking place than was implied by the simple rate expression given previously.

Since the kinetics indicate the presence of more than one mode of oxidation of cyanide by permanganate, the reaction conditions under which the second-order process (referred

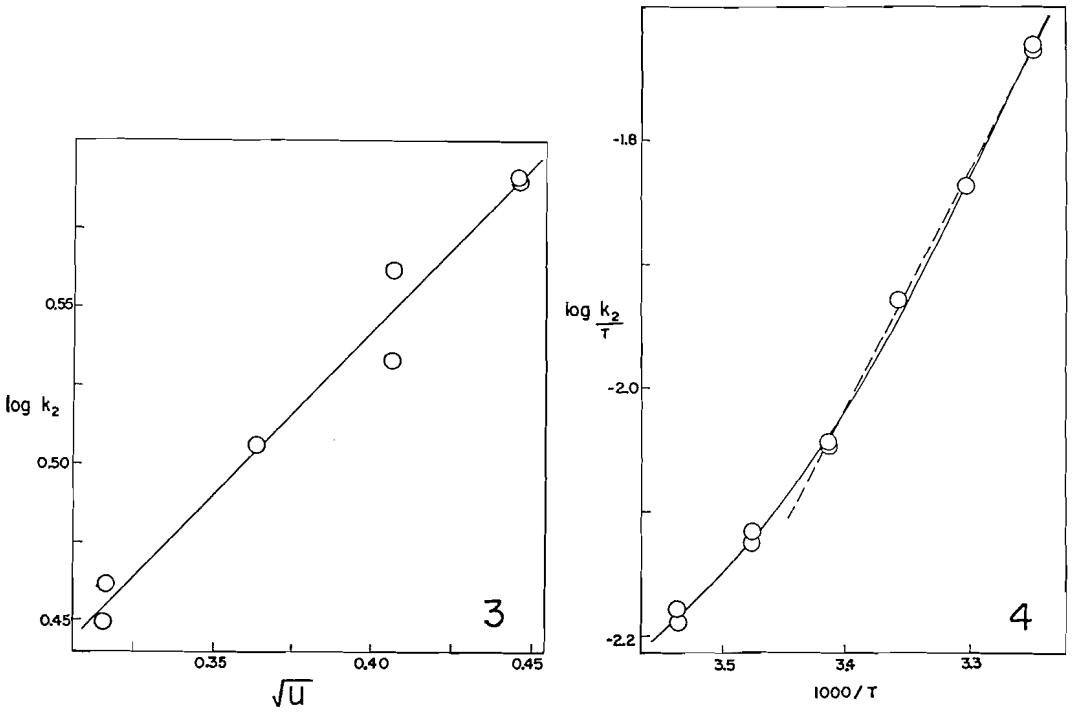

FIG. 3. Log k_2 vs. the square root of the ionic strength for the alkaline permanganate oxidation of cyanide. Slope = 1.0.

FIG. 4. Effect of temperature change on the rate of the permanganate–cyanide reaction in 0.2 *M* KOH. The straight line gives $\Delta H^{\ddagger} = 8.7$ kcal mole^{-1} and $\Delta S^{\ddagger} = -27$ e.u.

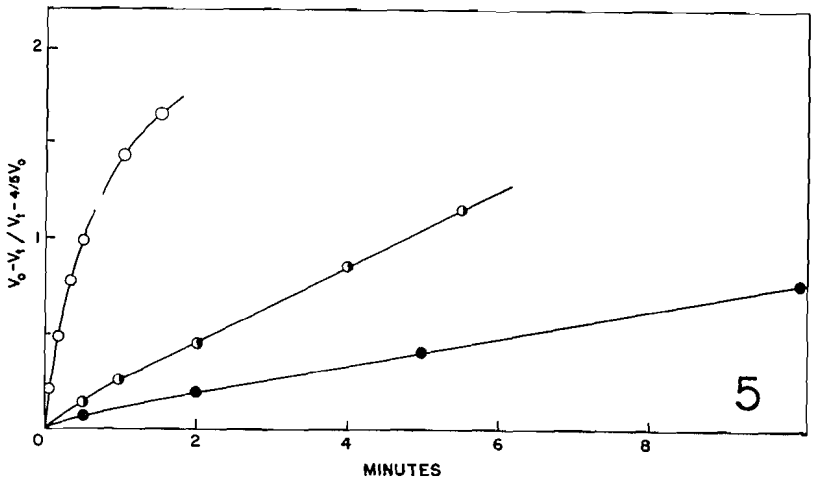
If second-order rate plots are attempted at higher concentration of reactants at the *same alkalinity* (Fig. 5) or lower alkalinities at the *same concentration of reactants* (Fig. 6), non-linear second-order rate plots are obtained and the rate was found to decrease with time. Under intermediate conditions (Fig. 6) the initial second-order rate plots are non-linear, becoming linear when the concentration of the reactants has been reduced.

The presence of a second mode of oxidation of cyanide is indicated (reaction B). Its rate appears to be a different function of concentration than the second-order process observed at lower concentrations and its rate is inhibited by high hydroxyl ion concentration. In an attempt to separate the two suspected reactions, concentration versus time plots were made for the rate data (Fig. 7) which gave non-linear second-order kinetics. These curves were smoothed and the slopes $(-d[MnO_4^-]/dt)_{A+B}$ obtained at various times.

Consider two parallel reactions contributing to the over-all rate,

$$\left(-\frac{dMnO_4^-}{dt}\right)_{A+B} = \left(-\frac{dMnO_4^-}{dt}\right)_A + \left(-\frac{dMnO_4^-}{dt}\right)_B,$$

where



$$\left(-\frac{dMnO_4^-}{dt}\right)_A = \tfrac{1}{2}k_2[MnO_4^-]^2,$$

and

$$\left(-\frac{d[MnO_4^-]}{dt}\right)_B \propto [MnO_4^-]^n.$$

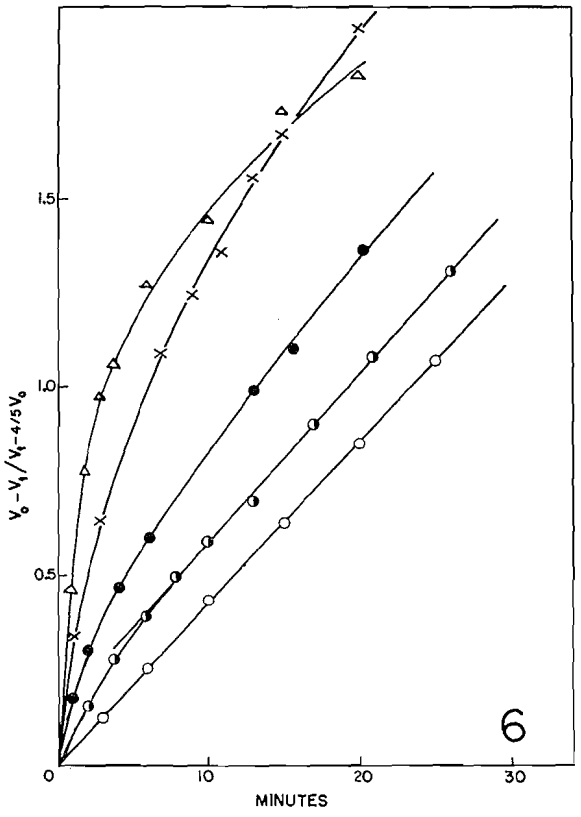

FIG. 5. Variation of the second-order rate function with reactant concentration in 0.1 M NaOH. $T = 25°$, $\mu = 2(KNO_3)$, $[MnO_4^-]_0 = 2[CN^-]_0$. ○ $[CN^-]_0 = 7.49\times10^{-4}$; ◑ $[CN^-]_0 = 4.04\times10^{-4}$; ● $[CN^-]_0 = 2.02\times10^{-4}$ mole/l.

FIG. 6. Variation of the second-order rate function with hydroxyl ion concentration. $[MnO_4^-] = 2[CN^-]_0 = 5.06\times10^{-4}$ mole/l., $\mu = 0.1$ (K_2SO_4), $T = 25°$. Δ = 0.01 M KOH; × = 0.02; ● = 0.04; ◑ = 0.06; ○ = 0.10.

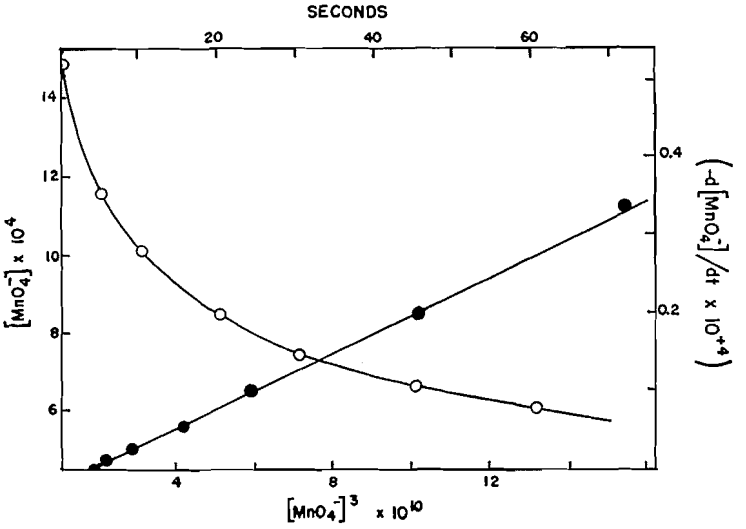

FIG. 7. Concentration vs. time (○) and the third-order rate plot (●) for the permanganate–cyanide reaction.
$[CN^-]_0 = 7.49\times10^{-4}$ mole/l., $[OH^-] = 0.1\ M$, $\mu = 2.0$.

Substituting for reaction A in the above equation and rearranging

$$\left(-\frac{d[MnO_4^-]}{dt}\right)_B = \left(-\frac{d[MnO_4^-]}{dt}\right)_{A+B} - \tfrac{1}{2}k_2[MnO_4^-]^2.$$

Therefore if k_2 is known at the same ionic strength and temperature and since reaction A is found to be independent of hydroxyl ion concentration, the rate of reaction A can be subtracted from the over-all rate.

A plot of $(-d[MnO_4^-]/dt)_B$ versus $[MnO_4^-]^3$ gives a straight line (Fig. 7). This technique was applied to a number of rate plots which gave non-linear second-order kinetics. The results although qualitative indicated that the reaction is third order and that the reaction is inhibited by hydroxyl ions.

Thus
$$\left(-\frac{d[MnO_4^-]}{dt}\right)_B = k_3[MnO_4^-]^3.$$

In order to determine the dependence of rate of reaction B on hydroxyl ion concentration more accurately, another plot using initial rates as obtained from the rate data from pH 12 to 13 was made. The initial point of the concentration–time plot was used to obtain $(-d[MnO_4^-]/dt)_{A+B}$ (Table VI).

The data in Table VI show that the initial rate multiplied by the hydroxyl ion concentration is very roughly a constant indicating that

$$k_3 \approx \frac{k_3'}{[OH^-]}.$$

The next stage in the investigation of this third-order process (reaction B) was to examine the kinetics of the very fast reaction when a 10-fold excess cyanide was used. Though the results are only qualitative a plot of log $[MnO_4^-]$ versus time (Fig. 8) at 0.03 *M* NaOH was approximately first order in permanganate after the first 5 seconds.

In an attempt to determine whether manganate was involved in a prior equilibrium step barium ions were added initially to the kinetic mixture. No marked change in rate was observed at 0.01 *M* and 0.04 *M* sodium hydroxide when insoluble barium manganate was precipitated. Also checks were made under various conditions using strontium nitrate to keep the ionic strength constant with no variation in rate being observed.

The spectrophotometric kinetic method led to marked non-linear second-order rate plots only at lower hydroxyl ion concentration, e.g. (0.02 *M* sodium hydroxide, μ = 0.1), since the permanganate and cyanide concentration used in this method were necessarily lower than those concentrations used in the iodometric method. It was observed that reaction B was greatly accelerated by increases in ionic strength.

Reduction of manganese to a lower valence state was considered as a possible cause for the observed faster reactions at lower alkalinities and higher reactant concentrations. If a deep-seated oxidation was taking place reducing permanganate or manganate to

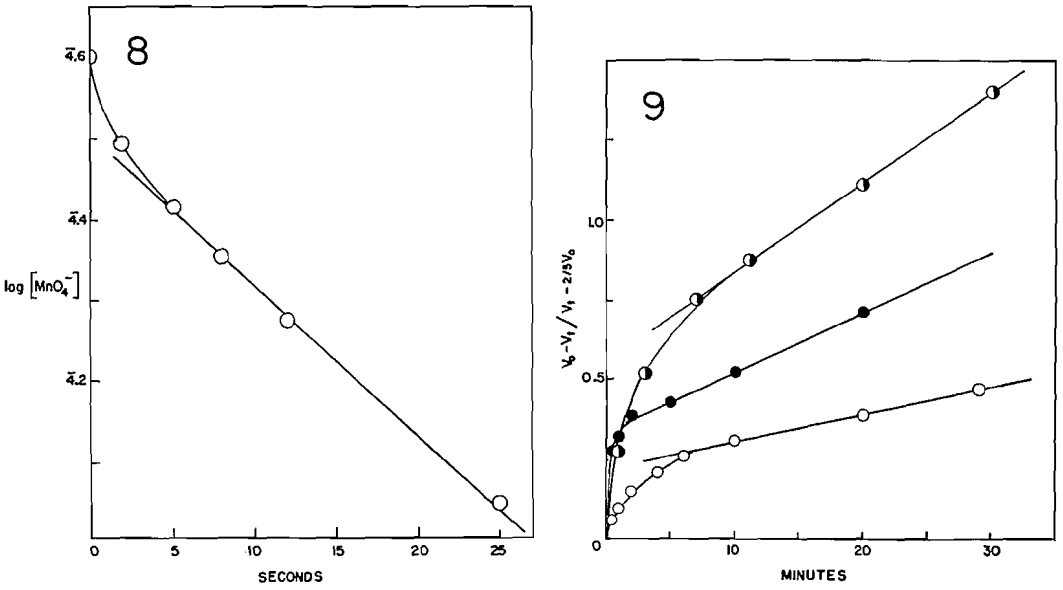

FIG. 8. Rate of disappearance of permanganate in presence of excess cyanide.
$[CN^-]_0 = 20.3 \times 10^{-4}$ mole/l., $[MnO_4^-]_0 = 4.03 \times 10^{-4}$ mole/l., $[OH^-] = 0.03$ mole/l., $T = 25°$, $k_1 = 0.0336$ sec^{-1}.

FIG. 9. Second-order rate function vs. time for the permanganate–cyanide reaction in weakly basic solution.

lower oxidation states, an excess of cyanide over permanganate should be observed as reaction proceeds. Therefore, the argentimetric method for following the rate of oxidation of cyanide was developed. Observation of the concentration–time plots, obtained by both argentimetric and iodometric methods for the faster process at 0.1 *M* and 0.01 *M* sodium hydroxide, indicate that the stoichiometric concentrations (in this case $[MnO_4^-]$:$[CN^-]$ 2:1 molar ratio) holds throughout a major portion of the plot.

Early in the kinetic study a number of rate plots were obtained for the reaction at low pH's, and a few of these plots are presented (Fig. 9). Since the kinetics were more complex than those studied in more basic solution, a relative rate study was undertaken. This was accomplished by measuring the rate of the permanganate–cyanide reaction over a wide pH range, stopping the reactions at a given time interval. The extent of the reduction of permanganate was determined in an iodometric titration and $V_0 - V_t$ plotted against pH for a number of reaction conditions (Fig. 10).

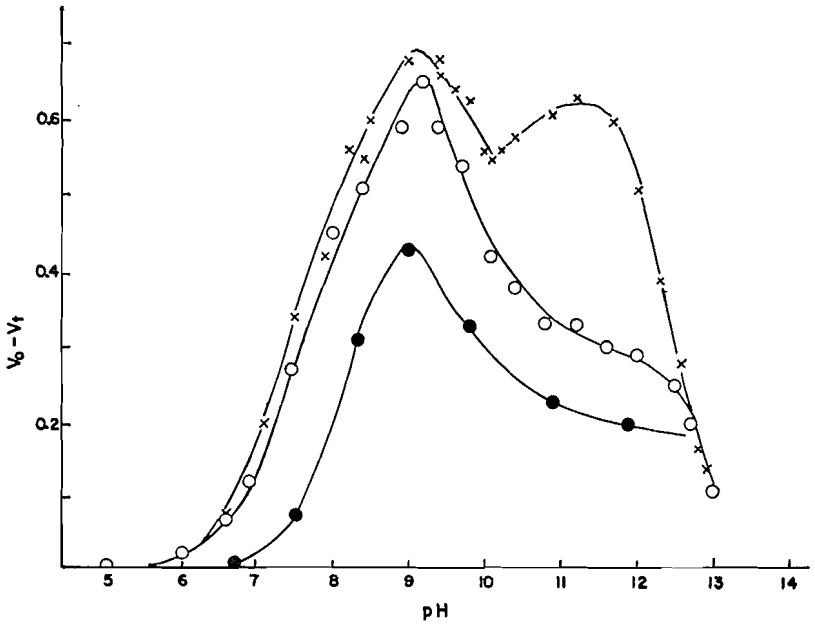

FIG. 10. Volume of thiosulphate consumed in a fixed time interval for the permanganate–cyanide reaction.

$T = 25°$, $\mu = 0.1$. ● $[CN^-]_0 = 3/2[MnO_4^-]_0 = 2.53\times10^{-4}$ mole/l., time interval = 2 minutes; ○ $[CN^-]_0 = 3/2[MnO_4^-]_0 = 2.09\times10^{-4}$ mole/l., time interval = 5 minutes; × $[CN^-]_0 = \frac{1}{2}[MnO_4^-]_0 = 2.09\times10^{-4}$ mole/l., time interval = 2 minutes.

Two important results might be noted:

(*a*) The rate of the permanganate-cyanide reaction is negligible in acid solution and increases markedly with increasing basicity.

(*b*) The maximum rate of the relative rate plots appears at the pK_a of HCN (pH = 9).

Oxygen-18 Tracer Results

Observation of Table VII shows that a transfer of oxygen has occurred from the oxidizing agent permanganate to the substrate cyanide. The percentage of O^{18} transferred appears to depend on the molar ratio and concentration of reactants as well as the alkalinity used in the experiments.

In order to determine whether the product cyanate exchanges its oxygen with the solvent, cyanate was equilibrated with H_2O^{18} (<1.4% enriched) for 30 minutes at 25° at various acidities (six experiments were performed over a pH range from 5 to 14.6). In all experiments a negligible amount of O^{18} (0 to 2%) was found in the cyanate recovered as the silver salt, indicating that cyanate does not exchange its oxygen with the solvent in the time required to perform the oxidation.

The variation in the amount of O^{18} transferred under apparently similar conditions (e.g., 4 M sodium hydroxide) is difficult to explain but it should be pointed out that exchange reactions (14) can serve only to decrease the apparent transfer of O^{18} and, therefore, the maximum percentage transfer at any given pH can be used as a criterion of mechanism.

The O^{18} tracer and kinetic data will be discussed in terms of mechanism further in the paper, but the important features of the tracer data might be itemized as follows:

(*a*) The maximum percentage of O^{18} transferred in any experiment was 82% in 4 M sodium hydroxide at 50°.

(*b*) A general increase in percentage of O^{18} transferred is observed as the alkalinity is increased from 0.04 M to 6 M sodium hydroxide, i.e., fourfold increase (Fig. 11).

(*c*) The low percentage of O^{18} transferred at 0.1 M sodium hydroxide is not affected when the reaction is carried out at high ionic strength, i.e., $\mu = 4$.

(*d*) Almost a twofold increase in O^{18} transfer occurred on diluting the reaction mixture by eightfold at 0.4–0.5 M sodium hydroxide whereas at 0.02–0.04 M sodium hydroxide no change in percentage transfer took place.

(*e*) No further increase in O^{18} transfer is observed when the reaction is carried out with excess permanganate–O^{18} at 4 M base whereas an approximate twofold increase is observed at 0.1 M sodium hydroxide.

(*f*) In weakly basic solution, pH <12, only a small percentage of the oxygen introduced into cyanate originates from the oxidant.

DISCUSSION

The correlation of kinetic, oxygen-18 tracer, and analytical data which were of necessity obtained under different reaction conditions presents considerable difficulty. The kinetic data could only be conveniently obtained under low reactant concentration conditions where the rate was relatively small, whereas oxygen[18] tracer and analytical experiments necessitated in most cases considerably higher reactant concentrations.

The main features of the analytical data obtained for the permanganate–cyanide reaction over the pH range 6 to 14.6 are the following: Above pH 12 the sole product of the reaction is cyanate in almost quantitative yield; below pH 12 the reaction becomes increasingly unstoichiometric, yielding cyanate, carbon dioxide, cyanide, and finally cyanogen, which is isolated at pH 9 to 6. Cyanogen is presumably formed at higher basicities in these reaction mixtures but hydrolysis is very rapid at any pH greater than 9.

A fair material balance was obtained for the reaction over most of the pH range studied except for nitrogen (Table VIII). The presence of cyanogen in the reaction mixture (15) gives a ready explanation for the production of carbon dioxide through a deep-seated oxidation with permanganate and consequent recovery of cyanide, since cyanogen is known to hydrolyze readily in aqueous solutions to a number of easily oxidizable compounds (16, 17). As a consequence most of the kinetic and oxygen-18 tracer experiments were performed in alkaline solution above pH 12.

The rate of permanganate oxidation of cyanide is found to be markedly dependent on

the pH of the medium and on the reactant concentrations. Thus the rate of reaction is negligible in acid solution at pH 6 or less, and above pH 7 the rate increases rapidly as the solution becomes more alkaline, reaching a maximum rate at pH 9.1. At this point the rate decreases again as the alkalinity is increased and at pH 13 (depending on reactant concentration) the rate levels off and becomes independent of pH except for an ionic strength effect (Fig. 29).

Two reaction paths, A and B, are indicated. Since the experimental evidence for reaction A is more clear-cut, this process will be discussed first.

Route A

(1) Second-order kinetics are observed over a limited reactant and hydroxyl ion concentration range indicating that the rate expression

$$\left(-\frac{d[MnO_4^-]}{dt}\right)_A = k_2[MnO_4^-]\,[CN^-]$$

holds for reaction A.

(2) A primary positive salt effect was observed indicating that the slow step was between two like singly charged ions, presumably permanganate and cyanide ions. This result is surprising in this case in view of the fact that the Brönsted–Debye–Hückel relationship normally holds for reactions carried out under more dilute aqueous conditions. Though the result is qualitatively correct, the close correlation to theory may be the result of an increased contribution from reaction B which is strongly ionic strength dependent.

(3) At constant ionic strength or under saturated salt conditions k_2 is found to be independent of the hydroxyl ion concentration, i.e., from 0.1 *M* to 2.4 *M* sodium hydroxide at low reactant concentrations. An increase in rate is observed at high alkalinities but in this region the effect of various electrolytes on the activity coefficients of the reacting molecules is difficult to predict and this effect will not be considered further here.

(4) The rate is not affected by the presence of initial quantities of manganate or barium ions. If an equilibrium was present such as

$$MnO_4^- + CN^- \rightleftharpoons MnO_4^{=} + CN\cdot,$$

an initial concentration of manganate should retard the reaction whereas the presence of barium ions would precipitate barium manganate and thereby increase the rate of reaction.

(5) The oxygen introduced into the product cyanate comes predominantly *from* the oxidizing agent rather than from the solvent. The maximum percentage of O^{18} transferred,

For personal use only.

80%, occurred when the tracer experiments were carried out at high alkalinities, e.g., 4 *M* sodium hydroxide. An explanation is necessary at this point. Most of the kinetic data was obtained in the low hydroxyl ion concentration region, 0.1 to 0.2 *M* potassium hydroxide, where only 15 to 25% O^{18} transfer was observed. The discrepancy between the kinetic and O^{18} results at low base concentrations is probably due to the large reactant concentration difference which exists between the two series of experiments, e.g., 0.02 *M* cyanide for the tracer experiments and 0.0004 *M* cyanide for the kinetic experiments. When the alkalinity is increased in the O^{18} tracer experiments, a gradual increase in percentage of O^{18} transfer is observed (Fig. 11) whereas k_2 remains essentially constant (Table III) for the same increase in base concentration, thus indicating that reaction A (the second-order process) involves the oxygen transfer mechanism. The changing kinetics at higher reactant concentrations at 0.1 to 0.2 *M* potassium hydroxide tends to confirm these ideas. In this connection a twofold increase in percentage of O^{18} transferred was observed at 0.5 *M* sodium hydroxide when the reactants were diluted eightfold as would be expected if reaction A was favored at the lower reactant concentrations.

(6) Though Arrhenius-type plots were made using the rate constants obtained under conditions where apparently only one reaction process was present, non-linear plots were observed. Approximate values of $\Delta H^{\ddagger} = 8.7$ kcal/mole and $\Delta S^{\ddagger} = -27$ e.u. were obtained for the study at 0.2 *M* potassium hydroxide. This enthalpy of activation corresponds very closely to that calculated from Freund's results (7), and the entropy of activation is reasonable for a reaction between two anions. The significant curvature observed in the plots further indicates the possibility that two processes are present each with a different activation energy.

A mechanism which fits most of the data for reaction A is the following:

$$MnO_4^- + CN^- \xrightarrow{k_2} (NC - - - O - - - MnO_3)^= \rightarrow MnO_3^- + {}^-OCN,$$

$$MnO_3^- + MnO_4^- + 2OH^- \xrightarrow{\text{fast}} 2MnO_4^= + H_2O.$$

The existence of a Mn(V) species as a reaction intermediate in permanganate oxidations has been well established (18).

Route B

Although the kinetic data for reaction B is of a qualitative nature certain aspects of this study, in particular, the O^{18} tracer experiments and the observation that cyanogen was produced in the reaction at lower pH, suggest a reasonable reaction path.

Linear third-order kinetic plots were obtained for some of the rate data. In some instances a much faster decrease in rate with time was observed for the initial portions of the rate plots than would be predicted for a third-order process, thus indicating that still more complex processes were occurring.

If the third-order kinetic relation is assumed to be due to a first-order dependence on permanganate ion and a second-order dependence on cyanide ion and if the approximately inverse dependence on hydroxyl ion is indeed correct the following relations hold for route B:

$$(-d[MnO_4^-]/dt)_B = k_3[MnO_4^-][CN^-]^2$$

$$= k_3' \frac{[MnO_4^-][CN^-]^2}{[OH^-]} \qquad \text{since } k_3 = k_3'/[OH^-]$$

$$= \frac{k_3' K_a}{K_w} [MnO_4^-][HCN][CN^-],$$

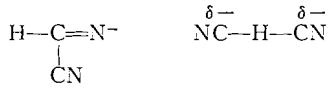
where K_a and K_w are the ionization constant and ion product of hydrocyanic acid and water, respectively.

A possible mechanism for route B is the following:

$$MnO_4^- + HCN + CN^- \xrightarrow{\text{slow}} MnO_4^{=} + (CN)_2^- + H^+$$

$$(CN)_2^- + MnO_4^- \xrightarrow{\text{fast}} (CN)_2 + MnO_4^{=}$$

$$(CN)_2 + 2OH^- \xrightarrow{\text{fast}} CN^- + NCO^- + H_2O$$



In this connection Adamson (19) has suggested that $(CN)_2^-$ is present as an intermediate in the ferricyanide oxidation of cyanide.

It is worth comparing the behavior of permanganate towards cyanide ion and towards formate ion. The latter has been shown by Taylor and Halpern to be oxidized by permanganate about 2000 times faster at room temperature than the neutral formic acid molecule (20). This is a rather similar situation to the cyanide reaction, the difference being that for the latter a path involving both a HCN molecule and a cyanide ion appears to exist (route B). If a species $H(CN)_2^-$ is in equilibrium with HCN and CN^- it could be oxidized by permanganate by a hydride transfer mechanism which would produce Mn (V) and cyanogen, which would then yield the observed reaction products.

$$HCN + CN^- \rightleftharpoons H(CN)_2^-$$

$$MnO_4^- \overset{\curvearrowleft}{H}\text{—}(CN)_2^- \rightarrow HMnO_4^{=} + (CN)_2 \rightarrow \text{products}$$

The hypothetical species $H(CN)_2^-$ might have either of the following structures,* the second being merely a hydrogen-bonded form.

An electron transfer from cyanide ion to permanganate ion is probably not an energetically reasonable step although electron transfer from hydroxyl ion to permanganate ion appears to take place in strongly basic solution (21, 22).

Finally it should be mentioned that hydrogen cyanide can be added to the list of compounds for which the anion reacts very much faster with permanganate ion than does the neutral molecule (23). These include alcohols (3, 24), formic acid (2, 20), and water (21, 22).

THE ROLE OF REACTION PRODUCTS IN THE SILVER-CATALYZED OXIDATION OF ETHYLENE[1]

KENNETH E. HAYES[2]

ABSTRACT

Initial-rate studies of the kinetics of the silver-catalyzed oxidation of ethylene oxide and carbon dioxide in a flow system have been made. It was found that, using carefully purified reactants, the effect of added carbon dioxide was to suppress the formation of ethylene oxide only. The initial rate of the formation of ethylene oxide is given by the equation

$$r = r^0\left(m + \frac{n}{1+kP_{CO_2}}\right) = r^0\left(\frac{1+mkP_{CO_2}}{1+kP_{CO_2}}\right)$$

where r^0 is the initial rate in the absence of CO_2; m, n, and k are constants with $m+n = 1$.

These results together with the results of oxygen exchange reactions between O^{18} and $C_2H_4O^{16}$, CO_2^{16} and H_2O^{16} are interpreted mechanistically.

INTRODUCTION

The silver-catalyzed oxidation of ethylene has been investigated by a large number of workers in the last 10 years: the researches of Twigg (1), Murray (2), and Orzechowski and MacCormack (3) should particularly be mentioned. At the time that this investigation was started there was no quantitative information regarding the influence of the reaction products on the reaction. This investigation was undertaken with a view to rectifying this omission, and also with the hope of obtaining a more detailed knowledge of the mechanism of the reaction.

EXPERIMENTAL

The apparatus used to investigate the role of carbon dioxide and water vapor on the rates of formation of ethylene oxide and carbon dioxide was essentially a conventional flow system as shown schematically in Fig. 1.

The nitrogen, oxygen, and ethylene, all of a nominal purity of 99.5% or better, were passed from their respective cylinders through purification trains consisting of (A) anhydrous magnesium perchlorate (anhydrone), (B) activated charcoal, (C) KOH pellets, (D) silver turnings, and then through U-tubes immersed in solid carbon dioxide/isopropyl alcohol at −80° C. From the purification trains the gases passed through their respective capillary flowmeters, the flow being controlled by "Edward's LB2" fine control needle valves; through more silver turnings; and then through a further set of U-tubes at −80° C. The oxygen and nitrogen were mixed and passed through a preheater filled with silver turnings before entering the reactor. The ethylene was admitted to the reactor at the same gas inlet.

The carbon dioxide was passed through a similar purification train except for the omission of the KOH and the first cold trap. After the carbon dioxide was passed through a flowmeter, it was admitted to the nitrogen stream at a point prior to the second cold trap in the nitrogen line.

Water vapor was admitted to the system by passing the purified ethylene through a

stainless steel, as was Part 1. For the detailed examination of the effect of CO_2 and H_2O on the reaction, the steel barrel of Part 2 was replaced by a sealed tube of "Mint Grade" silver. A 0.030-in. ring of annealed silver was used as a gasket between the two portions of the reactor. Temperature control was maintained by a mixture of Dowtherm A and E boiling under a pressure of nitrogen inside Part 2, heat being supplied by a sealed cartridge heater immersed in the Dowtherm. A copper condenser was attached to the reactor by means of the threads on Part 2. The temperatures reported in this work are the temperatures of the heat exchange medium measured by a chromel alumel thermocouple inserted into the boiling liquid. The temperature of the Dowtherm could be maintained within $\pm 1°$ C of a desired value. The temperature of the gas entering the reactor could also be measured by inserting a thermocouple into the thermocouple well situated right over the gas inlet of Part 1.

Samples of the gases issuing from the reactor were withdrawn by a similar technique to that described by Orzechowski and MacCormack (3) and the ethylene oxide and carbon dioxide were estimated in the customary manner by absorption in Lubatti reagent (4) and sodium hydroxide solution respectively. The absorbing solutions were added to the absorption bubblers by weight pipettes and the subsequent back titrations performed using weight burettes.

The catalysts used in this investigation were based on the "Cambron" (5) silver–calcium catalyst; 40- to 200-mesh 8.5% calcium in silver alloy was sprayed, under an atmosphere of nitrogen, onto the external surface of Part 2 of the reactor, this part being turned in a lathe during the spraying. The catalyst was cooled and then it was activated by the steam and acetic acid treatment already described (6). The reactor was then assembled and sealed into the system in the shortest possible time to avoid air-borne contamination.

Two other catalysts were examined in this investigation: a 1 wt.% gold in silver–8.5% calcium and a 1 wt.% antimony in silver – 8.5% calcium alloy. In each case the percentage of either gold or antimony was based on the amount of silver present and not on the combined silver–calcium weight. Both of these catalysts were sprayed and activated in the same manner as normal calcium–silver alloys.

The flow rates used in the investigation were multiples of 2/10/20 and 2/10/25 liters at S.T.P./hour for ethylene/oxygen/nitrogen. The maximum flow rates that could be conveniently handled were 7/35/70 and 6/30/75 liters at S.T.P./hour. Hence, for those experiments involving the catalyst deposited on the silver tube, the degree of reaction could be measured for values of M/F (where M is catalyst mass and F the total flow rate), varying between 0.191 and 0.669 and 0.193 and 0.578 g hour per liter for the two feeds, since the catalyst mass was 21.4 g and contained 0.083% calcium. When CO_2 was added to the feed it was added at the expense of the nitrogen thus maintaining the total flow rates at standard levels. The amount of CO_2 added to the feed was based on the ethylene in the feed. It then follows that when we speak of those experiments involving 10% CO_2 for example, the gas flow rates will be multiples of 2/10/19.8/0.2 and 2/10/24.8/0.2 liters at S.T.P./hour for $C_2H_4/O_2/N_2/CO_2$.

As has been shown by previous authors (3) the silver–calcium catalysts require approximately 75–100 hours operation under standard conditions before settling down to steady values of ethylene oxide and carbon dioxide produced. All of the results reported in this communication are for catalysts conditioned at standard flow rates of 2/10/20 liters at S.T.P./hour for at least 100 hours. It required a minimum of 3 hours for a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

catalyst to settle down to a steady state after the flow conditions had been altered.

The preliminary experiments were performed at a total pressure of 1200 mm Hg; the experiments involving CO_2 and H_2O additions to the feed were made at both 1200 mm Hg and 850 mm Hg. The series of experiments involving CO_2 additions were made in one continuous operation—the reactor was not shut down for any purpose until the conclusion of the series; the same tank of ethylene was used throughout this series and necessary replacement of oxygen or nitrogen tanks was made at such times as coincided with the necessary changes in flow conditions. All of these experiments were made using the bracketing technique. At the end of the CO_2 series the reactor was shut down under a gas stream of 2/10/20 and then stored under nitrogen for a few days. The experiments on the addition of water vapor were then started and carried out in one continuous operation.

The exchange reactions between ^{18}O and C_2H_4O, CO_2, and H_2O were carried out in the same conventional high-vacuum apparatus that was used in the study of the decomposition of nitrous oxide on these silver–calcium catalysts (6). Ten millimeters of $^{18}O_2$-enriched oxygen, prepared by the electrolysis of H_2O^{18} (10%), was admitted to 10 g of an activated silver–calcium powder containing 0.43% calcium, and, after sufficient time had elapsed for adsorption equilibrium to be attained, 10 mm of either C_2H_4O, CO_2, or H_2O vapor (all purified by repeated distillation) was added, small gas samples being removed periodically for mass spectrographic analysis.

RESULTS

The preliminary experiments indicated that the results obtained for the percentage ethylene converted to ethylene oxide and carbon dioxide were reproducible to better than 3%, both for repeated experiments at a constant flow rate and for experiments at this flow after operations at different flows. This is shown for a typical catalyst in Table I.

In addition to illustrating the reproducibility obtainable in this system, Table I

NOTE: Preliminary runs with 20 g of silver catalyst, % calcium, 0.1. Total pressure = 1200 mm Hg. Temperature, 250° for runs 1–11. Temperature, 245° for runs 12–23 after shutdown for major repairs. All analyses performed at 24-hour intervals.

also shows how easily the reaction level may be altered by uncontrolled changes in operating conditions. After run No. 11, a broken N_2 line resulted in a high concentration of ethylene and oxygen in the reactor leading to a runaway temperature and presumably causing sintering of the catalyst surface.

Table II compares the results obtained with normal calcium–silver catalysts and the special 1% gold–silver–calcium and 1% antimony–silver–calcium alloys. All of the results are for fully conditioned catalysts operating at 1200 mm Hg pressure, under standard conditions of 2/10/20 liters at S.T.P./hour.

TABLE II

The effect of alloying constituents on selectivity

Catalyst	% Calcium	Temp., °C	Cat. wt., g	% C_2H_4 converted to:		% Selectivity
				C_2H_4O	CO_2	
1% Sb–Ag	<0.01	243	20.0	15.4	35.5	30
1% Au–Ag	<0.01	225	17.0	19.8	57.7	25
Ag (1)	Appr. 0.1	250	20.0	47.4	21.3	69
Ag (2)	Appr. 0.1	250	20.0	40.4	14.9	72

It is seen from Table II that the presence of small quantities of gold or antimony in the silver alloy causes a marked decrease in the selectivity, although a high total activity is maintained. It is to be noted that the calcium content of these two catalysts is very low; as will be shown later, we would expect that the selectivity for these two "binary" catalysts containing calcium as the "impurity" should be low. However, if the calcium content is increased, the effect of the gold or antimony will be masked. Unpublished data of the author have shown that gold- and antimony-containing silver catalysts, containing also appreciable quantities of calcium, act as catalysts in the N_2O decomposition as though they were binary calcium–silver alloys containing less calcium, e.g. a 1% gold – 0.43% calcium in silver alloy acts as a calcium–silver alloy containing approximately 0.3% calcium.

Preliminary studies of the effect of CO_2 on the reaction showed that, within the limits of experimental error, added CO_2 had only a limited effect on the production of ethylene oxide, and no effect at all on the production of carbon dioxide. The quantitative results for the effect of CO_2 on ethylene oxide production are given in Table III and are illustrated in Fig. 3. The data of Table III are for four separate series of experiments, with flows which were multiples of 2/10/20, and 2/10/25 liters at S.T.P./hour for $C_2H_4/O_2/N_2$ and total pressures of 1200 and 850 mm Hg.

In Table IV the results of the effect of water vapor on the reaction are given. The temperatures refer to the temperature of the water in the saturators. Room temperature was between 25 and 27° during these runs; consequently, 22° C was the highest practical saturation temperature that could be used without heating the gas lines. It is apparent that, within the limits of experimental error, the addition of water vapor to the feed gas has no effect on the production of either ethylene oxide or carbon dioxide.

In Fig. 4, the results of the exchange between $^{18}O_2$-enriched oxygen chemisorbed in a silver catalyst and ethylene oxide, carbon dioxide, and water vapor are illustrated. It will be observed that the exchange involving ethylene oxide is much more rapid than that involving either of the other two gases. Of far greater importance is the fact that,

under similar experimental conditions, no oxidation of the ethylene oxide was observed until a temperature of 220° C had been reached, some 150° C above the temperature at which exchange takes place readily.

DISCUSSION

The experimental results of the silver-catalyzed oxidation of ethylene have been interpreted by two postulated mechanisms. The first, due to Twigg (1), assumed that ethylene oxide was formed by the interaction of ethylene with a single oxygen adatom;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and that deep oxidation was caused by the interaction of ethylene with a pair of suitably disposed oxygen adatoms. Orzechowski and MacCormack (3), on the other hand, interpreted their results on the basis of interaction between ethylene and chemisorbed oxygen atoms alone.

In 1952, DeBoer and Fortiun postulated (7) the existence of oxygen molecule ions O_2^- chemisorbed on silver, to account for the silver-catalyzed oxidation of cumene to cumene hydroperoxide. It was later postulated in this laboratory that chemisorbed O_2^- ions might be responsible for the deep oxidation of ethylene, with chemisorbed O^- ions being responsible for the formation of ethylene oxide. This viewpoint has subsequently been put forward by workers in this field. The conductivity measurements of Ljuburskij (8) have shown that oxygen abstracts electrons from a silver surface and this has been confirmed by the surface potential measurements of Kummer (9). In this latter paper, Kummer has also presented direct evidence for the existence of chemisorbed O_2^- ions on silver.

If oxygen is chemisorbed on silver, initially in the form of O_2^- ions, and subsequently as two O^- ions, we would expect that the addition of other components to the silver to decrease the work function would result in an increase in selectivity for the ethylene oxidation. A lowering of the work function would enhance the dissociation of O_2^- ions into O^- ions. Increasing the work function, on the other hand, would be expected to give the opposite effect, resulting in a lowering of the selectivity. The author has already shown (6), as a part of this investigation, that the addition of gold to silver increases the activation energy of the silver-catalyzed decomposition of N_2O. Since the rate-determining step in this decomposition involves the donation of an electron from the catalyst to the N_2O, an increase in activation energy is equivalent to an increase in work function. This same investigation also showed that by increasing the residual calcium in the catalyst (the silver–calcium alloys) the work function could be lowered.

The results in Table II show how the selectivities of the 1% gold in silver and 1% antimony in silver catalysts are markedly lower than the selectivities obtained from normal calcium–silver alloys. It is to be regretted that lowering the work function will not bring about as great an increase in selectivity under normal flow conditions, as we postulate that O^- ions are also responsible for the further oxidation of ethylene oxide to CO_2 and H_2O. A forthcoming publication (10) dealing with *initial-rate studies* on the silver-catalyzed oxidation of ethylene in a circulating system, in which the products are removed from the gas phase as they are formed, will show how the selectivity may be increased from 45% for pure silver to 65% for a 0.1% calcium in silver alloy.

If we now consider the poisoning of the reaction by added CO_2, we see from Fig. 4 that increasing the CO_2/C_2H_4 ratio in the feed gas over 0.30 has no further effect on the production of ethylene oxide. This means in effect that the initial rate of C_2H_4O formation in the presence of CO_2 falls to a steady value, greater than zero, as the partial pressure of CO_2 is increased. The data were analyzed in a manner similar to that used by Orzechowski and MacCormack, i.e., by considering the steady-state concentrations of the various adsorbed species (3). The two simplest assumptions regarding the adsorption of CO_2 are that CO_2 is either adsorbed on the free surface, at the expense of oxygen, or that it is adsorbed on top of the chemisorbed oxygen film at the expense of ethylene. Neither of these assumptions leads to a rate equation which fits our experimental data, since both derived rate equations require that the rate of production of C_2H_4O shall fall to zero if the CO_2 pressure is sufficiently high. If, on the other hand, it is assumed that the adsorption of CO_2 requires both a free surface site and an adsorbed O^- ion, leading

to a CO_3^- ion as the adsorption complex, then the initial-rate equation may be shown to be of the form

$$r_{EtO} = r^0_{EtO}\left(m+\frac{n}{1+kP_{CO_2}}\right) = r^0_{EtO}\left(\frac{1+k'P_{CO_2}}{1+kP_{CO_2}}\right)$$

where m, n, and k are constants, with $m+n = 1$ and $k' = mk$.

r_{EtO} = initial rate of C_2H_4O production in the presence of CO_2,

r^0_{EtO} = initial rate of C_2H_4O production in the absence of CO_2.

The rates, r, are given by the relation

$$r = \left(\frac{dx}{d(M/F)}\right)V_E$$

where x = fraction of ethylene converted to C_2H_4O,

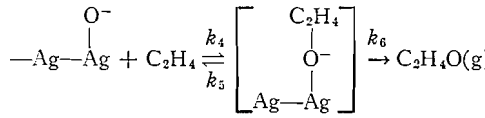
M = catalyst weight in grams,

F = total flow rate in liters at S.T.P./hour,

and V_E = volume fraction of ethylene in the feed.

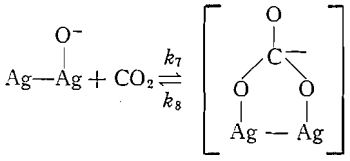
The constants m, n, and k were obtained from the data given in Table III(A). Values of $[dx/d(M/F)]V_E$ were then computed for the experimental conditions of Table III, (B), (C), and (D). The results are shown in Fig. 5, where the solid lines were calculated from the fitted points of A, the circles represent the experimentally determined points. The agreement is satisfactory.

Although the effect of added ethylene oxide on the production of ethylene oxide was not determined in this investigation, it has been shown by Roginskii and Margulis (11) that added C_2H_4O decreases the rate of production of C_2H_4O. This result could have been inferred from the exchange behavior of ethylene oxide with chemisorbed ^{18}O. We may visualize the exchange taking place as follows:



$$\begin{array}{l} {}^{18}O^- \\ |\\ -Ag-Ag- \end{array} + C_2H_4{}^{16}O \rightleftharpoons \begin{array}{c} CH_2-CH_2 \\ | \quad\times\quad | \\ {}^{18}O \qquad {}^{16}O \\ | \qquad\quad | \\ -Ag- \quad -Ag- \end{array} \rightleftharpoons \begin{array}{l} {}^{16}O^- \\ | \\ Ag-Ag \end{array} + C_2H_4{}^{18}O.$$

In view of the exchange behavior of water vapor, in which exchange possibly takes place via the formation of two OH^- ions in the surface, it is perhaps surprising that added water vapor has no apparent effect on either C_2H_4O and CO_2 production. It is possible, however, that water does inhibit the formation of ethylene oxide, in a manner analogous to that shown by CO_2, but the effect of water is so small that the water formed in the normal course of the reaction is sufficient to saturate the surface with respect to water vapor. We can summarize the basic postulates of this paper in the following reaction schemes:



$$-Ag-Ag- + O_2 \rightleftharpoons \left[\begin{array}{c} O_2^- \\ -Ag-Ag- \end{array}\right] \rightleftharpoons \begin{array}{l} O^- \quad O^- \\ | \quad\quad | \\ Ag-Ag-Ag \end{array} \qquad [1]$$

$$\left[\begin{array}{c} O_2^- \\ Ag-Ag \end{array}\right] + C_2H_4 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \left[\begin{array}{c} C_2H_4 \\ O_2^- \\ Ag-Ag \end{array}\right] \overset{k_3}{\rightarrow} CO_2 + H_2O \qquad [2]$$

In applying the steady-state treatment to this postulated mechanism it is possible to treat the surface in two ways; this in effect means that we can treat the adsorption of oxygen in two ways. The first is to assume that any part of the surface is capable of holding the adsorbed oxygen as either O_2^- or O^-, and the second is to assume that, because of marked a priori heterogeneity, only certain portions of the surface can hold adsorbed oxygen as O_2^- and that other portions can hold adsorbed oxygen as O^-. The first treatment is far more complicated than the second, and while it shows that the selectivity of the reaction is a function of oxygen pressure (10), it also shows that the effect of added CO_2 under *all possible* circumstances is to reduce the rate of production of both CO_2 and EtO to zero if the pressure of CO_2 is sufficiently high.

The second treatment, while being perhaps more naive, satisfactorily accounts for most of the data published to date. We assume that the rates of formation of both adsorbed O_2^- and O^- may be considered as independent of each other and that the two species are found on different portions of the surface. We further assume that *all* of the CO_2 produced in the *early stages of the reaction* comes from interaction between ethylene and adsorbed O_2^-, i.e., there is no formation of CO_2 by a secondary oxidation of EtO.

Let θ be fraction of surface covered by O_2^- and θ' be fraction of surface covered by O^- under steady-state conditions. Further, let α be the fraction of the O_2^--covered surface covered by adsorbed ethylene, and β be the fraction of the O^--covered surface covered by adsorbed ethylene under steady-state conditions.

Following Orzechowski and MacCormack (3), we shall assume further that the rates of formation of the adsorbed oxygen species are given by the simple form of the Elovic equation.

Then the steady-state concentration of adsorbed O_2^- is given, ignoring desorption of oxygen, by

$$jP_O(1 - m\theta) + k_2\alpha\theta = k_1P_{Et}(1 - \alpha)\theta, \qquad [1]$$

where P_O and P_{Et} are the pressures of oxygen and ethylene respectively. Similarly the steady-state concentration of adsorbed O^- is given by

$$j'P_O(1 - m'\theta') + k_5\beta\theta' = k_4P_{Et}(1 - \beta)\theta'. \qquad [2]$$

The steady-state concentration of ethylene adsorbed on the O_2^- is given by

$$k_1P_{Et}(1 - \alpha)\theta = (k_2 + k_3)\alpha\theta. \qquad [3]$$

and steady-state concentration of ethylene adsorbed on the O^- by

$$k_4P_{Et}(1 - \beta)\theta' = (k_5 + k_6)\beta\theta'. \qquad [4]$$

Hence the rate of formation of CO_2 is given by

$$r^0_{CO_2} = k_3\alpha\theta = \frac{k_3\alpha jP_O}{(k_3\alpha + jmP_O)}. \qquad [5]$$

and the rate of formation of ethylene oxide by

$$r^0_{EtO} = k_6\beta\theta' = \frac{k_6\beta j'P_O}{(k_6\beta + j'm'P_O)}. \qquad [6]$$

We see immediately that the selectivity S, equal to $r^0_{EtO}/(r^0_{EtO} + r^0_{CO_2})$ is given by

$$S = \frac{j'\left(1 + \frac{jmP_O}{k_3\alpha}\right)}{\left[j\left(1 + \frac{jmP_O}{k_3\alpha}\right) + j'\left(1 + \frac{j'm'P_O}{k_6\beta}\right)\right]} \qquad [7]$$

or at constant ethylene pressure, as α and β are constants, the selectivity is a function of the oxygen pressure. From equations 5 and 6 we see that

[8] $$r^0_{EtO} = \frac{k_6 j' B P_O P_{Et}}{k_6 B P_{Et} + j' m' P_O + j' m' B P_O P_{Et}}$$

and

[9] $$r^0_{CO_2} = \frac{k_3 j A P_O P_{Et}}{k_3 A P_{Et} + j m P_O + j m A P_O P_{Et}}$$

where

$$A = \frac{k_1}{k_2 + k_3}$$

and

$$B = \frac{k_4}{k_5 + k_6}.$$

Equations 8 and 9 will then apply to those situations where the rate of oxygen adsorption is of the same order of magnitude as the rate of production of CO_2 and EtO. If now the rate of adsorption of oxygen becomes the limiting rate of the reaction it is permissible to suppose that in this case θ and θ' will be very small and that α and β both approach unity so that the rate of production of EtO will be independent of P_{Et} and,

[10] $$r^0_{EtO} = \frac{k_6 j P_O}{k_6 + j' m' P_O} \sim K P_O^{1/n}$$

[11] $$r^0_{CO_2} = \frac{k_3 j P_O}{k_3 + j P_O m} \sim K' P_O^{1/m}$$

Similarly, if the rate of adsorption of oxygen is faster than r^0_{EtO} or $r^0_{CO_2}$, then we can expect that the over-all rate, r^0_{EtO} or $r^0_{CO_2}$, to be functions only of the ethylene pressure; this has been found by Kurilenko (12).

If we now consider the effect of CO_2 on r^0_{EtO} and $r^0_{CO_2}$, we find that the postulate of adsorption of CO_2 on either O^-(ads.) or on the free surface will lower the activity to zero at sufficiently high CO_2 pressures. Similarly, in general, two point attachment of CO_2 involving both O^- adsorption and a free site will lower the activity to zero. However, for a special case, two point attachment will lower r_{EtO} only, and that to a limiting value greater than zero.

Let us suppose that a fraction γ of the O^--covered surface is covered with CO_2 under steady-state conditions, then a fraction $\gamma\theta'$ of the free surface will be used to obtain two point attachment.

The general equations 1, 2, 3, and 4 now become

[12] $$jP_O(1 - m\theta - \gamma\theta') + k_2\alpha\theta = k_1 P_{Et}(1 - \alpha)\theta$$

[13] $$j'P_O(1 - m'\theta' - \gamma\theta') + k_5\beta\theta' = k_4 P_{Et}(1 - \beta)\theta'$$

[14] $$k_1 P_{Et}(1 - \alpha)\theta = (k_2 + k_3)\alpha\theta$$

[15] $$k_4 P_{Et}(1 - \beta - \gamma)\theta' = (k_5 + k_6)\beta\theta'$$

and for the adsorption of CO_2

[16] $$k_7 P_{CO_2}(1 - \beta - \gamma)\theta'(1 - (\theta' + \theta) - \gamma\theta') = k_8\gamma\theta'.$$

The equations are difficult to solve (without making assumptions as to the relative value of second and third degree terms), but predict that the effect of CO_2 in general

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

will be to inhibit both CO_2 and EtO production. A similar series of equations predict the same behavior for both added EtO and H_2O. This type of behavior, namely complete inhibition by reaction products, in the order $EtO > CO_2 > H_2O$, would have been predicted on the basis of the isotope-exchange studies and has been found by Kurilenko (12) and more recently by Gorokhovatskii (13).

The results of this paper may be rationalized by assuming, (*a*) two-site adsorption of CO_2; (*b*) that the amount of adsorbed CO_2 is sufficiently small that no sites on which O_2^- (ads.) may be formed are destroyed, and (*c*) that the adsorption of CO_2 on the O^- (ads.) layer does not effect the adsorption of ethylene on this layer. The steady-state equations comparable to 13, 15, and 16 then become

$$j'P_O(1 - m'\theta' - \gamma\theta') + k_5\beta\theta' = k_4P_{Et}(1 - \beta)\theta', \quad [17]$$

$$k_4P_{Et}(1 - \beta)\theta' = (k_5 + k_6)\beta\theta', \quad [18]$$

$$k_7P_{CO_2}(1 - \gamma)\theta'(1 - \theta' - \gamma\theta') = k_8\gamma\theta'. \quad [19]$$

On solving these equations, with the further assumption that $(\theta')^2$ and $\gamma^2(\theta')$ may be neglected, we find that r_{EtO} is given by

$$r_{EtO} = \frac{k_6\beta j'P_O\left[1+\frac{k_7}{k_8}P_{CO_2}\right]}{k_6\beta\left(1+\frac{k_7}{k_8}P_{CO_2}\right)+j'm'P_O\left[1+\frac{k_7}{k_8}\left(\frac{m'+1}{m'}\right)P_{CO_2}\right]}. \quad [20]$$

For given values of P_O and P_{Et} equation 6 may be transformed to

$$\frac{1}{r^0_{EtO}} = \frac{k_6\beta+j'm'P_O}{k_6\beta j'P_O} = \frac{a}{r^0_{EtO}}+\frac{b}{r^0_{EtO}} \quad [21]$$

where a and b are fractions and $a+b = 1$. Comparison of 20 and 21 then gives, after some rearranging,

$$r_{EtO} = r^0_{EtO}\left[\frac{\left(1+\frac{k_7}{k_8}P_{CO_2}\right)}{\left\{1+\frac{k_7}{k_8}\left(\frac{m'+b}{m'}\right)P_{CO_2}\right\}}\right]. \quad [22]$$

Equation 22 then satisfactorily accounts for the data of this paper.

NOTES

ON THE EXISTENCE OF TERNARY COMPOUNDS IN THE SYSTEM NH_3–H_2O_2–H_2O

K. E. MIRONOV

Recently a note was published in this Journal (1) on the existence of ternary compounds in the system NH_3–H_2O_2–H_2O. On the basis of appearance of maxima in the melting-point curve along the plane $H_2O_2 \cdot 2H_2O$–NH_3 it was concluded that two compounds are formed, namely $NH_3 \cdot 3H_2O_2 \cdot 6H_2O$, m.p. −28.9° C, and $(NH_4)_2O_2 \cdot 2H_2O$, m.p. around 15° C. That this conclusion is erroneous may be gathered from an investigation of the whole liquidus surface of that system (2).

Indeed, there are two maxima in the above-mentioned plane (Fig. 1, p. 2270), but these maxima provide no evidence for ternary compounds since the said plane is not a singular or stable one (3). The first maximum at −29° C comes from intersection of the ridge in crystallization field of ice, while the second maximum comes from crystallization of the the compound $NH_3 \cdot H_2O_2$.

There were indications (1) from the infrared spectrum of the presumed compound at 32% NH_3 that it contained the NH_4^+ ion as well as water of crystallization. As may be judged from Fig. 1, the infrared investigation is consistent with the presence in that solid of the compound $NH_3 \cdot H_2O_2$ (4, 5) together with ice. On the other hand, the conclusion (1) regarding the non-ionic nature of the compound $2NH_3 \cdot H_2O_2$ seems correct in view of its limited range of existence, from −93.5° to −107° C (6). There are no ternary compounds in the system NH_3–H_2O_2–H_2O.

The author is grateful to I. I. Vol'nov for drawing his attention to paper (1).

APPLICATION OF THE HAMMETT EQUATION TO THE HYDROLYSIS OF SUBSTITUTED BENZAMIDES

J. T. EDWARD,* H. S. CHANG,* K. YATES,† AND ROSS STEWART†

The hydrolysis of amides is believed to take place by the two-stage mechanism (1, 2, 3):

$$RCONH_2 + H^+ \underset{\text{fast}}{\rightleftharpoons} RCONH_3^+ \qquad [1]$$

$$RCONH_3^+ + H_2O \xrightarrow[\text{slow}]{k_2} RCO_2H_2^+ + NH_3 \qquad [2]$$

Recently Leisten (4), by working with acid solutions which he considered concentrated enough to have all the amide present as $RCONH_3^+$, has attempted to obtain the rate constants k_2 for various substituted benzamides in the second rate-determining step:

$$\text{rate of reaction } v = k_2[RCONH_3^+].$$

(The concentration of water was not included in the kinetic equation since it was effectively constant in the experiments carried out in any one acid concentration.)

Leisten used 5.86 *M*, 7.19 *M*, and 8.54 *M* perchloric acid at 95° C. He gives reasons for believing that the pK_{BH^+} values of amides at this temperature will be about the same as at room temperature. On the basis of early estimates (3) of the basicities of benzamides, these concentrations of acid were assumed to be sufficient for essentially complete protonation of the compounds listed in Table I. However, the pK_{BH^+} values

TABLE I

Corrected rate constants k_2 (in hr^{-1}) for the hydrolysis of substituted benzamides in perchloric acid

	Acid concentration		
Substituent	5.86 *M*	7.19 *M*	8.54 *M*
p-Methoxy	0.238	0.073	0.026
p-Methyl	0.437	0.131	
m-Methyl		0.192	0.057
Hydrogen	0.805	0.234	0.073
p-Bromo		0.410	
m-Bromo		0.627	0.174
p-Nitro		1.77	0.545
m-Nitro	6.33	1.34	0.455

now reported for these compounds (5) show this assumption to be incorrect. Consequently, the experimental rate constants k_e (3), based on the stoichiometric concentration of amide and defined by

$$v = k_e([RCONH_2]+[RCONH_3^+]),$$

are not equal to k_2, which in fact is given by

$$[3] \qquad k_2 = k_e([RCONH_2]+[RCONH_3^+])/[RCONH_3^+] = k_e(K_{BH^+}+h_0)/h_0$$

where $K_{BH^+} = -$antilog pK_{BH^+} and h_0 is Hammett's acidity function in its non-logarithmic form. The values of k_2 obtained from Leisten's results using eq. 3 are given in Table I.

The slopes of the least-squares plots of log k_2 against the σ values of the substituents (Fig. 1) give the values of the reaction constant ρ_2 for eq. 2 (6). These are listed below,

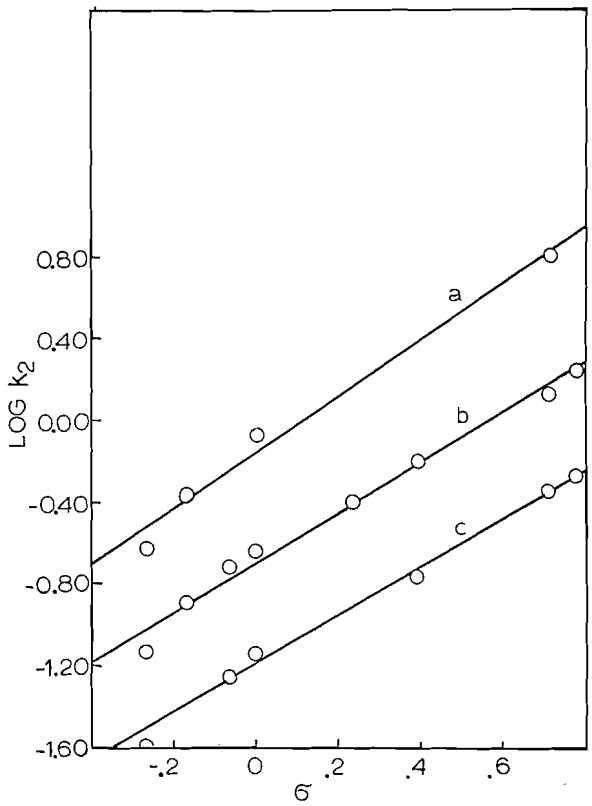

FIG. 1. Plots against Hammett's σ constants of log k_2 for substituted benzamides in the following concentrations of perchloric acid: *a*, 5.86 *M*; *b*, 7.19 *M*; *c*, 8.54 *M*.

with the number of results from which ρ_2 was determined (n), the standard deviation (s), and the correlation coefficient (r).

$HClO_4$ (M)	ρ_2	n	s	r
5.86	1.39	4	0.162	0.916
7.18	1.23	8	0.057	0.992
8.54	1.19	6	0.070	0.989

These values, slightly different from those of Leisten, are in better agreement with the value (1.42) calculated from the equation

[4] $$\rho_{0v} = \rho_1 + \rho_2$$

where ρ_{0v} is the reaction constant for the rates of hydrolysis of substituted benzamides in dilute acid (0.118, ref. 6), and ρ_1 ($= -1.30$) is the reaction constant recently determined (5) for eq. 1 in the direction shown.

TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS
PART VII. INTERNUCLEAR CYCLIZATION ONTO A PYRIDINE RING*†

R. A. ABRAMOVITCH

On the basis of two examples of internuclear cyclization of the Pschorr type onto a pyridine ring (1, 2) (one involving predominant electrophilic attack at the ring nitrogen) it was suggested (3) that the pyridine ring is more difficult to attack than a benzene ring in such reactions. The cyclization of 2-amino-*N*-methyl-*N*-3′-pyridylaniline (I) was studied to examine whether this was indeed so, as well as to provide a route to the δ-carboline ring system. Also, some evidence might thus be obtained to suggest a mechanism for the Pschorr reaction when carried out under such conditions, for the pyridine ring is known to be deactivated towards electrophilic substitution under mild conditions, but not towards homolytic attack. Should cyclization occur readily it was of interest to determine the orientation of the products since the isomer ratios for free radical phenylation of pyridine are in the order $\alpha > \beta > \gamma$ (4).

Decomposition of the aqueous diazonium sulphate of 2-amino-*N*-methyl-*N*-3′-pyridylaniline (I) with copper powder at room temperature resulted in a good yield of a mixture of cyclized products which was separated into *ind*-*N*-methyl-δ-carboline (III) (47.5% yield) and *ind*-*N*-methyl-β-carboline (II) (25.5% yield) by chromatography on a column of alumina. The structure of (III) was confirmed by the analytical results and by its infrared spectrum, which showed no monosubstituted phenyl bands, thus eliminating the possibility that the substance isolated was the deaminated product. Its ultraviolet absorption spectrum was very similar to that of an authentic specimen of δ-carboline obtained by an unambiguous synthesis (5). The structure was finally proved by comparison with an authentic specimen whose preparation from δ-carboline is described in the next part of this series (5). The total yield of cyclized product (73%) is comparable with that obtained (78%) when *N*-(3-amino-2-pyridyl)-*N*-methylaniline (IV) is ring-closed to *ind*-*N*-methyl-α-carboline (V) (2), i.e. a similar cyclization, with similar internuclear separation (6), onto a benzene ring. This clearly indicates that in the present case the pyridine ring is not deactivated towards nuclear attack and that under these very mild reaction conditions free radical intermediates (perhaps bound in some way with the copper catalyst) may be involved. An amino substituent in the pyridine is known to facilitate electrophilic attack of the ring due to the mesomeric effect of the electron pair of the amino nitrogen atom. Phenyl substitution at the 3-amino group is expected, however, to decrease the activating effect of this group and *o*-diazotization to decrease it still further. An attempt to eliminate this possible source of ambiguity by replacing the *N*-methyl group in (I) by an acyl grouping was made. 2-Nitro-*N*-3′-pyridylaniline (VI), however, resisted all attempts at acetylation, tosylation, or mesylation, so that the required starting material could not be obtained.

It is very likely (7) that in the absence of copper powder and at the boiling point of the aqueous acid the cyclization involves cationic intermediates so that in such a case, though the reaction conditions are more severe than in the one where copper powder is used, the yield of cyclized product would be expected to fall due to the resistance of the pyridine ring to electrophilic substitution. This was indeed found to be the case, the over-all yield of carbolines being 47.2%: *ind*-*N*-methyl-δ-carboline (33%), *ind*-*N*-methyl-β-carboline (14.2%). A product, whose picrate analyzed for that of the deaminated product, was also obtained under these conditions. It is to be noted, however, that in contrast to the above results ring closure of 2-amino-*N*-methyldiphenylamine under both sets of conditions gave comparable yields of *N*-methylcarbazole (6). Thus, by the action of copper powder on the cold solution of the diazonium sulphate a 66% yield of cyclized product was obtained; the action of heat upon the aqueous diazonium sulphate solution in the absence of copper resulted in a 60% yield of *N*-methylcarbazole. Here there is no decrease in yield on passing from a heterolytic to a presumably homolytic process since the benzene, unlike the pyridine ring, is not deactivated towards electrophilic attack. These observations also support the suggestion that the side-chain tertiary amino group is probably not activating the ring towards electrophilic attack in such aqueous acid solutions.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Ultraviolet absorption spectra were measured on a Beckman DK 2 recording spectrophotometer. For the chromatographic separations alumina supplied by Peter Spence and Sons, Ltd., as activated alumina type H, 100/200 mesh, was used.

N-Methyl-2-nitro-N-3′-pyridylaniline

A mixture of 3-bromopyridine (3.2 g), *N*-methyl-*o*-nitraniline (2.3 g), anhydrous potassium carbonate (2 g), and copper bronze (100 mg) in nitrobenzene (12 ml) was boiled under reflux for 24 hours. The suspension was steam-distilled and the residue extracted with chloroform, the extract dried ($MgSO_4$) and evaporated. The residue was distilled *in vacuo* giving a red viscous oil (1.4 g), b.p. 140–150°/2×10^{-2} mm, which formed a glass on cooling. The product was analyzed as *the picrate* which crystallized from ethanol as yellow needles, m.p. 168°. Found: C, 46.90; H, 2.99. Calc. for $C_{12}H_{11}O_2N_3$, $C_6H_3O_7N_3$: C, 47.17; H, 3.06.

2-Amino-N-methyl-N-3′-pyridylaniline

The above nitro compound (2.7 g), Raney nickel (1 g), and 100% hydrazine hydrate (10 ml) in alcohol (50 ml) were boiled under reflux for 15 minutes, the suspension filtered, and the filtrate evaporated to dryness leaving an oil (1.77 g) which slowly solidified. Vacuum distillation gave the *amine* as a colorless oil, b.p. 140–143°/0.4 mm, which solidified to a colorless solid. This was recrystallized from benzene – light petroleum (b.p. 60–80°) giving colorless needles, m.p. 93–94°. Found: C, 71.98; H, 6.24; N, 20.60. Calc. for $C_{12}H_{13}N_3$: C, 72.33; H, 6.57; N, 21.10.

Decomposition of the Aqueous Diazonium Sulphate of 2-Amino-N-methyl-N-3′-pyridylaniline

(i) With Copper Powder at Room Temperature

The amine (1.9 g) in concentrated sulphuric acid (4 ml) and water (50 ml) was diazotized at 0–5° with sodium nitrite (2 g) in water (20 ml), stirring at 0–5° being continued for ½ hour. Urea (1.5 g) was added to the clear solution to decompose the excess nitrous acid, and then copper powder (2 g) was gradually stirred in. The decomposition was complete in ½ hour as indicated by the cessation of effervescence and a negative alkaline β-naphthol test. The suspension was stirred at room temperature for a further ½ hour and then it was filtered from the copper, made alkaline with an excess of concentrated ammonia, and extracted with chloroform (2×200 ml). The dried ($MgSO_4$) extract was evaporated and the tarry black residue was taken up in benzene and chromatographed on a column of alumina (70 g). Elution with benzene first gave a colorless oil (0.82 g, 47%) which soon solidified, and had a melting point of 73–74°. Recrystallization from light petroleum (b.p. 60–80°) gave *ind-N-methyl-δ-carboline* as colorless plates, m.p. 74°. Found: C, 78.75; H, 5.72. Calc. for $C_{12}H_{10}N_2$: C, 79.09; H, 5.53. λ_{max} 263, 267, 306 mμ; λ_{infl} 235, 249 mμ; $\epsilon\times10^{-3}$ 18.92, 18.80, 11.83, 13.35, 10.62 (in ethanol). Infrared spectrum (Nujol mull) (main peaks only): 1628 (m), 1595 (m), 774 (m), 750 (m), 727 (s). The *picrate* separated from alcohol and was recrystallized from dioxane giving fine yellow needles, m.p. 229–230°. Found: C, 52.60; H, 3.0. Calc. for $C_{12}H_{10}N_2$, $C_6H_3O_7N_3$: C, 52.56; H, 3.19.

Further elution with benzene gave a brown oil which solidified very slowly. The solid was recrystallized from light petroleum (b.p. 60–80°) giving *ind-N*-methyl-β-carboline as colorless plates, m.p. 97° (0.45 g, 25%), undepressed on admixture with an authentic sample (8). Further recrystallization from light petroleum raised the melting point to 106–107°. Found: C, 79.03; H, 5.4. Calc. for $C_{12}H_{10}N_2$: C, 79.09; H, 5.53. The picrate separated from alcohol and was recrystallized from acetone giving fluffy yellow needles, m.p. 258°. Found: C, 52.31; H, 3.20. Calc. for $C_{12}H_{10}N_2$, $C_6H_3O_7N_3$: C, 52.56; H, 3.19. (Lit. (8) gives a melting point of 258°.)

(ii) By Boiling Without Copper Powder

The amine (2.0 g) was diazotized as before and the filtered diazonium solution was boiled under reflux for 10 hours. The cold solution was made just alkaline with aqueous sodium hydroxide and extracted with chloroform. The dried ($MgSO_4$) chloroform extract was evaporated, the residue taken up in benzene, and chromatographed on alumina as before. Elution with benzene gave first *ind-N*-methyl-δ-carboline (0.60 g, 33%), m.p. 73°, and then *ind-N*-methyl-β-carboline (0.26 g, 14.2%) as a very crude oil characterized as the picrate, m.p. and mixed m.p. 258°. Elution with ether gave a brown oil (0.10 g) which formed a picrate from alcohol. This picrate was recrystallized from acetone giving small yellow needles, m.p. 202–203° (decomp.), which analyzed for the *picrate* of *N*-methyl-*N*-3′-pyridylaniline. Found: C, 52.09; H, 3.14; N, 17.30. Calc. for $C_{12}H_{12}N_2$, $C_6H_3O_7N_3$: C, 52.21; H, 3.32; N, 16.94.

2-Nitro-N-3′-pyridylaniline

3-Aminopyridine (0.94 g), *o*-bromonitrobenzene (2.02 g), anhydrous potassium carbonate (2 g), and copper bronze (0.05 g) in xylene (20 ml) were boiled under reflux for 6 hours. The solvent was decanted off and the residue extracted repeatedly with boiling benzene, the combined extracts were treated with dilute hydrochloric acid, the acid solution made alkaline, saturated with sodium chloride, and extracted with benzene. The benzene solution was chromatographed on a short column of alumina. Elution with ether gave *2-nitro-N-3′-pyridylaniline* (0.62 g) as a dark red solid, m.p. 90°, which crystallized from water containing a little ethanol in slender orange-red needles, m.p. 95–96°. Found: C, 61.50; H, 4.51. Calc. for $C_{11}H_9O_2N_3$: C, 61.39; H, 4.42.

Attempted Tosylation of 2-Nitro-N-3′-pyridylaniline

The nitro compound (60 mg) and tosyl chloride (60 mg) in 2 ml of redistilled pyridine were boiled under reflux for 24 hours. Addition of water and recovery of the solid which precipitated gave unchanged starting material, m.p. 95–96°.

Similar results were obtained on attempted mesylation and acetylation (even in the presence of perchloric acid).

ACKNOWLEDGMENTS

Part of this work was carried out during the tenure of an I.C.I. Research Fellowship at King's College, London, England. The author is grateful to Dr. I. D. Spenser for an authentic specimen of *ind-N*-methyl-β-carboline and to Dr. L. Vining for the use of a recording Beckman DK 2 spectrophotometer.

THE CONDENSATION OF GLYOXAL WITH *p*-CRESOL

ALEX ROSENTHAL AND ALEC ZAIONCHKOVSKY

The preparation of condensation products from glyoxal and phenolic substances has been of considerable interest in the past decade. Chwala and Bartek (1) reported the condensation of glyoxal sulphate with phenol in the presence of mineral acids to yield a resin. At about the same time, Stevens and Dubbs (2) found that the reaction of 2-*tert*-butyl-4-methylphenol with glyoxal in the presence of acetic acid, hydrochloric acid, and zinc chloride afforded water-insoluble compounds. They also isolated, in unspecified yield, a substituted benzofuro[2,3-*b*]benzofuran. Groote and Keiser (3) have reported that the condensation of glyoxal with a phenol yielded low-stage resins.

In our investigation on the condensation of glyoxal with *p*-cresol, we employed two different reaction media. In the first runs, the reactants were condensed in an aqueous system using acetic acid and sulphuric acid as catalyst, whereas in later experiments the condensations were carried out in bis-(2-ethoxyethyl) ether using *p*-toluenesulphonic acid as catalyst.

When equimolar ratios of glyoxalmonohydrate and *p*-cresol were heated in aqueous acetic acid containing sulphuric acid as catalyst, a 70% yield of a crystalline material was obtained. Recrystallization of this substance from ethanol afforded 5,5¹-dimethyl-coumarano-3¹,2¹,2,3-coumaran (I). The structure of compound I was confirmed by direct comparison with an authentic sample (4).

(I)

It is interesting to compare the prominent infrared spectral bands of 5,5¹-dimethyl-coumarano-3¹,2¹,2,3-coumaran (listed in the experimental) with those of other cyclic as well as straight-chain ethers. The fact that the coumarano-coumaran exhibited pronounced absorption at 1250 cm^{-1} provides additional confirmation for the generalization that the C—O—C of ring compounds probably absorbs at something like the same frequency as it does in open-chain products (5, 6). The band at 1095 cm^{-1} is ascribed to the asymmetrical ring stretching vibration (7).

Repeated attempts to condense anhydrous glyoxal with *p*-cresol in bis-(2-ethoxyethyl) ether using *p*-toluenesulphonic acid as catalyst, under various temperatures and in closed and open systems, were unsuccessful. Almost quantitative conversion of glyoxal into polymeric form occurred.

EXPERIMENTAL

Anhydrous glyoxal was prepared by heating glyoxalmonohydrate with phosphorus pentoxide in a dry all-glass apparatus fitted with a condensing trap cooled in dry ice.

Condensation of Glyoxal with p-Cresol

Procedure A.—Glyoxal monohydrate (2.6 g) dissolved in 15 ml water, and *p*-cresol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(3.6 g) dissolved in 10 ml glacial acetic acid, were mixed and placed in an apparatus fitted with a condenser. To the stirred preheated mixture, 5 ml of concentrated sulphuric acid was added dropwise. The voluminous precipitate was removed by filtration, washed with hot water, and dried: yield, 3.5 g. The material was recrystallized several times from ethanol, m.p. 192–194° C; mixed m.p. with an authentic sample of 5,5¹-dimethylcoumarano-3¹,2¹,2,3-coumaran (4), 191–194° C; infrared data in Nujol: 1600 (w), 1495 (s), 1330 (w), 1250 (m), 1195 (w), 1130 (w), 1095 (w), 990 (s). Anal. Calc. for $C_{16}H_{14}O_2$: C, 80.65; H, 5.88. Found: C, 80.66; H, 6.26.

Procedure B.—Glyoxal monohydrate (5.3 g), *p*-cresol (7.1 g), and *p*-toluenesulphonic (0.25 g) were heated in a sealed Carius tube at 102° C for 14 hours. The product was extracted with acetone and precipitated by addition of water. Recrystallization of the product from ethyl alcohol gave 0.85 g of 5,5¹-dimethylcoumarano-3¹,2¹,2,3-coumaran.

Procedure C.—Fusion of the same reactants as described in procedure B at 130–140° C for 10 minutes gave 0.2 g of the coumaran.

Procedure D.—A solution of anhydrous glyoxal (0.72 g), *p*-cresol (1.30 g), and *p*-toluenesulphonic acid (0.050 g) dissolved in 15 ml of anhydrous bis-(2-ethoxyethyl) ether was allowed to react at 0° C in a sealed Carius tube for 24 hours. Addition of petroleum ether (200 ml) to the reaction mixture caused a precipitate (0.72 g) to form, m.p. 140–150° C (decomp.). This material showed strong absorption in the infrared at about 3400 cm^{-1}. The product, when heated to a temperature above 170° C, gave off yellowish fumes of glyoxal. When anhydrous gloxal was reacted with *p*-cresol in bis-(2-ethoxyethyl) ether at elevated temperatures only polymerized glyoxal was obtained.

I (*a*) $R_1 = CH_3$; $R_2 = R_3 = H$
(*b*) $R_1 = CH_3CH_2$; $R_2 = R_3 = H$
(*c*) $R_1 = R_2 = R_3 = CH_3$

The aromatic protons of N-acetylindoline (I*a*) appeared in two parts of the spectrum, the C_7 proton (split by the other protons in the ring) as a doublet centered at −0.93 p.p.m. (spacing of 8.5 c.p.s.) and the remaining ring protons as a complex multiplet centered at about 0.22 p.p.m.* The corresponding peaks in N-propionylindoline (I*b*) were at −0.94 p.p.m. (spacing of 8.5 c.p.s.) and at about 0.27 p.p.m., and in N-acetyl-2,3,3-trimethylindoline (I*c*) at −0.52 p.p.m. (unresolved) and at about 0.35 p.p.m. The appearance of the C_7 proton signal at low field is potentially diagnostic for the absence of other substitution at the equivalent position in alkaloids of this partial structure. The protons at positions 2 and 3 in both I*a* and I*b* gave rise to the pair of triplets predicted for an A_2B_2 system approaching the A_2X_2 limit (2). The low-field signal was centered at 3.27 p.p.m. in the former and at 3.43 p.p.m. in the latter, and the high-field signals were centered at 4.15 p.p.m. and 4.28 p.p.m., respectively (the spacing was 8.5 c.p.s. for both). The proton at position 2 in I*c* gave rise to the A part of an AX_3 system (the C_2—CH_3 is the X part) and appeared as a quartet centered at 3.28 p.p.m. (J = 6.5 c.p.s.), supporting the assignment made to the corresponding proton in aspidocarpine (3).

The acetyl protons of I*a* and I*c* gave rise to single sharp peaks at 5.10 and 5.08 p.p.m., respectively. The propionyl protons of I*b* produced the expected quartet (two protons of CH_2) centered at 5.00 p.p.m. and triplet (three protons of CH_3) centered at 6.13 p.p.m. (J = 8 c.p.s.).

The methyl groups at positions 2 and 3 of I*c* produced three sharp peaks (total area equivalent to nine protons) at 6.05, 6.18, and 6.30 p.p.m. with relative intensities 2:3:1, which could be accounted for in the following way. The C_2 methyl group split by the C_2 proton formed a doublet at 6.18 and 6.30 p.p.m., one peak of which accidentally overlapped the peak at 6.18 p.p.m. produced by one of the C_3 methyl groups. The second C_3 methyl group produced the peak at 6.05 p.p.m.

EXPERIMENTAL

N-*Acetylindoline*— m.p. 106–106.5°, was prepared from indoline and acetic anhydride (4).

N-*Propionylindoline*— white needles, m.p. 104.5–105° from 95% ethanol, was prepared from indoline and propionic anhydride. Anal. Calc. for $C_{11}H_{13}ON$: C, 75.40; H, 7.48; N, 7.99. Found: C, 75.68; H, 7.49; N, 8.26.

N-*Acetyl-2,3,3-trimethylindoline*.—2,3,3-Trimethylindolenine (Aldrich Chemical Co.) (232 mg) was hydrogenated with pre-reduced platinum oxide catalyst in acetic anhydride. One mole of hydrogen was taken up rapidly. The catalyst was removed by filtration and

**Spectra were obtained with a Varian Associates high-resolution nuclear magnetic resonance spectrometer operating at 60 Mc/sec frequency. Chloroform was employed both as a solvent and as an internal reference; its proton resonance was assigned a value of zero part per million and the scale was fixed from the position of the associated C^{13} (natural abundance) peaks which were shown to have a value of ±1.75 p.p.m. Solutions were approximately 0.5 M and solvent effects were neglected. Accuracy to ±0.04 p.p.m. was anticipated on this scale. Chloroform has the value 2.75 p.p.m. on the Tiers scale (1).*

SCISSION OF STERICALLY HINDERED *vic*-DIOLS*

H. R. GOLDSCHMID† AND A. S. PERLIN

The scission of *vic*-diols by lead tetraacetate (1) and periodic acid (2, 3) is strongly rate dependent on the stereochemistry of the glycol group attacked. This property has led to the view (4), now generally accepted, that the reaction usually involves formation of a coplanar cyclic intermediate complex between the glycol and oxidant. Complexing of this type is unlikely to occur if the projected valency angle of the glycol group is held rigidly in the region of 120–180° (5, 6, 7). Such a steric arrangement is found in several compounds that contain a *trans*-glycol group situated in a fused or bridged ring system, and the fact that these compounds fail to react with lead tetraacetate or periodate is in excellent agreement with the concept of the cyclic intermediate.‡ In this group of sterically hindered glycols are 1,6-anhydro-β-D-glucofuranose and -α-D-galactofuranose (8), the two *trans*-2,3-camphanediols (9), cholestane-3β,6β,7α-triol (10), 4,6-*O*-benzylidene methyl α-D-altropyranoside (11), and 2,6-anhydro-β-D-fructofuranose (12).

Steric effects that are strongly evident for oxidations with lead tetraacetate in acetic acid were noted by Hockett and Mowery (13) to be much less marked when pyridine was used as solvent. This observation suggested that the steric requirements for lead tetraacetate oxidation are less critical in pyridine than under the more usual reaction conditions, and prompted us to test the stability of the sterically hindered glycols towards lead tetraacetate in pyridine. Several of these compounds have now been examined and found, in fact, to be oxidized readily (Table I). That the reactions constitute true glycol cleavage is indicated by the degradation of 4,6-*O*-benzylidene methyl α-D-altropyranoside (I) (as well as the corresponding D-glucoside) to the dialdehyde isolated, as the hemialdal hydrate

**Issued as N.R.C. No. 5973.*

†Figures in parentheses give the number of moles of lead tetraacetate used per mole of substrate.
‡Closely similar data were obtained for the α-anomer.
§Temperature, 25° C.

(II) (14), formed by periodate oxidation of 4,6-*O*-benzylidene methyl α-D-glucopyranoside* (14, 15, 16).†

A normally "slow" diol (17), *trans*-1,2-cyclopentanediol, was very rapidly oxidized, the observed uptake being 0.9 to 1.0 mole of lead tetraacetate per mole in 5 minutes reaction time, irrespective of whether the excess of oxidant used was 0.25, 1.0, or 3.0 moles per mole. By contrast, the rate of oxidation of the hindered diols fell off sharply at well below

4,6-O-Benzylidene methyl α-D-glucopyranoside is oxidized at an unusually slow rate by periodate (11, 16). It also is extremely resistant to attack by lead tetraacetate in acetic acid, a property that is exhibited also by e,e trans-diols situated on 1,4-bonded central units of oligosaccarides (18). In pyridine, however, the benzylidene derivative is rapidly oxidized by lead tetraacetate (Table I and Experimental section).

†*Cholestane-3β,6β,7α-triol (10) (a sample of which was kindly provided by Prof. S. J. Angyal) is more resistant to oxidation than the other compounds examined: the observed rate of lead tetraacetate uptake (mole/mole(min)) was 0.34 (15), 0.55 (90), and 0.80 (360). This result contrasts strongly with the behavior of I (Table I), which also contains a diaxal glycol group, and may be related to the greater rigidity of ring B in the cholestane derivative than of the pyranoside ring in I.*

the theoretical level if an excess of only 1 to 2 moles of lead tetraacetate was used (Table I). With an excess of 3 to 4 moles the data were much more satisfactory (Table I). The marked drop in reaction rate at the lower level of concentration may possibly be related to Criegee's suggestion (4) that acetic acid, formed in the reduction of lead tetraacetate to the diacetate, can depress the rate of oxidation in a solvent other than acetic acid by a mass-action effect. Such an effect would be most readily apparent with the most highly hindered glycols.

Although the stoichiometry of the various reactions examined is close to the theoretical value under suitable conditions, slow overoxidation is always evident (Table I). Because of this non-specific overoxidation several hydroxylated compounds, other than 1,2-glycols, were examined. In this group were 1,2,3,4- and 2,3,4,6-tetra-*O*-acetyl-D-glucopyranose; 1,3-dihydroxypropane; 1,3-dihydroxy-2,2-dimethylpropane; pentaerythritol; 1,6-dihydroxyhexane; 2,5-dihydroxyhexane; and 1,3,6-trihydroxyhexane. Of these compounds, only 1,3-dihydroxypropane was attacked to a significant degree during the period of 1 to 2 hours (Table I) required for complete oxidation of the hindered glycols, the consumption in 2 hours reaction time being 0.12 mole of lead tetraacetate per mole. With a more prolonged oxidation period (8 to 24 hours), several of the compounds reduced a small proportion of oxidant (0.1 to 0.2 mole/mole), and with pentaerythritol the consumption reached a value of 0.6 mole/mole in 24 hours. It is clear, therefore, that in testing for the presence of a 1,2-diol group in an unknown compound with lead tetraacetate in pyridine, prolonged reaction periods should be avoided.

Pyridine is particularly suitable for the glycol-cleavage oxidation of certain classes of compounds which might be unstable or poorly soluble in media used more commonly. Hockett and co-workers (13, 19) first employed this solvent for lead tetraacetate oxidation of sucrose and trityl ethers of methyl D-arabopyranoside, compounds unstable in acetic acid. Similarly, we have found these conditions of oxidation useful for determining the structure of trityl- and tosyl-derivatives of ethyl α- and β-D-fructofuranoside (12). The 1,6-ditrityl ether of these glycosides exhibited behavior that is characteristic of the highly hindered diols described above, in that their oxidation rates dropped sharply when a small excess of lead tetraacetate was used (Table I). As shown by Smith and co-workers (20), periodate oxidation may be inhibited when a trityl or phenyl group is in close proximity to the *vic*-diol, the effect being attributed to steric interference. However, interference by bulky substituents does not appear to account fully for the retarded oxidation rate of the ditrityl-D-fructofuranosides, because the corresponding 1,6-ditosyl derivative reacts readily and quantitatively (Table I).

EXPERIMENTAL

Lead tetraacetate was dried *in vacuo* over solid potassium hydroxide, and pyridine was freshly distilled over solid potassium hydroxide.

Measurement of Lead Tetraacetate Uptake

The stopping solution (1) used (per milliliter of reaction mixture) contained potassium iodide (1.0 g), sodium acetate (2.7 g, anhydrous) in water (10 ml). Acetic acid (3 ml) was added to the stopping solution immediately before an aliquot of the oxidation mixture in order to complete the liberation of iodine. A bulky yellow precipitate is formed when lead tetraacetate in pyridine is mixed with the stopping solution; determination of the iodine with thiosulphate was facilitated by adding starch indicator at the outset, the suspension being titrated until the pea-green color was discharged.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In a typical experiment, 2,6-anhydro-β-D-fructofuranose (13.0 mg) in pyridine (4 ml) was treated at 0° C with a solution of lead tetraacetate (160 mg) in pyridine (6 ml). (The solution of lead tetraacetate in pyridine is deep brown in color, and the intensity of the color diminishes as oxidant is used up.) At chosen intervals, 1-ml portions of the reaction mixture were transferred to the stopping solution, and the liberated iodine was titrated immediately with thiosulphate.

Oxidation of 4,6-O-Benzylidene Methyl α-D-Altropyranoside (I)

To a solution of the benzylidene glycoside (282 mg) in pyridine (15 ml), lead tetraacetate (1.32 g) was added. After 25 minutes at room temperature the reaction mixture was treated with oxalic acid dihydrate (4.0 g) and a few drops of water. The precipitate was filtered off, the filtrate concentrated *in vacuo* at 45° C, and the residue obtained was taken up in hot aqueous acetone. A crystalline product (201 mg) was deposited from the cooled solution, and after recrystallization from aqueous acetone the product II (14) had a melting point of 130–133° C and $[\alpha]_D^{27}$ +62.8° (*c*, 1.9, pyridine). Calculated for $C_{14}H_{18}O_7 \cdot H_2O$: C, 53.16%; H, 6.37%. Found: C, 53.25%; H, 6.44%.

On treatment with hot phenylhydrazine acetate the product yielded glyoxal bis-phenylhydrazone, m.p. 164–166° C, undepressed.

The above hemialdal hydrate furnished a bis-cyclohexylamine derivative (14) with a melting point of 115–117° C and $[\alpha]_D^{27}$ −32.6° (*c*, 1.2, pyridine). Calculated for $C_{26}H_{38}O_4N_2$: C, 70.55%; H, 8.65%. Found: C, 70.48%; H, 8.86%.

Oxidation of 4,6-O-Benzylidene Methyl α-D-Glucopyranoside

The benzylidene glycoside (282 mg) was treated in pyridine (10 ml) with lead tetraacetate (618 mg) for 15 minutes at room temperature. Excess oxidant was reduced with oxalic acid, and the reaction mixture was worked up, affording compound II (14), m.p. 130–133° C, undepressed, and $[\alpha]_D^{27}$ +63.0° (*c*, 1.8, pyridine). Calculated for $C_{14}H_{18}O_7 \cdot H_2O$: C, 53.16%; H, 6.37%. Found: C, 53.54%; H, 6.16%.

On treatment with hot phenylhydrazine acetate the product yielded glyoxal bis-phenylhydrazone, m.p. 164–166° C, undepressed.

The derived bis-cyclohexylamine derivative (14) had a melting point of 115–117° C, undepressed and $[\alpha]_D^{27}$ −31.9° (*c*, 1.2, pyridine). Calculated for $C_{26}H_{38}O_4N_2$: C, 70.55%; H, 8.65%. Found: C, 70.56%; H, 8.59%.

The X-ray powder diagrams obtained from the above hemialdal hydrate and its bis-cyclohexylamine derivative were indistinguishable from the corresponding materials obtained from 4,6-*O*-benzylidene methyl α-D-altropyranoside.

The authors gratefully acknowledge a gift of *trans*-2-exo-3-endo- and -2-endo-3-exo-camphanediol from Prof. S. J. Angyal, and of 4,6-*O*-benzylidene methyl α-D-altropyranoside from Dr. A. C. Neish. They also thank Mr. J. W. L. C. Christ for technical assistance. Microanalyses were performed by Mr. M. Mazurek and X-ray powder diagrams were prepared by Miss Inez Gaffney.

THE SEPARATION OF SUGARS ON ION-EXCHANGE RESINS

PART I. SEPARATION OF OLIGOSACCHARIDES[1]

J. K. N. JONES, R. A. WALL, AND (*in part*) A. O. PITTET[2]

ABSTRACT

Fractionation according to molecular size has been achieved by development of oligosaccharide mixtures with water on columns of neutral salt forms of sulphonic acid type ion-exchange resins. The method was used to separate a synthetic mixture of raffinose, sucrose, and glucose and a number of hydrolyzates of polysaccharides to give clean, salt-free fractions of high purity. The procedure is rapid and economical and provides a useful extension of older methods of separating such mixtures.

INTRODUCTION

One of the major problems of carbohydrate chemistry is the separation of mixtures of sugars from hydrolyzates and synthetic reactions. Resolution is commonly achieved by using variations of the charcoal–celite columns of Whistler and Durso (1) or partition chromatography on cellulose columns (2). These procedures are usually very efficient and several grams of material can be separated per run, but the time required for fractionation may be of the order of weeks or even months. Moreover, the larger fragments are usually eluted at the end of the process, a reversal of the most desirable order.

The work of Wheaton and Bauman (3) and Samuelson *et al.* (4, 5, 6) on equilibria between aqueous solutions of polyhydroxy organic compounds and ion-exchange resins pointed the way to a new method of fractionation according to molecular bonding or size. It could be inferred from these data that small molecules are much more strongly attracted to the resin than are large molecules, and that column development of a mixture should result in the largest molecules appearing first in the eluate. Any further speculations had to be based on extrapolation, as no data were available for compounds of more than six carbon atoms (although Moore and Stein (7) were able to separate peptides by a similar process), but it seemed clear that bonding could vary greatly with the cross-linkage and salt form of the resin.

This extension of the data of Samuelson and Wheaton and Bauman was shown to be correct and separation of oligosaccharides and monosaccharides according to molecular size has been achieved on Dowex 50W (2% DVB, 200–400 mesh, Li^+ form). Many other types of ion exchangers with different degrees of cross-linking and in different salt forms were tried but were less satisfactory.

Synthetic mixtures of mono-, di-, and tri-saccharides and various polysaccharide hydrolyzates have been separated on the resin columns. Surprisingly, the same 2% DVB resin columns also gave some resolution of mixtures of *O*-alkylated monosaccharides,

[2]*Present address: Chemistry Department, Ohio State University, Columbus, Ohio.*

an interesting point being that the size order was reversed with these derivatives so that the most highly substituted molecules were eluted last.

The developing solvent was distilled water for most of the separations on the 2% DVB Dowex 50W columns, although 50% aqueous ethanol was used for some preliminary experiments. As predicted by theory the material of highest molecular weight was eluted first followed by lower oligosaccharides and continuing the order down to glycerol and ethylene glycol, which were partially separable. Fractionations were rapid (24–48 hours for complete elution) and the method is economical since the columns could be used many times and water was the only solvent used. The sugars were eluted in relatively concentrated aqueous solution such that direct spotting for paper chromatography was possible without evaporation of the eluate fractions.

EXPERIMENTAL

General Methods

Aqueous solutions were evaporated under reduced pressure at ca. 40° C. All melting points are uncorrected and were measured on a Kofler hot stage.

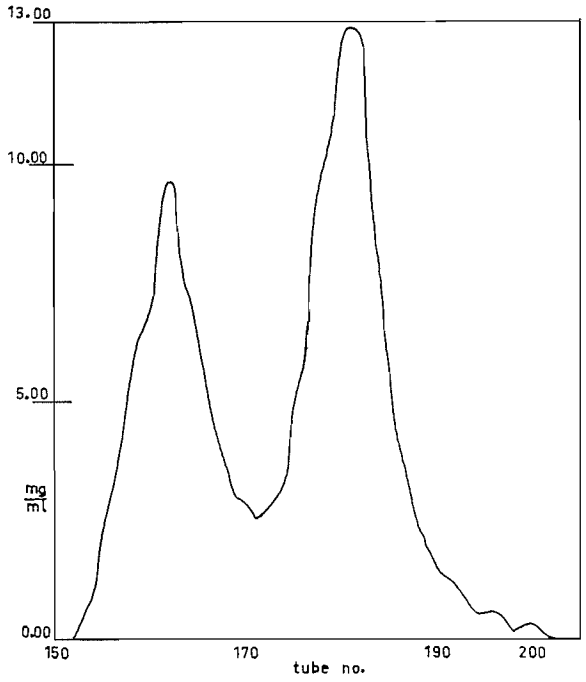

FIG. 1. Separation of raffinose (91 mg) and melibiose (130 mg); flow rate was 1.0 ml per 15-minute fraction. Recoveries calculated from the colorimetric analysis (9) were: raffinose 102% and melibiose 99%. Tubes 154–167 were concentrated to a syrup, and trituration with alcohol–acetone induced crystallization of prisms, m.p. 127–130° and mixed m.p. 131–135°, with authentic recrystallized raffinose of melting point 132–135° (seeded with the 127–130° material). The recovered compound had $[\alpha]_D^{23°}$ +115° (*c*, 1.2 in water) and an infrared spectrum (potassium bromide pellet) identical with that of authentic raffinose pentahydrate in the 700–1500 cm^{-1} region. Trituration with alcohol of the syrup from the contents of tubes 176–189 gave prisms which had a melting point of 181–184°, which was not depressed on admixture with authentic anhydrous melibiose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

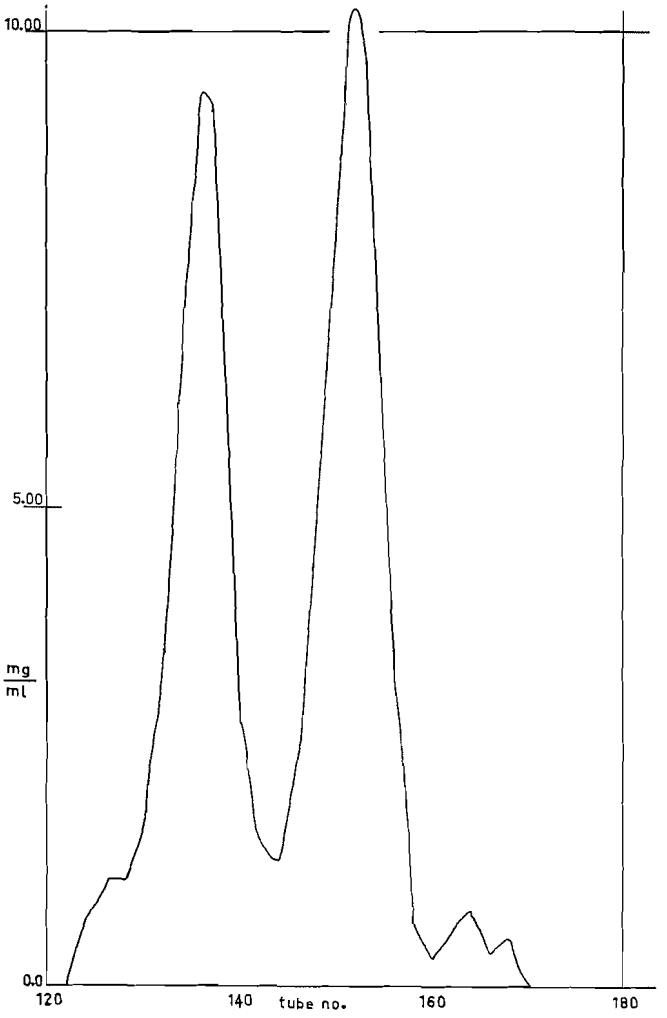

FIG. 2. Separation of D-glucose (115 mg) and maltose (115 mg) at a flow rate of 1.45 ml per 15-minute fraction. Calculated recoveries were: glucose 99% and maltose 97%. Treatment of the contents of tubes 131–140 as before gave prisms which had a melting point of 125–129° and an infrared spectrum (potassium bromide pellet) identical with that of authentic β-maltose hydrate. These crystals had $[\alpha]_D^{22°}$ +118° (10 minutes) → +131° (24 hours) (*c*, 1.1 in water) and gave on acetylation a crystalline acetate of melting point 161–163°, which did not depress the melting point of authentic α-maltose octaacetate. Crystalline D-glucose was obtained in a similar manner from the contents of tubes 148–160 and had a melting point and mixed melting point of 142–145°.

Preparation of Columns

Columns were sealed at the bottom with plugs of ½-in. thick polyurethane foam held in place with a tightly fitting rubber stopper with a short piece of glass capillary tubing through it. The capillary outlet was attached to a 4-ft length of 0.022 by 0.042 in. teflon tubing with a No. 24 syringe needle. This procedure allowed regulation of the rate of flow by changing the hydraulic head and gave very even flow.

A slurry of the resin (Dowex 50W X2, 200–400 mesh, Li^+ for oligosaccharides and *O*-alkylated monosaccharides) in water was poured into a glass tube of the desired size

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

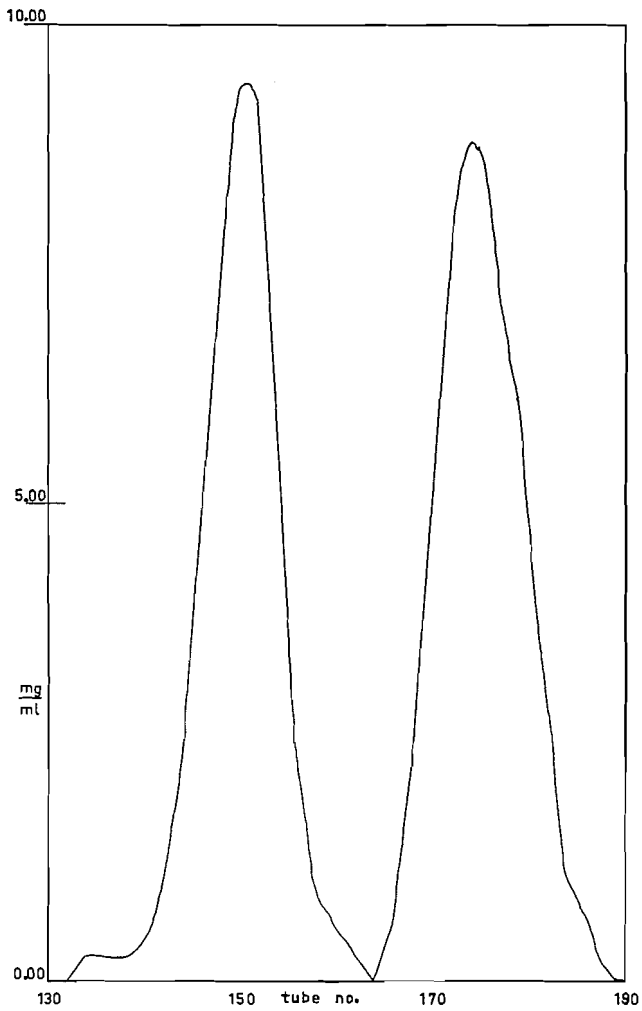

FIG. 3. Separation of lactose (94 mg) and D-galactose (108 mg) at a flow rate of 1.10 ml per 15-minute fraction. Calculated recoveries were: galactose 100% and lactose 105%. Treatment as before of the contents of tubes 141–160 gave crystalline α-lactose, m.p. and mixed m.p. 210–214° and $[\alpha]_D^{21°}$ +81.9° (9 minutes) → +60.6° (2 hours) → +56° (45 hours) (*c*, 2.4 in water). Crystalline α-D-galactose, m.p. and mixed m.p. 164–168°, was similarly obtained from the contents of tubes 165–180.

and backwashed for several hours at a rate sufficient to expand the bed to twice its final dimensions. After the fines, air bubbles, etc. had been removed, the backwashing was stopped and the resin was allowed to settle overnight by gravity. This slow settling is essential and should not be hastened by packing under pressure.

Different batches of both the Dowex 50W X2 used in the experiments detailed in this paper and the Dowex 50W X8 used in Part II were utilized at various times. No variation in separating power was ever found.

Oligosaccharide Separations

The first successful experiments with the new method were done by Dr. Pittet, who used Amberlite CG-120 (type 1, H^+) with 50% aqueous ethanol as the developing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solvent. Using this procedure he was able to separate completely glucose and maltose and to resolve partially the higher oligosaccharides from an enzymatic starch digest (335 mg on a 90×1 cm column). A larger column was used to fractionate a mixture (750 mg) of L-arabinose and an arabinosyl-arabinose obtained from partial hydrolysis of cherry gum. Crystalline L-arabinose (187 mg), m.p. 156° and mixed m.p. 159°, and a syrup (225 mg) having $[\alpha]_D^{21°}$ +165° (water) were isolated in this manner. The syrup gave a crystalline osazone, m.p. 238–241° (decomp.), which had an infrared spectrum identical with that of authentic 3-*O*-β-L-arabopyranosyl-L-arabinose phenylosazone. Unfortunately, use of the resin in the acid form gave rise to partial hydrolysis of labile oligosaccharides such as sucrose and raffinose, and modifications to reduce this difficulty were sought.

The most satisfactory resin was found to be Dowex 50W X2 (200–400 mesh, Li^+), and it was possible to separate in 48 hours raffinose, sucrose, and glucose (200 mg each) on a column (95×1.8 cm) with water as the sole developing solvent.

Elution diagrams of separations achieved in this manner are given in Figs. 1–3; the fractionations were followed with a modification of the orcinol reaction (9) and were all done on a column (112×1.8 cm) with flow rates of 1 to 2 ml per 15-minute fraction.

Separation of O-Alkylated Sugars

A hydrolyzate of fully methylated starch (1.0 g) was separated on a column (100 ×2.2 cm) of Dowex 50W X2 (200–400 mesh, Li^+) with water as sole developing solvent. The first run gave two fractions: the first contained mono-, di-, and tri-*O*-methyl-glucoses and the second apparently equal quantities of tri- and tetra-*O*-methyl-glucoses. This second fraction was refractionated on the same column and in this manner a syrup was obtained from which crystalline 2,3,4,6-tetra-*O*-methyl-D-glucose (60 mg) was isolated. Sublimation at room temperature and pressure of this material gave colorless needles of 2,3,4,6-tetra-*O*-methyl-α-D-glucose, m.p. and mixed m.p. 89–91°. The main fraction was stored as a viscous syrup and over a period of some months a tri-*O*-methyl-glucose of melting point 108–110° was obtained; presumably this was the expected 2,3,6-tri-*O*-methyl-D-glucose, but the melting point could not be raised to the literature (10) value of 121 to 123° by recrystallization.

THE SEPARATION OF SUGARS ON ION-EXCHANGE RESINS

PART II. SEPARATION OF MONOSACCHARIDES[1]

J. K. N. JONES AND R. A. WALL

ABSTRACT

Columns of neutral salt forms of sulphonic acid type ion-exchange resins have been shown to be useful in separations of monosaccharide mixtures with water as the developing solvent. A number of synthetic mixtures and a series of plant extracts have been resolved into clean, salt-free fractions by use of the new technique. The procedure is analogous to column partition chromatography, but in many cases it is more rapid and gives a useful extension of separability.

INTRODUCTION

During the initial investigations of the separation of oligosaccharides on acidic ion-exchange resin columns (1*a*, 1*b*) it was observed that the fructose produced by partial hydrolysis of the sucrose and raffinose standards was always partially separated from the glucose also present in the standard mixture. This observation was confirmed by examination of the behavior of a series of monosaccharides and by the publication of Felicetta and co-workers (2) of a successful separation of D-xylose and L-arabinose on columns of Dowex 50W X8 (50–100 mesh, Ca^{++}) with water as the development solvent. This article prompted study of the separation of a series of monosaccharides using columns of a slightly more efficient resin, Dowex 50W X8 (200–400 mesh, Ba^{++}).

Table I gives the effluent volume at which maximum concentration of the given sugar is reached on a column (70×2.2 cm) of the above resin with water as the sole developing solvent. Experience has shown that if the difference between two effluent volumes is more than 25 ml, it can be predicted that the corresponding sugars are readily separable, e.g. D-ribose and D-xylose are completely separable, but L-arabinose and D-xylose are not.

TABLE I

Sugar	Volume (ml)	Sugar	Volume (ml)
D-Glucose	157	D-Lyxose	188
N-Acetyl-D-glucosamine	160	D-Mannitol	198
D-Sorbose	164	D-Fructose	200
D-Galactose	170	D-Glycero-D-galacto-heptitol (perseitol)	238
D-Xylose	171	Dulcitol	241
D-Manno-heptulose	176	D-Sorbitol	252
D-Mannose	181	D-Xylitol	257
D-Altro-heptulose (sedoheptulose)	183	D-Ribose	342
L-Arabinose	188	D-Galacturonic acid	350

A series of determinations of percentage recoveries of amounts ranging from 50 mg to 1 g per component gave better than 85% recovery and 90–95% was usual. Separation of a mixture of D-sorbitol and *N*-acetyl-D-glucosamine (1 g each) on the above column gave ca. 90% recovery of each component in a crystalline, chromatographically pure state.

Methods were worked out for the concentration of sedoheptulose from sedum extracts; D-manno-heptulose and perseitol from the avocado pear; and the main products, D-talose and D-tagatose, from the epimerization of D-galactose.

EXPERIMENTAL

General Methods

All columns were made and used as previously described (1) but using the 8% DVB, Ba^{++} resin mentioned before. The values quoted in Table I were obtained by analysis of mixtures of two known components by paper electrophoresis with borate buffers (3) or by use of paper chromatography on Whatman No. 1 paper using the following solvent systems (v/v ratio):

(A) *n*-butanol:ethanol:water, 3:1:1;
(B) *n*-butanol:pyridine:water, 5:3:2;
(C) *t*-butanol:acetic acid:water, 4:1:1;
(D) ethyl acetate:acetic acid:formic acid:water, 18:3:1:4.

Reducing sugars were detected on chromatograms by the *p*-anisidine hydrochloride spray reagent (4). Non-reducing compounds were detected on chromatograms and electrophorograms by silver nitrate:sodium hydroxide (5) and potassium permanganate:sodium metaperiodate (6) sprays. The orcinol:trichloroacetic acid (7) spray was used to detect ketoses on chromatograms. Aqueous solutions were concentrated under reduced pressure at ca. 40° C on a rotary film evaporator. All melting points are uncorrected and were measured on a Kofler hot stage.

Separation of Standard Mixtures

Figure 1 illustrates the complete separation of D-xylose (179 mg) and D-ribose (178 mg) on the resin column (112×1.8 cm) at a flow rate of 4.0 ml per 15-minute fraction. The colorimetric analysis (benzidine – acetic acid reagent (8)) gave calculated recoveries: D-xylose 99% and D-ribose 99%. Trituration of the syrup obtained on evaporation of the tubes corresponding to the first peak with alcohol–acetone gave crystalline D-xylose, m.p. and mixed m.p. 142–145°. The syrup obtained similarly from the tubes corresponding to the second peak crystallized slowly on trituration with *n*-propanol and seeding with authentic D-ribose to give rosettes of needles which had a melting point and mixed melting point of 84–86°.

Figures 2A and 2B demonstrate the partial separation of a mixture of D-glucose (58 mg) and D-galactose (67 mg) on a column (112×1.8 cm) at an elution rate of 1.5 ml per 15-minute fraction. The sugars were determined colorimetrically using the orcinol reagent (9); the chromatogram shows that even with this poor separation ca. 25% of the individual components could be recovered chromatographically pure.

Experiments on the separation of natural and synthetic mixtures were also carried out, using a three-step column (29.5×2.2 cm, 27.5×1.65 cm, and 21.0×1.2 cm) to sharpen the fractionation (cf. Hagdahl (10)).

Fractionation of Sedum Extract

An extract (700 mg) of *Sedum* sp. prepared by the method of Benson (11) was separated on the three-step column to give three main fractions which contained: (A) aldohexose and aldopentose, (B) heptulose, and (C) ketohexose. There was considerable overlap of the components, but a refractionation of the main fraction (B) gave a syrup (400 mg) which contained traces of hexose and pentose; paper chromatography showed it to be ca. 90% heptulose. Treatment of an aliquot of the syrup with acid according to Hudson (12) gave sedoheptulosan, m.p. and mixed m.p. 154–156°, $[\alpha]_D^{25°}$ −138° (*c*, 1.2 in water) after two recrystallizations from *n*-propanol.

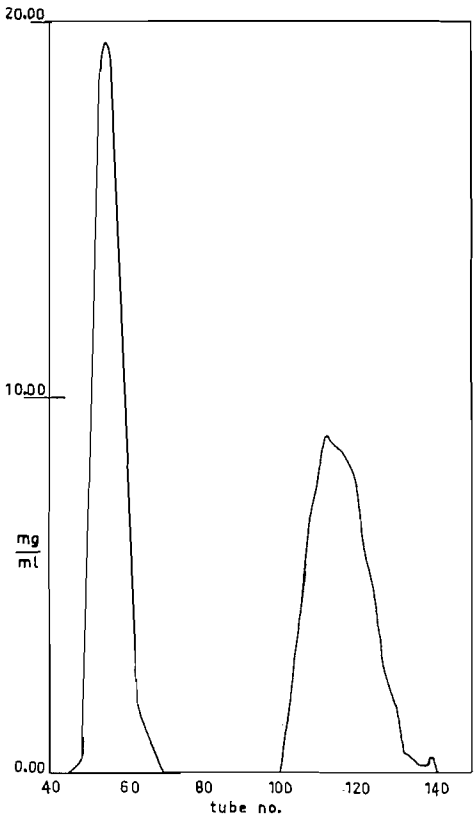

FIG. 1.

Fractionation of Avocado Extract

The acidic components of an alcoholic extract of the flesh of two ripe avocado pears were removed on a column (50×1.4 cm) of Amberlite CG-400 (type I, acetate) and the concentrated neutral effluent was passed down the three-step column to give four main fractions. These had as chief constituents: (A) disaccharide, (B) heptulose and aldohexose, (C) heptitol and ketohexose, and (D) ketohexose and unidentified reducing materials. The syrups obtained after several refractionations of mixtures (B) and (C) crystallized on standing overnight. In this manner D-manno-heptulose (2.2 g) was isolated from (B); it had a melting point and mixed melting point of 152–154.5° and $[\alpha]_D^{25°}$ +30° (10 minutes) (*c*, 2.4 in water) after two recrystallizations from ethanol. Mixture (C) gave rise to D-glycero-D-galacto-heptitol (0.5 g) of melting point 184–185° after two recrystallizations from aqueous methanol. The perseitol isolated in this experiment gave a heptaacetate of melting point 115.5–118.5° and $[\alpha]_D^{22°}$ −13.8° (*c*, 2.02 in chloroform) on treatment with acetic anhydride and pyridine.

Separation of the Epimerization Products of D-*Galactose*

D-Galactose (10 g) was epimerized by heating its solution in pyridine (100 ml) according to Karabinos (13). The published method was followed to the stage of removal of D-galactose by dilution with hot ethanol, and the resultant filtrate was evaporated under

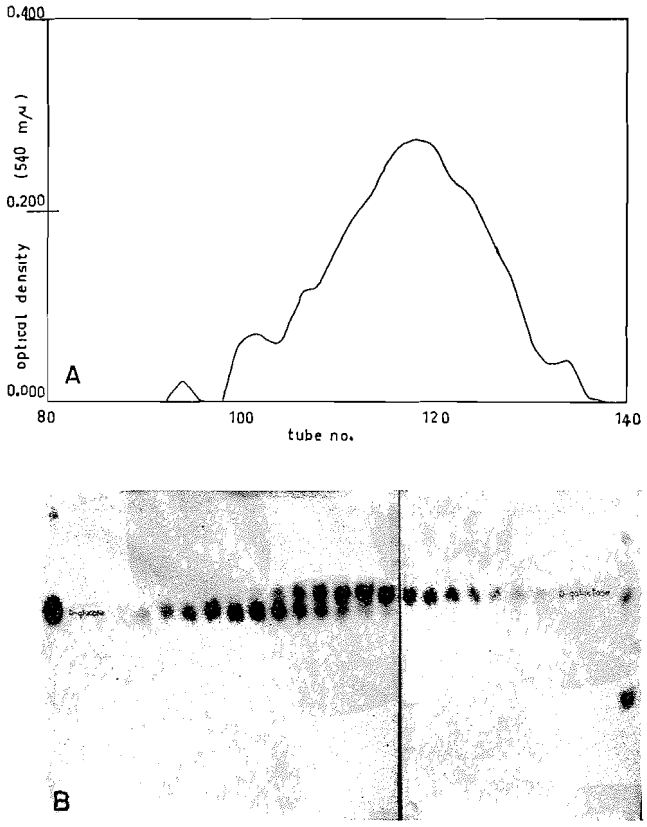

FIG. 2.

reduced pressure to a syrup which was dissolved in water (4 ml) and this solution was fractionated on the three-step column. The first separation gave three main fractions: (A) aldohexose and ketohexose, (B) ketohexose, and (C) aldohexose, of which only (C) was pure enough to crystallize directly from the syrup. Dissolution of (C) in hot ethanol left a small amorphous residue, which was removed by filtration. Colorless prisms (32 mg), which had a melting point and mixed melting point with authentic D-talose of 125.5 to 127.5° and $[\alpha]_D^{20°}$ +25° (10 minutes) (*c*, 1.0 in water), slowly crystallized from the clear filtrate. Refractionation of (A) and (B) gave syrups which crystallized on standing overnight. The solid from (A) was shown to be D-galactose, m.p. and mixed m.p. 162–166°, and $[\alpha]_D^{24°}$ +81° (10 minutes) (*c*, 1.2 in water). After two recrystallizations from ethanol the chief component of (B) was found to be D-tagatose (0.68 g), m.p. and mixed m.p. 130–132°, and its infrared spectrum (potassium bromide pellet) was identical with that of authentic D-tagatose; 85% of the initial D-galactose was recovered in a crystalline form.

PRIMARY QUANTUM EFFICIENCIES IN THE REACTION OF CYCLOPENTANE WITH MERCURY 6($^3P_1$) ATOMS[1]

RICHARD L. STOCK AND HARRY E. GUNNING

ABSTRACT

An investigation has been made of the reaction of cyclopentane with Hg 6($^3P_1$) atoms at a substrate pressure of 107 mm, under static conditions at 24° C. Low light intensities were used in order to minimize secondary reactions.

The products of the reaction, for small extents of decomposition, have been shown to be exclusively hydrogen, bicyclopentyl, and cyclopentene. With increasing duration of exposure, the cyclopentene-to-cyclopentane ratio achieves a steady-state value of 5.7×10^{-3}. Furthermore, it has been found that the same ratio is ultimately reached, upon prolonged exposure of a substrate initially containing cyclopentene at a concentration higher than the steady-state value. In the runs with added cyclopentene, a fourth product appeared in measurable quantities. Its molecular weight corresponded to the formula, $C_{10}H_{16}$, and it was assumed to be a cyclopentyl cyclopentene. The same compound appears in extensive decomposition of the pure substrate.

The addition of small amounts of nitric oxide was found to have a marked inhibiting effect on the reaction. Bicyclopentyl formation was completely suppressed when 0.7 mole% of nitric oxide was present; and the cyclopentene yield was reduced to one-fifth of its value for the pure substrate, by adding 0.98 mole% of nitric oxide.

In order to obtain primary quantum yields for the reaction, a series of runs were performed of 1 to 33 minutes in duration, with a cyclopentane which had been purified by gas–liquid chromatography. By a short extrapolation of the mean quantum yields of product formation to zero extent of reaction, it was found that the primary quantum yields for hydrogen, bicyclopentyl, and cyclopentene were respectively 0.8, 0.4, and 0.4.

On the basis of a simple four-step paraffinic mechanism, taken in conjunction with the primary quantum yield data, it is concluded that the reaction has a primary quantum yield of substrate decomposition of 0.8, and that cyclopentyl radicals have the same rates for disproportionation and recombination at 24° C.

INTRODUCTION

In two previous investigations (1, 2) of the reaction of cyclopentane vapor with Hg 6($^3P_1$) atoms, under static conditions, at 30° C, it was shown that the primary process involves scission of the C—H bond with formation of cyclopentyl radicals and H atoms. The products of the reaction were found to be hydrogen, bicyclopentyl, and cyclopentene. In the more recent of the two studies (2), limiting quantum yield values, at high substrate pressures, were used, in conjunction with a simple paraffinic free radical mechanism, to obtain values of 0.49 for the primary quantum yield, and 5.3 for the ratio of the rates of recombination to disproportionation for cyclopentyl radicals. The results reported in this paper represent the first phase in a study of the reaction as a function of temperature. In order to obtain more direct values for the primary quantum yields, the reaction has been studied at small extents of decomposition and low light intensities. The details of the investigation follow.

EXPERIMENTAL

The experiments were performed in cylindrical, fused, quartz reaction cells, 10 cm in length and 5 cm in diameter. For each run a breakseal, product trap, and filling tube were connected to the stem of the reaction cell. The product trap consisted of a short length of 7 mm O.D. tubing, with a constriction to facilitate removal by flame-cutting. In order to introduce the cyclopentane vapor, the cell was connected via the filling tube,

of 3 mm I.D. capillary, to the vacuum manifold, and pumped down to at least 10^{-3} μ. Mercury vapor for the reaction was supplied by placing several drops of mercury in a small depression in the connecting tube of the product trap. In all runs the cell was filled with cyclopentane vapor at a pressure of 107 mm, by placing an ice bath around the reservoir of liquid cyclopentane. After being filled, the cell was flame-cut from the manifold and placed in an oven which was maintained at 24±0.5° C, for the present series of runs.

The 2537-Å resonance radiation was supplied by a Hanovia, Sc-2537 source, which was wound in the form of a five-turn helix. The lamp was rigidly positioned with respect to the cell, in order to assure constant light input. The oven was provided with a filter of Vycor, 7910 glass, to prevent 1849-Å radiation from entering the cell.

At the end of each run, products condensable in liquid nitrogen were frozen into the product trap. In order to assure that high-boiling products were quantitatively transferred to the trap, the remainder of the cell was heated to 250° C during the transfer process. By connecting the cell, via its breakseal, to an analytical system, the non-condensable gases could be transferred, by means of a Toepler pump, to a gas burette. The hydrogen was determined by standard procedures involving combustion over heated copper oxide at 250° C.

The product trap, containing the condensable products, was flame-cut from the cell, and placed in a 4-in. length of 3/8-in. copper tubing, which, in turn fitted into a special sample-insertion device. This device was provided with double-compression fittings, a thumbscrew for shattering the product trap, and a preheater.

The sample-insertion device was placed in series with the hydrogen gas stream to a special gas–liquid chromatographic (G.L.C.) unit. The katharometer was of the Gow-Mac, T/C type, with temperature regulation. Ten-foot chromatographic columns were used, containing 30–60 mesh, silica gel. The analyses were made with the katharometer at 106° C.

The cyclopentane and cyclopentene used were Phillips, Research Grade (P.R.G.). G.L.C. analysis of the cyclopentane showed that the only impurity was 0.051 mole% of cyclopentene. For one series of runs at low conversion, the cyclopentane was further purified by isolating the G.L.C. fraction. This sample showed no detectable impurities. It is estimated that the purity was at least 99.999 mole%. The nitric oxide used was Matheson, C.P. grade, of 99 mole% purity. The gas was further purified by trap-to-trap distillation.

RESULTS

In order to minimize complexities associated with the localized build-up of products in the reaction zone, the runs were carried out at a low absorbed light intensity. By using propane as an actinometer (3), the absorbed light intensity was found to be $3.75\pm0.05\times10^{-7}$ einstein/minute. All quantum yields reported here are based on this light intensity.

In Fig. 1, the relations are shown between product yield and duration of exposure, for a series of runs with P.R.G. cyclopentane. The cyclopentene yields were corrected for the small amount of cyclopentene present initially in the substrate. From the graph, it is apparent that the rate of bicyclopentyl production is constant throughout the range of duration of exposure studied. For hydrogen production, there is a slight indication of a decreased rate in the runs of long duration. The fact that cyclopentene achieves a steady-state concentration after approximately 120 minutes of exposure is shown clearly in

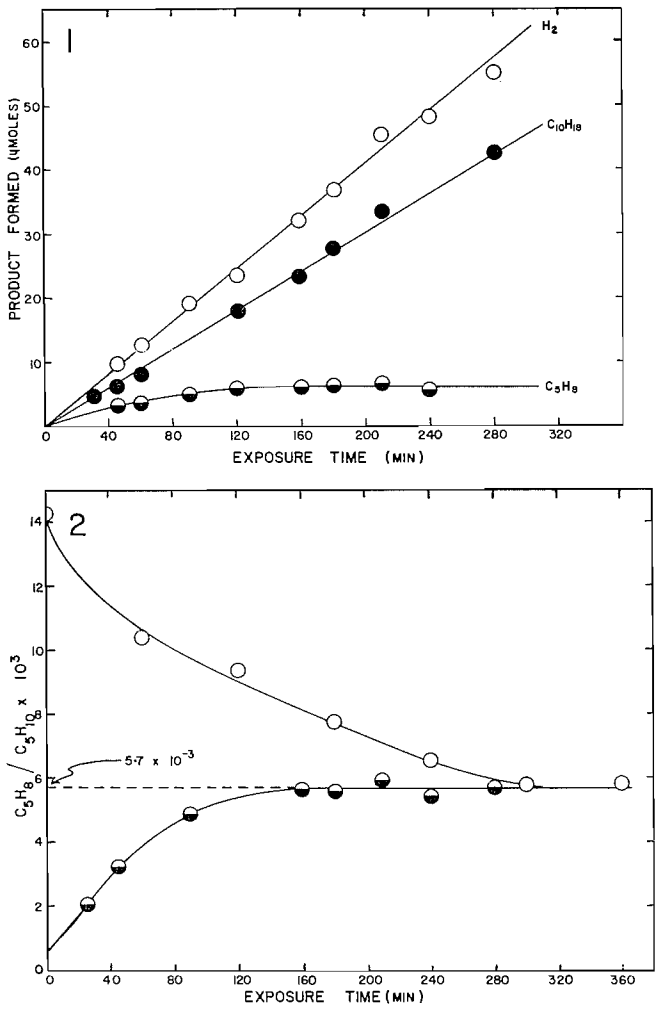

FIG. 1. Yields, in micromoles, for hydrogen, bicyclopentyl, and cyclopentene vs. exposure time in the mercury-photosensitized decomposition of Phillips, Research Grade (P.R.G.) cyclopentane.

FIG. 2. The change in the cyclopentene-to-cyclopentane ratio with increasing exposure time in the mercury-photosensitized decomposition of cyclopentane: ◒ P.R.G. cyclopentane, ○ cyclopentane containing 1.43 mole% of cyclopentene.

Fig. 1. In the runs exceeding about 200 minutes in duration, small amounts of a fourth product were detected in the G.L.C. analyses. This product is discussed in more detail below.

The lower curve in Fig. 2 shows the behavior of the cyclopentene-to-cyclopentane ratio, as a function of exposure time, for P.R.G. cyclopentane. The steady-state value for the $(C_5H_8)/(C_5H_{10})$ ratio was found to be $5.7\pm0.1\times10^{-3}$. In order to determine whether the same steady-state would be achieved with added cyclopentene, a series of runs were done with a sample of cyclopentane for which the $(C_5H_8)/(C_5H_{10})$ ratio was initially 14.3×10^{-3}. It can be seen from the upper curve in Fig. 2 that the same steady-state value is ultimately reached, as with the P.R.G. cyclopentane.

In the runs with added cyclopentene, it was noted that a fourth product appeared in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

measurable quantities. In the G.L.C. analysis, the retention time for this product was identical with that of the minor peak obtained in runs of long duration with the P.R.G. substrate. The product was isolated, and a parent-peak determination was made on a mass spectrometer. The molecular weight corresponded to the formula $C_{10}H_{16}$. It was concluded that the product was likely a cyclopentyl cyclopentene. On the assumption that the $C_{10}H_{16}$ product had the same sensitivity as bicyclopentyl (4), the $(C_{10}H_{16})/(C_5H_{10})$ ratio could be estimated. These values, together with the $(C_5H_8)/(C_5H_{10})$ ratios, are given in Table I, for the runs with added cyclopentene. It can be seen from the table that the $(C_{10}H_{16})/(C_5H_{10})$ ratio reaches a steady-state value of $1.6\pm0.1\times10^{-3}$. It should further be noted that the $C_{10}H_{16}$ product and cyclopentene reach their respective steady-state concentrations in essentially the same period of time.

TABLE I

Quantum yields and steady-state concentrations for runs with added cyclopentene*

*Initial cyclopentane pressure = 107 mm. Absorbed light intensity = 3.75×10^{-7} einstein/minute.

The data in Table I also show clearly that the quantum yield of bicyclopentyl formation is invariant in exposure time at 0.39 ± 0.03.

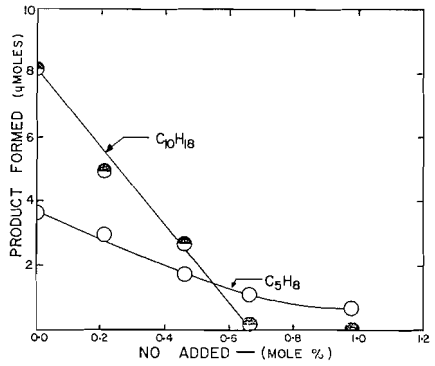

FIG. 3. The effect of added nitric oxide on the yields, in micromoles, of bicyclopentyl, and cyclopentene for 1-hour runs in the mercury-photosensitized decomposition of P.R.G. cyclopentane.

In Fig. 3 the effect is shown of the addition of small amounts of nitric oxide on the yields of cyclopentene and bicyclopentyl. The data are for 1-hour runs. The results demonstrate rather strikingly the free radical nature of the reaction. With 0.7% nitric oxide present, no bicyclopentyl is formed. With 0.98% added nitric oxide, the cyclopentene yield is reduced to 18% of its value for the pure substrate. In the 1-hour run,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with 0.98% nitric oxide, the total yield of cyclopentene was only 0.66 μmole. This small value is liable to considerable error, since correction must be made for the cyclopentene present in the P.R.G. substrate, apart from the inherent error in the determination. It can be concluded that the presence of approximately 1% nitric oxide completely inhibits bicyclopentyl formation, and reduces the cyclopentene yield to a very low value.

In Fig. 4, the mean quantum yields for the formation of hydrogen, bicyclopentyl, and cyclopentene are shown as a function of the exposure time, for P.R.G. cyclopentane. It should first be noted that the quantum yield of bicyclopentyl formation does not change with duration of exposure, maintaining throughout a constant value of 0.40±0.01. Reference to Table I shows that the value is the same as that obtained in the runs with added cyclopentene, within the experimental error. Extrapolation of the mean quantum yields of cyclopentene formation to $t = 0$ suggests a value of 0.4 for $\phi_{C_5H_8}$. From the stoichiometry $\phi^0_{H_2}$ must be 0.8.

In order to obtain more accurate data on the primary quantum yields of the reaction, a special batch of P.R.G. cyclopentane was purified by G.L.C. This ultrapure material showed no detectable impurities, and it was estimated that total impurities could not exceed 0.001 mole%. Runs were made with exposure times from 1.4 to 33 minutes. The

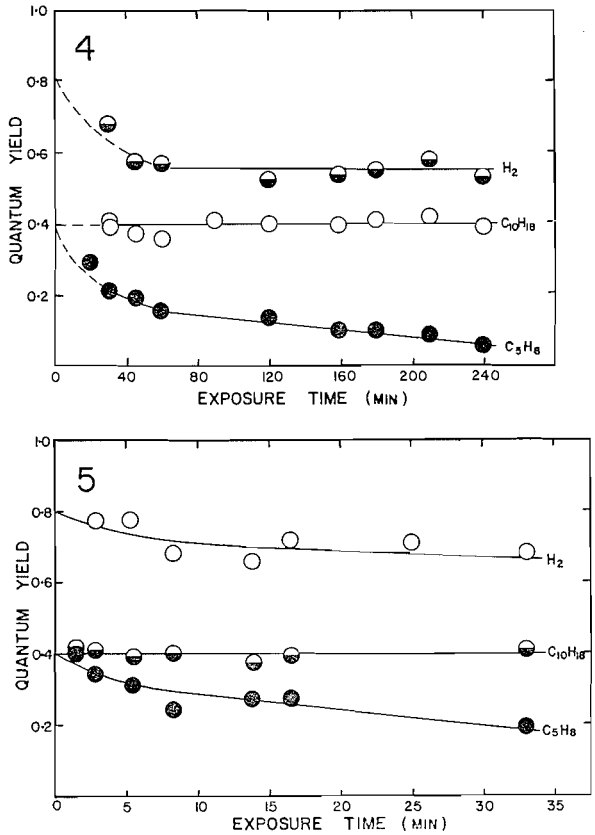

FIG. 4. The mean quantum yields of formation for hydrogen, bicyclopentyl, and cyclopentene vs. exposure time in the mercury-photosensitized decomposition of P.R.G. cyclopentane.

FIG. 5. The mean quantum yields of formation of hydrogen, bicyclopentyl, and cyclopentene vs. exposure time in the mercury-photosensitized decomposition of cyclopentane containing less than 0.001 mole% of impurities.

For personal use only.

mean quantum yields vs. exposure time are shown in Fig. 5. Again the invariance of the quantum yield of bicyclopentyl formation at 0.40 is to be noted. The extrapolation of $\phi_{C_5H_8}$ to $t = 0$ can now fairly confidently be said to lead to a value of 0.4 for $\phi^0_{C_5H_8}$. Under such conditions, $\phi^0_{H_2}$ must be 0.8, and an inspection of Fig. 5 shows that 0.8 is a reasonable extrapolation of the actual data on the mean quantum yield of hydrogen formation to $t = 0$.

DISCUSSION

As in the previous two studies (1, 2) on the cyclopentane reaction, the mechanism under initial conditions will be represented by the following paraffinic sequence:

$$C_5H_{10} + Hg\ 6(^3P_1) \rightarrow C_5H_9 + H + Hg\ 6(^1S_0) \quad [1]$$

$$H + C_5H_{10} \rightarrow C_5H_9 + H_2 \quad [2]$$

$$2(C_5H_9) \rightarrow C_5H_8 + C_5H_{10} \quad [3]$$

$$2(C_5H_9) \rightarrow C_{10}H_{18} \quad [4]$$

The above four-step sequence should apply only in the limiting case of zero extent of reaction. A steady-state treatment leads to the following expressions for the primary quantum yields: $\phi^0_{H_2} = K$, $\phi^0_{C_5H_8} = K[1/(1+r)]$, $\phi^0_{C_{10}H_{18}} = K[r/(1+r)]$, and $\phi^0_{C_5H_{10}} = K[(1+2r)/(1+r)]$. The constant K represents the fraction of the primary quenching collisions which lead to reaction, and r is the ratio k_4/k_3, or the relative rate of recombination to disproportionation for cyclopentyl radicals. Both K and r can now be obtained from the primary quantum yields of formation of hydrogen, cyclopentene, and bicyclopentyl, which, in turn, were derived by short extrapolations of the mean quantum yields of product formation for ultrapure cyclopentane, as shown in Fig. 5. Thus taking $\phi^0_{H_2} = 0.8$, and $\phi^0_{C_{10}H_{18}} = \phi^0_{C_5H_8} = 0.4$, we find that $K = 0.8$ and $r = k_4/k_3 = 1.0$. The data would therefore indicate that the primary chemical efficiency of the reaction is 80%, and that cyclopentyl radicals have the same rates for disproportionation and recombination.

In the earlier study of the cyclopentane reaction at 30° C by Beck, Kniebes, and Gunning (2), the primary quantum yields, and the efficiency constant, K, were calculated from the limiting high-pressure values for the mean quantum yields. Their data were obtained for runs of 60-minute duration, at an absorbed light intensity of 2.5×10^{-6} einstein/minute. It was further assumed that the cyclopentene achieved a steady-state concentration by the reaction

$$C_5H_8 + H \rightarrow C_5H_9. \quad [5]$$

In this study we have measured directly the change in cyclopentene concentration with increasing duration of exposure, at an absorbed light intensity of 3.75×10^{-7} einstein/minute. The data, represented in Fig. 2, as a plot of the ratio $(C_5H_8)/(C_5H_{10})$ vs. the duration of exposure, show unequivocally that a steady-state concentration is indeed achieved, after approximately 160 minutes of irradiation. The steady-state value of $(C_5H_8)/(C_5H_{10})$ was found to be 5.7×10^{-3}. At an absorbed light intensity of 2.5×10^{-6} einstein/minute, with all other reaction parameters remaining constant, we would expect the steady-state to be reached in ca. $160(3.75\times10^{-7})/(2.5\times10^{-6}) = 24$ minutes. If reaction [5] is assumed to be the only method whereby cyclopentene is consumed, then the conditions in the previous study (2) should indeed represent a steady-state situation for cyclopentene. However, in the present investigation, we have found that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

prolonged irradiation leads to the formation of an additional product, $C_{10}H_{16}$, which is assumed to be a cyclopentyl cyclopentene.

This product can be accounted for by the reactions

$$H + C_5H_8 \rightarrow C_5H_7 + H_2, \quad [6]$$

$$C_5H_7 + C_5H_9 \rightarrow C_{10}H_{16}, \quad [7]$$

where C_5H_7 represents a cyclopentenyl radical. Now, if hydrogen, cyclopentene, and bicyclopentyl are the only products of the reaction, the stoichiometry would demand that the mean quantum yields for hydrogen and bicyclopentyl formation approach each other with increasing exposure. From Fig. 4, it can be seen that the mean quantum yield of hydrogen formation is slightly larger than that calculated from the quantum yields of cyclopentene and bicyclopentyl. The discrepancy, furthermore, becomes greater with increasing duration of exposure. It should also be emphasized that the invariance of the quantum yield of bicyclopentyl formation strongly suggests that the secondary product, $C_{10}H_{16}$, arises by the decomposition of cyclopentene, rather than from bicyclopentyl. The most compelling evidence, however, for ascribing $C_{10}H_{16}$ formation to the secondary decomposition of cyclopentene is presented in Table I, and also in the upper curve of Fig. 2. For the series of runs in which cyclopentene was initially added, the $C_{10}H_{16}$ product becomes considerably more important than in the runs with the P.R.G. cyclopentane.

In comparing the results obtained in the previous investigation (2) with those in the present study, there is another factor which should be considered. In mercury photosensitization, the zone of reaction is concentrated near the window through which the radiation enters the cell. With increasing light intensity, there will be a localized build-up of reaction products near this incident window. Secondary reactions should therefore assume greater importance at higher light intensities. In the previous study (2), the light intensity was 6.7 times higher than in the present work.

Probably the most interesting result of this study is the fact that cyclopentyl radicals, at 24° C, have equal rate constants for recombination and disproportionation. There seems little doubt that the ratio k_3/k_4 is at least 1.0, and by inspection of Fig. 5, it can be seen that the initial rate of cyclopentene formation could conceivably be slightly greater than that for bicyclopentyl. That these rates are essentially identical might suggest that both recombination and disproportionation proceed through the same reaction intermediate.

The results of the runs with added nitric oxide demonstrate rather strikingly the free radical nature of the reaction. From Fig. 3, it can be seen that bicyclopentyl formation is completely suppressed by the addition of 0.7% of nitric oxide. With 1% nitric oxide present in the cyclopentane, there is no bicyclopentyl present after a 1-hour run, and the cyclopentene yield is reduced to about 18% of its value for the pure substrate. Such behavior would indicate that there is a fairly stable compound formed when cyclopentyl radicals interact with nitric oxide. A possible explanation would be that the $C_5H_9.NO$ intermediate rearranges to the stable cyclopentanone oxime,

$$C_5H_9.NO \rightarrow C_5H_8{:}NOH. \quad [8]$$

The fact that cyclopentene formation is not completely suppressed would suggest that the intermediate has an alternate mode of decomposition,

$$C_5H_9.NO \rightarrow C_5H_8 + NOH. \quad [9]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From the data represented in Fig. 2, for the change in the $(C_5H_8)/(C_5H_{10})$ ratio with duration of exposure, it is apparent that the same steady-state concentration of cyclopentene is ultimately achieved, regardless of the initial cyclopentene concentration. If we assume that the over-all reaction in the steady-state region can be described by steps [1] through [7], we find that the steady-state value, $(C_5H_8)/(C_5H_{10})_{SS}$, is related to the rate constants by the equation

$$(C_5H_8)/(C_5H_{10})_{SS} = k_2/(2k_6+k_5).$$

Now k_6, the rate constant for the abstraction reaction, should be considerably smaller than that for the addition reaction, k_5. To a first approximation, therefore,

$$(C_5H_8)/(C_5H_{10})_{SS} = k_2/k_5 = 5.7\times10^{-3}.$$

In other words, our results would indicate that reaction [5] is about 175 times faster than reaction [2].

CONCLUSIONS

As a result of this study, it has been shown that the reaction of cyclopentane vapor with Hg $6(^3P_1)$ atoms leads to the formation of cyclopentyl radicals and H atoms with a primary quantum efficiency of at least 80%. The complete free radical nature of the reaction has been demonstrated by showing that as little as 0.7 mole% of added nitric oxide leads to a complete inhibition of bicyclopentyl formation. From the fact that cyclopentene and bicyclopentyl have the same primary quantum yields, it is concluded that cyclopentyl radicals have identical rates for disproportionation and recombination at 24° C. The results of the investigation would further suggest that meaningful values for the ratio of the rates of disproportionation to recombination for free radicals can only be obtained when the reaction in question is studied at low light intensities and at very short durations of exposure.

THE NATURE OF POLYMERIZATION CATALYSTS PREPARED FROM METAL ALKYLS AND TITANIUM HALIDES[1]

M. H. JONES, U. MARTIUS, AND M. P. THORNE

ABSTRACT

A study has been made of the composition and structure of the insoluble complexes formed in the reaction of aluminum triisobutyl or lithium *n*-butyl with titanium tetrachloride or trichloride in heptane at room temperature by chemical and X-ray diffraction analyses. For the tetrachloride systems it has been shown that, with metal alkyl:titanium tetrachloride ratios of 0.5 to 4, at least 50% of the titanium is present in the tetravalent state and that there is considerable loss of chlorine and alkyl groups. The aluminum complexes are amorphous except at component ratios of 0.5 to 1, where the X-ray pattern indicated traces of titanium trichloride.

With the aluminum triisobutyl – titanium trichloride system, X-ray evidence has shown that the titanium trichloride remains essentially unchanged. This result, together with the low aluminum content (less than 0.5%), is consistent with Natta's suggestion that this catalyst for olefine polymerization consists of a trichloride surface on which small quantities of aluminum alkyl are chemisorbed.

The reaction between lithium butyl and titanium trichloride at ratios above unity results in the formation of a new crystalline compound having a sodium chloride type lattice with a lattice spacing of 5.20 Å. The compound is thought to be a double salt of the type $(LiCl)_n$. $TiCl_2$ or $(LiCl)_n$.TiCl. Evidence of a second crystalline component was also noted but it could not be identified.

Tentative reaction schemes are proposed for the formation of the various complexes and their structures are considered in relation to their ability to polymerize 1-butene.

INTRODUCTION

During the past five years widespread interest has been shown in new catalysts available for the polymerization of α-olefines and dienes which are also capable of controlling the orientation of the monomer units entering the polymer chain, so that long sequences of units in a head-to-tail arrangement have the same configuration. One type of such catalysts, first reported by Ziegler (1), is obtained by the interaction in a hydrocarbon solvent of an alkyl of a metal from groups one to three of the periodic table with a halide, or other derivative, of a transition metal from groups four to eight. Although considerable information is available in the literature on the use of different catalyst combinations of this kind for polymerization, and on the nature of the polymers, less attention has been directed towards their composition and structure.

The catalyst system AlR_3–$TiCl_4$ has been studied in most detail and it is considered that complex formation occurs by reduction of the transition metal to a lower valency state by the metal alkyl (2, 3). Chemical analyses of the insoluble complexes (3, 4, 5) have shown that they contain aluminum, titanium, chlorine, and alkyl groups, the composition depending on the starting ratio of aluminum alkyl to titanium tetrachloride and the temperature of preparation. Some doubt exists as to the valency state of the titanium in the complexes and its relationship to catalytic activity both for this system and that in which lithium alkyls are used (2, 6). However, it has been established that catalysts which show the greatest stereospecificity in the polymerization of α-olefines are those derived from lower titanium halides (3).

From these and other considerations several suggestions (3, 7, 8, 9) have been made concerning the nature of the active species and the mechanism by which stereoregular

[1]*Manuscript received July 11, 1960.*
Contribution from the Departments of Chemistry and Metallurgy, Ontario Research Foundation, Toronto 5, Ontario. Presented at the Ninth Canadian High Polymer Forum held at The Guild Inn, Scarborough, Ontario, October 26–28, 1959.

polymers are formed. In general, for heterogeneous catalysts, the active sites for stereospecific polymerization are believed to be locations on a reduced titanium halide surface where the metal alkyl is chemisorbed, the resultant complex and the electron characteristics of the adjacent surface providing control of the monomer orientation during the propagation step.

In the present work additional information concerning the nature of complexes prepared from aluminum triisobutyl or lithium butyl with titanium tetrachloride or trichloride has been obtained from chemical analyses and X-ray diffraction studies, and is considered in relation to their activity as catalysts for the polymerization of 1-butene.

EXPERIMENTAL

Preparation of Reagents

(1) Solvent.—High-purity heptane (Distillation Products Inc.), b.p. 96–97° C, was purified by shaking with concentrated sulphuric acid, washing with 2% sodium hydroxide solution and water, and drying over calcium chloride and metallic sodium. After distillation from a piece of sodium in a nitrogen-flushed apparatus, the heptane was stored over sodium wire.

(2) Nitrogen.—Before use, Linde nitrogen (99.99%) containing a maximum of 15 grains water per 1000 cu. ft, was passed over heated copper and magnesium perchlorate to remove traces of oxygen and moisture.

(3) Aluminum triisobutyl.—A 25% solution in heptane of a mixture of approximately 60% triisobutyl aluminum and 40% diisobutyl aluminum hydride (Hercules Powder Company) was distilled under reduced pressure in a nitrogen atmosphere. The solvent was removed at low temperature and the aluminum triisobutyl distilled as a colorless liquid, b.p. 55° C, at 1.5 mm. The diisobutyl aluminum hydride, having an appreciably lower vapor pressure, remained in the high-boiling residue. The aluminum content of the trialkyl, which was stored as an approximately 45% (w/w) solution, was determined gravimetrically with 8-hydroxyquinoline after hydrolysis in aqueous sulphuric acid (found: Al, 13.4%; calc.: Al, 13.8%).

(4) Lithium butyl.—Lithium butyl was prepared by treating a 20% solution of *n*-butyl chloride in heptane with lithium wire (15% excess over the theoretical quantity) in an argon atmosphere. Close to 100% yields were obtained if the reaction mixture was cooled to −20° C during the addition of the lithium and allowed to heat up to room temperature slowly. After the solution of lithium alkyl was shaken for 24 hours it was filtered under nitrogen and analyzed by titration of the lithium hydroxide produced on hydrolysis.

(5) Titanium halides.—Fisher C.P. grade titanium tetrachloride was distilled in an inert atmosphere before use. Solutions in heptane were water-white. The violet titanium trichloride obtained from the Stauffer Chemical Company was pumped under vacuum to remove traces of the tetrachloride. Analysis gave a composition of $TiCl_{2.72}$.

Preparation of the Catalysts

Boston round bottles fitted with self-sealing butyl rubber gaskets protected by neoprene were used for preparation of solutions and catalyst suspensions. Particular care was taken to ensure that all the apparatus and solvent was thoroughly flushed with nitrogen before use.

For the titanium tetrachloride catalysts a concentrated solution containing about $1.5.10^{-3}$ moles ml^{-1} was prepared by addition of the pure titanium tetrachloride to a weighed quantity of solvent. The bottle was then flushed with nitrogen, capped, reweighed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and pressurized with nitrogen. Samples were withdrawn with a hypodermic syringe for use in individual catalyst preparations. These titanium tetrachloride solutions could be used over a period of about 4 days, provided the cap was renewed each time a sample was removed.

For the titanium trichloride catalysts a separate suspension of the solid in heptane was prepared for each catalyst sample. The trichloride (1–2 g) was transferred to weighed bottles in a dry box, which was continuously flushed with nitrogen and gave a maximum dew point of −40° C. After reweighing the bottles, the heptane was added by means of a syringe.

All catalysts were prepared by injection of the metal alkyl solution into the solution or suspension of the halide in heptane. The bottles were shaken by hand during the addition of the alkyl. Concentrations of the catalysts, based on the amount of halide in the solvent, were of the order of 0.2 to 0.3 molar. The catalysts were aged for at least 1 hour before use.

Analysis of the Catalysts

X-Ray diffraction analyses were carried out on suspensions of the complexes in heptane using filtered copper radiation and a powder camera of 114.6 mm diameter. The diffraction patterns were measured and evaluated according to A.S.T.M. procedures. A nitrogen-flushed 0.5 mm bore Lindemann glass capillary tube was filled by lowering it into a sample of the suspension contained in a small tube blanketed by nitrogen. The capillary was sealed in a luminous flame. With careful manipulation no change in the appearance of a catalyst suspension could be detected. Also, once sealed, the complexes were stable over a period of at least several days as indicated by the reproducibility of the diffraction patterns.

For chemical analysis the complexes were isolated by filtration under nitrogen, washed with heptane, and dried under vacuum. About 1 g of dried solid was then hydrolyzed in 50 ml of 2 *N* sulphuric acid, also in a nitrogen atmosphere, and aliquot samples analyzed for titanium, chlorine, and aluminum or lithium.

Reduced titanium in the trivalent state was determined by running aliquot samples into an excess of ferric ammonium sulphate and estimating the ferrous iron thus produced by titration with 0.3 *N* potassium permanganate. Oxidation of the chloride ion in the solution was prevented by addition of an excess of a Zimmermann-Reinhardt solution (containing 50 g $MnSO_4.4H_2O$, 100 ml 98% H_2SO_4, and 100 ml 85% H_3PO_4 in 500 ml water). The total titanium was determined by a similar method after passing aliquot samples through a Jones' reductor.

Chlorine was determined by Volhard's method.

The aluminum analyses were carried out spectrographically* on a mixture of titanium and aluminum oxides obtained by precipitation with ammonium hydroxide and subsequent ignition.

Lithium was determined by flame photometry at a wavelength of 671 mμ.

Polymerizations

Butene polymerizations were carried out in a nitrogen atmosphere at 40° C in bottles with self-sealing gaskets. Matheson C.P. grade 1-butene, dried by passage through anhydrous calcium sulphate and phosphorus pentoxide, was condensed in the solvent at −30° C, the excess being allowed to boil off before capping the bottles. The catalyst

For personal use only.

suspensions were added with a syringe at room temperature. In cases where no polymerization occurred at 40° C the temperature was raised to 80° C.

Ethylene polymerizations were carried out at room temperature in a three-necked flask fitted with neoprene rubber stoppers containing inlet tubes for nitrogen and ethylene. The solvent and catalyst components were introduced and the ethylene bubbled in at approximately 50 ml min^{-1}.

At the end of a polymerization reaction the catalyst was killed by the addition of ethanol to the reaction mixture. Decomposition of the catalyst and removal of the solvent were effected by stirring the jelly-like mass in a 10- to 20-fold excess of ethanol in a Waring Blendor. The polymer was filtered and dried under vacuum.

RESULTS

Catalytic Activity of the Complexes

Table I shows the results of a comparative study of the activity of the four catalyst systems towards the polymerization of 1-butene. The aluminum triisobutyl – titanium trichloride complexes are active over the widest range of initial alkyl:halide ratios,

TABLE I

Activity of Ziegler–Natta type complexes towards polymerization of 1-butene, at 40° C

while the lithium systems only give polybutene under special conditions, i.e. with titanium tetrachloride at ratios above 1 provided the complex is prepared in the presence of the monomer. However, under these conditions, polymerization is rapid and almost complete for molar ratios of monomer to titanium up to at least 100. Polyethylene was obtained at ratios of unity and above from LiBu–$TiCl_4$ complexes prepared in the presence or absence of the monomer, but the LiBu–$TiCl_3$ complexes were completely inactive towards both ethylene and 1-butene.

Valency State of Titanium in Complexes

The method employed for the determination of reduced titanium cannot be used to establish the valency state of the metal since, on acid hydrolysis, divalent titanium is rapidly oxidized to the trivalent form (10), viz.

$$2Ti^{2+} + 2H_2O \rightarrow 2Ti^{3+} + 2OH^- + H_2.$$

However, from the two titanium analyses, an estimate of the residual tetravalent titanium can be made. These values for the insoluble products obtained from the reaction of lithium butyl or aluminum triisobutyl with titanium tetrachloride are plotted in Fig. 1 as a function of the initial component ratio. It is apparent that for both systems the titanium is present largely in the tetravalent state. With the LiBu–$TiCl_4$ complexes there is a trend to higher percentages of Ti^{4+} as the component ratio increases, while for the $Al(iBu)_3$–$TiCl_4$ complexes the percentage of Ti^{4+} remains essentially constant.

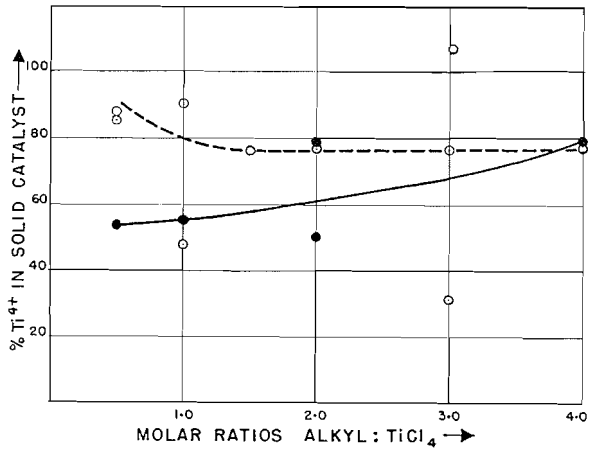

FIG. 1. Percentage of titanium in tetravalent state as function of component ratio. ○ $Al(iBu)_3$–$TiCl_4$, ● LiBu–$TiCl_4$.

Similar results for the lithium system have been reported by Friedlander and Oita (2) but with aluminum triisobutyl they found almost complete reduction of the titanium at component ratios above unity. In early experiments, where no special precautions were taken to ensure rapid dispersion of the metal alkyl during addition to the titanium tetrachloride solution, considerable reduction of titanium was noted (low values of Ti^{4+} at $Al(iBu)_3$:$TiCl_4$ ratios of 1 and 3). This may be one of the factors accounting for the discrepancy between the two results. Recently, it has been found that 90% of the titanium in the soluble complexes formed from these components at −78° C is in the tetravalent state (11).

Titanium, chlorine, and aluminum or lithium were found in all the solids analyzed. In calculating the elemental ratios in the insoluble reaction products, the alkyl content was taken as the difference between the weight of complex hydrolyzed and the total analysis of the other elements.

The Aluminum Triisobutyl – Titanium Trichloride System

Addition of the aluminum triisobutyl solution to a suspension of titanium trichloride in heptane resulted in the formation of a brown mixture which, on standing, settled into two layers consisting of a violet precipitate and a dark brown supernatant liquid. No marked difference in appearance was observed at $Al(iBu)_3$:$TiCl_3$ ratios in the range of 1 to 5. The dried solids were violet color and gave violet solutions on hydrolysis.

The chemical analyses for a series of the reaction products are recorded in Table II.

For personal use only.

The results show that the products consist principally of $TiCl_3$, independent of the initial $Al(iBu)_3$:$TiCl_3$ ratio, the aluminum content always being less than 0.5%. Similarly, the X-ray diffraction patterns of the various samples gave only lines of the violet form of titanium trichloride.

The Aluminum Triisobutyl – Titanium Tetrachloride System

The reaction of aluminum triisobutyl with titanium tetrachloride in heptane yields a precipitate whose color changes from a light reddish-brown to dark brown as the $Al(iBu)_3$:$TiCl_4$ ratio is increased. After filtration and vacuum drying, the color of the solid varies from light brown to purplish-black.

X-Ray analysis of suspensions of the complexes showed traces of titanium trichloride at initial component ratios of 0.5 and 1, but there was no indication of crystallinity at ratios below 0.5. Above the equimolar ratio the complexes were entirely amorphous. Natta *et al.* (12) have also reported that the complexes from the $Al(Et)_3$–$TiCl_4$ system are amorphous at component ratios above 0.7.

The results of the chemical analyses of a number of solids prepared at $Al(iBu)_3$:$TiCl_4$ ratios of 0.5 to 4 are given in Table III. The values for the atomic ratios are based on the

analyses for "total" titanium. It is apparent that there is an initial decrease in the Cl:Ti ratio and that the values lie between 2.5 and 1.5 over the whole range of compositions studied. These figures are considerably lower than those reported by Cooper and Rose (5) for similar catalyst systems. The low values for the Al:Ti and R:Ti ratios suggest that only a small proportion of the aluminum triisobutyl or its reaction products takes part in the formation of the precipitate, while the R:Al ratios, lying between 1.2 and 2.0, indicate loss of alkyl groups during the reaction. At least part of this loss is accounted for by the formation of C_4 hydrocarbons which were detected in gas chromatographic analysis of a sample of the vapor phase above a reaction mixture. Isobutane and isobutylene or 1-butene were the major constituents. A positive identification of the olefine could not be made, but it is probably isobutylene. Trace amounts of C_3 hydrocarbons were also detected.

Analyses of some of the filtrates from the complexes gave Cl:Ti ratios which steadily increased with increasing initial component ratio, having a value of 69 for an $Al(iBu)_3$:$TiCl_4$ ratio of 4. This implies that chlorine compounds soluble in heptane are formed during

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the reaction. In addition, the valency state of titanium found in the filtrate was observed to change with component ratio. For an $Al(iBu)_3$:$TiCl_4$ ratio of 0.5, 98% of the titanium in the filtrate was present as Ti^{4+}, but at a ratio of 3 all the titanium was in the reduced state. At the higher component ratio, the titanium in the filtrate presumably represents soluble titanium compounds or finely divided titanium trichloride which passed through the filter.

The Lithium Butyl – Titanium Trichloride System

The reaction between lithium butyl and titanium trichloride in heptane is highly exothermic and the violet form of the trichloride is converted to an insoluble green complex.

The X-ray diffraction patterns of the complexes were obtained under identical experimental conditions over the whole range of LiBu:$TiCl_3$ ratios from 0.5 to 4. At a ratio of 4 the diffraction pattern could not be identified by comparison with the reference data of the A.S.T.M. index and, consequently, an attempt was made to index the pattern from basic principles. Using the graphic method it was found to consist of two separate compounds, one of them being cubic and having a sodium chloride type lattice with a lattice constant of 5.20 Å. This is appreciably larger than the lattice constant of lithium chloride (5.14 Å), and the compound is considered to be a mixed crystal of lithium and titanium chlorides, probably of composition $(LiCl)_n.TiCl_2$ or $(LiCl)_n.TiCl$. Although alkali metal complexes of both tetravalent and trivalent titanium halides are known, none have been reported in which titanium is in a lower valent state. The pattern of the second component could not be identified, but its higher symmetry suggests that it may be an alkylated compound. Both compounds were also found at component ratios of 2 and 1. At the equimolar ratio the two strongest lines of titanium trichloride were also evident and at ratios of less than one the X-ray diffraction patterns consisted of the trichloride lines only. The *d* values and approximate line intensities of the patterns obtained at ratios of 2 and 4 are given in Table IV and those for lithium chloride are included for comparison. From the table it is apparent that the relative line intensities of the cubic

component and lithium chloride differ appreciably. This can be due to the different scattering power of the mixed crystal or to preferred orientation. Comparison of the patterns for the 2:1 and 4:1 complexes indicate that superposition of diffraction lines of the cubic component and the unknown constituent is not an important factor.

Hydrolysis of the dried solids in 2 *N* sulphuric acid was accompanied by considerable gas evolution, producing violet-colored solutions. In addition, at ratios of unity and above, increasing amounts of an insoluble blue solid were obtained, constituting, at the highest ratio, about 20% of the original weight of the complex. The compound was stable in air and different samples contained 55–61% titanium. Spectrographic analysis showed only traces of lithium. The X-ray diffraction pattern had considerable background scattering and was different from that of the complex before hydrolysis. This hydrolysis product is probably a hydrated form of one of the lower titanium oxides, i.e. of composition between Ti_2O_3 and TiO_2. Stable oxides of a similar color, corresponding to the nominal formulae Ti_3O_5 and Ti_7O_{12}, have been prepared (13) and are also resistant to strong acids except concentrated sulphuric acid.

The results of the chemical analysis of the reaction products for this system are given in Table V. The values for the 2.46 and 4.0 ratios are those for the solution with a correc-

tion for the titanium present in the insoluble material formed during hydrolysis. It can be seen that the Cl:Ti ratio remains essentially constant while there is a progressive increase in the Li:Ti and R:Ti ratios. It is apparent, also, that there is a considerable loss of alkyl on formation of the complexes. Again, gas chromatographic analysis has shown that, at least in part, this appears as *n*-butane and 1-butene or isobutylene, probably the former.

The Lithium Butyl – Titanium Tetrachloride System

The reaction between lithium butyl and titanium tetrachloride is exothermic, and brown, jelly-like precipitates are formed, the color darkening as the proportion of lithium butyl is increased.

X-Ray examination did not show the presence of any crystalline component at $LiBu:TiCl_4$ ratios of less than 1. However, at ratios of 1 and above, a faint diffraction pattern was observed, showing two broad lines in the position of the two main lines of the cubic compound found in the trichloride system.

There appears to be a small decrease in the Cl:Ti ratio with increasing proportion of lithium butyl, but within the range studied it remains above 3. The Li:Ti ratio increases

progressively with the initial component ratio and is at a much higher level than the corresponding relationship for the $Al(iBu)_3$–$TiCl_4$ complexes. It is very similar to that for the $LiBu$–$TiCl_3$ system. The low R:Li ratios indicate that considerable alkyl is lost in the formation of the complexes. The principal hydrocarbons found in the vapor phase above the reaction mixtures were *n*-butane and 2-butene (cis and trans). In addition, small amounts of 1-butene or isobutylene, C_3, and C_2 hydrocarbons were detected.

It was noted that, on hydrolysis of the insoluble complexes in sulphuric acid solution, a greasy deposit formed on the side of the flask. A few milligrams of a white insoluble material recovered from the flask was shown to be a hydrocarbon product, indicating the formation of a small amount of polymer.

DISCUSSION

The chemical and X-ray diffraction analyses of the $Al(iBu)_3$–$TiCl_3$ catalysts are in agreement with Natta's observations (3, 14) for a similar system in that they consist essentially of unchanged titanium trichloride on which a residual amount of the metal alkyl is chemisorbed. The precision of the aluminum and alkyl contents of the catalysts given in Table II is low because of the small amounts present, but the values are similar to those reported where C^{14}-labelled aluminum triethyl was used (14). This system is one of the simplest in providing a guide to the requirements for catalytic activity and the mechanism by which control of the steric configuration of the monomer units in the polymer chain is achieved. Titanium trichloride has a layered lattice structure and it has been postulated (3) that the active sites are defect locations, or the boundaries of crystal faces, where the metal alkyl can enter into a co-ordination complex with the transition metal atom, the two dissimilar metal atoms being bridged through chlorine or alkyl groups. Polymer growth probably occurs at the aluminum atom although evidence from other catalyst systems (15, 16) suggests that a Ti—C bond may be involved. Steric control during the propagation step is visualized as resulting from the localization of the monomer units in a particular configuration as they enter the complex.

The $Al(iBu)_3$–$TiCl_4$ system is more complex and any mechanism proposed to account for the formation of the complexes must take into consideration the following factors:

(i) the high percentage of Ti^{4+} in the solids,

(ii) the loss of chlorine from the solids,

(iii) the loss of alkyl from the solids.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

These factors can be accounted for, in a very general way, by the reaction scheme given below, which is based on suggestions by Natta (3) and Uelzmann (8).

$$TiCl_4 + AlR_3 \longrightarrow (TiCl_3)^+(AlR_3Cl)^- \quad [1]$$

$$(TiCl_3)^+(AlR_3Cl)^- \text{ decomp.} \begin{cases} \nearrow TiCl_3 + AlR_2Cl + R\cdot \\ \searrow TiCl_2 + AlR_2Cl + RCl \end{cases} \quad [2]$$

$$TiCl_4 + 2AlR_3 \begin{cases} \nearrow (TiCl_2R)^+(AlR_3Cl)^- + AlR_2Cl \\ \searrow (TiCl_2)^{2+}(AlR_3Cl)^-_2 \end{cases} \quad [3]$$

$$(TiCl_2R)^+(AlR_3Cl)^- \text{ decomp.} \begin{cases} \nearrow TiCl_2 + AlR_2Cl + 2R\cdot \\ \searrow TiCl + AlR_2Cl + RCl + R\cdot \end{cases} \quad [4]$$

Equations [1] and [3] represent the initial complex-forming reaction with increasing concentration of aluminum alkyl in which the titanium is stabilized in the tetravalent state. Decomposition of the first complex according to reaction [2] would account for the presence of crystalline titanium trichloride at low initial ratios of aluminum alkyl to titanium tetrachloride. Both the decomposition steps [2] and [4] can account for the loss of chlorine and alkyl through the formation of hydrocarbons and soluble halides. The detection in the reaction products of isobutane and a C_4 unsaturate which is probably isobutylene indicates that the isobutyl radicals undergo a disproportionation reaction. Part of the isobutane could also result from a hydrogen abstraction reaction with the solvent or metal alkyl. Also, the presence of alkyl chloride has been reported (17) in the reaction product from the $Al(Et)_3$–$TiCl_4$ system at low component ratios. However, it is obviously difficult to equate the analyses shown in Table III with the above scheme if the high Ti^{4+} content is related solely to this type of complex.

Uelzmann (8, 11) has proposed that the ionic complexes furnish the active polymerization sites but an alternative explanation is that they are formed by adsorption of alkyl upon the lower valent titanium halides formed in the decomposition steps, in analogy with the $Al(i\text{Bu})_3$–$TiCl_3$ system.

The catalysts from titanium tetrachloride give faster rates for the polymerization of 1-butene than the trichloride catalysts and yield polymers that are less crystalline. They are highly complex mixtures which presumably contain active sites of different configuration. Evidence for this suggestion (18) has come from an extensive study of the molecular weight distribution of polyethylene prepared from similar catalysts. The high degree of polydispersity observed is not compatible with a polymerization mechanism involving a single, well-defined catalyst site.

Since lithium is considerably more electropositive than titanium it is probable that the titanium is bound in complex anions and an acceptable mechanism to account for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

experimental observations on the two lithium systems, which is based on suggestions by Uelzmann, would be as follows:

$$LiR + TiCl_4 \longrightarrow Li^+(TiCl_4R)^- \quad [5]$$

$$Li^+(TiCl_4R)^- \xrightarrow{\text{decomp.}} \begin{matrix} LiCl.TiCl_3 + R\cdot \\ LiCl.TiCl_2 + RCl \end{matrix} \quad [6]$$

$$2LiR + TiCl_4 \longrightarrow (Li^+)_2(TiCl_4R_2)^= \quad [7]$$

$$(Li^+)_2(TiCl_4R_2)^= \xrightarrow{\text{decomp.}} \begin{matrix} 2LiCl.TiCl_2 + 2R\cdot \\ 2LiCl.TiCl + 2RCl \end{matrix} \quad [8]$$

or, considering the trichloride complexes:

$$LiR + TiCl_3 \longrightarrow Li^+(TiCl_3R)^- \quad [9]$$

$$Li^+(TiCl_3R)^- \xrightarrow{\text{decomp.}} LiCl.TiCl_2 + R\cdot \quad [10]$$

$$2LiR + TiCl_3 \longrightarrow (Li^+)_2(TiCl_3R_2)^= \quad [11]$$

$$(Li^+)_2(TiCl_3R_2)^= \xrightarrow{\text{decomp.}} 2LiCl.TiCl + 2R\cdot \quad [12]$$

The complex-forming reactions represented by the steps [5] and [7] would account for the preservation of titanium in the tetravalent state in the LiBu–$TiCl_4$ system, while the decomposition reactions [6], [8], [10], and [12] provide an explanation for the loss of alkyl either through the formation of hydrocarbon products or an alkyl chloride. The formation of an alkyl chloride may also account for the loss of chlorine in the tetrachloride complexes. The identification of the C_4 olefine in the tetrachloride catalyst as 2-butene is surprising since in a disproportionation reaction between *n*-butyl radicals this would involve a hydrogen atom rearrangement. The fact that only traces of 1-butene were detected in this case is consistent with its removal by polymerization.

Again, it is difficult to reconcile the low R:Ti ratio with the high percentage of tetravalent titanium, particularly for complexes with higher initial component ratios. A possible explanation for this inconsistency, which also appears in the Al(*i*Bu)$_3$–$TiCl_4$ system, is that certain complex anions or cations of titanium in a valency state of less than three may give tetravalent titanium on hydrolysis in acid media, the normal step preceding analysis. The formation of an oxide of probable composition between Ti_2O_3 and TiO_2 on hydrolysis of the LiBu–$TiCl_3$ complexes provides evidence for this suggestion since it indicates that oxidation can proceed beyond the trivalent stage. Also, similar behavior has been reported for halides of divalent zirconium and hafnium which are the next elements to titanium in group IVA of the periodic table. The lower valency states of titanium are progressively less stable and the simple monovalent titanium halides have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

not been isolated. As these will be odd electron compounds they are likely to exist only in dimeric form and will be extremely reactive.

The inability of the LiBu–$TiCl_3$ system to initiate polymerization may be attributable to the fact that the well-ordered crystalline compound formed does not provide the type of support on which a catalyst site of suitable configuration can form. It will be noted that this complex has the symmetrical sodium chloride type lattice as opposed to the layered lattice structure of titanium trichloride. Evidence for the formation of the same compound in the LiBu–$TiCl_4$ system, although to a lesser degree, may also be the explanation of the inactivity of these catalysts for the polymerization of 1-butene if prepared prior to the addition of the monomer. However, they will polymerize ethylene but at a much slower rate than when prepared in its presence. These differences in activity imply that the olefine can take part in complex formation, presumably leading to catalysts of somewhat different structure.

ACKNOWLEDGMENTS

This work was made possible by a research grant to the Ontario Research Foundation by the Province of Ontario.

NOTE ADDED

Since this paper was submitted for publication Dr. N. F. H. Bright* and Mr. R. C. Garvie* have completed an examination of one of our X-ray diffraction patterns of the blue solid obtained on hydrolysis in aqueous sulphuric acid of a complex prepared in the reaction of lithium butyl with titanium trichloride. They find that, although the pattern is ill-defined, it indicates that the crystalline constituents of the solid are titanium sesquioxide (Ti_2O_3) and rutile (TiO_2). As the titanium content (55%) of this particular sample is less than that of the higher oxide (TiO_2) they suggest that some amorphous hydrated TiO_2 is probably present. Evidence of an amorphous material was noted in the X-ray pattern.

Dr. Bright and Mr. Garvie also comment on the unusual fact that the TiO_2 content is in the rutile form. Normally, anatase is the crystal form in which TiO_2 is obtained when precipitated chemically.

REARRANGEMENT STUDIES WITH C^{14}

X. ETHANOL-2-C^{14} FROM THE IRRADIATION OF ETHANOL-1-C^{14} WITH Co^{60} GAMMA RAYS[1]

C. C. Lee and D. G. Lee[2]

ABSTRACT

The irradiation of aqueous solutions of ethanol-1-C^{14}, containing about 2% ethanol by weight, with up to 58.0 million rads of Co^{60} γ-rays led to the formation of up to 0.49% ethanol-2-C^{14} in the alcohol recovered after irradiation. The G value of this isotope position rearrangement was about 0.04 and amounted to approximately 2% of the G value for the total amount of ethanol decomposed. Possible mechanisms for the rearrangement are discussed.

In a review in 1956, Collinson and Swallow (1) pointed out that radiolysis of alcohols follows the general pattern of a fission of an α-carbon – hydrogen bond to give an α-hydroxyalkyl radical which can either dimerize to a glycol or be further oxidized to a carbonyl compound. In the case of ethanol, this generalization can be applied to account satisfactorily for the formation of the chief products derived from the ethanol, namely, acetaldehyde and 2,3-butanediol (2–6).

While a number of minor products have been quantitatively estimated for the radiolysis of pure ethanol with α-particles (3), the irradiation of dilute aqueous solutions of ethanol with X or Co^{60} γ-rays was reported to give, besides hydrogen and hydrogen peroxide, only acetaldehyde in the presence of oxygen and acetaldehyde and 2,3-butanediol in deaerated solutions (2, 5, 6). The organic products can, therefore, be regarded as being formed from the α-hydroxyethyl radical. The most recently suggested mechanism for the radiolysis of aqueous solutions of ethanol postulated reactions of H or OH radicals with the solute to give α-hydroxyethyl from the breaking of an α-carbon – hydrogen bond (6). No rupture of the carbon–oxygen bond was envisaged. In the present study, dilute aqueous solutions of ethanol-1-C^{14} was irradiated with Co^{60} γ-rays to ascertain whether any isotope position rearrangement to ethanol-2-C^{14} would result. Detection of such a rearrangement could possibly be regarded as indicating some rupture of the carbon–oxygen bond to give an ethyl radical followed by a 1,2-hydrogen shift in the radical analogous to 1,2-hydride shifts observed in certain reactions involving the ethyl cation (7, 8, 9).

A stock solution containing 2.02% ethanol by weight was made up with distilled water and ethanol-1-C^{14}.* Its C^{14} content was about 10 μc/ml. Three-milliliter aliquots were placed in 4-ml glass vials, stoppered and sealed with wax, and then irradiated at room temperature in fixed positions near a 90-curie Co^{60} source. The dose rates were measured by determining the ferric ions formed upon irradiating solutions of ferrous ammonium sulphate (10). Under the conditions of the present experiments, the dose rates were of the order of 1200 rads/minute.

After irradiation, the samples were analyzed for total decomposition of ethanol and for the presence of isotopically rearranged ethanol-2-C^{14} in the recovered alcohol. Before and after irradiation, equal aliquots of the solution were diluted with exactly the same amounts of absolute ethanol as a carrier. The diluted solutions were converted to ethyl

3,5-dinitrobenzoate and to iodoform. The decrease in activity in the ethyl 3,5-dinitrobenzoate after irradiation represented the ethanol decomposed during the irradiation. The ethanol so decomposed most likely was chiefly converted to the known products, acetaldehyde and 2,3-butanediol. The activity in the iodoform corresponded to the C^{14} in the C-2 position of ethanol and thus would be a measure of the rearrangement to ethanol-2-C^{14}. The results are summarized in Table I.

TABLE I

Decomposition and rearrangement in the irradiation of ethanol-1-C^{14}

	CHI_3	3.56			0.49	0.04
58.0	Benzoate	517	25.1	1.8		
	CHI_3	3.18			0.44	0.03

[a]Benzoate designates ethyl 3,5-dinitrobenzoate.
[b]C^{14} activity in millimicrocuries per millimole of sample was assayed as CO_2 gas with a vibrating reed electrometer.
[c]Corrected for the activity of iodoform from the ethanol before irradiation.

It may be noted that the iodoform obtained from degradation of the commercial ethanol-1-C^{14} before irradiation showed a small amount of radioactivity (Table I). This was subtracted from the activity of iodoform derived from the irradiated ethanol before rearrangement to ethanol-2-C^{14} was calculated.

In some preliminary experiments with radiation dosages of up to 7 million rads, only about 0.1% rearrangement to ethanol-2-C^{14} was indicated. With higher radiation doses as tabulated in Table I, more significant amounts of rearrangement were observed. The activities of iodoform from these experiments were quite large, being some 20 to 30 times that of background depending on the size of sample counted. Moreover, all iodoform samples were shown to have practically constant specific activity on repeated recrystallization, indicating that the iodoform activity was not due to contamination. It is, therefore, reasonable to conclude that rearrangement of ethanol-1-C^{14} to ethanol-2-C^{14} actually occurred during the irradiation. The G_r value, designating the number of molecules of ethanol-1-C^{14} rearranged to ethanol-2-C^{14} per 100 electron volts of energy absorbed, was calculated to be about 0.04. The ratio of G_r to G_d was of the order of 0.02, indicating that rearrangement to ethanol-2-C^{14} occurred only to about 2% of the extent of total decomposition.

Two possible explanations for the observed formation of ethanol-2-C^{14} from ethanol-1-C^{14} may be suggested. Firstly, minute amounts of ethylene could be produced during irradiation which remained in solution and subsequently reacted with water to give ethanol-1-C^{14} and ethanol-2-C^{14}.

$$CH_3C^*H_2OH \longrightarrow\!\!\!\!\sim\!\!\!\!\sim\!\!\!\!\sim

though no attempts have been made to detect or estimate ethylene in studies with aqueous ethanol (5, 6). The formation of some alcohol, assumed to be ethanol, upon gamma irradiation of mixtures of ethylene and oxygen in water under pressure has been reported by Henley and co-workers (11, 12). However, similar studies by Clay, Johnson, and Weiss (13) on the action of Co^{60} γ-radiation on aqueous solution of ethylene at different pressures did not report ethanol as a product. Considering this somewhat conflicting evidence from the literature, it is reasonable to conclude that upon irradiation of a dilute aqueous solution of ethanol, formation of ethylene followed by rehydration back to ethanol does not occur extensively. Neverthless, it is possible that such a process may take place to a minor extent during irradiation. Reaction sequence [1] given above is, therefore, a plausible explanation for the formation of the small amount of ethanol-2-C^{14} from the irradiation of ethanol-1-C^{14}.

A second explanation for the observed isotope position rearrangement involves the postulation of a 1,2-hydrogen shift in an ethyl radical. The chemical effects of ionizing radiation in dilute aqueous solutions are generally considered to be due primarily to the action of H and OH radicals from the net process

$$H_2O \longrightarrow H\cdot + OH\cdot . \qquad [2]$$

A mechanism for the rearrangement of ethanol-1-C^{14} to ethanol-2-C^{14} may then be postulated as follows:

$$CH_3C^*H_2OH + H\cdot \rightarrow CH_3C^*H_2\cdot + H_2O \qquad [3]$$

$$CH_3C^*H_2OH + OH\cdot \rightarrow CH_3C^*H_2\cdot + H_2O_2 \qquad [4]$$

$$CH_3C^*H_2\cdot \xrightarrow[\text{shift}]{\text{1,2-H}} \cdot CH_2C^*H_3 \qquad [5]$$

$$C^*H_3CH_2\cdot + H_2O \longrightarrow C^*H_3CH_2OH + H\cdot \qquad [6]$$

The G_r value for the rearrangement is low because the chief effects in the radiolysis of dilute aqueous ethanol result from the breaking of the α-carbon – hydrogen bond rather than the carbon–oxygen bond. Moreover, the H produced in reaction [6] does not necessarily have to propagate a chain leading to a high yield of ethanol-2-C^{14} because the H atoms can enter into other processes such as its reaction with ethanol to give the α-hydroxyethyl radical (6).

The 1,2-shift depicted in reaction [5] is not unreasonable as a number of reported isomerizations induced by irradiation have been explained in a similar way. The formation of isopropyl chloride from irradiation of *n*-propyl chloride (14) and of *t*-butyl chloride and bromide from isobutyl chloride and bromide, respectively (15, 16), were postulated to take place through rearrangement of the *n*-propyl to isopropyl and isobutyl to *t*-butyl radicals, processes which involve 1,2-hydrogen shifts.

In conclusion, the present work has shown that Co^{60} γ-irradiation of a 2.02% aqueous solution of ethanol-1-C^{14} led to the formation of some ethanol-2-C^{14}, the G value for this isotope position rearrangement being about 0.04. Two plausible explanations for the rearrangement have been suggested. From the present data, however, it is not possible to decide whether only one or both of the suggested mechanisms actually accounted for the observed formation of ethanol-2-C^{14} from ethanol-1-C^{14}.

ELECTRONIC STATES OF HYDRATED VANADIUM (II) ION[1]

RUTH M. BENNETT AND O. G. HOLMES

ABSTRACT

The optical absorption of a single crystal of $VSO_4.7H_2O$ was measured in the range 9000–35,000 cm^{-1}. The three observed bands were assigned to transitions between the four orbital levels resulting from cubic electrostatic perturbation of the spherical terms of configuration $3d^3$. Values of $Dq = 1200$ cm^{-1} and $E = 10{,}000$ cm^{-1} were derived from the spectral analysis.

INTRODUCTION

Ligand field theory has been applied with success to the hydrates and other complexes of ions of the first transition group metals. Several reviews of this work are available (1, 2, 3). The usual procedure is to consider the effect of the electrostatic potential generated by the ligands upon the electronic states of the central ion. Energy levels, magnetic and optical properties, etc. can then be evaluated for the perturbed ion. Some authors (4, 5, 6) have allowed for the possibility of covalent bonding by constructing appropriate molecular orbitals.

Inadequate optical data for hydrated V^{++} ion has led to some confusion about its electronic levels. We have therefore prepared $VSO_4.7H_2O$ crystals of sufficient size and purity for the accurate measurement of its optical absorption spectrum in the region 9000–35000 cm^{-1}. The observed bands have been assigned to transitions between levels derived from configuration $3d^3$ by a perturbing electrostatic field of cubic symmetry. Since both the "weak field" and "strong field" formalisms have become popular, we shall present both, even though they lead to identical results.

EXPERIMENTAL WORK

(a) Preparation of Hydrated Vanadium (II) Ion

The method of Jones and Colvin (7) was used for the preparation of $VSO_4.7H_2O$. Fisher reagent vanadium pentoxide was suspended in a sulphuric acid solution. Sulphur dioxide was bubbled through to reduce the vanadium to the plus four state (vanadyl). The filtered vanadium (IV) solution was reduced electrolytically at a mercury cathode to V^{++}. This solution was transferred to a flask under an atmosphere of nitrogen and ethyl alcohol poured over the surface. Over a period of several hours large well-formed violet crystals of $VSO_4.7H_2O$ deposited.

The total reducing power of the vanadium in the crystal was determined by titration to the plus five state with standard $KMnO_4$ (titer A). The vanadium concentration was found by reducing back to vanadium (IV) with sulphur dioxide and reoxidizing with $KMnO_4$ (titer B). The concentrations of V^{++} and V^{+++} were then calculated from titers A and B. The titration procedure was that suggested by Treadwell (8).

(b) Absorption Spectrum of Hydrated Vanadium (II) Ion

Figure 1 shows the optical absorption spectrum of a single crystal of $VSO_4.7H_2O$. These data were obtained with a Beckman DU spectrophotometer. Salient features of the spectrum are summarized in Table I.

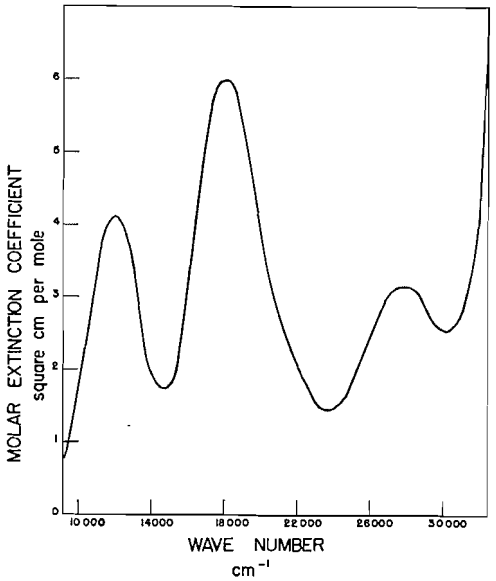

FIG. 1. Absorption spectrum of $VSO_4.7H_2O$.

TABLE I

Electronic transitions of hydrated V^{++}

Band peak, cm^{-1}	Peak extinction coefficient	f-Number	Transition	Calculated energy levels	
				E = 11,320 cm^{-1}	E = 10,000 cm^{-1}
12000	4.1	0.5×10^{-4}	$^4A_2$–$^4T_2$	(12000)	(12000)
18200	6.0	0.9×10^{-4}	$^4A_2$–$^4T_1$	18400	18000
27800	3.1	0.3×10^{-4}	$^4A_2$–$^4T_1$	28900	28000

The principal difficulty in measuring this absorption spectrum lies in the inevitable presence of V^{+++} generated by the very powerful reducing agent V^{++}. Since hydrated V^{+++} exhibits absorption bands at 17,800 and 25,700 cm^{-1}, respectively, with maximum extinction coefficients of 3.5 and 6.6 cm^2 per mole, as reported by Hartman and Schlafer (9), it interferes seriously with the spectral measurements.

For the spectrum in Fig. 1, a crystal of $VSO_4.7H_2O$ was chosen in which 97±1% of the vanadium was present as V^{++} with the V^{+++} concentration then being spectroscopically negligible.

ASSIGNMENT OF ABSORPTION BANDS

(a) Weak Field Treatment

Configuration $3d^3$ of V^{++} yields several terms which are separated by Coulombic electron interactions. However, only the ground state term ^4F and an upper ^4P term have the maximum spin multiplicity of four. If intercombination transitions are unimportant, all the other terms from $3d^3$ can be ignored.

In the heptahydrates of the transition ions for which the crystal structures are known, the central ion is surrounded by six water molecules at the corners of a regular octahedron,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with the seventh water molecule occupying a distant interstitial site. The electrostatic potential which perturbs the central ion has cubic symmetry and is of the form

$$V = D(x^4+y^4+z^4-\tfrac{3}{5}\bar{r}^4). \quad [1]$$

Such a field splits the ground term ^4F of V^{++} into three terms belonging to the cubic representations $^4A_2$, $^4T_2$, and $^4T_1$. The $^4A_2$ term is orbitally non-degenerate, the $^4T_2$ and $^4T_1$ terms threefold degenerate. The higher ^4P term is not split by V, but follows the representation $^4T_1$.

Thus a field with cubic symmetry produces four energy levels from the spin quartet terms. The three observed bands are then due to transitions between the $^4A_2$ ground level and the other three levels.

The matrix elements of V for the cubic orbitals are given in Table II, where D is the

TABLE II
Energy matrices for $3d^3$ in cubic field

	Weak field			
	$^4A_2$	$^4T_2$	$^4T_1(^4F)$	$^4T_1(^4P)$
$^4A_2$	$-12\,Dq$			
$^4T_2$		$-2\,Dq$		
$^4T_1(^4F)$			$6\,Dq$	$4\,Dq$
$^4T_1(^4P)$			$4\,Dq$	E
	Strong field			
	$^4A_2(t_2^3)$	$^4T_2(t_2^2e)$	$^4T_1(t_2^2e)$	$^4T_1(t_2e^2)$
$^4A_2(t_2^3)$	$-12\,Dq$			
$^4T_2(t_2^2e)$		$-2\,Dq$		
$^4T_1(t_2^2e)$			$-2\,Dq+12\,B$	$6\,B$
$^4T_1(t_2e^2)$			$6\,B$	$-8\,Dq+3\,B$

field parameter and $q = (2/105)\bar{r}^4$. Details of this treatment are given by Finkelstein and Van Vleck (10). The term separation matrix has been added to that for V, and appears as E, which is the $^4F-^4P$ energy in the absence of the cubic field.

Table III shows the cubic energy level diagram which results from the solution of the

TABLE III
Energy levels of hydrated V^{++}

Weak field origin	Cubic field	Strong field origin
^4P and ^4F	$^4T_1$	$3dt_2\ 3de^2$
^4F	$^4T_1$	$3dt_2^2\ 3de$
	$^4T_2$	
	$^4A_2$	$3dt_2^3$

secular determinant. The $^4A_2$ level is located at $-12\,Dq$, with respect to the free ion ^4F energy, and the $^4T_2$ level at $-2\,Dq$. The first observed transition energy 12,000 cm^{-1} is then $10\,Dq$, fixing Dq at 1200 cm^{-1}. The two $^4T_1$ levels depend upon the value of E. Table I shows the calculated positions of these levels with E = 11,320 cm^{-1}, which is the free ion value, and with E = 10,000 cm^{-1}, which gives the least difference between calculated and observed $^4T_1$ levels.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(b) Strong Field Treatment

In a cubic field the five $3d$ orbitals convert into an orbital triplet t_2 and an orbital doublet e at energy higher by 10 Dq. The ground state of V^{++} then is the term of highest multiplicity from $3dt_2^3$, which is $^4A_2$. Configuration $3dt_2^2 3de$ gives rise to $^4T_2$ and $^4T_1$ cubic terms, while $3dt_2 3de^2$ yields a $^4T_1$ term. No other spin quartet terms are possible.

The observed absorption bands are then allotted to transitions between the ground state $^4A_2$ and the three higher levels, these transitions involving the promotion of one or two t_2 electrons to e orbitals.

Tanabe and Sugano (11) have given the matrix elements for V between the strong field states. These elements have been added to the Coulombic repulsion elements in Table II, where $B = F_2 - 5F_4$, the F_n being Slater–Condon integrals. The identity of the roots of the strong field and weak field secular equations is apparent since $^4F - {}^4P = E = 15B$.

DISCUSSION

The dearth of optical data on the complexes of V^{++} has resulted in differing interpretations of their electronic states. Owen (4) assumed that the absorption bands of aqueous V^{++} reported by Dreisch and Kallscheuer (12) at 12,200 and 18,200 cm^{-1} corresponded to the two $^4A_2$–$^4T_1$ transitions and that another band should lie in the infrared region. This led to values for the parameters $Dq = 760\ cm^{-1}$ and $E = 9000\ cm^{-1}$.

On the other hand Jörgenson (2) used the band energies of 12,600, 18,200, and 26,500 cm^{-1} with the same assignment as presented here to calculate $Dq = 1260\ cm^{-1}$ (13).

On the basis of the spectrum of spectroscopically pure $VSO_4.7H_2O$, the "best values" we propose are $Dq = 1200\ cm^{-1}$ and $E = 10{,}000\ cm^{-1}$, which gives Racah's parameter $B = 670\ cm^{-1}$.

The decrease in E upon hydrating an ion such as V^{++} has been attributed by Owen (4) to covalent bonding between the central ion and the ligands. This would require that a small contribution from ligand orbitals be added to the $3d$ orbitals of the central ion to give the appropriate molecular orbitals. Then the distance between electrons would be increased and Coulombic interaction decreased, thus reducing term separations. Our results indicate that this effect is not so great for V^{++} as estimated by Owen.

The f-numbers for the three bands are listed in Table I. The value for the transition at 27,800 is not very reliable because the band is a shoulder on the strong charge transfer absorption and its area must be estimated. The relative intensities of the transitions are roughly 0.5:0.9:0.3. The higher T_1 band would be expected to have the lowest intensity since it requires that two $3dt_2$ electrons be promoted while the other transitions require only one promotion.

Nickel (II) with configuration $3d^8$ in $NiSO_4.7H_2O$ has the same energy level pattern as V^{++} and its three observed bands have f-numbers in order of increasing energy, 0.45×10^{-4}, 0.35×10^{-4}, and 0.6×10^{-4} (14). In this case contrary to expectations the higher transition $^3A_2$–$^3T_1$ has the greatest intensity. Several authors (see, for example, McClure (15)) have shown that this band includes transitions from the $^3A_2$ to $^1A_1$, $^1T_1$, and $^1T_2$ as well as $^3T_1$. However, Ballhausen and Liehr (16) have calculated recently that the intercombination transitions have negligible intensity for Ni^{++}, and that the intensity ratios can be explained with fair agreement by d–p mixing introduced through vibrational-electronic interaction. Calculations are under way to see if a similar mechanism applies to V^{++}.

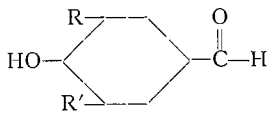
CELLULOSE COLUMN CHROMATOGRAPHIC SEPARATION OF LIGNIN OXIDATION PRODUCTS[1]

J. M. Pepper and M. Siddiqueullah[2]

ABSTRACT

A brief review is presented of the chemical nature and the methods of separation of those lignin derivatives obtained by the oxidation and/or alkaline hydrolysis of woody plants and isolated lignin or lignosulphonates. Nine such closely related derivatives, vanillin, syringaldehyde, *p*-hydroxybenzaldehyde, acetovanillone, acetosyringone, *p*-hydroxyacetophenone, vanillic acid, syringic acid, and *p*-hydroxybenzoic acid, were selected for a detailed study of their separation by cellulose column chromatography. Methods are presented whereby, by either a one- or two-stage process, a mixture of from any two to all nine of these compounds may be separated and the components recovered, using solvent systems which are suitable for subsequent quantitative spectrophotometric analysis. The application to a study of lignin chemistry is discussed.

INTRODUCTION



In recent years considerable attention has been given to the chromatographic separation of the products of oxidation and/or alkaline hydrolysis of the lignin component of woody plants and cereal straws. From the earlier work the characterization of these various lignin derivatives has contributed substantially to the present knowledge regarding the aromatic nature of lignin. More recently this phase of lignin research has been stimulated by an increased study of the fate of various C^{14}-labelled compounds which have been introduced into growing plants in a study of the biosynthetic pathway leading to lignin. The only reliable method whereby proof is obtained that the C^{14} has been incorporated into the lignin has been to obtain, from this fraction, purified degradation products whose specific activity may be measured. The larger the isolated lignin fragment the greater the structural significance that may be given to it and the more valuable the information that may be obtained from the position of the C^{14}-labelling. To date one of the more fruitful of such degradation studies has been the oxidation of lignin and, in particular, that using alkaline nitrobenzene as the oxidant system (1). By such means substantial yields of vanillin and a mixture of vanillin and syringaldehyde have been obtained from gymnosperms and angiosperms respectively. Along with both these compounds much smaller yields of *p*-hydroxybenzaldehyde have been found in the oxidation products of monocotyledons. This technique has been used by several workers interested in lignin chemistry and from various lignified materials the following other derivatives have been isolated and characterized (2, 3, 4): vanillic acid, syringic acid, *p*-hydroxybenzoic acid, acetovanillone, acetosyringone, 5-carboxyvanillin, 5-carboxyvanillic acid, 5-formylvanillin, 5-formylvanillic acid, dehydrodivanillin, and dehydrodivanillic acid.

In a series of investigations by both Pearl and McCarthy and their co-workers (5, 6, 7, 8, 9) using the alkaline cupric oxide, silver oxide, and mercuric oxide oxidations of lignosulphonates, many lignin degradation products have been obtained. These include

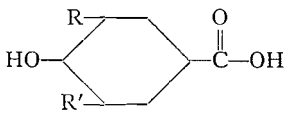
vanillin, syringaldehyde, vanillic acid, syringic acid, *p*-hydroxybenzoic acid, acetovanillone, acetosyringone, ferulic acid, *p*-coumaric acid, 5-carboxyvanillin, 5-carboxyvanillic acid, dehydrodivanillin, dehydrodivanillic acid, vanillil, 5-formylvanillin, 4,4′-dihydroxy-3,3′-dimethoxychalcone, vanillovanillone, and vanilloyl formic acid.



Apart from these lignin fragments that have been obtained from lignin under oxidizing conditions, many of the same compounds have been obtained by alkaline hydrolysis of the whole wood or of an isolated lignin. Hibbert (10, 11) early isolated vanillin and syringaldehyde by the alkaline hydrolysis of the lignin sulphonates from a deciduous wood. Smith (12) has reported the isolation of *p*-hydroxybenzoic acid from the products of a similar hydrolysis of the "native" lignin of *Populus tremula*. In another extensive investigation of the alkaline hydrolysis of various hardwoods and palms, Pearl and coworkers (13, 14, 15, 16, 17) isolated several phenolic compounds which may have arisen from the lignin fraction. The following such substances were identified: vanillin, syringaldehyde, *p*-hydroxybenzaldehyde, vanillic acid, syringic acid, *p*-hydroxybenzoic acid, ferulic acid, *p*-coumaric acid, acetovanillone, and acetosyringone. Stanek (18) using only an aqueous extraction, at 170°, of pre-extracted aspen wood obtained vanillin, syringaldehyde, coniferyl aldehyde, sinapaldehyde, vanillic acid, syringic acid, and *p*-hydroxybenzoic acid. Tanaka and Kondo (2) have reported the isolation also of both pyrogallol-1,3-dimethyl ether and 3,3′-dimethoxy-4,4′-dihydroxystilbene from the alkaline hydrolysis products of *Fagus cremata* and of the latter compound from red pine sawdust.

(I) R = H, R′ = OCH_3
(II) R = R′ = OCH_3
(III) R = R′ = H

(IV) R = H, R′ = OCH_3
(V) R = R′ = OCH_3
(VI) R = R′ = H

(VII) R = H, R′ = OCH_3
(VIII) R = R′ = OCH_3
(IX) R = R′ = H

Several methods have been devised for the separation of these compounds. Hibbert (19, 20, 21) reported separations of guaiacyl and syringyl compounds based upon the differential solubilities of their potassium and ammonium salts, upon fractional sublimation in high vacuum, and upon their conversion to the *p*-nitrobenzoate derivatives. The *m*-nitrophenylhydrazones of the phenolic aldehydes have been used also to assist in their separation (22). A qualitative paper chromatographic separation of vanillin and syringaldehyde was effected in 1949 by Bland (23). Later in 1951, a similar separation was reported by Pearl and Dickey (24) using a column of acid-washed Magnesol and Celite. Using benzene–ethanol (20:1) as the developer, Pearl and Beyer (25) were able to separate vanillic acid and protocatechuic acid on a similar type column. Stone and Blundell (26) further developed the paper chromatographic separation of the phenolic aldehydes into a quantitative analytical procedure. *n*-Butyl ether saturated with water separated vanillin and syringaldehyde but if *p*-hydroxybenzaldehyde were also present a suitable solvent system was petroleum ether (100–120°):*n*-butyl ether (6:1) saturated with water. These authors were the first to apply this method to the quantitative analyses of the products of the alkaline nitrobenzene oxidation of protolignin. In 1955, Brown and Neish (27) reported a partition chromatographic separation of these three aldehydes on a column of acid-washed Celite 535 using a two-step elution technique, i.e. isooctane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

containing 10% benzene and saturated with water to elute vanillin and syringaldehyde, followed by benzene saturated with water for elution of the *p*-hydroxybenzaldehyde. To separate the various combinations of the alkaline hydrolyses products referred to earlier, the principal method has been paper chromatography with a variety of developers. The following solvent systems have been used: butanol saturated with 2% ammonia (13, 16, 17, 18), butanol:pyridine:water (10:3:3) (13, 16, 17), *n*-heptane:*n*-butyl ether:water (6:1:1) (15, 17), benzene saturated with formic acid (11), *n*-butyl ether saturated with water (18). Stanek (18) also used petroleum ether (65–110°):ethanol (50:1) as the developer for an acid-washed Magnesol column.

In 1953, Newcombe and Reid (28) reported the complete separation of vanillin, acetovanillone, verataldehyde, and acetoveratrone using chromatographic paper that had been sprayed with dilute sodium bisulphite and a solvent system consisting of hexane:chloroform:water (9:1:10). Later Pearl (7) employing a paper that had been sprayed only partially with sodium bisulphite, and developing with *n*-heptane:*n*-butyl ether:water (6:1:1) successfully separated vanillin, syringaldehyde, acetovanillone, and acetosyringone. Leopold (3) found that a phosphate-buffered paper (pH 7.5) was advantageous for the separation of acids.

Three other analytical procedures have been applied to the separation of lignin oxidation products. Cellulose column chromatography using butanol – 2% aqueous ammonia as the developer has been used by Pearl and Beyer (5, 29). McCarthy *et al.* effected a separation using anion exchange resins and also electrophoresis. Recently Kratzl and Puschmann (30) have applied the semimicro thin-layer chromatographic technique, developed by Stahl, to the separation of C^{14}-labelled oxidation products.

It was therefore clear that in an extensive study of the products of lignin oxidation, the large variety of such possible derivatives had to be considered and any quantitative procedure for their estimation must ensure no interference of one with another. Starting with the established method of Stone and Blundell (26) using the solvent system of petroleum ether (100–120°):*n*-butyl ether:water (6:1:1) (15 hours), the possible interference of vanillic, syringic, *p*-hydroxybenzoic acids on the separation of vanillin and syringaldehyde was investigated. The vanillin and *p*-hydroxybenzaldehyde, which moved the farthest, were well resolved but the syringaldehyde, which moved only slightly, was not separated distinctly from the acids which tended to tail from the base line. This may account, in part, for the usually poorer reproducibility of the syringaldehyde analysis by this method if applied to the oxidation of lignin materials. Subsequently, a study of the separation of the three aldehydes (I, II, III) and the three ketones (IV, V, VI) showed that using the same solvent system (16 hours) the aldehyde and its corresponding ketone had similar R_f values. It became clear that the quantitative analysis for vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde by the Stone and Blundell method would be inaccurate should the conditions of oxidation be such that some of these other substances were also produced.

In an attempt to solve these interference problems and at the same time to devise a system whereby the products of large-scale oxidation may be separated, attention was directed to the use of cellulose column chromatography. Since usually not more than half of the original lignin can be accounted for in the form of the lower molecular weight oxidation products of the types outlined, it was hoped that this method would permit of the removal and separation of these units so that attention could then be directed to the purified lignin residues left on the column. The research reported here was limited to the study of the cellulose column chromatographic separation of the nine related possible

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

products of lignin oxidation: vanillin (I), syringaldehyde (II), *p*-hydroxybenzaldehyde (III), acetophenone (IV), acetosyringone (V), *p*-hydroxyacetophenone (VI), vanillic acid (VII), syringic acid (VIII), and *p*-hydroxybenzoic acid (IX). The study was conducted in three parts: (*a*) the resolution of a mixture of aldehydes alone, ketones alone, or acids alone; (*b*) the resolution of a mixture of any six components comprising the aldehydes and ketones, aldehydes and acids, or ketones and acids; and (*c*) the resolution of a mixture of all nine compounds. The synthetic mixtures were prepared from highly purified compounds using amounts ranging from 2 to 5 mg. The mixture of pure compounds was charged at the top of columns prepared from partially hydrated cellulose powder and the eluting solvents collected in 5-ml fractions. The presence of the phenolic substances was detected using the method of Barton *et al.* (31). In each case blanks using the individual pure compound were run to determine the order of elution.

Separation of Three-component Mixtures

Using the recommended (26) solvent system for the separation of aldehydes by paper chromatography (petroleum ether (100–120°):*n*-butyl ether:water (6:1:1) (organic phase)) good resolution was achieved on the cellulose column. A second developing system was found which resulted in an even more efficient separation using a shorter column. By this procedure the column was first eluted with cyclohexane saturated with water to remove and separate the vanillin (I) and syringaldehyde (II), and then with cylohexane: diethyl ether:water (6:1:1) (organic phase) (or an 8:1:1 mixture) to remove the *p*-hydroxybenzaldehyde (III). It is of interest to note the inversion in the order of elution of II and III using the two different solvents. The three ketones were separated in a similar manner. The elution and separation of the three acids was found to be best accomplished using a cyclohexane:diethyl ether:water (8:1:1) system to remove first the vanillic acid (VII) and then the *p*-hydroxybenzoic acid (IX). By increasing the solvent power using a similar system but in a 4:1:1 ratio, the syringic acid (VIII) was readily removed.

Separation of Six-component Mixtures

Since it was not possible to separate the aldehydes from the ketones by any of the solvent systems studied, recourse was made to the principle outlined by Newcombe and Reid (28) whereby the movement of aldehydes may be preferentially retarded using a sodium-bisulphite-sprayed paper. It was found that an effective separation may be obtained by using the technique whereby the six components were added to a cellulose column at the top of which was a small section containing cellulose saturated with sodium bisulphite. By first developing with the cyclohexane:water system the acetovanillone (IV) and the acetosyringone (V) were eluted and resolved in that order. The *p*-hydroxyacetophenone (VI) was then removed by changing to a cyclohexane:diethyl ether:water (8:1:1) system. Under these conditions it was proved, by a series of separate experiments, that no aldehydes were removed from the column nor were any ketones left on the column. To release, recover, and resolve the aldehydes, hydrochloric acid was added, the aldehydes washed through the column using diethyl ether, and then subsequently separated on a second column as described above.

In the case of the mixture of aldehydes and acids or ketones and acids the two-column technique was not necessary. Using the one cellulose column, and the following series of solvent changes, a complete separation and recovery of each compound of either six-component mixture was achieved. This was accomplished by using first the cyclohexane: water system to elute vanillin (I) (or acetovanillone IV), followed by syringaldehyde (II)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(or acetosyringone V), then the cyclohexane:diethyl ether:water (8:1:1) mixture to remove the *p*-hydroxybenzaldehyde (III) (or *p*-hydroxyacetophenone (VI)), the vanillic acid (VII), and the *p*-hydroxybenzoic acid (IX) in that order, and finally using cyclohexane:diethyl ether:water (4:1:1) to elute the syringic acid (VIII).

Separation of the Nine-component Mixture

To separate the components of a mixture of all nine components (I through IX), a two-stage procedure was required. A column of cellulose was used on the top of which was a smaller layer of cellulose saturated with sodium bisulphite. Elution of the ketones was done using cyclohexane–water to resolve the acetovanillone (IV) and acetosyringone (V) followed by cyclohexane:diethyl ether:water (8:1:1) to remove the *p*-hydroxyacetovanillone (VI). The three acids were then washed through the column with diethyl ether and the aldehydes first released by the addition of hydrochloric acid and then also washed through using ether. The recombined acids and aldehydes were charged to a second column and eluted and separated as described earlier.

This technique has been applied to the analysis of the products of the alkaline nitrobenzene oxidation, at 180°, of aspen wood lignin. Under these conditions no ketones were detected and hence this aspect of the interference objections raised earlier to Stone and Blundell's method is not valid. However, this does not mean that under either milder or stronger conditions of oxidation, the proportions of aldehydes, ketones, and acids may not vary and then this technique for their separation would become of value. This may be important for those studies requiring the isolation of purified C^{14}-labelled compounds especially of the C_6–C–C type. It is becoming evident that the other products of lignin oxidation, formed concurrently with the simple units discussed here, must be studied. It should be possible using this general technique to remove all the smaller molecular weight products from a cellulose column and thus leave behind the larger units which may subsequently be washed through and their structure investigated.

EXPERIMENTAL

Reagents

Genuine Whatman cellulose powder, standard grade, was obtained from W. and R. Balston, Ltd., England.

The syringaldehyde and acetosyringone were synthesized by previously reported methods (32, 33). All other chemicals were obtained from commercial sources and highly purified before use.

General Chromatographic Procedure

Preparation of Columns

The chromatographic columns were made of tubing 18 mm I.D. and 55 cm long, fitted at the lower end with a perforated disk immediately above a stopcock. The preferred method of packing the column was as follows. To each 10 g of cellulose powder was added 2.5 ml water and this mixture was intimately mixed until wetting was uniform and complete. This hydrated cellulose powder was then mulled using cyclohexane saturated with water (10 ml) and any lumps well broken before it was charged into the column using the wet method. Occasional pressing down of the cellulose during addition was beneficial. Each 10 g of cellulose packing was equivalent to about 3 inches in length.

The sodium bisulphite "traps" were prepared as follows. Each 2 g of cellulose powder was thoroughly mixed with a slurry of 1 g of sodium bisulphite in 1 ml of water. This mixture was then added onto the top of a cellulose column as described above for those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

separations involving aldehydes and ketones. Such a "trap" was approximately 0.5 inch in length.

Charging of Synthetic Mixtures

The samples were added in concentrated ether solution to 1 g of cellulose powder which had been thoroughly mixed with 0.5 ml water. After the ether had evaporated, the powder was moistened with a few drops of cyclohexane saturated with water before packing onto the top of the column as described above.

Nature of Eluting Solvents

Solvent A = petroleum ether (100–120°):*n*-butyl ether:water (6:1:1) (organic phase).
Solvent B = cyclohexane saturated with water.
Solvent C = cyclohexane:diethyl ether:water (6:1:1) (organic phase).
Solvent D = solvent C (8:1:1).
Solvent E = solvent C (4:1:1).

Elution Technique

The eluting solvent was allowed to pass through the column while under a slight positive pressure of nitrogen so that the rate of elution varied from approximately 0.5 drop/second for the short columns to 1 drop/second for the longer columns. For those experiments which required changing of the solvent, the first solvent was allowed to flow until its upper level coincided with the top of the packing, before addition of the second solvent system. All eluates were collected in 5-ml fractions and the presence of each phenolic substance was determined using the ferric chloride – potassium ferricyanide spray reagent described by Barton *et al.* (31).

Chromatographic Separation of Three-component Mixtures

Aldehydes

To a 50-g column a mixture of vanillin (I) (4.48 mg), syringaldehyde (II) (5.48 mg), and *p*-hydroxybenzaldehyde (III) (4.65 mg) was added. Upon development using solvent A, I appeared in fractions 25–36, III in 45–67, and II in 75–107.

A second resolution of these aldehydes was made using a 20-g column and a mixture of I (4.5 mg), II (4.1 mg), and III (3.8 mg). By eluting first with solvent B, I appeared in fractions 13–23, II in 44–75, but even after a further 150 fractions III did not appear. After changing to solvent C, III was found in fractions 7–12.

Ketones

To a 10-g column a mixture of acetovanillone (IV) (5.6 mg), acetosyringone (V) (5.4 mg), and *p*-hydroxyacetophenone (VI) (5.0 mg) was added. Using solvent B, IV appeared in fractions 4–12 and V in fractions 21–39. Then solvent C was used whereupon VI appeared in fractions 2–5.

Acids

To a 25-g column a mixture of vanillic acid (VII) (1.1 mg), syringic acid (VIII) (5.1 mg), and *p*-hydroxybenzoic acid (IX) (2.9 mg) was added. Using solvent D, VII appeared in fractions 58–85 and IX in 90–130. After changing to solvent E, VIII appeared in fractions 21–76.

Chromatographic Separation of Six-component Mixtures

Aldehydes and Ketones

To a 10-g cellulose column on top of which was a 2-g cellulose – sodium bisulphite column, a mixture of vanillin (I) (4.65 mg), syringaldehyde (II) (4.10 mg), *p*-hydroxybenzaldehyde (III) (4.18 mg), acetovanillone (IV) (4.34 mg), acetosyringone (V) (4.23

For personal use only.

mg), and *p*-hydroxyacetophenone (VI) (4.48 mg) was added. Using solvent B, IV appeared in fractions 5–18 and V in 28–55. After changing to solvent D, VI appeared in fractions 5–11. Excess hydrochloric acid (2 ml conc. in 6 ml water) was then added to the top of the column and forced through by means of nitrogen pressure. The released aldehydes were washed through the column using diethyl ether, the ether solution dried over anhydrous $MgSO_4$ and then concentrated to 1 ml. This sample was then charged to a 10-g column. Using solvent B, I appeared in fractions 3–19, and II in 25–48. After changing to solvent D, III appeared in fractions 4–13.

Aldehydes and Acids

(See procedure below.)

Ketones and Acids

To a 25-g column a mixture of acetovanillone (IV) (4.97 mg), acetosyringone (V) (4.68 mg), *p*-hydroxyacetophenone (VI) (5.06 mg), vanillic acid (VII) (0.9 mg), syringic acid (VIII) (3.29 mg), and *p*-hydroxybenzoic acid (IX) (3.64 mg) was added. Using solvent B, IV appeared in fractions 22–35 and V in 68–110. By changing then to solvent D, VI appeared in fractions 15–23, VII in 70–102, and IX in 115–175. After changing again to solvent E, VIII appeared in fractions 18–76.

Chromatographic Separation of Aldehydes, Ketones, and Acids

To a 10-g column, on top of which was a 2-g cellulose – sodium bisulphite column, a mixture of vanillin (I) (5.00 mg), syringaldehyde (II) (4.89 mg), *p*-hydroxybenzaldehyde (III) (5.62 mg), acetovanillone (IV) (5.42 mg), acetosyringone (V) (5.55 mg), *p*-hydroxyacetophenone (VI) (5.05 mg), vanillic acid (VII) (1.08 mg), syringic acid (VIII) (3.08 mg), and *p*-hydroxybenzoic acid (IX) (3.32 mg) was added. Using solvent B, IV appeared in fractions 6–20 and V in fractions 26–64. After changing to solvent D, VI appeared in fractions 6–12.

Diethyl ether (200 ml) was passed through the column to wash out the free acids. Excess hydrochloric acid (2 ml conc. HCl in 6 ml water) was added to the top of the column and passed through using slight nitrogen pressure. The released aldehydes were washed from the column using ether. The combined ether extracts were dried over anhydrous magnesium sulphate and concentrated to 1 ml. This sample was charged to a 25-g cellulose column. Using solvent B, I appeared in fractions 18–32 and II in fractions 58–90. After changing to solvent D, III appeared in fractions 14–22, VII in 73–112, and IX in 124–181. After changing again to solvent E, VIII appeared in fractions 23–73.

ACKNOWLEDGMENTS

We wish to express our thanks for the assistance given to one of us (M. S.) by the Pakistan Council of Scientific and Industrial Research during the tenure of a Colombo Plan Scholarship. We also gratefully acknowledge the support of the National Research Council, and the donation of vanillin from Howard Smith Chemicals Limited and of acetovanillone from the Ontario Paper Company, Limited.

PHOTOLYSIS OF AZOISOPROPANE[1]

R. H. RIEM[2] AND K. O. KUTSCHKE

ABSTRACT

The photolysis of azoisopropane has been reinvestigated in an attempt to obtain a better understanding of the discrepancies found between the behavior of *sec*-propyl radicals produced from this source (1) and other sources under similar experimental conditions.

Analytical difficulties encountered in an earlier investigation (1) were avoided through the extensive use of gas chromatography.

It was found necessary to include an internal conversion reaction among the primary processes to explain the observed phenomena. A rough estimate of $E_{\text{internal conversion}} - E_{\text{dissociation}} = (1.99 \pm 0.72)$ kcal/mole has been deduced. This is believed to be the first observation of $E_{\text{internal conversion}} > E_{\text{dissociation}}$. An explanation of this observation remains a matter of conjecture though a tentative suggestion is offered.

The data also leads to results in agreement with those found for other azo compounds and in agreement with the rates of reactions of *sec*-propyl radicals obtained from other sources under similar conditions.

INTRODUCTION

Recent studies of the rates of reactions of *sec*-propyl radicals (2, 3, 4) present a slightly different picture to that obtained by Durham and Steacie (1) in the photolysis of azoisopropane. To some extent these differences can be traced back to the analytical difficulties encountered by Durham and Steacie. Since many of these difficulties can now be avoided, a reinvestigation of the photolysis of azoisopropane, making extensive use of gas chromatography, was undertaken. A further reason for the reinvestigation was the rather poor agreement at lower temperatures between the mechanism proposed and the experimental data obtained by Durham and Steacie (1).

EXPERIMENTAL

The high-vacuum apparatus was in general of the design usually employed in these laboratories; however, stopcocks and oil diffusion pumps were used in order to obtain a mercury-free system. Part of the analytical line, consisting of a simple mercury-containing system used to handle noncondensable reaction products, was connected to the mercury-free system in the manner described by McElcheren, Wijnen, and Steacie (5).

The quartz reaction cell, 10 cm in length with a volume of 180 cc, was enclosed in a thermostatted hot box in which the temperature could be controlled to within 1/2° C. A medium pressure Hanovia S500 mercury arc was employed as the light source. This, in conjunction with the filter A described by Kasha (6), supplied incident radiation consisting of the 3662.9 Å and 3663.3 Å lines. The ultraviolet absorption spectrum of azoisopropane shows one large band extending from 2900 Å to 3900 Å with a flat maximum at 3540 Å. A 935 phototube positioned behind the reaction cell and outside the hot box was coupled to a sensitive galvanometer to measure the transmitted intensity. By using azomethane in the reaction cell as an actinometer and making the assumption that, with this compound, $\Phi_{N_2} = 1$ (7), it was possible to correlate directly the difference in galvanometer readings obtained with the empty cell and the filled cell with the number of quanta absorbed per cubic centimeter per second. The error introduced into the actinometer

measurements by any slight deviation from unity in the quantum yield of nitrogen for azomethane is felt to be no larger than the errors involved in the use of an external actinometer. Reproducibility in these measurements was found to be 3%.

A small cold finger attached to the reaction cell protruded slightly beyond the hot box; as this construction entailed a considerable amount of tubing outside the illuminated volume, the reactant was continuously circulated during a run by means of a small impeller. In an actual run the contents of the cell were condensed into the finger prior to opening the cell to the analytical line. By allowing the finger subsequently to warm very slowly, an effective separation of the noncondensables from the rest of the material, which shows a very strong tendency to occlusion, was obtained. In this manner it was found possible to obtain a quantitative separation in a reasonable time (1 hour). The analytical line consisted of two traps and a Ward–Le Roy still after which a two-way stopcock was placed to enable the products to be diverted either into the continuation of the mercury-free system to the introduction trap of a gas chromatography column, or into the small oil diffusion pump forming the first part of the bridge section (5) leading to the mercury system. The mercury system also consisted of a toepler pump, gas burette, and a mass spectrometer take-off.

The following fractions were removed and analyzed:

Noncondensables.—This contained only nitrogen, which was removed at −198° C and measured in the gas burette.

Second fraction −135° C.—This fraction consisted of C_3H_6 and C_3H_8. Analysis was done by mass spectrometry after the total pressure had been measured in the gas burette.

Liquid products.—All further material was introduced onto a 15-ft column (8) of 1/4-in. O.D. copper tubing packed with 30% bis-2,2-methoxyethoxyethylether (Eastman Kodak) on 30–60 mesh (Johns-Manville) Chromosorb (temperature, 40° C; flow, 64 ml H_2/minute). The reaction product 2,3-dimethylbutane emerged after 1/2 hour while the excess unreacted azoisopropane was retained for 2 hours. Though it was clearly not necessary to use such a long column for this separation, this length was necessary to obtain a separation between acetone and azoisopropane. This situation arose when purifying the starting material. The azoisopropane employed in this work was shown by gas chromatography to contain trace quantities of amines or hydrazines (mass spectrometric identification), 2,3-dimethylbutane, and approximately 5% acetone. As the separation of acetone from azoisopropane proved impossible by means of a Ward still distillation at −85° C (1) all material used in these experiments was purified by gas chromatography on the column described previously. Azoisopropane purified in this manner showed only a single peak when passed through a 10-ft column, 5 mm internal diameter, containing 25% dinonylphthalate + 5% glycerol on fire brick (temperature, 29° C; flow, 45 ml H_2/minute).

Azoisopropane has been subjected to thermal decomposition at different pressures at 127° C. Within the range of time employed in the photolytic experiments there was no evidence of thermal decomposition of azoisopropane.

RESULTS AND DISCUSSION

The following mechanism is proposed to explain the results obtained in the photolysis of azoisopropane between 34.7° C and 127° C. In the mechanism AIP refers to the normal ground-state molecule of azoisopropane while AIP* refers to an electronically excited state.

$AIP^* + AIP \rightarrow 2AIP$	k_2	[2]	Primary processes
$AIP^* \rightarrow AIP$	k_t	[6]	Primary processes
$2sec\text{-}C_3H_7 \rightarrow C_3H_6 + C_3H_8$	k_3	[3]	Secondary processes
$2sec\text{-}C_3H_7 \rightarrow C_6H_{14}$	k_4	[4]	Secondary processes
$sec\text{-}C_3H_7 + C_3H_7NNC_3H_7 \rightarrow C_3H_8 + C_3H_6NNC_3H_7$	k_5	[5]	Secondary processes

Primary Processes

Assuming a steady-state concentration of AIP* (10) one arrives at the following expression for the reciprocal quantum yield of nitrogen:

$$[I] \qquad 1/\Phi_{N_2} = 1+(k_2/k_1)[AIP]+k_t/k_1.$$

A plot of the reciprocal quantum yield of nitrogen against [AIP], at each temperature measured, should be linear with intercepts of $1+(k_t/k_1)$. The experimental data from Table I (units employed are quanta, cubic centimeters, seconds, and molecules) plotted in this manner in Fig. 1 do in fact give five lines with intercepts significantly larger than unity. Moreover, the values of these intercepts increase in a continuous manner with increasing temperature, this in contrast to the decreasing intercepts found with azoethane

mole and $A_2/A_1 = (3.2\pm1.9)\ 10^{-20}$ (molecule/cc)$^{-1}$.

The mechanism proposed above differs from that of Durham and Steacie (1) in the inclusion of reaction [6]. Neglecting this reaction leads to

[II] $$1/\Phi_{N_2} = 1+(k_2/k_1)\,[\mathrm{AIP}],$$

a relation which is not supported by the experimental data.

There is the possibility of a reduction in the quantum yield of nitrogen through an activated molecule of sufficient complexity, such as the AIP* molecule, whose large number of internal degrees of freedom would be able to contain the activating energy for a considerable time. Thus a certain portion of these activated molecules could reach the walls of the reaction vessel and there be deactivated. This process would entail including the following reaction in the mechanism:

$$\mathrm{AIP}^* + \mathrm{wall} \rightarrow \mathrm{AIP}, \qquad k_w \qquad [7]$$

which in turn would lead to

[III] $$1/\Phi_{N_2} = 1+(k_2/k_1)[\mathrm{AIP}]+k_i/k_1+k_w/k_1\,[\mathrm{AIP}],$$

where [AIP] is included in the denominator of the last term to take into account the variation of diffusion with pressure. Including this reaction, therefore, would require non-linearity in Fig. 1, the deviation from linearity depending on the ratio k_w/k_1, but in any case being most pronounced at low [AIP]. It is just in this region that the measurements become less accurate due to the small amount of light absorption. However, from [III] it can be shown that

[IV] $$[\mathrm{AIP}]/\Phi_{N_2} = k_2/k_1\,[\mathrm{AIP}]^2+(1+k_i/k_1)[\mathrm{AIP}]+k_w/k_1.$$

A plot of $[\mathrm{AIP}]/\Phi_{N_2}$ against [AIP] should therefore be parabolic with an intercept equal to k_w/k_1. The experimental data has been treated statistically using the least squares method for a quadratic parabola (11). For example, the data at 400° K (Fig. 2) are best described by the following expression:

$$[\mathrm{AIP}]/\Phi_{N_2} = (0.66\pm0.12)\ 10^{-18}[\mathrm{AIP}]^2+(1.549\pm0.058)[\mathrm{AIP}]+(0.045\pm0.70)\ 10^{-18}.$$

The uncertainties given are the statistical probable errors (12). Both from this and from the calculation of correlation coefficients it is clear that the data are best represented when wall deactivation is excluded. Under the present experimental conditions of pressure range and surface-to-volume ratio, wall deactivation may, therefore, be neglected.

As the amounts by which the intercepts in Fig. 1 are in excess of unity equals k_i/k_1 it is possible to obtain $E_i - E_1$ by the usual Arrhenius plot. Considering the standard deviation of these intercepts as given in Table II, it is obvious that this determination will not be highly accurate (Fig. 3). The best line calculated by weighing each point according

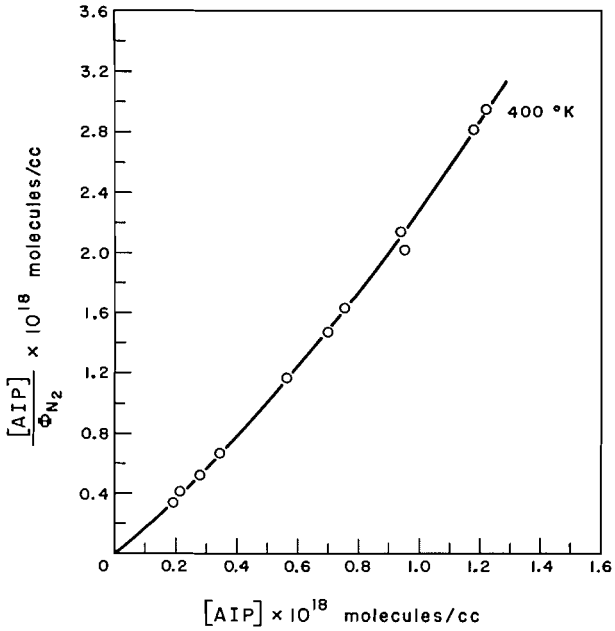

FIG. 2. Test for wall deactivation, expression [III].

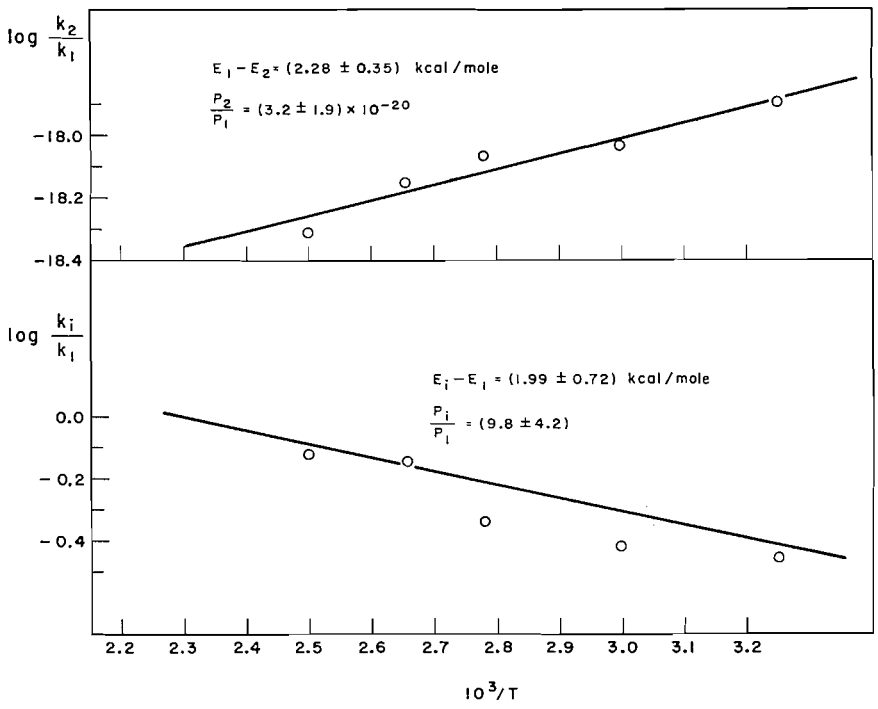

FIG. 3. Arrhenius plots of the ratio of rates of deactivation to decomposition and internal conversion to decomposition.

to its standard deviation (12) gives the values $E_1-E_1 = (1.99\pm0.72)$ kcal/mole and $P_1/P_1 = (9.8\pm4.2)$. This is believed to be the first case reported in which $E_1 > E_{\text{decomp}}$.

In an attempt to specify further the physical nature of the internal conversion reaction, luminescence measurements were made. No luminescence was discernible with 3660 Å incident radiation when a sensitive photomultiplier (IP 21) instrument normally used in studying the fluorescence of ketones was employed. As a logical extension of the theory of Franck and Livingston (13) it might be suggested that internal conversion of the excitation energy in the case of azoisopropane occurs through isomerization to a cis ground state when starting from trans ground state molecules. Fischer (14) has shown that *trans*-azobenzene in toluene solution, when irradiated with 3650 Å light until equilibrium has been obtained, consists of 91% of the cis form. The activation energy of this isomerization in various solvents, as determined by Hartley (15) and by Halpern, Brady, and Winkler (16), lies in the range 28.8 to 24.7 kcal/mole. As in the cis–trans isomerization of azobenzene, considerable resonance stabilization is possible of the unpaired electrons in the activated complex, a situation which does not exist in the case of azoisopropane, the activation energy for the cis–trans isomerization of the latter compound will undoubtedly be even higher. Since the energy supplied in the form of radiation is equivalent to only 78 kcal the resultant cis form will not contain sufficient energy to decompose unless it absorbs another quantum. If this were the only route to decomposition the quantum yield of nitrogen would be 0.5. The fact that this is not the case, both higher and lower values being observed, justifies the inclusion of the other steps in the primary process.

The large radical created in reaction [5] through abstraction from the parent compound was also generated in darkness through the thermal decomposition of di-*tertiary*-butyl peroxide at 127° C (17) in the presence of azoisopropane. Though methane was formed in the required manner, no nitrogen could be detected. Thus a chain reaction is not anticipated in the photolysis and the quantum yields discussed in the section on primary processes are not subject to correction for the possible further decomposition of the azoalkyl radical.

Secondary Processes

The preceding mechanism also leads to the following relations:

$$[V] \qquad R_{C_3H_6}/R_{C_6H_{14}} = k_3/k_4,$$

$$[VI] \qquad \frac{R_{C_3H_8}+R_{C_3H_6}}{R_{C_6H_{14}}} = \frac{R_{C_3}}{R_{C_6H_{14}}} = \frac{2k_3}{k_4}+\frac{k_5}{k_4^{\frac{1}{2}}}\frac{[\text{AIP}]}{R^{\frac{1}{2}}_{C_6H_{14}}},$$

$$[VII] \qquad \frac{R_{C_3H_8}-R_{C_3H_6}}{R_{C_6H_{14}}} = \frac{\Delta R_{C_3}}{R_{C_6H_{14}}} = \frac{k_5}{k_4^{\frac{1}{2}}}\frac{[\text{AIP}]}{R^{\frac{1}{2}}_{C_6H_{14}}}.$$

The various quantities necessary to test these expressions have been calculated from the experimental data and are given in Table I.

The ratio of k_3/k_4, as calculated for each individual run, is given in Table I. These values are compared with the values obtained from expression [VI] using Fig. 4 and Table III. From Table I it is seen that $R_{C_3H_6}/R_{C_6H_{14}}$ has a slight tendency to increase with increasing [AIP]. This tendency is, however, not very pronounced and seems in fact to have disappeared at the highest temperature employed. Further though there would

376.4	0.950	0.046	−0.0220	0.046	1.07	0.14	0.540	0.033	0.575	0.026
400.0	1.82	0.057	−0.069	0.057	1.78	0.12	0.511	0.022	0.540	0.033

at first seem to be an increase of $R_{C_3H_6}/R_{C_6H_{14}}$ with temperature, this is invalidated by the results at 127° C. Therefore within experimental error it is considered that k_3/k_4 is constant. Identical conclusions must be drawn from the results obtained using equation [VI]. It may be noted that constancy has also been found for this ratio of rates in the case of azoethane to 150° C (9) and in the case of diisopropyl ketone to 192° C (2). Since k_3/k_4 is independent of temperature, $E_3-E_4 = 0$. The actual numerical value of k_3/k_4 agrees well with the data of Heller and Gordon (2) and Robb and Boddy (4). The value reported by Kerr and Trotman-Dickenson (3) for this ratio of rates is, however, slightly higher.

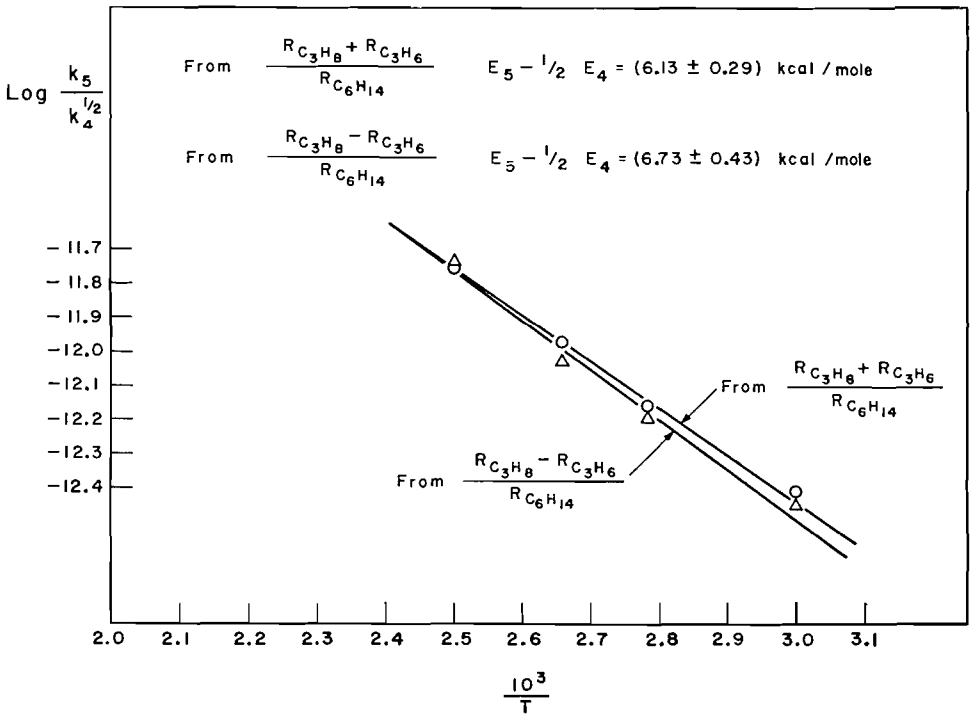

FIG. 5. Arrhenius plots relevant to the expressions [VI] and [VII]. ○ from expression [VI] and △ from expression [VII].

The ratio $k_5/k_4^{\frac{1}{2}}$ has also been obtained from both [VI] and [VII] (Table III). The Arrhenius plot for both cases is given in Fig. 5 and leads to

$$E_5-\tfrac{1}{2}E_4 = (6.12\pm0.29)\ \text{kcal/mole},$$

$$P_5\sigma_5^2/P_4^{\frac{1}{2}}\sigma_4 = 0.369\ 10^{-10}.$$

Assuming (10) that $\sigma_5 = 3$ Å and $\sigma_4 = 2.1$ Å leads to

$$P_5/P_4^{\frac{1}{2}} = 0.85\ 10^{-3}$$

when equation [VI] is used. If equation [VII] is employed it is found that

$$E_5-\tfrac{1}{2}E_4 = (6.73\pm0.43)\ \text{kcal/mole},$$

$$P_5\sigma_5^2/P_4^{\frac{1}{2}}\sigma_4 = 0.774\ 10^{-10} \rightarrow P_5/P_4^{\frac{1}{2}} = 1.8\ 10^{-3}.$$

These results are in good agreement with those of Heller and Gordon (2).

The experimental data in Table I show a decrease in the mass balance, i.e. $\{\frac{1}{2}(C_3H_6 + C_3H_8) + C_6H_{14}\}/N_2$, with increasing temperature. As no new compounds are found in the first two fractions removed in the runs at higher temperature it must be concluded that these new compounds are of high molecular weight and constitute part of the "liquid products". No positive identification of these new products could be made by mass spectrometry though it was noted that (*sec*-Pr)$_2$NN(*sec*-Pr)$_2$ would, among other compounds, be consistent with the observed spectrum.

THE OXIDATION OF MANGANATE BY PERIODATE[1]

M. W. Lister and Y. Yoshino

ABSTRACT

The reaction between periodate and manganate ions in alkaline solution has been examined, and at 35° C the rate is given by the equation, time being measured in minutes,

$$\text{rate} = 107[MnO_4^{--}]^2(1+167[H_3IO_6^{--}])(1+0.111[OH^-]^{-1}).$$

It is proposed that the main reaction mechanism is

$$2MnO_4^{--} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} MnO_4^- + MnO_4^{-3}, \quad \text{(i)}$$

$$MnO_4^{-3} + H_3IO_6^{--} \xrightarrow{k_3} MnO_4^- + IO_3^- + 3OH^-. \quad \text{(ii)}$$

Hence $k_1 = 107$ (g-molecule/l.)$^{-1}$ min^{-1} at 35° C, and it was found that the activation energy is about 13.9 kcal/g-molecule. Data of Carrington and Symonds (2), combined with the value for k_1, make $k_2 = 2.8\times10^6$ (g-molecule/l.)$^{-1}$ min^{-1}. Added permanganate ions slow up the reaction; this is ascribed to the reverse of reaction (i) competing with reaction (ii). This gives a value for k_3 of 2×10^7 (g-molecule/l.)$^{-1}$ min^{-1}; this is so large a rate constant as to make it probable that the hypomanganate ions are hydrolyzed. The effect of hydroxide concentration on the rate is ascribed to partial hydrolysis of manganate ions. The observed results would require the ionization constant of $HMnO_4^-$ to be 7×10^{-11}.

In a recent paper (1) the present writers prepared several complex manganese periodates, such as $Na_7H_4Mn(IO_6)_3.17H_2O$, containing tetravalent manganese. These were shown to decompose in solution to give manganate ions as the first product, and finally permanganate ions. The mechanism of the decomposition of the complex salt was investigated, and shown to go through a partial breaking up of the complex to simpler ions. The present paper reports an examination of the second stage of this reaction, that is, the oxidation of manganate to permanganate. Apart from its connection with the behavior of manganato-periodates, this reaction is of interest because it involves a change of two in the oxidation state of the iodine, and of one in the oxidation state of the manganese. Thus we might expect either a termolecular reaction, or a mechanism which avoided this. In the latter case, the reaction would have to go through an intermediate containing either iodine or manganese in a usual valency. As it turned out, the main route seemed to be through hypomanganate ions, containing the relatively rare pentavalent manganese. There is also evidence for a termolecular reaction.

The over-all reaction is

$$2MnO_4^{--} + H_3IO_6^{--} \rightarrow 2MnO_4^- + IO_3^- + 3OH^-.$$

EXPERIMENTAL METHOD

The reaction was followed by mixing known amounts of stock solutions of sodium manganate, sodium periodate, and sodium hydroxide, previously brought to the required temperature. The mixture was kept in a thermostat, and the extent of reaction was found by measuring the optical density of a sample.

The sodium manganate was prepared by boiling sodium permanganate in concentrated sodium hydroxide solution, as described by Carrington and Symonds (2). Sodium periodate was prepared by oxidation of a weakly alkaline sodium iodate solution by means of sodium hypochlorite at about 80° C; the fairly insoluble sodium periodate,

[1]*Manuscript received August 25, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

$Na_3H_2IO_6$, crystallized out, and was filtered off and thoroughly washed with distilled water.

The initial concentration of manganate in the runs was between 1.6×10^{-4} M and 6×10^{-4} M, and the initial concentration of periodate between 3×10^{-4} M and 13×10^{-4} M. Sodium hydroxide was present in sufficient excess for its concentration not to change appreciably during the runs; many runs were in 0.1 M sodium hydroxide.

The optical density was measured on a Beckmann DU spectrophotometer, with a 1-cm cell. The wavelength used was 610 mμ, which is at the absorption maximum for manganate ions. Measurements on several solutions gave a value of 1530 for the extinction coefficient of sodium manganate, and 207 for sodium permanganate (2, 3). The concentrations of the solutions were calculated assuming that only these two ions contributed to the optical density, and that all the manganese was present as one or other ion. This was supported by the fact that the solutions showed no signs of any precipitate of manganese dioxide. It was checked that the total oxidizing power of the solutions, as measured by the amount of iodine liberated by adding potassium iodide and sulphuric acid, did not change during the reaction; and finally it was checked that iodate caused no oxidation of manganate. Thus there is no evidence of any side reactions.

RESULTS

It was found that for all runs a plot of the inverse of the manganate concentration against time was linear, as in a second-order reaction. Accordingly the results are shown in the figures as graphs of this sort. The initial concentrations and temperatures are given in Table I. The ionic strengths of the solutions were close to 0.1, except for the

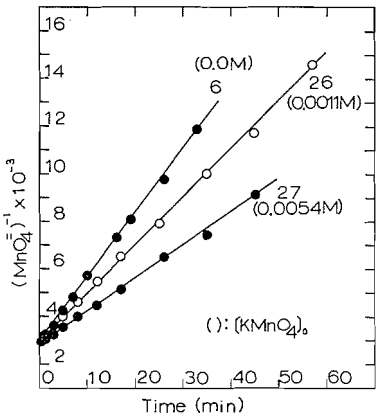

FIG. 2. Effect of permanganate concentration on rate.

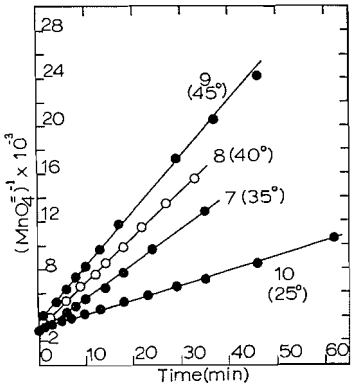

FIG. 3. Effect of temperature on rate.

three runs in 0.2 M sodium hydroxide, where the ionic strength was slightly above 0.2.

There are two comments to make on these graphs. Firstly the points at the time of mixing were calculated from the volumes of stock solution put in, the stock solution being standardized by adding potassium iodide and acid, and titrating with thiosulphate. These are plotted at $t = 0$, and the next point, usually at $t = 1$ minute, represents the first measurement of optical density. These first two points were always in reasonable agreement. The second comment is that the final points fall off somewhat from a second-order plot, though by this time the manganate concentration was usually less than 25% of its initial value. The best straight lines were drawn through the experimental points obtained before this falling off became apparent, and the slopes of these lines are given in the last column of Table I, headed "$d[MnO_4^{--}]^{-1}/dt$". Time is measured in minutes.

DISCUSSION OF RESULTS

Attention may first be drawn to runs 15 and 17 in which no periodate was present. These runs show that the disproportionation of manganate is much slower than the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

oxidation by periodate. In these runs a precipitate of manganese dioxide appeared, while in no run with periodate present was any precipitate observed. Although the rate of disproportionation is about 5% of the rate in the slowest runs with periodate, no correction was made for this in the calculations, because the absence of any sign of manganese dioxide made it doubtful if the disproportionation to manganese dioxide and permanganate was in fact occurring. The reason for this will appear later when the mechanism of the reaction with periodate is discussed.

Turning now to the main series of runs, the first point, of course, is that the rate is proportional to $[MnO_4^{--}]^2$. Secondly, when rates at different periodate concentrations are compared, it is seen that this has only a moderate effect on the rate. In runs at 35° C and 0.1 M sodium hydroxide, the average values of $d[MnO_4^{--}]^{-1}/dt$ at various periodate concentrations were:

$[H_3IO_6^{--}]$	12.56	7.85	3.14×10^{-4} M
$d[MnO_4^{--}]^{-1}/dt$	292	278	254

Over this range, the results approximately follow the equation

$$\text{rate} = [MnO_4^{--}]^2(241+4.0\times10^4[H_3IO_6^{--}]).$$

Although the term in periodate looks large, its contribution was fairly small.

The effect of hydroxide concentration can be seen from the runs at 35° C and 7.85×10^{-4} M periodate, and an ionic strength of 0.1.

$[OH^-]$	0.100	0.049	0.022	0.0091 M
$d[MnO_4^{--}]^{-1}/dt$	254	394	729	1485

If $[OH^-]^{-1}$ is plotted against $d[MnO_4^{--}]^{-1}/dt$, the first three results fall on a straight line, and the fourth is near the line, but a little low. The straight line has the equation

$$d[MnO_4^{--}]^{-1}/dt = 121+13.4[OH^-]^{-1}.$$

Combining these two equations, the total equation is

$$\text{(A)} \qquad \text{rate} = 107[MnO_4^{--}]^2(1+167[H_3IO_6^{--}])(1+0.111[OH^-]^{-1}).$$

This is for 35° C. It is evident that this could be written in terms of hydrogen ions,

$$\text{rate} = 107[MnO_4^{--}]^2(1+167[H_3IO_6^{--}])(1+4.83\times10^{12}[H^+]).$$

The mechanism which could give this equation must involve more than one reaction. However, at high hydroxide concentrations, the main part of the reaction is simply a second-order reaction in manganate ions. The most obvious suggestion is that the reaction goes through hypomanganate ions:

$$2MnO_4^{--} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} MnO_4^- + MnO_4^{---}, \qquad \text{(i)}$$

$$MnO_4^{---} + H_3IO_6^{--} \xrightarrow{k_3} MnO_4^- + IO_3^- + 3OH^-. \qquad \text{(ii)}$$

The scheme has the advantage that each stage is a simple bimolecular reaction. For the reaction to depend on the manganate concentration alone, it would be necessary for reaction (ii) to go much faster than the reverse of (i), so that all hypomanganate is oxidized to permanganate. Otherwise the permanganate formed during the run would cause a continuous extra decrease in the rate, which is not found until the reaction is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

nearly over. If this is the correct mechanism, then k_1, the rate constant of reaction (i) going to the right, is 107 (g-molecule/l.)$^{-1}$ min^{-1} at 35° C, from equation (A) above.

Carrington and Symonds (2) calculate that ΔF^0 for reaction (i) is 6.2 kcal at 25° C. This makes the equilibrium constant of reaction (i) 2.85×10^{-5} at 25° C. ΔH^0 is 5.5 kcal, so the equilibrium constant is 3.85×10^{-5} at 35° C. Hence k_2, the rate constant of reaction (i) going to the left, is 2.8×10^{6} (g-molecule/l.)$^{-1}$ min^{-1} at 35° C.

The dependence on $[OH^-]$ or $[H^+]$ probably means that the sodium manganate is partially hydrolyzed. One might expect this to give $Mn_2O_7^{--}$ ions, by analogy with the behavior of chromate, but this would require a dependence on the square of $[H^+]$; the first power of $[H^+]$ in the equation shows that the hydrolyzed species is $HMnO_4^-$, which then must react thus:

$$HMnO_4^- + MnO_4^{--} \overset{k_4}{\rightleftharpoons} MnO_4^- + HMnO_4^{--}. \qquad \text{(iii)}$$

On this hypothesis, if k_a is the ionization constant of $HMnO_4^-$ (to give H^+ and MnO_4^{--}), and k_4 is the rate constant of reaction (iii) going to the right, then it is easily found that the contribution of reaction (iii) to the rate is

$$k_4[MnO_4^{--}]^2\left\{\frac{[H^+]k_a}{(k_a+[H^+])^2}\right\}$$

where $[MnO_4^{--}]$ here means the total manganate present. The contribution of reaction (i) becomes

$$k_1[MnO_4^{--}]^2\left\{\frac{k_a^{\,2}}{(k_a+[H^+])^2}\right\};$$

so that the total equation is

$$\text{rate} = [MnO_4^{--}]^2\left\{\frac{k_1+k_4[H^+]/k_a}{(1+[H^+]/k_a)^2}\right\}.$$

Evidently if $[H^+]$ is low, and k_4 not too small, this will give an equation for the rate of the type actually found: by comparison, $k_4/k_1.k_a = 4.83\times10^{12}$. The slight decrease of the rate in 0.0091 M sodium hydroxide below what is calculated is presumably due to the term $(1+[H^+]/k_a)^2$; this explanation would require k_a to be 7×10^{-11}. This is perhaps a somewhat small value for k_a; for instance, the bichromate ion, $HCrO_4^-$, has an ionization constant of 3.2×10^{-7} (4). This value of k_a gives 340 for the ratio k_4/k_1, so that k_4 is 3.6×10^{4} (g-molecule/l.)$^{-1}$ min^{-1} at 35° C. This ratio is not unreasonable as MnO_4^{--} and $HMnO_4^-$ will repel each other less than two MnO_4^{--} ions.

The graphs of $[MnO_4^{--}]^{-1}$ against time cease to be linear towards the end of the reaction. It can be calculated that this is not due to the decrease in periodate concentration, which would cause only a very small decrease in the rate. Another possible explanation is that reaction (ii) is reversible, and that the equilibrium lies far from complete conversion to permanganate. Latimer (4) gives −0.564 volt for the standard potential of the half reaction: $MnO_4^{--} \rightarrow MnO_4^- + e^-$, and a rather doubtful −0.7 volt for $IO_3^- + 3OH^- \rightarrow H_3IO_6^{--} + 2e^-$. If this value of −0.7 volt is right, then the equilibrium lies at almost complete conversion to permanganate. A check on this was made by mixing potassium permanganate with a relatively large concentration of sodium iodate (and sodium hydroxide) and examining the spectrum of the mixture to see whether any manganate ions were formed. A small concentration of manganate ions did appear,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and a rough measurement showed that the equilibrium constant of reaction (ii) is at least 25 or larger (this is with the permanganate on top). Hence in concentrations of sodium hydroxide below 0.1 M, the equilibrium mixture will be almost entirely permanganate. It was calculated that, in a typical run such as run 6, at equilibrium 0.4% or less of the manganese would be present as manganate.

A more plausible explanation is that as the permanganate increases in concentration and periodate decreases, the reverse of reaction (i) starts to compete with reaction (ii). This suggestion was tested in runs 26 and 27, when appreciable amounts of permanganate were added initially, and it was found that the permanganate reduced the rate of reaction. If ordinary kinetic considerations are applied to these reactions, it is found that the concentration should follow the equation

$$\text{(B)} \qquad k_1 t - (\theta - \theta_0) = a\left[\frac{(2+2y_0\theta_0)(\theta-\theta_0)}{2b-1} - \frac{2\theta_0(2b+y_0\theta_0)}{(2b-1)^2}\ln\frac{\theta(2b-1)+\theta_0}{2b\theta_0}\right]$$

where $\theta = [MnO_4^{--}]^{-1}$, initially θ_0,
$a = k_2/k_3$,
b = initial value of the ratio $[H_3IO_6^{--}]/[MnO_4^{--}]$,
y_0 = initial $[MnO_4^{-}]$.

In the earlier runs, $y_0 = 0$. If k_2 is zero, this equation reduces to the usual second-order equation; and it is found that for moderate values of a, a plot of θ against t only deviates to any great extent from a straight line when the reaction is nearly over. This is in agreement with experiment, as the experimental points followed a second-order equation for a considerable time. The above equation gives

$$\left(\frac{d\theta}{dt}\right)_0 = \frac{k_1}{1+ay_0/[H_3IO_6^{--}]_0}$$

where $(d\theta/dt)_0$ is the initial value of $d\theta/dt$, and $[H_3IO_6^{--}]_0$ is the initial periodate concentration. Hence with no added permanganate, $(d\theta/dt)_0 = k_1$, as was assumed above. The value of a can be found (i) from the initial slopes, $(d\theta/dt)_0$, in runs 26 or 27, or (ii) by applying the full equation to the later points in runs with no added permanganate. The first method is obviously more accurate, but the values of a found by the second are in rough agreement.

For run 26, the initial $d\theta/dt$ is about 222, for conditions where $d\theta/dt$ without added permanganate is 278. The ratio $[MnO_4^{-}]/[H_3IO_6^{--}]$ is initially 1.38. This makes $a = 0.18$. In run 27, the initial $d\theta/dt$ is 137, with $[MnO_4^{-}]/[H_3IO_6^{--}]$ initially 6.88. This makes $a = 0.15$. Applying the second method above to the earlier runs gives slightly smaller values of a, mostly between 0.1 and 0.15. Hence the value of k_2/k_3 at 35° C is evidently about 0.15. From the value of k_2 obtained above, it follows that k_3 is about 2×10^7 (g-molecule/l.)$^{-1}$ min^{-1} at 35° C. This is a relatively large rate constant, and is surprisingly large if the reaction is one between MnO_4^{--} and $H_3IO_6^{--}$, because of the electrostatic repulsion of the ions. There seems to be no doubt that the periodate is mainly $H_3IO_6^{--}$ in these solutions, as Crouthamel, Hayes, and Martin (5) find pk_2 to be 8.36 and $pk_3 = 15$, for periodic acid. Hence at the concentrations of sodium hydroxide used in these experiments the periodate must be predominantly $H_3IO_6^{--}$. This is in agreement with the phase diagram for sodium hydroxide, periodic acid, and water, as determined by Hill (6). However, although the periodate ion is $H_3IO_6^{--}$, it is possible that the hypomanganate is hydrolyzed to ions of lower charge, $HMnO_4^{--}$ or $H_2MnO_4^{-}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

There are no values for the ionization constants of hypomanganic acid, and the most that can be said is that the present results provide some evidence for partial hydrolysis of hypomanganate ions in 0.1 M sodium hydroxide. The reaction might consist of hydrogen atom transfer from $H_2MnO_4^-$ to $H_3IO_6^{--}$.

The experimental rate equation (A) above contained a term in $[H_3IO_6^{--}]$, which suggests that part of the reaction is termolecular. However, it is necessary to be sure that this is not an indirect result of the varying success of the competition between the k_2 and k_3 reactions. Obviously a high periodate concentration will favor reaction (ii), with rate constant k_3. This will not affect the initial slope for $[MnO_4^{--}]^{-1}$ plotted against t, but as in practice the slope has to be obtained over a number of points, the periodate concentration may alter the slope in effect; in equation (B) this would be due to different values of b. It is found that if equation (B) is plotted, it gives very nearly a straight line for a considerable distance, after which the values of θ fall below the straight line. Over the range of θ used in the experiments (about 3,000 to 15,000) the curvature is slight, but the mean slope is altered by the value of b. If the slope is taken as unity for $b = 1$, it is 1.05 for $b = 2$, and 1.07 for $b = 4$. However, over this range of b (or periodate concentration) the relative observed slopes are about 1.067 for $b = 2$ and 1.16 for $b = 4$. The conclusion must therefore be that there is a direct effect due to periodate, apart from its alteration of the relative rates of the k_2 and k_3 reactions, that is, that there is a termolecular reaction, at least to a small extent.

The temperature dependence of the slope, $d[MnO_4^{--}]^{-1}/dt$, needs some comment. For the same values of $[OH^-]$ and $[H_3IO_6^{--}]$, the usual plot of $\log(d[MnO_4^{--}]^{-1}/dt)$ against $1/T$ gives nearly straight lines. The activation energies so obtained are: $[OH^-] = 0.05$ M, $E = 14.8$ kcal/g-molecule; $[OH^-] = 0.1$ M, $E = 13.9$ kcal/g-molecule; and $[OH^-] = 0.2$ M, $E = 12.7$ kcal/g-molecule. If the value of 13.9 kcal/g-molecule is taken to apply to k_1 deduced above, and if $k_1 = Ae^{-E/RT}$, then $\log A = 11.9$ (time measured in minutes). This is an unremarkable value. This activation energy may also be compared with that obtained (7) for the interchange of radioactive manganese between manganate and permanganate ions: here $E = 10.5$ kcal. As might be expected, this is somewhat less than the value for the reaction between two manganates, which involves the transfer of an electron between two doubly charged ions. If ΔH^0 is 5.5 kcal, then the activation energy for $MnO_4^{-3} + MnO_4^- \rightarrow 2MnO_4^{--}$ is only 8.4 kcal; however, the hypomanganate ion may be partially hydrolyzed, which would vitiate any arguments concerned with the size of the charges on the ions. The activation energy found above drifts to slightly lower values as the hydroxide concentration increases. The difference is not large, but the cause is at present obscure, as the change is in the opposite direction from what would be expected from the rate constants. The change is too large, and the rate constants too consistent, to ascribe this to experimental error.

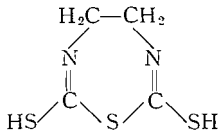
SOME OBSERVATIONS ON THE STRUCTURE OF ETHYLENETHIURAM MONOSULPHIDE[1]

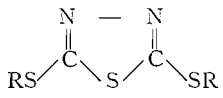
G. D. THORN



ABSTRACT

An attempt has been made to answer several apparent objections to the structure ethylenethiuram monosulphide assigned to the monomeric material of formula $C_4H_6N_2S_3$ obtained by air oxidation of disodium ethylenebisdithiocarbamate. Comparison of the ultraviolet and infrared absorption spectra, potentiometric titrations, and biological assays of the compound and several heterocyclic and other compounds containing the N–C–S grouping has eliminated two possible alternative structures containing thiadiazolidine and dithiazolidine ring systems and has led to the conclusion that the original assignment of structure was correct.

Vigorous aeration of dilute aqueous solutions of disodium ethylenebisdithiocarbamate (nabam) results in the formation of a yellow insoluble fungicidal material consisting mainly of a polymer $(C_4H_6N_2S_3)_n$, together with up to 20% of the corresponding monomer and varying amounts of elemental sulphur (1, 2). The compound $C_4H_6N_2S_3$ has been assigned the structure ethylenethiuram monosulphide (hexahydro-1,3,6-thiadiazepine-2,7-dithione) (IA), which can be written also as the enethiol (IB). Interpretation of the infrared spectrum of the compound favored the latter structure. The strong band at 1610 cm^{-1} was taken as indicative of C=N (3); the bands attributable to the thioamide group (4, 5) are absent, and there is no evidence of absorption in the N—H stretching region.

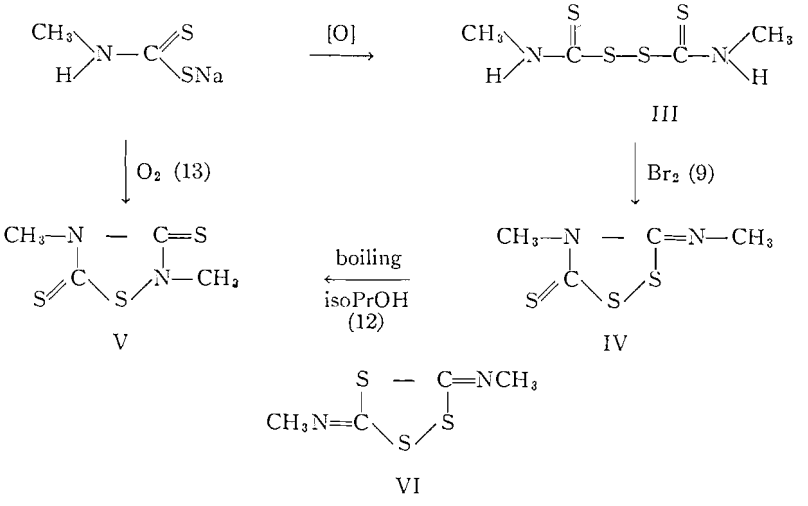


IA

IB

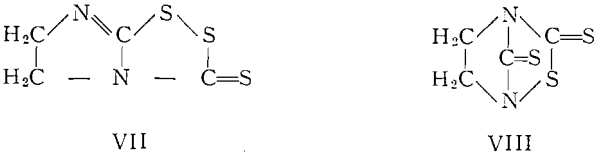
A number of objections can be raised to the formulation of the compound $C_4H_6N_2S_3$ as structure I. From a study of its infrared spectrum, two points can be made. Firstly, there is the lack of SH absorption in the 2600–2550 cm^{-1} region, and secondly, the observation that 2,5-di(methylmercapto)-1,3,4-thiadiazole (II, R = CH_3) does not display the "C=N absorption" in the 1650–1500 cm^{-1} region (6). From a chemical

II



standpoint, the formation of mono-addition products with HCl and $HClO_4$ (2) and with carbon disulphide* is suggestive of unequivalent nitrogens in the structure. Also, the

[1]*Manuscript received June 3, 1960.*
Contribution No. 175, Pesticide Research Institute, Canada Department of Agriculture, University Sub Post Office, London, Ontario.

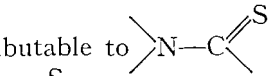


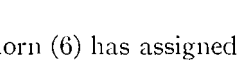
**The formation of an ethylenethiuram monosulphide – carbon disulphide complex has been recognized by Dr. G. J. M. van der Kerk and by Dr. I. A. M. Ford (personal communications) and by Kirby and Frick (7), but to our knowledge, analytical data have not been published.*

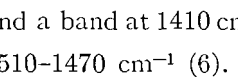
only other thiuram monosulphide derived from a primary amine which has been reported in the literature is in the recent work by D'Angeli and Iliceto (8), who described N,N'-dimethylthiuram monosulphide. This material is highly unstable either in solution or in the solid form, in contrast with the much more stable material designated ethylenethiuram monosulphide. Accordingly, further evidence was sought either to support the ethylenethiuram monosulphide structure, or perhaps to suggest that an entirely different structure might well be assigned to fit the data more adequately. The results of these investigations are reported in this paper.

Two compounds of interest in this study which are obtainable by oxidation of sodium methyldithiocarbamate or the intermediate dimethylthiuram disulphide (III) are 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV) and 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (V). These compounds were first prepared by Freund and coworkers (9, 10) and the assignments of structure by Hantzsch and Wolvekamp (11) confirmed by means of infrared absorption spectra by Bradsher *et al.* (12). Freund and Asbrand (10) had given structure VI to what is now considered to be the thiadiazolidine (V), but Bradsher *et al.* (12) discounted this assignment because of lack of C=N absorption in the 1660–1610 cm^{-1} region. It might be noted again that the thiadiazole (II) does not exhibit absorption in this region, but this point alone cannot be used as evidence for structure VI, as the compound exhibits "thioureide" absorption in the 1450 cm^{-1} region.

Since Benghiat *et al.* (13) have shown that the thiadiazolidine (V) can be obtained merely by conveying wet sodium methyldithiocarbamate in air through a pneumatic conveying drier, it is conceivable that disodium ethylenebisdithiocarbamate on aeration might yield, instead of a thiuram monosulphide (I), structures analogous to IV and V, namely VII and VIII, respectively.

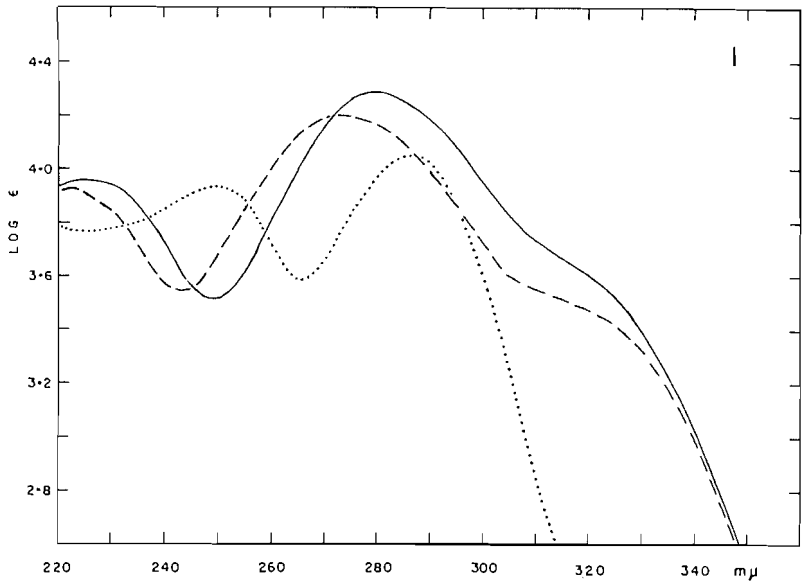






Compound VII especially answers several of the objections raised to the thiuram monosulphide structure designation. It was therefore considered important to make chemical and biological comparisons of ethylenethiuram monosulphide* with 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV) and 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (V).

Ultraviolet Absorption Spectra



The similarity in ultraviolet absorption spectra of ethylenethiuram monosulphide and of tetramethylthiuram monosulphide was used by Thorn and Ludwig (2) as part of the evidence in favor of the thiuram monosulphide structure for the former compound. However, making further comparisons shows a possible fallacy in this argument. Figures 1 and 2 give the ultraviolet absorption spectra (ethanol solution) of several of the compounds in question. For ethylenethiuram monosulphide, the peaks are at 280 mμ, ϵ = 19,600, and at 227.5 mμ, ϵ = 8800; for tetramethylthiuram monosulphide the maxima are at 280 mμ, ϵ = 16,300, and at 210 mμ, ϵ = 17,000; and for dimethylthiuram monosulphide maximum absorption is at 287 mμ, ϵ = 11,300,† and at 250 mμ, ϵ = 8700.† On the other hand, 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV) also shows an ultraviolet absorption spectrum (Fig. 1) very similar to that of ethylenethiuram monosulphide, with peaks at 274 mμ, ϵ = 16,000, and at 223 mμ, ϵ = 8250. Compound V, 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione, displays a different absorption to that of the above compounds (Fig. 2). Thus, on the basis of ultraviolet absorption, no decision can be made between a thiuram monosulphide or a dithiazolidine structure for "ethylenethiuram monosulphide".

Infrared Absorption Spectra

Table I summarizes the important absorption bands in the infrared region 2000–900 cm^{-1} of ethylenethiuram monosulphide and a number of other compounds containing the N–C–S linkage. The ethylenethiuram monosulphide structure is a more plausible assignment than that of a dithiazolidine structure (VII), based on the following observations. Methyl-methylimino-dithiazolidine-thione (IV) shows absorption at 1650 cm^{-1}, assignable to $\nu_{C=N}$ (3), at 1470 cm^{-1}, attributable to  (6) and at 1430 cm^{-1}, which Thorn (6) has assigned to the  grouping. Ethylenethiuram monosulphide also shows $\nu_{C=N}$ absorption, at 1615 cm^{-1}, and a band at 1410 cm^{-1} () but no thioureide absorption in the region of 1510–1470 cm^{-1} (6). The lack of C=N absorption in the region of 1600 cm^{-1} in the spectrum of 2,5-dimercapto-1,3,4-thiadiazole (II, R = H) can be accounted for by the pseudoaromatic character of the compound (14). Likewise, in 2,5-di(methylmercapto)-1,3,4-thiadiazole (II, R = CH_3), this band is missing. (In this latter compound the structure is rigidly held in the enethiol form, whereas in II, R = H, the thione–thiol tautomeric structure has been assigned (6).) On the basis of our interpretation of the infrared spectra, then, the assignment of the ethylenethiuram monosulphide structure originally proposed (2) can be taken as correct, the only unexplainable feature being the lack of SH absorption in the 2600–2550 cm^{-1} region.

*Although the remarks above raise doubt as to the actual structure, the name ethylenethiuram monosulphide will be used throughout this discussion for the sake of convenience.

†These values are approximate, owing to the instability of dimethylthiuram monosulphide.

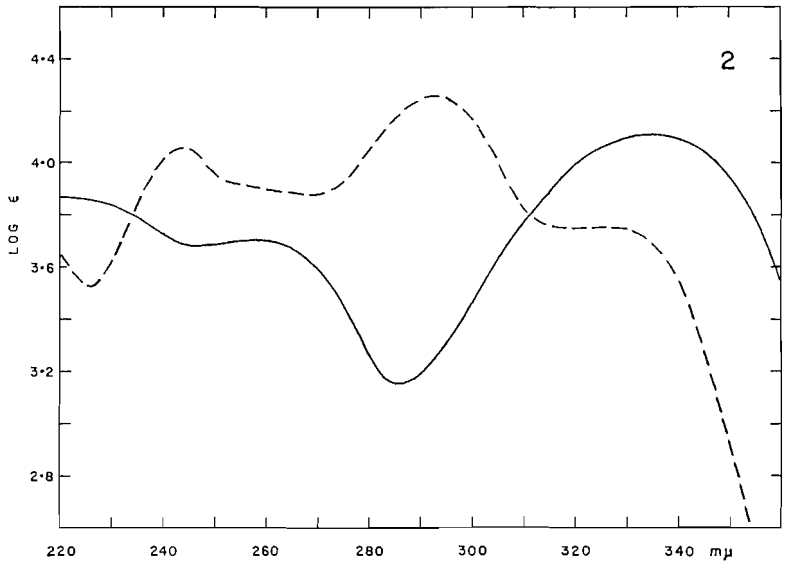


FIG. 1. Ultraviolet absorption spectra. ——— Ethylenethiuram monosulphide. – – – 4-Methyl-5-methylimino-1,2,4-dithiazolidine-3-thione. ····· Dimethylthiuram monosulphide.
FIG. 2. Ultraviolet absorption spectra. ——— 2,5-Dimercapto-1,3,4-thiadiazole. – – – 2,4-Dimethyl-1,2,4-thiadiazolidine-3,5-dithione.

In this connection, thiourea also displays a strong band at 1615 cm^{-1}, assignable to $\nu_{C=N}$ vibration, but shows no absorption band in the region 2600–2550 cm^{-1} given by Bellamy (15) as assignable to ν_{SH} vibration.

Potentiometric Studies

The apparent lack of SH according to the infrared spectrum in ethylenethiuram

monosulphide prompted potentiometric titrations to determine the presence or absence of weakly acid hydrogen in the compound in question. Harlow *et al.* (16) have shown the feasibility of potentiometric titration of very weak acids using tetrabutylammonium hydroxide as titrant in non-aqueous media. Structurally, 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV) and 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (V) should show no consumption of alkali. The other compounds tested, i.e., ethylenethiuram monosulphide, dimethylthiuram mono- and di-sulphide, and 3,5-dimercapto-1,3,4-thiadiazole (II, R = H) should each show two inflection points in its titration curve. The results of these titrations, using tetrabutylammonium hydroxide in isopropyl alcohol as titrant and acetonitrile as solvent, are given in Figs. 3 and 4. Pyridine was also used as solvent in a parallel series of titrations, but, except in the case of dimercaptothiadiazole, no greater resolution was obtained. Cundiff and Markunas (17) have demonstrated the possibility of titrating potentiometrically organic dibasic acids whose ionization constants (K_1 and K_2) are close together, and of obtaining two sharp inflections in the titration curve. As can be seen in Figs. 3 and 4, two inflections were obtained with

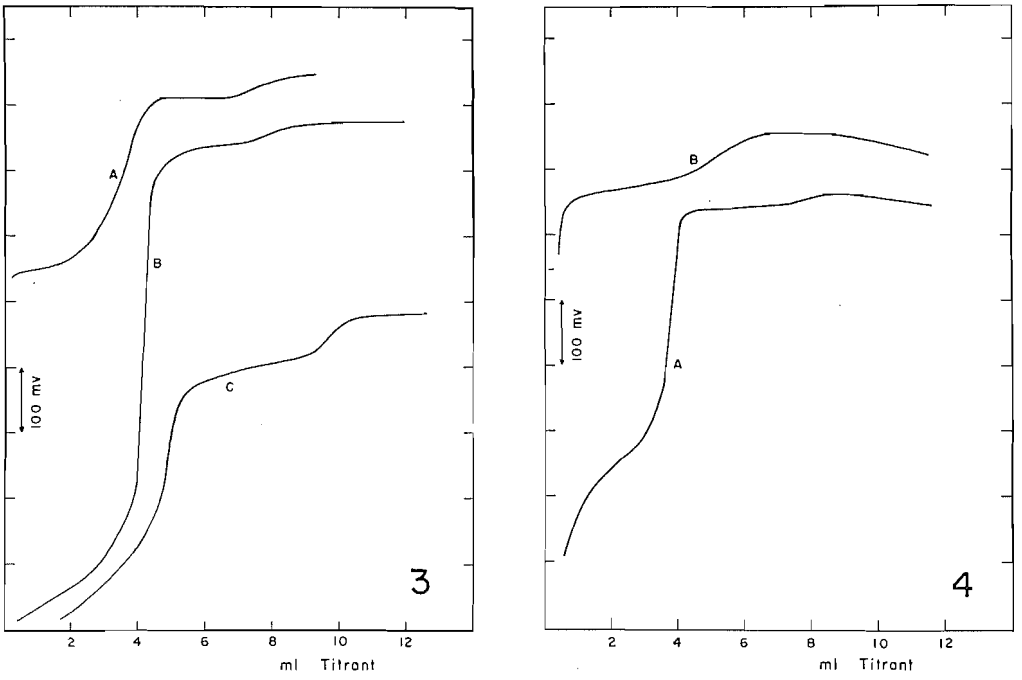

FIG. 3. Potentiometric titration curves. (A) Ethylenethiuram monosulphide. (B) Dimethylthiuram disulphide. (C) 2,5-Dimercapto-1,3,4-thiadiazole.
FIG. 4. Potentiometric titration curves. (A) Dimethylthiuram monosulphide. (B) 2,4-Dimethyl-1,2,4-thiadiazolidine-3,5-dithione.

all the above-mentioned compounds, except for IV and V. With ethylenethiuram monosulphide and dimethylthiuram disulphide, the inflections occurred at about 85% of equivalence, and with dimethylthiuram monosulphide, the inflections were at about 60–65% of equivalence. The discrepancy shown by dimethylthiuram monosulphide is not surprising in the light of the work of D'Angeli and Iliceto (8), who showed the instability of this compound in neutral solution and also the formation of molecular amounts

of sodium methyldithiocarbamate and methylisothiocyanate when the thiuram monosulphide was treated with an equivalent of sodium hydroxide. Similar decompositions probably occurred with ethylenethiuram monosulphide and dimethylthiuram disulphide during the titrations. It had been shown in earlier work (18) that ethylenethiuram monosulphide is converted to ethylenethiourea on treatment with alcoholic potassium hydroxide.

One unexpected result arising from these potentiometric titrations was the occurrence of a single weak inflection in the titration curve of dimethylthiadiazolidinedithione (V), at 80% of one equivalent of alkali. As expected, however, methyl-methylimino-dithiazolidine-thione (IV), on the other hand, gave no "titration curve".

Biological Studies

Ethylenethiuram monosulphide, 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV), 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (V), and 2,5-dimercapto-1,3,4-thiadiazole were tested for biological activity by the A.P.S.-recommended spore drop method (19) using *Monilinia fructicola* as test organism. Dimethylthiuram monosulphide was not assayed in view of its instability. The dosage response data are shown in Fig. 5, plotted on logarithmic probability grid. These data were subjected to probit analysis, and $Y = a+bx$, the linear regression equation of toxicity probit values on the dose metameter, determined for each toxicant according to Finney (20). From these equations not only is the median lethal dosage, $m = (5-a)/b$, obtainable, but also the spread in distribution of tolerance, σ^2, a second expression of the effectiveness of the toxicant. The variance, σ^2, is equal to the reciprocal of the square of the slope, b, of the regression line. Toxicants whose physiological effects are similar often have approximately equal variances for any given organism, even though they may display substantial differences in their median lethal dosages. In other words, the slope of the regression line is considered a criterion of mechanism of fungicidal action (21, 22). If two fungicidal compounds yield different dosage response slopes, a different mechanism of action is inferred. Parallel slopes are given by members of homologous series.

The regression line equations for ethylenethiuram monosulphide (I), 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV), and 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (V) were calculated to be: $Y_{\mathrm{I}} = 4.26+8.65 \log \lambda$, $Y_{\mathrm{IV}} = 3.45+0.12 \lambda$, and $Y_{\mathrm{V}} = 4.78+0.024 \lambda$. It will be noted that whereas I gives the more usual linear log-dosage response (20), a linear regression line is given by compounds IV and V according to the Parker–Rhodes equation (21). In most toxicity tests, the logarithm of λ is normally distributed, but occasionally λ itself has been found to be normally distributed. No explanation has as yet been advanced for this variation. The widely different values of b for the three compounds are thus indicative of differing chemical structure. This biological evidence complements the physicochemical evidence, presented above, that the structure of ethylenethiuram monosulphide is *not* given by VII, an analogue of the iminodithiazolidinethione (IV), but is in all likelihood structure (IB) as originally suggested (1, 2). It has been shown earlier (23) that ethylenethiuram monosulphide and 2,5-dimercapto-1;3,4-thiadiazole displayed regression lines of the same slope, differing in position, suggesting a similarity in structure.

Still unexplained is the formation of mono-addition compounds of ethylenethiuram monosulphide with HCl, $HClO_4$, and CS_2. The precipitation of these 1:1 compounds from solution as they are formed, together with electromeric influence through the

conjugated system to the second enethiol grouping, may be sufficient explanation for this apparent anomaly in structure.

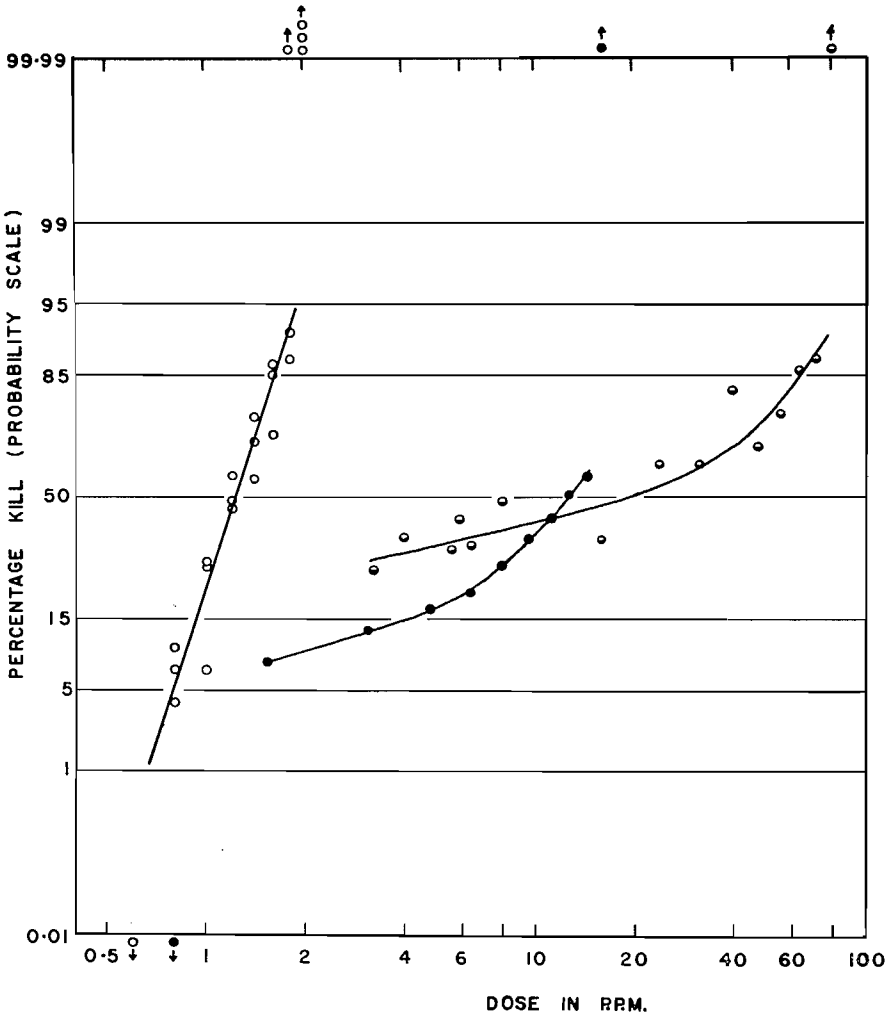

FIG. 5. An in vitro comparison of the fungicidal activities of ethylenethiuram monosulphide (○), 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (●), and 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (◒).

EXPERIMENTAL

Ultraviolet absorption spectra were obtained in ethanol solution, using the Beckman DK-1 spectrophotometer. Infrared spectra were obtained with the Perkin–Elmer model 21, with NaCl optics, in chloroform solution or in Nujol[R] mull. Potentiometric titrations were performed with the aid of the Radiometer Titrator, type TTT1 with standard plug-type calomel and glass electrodes. The sample, 0.100 g, dissolved in 50 ml acetonitrile or pyridine, was stirred magnetically under a blanket of nitrogen, and the e.m.f. measured with increments of titrant. The titrant, approximately 0.2 *N* tetrabutyl-

ammonium hydroxide in methanol, was prepared according to the method of Harlow *et al.* (16) and standardized potentiometrically against benzoic acid.

Ethylenethiuram monosulphide (I) was isolated from the mixture resulting from air oxidation of disodium ethylenebisdithiocarbamate (24) by extraction with chloroform, addition of concentrated HCl to precipitate the ethylenethiuram monosulphide hydrochloride (2), filtration and suspension of the hydrochloride in chloroform, and addition of sodium hydroxide solution to convert the insoluble salt to ethylenethiuram monosulphide. The yellow chloroform solution was filtered, dried with anhydrous sodium sulphate, and evaporated to dryness to yield the thiuram monosulphide free of elemental sulphur, m.p. 120–123°. Crystallization from chloroform–ethanol gave material of melting point 125–126°.

2,5-Dimercapto- and *2,5-di(methylmercapto)-1,3,4-thiadiazole* (II) were prepared according to Thorn and Ludwig (21) and Thorn (6), respectively.

4-Methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (IV) was obtained according to the method of Freund and Asbrand (10) by the action of bromine on ammonium methyldithiocarbamate. Crystallization from ethanol gave pale yellow material of melting point 84° (lit. (10), m.p. 86°). Calc. for $C_4H_6N_2S_3$: S, 53.9; N, 15.7%. Found: S, 53.7; N, 15.6%. *2,4-Dimethyl-1,2,4-thiadiazolidine-3,5-dithione* (V), obtained by rearrangement of IV with alcoholic ammonia (10), melted at 122–123° (lit. (12) gives 123–124°). Calc. for $C_4H_6N_2S_3$: S, 53.9; N, 15.7%. Found: S, 54.0; N, 15.5%.

Dimethylthiuram monosulphide was prepared by the reaction of equimolar amounts of methyl isothiocyanate and aqueous sodium methyldithiocarbamate (8). Addition of glacial acetic acid yielded colorless crystals of melting point 77–78° (lit. (8), m.p. 78–80°). Calc. for $C_4H_8N_2S_3$: S, 53.3; N, 15.5%. Found: S, 52.9; N, 15.6%.

The *ethylenethiuram monosulphide – carbon disulphide addition complex* was obtained by dissolving ethylenethiuram monosulphide in carbon disulphide. The brick-red complex, which precipitates within a few minutes, loses CS_2 upon heating above 100°, and melts at 125–126°. Calc. for $C_5H_6N_2S_5$: S, 63.0%. Found: S, 62.9%.

EXOTHERMIC REACTIONS DUE TO ANNEALING OF DEFECTS IN OXIDE LATTICES: STUDY OF THE DECOMPOSITION OF CARBONATES[1]

C. N. R. Rao,[2] S. R. Yoganarasimhan, and M. P. Lewis[3]

ABSTRACT

Small exothermic reaction peaks are observed in the differential thermal curves of carbonates. The heat evolution is probably due to the removal of internal crystal defects in the metastable oxide lattices.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Recently, Rao and Pitzer (1) have reported that when magnesium and calcium hydroxides are heated just beyond their decomposition temperatures, there is some evolution of heat of the order of 300 to 400 calories per mole. This exothermic reaction was explained as due to the removal of internal crystal defects in the metastable oxide lattices formed just after the decomposition of the hydroxides. The possibility that the reduction in surface area of the oxides also contributed to the heat evolution was not excluded. We have now studied the decomposition of a few carbonates to see if similar exothermic reactions are observed in the oxides obtained by their decomposition. Differential thermal analysis and X-ray diffraction analysis have been employed for the study.

EXPERIMENTAL

The differential thermal analysis was carried out using a high-sensitivity apparatus described by Pask and Warner (2). A constant heating rate of 12 degrees per minute was employed in all the runs. The reaction temperatures reported here are constant only for a given set of experimental conditions.

The carbonates studied are $MgCO_3$, $CaCO_3$, $CdCO_3$, $ZnCO_3$, and Ag_2CO_3. All the carbonates were obtained commercially. The X-ray diffraction patterns were taken using a Rich Seifert X-ray unit or a North American Philips diffractometer fitted with a Geiger counter recording device.

RESULTS AND DISCUSSION

Typical differential thermal analysis curves are shown in Fig. 1. All the carbonates first showed large endothermic reaction peaks due to their decomposition to the corresponding oxides and carbon dioxide; immediately following these were observed small exothermic reaction peaks. The exothermic reactions were irreversible and occurred at temperatures usually 40–80° higher than the decomposition temperatures of the carbonates (Table I). It was made certain by X-ray analysis that the carbonates had completely decomposed to the oxides before the exothermic reaction. There was no change in crystal structure or parameters of the oxides after the exothermic reaction. Thus, the heat evolution could not have resulted from a crystal structure transformation. However, marked decrease in X-ray line widths were noticed in samples heated just past the exothermic reaction temperature indicating greater crystallinity in the samples. The

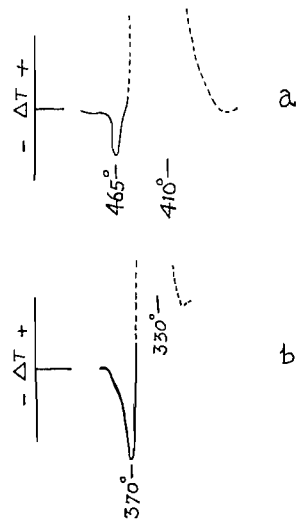

FIG. 1. Differential thermal analysis curves. (*a*) $MgCO_3$, (*b*) $ZnCO_3$. The dotted peaks correspond to the decomposition of the carbonates.

results reported in this communication on carbonates are similar to those observed in the decomposition of magnesium and calcium hydroxides (1).

The heats of the exothermic reactions were estimated by comparing the peak areas with the peak area for the α–β inversion of quartz (4.3 calories per gram). The heats thus estimated and the reaction temperatures for the different oxides are given in Table I. The values of ΔH are good to within $\pm 25\%$.

TABLE I

Carbonate	Endothermic reaction (decomposition) peak temperature, °C	Exothermic reaction peak temperature, °C	Estimated ΔH of the exothermic reaction, cal/mole of oxide
$MgCO_3$	410	465	360
$CaCO_3$	1015	1090	230
$ZnCO_3$	330	370	1000
$CdCO_3$	510	570	640
Ag_2CO_3	180	210	200

It is interesting to note that the heat evolution is very sharp and occurs over a short range of temperature in all the cases. It is known that the surface areas of oxides decrease with increase in temperature (3); but there is no reason why reduction in surface should result in a sharp evolution of heat over a short temperature range. When differential thermal analysis of oxides was extended to high temperatures where considerable reduction in surface area occurred, sharp exothermic reaction peaks were not noticed. The more important contribution to the heat evolution may be from the removal of internal crystal defects in the metastable oxide lattices. It is understandable that when a compound, say a hydroxide or carbonate, decomposes, it first gives a metastable or active oxide associated with a high degree of lattice disorder. This metastable oxide, when heated to a slightly higher temperature, goes into an ordered lattice. The decrease in the X-ray line widths apparently results from the annealing of these defects in the metastable oxide lattices. Such an interpretation of the decrease in X-ray line widths

is by no means new. It is therefore suggested that the observed evolution of heat mainly results from the disorder → order reaction (metastable oxide* → crystalline oxide) in the oxide lattice.

Exothermic reactions associated with large heats have been observed in the differential thermal analysis of hydrates of chromic and ferric hydroxides (4, 5) and titanium peroxide gel (6). The exothermic reactions are found just after the endothermic peaks due to the decomposition of the hydrate or the peroxide. It has been shown that the exothermic reactions in these cases result from the crystallization of the oxides from the amorphous state. The small exothermic reactions reported in this communication and elsewhere (1) may be similar to these crystallization reactions differing only in the magnitude of heat evolution. One may thus visualize the so-called disorder → order reaction in metastable oxide lattices as a crystallization process.

The formation of a metastable or active calcium oxide (CaO*) during decomposition of calcium carbonate has been proposed by Hyatt *et al.* (7) on the basis of their kinetic studies. These active CaO* groups are supposed to act as bridges between layers of well-crystallized cubic CaO and the decomposing $CaCO_3$. Razouk and Mikhail (8) have observed that the rate of crystallization of magnesium oxide obtained from the decomposition of magnesium hydroxide or carbonate at 500° is rather slow. This is probably reasonable. If the initial formation of a metastable MgO* similar to the CaO* proposed by Hyatt *et al.* (7) is postulated, the results of Razouk and Mikhail can be explained. Razouk and Mikhail have reported that some of the lines of the parent compound persist in the X-ray pattern of the oxides obtained by decomposition at 500° C. However, when the oxide was hydrated and then dehydrated at the same temperature only the pattern of the oxide was obtained. This indicates that Razouk and Mikhail have affected the crystallization of magnesium oxide by prolonged heating at 500° C, which would naturally render the process of rehydration difficult. If they had carried out their experiments at a slightly higher temperature, i.e. a temperature high enough for the exothermic disorder → order reaction of the metastable oxide, they would have probably obtained highly crystalline magnesium oxide in the first instance itself.

The crystalline and finely divided samples of magnesium oxide (9) and calcium oxide (10) have been reported to show large differences in their heat contents (~900 and 500 calories per mole respectively). The heat capacity of finely divided magnesium oxide is also found to be higher than that of crystalline magnesium oxide (9). The crystalline oxides were inevitably prepared by the decomposition of the hydroxides at high temperatures whereas the finely divided samples were prepared by decomposition at relatively low temperatures. On the basis of the investigations on the decomposition of carbonates and hydroxides (1), it is suggested that at least the major part of these heat content differences may be explained on the basis of the disorder → order reaction in oxides. A small irreversible exothermic reaction peak (ca. $\Delta H \sim -100$ calories per mole) has been noticed around 200° in the differential thermal analysis curve of silver oxide prepared by the dehydration of the freshly precipitated oxide (11). It is interesting to note that the oxide obtained by the decomposition of silver carbonate* also exhibits an irreversible exothermic reaction of the same magnitude (Table I). An irreversible heat evolution of about 300 calories per mole has been observed by Kobayashi (12) in the range 100–200° C during his measurements of the heat capacity of silver oxide. Kobayashi suggested

**The differential thermal analysis of curve Ag_2CO_3 first shows an endothermic peak due to decomposition of the carbonate to the oxide (Ag_2O^*) and CO_2 and then a small exothermic reaction peak around 210° C ($Ag_2O^* \rightarrow Ag_2O$, cryst.) followed by another endothermic peak due to the dissociation of Ag_2O.*

that the heat "originates in the melting of the *freezing in* of the crystal imperfections". Such "stabilization" of the silver oxide lattice at higher temperatures has successfully explained the discrepancies in the thermodynamics of the dissociation of silver carbonate (13). It therefore appears likely that the evolution of heat in the differential thermal analysis curves of silver oxide arises from the annealing of crystal defects.

REDUCTION OF MONOHALOGENATED NITROBENZENES WITH HYDRAZINE AND RANEY NICKEL

A CONVENIENT PREPARATION OF HALOGENATED ANILINES[1]

B. E. Leggetter and R. K. Brown

ABSTRACT

The isomeric fluoro-, chloro-, bromo-, and iodo-nitrobenzenes can be converted to the corresponding halogenated anilines in good yield by refluxing methanolic hydrazine hydrate in the presence of Raney nickel.

INTRODUCTION

The reduction of alcoholic solutions of substituted nitrobenzenes with hydrazine hydrate in the presence of Raney nickel provides a facile and convenient method for the preparation of aromatic amines. This method has in recent years been applied successfully not only to the reduction of nitro compounds directly to amines without affecting most functional groups (1, 2) or destroying heat sensitive amines (3) but also to the conversion of nitro compounds to intermediate azoxy and hydrazo derivatives (4, 5, 6) and of nitriles to the hydrazones of the corresponding aldehydes (7). Palladized charcoal (8–12), ruthenium on charcoal (11, 12), and platinum (8) have been used in place of Raney nickel quite successfully in hydrazine reductions. Copper and iron powder have also been employed though with inferior results (13).

The present work was undertaken in order to provide a convenient method for the preparation of halogenated anilines, particularly the iodo derivatives, via reduction of the corresponding nitro compounds.

Whilst previous methods of preparation of halogenated anilines by reduction of the nitro precursors with reagents such as stannous chloride and hydrochloric acid (14, 15), tin and hydrochloric acid (16), iron and hydrochloric acid (15, 17, 18), or hydrogen and a nickel catalyst (19, 20, 21) and rhodium on alumina (22) have given fair to good yields in the case of fluoro-, chloro-, and bromonitro-benzenes, the same methods applied to the iodonitrobenzenes caused considerable displacement of the iodine atom and generally gave very low yields of the halogenated amines. Baeyer (14), however, has reported good yields of *o*-iodoaniline from the low-temperature reduction of *o*-iodonitrobenzene with stannous chloride and hydrochloric acid. The same reagents were used to prepare the para and meta isomers from their nitro precursors but no yields were given although it was stated that because increased temperatures were necessary to effect reduction of the *p*-iodonitrobenzene the yield of the *p*-iodoaniline was low (14). We have found that when *m*-bromonitrobenzene was reduced with Raney nickel and hydrogen at low pressure and at room temperature much aniline was produced (23).

RESULTS AND DISCUSSION

A summary of the results of this work is presented in the accompanying table. The melting points and boiling points are recorded for convenience along with reported constants.

[1]*Manuscript received August 4, 1960.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta. Taken from the thesis to be submitted by B. E. Leggetter to the Graduate School of the University of Alberta in partial fulfillment of the requirements for the Degree of Doctor of Philosophy.

The reduction of methanolic solutions of iodonitrobenzenes to iodoanilines with freshly prepared Raney nickel and hydrazine hydrate proceeds smoothly in reasonably good yields (64 to 87%) with little or no displacement of the iodine atom. The results are even better when the fluoro (80 to 90%), chloro (95%), and bromo (80 to 90%) analogues are involved. A study of the reaction conditions showed that the reduction is best accom-

plished at elevated temperatures. Complete reduction of the nitro group to the amine occurs at the temperature of boiling methanol whereas reduction in methanolic solution at 25° was found to give in some cases only partially reduced products such as the azoxy or hydrazobenzene even though excess reducing agent is present. Furthermore, unless a large ratio of solvent to nitro compound is used, some products tend to precipitate as the less soluble intermediate compound. Furst and Moore (6) have also reported the formation of intermediate reduction products, the azoxybenzene and hydrazobenzene (but no azobenzene) particularly when a lower proportion of hydrazine to nitro compound is used, or when small volumes of solvent are employed. In addition, the quality of the Raney nickel catalyst has been shown by these authors to influence the extent of reduction (4).

In our work gradual addition of the hydrazine hydrate to a refluxing methanolic solution of the nitro compound to which Raney nickel had been added approximated the conditions of limited amount of reducing agent reported by Furst and Moore (6) and, especially when smaller amounts of solvent were employed, tended to produce intermediate reduction products as contaminants. Generally, best results were obtained when an excess of solvent was involved (solvent:solute $\approx$ 10:1 by weight) and the reducing agent (hydrazine:nitro compound $\approx$ 2:1) was always kept in excess by slow addition of the nitro compound to the refluxing alcoholic solution of hydrazine hydrate containing a small amount of Raney nickel. This modified procedure (method A in the experimental section) was found to be superior for the fluoro, chloro, and bromo analogues but gave somewhat lower yields than did the original method (method B in the experimental section) in the case of the iodo compounds. Attempts to reduce *m*-iodonitrobenzene to *m*-iodoaniline at 25° gave 3,3′-diiodoazobenzene rather than the expected *m*-iodoaniline.

EXPERIMENTAL

The methods of reduction employed for these experiments are shown in the following two examples. Commercially available reagent grade samples of the halogenated nitrobenzenes were used while the Raney nickel catalyst was prepared by published directions (24).

o-Bromoaniline by Method A

A methanolic solution of *o*-bromonitrobenzene (20.2 g, 0.1 mole) was added dropwise to a refluxing solution of hydrazine hydrate (64% hydrazine in water) (15.0 g, 0.3 mole) in methanol (70 ml) to which about 1 gram of Raney nickel had been added. The rate of addition of the *o*-bromonitrobenzene solution was such that the evolution of gases from the reaction mixture did not become too vigorous; generally about 10–15 minutes were required for this step. At the end of the addition, the solution was refluxed for 10 minutes by which time the characteristic yellow color of the nitro compound had disappeared. The Raney nickel was then separated by filtration. Evaporation of the solvent and purification of the product by steam distillation gave 15.5 g of material boiling at 88°/8 mm.

The following anilines were also prepared by this method, the percentage yields obtained being reported in the table: *o*-, *m*-, and *p*-fluoroaniline, *o*-, *m*-, and *p*-chloroaniline, and *o*-, *m*-, and *p*-bromoaniline.

m-Iodoaniline by Method B

A solution of *m*-iodonitrobenzene (13.0 g, 0.052 mole) in methanol (150 ml), containing 1 g of Raney nickel catalyst, was refluxed while hydrazine hydrate was added dropwise at such a rate that the evolution of gas did not become too vigorous. The addition of the hydrazine was discontinued when the reaction solution became colorless indicating complete reduction. Steam distillation of the residual oil obtained after removal of the solvent gave the required product, which was further purified by distillation under reduced pressure, b.p. 128°/5 mm, m.p. 22–24°; yield, 8.3 g (73%).

o-Iodo- and *p*-iodo-aniline were prepared by the above methods. Yields and physical constants are reported in the table.

A SYSTEM OF MOLECULAR THERMOCHEMISTRY FOR ORGANIC GASES AND LIQUIDS

PART II. EXTENSION TO COMPOUNDS CONTAINING SULPHUR AND OXYGEN[1]

EDWARD G. LOVERING AND KEITH J. LAIDLER

ABSTRACT

The system of bond and group energies described in Part I has been extended and applied to certain compounds containing sulphur and oxygen. The substances treated are the alkanethiols, the thiaalkanes, and the dithiaalkanes. The bond additivity scheme enables reliable values for heats of formation, combustion, atomization, and vaporization to be calculated for these compounds.

A similar treatment has been applied to the data for alcohols, ethers, and alkyl peroxides.

INTRODUCTION

In Part I of this series (1) a scheme of bond and group energies, suitable for the reliable calculation of heats of formation, combustion, and atomization of organic compounds, was developed. The method was applied in some detail to the paraffins, olefins, and acetylenes. For other compounds adequate data for homologous series were not available, and only approximate group contributions could be obtained. A method whereby the scheme could be extended to substituted homologous series, when sufficient reliable data became available, was also given. During the past few years excellent data have become available for alkanethiols (R—S—H), thiaalkanes (R—S—R), and dithiaalkanes (R—S—S—R), and in the present paper the scheme is applied to these. A few recent data are also available for certain alcohols, ethers, and peroxides, and the scheme has been extended to cover these compounds also.

The previous paper also provided a scheme for the calculation of heats of vaporization, and it is applied in the present work to the sulphur compounds mentioned above.

HEATS OF FORMATION, COMBUSTION, AND ATOMIZATION

The heat of atomization is the energy required to dissociate 1 mole of a compound, in the gaseous state, into its constituent atoms in their ground states. The heats of atomization given in this paper are calculated with the aid of the following relationships, which apply at 25.0° C:

$$\begin{aligned} \text{C (graphite)} &= \text{C(g, }^3\text{P)} \quad -171.7 \text{ kcal},\\ \tfrac{1}{2}\text{H}_2\text{ (g)} &= \text{H(g)} \quad -52.09 \text{ kcal},\\ \tfrac{1}{2}\text{O}_2\text{ (g)} &= \text{O(g)} \quad -59.16 \text{ kcal},\\ \text{S (rhombic)} &= \text{S(g, }^3\text{P)} \quad -57 \text{ kcal}. \end{aligned}$$

The choice of the first three values was discussed in Part I. The value for the heat of sublimation of rhombic sulphur has not been firmly established. Cottrell (2) has recently reviewed the chemical and spectroscopic evidence, on the basis of which he favors the value of 57 kcal. We have chosen to use this value in the present paper.

Based upon the above relations, the heat of atomization, Q_a, of compounds containing carbon, hydrogen, sulphur, and oxygen is obtained through the equation

$$[1] \qquad Q_a = Q_f + 171.7\, n_C + 52.09\, n_H + 57\, n_S + 59.16\, n_O.$$

[1]*Manuscript received August 8, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

Here Q_f ($= -\Delta H_f$) is the heat (evolved) of formation of the gaseous compound at 25° C and n_C, n_H, n_S, and n_O are the numbers of carbon, hydrogen, sulphur, and oxygen atoms, respectively.

The relationship between Q_a and the heat of combustion, Q_c, depends upon the combustion products. If these are carbon dioxide, water, and rhombic sulphur, then

$$[2] \qquad Q_a = -Q_c + 265.75\ n_C + 86.25\ n_H + 57\ n_S + 59.16\ n_O.$$

This equation is based upon heat of formation values for carbon dioxide and liquid water of 94.05 and 68.32 kilocalories per mole, respectively (3).

In view of the relationships between heats of combustion, formation, and atomization it is necessary to obtain a scheme for only one of them. In the following section this is done for heats of atomization.

EMPIRICAL SCHEMES FOR SULPHUR-CONTAINING COMPOUNDS

Heats of Atomization

The strength of all C—C bonds, denoted by c_1, and of the primary (p), secondary (s), and tertiary (t) C—H bonds is assumed to be the same as given in Part I, except in the case of C—H bonds when there is a sulphur atom bound to the carbon. These bonds, the bond symbol, and the bond strength are given in Table I.

TABLE I

Paraffin bond strengths

Bond	Symbol	Bond energy, kcal
C—C	c_1	85.40
C—H (primary)	p	98.47
C—H (secondary)	s	97.65
C—H (tertiary)	t	96.80

It is assumed that the presence of a C—S bond will affect the bond strength of hydrogen atoms bound to that carbon atom. These C—H bonds can be primary, secondary, or tertiary, and their strengths are denoted by p_s, s_s, or t_s respectively. It is further assumed that the S—C bond does not affect any other C—H bonds. Three types of bond directly involving sulphur atoms are considered. These are the S—H bond, of energy sh, the S—C bond, of energy sc, and the S—S bond, of energy ss. It is assumed that these bonds have the same energy in each of the three classes of sulphur compounds considered (alkanethiols, thiaalkanes, and dithiaalkanes).

Six quantities, sh, sc, ss, p_s, s_s, and t_s, must be determined from the experimental data. This has been done by a standard least-squares procedure, carried out on the IBM 650 computer through the courtesy of the staff of the Computing Center of the University of Ottawa. In this way the values given in Table II were obtained.

TABLE II

The bond strengths for sulphur compounds

$sh = 81.90$	$p_s = 98.14$
$sc = 66.36$	$s_s = 97.63$
$ss = 54.46$	$t_s = 97.14$

For personal use only.

Heats of atomization calculated from these values, together with those in Table I, are compared with the experimental heats of atomization for various compounds in Table III. The heats of formation of the gaseous compounds at 25° C are also given in Table III.

TABLE III

Sulphur compounds: heats of atomization

Compound	Bonds	Q_f(obs.), kcal/mole	Q_a(obs.), kcal/mole	Q_a(calc.), kcal/mole	Q(obs.) − Q(calc.)	Ref.
Ethanethiol C_2H_6S	$sh+sc+2s_s+3p+c_1$	11.03	724.0	724.3	−0.3	4

5-Thianonane $C_8H_{18}S$	$2sc+4s_s+6p+8s+6c_1$	40.3*	2408.5	2407.7	0.8	11

*T = 20° C; this compound was not included in the least-squares calculation.

The S—H, S—C, and S—S bond energies have also been given by Sunner (11). Since these are based upon heats of sublimation of graphite and rhombic sulphur of 138 and 66.3 kilocalories per mole, respectively, they are not directly comparable to the bond energies derived in this paper.

Heats of Vaporization

In Part I a scheme was developed which related the heat of vaporization (ΔH_v) to bond contributions. This scheme may now be extended to the sulphur compounds. The bond terms are the same as those used for the heats of atomization; they were evaluated by the least-squares procedure in the computer, and are given in Table IV. As in the

TABLE IV

Bond contributions to the heat of vaporization of sulphur compounds

sh = 2.209	p_s = 0.877
sc = 0.735	s_s = 1.002
ss = 2.349	t_s = 1.117

previous treatment, all C—C bonds are assumed to make a contribution of zero. The C—H contributions when there is no sulphur atom bound to the carbon are, as given in Part I,

$$p = 0.494 \text{ kcal/mole},$$
$$s = 0.579 \text{ kcal/mole},$$
$$t = 0.518 \text{ kcal/mole}.$$

Table V gives the experimental and calculated heats of vaporization, and the difference between them for each compound. The source of the heat of vaporization data is given in Table III.

HEAT OF ATOMIZATION CONTRIBUTIONS FOR COMPOUNDS CONTAINING OXYGEN

The data available for the oxygen analogues of the above sulphur compounds are not as plentiful, and in most cases they are not as reliable. The manner of treatment is the same as for the sulphur compounds: thus C—H bonds are assumed to be affected by the presence of oxygen only when the oxygen is attached to the same carbon atom, and all other interactions are neglected. The C—H bonds evaluated, with an oxygen bound to the carbon, and the symbols used to denote their energies are: the C—H primary, p_o; the C—H secondary, s_o; and the C—H tertiary, t_o. The bonds involving oxygen directly are the O—H bond, *oh*; the O—C bond, *oc*; and the O—O bond, *oo*. The bond energy terms were evaluated by putting the least-squares method in the computer. The bond energies are given in Table VI. The bonds involved, the heats of formation, and the experimental and calculated heats of atomization are given in Table VII.

TABLE VI
The bond strengths for oxygen compounds

oh = 109.79	p_o = 96.24

carbon dioxide, and rhombic sulphur. In practice the combustion products are carbon dioxide, and an aqueous sulphuric acid solution.

DISCUSSION

The differences between the experimental and calculated heats of formation indicate that the scheme is more successful with the sulphur compounds than with the oxygen compounds. This is probably because the experimental data are more accurate in the case of the former than the latter. The authors feel that the relatively poor agreement between the experimental and calculated heats of atomization of the oxygen compounds points out the need for more accurate heat of formation data on the various homologous series.

ABOUT THE PRIMARY ACT OF PHOTOCHEMICAL DECOMPOSITION REACTIONS OF MONOSUBSTITUTED COBALTIHEXAMINE IONS[1]

Z. SIMON

ABSTRACT

We will discuss the primary act of photochemical decomposition of $Co(NH_3)_5X^{n+}$ ions in aqueous solution. The potential energy surfaces are plotted correlating the complex ion's energy levels with those of the decomposition products. For this purpose spectral and kinetic data are used, as well as Wigner–Witmer correlation rules. The potential energy surfaces and certain rules regarding the radiationless transitions between them permit us to draw certain qualitative conclusions concerning these decompositions. Our conclusions seem to be confirmed by available experimental data.

INTRODUCTION

In order to describe the primary act of photochemical reactions, the potential energy surfaces of the molecules in their ground states and in electronically excited states, as well as the transition rates between the surfaces, should be known. Shuler (1) and Higuki (2) have discussed the photochemical decompositions of certain relatively simple molecules. They obtained the necessary surfaces by correlating the energy levels of the molecule and of the decomposition products, using the Wigner–Witmer correlation rules (3, 4). Linhard and Weigel (4*a*) have discussed the photochemical decomposition of the $Co(NH_3)_5X^{n+}$ ions based on ideas similar to those expressed in this article, without, however, taking into consideration the symmetry properties of the ions and the radiationless transitions.

In our paper we apply these correlation rules to more complicated molecules, namely to $Co(NH_3)_5X^{++}$ ions. We attach greater importance to the radiationless transitions than other authors and we use symmetry properties of the wave functions and the nuclear vibration co-ordinates. We proceed in the following manner: the decomposition of the molecule excited by light takes place following one of these processes:

1. The potential-energy surface for the excited state is unstable with respect to a vibrational co-ordinate along which the molecule is dissociated.

2. The electronic excitation energy is converted into vibrational energy of the ground state.

(*a*) If the vibration of a single valence bond is strongly enough excited, the molecule will immediately dissociate (predissociation).

(*b*) If a vibration which does not lead to direct dissociation is excited, the molecule will become vibrationally "overheated" and will either dissociate thermally or cool down without dissociation.

Should process 1 or 2 (*a*) take place, the quantum yield of the decomposition is about 1. Should process 2(*b*) take place, the quantum yield is small (ϕ smaller than about 0.01) for complex molecules as shown by Zimmermann (5) for the MnO_4^- ion. The correlation rules show whether process 1 or 2 takes place and indicate the decomposition products. If process 2 takes place, considerations regarding the radiationless transitions show whether it is a direct decomposition ($\phi \cong 1$) or a decomposition by the mechanism of the "hot" (i.e. containing excess vibrational energy) molecule ($\phi \lesssim 0.01$).

Experimentally, it has been established that $Co(NH_3)_5X^{++}$ ions irradiated in aqueous solution undergo aquation and oxidation–reduction decomposition. Photochemical and thermal aquation reactions follow, according to Adamson and Sporer (6), Basolo and Pearson (7), an S_N1 mechanism with the primary act,

$$Co(NH_3)_5X^{++}(aq.) \rightarrow Co(NH_3)_5^{+++}(aq.) + X^-(aq.). \quad [1]$$

The primary act of the oxidation–reduction decomposition is also a unimolecular decomposition (6),

$$Co(NH_3)_5X^{++}(aq.) \rightarrow Co(NH_3)_5^{++}(aq.) + X(aq.). \quad [2]$$

The quantum yields ϕ for irradiation with $\lambda = 370$ mμ and $\lambda = 550$ mμ, according to Adamson (6*a*), are given in Table I.

TABLE I

Experimental photochemical data (aqueous solutions 0.01*M*; 25° C) (6*a*)

Ion	ϕ and the nature of the reaction						Thermal aquation rate, k, min^{-1}

CORRELATION DIAGRAMS AND DECOMPOSITION PRODUCTS

The energy levels of $Co(NH_3)_5X^{++}$ ions were determined by using the spectral data of Nakamoto *et al.* (8) (and from tables (13)). The small differences of energy between the levels corresponding to the same spectral band are those calculated by Nakamoto *et al.* according to the simple molecular orbital method.

The energies for the ground states of the aquation reaction products (the right-hand equation [1] have been assumed equal to the activation energies for the thermal aquation reactions, that is about 1.1 ev (25 kcal/mole) for $X^{-1} = Cl^-$, Br^-, SCN^-, J^- and 1.5 ev (34 kcal/mole) for the aquation of the $Co(NH_3)_6^{+++}$ ion (7).

In order to calculate the energies of the ground states of oxidation–reduction decomposition products (the right-hand equation [2]), as sufficient data are not available to us, we will proceed as follows, based upon the observation of oxidation–reduction reaction traces at 370 mμ. We assume the energy of the ground state of $Co(NH_3)_5^{++}$ (aq.) + Cl (aq.) products should be 3.5 ev (a little more than the energy corresponding to 370 mμ), the corresponding energy of the $Co(NH_3)_5^{++}$ (aq.) + X (aq.) products being 3.5 ev plus the difference of energy ΔE_x between the process Cl^- (aq.) $\rightarrow$ Cl (aq.) + e and the processes:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$Br^- \text{ (aq.)} \rightarrow Br \text{ (aq.)} + e \qquad \Delta E_{Br} = -0.5 \text{ ev}$$

$$J^- \text{ (aq.)} \rightarrow J \text{ (aq.)} + e \qquad \Delta E_{J} = -1.0 \text{ ev}$$

$$NH_3 \text{ (aq.)} \rightarrow NH_3^+\text{(aq.)} + e \qquad \Delta E_{NH_3} = +1.5 \text{ ev}$$

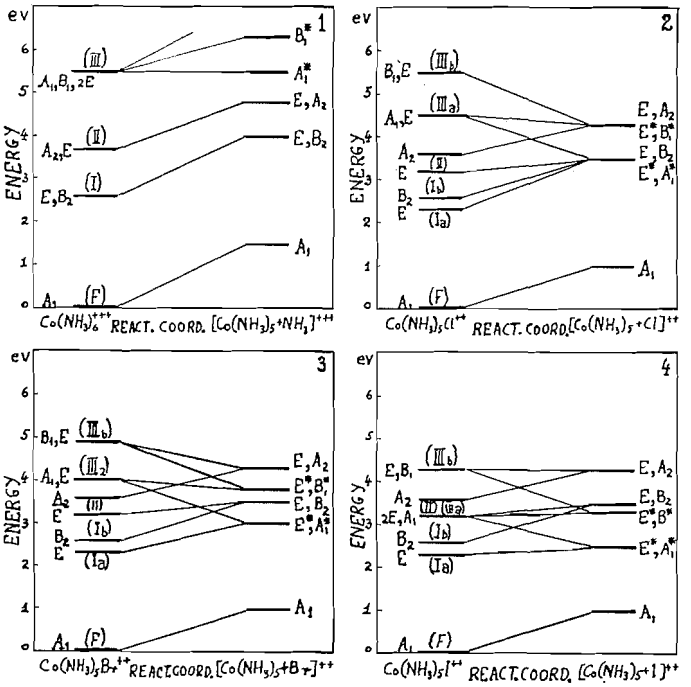
The values for ΔE_x were taken from (8) and thermochemical data (9).

A not very reliable, approximate, estimate of the difference between the energies of the products $Co(NH_3)_5^{++} + Cl$ and $Co(NH_3)_5^{+++} + Cl^-$ can be obtained identifying this difference with the enthalpy $\Delta H = \Delta H_2 - \Delta H_1 + \Delta H_3$ of the reactions:

$$Co(NH_3)_6^{++} \text{ (aq.)} \rightleftarrows Co(NH_3)_6^{+++} \text{ (aq.)} + e \qquad \Delta H_1$$

$$Cl^- \text{ (aq.)} \rightleftarrows \tfrac{1}{2}Cl_2\text{(g.)} + e \qquad \Delta H_2$$

$$\tfrac{1}{2}Cl_2\text{(g.)} \rightleftarrows Cl \text{ (aq.)} \qquad \Delta H_3$$



$\Delta H_2 - \Delta H_1 = 1.36 - 0.16 = 1.2$ ev (9) respectively Lamb and Larson (14), $\Delta H_3 \cong 1.2$ ev (9).

Thus $\Delta H \cong 2.4$ ev and the energy of the $Co(NH_3)_5^{++} + Cl$ products would be approximately $2.4 + 1.1 = 3.5$ ev. The value is perhaps an upper limit, as $Co(NH_3)_6^{+++}$ is more stable than $Co(NH_3)_6^{++}$ towards the dissociation of a NH_3 group.

We supposed that the energies of the first excited states of the $Co(NH_3)_5^{+++}$ are approximately equal to the excitation energies corresponding to the crystalline field bands in the $Co(NH_3)_5X^{n+}$ ions. This hypothesis appears plausible from the point of view of the crystalline field theory and from the fact that the position of the ligand field bands is approximately the same in the $Co(NH_3)_6^{+++}$, $Co(NH_3)_5Cl^{++}$, etc. ions (about 2.5 ev and 3.3 ev (8)). It also agrees with the result of the calculation based on the simple molecular orbital method (used for the excited energy levels of the aquation and oxidation-reduction decomposition products). The excited states of the halogen ions and of the NH_3 groups have not been taken into consideration because they have a very high energy. The position of the excited levels of the oxidation–reduction decomposition is less important (at least for not too short wave lengths) for the interpretation of the correlation diagrams because the energy of the ground state is high enough.

In Figs. 1, 2, 3, and 4 the energy levels of some complex ions have been listed on the left and the levels of the decomposition products on the right. The capital letters beside the energy levels represent electronic states having energy equal or approximately equal to that indicated by the level. The identification of the electronic states of complex ions with the energy levels observed spectroscopically was performed by taking into account the order of the molecular orbital energy levels calculated by Nakamoto *et al.* (8) and the degree of their occupation. The states of the oxidation–reduction decomposition products are starred. The capital letters show the species of the C_{4v} point group to which the respective electronic states belong. The states of the $Co(NH_3)_6^{+++}$ ion are recorded considering the resolution of the species belonging to the O_h point group to those of the C_{4v} point group. According to Nakamoto (8), the states marked in E(I), E(II), B_2, and A_2 which derive from the electronic configuration $(1e_g)^4(1a_{1g})^2(1f_{1u})^6(2f_{2g})^5(2e_g)$ belong to the two energy levels which correspond to the first two absorption bands of the $Co(NH_3)_6^{+++}$ ion. The attribution of these two states to the two energy levels is arbitrary. This does not affect the interpretation of the correlation diagrams, if the states of the dissociation products with which these states can be correlated are higher than the two first levels of the $Co(NH_3)_6^{+++}$ ion. This is the case if the first excited

FIGS. 1–4. Correlation diagrams for the $Co(NH_3)_6^{+++}$, $Co(NH_3)_5Cl^{++}$, $Co(NH_3)_5Br^{++}$, and $Co(NH_3)_5J^{++}$ ions.

state of the $Co(NH_3)_5^{+++}$ ion has approximately the same energy as in the $Co(NH_3)_6^{+++}$ ion; the reasons for this situation were discussed above.

In every case the energy of the complex ion's ground state was taken as origin in the scale of energies.

The energy levels of the complex ions are correlated with those of the aquation reaction products and of the oxidation–reduction decomposition products using the Wigner–Witmer correlation rules (3, 4). In the course of the decomposition (the elimination of X or X^-), the symmetry of the system remains C_{4v}. Although we are concerned with polyatomic molecules, we shall assume that only one vibrational co-ordinate varies. Thus, only the surfaces of different species of the molecular point group can intersect each other. In the case of the decomposition of the $Co(NH_3)_5X^{++}$ ions, no new valence bonds are formed, so that we assume that the electronic energy of different states changes continuously with respect to the reaction co-ordinate.*

Levels III from ultraviolet ($\lambda \gtrsim 300$ mμ) correlate with lower levels of the ionic and oxidation–reduction decomposition products. That is why in ultraviolet the quantum yield for the redox and aquation reactions should approach 1 (or be even greater if

If the energy levels were known more exactly, it would be useful to correlate first the "crystalline field (the Co^{+3}) states" of the reactants with those of the ionic decomposition products and the "charge transfer (the Co^{+2}) states" with those of the redox decomposition products. Afterwards, taking into account the configuration interaction which appears between some Co^{+3} and Co^{+2} states, a correlation diagram would be obtained which respects the Wigner–Witmer non-crossing rules and also indicates intermediate maxima on potential-energy curves. For example, the E(II) state of $Co(NH_3)_5Cl^{++}$ would correlate with the state E at about 4.3 ev of the ionic decomposition products; configuration interaction with the E(IIIa) (which without Cl correlates with the E level at 3.5 ev) state would produce the correlation with an E* level at about 3.5 ev, producing also a maxima on the E(II)–E* potential curve.*

For personal use only.

chain reactions are involved). The decomposition should take place by process 1. The I and II levels of the near ultraviolet and visible spectrum usually correlate with higher states of the decomposition products. For this reason, the decomposition at 370 mμ and 550 mμ for which ϕ was measured will take place via process 2. Figures 1, 2, 3, 4 show that the oxidation–reduction decomposition is favored by the increase in oxidizability of X^- in the series NH_3, Cl^-, Br^-, J^-. For instance, the level I (corresponding to the first crystalline field band) of $Co(NH_3)_5Cl^{++}$ correlate with higher levels of the decomposition products. For $Co(NH_3)_5J^{++}$ the first excited level $E(I)$ already correlates with level E^* of the oxidation–reduction decomposition products which is approximately isoenergetic. The correlation diagrams show that the complex ions in their ground state may only undergo aquation reaction. The data in Table I confirm the favoring of the oxidation–reduction decomposition passing from $Co(NH_3)_6^{+++}$ to $Co(NH_3)_5J^{++}$. The complex ions in Table I are placed, according to Adamson, approximately in the ascending order of oxidizability of X^-.

RADIATIONLESS TRANSITIONS. QUANTUM YIELDS

When we plotted the correlation diagrams we considered the singlet states alone. The neglect of the triplet states is justified by the following three circumstances: Nakamoto (8) succeeded in interpreting the absorption spectra of these complexes on the ground of only their singlet states. According to Kasha (10) the radiationless transitions between excited singlet states are much more rapid than those between singlet and triplet states. In some previous papers (11), we have shown that radiationless singlet–singlet transitions can occur with a high probability (corresponding to a rate of approximately 10^{10} sec^{-1}) if the interaction between the movement of the electrons and that of the nuclei is strong enough and the anharmonicity of the nuclear movement great enough. The interaction energy W_{AB}, which produces the transition between the potential-energy surfaces A and B, is equal to

$$[3] \qquad W_{AB} = \frac{h^2}{2\pi^2 M} \int \phi_A^* \frac{\partial \phi_B}{\partial r}\, dr \int X_A^* \frac{\partial X_B}{\partial r}\, dx.$$

X_A and X_B are electronic wave functions; ϕ_A and ϕ_B are vibrational wave functions in the Born–Oppenheimer approximation; x stands for electronic co-ordinates, r the vibrational (nuclear) ones, and M is the corresponding reduced nuclear mass. Formula [3] is obtained by a method of first approximation in relation to the Born–Oppenheimer approximation (11) (see likewise Hellmann (12)). In our case we have diluted aqueous non-fluorescent solutions (7). That is why we do not consider the possibility of intermolecular energy transfer between the complex ions and we shall assume that the radiationless transitions have a high rate ($> 10^{10}$ sec^{-1}) unless they are forbidden by symmetry considerations.

In this way, we can explain the low quantum yields for the aquations at $\lambda = 550$ mμ (see Table I) and also at 370 mμ for $Co(NH_3)_5Cl^{++}$ and the preceding ions. The correlation diagrams show that the decomposition in this case will take place according to process 2. Let us show that process 2(a) is prevented for reasons of symmetry, so that the decomposition actually takes place according to process 2(b), for which we must expect $\phi \gtrsim 0.01$. The dissociation of particle X in $Co(NH_3)_5X^{++}$ does not change the symmetry of the system, therefore the vibrational co-ordinate r and also $\partial/\partial r$ belong to the A_1 species. The electronic function of the ground state also belongs to A_1 species. In order that integral $\int X_A^*(\partial X_B/\partial r)dx$ should not vanish, the electronic wave function

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

X_B of the excited state must also belong to the A_1 species (independent of the vibrational wave functions ϕ_A and ϕ_B, which are not implied in this integral). As may be seen in Nakamoto's work (8), it is only by absorption in the relative distant ultraviolet that such a state can be obtained.

It remains to be explained why aquation is not produced by the elimination of the NH_3 molecule. The activation energy for the elimination of NH_3, at least from $Co(NH_3)_6^{+++}$, is greater than for the elimination of halogen (1.5 ev instead of 1.1 ev (7)). According to Zimmermann's arguments, this fact explains why NH_3 is eliminated with greater difficulty than X^- in the case of process 2(*b*). But process 2(*a*) is no longer prevented for reasons of symmetry, because the elimination of NH_3 considerably modifies the symmetry of the complex. For the ions under consideration, however, the five or six Co–NH_3 valency vibrations interact strongly. That is why the elimination of NH_3 can only be achieved by the simultaneous excitation of the five or six corresponding normal vibrations. The interaction energy W_{AB} (formula [3]) is also proportional to the integral $\int \phi_A^* (\partial \phi_B / \partial r) dr$. In this integral the derivative is only once performed with respect to a single normal vibrational co-ordinate. There remain as factors four or five overlap integrals amid a vibration function corresponding to a low vibrational quantum number (from ϕ_A) and a function for a high quantum number (from ϕ_B). We have shown that such overlap integrals are small (11). Therefore, the electronic excitation energy will be converted into the energy of a vibration that leads to the formation of a "hot" molecule (process 2(*b*)).

CONCLUSIONS

We applied the Wigner–Witmer correlation rules to discuss the photochemical decomposition of certain molecules more complex than those to which these rules have so far been applied. We discussed in greater detail than in other papers of this kind the radiationless transitions between different potential-energy surfaces. Theoretical considerations suggest the following mechanism for the photochemical decomposition of the $Co(NH_3)_5X^{++}$ ions:

(*a*) Through excitation with fairly short wave-length light ($\lambda \lesssim 220$ mμ for $Co(NH_3)_6^{+++}$, $\lambda \lesssim 350$ mμ for $Co(NH_3)_5Br^{++}$) unstable states with respect to the dissociation of atom X or of ion X^- (or rather NH_3^+ and NH_3) are obtained. Both aquation and oxidation–reduction decomposition should take place with a large total quantum yield ($\phi \cong 1$).

(*b*) Through excitation with longer wave-length light only ionic dissociation (followed by aquation) occurs according to the "hot" molecule mechanism. Hence the quantum yield is low. As we indicated above, the most stable of the ions is $Co(NH_3)_6^{+++}$.

The experimental data of Adamson (6*a*) (Table I) agree with this mechanism, which, however, differs from that suggested by Adamson and Sporer (6). They assume the same initial stage for all the wave lengths—an internal oxidation–reduction reaction—the final transformation of the ion depending on the subsequent stages.

Their mechanism also explains the photochemical decomposition characteristics of the complex ions, but according to the correlation diagrams by the excitation with $\lambda = 550$ mμ the energy is in many cases insufficient for redox decomposition. It is true that the value assumed for the ground state of the $Co(NH_3)_5^{++} + Cl$ (and therefore also for $Co(NH_3)_5^{++} + X$) is not too reliable. If, however, the redox decomposition products separate with an energy excess of 0.5 ev or more, considering the activation energy of

For personal use only.

diffusion in water (which is about 0.15 ev) it seems improbable that the cage effect of the solvent should be capable of providing the recombination of the dissociated particles, as stated by Adamson and Sporer (6).

ACKNOWLEDGMENTS

We are indebted to Dr. Léo Marion, who was so kind to give us the opportunity of seeing the preprint of a paper by Adamson (6*a*) (from the Discussion meeting of the Faraday Society, April 1960).

CONSTITUTION OF AN ARABINOGALACTAN FROM MAPLE SAP[1]

G. A. Adams and C. T. Bishop

ABSTRACT

An arabinogalactan ($[\alpha]_D^{25}$ −41°) has been isolated from maple sap in yields varying between 7.5 and 17.0 mg per 100 ml of sap. The polysaccharide was electrophoretically homogeneous and contained D-galactose, L-arabinose, and rhamnose in a molar ratio of 51:44:5. Methylation and hydrolysis of the polysaccharide yielded the following *O*-methyl ethers which were analyzed by gas–liquid partition chromatography: 2,3,5-tri-*O*-methyl-L-arabinose (4 moles); 2,5-di-*O*-methyl-L-arabinose (2 moles); 2,4-di-*O*-methyl-D-galactose (4 moles); 2,4,6-tri-*O*-methyl-D-galactose (7 moles); 2,3,4-tri-*O*-methyl-L-rhamnose (1 mole). A possible structure for the polysaccharide is proposed and discussed in relation to other arabinogalactans.

One of the reasons for studying non-cellulosic wood polysaccharides is that a knowledge of their structures may help in elucidating the modes of formation and the physiological roles of these materials in the plant. In recent years there have been reports of the synthesis of polymeric carbohydrates by transglycosidation reactions catalyzed by enzymes extracted from plants (1, 2, 3). It seemed possible that a physiologically active material like wood sap might be rich in products of transglycosidation reactions and that it would be interesting to see, by correlation of structures, if such products bore any significance as precursors in the formation of non-cellulosic wood polysaccharides. Maple wood was chosen for this study because of its high production of sap and because the non-cellulosic polysaccharides of this wood had already been examined (4, 5).

A previous publication (6) described the isolation of a polysaccharide from maple sap, some of its properties, identification of the component monosaccharides, and showed that it was a true sap constituent and not of bacterial or fungal origin. The present report describes methylation studies on the maple sap polysaccharide and compares the main structural features with those of other arabinogalactans.

The polysaccharide, isolated from the non-dialyzable sap constituents by precipitation with ethanol, contained D-galactose, L-arabinose, and rhamnose and showed one large pand one small component on electrophoresis (6). One repetition of the fractional precipitation with ethanol (7) yielded the larger component in a form which gave a single sharp peak ($\mu = 9.36 \times 10^{-5}$ cm^2 volt^{-1} sec^{-1}) on free-boundary electrophoresis in borate buffer (8). The relative amounts of constituent monosaccharides reported previously (6) were found to be inaccurate because of variations in reactivity of the different sugars with silver nitrate in the method used (9). The monosaccharide composition was therefore redetermined by a new method: the polysaccharide was hydrolyzed and the reducing sugars were converted to their glycosides which were then methylated completely by the Kuhn (10) procedure. The resulting mixture of fully methylated methyl glycosides was then analyzed by gas–liquid partition chromatography (11, 12) giving the separation shown in Fig. 1. Areas under the six peaks were measured and those arising from a single monosaccharide were totalled giving a molar ratio of galactose:arabinose:rhamnose of 51:44:5. It was possible to use this method here because each of the fully methylated monosaccharides was completely separated in both furanoside and pyranoside ring forms. It is interesting to note that considerable amounts of the furanoside forms of D-galactose and L-arabinose were present although the methanolysis was carried out under conditions that are generally considered to yield primarily pyranosides.

The polysaccharide was methylated to completion and hydrolyzed by formic acid (13). Paper chromatographic examination of this hydrolyzate revealed the presence of three components having the same mobilities as 2,3,5-tri-*O*-methyl arabinose; 2,4,6-tri-*O*-methyl galactose; and 2,4-di-*O*-methyl galactose. The mixture of *O*-methyl ethers was converted to methyl glycosides and examined by gas–liquid partition chromatography to give the separation shown in Fig. 2. Identities of the compounds listed were established by comparison of their retention volumes on the gas–liquid partition chromatogram with authentic samples and by their isolation as crystalline derivatives. The shoulder on peak 2, Fig. 2, was identified as methyl 2,3,4-tri-*O*-methyl α-L-(?)-rhamnopyranoside

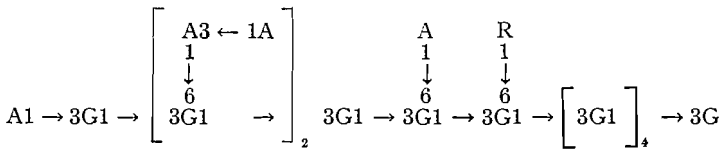
(10) Methyl 2,4-di-*O*-methyl-α-D-galactopyranoside.

by separation of the mixture on butanediol succinate polyester liquid phase (see, for example, Fig. 1). This procedure also permitted the quantitative estimation of the rhamnose component. The amounts of the rhamnose moiety obtained here and in the preliminary study (6) were not sufficient for measurement of specific rotation. Its assignment as the normally occurring L-enantiomorph must therefore be regarded as tentative, although probably correct.



The components giving peaks 3, 4, 5, and 6 could not be identified positively. Peaks 3 and 4 (together, about 7% of the total mixture) had retention volumes in the range predicted for di-*O*-methyl pentoses but were different from glycosides of 2,3-, 2,4-, and 2,5-di-*O*-methyl-L-arabinose on the gas–liquid chromatogram. These peaks could represent glycosides of 3,4- and 3,5-di-*O*-methyl-L-arabinose or could be the separated anomeric glycosides of one of these isomers; however, lack of authentic samples prevented further investigation of these components. The component represented by peak 5 constituted less than 1% of the total mixture and was therefore regarded as of doubtful structural significance. Component 6 was different, on the gas–liquid chromatogram, from glycosides of all available *O*-methyl ethers of L-arabinose and D-galactose. When the mixture was run on a polar liquid phase (butanediol succinate polyester) component 6 had a much higher retention volume indicative of the presence of hydroxyl or other polar groups (12). In an attempt to isolate component 6 the mixture of glycosides was hydrolyzed by aqueous hydrochloric acid and separated into three fractions by preparative paper chromatography. These three fractions were then methanolyzed and examined by gas–liquid partition chromatography. No trace of component 6 could be found in these fractions or in methanolyzates of eluates from blank areas of the paper chromatograms. It must therefore be concluded that component 6 was an acid-labile artifact produced during the formic acid hydrolysis of the methylated polysaccharide. Such an artifact could be either a formate ester or an anhydro sugar and the former is favored because of the polar characteristics mentioned above. Quantitative estimation of those components in Fig. 2 that were identified gave a molar ratio of galactose:arabinose:rhamnose of 61:33:6 (see Fig. 3). This is low in arabinose when compared with the composition of the original polysaccharide (galactose:arabinose:rhamnose 51:44:5) and indicated that component 6 was probably an arabinose derivative. When the disappearance of component 6 after acid hydrolysis was observed some of the other components had already been isolated as crystalline compounds and it was not possible to reconstitute the mixture to see which component had increased at the expense of component 6. No new compounds were found after the disappearance of component 6 so it must have been a derivative of one of the other compounds in the mixture. It should be mentioned that components 3–6 inclusive were not detectable by paper chromatography and, indeed, the 2,5-di-*O*-methyl-L-arabinose may have been missed because of the difficulty in separating it from tri-*O*-methyl-D-galactose by that technique. The detection of unknown components is to be expected in the application of gas–liquid partition chromatography to this field; their identification will depend on the accumulation of pure standards and on improved gas–liquid chromatographic procedures that will permit their isolation.

Despite the presence of some unidentified methyl ethers the identification and estimation of the major components in the methanolysis products revealed the gross structural features of the polysaccharide. Figure 3 shows the molar ratio of the methyl ethers that were identified and a structure that would give those results. This structure is not proposed as unique or complete for the arabinogalactan from maple sap but simply serves

to illustrate those structural features that are known. Thus the predominant *O*-methyl ether was 2,4,6-tri-*O*-methyl-D-galactose which must have arisen from 1 → 3 linked D-galactose units as illustrated. The 2,4-di-*O*-methyl-D-galactose represented the only branch points found and originated from D-galactose units substituted in positions 1, 3, and 6. The 2,5-di-*O*-methyl-L-arabinose arose from chain-forming units joined through positions 1 and 3 and, because arabinose but not galactose was released by partial hydrolysis of the polysaccharide (6), these units could not have been interposed between galactose units but must have been joined to other arabinose residues as shown in Fig. 3. The 2,3,5-tri-*O*-methyl-L-arabinose and 2,3,4-tri-*O*-methyl-L-(?)-rhamnose repre-

sented terminal, non-reducing units. Of course, the galactan portion of the molecule need not be straight as shown but could consist of a branch-on-branch structure of 1 → 3 linked chains joined by 1 → 6 linkages.

It is clear from the foregoing evidence that the polysaccharides in maple sap bear no structural relation to the non-cellulosic polysaccharides of the wood which are predominantly acidic xylans (4, 5). The possibility exists that the arabinogalactans found in aqueous extracts of numerous woods (14) might be of sap origin rather than components of the plant tissue. An attempt to obtain further evidence on this point by examination of the sap from a tamarack tree which is rich in arabinogalactan was frustrated by a lack of sap flow. However, an examination of the structures reported for various arabinogalactans reveals some differences in the galactan portions of the molecules. In most of the water-soluble arabinogalactans from woods the *unbranched* portion of the galactan chain is formed by 1 → 6 linkages and gives rise to 2,3,4-tri-*O*-methyl-D-galactose after methylation and hydrolysis (14). On the other hand, in the more complex group of polysaccharides which form the plant gums, the unbranched portion of the galactan chain is usually formed by 1 → 3 linkages giving rise to 2,4,6-tri-*O*-methyl-D-galactose after methylation and hydrolysis (15). In this respect, and in having rhamnose as an integral part of its structure, the arabinogalactan from maple sap resembles more closely the plant gums than the water-soluble arabinogalactans of coniferous woods.

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v ratio):

(A) 2-butanone:water, azeotrope;
(B) *n*-butanol:ethanol:water, 9:3:3;
(C) *n*-butanol:ethanol:water, 40:11:19.

Reducing sugars were detected on chromatograms by the *p*-anisidine hydrochloride spray reagent (16). Evaporations were carried out at 35° C or less under diminished pressure and specific rotations are equilibrium values unless stated otherwise. Melting points are corrected.

Gas–liquid partition chromatography was done as previously described (12). The Pye argon chromatograph was used for the qualitative and quantitative estimations. Samples isolated by gas–liquid partition chromatography were collected from the effluent gas stream after separation on a modified (11) Podbielniack "Chromacon" (series 9475-3V).

Isolation of Polysaccharide, Electrophoresis, and Estimation of Constituent Sugars

The isolation and yields of polysaccharide from maple sap were described previously (6). The crude polysaccharide which contained a large and a small component as shown by electrophoresis was refractionated from aqueous solution by gradient addition of ethanol (7). A portion (150 mg) of the main fraction (precipitated at an ethanol concentration of 65%) was dissolved in 0.05 *M* borate buffer (15 ml) and dialyzed through cellophane against 3 liters of the buffer. The solution of polysaccharide was then subjected to electrophoresis in a Tiselius-type Spinco Model-H apparatus and showed a single, sharp, peak with $\mu = 9.36 \times 10^{-5}$ cm^2 volt^{-1} sec^{-1}.

A sample (50 mg) of the polysaccharide was hydrolyzed by *N* sulphuric acid (2 ml) at 100° C in a sealed tube. Since no uronic acids were found in the previous investigation (6) the acid was neutralized by Amberlite IR-45 (OH) exchange resin and the filtrate was evaporated to dryness. The dried residue was refluxed with 4% methanolic hydrogen chloride for 20 hours, acid was neutralized with silver carbonate, and silver salts were filtered. The mixture of methyl glycosides obtained by evaporation of the filtrate was methylated by being shaken for 20 hours with silver oxide (200 mg) and methyl iodide (2 ml) in dimethylformamide (10 ml) (10). The silver salts were allowed to settle out and the clear supernatant was examined directly by gas–liquid partition chromatography to give the separation shown in Fig. 1. Areas under the peaks originating from a single monosaccharide were added together and the resulting three areas gave a molar ratio of galactose:arabinose:rhamnose of 51:44:5. Methyl α-D-glucopyranoside when methylated under the same conditions showed no partially methylated products detectable by gas–liquid partition chromatography or, after hydrolysis, by paper chromatography.

Methylation of Arabinogalactan

The polysaccharide (3.0 g) was methylated five times with 30% aqueous sodium hydroxide and dimethyl sulphate (17). The reaction mixture was extracted continuously with chloroform for 3 days and the extract was dried (anhydrous sodium sulphate) and evaporated to yield the partially methylated polysaccharide (2.08 g, methoxyl 34.7%; calc. methoxyl 41.3%). This product was methylated twice in tetrahydrofuran with solid sodium hydroxide and dimethyl sulphate (18) to yield a product having no hydroxyl absorption at 3500–3600 cm^{-1}. Precipitation from chloroform by addition of petroleum

ether (b.p. 30–60° C) yielded the fully methylated polysaccharide as a cream-colored powder, 1.47 g, $[\alpha]_D^{25} = -93°$ (*c*, 2% in chloroform), methoxyl = 40.7%.

Hydrolysis of Methylated Arabinogalactan

The fully methylated polysaccharide was hydrolyzed by formic acid according to the procedure of Jones and Wilkie (13). Paper chromatography of the hydrolyzate revealed three components with the following R_g values in solvents A and B respectively: component 1—1.01, 0.97; component 2—0.54, 0.82; component 3—0.22, 0.61. These values and the color reactions with the *p*-anisidine spray reagent were the same as those given by authentic samples of 2,3,5-tri-*O*-methyl-L-arabinose (component 1), 2,4,6-tri-*O*-methyl-D-galactose (component 2), and 2,4-di-*O*-methyl-D-galactose (component 3).

To obtain a quantitative estimate of the above components the mixture was refluxed for 20 hours with 4% methanolic hydrogen chloride and the methyl glycosides were analyzed by gas–liquid partition chromatography (11, 12). Figure 2 shows the separation obtained on a liquid phase of Apiezon M; separation on butanediol succinate polyester gave complete resolution of the shoulder on peak 2, which had the same retention volume as methyl-2,3,4-tri-*O*-methyl α-L-rhamnopyranoside, and permitted its quantitative estimation. The molar ratio of identified components (Fig. 3) was obtained by measurement of areas under the peaks on the gas–liquid partition chromatograms. These separations also provided additional evidence for the identities of the components which had the same retention volumes as authentic specimens.

In an attempt to isolate component 6, Fig. 2, the mixture of glycosides was hydrolyzed by *N* hydrochloric acid at 97° C for 24 hours. The hydrolyzate was neutralized by Amberlite IR-45 (OH) exchange resin and chromatographed on paper sheets in solvent C to give three fractions which were eluted from the papers and refluxed with 4% methanolic hydrogen chloride for 20 hours. Examination of the methanolyzates by gas–liquid partition chromatography showed that fraction 1 (R_g 0.9) contained only 2,3,5-tri-*O*-methyl-L-arabinose; fraction 2 (R_g 0.8) contained 2,4,6-tri-*O*-methyl-D-galactose and 2,5-di-*O*-methyl-L-arabinose; and fraction 3 (R_g 0.6) contained only 2,4-di-*O*-methyl-D-galactose. No component corresponding to peak 6, Fig. 2, was found in methanolyzates of eluates from blank areas of these chromatograms.

Identification of O-Methyl Ethers

2,3,5-Tri-O-methyl-L-arabinose

A sample of the mixed anomeric methyl glycosides of this component was collected from the effluent gas stream of the gas–liquid partition chromatogram. Hydrolysis, bromine oxidation, lactonization, and reaction with methanolic ammonia yielded 2,3,5-tri-*O*-methyl-L-arabonamide (19), which was crystallized from ethyl acetate:petroleum ether (b.p. 30–60° C) to a melting point of 134–136° C, $[\alpha]_D^{27} = +18°$ (*c*, 0.35% in methanol).

2,4,6-Tri-O-methyl-D-galactose

The anomeric glycosides were collected separately from the gas–liquid partition chromatogram. The faster-moving component (peak 7, Fig. 2) was crystallized from petroleum ether (b.p. 30–60° C) as fine needles, m.p. 108–109° C, $[\alpha]_D^{25} = -44°$ (*c*, 0.25% in methanol). The slower-moving component (peak 8, Fig. 2) was crystallized from petroleum ether (b.p. 65–110° C) to a melting point of 65–68° C, $[\alpha]_D^{25} = +149°$ (*c*, 0.45% in methanol). Bell and Williamson (20) report a melting point of 111–112° C, $[\alpha]_D^{25} = -40.9°$ (in chloroform), for methyl 2,4,6-tri-*O*-methyl-β-D-galactopyranoside and a melting point of 73–74° C, $[\alpha]_D^{25} = +163.9°$ (in chloroform), for the α-anomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The two crystalline fractions were combined and hydrolyzed to yield a sirupy reducing sugar which could not be crystallized. The crystalline anilide derivative had a melting point of 160–165° C raised to 178–179° C by recrystallization from methanol:ether, $[\alpha]_D^{25} = +35°$ (*c*, 1% in methanol). These are in good agreement with the reported values of melting point 179° C, $[\alpha]_D^{25}$ +38° (in acetone) for *N*-phenyl-2,4,6-tri-*O*-methyl-D-galactosylamine (21).

*2,4-Di-O-methyl-*D*-galactose*

The anomeric glycosides of this component (peaks 9 and 10, Fig. 2) were collected separately from the gas–liquid partition chromatogram. The faster-moving component crystallized in the collecting tube and was found to be methyl 2,4-di-*O*-methyl-β-D-galactopyranoside, m.p. 168–170° C (22). The slower-moving component was recrystallized twice from petroleum ether (b.p. 30–60° C) to yield methyl 2,4-di-*O*-methyl-α-D-galactopyranoside, m.p. 106.5–108° C (22).

Another sample of this component was isolated from preparative paper chromatograms as the reducing sugar, m.p. 98–100° C, $[\alpha]_D^{26} = +85°$ (*c*, 1% in water). These values agree with those reported for 2,4-di-*O*-methyl-D-galactose monohydrate (22).

*2,5-Di-O-methyl-*L*-arabinose*

The fraction from preparative paper chromatograms that contained 2,4,6-tri-*O*-methyl-D-galactose and 2,5-di-*O*-methyl-L-arabinose was rechromatographed on paper sheets in solvent A to yield a chromatographically pure sample of 2,5-di-*O*-methyl-L-arabinose. Bromine oxidation, lactonization, and reaction with methanolic ammonia yielded crystalline 2,5-di-*O*-methyl-L-arabonamide (23), m.p. and mixed m.p. 132° C.

THE POLYOXYPHENOLS OF WESTERN RED CEDAR (THUJA PLICATA DONN)

II. DEGRADATION STUDIES ON PLICATIC ACID, A POSSIBLE LIGNAN ACID[1]

J. A. F. GARDNER, B. F. MACDONALD, AND HAROLD MACLEAN

ABSTRACT

Plicatic acid, $C_{20}H_{22}O_{10}$, a polyoxyphenol from western red cedar heartwood, described in a previous paper, has been further characterized by preparation and analysis of additional crystalline derivatives. Crystalline trimethyl and triethyl ethers have been oxidized by alkaline permanganate. The trimethyl ether yielded 3,4,5-trimethoxybenzioc acid, 4,5-dimethoxyphthalic acid (*m*-hemipinic acid), a pentamethoxy anthraquinone, and a pentamethoxy *o*-benzoylbenzoic acid which decarboxylated to 3,4,5,3′,4′-pentamethoxy benzophenone. Correspondingly, the triethyl ether gave 3,4-diethoxy-5-methoxybenzoic and 4-ethoxy-5-methoxyphthalic acids, a mixture of pentaalkoxy anthraquinones and a pentaalkoxy *o*-benzoylbenzoic acid which decarboxylated to 3,3′,4-triethoxy-4′,5-dimethoxy benzophenone identified by cleavage to 3-ethoxy-4-methoxybenzoic and 3,4-diethoxy-5-methoxybenzoic acids. These results fix the positions of the two methoxyl, three phenolic hydroxyls, and mode of linkage of the two benzene rings. Further evidence is provided indicating plicatic acid is probably a lignan of the 4-aryltetrahydronaphthalene series.

In a previous paper (1), the isolation and properties of plicatic acid, a reactive polyoxyphenolic amorphous acid, occurring in the aqueous extractive of western red cedar, were described. Analysis of crystalline derivatives, methylation results, color tests, and spectra indicated it to be an *n*-propylphenol dimer, $C_{20}H_{22}O_{10}$, probably a lignan acid, in which one phenyl ring was 4-hydroxy-3-methoxyphenyl and the other was 3,4-dihydroxy-5-methoxyphenyl, but the mode of linkage was unknown. Thus the formula was given provisionally as $C_6H_3(OH)(OCH_3).C_5H_4(OH)_3(COOH).C_6H_2(OH)_2(OCH_3)$. This paper describes the alkaline permanganate oxidation of the crystalline trimethyl and triethyl ethers which establishes the aromatic substitution and indicates that plicatic acid is a lignan of the aryltetrahydronaphthalene series.

Alkaline permanganate oxidation of plicatic acid trimethyl ether (II*a*) gave a 15% yield of a crystalline colorless pentamethoxy keto-acid, $C_{19}H_{20}O_8$, m.p. 225.5–226°; smaller quantities of a neutral brilliant yellow crystalline substance, $C_{19}H_{18}O_7$, m.p. 209–210°, which gave qualitative tests and had spectral characteristics of an anthraquinone; 3,4,5-trimethoxybenzoic acid (V*a*); and 4,5-dimethoxyphthalic acid (IV*a*). The latter two acids were not isolated but their presence in the oxidation mixture was shown by paper chromatographic comparison with synthetic samples.

The pentamethoxy keto-acid decarboxylated to a benzophenone shown to be 3,4,5,3′,4′-pentamethoxybenzophenone by comparison with a synthetic sample. With concentrated sulphuric acid, the keto-acid readily gave a yellow anthraquinone. The infrared absorption spectrum of the acid was typical of the lactol form of a γ keto-acid (2) showing an alcoholic, but no acidic, hydroxyl band. These results indicate it to be an *o*-benzoylbenzoic acid, either 2,3,4-trimethoxy-6-(3′,4′-dimethoxybenzoyl)-benzoic acid or 3,4-dimethoxy-6-(3′,4′,5′-trimethoxybenzoyl)-benzoic acid (III*a*), either of which would give the same benzophenone (VIII*a*) on decarboxylation. Since Chatterjee and Chakravarti (3) had reported the isolation of an *o*-benzoylbenzoic acid of formula III*a* of much lower melting

Contribution from the Vancouver Laboratory, Forest Products Laboratories of Canada, a Division of the Forestry Branch, Department of Northern Affairs and National Resources, Ottawa, Canada. Paper presented in part at the Northwest Regional Meeting, American Chemical Society, Seattle, Washington, June 18–19, 1959, and at the I.U.P.A.C. Symposium on the Chemistry of Natural Products, Australia, August 15–25, 1960.

point, 210–211°, by the permanganate oxidation of the lignan, sikkimotoxin, and since plicatic acid gave some vanillin on alkaline nitrobenzene oxidation, the former was considered first. However, this possibility was eliminated when neither veratric acid nor 3,4,5-trimethoxyphthalic could be detected in the other oxidation products. The presence of 3,4,5-trimethoxybenzoic acid (V*a*) and 4,5-dimethoxyphthalic acid (IV*a*) as shown by paper chromatography required formula III*a*. It was concluded that Chatterjee and Chakravarti's compound, m.p. 210–211° from boiling water and dilute ethanol, must have been a mixture of the keto-acid (III*a*) and its lactol form (III*c*).

In the present work, the acid when purified by repeated recrystallization, was obtained in the lactol form (III*c*), m.p. 225.5–226°, as shown by the infrared absorption spectra. However, acidification of a dilute alkaline solution of the lactol gave a crystalline product, m.p. 180–185° depending on the rate of heating, which on the basis of its infrared absorption was the keto-acid (III*a*), i.e., a strong acidic hydroxyl band, no alcoholic hydroxyl band, and a shift of the carbonyl band to the benzoic acid region. This material was rapidly transformed on the melting point stage to the lactol form. The lactol nature was confirmed by the formation of a neutral crystalline acetate whose infrared absorption spectrum was clearly characteristic of a pseudoacetate, showing one broad enhanced carbonyl absorption band at 1758 cm^{-1} (2).

The anthraquinone obtained in nearly quantitative yield from the *o*-benzoylbenzoic acid by ring closure with concentrated sulphuric acid was found to be identical with that obtained as one of the permanganate oxidation products of plicatic acid trimethyl ether. Inspection of formula III*a* shows that ring closure of this substituted *o*-benzoylbenzoic acid, at either the 2′ or 6′ position, would give only one anthraquinone, namely, 1,2,3,6,7-pentamethoxy anthraquinone (VI).

Formation of the products III*a*, IV*a*, and V*a* proves that the position of aromatic substitutions in plicatic acid is as shown in formula I. To confirm the relative positions of the phenolic hydroxyl and methoxyl groups, which had been indicated by color tests and vanillin formation (1), the permanganate oxidation products at 100° of plicatic acid triethyl ether were examined. A crystalline monomeric acid was obtained which was shown to be 3,4-diethoxy-5-methoxybenzoic acid (V*b*) by comparison with a synthetic sample. The presence in the oxidation products of 4-ethoxy-5-methoxyphthalic acid (IV*b*) was demonstrated by paper chromatography in three solvent systems using a synthetic reference sample.

A neutral brilliant yellow crystalline product, giving qualitative tests for an anthraquinone, was also obtained in small yield. In contrast to the readily purified sharply melting anthraquinone obtained in the oxidation of plicatic acid trimethyl ether, the product in this case appeared to be a mixture since, after repeated recrystallizations, it melted over a wide range. This result was to be expected since, in the case of the ethylated derivatives, two anthraquinones, VII*a* and VII*b*, should result in approximately equal yield from ortho ring closure of the triethoxy-dimethoxy-*o*-benzoylbenzoic acid (III*b*).

The formation of 3,4-diethoxy-5-methoxybenzoic proves ring C to be 3,4-dihydroxy-5-methoxyphenyl and the formation of the 4-ethoxy-5-methoxyphthalic acid indicates the substitution pattern on ring A as shown in formula I for plicatic acid. Alkaline permanganate oxidation of the triethyl ether at lower temperature yielded mainly the ethylated keto-acid 4-ethoxy-3-methoxy-6-(3′,4′-diethoxy-5′-methoxybenzoyl)-benzoic acid (III*b*) which underwent conversion from its keto form III*b* to the lactol form III*d* near the melting point similar to the methylated derivative previously obtained. Decarboxylation gave the corresponding benzophenone, 3,3′,4-triethoxy-4′,5-dimethoxy benzo-

For personal use only.

phenone, which on cleavage with potassium *t*-butoxide yielded 3-ethoxy-4-methoxybenzoic acid (IX) and 3,4-diethoxy-5-methoxybenzoic acid (V*b*). The formation of these latter products fixes with certainty the position of the hydroxyl group on ring A, as shown in Fig. 1, formula I.

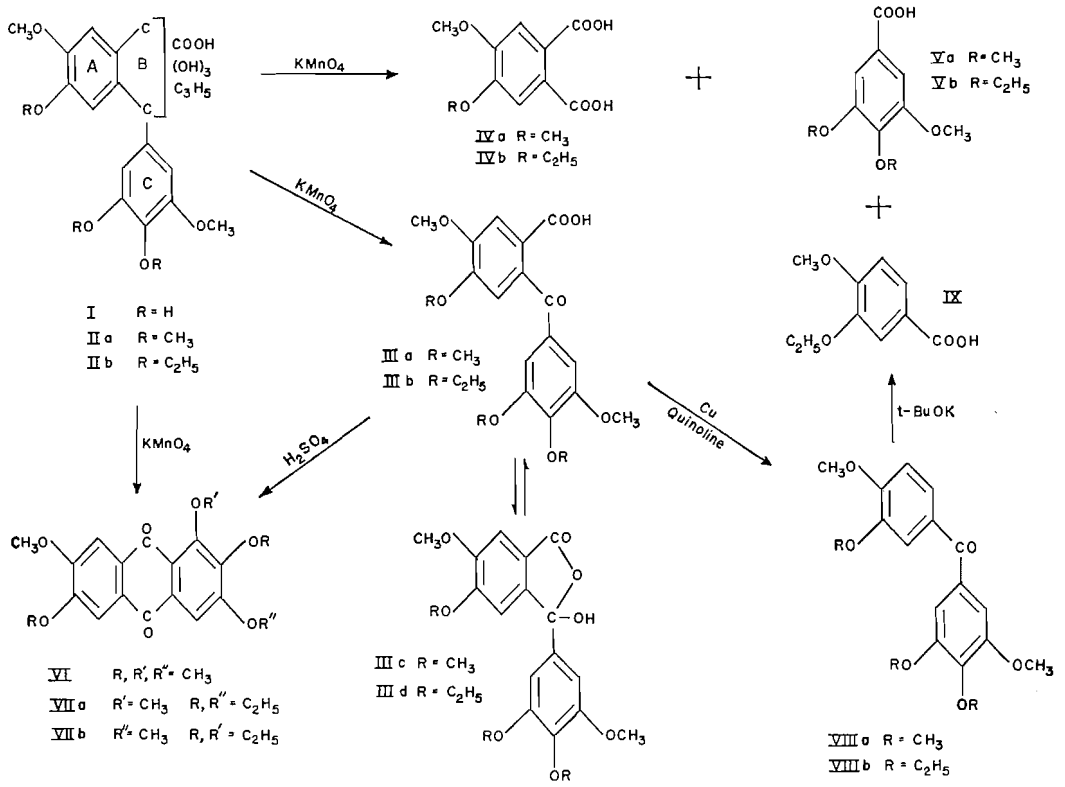

FIG. 1. Oxidation of methyl and ethyl ethers of plicatic acid.

The yield of vanillin (4%) obtained by alkaline nitrobenzene oxidation of plicatic acid (I) is in the same low range as that obtained from two other lignans, conidendrin and iso-olivil, 1 and 3% respectively (4). In the case of plicatic acid, since the C ring is a pyrogallol derivative, the vanillin formed must arise from the A ring via cleavage of an ortho-formylbenzophenone or decarboxylation of 6-carboxyvanillin. The vanillin from conidendrin and iso-olivil is probably derived similarly. This mode of vanillin formation is of interest in connection with alkaline nitrobenzene oxidation studies on lignins since a part of the vanillin formed could be so derived. While there is no evidence for the presence in lignin *in situ* of 3-methoxy-4-hydroxyphenylpropane structural units linked to the next through the 6-position, Richtzenhain (5) suggested the presence of such linkages in lignins isolated by acidic procedures to explain the formation of *m*-hemipinic acid by oxidation after methylation.

The presence of a monomethylated pyrogallol nucleus in plicatic acid explains the positive Mäule test, although this test is usually considered indicative of the dimethylated (syringyl) derivative. In contrast to the dimethylated (syringyl) derivatives, which occur widely in deciduous extractives and lignin, monomethylated derivatives of pyrogallol

For personal use only.

are very rare in all plant products, none having been reported in wood components heretofore. It will be of considerable interest to determine whether products of additional methylation, i.e., syringyl derivatives, are also present in the western red cedar phenols.

In view of the easy formation of the tropolone derivative purpurogallin from pyrogallol, the occurrence of pyrogallol derivatives as well as tropolones in western red cedar is of interest in considering possible modes of biogenesis of the latter substances.

The oxidation products obtained herein together with the formation of γ lactones by plicatic acid and its trimethyl ether (1) are consistent with plicatic acid being a lignan of the 4-aryltetrahydronaphthalene series. Experimental proof of this and the pattern of hydroxylation on the saturated ring is in progress.

EXPERIMENTAL

Plicatic Acid Trimethyl Ether (IIa)

Plicatic acid (20 g) in water (40 ml) was treated with dimethyl sulphate (28 ml) and 20% sodium hydroxide dropwise at reflux for 2 hours under nitrogen while maintaining the pH at 9–10. After addition of the dimethyl sulphate, sodium hydroxide (50%) was added to raise the pH to 14. On cooling of the solution, the sodium salt precipitated and was separated on the centrifuge. The precipitated salt was dissolved in a minimum of distilled water, the solution acidified to pH 7 with sulphuric acid, extracted with chloroform to remove tarry residues, filtered, and further acidified to pH 2 to precipitate the free acid product. After filtration an additional crop was obtained by partial evaporation of the filtrate. Crude yield, 14.79 g (74%). The product was recrystallized from boiling water using decolorizing charcoal. Yield, 10.52 g (53%). Anal. Calc. for $C_{23}H_{28}O_{10}$: neutral equivalent, 464; OCH_3, 33.4. Found: neutral equivalent, 467; OCH_3, 32.7.

On rapid heating, the product melted with foaming between 210° and 218° depending on the rate of heating. It slowly recrystallized on the melting point stage and remelted at 253–255°. On slow heating, the product underwent a change in crystal structure between 220° and 245° and melted at 253–255°. The gas evolved during this conversion was shown to be water vapor and the new product proved to be plicatic acid trimethyl ether lactone, previously prepared from plicatic acid trimethyl ether methyl ester through loss of methanol (1), by mixed fusion and comparison of infrared spectra.

3,4-Dimethoxy-6-(3′,4′,5′-trimethoxybenzoyl)-benzoic Acid (IIIa)

Plicatic acid trimethyl ether (IIa) (4.56 g) was dissolved in 4% sodium hydroxide (100 ml) on a steam bath and 4% potassium permanganate (511 ml) slowly added with stirring in 10-ml portions until 400 ml had been added, and then in smaller portions to a 15-minute end point. The manganese dioxide together with the small yellowish precipitate which floated on the reaction mixture was filtered out (precipitate A) and washed with hot water (200 ml). After the pink filtrate had been decolorized with a few drops of bisulphite solution and acidified to pH 2 with hydrochloric acid, cooling precipitated pale yellow crystals. Filtration (filtrate B) and recrystallization from methanol–water (1:2) gave colorless needles. Yield, 0.679 g (15%). Anal. Calc. for $C_{19}H_{20}O_8$: C, 60.78; H, 5.10; OCH_3, 41.28; neutral equivalent, 375.4; mol. wt., 375.4. Found: C, 60.86; H, 5.09; OCH_3, 41.00; neutral equivalent, 371.3; mol. wt. (isothermal distillation), 388. The product gave a positive test with 2,4-dinitrophenylhydrazine. Heating rapidly gave partial melting at 180–185° followed by recrystallization and remelting at 218–220°, m.p. after five recrystallizations 225.5–226°. Infrared absorption spectrum was characteristic of the lactol of a keto-acid. ν_{max}^{KBr} 3340, 1702, 1668, 1582, 1322, 1128, 997, 765.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Acidification of a dilute alkaline solution and vacuum drying at room temperature produced the pure keto-acid form (III*a*), m.p. 184–185°. ν_{max}^{KBr} no hydroxyl band, 2600, 1668, 1648, 1580, 1502, 1460, 1410, 1322, 1280, 1120, 1003, 772.

When treated with concentrated sulphuric acid, the product gave a brilliant purple color transformed in a few minutes warming to brown. Dilution of the brown mixture with water and neutralization precipitated a bright yellow crystalline substance, m.p. 207–208° from methanol, showing no mixed melting point depression with 1,2,3,6,7-pentamethoxy anthraquinone (VI) (see below).

Treatment with diazomethane in methanol–ether gave a crystalline monomethyl ester, m.p. 147–147.5°, showing no absorption bands for the hydroxyl group in the infrared spectrum. Anal. Calc. for $C_{20}H_{22}O_8$: OCH_3, 47.64; mol. wt., 390. Found: OCH_3, 46.87; mol. wt. (Rast), 390.

Refluxing with acetic anhydride in pyridine gave a crystalline acetate, insoluble in bicarbonate solution, m.p. 118–119° from methanol. The infrared absorption spectrum showed no hydroxyl band and had one broad intense carbonyl band at 1758 cm^{-1} typical of a lactol acetate (2).

1,2,3,6,7-Pentamethoxy Anthraquinone (VI)

"Precipitate A" after drying was triturated with chloroform (4×50 ml). The solution was then dried over sodium sulphate and evaporated to yield a brilliant yellow powder (0.154 g, 3% yield), melting point after two recrystallizations from methanol, 209–210°. This compound when heated with sodium hydrosulphite in alkali gave a red solution which precipitated the yellow starting material on air oxidation. The red solution on further reduction with zinc and alkali gave a pale yellow precipitate. These positive qualitative tests for anthraquinone structure were supported by formation of the same substance by ring closure of the keto-acid (III*a*) and by the absorption spectra. The ultraviolet absorption in methanol exhibited an intense maximum at 285 mμ ($\log \epsilon = 4.81$). The infrared absorption (KBr pellet) showed one weak and one very strong band attributable to the carbonyls at 1740 cm^{-1} and 1662 cm^{-1}, respectively, comparable to those of anthraquinone at 1740 cm^{-1} and 1665 cm^{-1}. Anal. Calc. for 1,2,3,6,7-pentamethoxy anthraquinone, $C_{19}H_{18}O_7$: C, 63.67; H, 5.06; OCH_3, 43.24; mol. wt., 358. Found: C, 63.56; H, 4.97; OCH_3, 42.80; mol. wt. (Rast), 360.

Identification of 3,4,5-Trimethoxybenzoic Acid (Va) and 4,5-Dimethoxyphthalic Acid (IVa)

"Filtrate B" was extracted with ether (3×100 ml) and the ether solution extracted with sodium bicarbonate (3×25 ml). The mixed acids were isolated by acidification of the bicarbonate solution, extraction into ether, and solvent removal to yield a light tan solid (135 mg, 3% yield). This material was compared by descending paper chromatography on Whatman No. 1 using two solvents, *n*-propanol:26% ammonia (3:2) (6) and *n*-butanol:2% ammonia (1:1) using reference samples of 3,4,5-trimethoxybenzoic acid and 4,5-dimethoxyphthalic acid (7). Spots at R_f's 0.79 and 0.29 and at 0.30 and 0.036 in the two solvents systems respectively, identical with those of the reference samples, were present. Detection was made first with short ultraviolet light which shows the acids as dark spots, then by spraying with universal indicator (B.D.H.). Since 4,5-dimethoxyphthalic acid (*m*-hemipinic acid) and 3,4-dimethoxyphthalic acid (hemipinic acid) (7) have very similar R_f's in these solvents, the oxidation product was also run in benzene:acetic acid:water (125:72:3) over a period of 16 hours, the solvent being allowed to run off the paper. The synthetic 4,5-dimethoxyphthalic and the oxidation product ran $15\frac{1}{4}$ inches while the 3,4-dimethoxyphthalic acid ran 17 inches. These acids

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

were detected with short ultraviolet light as dark spots. No spots corresponding to synthetic veratric and 3,4,5-trimethoxyphthalic acid (8) were detected.

3,4,5,3′,4′-Pentamethoxy Benzophenone (VIIIa)

3,4,5,3′,4′-Pentamethoxy benzophenone was prepared by dissolving the keto-acid (III*a*) (275 mg) and its copper salt (25 mg) as catalyst (9) in quinoline (7 ml) and refluxing for ½ hour. Metallic copper settled out on cooling. The reaction mixture was diluted with ether (20 ml) and filtered. The filtrate was washed with 2 *N* hydrochloric acid (5×10 ml) until nearly colorless, then with 5% sodium hydroxide (2×10 ml) to remove the trace yellow color, dried over sodium sulphate, and evaporated to colorless crystals. Yield, 123 mg (45%). Recrystallization from methanol:water gave colorless platelets, m.p. 120.5–121°, oxime, m.p. 149.5–150°. Mixed melting point with synthetic samples (10, 11) 123.5° and 148.5–149.5°, respectively, showed no depression and the infrared absorption spectra of the benzophenones were identical. ν_{max}^{KBr} 1632, 1582, 1518, 1466, 1415, 1326, 1268, 1125, 770.

Plicatic Acid Triethyl Ether (IIb)

Plicatic acid (28.1 g) in water (25 ml) was treated with diethyl sulphate (30 ml) and 20% sodium hydroxide dropwise at reflux for 3 hours under nitrogen while maintaining the pH at 9–10. After addition of the diethyl sulphate, sodium hydroxide (10 ml, 20%) was added and the reaction mixture refluxed for an additional hour. On cooling, the reaction mixture solidified. After stirring and centrifuging several times, the supernatant liquor was decanted, the precipitated sodium salt acidified, and the free acid taken up in chloroform. The chloroform solution was extracted with sodium bicarbonate solution, the bicarbonate solution acidified, and the precipitated product recrystallized from methanol:water (1:1), m.p. 113–114°. Yield, 10.74 g (38%). As this compound lactonized very readily at 140°, excessive heating during recrystallization and drying was avoided. Stable gels were formed by cooling benzene solutions. Calc. for $C_{26}H_{34}O_{10}$: alkoxyl as methoxyl, 30.6%; neutral equivalent, 506. Found: alkoxyl as methoxyl, 30.2%; neutral equivalent, 509.

Permanganate Oxidation of Plicatic Acid Triethyl Ether (IIb) at 100°

Oxidation of this ether (6.2 g) was similar to that of the trimethyl ether with the exception that 5% potassium hydroxide and 5% potassium permanganate were used and the solution kept boiling throughout the addition of the potassium permanganate (864 ml). Due to the more drastic oxidation conditions no ethyl-substituted *o*-benzoylbenzoic acid was obtained. The monomeric acids were obtained as a yellow plastic solid. Yield, 0.334 g (5.4%).

As in the case of oxidation of the trimethyl ether, brilliant yellow crystals precipitated from the boiling alkaline reaction mixture. Yield, 0.143 g (2%). Qualitative tests for anthraquinone structure were positive. A mixture of anthraquinones was suspected since two recrystallizations gave no change in the melting point range of 150–167°.

Isolation of 3,4-Diethoxy-5-methoxybenzoic Acid (Vb)

A portion of the mixed acids (0.09 g) was fractionated by column chromatography on silicic acid using the technique of Hathaway (6). Evaporation of the first fraction gave a crystalline product, m.p. 112–113°, from ethanol:water (1:1) identical with, by mixed melting point and infrared absorption spectrum, a reference sample synthesized from 5-hydroxy vanillin (12) by ethylation with diethyl sulphate followed by oxidation with cold 1% permanganate (13).

Detection of 4-Ethoxy-5-methoxyphthalic Acid (IVb)

A sample of the mixed acids was examined by descending paper chromatography in three solvent systems, *n*-propanol:26% ammonia (3:2), *n*-butanol:2% ammonia (1:1) and benzene:acetic acid:water (125:72:3). In each case, spots at R_f's identical with those of a synthetic sample of 4-ethoxy-5-methoxyphthalic acid were obtained. In the first two, the spots (R_f's 0.51 and 0.045 respectively) were detected first by short ultraviolet light and then by spraying with universal indicator (B.D.H.). In the last, the solvent was allowed to run off the paper to give 14 inches of migration by the acid and detection was by short ultraviolet light.

The reference sample of 4-ethoxy-5-methoxyphthalic acid (melting point of ethylimide, 204°) was obtained by the permanganate oxidation (13) of 4-ethoxy-5-methoxyphthalide synthesized from the ethyl ether of vanillic acid using the method of King and King (14).

4-Ethoxy-3-methoxy-6-(3',4'-diethoxy-5'-methoxybenzoyl)-benzoic Acid (IIIb)

Permanganate oxidation of plicatic acid triethyl ether (II*b*) at 50–55° was analogous to the previous oxidation for the trimethyl ether (II*a*). At this temperature only a trivial amount of the corresponding anthraquinones (VII*a* and VII*b*) was obtained. The main product was similarly a keto-acid, 4-ethoxy-3-methoxy-6-(3',4'-diethoxy-5'-methoxybenzoyl)-benzoic acid (III*b*) (8% yield). Anal. Calc. for $C_{22}H_{26}O_8$: neutral equivalent, 418. Found: 416. Heating rapidly gave a partial melting at 120–124° followed by recrystallization and remelting at 136–137°. Infrared absorption spectrum of the original material before melting was that of the keto-acid (III*b*). ν_{max}^{KBr} no hydroxyl band, 2600, 1670–1660 (doublet), 1580, 1500, 1418, 1320, 1270. After melting at 136–137° the spectrum was mainly that of the lactol (III*d*) contaminated with some of the keto-acid. ν_{max}^{KBr} 3250, 2600, 1705, 1680, 1580, 1500, 1418, 1320, 1270, 1120, 766.

3,3',4-Triethoxy-4',5-dimethoxy Benzophenone (VIIIb)

3,3',4-Triethoxy-4',5-dimethoxy benzophenone was prepared from the keto-acid (III*b*) in an analogous manner to the fully methylated benzophenone (VIII*a*). Yield, 68% of theoretical. Recrystallization from methanol:water (2:1) gave colorless needles, m.p. 96–96.5°. The infrared spectrogram was free of acid hydroxyl and acid carbonyl bands showing only the expected diaryl ketone carbonyl. ν_{max}^{KBr} 1640, 1580, 1518, 1420, 1322, 1262, 1122, 1023, 776.

Cleavage of 3,3',4-Triethoxy-4',5-dimethoxy Benzophenone (VIIIb)

In accordance with the procedure of Swan (15), potassium wire (30 mg, 0.00075 mole) was converted to potassium tertiary butoxide. A solution of the benzophenone (90.3 mg, 0.000242 mole) and water (4.8 microliters, 0.000265 mole) in anhydrous dioxane (5 ml) was added and refluxed at 90° for 18 hours under anhydrous conditions. The solvent was evaporated under reduced pressure, the residue dissolved in water, and extracted with ether (2×10 ml) to remove unreacted benzophenone and the neutral products. On acidification with HCl, the acids precipitated as colorless solids (36 mg, 80% yield). The mixed acids (30 mg) were separated by dissolving in acetone and streaking across a 9-in. wide No. 17 Whatman chromatographic paper. Development was with butanol – 2% ammonia (1:1) solvent and detection by short ultraviolet light. The spots were excised and Soxhlet extracted with acetone. After removal of the acetone under reduced pressure, the separated acids were taken up in bicarbonate, filtered, and precipitated with HCl. Yields were 3-ethoxy-4-methoxybenzoic acid (IX), 13 mg, m.p. 167.5–168° (R_f = 0.32

in butanol – 2% ammonia), and 3,4-diethoxy-5-methoxybenzoic acid (V*b*), 9 mg, m.p. 113–114° (R_f = 0.51 in butanol – 2% ammonia), identical with authentic samples by mixed melting point and infrared spectrogram.

PROTON MAGNETIC RESONANCE ABSORPTION IN ANHYDROUS SODIUM STEARATE[1]

R. F. GRANT[2] AND B. A. DUNELL

ABSTRACT

The proton magnetic resonance absorption in anhydrous sodium stearate has been investigated over the temperature range −182° C to 200° C. An abrupt change in the line width and the second moment has been observed between 113° C and 114° C, which corresponds to a known phase transition. The results suggest that at temperatures below 114° C the motion of the hydrocarbon-chain portion of the sodium stearate molecule is chiefly one of oscillation or rotation about the chain longitudinal axis. The hydrocarbon chains may be free to move about other axes at temperatures above 114° C, although the molecule as a whole retains a fixed position in the crystal lattice.

INTRODUCTION

The various mesomorphic phase transitions in sodium salts of long-chain fatty acids have been extensively studied by several physical methods (1). X-Ray, infrared, and nuclear magnetic resonance studies have indicated that the lower temperature transitions may represent the onset of rapid reorientation in the paraffin-chain part of the sodium soap molecule (2, 3, 4). Of particular interest are the phase transitions curd–supercurd at 89–92° C, supercurd–subwaxy at 110–117° C, and subwaxy–waxy at 125–135° C (4). The following is a proton magnetic resonance investigation of these transitions in sodium stearate, and is an extension and correction of the work in a previous communication (4).

EXPERIMENTAL

The sodium stearate was prepared from Eastman Kodak white label stearic acid, f.p. 68.1° C, which had been purified by repeated crystallization at −20° in acetone (5). The purified acid, f.p. 69.2° C, was dissolved in hot ethanol and titrated to a phenolphthalein end point with an aqueous ethanol solution of sodium hydroxide. The sodium stearate precipitate was filtered, dried in air, and melted under vacuum to remove residual solvents and to render it anhydrous (6). This compact, fused soap was remelted under vacuum in sample tubes; dry nitrogen was admitted to the system and the tubes were sealed off.

The nuclear magnetic resonance spectrometer and the methods of temperature control have been described previously (7). The temperature of the sample was measured with a thermocouple inserted in a well in the side of the sample tube. The line width was taken as the separation in gauss between points of maximum and minimum slope. The second moments of the resonance lines were obtained from the experimental derivative curves (8) by numerical integration and were corrected for the effects of modulation (9).

RESULTS

The proton magnetic resonance line widths, measured from −68° C to 130° C, are given by the open circles in Fig. 1. The line width was also measured at −182° C where it is 16.1 gauss. Particularly notable is the extensive decrease in the line width at temperatures above 30° C, and the abrupt change from a width of 2.8 gauss at 113° C to a width determined by the field homogeneity at 114° C. This abrupt narrowing coincides with

[1]*Manuscript received August 29, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C.
[2]*Holder of National Research Council Studentships. Present address: Division of Applied Chemistry, National Research Council of Canada, Ottawa.*

the supercurd–subwaxy phase transition. In all these measurements it was found necessary to maintain a given temperature for at least 2 hours before the proton magnetic resonance absorption was recorded. In most cases the temperature was maintained for about 4 hours, and above 100° C, in the vicinity of the phase transition, temperatures were held constant for about 12 hours. The filled circles in Fig. 1 represent one continuous experiment in which each temperature was maintained for only 30 minutes before the resonance

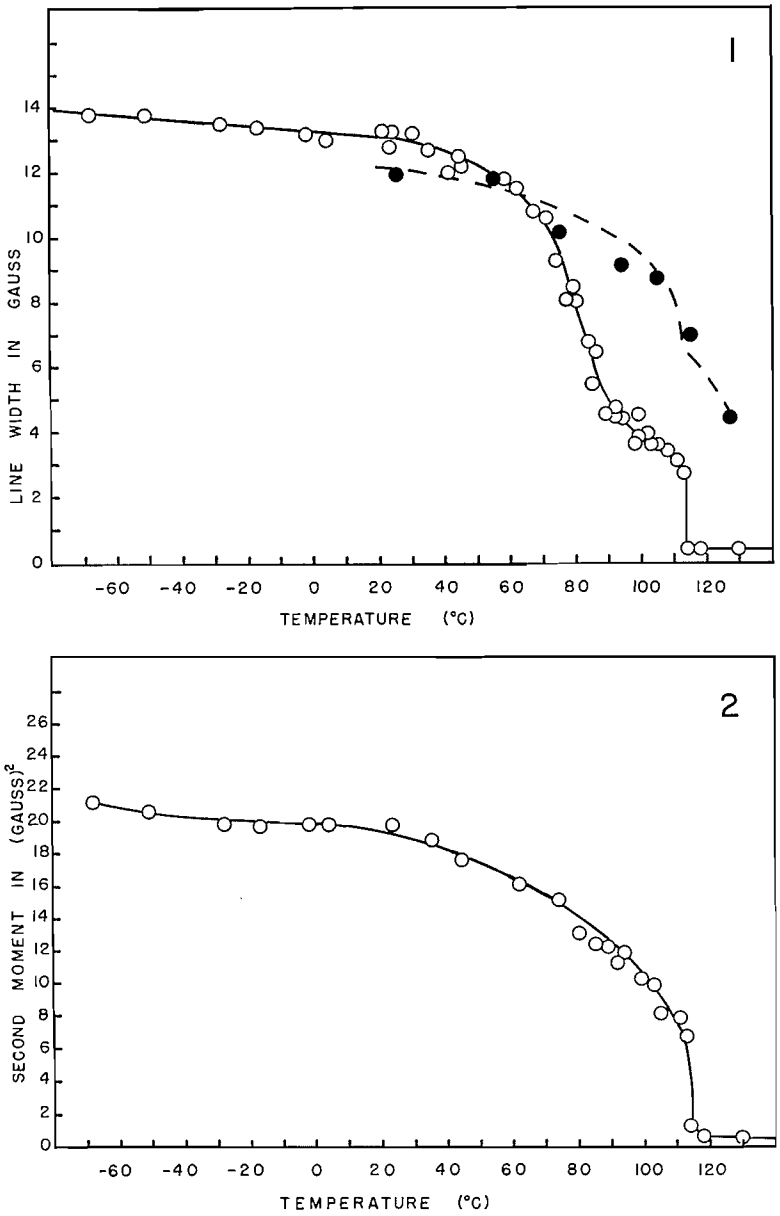

FIG. 1. Line width of sodium stearate as a function of temperature. Open circles, line width from samples at thermal equilibrium; filled circles, line width from samples not at thermal equilibrium; dashed line, line width from previous study.

FIG. 2. Second moment of sodium stearate as a function of temperature.

absorption was measured. These points fall closely along the discontinuous line in Fig. 1, which represents the course of the results in the original magnetic resonance studies on sodium stearate (4). It seems evident, therefore, that this previous work (4) reported a situation where thermal equilibrium had not been properly established although the line-width changes were reproducible.

The second moment of the proton magnetic resonance absorption in sodium stearate at $-182°$ C was found to be 28.0 ± 1.5 gauss^2. The behavior of the second moment over the temperature range $-68°$ C to 130° C is shown in Fig. 2. Like the line width, the second moment begins to decrease rapidly above about 30° C and changes abruptly from 6.7 gauss^2 to 1.2 gauss^2 as the temperature is raised through the supercurd–subwaxy transition. Above 114° C the second moment decreases even more: it is 0.6 gauss^2 at 118° C and 0.4 gauss^2 at 130° C, near the subwaxy–waxy transition temperature. Although the line width is very narrow above 114° C, the second moment does not approach zero because of small wings on the resonance absorption line. These wings decrease in amplitude and width as the temperature is raised, and there is some evidence for them up to 200° C; however, the amplitude becomes so small that it is difficult to determine a reliable second moment.

DISCUSSION

The X-ray diffraction analysis of most solid fatty acid salts shows that they have a layer structure in which the carboxyl ion ends lie in parallel sheets. Two such sheets form a double layer, and both individual sheets and the double layer are held together by positive ions. The long paraffin chains stick out parallel to each other from both sides of this electrically balanced double layer, with their longitudinal axes slightly inclined to it. Reliable and reproducible results are difficult to obtain from X-ray studies of sodium stearate and details of the molecular arrangement in the unit cell have not been determined (10). However, the unit cell cross section of sodium stearate (11) is almost identical with that of silver stearate (12), whose triclinic structure has been fairly well defined. Infrared studies have suggested that the higher sodium soaps also have a triclinic structure (3). In view of these similarities it seems reasonable to assume that the arrangement of sodium stearate molecules in the crystal lattice is very much the same as the arrangement of the silver stearate molecules. In the paraffin-chain portion, the carbon atoms are arranged in the zigzag configuration and it has been assumed that the bond angles are tetrahedral throughout. The carbon—hydrogen bond length is taken as 1.094 Å, and the carbon—carbon distance is 1.54 Å (13). On the basis of this knowledge of the structure of the sodium stearate unit cell, the second moment, S, of the proton magnetic resonance can be calculated (14).

For a polycrystalline sample the expression for the second moment S of the proton magnetic resonance in an assembly of protons and sodium nuclei is

$$[1] \qquad S = \frac{716}{N} \sum_{j>k} r_{jk}^{-6} + \frac{55}{N} \sum_{j,f} r_{jf}^{-6},$$

where N is the number of protons whose interactions are considered, r_{jk} is the distance between any two protons j and k, and r_{jf} is the distance between any proton j and sodium nucleus f. The contribution of the second part of equation [1] is very small for sodium stearate. The intramolecular second moment for sodium stearate was found to be 18.9 gauss^2 and the intermolecular second moment was 9.4 gauss^2 for a total of 28.3 gauss^2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

This compares quite well with the experimental value of 28.0 ± 1.5 gauss^2 found at $-183°$ C and it is assumed that molecular motion at frequencies comparable to or greater than the resonance line width is absent (15).

According to the theory of Gutowsky and Pake (16), both the width and second moment of the resonance absorption line should decrease when molecular reorientation becomes sufficiently rapid. A more recent treatment of the theory has shown that molecular motion should cause a change in the line shape such that the second moment remains constant at its rigid lattice value (17); as the line width narrows due to the motion, the tails of the line become extended. However, experimentally observed second moments usually decrease as the line width decreases, in agreement with the earlier theory (16). This is because the amplitude of the extended tail part of the resonance absorption line is comparable to the amplitude of the spectrometer noise, hence it is not observed when the experimental line is obtained. This seems to be the case with sodium stearate; the second moment and line width behave in roughly the same way with changing temperature and no extended tails were detected on the resonance absorption line with the spectrometer signal-to-noise ratio of 30.

Since the molecules in solid sodium stearate are arranged side by side as in a bundle of rods, one of the most likely forms of motion would be a rotation or oscillation about the longitudinal axis of the paraffin chain. The reduction in the intramolecular second moment due to the complete reorientation of the sodium stearate molecules about their longitudinal axes can be calculated by means of the treatment of Gutowsky and Pake (16). Also for some kinds of motion likely in solid long-chain paraffins, Andrew (18) has found that the intra- and inter-molecular contributions are reduced by about the same factor. Hence the total second moment for reorientation about the longitudinal axes of sodium stearate molecules is about 8.1 gauss^2. This corresponds to the experimental second moment found around 110° C or just prior to the supercurd–subwaxy transition as shown in Fig. 2. The second moment expected for torsional oscillation of the paraffin chains about their long axes in solid sodium stearate is given by the graph in Fig. 3. This was calculated by means of equation [2] originally derived by Andrew (18).

$$[2] \qquad \rho = 1 - \tfrac{3}{4}[(1 - J_0^2(\alpha)) \sin^2 2\gamma + (1 - J_0^2(2\alpha)) \sin^4 \gamma].$$

Here ρ is the ratio of the second moments for the oscillating and rigid cases, α is the angular amplitude of oscillation, γ is the angle between the internuclear vector and the axis of reorientation, and J_0 is a Bessel function.

The model of a paraffin chain undergoing torsional oscillation or complete reorientation about its longitudinal axis seems sufficient to account for most of the experimental results below 113° C. So far, however, the possible effect of the ionic layer formed at the carboxyl ends in solid sodium stearate has been ignored. It would seem reasonable to suppose that the portion of the paraffin chain nearest the strongly bonded ionic layer would be able to undergo torsional oscillation to a somewhat lesser extent than the portions of the chain farthest away from the ionic layer. Moreover, it has been shown that such a twisting about the longitudinal axis of the paraffin chain may require less energy of activation than is required in the case where the whole chain must be lifted over the potential barrier at the same time (19). A rigid ionic layer may also prevent the complete reorientation of the chain predicted for a second moment of about 8 gauss^2. However, this value could also be accounted for by a twisting chain that is also free to oscillate slightly in a direction perpendicular to the chain axis.

The very narrow line width which occurs between 113° C and 114° C is usually taken

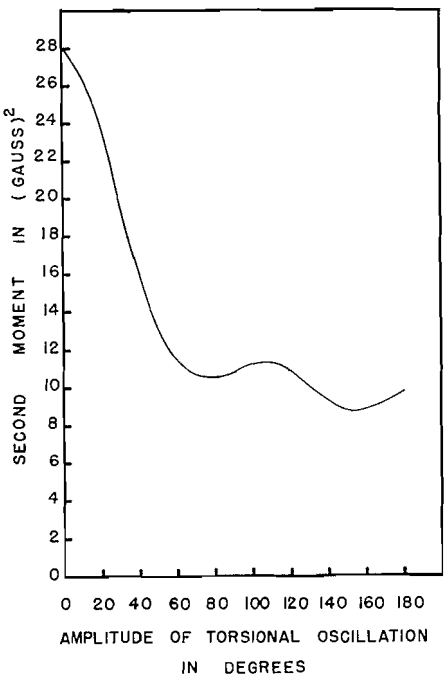

FIG. 3. Calculated effect of torsional oscillation on the second moment of sodium stearate.

to indicate that the whole molecule is reorienting about more than one axis (15). If molecular reorientation is isotropic, the intramolecular contribution to the second moment should average to zero. However, so long as the centers of mass of the molecules remain fixed, the intermolecular contributions will not average to zero and a small but finite second moment should be observed (20). The supercurd to subwaxy transition between 113° C and 114° C in sodium stearate appears to involve a change from rotation or twisting about the longitudinal axis of the paraffin chain to a condition where reorientation may be possible about other axes. Yet the second moment of 1.2 gauss² at 114° C suggests that the sodium stearate molecules are still fixed in the crystal lattice. This seems to agree with the conclusions drawn from recent X-ray studies on sodium stearate (2). Above the supercurd–subwaxy transition the lattice structure consists of a set of parallel ribbons, indefinite in length and packed in a rectangular array. The sodium carboxylate ends of the molecules fit into the ribbon and the hydrocarbon chains, in a liquid-like state (3), fill up the rest of the lattice.

The correlation frequency ν_c of the motion responsible for narrowing proton magnetic resonance absorption lines may be calculated (16) by means of the following equation:

$$[3] \qquad \nu_c = 4260\Delta H/\tan\left[(\pi/2)(\Delta H^2-B^2)/(A^2-B^2)\right].$$

Here ΔH is the line width in the line-narrowing region, B is the line width at temperatures above this region, and A is the line width below it. For sodium stearate B is taken as 2.8 gauss, which is the line width at 113° C just prior to the supercurd–subwaxy transition and A is 16.1 gauss, which is considered to be the rigid lattice line width at −182° C. The second moments, previously discussed, indicated that only motion about the molecular longitudinal axis is likely between these limits. It is assumed that for a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

given temperature this motion can be described by a single correlation frequency which varies with temperature T as

$$\nu_c = \nu_0 \exp (V/RT), \quad [4]$$

where V is analogous to an activation energy for the motion and R is the gas constant. The correlation frequencies from sodium stearate line widths, shown in Fig. 4, gave two

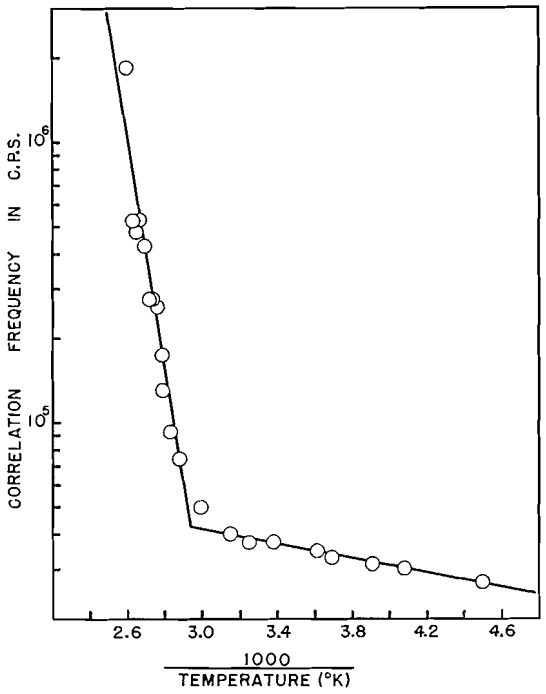

FIG. 4. Correlation frequency for sodium stearate as a function of inverse temperature.

activation energies: below about 65° C, V was 0.8 kcal/mole, and above 65° C, V was 19.2 kcal/mole. Finding two activation energies by this method may not be unusual, for a similar situation has been reported for polyethylene (21). For the small activation energy at low temperatures in polyethylene a small-amplitude torsional oscillation has been postulated, while at high temperatures the large activation energy is ascribed to rotational and translational modes of large amplitude (21). The case for sodium stearate may be similar, although the known crystal structure would not be expected to allow large translational modes below the supercurd–subwaxy transition. The activation energy of 19.2 kcal/mole seems to be of the right magnitude for a violent twisting or rotation of the paraffin chains (19) which leads to a radical change in the crystal structure.

ACKNOWLEDGMENTS

We thank the National Research Council for a studentship awarded to one of us (R. F. G.) and for a grant-in-aid of the research. We are also indebted to Professor C. A. McDowell for his interest in this problem.

CONSTITUTION OF AN ACIDIC XYLAN FROM TAMARACK (LARIX LARICINA)[1]

G. A. ADAMS

ABSTRACT

An acidic xylan isolated from tamarack wood contained arabinose, xylose, and uronic acid (1:17:3) and was homogeneous on examination by electrophoresis and sedimentation. Molecular weight estimations by four different methods showed a degree of polymerization of 20. Methylation and periodate oxidation showed that the xylan consisted of ca. 16 β-D-xylopyranose units joined by 1 → 4 glycosidic bonds with the possible occurrence of one 1 → 3 linkage. To this unbranched structure were attached as side branches, three single units of 4-*O*-methyl-D-glucuronic acid through C_2 and one unit of L-arabofuranose through C_3.

INTRODUCTION

The many xylans that have been isolated from land plants have all shown the same basic structure (1, 2, 3, 4). Variations in the xylans from individual species are provided by differences in the nature and number of single-unit side chains which are attached to the xylan chain and these differences have been summarized for a number of species of wood (4).

Xylans from softwoods have not been studied as extensively as those from hardwoods mainly because of the difficulty of separating them from glucomannans and other hemicelluloses. However, improved methods of fractionation will now permit this separation and the present paper reports the isolation and structure of an acidic xylan from tamarack.

The starting material was holocellulose prepared by chlorite delignification of extractive-free tamarack wood. Extraction with dilute alkali yielded a mixture of hemicelluloses from which the acidic xylan was separated by copper complexing. Evidence for the homogeneity of the purified hemicellulose was provided by single symmetrical peaks shown in the electrophoretic and sedimentation patterns (Fig. 1).

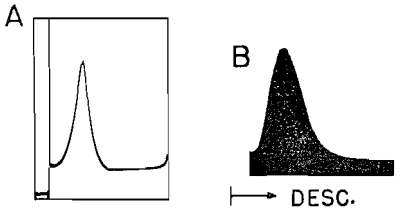

FIG. 1. (A) Sedimentation pattern of tamarack acidic xylan. (B) Electrophoresis pattern of tamarack acidic xylan.

The yield of purified hemicellulose, $[\alpha]_D$ −35°, was 1% (based on extractive-free wood) and arabinose, xylose, and uronic acid were present in a molar ratio of 1:17:3. There was a trace of rhamnose in the xylan hydrolyzate but no structural significance could be assigned to this sugar.

Hydrolysis of the hemicellulose yielded an aldobiouronic acid as the main acidic

product. Acetylation of the methyl ester methyl glycoside of the acid yielded a crystalline acetate (1) which established the identity of the original aldobiouronic acid as 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose. The hemicellulose was methylated and fractionated to give one main fraction. Methanolysis and hydrolysis yielded the following products: (1) methylated aldobiouronic acid (3.0 moles); (2) 2-*O*-methyl-D-xylose (1.0 mole); (3) 3-*O*-methyl-D-xylose (trace); (4) 2,3-di-*O*-methyl-D-xylose (10 moles); (5) 2,4-di-*O*-methyl-D-xylose (1.0 mole); (6) 2,3,4-tri-*O*-methyl-D-xylose (1.0 mole); (7) 2,3,5-tri-*O*-methyl-L-arabinose (0.90 mole).

Isolation of crystalline methyl-2-*O*-(2,3,4-tri-*O*-methyl-D-glucopyranosyl)-3-*O*-methyl-β-D-xyloside (2) from reduction of component 1 confirmed the earlier identification of the aldobiouronic acid and showed that the uronic acid was attached to C_2 of a xylose unit in the main chain.

The 2-*O*-methyl-D-xylose (component 2) represented branch points in the xylan chain and was found in the same molar amount as 2,3,5-tri-*O*-methyl-L-arabinose (component 7). It is probable, therefore, that the 2-*O*-methyl-D-xylose arose from those units in the xylan chain that carried single-unit L-arabofuranose side chains linked through C_3. The 3-*O*-methyl-D-xylose (component 3) probably arose from a slight amount of hydrolysis of the partially methylated aldobiouronic acid.

The 2,3-di-*O*-methyl-D-xylose (component 4) represented the main structural feature of the xylan, i.e. D-xylopyranose units joined in a straight chain by glycosidic bonds through C_1 and C_4. The presence of 1 mole of 2,4-di-*O*-methyl-D-xylose (component 5) could be accounted for by either a $1 \rightarrow 3$ linkage in the main chain or by incomplete methylation. It was unlikely that this component represented a non-reducing terminal xylose unit substituted at C_3 by an arabofuranose residue because all of the latter was accommodated by attachment to C_3 of xylose units in the chain. Xylans of red algae have been shown to contain $1 \rightarrow 3$ and $1 \rightarrow 4$ linkages (6) and there is evidence for $1 \rightarrow 2$ linkages in some of the xylans of aspen wood (7). On the other hand, Croon and Timell (8) have shown that C_3 is less reactive than C_2 in xylans and hence may not be completely methylated. Attempts to resolve this question by enzymic degradation of the tamarack xylan are now in progress.

The 2,3,4-tri-*O*-methyl-D-xylose (component 6) represented nonreducing terminal units and the amount found indicated a degree of polymerization (D.P.) of 20. The 2,3,5-tri-*O*-methyl-L-arabinose (component 7) was the only -*O*-methyl ether of arabinose present in the mixture and showed that all the residues of this sugar were attached as single-unit side chains. The ease with which the arabinose units were removed from the original hemicellulose by mild acid hydrolysis also confirmed that they were in the furanose form and attached as terminal groups. It has not been proved that these single arabofuranose units were attached directly to the main xylan chain with no xylose units interposed. However, this point has been established in other araboxylans by two different methods (9, 10) and it is very likely that the present araboxylan is similar.

From the foregoing evidence it was clear that the arabomethoxyglucuronoxylan consisted of 16 β-D-xylopyranose units linked $\beta 1 \rightarrow 4$ with the possible occurrence of one $\beta 1 \rightarrow 3$ linkage. To this unbranched structure were attached, as single-unit side chains, three 4-*O*-methyl-D-glucuronic acid units through C_2 and one L-arabofuranose unit through C_3.

Such a molecule would consume 0.85 mole of periodate and yield 0.15 mole of formic acid per monomer unit and the experimental values of 0.87 mole of periodate and 0.15 mole of formic were in agreement with these calculations. The D.P. of the polysaccharides

was 19–20 based on formic acid production by periodate oxidation and 20 on the basis of nonreducing terminal D-xylose units in the methylated products. The values are in reasonable agreement with those given by viscosity (D.P. 20–22) and by the method of vapor pressure lowering (11, 12) (D.P. 16). On the basis of this agreement between four methods of molecular weight estimation the molecule is considered to contain about 20 sugar units. This value is small in comparison with the D.P. values reported for xylans which range from 85–220 (13, 4). The xylan under examination was less than 10% of the original crude hemicellulose and represents a molecular species which is about equivalent in size to the repeating unit of other softwood xylans (14, 15). It seems probable that the xylans from one wood species exist in a wide range of molecular sizes. It has already been shown that xylans from one wood source have differences in chemical composition (16).

The structure of the arabomethoxyglucuronoxylan from tamarack is similar, in general, to that of other xylans isolated from coniferous woods. While the xylan of loblolly pine (16) and Norway spruce (17) do not contain L-arabinose units, those of European larch (18), Sitka spruce (15), and western hemlock (14) all contain small amounts of arabinose. The proportions of 4-*O*-methyl-D-glucuronic acid, L-arabinose, and D-xylose are almost the same in Sitka spruce (15), western hemlock (14), and tamarack.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated, melting points are corrected, and all evaporations were done at 35° C or less.

Paper Chromatography

Chromatographic separations were carried out using the following solvent systems (v/v ratios): (*a*) pyridine:ethyl acetate:water (2:1:2); (*b*) methyl ethyl ketone:water (2:1); (*c*) ethanol:benzene:water (47:200:15); (*d*) *n*-butanol:ethanol:water (40:11:19); (*e*) ethyl acetate:acetic acid:formic acid:water (18:3:1:4). Separations were made by the descending technique on Whatman No. 1 filter paper. Sugars were located on the paper by *p*-anisidine hydrochloride spray reagent (19).

Preparation of the Hemicellulose

A tamarack (*Larix laricina*) log, 47 years old, was converted to shavings, and then ground in a Wiley mill. The wood particles were thoroughly extracted successively with benzene:ethanol (2:1), ethanol, and water. From the aqueous solution an arabogalactan was recovered in about 6% yield; its constitution has been determined and was the subject of an earlier publication (20).

The water-extracted residue was converted to chlorite holocellulose (21) and was extracted with sodium hydroxide solution (1%) at room temperature for three successive 24-hour periods. The alkaline solutions and washings were combined, neutralized with acetic acid, concentrated at 25° C under reduced pressure, and the salts removed by dialysis in running water. The crude hemicellulose was recovered by freeze-drying, and the yield was 12.9% (extractive-free wood basis). Hydrolysis of the hemicellulose in *N* sulphuric acid for 12 hours at 100° C and chromatographic examination of the hydrolyzate ($[\alpha]_D^{25}$ +22°) showed the presence of xylose, arabinose, rhamnose, mannose, glucose, galactose, and a uronic acid. The number of sugars in the hydrolyzate indicated that more than one polysaccharide was present. Further evidence of heterogeneity was provided by electrophoretic examination in a Tiselius-type apparatus in borate buffer which showed two main peaks and indications of additional minor components.

Fractionation of the Hemicellulose

The crude polysaccharide (53 g) was dissolved, with stirring, in water (5 l.) and the insoluble material (fraction 1) was removed by centrifuging. A solution of 7% copper acetate solution (142 ml) was added to the supernatant and the precipitate which formed was removed by centrifuging (fraction 2). Addition of ethanol gave a series of fractions (No. 3 – No. 8) which were centrifuged off, freed of copper by acidification and dialysis, and recovered by freeze-drying. The results are shown in Table I.

TABLE I

Fractionation of hemicellulose
(53.14 g in 5 liters of water)

Fraction No.	Precipitating agent	Yield, g	Sugars present*				
			Xyl.	Arab.	Gal.	Glu.	Rham.
1	—	8.50	x	x	x	Tr.	Tr.
2	7% Copper acetate (143 ml)	3.41	x	x	x	Tr.	Tr.
3	Ethanol (570 ml)	22.91	x	x	x	Tr.	Tr.
4	Ethanol (142 ml)	1.22	x	x	x	Tr.	Tr.
5	Ethanol (199 ml)	2.01	x	x			Tr.
6	Ethanol (241 ml)	1.32	x	x			Tr.
7	Ethanol (285 ml)	1.24	x	x	Tr.		Tr.
8	Ethanol (570 ml)	1.72	x	x	x		Tr.
9	—	2.96	x	x	x		Tr.

*All fractions contain uronic acids.

On the basis of these results fractions No. 4 and No. 7 were combined and refractionated. The purified material was then combined with fractions No. 5 and No. 6. The last trace of copper was removed from the hemicellulose by passage of its aqueous solution over Amberlite IR-120.

The yield of purified xylan was 8.0% of the original crude hemicellulose. Analysis gave an arabinose:xylose:uronic acid ratio of 1:17:3; methoxyl, 2.9%; nitrogen, nil; and $[\alpha]_D^{25}$ −34.8° (*c*, 1.03% in water). The sugar mixture obtained on acid hydrolysis had $[\alpha]_D^{25}$ +24°.

Graded Hydrolysis

Hemicellulose (51 mg) was heated on a boiling-water bath with 5 ml of hydrochloric acid (0.01 *N*). At 30-minute intervals the hydrolyzate was examined chromatographically in solvent (*a*). In 3.5 hours the arabinose had been removed from the hemicellulose along with only a minor amount of xylose. The degraded hemicellulose was recovered with ethanol. Hydrolysis with *N* sulphuric acid and chromatographic examination of the hydrolyzate showed mainly xylose, some uronic acids, and only traces of arabinose.

Periodate Oxidation

Tamarack hemicellulose (100 mg duplicate samples) was dissolved in water (50 ml) and oxidized by 0.1 *M* sodium metaperiodate (50 ml) in the dark at 16° C. Analysis for periodate consumption and formic acid production (22) gave the following results.

Time, hours	24	48	72	120
Formic acid, moles per anhydropentose unit	0.14	0.145	0.15	0.16
Periodate consumption, per anhydropentose unit	0.54	0.61	0.86	0.87

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

In a separate experiment, the hemicellulose (50 mg) was oxidized for 120 hours as previously described. The excess periodate was destroyed by ethylene glycol and the solution was dialyzed. The oxidized hemicellulose was recovered by freeze-drying and then hydrolyzed with *N* sulphuric acid. Chromatographic examination of the hydrolyzate showed only xylose to be present; the amount was approximately 25% of that originally present in the hemicellulose.

Preparation of Uronic Acids from the Xylan

Xylan (100 g) was stirred overnight in 0.5 *N* sulphuric acid at room temperature and then heated at 100° C for 8 hours. After neutralization of the acid, the neutral sugars and uronic acids were separated on a column of Dowex 1-X[4] (HCO_3^-) and the uronic acids recovered by elution with *N* formic acid by procedures already described (23). Chromatographic examination in solvent (*e*) showed the presence of four components with R_x values (movement relative to xylose) as follows: 0.29, 0.42, 0.70, and 1.30 (fractions 1, 2, 3, and 4). Fraction 4 was chromatographically identical with 4-*O*-methyl-D-glucuronic acid.

The uronic acid fractions (2.1 g) were separated on a cellulose column (27×2.5 cm) using solvent (*e*). Fraction No. 3 was mixed with some of fraction No. 4 and was purified by reseparating on sheets of Whatman No. 1 filter paper using solvent (*e*). The acids were eluted with water and concentrated *in vacuo*. Hydrolysis of fraction No. 3 with *N* sulphuric acid for 20 hours at 100° C yielded xylose and 4-*O*-methyl-D-glucuronic acid.

Identification of 2-O-(4-O-Methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose

The aldobiouronic acid (fraction No. 3) was a slightly yellowish solid, $[\alpha]_D^{25}$ +98° (*c*, 1.0% in water). Anal. Calc. for $C_{12}H_{20}O_{11}$: OCH_3, 9.1%. Found: OCH_3, 9.0%. The acid (57 mg) was converted to methyl 2-*O*-[methyl-(4-*O*-methyl-α-D-glucopyranosyl)uronate]-D-xylopyranoside by heating with 2.5% methanolic hydrogen chloride (3 ml) for 8 hours. The methyl ester methyl glycoside was acetylated according to Timell (24). The acetylated product was recovered and crystallized from ethyl ether, yield 30.7 mg. Recrystallization three times from ethyl ether yielded crystalline methyl-2-*O*-[methyl-(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate]-3,4-di-*O*-acetyl-D-xylopyranoside, m.p. 201–203°, $[\alpha]_D^{25}$ +106° (*c*, 1.0% in chloroform). Anal. Calc. for $C_{22}H_{32}O_{15}$: OCH_3, 17.3%. Found: OCH_3, 17.2%. These values are in good agreement with the reported values (24).

Methylation of the Xylan

The xylan (6.1 g) was methylated five times with dimethyl sulphate (65 ml) and 45% sodium hydroxide (120 ml) and the product was isolated from the reaction mixture by continuous extraction with chloroform after acidification. Material that was not extracted by chloroform was recovered from the aqueous solution by dialysis and freeze-drying. The combined products (6.2 g) showed a definite hydroxyl absorption at 3500–3600 cm^{-1}. Four methylations with Purdies reagents (methyl iodide, 60 ml, and silver oxide, 10 g) yielded the fully methylated xylan (5.28 g) showing no hydroxyl absorption at 3500-3600 cm^{-1}; $[\alpha]_D^{25}$ −30° (*c*, 1% in chloroform); methoxyl, 39.23% (calculated methoxyl, 40.83%). Fractionation of this material by mixtures of chloroform:petroleum ether gave one main fraction constituting 94% of the mixture and having the same analytical values as given above.

Hydrolysis of Methylated Xylan

The fully methylated xylan (4.9 g) was heated in 8% methanolic hydrogen chloride at 80° C for 16 hours. Acid was removed by silver carbonate and the filtrate was evaporated by a stream of air at room temperature. The residue was heated at 65° C for 2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hours with a saturated solution of barium hydroxide to convert the uronosides to their barium salts. Methylated glucosides (3.78 g) were recovered from this solution by extraction with chloroform and methylated uronic acids (1.53 g) were isolated by evaporation of the aqueous residue after removal of the barium ions by Amberlite IR-120.

Methyl glucosides of the neutral sugars were analyzed by gas–liquid partition chromatography (25, 26) giving the quantitative data cited in the discussion. The procedure also provided additional evidence for the identities of the components by comparison of their relative retention volumes with those of authentic samples. To obtain sufficient amounts of the methylated sugars for complete identification the mixture of glycosides was hydrolyzed by 88% formic acid at 97° C for 24 hours. The mixture of sugars (2.43 g) recovered from the hydrolyzate after neutralization with Amberlite IR-4B(OH) showed the following components on paper chromatography in solvents (*b*) and (*c*): 2,3,5-tri-*O*-methyl-L-arabinose, R_g 1.07, R_g 1.02; 2,3,4-tri-*O*-methyl-D-xylose, R_g 1.03, R_g 0.89; 2,3-di-*O*-methyl-D-xylose, R_g 0.69, R_g 0.25; 2,4-di-*O*-methyl-D-xylose, R_g 0.55, R_g 0.25; 2-*O*-methyl-D-xylose, R_g 0.26, R_g 0.04; 3-*O*-methyl-D-xylose, R_g 0.27, R_g 0.08. An attempt to resolve this mixture by chromatography on a cellulose column using solvent (*b*) was unsuccessful, all fractions obtained being mixtures of two or more components. Separations were therefore carried out on paper sheets (Whatman No. 3 MM with Whatman No. I wicks) using solvents (*b*), (*c*), and (*d*).

Identification of Methylated Sugars

2,3,5-Tri-O-methyl-L-arabinose

The sugar was dissolved in water, clarified with charcoal, and dried to constant weight (134 mg), $[\alpha]_D^{25}$ −33° (*c*, 1% in water), and OMe, 48.0% (calculated for $C_8H_{16}O_5$: OMe, 48.4%). Chromatographic examination in solvents (*b*) and (*c*) showed that the sugar had a rate of movement identical with that of authentic 2,3,5-tri-*O*-methyl-L-arabinose. A portion of the sugar (70 mg) was oxidized with bromine to yield 2,3,5-tri-*O*-methyl-L-arabonic acid. Distillation (bath temperature, 120–145° C at 0.020 mm) lactonized the acid, which on treatment with methanolic ammonia, yielded 2,3,5-tri-*O*-methyl arabonamide in crystalline form. Recrystallization from methanol – petroleum ether solution yielded pure crystals, m.p. 136° C, $[\alpha]_D^{25}$ −18° (*c*, 1% in water); these values agree closely with those reported for this compound (27).

2,3,4-Tri-O-methyl-D-xylose

Chromatographic examination in solvents (*b*) and (*c*) showed the syrup to be 2,3,4-tri-*O*-methyl-D-xylose units with a trace of the trimethyl arabinose. The syrup was dissolved in ether and a few drops of petroleum ether added; on seeding with 2,3,4-tri-*O*-methyl-D-xylose, crystallization occurred. Recrystallization from the same solvent yielded crystals having a melting point of 88–89° C, $[\alpha]_D^{25}$ +20° (*c*, 1.0 in water). Anal. calc. for $C_8H_{16}O_5$: OMe, 48.4%. Found: OMe, 48.2%.

2,3-Di-O-methyl-D-xylose

The syrup (1492 mg) had $[\alpha]_D^{25}$ +23° (*c*, 1.1% in water) and OMe, 34.5%. Calculated for $C_7H_{14}O_5$: OMe, 34.8%. Chromatographic examination in solvents (*b*) and (*c*) showed that it moved at the same rate as 2,3-di-*O*-methyl-D-xylose. On cooling an ethyl ether solution of the sugar, crystals were obtained which on recrystallization from the same solvent had a melting point of 91–92° (undepressed with an authentic sample). The anilide was formed by refluxing aniline (200 mg) with the sugar (300 mg) in methanol (5 ml) for 2.5 hours. The crystalline anilide was recrystallized twice from ethyl acetate and had a melting point of 123–124° (undepressed with an authentic sample of 2,3-di-*O*-methyl-N-phenyl-D-xylosylamine.

For personal use only.

2-O-Methyl-D-xylose

The syrup (139 mg) had the same rate of movement on paper in solvents (*b*) and (*c*) as 2-*O*-methyl-D-xylose. After clarification with charcoal in 50% methanol, the syrup crystallized partially. Recrystallization from methanol – petroleum ether solution yielded 2-mono-*O*-methyl-D-xylose, m.p. 132–133°, $[\alpha]_D^{25}$ +34° (*c*, 1% in water).

3-O-Methyl-D-xylose

Electrophoresis of this sugar on paper strips in borate buffer (pH 9.2), with known references differentiated it from 2-*O*-methyl-D-xylose, which moves only slightly compared with the rapid migration of the 3-*O*-methyl sugar. The amounts recovered were too small to permit other identification.

Methylated Aldobiouronic Acid

The methylated aldobiouronic acid (1.53 g) which had been separated from the neutral glycosides was converted to the methyl ester methyl glycoside by refluxing for 6 hours with 4% methanolic hydrogen chloride. This product was then reduced with lithium aluminum hydride in ether solution to yield methyl 2-*O*-(2,3,4-tri-*O*-methyl-D-glucopyranosyl)-3-*O*-methyl-β-D-xyloside, which crystallized partially on standing. Recrystallization from ethyl acetate yielded a product with a melting point of 166–168° and $[\alpha]_D^{25}$ +80° (*c*, 1.05% in water) in good agreement with the reported values (14). Anal. Calc. for $C_{16}H_{20}O_{10}$: C, 50.25%; H, 7.91%; OMe, 40.6%. Found: C, 50.10%; H, 8.01%; OMe, 40.2%.

Electrophoresis

Hemicellulose (150 mg) was dissolved in 0.05 *M* borate buffer and dialyzed against the buffer at 4° C for 24 hours. The electrophoretic separation was made in a Spinco apparatus Model H for 270 minutes; the acidic xylan moved as a single symmetrical peak with mobility (μ) = 5.65×10^{-5} cm^2 v^{-1} sec^{-1}. The diagram is shown in Fig. 1.

Sedimentation

Hemicellulose (2%) in 0.05 *M* borate buffer was centrifuged in a Model E Spinco ultracentrifuge. The rotor speed was 59,780 r.p.m. and the photograph was taken on attaining full speed (after 8 minutes). The pattern shows one sharp peak (Fig. 1).

Molecular Weight

Two physical methods of estimating molecular weight were used.

Viscosity.—Viscosity measurements were made on cupriethylenediamine solutions of the hemicellulose at concentrations of 0.08, 0.04, 0.02, 0.01, and 0.005%. Flow times were measured in an Ostwald-Cannon-Fenske type viscometer in a bath maintained at 20°± 0.02° C. The value for intrinsic viscosity [η] was substituted in the equation D.P. = K [η], where value of K = 212 (13), D.P. value = 20–22.

Vapor Pressure.—The method used was that developed by Sirianni and Puddington (11). The methylated hemicellulose was dissolved in benzene and the difference in vapor pressure between the pure solvent and the solution was measured at concentrations of 5.20, 3.72, 3.01, 2.56, 2.11, 1.90, 1.06% (g/100 g solution). The molecular weight at infinite concentrations was calculated according to Raoult's law. A straight line was fitted through the experimental points and extrapolated to infinite dilution. The observed molecular weight (number average) was 2900, therefore D.P. = 16.

PYRAZOLINES. PART II[1]

DONALD E. MCGREER, WING WAI, AND GEORGE CARMICHAEL

ABSTRACT

Product analysis has been carried out on the pyrolysis reaction in the liquid and vapor phase of 4- and 5-methyl-3-carbomethoxy-Δ^2-pyrazolines and 3-methyl-3-carbomethoxy-Δ^1-pyrazoline. The proportion of cyclopropane product was found to be greater than earlier reports had indicated and was higher for the vapor-phase pyrolysis than for the liquid-phase reaction. Vapor-phase pyrolysis of Δ^2-pyrazolines was found to require a catalyst, such as potassium hydrogen phosphate, which is believed to make possible the transformation of the Δ^2-pyrazoline into the pyrolyzable Δ^1-pyrazoline.

The pyrolysis of carbalkoxypyrazolines and related compounds has been shown to be a useful synthetic method for the preparation of derivatives of cyclopropane only in a limited number of cases. The method is particularly useful when there are carbalkoxy groups in the pyrazoline nucleus at positions 3 and 4 (1–5) and when there is an alkyl substituent and carbalkoxy substituent at the 3 position (1, 6, 7). For example, von Auwers (1) reported that 3-methyl-3-carbomethoxypyrazoline gave a product which contained 63% of methyl 1-methylcyclopropanecarboxylate and that 3,4-dicarbomethoxy-4-methylpyrazoline gave methyl 1-methylcyclopropane-1,2-dicarboxylate as the sole product. In general it has also been found that 3-carbomethoxypyrazolines with alkyl substitution at the 4 or 5 positions yield no cyclopropane product.

Recently we reported (8) that 3-carbomethoxy-Δ^2-pyrazoline yields a product which contains 32% of methyl cyclopropanecarboxylate. In a continuation of this work the 4- and 5-methyl-3-carbomethoxy-Δ^2-pyrazolines and 3-methyl-3-carbomethoxy-Δ^1-pyrazoline have been found to yield products containing cyclopropane derivatives. Upon further investigation of the pyrolysis reaction we have found that the proportion of cyclopropane derivative in the product is increased considerably when the pyrolysis is carried out in the vapor phase. For example, under these conditions 3-carbomethoxy-Δ^2-pyrazoline yields a product which contains 62% of methyl cyclopropanecarboxylate, an increase of 30% over the liquid-phase reaction.

The results of the pyrolysis of the three isomeric methyl-3-carbomethoxypyrazolines is shown in Table I and illustrated in Chart I. The liquid-phase pyrolyses were carried out by heating the pyrazoline in a distillation apparatus to a temperature at which nitrogen evolution was rapid and distillation of the product occurred as it was formed. The vapor-phase pyrolyses were carried out by dropping the liquid pyrazoline on beads or other packing material in a vertical tube heated to about 200° and connected to a vacuum system which maintained a pressure of 2 to 5 mm in the tube. The Δ^1-pyrazoline readily pyrolyzed when a glass bead packing was used but the Δ^2-pyrazolines were unchanged even with the beads at 500° unless the tube was charged with a catalyst (potassium hydrogen phosphate was used) to promote transformation of the Δ^2-pyrazoline to the Δ^1-form. This observation may be taken as further evidence that it is the Δ^1-form of the pyrazoline which pyrolyzes and not the Δ^2-form. Jones (9) and Beech *et al.* (10) have also obtained strong evidence in support of this postulate.

It is not possible to determine with certainty whether pyrolysis in the tube is occurring in the vapor phase or on the surface of the packing material. The catalyst, potassium

TABLE I
Product analysis from pyrazoline pyrolyses

Substituent in 3-carbomethoxy-pyrazoline	Phase	Proportion of components in the product in %				
		Cyclo-propane	α,β-Unsaturated ester		β,γ-Unsaturated ester	
			cis	trans	cis	trans
None	Liquid	32	30	31	7	
	Vapor	62	20	12	6	
3-Methyl	Liquid	65	15	15	5*	
	Vapor	85	7	4	4	
4-Methyl	Liquid	4	88		8	
	Vapor	26	62		12	
5-Methyl	Liquid	29	23*	43*	—	5
	Vapor	74†	12	10	—	4

*These compounds have not been previously reported and are tentatively identified from their N.M.R. and infrared spectra.
†Chromatography through a dinonyl phthalate or Ucon Polar column did not effect separation of the cis and trans esters. Infrared analysis of the acid obtained from the ester by hydrolysis indicated it to be 40% cis and 60% trans.

hydrogen phosphate, when added to the liquid-phase pyrolysis of 3-carbomethoxy-Δ^2-pyrazoline gives a lower yield of product which has approximately the same composition as the normal liquid-phase pyrolysis product. Because of this fact and since the boiling points of the pyrazolines at 2.5 mm are below the temperature at which pyrolysis occurs it is assumed that the pyrolysis takes place in the vapor phase. Further studies are now underway to determine the effect of catalyst, temperature, and pressure on the vapor-phase pyrolysis and to develop the method as a synthetic route to cyclopropane derivatives.

The pyrazolines used in the pyrolysis studies were prepared by the addition of diazomethane to the appropriate α,β-unsaturated ester. 3-Methyl-3-carbomethoxy-Δ^1-pyrazoline is a colorless liquid whereas the 4- and 5-methyl and the unsubstituted 3-carbomethoxypyrazolines are low-melting colorless solids which readily become straw-colored in the presence of air. The latter three are assigned the Δ^2-structure resulting from conjugation of the double bond with the ester carbonyl on the basis of their infrared spectra, which show N—H stretch and a conjugated carbonyl absorption.

The products from the pyrazoline pyrolyses were isolated by vapor chromatography and were identified from their physical properties. Three of these products (methyl 2-methyl-3-butenoate and methyl *cis*- and *trans*-2-pentenoate) have not previously been reported and the structures are tentatively assigned from the analysis, N.M.R., and infrared data and from the fact that each occur in equilibrium studies on known isomeric olefins. The evidence for these assignments is given in the experimental section.

The composition of the olefin portion of the pyrolysis product is in general not an equilibrium mixture as can be seen by a comparison of the equilibrium results in Table II with the pyrolysis results in Table I. The equilibrium values were determined by heating olefin samples at 250° for 2 weeks. The equilibrium was reached in each case by starting with two isomeric olefins and the equilibrium mixtures were analyzed by vapor chromatography. In general the olefin product from the pyrolysis reaction is richer in the *cis*-α,β-unsaturated olefin than is the equilibrium mixture and in many cases the cis-to-trans ratio approaches 1. A ratio of about 1 would be expected if both olefins were formed from the same high-energy intermediate for which the transition state to each olefin would be approximated by the intermediate rather than the product (11).

TABLE II

Equilibrium composition in % after equilibration at 250° C

	α,β-Unsaturated ester		β,γ-Unsaturated ester	
Initial olefin	cis	trans	cis	trans
Methyl *trans*-crotonate (8)	12	83	5	
Methyl *cis*-crotonate (8)	12	84	4	
Methyl tiglate	14	84	2	
Methyl 2-methyl-3-butenoate	14	82	4	
Methyl senecioate	84		16	
Methyl 3-methyl-3-butenoate	86		13	
Methyl *trans*-2-pentenoate	7	47	—*	46
Methyl *cis*-2-pentenoate	7	48	—*	45

*A new peak appeared in the chromatogram having one-half the area of the *cis*-2-pentenoate but was not identified.

The percentage of β,γ-unsaturated ester formed in the various reactions studied thus far seems remarkably constant and does not seem to be dependent on the relative stability of α,β- and β,γ-unsaturated products. This may mean that the β,γ-unsaturated product is also formed from the same intermediate from which the other products are formed and possibly by a proton migration (12).

The change in product composition between the liquid-phase reaction and the vapor-phase reaction is quite interesting and may make the vapor-phase reaction a feasible method for the preparation of a number of cyclopropane derivatives not readily available at the present time. The effect of the phase on the reaction may indicate that at least part of the olefin product in the liquid phase is formed by a bimolecular process which is reduced in favor of unimolecular processes in the high dilution of the vapor phase. It is therefore possible that high dilution in a solvent may also be useful for the preparation of cyclopropane derivatives where reaction in the vapor phase is not possible.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Most boiling points were determined by the micro inverted capillary method. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrometer using sodium chloride optics. N.M.R. spectra were recorded on a 40 Mc/s Varian spectrophotometer with field stabilizer VK 3506 and the methylene chloride used as an external standard was observed to have a value of 4.60 τ. The vapor chromatograph unit was an Aerograph model A-100-C.

Methyl-3-carbomethoxypyrazolines

The pyrazolines were prepared from diazomethane plus methyl methacrylate, diazomethane plus methyl crotonate, and diazoethane plus methyl acrylate. Ether solutions of the diazoalkane were prepared from the corresponding nitrosourea by treatment with 40% potassium hydroxide and were dried over potassium hydroxide but were not distilled. The α,β-unsaturated ester was added slowly to the ether solution until the color of the diazoalkane disappeared. The reaction to form the 4-methyl derivative took several hours but the 3- and 5-methylpyrazolines formed almost immediately at room temperature. These pyrazolines have been reported previously (1) but the following physical constants were not included in the report. The yields given are based on the reagent used in lowest molar quantity indicated in parentheses after the yield.

3-Methyl-3-carbomethoxy-Δ^1-pyrazoline: b.p. 89°/1.5 mm, yield 57% (nitrosourea).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The infrared spectrum (10% in chloroform) showed no absorption due to N—H or C=N. The ester carbonyl appeared at 1734 cm^{-1}.

4-Methyl-3-carbomethoxypyrazoline: b.p. 98/1.2 mm, m.p. 26–27°, yield 35% (nitrosourea). The infrared spectrum (10% in chloroform) had bands at 3400, 1705, and 1566 cm^{-1} assigned to the N—H, C=O, and C=N functions (13).

5-Methyl-3-carbomethoxypyrazoline: b.p. 96°/1 mm, m.p. 37–38°, yield 77% (methylacrylate). The infrared spectrum (10% in chloroform) had bands at 3420, 1706, and 1568 cm^{-1} assigned to the N—H, C=O, and C=N functions (13).

Pyrolysis of 3-Methyl-3-carbomethoxy-Δ^1-pyrazoline

3-Methyl-3-carbomethoxy-Δ^1-pyrazoline (10 g, 0.07 mole) was heated in a distillation apparatus in an oil bath. At a bath temperature of 110° pyrolysis was indicated by the evolution of a gas and at 150° it became vigorous. Distillation yielded 7.0 g (88%) of a colorless product boiling up to 141°. Four components were isolated by vapor chromatography and were identified as indicated below where boiling point, refractive index, retention time in the vapor chromatogram using a 10-ft Ucon Polar column of 0.25-in. diameter with a helium flow rate of 67 cc/minute, and percentage of the total product determined by the weights of paper cuts of the peaks are given. In all chromatographic analyses it is assumed that the thermal conductivities of the components are close enough to each other compared to helium to be assumed equal.

Methyl tiglate: b.p. 137–139°, n_D^{24} 1.4353 (lit. (14) b.p. 139.4–139.6°, n_D^{20} 1.4370), 29.1 minutes, 15%.

Methyl angelate: b.p. 127–128°, n_D^{20} 1.4320 (lit. (14) b.p. 127.6–127.8°, n_D^{20} 1.4321), 19.5 minutes, 15%.

Methyl 1-methylcyclopropanecarboxylate: b.p. 122.5–123° (lit. (15) b.p. 121–123°), n_D^{24} 1.4198, 17.9 minutes, 65%.

Methyl 2-methyl-3-butenoate: b.p. 115–116°, n_D^{24} 1.4091, 13.3 minutes, 5%. Calc. for $C_6H_{10}O_2$: C, 63.11; H, 8.84. Found: C, 62.81; H, 8.79. The physical constants for the isomer methyl α-ethylacrylate are b.p. 122–123° and n_D^{20} 1.4243 (14). The structure was confirmed from the infrared spectrum (10% in carbon tetrachloride), which showed absorption at 1740 cm^{-1} and 1640 cm^{-1} indicative of a non-conjugated ester and a carbon–carbon double bond (16). The N.M.R. spectrum (0.20 ml per ml of carbon tetrachloride) had a complex multiplet in the olefin hydrogen region with peaks at 4.14, 4.36, 4.57, 4.82, 4.89, 5.22, and 5.27 τ. Other peaks were due to the ester methyl, 6.42 (singlet), the tertiary hydrogen, 6.88 (quartet with $J \simeq 7$ c.p.s.), and the alkyl methyl, 8.83 (doublet with $J \simeq 7.2$ c.p.s.) (17).

Vapor-Phase Pyrolysis of 3-Methyl-3-carbomethoxy-Δ^1-pyrazoline

The lower portion of a 50 cm × 25 mm tube was placed in a vertical position in a tube furnace 25 cm in length and heated to 200°. The tube was filled to 35 cm from its lower end with $\frac{5}{8}$ in. diameter pyrex beads. The portion of the tube above the furnace was heated to 100° with a heating coil. The tube was fitted at the top with a pressure-equalized dropping funnel and at the bottom with two traps in series connected to a vacuum system. The traps were cooled with acetone – Dry Ice mixtures.

Two grams of 3-methyl-3-carbomethoxypyrazoline, b.p. 89°/1.5 mm, was added dropwise to the pyrolysis tube held at a pressure of 2 to 5 mm. The pyrolysis product was analyzed by vapor chromatography as in the analysis of the liquid-phase pyrolysis product and was found to contain 4% of methyl 2-methyl-3-butenoate, 85% of methyl 1-methylcyclopropanecarboxylate, 7% of methyl angelate, and 4% of methyl tiglate.

Isomerization Studies on Methyl Tiglate and Methyl 2-Methyl-3-butenoate

Ampoules containing 100 mg of methyl tiglate and methyl 2-methyl-3-butenoate isolated from the pyrolysis mixture were heated in a furnace at 250° for 2 weeks. The samples were analyzed by vapor chromatography in the same manner as the product from the pyrolysis of 3-methyl-3-carbomethoxypyrazoline and was found to contain from methyl tiglate and methyl 2-methyl-3-butenoate, respectively, methyl 2-methyl-3-butenoate 2%, 4%; methyl angelate 14%, 14%; and methyl tiglate 84%, 82%. The only new peak which might possibly be due to the isomer methyl α-ethylacrylate was a peak at 11.7 minutes, which showed a maximum area of 0.5 that of the methyl 2-methyl-3-butenoate. Analysis with a dinonyl phthalate column failed to show any new peaks.

Vapor-Phase Pyrolysis of 3-Carbomethoxy-Δ^2-pyrazoline

The apparatus used was identical with that used for the pyrolysis of 3-methyl-3-carbomethoxy-Δ^1-pyrazoline except that the pyrolysis tube above the furnace was heated with heating tape to 90° and the 15-cm portion of the tube in the center of the tube furnace was packed with potassium hydrogen phosphate. Pyrolysis of a 2-g sample yielded a colorless product which was shown by vapor chromatographic analysis (8) to contain methyl vinylacetate 6%, methyl *cis*-crotonate 20%, methyl cyclopropanecarboxylate 62%, and methyl *trans*-crotonate 12%.

Pyrolysis of 3-Carbomethoxypyrazoline in the Presence of Potassium Hydrogen Phosphate

In a distillation apparatus was placed 5.2 g of 3-carbomethoxy-Δ^2-pyrazoline and 1.5 g of potassium hydrogen phosphate and the mixture was heated in an oil bath to 190°. Analysis of the distillate (1.8 g, 44%) (8) showed methyl vinylacetate 6%, methyl cyclopropanecarboxylate 27%, methyl *cis*-crotonate 35%, and methyl *trans*-crotonate 32%.

Pyrolysis of 4-Methyl-3-carbomethoxy-Δ^2-pyrazoline

4-Methyl-3-carbomethoxy-Δ^2-pyrazoline (23 g, 0.15 mole) was pyrolyzed in a distillation apparatus at 190° in a similar manner to that described for 3-methyl-3-carbomethoxy-Δ^1-pyrazoline to give 15 g (80%) of a colorless product boiling up to 138°. Three components were isolated by vapor chromatography and identified as indicated below where boiling point, refractive index, retention time in the vapor chromatogram using a 10-ft Ucon Polar column of 0.25-in. diameter with a helium flow rate of 67 cc/minute, and percentage of the total product are given.

Methyl senecioate: b.p. 136°, n_D^{24} 1.4368, 31.2 minutes, 88%. This sample was identical in all respects with an authentic sample prepared by the procedure of Wagner (18).

Methyl 3-methyl-3-butenoate: b.p. 125°, n_D^{23} 1.4171 (lit. (18) b.p. 41°/27 mm, n_D^{20} 1.4168), 21.2 minutes, 8%.

Methyl 2-methylcyclopropanecarboxylate: —, n_D^{23} 1.4220, 26.8 minutes, 4%. The infrared and N.M.R. spectra of this compound were identical with those of the sample isolated from the pyrolysis of 5-methyl-3-carbomethoxypyrazoline.

Vapor-Phase Pyrolysis of 4-Methyl-3-carbomethoxy-Δ^2-pyrazoline

The pyrolysis was carried out at 225° by the procedure described for the vapor-phase pyrolysis of 3-carbomethoxy-Δ^2-pyrazoline. Under these conditions 10% of the pyrazoline was not pyrolyzed and was frozen out of the product. Analysis of the product by vapor chromatography showed that the product contained methyl senecioate 62%, methyl 2-methylcyclopropanecarboxylate 26%, and methyl 3-methyl-3-butenoate 12%.

Isomerization Studies on Methyl Senecioate and Methyl 3-Methyl-3-butenoate

Samples of methyl senecioate and methyl 3-methyl-3-butenoate were heated at 250°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for 2 weeks. Analysis of the product showed, respectively, methyl senecioate 84%, 87%; and methyl 3-methyl-3-butenoate 16%, 13%.

Pyrolysis of 5-Methyl-3-carbomethoxy-Δ^2-pyrazoline

5-Methyl-3-carbomethoxy-Δ^2-pyrazoline (5.0 g, 0.33 mole) was pyrolyzed in a distillation apparatus at 190° in a similar manner to that described for 3-methyl-3-carbomethoxy-Δ^1-pyrazoline to give 3.0 g (80%) of a colorless liquid boiling up to 142°. Four components were isolated and identified as indicated below where boiling point, refractive index, retention time in the vapor chromatogram using a 10-ft Ucon Polar column at 100° with a helium flow rate of 45 cc/minute, and percentage of the total product are given.

Methyl *trans*-2-pentenoate: b.p. 142°, n_D^{21} 1.4315, 37.2 minutes, 43%. Calc. for $C_6H_{10}O_2$: C, 63.11; H, 8.84. Found: C, 62.90; H, 8.91. The infrared spectrum (10% in carbon tetrachloride) showed bands at 1712, 1662, and 981 cm^{-1} characteristic of a *trans*-α,β-unsaturated ester (16). The N.M.R. spectrum (0.5 g per cc of carbon tetrachloride) showed vinyl hydrogen signals at 3.16 τ (sextet with $J_{trans} \simeq 16$ c.p.s. and $J_{CH_2} \simeq 6.4$ c.p.s.) and 4.41 τ (doublet), ester methyl hydrogens at 6.50 τ (singlet), methylene hydrogens at 7.78 τ (multiplet), and alkyl methyl hydrogens at 9.05 τ (triplet $J \simeq 7.2$ c.p.s.). These data are consistent with the *trans*-α,β-unsaturated structure assigned to this compound (17).

Methyl *cis*-2-pentenoate: b.p. 128°, n_D^{20} 1.4281, 23.6 minutes, 23%. Calc. for $C_6H_{10}O_2$: C, 63.11; H, 8.84. Found: C, 62.91; H, 9.14. The infrared spectrum (10% in carbon tetrachloride) showed bands at 1723 and 1643 cm^{-1} characteristic of an α,β-unsaturated ester (16). The N.M.R. spectrum (0.5 g per cc of carbon tetrachloride) was similar to that of the trans ester except for the value of the vinyl splitting constant, which was smaller in magnitude. Signals were found at 3.89 τ (sextet $J_{cis} \simeq 11.6$ c.p.s. and $J_{CH_2} \simeq 6.8$ c.p.s.), 4.46 τ (doublet), 6.55 τ (singlet), 7.56 τ (multiplet), and 9.23 τ (triplet $J \simeq 7.2$). These data are consistent with the *cis*-α,β-unsaturated structure assigned to this compound (17).

Methyl 2-methylcyclopropanecarboxylate: b.p. 130°, n_D^{20} 1.4228, 27.2 minutes, 29%. Calc. for $C_6H_{10}O_2$: C, 63.11; H, 8.84. Found: C, 63.28; H, 8.76. Hydrolysis with 10% sodium hydroxide of a 2-g sample obtained from a large-scale pyrolysis run, from which the olefin product was removed by oxidation with potassium permanganate, gave 1 g of 2-methylcyclopropanecarboxylic acid, b.p. 190–191° (lit. (19) b.p. 190–191°), n_D^{26} 1.4381. The infrared spectrum (10% in carbon disulphide) showed bands at 1174 cm^{-1} and 1013 cm^{-1} characteristic of the cis and trans acids, respectively, as well as the other prominent bands reported for these acids (20). The mixture was analyzed by the baseline method of Heigl (21) using the bands at 1174 and 1013 cm^{-1} and the spectra of the pure cis and trans acids kindly provided by D. E. Applequist and A. H. Peterson and was found to be 40% cis and 60% trans.

Methyl *trans*-3-pentenoate: b.p. 137°, n_D^{21} 1.4220 (lit. (22) b.p. 128°/625 mm, n_D^{20} 1.4217), 30.4 minutes, 5%. No reason can be found for the discrepancy in the boiling point. A sample isolated from the isomerization mixture (see below) had a boiling point of 136°. The infrared spectrum (10% in carbon tetrachloride) showed bands at 1740 and 970 cm^{-1} characteristic of a trans olefin and an ester but no bands were found in the 1600 to 1700 cm^{-1} region possibly due to the symmetry of the double bond (16). The N.M.R. spectrum (0.3 g per cc of carbon tetrachloride) showed bands at 4.62 τ (multiplet), 6.46 τ (singlet), 7.12 τ (broad), and 8.50 τ (broad) as would be expected for the assigned

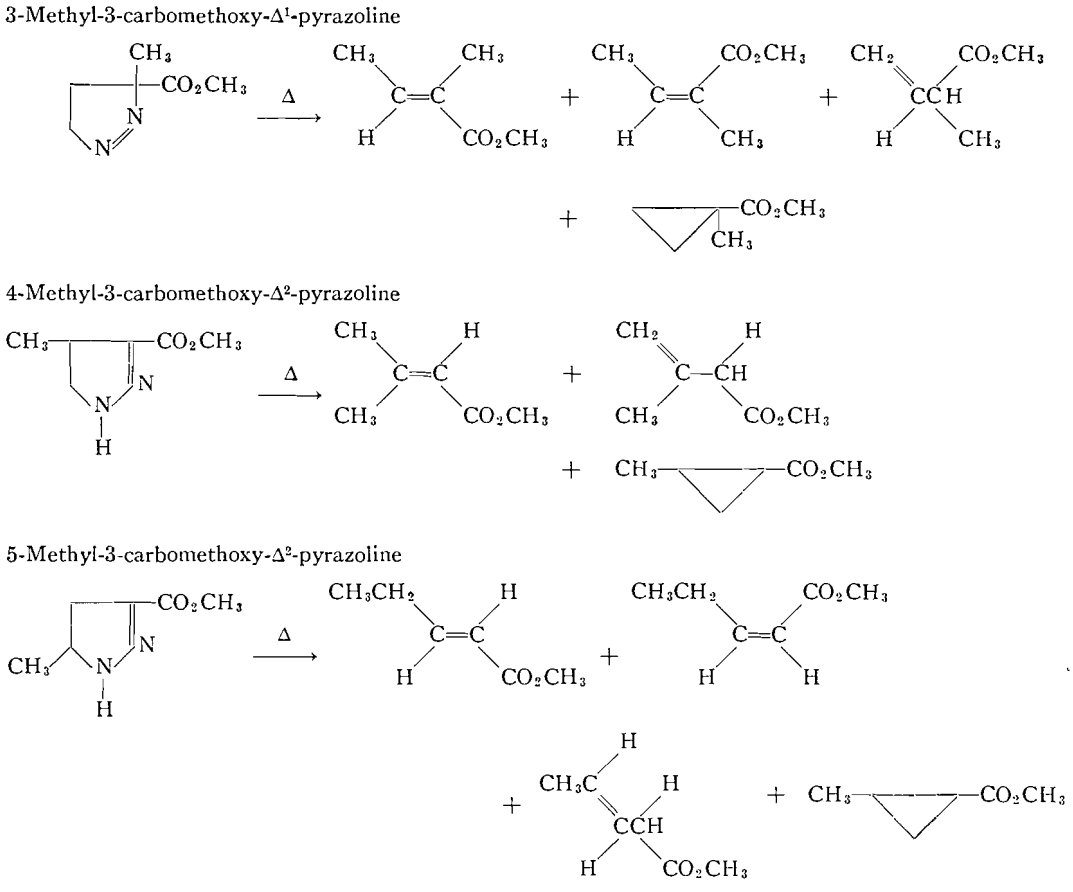

CHART I.

structure with broadening of the signals due to the large amount of long-range splitting possible (23).

Vapor-Phase Pyrolysis of 5-Methyl-3-carbomethoxy-Δ²-pyrazoline

The pyrolysis was carried out at 225° by the procedure described for the vapor-phase pyrolysis of 3-carbomethoxy-Δ²-pyrazoline. Analysis of the product showed the presence of methyl *trans*-2-pentenoate 10%, methyl *cis*-2-pentenoate 12%, methyl 2-methylcyclopropanecarboxylate 74%, and methyl *trans*-3-pentenoate 4%.

Isomerization Studies on Methyl trans-2-Pentenoate and Methyl cis-2-Pentenoate

Samples of methyl *trans*-2-pentenoate and methyl *cis*-2-pentenoate were heated at 250° for 2 weeks. Analysis of the product showed, respectively, methyl *cis*-2-pentenoate 7%, 7%; methyl *trans*-2-pentenoate 47%, 48%; and methyl *trans*-3-pentenoate 46%, 45%. In addition to these components a peak which had not previously been observed appeared in the chromatogram at 20.8 minutes. This peak was approximately one half of the area of that for methyl *cis*-2-pentenoate and might possibly be due to methyl *cis*-3-pentenoate. No new peaks were found when a dinonyl phthalate column was used.

THE KINETICS OF THE TERTIARY-AMINE-CATALYZED REACTION OF ORGANIC ISOCYANATES WITH THIOLS[1]

YOSHIO IWAKURA AND HISAO OKADA

ABSTRACT

The kinetics of the reactions of isocyanates with thiols in the presence of tertiary amines were examined. The rate of the reaction was of the first order with respect to the concentration of isocyanate, thiol, and tertiary amine. The catalytic action of tertiary amines decreased in the order of triethylenediamine, triethylamine, diethylcyclohexylamine, tributylamine, N-methylmorpholine, pyridine, and quinoline. The relative rate of the reaction of phenyl isocyanate with thiols decreased in the order of phenylmethanethiol, 1,4-butanedithiol, 1-butanethiol, 1-dodecanethiol, and thiophenol. The reaction took place more smoothly in strong ionizing solvents. These facts can be explained by the reaction mechanism indicated by the equations [6] to [8].

INTRODUCTION

The kinetics of the reactions of phenyl isocyanate in the presence of triethylamine with 1-butanethiol, 1-dodecanethiol, and 2-methylpropane-2-thiol in toluene solution at 25° have been investigated by Dyer and Glenn (1). Their work revealed the strong catalytic effect of triethylamine in the reaction, but did not elucidate the mechanism of the reaction. In the absence of a catalyst, the reaction of organic isocyanates with thiols proceeds at high temperatures (2, 3, 4). In the presence of triethylamine, however, the reaction proceeds very smoothly even at room temperature. In the presence of diethylcyclohexylamine, aromatic isocyanates react preferentially with the thiol group rather than the hydroxyl group in 2-mercaptoethanol (5).

In the present work, the catalytic effect of tertiary amines in the reaction between isocyanates and thiols has been kinetically studied and a reaction mechanism has been proposed. The results are compared with similar data from the reactions of isocyanates with alcohols (6, 7) and with carboxylic acids (8).

RESULTS AND DISCUSSION

It has been reported that, in the reaction of phenyl isocyanate with 1-butanethiol in the presence of triethylamine in toluene solution at 25°, the catalytic action was of the first order with respect to concentration of the amine; the reaction approximately followed the second-order kinetics during the early stages of the reaction (1).

The reaction of phenyl isocyanate in the presence of 0.0050 mole/liter of tributylamine catalyst with various initial concentrations of 1-dodecanethiol in benzene solution at 35° was examined kinetically and the results obtained are plotted in Fig. 1. The rate constants calculated for a second-order reaction are almost constant over the full course of the reaction and do not vary according to the initial concentration of 1-dodecanethiol. This indicates that the reaction followed second-order kinetics. Figure 1 and other data are summarized in Table I.

The reaction velocity of organic isocyanate with thiol in the presence of tertiary amine

is of the first order with respect to the concentration of isocyanate, thiol, and tertiary amine, and is shown to follow equation [1]:

$$[1] \qquad -d[\text{R—NCO}]/dt = k[\text{R—NCO}][\text{R—SH}][\text{R}_3\text{N}].$$

If [R_3N] is regarded as constant through a run, equation [2] is applicable, where k' is k[R_3N]:

$$[2] \qquad -d[\text{R—NCO}]/dt = k'[\text{R—NCO}][\text{R—SH}].$$

To compare the catalytic effects of tertiary amines in the reaction of phenyl isocyanate with 1-butanethiol, the rates of reaction catalyzed by seven tertiary amines were studied in toluene solution at 30°. In the absence of a catalyst, the reaction proceeded very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

slowly and the rate constant was regarded as almost zero, that is, k_0 was negligible in the equation [3],

$$[3] \qquad k_{obs} = k_0 + k_c[R_3N],$$

where k_{obs} is the second-order rate constant observed. The results obtained are listed in Table II.

TABLE II

The reaction of phenyl isocyanate with 1-butanethiol in toluene solution at 30°
(Initial concentration: $[C_6H_5NCO] = [n\text{-}C_4H_9SH] = 0.1250$ mole/liter)

"		0.010	Too slow	0.0314
N,N-Dimethylaniline	5.00	0.10	—	0.0

N,N-Dimethylaniline did not show any catalytic effect. This phenomenon confirms evidences obtained for the reaction of phenyl isocyanate with methyl alcohol (6*a*), the polymerization reaction of isocyanates (9), and the reaction of diisocyanates with polyols (10). The plot of $[R_3N]$ against k_{obs} gave a straight line, showing that the catalytic effect was directly proportional to the concentration of tertiary amines. The catalytic coefficient k_c in the equation [3] was calculated from this slope for each of the tertiary amines used; the value obtained are listed in the fifth column in Table II. The catalytic coefficients fall almost in the same order as the basicity of the tertiary amines with the exception of triethylenediamine. With such strongly basic tertiary amines as triethylamine, diethylcyclohexylamine, and tributylamine the catalytic coefficients for the reaction of phenyl isocyanate with 1-butanethiol are larger than for the reaction of phenyl isocyanate with ethanol in dibutyl ether (6), but with weakly basic tertiary amines the opposite is true, that is, the coefficients for the reaction with alcohol are larger. This possibly explains the difference in reactivity of the hydroxyl and the thiol group of 2-mercaptoethanol in the presence of diethylcyclohexylamine (5). Triethylenediamine was much more effective catalytically than would be expected from its basicity, but this effect was less than that in the reaction between phenyl isocyanate and alcohol (11, 12).

The reactions of phenyl isocyanate with a large excess of 1-dodecanethiol in toluene at various temperatures were kinetically examined. The second-order rate constants and the apparent energies of activation calculated from the Arrhenius equation are listed in Table III with respect to the seven tertiary amines.

The reactions between phenyl isocyanate and 1-butanethiol in the presence of tertiary amines were studied in various solvents; the results obtained are listed in Table IV. The rate constants of the reaction increased in the order of benzene, toluene, dibutyl ether, dioxane, methyl ethyl ketone, and nitrobenzene. This solvent effect increased with increasing ionizing power of the solvents and was contrary to the result of the reaction

of organic isocyanates with alcohols (7). This indicates that the rate-controlling step is represented by equation [8] and that the attack of the thiols on the complex-2 is accelerated by ionization of the thiols. In a powerful ionizing solvent, that is, a solvent having a greater dielectric constant, the thiols undergo ionization to a greater degree and gain more acidic character.

The reactions of phenyl isocyanate with different thiols in toluene at 30°, in the presence of triethylamine or diethylcyclohexylamine, was examined. The results obtained are listed in Table V. The reactivity of the thiols increased in the order of thiophenol,

In order to compare the reactivity of aromatic and aliphatic isocyanates and to examine the catalytic effect of tertiary amines on the two types, the kinetics of the reaction of ethyl isocyanate with 1-butanethiol in the presence of triethylamine in toluene at 30° were studied. The rate constants were 0.0422 liter mole^{-1} min^{-1} for 0.050 mole/liter and 0.0219 liter mole^{-1} min^{-1} for 0.025 mole/liter of triethylamine. The catalytic coefficients of triethylamine were 68.6 for phenyl isocyanate and 0.86 for ethyl isocyanate in their reaction with 1-butanethiol.

The work of Baker and Gaunt (6) indicates that the probable mechanism of the catalyzed reaction of phenyl isocyanate and alcohol follows the path shown by formulae [4], [5]:

$$\begin{cases} \text{R—NCO} + \text{R}_3\text{N} \rightleftharpoons \begin{pmatrix} \text{R—N=C=O} \\ \vdots \\ \text{R}_3\text{N} \end{pmatrix} \text{(complex)} & [4] \\ \text{complex} + \text{R—OH} \rightarrow \text{RNHCO}_2\text{R} + \text{R}_3\text{N}. & [5] \end{cases}$$

In equation [5], the active hydrogen-containing compound attacks the complex consisting of isocyanate and tertiary amine. In this case the rate of reaction is controlled by the acidity of the active hydrogen compound. Thiols are more acidic than alcohols; therefore, the catalytic coefficient of strongly basic tertiary amines in the reaction of isocyanate with thiol is larger than in the reaction with alcohol. With very weakly basic tertiary amines, however, the catalytic coefficient does not agree with the above presumption. From previously published (13) spectroscopic evidence of interaction between tertiary amines and thiols and from the experimental results given above, the probable mechanism of the catalyzed reaction of isocyanate and thiol seems to follow the kinetic scheme outlined below:

$$\begin{cases} \text{R—SH} + \text{R}_3\text{N} \overset{k_1}{\underset{k_2}{\rightleftharpoons}} \underset{\text{complex-1}}{(\text{R—SH---NR}_3)} & [6] \\ \text{complex-1} + \text{R—N=C=O} \overset{k_3}{\underset{k_4}{\rightleftharpoons}} \underset{\text{complex-2}}{\begin{pmatrix} \text{complex-1} \\ \vdots \\ \text{R—N=C=O} \end{pmatrix}} & [7] \\ \text{complex-2} + \text{R—SH} \overset{k_5}{\rightarrow} \text{RNHCOSR} + \text{R}_3\text{N} + \text{R—SH}. & [8] \end{cases}$$

Assuming a steady-state concentration of the complex, the following kinetic equation is obtained:

$$[9] \qquad \frac{d[\text{RNHCOSR}]}{dt} = \frac{k_1 k_3 k_5 [\text{R}_3\text{N}][\text{R—NCO}][\text{R—SH}]^2}{(k_2 + k_3[\text{R—NCO}])(k_4 + k_5[\text{R—SH}])}.$$

In this equation, if

$$[10] \qquad k_2 \gg k_3[\text{R—NCO}], \qquad k_4 \ll k_5[\text{R—SH}]$$

are effective, the equation [9] stands for the equation [1].

EXPERIMENTAL

Procedures

The reaction vessel used was a long-necked, round-bottomed flask of approximately 50-ml capacity. A thiol – tertiary amine solution was prepared using a volumetric flask at a specified reaction temperature. Two milliliters of the thiol – tertiary amine solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

was pipetted into the reaction vessel. The isocyanate solution was prepared by the same method as the thiol – tertiary amine solution. A kinetic run was initiated by adding 2 ml of the isocyanate solution into the reaction vessel. To the reaction mixture in each of the reaction vessels (seven or eight) 10 ml of dibutylamine–acetone solution was periodically added and allowed to stand for about 15 minutes to react completely the remaining isocyanate in the vessel. Reaction rates were determined by following the disappearance of the isocyanate group by a modified Stagg method (14). Unreacted dibutylamine in a reaction vessel was then titrated with 0.05 N hydrochloric acid – ethanol solution, using a semimicroburette and bromophenol blue as the indicator. Blank titration of dibutylamine and tertiary amine was also carried out and normality of the isocyanate solution was determined. In the case of a reaction with a large excess of thiol, 1 ml of tertiary amine solution and about 2 g of 1-dodecanethiol were mixed and 2 ml of isocyanate solution was added. Reproducibility of the experiments was good and agreement of duplicate runs was $\pm 2\%$.

Data were calculated and plotted according to the usual second-order reaction rate equation for reactants either at equal or at different initial concentration,

$$kt = \frac{x}{a(a-x)}, \qquad [11]$$

$$kt = \frac{2.303}{a-b} \log \frac{b(a-x)}{a(b-x)}, \qquad [12]$$

where a and b are initial concentration of isocyanate and thiol and x is concentration reacted at time t. In the case of a large excess of thiol, calculations were carried out using the first-order reaction rate equation. Representative rate plots are given in Fig. 1. Rate constants were determined from the slope of the best straight line drawn through the points of the plot (by the method of least squares).

In the literature (1) the autocatalytic effect of the product in this kind of reaction was described, but, in this present study, the autocatalytic phenomenon was not examined in detail. In the reaction catalyzed with a very weakly basic tertiary amine, however, very weak autocatalytic acceleration effect on the reaction was observed.

Materials

Diethylcyclohexylamine was prepared from hexylamine and ethyl iodide by a method described in the literature (15) and distilled, b.p. 185–192°. Triethylenediamine was recrystallized from ether, m.p. 156–157°. Other tertiary amines were dried over potassium hydroxide and fractionally distilled: b.p. triethylamine, 87–89°; tributylamine, 98–99°/19 mm; pyridine, 115.5°; N-methylmorpholine, 114°; N,N-dimethylaniline, 93°/29 mm; quinoline, 112°/14 mm. Commercial thiophenol was distilled, b.p. 68°/20 mm. Other thiols were synthesized starting from the corresponding alcohol or bromide and dried over calcium oxide and fractionally distilled under nitrogen atmosphere prior to use: b.p. 1-butanethiol, 95–99°; 1,4-butanedithiol, 96°/28 mm; 1-dodecanethiol, 116.5–117°/3 mm; phenylmethanethiol, 118°/29 mm. Commercial phenyl isocyanate and synthesized ethyl isocyanate were distilled before use: b.p. phenyl isocyanate, 164–165°; ethyl isocyanate, 60°. Toluene (16), dibutyl ether (6*a*), benzene (17), and dioxane (18) were purified by distillation from sodium. Nitrobenzene was dried over phosphorus pentoxide and distilled. Methyl ethyl ketone was dried over anhydrous potassium carbonate, refluxed for 2 days with a small amount of phenyl isocyanate, and fractionally distilled. Acetone, dibutylamine, and ethanol were used after distillation.

THE LOCATION OF XANTHATE GROUPS IN PARTIALLY SUBSTITUTED STARCH XANTHATES[1]

E. G. ADAMEK[2] AND C. B. PURVES

ABSTRACT

The rate of xanthation of starch with carbon disulphide in 17.8% potassium hydroxide at 23° was followed by converting the potassium salts to the *S*-methyl xanthate esters, and analyzing the latter for sulphur. These esters were tritylated without changing the xanthate D.S., and unity minus the trityl D.S. was assumed to represent xanthate D.S. in the primary alcohol positions of the starch. About 62% of the xanthate groups occupied secondary positions after 100 minutes of xanthation, but after 3350 minutes about 58% of the surviving xanthate groups were primary.

A sodium chlorite – pyridine – lactic acid mixture reduced the sulphur content of a fully acetylated starch *S*-methyl xanthate by about nine-tenths with little loss of acetyl groups, but the residual sulphur could not be eliminated and the resulting starch acetate could not be completely reacetylated or tosylated. The location of the hydroxyl groups in this acetate thus could not be studied by the tosylation–iodination method.

INTRODUCTION

A previous article (1) described attempts to discover the distribution of xanthate groups among the 2-, 3-, and 6-positions of cellulose sodium xanthates whose average degree of substitution (D.S.) ranged from 0.66 to 0.41. The xanthate salts were converted to the much more stable *S*-methyl esters, and the latter to completely substituted acetates, without significant loss in xanthate D.S. Attempts to dexanthate this acetate at 0° with chlorine dioxide buffered to pH 4.5, however, occasioned small losses in acetyl groups, and about one-tenth of the original sulphur content remained associated in an unknown chemical state with the dexanthated cellulose acetate. Fractional precipitation or dialysis of this acetate failed to remove the residual sulphur compounds. This failure diminished the reliability of the subsequent work, which consisted of determining distribution of unsubstituted hydroxyl groups in the dexanthated cellulose acetate (and hence of xanthate groups in the original cellulose xanthate) by the tosylation–iodination procedure. The present research was begun with a repetition of the above series of reactions with starch, since it was reasonable to hope that the great difference in the colloidal state of cellulose and starch might facilitate the study, particularly in the dexanthation step. A search of the literature (2) revealed a few articles and patents on the preparation and uses of starch sodium xanthates, but none on the distribution of the xanthate groups.

Since the primary object of the work was to explore possible methods of determining this distribution, it did not seem necessary to separate the original starch into the amylose and amylopectin components. The error caused by any incompleteness, or loss of acetyl groups, in dexanthation was reduced by starting with a starch potassium xanthate of relatively high D.S. (near unity). As expected (2), this product could be converted to the fully acetylated *S*-methyl ester with little or no change in the xanthate D.S. Subsequent attempts to remove the *S*-methyl xanthate groups selectively by aqueous chlorine dioxide, as used in the parallel work with cellulose *S*-methyl xanthates (1), resulted in poor yields of a starch acetate markedly deficient in acetyl groups and retaining 2.4, 4.6% of sulphur as residual sulphur compounds. About 20 attempts, briefly outlined

in the Experimental portion, were made to find a more selective method of dexanthation. Hydrogen peroxide or peracetic acid in buffered aqueous solution, or sodium persulphate–sodium chlorite in aqueous pyridine, degraded the starch acetate to water-soluble products on those occasions when they reduced the sulphur content substantially. The *S*-methyl xanthate group, unlike the primary tosyl group, was not eliminated by heating with sodium iodide in a ketone solvent.

Sanyal and his co-workers (3), however, had dexanthated a cellulose *S*-methyl xanthate acetate with sodium chlorite in 90% acetic acid, and it seemed worth while to explore the use of nearly anhydrous systems in which chlorine dioxide was liberated from sodium chlorite. Alkali chlorites were known to be reduced in aqueous solution by aldehydes (4), carbohydrates (5), formic acid, oxalic acid, citric acid (6, 7), and acetic anhydride (4), the action in at least the latter case appearing to be catalytic. Trial showed that formic acid or acetic anhydride, but not formaldehyde, in a glacial acetic acid – sodium acetate medium removed most of the *S*-methyl xanthate groups from the acetylated starch derivative. Since these additives might have altered the acyl substitution, they were replaced by lactic acid as the reducing or catalytic agent for the chlorite, and in its final form the method removed about 90% of the sulphur content of the starting material with the loss of only about 6% of the acetyl groups.

After dexanthation, the residual sulphur compounds in the resulting starch acetate were not removed by mercuric chloride. One of these dexanthated acetates was extracted with pyridine, in which 33% dissolved, but both the soluble portion and the undissolved gel retained the original sulphur content. Since the starch contained 33% of amylose, it was possible that the fractionation followed the amylose–amylopectin ratio rather than any difference in substitution. Such experiments, together with similar negative results in the cellulose field (1, 3) strengthened the view that the residual sulphur was part of groupings that were chemically combined with, rather than tenaciously adsorbed on, the residual starch acetate. The groups in question were probably thioesters, because complete deacetylation with sodium methylate yielded a nearly sulphur-free starch; further acetylation, provided the catalyst was sulphuric acid, also greatly reduced the sulphur content. The simplest, but not necessarily the correct, explanation was that the supposed thioesters were monothiocarbonates of the —O—CO—SCH_3 type formed as a by-product in the dexanthation. If so, the monothiocarbonate group was fairly stable toward chlorine dioxide or chlorite, and was hydrolyzed at a rate comparable to that of acetyl groups.

Repeated attempts were then made to reacetylate the dexanthated starch acetates to the maximum theoretical substitution of 3.0, but customary methods of acetylation, even if successful with the original starch *S*-methyl xanthate or repeated two or three times, yielded products of D.S. 2.0 to 2.4. Pacsu and Mullen (8) previously noted the resistance of starch itself to complete acylation, but successfully overcame it by first swelling the starch in aqueous pyridine. Their method increased the D.S. to only 2.6 in the present case and to 2.8 after a second identical acetylation. As might be expected from these negative results, the sulphur content of the dexanthated starch acetate increased by only 1.9% when tosylated under conditions that produced extensive substitution with the similar cellulose derivative. The tosylation–iodination method of locating *S*-methyl xanthate groups in starch was thus inapplicable and other methods had to be investigated.

An attempt was made to hydrolyze starch *S*-methyl xanthate to the corresponding mixture of glucose *S*-methyl xanthates, and to identify the latter by paper chromatog-

For personal use only.

raphy with butanol–water as eluent. Although this hydrolysis required much less drastic conditions than those required in the parallel hydrolysis of cellulose *S*-methyl xanthate (3) the result was the same; the two spots of R_F 0.56 and 0.70 derived from glucose 6-*S*-methyl xanthate were evident, but the 2- and 3-derivatives had failed to survive the hydrolysis. Neither a dextrinizing nor a saccharifying enzyme preparation produced glucose from starch *S*-methyl xanthate, although starch itself was readily degraded, even in presence of the xanthate.

Preliminary experiments then showed that starch and starch *S*-methyl xanthates, like cellulose (9) and cellulose *S*-methyl xanthates (1), could be successfully condensed with triphenylmethyl chloride (trityl chloride) in pyridine. The determination of the trityl group in the starch *S*-methyl xanthates was by weighing the triphenylmethyl carbinol produced by acid hydrolysis (9), but the earlier uncertainties originating in the formation of colloidal sulphur and traces of mercaptans (1) were overcome by correcting the weight of the crude carbinol for its sulphur content. In the final work, starch was xanthated by the "emulsion" technique while dispersed in aqueous potassium hydroxide, and samples of the starch potassium xanthate, isolated at various times by precipitation into methanol, were promptly converted to the pure *S*-methyl xanthates. These xanthate esters were then tritylated, over-all yields from the potassium salts being in all cases close to theoretical, and the D.S. of the products with respect to both trityl and *S*-methyl xanthate groups was determined by analysis. Comparison of the data (Table I, columns

3 and 6) showed that none of the *S*-methyl xanthate groups were lost during tritylation, and that the accuracy of the analytical work (D.S. $\pm$0.03) was satisfactory. By assuming that the trityl group selectively and completely substituted the primary alcohol positions left unoccupied by the *S*-methyl xanthate group, the substitution of the latter in the 6-position of the starch was calculated as unity minus the trityl D.S. given in column 7. The primary *S*-methyl xanthate D.S. thus being known, the average substitution in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

secondary 2- and 3-positions of the starch was found by difference from the total xanthate substitution (column 3 or 6).

When the rates of xanthation were plotted against time (Fig. 1), the plot for secondary

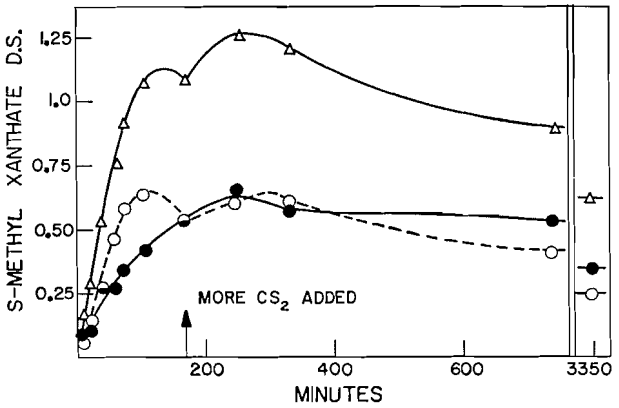

FIG. 1. Rate of xanthation of starch (see Table I, footnotes *a* and *d*). Total substitution, △; primary substitution, ●; secondary substitution, ○.

S-methyl xanthate D.S. (open circles) went through a maximum near 100 minutes which was reflected in the plot for total D.S. (triangles) but not in that for primary D.S. (filled circles), which continued to increase. About 38% of the substitution was in the primary, and 62% in the secondary, positions at this maximum. It was also evident from the shape of the plots that xanthation proceeded more rapidly in the secondary positions. When the maximum near 100 minutes was past, the addition of more carbon disulphide and alkali to the xanthating mixture produced higher maxima in all three plots after 250 to 300 minutes, and in this period the amounts of primary and secondary xanthation were almost the same. Thereafter, the substitution in the secondary positions declined more rapidly than that in the first; the plots crossed, and after 3350 minutes, when the experiment was terminated, almost 60% of the surviving xanthate groups occupied primary positions in the starch macromolecule. The course of the xanthation of starch was thus similar to that of cellulose, which was discussed in the previous publication (1) and which has now been studied in much greater detail by Philipp and Liu (10).

EXPERIMENTAL

Materials and Analytical Methods

The wheat starch used was a defatted, purified sample kindly supplied by Dr. K. M. Gaver of Ogilvie Flour Mills Limited, Montreal, Quebec. Preparation of the purified starch potassium xanthates, of D.S. near unity, and from them the corresponding *S*-methyl esters, were as previously described (2). All products were dried by solvent-exchange into ether and then *in vacuo* over phosphorus pentoxide at room temperature.

Analyses for sulphur by the Parr semimicro bomb method, for ash, and for acetyl groups by distillation with 30% chromic acid, were as previously described (1, 2). The method for acetyl was the most reliable found, but the results tended to be slightly high. In the analyses of tritylated starch *S*-methyl xanthate for trityl content by the method of Hearon and his collaborators (9), a 0.5-g sample was digested in 10 ml of concentrated sulphuric acid for 2 hours at room temperature. Dilution of the resulting clear, brown solution with 100 ml of water, which was added with cooling and shaking

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

as a fine stream, caused the precipitation of the crude triphenyl carbinol. After being allowed to settle overnight, the slurry could be conveniently filtered in a tared porous crucible. The residue was washed several times with water, was dried *in vacuo* over phosphorus pentoxide, and was weighed. The sulphur content of the triphenyl carbinol was determined and the weight of carbinol corrected accordingly. If the corrected weight was a, and the original sample weight was b, then % trityl = $24{,}300a/260b$.

If x and y represented the D.S. of trityl and *S*-methyl xanthate groups, respectively, in starch, their values were found by solving the simultaneous equations:

$$\% \text{ trityl} = 24300x/(162+242x+90y),$$
$$\% S = 6400y/(162+242x+90y).$$

The corresponding equations for *S*-methyl xanthates and their acetates were reported previously (1).

Acetylated Starch S-Methyl Xanthate

As noted previously (2), the acetylation of the *S*-methyl xanthate with sulphuric acid as catalyst gave a white, completely substituted product but occasioned a small loss in the xanthate D.S. Several acetylations with pyridine – acetic anhydride showed that no loss of *S*-methyl xanthate groups occurred, but that acetylations at 55° or 95° for 20 to 30 hours yielded a total D.S. of about 2.9. Prolonged acetylations of the above kind gave brown products, and one particularly dark sample contained 0.56% of nitrogen. This amount corresponded to the presence of 3.2% of pyridine, but extraction with cold *N* hydrochloric acid for 2 days at 5° failed to alter the sulphur and acetyl analyses significantly. The following method illustrated the final procedure.

Twenty grams of starch *S*-methyl xanthate (D.S. 1.20), 240 ml of pyridine, and 120 ml of acetic anhydride were heated together under gentle reflux (112°) for 45 minutes, with exclusion of moisture. After cooling, the turbid reaction mixture was poured slowly into 2 liters of vigorously stirred ice water. The resulting precipitate was recovered on a filter of coarse sintered glass; was washed several times with water, methanol, and ether in succession; was ground in a mortar; and was subjected once more to the washing sequence. When dried, the product was a white powder which was dispersible in chloroform and trichloroethylene but not to clear solutions. Yield, 23.6 g or 93% of theory. Found: S, 23.0; acetyl, 21.5%. Calculated for starch substituted to D.S. 1.25 with *S*-methyl xanthate and to D.S. 1.74 with acetyl groups: S, 23.0; acetyl, 21.5%. The total substitution was thus 2.99. When chloroform solutions of such products were examined in a Perkin–Elmer Model 21 double-beam spectrophotometer, the characteristic stretching frequencies of unsubstituted hydroxyl groups between wave numbers 3100 cm^{-1} and 3600 cm^{-1} were absent.

Attempted Dexanthations of Starch S-Methyl Xanthate Acetate

(*a*) Three grams of the above *S*-methyl xanthate acetate, 3 g of sodium iodide, 150 ml of acetonyl acetone, and 20 ml of allyl alcohol to remove any free iodine that formed were heated for 2 hours at 98° under reflux. The product, recovered by filtration, retained almost the original amount of sulphur. Yield, 2.9 g with S, 22.6%.

(*b*) The original *S*-methyl xanthate acetate, 1.5 g, dispersed in 40 ml of glacial acetic acid containing an excess of sodium acetate, was shaken with 12 ml of aqueous 30% hydrogen peroxide for 20 hours at room temperature. After dilution with 250 ml of water, the suspension was filtered and the product isolated. Yield, 1.1 g. Found: S, 7.3; acetyl, 24.4%. A repetition of this dexanthation caused the loss of more than half of the product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the liquors. The remainder had S, 0.8%. Dexanthation with hydrogen peroxide at 5° proceeded very slowly, and hardly at all with peracetic acid in buffered acetic acid at room temperature during 16 hours at 23°.

(*c*) A highly viscous dispersion of 1.5 g of the *S*-methyl xanthate acetate in 28 ml of pyridine was mixed with 60 ml of water containing sodium persulphate, 14 g, and sodium chlorite, 14 g. The mixture was heated under reflux for 45 minutes, but no starch acetate separated when it was poured into water, presumably because the product was highly degraded.

(*d*) Two grams of another starch *S*-methyl xanthate acetate (S, 18.8; acetyl, 25.5%), dispersed in 25 ml of chloroform, was transferred into a black-painted flask containing 20 ml of glacial acetic acid, 20 ml of acetic anhydride, and 10 g of sodium acetate. The mixture was cooled to 0° before 10 g of powdered sodium chlorite and then 10 ml of water were added; the initial reaction was vigorous, and the stopper of the flask was kept loose to permit large volumes of chlorine dioxide gas to escape. After being kept near 0° for 30 minutes, the flask and contents were tightly stoppered and shaken mechanically for 22 hours at room temperature. After recovery by precipitation into water saturated with sodium acetate, the product was washed and dried. Yield, 1.6 g. Found: S, 2.6; acetyl, 31.1%. The analysis showed that 90% of the *S*-methyl xanthate and 8.5% of the acetyl groups had been removed.

The replacement of the acetic anhydride, acetic acid, and sodium acetate in the above experiment with 30 ml of pyridine and 21 ml of anhydrous formic acid caused the loss of 92% of the *S*-methyl xanthate and no loss of acetyl groups.

(*e*) Another starch *S*-methyl xanthate acetate (with S, 24.1; acetyl, 20.3%; D.S. 1.22 and 1.65) was used in the last seven dexanthations, each of which was restricted to an 8-g scale to reduce the risk of chlorine dioxide exploding in the apparatus used. The sample, 8 g, dispersed in 60 ml of chloroform, was contained in a wide-necked, black-painted 350-ml jar equipped with a glass stopper. A mixture of 40 ml of pyridine and 30 ml of 85 to 90% lactic acid was added, and the whole was cooled to 0°. The addition of 15 g of powdered sodium chlorite caused a vigorous evolution of chlorine dioxide gas and the stopper was kept loose. When the initial reaction had been completed at 0°, the jar was stoppered and shaken mechanically at room temperature for 1 hour. The mixture, still yellow-green in color, was then poured with stirring into 1.5 liters of diethyl ether. The soft precipitate was recovered and kneaded several times with ether, and then with small amounts of water, alternated with grinding in a mortar. After drying in the air, and further washings with ether, the white product was dried *in vacuo*. Found: S, 3.0; acetyl, 28.4% (D.S. 0.11, 1.58). In this case 91% of the *S*-methyl xanthate and 4% of the acetyl groups had been lost; in other cases the losses ranged as high as 93% and 10%, respectively. A repetition of the dexanthation gave a product with S, about 0.4% with the loss of 15% of the acetyl groups.

Examination of the Dexanthated Starch S-Methyl Xanthate Acetate

(*a*) A 0.4-g sample (S, 6.5; acetyl, 29.3%) was extracted at room temperature with 10-ml volumes of pyridine, which were separated from a swollen, gelatinous portion on the centrifuge. The extraction was repeated until, after the fifth, a drop of the supernatant liquor yielded no precipitate when diluted with ether. The combined extracts were then poured into much ether and the precipitate washed with water and ether and dried. Yield, 0.13 g or 33%. Found: S, 6.2; acetyl, 28.8%. The gel insoluble in pyridine was recovered in the same way. Yield, 0.21 g or 53%. Found: S, 6.4; acetyl, 28.8%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*b*) The above dexanthated starch *S*-methyl xanthate, 1.7 g, was deacetylated by being heated under reflux for 20 minutes with 100 ml of anhydrous methanol in which 1 g of sodium had been dissolved. After recovery on a filter, the product was ground in a mortar and deacetylated again in the same way. After washing in dilute acetic acid, methanol, and ether, the product weighed 1.3 g. Found: S, 0.29%. This sulphur content was not changed when an aqueous suspension was dialyzed through "Cellophane" against water for 55 hours.

(*c*) Another sample, 0.5 g, of dexanthated starch *S*-methyl xanthate acetate (with S, 2.0%; acetyl, 34.4%) was kept at 80° for 10 minutes while suspended in 20 ml of glacial acetic acid containing 1 g of mercuric acetate. The mixture was kept near 20° for 24 hours before being poured into water to isolate the product, which agreed with the original sample in yield and sulphur content.

(*d*) A sample, 0.8 g, of the composition noted in (*c*) was dispersed in 15 ml of dry pyridine to which 4.3 g of pure *p*-toluenesulphonyl chloride was added. The product was isolated after being kept near 20° for 24 hours, a period long enough to tosylate a similar cellulose derivative extensively (1). Found: S, 3.9%. The starch acetate thus resisted tosylation.

(*e*) Acetylation of similar dexanthated starch *S*-methyl xanthate acetates with pyridine and acetic anhydride, under conditions that led to the complete acetylation of the original starch *S*-methyl xanthate (see above) diminished the sulphur content somewhat but failed to raise the total substitution above 2.4, even when the acetylation was repeated. The use of sulphuric acid as the catalyst, of chloroacetic acid as impeller with magnesium perchlorate as catalyst (11), or of acetyl chloride in pyridine (12) gave no better results, although these methods gave complete, or almost complete, substitution with cellulose. Dexanthated starch *S*-methyl xanthates that had never been dried did not acetylate more completely than other samples. Although still unsatisfactory, the best method of acetylation found was that of Pacsu and Mullen (8). Two grams of a sample (with S, 2.3%; acetyl, 33.0%) was soaked in 30% aqueous pyridine, which was then replaced by 30 ml of anhydrous pyridine by distillation of the pyridine–water azeotrope. Acetic anhydride, 30 ml, was then added and the mixture kept at 115° for 1 hour. Found for the nearly white product: S, 1.9; acetyl, 39.4%, corresponding to D.S. 0.08, 2.52, respectively. The total D.S. was thus only 2.6.

Tritylation of Starch S-Methyl Xanthate

The procedure for tritylating cellulose (9) was slightly modified. In a typical experiment the pure, dry starch *S*-methyl xanthate, 2.5 g, was dispersed in 30 ml of pyridine contained in a flask fitted with a reflux condenser and protected from atmospheric moisture. The flask and contents were heated at 70° for 3 days, since it was found that some dexanthation occurred when a higher temperature (106°) was used for 20 hours. After being cooled, the light brown liquor was poured with stirring into 500 ml of ice and water, and the resulting precipitate was recovered on a filter of sintered glass. The product was washed with water, methanol, and ether, was ground in a mortar, washed again in the same sequence, and dried. Yields were close to those calculated from the content of *S*-methyl xanthate and trityl groups.

REACTIONS OF OXODELCOSINE AND INTERRELATION OF DELCOSINE AND DELSOLINE[1]

VINKO SKARIĆ[2] AND LÉO MARION

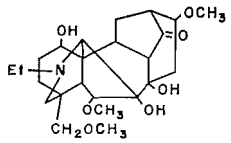
ABSTRACT

The oxidation of diacetyldelcosine produces a lactam which, after hydrolysis of the acetyl groups, can be oxidized further to a diketo-lactam in which one of the keto groups is in a five- and the other in a six-membered ring. This result leads to an alteration of the previously suggested structure of delcosine. The new structure suggests a close relationship between delcosine and delsoline which is confirmed by the methylation of the former. The reaction is selective and gives rise to a monomethyldelcosine identical in every way with delsoline. Reduction of the diketo-lactam (didehydro-oxodelcosine) with sodium borohydride gives oxodelcosine. Dehydro-oxodelcosine is also described, and its oxidation with lead tetraacetate as well as that of oxodelcosine lead to the formation of keto-products which lend supporting evidence for the structure assigned to delcosine.

Delcosine, an alkaloid isolated from *Delphinium consolida* L., has been investigated previously. The results then obtained (1) are best interpreted by assuming that the alkaloid possesses the same carbon–nitrogen skeleton as lycoctonine (2), and have led to the suggestion of tentative structure I (R = CH_3, R′ = R″ = H) for delcosine.

I

Although in this formula R″ = H has been established and the presence of a ditertiary vicinal glycol has been demonstrated chemically (3), the evidence for R′ = H is very meager and rests only on the interpretation of the formation of a carbinolamine ether (1) which requires the presence of a hydroxyl in the vicinity of the nitrogen. The work now described was designed to establish the nature of the substituents R and R′ in I.



It has already been shown that the oxidation of delcosine ($C_{24}H_{39}O_7N$) with chromic acid in acetic acid gives rise to dehydrodelcosine (II) in which the keto group forms part of a five-membered ring (1). When diacetyldelcosine (4) is oxidized with potassium permanganate, or with chromic acid – pyridine complex (Sarett's method), a lactam, diacetyl-oxodelcosine (III), m.p. 103–108° ($C_{28}H_{41}O_{10}N$), is obtained, which on hydrolysis, produces the neutral product, oxodelcosine (IV) ($C_{24}H_{37}O_8N$), m.p. 245–246°. Oxodelcosine (IV) in glacial acetic acid is oxidized by sodium dichromate to a diketone, didehydro-oxodelcosine (V) ($C_{24}H_{33}O_8N$), m.p. 211–212°, which in the infrared shows absorption bands at 1757 cm^{-1} (five-membered cyclic ketone), 1720 cm^{-1} (six-membered cyclic ketone), and 1653 cm^{-1} (six-membered lactam). The product V, which is also obtainable by direct oxidation of delcosine with Sarett's reagent, is converted back to oxodelcosine (IV) by reduction with sodium borohydride.

This result confirms that the nitrogen forms part of a six-membered ring, but indicates that contrary to the original assumption only one of the two secondary hydroxyl groups

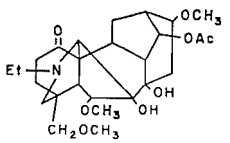
present in delcosine is on a five-membered ring, while the other is on a six-membered ring. The substituents, therefore, cannot be as represented in structure I (R = CH_3, R′ = R″ = H) since, were R′ = H, both keto groups in V should have been in five-membered rings. To account for this experimental result and the formation of the carbinolamine ether previously described (1), which requires that one hydroxyl group be in close proximity to the nitrogen, it is necessary to alter the suggested structure of delcosine to I (R = R″ = H, R′ = CH_3). This new structure has already been reported in a preliminary communication (5).



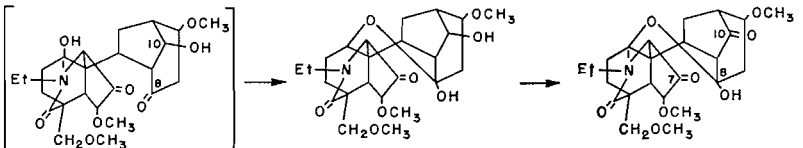
The fact that one of the two secondary hydroxyl groups is attached to a six-membered ring is confirmed by the oxidation with Sarett's reagent of monoacetyldelcosine (4), which gives rise to a monoacetyldehydro-oxodelcosine (VI) ($C_{26}H_{37}O_9N$), m.p. 107–110°, hydrolyzed by potassium hydroxide to dehydro-oxodelcosine (VII) ($C_{24}H_{35}O_8N$), m.p. 228–229°, in which the keto group, according to the infrared spectrum (1719 cm^{-1}), is in a six-membered ring. The formation of VII from monoacetyldelcosine also establishes

II

VII

VI

that it is the secondary hydroxyl group attached to the five-membered ring that is more readily and preferentially acetylated. Hence, compound II should be designated 10-dehydrodelcosine, whereas compound VII is 1-dehydro-oxodelcosine.



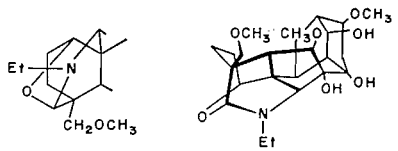
If structure I (R = R″ = H, R′ = CH_3) be the correct one, then delcosine must be very closely related to delsoline, which has been assigned structure I (R = H, R′ = R″ = CH_3) (6). In order to ascertain this point, delcosine was methylated by means of sodium hydride and methyliodide in dioxane according to the method used by Carmack *et al.* (7) in establishing the relationship of deltaline, delphaline, and lycoctonine. The product obtained after chromatography on alumina melted at 215–216°, undepressed on admixture with delsoline, and its optical rotation, infrared spectrum, and Debye–Scherrer diagram were all identical with the corresponding physical constants of delsoline. The methylation was therefore selective and affected only the secondary hydroxyl located on the five-membered ring which is also the hydroxyl that is the more readily acetylated.

The selective methylation of delcosine occurred only if the reaction was allowed to proceed at room temperature. When the reaction mixture was heated under reflux, the methylation was no longer selective and the product was di-*O*,*O*-methyldelcosine, $C_{26}H_{43}O_7N$, m.p. 203–206°.

The oxidation with periodic acid of the carbinolamine ether, anhydro-hydroxydelcosine, indicating the presence of a vicinal glycol in delcosine, has been reported previously (3). The action of lead tetraacetate on oxodelcosine has now been investigated. Preliminary studies showed that 1 mole of the oxidizing agent is consumed in 1 hour. In this oxidation oxodelcosine is converted to a compound VIII ($C_{24}H_{35}O_8N$), m.p. 191–193°, which in the infrared shows two absorption bands (3408 and 3360 cm^{-1}) in the hydroxyl region, a band at 1763 cm^{-1} attributable to a five-membered cyclic ketone, and one at 1654 cm^{-1} due to the lactam carbonyl. This oxidation indicating a vicinal glycol should give rise to a dicarbonyl derivative. The absence of an absorption band in the infrared region

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1700–1720 cm^{-1} shows that the expected six-membered cyclic ketone carbonyl is not present, and consequently that it must have become masked by a secondary reaction. On the other hand, the further oxidation of VIII with Sarett's reagent gives rise to a compound IX ($C_{24}H_{33}O_8N$), m.p. 209–210°, which in the infrared contains only one hydroxyl band (3320 cm^{-1}) and two five-membered cyclic ketone carbonyls (1766, 1758 cm^{-1}) as well as the lactam carbonyl (1657 cm^{-1}). Hence, of the two hydroxyl groups present in VIII, only one (on a five-membered ring) is secondary. These results are explainable



VIII IX

if in the secodiketone originally formed in the reaction, the carbonyl at 8 is assumed to have condensed with the secondary hydroxyl at 1 to form a hemiketal. There would result a tertiary hydroxyl at 8, and in the further oxidation of VIII to IX only the hydroxyl at 10 could be converted to a keto group.

In support of this interpretation, 1,10-didehydro-oxodelcosine (V), in which no secondary hydroxyl group is present, is oxidized by lead tetraacetate to 1,10-didehydroseco-oxodelcosine diketone (X) ($C_{24}H_{31}O_8N$), m.p. 175–177°, which according to its infrared absorption spectrum contains no hydroxyls. Further, 1-dehydro-oxodelcosine (VII), in which the hydroxyl at 1 is no longer present, is oxidized by lead tetraacetate to 1-dehydro-seco-oxodelcosine diketone (XI) ($C_{24}H_{33}O_8N$), m.p. 181–183°. In the infrared XI shows a hydroxyl band at 3344 cm^{-1}, one five-membered cyclic ketone (1776 cm^{-1}), two six-membered cyclic ketones (1712; 1688 cm^{-1}), and a lactam carbonyl (1655 cm^{-1}). Hence, in the absence of a secondary hydroxyl in ring A (position 1) no hemiketal is formed in the secodiketones.

Every one of the reactions of delcosine reported so far is accommodated by the new structure I (R = R″ = H, R′ = CH_3) assigned to the alkaloid, including the formation

XII

of the carbinolamine ether previously described (1). Notwithstanding a recently expressed view that the structure XII assigned to the carbinolamine ether (anhydrohydroxy-delcosine) is geometrically impossible (8), this structure when built with Courtauld models is remarkably strainless. It involves boat conformations for ring A and the nitrogen-bearing ring, and in this structure the ethyl group attached to the nitrogen is much less hindered than in delcosine itself. Consequently, the above statement of Büchi (8) does not appear to constitute a very serious argument.

It had been suggested previously (4) that the alkaloid delphamine (9) was very probably identical with delcosine. Due to the courtesy of Drs. L. S. Chetverikova and A. D. Kuzovkov, who sent us a sample of delphamine for comparison, this has been confirmed. The two bases have the same melting point, which is not depressed on admixture, and the infrared spectra and X-ray powder diagrams of both are identical.

For personal use only.

As already reported by Ochiai, Okamoto, and Kaneko (10), their Takaobase-I has been found to be identical with delcosine. Through the kindness of Professor Ochiai, we have been able to compare their Shimoburobase-II with 10-dehydrodelcosine and find that the melting points of the bases and their mixture, their infrared spectra, and their X-ray powder diagrams are identical.

The alkaloids lucaconine and monoacetyllucaconine have been described in the literature (11) and some degradative work on the former has been recorded recently (12) as well as a corrected formula (13), which is the same as that of delcosine. The physical and chemical properties of lucaconine and its derivatives are so strikingly similar to those of delcosine and its corresponding derivatives that it is most probable that the two bases are identical and that monoacetyllucaconine is identical with monoacetyldelcosine.

EXPERIMENTAL

The physical constants were determined as follows: the melting points, uncorrected, were taken on a Kofler hot stage; optical rotations were measured in chloroform unless otherwise stated; the ultraviolet spectra were measured in 95% ethanol on a Beckman DU spectrophotometer, and the infrared absorption spectra were recorded on a Perkin–Elmer double-beam instrument Model 21B. The infrared absorption bands are reported in wave numbers followed by a number in parentheses which designates the percentage absorption. The neutral alumina used for adsorption chromatography was standardized according to Brockmann.

Diacetyloxodelcosine (III)

Diacetyldelcosine prepared as previously described (4) (200 mg) was dissolved in acetone (4 ml) containing water (0.15 ml) and acetic acid (0.1 ml) and the solution heated under reflux. To the refluxing solution powdered potassium permanganate (220 mg) was added portionwise with agitation over a period of 2 hours. The reaction mixture was then kept at room temperature overnight. Sulphur dioxide was bubbled in the solution, which was subsequently filtered and evaporated under reduced pressure to a syrup. The syrup was partitioned between 0.5 *N* sulphuric acid and chloroform and the chloroform solution washed with 4% aqueous sodium carbonate. The chloroform extract was dried, evaporated under reduced pressure, and the microcrystalline residue (169 mg) fractionally recrystallized from ether–hexane. The middle fractions (80.3 mg) were recrystallized from hexane from which diacetyloxodelcosine separated as colorless microcrystals, m.p. 103–105°. $[\alpha]_D^{25}$ +24.6±1.4° (*c*, 0.71). Found: C, 60.95; H, 7.42. Calc. for $C_{28}H_{41}O_{10}N$: C, 60.96; H, 7.49%. Infrared (nujol mull): 3454(50), 1738(92), 1644(84), 1245(95) cm^{-1}.

Diacetyloxodelcosine is also obtained in 65% yield from diacetyldelcosine by oxidation with chromic anhydride – pyridine complex.

Oxodelcosine (IV)

Diacetyloxodelcosine (54.0 mg) was refluxed for 2 hours with 5% potassium hydroxide in (1:1) aqueous methanol. After it was cooled, the solution was evaporated to a syrup under reduced pressure, water was added, and the product extracted with chloroform. The chloroform extract was washed with 0.5 *N* sulphuric acid, washed with water, dried, and evaporated under reduced pressure. The residue (47.9 mg) was crystallized from ether, m.p. 236–245°, dissolved in benzene, and chromatographed on alumina (activity II). Elution of the column with chloroform gave oxodelcosine, which crystallized from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a mixture of acetone, ether, and hexane as colorless prisms, m.p. 245–246.5, $[\alpha]_D^{23}$ +44.3 ±0.6° (*c*, 1.83). Found: C, 61.75; H, 7.93. Calc. for $C_{24}H_{37}O_8N$: C, 61.65; H, 7.98%. Ultraviolet spectrum: shoulder λ_{max} 210 mμ, log ε 3.8. Infrared spectrum (nujol mull): 3446(72), 3406(69), 1649(93), 1622(56) cm^{-1}; (chloroform solution): 3608(17), 3468(43), 1638(86) cm^{-1}.

1,10-Didehydro-oxodelcosine (V)

(*a*) *From oxodelcosine.*—To a solution of oxodelcosine (200 mg) in glacial acetic acid (15 ml), sodium dichromate (100 mg) dissolved in glacial acetic acid (15 ml) was added dropwise. The solution was set aside for 1 hour at room temperature. Sulphur dioxide was bubbled into the reaction mixture to destroy excess reagent and the solvent was removed under reduced pressure, leaving a residue which was partitioned between 0.5 *N* sulphuric acid and chloroform. The chloroform layer was washed with 4% sodium carbonate, dried, and evaporated under reduced pressure. The residue was crystallized from acetone–ether–hexane (wt. 136.3 mg, m.p. 202–208°), dissolved in benzene, and chromatographed on alumina (activity II–III) and eluted with benzene. Didehydro-oxodelcosine (88.3 mg) obtained from the eluate was recrystallized from benzene–hexane, m.p. 208–211°. Further elution with methanol gave another 46.5 mg of the product, m.p. 202–206°. On recrystallization from benzene–hexane the product was obtained as colorless prisms, m.p. 211–212°, $[\alpha]_D^{21}$ +135±0.9° (*c*, 1.11). Found: C, 62.35; H, 7.12. Calc. for $C_{24}H_{33}O_8N$: C, 62.19; H, 7.18%. Ultraviolet spectrum: λ_{max} 297 mμ, log ε 2.07, λ_{min} 267 mμ, log ε 1.63. Infrared spectrum (nujol mull): 3446(69), 1757(90), 1720(80), 1653(92) cm^{-1}; (chloroform solution): 3540(25), 3476(27), 1761(81), 1721(72), 1643(89) cm^{-1}.

(*b*) *From delcosine.*—Chromic anhydride (1.5 g) was added gradually with stirring to dry, freshly distilled pyridine (15 ml) previously cooled to 0°. The yellow complex began to precipitate and the mixture was allowed to warm to room temperature. A solution of delcosine (0.5 g) in pyridine (10 ml) was then added and the mixture allowed to stand at room temperature for 20 hours in a stoppered flask. The solvent was distilled off under reduced pressure, and, to the residue, cracked ice and 0.5 *N* sulphuric acid were added. Sulphur dioxide was bubbled into the solution which was then extracted with chloroform. The extract was washed with 0.5 *N* sulphuric acid, with 4% aqueous sodium carbonate, and with water. The didehydro-oxodelcosine recovered from the chloroform solution was purified as described above, m.p. 209–211°, wt. 233.9 mg.

Reduction of Didehydro-oxodelcosine

To a solution of didehydro-oxodelcosine (100 mg) in 80% methanol (25 ml), sodium borohydride (600 mg) was added and the mixture was kept at room temperature for 2 hours. The solvent was evaporated, 0.5 *N* sulphuric acid added to the residue and the mixture was extracted with chloroform. The extract was washed with 4% aqueous sodium carbonate and evaporated under reduced pressure. The residue was crystallized from ether (wt., 88 mg) and purified by chromatography in chloroform on neutral alumina and recrystallization from acetone–hexane, m.p. 241–243°, $[\alpha]_D^{23}$ +43.6±0.8°. The infrared spectrum (in chloroform solution) was superimposable on that of oxodelcosine.

10-Monoacetyl-1-dehydro-oxodelcosine (VI)

Monoacetyldelcosine (4) (190 mg) in pyridine (3.6 ml) was oxidized with chromic oxide – pyridine complex. The complex was prepared in the usual way from chromic anhydride (360 mg) and pyridine (3.6 ml). The product was isolated exactly as described above. The monoacetyldehydro-oxodelcosine thus obtained and crystallized from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hexane consisted of microcrystals, m.p. 107–110°, $[\alpha]_D^{26}$ +94.6±1.3° (*c*, 0.74). Found: C, 62.01; H, 7.68. Calc. for $C_{26}H_{37}O_9N$: C, 61.52; H, 7.35%. Ultraviolet spectrum: λ_{max} 298 mμ, log ε 1.873 and shoulder at λ 214 mμ, log ε 3.382. Infrared spectrum (nujol mull): 3436(53), 1738(86), 1721(78), 1645(86), 1253(86) cm^{-1}; (in chloroform solution): 3520(18), 3440(25), 1732(75), 1723(79), 1645(81), 1248(84) cm^{-1}.

1-Dehydro-oxodelcosine (VII)

Monoacetyldehydro-oxodelcosine (186 mg) was saponified by refluxing for 2 hours with 5% potassium hydroxide in 1:1 methanol–water. The solution was evaporated to a syrup under reduced pressure, water was added, and the mixture was extracted with chloroform. The extract was washed with 0.5 *N* sulphuric acid, dried, and evaporated under reduced pressure. The residue (137 mg) was dissolved in benzene and chromatographed on a column of alumina of activity IV. The column was eluted with benzene and the eluate yielded a fraction of the product (86 mg), m.p. 221–225°, and a less pure fraction (43 mg), m.p. 208–216°. The first fraction was crystallized twice from acetone–hexane from which it separated in long, colorless needles, m.p. 228–229°, $[\alpha]_D^{23}$ +120±0.9° (*c*, 1.08). Found: C, 61.83; H, 7.45. Calc. for $C_{24}H_{35}O_8N$: C, 61.92; H, 7.58%. Ultraviolet spectrum: λ_{max} 297 mμ, log ε 1.937 and shoulder at λ 211 mμ, log ε 3.479, λ_{min} 267 mμ, log ε 1.565. Infrared spectrum (nujol mull): 3476(34), 3358(64), 1719(53), 1633(91) cm^{-1}.

Di-O,O-Methyldelcosine

To a solution of delcosine (76 mg) in dioxane (6 ml), sodium hydride (80 mg) and methyliodide (2 ml) were added, and the mixture kept overnight at room temperature. It was then refluxed for 8 hours. After it had cooled the reaction mixture was filtered and the filtrate evaporated to dryness under reduced pressure. The residual product (quantitative yield) was crystallized from acetone–ether (49 mg), m.p. 203–206°, $[\alpha]_D^{24}$ +48.6±1.3° (*c*, 0.74). Found: C, 65.00; H, 9.06; OCH_3, 31.60. Calc. for $C_{26}H_{43}O_7N$: C, 64.84; H, 9.00; $5OCH_3$, 32.21%.

O-Methyldelcosine (Delsoline)

To a solution of delcosine (45.4 mg) in dioxane (2 ml), sodium hydride (30 mg) and methyliodide (0.5 ml) were added and the mixture was allowed to stand at room temperature for 21 hours in a flask protected by a calcium chloride tube. After this period the mixture was filtered through a hyflo-supercel column and the filtrate was evaporated to dryness under reduced pressure. The residue, which was crystalline, was recrystallized from benzene–hexane, m.p. 213–216°, wt. 42 mg. It was dissolved in benzene, chromatographed on a column of alumina grade IV (370 mg), and eluted with benzene. The benzene eluate yielded 26 mg of base and further elution with methanol yielded another 11 mg. Recrystallization of the product in benzene–hexane gave colorless prisms, m.p. 215–216°, undepressed on admixture with an authentic sample of delsoline. Its optical activity, $[\alpha]_D^{22}$ +53.4±0.5° (*c*, 2.04), was the same as that of delsoline, $[\alpha]_D^{27}$ +53.5±0.5° (*c*, 2.11). Found: C, 64.43; H, 8.79. Calc. for $C_{25}H_{41}O_7N$: C, 64.22; H, 8.84%. The infrared spectrum of the product was superimposable on that of delsoline, and its Debye–Scherrer powder diagram was identical with that of delsoline.

Internal Hemiketal of Seco-oxodelcosine Diketone (VIII)

Oxodelcosine (75 mg) was dissolved in a saturated solution of lead tetraacetate in glacial acetic acid (50 ml) and the solution was kept in the dark for 2 hours at room temperature. Excess lead tetraacetate was reduced with sulphur dioxide, water was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

added, and the mixture was cooled for 1 hour. The precipitate was filtered off and the filtrate evaporated under reduced pressure to dryness. Sulphuric acid (0.5 *N*) was added to the residue and the mixture extracted with chloroform. The extract was washed with 4% aqueous sodium carbonate, dried, and evaporated. The neutral residue was crystallized in acetone–hexane, wt. 50 mg, m.p. 183–186°. Several recrystallizations from dichloromethane–ether yielded colorless prisms, m.p. 191–193°, $[\alpha]_D^{24}$ +1.5±0.8° (*c*, 0.65). Found: C, 62.06; H, 7.42. Calc. for $C_{24}H_{35}O_8N$: C, 61.92; H, 7.58%. Ultraviolet spectrum: λ_{max} 215 mμ, log ε 3.72, λ_{max} 322 mμ, log ε 2.40, λ_{min} 275 mμ, log ε 1.86. Infrared spectrum (nujol mull): 3408(55), 3360(52), 1763(84), 1654(93) cm^{-1}.

Internal Hemiketal of 10-Dehydroseco-oxodelcosine Diketone (IX)

To dried, freshly distilled pyridine (2.2 ml) cooled to 0°, chromic anhydride (116 mg) was added portionwise with shaking. The mixture from which a yellow complex had separated was allowed to warm to room temperature and to it was added a solution of the hemiketal of seco-oxodelcosine diketone (58 mg) in pyridine (1.2 ml). The reaction flask was stoppered and allowed to stand at room temperature for 20 hours. The solvent was then removed under reduced pressure and to the residue ice and 0.5 *N* sulphuric acid were added. Excess oxidizing agent was destroyed with sulphur dioxide and the solution was extracted with chloroform. The extract was washed with 0.5 *N* sulphuric acid, with 4% aqueous sodium carbonate, dried, and evaporated. The neutral residue crystallized on trituration with ether (wt. 31 mg) and was recrystallized from benzene–hexane from which it separated as colorless needles, m.p. 209–210°, $[\alpha]_D^{26}$ +13.7±1.0° (*c*, 1.1). Found: C, 62.33; H, 7.19. Calc. for $C_{24}H_{33}O_8N$: C, 62.19; H, 7.18%. Ultraviolet spectrum: λ_{max} 319 mμ, log ε 2.52, shoulder λ 213 mμ, log ε 3.80, λ_{min} 270 mμ, log ε 2.11. Infrared spectrum: 3320(56), 1766(86), 1758(78), 1657(90) cm^{-1}.

1,10-Didehydroseco-oxodelcosine Diketone (X)

Didehydro-oxodelcosine (75 mg) was dissolved in a saturated solution of lead tetraacetate in glacial acetic acid (50 ml) containing water (2.5 ml) and kept at room temperature in the dark for 3 hours. Sulphur dioxide was bubbled through the solution and the precipitate filtered off after the mixture had been cooled. The filtrate was evaporated to dryness under reduced pressure, 0.5 *N* sulphuric acid was added to the residue, and the mixture was extracted with chloroform. After it was washed with acid and sodium carbonate as described above, the extract yielded a product which crystallized on trituration with ether, wt. 46 mg, m.p. 161–167°. Recrystallization from benzene–ether gave colorless plates, m.p. 175–177°, $[\alpha]_D^{27}$ +77.4±1.0 (*c*, 1.2). Found: C, 62.34; H, 6.75. Calc. for $C_{24}H_{31}O_8N$: C, 62.45; H, 6.77%. Ultraviolet spectrum: λ_{max} 312 mμ, log ε 2.29, λ_{min} 272 mμ, log ε 1.98. Infrared spectrum (nujol mull): 1780(84), 1764(77), 1717(89), 1652(87) cm^{-1}; (in chloroform solution): 1776(89), 1722(85), 1658(84) cm^{-1}.

1-Dehydroseco-oxodelcosine Diketone (XI)

1-Dehydro-oxodelcosine (49 mg) was oxidized with a saturated solution of lead tetraacetate in glacial acetic acid (35 ml) and water (1.8 ml). The solution was kept for 1.5 hours in the dark at room temperature and the product isolated exactly as described above, wt. 30 mg. After recrystallization from benzene–ether the product consisted of colorless hexagonal prisms, m.p. 181–183°, $[\alpha]_D^{28}$ +57.1±2.1° (*c*, 0.28). Found: C, 62.36; H, 6.90. Calc. for $C_{24}H_{33}O_8N$: C, 62.19; H, 7.18%. Ultraviolet spectrum: λ_{max} 323 mμ, log ε 2.36, λ_{min} 274 mμ, log ε 1.87. Infrared spectrum (nujol mull): 3344(55), 1776(70), 1712(73), 1688(81), 1655(92) cm^{-1}.

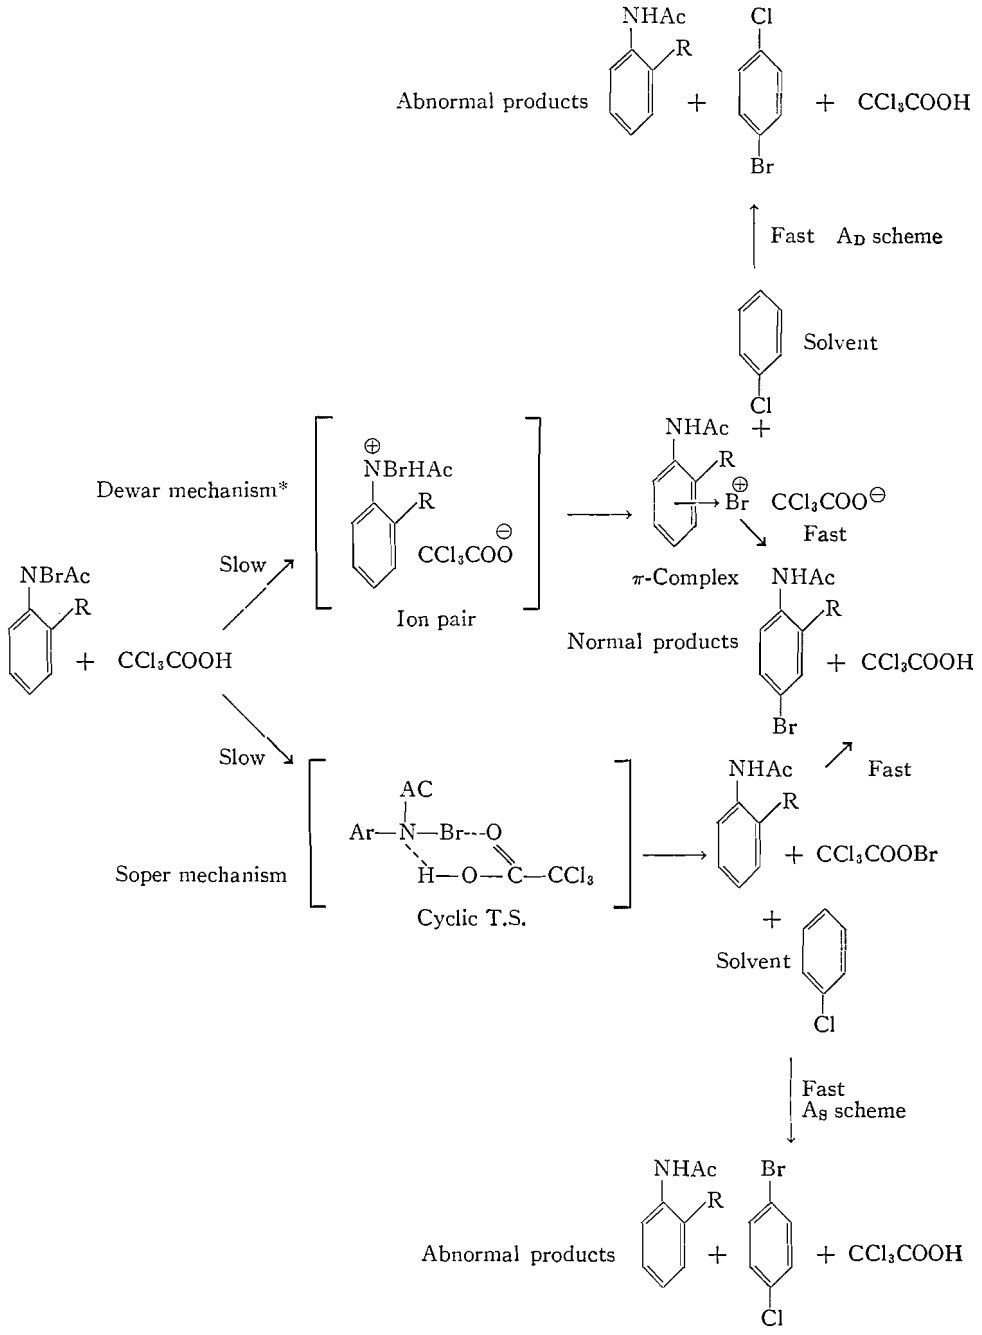
THE ORTON REARRANGEMENT IN APROTIC SOLVENTS

SOME OBSERVATIONS ON THE REACTIONS OF *p*-SUBSTITUTED N-BROMOACYLANILIDES IN CHLOROBENZENE AND TRICHLOROACETIC ACID[1]

J. M. W. Scott[2]

ABSTRACT



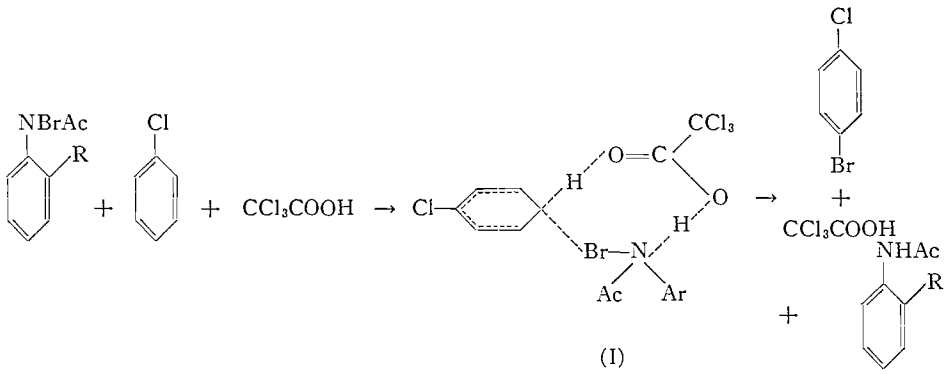
The qualitative and kinetic behavior of a series of *p*-substituted N-bromoacylanilides when treated with trichloroacetic acid in chlorobenzene has been studied. The abnormal reaction which was previously demonstrated for the *o*-nitro derivative has been shown to occur with the *p*-isomer. The mechanisms of the normal and abnormal reactions are discussed. Some derivatives of 4-fluoro-3-bromoaniline are described.

Recently interest in the Orton rearrangement has been revived with a view to substantiating the 'π-complex' mechanism originally proposed by Dewar (1). In one of a series of publications (2) evidence for the production of an intermediate (acetyl hypobromite) was reported which appeared to support the alternative mechanism proposed by Soper (3). A closer examination of the experimental conditions under which this intermediate was produced has revealed that the intermediate was due to a slight trace of impurity in the reaction media (4). Although a further attack on the problem has been made using tracer techniques some aspects of the problem of the mechanism remained unsolved (5).*

One of the most interesting facts which the previous work revealed, and one with which this paper is particularly concerned, was the failure of N-bromo-2-nitroacetanilide to rearrange when treated with trichloroacetic acid in chlorobenzene (6). The bromine migrated to the solvent to give *p*-bromochlorobenzene. There are several mechanistic alternatives for this migration and it is of interest to assess their relative merits, and examine any implications they may have with respect to the normal rearrangement.

The rate-determining step for the rearrangement is considered to be a proton transfer and there is much evidence to support this (7–9). On the Dewar mechanism this yields an ion pair which rapidly and irreversibly forms a 'π-complex'. On the Soper mechanism it has been proposed (2) that the proton transfer is accompanied by a concerted attack of the carbonyl oxygen on the bromine atom to give a cyclic transition state which subsequently breaks down into the anilide and the acid hypohalite. These alternatives are represented schematically for both the 'normal (N)' and 'abnormal (A)' reactions:

[1]*Manuscript received July 8, 1960.*
Contribution from Queen Mary College, University of London and Services Electronics Research Laboratories, Harlow, Essex, England.
[2]*Present address: American Cyanamid Co., 1937 West Main St., Stamford, Conn., U.S.A.*
**When the present investigation was started the Dewar and Soper mechanisms were the only schemes available which were capable of explaining the experimental facts. Although the subsequent investigations described in reference 4 show that the approach outlined here is oversimplified, we feel that this is the best way of presenting our data.*



**It is possible that the stages* N-*bromoanilide + acid → ion pair → π-complex may be concerted.*

On the A_D scheme the 'π-complex' acts as a brominating agent, the reactivity of the bromine being enhanced in the particular instance R = NO_2 by the electron-withdrawing properties of the nitro substituent. A similar explanation has been advanced by Dewar to account for the intermolecular transfer observed by Soper *et al.* (3) when N-bromo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acetanilide was treated with acetic acid in phenetole and anisole. On the Soper scheme the A_S reaction results from the competition for the bromine in the second bimolecular step between the anilide and the solvent. In the case R = NO_2 although the anilide may possibly have a more reactive *p*-position than the solvent, this is offset by the high concentration of the latter. The preceding discussion demonstrates that both mechanisms will superficially account for the observed experimental facts for both the A and N reactions. However, the possibility of other transition states for the A reaction must be considered. Two other schemes may be invoked in the case of R = NO_2. The first of these consists of a termolecular reaction:

(I)

Some evidence for such transition states has been obtained when N-bromoacetanilide is 'rearranged' in the presence of anisole, i.e.

$$\text{rate} = k[\text{anisole}]^n[\text{N-bromoacetanilide}]\,[\text{acid}].$$

However, the order (*n*) with respect to anisole shows a complex behavior with variation in the anisole concentration (4), which precludes any simple formulation of transition states such as I.

The transition state (I) bears obvious analogy to that proposed for the N_S reaction, the ring now being effectively six-membered instead of five. It would bear some resemblance to the transition state for the A_D fast reaction since the same molecules must be involved. Finally it may be envisaged that the bromine, the ion pair, or π-complex stage, forms some type of internal complex with the *o*-nitro group. This could then brominate the solvent. This hypothesis may be safely discarded since it has been demonstrated (see below) that the *p*-nitro compound behaves similarly and in this case the possibility of such an intermediate is very unlikely.

The problem, at this stage, appears to be reduced to deciding between the termolecular scheme on one hand and Dewar and Soper schemes on the other, since the latter appear almost indistinguishable experimentally. This was approached in the following manner. If the transition states leading to the A and N reactions are identical the rate of reaction for a series of *p*-substituted N-bromoacylanilides should presumably be related by the equation $\log k = x \log K_b +$ constant where K_b is the dissociation constant of the amine corresponding to the N-bromoacylanilide and *x* is a constant. If the abnormal reaction involves a termolecular transition state, this should not obey equation [1]. The use of equation [1] implies the use of a single catalyzing acid to compare the rates.

The above discussion shows that the investigation of the series of compounds R = NO_2, Cl, F, Br, Me, Ph, and H might be expected to aid in the elucidation of the problem and the result of such investigations is reported below.

EXPERIMENTAL

Materials

Acetanilides

p-Nitro-, *p*-bromo-, *p*-methyl- and *p*-chloro-acetanilides were purchased commercially and purified where necessary. *p*-Aminobiphenyl was purchased commercially and acylated with acetyl chloride in dry pyridine (10). *p*-Fluoroacetanilide was prepared by the route described for the *o*-isomer (6).

N-Bromo-4-fluoroacetanilide

p-Fluoroacetanilide (2.2 g) in chloroform (150 ml) was vigorously stirred (30 minutes) with a solution of sodium hypobromite prepared by dissolving bromine (5 ml) in 0.5 *N* NaOH (500 ml) also containing potassium bicarbonate (4 g). The chloroform layer was then washed with dilute potassium bicarbonate solution and dried over anhydrous sodium sulphate. Removal of the chloroform under reduced pressure and treatment with light petroleum (b.p. 40–60°) yielded a pale yellow solid which crystallized in plates from benzene and light petroleum (b.p. 40–60°), m.p. 95–97° (decomp.). (Active bromine 34.5, 34.6. C_8H_7NOBrF requires Br, 34.4%.)

N-Bromo-4-nitro-, chloro-, and bromo-acetanilides all previously characterized were prepared in the same way as the 2-fluoro derivative. The 4-nitro compound could not be obtained pure.

N-Bromo-p-acetaminobiphenyl

This compound was prepared by the same route as was used for the *o*-isomer (6). It crystallized from chloroform and light petroleum (b.p. 40–60°) yellow prisms, m.p. ca. 83° (decomp.). (Active bromine 27.3, 27.2. $C_{14}H_{13}NOBr$ requires Br, 27.5%.) N-Bromo-4-methylacetanilide was prepared by the dioxane method (6). It had previously been characterized and was found to be extremely labile.

3-Bromo-4-fluorotoluene

2-Bromo-*p*-toluidine hydrochloride (10 g) was suspended in hydrofluoroboric acid solution (10.3 g, 42% w/w) and cooled to 0°. Sodium nitrite (4 g) in the minimum of water was added dropwise with vigorous stirring, maintaining the temperature of the solution below 10°. After a further 30 minutes the diazonium salt was collected, washed with several small portions of ether, and dried over phosphorus pentoxide in a vacuum desiccator (11.8 g, 73.5%). The dry diazonium salt was decomposed in 30- to 50-g portions, the reaction being moderated by an equal weight of dry sand. The product was washed with dilute alkali and steam distilled. It was dried over calcium chloride and distilled under reduced pressure, b.p. 69–70°/11 mm (76.7 g, 43%). Found: C, 45.2; H, 3.5. C_7H_6BrF requires C, 44.5; H, 3.2%.

3-Bromo-4-fluorobenzoic Acid

3-Bromo-4-fluorotoluene (30 g) was oxidized with aqueous potassium permanganate (50 g). (For details see reference 2.) The product crystallized from aqueous alcohol in needles (10 g), m.p. 137°. Found: equivalent, 219; C, 38.7; H, 1.8. $C_7H_4O_2BrF$ requires equivalent, 219; C, 38.4; H, 1.8%. K_D (uncorr.) = 1.38×10^{-5} in 50/50 absolute ethanol water by volume, T = 21–22°.

3-Bromo-4-fluorobenzoyl Chloride

3-Bromo-4-fluorobenzoic acid (5 g) was boiled with thionyl chloride for 1 hour. The excess thionyl chloride was removed under reduced pressure and the residue distilled, b.p. 110–112°/11 mm. The distillate solidified giving colorless blades which were crystallized from light petroleum (b.p. 40–60°), m.p. 43–45°. Found: solvolysable Cl, 14.9. $C_7H_3O_2ClBrF$ requires Cl, 14.9%).

3-Bromo-4-fluorobenzamide crystallized in fine needles from anisole and light petroleum (b.p. 100–120°), m.p. 133° C. Found: C, 38.8; H, 2.3; N, 6.4. C_7H_5NOBrF requires C, 38.6; H, 2.3; N, 6.4%.

3-Bromo-4-fluorobenzanilide crystallized in needles from toluene, m.p. 148–149°. Found: C, 53.4; H, 3.3; N, 4.9. $C_{13}H_9NOBrF$ requires C, 53.1; H, 3.1; N, 4.8%.

3-Bromo-4-fluorobenz-p-toluidide crystallized in needles from toluene, m.p. 153–155°. Found: C, 54.3; H, 3.7; N, 4.7. $C_{14}H_{11}NOBrF$ requires C, 54.6; H, 3.6; N, 4.6%.

3-Bromo-4-fluoroaniline

3-Bromo-4-fluorobenzoic acid (6.6 g) in chloroform (200 ml) was treated with hydrazoic acid (2 moles) and concentrated sulphuric acid (40 ml) at 50–55° C on a steam bath. Working up in the usual fashion gave an amine (2 g, 36%) distilling at 124°/11 mm.

The *3-bromo-4-fluoroacetanilide* crystallized from toluene in prisms, m.p. 114°. Found: C, 41.4; H, 2.9; N, 6.1. C_8H_7NOBrF requires C, 41.4; H, 3.0; N, 6.0%.

The *3-bromo-4-fluoroformanilide* crystallized in needles from benzene – light petroleum (b.p. 40–60°), m.p. 91–92°. Found: C, 38.6; H, 2.1; N, 6.3%. C_7H_5NOBrF requires C, 38.6; H, 2.3; N, 6.4%.

The *N-benzoyl-3-bromo-4-fluoroaniline* crystallized from aqueous alcohol in plates, m.p. 125–127°. Found: C, 54.3; H, 2.8; N, 5.0. $C_{13}H_9NOBrF$ requires C, 53.1; H, 3.1; N, 4.8%.

Rearrangements

These were all carried out in a solution of 0.617 *N* A.R. trichloroacetic acid in chlorobenzene, the solution being prepared as described in the section dealing with the kinetic data. The rearranging solutions of the N-bromoamide and acid were left in the dark until they displayed negligible oxidizing properties towards acid potassium iodide solution. The N-bromoacylanilides were pure samples unless otherwise stated.

(*a*) *N-Bromo-p-methylacetanilide* (16 g) on treatment with the acid solution (ca. 30 ml) gave on removal of acid and the bulk of solvent a gummy product (11.8 g, 73.5%). Chromatography of a portion of the product on alumina from benzene/light petroleum (b.p. 60–80°) yielded a compound which crystallized from the same solvent in fine white needles, m.p. 117° C (lit. 2-bromo-4-methyl acetanilide 117° C). Because of the tarry nature of the product this reaction was not studied kinetically.

(*b*) *N-Bromo-p-acetaminobiphenyl* (5 g) on treatment with acid solution (ca. 10 ml) yielded a clean product (4.67 g, 81.4%), m.p. 139–142° C. C, 58.5; H, 4.1; N, 5.00; Br, 26.9. Calc. for $C_{14}H_{12}NOBr$: C, 58.0; H, 4.2; N, 4.8; Br, 27.5%. Hydrolysis of the product yielded an amine crystallizing in needles from light petroleum (b.p. 40–80°), m.p. 66–68° (lit. for 2-bromo-*p*-aminobiphenyl 66° C).

(*c*) *N-Bromo-4-bromoacetanilide* (10.35 g) on treatment with acid solution (ca. 20 ml) yielded a very clean product (9.6 g, 92.7%), m.p. 145–147° (lit. for 2,4-dibromoacetanilide 146° C).

(*d*) *N-Bromo-4-chloroacetanilide* (9.97 g) on treatment with acid solution yielded a very clean product (8.39 g, 84%), m.p. 134–136° (lit. for 2-bromo-4-chloroacetanilide 135°). Hydrolysis of product yielded an amine which crystallized in needles from light petroleum, b.p. 40–60°, m.p. 65–67° (lit. for 2-bromo-4-chloroaniline 69°).

(*e*) *N-Bromo-4-fluoroacetanilide* (1 g) on treatment with acid (2 ml) gave a clean product which appeared to be a mixture of the ring-brominated product and anilide formed possibly by loss of bromine to the solvent. Separation of the product was not achieved.

For personal use only.

(*f*) *N-Bromo-4-nitroacetanilide* (10.84 g), 90.9% pure, when treated with acid yielded *p*-bromochlorobenzene (3.5 g, 50%), m.p. 64–67° C (lit. 67° C), and unchanged anilide (4.28 g, 72.2%), m.p. 215° C (lit. 215° C).

Kinetic Experiments

The kinetic experiments were mainly carried out as previously described (2) but with certain modifications. All the glass apparatus used was carefully washed with distilled water and dried in a vacuum oven.*

Chlorobenzene

Chlorobenzene was treated as previously (2) and then distilled twice from an all-glass apparatus with liberal rejection of initial and tail fractions. Its physical properties were essentially the same as those previously reported.

Solutions of Trichloroacetic Acid

A suitable weight of trichloroacetic acid (A.R. grade) was introduced into a 250-ml flask which was then attached to a vacuum line. The flask was then warmed (ca. 50° C) and pumped for about 2 hours. Air was then admitted through the silica-gel drying train, followed by a suitable volume of purified chlorobenzene. The solutions so prepared were standardized as before (2).

Solutions of the N-Bromoacylanilides

These were prepared and stored as previously described (2). The purity of each sample was >97% except in the case of N-bromo-4-nitroacetanilide, which could be obtained only ca. 90% pure. In consequence the purity of the sample was determined and the weight of the impure sample required to give a solution of the desired strength calculated. The solutions thus prepared eventually precipitated unchanged 4-nitroacetanilide (obviously the main impurity) and this was removed by filtration. The precipitation of the anilide was not due to any reaction of the N-bromo-4-nitroacetanilide with the solvent since the oxidative power of the solutions towards acid potassium iodide solution remained constant over a period of months.

Comparison of Rates

The meaningful comparison of rate constants between the various N-bromoacylanilides is rather uncertain for the following reasons.

(*a*) The reaction is not strictly first-order with respect to the N-bromoacylanilide, the first-order constants showing a variation with the initial concentration (C_1) of the N-bromo compound (see references 2 and 8).

(*b*) The variation of the first-order rate constants with the concentration (C_a) of the catalyzing acid is complex (see Bell (7)).

The following procedure was adopted. The first-order rate constants (k) for each N-bromoacylanilide were determined for three values of C_1 and three values of C_a giving nine rate constants at 45° C. A second-order rate constant k_m for each compound was evaluated from these results in the following rather arbitrary manner.

Within the range C_a 0.2 *M*–0.1 *M*, k is approximately linear in C_a. The measured rates were consequently reduced to unit acid concentration to give nine values of a quantity k_u. Bell and Levinge (8) have shown that the variation of k with C_1 can be represented by an equation of the form

$$1/k = A + BC_1$$

where A and B are empirically determined constants. Thus three k_u values for a given

**The spurious production of an intermediate previously reported was almost certainly due to traces of acetone in the reacting system; in consequence the use of acetone for washing glassware was completely avoided.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

value of C_a were fitted to the above equation by the method of least squares and a value of k_u for $C_i = 0.01\ N$ was determined from the above equation. This procedure was repeated on the k_u values from the remaining two C_a values giving in all, three values of k_u at $C_i = 0.01\ N$. The mean of these three values of k_u was defined as k_m and was expressed with a standard deviation.

This procedure for treating the reported rate data was found satisfactory for the 4-nitro-, 4-chloro-, 4-bromo-, and 4-fluoro-N-bromoacylanilides. One rate constant for the N-bromo-4-bromoacetanilide ($C_i = 0.0309\ N$; $C_a = 0.199\ M$, see Table I below) failed

TABLE I

to conform to the general pattern observed and the rates of the N-bromo-4-phenylacetanilide showing a curious minimal reactivity at the intermediate N-bromoamide concentration. In consequence the rate constants for the latter compound are reported without the evaluation of k_m. The anomalous behavior of the odd N-bromo-4-bromoacetanilide rate constant and all the N-bromo-4-phenylacetanilide rate constants do not invalidate the general conclusions which we wish to make in this instance.

TABLE II

N-Bromo-4-chloroacetanilide	10.19	10.6±0.6
N-Bromo-4-bromoacetanilide	10.09	10.9±0.5

*The calculation of the rate constant for N-bromoacetanilide at 45° C was made in the following way. The first-order rate constants (C_i = 0.01 N) reported by Bell (7) at 15° C are linear in C_a over a range 0.07 M–0.2 M. Values of k at 15° C C_a = 0.102 M, 0.150 M, and 0.199 M were thus interpolated from Bell's results, and from these, three values of k_u calculated. Using these values in conjunction with the Arrhenius equation (E_a = 11.8 kcal) three values of k_u at 45° C were calculated. These were then averaged and the mean value indentified with k_m as in the previous treatment. It should be noted that Bell's rate constants must be multiplied by a factor 2.3026/3600 to bring them to the units used in this paper.

DISCUSSION

The examination of the reaction products which preceded the kinetic studies revealed that the reactions of the 4-substituted N-bromoacylanilides were similar to those of the corresponding 2-substituted compounds. The 4-nitro compound was again exceptional, the bromine being transferred to the solvent to give 4-nitroacetanilide and 4-bromochlorobenzene. The products from the rearrangement of N-bromo-4-fluoroacetanilide also appeared complex and possibly contain 2- and 3-bromo-4-fluoroacetanilides, 4-fluoroacetanilide, and 4-bromo-chlorobenzene. An unambiguous synthesis of 3-bromo-4-fluoroacetanilide was devised with the hope that both 2- and 3-bromo-4-fluoroacetanilides could be characterized. However, the complexity of the products from the rearrangement of N-bromo-4-fluoroacetanilide (which it was hoped would yield 2-bromo-4-fluoroacetanilide as the sole product) prevented this project from being completely realized.

The recent work of Dewar and Couzens (4, 5) show that the premises on which the kinetic work was based are vastly oversimplified. It now appears that the Dewar and Soper formulations as originally postulated are insufficient to account for the observed complexities of the reacting system. However, two useful points appear to emerge from the present investigation.

(*a*) There is a rough correlation between log k_m and the logarithm of the dissociation constant of the parent amine (Table IV and Fig. 1). The slope of this line is very small, i.e. the reaction is very insensitive to substituent effects.

(*b*) Although the 2- or 4-substituted nitro group and possibly the 4-fluoro group induce the reaction to give different products, this does not appear to alter the nature of the rate-determining step, i.e. the differentiation in products occurs subsequent to the rate-determining step.

POTASSIUM DERIVATIVES OF FLUORENE AS INTERMEDIATES IN THE PREPARATION OF C_9-SUBSTITUTED FLUORENES

II. COMPARATIVE REACTIVITIES OF THE ALKALI METALS, LITHIUM, SODIUM, AND POTASSIUM, WITH FLUORENE IN GLYCOL DIMETHYL ETHER, GLYCOL DIETHYL ETHER, TETRAHYDROFURAN, AND DIOXANE[1]

G. W. H. Scherf and R. K. Brown

ABSTRACT

In the solvents 1,2-dimethoxyethane (DME), 1,2-diethoxyethane (DEE), tetrahydrofuran (THF), and dioxane, potassium reacts much more readily with fluorene than does sodium or lithium. Lithium is generally more reactive than is sodium. The order of effectiveness of the ethers is DME > DEE ≈ THF > dioxane. Although practically no reaction of these metals with fluorene occurs in toluene, the addition of small amounts of these ethers to toluene does accelerate such reaction. All three organometallic compounds are soluble in refluxing and cold (22°) DME, THF, and DEE except the 9-fluorenyllithium, which precipitates largely from cold DEE. The results are explained in terms of the relative electropositivities of the metals, their size, and the structure of the ethers. It is suggested that these ethers actually participate in the formation of the organometallic compound from the metal.

Sodamide and lithium amide react as readily as or more readily than the metals with fluorene in DME to produce the organometallic compounds.

Diphenylmethane and triphenylmethane react reasonably well with potassium in DME, but too slowly with lithium and sodium to be useful.

INTRODUCTION

It was recently reported (1) that 9-fluorenylpotassium could be prepared by the direct action of potassium with fluorene in dioxane solvent. The organometallic compound was a reddish-brown precipitate singularly free of tarry impurities and quite useful for the synthesis of 9-substituted fluorenes. The simplicity of preparation led us to study the scope of this reaction in greater detail.

In a preliminary examination of the effects of solvents on the preparation of 9-fluorenylpotassium (2), it was found, in agreement with general information already established in the literature (3), that dioxane, dialkyl, alkylaryl, or diaryl ethers as well as tertiary amines promoted the reaction of potassium with fluorene. Generally no reaction was observed in hydrocarbon solvents. The tertiary amines proved to be either less effective than the ethers or themselves reacted with the organometallic substance formed.

Since, of all the pure ethers examined, dioxane was the most effective, and because addition of ethers to the normally ineffective hydrocarbons to the extent of 20% gave reactions of the metal with fluorene in the case of dioxane but not for dialkyl or arylalkyl ethers, it was suggested that the presence of *two* ether oxygen atoms in a single molecule, suitably situated as in the unstable boat form of dioxane, and/or sterically less hindered oxygen atoms (4) might be responsible for the preferred reaction found for dioxane. This viewpoint, augmented by the reports that certain ethers such as those of ethylene glycol (5, 6) dissolve small amounts of potassium metal at low temperatures to form blue, electrically conducting solutions, while dialkyl ethers do not, led to the investigation of the comparative efficiencies of ethers of ethylene glycol, as well as tetrahydrofuran as solvents for the reaction of the alkali metals, lithium, sodium, and potassium, with fluorene. This paper presents the results of experiments in this direction.

Gilman and Gorsich (7) have reported that lithium does react directly with fluorene and with cyclopentadiene in tetrahydrofuran to form the corresponding 9-fluorenyllithium and cyclopentadienyl lithium. Recently a paper by Normant and Angelo (8) described the metalation of a number of hydrocarbons with reactive hydrogen atoms in tetrahydrofuran, primarily with sodium but in some examples with lithium or potassium, using as the intermediate metalating agent the product arising from the combination of the metal with naphthalene. The mixture of naphthalene, tetrahydrofuran, metal, and active hydrogen compound gave metalation of a number of hydrocarbons which previously had reacted very slowly or failed to react at all with metallic sodium. The use of amines and of special ethers such as dimethyl ether and 1,2-dimethoxyethane to facilitate the addition of alkali metals to hydrocarbons such as naphthalene, biphenyl, etc., and the utility of these addition compounds to prepare alkali metal salts of active hydrogen-containing hydrocarbons had been pointed out previously by Scott *et al.* (9). However, the presence of naphthalene and the dihydronaphthalene by-product complicated isolation and purification. The results of our work show that in the case of fluorene, the hydrocarbon under examination in this laboratory, the addition of naphthalene is an unnecessary factor in the reaction of alkali metals with fluorene to form the organometallic compound and hydrogen.

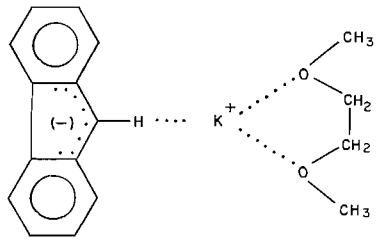
RESULTS AND DISCUSSION

For the comparative studies, equivalent amounts of metal and fluorene were used in the appropriate solvent. The particular quantities upon which time and extent of reaction are quoted were 0.05 mole of fluorene, 0.05 gram-atom of the metal, and 50 ml of the solvent. Reactions were protected by nitrogen atmosphere and anhydrous conditions were employed at all times. The results are compiled in the accompanying table for convenience. The metals lithium, sodium, and potassium were studied while the solvents examined were 1,2-dimethoxyethane (DME), 1,2-diethoxyethane (DEE), and tetrahydrofuran (THF). The results in these solvents are compared with those obtained for dioxane in the previous work (2). For those cases where the metal remained solid under the conditions employed, we did attempt to use pieces of roughly similar size, about 1 mm^3. Solid pieces of sodium, especially at higher temperatures, had a strong tendency to stick together, hence presenting a smaller surface area to the reagent than was originally obtained. Molten sodium did not show this property. A similar behavior for potassium was not found, probably due to the greater rate of reaction with fluorene at the surface preventing adhesion of metal particles. Lithium particles did not stick together at all.

The extent of metalation was estimated by methylation of the salt by addition of methyl iodide, and, after isolation of the product, measurement of the amount of mono- and di-methylfluorene and of unchanged fluorene by infrared spectroscopy (1).

From the results shown in Table I, and from previous work (2), it is seen that, generally, hydrocarbon–ether mixtures are less effective solvents for the reaction of these alkali metals with fluorene than are the pure ethers, and also cause precipitation of the product even from the hot solutions. However, a mixture of 20% DME in *heptane* not only gave nearly complete metalation with potassium in 3 hours, but showed no precipitation of the organometal. Instead, during the reaction, there was observed the formation of a nearly colorless upper layer composed of heptane, unreacted fluorene, and some DME, and a dark-red lower layer containing 9-fluorenylpotassium and DME contaminated with some heptane. The formation of this lower layer apparently approximated the conditions for DME only as solvent and would account for the greater extent of reaction.

TABLE I



Solvent	Metal	Temperature	Observation	Extent of Metalation
Dioxane (98°/700 mm)	Li	Reflux	Little reaction in 4 hours	<5%
	Na	Reflux	Little reaction in 4 hours	<5%
	K	Reflux	Complete in 4 hours. Product largely insoluble hot	80–90%
	K	22°	Some reaction in 12 hours. Product largely insoluble hot	~30%
DME (85°/700 mm)	Li	22°	Small pieces. Complete reaction in ~5 hours. Product soluble R.T.	~80–90%
		Reflux	Small pieces. Complete reaction in ~5 hours. Product soluble R.T.	~80–90%
	Na	22°	Small pieces. Complete reaction in ~8 hours. Product soluble R.T.	~80–90%
		Reflux	Small pieces. Complete reaction in ~10 hours. Product soluble R.T.	~80–90%
	K	22°	Complete in 2 hours. Product soluble R.T.	~90–95%
		Reflux	Complete within 1 hour. Product soluble R.T.	~90–95%
DEE (118°/700 mm)	Li	22°	About 20% unreacted after 50 hours. Product largely insoluble R.T.	—
		Reflux	Complete in 5–6 hours. Product soluble in hot, insoluble R.T.	70–80%
	Na	22°	Incomplete in 50 hours	—
		Reflux	Nearly complete in 30 hours. Product largely soluble R.T.	70–80%
	K	22°	Complete in ~3 hours. Product soluble R.T.	~70–80%
		Reflux	Complete in ~2 hours. Product soluble R.T.	~70–80%
THF (65°/700 mm)	Li	22°	Little reaction in 4 hours. Complete in 50 hours. Product soluble R.T.	~80%
		Reflux	Complete in 7–8 hours. Product soluble R.T.	~80%
	Na	22°	Incomplete in 50 hours. Product soluble R.T.	—
		Reflux	Incomplete in 48 hours. Product soluble R.T.	—
	K	22°	Complete in ~2½ hours. Product soluble R.T.	—
		Reflux	Complete in 1 hour. Product soluble R.T.	~70%
Toluene +20% dioxane	K	Reflux	In 5 hours incomplete. Product largely insoluble hot	40–50%
Toluene +20% DME	K	Reflux	Complete in 2 hours. Product largely insoluble hot	60–70%
Toluene +20% DEE	K	Reflux	Nearly complete in 4 hours. Product largely insoluble hot	60–70%
Toluene +20% THF	K	Reflux	Incomplete in 4 hours. Product largely insoluble hot	~50–60%
Toluene +1% dioxane	K	Reflux	In 4 hours, very little reaction	—
Toluene +1% DME	K	Reflux	In 4 hours, red solution + some precipitate	~10–15%
Toluene	K	Reflux	In 4 hours very little reaction	~ 2–3%
Dioxane +10% DME	Li	Reflux	Complete in 10 hours. Product soluble at R.T.	~90%
	Na	Reflux	Incomplete in 24 hours. Product soluble at R.T.	~50%
	K	Reflux	Complete in 2 hours. Product largely soluble at R.T.	~90%
Heptane +20% DME	K	Reflux	Complete in 3 hours. Two layers. Product soluble R.T.	~90%

NOTE: R.T. = room temperature (22°).
In all solvents, solutions of the potassium salt were very dark red, those of the sodium or lithium salts were quite light red (those of the lithium salt somewhat lighter than those of the sodium salt).

The same separation into two layers, with the formation of no precipitate, was observed when a solution of 9-fluorenyl-potassium (-sodium or -lithium) in DME only was diluted with heptane. A similar dilution of a dioxane *solution* of 9-fluorenylpotassium caused the precipitation of most of the salt and when this salt was washed three times with hexane,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

it was apparently free of dioxane since no ether–oxygen band was discernible in the infrared spectrum of a Nujol mull of the salt. However frequent, heptane washes of the dark-red layer obtained from the heptane diluted DME solutions failed to yield any solid precipitate or to remove the ether from the organometal. It is quite clear that with DME as solvent or cosolvent the diluting aliphatic hydrocarbon competed with the metalated fluorene for the ether far less effectively than did the hexane versus 9-fluorenylpotassium for dioxane, no doubt due to the stronger association of the DME with the organometallic compound. Diethyl ether, a solvent more compatible with DME, and also capable of dissolving the 9-fluorenylpotassium only to a limited extent, did cause a precipitation of an oily solid which, however, could not be completely freed from ether. Toluene, however, added to a DME solution of 9-fluorenylpotassium slowly precipitated a portion of the red salt. In contrast, a DME solution of 9-fluorenyl*lithium* poured into excess diethyl ether caused much precipitation of solid 9-fluorenyllithium which was readily freed from ether by hexane washes, showing that the greater polar character of the potassium–carbon bond intensifies the association of the type shown below.

That the lithium salt remains quite soluble in DME is most likely due to the small size of the lithium atom which compensates largely for the lower polarity of the lithium–carbon bond. The lithium atom thus can approach the two oxygen atoms of the glycol ether more closely than can potassium or sodium and because of this close approach will develop more polar character and hence a stronger association of the type shown above. A similar structure has been suggested by Wittig (11) to explain the difficultly soluble molecular complex between phenyllithium and 1,2-dimethoxyethane.

The larger sodium and potassium ions must then depend primarily upon the original polar character of the metal–carbon bond (somewhat augmented upon approach to the ether) for their degree of association with the ether. On the basis of only the original polarity of the metal–carbon bond, the sodium salt should then associate with DME less firmly than does the potassium compound but more so than does the lithium compound. One might therefore expect that small steric factors should affect the degree of proximity of the lithium atom to the ether oxygens, therefore the degree of polarization of the lithium–carbon bond by the glycol ether and hence the strength of association, more than would be the case for the sodium or potassium analogues.

Some evidence for this is given in the results found for the solubilities of the organometallic compounds in DEE. The 9-fluorenyllithium is quite soluble in hot DEE but precipitates largely from the cold solution (at R.T.). On the other hand, both the potassium and sodium compounds remain almost completely soluble in DEE at room temperature. The larger steric interference of the ethyl group in DEE thus hinders close approach of the lithium to the two oxygen atoms. This small difference is of great significance in the association of 9-fluorenyllithium with the glycol ethers, but not as critical with the more ionic sodium and potassium compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

It is noteworthy that the red-orange solid 9-fluorenyllithium (obtained from DEE as above) dissolved readily in dioxane. Diethyl ether dissolved only a small amount of the lithium salt while toluene failed to dissolve any of it.

It is furthermore quite clear that for the preparation of the lithium, sodium, or potassium salts of fluorene, the solvents of choice are, in order of effectiveness, DME > DEE ≈ THF > dioxane > dialkyl ethers.* In all cases, potassium reacts much more vigorously with fluorene than does sodium or lithium, as expected on the basis of the difference in electropositivity between potassium and the other two metals. The presence of two favorably situated oxygen atoms such as found in the ethers of ethylene glycol promotes this reaction. The larger bulk of the ethyl group over that of the methyl group (in DEE vs. DME) is thus expected to, and does, offer steric hindrance to co-ordination. Ferguson (4), in his discussion of solubility of ethers in water, points out that the methyl groups of diethyl ether partially shield the oxygen atom from facile approach by water, thus accounting for the much greater water solubility of dimethyl ether, tetrahydrofuran, and dioxane over that of diethyl ether. That THF is a better solvent for the metalation reaction than is dioxane is also expected since the co-ordinating electrons of the oxygen atom in the former are exposed to a greater extent than they are in the latter molecule, a fact which is readily discerned by consideration of the models of these two molecules.

That the reactivity of lithium is similar to and sometimes greater than that of sodium,† although its electropositivity is less, is quite likely due to its smaller size, which permits closer approach to the favorably located and exposed oxygen atoms in DME, DEE, and THF.

The observation that the solid, dioxane-free 9-fluorenylpotassium, suspended in heptane, is quite definitely deeply colored, and that even the very reactive molten potassium shows no coloration of the bright surface of the metal, when it is refluxed with fluorene in heptane, but upon addition of dioxane a reaction does occur (2) indicates that the ether not only hastens metalation by removing the product from the surface of the metal but also actually participates in the formation of the organometallic compound. Further support for this point of view is given by the fact that ether-free 9-fluorenyllithium, made in DEE, dissolves readily in dioxane but that the reaction of lithium and fluorene in dioxane was found to be very slow, the refluxing solvent in 15 hours developing only a slight color. Removal of the product from the surface of the metal cannot therefore be the controlling factor in this case. A concerted reaction of the type suggested below is thus indicated.

Generally, increased temperature facilitates metalation. Thus in tetrahydrofuran, DEE, and dioxane, both sodium and lithium react faster at reflux temperature than at room temperature while potassium does so in these three solvents *and* in DME. The

*Dimethyl ether, no doubt, is an exception since it has been shown to co-ordinate readily with water due to the lower steric effect of the methyl groups (4, 9).

†W. Schlenk and E. Bergmann (Ann. **463**, 1 (1928)) have found that lithium metal in ether suspension adds more readily to hydrocarbons, such as biphenyl and naphthalene, than does sodium.

similarity of the reaction of sodium at room temperature and at the boiling point in DME may be accounted for by the tendency of the warmed solid metal to agglomerate. However, though lithium reacts about equally well in DME at room temperature and at reflux temperature, the explanation offered for the behavior of sodium cannot apply. This similar time of reaction of lithium at high and low temperatures has been observed in several repetitions of the same experiment. It might be that the increasing rate of reaction due to elevation of temperature does occur but is offset by the increased thermal agitation of the molecule which hinders the attainment of the favorable conformation of the ether and hence the simultaneous close approach to the two oxygen atoms required for the reaction with lithium.

Reaction of Fluorene with Lithium Amide and Sodium Amide in DME

In DME, both lithium amide and sodium amide react quite readily with fluorene. 9-Fluorenylsodium of good quality can thus be prepared more rapidly using sodamide rather than metallic sodium. In 3 hours, 0.05 mole of a good grade of sodamide reacted completely with an equivalent amount of fluorene in refluxing DME as compared with 10 hours required for reaction of 0.05 mole of sodium under the same conditions. Extent of the reaction was again measured by methylation. The lithium amide used was a technical grade, but it reacted completely in 5 hours yielding about 60% metalation. The clear solutions of the organometallic compounds in DME obtained in this manner possessed a deeper red color than those obtained by the direct action of the metal with fluorene. This may be due to the presence of ammonia since the addition of dry gaseous ammonia to 9-fluorenylsodium prepared from sodium reacting with fluorene in DME actually caused intensification of color.

Reaction of Triphenylmethane and Diphenylmethane with Lithium, Sodium, or Potassium in DME as the Solvent

Triphenylmethane was found to react with potassium, showing the red color characteristic of the metal salt after 30 minutes of reflux, and being completely consumed in 10 hours. Reaction with benzyl chloride gave the expected 1,1,1,2-tetraphenylethane in good yield.

Both sodium and lithium under the same conditions reacted very slowly with triphenylmethane and in a period of 100 hours had reacted only to the extent of about 10% as judged by the weight of the unreacted metal.

Diphenylmethane after 3 days' reflux in DME had consumed nearly all the potassium. However, lithium under the same conditions in 30 hours showed only a slight accumulation of red solid on the surface of the metal but no solution of the product.

EXPERIMENTAL

Details for the comparative reactions of the metals in the various solvents and isolation and estimation of products followed published directions (1). In all cases, 0.05 mole of fluorene, 0.05 mole of metal, and 50 ml of purified, dry solvent were used. A constant stream of pure, dry nitrogen supplied a protective atmosphere for the reactions.

The solvents were generally commercially available reagent grade materials but were further purified by distillation from potassium. Only a technical grade of 1,2-diethoxyethane was available. This was treated carefully with metallic potassium, over which the liquid stood for 24 hours. Distillation from the metal gave a glycol ether of good quality.

Metalation of Triphenylmethane

Triphenylmethane (12.2 g, 0.05 mole) and potassium (1.95 g, 0.05 mole) were refluxed in 50 ml 1,2-dimethoxyethane. The solution showed a red color after 30 minutes and in 10 hours all the metal was consumed. To the deep-red solution, containing the completely dissolved triphenylmethylpotassium was added 6.3 g (0.05 mole) of benzyl chloride. The solution, which decolorized rapidly, was then diluted with 150 ml of water, extracted with ether, and the ether extracts dried ($CaCl_2$). Removal of the ether gave a yellow solid which was triturated with pentane to remove unreacted triphenylmethane. Colorless 1,1,1,2-tetraphenylethane requiring no further purification was obtained in good yield, m.p. 140° uncorr., lit. 140–142° (12).

When sodium replaced potassium in a similar experiment a light-red color developed only after 12 to 15 hours of reflux. The small pieces of sodium had formed a single spherical piece of metal. After 100 hours of reflux, 90% of the metal (by weight) remained unreacted. Lithium showed red coloration of the surface of the metal in 5 hours, but gave only 10% reaction of the metal after 100 hours reflux.

Metalation of Diphenylmethane

Details for the reaction between diphenylmethane and potassium followed those described for the triphenylmethane. Evidence of the reaction, via appearance of a red color in the solution, occurred within 3 hours. In 3 days, nearly all the potassium had disappeared giving a product quite soluble in DME. Treatment of the salt with benzyl chloride gave 1,1,2-triphenylethane, m.p. 53°, lit. 54° (13).

Lithium, under the same conditions, formed only a small amount of red precipitate on the metal surface but no change occurred after 30 hours of reflux.

THE MECHANISM OF THE CARBONYL ELIMINATION REACTION OF BENZYL NITRATE

KINETIC ISOTOPE EFFECTS AND DEUTERIUM EXCHANGE[1]

ERWIN BUNCEL[2] AND A. N. BOURNS

ABSTRACT

The carbonyl elimination reaction ($E_{CO}2$) of benzyl nitrate has been investigated with the object of distinguishing between the concerted and carbanion mechanisms. A deuterium exchange experiment resulted in a very small amount of deuterium pickup. The nitrogen isotope effect, k_{14}/k_{15}, associated with formation of the nitrite ion was found to be 1.0196 $\pm$0.0007 at 30° C. The two results taken together exclude the formation of a carbanion intermediate but are consistent with a concerted mechanism.

Benzyl-α-d_2 nitrate has been prepared and the rate of its carbonyl elimination reaction compared with that of the undeuterated compound. The deuterium isotope effect was 5.04$\pm$0.25 at 60° C. The significance of the magnitude of the nitrogen and deuterium isotope effects and of their interrelationship with the Hammett reaction constant *rho* is discussed in terms of the nature of the transition state and a comparison is made with other $E2$ elimination reactions.

Nitrate esters have been extensively studied during the last decade and are the subject of a recent review article (1). Several types of reaction have been observed with nucleophilic reagents (2, 3). The reaction followed in a given system depends on the structure of the nitrate, the nature of the nucleophilic reagent, and the solvent, and often two or more of the reactions take place simultaneously.

1. Substitution on carbon:

$$RCH_2—CH_2—O—NO_2 + Y^- \longrightarrow RCH_2CH_2—Y + NO_3^-.$$

2. Substitution on nitrogen:

$$RCH_2—CH_2—O—NO_2 + Y^- \longrightarrow RCH_2CH_2O^- + Y—NO_2.$$

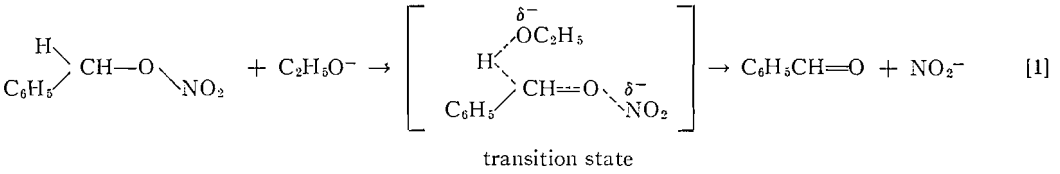
3. β-Hydrogen elimination:

$$RCH_2—CH_2—O—NO_2 + Y^- \longrightarrow RCH{=}CH_2 + NO_3^- + YH.$$

4. α-Hydrogen elimination:

$$RCH_2—CH_2—O—NO_2 + Y^- \longrightarrow RCH_2CH{=}O + NO_2^- + YH.$$

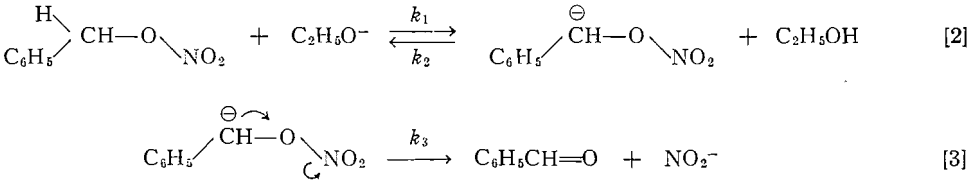
The substitution reaction on carbon has been shown (2) to follow either the S_N1 or the S_N2 mechanism, the factors determining the course of reaction being analogous to those for alkyl halides. For example, in 90% ethanol the rate of reaction of *tert*-butyl nitrate is first order, being independent of the hydroxide ion concentration, while for ethyl nitrate the rate is second order, being proportional to both the nitrate and the hydroxide ion concentrations. Evidence for substitution on nitrogen (reaction 2) is based on oxygen-18 studies of the position of bond fission in the hydrolysis of *n*-butyl and *n*-octyl nitrate (4) and on stereochemical studies in the hydrolysis of optically active 2-octyl nitrate (5). This reaction differs from the others in that it results in the nitration of the base, and this property has been utilized as a synthetic method for the nitration of amines and active methylene groups (6, 7). The β-hydrogen elimination of



[1]*Manuscript received August 16, 1960.*
Contribution from the Burke Chemical Laboratories, Hamilton College, McMaster University, Hamilton, Ontario.
[2]*National Research Council of Canada Postdoctorate Fellow 1958–60.*

alkyl nitrates (reaction 3) has also been shown to proceed by the unimolecular or bimolecular mechanisms (2) and often occurs concurrently with substitution on carbon.

Whereas the first three types of reaction cited have counterparts in the reactions of carboxylic esters or alkyl halides, the α-hydrogen elimination finds no direct analogy in the reactions of these compounds. It has been named a carbonyl elimination reaction (2) and has been designated $E_{CO}2$ since it always shows the characteristics of a typical bimolecular reaction, viz., a strong base is necessary to remove the α-hydrogen atom and the reaction has never been observed under solvolytic conditions. From a thorough study Baker and Heggs concluded that the $E_{CO}2$ reaction is strongly facilitated by increased acidity of the eliminated hydrogen and by substituent groups which can conjugate with the forming carbonyl bond (8). The importance of these factors in determining the rates of the $E_{CO}2$ reaction and the yields of aldehyde product is demonstrated by the following data, obtained in 90% aqueous ethanol at 60° C (8): ethyl nitrate, 0.2×10^{-5} l. mole^{-1} sec^{-1}, 2%; *p*-methylbenzyl nitrate, 3×10^{-3} l. mole^{-1} sec^{-1}, 54%; benzyl nitrate, 8×10^{-3} l. mole^{-1} sec^{-1}, 87%; and *p*-nitrobenzyl nitrate, 3×10^{2} l. mole^{-1} sec^{-1}, 100%. The Hammett reaction constant ρ for *m*- and *p*-substituted benzyl nitrates has the high positive value of +3.40.



By analogy with other elimination reactions, two mechanisms must be considered for the carbonyl elimination reaction of organic nitrates.

Concerted mechanism

transition state

Two-step mechanism

In the concerted mechanism the removal of hydrogen by base is synchronous with formation of the carbon–oxygen double bond and separation of nitrite ion. This is analogous to the *E*2 mechanism observed in olefin-forming eliminations of alkyl halides, ammonium and sulphonium salts (9). The alternative possibility is a two-step process in which the base first removes the hydrogen to form a carbanion intermediate which subsequently eliminates the nitrite ion with formation of aldehyde. This corresponds to the *E*1*cb* mechanism suggested by Ingold as a possible path in olefin-forming eliminations, and may be designated $E_{CO}1cb$ (8). Cristol has proposed that the *E*1*cb* mechanism does indeed occur in cyclic systems where the eliminated groups have cis orientations (10, 11).

The carbonyl elimination reaction is one in which the carbanion mechanism is expected to be "inherently probable" (8), and a particularly favorable system should be that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

benzyl nitrate. The high positive value for the Hammett reaction constant ρ, +3.40, obtained for *m*- and *p*-substituted benzyl nitrates, and the fact that the σ^* value (12) for the para-nitro group must be used for a linear relationship to hold between log k and σ clearly show that the transition state of the reaction has a high degree of carbanion character. Further, the strongly electron-attracting nitrate group will have an appreciable effect on the acidity of the eliminated hydrogen, and this would be expected to promote reaction by a carbanion mechanism.[3]

The present investigation was undertaken with the object of establishing which of the two possible mechanisms, the concerted or the two-step, is being followed in the carbonyl elimination reaction of benzyl nitrate.

Deuterium Exchange Test

An established method for detecting a carbanion intermediate in an elimination reaction is the deuterium exchange test of Skell and Hauser (14). The reaction between substrate and base is carried out in hydroxyl-deuterated solvent (the solvent being the conjugate acid of the base) to partial completion and the unreacted substrate is isolated and examined for its deuterium content. If a true carbanion intermediate is present then the reverse of the first stage will result in deuterium pickup by the substrate.

An appreciable pickup of deuterium by the substrate would unquestionably prove that a carbanion intermediate is formed. The absence of deuterium pickup, however, would not necessarily exclude the intervention of a carbanion intermediate, since the rate at which the carbanion decomposes to product could be so much greater than its rate of return to reactant by combination with solvent (i.e., $k_3 \gg k_2$) as to preclude the observation of deuterium in the recovered substrate by the available experimental methods.

A deuterium exchange test was carried out with benzyl nitrate and ethoxide ion in anhydrous 99% ethanol-1-*d*. The reaction was interrupted at about 40% completion by the addition of *p*-toluenesulphonic acid. The unchanged benzyl nitrate was recovered and purified by fractional distillation. It was analyzed for deuterium by combustion to water and measurement of the O–D absorption at 2500 cm^{-1} (15). The purest sample of benzyl nitrate isolated, as judged by the identity of its infrared spectrum with authentic benzyl nitrate, analyzed for a deuterium content of 0.007 ± 0.003 atom% excess of deuterium. The significance of such a small deuterium content is open to more than one explanation. It could result from the actual presence of $C_6H_5CHDONO_2$ (0.05 mole% excess) formed by the reaction of a carbanion intermediate with deutero-ethanol. In this case the observed deuterium enrichment would require that for every one carbanion that reverts to reactant 1200 decompose to product (see Experimental), i.e., $k_3/k_2 = 1200$, where k_3 includes the concentration of solvent deutero-ethanol.[4] An alternative explanation, however, is that this very small deuterium enrichment is caused by the presence of some deuterium-containing contaminant.[5]

In past studies of elimination reactions the interpretation given to the observation of a very small deuterium enrichment in the recovered reactant has varied. Some workers

[3]*Cristol found that in a cis dehydrochlorination the replacement of a chlorine substituent by the strongly electron-attracting p-toluenesulphonyl group increased the rate of reaction by a factor of about 10^{10} (13).*

[4]*Because of a possible isotope effect associated with the reaction of deutero-ethanol with carbanion, the k_3/k_2 ratio in undeuterated ethanol may differ somewhat from this figure (16).*

[5]*Some enrichment will undoubtedly arise from a kinetic isotope effect involving the reactant, which originally has the natural isotopic abundance of deuterium. It can be shown, however, that this factor could account for no more than a quarter of the observed enrichment.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

have taken the result to mean the absence of exchange and have inferred that a concerted mechanism is being followed (14), while others have concluded that the enrichment is evidence in support of a carbanion intermediate (10).

Kinetic Nitrogen Isotope Effect

In previous applications of the deuterium exchange test the ambiguity presented by an apparent very small deuterium pickup could not be resolved. It has been possible to resolve this problem in the present reaction system by an evaluation of the kinetic nitrogen isotope effect. In the concerted process (equation [1]) the O—NO_2 bond is broken in the rate-determining step and this should result in a nitrogen isotope effect of considerable magnitude, i.e., of the order of 1–3% (*vide infra*). In the carbanion mechanism with $k_3 \gg k_2$, which is the only possibility for a carbanion mechanism permitted by the results of the deuterium study, the rate-determining step is the formation of the carbanion in which the bonds associated with nitrogen are still intact. In this case there should be no nitrogen isotope effect, or at the most an isotope effect of a few tenths of a per cent.

A kinetic nitrogen isotope effect study was undertaken with benzyl nitrate of normal isotopic composition. The procedure consisted of allowing reaction between benzyl nitrate and ethoxide ion to proceed to 10% completion and comparing the nitrogen isotopic composition of the formed nitrite ion with that of the starting benzyl nitrate. Since a simultaneous substitution reaction results in displacement of nitrate ion, a separation of the nitrate ion formed in the carbonyl elimination reaction was required.[6] This separation was achieved by selective reduction of the nitrite and nitrate ion to ammonia (17). The ammonia was subsequently oxidized to nitrogen (18), which was analyzed by mass spectrometry. The total nitrite and nitrate ion obtained from the 100% reaction was similarly converted to nitrogen and analyzed by mass spectrometry. The results of these experiments are shown in Table I.

TABLE I

N^{14}/N^{15} ratios in $E_{CO}2$ reaction of benzyl nitrate at 30° C

This isotope effect, which is one of the largest observed for nitrogen in a rate process unequivocally establishes that the O—N bond is undergoing rupture in the rate-determining step. Since the observation of no significant deuterium exchange has ruled out a carbanion mechanism in which the step involving O—N bond rupture is rate determining, it follows that only a concerted process is consistent with the results of both the nitrogen isotope effect and the deuterium exchange studies.

Although the results of this investigation clearly exclude the carbanion mechanism for the reaction of benzyl nitrate the possibility still exists for reaction by this mechanism with reactants in which structural features would provide greater stability to a carbanion. Systems of this type are under investigation.

It was convenient to determine the nitrogen isotope effect in the competing substitution reaction forming nitrate ion since this had been converted to ammonia in the process of separating it from the elimination product. The isotopic ratio for the nitrogen of nitrate ion (combined products of experiments 6–10) was 265.52, which is identical, within the limit of measurement, with the mean value obtained for the product of 100% reaction. This observation of a zero isotope effect is consistent with a nucleophilic substitution of ethoxide ion on carbon with displacement of nitrate ion.

Hydrogen–Deuterium Isotope Effect

To gain greater insight into the nature of the transition state of the carbonyl elimination reaction the hydrogen–deuterium isotope effect for the reaction has also been determined. This was measured by separately evaluating the specific reaction constants for $C_6H_5CH_2ONO_2$ and $C_6H_5CD_2ONO_2$. Benzyl-α-d_2 nitrate was prepared by the lithium aluminum deuteride reduction of ethyl benzoate to benzyl-α-d_2 alcohol which was converted to benzyl-α-d_2 chloride and to benzyl-α-d_2 nitrate by usual procedures. The kinetics were conducted in anhydrous ethanol. The total rate was followed by acid–base titration and the rate constants for the carbonyl elimination reaction, $k_{E_{CO^2}}$, and for the substitution reaction, k_{S_N2}, were evaluated from the relative yields of nitrite and nitrate ions. These yields remained constant throughout the reaction, demonstrating that the two ions were formed by reactions of the same kinetic order. The rate data are shown in Table II. It is seen that the carbonyl elimination reaction shows an isotope effect of 5.0 at 60° C. From the data given in Table II one may also calculate a k_H/k_D ratio of 1.16 for the substitution reaction. No significance, however, is attached to the difference between this value and unity because of the rather large percentage error in the determination of the small amount of nitrate ion.

Nature of the Transition State in the $E_{CO}2$ Reaction

Information concerning charge distribution and extent of bond rupture in the transition state of a bimolecular elimination reaction of the type

transition state

is provided by three quantities: (*a*) the deuterium isotope effect, (*b*) the isotope effect associated with the leaving group X, and (*c*) the Hammett ρ value. A large k_H/k_D value implies a large degree of carbon–hydrogen bond stretching with the release to the rest of the molecule of the electron pair associated with this bond. The resulting negative charge may reside largely on the carbon atom and its attached aryl group, in which case the transition state may be described as having a high degree of carbanion character and the reaction will be characterized by a large positive Hammett ρ, or the charge may reside in part or in whole on the leaving group X. Other factors being equal, the greater the extent to which this charge is accommodated in the transition state by the leaving group the more highly concerted the reaction, the larger the isotope effect associated with X, and the smaller the ρ value.

The k_H/k_D value of 5.0 at 60° C for the $E_{CO}2$ reaction of benzyl nitrate (X = NO_2, Y = O, and Z = H in equation [4]) is large, being only slightly smaller than that calculated (ca. 5.6) for the complete loss of the carbon–hydrogen bond stretching frequency in the transition state (16). The ρ value, +3.4, for the $E_{CO}2$ reaction of substituted benzyl nitrates is large also; indeed, it is larger than the ρ values observed in other bimolecular elimination reactions involving ethoxide ion (20), and is one of the largest found for a rate process (12). To a considerable extent, then, the negative charge which is developed as a result of the large carbon–hydrogen bond stretching resides on the benzyl carbon, and the transition state, therefore, may be described as having a high degree of carbanion character.

That the oxygen–nitrogen bond is also considerably weakened in the transition state of the $E_{CO}2$ reaction of benzyl nitrate is evident from the magnitude of the nitrogen isotope effect, 2.0% at 30° C. Although this value is considerably smaller than the 3.8%[7] calculated on the assumption of complete oxygen–nitrogen bond rupture in the transition state, it is significantly greater than the nitrogen isotope effect of 1.3% found in this laboratory (24) for the *E*2 Hofmann elimination reaction of β-phenylethyltrimethylammonium bromide (X = $\overset{+}{N}(CH_3)_3$, Y = CH_2, and Z = H in equation [4]) with ethoxide ion at the same temperature. Since the deuterium effect is also larger, 5.0 at 60° C compared with 3.0 at 50° C observed by Saunders for the Hofmann reaction (25), it would appear that rupture of both C—H and Y—X bonds is more fully developed in the transition state of the carbonyl elimination reaction. On the other hand, the transition state for the $E_{CO}2$ reaction must have considerably more carbanion character than that of the bimolecular elimination with ethoxide ion of the structurally related β-phenylethyl bromide (X = Br, Y = CH_2, and Z = H in equation [4]). The deuterium

[7]*This value is obtained from the Bigeleisen expression (21) using 860.6 cm^{-1} for the stretching vibration of the* O—NO_2 *bond (22) in evaluating the free-energy term and the Slater theorem for the effective mass term. Using the mass fragment method of evaluating the mass term (23), the calculated effect is 2.8%.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

isotope effect for this dehydrobromination reaction has the abnormally large value of 7.1 at 30° C (25), while the ρ value for the reaction of substituted β-phenylethyl bromides is only +2.18 (20), compared with the +3.4 found for the $E_{CO}2$ reaction of the benzyl nitrates. More of the negative charge developed in the transition state must, therefore, reside on the bromine atom in the halide reaction than on the nitro group in the carbonyl elimination, and carbon–bromine bond rupture must have progressed further than oxygen–nitrogen bond rupture.

From these considerations it would appear that with respect to the extent to which bonds have been weakened, the transition state for the carbonyl elimination of benzyl nitrate is intermediate between the transition states for the $E2$ reaction of β-phenylethyltrimethylammonium ion and of β-phenylethylbromide.

EXPERIMENTAL

Materials

Benzyl nitrate.—This was prepared from benzyl chloride and silver nitrate in acetonitrile (26). The product, purified by fractional distillation from silver nitrate and calcium carbonate, was obtained in 75% yield (b.p. 45°/0.5 mm, n_D^{20} 1.5209).

Benzyl-α-d_2 nitrate.—The steps involved in the synthesis of benzyl-α-d_2 nitrate were: (1) reduction of ethyl benzoate to benzyl-α-d_2 alcohol with lithium aluminum deuteride; (2) conversion of benzyl-α-d_2 alcohol to benzyl-α-d_2 chloride with zinc chloride and hydrochloric acid; and (3) reaction of benzyl-α-d_2 chloride with silver nitrate in acetonitrile. The over-all yield of benzyl-α-d_2 nitrate (b.p. 45°/0.5 mm, n_D^{20} 1.5203) was 62%. A N.M.R. analysis[8] showed that the product was 99% $C_6H_5CD_2ONO_2$.

Benzyl-α-d_2 alcohol.—Ethyl benzoate (28.5 g, 0.190 mole) was reacted for 4 hours with lithium aluminum deuteride (3.94 g, 0.099 mole) in 400 ml ether which had been distilled from lithium aluminum hydride, and the complex was then decomposed with 10% sulphuric acid. The product, recovered by ether extraction, was treated with aqueous alcoholic sodium hydroxide to hydrolyze any unreacted ethyl benzoate. After removal of ethanol and extraction with ether, distillation yielded benzyl-α-d_2 alcohol (b.p. 76°/5 mm, n_D^{20} 1.5398) in 84% yield.

Benzyl-α-d_2 chloride.—Benzyl-α-d_2 alcohol (17.4 g, 0.158 mole) was added during 1 hour to 77 g of a stirred solution of hydrochloric acid and zinc chloride (Lucas' reagent (27)) at 0° C. Stirring was continued for 1 hour at 0° C and 2 hours at room temperature. The reaction mixture separated into two layers and was extracted with a 1:1 mixture of ether and petroleum ether. Distillation yielded benzyl-α-d_2 chloride (b.p. 64°/12 mm) in 86% yield.

Deuterium Exchange Experiment

Ethanol-1-*d* was prepared by the action of 99.4% deuterium oxide on sodium ethoxide, prepared from molecular sodium (28) under strictly anhydrous conditions in a nitrogen atmosphere. The product was shown by N.M.R.[8] to be at least 99% deuterated on the hydroxyl group. A solution of sodium ethoxide in the deutero-ethanol (ca. 0.5 *M*) was prepared by dissolution of sodium metal and was standardized by titration with acid. Fifty milliliters of the ethoxide solution was added to an equimolar quantity of benzyl nitrate and reaction was allowed to proceed at 30° C to an appropriate extent of completion when it was quenched by addition of *p*-toluenesulphonic acid. Solvent was removed under reduced pressure and the residue was taken up in ether and washed

[8]*N.M.R. analyses were performed by Dr. R. J. Gillespie.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with ice-cold water. The extent of reaction was determined by an acid–base titration of the aqueous washings. The ethereal solution was evaporated and treated with three 25-ml quantities of methanol, each of which was removed by distillation through a Vigreux column. The purpose of this methanol treatment was to remove last traces of deutero-ethanol and to exchange any hydroxyl-deuterated benzyl alcohol which may have been formed by hydrolysis following the quenching. The product of this treatment was fractionally distilled through a 15-cm tantalum spiral column. Deuterium analysis was carried out by combustion of the recovered benzyl nitrate and measurement of the O—D absorption at 2500 cm^{-1} in the water formed (15).

In the first exchange experiment, carried to 44% completion, two fractions of benzyl nitrate were collected, both of which showed some contamination with benzaldehyde, as shown by a carbonyl absorption in the infrared spectra, although the higher boiling fraction was the purer. The analysis results for the two fractions were 0.029 ± 0.006 and 0.015 ± 0.003 atom% excess deuterium, respectively. In a second exchange experiment, carried to 37% completion, the recovered material was more carefully purified and a fraction which was almost completely carbonyl-free was obtained. This fraction was found to contain 0.007 ± 0.003 atom% excess deuterium.

On the basis of the carbanion intermediate mechanism one can calculate the k_3/k_2 ratio corresponding to a deuterium pickup of 0.007 atom%. Assuming that only one hydrogen in the benzyl nitrate exchanges, the following can be derived from equations [2] and [3]. (The rate constant for the reverse step in equation [2] will here also be denoted by k_2 even though it now applies to the reaction of carbanion with deutero-ethanol.)

$$\frac{d}{dt}[C_6H_5CHDONO_2] = k_2[C_6H_5\overset{\ominus}{C}HONO_2][C_2H_5OD] \qquad [5]$$

$$\frac{d}{dt}[\text{product}] = k_3[C_6H_5\overset{\ominus}{C}HONO_2] \qquad [6]$$

Dividing equations [5] and [6] and integrating one obtains

$$\frac{[C_6H_5CHDONO_2]}{[C_6H_5CHDONO_2]+[C_6H_5CH_2ONO_2]} = \frac{k_2[C_2H_5OD]}{k_3} \times \frac{[\text{product}]}{[C_6H_5CHDONO_2]+[C_6H_5CH_2ONO_2]}. \qquad [7]$$

Substituting $[(0.007\times7)/100] = 0.00049$ for the mole fraction excess of $C_6H_5CHDONO_2$ in the benzyl nitrate recovered after 37% reaction, it follows that

$$\frac{k_3}{k_2[C_2H_5OD]} = \frac{37}{63\times0.00049} = 1200.$$

Kinetic Measurements with $C_6H_5CH_2ONO_2$ *and* $C_6H_5CD_2ONO_2$

A solution of benzyl nitrate (0.04–0.05 *M*) and sodium ethoxide (0.05–0.08 *M*) in anhydrous ethanol was prepared by the addition of standard sodium ethoxide solution to a weighed amount of the nitrate and was maintained in a constant temperature bath to $\pm0.03°$ C. At suitable intervals of time aliquots of 2 ml each were removed and added to 15 ml of ice-cold water for quenching the reaction. Following titration with standard acid the unreacted nitrate ester was extracted with petroleum ether. The aqueous extract was analyzed for nitrite and nitrate ions by a modification of the method described by Varner *et al.* (17). This method is based on the differential rates of reduction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

of nitrite and nitrate to ammonia. While nitrite ion is rapidly reduced by ferrous hydroxide alone, the presence of a silver ion catalyst is required for the reduction of nitrate ion.

The solution containing nitrite and nitrate was placed in a Kjeldahl-type distillation apparatus constructed with a double splash-head. A 40% aqueous sodium hydroxide solution (15 ml) was added and steam was passed through until all the ethanol had distilled over. This initial removal of ethanol was found to be necessary for quantitative reduction. A 20% aqueous solution of ferrous sulphate (5 ml) was added and steam distillation continued for 3 minutes during which time the nitrite ion was reduced to ammonia which was collected in 5% boric acid solution. The nitrate ion was then reduced on the addition of a saturated silver sulphate solution (5 ml) and the ammonia formed was distilled during 5 minutes into a fresh receiver containing boric acid solution. The ammonia from the reductions was titrated with 0.01 *N* sulphuric acid using methyl red–methylene blue indicator. A complete analysis involving the reduction of both nitrite and nitrate was performed without interruption of steam distillation.

The over-all rate constant for the reaction was calculated from the usual second-order plot using the data from the acid–base titrations. At least two kinetic runs were performed with each compound at a given temperature, and rate constants agreed within ±2%. The nitrite and nitrate analyses were performed for at least five points in each kinetic run. The yields of nitrite and nitrate ion were reproducible within ±1% absolute and the mean values were used to calculate the rate constants of the component $E_{CO}2$ and S_N2 reactions.

Nitrogen Isotope Effect

The kinetic nitrogen isotope effect in the $E_{CO}2$ reaction was obtained by comparing the nitrogen isotopic abundance in the nitrite ion formed in reactions carried out to some small known extent of completion with the isotopic abundance in the starting compound. The latter was obtained by measuring the isotopic abundance in the combined nitrite and nitrate ion product formed in reactions allowed to proceed to completion.

Benzyl nitrate (0.05 *M*) and sodium ethoxide (0.05 *M*) in 50 ml of anhydrous ethanol were allowed to react at 30° C for a length of time corresponding to 10% reaction. The solution was then added to a mixture of ice-cold petroleum ether and 0.1 *N* aqueous sodium bicarbonate (5% excess over the remaining ethoxide) and the two layers were separated. The bicarbonate served to neutralize excess ethoxide which otherwise would react with the small amount of benzyl nitrate not removed in the petroleum ether. (Neutralization with 0.1 *N* sulphuric acid resulted in some loss of nitrite and nitrate ion, possibly by reaction of nitrous acid with ethanol.) The aqueous ethanol solution was concentrated to a small volume on a rotary evaporator and the last trace of benzyl nitrate was extracted with petroleum ether. Nitrite and nitrate ion were separately reduced, following the procedure described in the previous section, and the ammonia absorbed in 0.01 *N* sulphuric acid. The extent of reaction was calculated from the total yield of ammonia obtained in the reductions. The solution of ammonium sulphate obtained from the reduction of nitrite ion was concentrated to about 3 ml and transferred to a high-vacuum system where it was oxidized by means of sodium hypobromite solution (18) to nitrogen gas for mass spectrometric analysis. The nitrogen was purified by continuous circulation over copper and copper oxide, both at 750° C, and through a trap cooled in liquid nitrogen.[9] Sufficient ammonium sulphate was present to give on oxidation 2 ml of nitrogen at atmospheric pressure.

[9]*Details of the purification procedure will appear in a subsequent publication.*

Since the amount of nitrogen which would be formed from the nitrate ion produced in a single experiment would be much too small for mass spectrometric analysis, the ammonium sulphate solutions from all the nitrate ion reductions were combined and oxidized to give a single nitrogen sample for analysis.

The nitrogen isotopic abundance in the starting benzyl nitrate was determined as follows. Benzyl nitrate (0.04–0.05 *M*) was completely hydrolyzed by sodium ethoxide (0.05–0.10 *M*) in anhydrous ethanol at 60° C. An aliquot of 5 ml was then removed and the nitrite and nitrate reduced to ammonia by the method described in the section on Kinetic Measurements, except that no titration of ethoxide was performed and the ammonia from nitrite and nitrate was collected in the same acid solution. The ammonium sulphate solution was oxidized to nitrogen and the latter was measured mass spectrometrically as described previously. From two separate reactions carried out to completion a total of five nitrogen samples was prepared.

The mass spectrometric analysis was carried out using a 90° sector type instrument, similar to the one described by Wanless and Thode (29). It was capable of measuring *relative* isotopic abundance ratios, $N^{14}-N^{14}/N^{14}-N^{15}$, to $\pm 0.02\%$.

The kinetic isotope effect was calculated from the expression (19)

$$k_{14}/k_{15} = \frac{\ln(1-f)}{\ln(1-rf)}$$

where

$$r = \frac{(N^{14}/N^{15})_{\text{reactant}}}{(N^{14}/N^{15})_{NO_2^-}}$$

and $f = 0.09$, the mole fraction of reactant which has undergone decomposition to nitrite ion.[10]

LES SPECTRES INFRAROUGES DE L'ACIDE SULFURIQUE ET DES OLÉUMS[1]

PAUL A. GIGUÈRE ET RODRIGUE SAVOIE

RÉSUMÉ

On a mesuré les spectres infrarouges, entre 2 et 30 μ, de l'acide sulfurique et de ses solutions aqueuses à diverses concentrations de même que celui de l'acide deutéré, D_2SO_4. On a aussi mesuré à l'état solide les spectres de l'acide pur et de ses hydrates à une, deux et quatre molécules d'eau. Les fréquences observées ont pu être attribuées aux différents modes de vibration de la molécule H_2SO_4. Les résultats confirment et complètent ceux déjà obtenus par d'autres méthodes quant à la nature et l'abondance relative des diverses espèces ioniques (y compris H_3O^+) et moléculaires présentes dans ces solutions. En particulier, on a vérifié l'auto-dissociation de H_2SO_4 pur et l'ionisation incomplète de l'eau, même dans l'acide très concentré. Enfin on a étudié de la même façon les spectres des oléums contenant jusqu'à 70% de l'anhydride SO_3. En augmentant la concentration de ce dernier, on voit apparaître graduellement les bandes de $H_2S_2O_7$, $H_2S_3O_{10}$ et enfin SO_3.

INTRODUCTION

Les spectres moléculaires de l'acide sulfurique et de ses solutions offrent un intérêt particulier en ce qu'ils permettent d'identifier les diverses espèces, ioniques et autres, présentes dans ces systèmes relativement complexes. D'autres méthodes physico-chimiques, surtout colligatives et partant moins sélectives, en particulier la conductivité électrique, la cryoscopie (voir les importants travaux de Gillespie, dans la revue récente (1)), la calorimétrie (2) et la résonance nucléo-magnétique (3), ont déjà servi à élucider la question. Quant aux spectres, seul l'effet Raman avait été étudié jusqu'ici surtout par Chédin (4) et plus récemment par Millen (5) et Young (6). Dans l'infrarouge, le caractère extrêmement corrosif et la grande absorptivité des solutions d'acide sulfurique présentaient des difficultés qui n'ont pu être surmontées que dernièrement grâce à l'invention du chlorure d'argent de qualité optique. C'est par ce moyen que Marcus et Fresco (7) ont obtenu un premier spectre infrarouge de l'acide pur au cours d'un travail sur les mélanges nitrifiants, et que dans ce laboratoire nous avons précédemment étudié les solutions diluées d'acide sulfurique (8) afin de mettre en évidence le spectre de l'ion H_3O^+. Il nous a semblé utile de compléter ce travail par une analyse systématique des spectres infrarouges de l'acide liquide et de ses solutions aqueuses, de même que ceux des hydrates à une, deux et quatre molécules d'eau à l'état solide. Comme prolongement naturel de ce travail nous avons été conduits à mesurer pour la première fois l'absorption infrarouge des oléums à des concentrations allant jusqu'à 70%. Rappelons que par convention le titre $X\%$ d'un oléum signifie une composition pondérale de X parties d'anhydride sulfurique SO_3 et $(100-X)$ parties d'acide sulfurique pur.

MÉTHODE EXPÉRIMENTALE

Pour l'étude des spectres entre 3500 et 500 cm^{-1} on préparait les échantillons simplement en pressant une goutte de solution de concentration appropriée entre deux disques de chlorure d'argent fraîchement polis au moyen d'une grande lime douce trempée dans l'eau. L'épaisseur des films ainsi obtenus est évaluée à quelque 10 μ d'après la quantité d'acide employée et la surface recouverte. Comme le chlorure d'argent commence à absorber vers 500 cm^{-1}, il a fallu utiliser du côté des basses fréquences des plaques d'iodure de césium protégées par un mince film de polyéthylène. En effet, ce matériau est à la

fois résistant à l'acide sulfurique et assez transparent dans l'infrarouge moyen, sauf pour une forte bande d'absorption vers 730 cm^{-1}; par contre il s'est révélé inutilisable avec les oléums. Il en fut de même du Teflon qui, bien que non attaqué par le liquide, semblait perméable aux vapeurs corrosives. En fait, aucun des matériaux couramment utilisés pour l'infrarouge n'a permis d'observer les spectres d'absorption des oléums dans la région des basses fréquences au delà de 450 cm^{-1}.

Pour l'étude des solides, on s'est servi d'une cellule de type conventionnel (9) dans laquelle les films de liquide pressé entre deux plaques de chlorure d'argent étaient refroidis, sous vide, à l'aide de mélanges d'acétone et de neige carbonique. Après une première solidification du film, on laissait remonter la température (mesurée avec un thermocouple) jusqu'à 4° ou 5° au-dessous du point de fusion de l'hydrate en question; puis on refroidissait de nouveau, et très lentement. Cette opération était répétée plusieurs fois afin d'obtenir un solide cristallin et non pas vitreux. Toutefois, si l'on en juge par l'allure des bandes, il n'est pas certain que ce but aît été atteint entièrement.

L'acide sulfurique commercial (96%) fut employé tel quel, soit pur, soit additionné d'eau distillée ou d'oléum à 23% suivant le cas. Ce dernier (General Chemical Co.) était d'abord distillé dans un appareil en Pyrex assemblé par rodages et comprenant une colonne Vigreux mais sans réfrigérant. Pour obtenir des concentrations supérieures à 23%, on faisait barboter à froid dans cet oléum des vapeurs provenant de la distillation d'un autre échantillon du même oléum. De cette façon, on a pu atteindre progressivement un titre de quelque 70%. Tous les échantillons étudiés au cours de ce travail étaient liquides à température ordinaire, sauf celui à 28.5% qui cristallisa partiellement au bout de quelques semaines. Une étude préliminaire de l'absorption infrarouge des vapeurs blanches dégagées par les oléums a montré les bandes de l'acide sulfurique et celles, beaucoup plus faibles, de l'anhydride SO_3. Le titre des oléums fut déterminé par alcalimétrie selon la méthode usuelle. L'échantillon de D_2SO_4 fut obtenu en faisant absorber très lentement dans un peu d'eau lourde (à 99% de D_2O), refroidie dans la glace, des vapeurs d'anhydride sulfurique provenant de la distillation d'oléum commercial. Par titrations et dilutions successives, on a réussi à atteindre exactement la concentration $100 \pm 0.2\%$ de D_2SO_4.

Pour enregistrer les spectres, on s'est servi alternativement d'un spectrophotomètre Beckman (modèle IR-4) à double faisceau, et d'un appareil Perkin–Elmer (modèle 112-C) avec prismes de chlorure de sodium et de bromure de césium. Afin de diminuer l'absorption par le gaz carbonique et l'humidité, on faisait circuler un courant d'azote sec à travers l'appareil avant et pendant les mesures.

DISCUSSION DES RÉSULTATS

Les fréquences au maximum des diverses bandes d'absorption sont énumérées dans les Tableaux I, II, III et IV; quelques spectres infrarouges sont reproduits dans les Figures 1 et 2. Pour faciliter la discussion, on considérera successivement les solutions aqueuses, l'acide sulfurique pur, les hydrates solides et enfin les oléums.

(A) Les solutions liquides

Dans les solutions diluées l'espèce moléculaire la plus abondante H_2O cause une forte absorption dans les régions de 3400 cm^{-1} (ν_3), 1650 cm^{-1} (ν_2) et 730 cm^{-1} (ν_R). Les deux premières sont encore nettement visibles dans les solutions à environ 80% (Fig. 1, A); c'est là une confirmation directe de la déduction de Gillespie (10), basée sur des données cryoscopiques, à l'effet que l'ionisation de l'eau est incomplète dans l'acide sulfurique même aux fortes concentrations. Fait remarquable, l'addition de H_2SO_4 affecte à peine

la fréquence de libration ν_R de l'eau, contrairement aux électrolytes du type KCl qui l'abaissent considérablement (8). La différence vient de ce que ces électrolytes affaiblissent la structure de l'eau liquide en diminuant le nombre de liaisons hydrogène. Dans

l'acide sulfurique, au contraire, on a en moyenne le même nombre de liaisons hydrogène (soit quatre) par molecule (ou ion).

Viennent ensuite les espèces ioniques: d'abord H_3O^+ dont les bandes caractéristiques à 1750 et 1200 cm^{-1} (8) augmentent d'intensité avec la concentration jusqu'à un maximum vers 80% d'acide (Tableau I). Il en est de même de l'ion bisulfate HSO_4^- pour lequel Young et ses collaborateurs (5) ont établi avec précision les fluctuations de concentration en se basant sur l'intensité des bandes Raman. Plusieurs des bandes de l'anion HSO_4^- se confondent avec celles de la molécule H_2SO_4 comme on pouvait le prévoir; les trois plus caractéristiques, à 584, 890 et 1052 cm^{-1}, ont leur équivalent en Raman (Tableau II). Les deux ions H_3O^+ et HSO_4^- sont donc les plus abondants dans les solutions aqueuses d'acide sulfurique. À noter que la bande à 1050 cm^{-1} est encore perceptible dans le spectre de H_2SO_4 pur, une autre confirmation expérimentale de l'auto-dissociation déjà démontrée par la cryoscopie et la conductivité électrique (1). Les spectres Raman ne permettent pas de vérifier ce point, pas plus d'ailleurs que mettre en évidence l'ion H_3O^+ (11).

Quant à l'anion sulfate SO_4^{--} sa concentration maximum (moins de la moitié de celle de l'ion bisulfate) se trouve entre 40 et 60% d'acide, toujours d'après les spectres Raman (5). C'est de cette façon que varie l'intensité des deux bandes à 445 et 500 cm^{-1} que nous attribuons pour cette raison aux modes de déformation asymétrique de l'ion sulfate. Dans les spectres infrarouges des sulfates ioniques cristallins (12) ces fréquences sont notablement plus élevées, soit environ 600–650 cm^{-1}. Le décalage observé dans les solutions d'acide provient peut-être de l'hydratation des ions. Par ailleurs la bande très faible à 1100 cm^{-1} dans la solution la plus diluée, et qui va se perdre dans la forte absorption vers 1050 cm^{-1} aux grandes concentrations d'acide, provient également de l'anion sulfate (12). Elle est due à la vibration de valence S—O asymétrique; la fréquence symétrique correspondante est 982 cm^{-1} en Raman (13).

Au delà de 80% d'acide, une douzaine de bandes appartenant à la molécule H_2SO_4 (Tableau II) émergent graduellement alors que celles de l'ion bisulfate s'affaiblissent. Au moins trois de ces bandes (i.e. à 907, 1365 et 2950 cm^{-1}) sont communes à l'acide et à l'anion comme le prouvent les variations d'intensité avec la composition. Le problème de la constitution des solutions très concentrées (au-dessus de 80%) d'acide sulfurique n'est pas entièrement élucidé. Dans l'acide pur, outre l'auto-dissociation déjà mentionnée,

$$2H_2SO_4 \rightleftarrows HSO_4^- + H_3SO_4^+; \qquad [1]$$

une seconde, moins importante, est censée exister (1), soit

$$2H_2SO_4 \rightleftarrows H_3O^+ + HS_2O_7^-. \qquad [2]$$

Cependant les ions ainsi produits sont si peu abondants qu'on ne saurait les déceler par spectroscopie, sauf dans les cas les plus favorables (telle la bande de HSO_4^- à 1050 cm^{-1} citée plus haut). Ainsi il est à prévoir que le spectre du cation $H_3SO_4^+$ diffère assez peu de celui de la molécule H_2SO_4. Les seuls indices qu'on pourrait lui attribuer dans les présents spectres, en se basant sur le critère intensité, sont deux bandes très diffuses, l'une vers 740 cm^{-1} et l'autre à 2250 cm^{-1}. La première, en particulier, a une fréquence appropriée pour un mode de balancement (wagging) des hydrogènes. Par contre, la seconde fréquence à 2250 cm^{-1} semble un peu trop basse pour une vibration de valence O—H; elle doit plutôt appartenir à quelque combinaison ou harmonique des bandes plus fortes de H_2SO_4.

Par ailleurs, diverses propriétés physiques (14) conduisent à postuler l'existence d'un ion solvaté $H_3O^+(H_2SO_4)$ dans les solutions très concentrées (au-delà de 90%). La présence

des bandes caractéristiques de l'ion hydroxonium dans les solutions à plus de 95% d'acide renforce cette hypothèse au détriment d'une autre mise récemment de l'avant par Young et Walrafen (15) et qui fait appel à une espèce nouvelle $H_5SO_5^+$. En effet, tout laisse prévoir que ce cation hypothétique aurait une structure, et partant un spectre de vibration nettement différents de ceux des espèces H_2SO_4, $H_3SO_4^+$ et HSO_4^-.

(B) Les vibrations normales de H_2SO_4

Dans les travaux antérieurs sur le spectre moléculaire de l'acide sulfurique on ne s'est pas préoccupé d'attribuer les fréquences des bandes observées aux divers modes de vibration de la molécule. La diffraction aux rayons-X (16) a confirmé la structure la plus probable, soit un arrangement quasi-tétraédral des oxygènes autour du soufre, les deux hydrogènes étant normalement situés dans le plan Z (Fig. 3). La molécule appartient

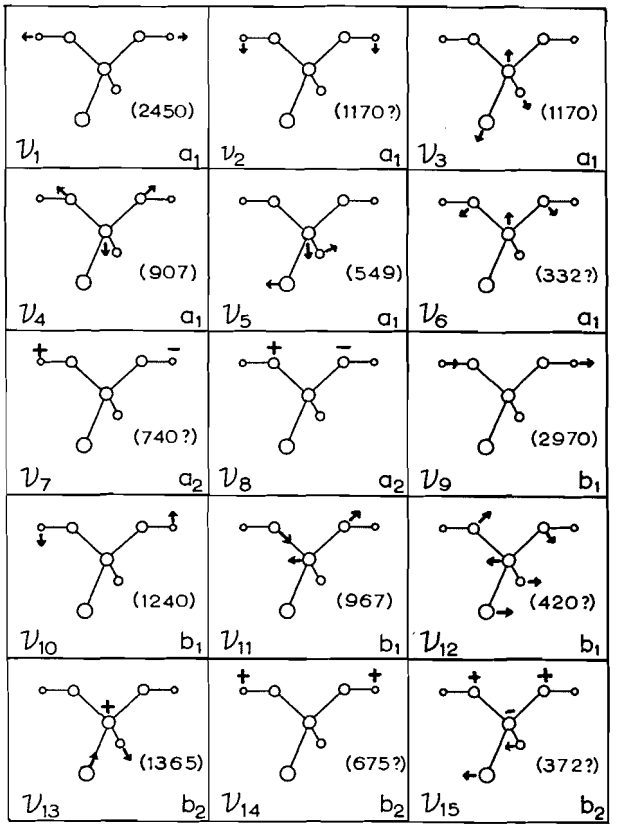

FIG. 3. Modes de vibration de la molécule H_2SO_4. Les nombres entre parenthèses indiquent les fréquences en cm^{-1}.

donc au groupe de symétrie C_{2v} et la théorie (17) prévoit que ses 15 vibrations normales sont réparties en deux classes: soit 8 symétriques par rapport à l'axe (dont 6 du type a_1 et 2 du type a_2) et 7 asymétriques (dont 4 du type b_1 et 3 du type b_2). Les vibrations de type a_2 étant inactives en infrarouge, on observera donc au maximum 13 vibrations fondamentales, du moins pour la molécule à l'état libre. Pour fins d'identification on peut séparer les vibrations en deux groupes de 6 et 9 respectivement, suivant qu'elles font intervenir directement ou non les atomes d'hydrogène. On a représenté sur la Fig. 3

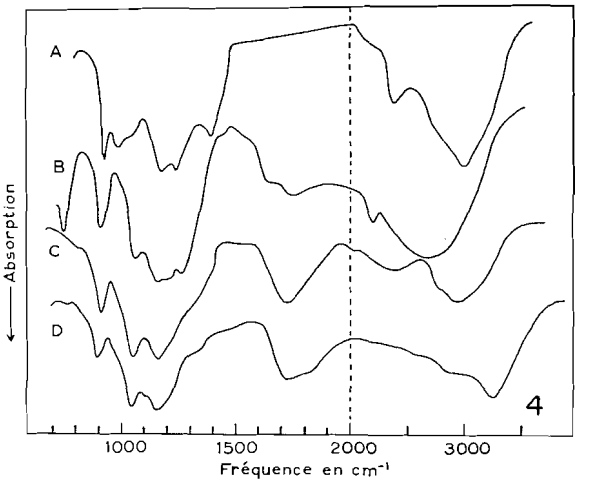
ces divers modes de vibration de la molécule H_2SO_4 avec la fréquence probable de chacune. Les vibrations de valence O—H, ν_1 et ν_9, se retrouvent ici presque exactement aux mêmes fréquences que dans le cas de l'acide sélénieux (18); elles sont décalées à 1860 et 2280 cm^{-1} dans D_2SO_4. Ces fréquences relativement basses confirment l'existence de fortes liaisons hydrogène dans l'acide sulfurique et ses solutions. D'autre part, les vibrations de déformation $\angle$SOH sont difficiles à identifier parce qu'elles tombent dans une région de forte absorption due aux bandes de valence S—O. Pour la même raison, les décalages isotopiques dans D_2SO_4 sont de peu d'utilité ici. Cependant, en comparant minutieusement les spectres des deux molécules on peut déceler dans le cas de H_2SO_4 un léger excédent d'absorption vers 1240 cm^{-1} qui doit provenir d'une bande de déformation $\angle$SOH. Etant donné sa faible intensité, il s'agit peut-être de la vibration asymétrique ν_{10} qui affecte assez peu le moment polaire de la molécule. Si cette explication est valide, il est alors possible que la vibration symétrique correspondante soit comprise dans la forte bande à 1170 cm^{-1} (ν_3) qui effectivement semble encore plus large pour H_2SO_4 que pour D_2SO_4. Dans les solutions aqueuses d'acide sélénieux, on ne trouve qu'une seule bande intense de déformation $\angle$SeOH à 1236 cm^{-1}. Enfin, le seul des deux modes de balancement (wagging) des hydrogènes qui soit actif en infrarouge, ν_{14} n'a pas lui non plus été identifié avec certitude dans les présents spectres. Par analogie avec diverses molécules, en particulier des alcools et des acides organiques, on peut prévoir pour ce mode une fréquence de l'ordre de 650 à 700 cm^{-1}. La bande assez floue à 675 cm^{-1} conviendrait bien à cet égard, quoique son intensité semble un peu faible. Dans l'anion HSO_4^- ce mouvement de l'unique hydrogène se traduit par une bande à 584 cm^{-1}.



Pour sa part le groupe SO_4 dans l'acide sulfurique possède neuf vibrations caractéristiques non dégénérées. Du côté des hautes fréquences on rencontre d'abord les vibrations de valence double S=O, ν_3 à 1170 et ν_{13} à 1365 cm^{-1}, soit presque exactement les mêmes valeurs que dans SO_2. Les distances interatomiques sont aussi identiques, 1.42 Å (19). Les deux vibrations de valence simple S—O ont des fréquences sensiblement plus basses, ν_4 à 907 et ν_{11} à 967 cm^{-1}, en accord avec les longueurs plus grandes, 1.52–1.55 Å, de ces liaisons. Dans l'anion HSO_4^- les fréquences correspondantes se trouvent à 895 et 1052 cm^{-1} respectivement. Quant aux diverses fréquences de déformation, nous avons essayé de les identifier par comparaison avec la molécule SO_2F_2 déjà étudiée par spectroscopie infrarouge (20) et centimétrique (21). Outre que la symétrie est la même dans les deux cas, les masses et les distances diffèrent assez peu. Ainsi, on retrouve dans les deux spectres une bande à environ 550 cm^{-1} attribuable au mode de déformation commun $\angle$OSO. Des trois autres bandes qui restent dans le spectre de H_2SO_4 à 420, 372 et 332 cm^{-1}, on serait porté a priori à assigner la première au mode de déformation $\angle$OSO impliquant les groupements hydroxyles (ν_6) étant donné les liaisons hydrogène qui doivent en augmenter la fréquence. Cependant, seules les deux faibles bandes à 420 et 372 cm^{-1} ont leur équivalent dans le spectre Raman (Tableau II). Vu la similitude des deux modes de balancement ν_{12} et ν_{15}, il semble plus logique de leur attribuer les deux premières bandes, ce qui laisse la dernière à 332 cm^{-1} pour ν_6. Toutefois, cette interprétation n'est que provisoire.

(C) Les hydrates solides

Lors de la solidification, les bandes infrarouges de l'acide sulfurique et de ses solutions aqueuses deviennent plus nettes et plus minces comme c'est généralement le cas. Par comparaison avec celui du liquide (Fig. 2, A) on note les particularités suivantes dans le spectre de l'acide pur à l'état solide (Fig. 4, A). Les deux bandes à 910 et 1050 cm^{-1}

caractéristiques de l'ion bisulfate sont nettement plus intenses, confirmant par là que l'auto-dissociation est plus forte à l'état solide. Par ailleurs, la bande de déformation $\angle$SOH à 1225 cm^{-1} est maintenant très distincte de la bande de valence S=O à 1165 cm^{-1}. L'harmonique de cette dernière fréquence se retrouve sans doute dans la bande très diffuse à 2150 cm^{-1}, de même que la combinaison des deux fondamentales à 1365 et 910 cm^{-1}.

Le monohydrate $H_2SO_4 \cdot H_2O$ montre un spectre (Fig. 4, B) entièrement différent de ceux *non seulement* de l'acide *pur mais encore* des solutions liquides de composition voisine (comp. Fig. 1, B). Notons en passant que le monohydrate contient 84.5% de H_2SO_4, le dihydrate, 73.15% et le tétrahydrate, 57.7%. L'effet Raman (11) et la résonance nucléo-magnétique (22) ont donné pour ce solide des résultats compatibles avec

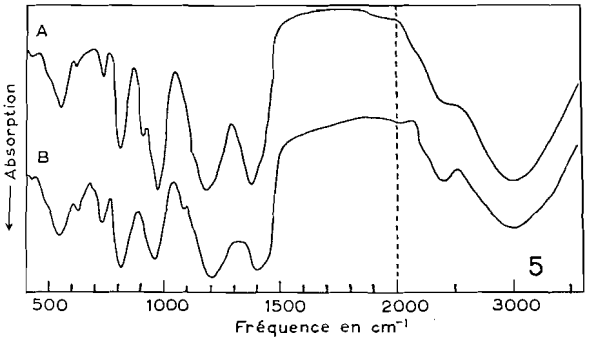


FIG. 4. Spectres de l'acide sulfurique et de ses hydrates à l'état solide. (A) H_2SO_4; (B) monohydrate (C) dihydrate; (D) tétrahydrate.
FIG. 5. Spectres infrarouges entre 2 et 25 μ des oléums. (A) 23% SO_3; (B) 69% SO_3.

la structure ionique $(H_3O^+)(HSO_4^-)$. Effectivement, la majorité des bandes rapportées ici (Tableau III) peuvent s'interpréter sans ambiguité d'après ces deux ions, à savoir celles de H_3O^+ à 732, 1142, 1730 et 2125 cm^{-1} (23) et celles de HSO_4^- à 890, 1046 et 1240 cm^{-1} (12). Cependant, la bande à 732 cm^{-1} constitue ici une énigme en ce qu'elle est beaucoup trop intense pour provenir uniquement de l'ion hydroxonium. En effet,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

elle est à peine visible dans les deux autres hydrates (Fig. 4, C et D). Nous nous proposons d'étudier cette question plus en détail. Dans les spectres du dihydrate toute trace d'acide non-ionisé a disparu et les bandes de H_2O sont bien évidentes. Enfin dans le cas du tétrahydrate la bande de l'ion sulfate à 1100 cm^{-1} se détache nettement de celle de l'ion bisulfate à 1045 cm^{-1} contrairement au cas des solutions liquides.

(D) Les oléums

Les spectres Raman des oléums à diverses concentrations sont déjà bien connus à la suite des travaux originaux de Chédin (4) et de ceux plus récents de Millen (5). Ce dernier a attribué les bandes observées à des acides supérieurs tels $H_2S_2O_7$, $H_2S_3O_{10}$, etc. dont l'existence avait été révélée par les mesures cryoscopiques de Gillespie (24). Les présents résultats (Tableau IV) confirment en général cette interprétation. Ainsi la bande d'absorption à 907 cm^{-1}, caractéristique de H_2SO_4, s'affaiblit graduellement lors de l'addition de SO_3 et finit par disparaître dans les oléums à environ 45%, composition correspondant à l'acide disulfurique $H_2S_2O_7$. Quant aux autres bandes de H_2SO_4 à 550, 970, 1170 et 1368 cm^{-1}, ainsi que les bandes de valence OH vers 3–4 μ, si elles semblent garder la même intensité à toutes concentrations, c'est qu'elles sont communes aux acides supérieurs et leurs ions, comme on pouvait le prévoir. Dans la plupart des cas on observe un léger déplacement du maximum de ces bandes suivant la concentration. En fait, seules quelques-unes des bandes rapportées ici peuvent servir à identifier sans ambiguité l'une quelconque des espèces moléculaires ou ioniques présentes dans les oléums.

En se basant sur des considérations de structure on doit s'attendre à des vibrations caractéristiques du "pont" S—O—S présent dans tous les acides supérieurs de formule générale $H_2SO_4 \cdot (SO_3)_n$. Aussi attribuons-nous aux vibrations de valence de ce groupe les deux bandes à 732 et 806 cm^{-1} qui sont de fréquence et d'intensité relative appropriées. Comme la première seule apparaît en Raman, elle doit correspondre à la vibration symétrique S—O. En ceci, notre interprétation diffère de celle de Millen (5) qui considère cette bande comme un diagnostic sûr de la molécule $H_2S_2O_7$ à l'exclusion des acides supérieurs. En fait, nos spectres infrarouges ne montrent aucune diminution appréciable d'intensité des deux bandes à 732 et 806 cm^{-1} pour des concentrations supérieures à 45% (i.e. $H_2S_2O_7$) ce qui concorde bien avec l'explication que nous proposons ici. Les autres bandes, qui d'après la distribution d'intensité pourraient être assignées à la molécule $H_2S_2O_7$, se trouvent à 618 et 640–655 cm^{-1}; cette dernière appartient peut-être à l'anion $HS_2O_7^-$ sur la concentration duquel on ne possède pas de données précises.

Quant à l'acide trisulfurique $H_2S_3O_{10}$ qui, selon les mesures cryoscopiques de Gillespie (24) existe aux concentrations supérieures à 30%, on peut lui attribuer avec assez de certitude les deux bandes à 688 et 1430 cm^{-1}. Dans les spectres Raman on observe à 480 cm^{-1} une bande qui semble bien provenir de cet acide, du moins si l'on s'en rapporte à son intensité. Son équivalent (à 472 cm^{-1}) dans les présents spectres ne montre pas le même profil d'intensité, mais ceci provient sans doute de difficultés expérimentales (lumière diffractée, etc.) dans cette région située à la limite utile de notre instrument.

Par ailleurs, nous n'avons pu déceler dans les spectres des oléums, même les plus concentrés, d'indices certains de l'acide tétrasulfurique $H_2S_4O_{13}$. Des deux fréquences Raman attribuées par Millen à cet acide, la première à 245 cm^{-1} tombe loin en dehors de la région étudiée ici et la seconde à 688 cm^{-1} apparaît déjà à 28% dans nos spectres, d'où l'attribution à $H_2S_3O_{10}$ ci-haut. Enfin, la faible bande à 1075 cm^{-1} dans les oléums

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

à plus de 45% de SO_3 révèle la présence de cette dernière molécule comme l'a démontré Chédin (4) à partir des spectres Raman. Selon toute apparence, l'anhydride SO_3 se trouve ici à l'état de monomère puisque les bandes caractéristiques du polymère S_3O_9 (25), en particulier celle à 860 cm^{-1}, n'apparaissent pas dans les spectres infrarouges des oléums même à 70%. Notons en terminant que, pas plus que pour les solutions aqueuses d'acide sulfurique, nous n'avons pu trouver dans les spectres des oléums d'évidence positive pour l'espèce $H_3SO_4^+$ bien que, d'après la stoéchiométrie, ce cation doive exister dans ce milieu.

REMERCIEMENTS

Les auteurs désirent remercier le Conseil National des Recherches du Canada pour l'aide financière qui leur a permis d'exécuter ce travail.

SUMMARY

The infrared absorption spectra from 2 to 30 μ have been measured for sulphuric acid, its aqueous solutions at various concentrations, the solid acid and its three hydrates, and finally the deuterated acid D_2SO_4. The results confirm and extend our knowledge as to the nature and relative abundance of the ionic and molecular species present in these systems. In particular, direct evidence was found for the self-dissociation of the pure acid as well as for the incomplete ionization of water even in very concentrated sulphuric acid. It was possible to assign most of the observed frequencies to the various vibrational modes of the H_2SO_4 molecule. Likewise the infrared spectra of oleums in concentrations up to 70% have been studied, and the higher acids, $H_2S_2O_7$ and $H_2S_3O_{10}$, have been identified.

THE COPPER/ARSENIC SYSTEM AND THE COPPER ARSENIDE MINERALS[1]

R. D. Heyding and G. J. G. Despault

ABSTRACT

In addition to the α solid solution of arsenic in copper, three intermediate phases exist in the copper/arsenic system. The ϵ phase, stable only below ca. 340° C, has the hexagonal $A3$ (D^4_{6h}, $P6_3/mmc$) structure with $a = 2.588$, $c = 4.226$ Å, and the approximate formula Cu_8As. The compound $Cu_{3-x}As$, with $0 \leqslant x \leqslant 0.3$, is trigonal ($D^4_{3d}$, $P\bar{3}c1$) with $a = 7.132$, $c = 7.304$ Å at $x = 0$. This compound has no polymorphic forms between 200° C and the melting point. The arsenic-rich compound $Cu_{5-u}As_2$, with $0 \leqslant u \leqslant 0.1$, melts incongruently at about 700° C, and decomposes at 300° C to arsenic and Cu_3As. The structure has not been determined, but the powder diffraction pattern is recorded. The solubility of copper in arsenic appears to be negligible.

It is suggested that the mineral α domeykite is a high-pressure phase, and that the mineral algodonite is a high-pressure modification of the ϵ phase. The mineral β domeykite is isostructural with Cu_3As.

According to the phase diagram (1), two compounds are formed in the binary copper/arsenic system. The first of these, Cu_3As, has been synthesized by Katoh (2) and the structure determined by Steenberg (3). It is trigonal (D^4_{3d}, $P\bar{3}c1$), and exists over a short composition range. A transition on the copper-rich side of Cu_3As at 380° C has been interpreted by Hansen (1) as the transformation of Cu_3As into a polymorphic low-temperature form, although Steenberg was unable to prepare Cu_3As with other than the trigonal structure mentioned above. Bolfa *et al.* (4) have reported the formation of a phase at relatively high pressure which is isostructural with the mineral *domeykite*, but the diffraction pattern and unit cell dimensions were not recorded.

Although the exact composition of the second compound in the binary phase diagram is not known, Hansen has assumed the formula to be Cu_5As_2, and has attributed the transitions at 700° and 300° C on the arsenic-rich side of Cu_3As to incongruent melting and peritectoid decomposition of this compound.

Recently, Schubert *et al.* (5) have reported the synthesis of a compound Cu_9As which does not appear on Hansen's phase diagram. It has the hexagonal close-packed $A3$ structure, and is stable only below 400° C.

The present study was undertaken to confirm the composition of the phase reported by Schubert, to search for transitions in Cu_3As, and to investigate the composition and structure of the arsenic-rich compound.

EXPERIMENTAL

Twenty-four alloys containing 2.5 to 36 at.% As in copper were prepared by heating the elements in sealed evacuated pyrex, vycor, or quartz tubes in the usual manner. The copper was prepared by reduction of powdered copper oxide with purified hydrogen. Spectroscopic analysis indicated impurity limits (in p.p.m.) of: Ag, 5–10; Fe, 5; Ni, 5; Si, 3; and Mg, 2. ASARCO metallic arsenic of 99.999% spectroscopic purity was sublimed prior to use to remove traces of oxide and to facilitate crushing.

Alloys containing less than 20 at.% As were melted and quenched, annealed at 680° C, and cooled slowly to room temperature. Filings of the specimens were placed in quartz

[1]*Manuscript received September 1, 1960.*
Contribution of the Division of Applied Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 6013.

X-ray capillaries which were in turn sealed under vacuum in larger vycor or pyrex capillaries for heat treatment. Alloys containing more than 20 at.% As were readily crushed by mortar and pestle, and subsequent heat treatment was conducted on bulk powders.

Some of the copper-rich alloys were annealed at moderate pressures and temperatures by heating open capillaries or tubes in a steel bomb under argon at 1500 to 2500 p.s.i.

X-Ray diffraction patterns were obtained in Norelco 11.46-cm Debye–Scherrer cameras using CuK_α radiation.

RESULTS AND DISCUSSION

The Copper-rich Region: The ϵ Phase

Diffraction patterns of alloys containing less than 25% As quenched from temperatures between 350° and 660° C showed only patterns of the α solid solution, or the α solid solution and Cu_3As. The unit cell dimension of the saturated α phase in equilibrium with Cu_3As was found to be 3.647 ± 0.001 Å, in good agreement with Mertz and Mathewson's value of 3.6483 Å (6).

A third phase appeared in alloys quenched or cooled slowly from 300° C with a corresponding decrease in intensities of the patterns of the α phase and Cu_3As. This phase was never obtained pure, even after cold-working and prolonged annealing. It has the approximate composition Cu_8As, and is isostructural with the compound Cu_9As recorded by Schubert, with hexagonal unit cell dimensions $a = 2.588 \pm 0.001$, $c = 4.226 \pm 0.001$ Å, $c/a = 1.633$. This $A3$, Mg-type structure (D^4_{6h}, $P6_3/mmc$) is also found in the ϵ phases of the Cu/Sb, Ag/As, and Ag/Sb systems (1, 7), and by analogy, should be referred to as the ϵ phase. Like the other ϵ phases, decomposition occurs at relatively moderate temperatures. Our inability to prepare a uniphase specimen may have been due either to a sluggish transformation or to the existence of a lower stability limit such as that observed in the Ag/As system, or both. In either event, the unit cell dimensions are not sensitive to total alloy compositions, and consequently the homogeneity range appears to be quite narrow under normal conditions.

The mineral *algodonite* is obviously isostructural with the ϵ phase, although compositions reported for the mineral range from Cu_7As (8) to Cu_4As (3). The diffraction pattern given by Peacock (9) for algodonite with the composition Cu_6As is identical with that of the ϵ phase, with minor variations in intensities of some of the reflections. One might expect the homogeneity limit of this close-packed phase to alter under pressure at the expense of the Cu_3As phase, and indeed, we have found that even at 2500 p.s.i. appreciable quantities of the ϵ phase (with slightly altered lattice parameters) appear in alloys of the composition Cu_4As. The variation in composition of the mineral, and the apparent discrepancy between composition of mineral and synthetic specimens can be attributed to differences in ambient pressures during formation of the phase.

The transition at 380° C in the phase diagram is, as far as we are able to estimate, 30 to 80° C higher than the temperature at which the peritectoid decomposition of the phase occurred in our alloys. There is some uncertainty in the figure given in the diagram, since it is based on an inflection in the solubility limit of arsenic in copper. It is not likely that the transition would be observed by differential thermal analysis unless the alloys were cold-worked before analysis.

The Compound Cu_3As

In alloys containing 22 to 27 at.% As, hexagonal Cu_3As or Cu_3As and the second phase appropriate to the two-phase region (α solid solution or the ϵ phase) were the only phases observed regardless of formation temperature or heat treatment between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

200° and 660° C. The unit cell dimensions and the analyses of homogeneous alloys at the copper- and arsenic-rich limits, quenched from 560° C, are:

As, (at.%)	Composition	a (Å)	c (Å)	c/a
24.92	$Cu_{3.01}As$	7.132	7.304	1.024
26.87	$Cu_{2.72}As$	7.113	7.272	1.022

These dimensions are in excellent agreement with Katoh's values for the terminal alloys (2), but the limits are somewhat richer in arsenic than those proposed by Katoh.

The mineral *β domeykite*, also with the formula Cu_3As, is isostructural with this phase, with unit cell dimensions of $a = 7.10$ kX and $c = 7.25$ kX (8).

There was no indication of a polymorphic transformation in Cu_3As within 2- to 3-week annealing periods at temperatures below 400° C. Moreover, an alloy prepared by heating the elements at 200° C for 2 months exhibited only the pattern of Cu_3As, although traces of unreacted copper and arsenic were visible under the microscope. We conclude that this phase exists only in the trigonal form described by Steenberg.

The Arsenic-rich Phase

Alloys containing 27 to 36 at.% As exhibited the diffraction patterns of Cu_3As and arsenic when quenched from 700° C or annealed and cooled slowly to room temperature from 280° C. A new phase was observed in alloys quenched from intermediate temperatures, with arsenic the second phase in alloys containing greater than 30 at.% As. Hansen's interpretation of the transformations at 700° and 300° C, incongruent melting and peritectoid decomposition of the arsenic-rich phase, is confirmed.

The decomposition at 300° C is rapid, and quenching was invariably attended by deposition of an arsenic mirror on the wall of the ampoule. Analysis of an alloy quenched from 550° C when in equilibrium with metallic arsenic at 450° C indicated a maximum copper content corresponding to $Cu_{2.5}As$ and a minimum content corresponding to $Cu_{2.45}As$.

The first 33 lines of the rather complicated diffraction pattern are recorded in Table I. The compound does not appear to be isostructural with any of the transition metal

or copper family chalcogenides or phosphogenides of approximately the same composition, although there is some superficial similarity to $Ni_{2.5}As$ (10) and $Ni_{2-2.5}Sb$ (11). The pattern can be indexed on a tetragonal cell with $a = 7.48$ Å, $c = 7.12$ Å, but this analysis must be regarded as provisional.

The Copper/Arsenic Minerals Algodonite and Domeykite

Three copper/arsenic minerals are recognized: hexagonal algodonite mentioned previously, the trigonal Cu_3As mineral called β domeykite by Paděra (8) and 'artificial domeykite' by Katoh (2) and Steenberg (3), and the cubic Cu_3As mineral called α domeykite by Paděra and domeykite or mineral domeykite by Katoh and Steenberg. The uncertainty in composition of the phases these minerals represent and the misinterpretation of the transformations they undergo has led to some confusion in the literature not only with respect to the minerals but with respect to the phase diagram as well.

The cubic mineral α domeykite decomposes at 225° C with the formation of algodonite and trigonal Cu_3As.* The composition of cubic α domeykite corresponds to Cu_3As, and Steenberg has argued that if cubic α domeykite and trigonal β domeykite are both Cu_3As, the transition at 225° cannot be explained unless algodonite is also, ideally, Cu_3As. This interpretation has been the basis for the assumption in subsequent literature that Cu_3As has two or three modifications. We have found no such modifications. Moreover, Pearson (7) has observed that cubic α domeykite is isostructural with $Cu_{15}Si_4$, and has suggested that the correct formula is $Cu_{15}As_4$ rather than Cu_2As. Finally, algodonite itself decomposes to trigonal β domeykite and the α solid solution at 250° C (3, 12), an impossible transformation unless algodonite lies between the solid solution and Cu_3As in the phase diagram.

We attempted to repeat the synthesis of the high-pressure Cu_3As phase described by Bolfa (4) without success, probably because the pressures we could attain were too low. It is unfortunate that Bolfa and his co-workers did not give the diffraction pattern of their product, but we must assume that it was identical with the mineral they used for comparison, and that the mineral was indeed cubic α domeykite.

With this assumption, the relationship of the minerals to the binary phase diagram can be explained quite simply. Cubic α domeykite is a high-pressure phase, probably with the formula $Cu_{15}As_4$, which decomposes on heating to trigonal Cu_3As (which is identical with trigonal β domeykite) and the ϵ phase. Algodonite is a high-pressure modification of the ϵ phase with variable composition, which decomposes at 250° C, somewhat below the normal transition temperature, with the formation of the α solid solution and trigonal Cu_3As. Neither of the high-pressure phases, algodonite and α domeykite, will appear on the normal phase diagram, and there is no reason to expect that the compound Cu_3As exists other than with the trigonal lattice.

As a result of this investigation we submit that three modifications are required in the phase diagram shown and described in Hansen:

1. The transition at 380° C, on the copper-rich side of Cu_3As represents the peritectoid decomposition of the ϵ phase rather than a polymorphic transition in Cu_3As. The ϵ phase has very narrow homogeneity limits at about Cu_8As.

2. The homogeneity limits of Cu_3As at 560° C are $Cu_{3.0}As$ and $Cu_{2.7}As$, somewhat richer in arsenic than indicated in the diagram.

**The description in Hansen of cubic α domeykite as a high-temperature phase is obviously a misprint.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

3. The composition of the arsenic-rich phase can be represented by the expression $Cu_{5-u}As_2$ in which u, the uncertainty, is within the limits $0 \rightarrow 0.1$. We have found no evidence to indicate that a compound richer in arsenic is formed at normal pressure.

ACKNOWLEDGMENTS

We are indebted to Mrs. T. M. Dolan for assistance in obtaining Debye–Scherrer patterns, and to Mr. P. Tymchuk and Mr. G. R. Duval for analysis of reactants and products.

A METHOD FOR ADIABATIC COMPRESSION OF GASES UNDER CONTROLLED CONDITIONS[1]

G. D. GRAHAM[2] AND O. MAASS[3]

ABSTRACT

A preliminary account is given of an experimental technique by means of which the specific heats of gases may be measured at high temperatures and pressures. With the transducer employed consistent results were obtained up to 7000 p.s.i. and it is proposed to incorporate a transducer having a much higher pressure range where it is estimated that temperatures up to 10,000° K can be recorded.

INTRODUCTION

In a number of research directions it is of considerable interest to determine the properties of gases at high temperatures. In this paper an experimental procedure is described where the ratio of specific heats can be determined at temperatures above 1000° K.

This paper must be considered as a preliminary one in which the method of approach is described in some detail, and where measurements have been carried out as yet only to the relatively low temperature of 3000° K. By using the term low temperature it is implied that with the incorporation of a transducer which is adaptable to higher pressure measurements than the one used so far it is hoped that it will be possible to get useful information up to temperatures at least as high as 10,000° K. The procedure to be described involves the application of a high pressure impinging on one end of a double-headed piston which causes the other piston head to compress the gas under examination suddenly and under controlled conditions.

To make this possible the use of a double diaphragm is incorporated. This can be ruptured in such a way by an impinging pressure which exerts its full force on the upper piston head. This makes it possible to have an immediate and controlled impinging pressure to a high degree of accuracy whereby insuring reproducible results.

To recapitulate, the device to be described enables one to compress a gas to a predetermined volume with a high degree of accuracy and in a small fraction of a second.

The incorporation of a transducer which is adaptable to higher pressure measurements involving higher temperatures should make it possible to approach the main objective, namely to go to the high temperature mentioned above. This is under immediate consideration but it is thought that publication of the experimental procedure is warranted.

Before going on to a description of what has been accomplished so far, it may be pointed out that a transducer has been procured which will enable pressure measurements to be made up to 150,000 p.s.i. It is claimed by the manufacturer that this transducer can make reproducible measurements at this pressure but has been found to give non-reproducible results in the range below 10,000 p.s.i.

EXPERIMENTAL

The experimental procedure which is to be described may seem somewhat complicated and it is to be hoped that the diagrammatic sketch of the apparatus (Fig. 1) may help to elucidate this.

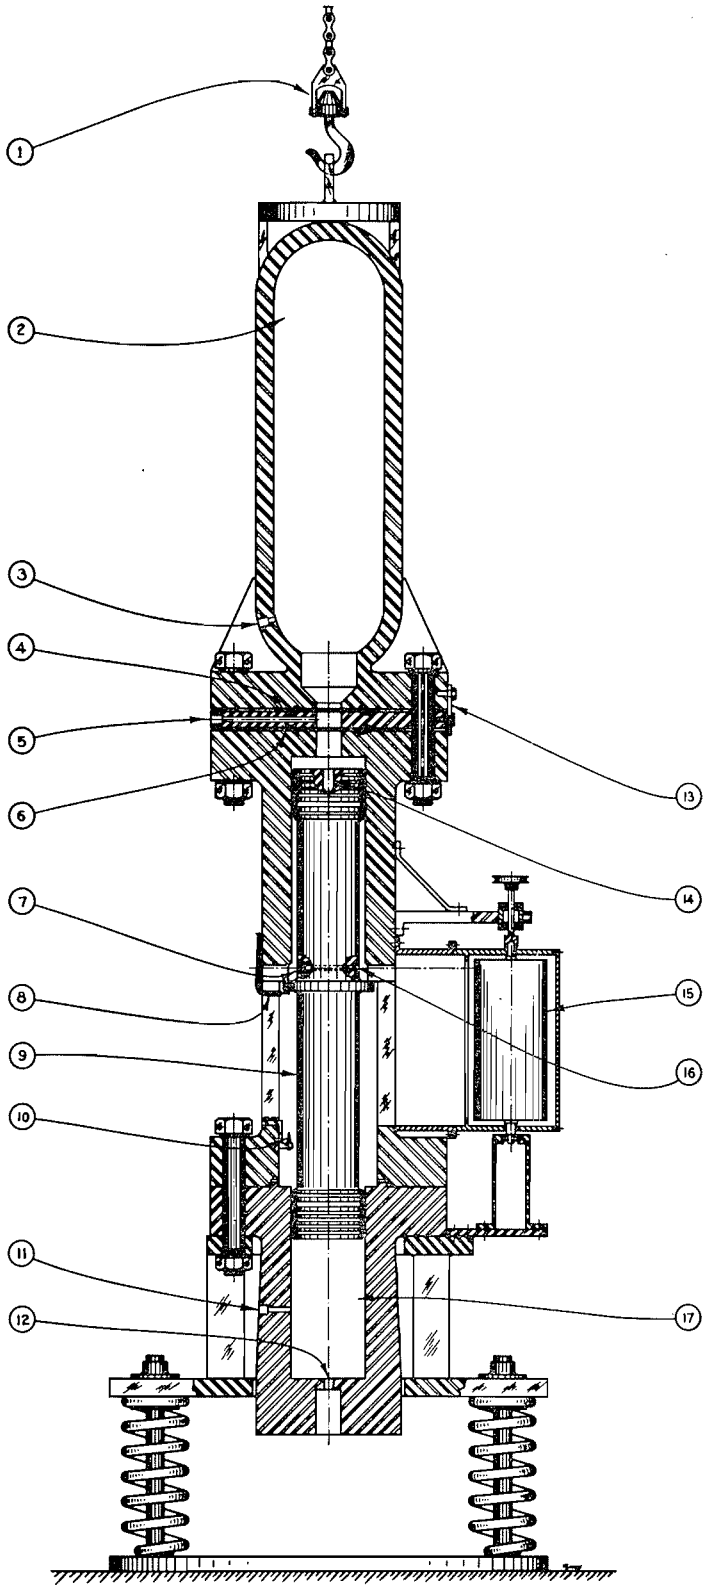

FIG. 1.

A gas of known volume is to be compressed suddenly and this to be done under controlled conditions in such a small fraction of time that adiabatic conditions prevail. This will be described under Apparatus, Measurements, and Procedure.

APPARATUS

The entire apparatus is mounted on eight automobile springs (Fig. 1). The gas under examination is contained in compression chamber (17)* which may be evacuated and filled through inlet (11). The chamber was forged from stainless steel No. 410 and was designed to withstand pressures of at least 150,000 p.s.i. The internal dimensions are 6 in. diameter and 16 in. high with a surface finish of 32 microns. In the bottom of the chamber is a threaded cavity (12) into which a suitable transducer can be flush mounted.

The double-headed piston (9) is of forged aluminum alloy weighing approximately 100 pounds and is fitted at both ends with five aircraft piston rings. Although the rings were fitted so as to have zero gap, as an added precaution against leakage, a rubber "O" ring was fitted to the bottom end in place of one of the piston rings. At its middle as shown in Fig. 1 the piston is flanged; this acts as a stop when the piston is raised into firing position and as a reference point in volume measurements. To facilitate dismantling and assembling there is a threaded hole (14) in the upper end of the piston into which a hoisting device may be inserted.

The upper end of the piston travels in a cylinder which was forged from stainless steel No. 410. To enable volume measurements to be carried out two openings were cut on opposite sides in the lower half of this cylinder. Both the compression chamber and cylinder are held securely together by means of sixteen 1 in. diameter bolts.

The air reservoir (2), which has a volume of 2 cubic feet, contains the propelling gas and is filled through inlet (3) from compressed air cylinders. This reservoir pressure is later on referred to as the impinging pressure.

Between the cylinder and air reservoir the firing assembly is located. This consists of two identical brass disks separated by a 1-in. thick, washer-shaped, steel plate. The volume so formed between the disks is known as the compensating chamber and has a volume of approximately 50 cc which is insignificant to the volume pressure changes which take place. Compressed air may be fed into this chamber through inlet (5). To insure a rigid and leakproof seal, "O" rings (6) are situated on both faces of each disk. The air reservoir, firing assembly, and cylinder are fastened together with sixteen 1 in. diameter bolts. Either disk will burst instantaneously if subjected to a force somewhat above its breaking pressure. Knowing the approximate breaking pressure of the disks, it is possible to contain a pressure in the air reservoir greater than the breaking pressure of the upper disk by admitting a balancing pressure to the compensating chamber. For example, if the desired impinging pressure is 200 p.s.i. one would select disks having a breaking pressure of approximately 150 p.s.i. plus or minus 15 p.s.i. In this case the compensating chamber may be pressurized to 100 p.s.i. and concurrently the air reservoir to 200 p.s.i. without fear of rupture of either disk. Release of the compensating pressure by bleeding through a valve will result in the bursting of the upper disk whereupon the 200 p.s.i. pressure will burst the lower disk, thus exerting the full force of the impinging pressure on the piston. It may be pointed out here that it is important to know the impinging pressure accurately so as to be able to reproduce and vary these impinging pressures. If only one disk is used it would be almost impossible to reproduce the impinging pressure because such a disk might have a variation in its breaking pressure of

**Throughout the paper, numbers in parentheses refer to circled numbers in Fig. 1.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

possibly 20%. Furthermore in the investigation underway it was of considerable interest to be in a position to vary the impinging pressure by relatively small amounts. By having perfect metal disks that would break at say 95.0 p.s.i., 100.0 p.s.i., or 105.0 p.s.i. in a reproducible way enabling only one disk to be used would entail considerable cost in procuring such disks. With the double-disk procedure reproducible impinging pressures can be obtained at say 95 p.s.i., 100 p.s.i., or 105 p.s.i. or any other arbitrary pressure within small variations using the same sheet of foil from which the disks are cut. It also makes it possible to initiate the experiment with relative ease. The impinging pressure in the range used to date can be determined to within 0.5% by use of a pressure gauge with 1 p.s.i. per division markings.

MEASUREMENTS PROCEDURE

The maximum pressure attained in the initial compression is measured by means of a transducer. The choice of transducer is governed by the pressure range being investigated. For the work to date an Endevco No. 5000 piezoelectric gauge having a pressure range of 0 to 2500 p.s.i. has been used. The signal from the transducer is fed through a high-impedance (500-megohm) amplifier and then into a Hughes Memoscope Model No. 104. The peak height of the trace observed in the memoscope is measured by means of a cathetometer and from a previous calibration of the transducer this is converted to a pressure. A permanent record of the trace is obtained by photographing with a polaroid Land camera (see Fig. 2).

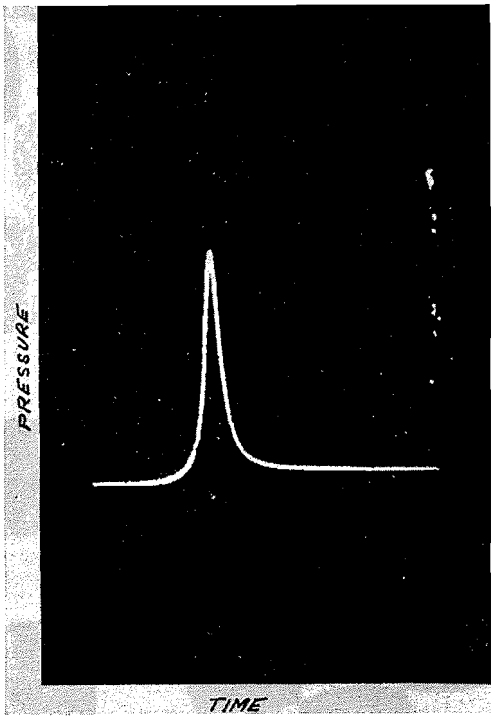

FIG. 2.

The volume at maximum pressure is measured by means of a small lead pyramid (10) which is attached by means of a screw to a small platform. When the piston is propelled downward the flange on the piston body strikes the lead. The depression of the lead is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

then measured and the volume calculated. The accuracy of these volume measurements were confirmed by placing a lead pyramid directly under the piston during a run. This pyramid was then measured and it was found that the calculated volume based on the measurement of the outside pyramid was in agreement within 0.1%.

The drum camera (15), which records the oscillations of the piston, is mounted on the side of the apparatus at one of the openings. A variable speed motor drives the drum at any desired speed and by means of a zirconium arc lamp (7) inserted in the piston a light beam is pinpointed on the camera through lens (16). A manually operated shutter is opened just before the piston is propelled and closed after the oscillations have ceased. In Fig. 3 a photographic copy of a typical drum camera trace is shown. It is believed that considerable data can be obtained from such a trace.

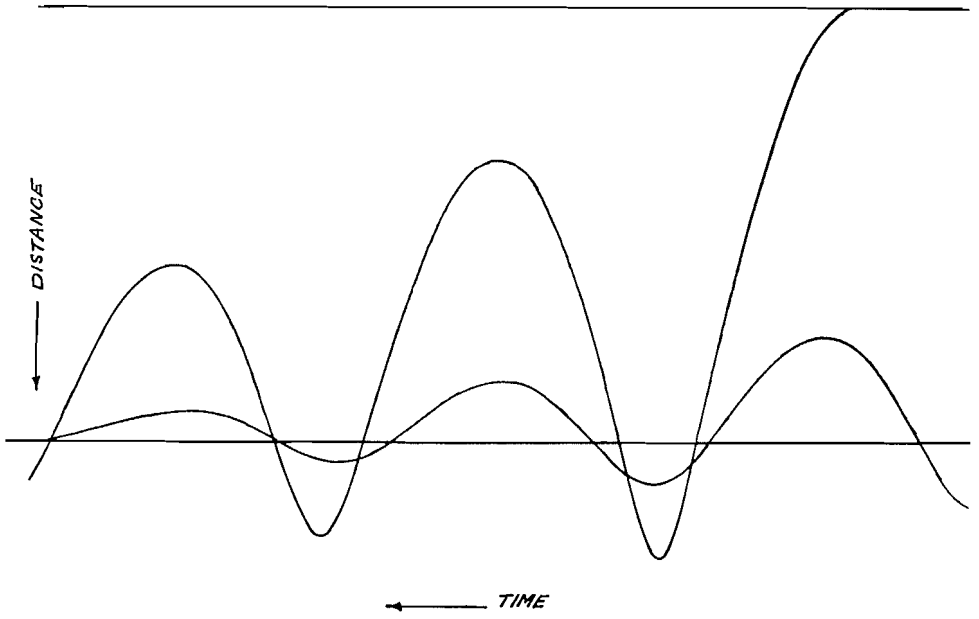

FIG. 3.

PROCEDURE

In Fig. 1 the apparatus is shown ready for an experiment. The propelling gas is fed into the cylinder and at the same time into the compensating chamber between the shims through inlet (5). When the desired pressures have been reached the valves are closed. The shutter on the drum camera (15) is opened and the compensating pressure is bled off through inlet (5). The disks break, as explained above, propelling the piston downward compressing the gas under observation in compression chamber (17). As the piston starts to move down it triggers the memoscope sweep by means of trigger (8).

To reload for the next experiment the piston is raised by opening inlet (11) and evacuating the reservoir above the piston. The bolts holding the upper sections are loosened and hooks (13) (there are three hooks spaced 120° apart) are set in place. By means of hoist (1) the air reservoir and steel plate are raised enabling the lower brass shim (6) to be replaced. The hoist is then lowered and the three hooks removed. The air reservoir is now hoisted alone and the upper shim (4) replaced. The air reservoir is again lowered and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the bolts tightened. The drum camera is reloaded and the lead volume indicator replaced. The piston is then held securely in position (by means of a wooden block placed between the piston flange and the lower edge of the opening) and the compression chamber (17) is evacuated. The gas under test is then fed into the chamber at atmospheric pressure and inlet (11) is closed. The wooden block holding the piston is removed and the apparatus is now ready for another experiment.

RESULTS

It is recognized that using ideal gas laws to make any calculations is not justified; nevertheless to make certain approximations is a reasonable approach. Having done this the following data is tabulated in Table I. The results of many experiments are summarized

TABLE I

Gas	Impinging pressure, p.s.i.	Temperature, °K	Pressure, p.s.i.	Ratio specific heats
Argon	140	1690	1280	1.630
	150	1790	1470	1.632
	170	1930	1984	1.634
	200	2000	2572	1.610
	450	3100	7203	1.603
Nitrogen	100	600	397	1.270
	110	675	544	1.290
	150	850	911	1.320
	190	1380	985	1.344
	200	1450	1029	1.354
Carbon dioxide	100	650	1411	1.203
	130	700	1500	1.224
	150	875	2675	1.258
	180	1000	4778	1.305
	200	1325	5880	1.327

as far as argon is concerned and the wide pressure and temperature range show how constant the specific heats remain. The results for nitrogen and carbon dioxide are consistent.

None of the results tabulated should be taken as establishing data which approach the accuracy of those previously established by others. It may be stated again that the purpose of this paper is to describe an experimental technique which is useful for exploring a higher-temperature region which has not yet been adequately explored.

REMARKS

There are a number of side issues for which this equipment can be usefully employed because a relatively large (5 liters) initial volume of gas can be used.

For example, it can be used to compress adiabatically a gas which undergoes chemical decomposition at high temperatures and under controlled conditions. The resulting products can be withdrawn for analysis and, as can be readily seen, a wide range of temperatures can be covered.

THE DETERMINATION OF ZIRCONIUM WITH BENZOYLPHENYLHYDROXYLAMINE[1]

D. E. RYAN

ABSTRACT

Zirconium is completely precipitated by benzoylphenylhydroxylamine from 0.5 *N* acid solutions. The complex formed in sulphuric acid solutions has a constant composition, $Zr(C_{13}H_{10}O_2N)_4$, and is used for the direct weighing of zirconium; the factor is 0.0970. The product precipitated from hydrochloric acid solutions must be ignited to the oxide. The reaction is sensitive, 1 p.p.m. of zirconium being detectable, and quantitative determination of 0.2 mg is possible. Thorium and the rare earths do not interfere.

INTRODUCTION

Benzoylphenylhydroxylamine (BPHA),* where the benzoyl group has replaced the nitroso group in cupferron, has become an important reagent in the past 10 years. It has been used for the determination of iron, copper, aluminum, and titanium (1); for tin (2); for vanadium (3, 4); and for tantalum and niobium (5, 6, 7). It is recommended as superior to cupferron, when applicable, because it is more sensitive to hydrogen ion concentration, is much more stable to heat and light, and forms complexes that can, in some instances, be dried at 110° C (1, 2). BPHA has been stated to form a complex of definite composition with zirconium (8) that does not decompose at 110° C. Since only a few reagents, from the many precipitants available for zirconium, are suitable for direct weighing and as BPHA yields no precipitates with thorium or trivalent rare earths in acid solution, a detailed investigation into its possibilities for the determination of zirconium was considered worth while.

EXPERIMENTAL

From hydrochloric acid solutions of zirconium a flocculent white precipitate is obtained on adding a solution of BPHA; the precipitate becomes granular on digestion upon the steam bath and filters easily. No zirconium was detected by alizarin in filtrates from solutions containing 5% of concentrated hydrochloric acid. Under these conditions the following ions are not precipitated by the reagent: Cu^{++}, Al^{+++}, Bi^{+++}, Cd^{++}, Cr^{+++}, Pb^{++}, Mg^{++}, Mn^{++}, Ni^{++}, Zn^{++}, UO_2^{++}, Th^{++++}, Y^{+++}, Ce^{+++}, Sm^{+++}, La^{+++}, Pr^{+++}, Gd^{+++}, Nd^{+++}, and Dy^{+++}. The soluble 1:1 purple complex (9) is formed in ferric iron solutions whereas tin, vanadium V, cerium IV, and titanium react to give the usual precipitates.

Zirconium is readily precipitated by BPHA in sulphate solutions and precipitation is quantitative in 0.5 *N* sulphuric acid. BPHA fails to precipitate zirconium from solutions containing fluoride.

The compound precipitated from sulphate solutions contains, found after drying at 110° C and ignition to the oxide, 9.71% zirconium. $(C_{13}H_{11}O_2N)_4Zr$, in which four molecules of BPHA are combined with one atom of zirconium, has a zirconium content of 9.70%. This complex is stable to several hours' drying at 130° C but at 160° C some decomposition occurs, the compound becoming buff rather than white in color.

[1]*Manuscript received June 15, 1960.*
Contribution from the Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, with financial assistance from the National Research Council, Ottawa, Canada.
**Hereafter designated by BPHA.*

Reagents

N-*Benzoylphenylhydroxylamine.*—The reagent was prepared as previously described (2) and recrystallized from hot water; the compound can be purchased from leading chemical supply houses. A solution was prepared by dissolving 4 g in 100 ml of 95% ethyl alcohol.

Standard zirconium solutions.—The zirconium solutions were prepared from Matthey specpure zirconium oxychloride and zirconium sulphate. The chloride solutions, even in 5% hydrochloric acid, were found to be unstable over a convenient period of time and fresh solutions were prepared for each series of determinations. The sulphate solutions, in 2% sulphuric acid, caused no such difficulty. The zirconium content was determined gravimetrically by means of cupferron and mandelic acid.

Procedure

1. Ignition to the Oxide

Varying amounts of acid were added to samples of the zirconium standards and the solutions diluted to 150–200 ml. Reagent, in excess of the theoretical quantity required for the zirconium present, was added and the solutions digested for half an hour on the steam bath. After the samples were cooled to room temperature, they were filtered through Whatman No. 42 filter paper, washed with a saturated aqueous reagent solution, and ignited to the oxide. The results are shown in Table I.

TABLE I

Precipitation of zirconium by benzoylphenylhydroxylamine and subsequent weighing as the oxide

No.	Zr taken, mg	Zr found, mg	Conditions
1	2.70*	2.72	Solution 1% in concentrated HCl
2	2.70*	2.75	Solution 3% in concentrated HCl
3	2.70*	2.71	Solution 5% in concentrated HCl
4	2.70*	2.36	Solution 7% in concentrated HCl
5	8.42	8.42	Solution 5% in concentrated HCl
6	11.55	11.55	"
7	11.55	11.53	"
8	17.90	17.90	"
9	21.80	21.75	"
10	8.42	8.42	Solution 1.5% in concentrated H_2SO_4
11	8.42	8.31	Solution 2% in concentrated H_2SO_4
12	8.42	5.45	Solution 5% in concentrated H_2SO_4
13	8.42	5.50	Solution 10% in concentrated HCl
14	8.42	8.41	As sample No. 5 but 10 mg Th present
15	8.42	8.45	As sample No. 5 but 50 mg Th present
16	8.42	8.44	As sample No. 5 but 70 mg rare earths present
17	8.42	8.51	As sample No. 5 but 10 mg Ce^{++++} present reduced with H_2O_2
18	8.42	8.54	As sample No. 5 but 10 mg Ti^{++++} present complexed with H_2O_2

*These results were obtained independently by a member of this laboratory.

These results show that precipitation of zirconium by BPHA is quantitative in solutions containing up to 5% of concentrated hydrochloric acid and 1.5% of concentrated sulphuric acid (approximately 0.5 to 0.6 *N* in hydrogen ions); precipitation is incomplete at higher acidities. Thorium and the trivalent rare earths do not interfere. The interference of titanic and ceric ions is largely removed in one precipitation by complexing the titanium or reducing the cerium with hydrogen peroxide.

Attempts to remove interference of quinquevalent vanadium by complexing with hydrogen peroxide were unsuccessful; the result obtained for 8.42 mg of zirconium taken

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was 9.91 mg in the presence of 10 mg of vanadium. In the presence of 20 mg of iron, the result was 0.5 mg higher than for the 8.42 mg of zirconium taken on a single precipitation.

THE DIRECT WEIGHING OF ZIRCONIUM COMPLEXES

Complexes that are capable of direct weighing eliminate the necessity of ignition to an oxide and permit, by virtue of their favorable factor, smaller quantities of metal ions to be determined more accurately. For zirconium, where one must invariably consider hafnium and its similar chemical behavior, there is the additional advantage that formation of such complexes permits the ready determination of the hafnium-to-zirconium ratio.

Of the many precipitants available for zirconium only 8-hydroxyquinoline, mandelic acid and its derivatives, and, more recently, tartrazine have been recommended as forming precipitates suitable for direct weighing. Balanescu (10) found that zirconium precipitates with 8-hydroxyquinoline could be dried at 140° C if precipitated from nitrate solutions buffered with acetate; precipitates varying in composition were obtained in chloride solutions.

There has been some disagreement regarding the mandelic acid derivatives. Oesper and Klingenberg (11) claimed good results on drying at 110° C for the *p*-bromo derivative whereas Belcher *et al.* (12) stated that consistent but low results were found with this same compound. Astanina and Ostroumov (13) found that mandelic acid gave zirconium precipitates that could be dried at 110° provided the final solutions were 20% by volume in concentrated hydrochloric acid; Hahn and Baginsky (14) reported also that complexes of constant composition were precipitated by mandelic acid from strong hydrochloric acid solutions and stated that low results in less acid solutions were due to basic salts; similar results have been found in this laboratory.

Tartrazine (15) has been recently recommended for the direct weighing of zirconium. The zirconium is precipitated at 80° C from chloride or nitrate solutions at pH 1; the factor used was for a compound with the formula Zr_3 (tartrazine)$(OOH)_3$. In view of the ease of hydrolysis of zirconium solutions and the failure to obtain precipitates of constant composition by well-known reagents under these conditions, further confirmation on the usefulness of this reagent is necessary.

The zirconium precipitates obtained with benzoylphenylhydroxylamine from 5% hydrochloric acid solutions are stable but are not of a constant composition; as expected, compounds precipitated from chloride solutions of zirconium at this acidity are not suitable for direct weighing. From sulphuric acid solutions, however, complexes having the composition $(C_{13}H_{11}O_2N)_4Zr$ are obtained and precipitation is complete at acidities up to 0.5 *N*; apparently the sulphate complexes of zirconium prevent the formation of unwelcome basic salts and permit compounds of unvarying composition to be precipitated. Mandelic acid, used subsequently in these solutions, gives also zirconium complexes suitable for direct weighing.

Procedure

2. Direct Weighing of Zirconium Complex with Benzoylphenylhydroxylamine

Samples of zirconium sulphate standard solution were diluted to 100–150 ml and the solutions made not more than 0.5 *N* in sulphuric acid. Reagent, in slight excess (not more than 40 mg for every 100 ml of solution) of the theoretical quantity required for the zirconium present, was added dropwise with stirring and the solutions digested on the steam bath for an hour. The samples, after cooling, were filtered through porous-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

based porcelain crucibles and washed with cold water. The precipitates were then washed with two or three 5-ml aliquots of hot water (80° C) and dried at 110° C. The weight of the complex was multiplied by the theoretical factor 0.0970 to obtain the weight of zirconium. Results are shown in Table II.

10	0.51	0.51	As sample No. 9 but digested overnight
11	0.17	0.15	As sample No. 9 but digested overnight

The results show that benzoylphenylhydroxylamine is a suitable reagent for the direct weighing of zirconium when applied to dilute sulphuric acid solutions. Complete precipitation of the zirconium is possible from 0.7 *N* H_2SO_4 solutions, but at acidities greater than 0.5 *N* an overlong digestion period is necessary. Results 9, 10, and 11 show that a prolonged digestion period is required for solutions containing very small amounts of zirconium.

From 5% hydrochloric acid, although precipitation is complete, the weights of complex obtained are low and the compositions vary with the amount of zirconium present in solution; for 8.42 mg of zirconium, in one instance, the weight of complex found was 0.0845 g (theoretical 0.0868) and for 21.05 mg of zirconium was 0.2063 g (theoretical 0.2170). Since degree of hydrolysis in zirconium solutions is dependent on time, temperature, and acid present, these results are undoubtedly due to simultaneous precipitation of varying amounts of basic salts; a distinct cloudiness, for example, develops on heating 5% hydrochloric acid solutions of zirconium oxychloride for less than an hour on the hot plate.

From sulphuric acid solutions, zirconium complexes suitable for direct weighing are also precipitated by mandelic acid. A typical result obtained for 8.41 mg taken was 8.42 mg, the weight of mandelic acid complex (precipitated from 0.5 *N* sulphuric acid solution) being 0.0643 g.

Mandelic acid and its derivatives, although undoubtedly the most useful of the organic reagents used for zirconium, have been criticized (16) because of their non-sensitivity and the large amounts of reagent thus required for each precipitation. It is worth while noting, therefore, that benzoylphenylhydroxylamine detects as little as 0.1 mg of zirconium in 100 ml of solution and quantitative precipitation of 0.2 mg is possible.

This work was carried out at the Imperial College of Science and Technology, London, England, and was supported by a travel grant from the National Research Council.

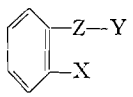
THE APPLICATION OF THE HAMMETT EQUATION TO ORTHO-SUBSTITUTED BENZENE REACTION SERIES[1]

MARVIN CHARTON

ABSTRACT



The Hammett equation is directly applicable to ortho-substituted benzene reaction series in which reaction site and benzene ring are separated by some group Z, apparently due to the absence of steric effects in these series. The σ_p values are used in the correlations. Fourteen ortho-substituted benzene reaction series have been correlated. The electrical effect of a substituent in the ortho position is found to be about 0.75 times its effect in the para position. The effect of the side-chain Z in the transmission of substituent effects is $OCH_2 > SCH_2 > CH{=}CH > SeCH_2 > CH_2CH_2$.

INTRODUCTION

Linear free-energy relationships have been shown to be of great value for the correlation of reaction rates, equilibria, and physical properties with variations in structure. The Hammett equation,

$$\log(K_X/K_H) = \rho\sigma_X, \qquad [1]$$

has been widely applied to meta- and para-substituted benzene reaction series (2, 3) and to olefins (4, 5) and acetylenes (6). In modified form, it has been applied to aliphatic and to ortho-substituted benzene reaction series (7). Direct application of the Hammett equation to ortho-substituted benzene derivatives is unsuccessful, due to steric effects. Taft (7) has been able to correlate a few ortho-substituted benzene reaction series by an approach which is dependent upon the elimination of the steric effect in the evaluation of the substituent constants. Mammalis and Rydon (8) have suggested that substituent constants for ortho substituents be defined from reaction series in which the reaction site is not adjacent to the substituent. It has been suggested by a number of authors that the inductive and resonance effects of an ortho substituent are similar to those of the same substituent in the para position. It is of interest to compare the σ_o^* substituent constants obtained by Taft (7), by elimination of steric effects, with the σ_p substituent constants. Considering the degree of uncertainty in the values of substituent constants, they are almost identical. These results suggested the possibility of direct application of the Hammett equation, using the σ_p substituent constants, to ortho-substituted benzene reaction series in which the reaction site is not directly attached to the ring (I). As the reaction site and substituent are not adjacent in such reaction series, hydrogen bonding and other secondary bonding interactions between them cannot occur, and no hindrance to the attack of reagent should exist. The literature was searched for reaction series of this type. Fourteen such reaction series have been examined, seven involving equilibrium data and seven involving rate data. The correlations were made by the method described by Jaffé.

Contribution from the Department of Chemistry, Pratt Institute, Brooklyn 5, New York.

RESULTS AND DISCUSSION

Data and Correlations

The data used in the correlations are given in Table I. The substituent constants used are those given by Jaffé (3) and by McDaniel and Brown (9) except for the carbomethoxy group, which was taken from Charton and Meislich (4). A statistical factor of 1/2 was used in reaction series 12 for methyl phthalate to account for the presence of two potential reaction sites. The results of the correlation are shown in Table II; Figs. 1 and 2 are typical curves.

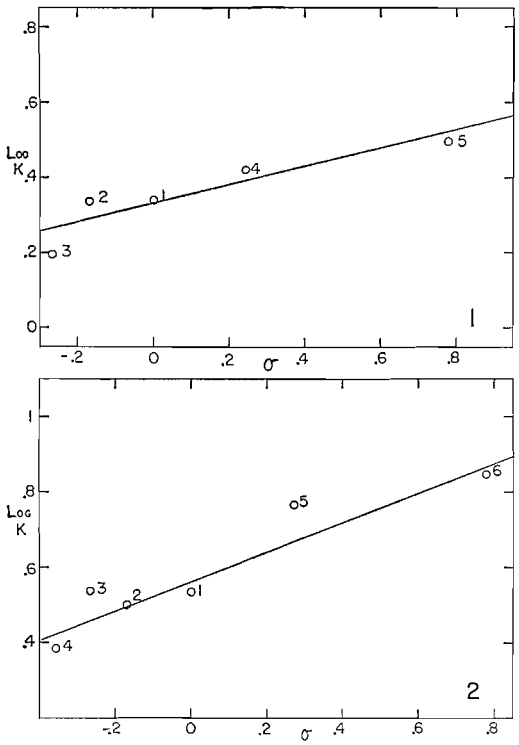

FIG. 1. Hammett equation plot of log $10^5 K$ vs. σ for 3-(2′-substituted)phenyl propanoic acids. The substituents are: 1, H; 2, Me; 3, MeO; 4, Cl; 5, NO_2.

FIG. 2. Hammett equation plot of log $10^5 K$ vs. σ for *trans*-2-substituted cinnamic acids. The substituents are: 1, H; 2, Me; 3, OMe; 4, OH; 5, Cl; 6, NO_2.

The results of the correlations are as good as those generally obtained for meta- and para-substituted benzene reaction series. Of the 14 reaction series examined, six show fair correlation ($0.90 \leqq r \leqq 0.95$), five show good correlation ($0.95 \leqq r \leqq 0.99$), and three show excellent correlation ($0.99 \leqq r$), according to the empirical scale proposed by Jaffé (3, 18). Jaffé (3) has pointed out that the correlation coefficients decrease with decreasing absolute values of ρ. Of the six reaction series which had fair correlation, the value of ρ_0 (19) was less than 0.400 in five (20).

Structural Requirements for Correlation

Apparently, the side-chain Z must consist of at least two atoms, for satisfactory correlation to result. No satisfactory correlation is obtained in the case of the ionization constants of 2-substituted phenylacetic acids, however, although the available data (for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

X = H, Cl, Br, I, NO_2) is insufficient to support a conclusive statement. Examination of the Stuart–Briegleb models for this reaction series, and for others in which the side chain is a methylene group indicates the possibility of considerable interaction between the substituent and the reaction site.

The Effect of Side Chain on Transmission of Substituent Effect

A comparison of the ρ_o values obtained from the correlation of ortho-substituted benzene reaction series with the ρ values for the corresponding meta- and/or para-substituted benzene reaction series may be used to determine variation in transmission

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of substituent effects through different side chains. The ratio of the $\rho_{o,Z}$ value for some side-chain Z to that for the CH_2CH_2 side chain, ρ_{o,Z^0}, for a given reaction under identical reaction conditions, provides a method of making such comparisons (3). Those values of ρ, r, s, n, and $-\log K$ for the corresponding meta- and/or para-substituted reaction series which are available are given in Table II.

Thus,

$$[2] \qquad \rho_{oZ}/\rho_{oZ^0} = q_o, \qquad \rho_Z/\rho_{Z^0} = q.$$

Values of q_o obtained from reaction series 1, 2, 4, 5, and 6 are shown in Table II. The values for the OCH_2, SCH_2, and $SeCH_2$ groups are of about the same order of magnitude as that for the CH=CH group, and increase in order of increasing electronegativity of the group VI element. This might be explained in the case of the SCH_2 and $SeCH_2$ groups by hyperconjugation and an expansion of the S or Se valence shell from an octet to a decet, but such an explanation is, of course, not possible for the OCH_2 group, which exhibits the greatest transmission of the substituent effect.

The values of q for the corresponding meta- and/or para-substituted reaction series are also given in Table II. It is notable that although the distance between the reaction site and the substituent is greater for meta- and para-substituted compounds than it is for ortho-substituted compounds, it appears that the effect of the substituent is not transmitted to the reaction site to as great an extent in the ortho-substituted reaction series as it is in the meta- and para-substituted reaction series. Transmission through the side chain from the limited data available appears to be about 1.5 times as effective for meta- and para-substituted compounds as for ortho-substituted compounds. This might be due to some distortion of the bond angle in the ortho-substituted reaction series which decreases the overlap of the p orbitals in O, S, and Se, or the π orbital of the CH=CH group, with the π orbital of the ring.

The Magnitude of the Electrical Effect of an Ortho Substituent

In the absence of steric effects and secondary bonding,

$$[3] \qquad \sigma_{oX} = C\sigma_{pX}.$$

The correlations made in this paper have used the Hammett equation in the following form,

$$[4] \qquad \log(K_{oX}/K_H) = \rho_o\sigma_{pX}.$$

If the substituent constants for ortho substituents were available, then assuming steric effects are nonexistent, ortho-, meta-, and para-substituted benzene reaction series would be included in a single correlation with the same value for ρ. Thus

$$[5] \qquad \log(K_{o,m,p\ X}/K_H) = \rho\sigma_{o,m,p\ X}$$

or considering only ortho substitution,

$$[5a] \qquad \log(K_{oX}/K_H) = \rho\sigma_{oX}.$$

To a good first approximation, steric effects will not exist in ortho-substituted benzene reaction series of type I, and therefore use of equation 5*a* is justified for these reaction series. It is, of course, not applicable to ortho-substituted benzene reaction series in which the substituent and reaction site are directly attached to the ring.

From equations 2, 4, and 5*a*, equation 6 is obtained

$$C = \rho_o/\rho \qquad [6]$$

where C represents approximately the electrical effects of a substituent in the ortho position as compared with its electrical effects in the para position. Actually, C is subject to variations in ρ_o due to phenomena such as a bulk effect between the ortho substituent and the side-chain Z which may cause decreased orbital overlap in unsaturated side chains, and to variations in solvation as compared with meta- and para-substituted benzene reaction series. Values of C obtained from those reactions series for which both ρ_o and ρ are available are shown in Table II. Although the values of C vary considerably, they are all of the same order of magnitude, and in view of the uncertainties inherent in ρ values, the variation found is reasonable. The magnitude of $\bar{C}$ shows that the electrical effects of a substituent in the ortho and in the para positions are of the same order of magnitude.

TABLE III

Reaction series C		Reaction series C	
1	1.147	7	0.590
2	0.835	8	0.500
3	0.646	9	0.480
5	0.704	10	0.913
6	0.838	11	0.613
$\bar{C} = 0.736$		13	0.830

SUMMARY

On the basis of the above results, ortho-substituted benzene reaction series in which substituent and reaction site are not adjacent, can be correlated directly by the Hammett equation using the σ_p substituent constants. Ortho substituents in such reaction series have the same type of electrical effects as para substituents. These effects are about the same order of magnitude for ortho as for para substituents. Steric effects are largely absent for these reaction series.

17. T. THOMSON and T. S. STEVENS. J. Chem. Soc. 55 (1932), reported that 12–15% of a by-product which could not be further characterized was found in this reaction. They claimed to have developed an analytical method which allowed determination of both rearrangement products and unreacted starting material without interference from the by-product. For a further discussion of the results of these authors see J. H. BREWSTER and M. W. KLINE. J. Am. Chem. Soc. **74**, 5179 (1952).
18. It has also been suggested that for $r \geqslant 0.90$ correlation is very poor, for $r \geqslant 0.95$ correlation is fair.
19. ρ_o will be used to denote rho for the ortho-substituted benzene reaction series obtained by correlation with σ_p values. ρ will be used to denote rho for the meta- and/or para-substituted benzene reaction series obtained by correlation with the appropriate σ_m or σ_p constants.
20. One of the referees has pointed out that Wepster has shown one group ortho to a bulky substituent to be sufficient to appreciably decrease resonance interaction between the substituent and the benzene ring (B. M. WEPSTER. Progress in stereochemistry. Vol. II. Butterworth Scientific Publications, London. 1958. p. 99). This is a likely cause of the poorer results obtained in some of the correlations.

CONJUGATED FATTY ACIDS OF TRAGOPOGON AND CALENDULA SEED OILS[1]

MARY J. CHISHOLM AND C. Y. HOPKINS

ABSTRACT

The seed oil of *Tragopogon porrifolius* L. was found to contain about 4% of conjugated diene hydroxy fatty acids, identified as 9-hydroxy-10,12- and 13-hydroxy-9,11-octadecadienoic acids. On dehydration, the products were 8,10,12- and 9,11,13-octadecatrienoic acids. The diene acids were *cis,trans* or *trans,cis* and the triene acids were judged to be all-*trans*.

The conjugated triene acid of *Calendula officinalis* L. seed oil was isolated and identified as *trans*,8:*trans*,10:*cis*,12-octadecatrienoic acid by spectral analysis, by the structure of the maleic anhydride adduct, and by identification of degradation products. All-*trans*-8,10,12-octadecatrienoic acid was found to react with maleic anhydride at both the 8,11 and 10,13 positions.

INTRODUCTION

During the isolation of an epoxy fatty acid from the seed oil of *Tragopogon porrifolius* L. (family Compositae) (1) it was observed that a small proportion of an unsaturated acid of unusual characteristics was also present. It amounted to about 4% of the total fatty acids and had a conjugated diene linkage. On heating with glacial acetic acid it was converted to a conjugated triene acid. Both the diene and triene acids were unstable. Their structures were determined as described below, each proving to be a mixture of two position isomers.

The diene acids were found to have a hydroxy group and were identified as 9-hydroxy-10,12-octadecadienoic acid and 13-hydroxy-9,11-octadecadienoic acid. The triene acids were identified as 8,10,12- and 9,11,13-octadecatrienoic acids.

A naturally occurring triene acid was isolated from the seed oil of *Calendula officinalis* L. (family Compositae) and shown to be *trans*,8:*trans*,10:*cis*,12-octadecatrienoic acid. The isomerized form (all-*trans*) of this acid had been prepared previously by McLean and Clark from the same species (2). The configuration of the natural acid (*trans, trans,cis*) is opposite to that of α-eleostearic acid (*cis,trans,trans*).

Shortly after this work was completed, Morris, Holman, and Fontell reported the occurrence of two hydroxy diene acids in the seed oils of certain other species, apparently identical with the hydroxy acids described herein (3). Their evidence, based on spectral data and thin-layer chromatography, is in agreement with ours, which is based on spectral data and chemical degradative results. All of the results lead to the conclusion that the substances are 9-hydroxy-10,12- and 13-hydroxy-9,11-octadecadienoic acids.

RESULTS AND DISCUSSION

Conjugated Acids of Tragopogon Oil

The oil had ultraviolet absorption characteristic of diene conjugation, indicating the presence of about 4% of a diene acid, based on the total fatty acids. There was no appreciable triene absorption. After saponification in the cold and removal of unsaponifiable matter, the fatty acids were partitioned between petroleum ether and aqueous ethanol (1 volume H_2O: 4 volumes EtOH). The alcoholic portion contained both diene acid and epoxy acid in about equal amounts. Further partitioning and crystallization from acetone

[1]*Manuscript received September 1, 1960.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 6017.

at low temperature yielded a concentrate consisting mainly of conjugated diene acid (ultraviolet max. 233 mμ). It had infrared absorption at 3580 cm^{-1}, indicating an hydroxyl group, and two peaks of nearly equal intensity at 945 and 980 cm^{-1}, characteristic of a conjugated *cis,trans* or *trans,cis* diene (4).

The substance was subjected to oxidative splitting by periodate–permanganate (5) and the acidic products were converted to methyl esters, avoiding loss of volatile components (6). The mixture of methyl esters was examined by gas chromatography. Peaks corresponding to hexanoate and azelate were observed, indicating unsaturated centers at the 12,13 and 9,10 positions, respectively. Since these could not both be present in one conjugated diene acid, it is concluded that the substance was a mixture of two acids, one being $\Delta^{9,11}$ and the other $\Delta^{10,12}$. Neither heptanoic nor sebacic esters appeared, hence the hydroxyl group must have been attached to the terminal fragment in the 9,11 acid and to the carboxyl fragment in the 10,12 acid (III, I).

Boiling the hydroxy diene acid mixture with glacial acetic acid gave a solid acid (or acids), shown by spectral analysis to have a conjugated triene structure and no hydroxyl group. This substance absorbed 3 moles of hydrogen to give stearic acid, hence it had a straight chain of 18 carbon atoms. The triene acid was split by periodate–permanganate and the fragments were shown by gas chromatography to consist of valeric, hexanoic, suberic, and azelaic acids. The substance was therefore a mixture of two octadecatrienoic acids (II and IV) having double bonds in the 8,10,12 and 9,11,13 positions, respectively.

$$CH_3(CH_2)_4CH{=}CHCH{=}CHCH(CH_2)_7COOH \quad (I)$$
$$\qquad\qquad\qquad\qquad\quad \downarrow \qquad\quad |$$
$$\qquad\qquad\qquad\qquad\quad \downarrow \qquad\quad OH$$
$$CH_3(CH_2)_4CH{=}CHCH{=}CHCH{=}CH(CH_2)_6\,COOH \quad (II)$$
$$CH_3(CH_2)_4CHCH{=}CHCH{=}CH(CH_2)_7COOH \quad (III)$$
$$\qquad\qquad |\qquad\quad \downarrow$$
$$\qquad\quad OH \qquad\quad \downarrow$$
$$CH_3(CH_2)_3CH{=}CHCH{=}CHCH{=}CH(CH_2)_7COOH \quad (IV)$$

This result confirms the positions of the two double bonds in the diene acids as reported above (10,12 and 9,11). It also provides evidence for the location of the hydroxyl group. Thus, in the 10,12-diene acid, the hydroxyl group must be attached to carbon 8 or 9 to produce an 8,10,12-triene. Because of the ease with which dehydration takes place, it is almost certain that the hydroxyl is at position 9, where it is activated by the adjacent double bond (I). By similar reasoning, the 9,11-diene acid is considered to have the hydroxyl at position 13 (III), giving the 9,11,13-triene on dehydration. 9-Hydroxy-10,12-octadecadienoic is evidently a geometric isomer of dimorphecolic acid, discovered by Smith and co-workers (7), in which the double bonds are *trans,trans*, and which underwent dehydration with the same readiness.

Confirmation of the position of the hydroxyl group was obtained by hydrogenating the mixture of hydroxy diene acids. The product melted at 65–66° and appeared to be a mixture of monohydroxystearic acids. Oxidative splitting by solid permanganate in acetic acid was performed first on a model substance, 12-hydroxystearic acid. The fragments therefrom, identified by gas chromatography, were hexanoic, heptanoic, undecanedioic, and dodecanedioic acids. Thus splitting took place at two positions, 11,12 and 12,13. Minor proportions of azelaic and sebacic acids were also produced. Applying this procedure to the hydrogenated acids gave four monobasic acids, pentanoic, hexanoic, nonanoic, and decanoic (Table I), hence the original hydroxyl group must have been on the 13th

TABLE I

Oxidative splitting of hydrogenated acids

$CH_3(CH_2)_4\underset{\underset{OH}{\vert}}{CH}(CH_2)_{11}COOH \xrightarrow{O}$	$CH_3(CH_2)_3COOH$	$HOOC(CH_2)_{11}COOH$
	$CH_3(CH_2)_4COOH$	$HOOC(CH_2)_{10}COOH$
$CH_3(CH_2)_8\underset{\underset{OH}{\vert}}{CH}(CH_2)_7COOH \xrightarrow{O}$	$CH_3(CH_2)_7COOH$	$HOOC(CH_2)_7COOH$
	$CH_3(CH_2)_8COOH$	$HOOC(CH_2)_6COOH$

carbon atom in one acid (III) and on the 9th carbon atom in the other (I). There were minor amounts of heptanoic and octanoic acids. One pair of the corresponding dibasic acids was identified, viz. suberic and azelaic, both in substantial amount. The C_{12} and C_{13} dibasic acids were in smaller amount, apparently having been partially degraded by the oxidizing agent, as occurred in the oxidation of 12-hydroxystearic acid.

The two hydroxy diene acids appeared to be present in about equal amounts in the original oil. This was determined from the relative amounts of the respective fragments of the oxidized hydroxy diene acids and of the oxidized triene acids, estimated from the gas chromatograms.

The possible presence of 11-hydroxy-9,13-octadecadienoic acid was considered but was judged unlikely. Oxidation of the hydrogenated hydroxy acids gave no sebacic acid, one of the expected products from 11-hydroxystearic acid.

The concentrate of the hydroxy diene acids had infrared maxima of nearly equal intensity at 945 and 980 cm^{-1} (Fig. 1). By analogy with the spectra of the simple conjugated diene acids (4), this is strong evidence that both hydroxy acids are mainly, if not entirely, *cis,trans* or *trans,cis* in configuration. The mixture of the two triene acids obtained on dehydration, however, had a single strong infrared band at 990 cm^{-1} and no other maxima in the 900–1000 cm^{-1} region. It is concluded that these acids are all *trans*. Since the diene acids had one *trans* bond and dehydration may be expected to produce a second *trans* bond, the original *cis* bond must have isomerized spontaneously to *trans* during the dehydration to give the all-*trans* triene product. The all-*trans* structure was confirmed when an attempt to isomerize it by iodine in pentane produced no change in melting point or other properties.

Conjugated Acid of Calendula Oil

Saponification of calendula oil and crystallization of the acids from acetone at low temperature yielded a conjugated triene acid, $C_{18}H_{30}O_2$, as determined by elementary analysis and ultraviolet absorption. It gave stearic acid on hydrogenation. Oxidative splitting of the triene acid gave hexanoic and suberic acids, identified by gas chromatography. The double bonds must have been, therefore, at positions 8, 10, and 12 (V).

The infrared spectrum prepared from a solid film of the acid had a very strong peak at 990 cm^{-1} and a medium strong band at 940–975 cm^{-1}. The solution spectrum, in CS_2, had maxima at 987 (vs), 955 (m), and 920 cm^{-1} (m). This type of spectrum suggests a grouping of two *trans* and one *cis* bond, although it is not exactly the same as that of α-eleostearic acid (8). The ultraviolet spectrum showed maxima at 262, 272, and 283 mμ, also indicative of two *trans* and one *cis* bond in conjugation, by analogy with α-eleostearic acid (8, 9).

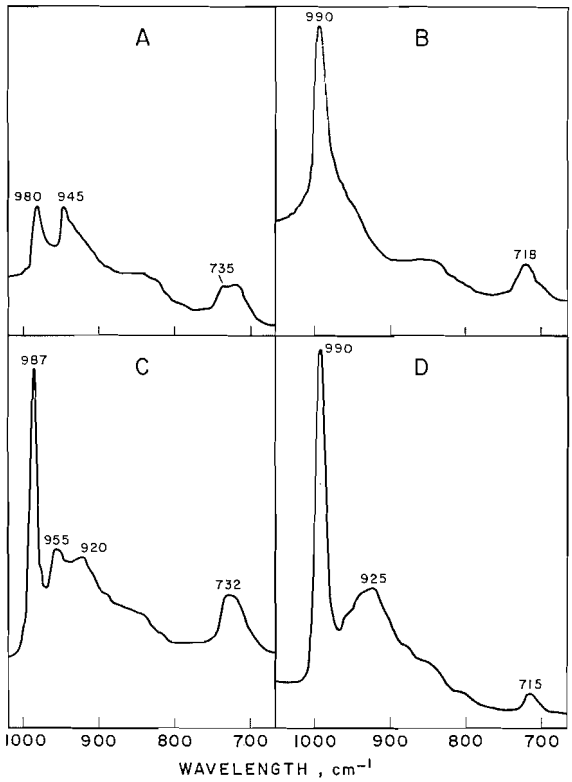

FIG. 1. Infrared spectra, between 700 and 1000 cm^{-1}, determined in CS_2 solution. A, concentrate of hydroxy diene acids from tragopogon; B, methyl esters of triene acids obtained by dehydration of the hydroxy diene acids; C, triene acid from calendula; D, all-*trans* isomer of triene acid from calendula.

The acid reacted readily with maleic anhydride and the adduct was easily purified, showing the presence of two adjacent *trans* double bonds. On splitting the adduct by permanganate–periodate, only one straight chain acid was obtained as a major product. It was identified by gas chromatography as hexanoic acid. There was only a trace of suberic acid. Thus the adduct must have been formed by reaction at the 8 and 11 positions, leaving the 12,13 double bond free (VI).

$$CH_3(CH_2)_4\,CH{=}\overset{c}{C}HCH{=}\overset{t}{C}HCH{=}\overset{t}{C}H(CH_2)_6\,COOH \qquad \text{(V)}$$

maleic anhydride

$$CH_3(CH_2)_4\,CH{=}CHCHCH{=}CHCH\,(CH_2)_6\,COOH \qquad \text{(VI)}$$

The infrared spectrum of the adduct (VI) had no peak in the region 950–975 cm^{-1} and hence no *trans* exocyclic double bond. The 12,13 double bond was therefore *cis* and the original acid was *trans*,8:*trans*,10:*cis*,12-octadecatrienoic acid. The reasoning is similar to that employed by Paschke and co-workers in determining the configuration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the eleostearic acids (10). The maleic anhydride adduct of all-*trans*-8,10,12-octadecatrienoic acid was prepared for comparison. Its infrared spectrum had a peak at 963 cm^{-1} (*trans* exocyclic double bond).

The *trans*,8:*trans*,10:*cis*,12 acid, m.p. 40–40.5°, was readily converted to the all-*trans* form, m.p. 77–78°, by treatment with iodine in pentane. The infrared spectrum (CS_2 solution) had a strong single peak at 990 cm^{-1}, indicative of the all-*trans* structure, and very little absorption in the vicinity of 950 cm^{-1}. An all-*trans* conjugated triene acid may be expected to react with maleic anhydride in two ways. Thus, Bickford and coworkers found evidence that addition occurs to β-eleostearic acid at both the 9,12 and 11,14 positions (11). In the present work, proof was obtained that two different adducts are formed in the reaction of all-*trans*-8,10,12-octadecatrienoic acid with maleic anhydride. The reaction product was oxidized by permanganate–periodate and the fragments were examined by gas chromatography. Both hexanoic acid and suberic acid were found in substantial amounts, showing that addition of maleic anhydride had occurred at the 10,13 as well as the 8,11 positions, forming two separate adducts.

The name calendic acid is proposed for *trans*,8: *trans*,10: *cis*,12-octadecatrienoic acid.

EXPERIMENTAL

Methods

Infrared spectral data were obtained with a Perkin–Elmer Model 21 infrared spectrophotometer with sodium chloride prism. Samples were in carbon disulphide solution unless stated otherwise. Ultraviolet measurements were made in cyclohexane or isooctane solution. Gas–liquid chromatography of methyl esters was conducted at various column temperatures from 70° to 170°, according to the chain length of the sample. The detector was a thermistor type of thermal conductivity cell. Column length was 1 meter, helium flow rate 95 ml/min, and inlet pressure 7 to 12 p.s.i., depending on the column temperature. Identification of the various esters was made by comparing the emergence time with that of a standard sample of the same ester under the same conditions on the same day.

Tragopogon oil

Seed of *Tragopogon porrifolius* L. was purchased from a commercial seed house. It was of the current year's stock. The seed (450 g) was ground and extracted with petroleum ether by stirring with successive lots of the solvent at room temperature. The solvent was removed at 25–30° under nitrogen. The oil had ultraviolet absorption maximum at 233 mμ, $E^{1\%}_{1\,cm}$ 47.5, equivalent to 4.0% conjugated octadecadienoic acid based on the total fatty acids. There was no measurable absorption at 268 mμ (conjugated triene).

The oil (83 g) was saponified at room temperature (25°) by letting it stand for 18 hours with a solution of 25 g of potassium hydroxide in 500 ml of ethanol. The unsaponifiable matter was removed by extraction and the fatty acids were partitioned between petroleum ether and ethanol:water (4 volumes EtOH:1 volume H_2O). The partitioning was carried out in three stages and the products recovered from the alcohol portions were analyzed for conjugated diene by ultraviolet absorption and for oxirane oxygen by Swern's method (12) with the following results:

Portion	Wt. of acids, g	Conjugated diene acid, %	Oxirane oxygen, %
1	7.0	32.0	2.1
2	7.2	8.7	1.2
3	4.4		0.7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The acids from the first portion were estimated to contain 32% conjugated diene acid and 37% epoxy acid, assuming that both are of chain length C_{18}. This mixture was treated further by solvent partition and the alcohol-soluble portion, on crystallization from acetone at −70°, yielded an oil (0.34 g) which was a concentrate of the conjugated diene acid. It had ultraviolet maximum 233 mμ and $E^{1\%}_{1cm}$ 561.

Identification of Diene Acids

The concentrate had an infrared peak at 3580 cm^{-1} (OH) and two peaks of equal intensity at 945 and 980 (conjugated *cis,trans* double bonds). Oxidative splitting by permanganate–periodate (5) and examination of the esterified fragments by gas chromatography (6) showed that they were hexanoate and azelate. There was no heptanoate or sebacate. There was some evidence of other compounds at longer emergence times, possibly fragments carrying the hydroxy group.

On hydrogenation of the diene acid concentrate (1.0 g) with Adams catalyst in ethyl acetate and successive crystallizations from ethyl acetate and from hexane, the product (0.33 g) melted at 65–66° and was evidently a mixture of monohydroxystearic acids. Calculated for $C_{18}H_{36}O_3$: C, 71.95; H, 12.08. Found: C, 71.83; H, 11.70. Infrared maximum, 3600 cm^{-1} (OH). Oxidative splitting of the hydrogenated product by solid permanganate in glacial acetic acid at 50° (13) gave a mixture of monobasic and dibasic acids which was esterified and submitted to gas chromatography. A similar oxidation of 12-hydroxystearic acid gave two monobasic acids, hexanoic and heptanoic, and two dibasic acids, undecanedioic and dodecanedioic, along with minor proportions of azelaic and sebacic acids. The monobasic acids obtained from the oxidation of the hydrogenated diene acids were chromatographed (as methyl esters) at 55°, 70°, and 93°. They were mainly pentanoic (15%), hexanoic (22%), nonanoic (25%), and decanoic (28%), with smaller amounts of heptanoic (5%), and octanoic acids (5%). Suberic and azelaic acids were observed in substantial amount (as esters) when chromatographed at 175°. There were also dodecanedioic and tridecanedioic acids, in smaller proportions, along with pimelic and undecanedioic. There was little or no sebacic acid.

Dehydration to Triene Acids

The mixed hydroxy diene acids were dehydrated as follows. The concentrate (3.4 g) was refluxed with glacial acetic acid (17 ml) for 4 hours, the acetic acid was removed under reduced pressure and the residue was heated for 1 hour with 35 ml of *N* alcoholic KOH. The crude acids were crystallized from 15 ml of acetone at −35°, giving 0.9 g of glistening plates, m.p. 58–60°. Further crystallization from ethyl acetate raised the melting point to 60–61° but no higher. (Found: C, 77.69; H, 10.65. Octadecatrienoic acid, $C_{18}H_{30}O_2$, requires C, 77.65; H, 10.85.) The substance had ultraviolet absorption maxima at 260, 269, 280 mμ (all-*trans* conjugated triene). The infrared spectrum (solid film) had a single strong peak at 985–995 cm^{-1}, also characteristic of the all-*trans* form. There was no OH peak. The spectrum of the methyl ester (in CS_2) showed a similar all-*trans* band at 990 cm^{-1}. When hydrogenated in methanol with Adams catalyst, the acid (0.37 g) absorbed 3.06 moles of hydrogen, and the product was stearic acid (0.34 g), m.p. and mixed m.p. 69–70°, equivalent weight 284.9 (calc. 284.4).

A portion of the triene acid was oxidized by periodate–permanganate (5) and the products were converted to methyl esters (6) for identification by gas chromatography. Valerate and hexanoate were identified at 80°, in approximately equal amounts (53:47). Suberate and azelate were observed at 170°. A larger portion was oxidized by the procedure of McLean and Clark (2). Azelaic acid, m.p. and mixed m.p. 104–105°, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

isolated with some difficulty by crystallizing the mixture of products. It was judged that more than one dibasic acid was present.

An attempt to isomerize the triene acids by iodine in hexane solution produced no change in melting point.

CALENDULA OIL

trans,8:trans,10:cis,12-Octadecatrienoic Acid (Calendic Acid)

Seed of *Calendula officinalis* L. was purchased from a commercial seed house. It was ground and the oil was extracted with petroleum ether in a Soxhlet. Ten grams of the oil was saponified by heating for 1 hour with 6% alcoholic potassium hydroxide under nitrogen. The unsaponifiable matter was removed and the fatty acids were crystallized fractionally from acetone at temperatures from 0° to −40°, giving 2.5 g of an acid, m.p. 40–40.5°. The acid was highly unstable in air, becoming sticky in a few minutes if exposed at room temperature. It was kept under nitrogen at the temperature of solid carbon dioxide. Calculated for $C_{18}H_{30}O_2$: C, 77.65; H, 10.85. Found: C, 77.97; H, 10.92. Ultraviolet maxima at 262, 272, and 283 mμ. Infrared maxima (solid film) at 990 (vs), 940–975 (m), and 740 (m); (in CS_2) at 987 (vs), 955 (m), 920 (m), and 732 cm^{-1} (m).

Hydrogenation with Adams catalyst in methanol gave stearic acid, m.p. and mixed m.p. 69.5–70°. The triene acid was oxidized by permanganate–periodate (5) and the products were examined as methyl esters by gas chromatography (6). Peaks corresponding to hexanoate and suberate were observed. There were no other peaks.

The triene acid was heated with maleic anhydride in benzene for 1 hour, forming an adduct, m.p. 73–74° after several crystallizations from ether:petroleum ether (1:5). Calculated for $C_{22}H_{32}O_5$: C, 70.18; H. 8.57. Found: C, 70.18; H, 8.55. The infrared spectrum showed no peak or shoulder in the region of 950–975 cm^{-1}. The adduct was oxidized by permanganate–periodate and the fission products were converted to methyl esters and chromatographed. There was a large peak identified by its emergence time as hexanoate and a very small peak identified as suberate.

The content of conjugated triene acid in the oil was estimated to be 47%.

All-trans-8,10,12-Octadecatrienoic Acid

On treatment with iodine in pentane, the triene acid (2.5 g), m.p. 40–40.5°, was quickly converted to the all-*trans* isomer which melted at 77–78° after crystallization from ethanol at 0° (1.9 g). Infrared maximum 990 cm^{-1} (vs); ultraviolet maxima 259, 269, and 280 mμ. McLean and Clark reported ultraviolet maxima 258, 268, and 280 mμ (2). The maleic anhydride adduct was prepared. It was more difficult to purify than that from the unisomerized acid and melted no higher than 70–71° (McLean and Clark, 71°). The yield was 1.5 g from 1.9 g of the *trans* acid. In admixture with the adduct from the unisomerized acid it melted at 56–58°. Its infrared spectrum showed a small but distinct peak at 963 cm^{-1}. The adduct was oxidized by permanganate–periodate and the fragments were identified by gas chromatography as hexanoate and suberate, both in considerable amount.

ACKNOWLEDGMENTS

The authors are indebted to Mr. R. Lauzon for determination of infrared spectra and to Mr. H. Seguin for C and H analyses.

STRUCTURAL AND SOLVENT EFFECTS ON THE $n \rightarrow \pi^*(^1U \leftarrow {}^1A)$ TRANSITIONS IN ALIPHATIC CARBONYL DERIVATIVES: EVIDENCE FOR HYPERCONJUGATION IN THE ELECTRONICALLY EXCITED STATES OF MOLECULES[1]

C. N. R. Rao,[2] G. K. Goldman,[3] and A. Balasubramanian

ABSTRACT

The $n \rightarrow \pi^*$ transition of the carbonyl group has been studied in solvents of varying degree of polarity and hydrogen-bonding ability, in a number of aliphatic carbonyl derivatives. Evidence for hyperconjugation of the alkyl groups in the electronically excited states of molecules has been presented.

INTRODUCTION

The long-wavelength low-intensity absorption between 2600 and 3000 Å in carbonyl compounds has been shown (1, 2) to be due to a singlet–singlet symmetry forbidden transition* arising from the excitation of an electron from a nonbonding orbital(n orbital) to an antibonding orbital (π^* orbital). Empirical criteria which permit distinctions between the pure π-electron transitions and the $n \rightarrow \pi^*$ transitions have been formulated (3, 4, 5). The solvent effects on $n \rightarrow \pi^*$ transitions have been characterized (4) and, in general, the transition energies are found to increase with the increase in the polarity of the solvent. We have now studied the substituent and solvent effects on the $n \rightarrow \pi^*$ transitions in aliphatic carbonyl derivatives with the purpose of understanding the nature of alkyl group interaction in the electronically excited states of molecules† since it has not been possible to evaluate the contributions from the inductive and the hyperconjugation effects from the earlier studies (6).

EXPERIMENTAL

All the solutes and solvents were subjected to suitable purification and fractionation before use. Particular care was taken in distilling trifluoromethylacetone from phosphorus pentoxide just before running the spectrum, since it readily forms the hydrate.

The ultraviolet absorption spectra were recorded using a Cary Model 11 recording spectrophotometer and a Hilger spectrophotometer, H700. The absorption maxima have been recorded in cm^{-1} (ν') and the intensities in terms of the molar extinction coefficients (ϵ).

RESULTS AND DISCUSSION

The $n \rightarrow \pi^*$ transition frequencies and intensities of some aliphatic carbonyl derivatives are summarized in Table I. The results are in general agreement with the earlier work (6). The results satisfy all the necessary criteria (3, 4, 5) proposed for $n \rightarrow \pi^*$ transitions. In Fig. 1 the $n \rightarrow \pi^*$ bands of acetaldehyde and methyl *i*-propyl ketone are reproduced.

*Center of the nearly symmetric band system.

†Acetylacetone does not exhibit the $n \rightarrow \pi^*$ transition in this region. It gives a band around 37,175 cm^{-1} in heptane, which shows solvent red shift (4). This is because of the aromatic nature resulting from enolization.

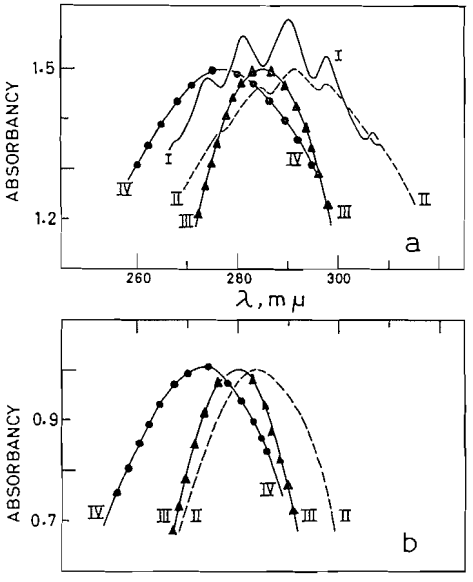

FIG. 1. The $n \rightarrow \pi^*$ transition of the carbonyl group of (*a*) acetaldehyde, (*b*) methyl *i*-propyl ketone: I, in gas phase; II, in heptane solution; III, in methanol solution; and IV, in water solution.

Acetaldehyde shows vibrational fine structure in heptane just as it does in gas phase except that there is a slight bathochromic shift in the former case. The fine structure is not seen in the spectrum taken in methanol or water. Ketones do not show any recognizable fine structure even in heptane solutions. However, all the carbonyl derivatives do show increasing $n \rightarrow \pi^*$ transition energies with the increasing polarity or hydrogen-bonding ability of the solvents.

The intensities of the $n \rightarrow \pi^*$ bands in all the derivatives studied are seen to be weak. The ϵ value for acetone is not much different from that of acetaldehyde, even though the two molecules differ in symmetry (C_{2v} and C_s). Similarly, methyl ethyl ketone and acetone exhibit nearly comparable intensities. The intensity of the forbidden $n \rightarrow \pi^*$ transition in all these molecules is undoubtedly derived in the same manner. Thus, all the aldehydes and saturated ketones seem to retain the C_{2v} symmetry characteristics of the formaldehyde molecule. The intensity-borrowing mechanism of the $n \rightarrow \pi^*$ transition in formaldehyde has been shown (5) to be due to the vibrationally induced mixing of the electronic states. The out-of-plane vibration, ν_6, is considered responsible for the intensity of the $n \rightarrow \pi^*$ transition in formaldehyde. The mode of motion responsible for the intensity of the transition in acetone should then be ν_6, in which the two carbon atoms and the oxygen atom bonded to the central carbon atom are displaced out of the plane of symmetry in one direction and the central carbon in the opposite direction. Among the saturated aliphatic ketones, the $n \rightarrow \pi^*$ transition intensity is least in acetone and it is slightly greater in other cases. It can be seen from the data in Table I that the $n \rightarrow \pi^*$ transition intensity increases with the increasing polarity or hydrogen-bonding ability of the solvent.

It has been generalized (5, 7, 8) that electron-donating substituents shift the $n \rightarrow \pi^*$ transition to shorter wavelengths due to the increase in the energy of the excited state caused by the accumulation of electronic charge in a localized region. In the $n \rightarrow \pi^*$ transition of the carbonyl group, the electronic charge is transferred from oxygen to carbon. Electron-donating groups like —Cl, —OCH_3, etc., when attached to the carbon atom, produce large intramolecular blue shifts of the transition. Interestingly enough, aliphatic carbonyl compounds (RCOR′ where R = CH_3), with R′ as CH_3, C_2H_5, i-C_3H_7, and t-C_4H_9, exhibit the $n \rightarrow \pi^*$ transitions at 36133, 36036, 35242, and 34965 cm^{-1}, respectively, in a hydrocarbon solvent. Such a trend cannot be explained in terms of inductive effect alone because acetaldehyde (R′ = H) and trifluoromethylacetone (R′ = CF_3) show the transition at 34360 and 36036 cm^{-1}, respectively, in heptane. There is no proportionality between the $n \rightarrow \pi^*$ frequencies and the polar effects of groups in these carbonyl derivatives, as can be seen from Fig. 2(a), where ν' is plotted against Taft's aliphatic polar substituent constants (9), $\Sigma\sigma^*$. However, the infrared carbonyl stretching frequencies in aliphatic ketones bear a linear relation to $\Sigma\sigma^*$ of groups (10, 11) showing that there may be no hyperconjugative effect of alkyl groups in the ground electronic states of molecules. In fact, it has been fairly well accepted nowadays that hyperconjugation may not play a prominent role in the electronic ground states of molecules (12). If one assumes that there is some contribution by the resonance interaction of the alkyl groups in the electronically excited states of molecules, one may be able to explain the observed $n \rightarrow \pi^*$ frequencies in the aliphatic carbonyl derivatives. The frequency is highest in acetone (where both R and R′ are methyl groups), just what one would expect if there were electron donation by C—H hyperconjugation.

Kreevoy and Taft (13) applied the linear inductive energy relationship to study the nature of the electronic interaction of alkyl groups in the acid-catalyzed rates of hydrolysis of diethyl acetals and ketals. Assuming that only C—H hyperconjugation was operative in addition to the inductive effect, they proposed the relation

$$\text{(i)} \qquad \log (k/k_0) = (\Sigma\sigma^*)\rho^* + \Delta n h$$

where Δn is the difference in the number of α-hydrogens actually available for C—H

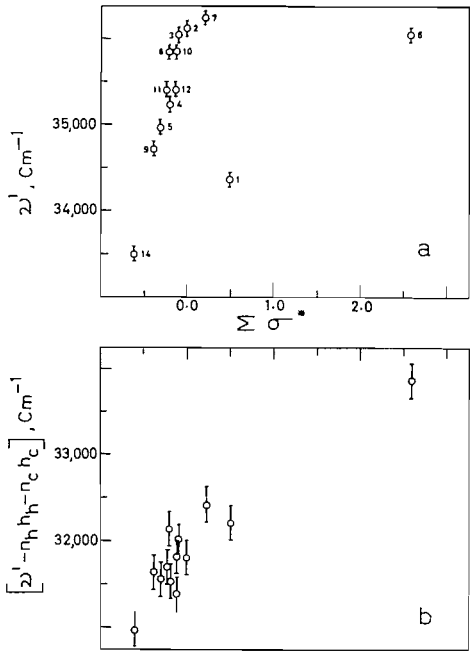

FIG. 2. (*a*) Plot of the $n \rightarrow \pi^*$ transition frequencies (ν') in aliphatic carbonyl derivatives against the polar substituent constants of Taft, $\Sigma\sigma^*$.
(*b*) Plot of $(\nu' - n_h h_h - n_c h_c)$ against $\Sigma\sigma^*$. The maximum limits of uncertainty on the frequencies have been shown.

hyperconjugation compared with the maximum number of six and h is the hyperconjugation constant. A similar treatment of the $n \rightarrow \pi^*$ frequencies of aliphatic carbonyl derivatives, taking into consideration only the inductive and C—H hyperconjugative effects of alkyl groups, was carried out by employing the equation

(ii) $$\nu' = \nu_0' + (\Sigma\sigma^*)\rho^* + n_h h_h$$

where ν' is the observed $n \rightarrow \pi^*$ frequency in cm^{-1}, n_h is the number of α-hydrogens available for C—H hyperconjugation, and h_h is the hyperconjugation constant. The value of h_h was estimated to be 385 cm^{-1} (in heptane solution) by solving simultaneous equations. The plot of $(\nu' - 385\ n_h)$ versus $\Sigma\sigma^*$ showed considerable scatter of the points. The standard deviation of the points was found to be 348 cm^{-1} and the correlation coefficient was 0.557. In view of the rather poor correlation obtained, it was decided to consider possible contribution by the C—C hyperconjugation of the alkyl groups.

Taft and Lewis (14) have recently proposed a modified treatment which takes into account both C—H and C—C hyperconjugation. The quantitative relation between the measured reactivity effects and the sum of the inductive and the hyperconjugation effects has been expressed as

(iii) $$\log (k/k_0) = (\Sigma\sigma^*)\rho^* + R$$

and $R = n_n h_n + n_c h_c$, where n_h and n_c are the number of α-C—H and α-C—C bonds of the alkyl group and h_n and h_c are the C—H and C—C hyperconjugation constants. The quantity $[\log(k/k_0) - R]$ should then depend only on the polar effects of groups.

Such a relation has been found to explain quantitatively the reaction rate data in several alkyl-substituted systems (14, 15). The effects of alkyl groups on the transition energies of the 0–0 bands of gaseous benzene spectra were also found to follow equation (iii). The $n \rightarrow \pi^*$ transition frequencies in Table I may be treated similarly, by employing the equation

$$\text{(iv)} \qquad \nu' = \nu_0' + (\Sigma\sigma^*)\rho^* + n_h h_n + n_c h_c.$$

By assuming a linear relation between the points for acetaldehyde and trifluoromethylacetone in Fig. 2(*a*), the constants h_h and h_c were found to be approximately 720 and 410 cm^{-1}, respectively, for the data in heptane. An approximate proportionality is found between $(\nu' - 720\, n_h - 410\, n_c)$ and $\Sigma\sigma^*$ as shown in Fig. 2(*b*). The standard deviation of the points and the correlation coefficient are 276 cm^{-1} and 0.920, respectively.

It is seen that the correlation coefficient for equation (iv) is much greater than for equation (ii).* Thus, it appears that the contributions from the inductive and the C—H and C—C hyperconjugative effects are necessary to explain the $n \rightarrow \pi^*$ transition frequencies of aliphatic carbonyl derivatives. The ratio h_h/h_c is seen to be about 1.75, which is greater than the value of 1.3 generally found in aromatic systems (14). Apparently, the contribution from C—H hyperconjugation, compared with C—C hyperconjugation, is much greater in the aliphatic systems than in the aromatic systems.

The $n \rightarrow \pi^*$ frequencies of acetone, methyl ethyl ketone, methyl *i*-propyl ketone, and methyl *t*-butyl ketone in heptane solution are in the Baker-Nathan order, i.e., $CH_3 > C_2H_5 > i\text{-}C_3H_7 > t\text{-}C_4H_9$. The same trend is maintained in solvents of varying degree of polarity or/and hydrogen-bonding ability, as can be seen from Fig. 3. There is no indication of an inversion of this order with the change in solvents as observed by Schubert *et al.* (16) in *p*-alkylacetophenones and *p*-alkylnitrobenzenes. The results of Schubert

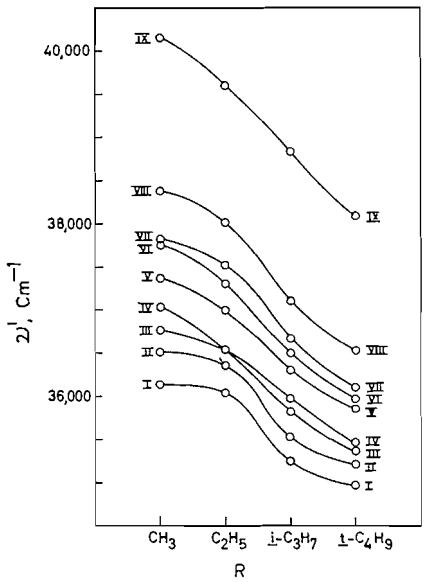

FIG. 3. Solvent effects on the $n \rightarrow \pi^*$ transition frequencies of CH_3COR: I, heptane; II, acetonitrile; III, *i*-propanol; IV, methanol; V, acetic acid; VI, 2,2,2-trifluoroethanol; VII, water; VIII, 30% perchloric acid; and IX, 60% perchloric acid.

**The authors are thankful to the referee for suggesting the statistical analyses of the relations.*

et al. (16) may be explained (14) as due to possible errors in fixing the positions of the 0–0 bands and also due to the uncertainty in the mechanism of the substituent effects on the transition. In general, it may be said that the effect of alkyl groups on the near ultraviolet absorption spectra of aromatic systems is not consistent. The evidence for hyperconjugation in the excited states of molecules presented in this study seems to be quite reasonable because (*a*) the molecules studied are aliphatic and so no other type of resonance interaction can occur, (*b*) the infrared carbonyl stretching frequencies in these molecules are proportional to Taft's aliphatic polar parameters of groups, thus indicating that hyperconjugation may be unimportant in the ground electronic states, (*c*) the $n \rightarrow \pi^*$ transition is very sensitive to change in structure and solvent, and (*d*) similar trends of the $n \rightarrow \pi^*$ frequencies are found in solvents of varying degree of polarity or/and hydrogen bonding.

All the carbonyl derivatives show increasing solvent blue shifts* with the increasing polarity or/and hydrogen-bonding ability of the solvent.† In the series of ketones, RCOR′ (with R = CH_3), the solvent blue shift is maximum in acetone (where R′ is also a methyl group) in all the solvents studied. The significance of this observed effect is not completely clear.†

CATALYZED RECOMBINATION OF NITROGEN ATOMS, AND THE POSSIBLE PRESENCE OF A SECOND ACTIVE SPECIES IN ACTIVE NITROGEN[1]

ROGER KELLY[2] AND C. A. WINKLER

ABSTRACT

The reactions of ethylene, ethane, and ammonia with active nitrogen have been studied over the pressure range 0.3 to 4 mm *using an unheated reaction vessel.* The object was to determine why each reactant shows, as is well-known, a smaller extent of reaction at lower temperatures than would be predicted from the atom concentration. It was concluded that ethylene probably brought about *homogeneous catalyzed recombination*, i.e. the process $N + C_2H_4 \rightleftarrows N \cdot C_2H_4$, followed by $N + N \cdot C_2H_4 \rightarrow N_2 + C_2H_4$. The over-all third-order rate constant appeared to be very large, about 1.8×10^{-28} cc^2 molecule^{-2} sec^{-1}. The behavior of ammonia was quite different from that of ethylene and it was, in fact, possible to show that the extent of reaction was not governed by the instantaneous atom concentration at all. The results can be explained qualitatively, however, if it is assumed that excited molecules formed in the course of homogeneous atom decay constitute a second active species in active nitrogen. This view serves also to explain the failure in such work as that of Kistiakowsky *et al.* to observe ammonia destruction or excited molecules when especially low atom concentrations are used. The few experiments involving ethane were sufficient to show that the reactivity was low for a different reason than with ethylene.

In a previous study (1), active nitrogen was produced in a condensed discharge at pressures between 0.3 and 4 mm and under conditions of approximately complete initial dissociation. It was then allowed to flow rapidly through a "decay tube" to a reaction vessel, where the limiting (i.e. maximum) rate of HCN production from ethylene or ethane at 350° C was assumed to measure the flowrate of residual N atoms. Information on the rate constants for N atom decay was thus obtained. The present experiments have been conducted along similar lines, the same apparatus being used; however, the "activity" of the active nitrogen has been derived *with the reaction vessel unheated.* Measurements were made of HCN production from ethylene and ethane, and also of the decomposition of ammonia.

Ethylene and ethane are of particular interest at lower temperatures since they are typical of several substances with which the extents of reaction at all temperatures approach well-defined limiting values as the flowrate of reactant is increased, yet these values are significantly temperature dependent and, except at the highest temperatures, are substantially less than might be expected from the available N atom concentration (2, 3, 1). An explanation for such behavior has been given by Forst *et al.* (4), who suggested that N atom reactions might be accompanied by extensive recombination of the atoms catalyzed by the *reactant.* (Such a process is not eliminated by increasing the flowrate of reactant provided it is of the same order in reactant as the main reaction. On the other hand, ordinary homogeneous and surface decay, as well as recombination catalyzed by a *product*, would necessarily be swamped in the presence of a large excess of reactant, and would therefore have no effect whatsoever on a limiting reactivity.) By contrast, the destruction of ammonia by active nitrogen, while occurring to only a small extent, appears to be unaffected by moderate changes in temperature, is quite rapid (5),

[1]*Manuscript received April 13, 1960.*

is accompanied by only partial quenching of the afterglow (6, 7), and apparently does not involve N atoms in the rate-controlling step (6, 8).[3] The behavior of ammonia is therefore, at least superficially, not consistent with a combination of N atom attack plus catalyzed recombination and has, in fact, seemed to require an alternative explanation in which it is assumed that an active species other than the N atom is present in active nitrogen (see, for example, 5, 9, 10).

It will be the object of the present work to determine whether the depressed reactivity of each substance studied can be better explained in terms of catalyzed recombination or a second active species.

EXPERIMENTAL

The apparatus was identical with that described earlier (Fig. 1 of reference 1), except that a decay tube (volume = 281 cc) was used only in series 1 to 3. In series 4 and 5 the decay tube was removed altogether. The reaction vessel was then connected directly to the discharge tube at a point *near the end of one electrode* and with the usual constriction present at the entrance to the reaction vessel (Fig. 1). Nitrogen was admitted

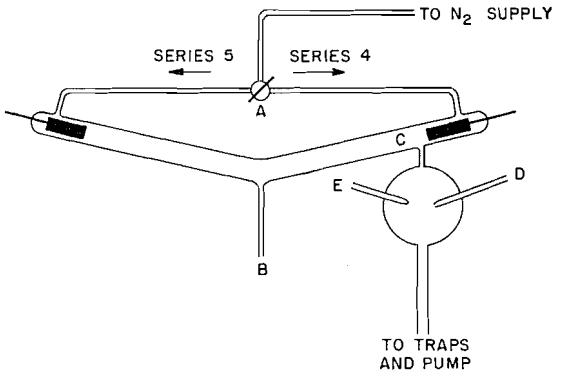

FIG. 1. Arrangement of the discharge tube and reaction vessel in series 4 and 5. (A) is a stopcock, according to the position of which the nitrogen enters the discharge tube either at the right electrode (series 4) or at the left (series 5). (B) is a constricted outlet from the discharge tube which served *in series 4* to set up a slight flow of gas *away* from the outlet to the reaction vessel, and thereby to minimize the diffusion of active nitrogen from region (C) into the reaction vessel. (D) is the reactant jet and (E) the thermocouple well. Further details of the apparatus are the same as in Fig. 1 of reference 1.

to the discharge tube either at the end to which the reaction vessel was sealed (series 4), or at the opposite end (series 5). The polarity of the electrodes was shown not to affect the results (cf. p. 2334 of reference 11).

In all experiments the system was poisoned with Na_2HPO_4 since this poison, in contrast to HPO_3, is unreactive towards ammonia. The electrical circuit and analytical procedures were as described previously (1) and, as before, the reactant flowrates were sufficiently high that the extents of reaction were at their limiting values for the temperatures used.

Whether or not complete initial dissociation was achieved is of no consequence to the arguments to follow.

[3]*The conclusion that* N *atoms do not participate in the rate-controlling step follows from the observations that, when ammonia is added to active nitrogen of microwave origin in amounts as great as 10 times the atom concentration, neither the atom concentration itself (6) nor the ability of the active nitrogen to destroy* NO *(8) is affected.*

THEORY

If the reactivity towards active nitrogen shown by a substance were depressed due to the fact that the substance catalyzed the recombination of the N atoms, then it should be possible to account for the details of the reaction by means of some combination of elementary N atom reactions. The possible elementary reactions include, firstly, those which lead to product formation:

$$[1] \qquad N + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NM,$$

followed by one of

$$[2] \qquad NM \xrightarrow{k_2} n(\text{HCN, CNCl, NH, etc.}) + p_2(\text{reactive fragments}), \quad \text{(cf. 10, 12, 13)}$$

$$\left.\begin{aligned} [3] \qquad & N + NM \xrightarrow{k_3} N_2 + M^*, \quad M^* \rightarrow p_3(\text{reactive fragments}), \\ [4] \qquad & NM + NM \xrightarrow{k_4} N_2 + M + M^*, \quad M^* \rightarrow p_4(\text{reactive fragments}). \end{aligned}\right\} \text{(cf. 2, 10, 12, 14)}$$

Here M is the reactant, M* is an unspecified excited state of M, n is the number of molecules of HCN, etc., formed in the primary step of [2] (*one*, except in special cases, as when M is a cyanide), and p_2, p_3, and p_4 are the numbers of N atoms lost in rapid secondary reactions involving fragments of M. The values of p_2, etc. are not necessarily integral (cf. footnote 4).

Next there are reactions leading solely to recombination:

$$[5] \qquad N + NM \xrightarrow{k_5} N_2^* + M, \qquad \text{(cf. 4)}$$

$$[6] \qquad NM + NM \xrightarrow{k_6} N_2^* + 2M,$$

$$[7] \qquad NM + \text{surface} \xrightarrow{k_7} N\cdot\text{surface} + M,$$

where N_2^* represents an excited state of N_2. In principle, the M on the right side of [5], [6], and [7] might be excited; however, if so, it is assumed to revert to the ground state.

As mentioned previously, ordinary homogeneous and surface decay, as well as recombination catalyzed by a product, need not be considered provided the experiments are confined to conditions when the reactant is in excess.

If a low extent of reaction were due, not to catalyzed recombination, but to the fact that the reaction was initiated by a species other than the N atom, it is obviously true that experimental results would be consistent with no combination of elementary N atom reactions. However, a far simpler way of demonstrating the involvement of a second active species would be to show that the reactivity of a substance could be varied significantly by some act affecting the active nitrogen prior to its entry into the reaction vessel, yet which leaves the atom concentration within the reaction vessel essentially unchanged.

RESULTS AND DISCUSSION

The following abbreviation will be used henceforth: $[N]_a \equiv$ "apparent atom concentration" = reactivity.

Ethylene

In Figure 2 are shown the HCN production from ethylene as a function of pressure

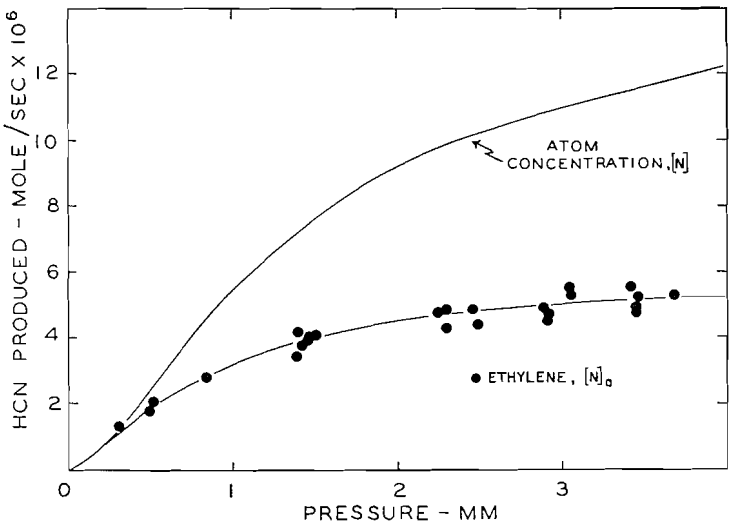

FIG. 2. Series 1. HCN production from ethylene as a function of pressure with both the decay tube and reaction vessel unheated. The reaction temperature varied between 55 and 85° C, depending on the pressure.

with both the decay tube and reaction vessel unheated (*series 1*), together with the corresponding atom concentrations, obtained by reacting ethylene or ethane at 350° C (identical with series 5 of reference 1). The reaction temperature varied from 55 to 85° C, depending on the pressure. The afterglow was completely extinguished in all the experiments of the series.

If the reactivity of ethylene at a given temperature is defined in terms of the HCN production, i.e. $[N]_a = [HCN]$, it follows from Fig. 2 that at the temperature used in the present work $[N]_a < [N]$. This is true in spite of the fact that the suggested mechanism for the ethylene reaction requires that $[N]_a = [N]$ (15, cf. 16). To determine whether the depression of the reactivity is due to catalyzed recombination or to a second active species, it will be noted that $[N]_a \rightarrow [N]$ as $[N] \rightarrow 0$. In other words, taking into consideration that, when the reactant is present in excess, the applicable elementary reactions will have the same order in M, the ethylene reaction appears to involve a combination of reactions [1] and [2] with *one or both* of [3] and [5]. The adequacy of these reactions may be tested by comparing the observed and predicted relations between $[N]_a$ and [N]. The predicted relations will be derived assuming (i) that the reactant M is in excess, (ii) that the NM complexes exist in steady-state (cf. footnote 5), and (iii) that reactions between N atoms and fragments of M give rise to HCN. Then, for the combination

[1] + [2] + ([3] and/or [5]), where $p_3 = 0$, one has

$$d[N]/dt = -(1+p_2)k_2[NM]-2(k_3+k_5)[N][NM],$$

$$d[N]_a/dt = d[HCN]/dt = (n+p_2)k_2[NM].$$

Hence, proceeding as in reference 4,

$$[8] \qquad [N]_a = \frac{(n+p_2)k_2}{2(k_3+k_5)} \ln\left\{1+\frac{2(k_3+k_5)[N]}{(1+p_2)k_2}\right\}.$$

Similarly, for a combination [1] + [2] + [3], where $p_3 > 0$, one has

$$[9] \qquad [N]_a = \frac{p_3[N]}{2+p_3} + \frac{k_2[2(n+p_2)+(n-1)p_3]}{(2+p_3)^2k_3} \ln\left\{1+\frac{(2+p_3)k_3[N]}{(1+p_2)k_2}\right\}.$$

For the ethylene reaction $n = 1$, while p_3 will lie somewhere between 0 and 2. The experimental data should therefore be consistent either (i) with equation [8] ($n = 1$), (ii) with equation [9] ($n = 1$, $p_3 = 2$), or (iii) with some intermediate type of behavior. It is seen in Table I that equation [8] is by itself sufficient to correlate the data. One thus concludes that the ethylene reaction can be adequately explained in terms of a combination of reactions [1] and [2] with [3] and/or [5], where $p_3 \rightarrow 0$, the last two processes being varieties of what may be called *homogeneous catalyzed recombination*. It is not necessary to introduce a second active species.

TABLE I

HCN production from ethylene in the region 55 to 85° C

Pressure (mm)	$[N]_a$ = [HCN]* (mm)	[N]* (mm)	Predicted values of $[N]_a$ when $(k_3+k_5)/(1+p_2)k_2 = 8$ mm^{-1} or 2.8×10^{-16} cc molecule^{-1} (using equation [8] with $n = 1$)†	Predicted values of $[N]_a$ when $k_3/(1+p_2)k_2 = 32$ mm^{-1} (using equation [9] with $n = 1$ and $p_3 = 2$)†

*The experimental values of $[N]_a$ and [N], as given in Fig. 2, have been converted from *micromole sec*$^{-1}$ to *millimeter* using the factors given in Table I of reference 1. A slight error is associated with this change of units, since the conversion factors do not take into account the presence of the reactant and products. When referring to Table I of reference 1, the following change should be made in the heading of column 2: delete "$\times10^6$".

†The values assigned to the constants $(k_3+k_5)/(1+p_2)k_2$ and $k_3/(1+p_2)k_2$ have been chosen by trial and error so as to give the best fit to the data at 1 mm pressure.

The conclusion that $p_3 \rightarrow 0$, i.e. that the reactive fragments formed in reaction [3] do not consume an appreciable quantity of N atoms, may seem surprising. However, it is in accord with the work of Dunford *et al.* (17), where there was indication that ethylene which is excited by a process like [3] tends to revert to the ground state rather than to C_2H_2 or CH_2.

Several interesting rate constants can be obtained from the ratio $(k_3+k_5)/(1+p_2)k_2$ as given in Table I. Assuming that $p_2 = 1$,[4] and combining the above ratio with the over-all second-order rate constant for HCN production from ethylene as estimated by Milton and Dunford (18), i.e. $k_2k_1/k_{-1} \approx 1.6\times10^{-13}$ cc molecule^{-1} sec^{-1} at 40° C, one obtains the over-all third-order rate constant for N atom recombination catalyzed by

[4]*One* CH_3 *is believed to form in the ethylene reaction along with each primary* HCN *(15). The value* $p_2 = 1$ *therefore corresponds to complete conversion of the* CH_3 *to secondary* HCN, *so that a value slightly less than 1 might be more consistent with the recovery of small amounts of methane and ethane.*

ethylene, namely $2(k_3+k_5)k_1/k_{-1} \approx 1.8\times10^{-28}$ cc^2 molecule^{-2} sec^{-1}.[5] Combining the ratio with *upper* limits for (k_3+k_5) and k_1, as derived from the collision frequencies, one obtains the values $1/k_2 \geqslant 1\times10^{-6}$ sec for the lifetime of the $N\cdot C_2H_4$ complex with respect to decomposition into $HCN + CH_3$, and $1/k_{-1} \geqslant 5\times10^{-10}$ sec for the lifetime with respect to dissociation into $N + C_2H_4$. (In calculating (k_3+k_5) and k_1, the values $\sigma_N = 3\times10^{-8}$ cm and $\sigma_{C_2H_4} = \sigma_{N\cdot C_2H_4} = 5\times10^{-8}$ cm were used, and a temperature of 70° C was assumed.)

The value obtained for the rate constant of N atom recombination catalyzed by ethylene is compared with certain related constants in Table II. It is seen that the catalyzed

TABLE II

Comparison of third-order processes involving N atoms

Process*	Temperature (°C)	Third-order rate constant (cc^2 molecule^{-2} sec$^{-1}\times10^{33}$)	Lifetime of the relevant bimolecular complex with respect to dissociation (sec)	Reference
Homogeneous catalyzed recombination in the presence of C_2H_4	55 to 85	180,000	$\geqslant5\times10^{-10}$ (i.e. $1/k_{-1}$)	Present
Homogeneous catalyzed recombination in the presence of CH_3CN	70	700	$\geqslant2\times10^{-12}$ (i.e. $1/k_{-1}$)	4†
Collision rate $\times2$ (using $\sigma = 3\times10^{-8}$ cm)	70	40	$\sim4\times10^{-13}$	—
Homogeneous decay	Ambient	15 to 33	?	8, 19, 20
	~55	3 to 5‡	?	1, 21

*Though surface decay is not a third-order process, it is interesting to note that, as shown on p. 73 of reference 1, this process is perhaps an order of magnitude *more* efficient than homogeneous decay, and therefore much *less* efficient than the particular examples of catalyzed recombination.

†The rate constants in Table I of reference 4 have been extrapolated to 70° C in a plot of log k vs $1/T$. The value of $1/k_{-1}$ was then found as in the present work. The lifetime of the $N\cdot CH_3CN$ complex with respect to *reaction* (i.e. $1/k_2$) is not included in Table II; its value is $\geqslant4\times10^{-6}$ sec, which is comparable to the value for $N\cdot C_2H_4$ as given in the text.

‡The range of values 1.3 to 2.4 was given in reference 1; however, a recalculation of the results of reference 1 using improved values for the time of decay gives 3 to 5 (21).

recombination is particularly rapid, and, as would be expected, that the rapidity is associated with a relatively long-lived NM complex.

It is obvious that the preceding treatment of the ethylene reaction is valid only in so far as the elementary processes considered (equations [1] to [7]) represent all that are relevant.

Ethane and Ammonia

The production of HCN from ethane and the destruction of ammonia were next investigated, the reaction vessel being unheated and the decay tube either unheated (*series 2*), at 400° C (*series 3*), or removed altogether as shown in Fig. 1 (*series 4 and 5*). The results, together with the corresponding atom concentrations estimated from the reactions of ethylene or ethane at 350° C (for series 2 and 3 identical with series 5 and 6 of reference 1), are shown in Figs. 3A, 3B, and 3C. The afterglow was weakened, but not extinguished, in the presence of ammonia.

In marked contrast to ethylene, the extents of reaction of ethane and ammonia at lower temperatures, i.e. $[N]_a$, remain substantially less than the atom concentration in

[5] *The over-all rate constants for* HCN *production and catalyzed recombination take on the simple forms given only (i) if the* NM *complexes are in steady-state, i.e.* $k_{-1} \gg k_1[M]$ *(cf. equation [44] of reference 4), and (ii) if* $k_{-1} \gg (k_2+(k_3+k_5)[N])$. *That these inequalities are reasonable is borne out by the values actually obtained for the various constants.*

the limit $[N] \rightarrow 0$. The very low ammonia reactivity in the experiments of series 4 is perhaps especially to be noted. The low reactivities of ethane and ammonia are therefore clearly due to some effect other than the combination [1] + [2] + ([3] and/or [5]) as with ethylene. Considering ammonia alone, all other combinations of elementary reactions can be eliminated on the basis of the fact that the reactivity of ammonia can be varied over wide limits by acts affecting the active nitrogen prior to its entry into the reaction vessel, yet which in certain cases leave the atom concentration within the reaction vessel essentially unchanged. For example, in series 2 at 1 mm pressure, $[N] = 5.4$ micromole sec^{-1} and $[N]_a = 0.50$; in series 5, on the other hand, though the value of $[N]$ at 1 mm was nearly the same (4.6), the value of $[N]_a$ was very low (0.00).

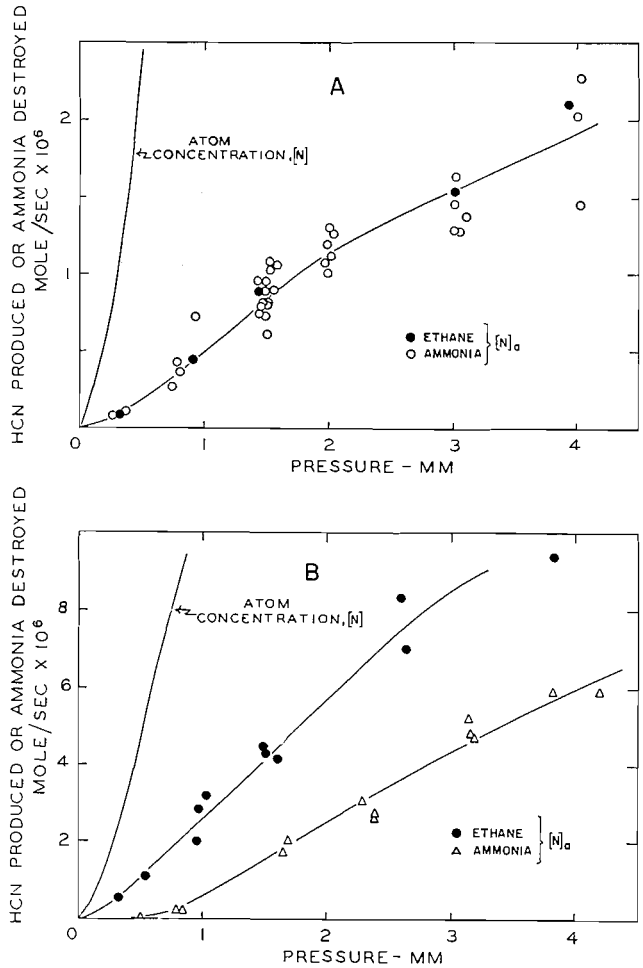

FIG. 3. (A) Series 2. HCN production from ethane and ammonia destruction as functions of pressure with both the decay tube and reaction vessel unheated. Temperature of reaction vessel = 40 to 70° C.

(B) Series 3. HCN production from ethane and ammonia destruction as functions of pressure with the reaction vessel unheated, as before, but the decay tube at 400° C. The reactivity of ethane is probably spuriously high due to the proximity of the hot decay tube. Temperature of reaction vessel = 50 to 130° C.

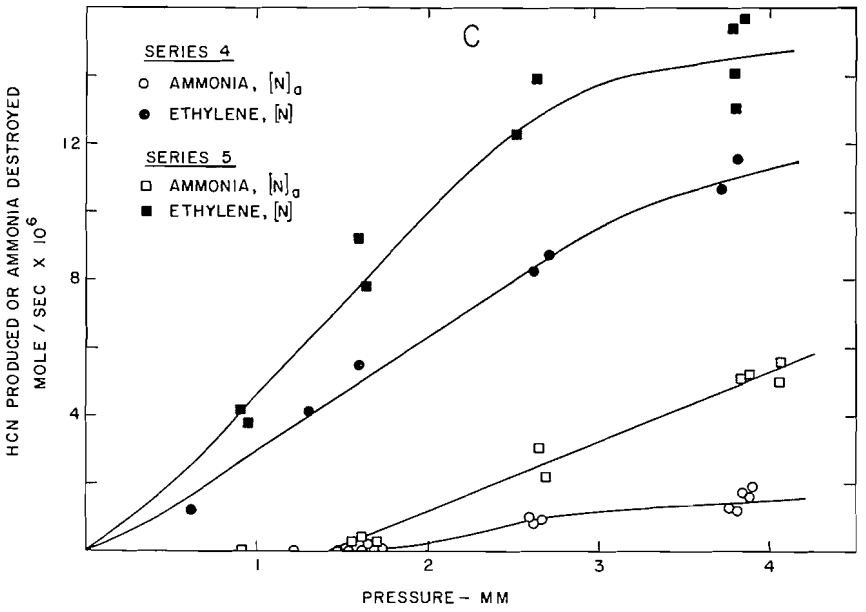

FIG. 3. (C) Series 4 and 5. Ammonia destruction as a function of pressure with the reaction vessel attached directly to the discharge tube near an electrode. In series 4 the nitrogen entered the discharge tube at the end to which the reaction vessel was attached, while in series 5 it entered at the opposite end. The reaction vessel was unheated, the temperature being 55 to 100° C in series 4, and 60 to 150° C in series 5.

The failure of the ammonia reactivity to be governed by the instantaneous atom concentration is strong evidence that an active species other than the N atom initiates the ammonia reaction, a conclusion in essential agreement with previous work (see introductory section). Whether the ethane reaction involves a second active species, or merely a combination of elementary reactions different from those involved with ethylene, cannot be determined from the present data. In particular a better control of temperature is needed since, while the ammonia reaction is virtually independent of temperature in the region of interest (5), the ethane reaction is not. H atom attack might also serve to complicate the ethane reaction (3).

An indication of the mode of formation of the species which reacts with ammonia can be obtained from series 4. In this series, the reaction vessel was attached directly to the discharge tube *near the point of entry of the nitrogen*, so that the active nitrogen formed in the proximity of a metal electrode. The atom concentration therefore fell rapidly from the high value necessarily existing at the instant of each flash. Accordingly, the observation in series 4 that the ratio $[N]_a/[N]$ was lower at a given pressure than in any other series, and also lower than in the work of references 5, 22, and 23, implies that the second active species is formed by homogeneous atom decay.

A species formed by homogeneous atom decay is necessarily an excited molecule.

It is not possible, with the information available, to determine whether the reactivity of ammonia can be predicted quantitatively in terms of a second active species; however, the fact that the species is formed by a *multiorder* mode of atom decay is certainly consistent with the trend that is revealed by examining the data in Figs. 3A, 3B, and 3C for the ratio $[N]_a/[N]$ to increase as [N] is increased. A similar trend was observed in references 22 and 23, in both of which a condensed discharge was used as in the present

work. A multiorder origin for the second active species also serves to explain the observations that, when a microwave discharge is used so that the atom concentration is very low even in the discharge tube, little or no ammonia destruction is found (6, 8), and excited molecules are not observed by mass spectrometry (11, 24).

The observation of Kaufman and Kelso (25) that, under conditions similar to those where essentially *no* ammonia destruction is observed (6, 8), certain thermal effects appear to be caused by excited molecules would seem at first sight contradictory to the present work. Note, however, that Dressler (26) has observed ground-state nitrogen in the first vibrational level as a component of active nitrogen. Provided this species were formed in the discharge process, it would be expected to persist even at the very low atom concentrations of reference 25; moreover, though the species would be comparatively inert chemically, it could lead to simple thermal effects.

The subject of the identity of the species reacting with ammonia will be considered in a subsequent paper.

NOTES

INDOLYL-3-ACETALDOXIME

A. Ahmad, I. Eelnurme, and Ian D. Spenser

In connection with our work on the biosynthesis of indolyl-3-acetonitrile (1) we have prepared and characterized indolyl-3-acetaldoxime, which had been postulated (2) as the biological precursor of indolyl-3-acetonitrile, but does not appear to have been described.

EXPERIMENTAL

Indolyl-3-acetaldoxime

The sodium bisulphite adduct of indolyl-3-acetaldehyde (3) (1.310 g, 0.005 mole) was suspended in water and the pH of the mixture was adjusted to pH 8 by addition of 5% Na_2CO_3 solution. A solution of hydroxylamine hydrochloride (0.380 g, 0.0055 mole) in water, similarly adjusted to pH 8, was added, the mixture was stirred for a few minutes, filtered, and kept at 5°. After 12 hours the product (0.450 g, 52%), melting at 127–128° was filtered off. Recrystallization from chloroform gave indolyl-3-acetaldoxime as silvery plates, melting at 140–141°. (Found: C, 68.8; H, 5.9; N, 15.9. $C_{10}H_{10}N_2O$ requires: C, 69.0; H, 5.8; N, 16.1%.) Infrared absorption in Nujol (cm^{-1}): 3385 (s), 3220 (s), 1642 (m). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)) in ethanol: 220(4.58), 275 (shoulder) (3.83), 281(3.85), 290(3.77).

Conversion of Indolyl-3-acetaldoxime to Indolyl-3-acetonitrile

The oxime (0.210 g, 0.0012 mole) was dissolved in 5 ml acetic anhydride and allowed to stand 18 hours at room temperature. The dark mixture was treated with excess 10% NaOH solution and extracted with ether. The ether extract was dried (Na_2CO_3) and concentrated, and the residual oil was distilled at 100–110° and 2.10^{-3} mm yielding indolyl-3-acetonitrile as an oil (0.055 g, 30%) whose infrared absorption was identical with that of an authentic specimen (1). The oil crystallized on seeding with authentic indolyl-3-acetonitrile, melting point 34–36°.

The same product was obtained when $POCl_3$ was used in place of acetic anhydride.

Reduction of Indolyl-3-acetaldoxime to Tryptamine

A solution of the oxime (0.250 g, 0.00144 mole) in dry ether was added dropwise to a boiling suspension of $LiAlH_4$ in ether. After complete addition the mixture was refluxed for 1 hour, allowed to cool, decomposed by pouring into water, and acidified with 2 *M* H_2SO_4 until a clear solution was obtained, which was extracted with ether. The aqueous layer was made alkaline with 10% NaOH and some LiOH was filtered off. The filtrate was repeatedly extracted and the precipitate washed with ether. The combined ether extracts and washings were dried (NaOH), the solvent evaporated, and the oily residue distilled at 105–110° and 5.10^{-3} mm yielding tryptamine (0.132 g, 57%), melting at 116–118°, identical with an authentic specimen in melting point, mixed melting point, and infrared absorption.

STRETCHING VIBRATIONS OF THE FREE $\overset{+}{N}H_3$ GROUP

P. CHEVALIER AND C. SANDORFY

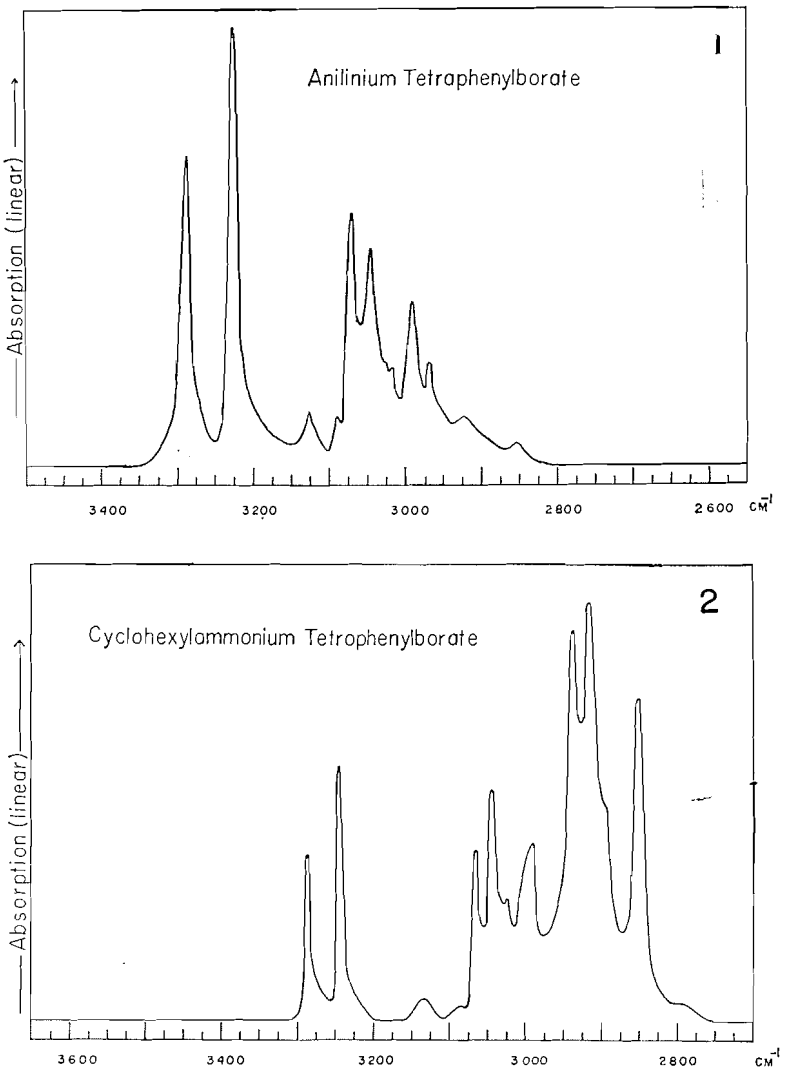
The usual method of measuring vibrational frequencies of free X–H groups i.e. taking the spectra of dilute solutions in a non-polar solvent cannot be applied to the case of the protonated amino group because of the insolubility of amine salts in such solvents. Even if they were soluble the hydrogen bonds which are of the $\overset{+}{N}$—H— — — halogen$^-$ type would probably still prevail.

The only possibility seems to be, therefore, to prepare salts with bulky anions where steric hindrance would prevent the formation of hydrogen bonds. This method was applied by Nakamoto, Margoshes, and Rundle (1) and by Nakanishi, Goto, and Ohashi (2), who used the tetraphenylborate anion. They obtained $\overset{+}{N}H_3$ stretching bands which lie around 3100 cm^{-1} for methyl and ethyl amine salts.

There is some doubt, however, whether these bands can be considered as "free" $\overset{+}{N}H_3$ stretching bands. First, the half-width of these bands as found by us is between 30 and 40 cm^{-1} while, for example, the half-width of the free OH band in phenol is about 15 cm^{-1}. Secondly, we have observed (3) that perchloric acid salts of amines have $\overset{+}{N}H_3$ stretching bands in the same frequency range but they are broad. It seems to be likely therefore that the bonds described by the above-mentioned authors correspond actually to weakly hydrogen-bonded $\overset{+}{N}H_3$ groups and the really free $\overset{+}{N}H_3$ groups give bands at higher frequencies.

Whether the $\overset{+}{N}H_3$ groups are "free" or hydrogen-bonded seems to depend, even in the case of tetraphenylborates, on the particular spacial requirements in the given crystal.

Here are some of the frequencies and half-widths related to cases where the $\overset{+}{N}H_3$ group appears to be "free" in a very good approximation:



Anilinium tetraphenylborate	3286 cm^{-1}	3225 cm^{-1}
	11 cm^{-1}	12 cm^{-1}
α-Naphthylammonium tetraphenylborate	3313 cm^{-1}	3260 cm^{-1}
	12 cm^{-1}	13 cm^{-1}
β-Naphthylammonium tetraphenylborate	3313 cm^{-1}	3260 cm^{-1}
	14 cm^{-1}	16 cm^{-1}
Cyclohexylammonium tetraphenylborate	3286 cm^{-1}	3246 cm^{-1}
	9 cm^{-1}	11 cm^{-1}

Figure 1 gives the spectrum of the anilinium salt, and Fig. 2 the one of the cyclohexylammonium salt (dried in vacuum at 105° C). They were measured in fluorocarbon oil mulls.

Since this work was started Kynaston, Larcombe, and Turner (4) reported the spectra of a number of tetrachloroborates and a few tetrafluoroborates. They found the bands pertaining to the free $\overset{+}{N}H_3$ group in the case of methylammonium tetrafluoroborate to

FIGS. 1 AND 2.

lie at 3282 and 3223 cm^{-1}. As may be inferred from their data, weak hydrogen bonds occur in all the other compounds.

From our data it is possible to measure the shift from the "free" bands to the bands in hydrochlorides.

Taking the arithmetic means of the two free $\overset{+}{N}H_3$ frequencies and the "center of gravity" of the broad composite hydrochloride bands (see 5 and 6) we obtain the following values:

Cyclohexylammonium	3266–2980 = 286 cm^{-1}
Anilinium	3256–2810 = 446 cm^{-1}
α-Naphthylammonium	3286–2810 = 476 cm^{-1}
β-Naphthylammonium	3286–2850 = 436 cm^{-1}

These values indicate medium strong hydrogen bonding in the hydrochlorides.

It is of interest to mention in this respect that Côté and Thompson (7) found 3332 cm^{-1} for the frequency of the triply degenerate stretching vibration of the ammonium ion in NH_4BF_4 where it very probably does not form hydrogen bonds and that Wagner and Hornig (8) found the corresponding band of the hydrogen-bonded ion at 3086 cm^{-1} in NH_4Cl.

Work is going on in this laboratory in order to prepare tetraphenylborates of many more primary, secondary, and tertiary amines. The results and further discussion will be given later.

2,6-Di(methoxycarbonylmethyl)-nitrobenzene[g]	—	—	54.4	101–102[h]	—

[a]These melting points are in agreement with those stated in "A textbook of practical organic chemistry", *edited by* A. I. Vogel. Longmans, Green and Co. Ltd., London. 1948.

[b]Recrystallized from ethanol – petroleum ether (b.p. 80–100°). Calc. for $C_{16}H_{13}O_2N_2$: C, 71.09; H, 6.71%. Found: C, 71.33; H, 6.70%.

[c]Recrystallized from ethanol. Calc. for $C_8H_{11}ON$, $C_6H_3O_7N_3$: C, 45.90; H, 3.85%. Found: C, 46.19; H, 3.97%.

[d]J. T. Edward (J. Chem. Soc. 222 (1956)) reported m.p. 46–47°.

[e]P. Grammaticakis (Bull. Soc. chim. France, 951 (1951)) reported m.p. 75°.

[f]Recrystallized from ethanol – petroleum ether (b.p. 80–100°). Calc. for $C_8H_{11}O_2N$: C, 62.72; H, 7.24%. Found: C, 63.13; H, 7.22%.

[g]F. A. L. Anet and E. Nishizawa (unpublished work) give m.p. 144–145°.

[h]Recrystallized from ethanol – petroleum ether (b.p. 80–100°). Calc. for $C_{10}H_{15}O_2N$: C, 66.27; H, 8.34%. Found: C, 65.96; H, 8.33%.

increasing steric hindrance around the nitro group. The formation of azo compounds is known to take place by the condensation of the nitroso compound and the hydroxylamine or the amine (10) and these reactions would be expected to be sensitive to steric hindrance. The 2,6-disubstituted nitrobenzenes investigated gave mainly the amine. On the other hand, Nystrom and Brown (1) report a 71% yield of azomesitylene, while in our hands 61% mesidine and 11% azomesitylene were obtained on reduction of nitromesitylene, even under conditions identical with those given by these workers.

It appears that such anomalous reductions are not completely unknown. Ried and Müller (8) obtained 4,4′-diaminoazobenzene by lithium aluminum hydride reduction of 4,4′-dinitroazobenzene. Adams *et al.* (9) were unable to reduce 3-chloro-2-nitroanisole to the azo derivative. They do not, however, mention what, if any, product was isolated. Wiberg and Jahn (11) have reported the formation of *p*-toluidine from *p*-nitrotoluene by reduction with lithium aluminum hydride, but only in presence of aluminum chloride. In the absence of aluminum chloride *p*-azotoluene was the main product.

EXPERIMENTAL

Melting points and boiling points are uncorrected.

The lithium aluminum hydride reductions were carried out in one of two ways depending on the solubility of the starting material in ether.

(i) When the nitro compound was ether soluble, its ether solution was added in a dropwise manner to a suspension of a half-molar excess of the hydride in anhydrous ether. When the addition was complete, the mixture was boiled under reflux for 6 hours. Amines formed were extracted with 10% hydrochloric acid and identified as their picrates (melting points and mixed melting points). The azo compounds were crystallized from the appropriate solvent and identified by comparing their properties with those given in the literature.

For personal use only.

(ii) If the nitro compounds* were only slightly soluble in ether, they were introduced to the hydride suspension (over a period of 24 hours) by the Soxhlet extractor technique. No azo compounds were formed in these cases and the amines were isolated by filtration of the organic layer, evaporation to dryness, and crystallization of the solid residue from the appropriate solvent system.

NOTE ON THE THERMAL NEUTRON CAPTURE CROSS SECTION OF Cs^{133}*

A. P. BAERG† AND R. M. BARTHOLOMEW

During the course of recent investigations relating to the detection efficiency of 4π beta proportional counters for Cs^{134m} (1) it was noted that in the neutron irradiation of Cs^{133} the amount of Cs^{134m} produced is several orders of magnitude greater than would be estimated from the 17-millibarn cross section quoted for this reaction (2). The $Cs^{133}(n,\gamma)$ Cs^{134m} cross section was therefore re-examined. At the same time it was possible to check the cross section for the reactions leading to the ground state.

Irradiations

Samples of about 500 μg each of CsCl, together with cobalt wire neutron flux monitors (0.0127 cm diameter) (3), were irradiated in an empty fuel rod position of the NRX reactor. The CsCl was prepared by weighing a solution of known concentration into quartz tubes. These samples were evaporated to dryness in the tubes, which were then sealed for irradiation. Two samples in iron capsules were irradiated for 3 hours each and two others, in 0.076-cm cadmium-lined iron capsules, for a period of 16.5 hours each. The reactor power remained constant during any one irradiation and to within a few per cent throughout these irradiations.

Purification and Counting

The irradiated quartz capsules were crushed under a solution 9 N in hydrochloric acid

and the resulting solution of cesium was then passed through a Dowex A-1 anion exchange column to remove particulate silica. The effluent was evaporated to dryness and the cesium further purified by elution from a Dowex-50 cation resin column (1). Quantitative recovery of the cesium, to within 1/10%, throughout the purification was ensured by suitable monitoring. Weighed aliquots of the cesium solution from the cation resin column were mounted and dried on thin plastic, gold-coated films (4) for counting.

Special precautions were taken to ensure that the cesium was pure and, in particular, free of 2.6-hour Si^{31} from the quartz irradiation capsules. In each experiment, portions of the purified cesium solution were taken for precipitation of the cesium as silicotungstate (5). This cesium was then extracted several times with an amyl acetate solution of sodium tetraphenyl boron (see reference 1). This extraction, though very inefficient for macro amounts of cesium, provided ample activity for study. The decay characteristics of this specially purified material were carefully compared with those of the samples used for the cross-section measurements. The beta decay of all samples showed a half-life of 2.91±0.01 hours (1) after subtraction of the 2.19-year Cs^{134} contribution (less than 1%).

The cobalt wire flux monitors were dissolved, and weighed aliquots dried on plastic films for counting.

All samples were counted with a 4π beta–gamma coincidence counter similar to that described by Campion (6). The method used for determining the detection efficiency of the 4π beta counter for Cs^{134m} is described in reference 1. In the counting of Cs^{134}, the gamma rays in the energy range 0.47 to 1.17 Mev were counted in coincidence with the beta radiations to arrive at the absolute disintegration rates.

Calculations and Results

The distintegration rates observed, referred to the end of the irradiations, are given in Table I together with irradiation times and the cadmium ratios (i.e. the ratio of observed

TABLE I

Experimental data

2. Uncovered	3	1.075×10^{3}	5.40×10^{5}	1.318×10^{3}
3. Cadmium-covered	16.5	1.882×10^{2}	2.55×10^{5}	2.052×10^{3}
4. Cadmium-covered	16.5	1.892×10^{2}	2.44×10^{5}	1.971×10^{3}
Cadmium ratio (average)		20.26±0.5	4.19±0.12	3.59±0.09

rates of reaction without and with cadmium filter). The half-life values used to calculate the reaction rates are given in Table II. Self-shielding correction factors of 1.04 and 1.62, respectively, for uncovered and cadmium-covered irradiations were also applied to the cobalt data (7).

The cross-sections were calculated using the convention described by Westcott (8) (see also reference 9). A very brief outline only is given here to indicate the method which was used.

The measured reaction rate, R, is equated to the product of the effective cross section, $\hat{\sigma}$, and the conventional flux, nv_0, where n is the neturon density and v_0 is 2200 m/sec.

[1] $$R = \hat{\sigma} n v_0.$$

TABLE II

Values of parameters used in calculations of cross sections

Co^{59} self-shielding correction factor, cadmium-covered	1.62 (7)
Co^{59} self-shielding correction factor, uncovered	1.04 (7)
Half-life of Co^{60}	5.28 years (2)
Half-life of Cs^{134m}	2.91 hours (1)
Half-life of Cs^{134}	2.19 years (10)
Co^{59} 2200 m/sec cross section	36.68 barns (2)
Co^{59} resonance integral, RI	75 barns (13)
$r\sqrt{T/T_0}$ (measured for irradiation position used)	0.0223±0.0004

The effective cross section is defined by

$$\hat{\sigma} = \sigma_0(g+rs) \qquad [2]$$

where σ_0 is the 2200 m/sec cross section, r is a measure of the relative density of epithermal neutrons, and g and s are factors which depend on the departure of the cross sections from the $1/v$ law. In the present experiment it is assumed that $g = 1$ and the factor s is written as $\sqrt{(T/T_0)}s_0$; thus

$$\hat{\sigma} = \sigma_0\left(1+r\sqrt{\frac{T}{T_0}}s_0\right) \qquad [3]$$

where T is the neturon temperature and T_0 is 293.6° K corresponding to 2200 m/sec neutrons. The term $r\sqrt{T/T_0}$, which is a constant of the reactor for the irradiation position used, is then related to the cadmium ratio, R_{Cd}, and s_0 as follows:

$$r\sqrt{\frac{T}{T_0}} = \frac{1}{R_{Cd}\{s_0+(1/K)\}-s_0}. \qquad [4]$$

Here K is a function of the cadmium cross section and the thickness of filter used, having the value 2.2 in the present experiment (8). The factor s_0, in turn, is given by

$$s_0 = \sqrt{\frac{4}{\pi}}\left(\frac{RI}{\sigma_0}\right)-\frac{1}{K} \qquad [5]$$

where RI is the resonance integral, evaluated above the cadmium cutoff and includes the $1/v$ part above this energy.

The conventional flux, nv_0, is first obtained in the following way from the cobalt data. The factor s_0 is calculated from the known values of RI and σ_0 for cobalt (Table II). The factor $r\sqrt{T/T_0}$ is obtained from equation 4 using the measured cadmium ratio for cobalt and the calculated value of s_0. Then the effective cross section for cobalt (equation 3) is used in equation 1 to get the conventional flux, nv_0.

The effective cross section for cesium was obtained from equation 1 using the observed reaction rate and the conventional flux, nv_0 from the cobalt data. The factor s_0 for cesium is calculated (equation 4) from the observed cadmium ratio and the already known value of $r\sqrt{T/T_0}$. The 2200 m/sec cross section, σ_0, then follows from equation 3 and the resonance integral, RI, from equation 5.

The average cross-section values obtained in this way are given in Table III. The errors quoted are based on an estimated combined uncertainty of 1% in the determination of distintegration rates and a 2% uncertainty in the relative neutron fluxes for the cadmium-covered and uncovered irradiations. Possible errors associated with the parameters listed in Table II (except for $r\sqrt{T/T_0}$) have not been included.

TABLE III

Cross sections calculated from experimental data and the parameters of Table II

Reaction	$Co^{59}(n, \gamma)Co^{60}$	$Cs^{133}(n, \gamma)Cs^{134m}$	All reactions leading to the ground state
Effective cross section, $\hat{\sigma}$ (barns)	38.19±0.04	3.67±0.07	41.6±0.9
2200 m/sec cross section, σ_0 (barns)	—	2.82±0.07	30.4±0.8
Resonance integral, *RI* (barns)	—	34.4±1.9	461±25

The value obtained in this work for σ_0 (2.82±0.07 barns) for the production of Cs^{134m} is very much greater than that (17 millibarns) quoted in reference 2.

The effective cross section for the reactions leading to the ground state Cs^{134} (41.6 ±0.9 barns) is found to be in good agreement with those obtained by Bidinosti *et al.* (40 barns) (11) and Brown *et al.* (40.9±4.1 barns, which was also measured in a vacant fuel rod position in the NRX reactor) (12). The value obtained for σ_0 is in good agreement with 30±1 barns reported in BNL-325 (2) but differs by somewhat more than the combined errors from the value obtained by Brown. The difference would appear to be accountable to the inherent difficulties in measuring cadmium ratios and uncertainties in neutron energy spectra (see discussion by Brown (12)).

twigs and branches. It is common throughout the Prairie provinces. Wall *et al.* (1), in a general survey of steroids, flavones, and tannins in plants, report that an extract of the whole plant gave a positive test only for tannins. In the current study, the leaves and stems of plants from the Saskatoon district were found to be devoid of flavonoid compounds, but a positive color reaction was obtained with an alcoholic extract of the red stem bark.

About 10% of the air-dried stem bark was ethanol-soluble. This extract was solvent fractionated and the chloroform-insoluble portion was chromatographed on a cellulose powder column. One of the products obtained (0.075% yield, based on the weight of bark) was a flavone glycoside, m.p. 238° C, $[\alpha]_D$ −19.7°, identified as hyperin (quercetin-3-galactoside) by mixed melting point. Hyperin was isolated for the first time by Jerzmanowska (2) from the herb *Hypericum perforatum* L.

In addition to hyperin, the alcohol extract contained fumaric acid, tannins, and a mixture of long-chain fatty acids. The latter mixture was resolved by gas–liquid chromatography (3) and found to consist of *n*-C_{24}- (66.7%), *n*-C_{26}- (22.8%), and *n*-C_{28}-carboxylic acids. In one experiment, when fresh bark was extracted at once, these fatty acids were obtained only after saponification, showing that hydrolysis may occur during storage of the plant.

EXPERIMENTAL

Melting points were determined on a Leitz hot-stage microscope, and infrared spectra were recorded with a Perkin–Elmer Model 21 double-beam spectrophotometer. Gas–liquid chromatography was carried out on a Beckman GC-2 chromatograph, using the technique previously described (4).

Air-dried stem bark (1000 g) of dogwood was extracted with ethanol (5 l.) in the cold. The solvent was evaporated, leaving a brownish-red sirupy residue (102 g). This material was extracted with chloroform to remove chlorophyll, waxes, etc. (22 g). An aliquot (16.5 g) of the chloroform-insoluble residue was chromatographed on a 60×7 cm cellulose powder column, using 15% acetic acid as solvent. Aliquots of 20 ml were collected and fractions 33 to 40 on evaporation gave a solid material (150 mg) which gave a pink color reaction when treated with magnesium and dilute hydrochloric acid. The material was crystallized from dilute alcohol, m.p. 238° C, $[\alpha]_D$ −19.7° (*c*, 3.9 H_2O–acetone 1:1). Found: C, 51.87%; H, 4.70%. Calculated for $C_{21}H_{20}O_{12}\cdot 2H_2O$: C, 52.43%; H, 4.87%. The infrared absorption spectrum corresponded to that of a flavone glycoside. The glycoside (20 mg) was hydrolyzed with dilute sulphuric acid and the aglycone and sugar portions were worked up in the usual manner. Paper chromatography showed these to correspond to quercetin and galactose respectively. The glycoside had the same R_f value (0.32, using 15% acetic acid) as hyperin, and its melting point was undepressed in admixture with an authentic specimen of hyperin.

Fractions 41–43 in the cellulose powder fractionation contained the bulk of the material (12.5 g) and appeared to be mainly tannin-like. On rechromatographing on cellulose powder, using ethyl acetate:ethanol:acetic acid (41:2:1 v/v) as eluent, a small amount of fumaric acid (characterized by mixed melting point and its infrared spectrum) was obtained.

The chloroform-soluble portion was dried and chlorophyll was removed by extraction with petrol (b.p. 40–60° C) in the cold. The insoluble residue was chromatographed on a silicic acid column, using petrol:benzene (1:1) as eluent. The only crystalline material isolated was a mixture of fatty acids, m.p. 78–79° C. Similar material was also found in

the petrol-soluble portion. The mixture was methylated with diazomethane and small aliquots (1 μl) were analyzed by gas–liquid chromatography on a silicone column (18×1/4 in.) at 240° C (3, 4). Three peaks corresponding to n-C_{24}, n-C_{26}, and n-C_{28} methyl ester were recorded in the proportion of 6.7:2.3:1.

We are grateful to Miss I. M. Gaffney and Mr. M. Mazurek for recording the infrared spectra and microanalyses.
