(*vii*) *Methyl α-D-altropyranoside.*—Methyl α-D-altropyranoside (1.80 g) on hydrogenation gave a syrup which yielded crystals (0.19 g) from ethyl acetate – ethanol that corresponded to methyl α-D-mannopyranoside with m.p. and mixed m.p. 191–193° C. Cellulose chromatography afforded three main fractions, the first of which (66 mg) appeared to be a polyol. The next fraction (0.13 g) afforded a sugar with R_{Rh} 1.0 on hydrolysis which was not identified. The last portion of the column eluate gave a mixture (0.61 g) of polyol and methyl α-D-talopyranoside which had OCH_3 9.4% which indicated a glycoside content of 59%. Acid hydrolysis of the mixture afforded an aldose of R_F = talose which, on treatment with 4 moles of aqueous phenylhydrazine acetate at 80° C for 6 hours, gave D-lyxohexose phenylosazone identified by its X-ray diffraction pattern.

(*viii*) *Methyl β-D-altropyranoside.*—Cellulose chromatography of the hydrogenation product of methyl β-D-altropyranoside (1.04 g) afforded three fractions. The first was a

mixture of materials (164 mg) with mobility on a paper chromatogram greater than methyl β-altroside. The following fraction (253 mg) consisted of unchanged glycoside characterized as its tetraacetate, m.p. and mixed m.p. 98–99° C. Calculated for $C_{14}H_{19}O_9 \cdot OCH_3$: OCH_3, 8.35%. Found: OCH_3, 8.6%. The last material from the column was methyl β-D-mannopyranoside (155 mg), characterized as its tetraacetate, m.p. and mixed m.p. 161–163° C. Calculated for $C_{15}H_{22}O_{10}$: C, 49.7%; H, 6.1%. Found: C, 49.8%; H, 6.2%.

(*ix*) *Methyl α-D-talopyranoside.*—Paper chromatography of the product (0.31 g) from hydrogenated methyl talopyranoside (0.34 g) indicated that the material was mainly unchanged taloside with R_{Rh} 1.4. Only a trace of slower-moving material was detected. The product had OCH_3 16.2% indicating that removal of the methoxyl group had not occurred. Acid hydrolysis of the product furnished an aldose, which on treatment with 1 mole of 1-methylphenylhydrazine (31) in refluxing ethanol gave crystals characterized as D-talose 1-methylphenylhydrazone, m.p. and mixed m.p. 150–152° C.

(*x*) *Methyl β-D-allopyranoside.*—Hydrogenation of the glycoside (0.48 g) yielded a syrup (0.36 g) which on cellulose chromatography was found to consist of 0.17 g of materials with $R_{Rh} > 1.0$ on a paper chromatogram and 122 mg of a mixture of methyl β-D-allo- and -gluco-pyranosides. Fractional crystallization from ethyl acetate – ethanol gave 19 mg of the former with m.p. and mixed m.p. 154–156° C and 29 mg of the latter which had m.p. and mixed m.p. 115–116° C.

(*xi*) *Methyl α-L-arabopyranoside.*—The glycoside (2.22 g) was hydrogenated and the resulting mixture chromatographed on cellulose. The first fraction consisted of polyols (0.50 g) and tosylation of the mixture (14) gave a product which was fractionally crystallized to yield ditosyl-*trans*-tetrahydropyrandiol, m.p. and mixed m.p. 157–161° C, and ditosyl-*cis*-tetrahydropyrandiol, m.p. 125–129° C. A second fraction (0.26 g), $[\alpha]_D$ −98° (*c*, 1.0, H_2O), from the column crystallized to give methyl β-D-ribopyranoside from Skelly "F"–ethyl acetate, m.p. and mixed m.p. 83–84° C. The next material eluted (0.13 g) was shown to be methyl α-L-lyxopyranoside, m.p. 109–110° C and $[\alpha]_D$ −57° (*c*, 1.0, H_2O), after two recrystallizations from ethyl acetate – ethanol, which gave an X-ray diffraction pattern identical with that of the D-isomer. Calculated for $C_6H_{12}O_5$: C, 43.9%; H, 7.4%. Found: C, 44.1%; H, 7.4%. The last fraction from the column weighed 0.16 g and from this 16 mg of methyl β-D-xylopyranoside, m.p. and mixed m.p. 159–161° C, was obtained after two recrystallizations from ethanol – ethyl acetate.

(*xii*) *Methyl β-L-arabopyranoside.*—The hydrogenolysis product from methyl β-L-arabopyranoside (2.22 g) was very complex and acid hydrolysis showed that it contained all four chemically different pentosides. On cellulose chromatography a polyol fraction (0.66 g) was obtained corresponding to the two possible tetrahydropyrandiols. Very little further fractionation was obtained although methyl β-L-arabopyranoside (0.22 g), m.p. and mixed m.p. 167–168° C, was crystallized from ethanol and later 109 mg of a syrupy glycoside, with $[\alpha]_D$ +128° (*c*, 2.2, H_2O) which gave xylose on acid hydrolysis, was obtained. Although the latter product did not crystallize it appears that it was methyl α-D-xylopyranoside.

(*xiii*) *Methyl α-D-lyxopyranoside.*—The glycoside (2.22 g) was hydrogenated and on cellulose chromatography three fractions were obtained. A considerable proportion of tetrahydropyrandiols (0.97 g) was shown to be present. In this fraction it appeared that some methyl riboside was present since ribose was obtained on a paper chromatogram by hydrolyzing the syrup with acid. The next fraction (0.29 g) contained methyl α-D-lyxopyranoside, m.p. and mixed m.p. 107–109° C and the last portion (0.33 g) from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the column was shown to contain xyloside, arabinoside, and lyxoside by acid hydrolysis followed by paper chromatography.

(*xiv*) *Methyl β-D-ribopyranoside.*—When methyl β-D-ribopyranoside (2.20 g) was hydrogenolyzed and the product chromatographed on cellulose a considerable proportion of polyol (1.11 g) was found. The polyol had OCH_3 6.3% and on acid hydrolysis some ribose was formed, which indicates that 31% of the mixture consisted of methyl riboside. The remainder of the column eluate (0.16 g) consisted of a mixture of xyloside, riboside, and arabinoside as shown by paper chromatography of the acid hydrolyzate.

(*xv*) *Methyl β-D-xylopyranoside.*—The xyloside (1.11 g) was hydrogenolyzed and chromatographed on cellulose in the usual way. The initial fraction appeared to be tetrahydropyrandiols (0.32 g) and later portions were obtained which consisted of methyl-β-D-ribopyranoside (m.p. and mixed m.p. 80–81° C; 0.19 g) from ethyl acetate – Skelly F, and a xyloside (0.13 g) which could not be crystallized but which gave xylose on acid hydrolysis.

C. Hydrogenation of Glycosides at Temperatures > 180° C

1,5-Anhydro-4-deoxy-D-hexitols from Hydrogenolysis of Methyl α-D-glucopyranoside at 240° C

The hydrogenolysis of methyl α-D-glucopyranoside at 240° C was described by von Rudloff, Bauer, and Stuetz, who acetylated the product and fractionally distilled the acetates (1). Their still residue contained acetates of the 1,5-anhydro-4-deoxy-D-hexitols and this (7.32 g) was deacetylated with 0.1 mole of sodium methoxide in methanol (150 ml) for 3 hours. The polyols (4.92 g) obtained on evaporation consisted of two main fractions of R_{Rh} 1.1 and 1.3. Cellulose chromatography gave a syrup (1.81 g) consisting of mainly the former and this was heated at 80° C for 1 hour with *p*-nitrobenzoyl chloride (13 g) in pyridine (30 cc). The solution was poured into excess aqueous sodium bicarbonate and after 30 minutes stirring the precipitate was collected, washed with water, and dried. Three recrystallizations from ethyl acetate – Skelly F brought the tris-*p*-nitrobenzoate (4.84 g) to a constant m.p. of 113–115° C; it had $[\alpha]_D$ −83° (*c*, 1.1, $CHCl_3$). Calculated for $C_{27}H_{21}O_{13}N_3$: C, 54.6%; H, 3.6%. Found: C, 54.7%; H, 3.3%. Debenzoylation of the product (4.8 g) with 0.1 mole of sodium for 1 hour in boiling methanol (200 cc), followed by evaporation and deionization yielded crystals which were recrystallized twice from ethyl acetate – methanol. Yield, 0.37 g. The 1,5-anhydro-4-deoxy-D-hexitol corresponded to the fraction having R_{Rh} 1.1 and had m.p. 80–81° C, $[\alpha]_D$ −50° (*c*, 0.8, H_2O) and consumed 1.0 mole of aqueous sodium periodate overnight. Calculated for $C_6H_{12}O_4$: C, 48.6%; H, 8.2%. Found: C, 48.7%; H, 8.2%.

The polyol having R_{Rh} 1.3 was eluted later from the cellulose column and it (1.08 g) gave a tris-*p*-nitrobenzoate having m.p. 115–119° C and $[\alpha]_D$ +59° (*c*, 1.1, $CHCl_3$). Calculated for $C_{27}H_{21}O_{13}N_3$: C, 54.6%; H, 3.6%. Found: C, 54.5%; H, 3.9%. Catalytic debenzoylation furnished a syrupy 1,5-anhydro-4-deoxy-D-hexitol with R_{Rh} 1.3 and $[\alpha]_D$ +19° (*c*, 1.1, H_2O), which consumed 1.0 mole of aqueous sodium periodate in 18 hours.

Structure of the 1,5-Anhydro-4-deoxy-D-hexitols

The anhydro deoxyhexitol of R_{Rh} 1.1 (150 mg) was oxidized with 0.1 *M* periodic acid (1.5 moles) for 18 hours, the solution neutralized ($BaCO_3$) and filtered into an aqueous solution (10 ml) of sodium borohydride (100 mg). After 30 minutes the solution was acidified with acetic acid, treated with Amberlite IR-120, filtered, and evaporated to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

crust which was repeatedly dissolved in methanol which was then evaporated. The syrupy polyol (132 mg) had $[\alpha]_D$ −20° (*c*, 2.0, H_2O) and 75 mg of it was *p*-nitrobenzoylated in a manner similar to that described above to yield after three recrystallizations from ethyl acetate – pentane a tris-*p*-nitrobenzoate with m.p. 103–104° C and $[\alpha]_D$ −26° (*c*, 2.3, $CHCl_3$). Calculated for $C_{27}H_{23}O_{13}N_3$: C, 54.3%; H, 3.9%. Found: C, 54.3%; H, 3.9%.

Similar treatment of the anhydro deoxyhexitol of R_{Rh} 1.3 (60 mg) with periodic acid and sodium borohydride gave the open chain polyol with $[\alpha]_D$ −16° (*c*, 1.0, H_2O) from which gave an identical tris-*p*-nitrobenzoate, m.p. 98–102° and $[\alpha]_D$ −22° (*c*, 1.4, $CHCl_3$) was prepared. It had an X-ray crystal diagram similar to that of the *p*-nitrobenzoate obtained from the triol of R_{Rh} 1.1. Calculated for $C_{27}H_{23}O_{13}N_3$: C, 54.3%; H, 3.9%. Found: C, 54.5%; H, 3.9%.

Twenty-five milligrams of each 1,5-anhydro-4-deoxy-hexitol was dissolved in water (0.3 ml) and acetic acid (10 ml). A 1% solution of lead tetraacetate in acetic acid (10 ml) was added, the consumption of oxidant followed and the following values obtained:

Time (minutes)	10	35	70	135	205
Material of R_{Rh} 1.1, uptake in moles/mole	0.26	0.62	0.79	0.89	0.88
Material of R_{Rh} 1.3, uptake in moles/mole	0.07	0.16	0.25	0.30	0.34

Hydrogenolysis of Methyl β-D-galactopyranoside at 200° C

Methyl β-D-galactopyranoside (2.00 g) was hydrogenolyzed at 200° C using the proportions described previously. Paper chromatographic examination of the product indicated that all the starting material had been destroyed. In order to decompose any deoxy glycosides that may have been formed in the reaction, the product was heated for 18 hours at 100° C in *N* H_2SO_4. The solution was then neutralized ($BaCO_3$), filtered, and evaporated to a syrup (1.56 g), 0.69 g of which was fractionated on a cellulose column using benzene–ethanol–water (500:50:1 v/v) as solvent. From the column, dihydro-D-altral (80 mg), m.p. 105–106° C, dihydro-D-glucal (213 mg), m.p. 75–76° C, and dihydro-D-galactal (82 mg), m.p. 130–132° C, were obtained. All the above melting points were undepressed on admixture of the crystals with authentic specimens.

ACKNOWLEDGMENTS

The author wishes to thank Dr. A. S. Perlin for helpful discussions during the course of this work, and to Drs. E. von Rudloff, H. F. Bauer, and D. E. Stuetz for the gift of 1,5-anhydro-4-deoxy-hexitol acetates. Thanks are also due to Mr. J. A. Baignée and Mr. M. Mazurek for microanalytical determinations and Miss S. Lubin for technical assistance.

THE ENERGY OF HYDROGEN BONDING IN THE SYSTEM: ACETONE–CHLOROFORM

A. N. Campbell and E. M. Kartzmark[1]

ABSTRACT

It is shown that
(1) acetone and chloroform form a compound stable in the solid state;
(2) acetone and carbon tetrachloride do not form a compound;
(3) the enthalpies of mixing of acetone and chloroform and of acetone and carbon tetrachloride have been determined;
(4) from these figures the energy of hydrogen bonding in the acetone–chloroform system is evaluated as 2.7 kcal ±0.1.

The authors are engaged in a general investigation, including heats of mixing, of the ternary system: acetone–benzene–chloroform. It was pointed out to us, by Dr. W. Schneider of the National Research Council of Canada, that the data obtained would, with slight extension, enable us to determine the energy of formation of the linkage in the compound

The existence of a compound, $(CH_3)_2CO.CHCl_3$, has been long suspected. Indeed, Dolezalek (1) thought that he had proved the existence of this compound by an argument which would not now be considered completely acceptable. Nevertheless, the palpable evolution of heat when acetone and chloroform are mixed indicates, at least, that something of the nature of compound formation is taking place. It was therefore necessary, first, to demonstrate that acetone and chloroform do form a molecular compound and then to determine the enthalpies of mixing of acetone with carbon tetrachloride. Finally, it had to be shown that acetone and carbon tetrachloride do not form a compound as, indeed, from the nature of their formulae, is hardly likely.

EXPERIMENTAL

The existence of a compound was demonstrated by a study of the freezing-point diagram. A copper–constantan thermocouple and a Brown recorder were used; liquid nitrogen was the cooling agent. The mixture was placed in a double-jacketed vessel. The degree of vacuum in the jacket could be varied to produce any desired rate of cooling. All mixtures were stirred vigorously. The reagents were of highest purity and were distilled. The thermocouple was calibrated with acetone, chloroform, and mercury, whose freezing points were taken as −95° C, −63.5° C, and −38.87° C respectively.

The same technique was employed in the investigation of the system acetone – carbon tetrachloride, except that the very small heat of fusion of carbon tetrachloride (4.16 cal per gram) made thermal analysis an insensitive method, for mixtures containing large amounts of carbon tetrachloride. Hence, when dealing with such mixtures, where no appreciable halt or point of inflection could be detected on the cooling curve, the partially

[1]*Manuscript received January 13, 1960.*
Contribution from the Chemistry Department, University of Manitoba, Winnipeg, Manitoba.

frozen mixtures were allowed to heat up slowly, with vigorous stirring and the temperature of disappearance of the last crystals noted. This, admittedly, tends to give high results. Mixtures richer in acetone showed both primary freezing and eutectic halt, without any difficulty.

Heats of mixing were determined by having a weighed amount of one liquid in a magnetically stirred vacuum-walled calorimeter and the second liquid, also weighed, in a second such vessel. One set of junctions of a 20-junction copper–constantan thermopile was in the calorimeter and the other set was in the other vessel, so that the thermopile measured the difference in temperature of the two; allowance was made for any slight original difference in temperature. The thermopile had a sensitivity of about 0.2° C, corresponding to the minimum reading of the recorder chart. A suitable quantity of the second liquid was forced through a coarse capillary into the calorimeter, the amount being obtained by weighing at the end of the experiment. The average rise in temperature was about 7°. The mixing of acetone and carbon tetrachloride is an endothermal process and here the fall in temperature is much less. The usual method of radiation correction was applied and the water equivalent of calorimeter and contents was determined electrically, for each individual experiment. Current through the immersed platinum heating coil was determined from the voltage drop over a standard resistance. By this method, temperatures are not measured as such; the electrical input is multiplied by the ratio of two vertical lines on the recorder graph.

RESULTS

TABLE I

Freezing points of the system: acetone–chloroform

Mole % acetone	F.p. in °C	Eutectic halt
9.8	−72	−108
20.2	−80	−107
20.5	−81	−108
29.8	−93	−107
30.9	−103	−108
34.2	Eutectic	−108.5
34.8	−107	—
40.2	−106.5	−108.5
45.1	−106	−107.5
49.9	−106	—
50.1	−106	—
55.1	−107	—
60.3	−108	—
65.4	−110	—
69.2	−112	—
70.0	−112	—
77.3	−110	−115
90.0	−99	—

When the above results are plotted, a three-branch curve with an extremely flat maximum at 50 mole % composition is obtained. This indicates that the compound $(CH_3)_2CO.CHCl_3$ exists in the solid state but that it is highly dissociated in the molten state. The melting point of the compound is −106° C and the two eutectics lie at −108° (31 mole % acetone) and −115° (74 mole % acetone).

When the above figures are plotted a simple two-branch curve results, with a eutectic

TABLE II

Freezing points of the system: acetone – carbon tetrachloride

Mole % acetone	F.p. in °C	Eutectic halt
12.7	−39	—
24.6	−51	—
36.0	−55.5	—
41.4	−58	—
46.8	−61.5	—
50.0	−65	—
56.8	−68	—
66.3	−75	—
83.9	−95	−105
92.3	−102	−105

lying at 87.5 mole % acetone and at −105° C. Hence acetone and carbon tetrachloride do not form a compound.

The enthalpies of mixing of acetone and chloroform have been determined by Hirobe (5), by an ingenious and apparently accurate method. Our results are given in Table III.

Wyatt (2), from a study of the freezing-point diagram, finds a 1:1 compound of acetone and chloroform, melting congruently at −99.5° C, the two eutectics lying at −117° (73 mole % acetone) and −114° (38 mole % acetone). Wyatt (3) also claims the existence of a 1:1 compound of acetone and carbon tetrachloride, melting incongruently, with a peritectic at −75.5°, and a eutectic at −101°, and 8.5 mole % carbon tetrachloride. Our figures for the eutectic temperature and composition are in fair agreement with those of Wyatt and our figures do not disprove Wyatt's statement of an allotropic transformation of carbon tetrachloride at −48°. Timmermans (4), however, is unable to find this compound.

On the face of it, the formation of a compound does not seem very likely, since the enthalpy of mixing is positive. For the system, acetone–chloroform, where a compound definitely exists, the enthalpy is strongly negative.

TABLE III

Enthalpies of mixing of acetone and chloroform

Mole % chloroform	ΔH in gram calories per mole mixture	ΔH in gram calories per mole acetone
5.9	−68.3	−72
15.7	−174.2	−206
30.3	−328.1	−471
40.6	−399.7	−673
48.2	−434.1	−838
51.0	−449.7	−918
59.3	−465.9	−1145
70.7	−441.9	−1505
78.2	−362.6	−1664
88.0	−223.3	−1861
93.6	−126.1	−1970

When the above results are plotted along with those of Hirobe, the agreement is seen to be rather close. Our maximum occurs at 59.3 mole % chloroform and $\Delta H = -465.9$, while Hirobe's maximum occurs at 54.8 mole % chloroform and $\Delta H = -471.5$.

For personal use only.

TABLE IV

Enthalpies of mixing of acetone and carbon tetrachloride

Mole % carbon tetrachloride	ΔH in gram calories per mole of mixture	ΔH in gram calories per mole acetone
4.9	6.5	6.8
9.4	5.1	5.6
17.1	11.6	14.0
31.7	16.2	23.7
41.4	30.7	52.0
42.1	30.8	53.2
49.0	40.5	79.4
49.7	45.2	90.0
51.1	50.0	102
62.5	57.0	152
67.6	55.0	170
74.4	55.4	216
74.7	54.8	217
78.9	48.9	232
88.1	41.8	351
92.8	32.9	457

The only reference in the literature to the enthalpy of mixing of acetone and carbon tetrachloride is by Timofeev (6), who gives $Q = -1.7$ kilojoule per mole solute (heat absorbed). The dilution is not stated. The graph of our results exhibits a very flat maximum at about 65 mole % carbon tetrachloride and $\Delta H = 57.0$ cal per mole mixture.

DISCUSSION

Acetone and chloroform form a compound, $(CH_3)_2CO.CHCl_3$, stable in the solid state though highly dissociated in the molten state. In agreement with this, the enthalpy of mixing is negative. Acetone and carbon tetrachloride form no such compound and the enthalpy of mixing is small and positive. This is what would be expected of an ideal mixture (no appreciable interaction other than dilution). Although the compound of acetone and chloroform is highly dissociated in the liquid state, presumably the dissociation will be reduced to zero in the presence of an infinite excess of either chloroform or acetone. It is for this reason that we have evaluated the enthalpies of mixing per mole of acetone. When these values are extrapolated to 100 mole % chloroform (infinite excess per mole of acetone), we obtain, for the acetone–chloroform system, $\Delta H = -2090$ calories, and for the acetone – carbon tetrachloride system, $\Delta H = +625$ calories. We therefore deduce the enthalpy of formation of the compound (energy of hydrogen bonding) to be $-2090-625 = -2715$ calories, say 2.7 ± 0.1 kcal, since the calculation of ΔH for small percentages of acetone involves multiplication by a large factor (say 15) with consequent magnification of experimental error. The form of the graph, however, rules out extreme error, so that the value given for the hydrogen bond is correct to the limits given.

A CHROMATOGRAPHIC ANALYSIS OF THE PRODUCT FROM THE TRITOSYLATION OF SUCROSE: CRYSTALLINE 6,6′-DI-*O*-TOSYLSUCROSE[1]

R. U. LEMIEUX AND J. P. BARRETTE

ABSTRACT

Chromatographic analysis on silicic acid of the so-called "tri-*O*-tosylsucrose" which is formed in 95% yield on the reaction of 3 moles of *p*-toluenesulphonyl chloride with 1 mole of sucrose in pyridine at 0° has shown the substance to contain penta-, tetra-, tri-, and di-*O*-tosylsucroses in the molar ratios 0.05:0.33:1:1, respectively. Any mono-*O*-tosylsucrose present in the reaction mixture may have been lost in the isolation of the product. The composition of the product was substantially the same when the reaction was performed at −18°. The chromatogram separated the tritosylates into two subfractions. The major subfraction represented 29% by weight of the original "tri-*O*-tosylsucrose" and could be converted to 1′,2:3,6:3′,6′-trianhydrosucrose in 77.4% yield. Therefore, the so-called "tri-*O*-tosylsucrose" can contain only 25–29% of 1′,6,6′-tri-*O*-tosylsucrose. 6,6′-Di-*O*-tosylsucrose crystallized from the di-*O*-tosylsucrose fraction in 10% over-all yield.

Compton (1) obtained evidence that primary hydroxyl groups can undergo tosylation substantially more rapidly than do the secondary positions in a carbohydrate structure. He obtained yields of 41% and 36% of the 6-*O*-tosyl derivatives on monotosylations of the methyl β- and α-D-glucopyranosides, respectively. These results indicate a difference in reactivity between the primary position and the average secondary position in these compounds in the order of 7. On the other hand, Hockett and Downing (2) found that the hydroxyl groups in 1,2:5,6-di-*O*-isopropylidene-α-D-glucose and 1,2:3,4-di-*O*-isopropylidene-α-D-galactose differed in reactivity by a factor of 70. Little is known about the factors responsible for such differences in reactivity. Undoubtedly, non-bonded interactions in the transition state are important and probably mainly responsible for the generally greater reactivity of primary positions (3, 4). It should be noted, for example, that the large difference in reactivity found for the di-*O*-isopropylidene derivatives of glucose and galactose may be mainly due to the fact that the 3-hydroxyl group of the glucose derivative is eclipsed with the 4-position. Lemieux and McInnes (5) have recently shown that intramolecular hydrogen bonding also can strongly influence the rate of reaction. Furthermore, little information is available on the relative rates for the tosylation of the starting material and the first product of tosylation. Experience in related fields has shown (6, 7, 8) that this can be a dominant feature of the esterification of polyhydroxy compounds with hydrophobic reagents. Thus, when it is considered that the reactivities of both the primary and the secondary hydroxyl groups must vary considerably amongst themselves, it seems clear that attempts at preferential tosylations of the primary positions of polyhydroxy compounds can be expected to proceed in widely varying yields.

Hockett and Zief reported the preparation (9) of a substance termed "tritosylsucrose" by treatment of 1 mole of sucrose with 3 moles of tosyl chloride in pyridine at 0°. The product was not well characterized; nevertheless, it was suggested that the compound was probably "almost entirely" substituted at the three primary positions. The product is in fact highly substituted at the 6- and 6′-positions, since reaction with sodium iodide in acetone (10, 11, 12) affords material containing two iodine atoms per tosyl group. Lemieux and Barrette (13) have shown that the 1′-tosyloxy group of 1′,4,6′-tri-*O*-tosyl-

sucrose pentaacetate is not replaced by iodine when treated with sodium iodide in acetone. Since no information was gained regarding the nature of the third tosyloxy group of the so-called "tri-*O*-tosylsucrose" and since the substance is amorphous, the results shedded no light on either the extent of substitution at the 1′-position or the distribution of the tosyl groups among the sucrose residues. The so-called "tri-*O*-tosylsucrose" was obtained in yields above 95% and analyzed well for a sucrose tritosylate. Consequently, it can be assumed that there is no appreciable tendency for a pile-up of tosyl groups on relatively few sucrose molecules. Bragg and Jones (12) have made a study of the so-called "tri-*O*-tosylsucrose" by methylation, followed by reductive detosylation and hydrolysis, and inspection of the partially methylated D-glucose and D-fructose derivatives thus formed. Inspection of their results reveals no basis for the contention that the substance "consisted mainly therefore of 6,1′,6′-tri-*O*-tosylsucrose". The present authors entertained considerable doubt as to this characterization first of all in view of ordinary kinetic considerations and also in view of the low yield (3.5%) of 1′,2:3,6:3′,6′-trianhydrosucrose which was isolated (13, 14) on alkaline alcoholysis of the substance. It was believed of real interest to obtain a proper characterization of the substance in order the better to orientate our thinking and to justify our suspicions of previous interpretations of experimental results related to this problem. Our approach was to analyze the so-called "tri-*O*-tosylsucrose" by chromatography on silicic acid columns, a procedure which Jeanloz (15) has shown to be of great value for the separation of certain carbohydrate derivatives.

"Tri-*O*-tosylsucrose" was prepared by the method of Hockett and Zief (9) both at 0° and at −18°. The amorphous products were chromatographed on paper impregnated with silicic acid (16), using diisobutyl ketone:acetic acid:water (40:25:5) as solvent. The zones were located by dipping the paper in an aqueous solution of Rhodamine 6G (16). Fluorescent spots were observed under ultraviolet light at R_f values of 0.15, 0.40, 0.65, and 0.90. It was established that these corresponded to zones of di-, tri-, tetra-, and penta-*O*-tosylsucrose, respectively, by the chromatography of the components isolated by *column* chromatography on silicic acid using the same solvent system. This paper chromatographic technique proved extremely useful for a rapid preliminary inspection of a product and the establishment of an appropriate solvent system for the column chromatography.

The column chromatograms allowed the isolation of fractions that require the "tri-*O*-tosylsucrose" prepared at 0° to be, chemically, a highly heterogeneous substance containing penta-, tetra-, tri-, and di-*O*-tosylsucroses in the molar ratios 0.05:0.33:1:1, respectively (see Table I).

TABLE I

Chromatography of "sucrose tritosylates"

	Penta-*O*-tosylsucrose	Tetra-*O*-tosylsucrose	Tri-*O*-tosylsucrose		Di-*O*-tosylsucrose

The tri-*O*-tosylsucrose fraction could be resolved into two subfractions which comprised 29.0% (tri-*O*-tosylsucrose A) and 13.0% (tri-*O*-tosylsucrose B) by weight of the original "tri-*O*-tosylsucrose". Both these fractions have thus far resisted crystallization. Their sulphur contents were in good agreement with that expected for sucrose tritosylates. That the substances were in fact different was obvious from the following properties. Whereas the A fraction gave a yellow fluorescence with Rhodamine 6G, and readily consumed 2.82 moles of periodate per mole, the B fraction produced a pink fluorescence and consumed only 1.75 moles of periodate per mole. Furthermore, the A and B fractions underwent replacement of 1.87 and 1.63 tosyloxy groups when treated with sodium iodide in acetone. These results clearly indicate that both fractions are mixtures of tritosylated sucroses. However, the high periodate consumption by the A fraction shows that it must be mainly (about 78%) 1′,6,6′-tri-*O*-tosylsucrose. This conclusion was substantiated by the formation of 1′,2:3,6:3′,6′-trianhydrosucrose (13) in 77.4% yield on treatment of the A fraction with sodium methoxide in methanol. These results provide unequivocal evidence that the trianhydrosucrose in fact arises from 1′,6,6′-tri-*O*-tosylsucrose (14).

The di-*O*-tosylsucrose fraction deposited a 10% over-all yield (by weight) of crystalline compound (fraction C), m.p. 108–110°, $[\alpha]_D$ +54° in ethanol. The sulphur content corresponded to that expected for di-*O*-tosylsucrose and the compound only reduced Fehling's solution after acid hydrolysis. The compound was acetylated and the acetyl derivative, on treating with sodium iodide in acetone at 100°, produced a substance with the iodine content expected for a diiododideoxysucrose hexaacetate. Also, the nuclear magnetic resonance spectrum of the diiodo compound was devoid of the signals characteristic for the tosyl group. These properties require that the compound be 6,6′-di-*O*-tosylsucrose. The syrup (fraction D) which remained after crystallization of the 6,6′-di-*O*-tosylsucrose had a sulphur content close to that expected for a sucrose ditosylate (see Table I). Treatment of the hexaacetate derivative with sodium iodide in acetone replaced only 1.10 of the tosyloxy groups. This result shows that the 1′-hydroxyl group and perhaps certain secondary groups can compete favorably with the 6- or 6′-hydroxyl groups, or both in the tosylation reaction. It will be seen later on that the competition is undoubtedly mainly from the 1′-position and that, consequently, the di-*O*-tosylsucrose fractions (C and D combined) may be almost entirely composed of not greatly different amounts of the 1′,6-, 1′,6′-, and 6,6′-di-*O*-tosylsucroses.

The substances isolated from the other two bands of the chromatogram possessed sulphur contents in good agreement with those expected for tetra- and penta-*O*-tosylsucroses. The results of the chromatogram are listed in Table I and the course of the tosylation is described in Fig. 1.

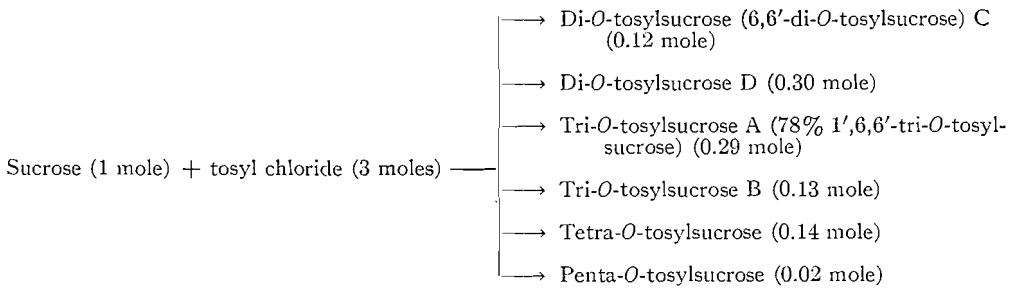

FIG. 1. Distribution of the tosylated sucroses formed in the reaction of 1 mole of sucrose with 3 moles of tosyl chloride in pyridine at 0°.

A consideration of Fig. 1 shows that the so-called "tri-*O*-tosylsucrose" does in fact contain 1′,6,6′-tri-*O*-tosylsucrose as the main component. However, the compound is only present to an extent of about 0.29 mole per mole of sucrose reacted. The fact that the compound was formed in an amount more than twice that of any other tri-*O*-tosylsucrose shows that the 1′-position is substantially more reactive than any secondary hydroxyl group. Consequently, as was discussed above, the uncharacterized di-*O*-tosylsucrose (fraction D) can be expected to consist mainly of 1′,6- and 1′,6′-di-*O*-tosylsucrose. In this respect, it is of interest to note that Hockett and Downing (2) found 2,3:4,6-di-*O*-isopropylidene-L-sorbose to undergo tosylation half as rapidly as 1,2:3,4-di-*O*-isopropylidene-D-galactose. The results clearly render it unlikely that sucrose can be acylated preferentially in high yield at the 6- and 6′-positions only. This conclusion is substantiated by the foregoing results of a ditosylation experiment. The tritylation of sucrose has been shown (17) to yield 1′,6,6′-tri-*O*-tritylsucrose pentaacetate in 45% yield. Table II describes the composition of the product obtained on a tritosylation of sucrose at −18°. It is seen that the course of the reaction was not appreciably affected by the lowering of the reaction temperature.

NOTE: The material, 10 g, was prepared at 0°.
*Crystalline 6,6′-di-*O*-tosylsucrose.

The product formed on the ditosylation of sucrose was analyzed chromatographically. The results are presented in Table III and Fig. 2. A comparison of the yields reported in Figs. 1 and 2 shows that the ditosylation produced, as would be expected, a greater yield of 6,6′-di-*O*-tosylsucrose (fraction C). The yield of other sucrose ditosylates (fraction D) was, however, about the same as that obtained in the tritosylation. This result clearly indicates that the 6- and 6′-positions both undergo tosylation somewhat more rapidly than does the 1′-position. The fact that the ditosylation produced nearly as much 1′,6,6′-tri-*O*-tosylsucrose as did the tritosylation clearly reflects the greater reactivity of the three primary positions over the secondary positions of sucrose.

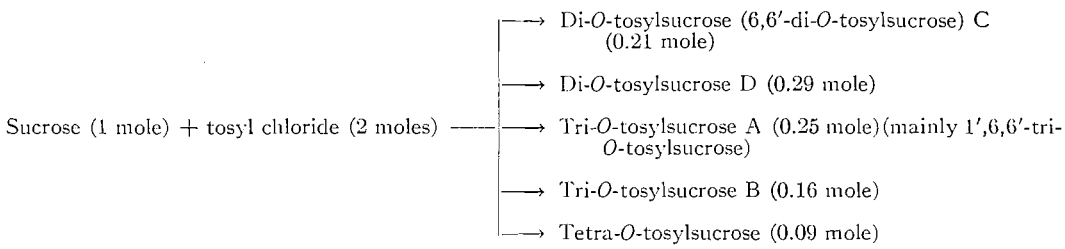

FIG. 2. Distribution of the tosylated sucroses formed in the reaction of 1 mole of sucrose with 2 moles of tosyl chloride in pyridine at 0°.

EXPERIMENTAL

The melting points are uncorrected and were determined on a microheating stage. Mallinckrodt reagent grade (100-mesh, lot 2847) silicic acid was used throughout.

"Tri-O-tosylsucrose"

A preparation was made at 0° in 95% yield using the method described by Hockett and Zief (9) and had a softening point of 65° to 85°, $[\alpha]_D$ +43° (*c*, 2.88 in chloroform). Anal. Calc. for $C_{33}H_{40}O_{17}S_3$: S, 11.93%. Found: S, 11.11%. The composition of this product is described in Table I and in Fig. 1.

A second preparation was made at −18° in a refrigerated bath using the following procedure. Sucrose, 34.2 g (0.1 mole), was dissolved in dry pyridine, 600 ml, by refluxing the mixture for a short time. The solution was then cooled to −18° with vigorous stirring for 2 hours. Tosyl chloride, 57 g (0.3 mole), was dissolved in 150 ml of dry pyridine and the solution was added dropwise to the solution of sucrose over a period of 2 hours. The reaction was left with continuous stirring at −18° for 5 days. The product, isolated in the usual manner, weighed 74.3 g (92.5%) with m.p. 65–85°, $[\alpha]_D$ +42° (*c*, 2.5 in chloroform). Anal. Calc. for $C_{33}H_{40}O_{17}S_3$: S, 11.93%. Found: S, 11.66%. The composition of this product is described in Table II.

Chromatography of "Tri-O-tosylsucrose" on Paper Impregnated with Silicic Acid

The silicic-acid-impregnated paper was prepared by the method of Marinetti, Erbland, and Kochen (16) but using Whatman No. 3 chromatographic paper. The chromatograms were developed by the descending method using the solvent system, diisobutyl ketone: acetic acid:water (40:25:5). The dried paper was immersed in 0.01% aqueous Rhodamine 6G solution (16) and examined under ultraviolet light in a dark room. Both "tri-*O*-tosylsucrose" preparations gave spots of similar intensities having R_f values of 0.15, 0.40, 0.65, and 0.90.

Silicic Acid-Column Chromatography of "Tri-O-tosylsucrose"

The silicic acid, 200 g, was packed as a slurry in chloroform in a 2.5-cm (diameter) column. The "tri-*O*-tosylsucrose", 9–10 g, was dissolved in 20 ml of chloroform and applied to the top of the column. The column was then developed with the solvent system, diisobutyl ketone:acetic acid:water (40:25:5). After the solvent front had displaced all of the chloroform from the column, 3-ml fractions were collected at a rate of 1 tube every 2 minutes. A total of 110 tubes were collected. Further eluant was free of material. The tubes were examined by spotting on paper and applying the Rhodamine 6G color test. Five different zones were apparent in the series of tubes. After the tubes within each zone had been combined, the solvent was removed *in vacuo* and the weights of the residues were determined.

The results are given in Tables I and II. Crystals were deposited in the fraction which proved to correspond to the fraction of di-*O*-tosylsucroses. In the case of the "tri-*O*-tosylsucrose" prepared at 0°, the crystalline substance (fraction C) was collected before evaporation of the solvent. The extremely fine needles, 0.92 g, m.p. 101–106°, were extremely soluble in methanol, but sparingly soluble in water, ethanol, or chloroform. After three recrystallizations from water, this compound melted at 108–110°, $[\alpha]_D$ +54° (*c*, 1.66 in ethanol). The compound only reduced Fehling's solution after acid hydrolysis. Anal. Calc. for $C_{26}H_{34}O_{15}S_2$: C, 47.8%; H, 5.22%; S, 9.85%. Found: C, 47.2%; H, 5.29%; S, 10.12%. The experiments described below established the compound to be 6,6′-di-*O*-tosylsucrose.

6,6′-Diiodo-6,6′-dideoxysucrose Hexaacetate

6,6′-Di-*O*-tosylsucrose (fraction C), 0.1 g, was dissolved in 1 ml of dry pyridine, and 2 ml of acetic anhydride and left at 4° for 2 days. The acetate, 126 mg, was isolated in the usual manner. The amorphous solid resisted crystallization. The substance, 76.5 mg, was dissolved in 15 ml of 10% sodium iodide in acetone and the solution was heated at 120° for 16 hours. The sodium tosylate, 36.2 mg, which precipitated represented a replacement of two tosyloxy groups. The syrupy product, 59.2 mg, was isolated in the usual manner. Its nuclear magnetic resonance spectrum was devoid of signals for the aromatic and *C*-methyl hydrogen atoms of the tosyl group. Anal. Calc. for $C_{24}H_{32}O_{15}I_2$: I, 31.4%. Found: I, 29.3%.

Monoiodomonodeoxymono-O-tosylsucrose Hexaacetate

The syrupy di-*O*-tosylsucrose (fraction D), 2.11 g, remaining after the removal of the crystalline 6,6′-*O*-tosylsucrose (see above) was acetylated and the product was subjected to the sodium iodide in acetone treatment. The amount of sodium tosylate recovered represented a replacement of 1.1 tosyloxy groups.

Reaction of Tri-O-tosyl Sucroses A and B with Sodium Iodide

Acetylated samples of tri-*O*-tosylsucrose fractions A, 135 mg, and B, 128 mg, were treated as described above with 10% sodium iodide in acetone. The amounts of sodium tosylate recovered were 49.69 mg and 41.58 mg, respectively. These amounts represent the replacement of 1.87 and 1.63 tosyloxy groups per mole, respectively. Anal. Calc. for $C_{29}H_{36}O_{16}I_2S$: I, 30.7%. Found: I, 28.6% (fraction A) and I, 27.8% (fraction B).

1′,2:3,6:3′,6′-Trianhydrosucrose Diacetate

Tri-*O*-tosylsucrose A, 200 mg, was dissolved in methanol *M* in sodium methoxide and the solution was refluxed for 30 minutes. The reaction mixture was evaporated to dryness and the residue was shaken with boiling pyridine, 50 ml, for 15 minutes. After the mixture was cooled to 0°, 10 ml of acetic anhydride was added. The syrupy product, isolated in the usual manner, crystallized on trituration with methanol. The yield was 71.6 mg (77.4% of theory) of 1′,2:3,6:3′,6′-trianhydrosucrose diacetate, m.p. 179–181°, undepressed when admixed with an authentic specimen.

Periodate Oxidation of the Tri-O-tosylsucroses A and B

To a sample of the tosyl ester, 0.05 millimole, dissolved in 80 ml of glacial acetic acid, 10 ml of 0.25 *N* sodium metaperiodate was added and the solution made up to 100 ml with water. Aliquots, 10 ml, were taken at suitable time intervals and were reacted with potassium iodide and an excess of 0.1 *N* sodium thiosulphate solution (18). The excess thiosulphate was determined by titration to the starch end point with standard

0.005 *N* iodine solution. Periodate was not consumed in the blank determinations. The periodate uptake by fraction A was 0.61, 1.53, 2.02, 2.18, 2.41, 2.78, and 2.82 moles of oxidant per mole of A after 0.5, 1, 10, 18, 32, 85, and 108 hours. The periodate uptake by fraction B was 0.49, 0.51, 0.98, 1.18, 1.59, 1.72, and 1.75 moles of oxidant per mole of B after 0.5, 1, 10, 18, 32, 85, and 108 hours.

Ditosylation of Sucrose

Sucrose, 34.2 g (0.1 mole), was dissolved in 600 ml of dry pyridine and cooled to 0°; tosyl chloride, 38 g (0.2 mole), was added and the reaction mixture was kept at 0° for 5 days. The reaction mixture was then shaken at room temperature with 5 ml water for 30 minutes. The excess pyridine was removed *in vacuo* at 40° to leave a thick syrup. This syrup was dissolved in 1 liter of chloroform and washed with 200 ml of ice-cold 2 *N* sulphuric acid followed by 200 ml of saturated sodium bicarbonate and finally with 200 ml of water. The chloroform solution, after drying over anhydrous sodium sulphate, was evaporated to a dry, amorphous solid, 56 g (86% of theory). Chromatography on silicic-acid-impregnated paper revealed three components, R_f values, 0.13, 0.38, and 0.6. Column chromatography of 10 g of the material allowed the isolation of the fractions described in Table III and in Fig. 2.

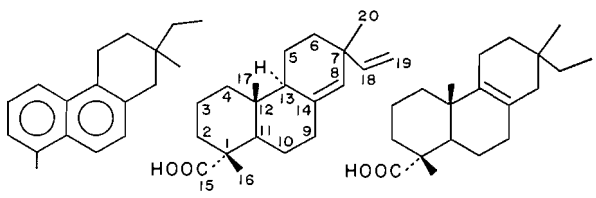
THE STRUCTURE OF SANDARACOPIMARIC ACID[1]



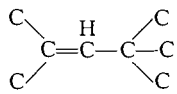
O. E. EDWARDS, A. NICOLSON,[2] AND M. N. RODGER[2]

ABSTRACT

Sandaracopimaric acid has been shown to be 7-epipimara-8(14),18-dienoic acid (II), and Ukita's acid to be 7-epi-13β-pimara-9(14),18-dienoic acid (VI). A hydroxyl-containing acid from Sandarac resin is described.

Sandaracopimaric acid was isolated by Henry (1) and by Tschirch and Wolff (2) from the resin of the N. African sandarac tree (*Callitris quadrivalvis*). Recently an improved isolation procedure was described by Petru and Galik (3), who also demonstrated that the acid belonged to the pimaric group. They claimed (4) that both pimaric acid and sandaracopimaric acid gave the same partial dehydrogenation product I and hence had the same configuration at C-7. Even if this conclusion had been correct their work left the location of the double bond and the stereochemistry at the other asymmetric centers unknown.

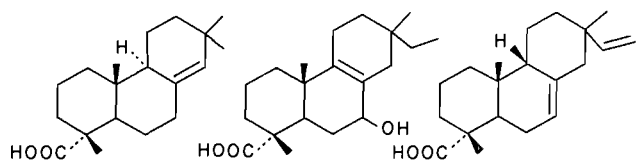
In continuance of our interest in the stereochemistry of the pimaric acids[3] we have examined sandaracopimaric acid, and proved it to be the C-7 epimer (II) of pimaric acid (7-epipimara-8(14),18-dienoic acid).[4]



(I) (II) (III)

Using the method of Petru and Galik (3) we obtained an ether-soluble ammonium salt from the resin. This was converted into the sodium salt, which was then precipitated from its aqueous solution by addition of concentrated sodium hydroxide solution. The precipitate did not crystallize readily, so the acids liberated from it were chromatographed on silica gel. In this way a 2.2% yield of sandaracopimaric acid and a 1.3% yield of a higher melting acid were obtained. The latter had m.p. 270° and $[\alpha]_D$ −11° in ethanol. The melting point is close to that of sandaricinolic acid (2), but our analytic figures, which correspond to a hydroxypimaric acid, are widely different from those of Tschirch and Wolff. The infrared spectrum of the high melting acid had rather weak bands which could be ascribed to a vinyl group and a trisubstituted double bond, and a strong hydroxyl band at 3360 cm^{-1}. We hence suggest that it is a hydroxypimaric acid.

[1]*Manuscript received January 12, 1960.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 5627.
[2]*National Research Council of Canada Postdoctorate Fellow.*
[3]*We wish to thank Dr. R. Howe, who first aroused our interest in sandaracopimaric acid.*
[4]*It seems desirable to have a systematic nomenclature for the pimaric acids, in particular to designate transformation products. However, the trivial names for the natural acids provide a convenient shorthand. We suggest that pimaric acid be designated pimara-8(14),18-dienoic acid, from which the other names follow as illustrated in the text. We do not consider the configuration at C-7 in pimaric acid to be settled, hence avoid commitment on this point.*



The physical constants for sandaracopimaric acid, m.p. 169°, $[\alpha]_D$ −20° in ethanol, were in good agreement with those reported by the Czech workers. Its rotatory dispersion curve was plain and negative. Its infrared spectrum suggested the presence of a vinyl group (ν_{max} 913 and 994 cm^{-1}) but there was no clear band corresponding to a trisubstituted double bond. The acid was rapidly reduced in the presence of palladium to a dihydro derivative, m.p. 178° (Petru and Galik (3) report m.p. 180°), which now gave a spectrum containing a band at 824 cm^{-1} () but lacking the vinyl absorption. The N.M.R. spectrum of the dihydro compound contained a single signal in the vinyl hydrogen region which was not split by coupling with adjacent hydrogens (band width ca. 4 c.p.s.). This suggests the presence of the system

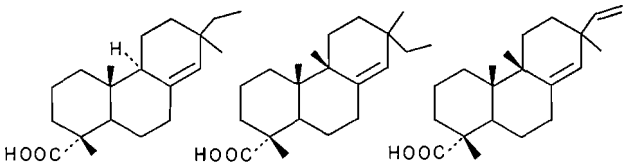
in the acid.

The presence of the pimaric acid skeleton and the isopimaric configuration at C-7 were next demonstrated by conversion of dihydrosandaracopimaric acid to 7-epipimar-13-enoic (Δ^{13}-dihydroisopimaric) acid (III) using dry hydrogen chloride in chloroform (5). Since a nuclear double-bond location at 8(14) is the only one consistent with the N.M.R. spectrum and formation of III, and since C-13 is the only remaining center at which sandaracopimaric acid can differ from isopimaric acid, it must have structure II.

This conclusion was confirmed in the following way. Sandaracopimaric acid was hydroxylated with osmium tetroxide. The main product was a diol acid, m.p. 255°, in which the vinyl group had been oxidized. The glycol system was rapidly cleaved by periodic acid to an aldehydo acid, m.p. 215°. On Wolff–Kishner reduction this gave 19-norpimar-8(14)enoic acid (IV), identical in all respects with the gem-dimethyl acid prepared earlier from pimaric acid (6). This observation proves the identity of double-bond location and C-13 configuration in pimaric and sandaracopimaric acids, and hence structure II must correctly represent the latter.[5]

(IV) (V) (VI)

This finding removes the last doubt about the structure and stereochemistry of Ukita's acid (5). There was slight possibility that this acid had structure II although no obvious mechanism existed for the transformation of its dihydro derivative to V with selenium dioxide under mild conditions. The rotatory dispersion curve did not exclude II from consideration (7). However, the above results coupled with the rotatory dispersion now require that the acid be 7-epi-13β-pimara-9(14),18-dienoic acid (VI).



Wenkert has pointed out[6] that the rotatory dispersion curves of dihydropimaric (VII)

The rotatory dispersion observations of Bose and Struck (7) provide an important addition to the body of evidence (6, 8, 9) suggesting that the C-13 hydrogen in pimaric acid is α oriented.

[6]*Personal communication from Professor E. Wenkert.*

and dihydroisopimaric (VIII) acids (7) are readily interpreted if a small positive contribution from the asymmetric centers in ring A is superimposed on the positive and negative plain curves due to the two mirror image situations in ring C. Extending this

(VII) (VIII) (IX)

argument, since sandaracopimaric acid has a plain negative curve the unknown pimaric acid IX whose ring C is the mirror image of that in II should have a plain positive curve. Hence cryptopimaric acid which has a plain negative curve (7) cannot be this isomer and hence must be a double-bond isomer. Bruun, Ryhage, and Stenhagen (9) concluded that cryptopimaric acid had structure II on the basis of mass spectrometry. This cannot be correct unless the physical constants of cryptopimaric acid are in error. However, their results do suggest the great importance of the C-13 stereochemistry in determining the fragmentation pattern when the nuclear double bond is in the 8(14) position. The uncertainty as to whether this applies to other double bond isomers, and the probable large effect of the vinyl group on the rotatory dispersion curve[7] make it unwise to suggest a structure for cryptopimaric acid at present.

EXPERIMENTAL

Unless otherwise stated, rotations were of ethanol solutions, infrared spectra were of Nujol mulls, and melting points were taken on a Kofler hot stage.

Sandarac Resin Acids

Commercial sandarac resin (900 g) dissolved nearly completely in ether. Ammonia was bubbled through the ether solution until precipitation ceased. The insoluble ammonium salts were removed by filtration and the filtrate extracted with 2% sodium hydroxide solution. The aqueous solution of sodium salts was acidified using 2% acetic acid, the acids collected on a filter, and washed well with water (yield 169 g). The sodium salts of this acid mixture did not crystallize readily, hence the acids were chromatographed on silica gel.

A benzene solution of approximately half the acid (87 g) was added to a column of 100- to 200-mesh silica gel (1.3 kg) and 100 cc eluate fractions collected.

Eluant	Fraction	Weight, g	Remarks
Benzene	1–9	4.5	Amorphous
Benzene–ether 20:1	10–14	6.4	Amorphous
Benzene–ether 10:1	15–20	26.2	8.8 g crystalline material
Benzene–ether 3:1	20–30	9.6	Amorphous
Benzene–ether 1:1	31–44	18.6	5.4 g crystalline material

The remaining fractions did not crystallize.

[7]*Hydrogenation of the vinyl group of sandaracopimaric acid reverses the sign of rotation, hence presumably the sign of the rotatory dispersion curve.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Sandaracopimaric Acid

The yield of crude crystals from fractions 15–20 was 8.8 g (2.2% of the resin). The acid was purified by recrystallization from aqueous methanol, recrystallization of its sodium salt, and further recrystallization of the acid. It then had m.p. 169°, $[\alpha]_D$ −20° (*c*, 2.6). Its infrared spectrum had bands at 913 and 994 cm^{-1} (vinyl group), 825 cm^{-1} (very weak) ($>C=C<^{H}$), and at 1692 cm^{-1} (—COOH). Its rotatory dispersion curve was plain and negative, with $[\alpha]_{460}$ −50° and $[\alpha]_{290}$ −250°.

The Hydroxy Acid

The yield of crude crystals from fractions 31–44 was 5.4 g (1.3% of the resin). When recrystallized from aqueous methanol it separated as plates, m.p. 270°, $[\alpha]_D$ −11° (*c*, 0.8). Found: C, 75.59; H, 9.74. Calc. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Its infrared spectrum had rather weak bands at 904 and 987 cm^{-1} (vinyl group) and 822 cm^{-1} ($>C=C<^{H}$), a strong band at 3360 cm^{-1} (hydroxyl group), and a band at 1695 cm^{-1} (—COOH).

Dihydrosandaracopimaric Acid

Sandaracopimaric acid (200 mg) in 15 ml of ethanol was reduced with hydrogen in the presence of 150 mg of presaturated 30% palladium on charcoal. In 5 minutes 16.3 ml of hydrogen was absorbed (calc. for 1 mole, 16.1 ml). The product was recrystallized three times from aqueous methanol giving 128 mg of needles, m.p. 174–178°, $[\alpha]_D$ +21° (*c*, 1.83). Found: C, 78.78; H, 10.54. Calc. for $C_{20}H_{32}O_2$: C, 78.94; H, 10.52. Infrared spectrum: ν_{max} 1692 cm^{-1} (—COOH); 824 cm^{-1} ($>C=C<^{H}$).

Isomerization of Dihydrosandaracopimaric Acid

Dry hydrogen chloride was passed into a solution of 73 mg of dihydrosandaracopimaric acid in dry ethanol-free chloroform at −5° for 4 hours. The solution was then washed free of mineral acid with water, dried, and evaporated. The product (58 mg) crystallized from aqueous acetone as needles, m.p. 109–112°, $[\alpha]_D$ +75° (*c*, 1.0 in chloroform). It did not depress the melting point of Δ^{13}-dihydroisopimaric acid (5) (m.p. 109–112°) and X-ray powder patterns of the two substances were identical.

Hydroxylation of Sandaracopimaric Acid

A solution of 636 mg of sandaracopimaric acid and 530 mg of osmium tetroxide in 10 ml of dry ether was left overnight at 0°. The black precipitate (1.2 g) was collected by filtration. It was then heated for 1 hour on a steam bath in 15 ml of water containing 2.7 g of mannitol and 0.5 g of sodium hydroxide. The resulting solution was acidified with acetic acid and the precipitated acid collected by filtration. This was boiled with methylene chloride to remove more soluble material, and the residue recrystallized three times from methanol. The diol acid separated as needles (410 mg), m.p. 255°, $[\alpha]_D$ +39° (*c*, 0.35). Found: C, 71.58; H, 9.75. Calc. for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59. Infrared spectrum: ν_{max} 825 cm^{-1} ($>C=C<^{H}$), 1685 cm^{-1} (—COOH).

Aldehydo Acid

A solution of 200 mg of the above diol acid in 80 ml of aqueous dioxane (10% water) containing 290 mg of periodic acid was left for 1 hour at room temperature in the dark. The reaction mixture was then concentrated to around 6 ml under reduced pressure,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

water added, and the solution extracted with methylene chloride. The methylene chloride solution was washed with water, dried, and evaporated, leaving 170 mg of crystalline residue. This was absorbed from benzene on 4 g of silica gel. Benzene eluted a small quantity of material. Benzene–ether (50:1, 40 ml fractions) eluted the bulk of the compound. Fractions 2 and 3 had m.p. 200–215° (evacuated capillary). These were combined and recrystallized twice from ether–hexane giving 141 mg, m.p. 215° (evacuated capillary), $[\alpha]_D$ −2° (*c*, 1.3). Found: C, 74.89; H, 9.31. Calc. for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27. Infrared spectrum: ν_{max} 2700, 1727 cm^{-1} (—CHO), 1693 cm^{-1} (—COOH), 823 cm^{-1} ($\rangle C{=}C\langle^{H}$).

19-Norpimar-8(14)-enoic Acid

A solution of the above aldehydo acid (54 mg) in 2 ml of triethylene glycol and 0.5 ml of 95% hydrazine was heated on a steam bath for 30 minutes and at 140° for 30 minutes under an air condenser. Potassium hydroxide (0.64 g) was then added cautiously, the temperature raised to 205°, and maintained at that temperature for 4 hours, while a slow stream of nitrogen was introduced halfway down the condenser. The reaction mixture was then cooled, diluted with water, and extracted with methylene chloride. The methylene chloride was extracted with dilute sodium hydroxide solution, then the combined aqueous layers carefully acidified with 6 *N* sulphuric acid. The acid was again extracted into methylene chloride, the solution washed with water, dried, and distilled. The residual solid was recrystallized from methanol, giving 44 mg of needles, m.p. 238°, $[\alpha]_D$ +18° (*c*, 0.6). This did not depress the melting point of the gem-dimethyl acid from pimaric acid (6), m.p. 238°. Their X-ray powder patterns and infrared spectra were identical.

ACKNOWLEDGMENTS

We wish to thank Professor A. K. Bose for sending his manuscript before publication and for the rotatory dispersion curve of sandaracopimaric acid, Professor E. Wenkert for valuable comments on the rotatory dispersion curves, Professor F. A. L. Anet for the N.M.R. spectrum, Dr. M. Przybylska and Miss C. Philo for the X-ray pattern comparisons, Mr. R. Lauzon for the infrared spectra, and Mr. A. Knoll for technical assistance.

MOLECULAR AREAS OF SOAPS AT THE SURFACE OF LATEX PARTICLES[1]

R. J. Orr and L. Breitman

ABSTRACT

The molecular area (i.e., the area occupied by a molecule of soap adsorbed on a surface) has been determined for a number of anionic, cationic, and non-ionic emulsifiers, adsorbed on latex particles. Measurements were made by surface tension and electron microscopic techniques. The composition of the polymer did not affect the molecular area of either anionic or cationic soaps. When a mixture of non-ionic and anionic soaps was used, interaction between the soaps prevented application of the conventional methods for measuring molecular area. The interaction is manifested by a decrease in the area occupied by an anionic soap molecule which can be explained in terms of reduction in electrostatic repulsive forces between ionic soap molecules. The configuration of the polyethylene oxide chain of the non-ionic on the surface of the latex particle is deduced to be that of caterpillarlike folds.

INTRODUCTION

The emulsion of rubber in water, known to the rubber industry as latex, offers special opportunities for study of physical properties of soaps at the polymer–water interface. This fact was first noted and used by Maron (1), who determined the minimum area which soap molecules in a monolayer occupy at the polymer–water interface. The specific property of the latex on which such studies depend is the ability of the polymer–water interface to adsorb more soap after the synthesis of the latex is complete. The main objectives of the study reported here were

(i) to increase the applicability of titration methods in determining latex particle size and surface areas of adsorbed soaps,

(ii) to learn something about the molecular geometry of the emulsifier at the interface which might be helpful in developing hypotheses concerning the mechanism of stabilization of latex.

THEORETICAL

Soap Titration in One-Component Systems

The area (A) occupied by an adsorbed soap molecule may be obtained from Maron's equation

$$[1] \qquad A = \frac{A_T}{N(S_1+S_a)}$$

where A_T = surface area/g polymer,
S_1 = number of moles of soap adsorbed/g polymer in final latex,
S_a = additional number of moles of soap adsorbed/g polymer, when sufficient soap is added to obtain the critical micelle concentration (c.m.c.) in the aqueous phase,
N = Avogadro's number.

Suppose that two different substrates are dispersed in water, that A_T is the same for both dispersions, and that soap is added to the aqueous phase until the c.m.c. is reached. The substrate with the greater affinity for the soap will adsorb more soap and, from equation [1], it follows that the value of A will be lower for this substrate. Comparison of affinities of soap for polymer by this method is not valid when the c.m.c. is so high

[1]*Manuscript received December 3, 1959.*
Contribution from Polymer Corporation Limited, Research and Development Division, Sarnia, Ontario.

that both substrates adsorb sufficient soap to form a condensed and incompressible monolayer. Since these conditions do not, in general, exist, low values of A may be taken as evidence of high affinity of substrate for soap.

Soap Titration in Two-Component Systems

If two portions of the same latex are titrated to the c.m.c., one with soap A and the other with soap B, then, according to Maron, the following relation holds:

$$S_a^A A^A = S_a^B A^B = A_T - S_1 AN. \quad [2]$$

The superscripts refer to the two soaps, A and B.

Equation [2] enables one to determine areas of soaps which, for practical reasons, cannot be used to prepare the original latex. This equation is valid if the following conditions hold:

(i) no desorption of the original soap occurs during titration with a different soap, and

(ii) at the titration end point, the area per molecule of the initial soap corresponds to its area at its own c.m.c.

As is shown later, these conditions are not always fulfilled.

Determination of A_T by Electron Microscopy

When the latex is not monodisperse, results of electron microscope analysis are readily expressed by the number average particle diameter ($\bar{X}$) and a standard deviation (σ). It may then be shown (see Appendix) that A_T is given by

$$A_T = \frac{6}{\bar{X}d}\left(\frac{\bar{X}^2+\sigma^2}{\bar{X}^2+3\sigma^2}\right) \quad [3]$$

where d is the polymer density.

Use of Surface Tension to Determine Critical Micelle Concentration

The surface tension method was selected for the determination of the c.m.c. of both ionic and non-ionic soaps, since the electrical conductivity method obviously cannot be used for non-ionics. Although the validity of the surface tension method for ionic soaps has been questioned (2), we have found the procedure to be satisfactory (see Results). The theoretical basis for this procedure with non-ionics has been provided by Bury (3). Some insight as to the significance of a surface tension measurement with an ionic soap may be provided by the following argument.

Only one of the ions of a soap is normally capillary-active, but the adsorption of capillary-active ions on the surface sets up an electrical field which tends to attract ions of the capillary-inactive species.

The Gibbs adsorption isotherm for a uni-univalent emulsifier may then be written as

$$-d\gamma/RT = \Gamma_+ d \ln a_+ + \Gamma_- d \ln a_-$$

where a and Γ represent bulk activities and surface excesses respectively of the two ions. At low concentrations of emulsifier, the activities of the ions are equal (4).

The substitution

$$a^+ = a^- \equiv a$$

gives

$$-d\gamma/RT = d \ln a(\Gamma_+ + \Gamma_-).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

At high ionic strength, where $\Gamma_+ \rightarrow \Gamma_-$, the above equation reduces to the expression given by Pethica (5) for these conditions.

A plot of γ versus ln c (or ln a) is usually a curve with a more or less sharp change in slope at a concentration which is assumed to be the critical micelle concentration.

CHEMICALS

The various commercial soaps used in this investigation are listed below with trade names, formulae, and suppliers.

Trade name	Formula	Supplier
Agent 180 BK	$(C_9H_{19})_2C_6H_3O(C_2H_4O)_{15}H$	Chemical Developments of Canada
Armac 10	$C_{10}H_{21}NH_2 : CH_3COOH$	Armour Company
Armac 14	$C_{14}H_{31}NH_2 : CH_3COOH$	Armour Company
Brij 30	$C_{12}H_{25}O(C_2H_4O)_4H$	Atlas Powder Co.
Daxad 11	Polymerized sodium salt of alkyl naphthalene sulphonic acid	Dewey and Almy
Dresinate 214	$C_{20}H_{28}O_2K$	Hercules Powder Co.
Igepal CO-880	$C_9H_{19}C_6H_4O(C_2H_4O)_{32}H$	General Aniline Corp.
LOP-100	$C_9H_{19}C_6H_4O(C_2H_4O)_{20}H$	Chemical Developments of Canada
Nacconol	$C_{12}H_{25}C_6H_4SO_3Na$	National Aniline Corp.
Rosin amine D	$C_{19}H_{27}NH_2 : CH_3COOH$	Hercules Powder Co.

EXPERIMENTAL

Impurities in soap may be surface-active or inert. Electrolytes, apart from a slight effect on the critical micelle concentration of the soap, are of no importance. Surface active contamination is serious since small amounts of such impurities have a strong influence on the $\gamma - \ln c$ relation. Miles and Shedlovsky (6) found that minima in the surface tension – concentration relation indicate surface-active impurities. Hutchinson (7) showed that small amounts of octyl alcohol had a pronounced effect on the surface excess of sodium dodecyl sulphate.

The C_{10} and C_{14} *n*-alkyl amines and the rosin amine were purified by steam distillation of the amine regenerated from the commercial emulsifier. The amine was reacidified with C.P. glacial acetic acid. Nacconol, Dresinate 214, and cetyl pyridinium chloride were used without further purification. Other ionic emulsifiers were prepared from C.P. reagents. No sharp minima in the surface tension – concentration relation, characteristic of surface active contamination, were observed with these emulsifiers. A much smaller minimum was observed with Armac 14, the acetate of a C_{14} *n*-alkyl amine, but, since this disappeared when electrolyte was added, it is suggested that this minimum is associated not with impurities, but perhaps with absorption of micelles on the surface, as reported by Judson (8), and Ruyssen and Maebe (9). The Nacconol was 93% pure, having 6% sodium sulphate and 1% volatile (10). The Dresinate 214 and cetyl pyridinium chloride were 100% active. The non-ionic emulsifiers exhibited a distribution of ethylene oxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

content but were certified as 100% active by the suppliers. Of the non-ionics, only Igepal CO-880 displayed a surface tension minimum (~ 2 dynes/cm).

All surface tension measurements were done with a CENCO du Nuöy ring tensiometer. Readings were corrected for ring diameter and wire thickness by the method of Harkins (11).

Area/gram ratios were calculated from equation [3] with a polymer density of 0.94 for butadiene/styrene and 0.96 for butadiene/acrylonitrile and butadiene/methyl methacrylate copolymers (12).

Preparation of Latices

Latices stabilized with all three types of soap—anionic, non-ionic, and cationic—were prepared by conventional emulsion polymerization techniques. The reaction temperature was 50° C and the source of initiating free radicals was obtained by reaction of a ferrous iron – potassium pyrophosphate complex with diisopropyl benzene hydroperoxide. After 60 to 80% conversion of monomers to polymers, the reaction was stopped and residual monomers were removed by steam distillation. Coagulum formation during polymerization was objectionable since this made estimation of S_1 difficult. It was possible to avoid excessive coagulum formation in all cases, except when cetyl pyridinium chloride was used. Determinations of the area of cetyl pyridinium chloride were made with two coagulum levels in the latex.

Comonomers used with butadiene were styrene, acrylonitrile, and methyl methacrylate. Monomer charge ratios were 70/30 butadiene/styrene and 66/33 butadiene/acrylonitrile, except where otherwise specified.

Electron microscope data on the above latices were determined and are shown in Table I.

TABLE I

Electron microscope data on latices

Emulsifier	Soap in reaction per 100 parts monomer (parts)	Comonomer	Bd in comonomer charge (%)	Average particle diameter (Å)	Standard deviation (σ)
Dodecyl amine acetate	5.0	Styrene	70	915	60
		Styrene	70	1077	104
		Acrylonitrile	80	794	95
		Methyl methacrylate	80	950	146
Cetyl pyridinium chloride	3.0	Styrene	70	1340	10
	4.0			1237	90
	3.0			1028	57
Igepal CO-880, Nacconol	0.5*	Styrene	70	1129	236
	1.0*			1051	208
	1.5*			877	255
Igepal CO-880, K-oleate	0.5*	Styrene	70	1090	247
	1.0*			1026	183
	1.5*			870	187
Dresinate 214, Na fatty acid	—	Styrene	72	570	10

Soap Titration

The amount of soap necessary to reach the c.m.c in latex was determined from a plot of log (cc added soap) versus surface tension, as shown in Fig. 1. The soap was added

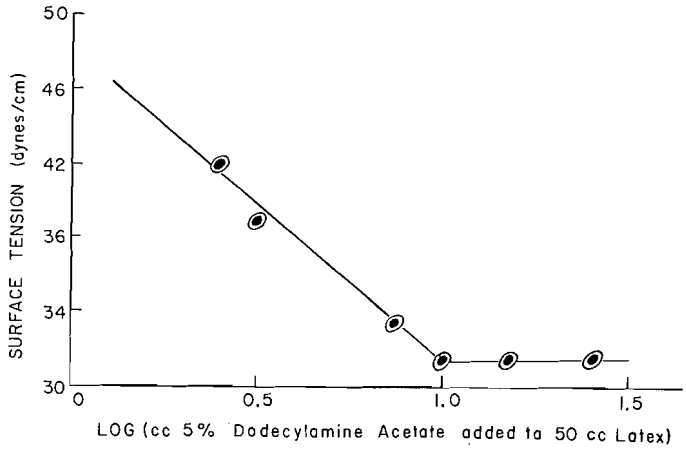

FIG. 1. Variation in surface tension with soap content for 80/20 butadiene-acrylonitrile latex.

to latex which had been adjusted to a solids content of 15%. The pH was maintained at fixed values to prevent hydrolysis of the soap. With cationic lattices, the pH was 4 and with anionic lattices, the pH was 10. Some experiments (where there was a high ratio of non-ionic to anionic) were done at two values of pH, 7 and 10. The temperature was maintained at 26°±1° C.

RESULTS

Surface tension was plotted against logarithm of the concentration for anionic, cationic, and non-ionic soaps. The concentration at which there is a sharp change in the slope of the relation was taken at the c.m.c. Measured values of the c.m.c. were compared, when possible, with those calculated from an empirical equation due to Klevens (13):

$$[4] \qquad \log \text{c.m.c.(mole/liter)} = 2.26 - 0.231\ (\text{length of surface active ion in Å}).$$

TABLE II

Critical micelle concentrations of ionic soaps by the surface tension method (pH = 7)

	Critical micelle concentration (moles/liter)		
	Observed		Calculated from
Soap	% salt	0.1% NaCl	equation [4]
Armac 10	2×10^{-2}	3×10^{-2}	5×10^{-2}
Dodecyl amine acetate	1×10^{-2}	4×10^{-3}	1×10^{-2}
Armac 14	2×10^{-3}	2×10^{-3}	3×10^{-3}
Rosin amine acetate	9×10^{-3}	9×10^{-3}	
Cetyl pyridinium chloride	6×10^{-3}	8×10^{-3}	
Nacconol	1.0×10^{-3}*	7×10^{-4}	
Potassium oleate	9×10^{-4}	1.8×10^{-4}	1×10^{-3}

*2.1×10^{-3} moles per liter Na_2SO_4.

TABLE III
Critical micelle concentration of non-ionic soaps (pH = 7)

Soap	Hydrophobic group	C_2H_4O, units/molecule soap	Molecular weight	Critical micelle concentration	
				0% salt	0.1% NaCl
Triton X-45	Iso-octyl phenol	5	426	0.6×10^{-4}	0.64×10^{-4}
Brij 30	Lauryl alcohol	4	360	1.25×10^{-5}	4.3×10^{-6}
LOP-100	Nonyl phenol	20	1100	1.8×10^{-4}	—
Brij 35	Lauryl alcohol	23	1200	6.2×10^{-5}	5.0×10^{-5}
Igepal CO-880	Nonyl phenol	32	1628	1.5×10^{-4}	—

Results are listed in Tables II and III. Data in Table III may be compared with results obtained by a similar method by Hsiao, Dunning, and Lorenz (14). The value for LOP-100 agreed closely. The value for Igepal CO-880 was lower, possibly due to the masking effect of the minimum we observed in the surface tension – concentration plot. The good agreement between the calculated and observed values of the c.m.c. confirms the reliability of the surface-tension method.

Area of Cationic Soaps

In calculation of area/soap molecule (A), the values of S_a in equation [1] were determined by subtracting the c.m.c. in water from the amount of soap necessary to reach the c.m.c. (or titration end point) in latex. The change in the c.m.c. in water caused by 0.1% NaCl (see Table II) has negligible effect on the calculated soap area. The areas of dodecyl amine acetate and cetyl pyridinium chloride at titration end point are shown in Table IV. The difficulty in obtaining good reproducibility with cetyl pyridinium chloride

TABLE IV
Molecular areas of cationic soaps at titration end point (equation [1])

Soap	Comonomer	Bd in comonomer charge (%)	Molecular area (Å²)	Average
Dodecyl amine acetate	Styrene	70	22.6	
	Styrene	70	25.0	25.6
	Acrylonitrile	80	27.0	
	Methyl methacrylate	80	26.2	
Cetyl pyridinium chloride	Styrene	70	42.4	46.0
			41.5	
			54.0	

was due, as already mentioned, to the formation of coagulum during polymerization. The areas of dodecyl amine acetate indicate that there is little, if any, difference in the degree of binding of this soap to the different substrates.

Equation [2] was used to determine the areas A^B of cationic soaps which were not used in the polymerization of the latex. Values for A^A were the directly determined ones in Table III. Dodecyl amine acetate or cetyl pyridinium chloride was used as the emulsifier in the polymerization step. The molecular areas so determined are listed in Tables V and VI. The data in these tables indicate that the nature of the polymeric

TABLE V

Molecular areas of cationic soaps at titration end point by comparative soap adsorption (equation [2])

Soap	Comonomer	Bd in comonomer charge (%)	Area covered by dodecyl amine acetate in original latex (%)*	A^B molecular area (Å²)
Armac 10	Styrene	70	45	19.4
	Acrylonitrile	80	55	19.2
	Methyl methacrylate	80	64	17.2
Armac 14	Styrene	70	45	27.6
	Acrylinotrile	80	55	30.5
Rosin amine D	Styrene	70	45	26.5

*"% area covered" is defined by $NS_iA/A_T \times 100$.

TABLE VI

Molecular areas of cationic soaps at titration end point by comparative soap adsorption (equation [2])

Soap	Comonomer	Bd in comonomer charge (%)	Area covered by cetyl pyridinium chloride in original latex (%)	A^B molecular area (Å²)
Armac 10	Styrene	70	70	20
Armac 14	Styrene	70	70	23

substrate does not significantly affect the molecular area of the cationic soaps at the interface.

The molecular areas of ARMAC 10 and ARMAC 14 may be compared with the value of 26 Å² for lauryl amine hydrochloride at the water–air interface reported by Harkins and co-workers (17).

Areas of Anionic Soaps

Two portions of an anionic latex were titrated, one with potassium oleate (B) and the other with the soap (A) whose area A^A is sought. A^A is calculated from equation [2] in which A^B, the area of the oleate molecule, was taken as 28.2 Å² (1). The results so obtained are shown in Table VII.

TABLE VII

Molecular areas of anionic soaps at titration end point by comparative soap adsorption (equation [2])

Soap	Comonomer	Bd in comonomer charge (%)	Molecular area (Å²)
Sodium dodecyl benzene sulphonate	Styrene	72	32 40
Dresinate 214	Acrylonitrile	66	34 40
	Styrene	50	38 38
Daxad 11*	Acrylonitrile	66	12.8×10^{22} Å²/g soap

*Determined by electron microscopy and titration with oleate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

It should be noted that there is some question about the accuracy of the area of the oleate molecule assumed here, since values as high as 47 Å² (15) have been reported. For two butadiene/styrene latices the total surface area, as measured by electron microscopy, compared well with that calculated from the values determined from the soap titration data. These results appear to substantiate the low value for the area of oleate.

The area of Daxad 11 (12.8×10^{22} Å²/g) on a butadiene/acrylonitrile latex containing Nacconol compares reasonably well with the value of 11.2×10^{22} Å²/g given by Maron (16) on a butadiene/styrene substrate.

Molecular Areas of Non-ionic Soaps

It was not possible to prepare latices with non-ionic soap alone in which the soap concentration in the aqueous phase was less than c.m.c. It was, therefore, impossible to obtain a titration end point on addition of soap and, accordingly, only a minimum value of the area per molecule could be directly determined. For a nonyl phenyl ethylene oxide condensate (Igepal CO-880) containing 30 moles ethylene oxide per mole nonyl phenol, a minimum value of 120 Å²/molecule was obtained by the procedure described for anionic and cationic soaps with the use of equation [1]. Separate portions of an undercovered anionic latex (i.e. a latex capable of adsorbing more soap at the oil–water interface) were titrated with potassium oleate and the non-ionic soap. Application of equation [2] to the titration data gave the values of molecular area listed in Table VIII.

TABLE VIII

Molecular areas of non-ionic soaps at titration end point by comparative soap adsorption (equation [2])

Comonomer	Bd in comonomer charge (%)	Emulsifier	C_2H_4O, units/molecule soap	Molecular area (Å²)
Styrene	72	Polyoxyethylene Nonyl phenol	30 (Igepal CO-880)	162
			20	125
		Polyoxyethylene Lauryl alcohol	4	40
Styrene	50	Polyoxyethylene Nonyl phenol	20	110
Acrylonitrile	66	Polyoxyethylene Nonyl phenol	30 (Igepal CO-880)	143
		Polyoxyethylene Isopropyl phenol	5	28.1
		Polyoxyethylene Dinonyl phenol	16	73

The correctness of these values, as well as of those in Tables V, VI, and VII, depends upon the validity of the two previously stated assumptions.

Another set of experiments was designed with the object of obtaining undercovered latex particles in which the fraction of surface occupied by the non-ionic could be varied over a wide range. This was accomplished by using varying ratios of non-ionic to ionic soap in the polymerization recipe. It was expected that interactions between the two types of soap in the adsorbed phase would be reflected in the observation that the molecular area at the titration end point is different when a second soap is present.

Separate portions of a given latex with a high ratio of non-ionic to ionic soap were titrated with an anionic soap (A) and a non-ionic soap (B) to obtain values of S_a^A and S_a^B. When the value of A^A was taken to be its characteristic value in the absence of a non-ionic, and the value of A^B was calculated from equation [2], these values of A^A

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and A^B led to a total area of the latex particles which exceeded by about 50% the total area directly determined by electron microscopy. This result demonstrated that equation [2] is inapplicable to systems containing mixtures of ionic and non-ionic soaps, either because of interaction of the two types of soap in the adsorbed phase, or because of displacement of one soap by the other. It was not possible, on the basis of our experiments, to decide between the two alternatives. However, if it is assumed that displacement does not occur, it is then possible to obtain estimates of the changes in molecular areas that resulted from the interaction of the two soap species.

Separate portions of a given latex containing known amounts of anionic soap (S_i^A) and non-ionic soap (S_i^B) may be titrated with an anionic soap (A) and a non-ionic soap (B) to obtain values of S_a^A and S_a^B respectively. The relation between A_T and the concentrations of adsorbed soap is

$$[5] \qquad A_T/N = (S_i^A+S_a^A)A_x^{A*}+S_i^B A_x^{B*} = (S_i^B+S_a^B)A_y^{B*}+S_i^A A_y^{A*}.$$

A_x^{A*} and A_x^{B*} are the molecular areas of anionic and non-ionic soap, respectively, at the titration end point with anionic soap.

A_y^{A*} and A_y^{B*} are molecular areas of anionic and non-ionic soap, respectively, at the titration end point with non-ionic soap.

If it be assumed that the molecular area of a soap in an anionic/non-ionic soap mixture is independent of the relative concentrations of these soaps over the range investigated, one can write

$$[6] \qquad A_x^{A*} = A_y^{A*} \equiv A^{A*}$$

and

$$[7] \qquad A_x^{B*} = A_y^{B*} \equiv A^{B*}.$$

Values of A^{A*} and A^{B*} obtained from solution of equations [5], [6], and [7] are shown in Table IX. The asterisk symbol is used to differentiate molecular area in the mixed soap monolayer from that in a one-component monolayer.

TABLE IX

Molecular areas of anionic soaps and Igepal CO-880 at titration end point (equations [5], [6], and [7])

Anionic emulsifier in polymerization		Area covered by:		Molecular area (Å²)	
Type	Parts	Original anionic	Igepal CO-880	Anionic	Igepal CO-880
Nacconol	0.5	4.1	59.0	18.1	126
Nacconol	1.0	6.5	54.0	19.0	131
Potassium oleate	0.5	4.6	70.0	19.5	130
Potassium oleate	1.0	8.4	60.0	21.0	123

The estimate for the molecular area of Igepal CO-880 in the mixed soap system (Table IX) is about 30 Å² less than the value based on methods that assume no soap interaction. This method of determining areas of the non-ionic soap in the presence of anionic soap was limited to Igepal CO-880 since other non-ionic soaps do not support polymerization. If the area in mixed soap systems is independent of the nature of the non-ionic, then the molecular areas of the non-ionic soaps (Table VIII) determined by equation [2] are all too high. The data in Table VIII were revised on the basis of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

molecular area for the oleate molecule at 20.2 Å² (Table X) rather than at 28.2 Å² to obtain the values in Table X.

TABLE X

Molecular areas of non-ionic soap at titration end point by comparative soap adsorption (equation [2])

Comonomer	Bd in comonomer charge (%)	Emulsifier	C_2H_4O, units/ molecule soap	Molecular area (Å²)
Styrene	72	Polyoxyethylene Nonyl phenol	30	116
		Polyoxyethylene Lauryl alcohol	20	89
			4	28.6
Styrene	50	Polyoxyethylene Nonyl phenol	20	78
Acrylonitrile	66	Polyoxyethylene Nonyl phenol	30	103
		Polyoxyethylene Isopropyl phenol	5	19.8
		Polyoxyethylene Dinonyl phenol	16	52

The best estimates for the anionic soaps in the mixed soap system are about 8 Å² for oleate, and about 20 Å² for Nacconol, less than those values obtained in systems where there is no soap interaction (Tables V, VI, VII). The decrease in the area of anionic soaps in the presence of non-ionic soaps may be attributed to the absence of electrostatic repulsion forces between anions and neighboring neutral non-ionic soap molecules. A plot of molecular areas (Table X) versus number of C_2H_4O units/soap molecule is shown in Fig. 2. The linearity of the relation indicates that the area per ethylene oxide unit is constant. This constancy is consistent with an orientation of the ethylene

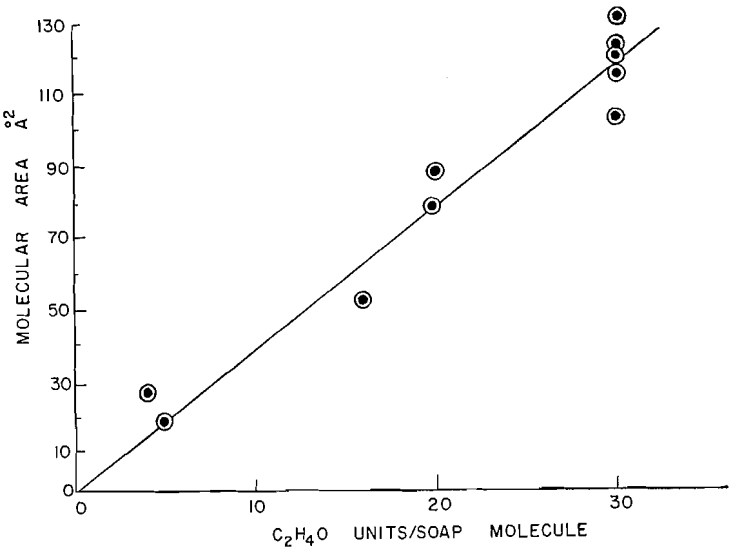

FIG. 2. Variation in area with ethylene oxide content.

oxide chain which is folded over the surface in a caterpillarlike manner. Such a view is supported by the results of Rosch (18), who suggested that chain contraction in polyethylene oxide chains is caused by the electrostatic attraction of the dipoles formed along the ethylene oxide chain. The actual dimensions of each fold may be determined only if the degree of hydration is known since the height of the fold should increase with increasing hydration. The work of Greenwald and Brown (19), showing a relation between salt content, temperature, and degree of hydration, suggests that measurements of area as a function of salt content would be instructive.

A set of dimensions was calculated for the unhydrated molecule from projections of Fischer–Hirschfelder models and the schematic representation in Fig. 3 was derived in which each fold is 16 Å high and contains 9 ethylene oxide units.

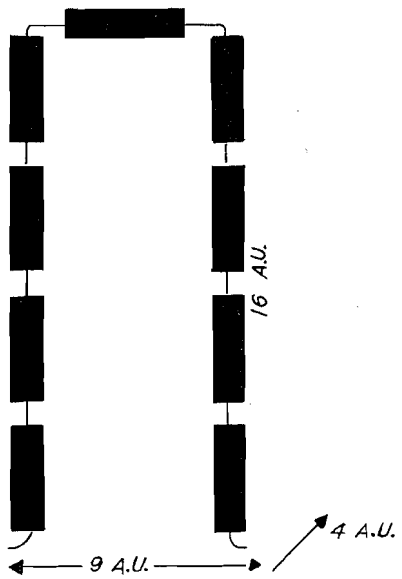

FIG. 3. Diagram of ethylene oxide chain at latex particle surface.

Comparison of Behavior at Air–Water and Polymer–Water Surface

Van Voorst Vader (20) has studied molecular areas of non-ionic and anionic soaps at the air–water interface. Measurements were made of saturation adsorptions, defined by Van Voorst Vader as the area occupied by a soap molecule at soap concentrations, where this area became independent of bulk concentration.

When non-ionic and ionic soaps were mixed, the molecular area of the non-ionic was not changed. The molecular area of the ionic soap was found to increase when non-ionic was added. This was explained by the increased ease of hydration of the ionic soap. When two dissimilar groups are present in the adsorbed soap layer, the water molecules are believed to be oriented to a configuration more suitable for co-ordination with ionic soap. Greater ease of co-ordination should increase the molecular area, since it will tend to decrease the affinity of the soap for the surface. The results we observed at the surface of latex particles, where the molecular area of the ionic soap is found to decrease in the presence of non-ionic, differ from Van Voorst Vader's results. Comparison of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

molecular areas of non-ionic soaps at the surface of the latex particles with those at the surface of the air–water interphase shows that non-ionic soaps have a greater affinity for the latter interphase. It appears reasonable to attribute the differing behavior of the ionic soap at the two interfaces to the differing affinity of the non-ionic for the surface.

APPENDIX

This treatment is adapted from a similar problem with carbon black (21). The volume of N spherical particles is

$$V = \frac{\pi}{6}\sum_{i=1}^{N} X_i^3 = \frac{\pi}{6}\sum_{i=1}^{N} (\bar{X}-\rho_i)^3 = \frac{\pi}{6}\sum_{i=1}^{N} (\bar{X}^3 - 3\bar{X}^2\rho_i + 3\bar{X}\rho_i^2 - \rho_i^3)$$

where $\bar{X}$ is the average particle diameter.

Now

$$\sum_{i=1}^{N} \rho_i^2 = N\sigma^2,$$

where σ is the standard deviation, and, for symmetrical distribution,

$$\sum_{i=1}^{N} \rho_i = 0 = \sum_{i=1}^{N} \rho_i^3.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Appropriate combination of the three preceding equations gives

$$V = \pi \frac{N}{6} (\bar{X}^3 + 3\bar{X}\sigma^2).$$

In a similar way, it can be shown that the area of N particles is

$$\pi N (\bar{X}^2 + \sigma^2).$$

The area/volume ratio is then

$$\frac{6}{\bar{X}} \frac{(\bar{X}^2 + \sigma^2)}{(\bar{X}^2 + 3\sigma^2)}.$$

The maximum error introduced by the assumption of symmetry was calculated as 3% from the most unsymmetrical distributions obtained.

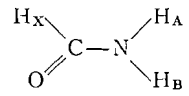
PROTON MAGNETIC RESONANCE MEASUREMENTS OF FORMAMIDE[1]



B. SUNNERS,[2] L. H. PIETTE, AND W. G. SCHNEIDER

ABSTRACT

The high-resolution proton resonance spectrum of formamide has been measured and analyzed. Quadrupole broadening of the resonance signals due to the N^{14} nucleus was eliminated by substitution of the isotopic nucleus N^{15}. Twenty-four lines were resolved in the spectrum, which is consistent with restricted rotation about the C—N bond. The non-equivalence of the two protons in the $N^{15}H_2$ group is characterized by a smaller screening constant and a greater spin–spin interaction of the proton which is in the *trans* position relative to the carbonyl group. It is suggested this difference in the spin coupling of the two protons may be associated with different N—H bond lengths. Pronounced changes in the chemical shifts and spin-coupling constants result when formamide is dissolved in dilute solution in water and acetone. In water solution the relative magnitudes of the spin coupling of the two protons in the NH_2 group is reversed from that observed in pure formamide and the coupling of the aldehyde proton to N^{15} varies by nearly 50%. Heating of formamide above room temperature causes rotation of the NH_2 group as well as proton exchange between neighboring molecules. The two effects could be separated. From the observed changes in the proton spectra as a function of temperature the barrier hindering rotation (measured in a 10 mole % solution of formamide in acetone) was found to be 18±3 kcal/mole. The activation energy for proton exchange in pure liquid formamide was found to be 10±3 kcal/mole.

INTRODUCTION

Formamide is generally regarded as an approximately planar molecule. In the absence of free rotation about the C—N bond, the proton resonance spectrum may be expected to be of the type ABX (1) containing a minimum of 12 lines. Assuming the two protons on the nitrogen atom are only slightly non-equivalent the three protons may be labelled as follows:

The observed spectrum of ordinary formamide contains only a broadish doublet partially overlapped by a very broad signal arising from the NH_2 group. The incomplete resolution and the broad nature of the lines derive from the quadrupole coupling of the N^{14} nucleus. This difficulty has been partially overcome by Piette, Ray, and Ogg (2) by use of the double-irradiation technique (3) to decouple the N^{14} nucleus. The resulting spectrum showed six lines of which four could be assigned to the "aldehyde" hydrogen and yielded the coupling constants corresponding to the spin interaction with the two protons in the amide group. The spectrum of the latter could not be completely resolved presumably because of incomplete saturation of the N^{14} nucleus. In the present work an alternative approach has been followed. Quadrupole broadening by N^{14} was eliminated by substitution of the nitrogen isotope N^{15}. Since this has spin $I = \frac{1}{2}$, sharp-line proton signals result, permitting a complete resolution and analysis of the spectrum as well as a study of proton exchange behavior and internal rotation about the C—N bond.

EXPERIMENTAL

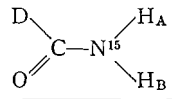
Two isotopically substituted compounds, $HCON^{15}H_2$ and $DCON^{15}H_2$, prepared by Dr. L. Leitch, Pure Chemistry Division, National Research Council, were studied. The formamide-N^{15} was prepared from ethyl formate and ammonia-N^{15}, whereas the deuterated compound was similarly obtained from deuterated ethyl formate. The pure samples (containing at least 95% N^{15}) were vacuum-distilled into 5-mm O.D. glass sample tubes, which were then sealed.

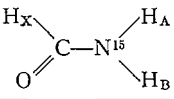
The proton resonance spectra were recorded at 40 Mc/s and at 60 Mc/s with a Varian V-4300 high-resolution spectrometer. Satisfactory resolution of the spectrum of the deuterated compound was obtained at both frequencies. However, the 40-Mc/s spectrum of the undeuterated compound was unsatisfactory for a complete analysis of the spectrum due to extensive overlapping of individual lines. The 60-Mc/s spectrum showed 20 (and in some cases 21) resolved lines out of the possible 24.* Since the spectrum extended over a wide range (~122 cycles/sec), measurement of the more widely separated line spacings tend to be somewhat more inaccurate due to residual drift in the instrument. Where possible, some lines were checked by superposition of sidebands on the oscilloscope screen but most separations were obtained with the aid of sidebands recorded with the spectrum. A further check was provided by superposing a signal from another part of the spectrum on a given signal. This signal was then repeatedly traversed and recorded, the frequency being adjusted to maximize the signal. For well-resolved signals this procedure permits the determination of signal separation to an accuracy of about 0.1 cycle/sec.

RESULTS

The proton resonance spectrum of $DCON^{15}H_2$ recorded at 60 Mc/s is shown reproduced in Fig. 1. If the two protons on the nitrogen atom are non-equivalent, a simple four-line AB-type spectrum is to be expected. Each line of this spectrum would, however, have a large splitting due to spin coupling with N^{15}. It is apparent that the observed spectrum contains additional (triplet) splitting due to the deuterium atom ($I = 1$), but this splitting is observable only on proton H_B, which is in the *trans* position relative to the deuterium atom. The value of the coupling constant, J_{DB}, is 2.1 cycles/sec. From the ratio of the nuclear gyromagnetic ratio of the proton and deuteron, the corresponding proton–proton coupling is calculated to be about 13.7 cycles/sec, in fair agreement with the value reported by Piette, Ray, and Ogg (2). This therefore identifies the signals of proton H_B, which appear at a higher field than those of proton H_A. With this assignment,† a complete analysis of the spectrum yields the chemical shift and spin-coupling constants shown in Table I.

An interesting feature of the above spectrum (cf. Fig. 1) is the noticeably larger separation of the H_A and H_B signals in the low-field half of the spectrum compared with those in the high-field half. The chemical shift, $\nu_0\delta_{AB}$, must of course be identical in both halves of the spectrum. It must be concluded therefore that the spin interaction





*In a 10 mole % solution of $HCON^{15}H_2$ in acetone all 24 lines of the spectrum could be resolved.

†As in reference 2, the assignment of signals in the spectrum to protons H_A and H_B is made on the assumption that trans coupling constants are much greater than cis coupling constants. This relationship of the coupling constants is well established for olefinic compounds (7, 8) and may be expected to hold also in formamide which is only slightly nonplanar. Moreover, the proton assignment arrived at on the basis of this assumption implies a slightly smaller shielding of the H_A proton compared with that of H_B, which is consistent with the order to be expected from the polar effects of the carbonyl group in the molecule (see below).

of proton H_A with the N^{15} nucleus is greater than that of H_B. The difference in the spin-coupling constants is about 4 cycles/sec.

TABLE I

Proton chemical shifts* and spin-coupling constants of formamide (in cycles/sec)

			8 mole % $HCON^{15}H_2$ in water	10 mole % $HCON^{15}H_2$ in acetone
$\nu_0\delta_{AB}$	12.1	12.0	20.5	12.8

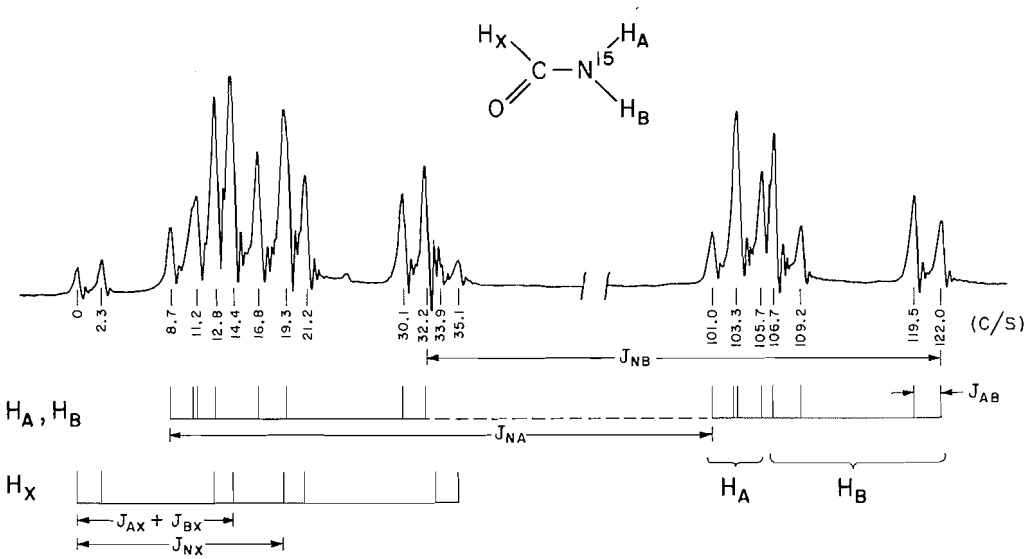

FIG. 2. Proton resonance spectrum of $HCON^{15}H_2$ at 60 Mc/s. The assignment of lines is indicated schematically at the bottom of the spectrum.

Figure 2 shows the complete spectrum of $HCON^{15}H_2$, at 60 Mc/s. If each signal is split by N^{15} the spectrum should contain at least 24 lines. Of these, 20 are clearly resolved. Unfortunately the large splitting of protons H_A and H_B by the N^{15} nucleus causes half of the AB part of the spectrum to be superimposed on the X part of the spectrum (H_X signals). The latter shows a much smaller splitting by the N^{15} nucleus. The assignment of the spectrum is indicated in Fig. 2. The analysis of the spectrum was carried out on the basis of an ABXY system, where Y is the N^{15} nucleus, and assuming the coupling constants J_{AY} and J_{BY} (designated J_{NA} and J_{NB} in Table I) to be unequal. Since J_{AY} and J_{BY} are large, this leads to an effective "chemical shift" of the H_A and H_B nuclei in the low-field and in the high-field spectra of $\nu_0\delta_{AB}+\frac{1}{2}(J_{AY}-J_{BY})$ and $\nu_0\delta_{AB}-\frac{1}{2}(J_{AY}-J_{BY})$ respectively. The X spectrum consists of two sets of four lines. The outer members in each set are separated by $(J_{AX}+J_{BX})$, whereas the separation of the corresponding lines between the two sets is J_{XY} (indicated by J_{NX} in Fig. 2). The separation between the inner lines of the low-field quartet is $2|A_+-A_-|$ and that of the inner lines of the high-field quartet is $2|B_+-B_-|$, where

$$[1] \qquad A_\pm = \tfrac{1}{2}\{[\nu_0\delta_{AB}+\tfrac{1}{2}(J_{AY}-J_{BY})\pm\tfrac{1}{2}(J_{AX}-J_{BX})]^2+J_{AB}^2\}^{1/2},$$

$$[2] \qquad B_\pm = \tfrac{1}{2}\{[\nu_0\delta_{AB}-\tfrac{1}{2}(J_{AY}-J_{BY})\pm\tfrac{1}{2}(J_{AX}-J_{BX})]^2+J_{AB}^2\}^{1/2}.$$

The results of the analysis are given in the third column of Table I. The estimated error in the chemical shifts and spin-coupling parameters is about ± 0.15 cycle/sec. It was not possible to determine relative signs of the spin-coupling constants.

The spin-coupling interaction of the N^{15} nucleus is again found to be greater with proton H_A than with proton H_B. This is a rather unexpected result if the two protons are symmetrically disposed with respect to the C—N bond axis. A very probable interpretation is, however, suggested by a recent structure determination of formamide by Costain and Dowling (4) from the microwave spectrum of the vapor, which showed the molecule to be nonplanar. The NH_2 (amide) group was found to have a pyramidal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

structure with a characteristic inversion frequency. Moreover the two N—H bonds have unequal lengths, that which is *trans* to the carbonyl group having a bond length of 1.000 Å while that of the other is 1.012 Å. This difference in bond lengths would seem to provide a simple explanation for the observed difference in the coupling constants J_{NA} and J_{NB} since it is reasonable to expect a greater spin-coupling interaction in the shorter bond.*

The relative screening constants of protons H_A and H_B may also be expected to be affected by the difference in the N—H bond lengths and bond hybridization and to make the two protons non-equivalent. However, there are undoubtedly other contributing factors to the screening constants. In the first place the results show the proton H_A to be less screened (resonance at lower field) than H_B. This is not the relative order to be expected if the N—H_A bond length is shorter than that of N—H_B. In the liquid state the molecules are strongly hydrogen-bonded which could conceivably alter the degree of planarity of the molecule and the N—H bond lengths from those determined in the gaseous state, thus altering the relative screening constants (and possibly also the spin-coupling constants). The polar effect of the carbonyl group will also contribute to the screening constants of protons H_A and H_B. This contribution will tend to reduce the screening of proton H_A in the isolated molecule (5) and will become further enhanced in the liquid due to the "reaction" field of the surrounding molecules (6).

The present results confirm the large (six-fold) difference between the *cis* and *trans* proton-coupling constants in formamide. The observed values, $J_{AX} = 2.1$ cycles/sec and $J_{BX} = 12.9$ cycles/sec, are in good agreement with those reported by Piette, Ray, and Ogg (2). The relatively small value of J_{AB} (2.4 cycles/sec) is comparable to the small proton–proton coupling constants observed for the gem hydrogens of substituted ethylenes (7).

Solutions of Formamide in Water and Acetone

Proton resonance spectra of an 8 mole % solution of $HCON^{15}H_2$ in water and of a 10 mole % solution in acetone were measured. The results are shown in Table I. Of particular interest are the changes in the chemical shifts and some of the spin-coupling constants compared with those observed in the pure liquid. All three systems are characterized by strong hydrogen-bonding interactions between the molecules and the observed changes in chemical shifts and spin-coupling constants must arise from the different nature of the interaction in the three systems. Changes in hydrogen-bonding interactions are known to produce large changes in proton chemical shifts, but ordinarily proton spin-coupling constants are not appreciably affected by such changes. In the present systems the spin-coupling constants show surprisingly large variations, amounting in one case, J_{NX}, to nearly 50%. Also for the water solution J_{NB} is increased by $\sim$7 cycles/sec and in this instance its magnitude exceeds that of J_{NA}, a reversal of the situation found in the other two systems. Such changes in the coupling constants, which are not well understood at present, may involve in the present example a change in the molecular geometry in addition to changes in molecular charge distributions. There are of course important differences in the nature of the hydrogen-bonding interactions in these systems. Thus in the acetone solution it may be supposed that the protons of the NH_2

This difference in the two coupling constants may also be modified to some extent by small differences in bond hybridization (see, for example, Muller and Pritchard, J. Chem. Phys. **31, 768 (1959) and Karplus and Grant, Proc. Natl. Acad. Sci. **45**, 1269 (1959)). The bond angles ∠ CNH_A and ∠ CNH_B are respectively 120°17′ and 117°11′ with the ∠ H_ANH_B being 119°22′ (ref. 4). Thus if the N—H_A bond has a slightly greater s-character than the N—H_B bond this could contribute to making J_{NA} slightly greater than J_{NB}. We are indebted to a referee for pointing out this possibility.*

group are strongly bonded to the acetone carbonyl group, leaving the carbonyl group in the formamide molecule itself relatively free. However, in a dilute solution in water the carbonyl group will be monopolized by the water protons, leaving the NH_2 protons to be bonded to the oxygen atoms of neighboring water molecules. The proton resonance spectrum of the water solution at room temperature showed no evidence of proton exchange of the amide protons.

Hindered Internal Rotation and Proton Exchange in Formamide

By analogy with dimethyl formamide, which has a relatively high barrier hindering rotation about the C—N bond (9, 10), an observable hindered rotation of the NH_2 group in formamide may be expected. The onset of the rotation will be characterized by a broadening and ultimate coalescence of lines in the proton spectrum. This does in fact occur when the pure compound is heated above room temperature. It is possible to demonstrate, however, that proton exchange involving the NH_2 groups also sets in and contributes to the observed signal broadening and coalescence. Proton exchange can be satisfactorily eliminated over the required temperature range by working with a dilute solution of formamide in acetone. Under these conditions the formamide molecules are relatively isolated from each other and are hydrogen-bonded to the acetone with which they cannot exchange.

In order to measure the barrier hindering rotation of the NH_2 group the proton spectrum of a 10 mole % solution of formamide in acetone was recorded at intervals of 2 or 3° C as the solution was progressively heated above room temperature. A few illustrative traces are reproduced in Fig. 3. It may be noted that at 25° C all 24 lines of the spectrum are clearly resolved. By far the most striking changes which appear in the spectrum on raising the temperature are those that occur in the H_X spectrum, which consists of eight lines on the extreme left (low-field side) of the spectrum. As mentioned earlier these eight lines result from the N^{15} doubling of the ordinary four-line X spectrum (cf. Fig. 2). For the present purpose we need only consider the quartet at lowest field, i.e. the four lines on the extreme left of the spectrum in Fig. 3. The two outer lines in this quartet have the separation $|J_{AX}+J_{BX}|$ while the two inner lines are separated by $2|A_+-A_-|$, where A_+ and A_- are given by equation [1]. It is apparent from Fig. 3 that as the temperature is raised and internal rotation sets in, the two outer lines remain sharp and unaltered in position whereas the two inner lines broaden and ultimately coalesce. When the rotation of the NH_2 group becomes sufficiently rapid, the quantities $\nu_0\delta_{AB}$, J_{AB}, $(J_{AY}-J_{BY})$, and $(J_{AX}-J_{BX})$ all average to zero, and therefore the quantities A_+ and A_- (see eq. [1]) both become zero and the two inner lines must coalesce. However, the quantity $|J_{AX}+J_{BX}|$ is unaffected and the two outer lines remain unchanged. This sequence of changes converts the quartet to a triplet, the central component being doubly degenerate and separated by $\frac{1}{2}(J_{AX}+J_{BX})$ from the two outer lines. Thus the total formamide spectrum has been changed from one of type ABXY to one of type A_2XY by virtue of rapid rotation of the NH_2 group. This fact suggests that even at 98° proton exchange is still relatively unimportant. If proton exchange were rapid the final spectrum would have consisted of a doublet for the H_X signals, resulting from the N^{15} splitting, and a single line for the NH_2 group. It is apparent, however, that the traces at 75° and 98° in Fig. 3 have broader lines in the X spectrum which may be attributed to the onset of slow proton exchange at these higher temperatures. The progressive shift of the H_A and H_B signals toward higher field with increasing temperature results from increased dissociation of the hydrogen bonds formed by these hydrogens with the acetone solvent.

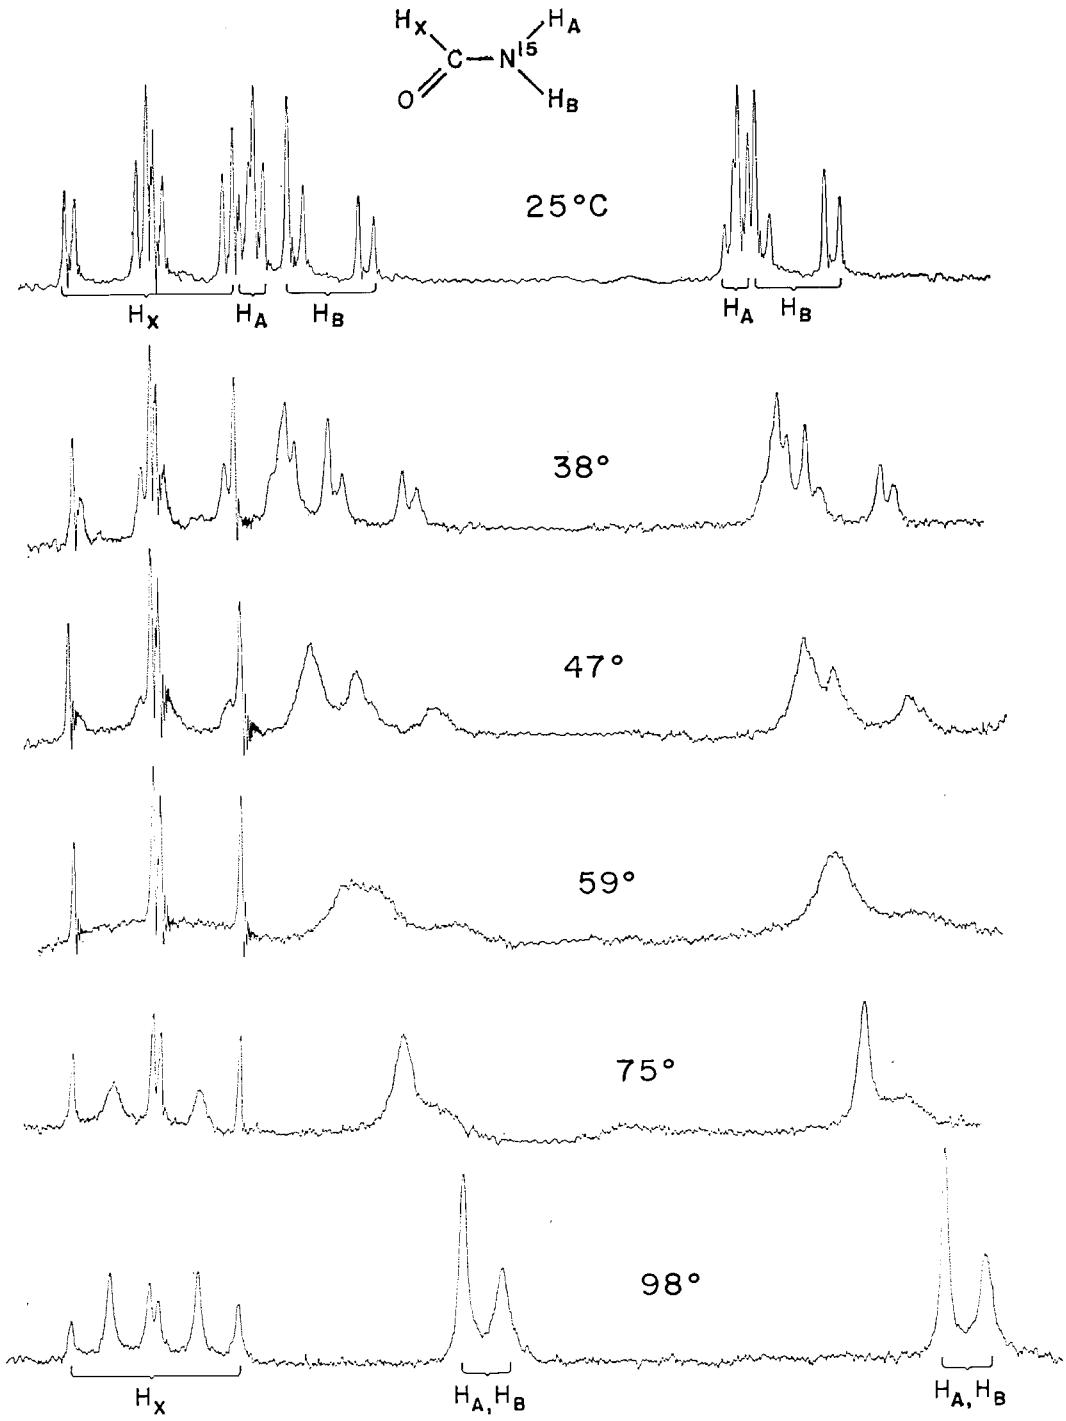

FIG. 3. Proton magnetic resonance spectrum of 10 mole % solution of $HCON^{15}H_2$ in acetone at various temperatures showing signal broadening and coalescence due to hindered rotation of the NH_2 group.

In order to evaluate the potential barrier hindering rotation, the lifetimes, τ, of the protons at positions H_A and H_B were evaluated from the broadening of the lines in the X spectrum from the simple relation

$$[3] \qquad \frac{1}{\tau} = \frac{1}{T_2'} - \frac{1}{T_2}$$

where $1/T_2'$ is taken as the half-band width of the broadened line and $1/T_2$ the effective line width in the absence of rotational broadening. The latter could be conveniently measured from the outer (unbroadened) lines in the X spectrum. To extend the range of observable τ values the additional relation (10)

$$[4] \qquad \tau = \frac{\sqrt{2}}{2\pi\Delta\nu}$$

was employed. Here $\Delta\nu$ (in cycles/sec) is the separation of appropriate spin multiplet peaks in the AB spectrum whose coalescence is observed. The data employed were obtained in the temperature range of 25° to 62° C. From a plot of $\ln \tau$ vs. $1/T$ the mean value of the rotational barrier was found to be 18 ± 3 kcal/mole.

Proton exchange measurements were carried out on samples of pure formamide rather than on the acetone solution. At higher temperatures, where internal rotation is already rapid, a further broadening and signal coalescence results from the onset of rapid proton exchange. Values of τ were evaluated with the aid of the relations given in equations [3] and [4]. A somewhat greater scatter of individual τ values compared with those obtained at lower temperatures was evident. The mean activation energy for proton exchange between formamide molecules was found to be 10 ± 3 kcal/mole.

ELECTRON SPIN RESONANCE STUDIES OF THE RADIATION-INDUCED ADDITION OF HBr TO C_2H_4 IN THE SOLID STATE[1]

F. W. MITCHELL,[2] B. C. GREEN, AND J. W. T. SPINKS

ABSTRACT

Electron spin resonance measurements at 77° K have been used to study the hydrobromination of ethylene induced by γ irradiation of the solid mixture at liquid nitrogen temperatures. The evidence resulting from these studies has given valuable information regarding the reaction intermediates and has been used in formulating a likely reaction mechanism.

INTRODUCTION

The addition of hydrogen bromide to ethylene under the influence of γ rays has been previously studied by Armstrong and Spinks (1, 2). The reaction is a chain reaction in the gas, liquid, and solid states; for example, with a dose rate of 450 r per minute, an initial G value of about 10^5 was found for additions in the liquid phase. G values in the solid phase were appreciably lower, particularly for long irradiations at liquid nitrogen temperatures.

A free radical chain reaction has been suggested for the reaction. The present work describes additional experiments, emphasizing e.s.r. techniques, bearing on the suggested mechanisms.

EXPERIMENTAL

Purification of Materials

Cylinder HBr and C_2H_4 were passed through a P_2O_5 drying tube and then subjected to a number of bulb-to-bulb distillations under high vacuum at liquid nitrogen temperatures. Both were finally distilled from a bath at −78° C.

Apparatus

A general purpose high vacuum apparatus was used. After measurement the reactants were distilled into a simple reaction vessel constructed of 7-mm Pyrex tubing fitted with stopcock and joint. The volume of solid resulting from the usual amounts of reactants was very close to 0.5 ml.

Irradiations were conducted in a Dewar vessel of liquid nitrogen employing Co^{60} sources of both 90 curies and 1100 curies.

Gas chromatographic studies were made using various columns and introducing the reaction products in the gaseous form. Column temperature control was available.

Electron spin resonance studies were made with a Varian V 4500 spectrometer. A cavity and Dewar were constructed to enable studies to be performed at 77° K. Some quantitative spin measurements were attempted using a range of DPPH solutions in dry benzene as standards.

Hyperfine splittings and line widths were determined by means of a Varian standard supplied by the manufacturers. Ferrous sulphate dosimetry was employed for dose rate estimations.

Results

The normal experimental technique adopted was to mix the reactants after pressure measurements and condense them rapidly into the tip of the reaction vessel. After

[1]*Manuscript received January 21, 1960.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*National Research Council Postdoctorate Fellow, 1958–1960.*

irradiation, the vessel was reattached to the vacuum line and allowed to warm up to room temperature. In agreement with the simple scheme,

$$C_2H_4 + HBr \rightarrow C_2H_5Br,$$

equimolar amounts of reactants undergo a 50% pressure reduction for 100% addition (2). This does not preclude the formation of small amounts of other products, and accordingly the nature of the reaction products was further investigated by gas chromatography.

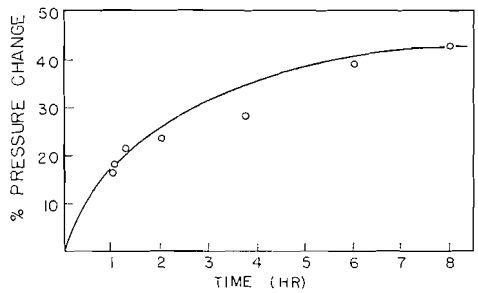

FIG. 1. Pressure change curve.

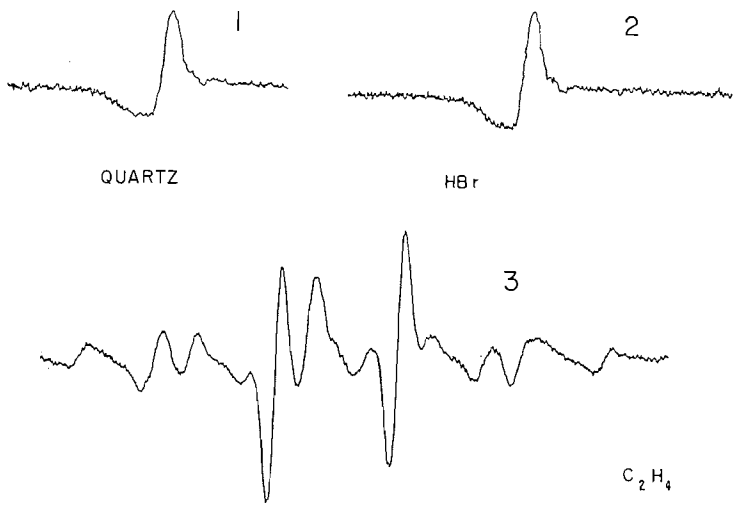
Figure 1 depicts the percentage pressure change plotted against time for single irradiations of equimolar solid mixtures. It can be seen that a 50% change could not be achieved (though stepwise irradiation of the same mixture with interim melting and cooling results in such a change). A 13-hour single irradiation gave a result slightly lower than that at 8 hours so that the limiting value of percentage of ΔP may be taken as about 42%.

Gas Chromatography

Columns of dinonyl phthalate and silicone Hyvac grease on inert supports were used for the detection of products. Runs in which at least 80% addition had occurred were taken for analysis.

The principal product was clearly ethyl bromide, which had a retention time of 16 minutes at room temperature in a 4-ft DNP column. GLC revealed that attempts to separate mixtures of HBr, C_2H_4, and C_2H_5Br by fractionation at $-120°$ C had been unsatisfactory.



Of interest was the appearance of unknown peaks after 2 minutes at 26° C on the DNP column and 16 minutes at 50° C on the silicone column. Quantitative measurements based on relative peak areas indicated both to be present in a ratio of about 1:4000 compared with the amount of ethyl bromide. A sample of ethylene dibromide was taken and shown to have a retention time identical with that of one of the unknown peaks (16-minute one). The other unknown has a retention time suggesting that it is butene-1.

Electron Spin Resonance Studies

Samples of C_2H_4, HBr, C_2H_5Br, and C_2H_4–HBr mixtures were irradiated at 77° K in a 1100-curie cobalt-60 unit in 5-mm quartz tubing. Previous to irradiation, they were measured and degassed on the vacuum line. The dose rate for all samples was 1545 r per minute, or 8.42×10^{16} ev/g per minute.

The samples which had been irradiated in the dark were then transferred within 1 second to a specially constructed light-tight Dewar vessel, containing liquid nitrogen,

TRACE 1. Irradiated quartz.
TRACE 2. Irradiated hydrogen bromide.
TRACE 3. Irradiated ethylene.

the tip of which extended into the spectrometer cavity. Some examples of the traces obtained are given.

Trace 1 depicts the thermoluminescence peak arising from an evacuated quartz blank which had been given a dose of 9.26×10^5 r. The entire quartz trace was found to disappear on warming to room temperature. Bleaching with tungsten light at 77° K resulted in an almost complete disappearance of the trace.

Trace 2 arises from 118 cc NTP of HBr at identical spectrometer settings with trace 1 and results from the same dose, i.e., 9.26×10^5 r. No evidence of radical absorption from the sample can be seen. More extensive investigation revealed absorption due to the presence of H atoms but not due to anything else.

Trace 3 was obtained from 118 cc NTP of C_2H_4. On integration and correction for the central thermoluminescence peak (due to the quartz, i.e., trace 1), the corrected absorption curve is as in Fig. 2. The outside line separation was 145.2 gauss and the quartet

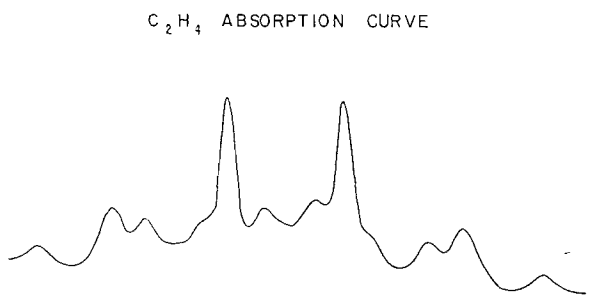

FIG. 2. True ethylene absorption curve (corrected).

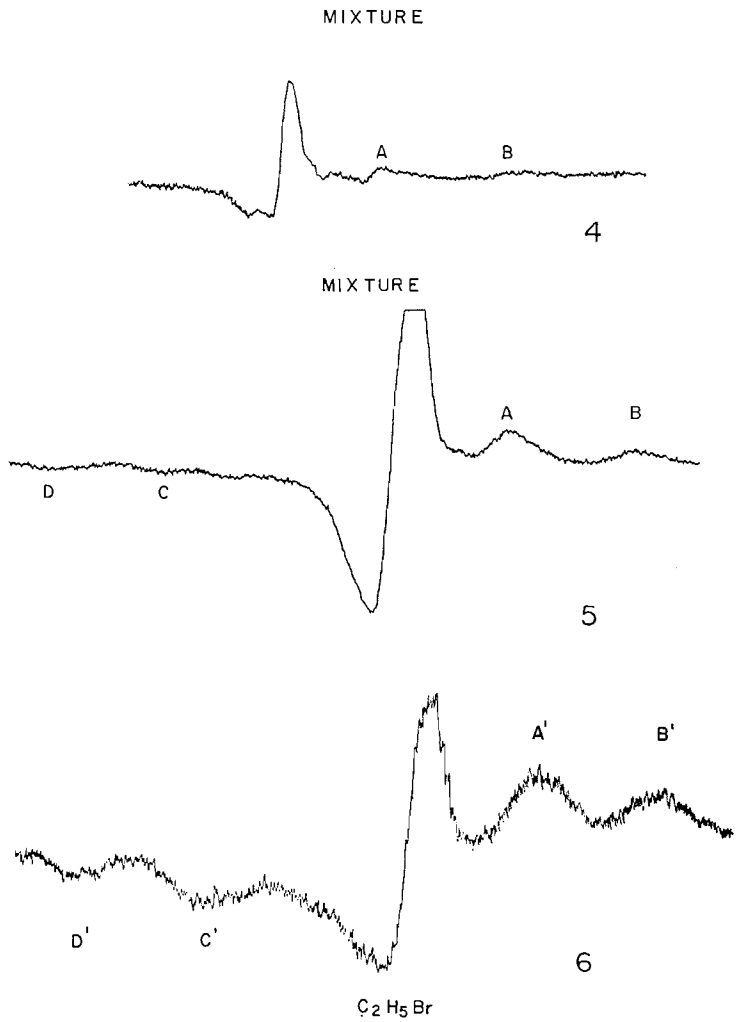
separation 87 gauss, the average separation between the quartet peaks being 29 gauss. This appears to correspond well with the quartet of triplets reported by Smaller and Matheson (3), resulting from the γ irradiation of ethane, ethylene, and ethyl chloride (quartet separation 79 gauss).



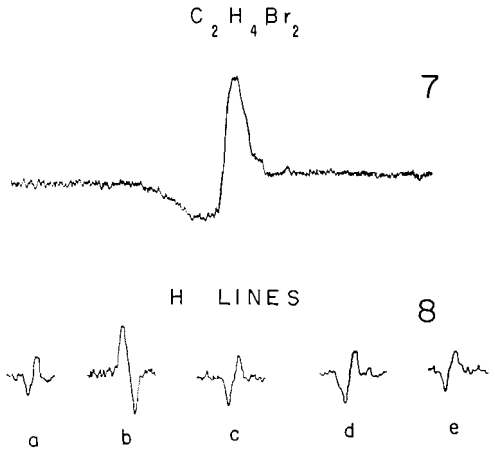
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The number of ethylene molecules present was 3.18×10^{21}. Comparison of trace 3 with a standard DPPH sample in dry benzene indicated that there were 5.4×10^{16} spins present. If the trace arises from ethyl radicals, this indicates their concentration to be about 1 in 5×10^{4} of the ethylene molecules present. The total dose was 9.26×10^{5} r or 0.85×10^{19} ev. Assuming no ethyl radical decay, this gave a G value for their formation of 0.63.

Trace 4 was obtained from a mixture of 59 cc C_2H_4 and 59 cc HBr given a dose of 9.26×10^{5} r. All evidence of ethyl radicals arising in trace 3 was absent. The small 'peaks' at A and B arise from radical structure but are very weak.

Traces 1–4 were made at identical power and spectrometer settings and, as such, are directly comparable.

Trace 5 arises at higher gain settings than trace 4 and brings out the peaks A and B more clearly. An unsuccessful attempt was made to split peak A into hyperfine lines.



TRACE 4. Irradiated equimolar ethylene – hydrogen bromide mixture.
TRACE 5. As trace 4; higher spectrometer settings.
TRACE 6. Irradiated ethyl bromide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Further very weak "peaks" at C and D appear to be present in this trace. The splitting from A to C is 81.6 gauss and from A to B 30.5 gauss.

Trace 6 arises from a sample of ethyl bromide which was degassed, sealed under vacuum, and given a dose of 4.63×10^5 r, i.e., half that of the other samples. The positions of A′, B′, C′, and D′ are identical with those of A, B, C, and D in trace 5. The difference in appearance arises, no doubt, from differing amounts of radicals, but it appears likely that the same radical species is involved in both cases.

TRACE 7. Irradiated 1,2-dibromoethane.
TRACE 8. H lines: (*a*) quartz, (*b*) C_2H_4, (*c*) HBr, (*d*) C_2H_4–HBr, (*e*) $C_2H_4Br_2$.

Trace 7 was obtained from a sample of dibromoethane which had been degassed, sealed under vacuum, and given a dose of 9.26×10^5 r. Surprisingly, no trace of radical structure was observable, and the trace is identical with that arising from quartz treated similarly.

Trace 8 illustrates the high field H lines from (*a*) a quartz blank, (*b*) 118 cc NTP C_2H_4, (*c*) 118 cc NTP HBr, (*d*) 118 cc NTP equimolar C_2H_4–HBr mixture, (*e*) dibromoethane treated as described above. It can be tentatively inferred that the H atom concentration was highest in the ethylene samples, although the unexpected H line resulting from an evacuated quartz blank makes it impossible to ascertain from trace 8 whether H atoms are present in samples other than ethylene. Comparison with a standard sample of DPPH in benzene suggested that the H atom concentration in ethylene was a factor of the order of 10^3 lower than the ethyl radical concentration in the same sample. This is in partial disagreement with Matheson (3), who did not find any H atom doublet for ethylene but did find that at 77° K the hydrogen atom doublet for irradiated ethane was relatively weak compared with the ethyl radical trace.

DISCUSSION

The foregoing work helps to clarify the reaction mechanism suggested by Armstrong and Spinks (1). The presence of small amounts of ethylene dibromide among the end products suggests the reaction:

$$Br + C_2H_4Br \rightarrow C_2H_4Br_2 \qquad [1]$$

as a main termination reaction. The presence of butene-1, if confirmed, would possibly indicate the reaction

$$C_2H_5 + C_2H_3 \rightarrow C_4H_8. \qquad [2]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The main evidence of interest stems from the e.s.r. work which indicates that ethyl radicals result from the irradiation of ethylene and that H atoms result from the irradiation of ethylene. Of great interest is the fact that irradiation of C_2H_4–HBr mixtures shows no measurable trace due to ethyl radicals, indicating that the C_2H_5 radical reacts very rapidly even at liquid nitrogen temperatures. That the radical species present in a C_2H_4–HBr mixture and C_2H_5Br after irradiation should be identical (traces 5 and 6) is also of extreme interest and could possibly be taken to indicate that the chain reaction had already occurred before warming. However, the difficulty of diffusion of large radicals such as C_2H_4Br in the mixture and the energy requirements of the chain propagating steps would make this unlikely at 77° K. A more satisfactory suggestion would be that the radical species involved is C_2H_4Br, which would be the most likely radiation product of C_2H_5Br and which could arise in C_2H_4–HBr mixtures at 77° K in the manner indicated below. Nothing is known of the e.s.r. structure of such a radical at present, but the presence of a bromine isotope with a nuclear spin of 3/2 would undoubtedly make it complex.

As has been mentioned above, an extensive examination of the trace resulting from irradiated HBr revealed no absorption other than that arising from the quartz sample tube. It would also be difficult to state that the hydrogen line arising in trace 8 resulted from any higher concentration of hydrogen atoms than was present in the quartz blank. Bromine atoms, if present, would be paramagnetic and give rise to e.s.r. absorption. It would thus appear likely that neither hydrogen nor bromine atoms produced in the primary radiation processes had escaped recombination. The following series of reactions were proposed by Zubler, Hamill, and Williams (4) to be consistent with their studies on the X radiolysis of HBr.

$$HBr \rightarrow HBr^+ + e \quad [3]$$

$$e + HBr \rightarrow H + Br^- \quad [4]$$

$$Br^- + HBr^+ \rightarrow H + 2Br \quad [5]$$

$$H + HBr \rightarrow H_2 + Br \quad [6]$$

In the solid phase at 77° K the above mechanism is a likely one, and dissociative electron capture by the parent ion will be of increased importance.

$$HBr^+ + e \rightarrow HBr^* \quad [7a]$$

$$HBr^* \rightarrow H + Br \quad [7b]$$

The γ irradiation of pure ethylene might be expected to occur as follows:

$$C_2H_4 \rightarrow C_2H_4^+ + e \quad [8]$$

$$C_2H_4^+ + e \rightarrow C_2H_4^* \quad [9a]$$

$$C_2H_4^* \rightarrow C_2H_3 + H \quad [9b]$$

$$C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3 \quad [10]$$

Again reaction [9*a*] is a more likely one in the solid phase. The charge transfer reaction [10] which was proposed by Field *et al.* (5) in the electron radiolysis of ethylene can doubtless result in other alternative products.

The e.s.r. studies (traces 3 and 8) strongly suggest that the only radical species present is the ethyl radical and that H atoms are present in the solid phase before warming. Ethyl radicals could arise from the reaction,

$$H + C_2H_4 \rightarrow C_2H_5, \quad [11]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

which is likely to have a very low activation energy (6) and which has been shown to occur at liquid air temperatures (7). This mechanism receives strong support from recent work (12, 13) which has indicated that hydrogen atoms readily add to olefins at 77° K to produce alkyl radicals in a manner which is likely to result in their stabilization in the matrix.

If reaction [9*b*] is the chief source of hydrogen atoms, the ethylenyl radical, C_2H_3, presumably disappears by some radical combination reaction such as (2).

In the irradiation of ethylene – hydrogen bromide mixtures energy transfer processes can readily occur.

$$HBr^+ + C_2H_4 \rightarrow HBr + C_2H_4^+ \qquad [12a]$$

$$HBr^* + C_2H_4 \rightarrow HBr + C_2H_4^* \qquad [12b]$$

Ethylene, having a ground state containing a considerable number of states of higher multiplicity than the singlet, is a particularly effective quencher (8).

Traces 4 and 5 indicate that the ethyl radicals arising in the irradiation of pure ethylene are not present in the mixture at 77° K. A simple explanation of their disappearance would be the occurrence of the combination reaction,

$$C_2H_5 + Br \rightarrow C_2H_5Br, \qquad [13a]$$

which is likely to have zero activation energy.

Alternatively, the ethyl radical might disappear by the hydrogen abstraction reaction

$$C_2H_5 + HBr \rightarrow C_2H_6 + Br. \qquad [13b]$$

This has been calculated to have a low activation energy (2 kcal) by Anderson *et al.* (9). The presence of excited HBr molecules would enhance the likelihood of reaction [13*b*].

The identical nature of the radical species present in ethyl bromide and the mixture (traces 5 and 6) might very well be due to the presence of the C_2H_4Br radical, which is the most probable common radiation product of the two systems at 77° K.

Quantitative observations based on DPPH standards suggest that the number of radical spins in the irradiated mixture is very much less than 5.4×10^{16}, which is the calculated value for the ethyl radicals in trace 3.

Vaughan *et al.* (10) proposed a chain mechanism for the photo-addition of hydrogen bromide to ethylene in which the propagating steps were

$$Br + C_2H_4 \rightarrow C_2H_4Br, \qquad [14]$$

$$C_2H_4Br + HBr \rightarrow C_2H_5Br + Br. \qquad [15]$$

It is most probable that the same propagating mechanism is involved in the radiation-induced addition being studied here and the occurrence of reaction [14] at 77° K could obviously account for the presence of C_2H_4Br radicals in the mixture before warming. The activation energy for this reaction has been shown to be zero from studies on the photobromination of ethylene (11).

Evidence exists to show that ethylene and hydrogen bromide form a loose compound ($C_2H_4.HBr$) on condensing the mixture in the solid phase. Thus, the occurrence of the ionization and electron capture reactions [8] and [4], respectively, might well, as a result of proximity, favor the charge neutralization process

$$C_2H_4^+ + Br^- \rightarrow C_2H_4Br \qquad [16]$$

which, therefore, would be an alternative source of C_2H_4Br radicals.

For personal use only.

Termination of the reaction chain can occur in a number of ways as suggested by Armstrong and Spinks in reactions [17] to [20*b*] of their paper (1).

The nature of the radical species present in irradiated ethyl bromide and C_2H_4–HBr mixtures together with other alkyl halides, and the reasons for the somewhat abnormal appearance of their e.s.r. traces are being further investigated. Temperature control above 77° K of samples examined by e.s.r. techniques would obviously be very informative with regard to the warm-up of the irradiated solid mixture.

ACKNOWLEDGMENTS

We are grateful to Dr. J. Bardwell for assistance with the gas chromatography measurements and to the Atomic Energy Control Board for financial assistance. One of us (F. W. M.) is indebted to the National Research Council of Canada for the award of a Postdoctorate Fellowship.

POTASSIUM DERIVATIVES OF FLUORENE AS INTERMEDIATES IN THE PREPARATION OF C_9-SUBSTITUTED FLUORENES

I. THE PREPARATION OF 9-FLUORENYL POTASSIUM AND THE INFRARED SPECTRA OF FLUORENE AND SOME C_9-SUBSTITUTED FLUORENES[1]

G. W. H. Scherf and R. K. Brown

ABSTRACT

9-Fluorenylpotassium and 9,9-fluorenyldipotassium have been prepared from the reaction of potassium metal with fluorene in dioxane. These organometallic compounds upon reaction with alkyl and aralkyl halides gave 9-substituted fluorenes.

Six different absorption bands in the spectrum of fluorene could be associated with the methylene group: 2930, 1400, 1298, 952, and 692 cm^{-1}. Evidence for this assignment was obtained from deuteration of the organometallic compounds of fluorene and from 9-substituted fluorenes.

INTRODUCTION

During a study of the reactions of certain substances with fluorene it was found desirable to have at hand direct and relatively simple methods for the preparation of C_9-mono- and C_9-di-substituted fluorenes uncomplicated by contaminating side reactions due to addition of bases (1) usually required to effect reaction at the methylene group. In addition, quite indispensable would be a reliable and rapid method for distinguishing between mono- and di-substitution at C_9, which would thus simplify the assessment of mixtures of 9-mono- and 9-di-substituted fluorenes and permit the investigator to follow more conveniently the separation of such mixtures. It was thought that monovalent metal "salts" of fluorene might lend themselves readily to the attainment of the first goal, while infrared spectroscopy should be most admirably suited to the second. Both the literature evaluation and the experiments described in this report show that this is indeed the case.

9-SUBSTITUTED FLUORENES FROM 9-FLUORENYLSODIUM AND 9,9-FLUORENYLDIPOTASSIUM

Synthesis of C_9-substituted fluorenes has been reviewed by Rieveschl and Ray (2). Generally, alkaline conditions promote the transient formation of the 9-fluorenyl carbanion which then by nucleophilic attack upon compounds of suitable structure produces the desired structure (2, 3). Equimolar proportions of fluorene, base, and substrate are expected to form 9-monosubstituted fluorenes, but there are reports which show that di- rather than mono-substitution has in fact occurred (4).

The formation of 9-fluorenylsodium by direct reactions between fluorene and metallic sodium, although reported in the patent literature, has been found highly unsatisfactory both in this laboratory and by other workers (3). However, Greenhow *et al.* describe the preparation of 9-fluorenylsodium in good yield by the reaction of sodamide with fluorene in boiling decalin (3). Through this organometallic compound the C_9-monosubstituted fluorenes are accessible (3, 5–8). Indirect preparation of 9-fluorenylsodium via interchange with triphenylmethyl sodium (9) and, more conveniently, of 9-fluorenyllithium from alkyllithium compounds (10, 11) provide other routes, though somewhat more complicated, to the preparation of 9-substituted fluorenes. The Grignard reagent, 9-fluorenyl-

[1]*Manuscript received January 4, 1960.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

magnesium bromide, is reported to lead to monosubstitution at C_9, but reactions leading to dimeric products occur in some of the cases studied (10).

We have repeated the preparation of 9-fluorenylsodium according to Greenhow (3) and although the reported high yields and fine quality of the organometallic compound could not be duplicated, the salt was obtained in reasonable yield and in a state suitable for the synthesis of the 9-monosubstituted fluorenes as described by Greenhow and co-workers (3, 5). The 9-methyl-, 9-allyl-, and 9-benzyl-fluorenes required for this work were made by this method.

The 9,9-disubstituted fluorenes were readily obtained from 9,9-fluorenyldipotassium. Little work appears in the literature concerning the potassium salt of fluorene. Weissgerber (12) reported the preparation of 9-fluorenylpotassium by fusion of solid potassium hydroxide with fluorene at 280° from which was isolated a substance whose analysis indicated the composition $C_{13}H_9K$. This substance he then treated with benzyl chloride to form the 9-benzylfluorene. However, as Thiele and Henle have shown (13), the compound actually obtained was 9,9-dibenzylfluorene. A repetition of Weissgerber's experiment led to the conclusion that this method for the preparation of fluorenylpotassium also was quite unsatisfactory for our purpose.

It was found in this laboratory that potassium metal reacts readily with fluorene in boiling dioxane, protected by an atmosphere of nitrogen, to produce at will either the mono- or di-potassium salt as a reddish-brown precipitate. Hydrogen gas is evolved. This precipitate can be freed of unreacted fluorene by filtration and washing with dry hexane. The monopotassium derivative, obtained by the reaction of equimolar proportions of potassium and fluorene, can be isolated under nitrogen as a solid* quite suitable for further reaction. Usually it is more convenient to leave the solid suspended either in the original dioxane, or in the hexane wash liquid where it can be kept for some time with little decomposition. Exposure to air causes rapid decomposition to a dark mass which is essentially potassium hydroxide, 9-fluorenone, 9-fluorenol, and fluorene, the relative amounts of these depending upon the accessibility to oxygen or water of the air. Attempts to analyze the isolated monopotassium salt gave low values for potassium presumably due to absorption of water and/or oxygen from the air during weighing manipulations. Three analyses gave an average value of 15.3% of potassium. The theoretical value is 19.15%. It was felt that the highly elaborate procedure obviously necessary for a satisfactory potassium analysis was superfluous to our work at this time hence further attempts in this direction were abandoned.

The dipotassium compound, precipitated from the reaction of one equivalent of fluorene with two of potassium, could not be isolated readily as above, and therefore was used in dioxane suspension immediately following its preparation. That we were actually dealing with the dipotassium compound was supported by (*a*) the fact that *two* equivalents of potassium metal were totally consumed by *one* equivalent of fluorene whereas potassium metal itself showed no visible reaction when heated alone with dioxane over a period of 8 hours, (*b*) the infrared spectrum of dideuterated fluorene (described later) obtained from the dipotassium compound, and (*c*) the nuclear magnetic resonance analyses for deuterium† which showed the absence of any peak corresponding to the methylene group of fluorene. On the other hand, the monopotassium compound, when deuterated, showed strong evidence from the infrared spectra that essentially 9-monodeuterofluorene had been obtained, contaminated with a small amount of unreacted

*The presence of particles of unreacted potassium accelerates the decomposition of the organometallic compound hence it is advisable to carry the reaction to completion with respect to the metal.

†The deuterium analyses were made by Dr. W. Schneider of the National Research Council of Canada in Ottawa.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

fluorene and some 9,9-dideuterofluorene. This is supported by the nuclear magnetic resonance spectra which indicate approximately 75% monodeuteration. Rather than postulate that the "9-fluorenylpotassium" contained fluorene *and* 9,9-fluorenyldipotassium (a condition highly unlikely due to the great reactivity of the dipotassium compound) the results can be better explained by assuming that in the presence of KOD and excess D_2O, during the preparation and isolation procedure, a hydrogen–deuterium exchange has occurred, thus producing some C_9-dideuterated fluorene.

The addition of slightly more than two equivalents of alkyl or aralkyl halide to the suspension of the dipotassium compound in dioxane produced 9,9-disubstituted fluorenes in yields of about 65%. No further attempts were made at this time to improve yields since the reactions of the metallated fluorenes will be elaborated in a subsequent publication. In this way 9,9-dimethyl-, 9,9-dibenzyl-, and 9,9-diallyl-fluorene were prepared.

Reaction of the mono- and di-potassium compounds, in dioxane, with excess deuterium oxide gave 9-monodeutero- and 9,9-dideutero-fluorene respectively.

THE INFRARED SPECTRA OF FLUORENE AND SOME OF ITS C_9-MONO- AND C_9-DI-SUBSTITUTED DERIVATIVES

The information concerning the infrared studies of fluorene and its 9-substituted derivatives is meager. Fox and Martin (14) in a study of the absorption in the 3000 cm^{-1} region, due to the methylene group in a number of organic compounds, attributes two frequencies, 2901 cm^{-1} and 2795 cm^{-1}, to the $=CH_2$ of fluorene. In the present work the spectra of fluorene determined in carbon tetrachloride did not reveal absorption at these two frequencies which could be associated with the methylene group in fluorene. Richards and Thomson (15), investigating the spectral changes occurring in liquid–solid state transitions give two frequencies, 1303 cm^{-1} and 1482 cm^{-1}, apparently characteristic of fluorene. Both of these frequencies are found in this work, that in the 1300 cm^{-1} region is definitely associated with the CH_2 group while the 1482 cm^{-1} band appears to be due to some other part of the fluorene structure.

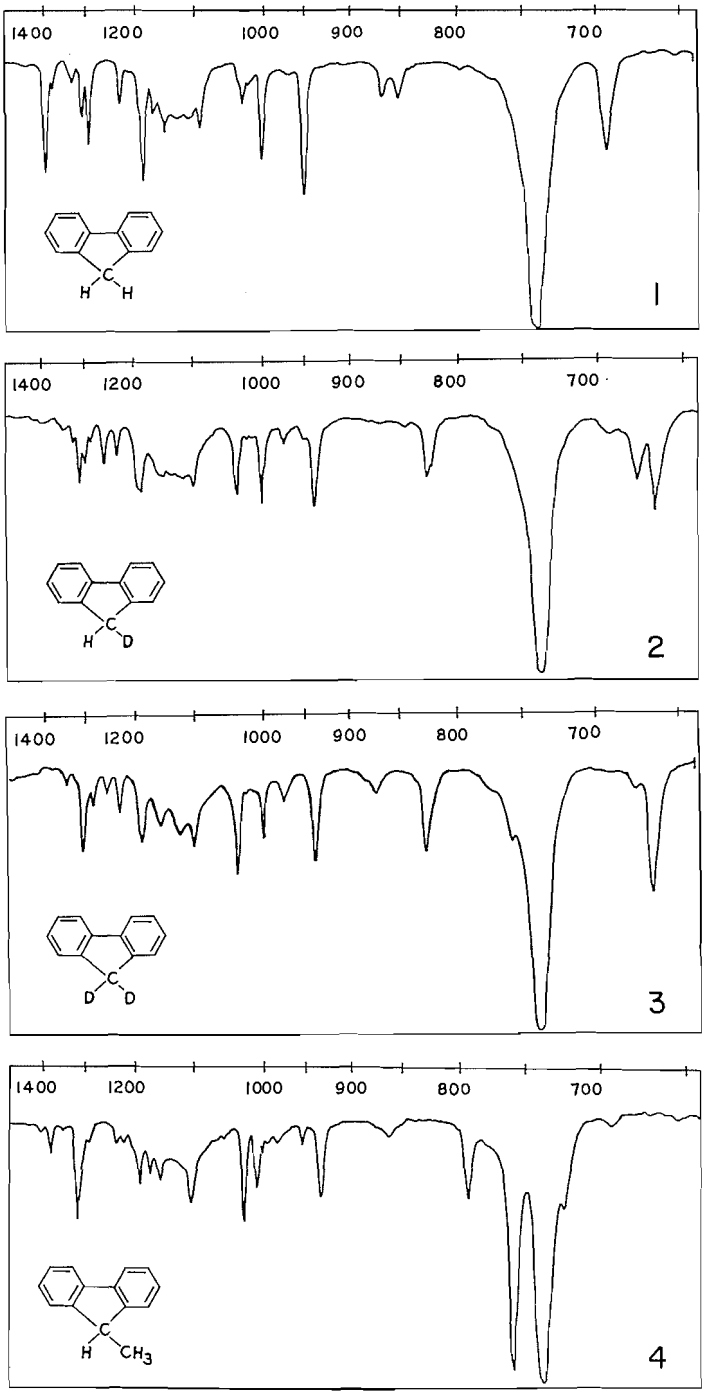
In this paper are reported the infrared spectra of the following compounds: fluorene, 9-mono- and di-deutero-, mono- and di-methyl-, mono- and di-benzyl-, mono- and di-allyl-fluorene as well as 9-benzylidenefluorene. They were found in both carbon disulphide and carbon tetrachloride solution to provide the whole range of absorption from 4000 cm^{-1} to 600 cm^{-1} except for a small region about 1450 cm^{-1} to 1600 cm^{-1} where both solvents show some absorption themselves (16). The instrument available was a Perkin–Elmer double-beam infrared spectrophotometer, equipped with a sodium chloride prism. Six frequencies of medium intensity were found definitely due to the methylene group of fluorene. These are at 2930, 1400, 1298, 1190, 952, and 692 cm^{-1} (Fig. 1). Whether these are all fundamental frequencies or not is not known. There are, no doubt, other frequencies due to the methylene group arising from overtones and combinations, but these were felt to be unnecessary for our work and hence not examined. Two such frequencies of low intensity might be 867 and 853 cm^{-1} (Fig. 1). All six frequencies can be clearly discerned and are of approximately the same intensity in both solvents employed. Since additional frequencies associated with substituting groups appear in the 1400 to 600 cm^{-1} region this area was examined carefully and thus only the spectra for this region, found in carbon disulphide, are reported and shown in Figs. 1 to 13. Each of the six frequencies mentioned is markedly affected by substitution or deuteration at C_9. In all cases, monosubstitution by an alkyl or aralkyl group greatly reduces or eliminates the absorption at these frequencies while disubstitution removes it completely. The removal of some is masked by neighboring frequencies or new frequencies due to the substituting groups but can still

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

be readily observed. Mono- and di-deuteration reduces or removes these frequencies similarly but new bands appear for the C—D functions at a lower frequency as expected (Figs. 2 and 3). The relative positions of these new C—D frequencies were estimated beforehand from Fig. 1 by using the suggested factor of 0.73 (16) and thus the new frequencies could be related at least tentatively, if not exactly, to the former C—H frequencies. The experimentally found ratio of the new C—D frequency to the original C—H frequency is approximately 0.7, in agreement with the shift expected by a simple application of Hooke's Law (16). The frequencies for the original C—H group, the new C—D group, the remaining C—H group on monodeuteration, and the ratio of the first two, both calculated and found, are shown in Table I.

TABLE I

Frequencies associated with the methylene group in fluorene and in monodeuterofluorene (cm^{-1})



Observed for CH_2	Calculated[a] for HC—D	Observed for HC—D	Observed $\nu C—D / \nu C—H$	Observed for remaining DC—H

1298	947	939	0.72	—[d]
1400	1022	974	0.70	—[d]
2930	2050	2150[c]	0.73	—[d]

[a]The product of the observed frequency in column 1, and the factor 0.73 obtained from reference 16.
[b]Beyond the range of the instrument.
[c]This is a very weak absorption and is not certain.
[d]Overlapping and multiplicity of neighboring absorption makes any assignment highly questionable.

The 692 cm^{-1} Band

This band, probably due to methylene rocking vibrations (16), is quite distinct. Monodeuteration (via the monopotassium compound) reduces it markedly (Fig. 2). The residual absorption noticeable at this frequency is most likely due to unreacted fluorene, a contaminant undoubtedly present since the deuterium oxide available at the time of these experiments contained 95% of D_2O. A three- to five-fold excess of deuterium oxide was used to ensure as complete a reaction as possible with the precipitated potassium compound. Purification by separation of deuterated from undeuterated fluorene obviously is extremely difficult. Dideuteration via the dipotassium compound completely eliminates the 692 cm^{-1} band (Fig. 3). The spectrum of the monodeuterated fluorene shows a new band at 677 cm^{-1} which is thought to be associated with the remaining DC—H, shifted from the original frequency of 692 cm^{-1} by the presence of the deuterium atom. This point of view is supported by the fact that dideuteration reduces this 677 cm^{-1} band to a very small value, this residual absorption arising, no doubt, from contaminating monodeuterated fluorene. The frequency corresponding to the new HCD— group, calculated to be in the region of 505 cm^{-1}, is beyond the range studied.

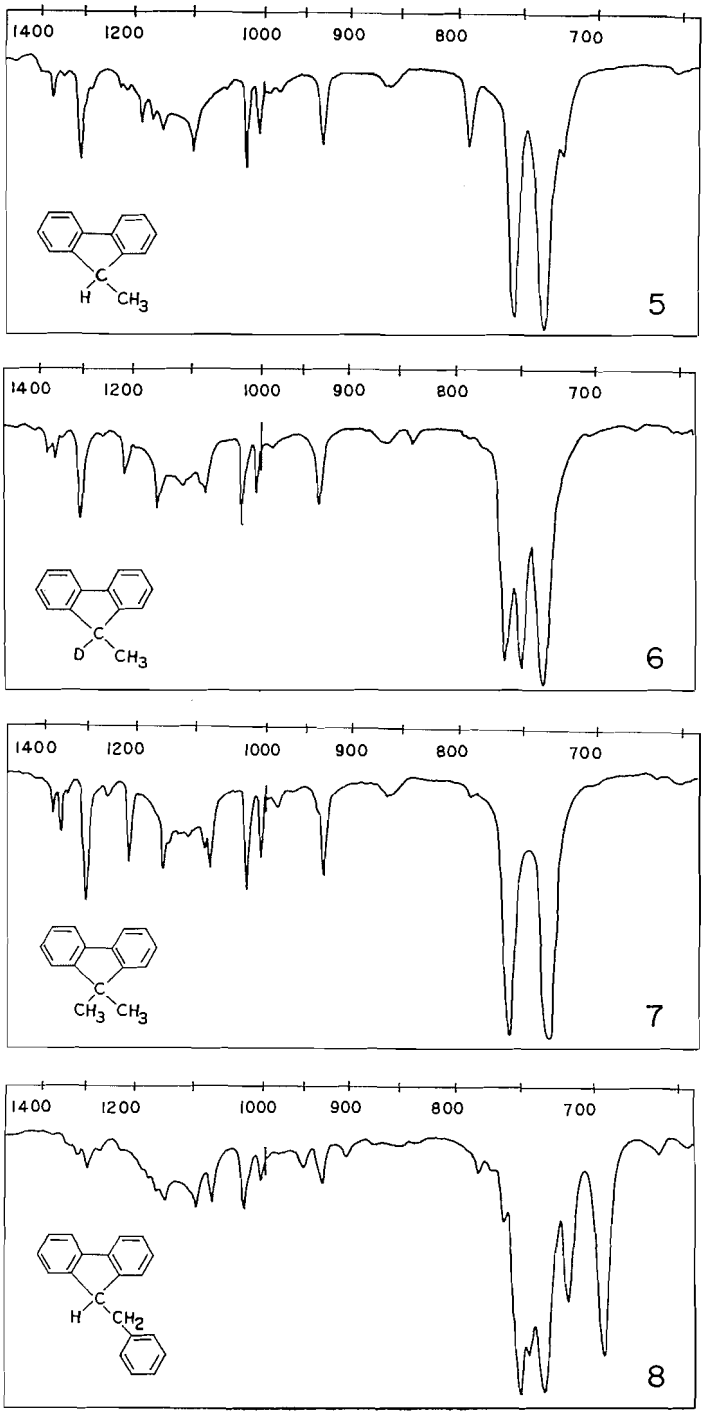
For personal use only.



FIGS. 1–4.

Monomethylation reduces the band at 692 cm^{-1} to one of weak absorption at the same frequency (Fig. 4). This was found to be due to contamination by unreacted fluorene since repeated purification by chromatography on activated alumina eliminated the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

absorption at 692 cm^{-1} (Fig. 5). The melting point of the "contaminated" monomethylfluorene is 43–44° C whereas that of the "pure" monomethylfluorene is 45–46° C. Thus, a routine melting point determination of this compound should be carefully done to

FIGS. 5–8.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

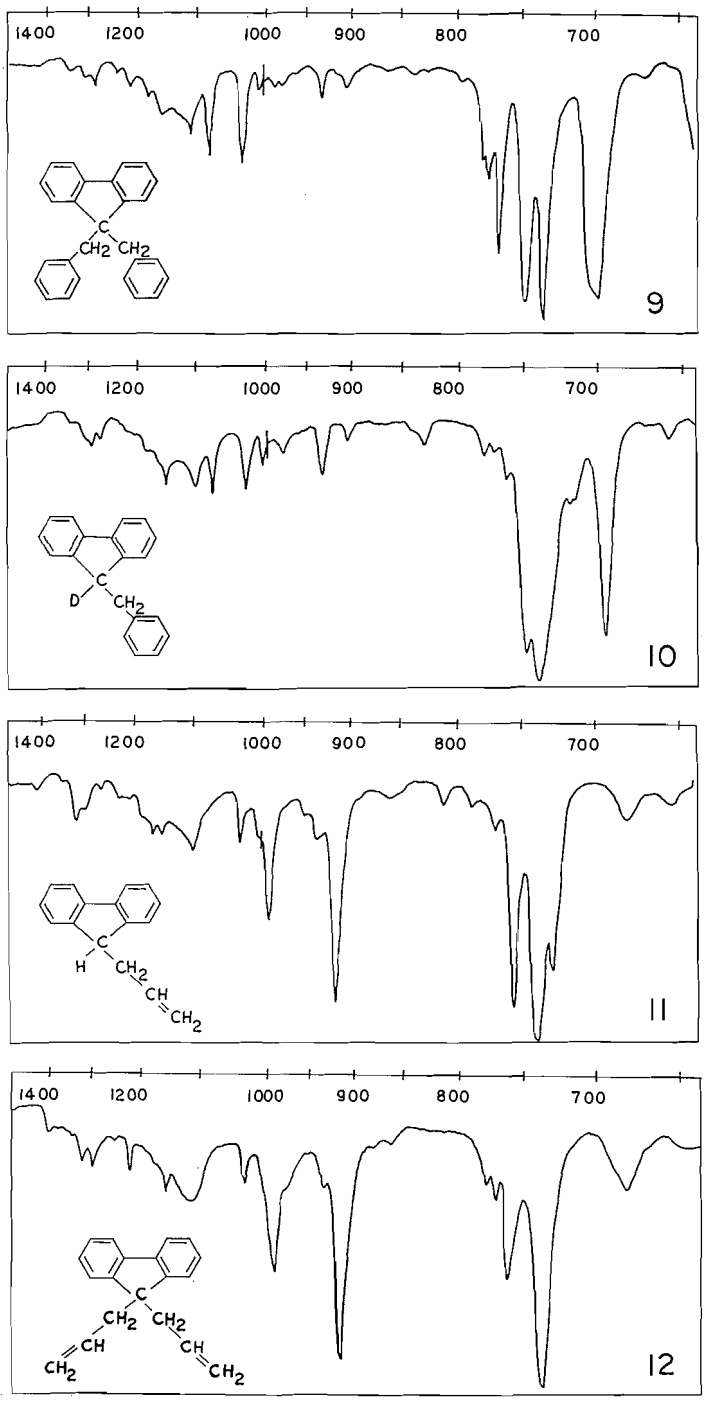
differentiate between 100% purity and slight contamination, sufficient to be visible clearly in the infrared spectrum.

The melting point found for 9-methylfluorene is the same as that reported by Greenhow (3). However, other workers give a melting point of 58° (17). This may be another example of two polymorphic forms, a situation already demonstrated in the case of 9,9-dimethylfluorene (18).

The disappearance of the 692 cm^{-1} band on monobenzylation and dibenzylation (Figs. 8 and 9) is masked by the strong absorption at 697 cm^{-1} due to out-of-plane C—H vibrations of monosubstituted benzene (16). Mono- and di-allylation (Figs. 11 and 12) show more clearly the disappearance of the 692 cm^{-1} band.

The expected complete elimination of the 692 cm^{-1} absorption in the 9-benzylidenefluorene (Fig. 13) is obscured by the strong absorption at 697 cm^{-1} due to monosubstituted benzene.

The 952 cm^{-1} Band

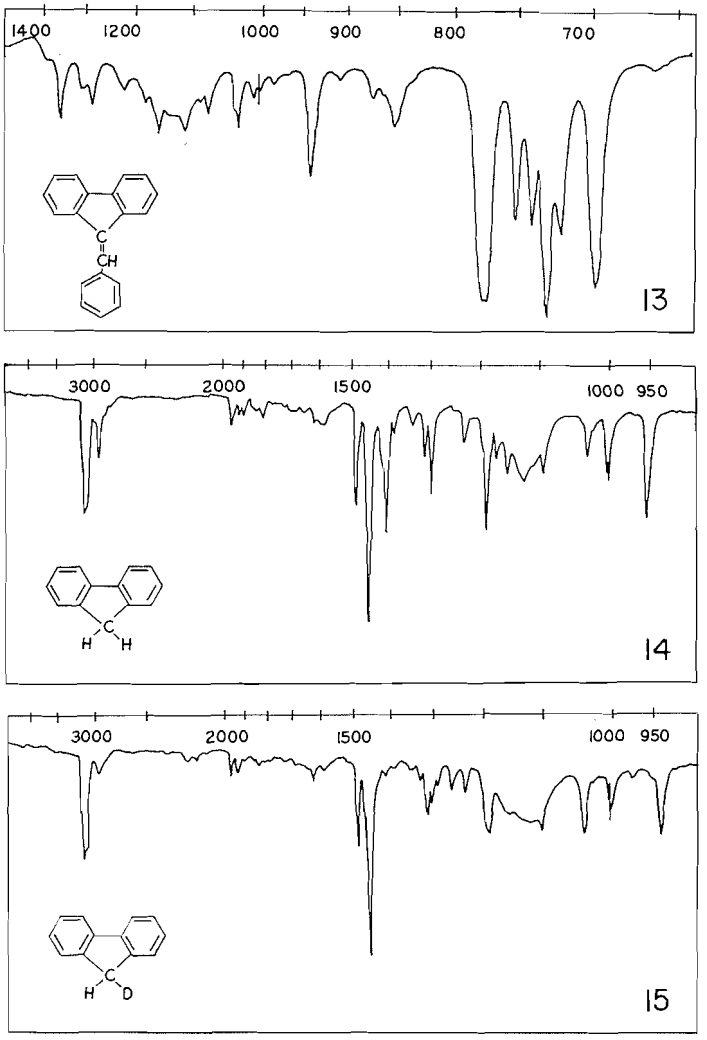


This band whose origin is unknown to us is also quite distinct (Fig. 1). It is nearly eliminated by monodeuteration, the residual absorption most likely being due to contaminating fluorene (Fig. 2). Dideuteration causes complete disappearance of absorption at this frequency. The corresponding HC—D band, calculated to occur in the region of 694 cm^{-1} appears at 667 cm^{-1} and its intensity increases markedly upon dideuteration. The considerably greater intensity of the HC—D band at 667 cm^{-1} as compared to that of the DC—H band at 677 cm^{-1} indicates that in deuteration of the monopotassium compound with excess D_2O, some dideuteration had occurred probably by hydrogen–deuterium exchange.

The band due to the remaining DC—H, if analogous to that of 677 cm^{-1} found for the 692 cm^{-1} band, should occur in the region of 935 cm^{-1}. One actually does appear at 939 cm^{-1} and may contain the DC—H absorption. However, the magnitude of its intensity as well as the fact that dideuteration makes no significant change in its size favors the view that the 939 cm^{-1} band is due in part to the methylene absorption originally at 1298 cm^{-1}, shifted due to formation of the —C—D bond, and in part to absorption from the remaining —C—H bond affected by the deuterium atom.

The monomethyl-, monobenzyl- and monoallyl-fluorene (Figs. 4, 5, 8, 11) all show very strong reduction of intensity or complete elimination of absorption at 952 cm^{-1}, any residual absorption again being due to contamination by unreacted fluorene.

As expected, 9-benzylidenefluorene shows no absorption in the 950–956 cm^{-1} region



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

FIGS. 9–12.

(Fig. 13). A similar result occurs for the other 9,9-disubstituted fluorenes (Figs. 7, 9, 12). The position of the absorption for the remaining C_9—H bond in the monosubstituted fluorenes is determined by deuteration. Comparison of Figs. 5 and 6 show that two bands,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

FIGS. 13–15.

792 cm^{-1} and 722 cm^{-1}, are eliminated on deuteration, hence it is clear that these are due to C_9—H in 9-monomethylfluorene. Whether one of these corresponds to the absorption of the methylene group at 952 cm^{-1} is not known. Similarly, the bands at 787 cm^{-1} (weak) and 719 cm^{-1} (strong) in the spectrum of 9-monobenzylfluorene (Figs. 8 and 10) and those at 789 cm^{-1} (weak) and 727 cm^{-1} (strong) in the 9-monoallylfluorene (Fig. 11) are likewise to be associated with the remaining C_9—H bond, since deuteration or disubstitution eliminates the absorption.

In addition it might be pointed out that the bands at 1100, 1167, and 1185 cm^{-1} are eliminated upon deuteration of the 9-monomethylfluorene (Figs. 5 and 6) hence can be considered as associated with the remaining C_9—H bond.

The 1190 cm^{-1} Band

The cause of absorption at this frequency is not known. It was at first believed to be composed of absorption due to the methylene group *and* to some other structural feature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

since monodeuteration reduces it to about one-half its former intensity while dideuteration produces little further change (Figs. 1–3). However, monosubstitution reduces the band markedly while disubstitution practically removes it, hence the absorption seen at 1190 cm^{-1} in the dideuterated molecule may be due to shifts, or combinations of overtones, stemming from deuteration at C_9.

The frequency of the $\begin{array}{c}|\\ -C-D\\ |\end{array}$ bond is thought to appear at 827 cm^{-1} in agreement with the calculated value.

The position of absorption of the remaining $\begin{array}{c}|\\ -C-H\\ |\end{array}$ bond as affected by the presence of the deuterium atom could not be defined in view of the complexity of the neighboring bands.

The 1298 cm^{-1} Band

This absorption is probably due to methylene wagging vibration (16) and, in agreement with previous observations, is of lower intensity than that from rocking vibration. The band is reduced on monodeuteration or monosubstitution at C_9 while dideuteration or disubstitution largely eliminates it. Neighboring absorption bands mask these effects somewhat with the result that this frequency is less useful than are the others mentioned above.

The $\begin{array}{c}|\\ -C-D\\ |\end{array}$ bond frequency appears at 939 cm^{-1} in the monodeuterated molecule. Since its intensity is practically unchanged upon dideuteration, the view is supported that it is a composite band in the monodeuterated structure, with a contribution from the remaining $\begin{array}{c}|\\ -C-H\\ |\end{array}$ band shifted slightly from 952 cm^{-1}. Dideuteration removes this contribution but adds that from the second C—D bond in dideuterated fluorene (1298 cm^{-1} shifted to 939 cm^{-1}).

The 1400 cm^{-1} Band

This absorption is quite likely derived from scissoring vibration of the methylene group (16) since any type of mono- or di-substitution at C_9 eliminates this band. The absorption attributed to the new —C—D bond obtained on monodeuteration might be that appearing at 974 cm^{-1} and increasing on dideuteration. This agrees quite well with the calculated value (Table I). The band at 1038 cm^{-1} appearing on monodeuteration and increasing in magnitude upon dideuteration agrees roughly with the calculated shift, but examination of the spectra of mono- and di-substituted compounds (Figs. 1–13) shows that *any mono- or di-substitution* at C_9 gives rise to a band, increasing upon disubstitution, at about the same frequency. Hence the absorption at 1038 cm^{-1} certainly cannot be due to the $\begin{array}{c}|\\ -C-D\\ |\end{array}$ bond.

The 2930 cm^{-1} Band

This absorption, arising from C—H stretching frequency, must be due to the methylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

group since it disappears upon deuteration (Figs. 14 and 15).* No firm assignment could be made for the —C—D band, although weak absorption appears at 2150 cm^{-1} in the deuterated molecule (Table I) in agreement with the calculated shift.

USEFUL BANDS ASSOCIATED WITH PARTICULAR SUBSTITUENTS AT C_9

In all the spectra there is clearly discernible a characteristic strong band at 738 cm^{-1} originating from the two ortho disubstituted benzene nuclei in fluorene (16). Monomethyl-, monoallyl-, and monobenzyl-fluorene and 9-benzylidenefluorene all show weak absorption between 787 and 793 cm^{-1} and strong absorption in the region of 719 to 728 cm^{-1} (overlapping to some extent with the major 738 cm^{-1} band). Only for monomethylfluorene is this latter absorption of weaker intensity, though still quite readily discernible, and the former stronger than in all the other cases examined. Disubstitution at C_9 removed this absorption completely. We have attributed these two bands to the remaining C_9—H bond. The 719–728 cm^{-1} band has been used to differentiate between the mono- and di-substitution and, in particular, to follow the preparation, purification, and identification of 9-monoallylfluorene and 9,9-diallylfluorene whose mixtures with each other and with fluorene itself are separated with difficulty.

Clear distinction of the methylated fluorenes from the allyl or benzyl fluorenes may be made by observation of the strong, isolated band at 758 cm^{-1} in the spectrum of monomethylfluorene, which doubles in intensity upon dimethylation. The monomethyl compound shows another medium-weak, though impressive, band at 793 cm^{-1} which is eliminated upon dimethylation or on deuteration of the remaining C_9—H. Allylfluorenes absorb at 913 cm^{-1}, the intensity of the diallyl being approximately double that found for the monoderivative. This absorption is no doubt that associated with the C—H out-of-plane bending found in olefinic structures (16). The band appearing at 681 cm^{-1} for mono- and di-allylfluorene may also be of analytical value.

The strong absorption at 700 cm^{-1} in 9-monobenzylfluorene (approximately doubled in the dibenzylfluorene) is due to the monosubstituted benzene moiety. Also of some assistance in identifying 9-benzylated fluorenes is the weak band at 905 to 909 cm^{-1}. This appears to be present in 9-benzylidenefluorene. Whether the same absorption is to be found in the allyl fluorenes cannot be shown since the strong 913 cm^{-1} band interferes.

Of some assistance is the strong absorption at 761 to 764 cm^{-1} for *di*allyl- and *di*benzyl-fluorene, whereas for the *mono*allyl- and *mono*benzyl-fluorenes a similar strong absorption occurs at 754 cm^{-1}. Furthermore, a band at 746 to 748 cm^{-1} appears for the mono- and di-benzylfluorene but not for mono- and di-allylfluorene.

The view that the dipotassium compound had been made from two equivalents of potassium and one of fluorene is supported by deuteration experiments. The 9-fluorenylpotassium (also the 9-fluorenylsodium, prepared by Greenhow's method (3)), treated with excess deuterium oxide gave a spectrum (Fig. 2) in which the shifted frequency, due to C_9—H, is thought to be at 677 cm^{-1}. If this assignment is correct, dideuteration should eliminate this band. Such elimination is actually observed in the spectrum of the dideuterated compound obtained from the experiment wherein two equivalents of potassium to one of fluorene were used. No change in extent of deuteration was found when a greater proportion of potassium metal was employed.

**The spectra for Figs. 14 and 15 were obtained in* CCl_4 *solution.*

EXPERIMENTAL

The fluorene used in this work was Eastman Kodak 98% practical grade.

Infrared spectra were obtained with the aid of a Perkin–Elmer model 21 double-beam spectrophotometer equipped with a sodium chloride prism. Solutions in carbon tetrachloride and carbon disulphide, containing 20 mg solute per ml of solvent were measured in sodium chloride cells of 0.5-mm thickness.

All melting points are uncorrected.

9-Fluorenylpotassium

Fluorene (8.3 g, 0.05 mole) and potassium metal (1.95 g, 0.05 mole) were heated in refluxing purified dioxane (19) protected by an atmosphere of purified dry nitrogen. In 3 hours all the potassium was consumed. The reaction mixture was cooled to room temperature and the reddish-brown precipitate isolated by filtration under suction and washed with dry hexane to remove unreacted fluorene. Isolation of the monopotassium compound was best carried out in a dry box containing an atmosphere of nitrogen. Samples for analysis were prepared by freeing the fluorenyl potassium from adhering solvent with a stream of nitrogen drawn through the solid product by suction. Analysis was carried out by first treating a weighed portion of the solid with water then titrating the basic solution with standard acid. In three attempts at analyses the "purified" precipitate showed values of 14.9, 15.3, and 15.7% for potassium. The value required for $C_{13}H_9K$ is 19.15%.

9-Deuterofluorene

The 9-fluorenylpotassium was prepared from 1.66 g of fluorene and 0.39 g of potassium in 5 ml of pure dioxane refluxed for 3 hours until all the potassium had reacted. One milliliter of D_2O* (95%) was slowly added and the mixture then stirred for 1 hour. Following the addition of ether, the dioxane and potassium hydroxide were readily removed by extracting the solution of deuterated fluorene with water. When the ethereal solution was dried and the solvent removed there was obtained, upon crystallization of the resulting solid from alcohol, 1.58 g of monodeuterated fluorene.

Analysis for deuterium by N.M.R. show approximately 75% monodeuteration.

9,9-Dideuterofluorene

A mixture of 0.01 mole (1.66 g) of fluorene and 0.02 mole (0.78 g) of potassium was heated for 3.5 hours in 5 ml of refluxing dioxane till all the potassium had been consumed. The addition of 1.5 ml of D_2O and isolation of the product as before gave 1.56 g of dideuterated fluorene.

N.M.R. analysis shows complete absence of absorption at the position attributable to $\diagdown\!\!\diagup CH_2$, indicating complete dideuteration.

9-Methylfluorene

This compound was prepared by the following modification of Greenhow's procedure (3). Fluorene (18 g) and finely powdered sodamide (3.9 g) were heated in a nitrogen atmosphere for 5 hours at 180° C in 50 ml of decahydronaphthalene (dried with sodium and distilled). When the reaction mixture had cooled to room temperature, the solvent was decanted and the remaining black amorphous solid which adhered to the lower portion of the flask was washed several times with hexane (dried with sodium). Methyl iodide (12 ml) in 50 ml of hexane was then added and the magnetically stirred mixture refluxed for 12 hours under nitrogen. After the cautious addition of water to dissolve the

**The D_2O was donated by the National Research Council of Canada.*

potassium iodide, the hexane layer was separated, dried, and the solvent removed. The yellow oil obtained, dissolved in pentane and cooled in a refrigerator, deposited unchanged fluorene. Further purification was accomplished by chromatography of the pentane mother liquor on a 50-cm column of dry, activated alumina (80–200 mesh). The first fraction, obtained by elution with hexane, gave 9-methylfluorene, m.p. 43–44° C. Further purification by repeated chromatography altered the infrared spectrum slightly and changed the melting point of the compound to 45–46° C, lit. 45–47° C (3). (Compare the melting point of 58° reported by Wieland (17).)

9,9-Dimethylfluorene

A solution of 16.6 g of fluorene in 80 ml of dioxane containing 7.8 g of potassium was boiled for 5 hours under an atmosphere of nitrogen. All the potassium was consumed in this time. The slow addition of 20 ml of methyl iodide, to the cooled mixture, produced a vigorous but controllable reaction. Stirring was continued for 1 hour whereupon both ether and water were added to the reaction flask. Several extractions of the ethereal solution with water removed the dioxane. The dried ($CaCl_2$) solution was freed from ether and gave a yellow oil which could not be purified adequately by fractional distillation. However, chromatography with alumina of an hexane solution of this oil separated the unchanged fluorene and monomethyl compound from dimethylfluorene. The first fraction gave the 9,9-dimethylfluorene, m.p. 88–89° C, but when crystallized from methanol melted at 95–96° C, lit. 95–96° C (20). It is interesting that recrystallization from pentane of the 95–96° C melting compound gave a lower and less definite melting point, found in one case to be 78–83° C, which after a second crystallization from pentane gave 81–87° C.

9-Benzylfluorene

The 9-fluorenylsodium was prepared from 18.3 g of fluorene and 3.9 g of sodamide heated in decahydronaphthalene for 4 hours at 180° C under a nitrogen atmosphere (3). The black solid, deposited in the flask, was washed with hexane as in the preparation of 9-methylfluorene and treated with a solution of 40 ml of benzyl chloride in 40 ml of hexane. This mixture was refluxed for 20 hours. To the hexane solution, now diluted with ether, was added water to remove the sodium chloride. Removal of the ether hexane solvent gave a yellow amorphous product which after solution in alcohol deposited 12.5 g of crystalline 9-benzylfluorene melting sharply at 134° C, lit. 135° C (3). Further purification by chromatography on activated alumina raised the melting point to 136° C. Crystallization from alcohol did not change the melting point.

9,9-Dibenzylfluorene

(a) From fluorene.—To the dioxane containing 9,9-fluorenyldipotassium (made from 16.6 g of fluorene and 7.8 g of potassium in 80 ml of dioxane) was added 21 ml of benzyl chloride (an excess). The product of this reaction, only slightly soluble in ether, was isolated quite simply by the addition of water and ether to the dioxane solution whereupon the solid which formed could then be removed by filtration. The 9,9-dibenzylfluorene weighed 11.2 g and melted at 146° C (from alcohol), lit. 147–148° C (13).

(b) From 9-benzylfluorene.—A mixture of 2.6 g of 9-benzylfluorene and 0.39 g of potassium metal (equimolar portions) in 12 ml of dioxane was heated till solution of the metal was complete. Forty minutes of refluxing with 1.2 ml of benzyl chloride gave a solid, isolated as above, with properties and melting point identical with those of 9,9-dibenzylfluorene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

9-Deutero-9-benzylfluorene

Dioxane (15 ml) containing 2.56 g of *9-benzylfluorene* and 0.39 g of potassium was boiled for 40 minutes, cooled to room temperature, and treated with 0.8 ml (excess) of D_2O. The red precipitate disappeared and the product, isolated as usual by employing ether and water, and crystallized from alcohol, melted at 131° C, yield 0.5 g. Chromatography raised the melting point to 134° C, which crystallization from alcohol did not change.

9-Deutero-9-methylfluorene

This compound was prepared in the same manner as for 9-deutero-9-benzylfluorene and isolated as was 9-methylfluorene, m.p. 45.5° C.

9-Benzylidenefluorene

The procedure was a modified version of that employed by Thiele and Henle (13). The use of potassium ethylate, rather than sodium ethylate, gave the product in 3 days as compared with 14 days reported for Thiele and Henle's method.

To a solution of 2.5 g of potassium in 125 ml of dry ethyl alcohol was added 5 g of fluorene. Freshly distilled benzaldehyde (4.5 g) in 10 ml of alcohol was added and the reaction mixture kept at 45° C for 3 days. The 9-benzylidenefluorene (3.6 g) deposited from the solution was crystallized once from alcohol, m.p. 74°–75° C, lit. 76° C (13).

9-Allylfluorene

This compound was prepared by a modification of Greenhow's method (3).

Sodamide (3.9 g) and fluorene (18 g) were heated in refluxing decalin (40 ml) for 4 hours (nitrogen atmosphere). The decalin was then replaced by pentane (50 ml) and the 9-fluorenylsodium treated with 50 ml of allyl bromide (excess). After 8 hours reflux the product was isolated by removing the sodium chloride with water, then eliminating the solvent as well as the excess allyl bromide. Vacuum distillation gave 11.5 g of a light-yellow liquid boiling at 132–137° C/3 mm. Elution chromatography as described for the methylated fluorenes gave a sample suitable for infrared analysis.

9,9-Diallylfluorene

Fluorene (8.3 g) and potassium metal (3.9 g) were boiled for 4 hours in 100 ml of dioxane (N_2). When the reaction mixture was cooled to room temperature and treated with 8.65 ml of allyl bromide, added dropwise, an exothermic reaction occurred with simultaneous disappearance of the reddish-brown precipitate. After an additional period of stirring for 5 hours the product was isolated as usual by the additon of ether and water. The crude oil (12.1 g) obtained from the ether layer was fractionally distilled under vacuum to yield 7.9 g of light-yellow oil, b.p. 144° C/3 mm, which was submitted to chromatography for additional purification.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council of Canada for funds which enabled one of us (G. S.) to continue work on this project during the summer months.

Grateful acknowledgment is given to Dr. J. Harrold of the Physics Department of the University of Alberta, Edmonton, and to Dr. P. Krueger of the Chemistry Department of the University of Alberta at Calgary for helpful discussions of the work reported in this paper.

THE PREPARATION OF SOME THIOSEMICARBAZONES AND THEIR COPPER COMPLEXES. PART I[1]

B. A. Gingras, R. W. Hornal, and C. H. Bayley

ABSTRACT

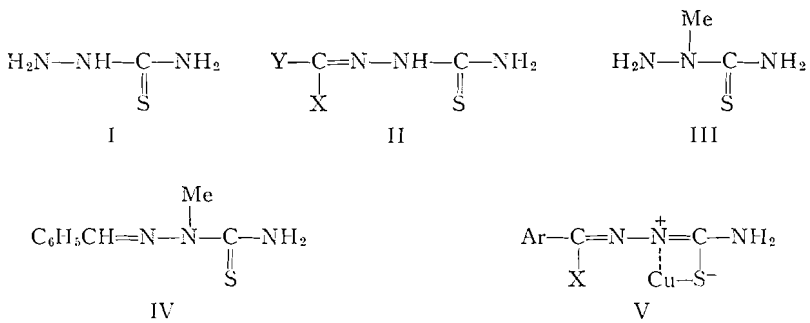
A number of thiosemicarbazones and their 1:1 copper complexes are described and the possible structures of the latter are discussed. Formation of copper complexes from aromatic aldehyde and ketone thiosemicarbazones results in a loss of one H atom as indicated by infrared spectra. In the aliphatic series, no loss of H atom is apparent upon complex formation. It is reasonable to assume that different processes are involved resulting in two possible structures for the aromatic and the aliphatic copper complexes. Some chemical evidence supports this view.

Since the discovery by Domagk (1) of the antitubercular activity of thiosemicarbazones, a number of papers on the pharmacology of this type of compounds have been published (2, 3, 4, 5). Thiosemicarbazones have also been found active in preventing the growth of certain fungi (6, 7). It has been assumed that the microbial activity of thiosemicarbazones is due to their ability to chelate traces of metal (e.g. copper), the metal complexes themselves being the active ingredients (8).

This hypothesis has been substantiated somewhat by the fact that selenosemicarbazones, in which the sulphur atom is replaced by selenium, are more active against fungi than the corresponding thiosemicarbazones, which in turn are more active than semicarbazones. This difference in activity is attributed to the formation of metal complexes which would occur more readily in the case of selenosemicarbazones (9).

There is considerable experimental evidence to support the view that formation of a toxic metal–organo complex is a possible mechanism of fungicidal action. Albert *et al.* (10) have shown that *8*-hydroxyquinoline is relatively non-toxic in triple-distilled water, but that addition of a trace of an iron salt makes it effective. Similarly, Cymerman-Craig *et al.* (11) showed quite conclusively that the high specific activity of isonicotinic hydrazide against *Mycobacterium tuberculosis* is due to formation of a metal complex. The high fungistatic activity of the dithiocarbamates is also believed to be due to their ability to bind metals (12, 13). It is also of interest to note that activity is lost completely when the terminal $-NH_2$ group of *p*-acetamidobenzaldehyde thiosemicarbazone is replaced by $-SCH_3$, the most likely explanation being that the latter group would prevent chelation (14).

In a search for new fungicides and also to test further the hypothesis discussed above, a number of thiosemicarbazones (II) of aliphatic and aromatic aldehydes and ketones and their copper complexes have been prepared, and their activity against two fungi have been examined.



Previous workers have described copper complexes of *p*-substituted benzaldehyde thiosemicarbazones (namely *p*-methoxy- and *p*-acetamido-) and their use in chemotherapy of tuberculosis has been discussed briefly (15). Metallic complexes of a few thiosemicarbazones have also been obtained and their properties discussed mostly in connection with methods of quantitative analysis for cations; the fungicidal activity of the mercury complexes of these compounds has been investigated and they have been found to be inactive (16).

No systematic investigation of the thiosemicarbazones and the possibility of their chelation with metals in relation to their microbiological activity seems to have been made. The purpose of the work described in this paper was to prepare a series of thiosemicarbazones and their copper complexes for use in subsequent studies of their fungicidal properties.

Most of the thiosemicarbazones listed in Table I gave copper complexes. A number of thiosemicarbazones and all of the copper complexes shown are described for the first time. The latter are colored solids of very low solubility in water and organic solvents. The least soluble were the aliphatic ones and consequently, their purification has been particularly tedious and in the case of the C_3, C_4, and C_5 compounds the elementary analysis remains unsatisfactory. However, since they show the expected infrared spectra and copper contents which are in good agreement with the theoretical values, they have been included in the data presented. Some others, viz. acetophenone and *p*-bromoacetophenone, decomposed during the various purification treatments used. The copper complexes are listed in Table II. Most of them underwent no change in color as the result of exposure to daylight and artificial light in the laboratory. In only two, i.e. furfural and *m*-nitrobenzaldehyde, was there any evidence of decomposition.

On the basis of elementary analysis, there can be no doubt that copper and thiosemicarbazones react in a 1:1 ratio. In the aromatic series the infrared spectra of the copper complexes show only two bands in the —NH— stretching region (at about 3450 cm^{-1} and 3350 cm^{-1}, see Table II) whilst the grouping —NH—CS—NH_2 accounts for three bands (at about 3440, 3240, and 3150 cm^{-1}, see Table I) in the case of the free thiosemicarbazones. This indicates that one hydrogen atom is involved in the complex formation.

By a study of the infrared spectra alone, it is difficult to discriminate between those three bands as any of the H atoms in II may take part in bonding, with a resulting shift to lower frequencies (17).

However, in the case of benzaldehyde, when the H atom of the —NH— group in II (Y = C_6H_5, X = H) was replaced by a methyl group, the resulting benzaldehyde methylthiosemicarbazone (IV) did not form a copper complex. Although more experimental evidence is required, this suggests that the H atom of the secondary —NH— group is responsible for the complex formation. A logical structure for the aromatic copper complexes would thus be as in V. It is now possible to speculate that the vibrations of the terminal —NH_2 group are responsible for the two bands at higher frequencies, since these are also present in the spectra of the copper complexes at about the same

frequencies, or, at the most, with only a slight shift to the left. In the thiosemicarbazones the secondary —NH— group would be responsible for the lower frequency band at about 3150 cm^{-1}.

There is no doubt that the nature of Y and X in formula II has a definite effect on the availability of the H atom of the secondary —NH— group to take part in complex formation. When Y is aromatic, both the inductive (−I) and mesomeric effects may alter the electronic density at the nitrogen atom resulting in the weakening of the —N—H bond. When Y is aliphatic, the inductive effect (+I) would affect the —N—H bond in a reverse manner and it is likely that the formation of a copper complex proceeds by another route. Infrared spectra in these cases show consistently three bands in the —NH— stretching region for both free thiosemicarbazones and their copper complexes. On this basis pyruvic acid thiosemicarbazone – copper would be expected to behave like the aromatic compounds, because of the (−I) inductive effect of the carboxyl group. This is indeed the case, as the infrared spectrum of this complex shows two bands, instead of three, in the —NH— region. Similarly, the infrared spectrum of cyclohexanone thiosemicarbazone – copper is similar to that of the aliphatic compounds, whereas furfural thiosemicarbazone – copper gives a spectrum typical of an aromatic compound in the —NH— stretching region.

In the case of the aromatic hydroxy compounds, it is also possible that the hydroxyl groups are involved in the metal binding process, since their infrared spectra do not show a band in the OH region.

More work is being done at the moment on the structure of those copper complexes.

Although a full discussion of the microbiological data will appear elsewhere (18), it is interesting to note that antifungal activity is restricted to the thiosemicarbazones themselves, most of the copper complexes being found inactive.

EXPERIMENTAL

Carbonyl compounds were obtained from commercial sources except in the case of the four fluorobenzaldehydes which were prepared from the corresponding fluorotoluenes by Etard's reaction (21). Thiosemicarbazones were prepared by the method of Sah and Daniels (19). Copper complexes were made by a method similar to that used by Kuhn and Zilliken (15) using cuprous chloride in ammonium hydroxide. 2-Methylthiosemicarbazide (III) and its benzylidene derivative (IV) were made by the method of Greer and Smith (20). Melting points, yields, solvents used in purification, bonds in the —NH— region of the infrared spectrum, and analyses are reported in Tables I and II. Melting points were taken on a Fisher–John apparatus and are not corrected.

o-Fluorobenzaldehyde Thiosemicarbazone

o-Fluorobenzaldehyde was first prepared using 40 g (0.36 mole) *o*-fluorotoluene (from *o*-toluidine; b.p. 114°, lit. b.p. 114°) (22) in glacial acetic acid (570 ml), acetic anhydride (565 ml), concentrated sulphuric acid (85 ml), and chromium trioxide (100 g). There was obtained *o*-fluorobenzaldiacetate (18 g, 40%, m.p. 25–27°), which was hydrolyzed to the free aldehyde by heating under reflux for $\frac{1}{2}$ hour in a mixture of ethyl alcohol (50 ml), water (25 ml), and sulphuric acid (10 ml). A sample of the resulting solution treated with phenylhydrazine afforded *o*-fluorobenzaldehyde phenylhydrazone (m.p. 89°, lit. m.p. 89.5°) (23).

The rest of the solution was neutralized to litmus and to this was added a solution of thiosemicarbazide (I) (9.1 g, 0.1 mole) in water (150 ml) and acetic acid (10 ml). *o*-Fluorobenzaldehyde thiosemicarbazone (II, Y = *o*-FC_6H_4, X = H) crystallized at once.

m-Fluorobenzaldehyde Thiosemicarbazone

m-Fluorobenzaldehyde was prepared by the same method using *m*-fluorotoluene (31.5 g, 0.28 mole; from *m*-toluidine: b.p. 116°, lit. b.p. 116°) (22). The *m*-fluorobenzaldiacetate obtained had m.p. 37° (18 g, 27%). Anal. calc. for $C_{11}H_{11}FO_4$: mol. wt., 226; C, 58.4; H, 4.9. Found: C, 59.1; H, 5.7.

Hydrolysis of the latter with sulphuric acid (10 ml) in aqueous alcohol gave a solution of *m*-fluorobenzaldehyde. A portion of this solution, reacted with phenylhydrazine to give the expected phenylhydrazone (m.p. 113°, lit. m.p. 114°) (22). After neutralization, the remaining solution was mixed with 300 ml of an aqueous solution of thiosemicarbazide (9.1 g, 0.1 mole) and the thiosemicarbazone crystallized immediately.

p-Fluorobenzaldehyde Thiosemicarbazone

This preparation was carried out as above using *p*-fluorotoluene (11.7 g, 0.1 mole; b.p. 116°, lit. b.p. 117° (22) from *p*-toluidine). The diacetate did not crystallize in this case but was extracted with ether. After evaporation of the solvent, the residual oil was hydrolyzed in the usual manner and its reaction with thiosemicarbazide gave the expected thiosemicarbazone.

For personal use only.

2-Fluoro-5-nitrobenzaldehyde Thiosemicarbazone

This compound was prepared as the previous ones starting with 2-fluoro-5-nitrotoluene (24) (40 g, 0.24 mole). The diacetate was obtained as an uncrystallizable oil (26 g, 38%), which after hydrolysis and reaction with thiosemicarbazide gave the expected thiosemicarbazone.

Preparation of Copper Complexes

The preparation of benzaldehyde thiosemicarbazone – copper complex illustrates the general method used.

To a gently refluxing solution of benzaldehyde thiosemicarbazone (9.8 g, 0.05 mole) in methyl alcohol (200 ml) was added dropwise a solution of cuprous chloride (5 g, 0.05 mole) in ammonium hydroxide (100 ml, sp. gr. 0.9). A yellow precipitate was formed and the mixture was stirred for ½ hour to complete the formation of the complex. After cooling, the solid was collected by filtration and washed with dilute hydrochloric acid, water, and alcohol.

Other purifying procedures are listed, for each compound, in Table II.

ACKNOWLEDGMENTS

Our thanks are due to Mr. E. C. Goodhue and Mr. R. Ironside, both of the Analytical Section, for carrying out the copper analyses and for taking the infrared spectra respectively.

DISTRIBUTION OF SUBSTITUENTS IN A PARTIALLY METHYLATED 4-*O*-METHYLGLUCURONOXYLAN[1]

INGEMAR CROON[2] AND T. E. TIMELL

ABSTRACT

A 4-*O*-methylglucuronoxylan has been partially methylated and the distribution of the substituents has been established. The hydroxyl group at C_3 was less reactive than that at C_2 in both the main xylan chain and in the acid side chains. Caution should be exercised in attributing structural significance to the presence of small amounts of sugars containing C_3 hydroxyl groups in hydrolyzates from methylated xylans.

In a previous investigation (1) the distribution of the substituents in a partly methylated xylan from esparto grass was established. This paper is concerned with the location of the substituents in a partially methylated 4-*O*-methylglucuronoxylan from white birch wood, a type of xylan more frequently encountered than the neutral polymer occurring in esparto.

RESULTS AND DISCUSSION

The polysaccharide was isolated by alkaline extraction of a birch chlorite holocellulose (2). It had previously (3) been found to contain 120 (1 → 4)-linked β-D-xylopyranose residues in a linear chain to which single side chains of 4-*O*-methyl-α-D-glucuronic acid residues were attached through C_2 of every tenth, on the average, of the xylose residues. The xylan was methylated with dimethyl sulphate and alkali until a methoxyl content of 26.6% had been reached. The partly methylated product was subjected to methanolysis and neutral and acidic sugars were separated on a column of anion exchange resin. The acid portion contained as sole component a partly methylated aldobiouronic acid, composed of xylose and glucuronic acid residues. It was esterified, reduced, and hydrolyzed to yield a mixture of reducing sugars. Hydrolysis of the neutral fraction gave a similar sugar mixture.

Both mixtures were separately resolved on a column of charcoal and Celite (4) by gradient elution (5) with aqueous ethanol (6). With one exception, complete resolution was achieved throughout. All sugars were either obtained crystalline or were converted to crystalline derivatives. The results are presented in Table I.

TABLE I

Molar composition in percentage of neutral and acid portions of the 4-*O*-methylglucuronoxylan

Neutral portion		Acid portion	
D-Xylose	10.6	D-Xylose	7.8
2-*O*-Methyl-D-xylose	12.3	3-*O*-Methyl-D-xylose	39.5
3-*O*-Methyl-D-xylose	9.8	4-*O*-Methyl-D-glucose	5.9
2,3-Di-*O*-methyl-D-xylose	67.3	2,4-Di-*O*-methyl-D-glucose	7.0
		3,4-Di-*O*-methyl-D-glucose	3.4
		2,3,4-Tri-*O*-methyl-D-glucose	36.4

[2]*Harold Hibbert Memorial Fellow, McGill University, 1959.*

In the case of the esparto xylan, a direct comparison between found and statistically calculated distributions (1) showed that the C_2 hydroxyl group was approximately 2.5 times as reactive as the C_3 hydroxyl but that methylation at C_2 doubled the reactivity of the remaining C_3 hydroxyl (7). Such a calculation is less easily applied in the present case. It is evident, however, that in those xylose residues in the main chain which carried no acid side groups, the ratio between the relative reactivities of the C_2 and C_3 hydroxyl groups was lower than the corresponding value for the esparto xylan. The distribution of the C_2 and C_3 methoxyl groups in the acid side chains corresponded to that expected for a partly methylated polysaccharide containing two hydroxyl groups, one of which was two to three times as reactive as the other. Those xylose residues which carried side chains were almost completely substituted.

The results indicate that the C_2 hydroxyl group is more reactive than that at C_3 in both the main xylan chain and in the side chains of a 4-*O*-methylglucuronoxylan. Due to changes in the electron density distribution (1, 7), the reactivity of the C_3 hydroxyl is probably enhanced by substitution at C_2. Complete methylation of polysaccharides is sometimes extremely difficult to achieve. It is clear from the present results that incomplete methylation is likely to cause the presence of mainly 2-*O*-methyl-D-xylose and 2,4-di-*O*-methyl-D-glucuronic acid in the acid hydrolyzate of 4-*O*-methylglucuronoxylans. Caution should be exercised in attributing structural significance to these sugars, even in the absence of the corresponding 3-*O*- and 3,4-di-*O*-substituted derivatives.

EXPERIMENTAL

Specific rotations were equilibrium values and were determined at a temperature of +25° C, at a concentration of 2.0, and with water as solvent. All melting points are corrected. Paper chromatography was carried out with a butan-2-one-water mixture (89:11) and sugars were located by spraying with *o*-aminodiphenyl (8). Paper electrophoresis was carried out with a 0.05 *M* borate buffer at a pH of 9.4.

Methylation of the Hemicellulose

A 4-*O*-methylglucuronoxylan was prepared in 29% yield (based on the wood) from a white birch chlorite holocellulose (2). The hemicellulose gave only xylose and uronic acids on hydrolysis and had a number-average degree of polymerization of 120 (osmometry). 4-*O*-Methylglucuronoxylan (25 g) was dissolved in 24% (w/w) potassium hydroxide (600 ml) in an atmosphere of nitrogen, and dimethyl sulphate (400 ml) was added dropwise at room temperature over a period of 18 hours. The reaction mixture was neutralized with acetic acid and was dialyzed against distilled water for a week. Freeze-drying of the solution gave a white, fluffy material (22 g), OMe, 26.6%.

Methanolysis and Separation of Neutral and Acidic Sugars

The partly methylated hemicellulose (21.5 g) was boiled under reflux for 10 hours with 2% methanolic hydrogen chloride in the presence of Drierite. Neutralization with silver carbonate, filtration through Celite, and evaporation to dryness yielded a pale, yellow sirup (21 g). The mixture of glycosides was dissolved in water (200 ml) and treated with barium hydroxide (10 g) at 70° for 2 hours (9). Excess barium carbonate was removed by addition of solid carbon dioxide, followed by filtration through Celite, after which the solution was treated with Amberlite IR-120 exchange resin and concentrated to 200 ml. The acidic solution was added to the top of a column (5×30 cm) containing Dowex 1-X4 exchange resin (20–50 mesh, acetate cycle). Neutral sugars

For personal use only.

(15.2 g) were eluted with water (5–6 liters), after which an acid fraction (2.5 g) was obtained by elution with 30% aqueous acetic acid (4 liters).

Reduction of the Acid Fraction and Hydrolysis of the Glycosides

The acid fraction was boiled under reflux with 2% methanolic hydrogen chloride and the ester–glucoside mixture was reduced with lithium aluminum hydride (2.5 g) in dry tetrahydrofuran (100 ml). Hydrolysis of the neutral fraction and of the reduced acid fraction yielded two mixtures of reducing sugars (A and B, respectively).

Resolution of Sugar Mixture A

A portion of the mixture of neutral sugars (A) (1.55 g) was added to the top of a Darco G-60 charcoal – Celite column (4) (1:1 w/w, 3.5×55 cm) and the sugars were recovered by gradient elution with aqueous ethanol as described previously (1). Four fractions containing only one compound were obtained, in addition to one which was a mixture of mono-*O*-methylxyloses and which was further resolved by paper electrophoresis. Amount recovered: 1.41 g.

Identification of Sugars

D-*Xylose.*—The first fraction (131 mg) crystallized, m.p. and mixed m.p. 145–146° C, $[\alpha]_D$ +19°.

3-O-Methyl-D-*xylose.*—This sugar (132 mg) also crystallized, m.p. and mixed m.p. 102–103° C, $[\alpha]_D$ +18°.

2-O-Methyl-D-*xylose.*—The crystalline sugar (166 mg) had m.p. and mixed m.p. 133–134° C, $[\alpha]_D$ +36°.

2,3-Di-O-methyl-D-*xylose.*—This sugar which constituted the last fraction (982 mg) had m.p. 101° C after recrystallization from ethyl acetate (10, 11), $[\alpha]_D$ +22°.

Resolution of Sugar Mixture B

Sugar mixture B (2.2 g) was added to the top of the same charcoal–Celite column and successively eluted with the following solvents: water (3 liters) → 10% ethanol (3 liters), 10% ethanol (2 liters) → 20% ethanol (2 liters), 20% ethanol (1 liter) → 50% ethanol (1 liter). The total amount of material recovered was 2.0 g.

Identification of Sugars

D-*Xylose.*—The first fraction (124 mg) crystallized, m.p. and mixed m.p. 145° C, $[\alpha]_D$ +18°.

3-O-Methyl-D-*xylose.*—The crystalline sugar (671 mg) had m.p. and mixed m.p. 102–103° C, $[\alpha]_D$ +18°.

4-O-Methyl-D-*xylose.*—The sirupy sugar (121 mg), $[\alpha]_D$ +61°, was converted to its crystalline osazone, m.p. and mixed m.p. 157–158° C. Its infrared spectrum was identical with that of an authentic specimen.

2,4-Di-O-methyl-D-*glucose.*—This fraction was contaminated with an unknown compound, travelling faster on the paper chromatogram. The mixture (168 mg) was added to the top of a cellulose column (3.8×35 cm) and eluted with butan-2-one saturated with water to yield a pure di-*O*-methylglucose (154 mg). The sirupy sugar, $[\alpha]_D$ +76°, was converted to the crystalline 2,4-di-*O*-methyl-N-*p*-nitrophenyl-D-glucosylamine, m.p. 250–251° C, undepressed on admixture with an authentic sample.

3,4-Di-O-methyl-D-*glucose.*—The crystalline sugar (76 mg) had m.p. and mixed m.p. 113–115° C, $[\alpha]_D$ +95°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12

ELECTRON SPIN RESONANCE ABSORPTION OF DIPHENYLPICRYLHYDRAZYL – ZINC OXIDE MIXTURES[1]

Y. MATSUNAGA[2] AND C. A. MCDOWELL

ABSTRACT

Electron spin resonance measurements on mixtures of αα-diphenyl-β-picrylhydrazyl (DPPH) and zinc oxide when compared with corresponding determinations on DPPH itself, and with DPPH – potassium chloride mixtures, indicate that there is a transfer of electrons between the DPPH and the zinc oxide. These observations support earlier published views of Harrison and McDowell, who found that the above mixture was able to enhance the catalysis of the ortho–para hydrogen conversion, and the hydrogen–deuterium exchange reaction.

INTRODUCTION

Mixtures of αα-diphenyl-β-picrylhydrazyl (DPPH) and zinc oxide have been found to be more efficient catalysts of the ortho–para hydrogen conversion (1, 2) than either of the two components alone. This led Harrison and McDowell (2) to postulate that the enhancement of the catalysis was caused by an electron transfer process occurring at the DPPH – zinc oxide interface. More recently Eley and Inokuchi (3) have found evidence for partial transfer processes in the systems DPPH–hydrogen, and also in DPPH – hydrogen sulphide. We here report the results of some experiments on the electron spin resonance absorption of mixtures of DPPH and potassium chloride, and DPPH and zinc oxide. These observations, as do also some less complete ones on DPPH – nickel oxide mixtures, confirm the earlier views of Harrison and McDowell (2) that electron transfer processes occur at the DPPH – zinc oxide interface.

EXPERIMENTAL

Pure non-sintered zinc oxide was prepared by treating a slightly acidic solution of zinc sulphate with metallic zinc to remove heavy metal ions. Ferrous iron was oxidized with hydrogen peroxide and removed by coprecipitation with zinc hydroxide by addition of a small quantity of ammonium hydroxide solution. Zinc oxalate was prepared from thus purified solution of zinc sulphate and calcined at 400° C for 6 hours.

αα-Diphenyl-β-picrylhydrazyl (DPPH) was prepared by oxidation of the corresponding hydrazine, supplied by Eastman–Kodak, with lead dioxide and recrystallized from a mixture of benzene and ligroin. Our sample contained crystalline benzene, but the mole ratio is less than one (6). Therefore, there is to be expected an "oxygen effect" as reported by Bennett and Morgan (5).

DPPH and zinc oxide mixtures were prepared, in a ratio of 1:9 by weight, by grinding the compounds in a mortar. The derivative of the electron spin resonance absorption was recorded on our electron spin resonance spectrometer at a frequency of 9000 Mc/sec. For convenience the distance between points of maximum slope ΔH_{ms} and the peak-to-peak intensity I_p on derivative curve will be used in this paper. The area A under the absorption curve can be estimated by the product of the square of ΔH_{ms} and I_p (3). The value of I_p of DPPH in vacuum is taken as unity.

RESULTS AND DISCUSSION

The DPPH used in this experiment had a ΔH_{ms} of 1.4 oersteds *in vacuo*, and a ΔH_{ms} of 1.45 oersteds and an I_p of 0.66 in air. The value of ΔH_{ms} of crystalline solvent-free DPPH

[1]*Manuscript received December 9, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C.
[2]*National Research Council Postdoctorate Fellow, 1957–59 (on leave of absence from The Department of Chemistry, University of Tokyo, Tokyo, Japan).*

has been reported to be 0.85 oersted and that with 0.8 mole of crystalline benzene 4.6 oersteds (3). No electron spin resonance absorption was detected in zinc oxide under the conditions of the present experiments.

A preliminary examination of the interaction between DPPH and zinc oxide was carried out in air without considering the oxygen effect. By grinding the compounds for a few minutes the value of I_p decreased to less than 0.4. A further, more rapid, decrease in I_p was caused by prolonged mixing. I_p was also observed to decrease slowly on standing. These results are shown in Fig. 1.

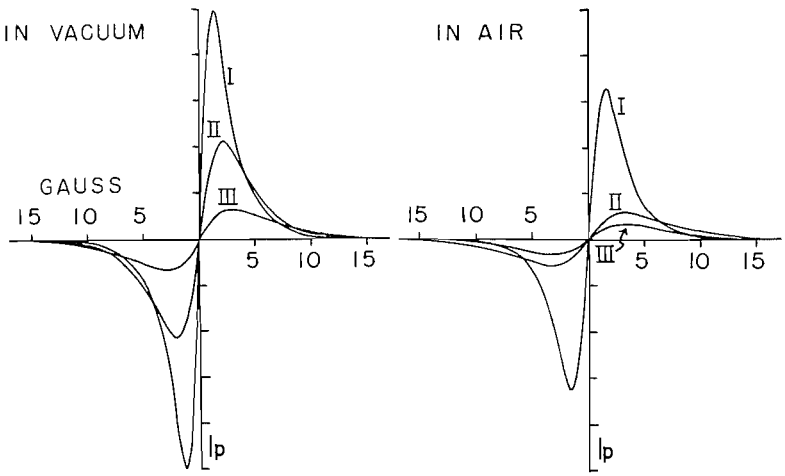

FIG. 1. Electron spin resonance absorption of mixtures of diphenylpicrylhydrazyl and zinc oxide. Curve I refers to DPPH alone; curve II refers to the DPPH–ZnO mixture No. 2 in Table I; curve III refers to the DPPH–ZnO mixture No. 4 in Table I. The value of I_p for DPPH in vacuum is taken as unity.

The variation of I_p with time is shown in Fig. 2. Curves A and B in this figure refer to measurements on the same mixture but at different degrees of mixing. Although the I_p of DPPH shows a marked decrease by grinding with zinc oxide, the area under the

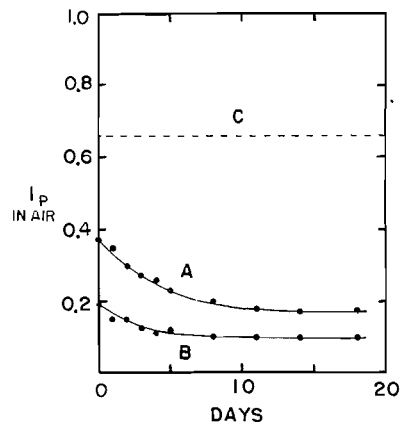

FIG. 2. Variation of the electron spin resonance absorption of mixtures of diphenylpicrylhydrazyl and zinc oxide (1:9) with time. Curves A and B refer to two mixtures with different degrees of admixing (B is the result of prolonged mixing). Curve C refers to a mixture of diphenylpicrylhydrazyl and potassium chloride (1:9); DPPH alone also gives a signal of this magnitude.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

absorption curve, which is proportional to the electron spin concentration, does not change so much because of the increase of ΔH_{ms}. No change of g-value was observed.

The results shown in Figs. 1 and 2 indicate that the values of ΔH_{ms} and I_p mixtures of DPPH and potassium chloride (1:9) do not change with time, nor do these data differ from the values for DPPH alone. Therefore, the observed line broadening in DPPH – zinc oxide mixtures suggests that there is a change of environment of the unpaired electrons by some kind of interaction between the DPPH and the zinc oxide. As this solid–solid interaction proceeds fairly rapidly by grinding, it was found quite difficult to prepare homogeneously mixed samples in different stages of the interaction. A few preparations, which could be considered to be well mixed, were examined *in vacuo* and in air. The results are given in the following table.

TABLE I

Electron spin resonance absorption of DPPH–ZnO mixtures

		In vacuum			In air		
		ΔH_{ms}	I_p	A^*	ΔH_{ms}	I_p	A^*
DPPH–KCl		1.4	1.00	1.0	1.45	0.66	0.7
DPPH–ZnO	(1)	1.85	0.63	1.1	2.5	0.22	0.7
	(2)	2.1	0.43	1.0	3.2	0.12	0.6
	(3)	2.2	0.31	0.8	3.2	0.10	0.5
	(4)	2.85	0.13	0.5	3.5	0.07	0.4

NOTE: The numbers, for example (1), after the DPPH–ZnO refer to different mixtures.
*Estimated error ±0.1.

The data obtained *in vacuo* show that the absorption line is broadened by interaction between DPPH and zinc oxide. The electron spin concentration seems to be constant in the initial stages of mixing, but a permanent decrease is found as time increases. It is not clear whether this apparent loss of spin is due to the real disappearance of unpaired electrons or the fact that some of unpaired electrons are in a different state and show too broad a resonance absorption to be detected. It is, however, apparent that there is some transfer of electrons, though whether this transfer is from the DPPH to the zinc oxide, or vice versa, cannot be deduced from our results.

The decrease of I_p by admission of air is several times larger in DPPH – zinc oxide mixtures than in DPPH alone. This oxygen effect on electron spin resonance absorption is instantaneous and reversible in DPPH (2) and also in DPPH – zinc oxide.

Since zinc oxide is an excess, or n-type, semiconductor, it was of interest to see if the effects observed with mixtures of this compound and DPPH would also occur with a defect, or p-type, semiconductor and DPPH. A few experiments were carried out with DPPH and nickel oxide which is a p-type semiconductor. The nickel oxide was prepared by calcination of the nitrate. The results are shown in Table II.

TABLE II

Electron spin resonance absorption of DPPH–NiO mixtures

		In vacuum			In air		
		ΔH_{ms}	I_p	A^*	ΔH_{ms}	I_p	A^*
DPPH–CCl		1.4	1.00	1.0	1.45	0.66	0.7
DPPH–NiO	(1)	1.7	0.22	0.3	2.0	0.18	0.4
	(2)	2.8	0.045	0.2	3.1	0.036	0.2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The same trends are observed in the results for the DPPH – nickel oxide mixtures as we found for the DPPH – zinc oxide mixtures. These observations must, therefore, be taken as additional evidence that electron transfer processes do occur at DPPH–oxide interfaces.

ACKNOWLEDGMENTS

We wish to thank the National Research Council of Canada for generous grants-in-aid of this research work.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART III. THE STRENGTH OF THE DIMERIC HYDROGEN BOND IN SUBSTITUTED BENZOIC ACIDS AS A MEASURE OF ELECTRONIC AND STERIC INTERACTIONS[1]

W. F. FORBES,[2] A. R. KNIGHT,[3] AND D. L. COFFEN[4]

ABSTRACT

The strength of the intermolecular (dimeric) hydrogen bond in substituted benzoic acids, as estimated from the observed concentration dependence of the ultraviolet absorption spectra, is found to vary with the nature and the position of the substituent. The effects of a number of substituents on the strength of the dimeric hydrogen bond can be rationalized in terms of the usual electronic and steric interactions. The data indicate that *o*-methoxybenzoic acid forms a stronger intramolecular hydrogen bond than *o*-fluorobenzoic acid.

INTRODUCTION

In Part II (1) it was shown that the observed concentration dependences of the main absorption band in the ultraviolet spectra for a number of benzoic acids could be satisfactorily explained by supposing that these changes are caused by the effect of dilution on the benzoic acid monomer–dimer equilibrium. The greatest concentration at which a marked concentration dependence is first observed was taken as an approximate measure of the dimeric bond strength. This "critical" concentration was greater when the intermolecular hydrogen bond was assumed to be weak than if the bond was assumed to be strong. The purpose of the present paper is to summarize the available concentration dependences and to compare these values with other available data.

EXPERIMENTAL

The method of determining the ultraviolet spectra has been described in Part II (1), which also lists some of the relevant concentration dependences. Additional data are listed in Figs. 1, 3, and 4, and Table I lists all the available critical maximal concentrations and the infrared data.

Critical maximal concentrations were used for comparison purposes, rather than to attempt to obtain the dimerization constants, for the following reasons:

(i) It was found impossible to obtain a value of the extinction coefficient which could confidently be associated with the absorption of the monomeric form (see Figs. 1, 3, and 4, which show that no definite flattening out occurs at the left-hand side of the plots). Calculations using the accepted value of K_D ($K_D = [D]/[M]^2$, [D] = concn. of dimer, [M] = concn. of monomer) indicate that the minimal critical concentrations should occur only at ca. 10^{-6} *M*, which lies outside the investigated concentration range. This

confirms the experimental observation that measurements for solutions containing only monomeric species cannot be obtained directly. Moreover, extrapolation to zero concentration of the observed curve to obtain the value corresponding to monomer absorption is considered unreliable since the curve does not obey exactly the relationship suggested by a simple monomer–dimer equilibrium (see below).

(ii) It was found impossible to obtain a reliable value for the absorption of the dimeric form. Although the absorption beyond the critical concentration remains approximately constant, this cannot be assumed to correspond to pure dimer absorption, since the infrared data indicate the presence of monomer even beyond this critical concentration (see Fig. 2). Using the accepted value for K_D of ca. $1.6\times10^{+4}$ for benzoic acid it was found that a theoretical plot of concentration against percentage of dimerized acid afforded a curve approximately but not entirely similar to that shown in Fig. 1, and that at the critical concentration the proportion of monomer would be ca. 82%. Comparison between the calculated and experimentally obtained curve for benzoic acid shows that only in the experimentally obtained curve is a critical maximal concentration dependence obtained. It is difficult to ascribe a reason for this behavior, but we can deduce from this

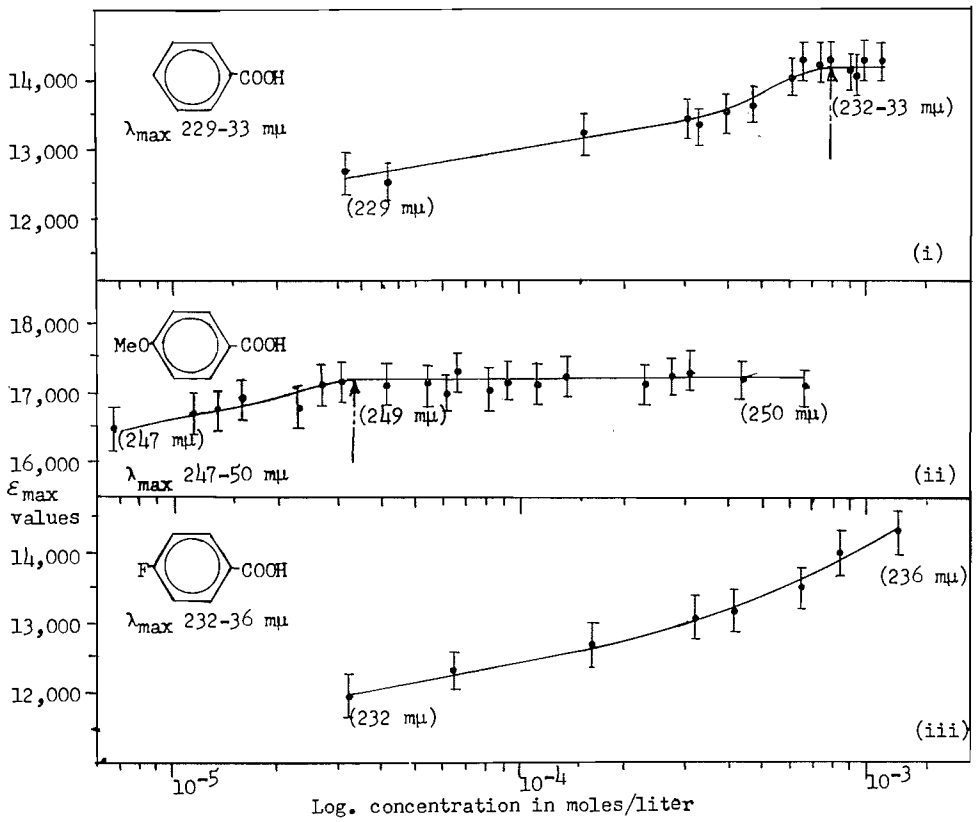

FIG. 1. The variation of ϵ_{max} on changing the solute concentration for (i) benzoic acid in cyclohexane solution, (ii) *p*-anisic acid in cyclohexane solution containing 5% ether,* and (iii) *p*-fluorobenzoic acid in cyclohexane solution.

**It has been shown (1) that the critical maximal concentration is not affected by small quantities of ether in solutions of cyclohexane.*

that the observed relationship only approximates, but does not correspond exactly to, the simple mass action law relationship. It may also be noted that the infrared carbonyl spectra at concentrations within the solute concentration range 0.5×10^{-2} to 0.5 M—that is above the "critical" level, where the ultraviolet absorption is constant—indicate that the dimer concentration still increases, but the monomer concentration significantly does *not* show a corresponding intensity decrease. This again is taken to indicate that deviations occur from the simple mass action law relationship.

Since the accurate absorption values of both the monomeric and dimeric form are required for the simple mass-law treatment, dimerization constants calculated from the simple mass action law using estimated values were found to afford a wide spread, although the values were approximately of the right order, that is, ranging between $0.5\times10^{+4}$ to $3.5\times10^{+4}$ for the value of K_D.

The infrared spectra at different solute concentrations were determined at 30° C in cyclohexane or carbon tetrachloride on a Unicam SP100 spectrophotometer in 0.5-mm cells, normally using a diffraction grating. Results are listed in Table I and Fig. 2. Figure 2 records the spectra in carbon tetrachloride solution because the lack of solubility of a number of acids in cyclohexane prevented the determination of the spectra in the latter solvent. However, when the acid was soluble in cyclohexane, the spectra were determined in both solvents and were found to be almost identical.

THE STRENGTH OF THE DIMERIC HYDROGEN BOND IN SUBSTITUTED BENZOIC ACIDS

The observed spectral changes for a number of substituted benzoic acids on altering the solute concentration are listed in Figs. 1, 3, and 4 and all the available critical maximal concentrations are listed in Table I.

In the absence of a more quantitative interpretation of the underlying effect, which causes the observed concentration dependences, a detailed analysis of the individual compounds in terms of inductive, mesomeric, and steric effects is perhaps not justified at this stage, but the following observations may be made:

(i) The critical maximal concentrations, which represent a qualitative measure of the strength of the dimeric hydrogen bond in substituted benzoic acids, may be compared with the results obtained from other measurements, for example, with the changes in acid strength on introducing a substituent in benzoic acid, with the wavelength displacements

TABLE I

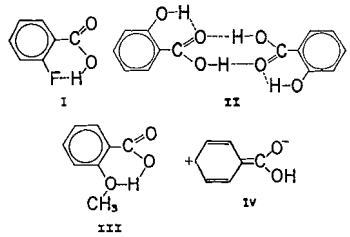
‡Not within range.

observed in the ultraviolet region, and with the standard heats of dissociation, ΔH, of different benzoic acids (cf. refs. 2, 3, 4, 5). These comparisons are found to show general similarities since all the data indicate that a *m*-methyl, *p*-methyl, or *p*-hydroxy substituent in benzoic acid strengthens the dimeric hydrogen bond and that an *o*-methyl, *o*-hydroxy, or *o*-methoxy substituent weakens the dimeric hydrogen bond. Most of the data, though not all, agree in indicating that a *p*-methoxy substituent strengthens the intermolecular hydrogen bond in benzoic acid and that a *m*-fluoro substituent weakens the intermolecular hydrogen bond. The disagreements in the latter two benzoic acids require further investigation.



(ii) Conflicting conclusions are suggested by the data for *p*- and *o*-fluorobenzoic acid. Particularly for *o*-fluorobenzoic acid, the almost complete absence of monomer in the infrared carbonyl absorption (see Fig. 2) suggests that the monomer is destabilized by the *o*-fluoro substituent, and this therefore points against any significant contribution of structures of type I. Other data, however, suggest the presence of such an intramolecular hydrogen bond (cf. ref. 5).

Moreover, the present data also suggest that a *m*-methoxy or a *m*-hydroxy substituent strengthens the intramolecular hydrogen bond in benzoic acid (see Table I and Fig. 3). This is of interest since the ordinary inductive effect of these *m*-substituents, on account of the greater electronegativity of the oxygen atom, would be expected to cause an electron withdrawal from the carboxyl group thus leading to an increase in the proportions *both* of the ionized acid and the monomeric species. Moreover, the increased acidity is, in fact, observed (4).

(iii) Steric interactions—that is, the loss of resonance energy because of non-planarity —presumably account for the greater critical maximal concentration in *o*-toluic acid (see Fig. 4). Incidentally, there is no evidence, as judged from the intensities of the infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

carbonyl bands, that steric interactions completely prevent dimer formation, since even for 2,4,6-tri-*t*-butylbenzoic acid at a solute concentration of 2.5×10^{-2} moles/liter the apparent ratio of intensities ($B_{\text{dimer}}/B_{\text{monomer}}$) is still ca. 10:1 (cf. Table I).

(iv) An intramolecular hydrogen bond has previously been postulated to weaken the dimeric hydrogen bond in salicylic acid (1). An intramolecular hydrogen bond in *o*-methoxybenzoic acid may likewise account for the absence of concentration dependence within the investigated concentration range for the solutions of *o*-methoxybenzoic acid (see Fig. 4), if it is assumed that the molecule exists in the monomeric form. The difference between the ultraviolet data in Table I (which indicate that salicylic acid forms a weak dimeric hydrogen bond, whereas *o*-methoxybenzoic acid forms no dimeric bond under identical conditions) and the acid dissociation data (which indicate the opposite tendency in the relative strengths of the intramolecular hydrogen bonds (4)) can be related to the observation that while the intramolecularly hydrogen-bonded form of salicylic acid is still able to form a dimeric hydrogen bond as in II, though not necessarily at the same time, this is not readily possible for the intramolecularly hydrogen-bonded form of *o*-methoxybenzoic acid (III).* A different argument, however, applies to the acid dissociation data, where the intramolecular hydrogen bond in structure II may be assumed to decrease the electron density on the carboxyl oxygen atoms and in this way *increase* the acidity of the carboxyl group; for *o*-methoxybenzoic acid, on the other hand, the *only* intramolecularly hydrogen-bonded form possible (III) tends to retain the active hydrogen atom by means of this hydrogen bond and in this way the acidity may not be increased to nearly the same extent as in salicylic acid (see ref. 4). Further evidence for the presence of a fairly strong intramolecular hydrogen bond in *o*-methoxybenzoic acid is provided by the intensity ratios of the infrared carbonyl bands which clearly indicate the relative predominance of the monomer in *o*-methoxybenzoic acid compared with the much smaller proportion of monomer in other substituted benzoic acids (see Fig. 2 and Table I).†

ACKNOWLEDGMENTS

The receipt of research grants from the National Research Council of Canada and from the Research Corporation of New York is gratefully acknowledged.

cf. Reference 5 which also reports considerably more dimeric dissociation for o-methoxybenzoic acid than for salicylic acid and see footnote 19 of that paper for a discussion of the structure of o-methoxybenzoic acid.

†*The similarity of the ultraviolet maxima for benzoic acid (monomer) and o-methoxybenzoic acid at ca. 230 mμ (see Fig. 4) is also of interest since it suggests that the ultraviolet maxima are not appreciably affected by intramolecular hydrogen bonding of type* III, *whereas intramolecular hydrogen bonds as shown in* II *give rise to appreciable bathochromic wavelength displacements (1). This is consistent with the explanation that resonance structures of type* IV *may be considered to be of predominant importance in determining these wavelength displacements in the ultraviolet region.*

A STUDY OF THE DIMER OF ETHYLENE PLATINOUS CHLORIDE BY PROTON MAGNETIC RESONANCE[1]

LEONARD W. REEVES

ABSTRACT

The proton magnetic resonance line of the powdered ethylene platinous chloride dimer complex has a second moment of 13.68 ± 1 gauss^2 at 77° K and an over-all line width of 11.15 ± 0.4 gauss. Measurements at various temperatures between 77° and 329° K show that both second moment and line width decrease slightly with temperature. The mean separation of the doublet observed at 77° K is found to be 4.80 ± 0.3 g.

The results are interpreted in terms of a distorted ethylene molecule whose interproton distances correspond to an intermediate structure between ethylene and an ethane in a cis configuration but with two of the cis protons removed. This is consistent with earlier studies of the Raman spectrum. The π-type bond formed between a metal d orbital and an ethylene π^* orbital is also consistent with the lack of rotation of ethylene at elevated temperatures.

Available results from high-resolution proton resonance studies of ethylene complexed to metal atoms in solutions is discussed.

The bonding of ethylene to the metal in a series of olefin complexes of platinum and palladium II has been treated by Chatt and Duncanson (1). A satisfactory explanation of the infrared and dielectric studies has been achieved in terms of a σ and π bond. The ethylene is co-ordinated to a dsp_2 metal orbital by use of the ethylene π electrons in a σ bond. It has also been suggested that a donation of charge from a metal d orbital into the ethylene π^* orbital forms a π-type bond which also contributes to the stability of the complex.

Further studies of these compounds by X-ray diffraction of the solid have confirmed the suggestions of the earlier workers. Studies of Zeise's salt (2), ethylene palladium chloride dimer (3), and styrene palladium chloride (4) show that the ethylene is at one corner of the square planar complex with the metal at the center. Resolution was adequate to show the scattering from the carbon electrons indicating that the carbon atoms are an equal distance above and below the plane of the complex. In the dimers, such as $[PdCl_2C_2H_4]_2$, there are two chlorine atoms which act as a bridge between the two palladium atoms; the ethylene in the dimer units complexes in the trans positions.

The infrared studies of the C—C stretching mode region indicate the loss of a center of symmetry by the olefin since a weakly allowed infrared absorption occurs in ethylene platinous chloride. The transition moment of this band in the 1500 cm^{-1} region is very low and it is not observed in Zeise's salt. It is thus evident that the symmetry of ethylene is very little changed by co-ordination. Well-defined C—H stretching frequencies at 3068, 3034, and 3010 cm^{-1} can be assigned to the three olefin stretching modes in the spectrum of $K[C_3H_6PtCl_3].H_2O$, a propylene complex.

Since the X-ray studies are unable to detect the proton positions and a certain loss of symmetry of ethylene is suggested by infrared measurements, the present study of proton resonance in the powdered solid ethylene platinous chloride is designed to detect any change in the interproton distances of ethylene on co-ordination and confirm the σ and π bonding proposed (1) by showing the absence of rotation of ethylene about the platinum–platinum axis at elevated temperatures.

EXPERIMENTAL

The Varian 40-Mc/s n.m.r. spectrometer V-4250 was used to take spectra at various temperatures from 77° K to 56° C. Spectra at liquid nitrogen temperature were measured using a Dewar which was mounted in a threaded cylinder replacing the Varian high-resolution spinner turbine housing on the induction probe. This was machined inside to fit a standard ground-glass joint. The small half-silvered Dewar was made with a standard taper joint on the outside and during the experiment the Dewar was located in the aluminum cylinder so that the Dewar was just fitted into the 15-mm 40-Mc/s Varian insert and was clear of the bottom of the insert by 1 mm. By careful machining of the locating cylinder actual contact of the insert with the Dewar was avoided so that changes in probe balance due to vibration and movement of the whole probe could be prevented. By thinning out the glass walls of an 8-mm sample tube a favorable proton-packing factor could be achieved. The liquid nitrogen was filtered through glass wool to prevent ice passing into the the Dewar. The Dewar contained enough liquid nitrogen to allow one spectrum to be taken without refilling. Exact reproduction of spectra was obtained. Above −30° C spectra were obtained by use of a second apparatus which will be described in a forthcoming paper by Reid and Connor (7), or with an apparatus described by Bernstein, Schneider, and Pople (7).

The main magnetic field was modulated at 80 c.p.s. and swept across resonance at calibrated rates. Calibration was achieved by observing the signal from liquid water with a modulation width of 30 milligauss and superimposing 5-, 10-, or 20-kilocycle side bands from a Hewlitt–Packard audio oscillator, which was, in turn, calibrated against a Hewlitt–Packard Model 5243 electronic counter. The recorder chart paper could thus be calibrated in gauss per centimeter before and after each series of experiments. No variation in calibration of sweep rates at a given setting was observed throughout the whole series of experiments.

The ethylene platinous chloride showed 98% purity in ethylene content as determined by comparison of the intensity of the high-resolution proton resonance in standard acetonitrite solutions with standard solutions of ethylene gas in the same solvent. The compound was prepared in the laboratory of Professor Orchin at the University of Cincinatti and kindly supplied by courtesy of the Gulf Oil Multiple Fellowship at the Mellon Institute.

RESULTS

Preliminary experiments showed that except at very low r.f. power there was some saturation of the proton resonance. The low power required to avoid signal distortion due to saturation was not practicable for good quantitative measurement of the resonance line parameters. A short irradiation of $\frac{1}{2}$ hour with 50-kv X rays produced sufficient paramagnetic impurity to allow the use of much higher r.f. power giving a signal-to-noise ratio of approximately 30 to 1, with modulation widths of 1 gauss. The paramagnetic impurities persisted at the highest temperature 56° C. There was no systematic difference in line width parameters calculated from the experiments with low r.f. power and those with higher r.f. power with irradiated samples. Thus the impurities introduced by X irradiation did not reach a concentration at which broadening of resonance lines occurs because of large local fields due to the electronic paramagnetism of the impurities (8).

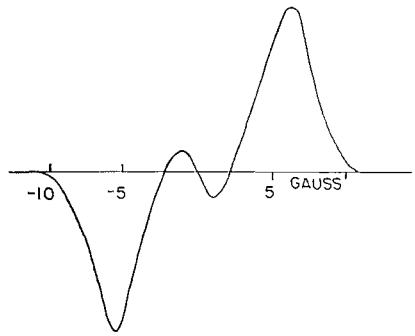

FIG. 1. Proton resonance in powdered ethylene platinous chloride dimer at 77° K.

Figure 1 shows the spectrum of solid ethylene platinous chloride at liquid nitrogen temperature. The curve represents the derivative of the resonance absorption curve obtained by modulating the large magnetic field H_2 and detecting the slope of the absorption curve over the modulation width with a phase-sensitive detector. The curve shown is the average of five spectra with a signal-to-noise ratio of 30 to 1. The derivative curve shows a clear doublet structure for the absorption as would be expected for the ethylene molecule where two closely spaced protons occur (9). The separation of the two peaks in the absorption curve determined from the average of five spectra at 77° K is 4.78 ± 0.3 gauss. The over-all line width determined from the separation of the positions of maximum and minimum slope in the derivative curve is 11.15 ± 0.4 gauss.

A spectrum at $+56°$ C is shown in Fig. 2. Above $-30°$ C the doublet structure of the

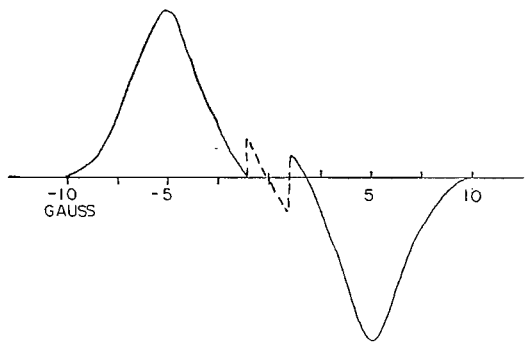

FIG. 2. Proton resonance in powdered ethylene platinous chloride dimer at 329.7° K.

derivative curve is marred by the appearance of a small impurity peak at the resonance center of modulation width preventing an estimation of the doublet separation. It is possible that this impurity may be traces of solvent used in the preparation or a certain amount of free ethylene with considerable motion in the solid lattice at $-30°$ C.

The second moments obtained are quoted in Table I at all temperatures studied. In each case they are the average values taken for at least three curves. They were computed using the formulas given by Andrew (10).

TABLE I

Line width and second moments of powdered ethylene platinous chloride

Temp., °K	$\Delta(H)_{\frac{1}{2}}$ line width, gauss	$(\Delta H)^2$ second moment, gauss^2
77	11.15±0.4	13.68±1.0
248	10.00	10.6
267	10.10	10.5
301	10.00	10.6
313	10.17	11.1
320	10.33	10.9
329	10.32	11.2

NOTE: Line widths varied for a given temperature up to 0.4 gauss from the mean; second moments deviated up to 1 gauss^2 from the mean.

The narrow component of modulation width shown in Fig. 2 did not grow in intensity with increasing temperature.

DISCUSSION

The Lewis acid–base reaction involving π electrons in olefinic systems and metal ions such as silver, or the halogen molecules, has been studied extensively in optical spectroscopy by observation of the familiar charge transfer bands (11). In the silver–olefin systems an interaction is detected in the Raman spectrum of the olefin by observation of the frequency shift of the C=C stretch (12). This frequency shift in the platinum olefin complexes is about twice that in the silver–olefin association (1).

The chemical shift of the protons from nuclear resonance signals detected in solutions of silver perchlorate in benzene or olefins is almost identical with the proton resonance position in pure benzene or olefin (13). This result is not surprising in view of the fact that π electron density influences the nuclear shielding parameter of a proton directly attached to the olefinic carbon only to a minor extent providing the lifetime of the complex in solution is very short (14). Larger changes in the chemical shift of ring protons in aromatic systems due to complex formation can be ascribed to a specific interaction of a solvent molecule with this proton rather than with π electrons. Large changes in proton chemical shifts (2–5 p.p.m.) in olefins complexed to metal atoms have been observed by Green, Pratt, and Wilkinson (15) and by Lauterbur and Reeves (16). It is expected (15) that such changes in chemical shift in strongly complexed ethylene is due to diamagnetic anisotropy introduced by bonds in the rest of the platinum complex or introduced by σ bond formation using π electrons from the olefin. The bond energy in the platinum–olefin complex is certainly greater than in silver–olefin complexes so that it is possible for chemical exchange effects to minimize chemical shift changes due to diamagnetic anisotropy of an individual complex in the latter case. Further results will be reported in conjunction with Lauterbur at a later date on studies using high-resolution n.m.r.

The suggestions of Chatt and Duncanson (1) are in general confirmed by high resolution studies of proton resonance in solution but these are limited in scope when effects of chemical exchange are not properly taken into account (12). The study of solid complexes using proton resonance will show changes in interproton distances after complex formation (10). The second moment of the resonance absorption line is related to the internuclear distances by the following equation:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[1] $$S = \frac{6}{5} \cdot I(I+1) g^2 \mu_0^2 N^{-1} \sum_{j>k} r_{jk}^{-6} + \frac{4}{15} \mu_0^2 N^{-1} \sum_{j,f} I_f(I_f+1) \cdot g_f^2 \cdot r_{j,f}^{-6}.$$

S = second moment of absorption line,
I = nuclear spin quantum number of the proton (nucleus under study),
g = nuclear "g" factor for the protons,
μ_0 = nuclear magnetion,
N = number of protons in the system,
r_{jk} = internuclear distance between nuclei j and k in the system,
g_f = nuclear g factor of nuclear species f in the system,
I_f = nuclear spin quantum number of nuclear species f,
r_{jf} = internuclear distance between proton j and a nucleus f of the f system.

The second moment of an isolated ethylene molecule is calculated to be 11.05 gauss^2. A theoretical second moment for an undistorted ethylene molecule, complexed in the platinum ethylene chloride dimer, can be estimated using the crystal structure of the ethylene palladium chloride dimer since the atomic radius of palladium is very little different from platinum (3). The proton nuclear moment system gives rise to a second moment contribution almost equal to that in the isolated ethylene molecule. The closest approach of a proton outside the ethylene molecule in the crystal is 4.67 Å. The contribution of protons in the crystal outside the ethylene molecule can be obtained by replacing the first summation in equation 1 by an integral between 4.67 Å and infinity (18). The volume of unit cell is 1038 Å and this contains four dimers or 16 protons or 1.54×10^{-2} protons per cubic Å

[2] $$S_{\text{Inter}} = \frac{4 \cdot \pi \cdot 357 \cdot 8 \cdot \rho}{3} \left(\frac{1}{r^3}\right)_{\infty}^{4.47}.$$

The first summation replaced by an integral is given by equation 2, where 357.8 corresponds to the presummation term evaluated for r expressed in Å, ρ is the density of protons per cubic Å. Sinter (evaluated between 4.67 Å and ∞) gives a value 0.22 gauss^2. There will be small contributions from the 33.7% Pt^{195} and Cl^{35} and Cl^{37}; these will only be effective within the same dimer. The platinum nuclear moment contributes only 5×10^{-3} gauss^2 and this has been neglected. The chlorine contributions are approximately 1×10^{-2} gauss^2 and can also be neglected in the second moment.

The theoretical second moment for the proton resonance line in ethylene platinous chloride is therefore 11.3 gauss^2. This is considerably less than the measured value and the discrepancy can only be due to a modification of the interproton distances in the ethylene molecule.

The modification of distances is expected to involve a lengthening of the C—C bond due to lowering of bond order since some π electron density is located between the C—C axis and the platinum atom in the σ bond. The C—H bond distances would not be expected to change greatly but the complexing will cause this —C—H bond to lean back from the direction of the platinum atom. In fact the general structure of the ethylene in the complex will approach that of ethane with one hydrogen missing on each carbon.

The second moment calculated from such a hypothetical arrangement in the crystal of ethylene platinous chloride would be 14.75 gauss^2. The experimental second moment of 13.68 gauss^2 has an intermediate value between the undistorted ethylene and ethane structures. Since the lowering of bond order in the C—C bond tends to lower the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

theoretical moment and the leaning back of the C—H bonds tends to raise it, then it is possible to fit the experimental second moment with a wide range of C—C distances and H—C—H angles. It is evident, however, that the distortion of ethylene suggested by Chatt and Duncanson (1) is consistent with the present study.

The n.m.r. spectrum of a rigid closely spaced proton pair in a polycrystalline material is a doublet provided all other interacting protons are sufficiently distant. The separation of the doublet is related to the proton separation in the pair by (10)

$$[3] \qquad \frac{3\mu}{r^3} \cong \Delta H_{\text{doublet}}.$$

This separation is a minimum value of the splitting since the system consists of nuclei outside the closely interacting and this causes broadening of the doublet and a reduction of the splitting. Equation 3 gives a value of $r = 2.08$ Å in this case. The separation of 1.1 protons in pure ethylene is 1.85 Å and in ethane 1.78 Å. The precision of the present result is particularly limited since the distance between cis protons in ethylene is 2.42 Å. The cis proton–proton distance invalidates the 'interacting pair' assumption and causes the observed doublet structure to correspond to proton separations between 1.85 and 2.42 Å. The second moments observed and calculated in this work are consistent with the results obtained previously from Raman spectra of this compound in solution (1).

If the ethylene were not located by π^* bonds it is likely that rotation about an axis perpendicular to the C—C axis would occur. This is not observed. The small decrease in second moment between 77° K and 329° K can be accounted for on the basis of rocking motions perpendicular to platinum–ethylene bond and on wagging about the C—C axis. This is a good evidence therefore for the additional π^* attachment suggested.

This work was supported by the National Research Council of Canada and the Research Corporation.

HEAT OF MIXING OF CARBON TETRACHLORIDE WITH FURFURAL

S. K. Jeun and Benjamin C.-Y. Lu

In the course of investigations of various thermodynamic properties of solutions, the heat of mixing of carbon tetrachloride and furfural over the complete concentration range was determined at 27° and 40° C in a Dewar calorimeter of a type similar to that used by Tsao and Smith (1) and Murti and van Winkle (2). Heating and cooling curves were taken before and after mixing for each determination and were used to eliminate the possible errors due to radiation, vaporization, and condensation, following a procedure which modified that proposed by Williams (3) for determining specific heats of liquids.

The heat-of-mixing data are expressed in terms of the amount of heat absorbed per mole of mixture when the pure components are mixed at constant temperature and pressure. The results are listed in Table I and are represented in functions of the mole

TABLE I
Experimental data

System carbon tetrachloride – furfural at 27° C		System carbon tetrachloride – furfural at 40° C

fraction of furfural by Fig. 1. The maximum error resulting from vaporization and condensation effects and in the measurement of experimental data was estimated to be 2%. Repeated runs at fixed condition indicated that the data were reproducible with a discrepancy of less than 1%. It is believed that the results presented have an accuracy of 2% or better.

It is observed that the heat of mixing data are positive over the temperature range investigated. The temperature effect on heat of mixing in the diluted furfural solutions seems to be negligible, while in the concentrate furfural solutions the heat of mixing is increased by increasing the temperature. It may be concluded that over the temperature range investigated the logarithm of the activity coefficient of furfural at infinite dilution

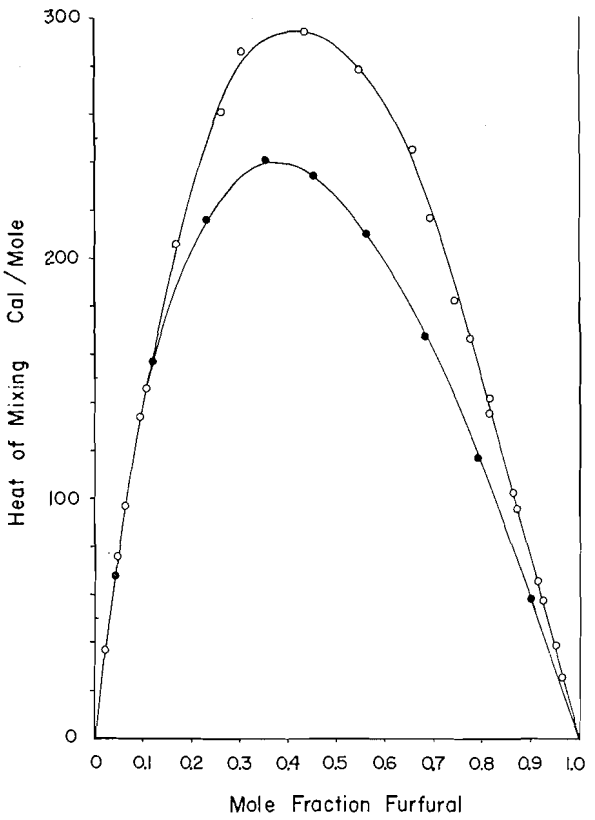

FIG. 1. Heat of mixing data for system carbon tetrachloride – furfural. ● 27° C, ○ 40° C.

varies linearly with the reciprocal of the absolute temperature and that the temperature effect on the activity coefficient of carbon tetrachloride at infinite dilution is more complex.

A POSSIBLE MECHANISM FOR THE PRODUCTION OF $O_2^*(^3\Sigma_u^-)$ IN FLAMES

ROBERT J. FALLON, IRWIN TOBIAS, JOSEPH T. VANDERSLICE, AND WILLIAM G. MAISCH

The emission spectra of a number of flames containing oxygen show the Schumann–Runge (1–6) bands which are associated with the transition $B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-$ in O_2. The mechanism for the production of $O_2^*(^3\Sigma_u^-)$ in flames has been a matter of concern for some time (4–6). Originally, it was suggested that it might be produced through a chemical reaction (7), and both Laidler (7) and Shuler (8) have suggested possible reactions which might account for the presence of these bands in various flames. It is now felt, however,

A POSSIBLE MECHANISM FOR THE PRODUCTION OF $O_2^*(^3\Sigma_u^-)$ IN FLAMES

ROBERT J. FALLON, IRWIN TOBIAS, JOSEPH T. VANDERSLICE, AND WILLIAM G. MAISCH

The emission spectra of a number of flames containing oxygen show the Schumann–Runge (1–6) bands which are associated with the transition $B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-$ in O_2. The mechanism for the production of $O_2^*(^3\Sigma_u^-)$ in flames has been a matter of concern for some time (4–6). Originally, it was suggested that it might be produced through a chemical reaction (7), and both Laidler (7) and Shuler (8) have suggested possible reactions which might account for the presence of these bands in various flames. It is now felt, however,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

that the $O_2^*(^3\Sigma_u^-)$ is formed thermally and not as a result of any chemical process (5, 9).

Laidler (4) has pointed out that, although the mode of formation of $O_2^*(^3\Sigma_u^-)$ might be specific for each flame, the fact that this species occurs in so many different flames would seem to indicate that the reactions leading to the production of $O_2^*(^3\Sigma_u^-)$ are common to all flames and thus independent of the nature of the fuel. He has suggested, therefore, that the reaction initially proposed by Feast (10) to explain the production in a high pressure arc

$$O(^3P) + O(^1D) + M \rightarrow O_2(^3\Sigma_u^-) + M \qquad [1]$$

must be considered as a possible source of the excited O_2 molecule since atomic oxygen is definitely present in H_2/O_2 and CO/O_2 flames (11). The $O(^1D)$ may be produced thermally since its excitation energy is only 1.97 ev or it may be produced by the thermal dissociation of one of the reaction intermediates.

There are several difficulties in considering reaction [1]. No evidence for excited atomic oxygen has been found in the CO/O_2 flame (1). Also, if reaction [1] were responsible for the production of the Schumann–Runge bands, one might expect that transitions involving some of the higher vibrational levels of the $B^3\Sigma_u^-$ state would be observed. However, only the lower vibrational levels ($v' = 0, 1, 2$) have been seen in the CO/O_2 and H_2/O_2 flames (1, 6).

The purpose of this note is to suggest a mechanism for the production of thermally excited $O_2^*(^3\Sigma_u^-)$ in flames on the basis of some recently determined potential curves of O_2 (12). The methods of obtaining these curves are discussed in reference (12) and those of importance in the present discussion are shown in Fig. 1. It is found that the $^3\Pi_u$ and

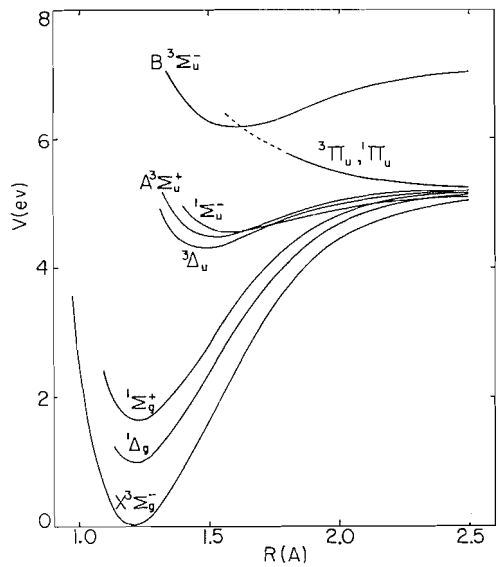

FIG. 1. Potential energy curves for O_2.

the $^1\Pi_u$ have approximately the same energy of interaction and seem to cross the curve for the $B^3\Sigma_u^-$ state around the minimum. Of all the repulsive states which arise from the interaction of two ground-state atoms, only the $^3\Pi_u$ can predissociate the $B^3\Sigma_u^-$ state strongly according to Kronig's rules (13). An oxygen molecule in the $^3\Pi_u$ state can, there-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/04/12
For personal use only.

fore, make a non-radiative transition to the B state. This process can be represented as

$$O(^3P) + O(^3P) \rightarrow O_2(^3\Pi_u) \rightarrow O_2^*(^3\Sigma_u^-) \quad [2]$$

and requires an energy of only about 1 ev. An excitation process like [2] would explain why the observed Schumann–Runge bands originate only from the lower vibrational levels of the B state. One might also expect that the rate of reaction [2] is much greater than that of [1] since the latter is a three-body collision.

If the above mechanism is correct, then it would be of interest to speculate on possible processes that might contribute to the continuum that has been noticed in some flames (14). In the H_2/O_2 and NH_3/O_2 flat diffusion flames, a continuum has been observed that lies roughly in the same region as the Schumann–Runge emission. Since this is near the oxygen side of the flame, Gaydon (14) suggests atomic oxygen as one of the reactants. Radiative transitions from the $^3\Pi_u$ or $^1\Pi_u$ state to some of the lower attractive states would result in a continuum. One would expect this continuum to arise from the same region of the flame as the Schumann–Runge bands in agreement with the observations. There are other transitions that could contribute to the continuum, for example, a transition from the repulsive side of the $A^3\Sigma_u^+$ state to the ground state. One might expect, however, that these would not be strong since they are not permitted by the selection rules although the latter might well be relaxed at these pressures.

A continuum has also been observed in flames containing carbon monoxide (15). This has been studied recently by Kaskan (16), who concludes that the production reaction involves an oxygen atom and a carbon monoxide molecule. However, since the Schumann–Runge bands are observed in these flames (15) there is a possibility that a small amount of the continuum might be due to the interaction of two oxygen atoms as suggested by Hoare and Walsh (17) and Hornbeck (18).

In conclusion, we would like to suggest that the $O_2^*(^3\Sigma_u^-)$ found in flames burning with O_2 is formed by the thermal collision of two $O(^3P)$ atoms interacting along the $^3\Pi_u$ repulsive curve which undergoes a radiationless transition to the $^3\Sigma_u^-$ state. Also, part of the continuum observed in these flames might arise from transitions from the repulsive branches of the $A^3\Sigma_u^+$, $^3\Delta_u$, or $^1\Sigma_u^-$ states down to one of the lower attractive states.

3-BENZYL-2-METHYL-3,4-DIHYDRO-4-KETOQUINAZOLINE

RAGINI ANET* AND S. SOMASEKHARA

As a part of investigations (1) on fused heterocyclic systems incorporating the quinazoline nucleus, 3-benzyl-2-methyl-3,4-dihydro-4-ketoquinazoline (I) was required. A preparation of this base was reported by Bogert and Beal (2) from acetylanthranil and benzylamine. However, these workers analyzed their compound, m.p. 123°, for nitrogen only, and did not prepare any derivatives. A hydrochloride, m.p. 232°–234°, of the required base was prepared by Grimmel, Guenther, and Morgan (3) from acetylanthranilic acid and benzylamine in presence of phosphorus trichloride. Once again, the compound was poorly characterized, no analysis figures were reported, nor was the free base or any derivatives prepared. As 2-methyl-4-hydroxy-quinazoline (II) was readily available, we studied its alkylation with benzyl chloride.

I

Treatment of the potassium salt of II with benzyl chloride in acetone gave a product whose analysis and infrared spectrum (4) were consistent with structure I. The melting point (74°) was different from that reported by Bogert and Beal, although that of the hydrochloride of our base was in agreement with that reported by Grimmel *et al.* The alkylation of 4-hydroxyquinazolines with alkyl halides in presence of alkali normally gives the 3-alkyl derivatives but in view of the reported ethylation of the sodium salt of 4-hydroxyquinazoline with ethyl iodide in alcohol to give largely the 4-ethoxy derivatives (5), an alternate synthesis of I was carried out from *o*-nitrobenzoyl chloride via N-benzyl-*o*-nitrobenzamide, N-benzyl-*o*-aminobenzamide, and N-benzyl-*o*-acetylaminobenzamide (III). The quinazoline derivative obtained by the cyclization of III with aqueous benzylamine was identical (mixed melting points and infrared spectra) with our benzylation product.

Having established that the product obtained on benzylation of II was indeed the required base I, it was of interest to find out the nature of Bogert and Beal's compound. Repetition of their work gave at first a product identical with our benzylation product. However, if slightly less than the calculated amount of benzylamine was used, a compound, m.p. 118°, could be obtained. Its infrared spectrum showed all the bands present in the spectrum of I but in addition showed bands in the —NH or —OH stretching region similar to those shown by the spectrum of N-benzyl-*o*-acetylaminobenzamide III. In fact, the compound was an equimolecular complex of I and III. This was shown by its elementary analysis and by its separation with cold benzene into the two components. Oxidation of I with selenium dioxide in aqueous dioxan gave the 2-aldehyde, which was characterized as its 2,4-dinitrophenylhydrazone.

It is of interest to note that the hydrochloride of I underwent debenzylation at its melting point.

EXPERIMENTAL

3-Benzyl-2-methyl-3,4-dihydro-4-ketoquinazoline (I)

2-Methyl-3,4-dihydro-4-ketoquinazoline (8.5 g), benzyl chloride (7 g), and powdered potassium hydroxide (12 g) were refluxed in 500 ml of acetone for 6 hours. After removal of the solvent, the residue was extracted with chloroform and the chloroform evaporated. The oil thus obtained was treated with cold dilute hydrochloric acid to give a crystalline hydrochloride. Liberation of the base in the usual manner gave 5 g of the 3-benzyl derivative (I), which was crystallized from benzene – petrol ether (30°–60° b.p.) in plates, m.p. 74°. Found: C, 76.6; H, 5.5; N, 11.0%. Calc. for $C_{16}H_{14}NO_2$: C, 76.8; H, 5.6; N, 11.2%.

The hydrochloride, prepared by cooling a hot solution of the base in hydrochloric acid, formed needles, m.p. 233° (lit. (2), m.p. 232°–234°). Found: N, 9.2%. Calc. for $C_{16}H_{15}N_2OCl.H_2O$: N, 9.2%.

Acetylanthranil (0.9 g) and benzylamine (0.6 g) were heated together at 150° for 30 minutes. On cooling, the melt solidified and was treated with aqueous sodium bicarbonate to give 0.9 g of a white solid. After several crystallizations from ethanol it melted at 118°. (Bogert and Beal (2) give m.p. 123°.) Found: C, 74.0; H, 5.9; N, 10.8%. Calc. for $C_{16}H_{14}N_2O.C_{16}H_{16}N_2O_2$: C, 74.1; H, 5.8; N, 10.8%.

The compound was soluble in hot benzene, alcohol, and chloroform. Treatment with a small quantity of cold benzene gave a benzene-soluble compound, m.p. 74°, identical with I and a residue, m.p. 129°–137°, which after crystallization from aqueous alcohol melted at 147° to 148°, identical with N-benzyl-*o*-acetylaminobenzamide (IV) described below.

Repetition of the above experiment with a slight excess of benzylamine gave I exclusively.

3-Benzyl-3,4-dihydro-4-ketoquinazoline-2-aldehyde

Freshly prepared selenium dioxide (0.42 g) was added to 1 g of I in 25 ml dioxan and the mixture was refluxed for 1 hour. The precipitated selenium was filtered off and the filtrate passed through a 3-in. column of alumina to remove colloidal selenium. The dioxan solution was concentrated and the residue treated with petrol ether to give 1 g of the aldehyde, which crystallized from benzene in needles, m.p. 143°–144°. Found: C, 72.4; H, 4.6; N, 10.7%. Calc. for $C_{16}H_{12}O_2N_2$: C, 72.7; H, 4.5; N, 10.6%.

The 2,4-dinitrophenylhydrazone prepared in the usual manner gave needles, m.p. 275°–277°. Found: N, 19.1%. Calc. for $C_{22}H_{16}N_6O_5$: N, 18.9%.

N-*Benzyl-o-nitrobenzamide*

o-Nitrobenzoic acid (1 g) and thionyl chloride (3 ml) were refluxed in 5 ml of dry benzene for 1 hour. The solution was concentrated under reduced pressure and the residue was dissolved in 2 ml of dry benzene. To a cold solution of the acid chloride, a solution of 1 ml benzylamine in 3 ml benzene was added, followed by 10 ml of petrol ether. The crude benzamide (1.1 g), m.p. 122°–123°, separated out and was crystallized from benzene. Found: N, 10.9%. Calc. for $C_{14}H_{12}O_3N_2$: N, 10.9%.

N-*Benzyl-o-aminobenzamide*

A 1-g quantity of the *o*-nitrobenzamide was gently refluxed with 3 g of zinc dust in 100 ml of 5% acetic acid for 2 hours, and filtered hot. The filtrate, on cooling, gave the *o*-amino derivative, m.p. 123°. It was crystallized from aqueous alcohol in needles, m.p. 124°. Found: N, 12.6%. Calc. for $C_{14}H_{14}ON_2$: N, 12.4%.

N-*Benzyl-o-acetylaminobenzamide* (III)

One hundred milligrams of the *o*-amino derivative was heated with 3 ml of acetic anhydride at 100° for 10 minutes. The reaction mixture was cooled and poured into water to give 100 mg of the acetyl derivative. It was crystallized from aqueous alcohol in needles, m.p. 147°–148°. Found: C, 71.4; H, 5.9; N, 10.5%. Calc. for $C_{16}H_{16}N_2O_2$: C, 71.6; H, 6.0; N, 10.5%.

Cyclization of the N-*Benzyl-o-acetylaminobenzamide*

Fifty milligrams of the acetylamino derivative was added to 3 ml of water containing two drops of benzylamine. The mixture was boiled for 2 to 3 minutes and cooled. Dilute hydrochloric acid precipitated the hydrochloride (40 mg), which was converted to the base with potassium hydroxide. Chloroform extraction gave an oil which crystallized from benzene – petrol ether in plates, m.p. 73°–74° (mixed m.p. with I, 73°–74°).

Debenzylation of the Hydrochloride of I

The hydrochloride of I (0.8 g) was maintained at 235° for 30 minutes. The product was washed with a 5% sodium carbonate solution. Crystallization of the solid from dilute ethanol (charcoal) gave 0.15 g of 2-methyl-4-hydroxyquinazoline (II), m.p. 234° (5). Mixed melting point with an authentic sample was undepressed.

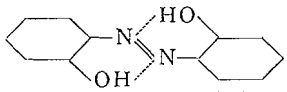
The substituents introduced into the aromatic ring systems will be identified by skeleton type I or II and substitution position related to above numbering system. The correlation of hydrogen bonding strength with nuclear shielding parameter ($\sigma_{reference} - \sigma_{OH}$) is now well established (3) although quantitative comparison of ($\sigma_{ref} - \sigma_{OH}$) and heat of formation directly is rarely possible. Spectral shifts in the infrared are more often used as the correlative parameter (3, 4). There is an advantage in measuring the shielding parameter in intramolecular hydrogen bonds since in dilute solution the entropy term due to dilution is not dominant in causing dissociation of the bond. This is shown clearly in many dilution shift studies (5, 9, 10) where intramolecular hydrogen bonds exist. If the intramolecular hydrogen bond is fairly weak as in O-chloro phenol, competition with stronger intermolecular hydrogen bonds in concentrated solutions causes dilution chemical shifts in this region. However, even in this case isolation of the hydrogen-bonding species in an inert solvent such as CCl_4 enables a nuclear shielding parameter for an undissociated intramolecular hydrogen bond to be obtained (5). Charges in nuclear shielding due to hydrogen bonding has been treated theoretically by Marshall and Pople (11).



EXPERIMENTAL

Measurements were made using a solvent 99.5 mole % CCl_4 and 0.5 mole % cyclohexane in which the compounds were soluble up to 1 mole %, except for nitro derivatives. A 40-Mc/s Varian spectrometer V4300 with field stabilizer VK3506 was used and samples were made up in 5-mm O.D. tubes. The 0.5% cyclohexane served as an internal reference. Chemical shifts were measured by the usual side band technique with an audio oscillator calibrated by using 'lissajoux' figures at multiples of the 60 c.p.s. mains frequency.

RESULTS AND DISCUSSION

Column 2 of the Table I shows the value of ($\sigma_{cyclohexane} - \sigma_{OH}$) measured directly in the manner described. In an attempt to correct for the difference in shielding effect at the proton under study due to the additional diamagnetic anisotropy introduced by the naphthalene rings, a correction has been made to all compounds for the low field shift

TABLE I

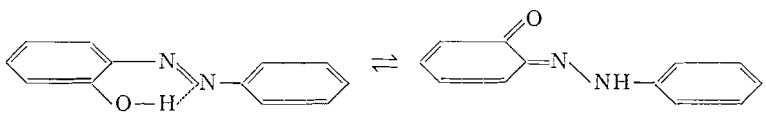
due to currents in all aromatic rings. The correction to high field is slightly larger for the naphthalene compounds. The free electron model of Pople was used (6) and the interatomic distances were those for trans azo benzene (7). In addition the C—O—H bond, lengths and angles were taken to be the same as those in a phenol. The molecule is probably



very nearly planar and was taken to be so in the calculation. Column 3 in the table contains shielding parameters corrected in this manner. These values are more correct when comparing with shielding parameters of strong hydrogen bonds in systems without large magnetically anisotropic centers.

The main feature of the results is the large shift of ~3 p.p.m. to low field in the naphthalene derivatives indicating a much stronger hydrogen bond. A good measure of the decreased shielding is shown in compounds 1 and 6 which differ by 3.08 p.p.m. It is clear that the electron-withdrawing action of the larger resonance system in naphthalene makes the hydroxyl group a much stronger acceptor. A parallel can be drawn in the greater acidity of the β hydroxy naphthalene over that of phenol (8).

Among the trans azo benzene derivatives the dihydroxy compound 2 has greatest shielding and is thus the weakest hydrogen bond of this series. It is expected that the donor properties of one nitrogen will be affected to a small degree by the use of the other in a hydrogen bond. Methyl substitution is not effective in changing the hydrogen bond strength; however the replacement of one nitrogen by a —CH= group leads to decreased shielding of the hydrogen-bonding proton. The difference in electronegativity of nitrogen and the —CH= group will increase the donor property of the nitrogen and thus to a small degree the hydrogen bond formed will be stronger.

In the β OH naphthalene derivatives substitution on the benzene ring only was studied. Chlorine substitution has very little effect on chemical shift but the inductive effect of methyl substitution appears to increase donor properties of the conjugated nitrogen considerably, resulting in a stronger hydrogen bond.

Some of these compounds were studied in the melt at higher temperature. In all cases the OH peak showed broadening indicative of proton exchange. The signals in 1% CCl_4 solution were quite sharp. As the temperature was further raised some OH peaks broadened below noise level (over 40 c.p.s. half width). This proton transfer process may be intermolecular or involve transfer across the intramolecular hydrogen bond. In the latter case the imino form of these compounds would appear in equilibrium with the azo form.

It is of some interest that the imino form has been shown to exist in the solid state in these compounds (12, 13) and the existence in solution is also suggested. Other workers (14) have shown, however, that the azo form of *o*-azophenols is the only stable species in solution. Since it is unlikely that proton transfer to the imino form occurs in dilute CCl_4 solution at room temperature where the proton resonance of the —OH proton is sharp, then the nuclear shielding parameters are attributed to pure azo form. Measurements of the intensity of the methyl resonance in methyl derivatives compared with the intensity of the —OH peak showed that no appreciable amount of material is in the imino form. It is presumed that protons transferred to the imino form will not show resonance peaks because of quadrupole relaxation. Intensity measurements in dilute solution cannot be better than $\pm 5\%$ in this experiment.

Previous studies of tautomerism (1) have shown that the proton transfer process is quite slow at room temperature and that the lifetime in individual environments is greater than a millisecond. In this case also, the nuclear shielding parameters measured

here would correspond to the azo form only since quadrupole relaxation will prevent detection of a small amount of imino form.

The author wishes to thank the National Research Council of Canada and the Research Corporation for financial aid in this research. The chemicals were obtained from Dr. Y. Matsunaga, Department of Analytical Chemistry, University of Tokyo. I am grateful for the gift of these compounds.

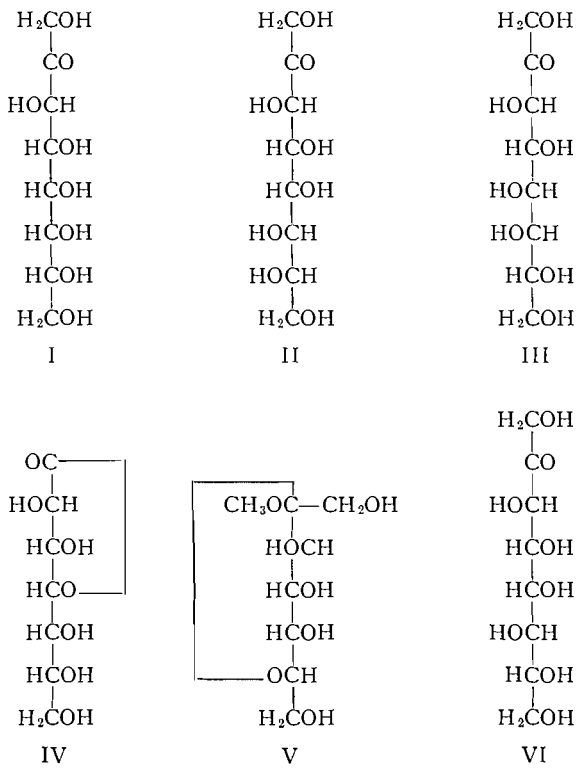
SYNTHESIS OF SUGARS FROM SMALLER FRAGMENTS

PART XII. SYNTHESIS OF D-GLYCERO-D-ALTRO-, L-GLYCERO-L-GALACTO-, D-GLYCERO-L-GLUCO-, AND D-GLYCERO-L-GALACTO-OCTULOSE[1]

J. K. N. JONES AND H. H. SEPHTON[2]



ABSTRACT

1,3-Dihydroxy-2-propanone phosphate condenses with D-ribose, L-arabinose, D-lyxose, and D-xylose in the presence of rabbit muscle aldolase to yield octulose phosphates from which the octuloses named in the title were prepared.

Previous publications (1, 2, 3) have demonstrated that 1,3-dihydroxy-2-propanone phosphate (dihydroxyacetone phosphate) will combine with aldehydes, in the presence of the enzyme aldolase, to yield 2-keto-sugars in which the hydroxyl groups on C_3 and C_4 have the D-threo-configuration. Thus, with glycolaldehyde a D-threo-pentulose is produced, L-lactaldehyde yields 6-deoxy-L-sorbose, and D-erythrose gives rise to D-altro-heptulose. It was of interest to see whether aldolase would cause dihydroxyacetone phosphate to condense with pentoses and thus form octuloses. At about the time that we had obtained paper chromatographic evidence that such a reaction was taking place, albeit in very small yield, Dr. N. K. Richtmyer informed us that he and Dr. A. J. Charlson had isolated an octulose from the avocado (4). This octulose was the first found in nature and was shown to have the D-glycero-D-manno-configuration. It has subsequently also been isolated from a species of the *Sedum* plant (5). We have prepared four octuloses by the aldolase-catalyzed condensation of dihydroxyacetone phosphate with D-ribose, L-arabinose, D-lyxose, and D-xylose. The first three products have been shown to be D-glycero-D-altro- (I), L-glycero-L-galacto- (II), and D-glycero-L-gluco-octulose (III) respectively. These octuloses are syrups (glasses) and were characterized as their crystalline 2,5-dichlorophenylhydrazones (from I and II) and as the phenylosazones (from II and III). The fourth product (from D-xylose) appears to be D-glycero-L-galacto-octulose (VI). All these sugars possess the D-threo-configuration of hydroxyl groups on C_3 and C_4. They give a characteristic color reaction on paper chromatograms when sprayed with the orcinol spray reagent for ketoses (6) and heated at 110°, viz. crimson that fades to grey. D-Glycero-L-gluco-octulose has also previously been obtained from the corresponding heptonyl chloride by Wolfrom and Cooper by diazomethane synthesis (7).

The products were identified in the following manner: D-glycero-D-altro-octulose (I) was oxidized with oxygen in alkaline solution (8) and yielded the known crystalline D-glycero-D-altro-heptono-γ-lactone (IV); its configuration was thus proved. L-Glycero-L-galacto-octulose (II) was identified with its known enantiomorph (9) by optical rotation

data and by infrared absorption and melting point data on the 2,5-dichlorophenylhydrazone derivatives of the enantiomorphs. The methyl glycoside of the second octulose (II) was oxidized with 1 mole of periodate and the product reduced with sodium borohydride. The resulting heptuloside (V) was hydrolyzed and found to behave like L-galacto-heptulose on a paper chromatogram (orcinol spray test). This observation is in accord with the expected high susceptibility to periodate attack of the C_7—C_8 bond of the octuloside in the pyranose form. The third octulose (III) when heated in aqueous solution with phenylhydrazine acetate yielded D-glycero-L-gluco-octose phenylosazone, which was found to be identical with a phenylosazone prepared from a specimen of the known synthetic D-glycero-L-gluco-octulose (7). The small quantity of the fourth octulose (VI) obtained precluded its positive identification. It was oxidized with oxygen in alkaline medium (8) and the lactone produced was found to behave like D-glycero-L-galacto-heptonic lactone (10) on a paper chromatogram. The methyl glycoside of this octulose (VI) was oxidized with 1 mole of periodate and the product reduced with potassium borohydride and hydrolyzed. The reducing compound thus obtained moved at the same rate as L-galacto-heptulose on a paper chromatogram.

When L-arabinose-1C^{14} was used as a substrate, a radioactive octulose 1-phosphate was produced. This on hydrolysis with acid gave an octulose which was indistinguishable chromatographically from L-glycero-L-galacto-octulose. The radiogram also indicated that a faster-moving material, probably an anhydro octulose (orcinol spray test), had also been formed. A similar product was also readily obtained upon acid hydrolysis of either the 1-phosphate or the methyl glycoside of D-glycero-D-altro-octulose. To avoid as far as possible the formation of anhydro octulose derivatives, phosphate groups were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

removed from the octulose phosphate preparations by means of the enzyme phosphatase. All condensations were carried out at pH 6.7 to avoid non-enzymic-type condensation. The aldolase was prepared from rabbit muscle and was twice recrystallized. Two other enzymic syntheses of an octulose have been recorded: an octulose 8-phosphate was prepared from the action of transaldolase on a mixture of D-ribose 5-phosphate and D-fructose 6-phosphate (11), and in a footnote to this publication reference is made to the preparation of an octulose 1,8-diphosphate, which was prepared by Dische from ribose 5-phosphate, dihydroxyacetone phosphate, and muscle aldolase. These products were not characterized and their probable configurations (D-glycero-D-altro-octulose) were not discussed.

The stereospecificity of the aldolase condensation as illustrated above precludes it as the mechanism by which D-glycero-D-manno-octulose (4) is formed in nature unless the latter arises from D-glycero-D-altro-octulose phosphate by the action of an epimerase on C_4.

EXPERIMENTAL

General Methods

Distilled aqueous 1-butanol was used to elute cellulose column chromatograms. Materials to be chromatographed were dissolved in methanol, cellulose powder was added, and the solvent subsequently removed under vacuum from the suspension to precipitate the material onto the cellulose powder. The latter was resuspended in 1-butanol and allowed to settle under gravity in the form of a horizontal band on top of the packed cellulose column before elution was begun. Individual fractions from the columns were examined by paper chromatography using 1-butanol – ethanol – water (3:1:1) by the descending method. Sugars were detected by the silver nitrate spray in acetone followed by the ethanolic sodium hydroxide spray reagent (12) and ketoses by the orcinol and trichloroacetic acid in tertiary butanol spray reagent (6). Octuloses and anhydro octuloses were found to give a characteristic color reaction upon heating at 110° with the latter reagent, viz. a bright crimson which upon further heating fades to a more or less stable grey. Individual fractions were reduced to small volume by evaporation under vacuum in a rotary evaporator with a bath temperature of less than 50°.

Rabbit Muscle Aldolase

One fully grown female rabbit was anesthetized by intravenous injection of Nembutal and most of the blood drained through one of the jugular veins. The carcass was rapidly skinned and the main skeletal muscles cut out. Subsequent operations were carried out at 4° following the procedure described by Taylor (13). The microcrystalline enzyme obtained was kept as a suspension in 50% ammonium sulphate solution (1500 ml) at 4°. Under these conditions no appreciable loss in enzyme activity was observed after 5 months' storage.

Preparation of Substrates

Barium D-fructose 1,6-diphosphate (Nutritional Biochemicals Corp.), a biochemical source of dihydroxyacetone phosphate, was purified by reprecipitation and washing according to the method detailed by Dounce and Beyer (14). Substrates were prepared by stirring the barium salt in a small volume of distilled water to which Amberlite IR-120 resin was added as required to effect solution. Decationization was completed (negative test for barium) by passing the solution through a column of this resin. The pH of the fructose diphosphate solution obtained was adjusted to 6.7 by the addition of 2 *N* sodium hydroxide.

Preparation of D-*Glycero*-D-*altro-octulose* (I)

A substrate (pH 6.6) of disodium fructose diphosphate was prepared from purified barium fructose diphosphate (7 g) and D-ribose (4.5 g) was added. Rabbit muscle aldolase was collected from the ammonium sulphate suspension preparation (200 ml) by filtration and washed through the filter paper into the substrate with distilled water. The pH of the medium (500 ml) was readjusted to 6.7 and toluene (2 drops) was added. The flask was covered with aluminum foil and placed in an incubator at 32° for 4 days, during which time the pH of the medium dropped to 6.4. The enzyme protein was coagulated by heating the reaction mixture to 80° on the boiling-water bath and removed by filtration. Amberlite IR-120 resin was cautiously added to the cooled filtrate to adjust the pH to 4.3 and immediately removed by filtration. Acid phosphatase (Nutritional Biochemicals Corp.) (0.3 g) was added to the filtrate; the flask was covered and left in the incubator at 32° for 2 days. The protein was coagulated by heating the substrate to 80° on the boiling-water bath and the solids were removed by filtration. The cooled filtrate was completely deionized by passage through columns of Amberlite IR-120 and Duolite A-4 resins respectively and evaporated to a syrup (4.37 g). Paper chromatograms indicated the presence of D-ribose (R_f, 0.26), D-fructose (R_f, 0.18), and an octulose (R_f, 0.10) (orcinol spray). The syrup was separated by chromatography on a column of packed cellulose powder (4.5×25 cm) and eluted with aqueous 1-butanol. Three distinct fractions were obtained but the octulose (third) fraction (0.120 g) was slightly contaminated with D-ribose as a result of relative overloading of the column with respect to the latter constituent. The contaminating D-ribose was removed by rechromatographing the octulose fraction on a cellulose column (2.5×25 cm). The product (86 mg) had $[\alpha]_D^{22}$ +7.9° (*c*, 3.3 in methanol). Two additional batches of the octulose were prepared by similar procedures.* One had $[\alpha]_D^{26}$ +8.0° (*c*, 2.5 in methanol) with $[\alpha]_D^{26}$ +2.9° (*c*, 1.4 in water, inaccurate) and the other $[\alpha]_D^{27}$ +8.4° (*c*, 5.5 in methanol) (no mutarotation observed). These products were obtained (in 3.1%, 2.1%, and 1.1% yields respectively, based on fructose diphosphate, FDP) as hygroscopic amorphous solid foams upon removal of solvents under vacuum. When acid hydrolysis (pH 1 at 50° for 6 hours) was employed in another experiment to split the phosphate esters, an octulose, chromatographically identical with the above products, was obtained. In addition, the presence of an anhydro octulose in the acid hydrolyzate was indicated by paper chromatography (R_f, 0.28; orcinol spray reagent). This product was also readily formed upon acid hydrolysis of the pure octulose methyl glycoside.

D-*Glycero*-D-*altro-octulose 2,5-Dichlorophenylhydrazone*

The octulose (0.070 g) was treated with an equal weight of 2,5-dichlorophenylhydrazine in dry methanol (2.5 ml) under reflux for 2 hours. The solvent was removed under vacuum, the solid residue washed with ether by decantation to remove excess reagent, and the product recrystallized from a small volume of methanol, m.p. 169.5–170.5° (decomp.) (Kofler microstage, corrected). $C_{14}H_{20}Cl_2N_2O_7$ requires: C, 42.2; H, 5.0; Cl, 17.8; N, 7.0. Found: C, 42.3; H, 5.2; Cl, 18.0; N, 6.9.

Oxidative Degradation of D-*Glycero*-D-*altro-octulose to* D-*Glycero*-D-*altro-heptono*-γ-*lactone*

The octulose (0.049 g) was shaken with *N* potassium hydroxide (1.5 ml) in a small flask filled with oxygen and connected to an oxygen burette, at room temperature (28.5°) and atmospheric pressure. The volume of oxygen absorbed was measured after

**The conditions used were not necessarily the optimum conditions nor were the yields obtained necessarily the opitmum yields.*

suitable time intervals (4.0 ml; 4 hours) until it remained constant (7.5 ml; overnight). The alkaline solution was decationized with Amberlite IR-120 resin, filtered, and the volatile acidic products removed by evaporating the aqueous solution to dryness several times. The syrupy product (0.030 g) was examined by paper chromatography. The presence of at least six reducing components was revealed by alkaline silver nitrate spray reagent; the main component (R_f, 0.23) moved with the same speed as authentic D-glycero-D-altro-heptono-γ-lactone (kindly provided by Dr. N. K. Richtmyer). This component was isolated on Whatman No. 3 mm paper and obtained as a clear syrup (0.010 g) which crystallized upon nucleating with authentic D-glycero-D-altro-heptono-γ-lactone. The syrup had $[\alpha]_D^{30}$ +22.2° (*c*, 0.9 in water) (no mutarotation observed). The crystals, washed with methanol, had m.p. 122–123.5°, undepressed by mixing with authentic D-glycero-D-altro-heptono-γ-lactone.

Preparation of L-*Glycero*-L-*galacto-octulose* (II)

A substrate was prepared as described above from purified barium fructose 1,6-diphosphate (16 g) and adjusted to pH 6.7 (450 ml). Muscle aldolase was collected from the enzyme preparation (280 ml) by filtration and washed through the filter into the substrate with distilled water (150 ml). The pH of the preparation was readjusted to 6.7 and L-arabinose (12 g) added, followed by toluene (2 drops). The preparation was incubated at 32° for 4 days. The protein in the solution (pH 6.4) was coagulated by heating it to 80° on a boiling-water bath and the precipitate removed by filtration. The filtrate was adjusted to pH 4.3 by careful addition of Amberlite IR-120 resin and filtration. Acid phosphatase (1.0 g) was added to the filtrate and the solution was left in the incubator (32°) for 2 days. The enzyme was denatured by heating the solution to 75° on the boiling-water bath and removed by filtration. The filtrate was deionized by passage through columns of Amberlite IR-120 and Duolite A-4 and concentrated to a syrup. The octulose (0.318 g) was obtained from the syrup after chromatographing twice on cellulose columns as described for the previous octulose preparation (yield: 5.1% based on FDP). The product was obtained as a clear amorphous hygroscopic glassy foam after removal of all solvents under vacuum; $[\alpha]_D^{25}$ −62° (*c*, 0.105 in water) (no mutarotation observed). A second reducing product was eluted from the cellulose column following closely on the octulose. This material did not give the typical octulose color reaction. It was rechromatographed and a homogeneous product (0.085 g) obtained having $[\alpha]_D^{25}$ −20° (*c*, 0.8 in methanol). This material was not investigated.

L-*Glycero*-L-*galacto-octulose Phenylosazone*

The octulose (0.0095 g) was heated in a 10-ml test tube with water (0.5 ml), phenylhydrazine (0.05 ml, redistilled), and acetic acid (0.05 ml) for 7 minutes in a steam bath. The osazone started to crystallize at this stage and the solution was allowed to cool slowly to room temperature. The crystalline phenylosazone was collected by filtration on a small Büchner funnel, washed with water and methanol, and dried in vacuum over P_2O_5. The product (0.005 g) had m.p. 202–206° (decomp.). $C_{20}H_{26}N_4O_6$ requires: N, 13.4. Found: N, 13.0.

L-*Glycero*-L-*galacto-octulose 2,5-Dichlorophenylhydrazone*

The octulose (0.040 g) was heated with an equal weight of 2,5-dichlorophenylhydrazine in methanol (3 ml) under reflux for 2 hours. The solvent was removed under vacuum and the solid residue washed with ether by decantation. The residue was recrystallized from a small volume of methanol. Thrice-recrystallized material (12 mg) had m.p.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

194–195° (decomp. corrected). $C_{14}H_{20}Cl_2N_2O_7$ requires: C, 42.2; H, 5.0; Cl, 17.8; N, 7.0. Found: C, 41.9; H, 5.3; Cl, 16.5; N, 6.8. The 2,5-dichlorophenylhydrazone prepared as above from D-glycero-D-galacto-octulose (0.018 g) (kindly provided by Professor M. L. Wolfrom) had m.p. 196–197° (decomp. corrected). $C_{14}H_{20}Cl_2N_2O_7$ requires: C, 42.2; H, 5.0; Cl, 17.8; N, 7.0. Found: C, 42.5; H, 5.3; Cl, 16.5; N, 6.6. The mixed melting points of these two substances lay between those of the individual constituents. The infrared spectra of these materials (0.8% in KBr) were recorded and were found to have closely corresponding absorption peaks throughout.

Periodate Oxidation of Methyl L-*Glycero*-L-*galacto-octuloside*

The octulose (0.004 g) was treated with 2% methanolic hydrogen chloride (3 ml) under reflux for 3 hours. The solution was neutralized to pH 7.8 (dilute sodium hydroxide) and the methanol removed under vacuum. The remaining aqueous solution (10 ml) was filtered and a 25% aliquot (2.5 ml) used for the oxidation. Sodium metaperiodate (0.46 ml 0.01 *N*) (1 mole) was added and the solution left at room temperature (27°) for 12 minutes. Excess sodium borohydride was added and the solution was left at room temperature for 3 hours. The solution was rendered acidic by the addition of Amberlite IR-120 resin and filtered. The methyl glycosides were hydrolyzed by heating the solution on the boiling-water bath for 1 hour. The solution was evaporated to dryness under vacuum and this was repeated several times after addition of methanol (5 ml) to remove methyl borate. The residue was taken up in water and deionized on Duolite A-4 resin. The neutral solution was evaporated to a syrup and chromatographed on Whatman No. 1 filter paper. The orcinol – trichloroacetic acid spray reagent indicated the presence of a heptulose (intense blue spot) which had an R_f value similar to that of L-galacto-heptulose.

Preparation of D-*Glycero*-L-*gluco-octulose* (III)

The substrate was prepared as detailed above using barium fructose 1,6-diphosphate (12 g) and D-lyxose (10 g) in water (500 ml) at pH 6.7 with muscle aldolase from the above enzyme preparation (190 ml). The mixture was incubated at 32° for 5 days and worked up as in the previous case, using acid phosphatase (0.3 g) to hydrolyze the phosphate esters. After removal of the protein the deionized solution was evaporated to a syrup, dissolved in methanol (10 ml), and nucleated with D-lyxose. Crystalline D-lyxose (7 g) was removed by filtration and the octulose isolated from the mother liquors by chromatography on a cellulose column. The product (0.186 g) was obtained as a hygroscopic solid glassy foam (yield 4.0% based on FDP); $[\alpha]_D^{27}$ −46.9° (*c*, 2.73 in water) (no mutarotation observed).

The phenylosazone, prepared from the octulose (0.0098 g) as described above, had m.p. 199–202° (decomp. corrected). A similar osazone, prepared from D-glycero-L-gluco-octulose obtained from Professor Wolfrom (7) had m.p. 199–204° (decomp.). The mixed melting point of these two derivatives was 199–202° (decomp.). The infrared spectra of these two osazones were obtained (0.6% in KBr) and were found to be closely similar.

Preparation of D-*Glycero*-L-*galacto-octulose* (VI)

The substrate was prepared as previously described using disodium fructose 1,6-diphosphate (0.4 g) and D-xylose (1 g) in water (50 ml) at pH 6.7 and muscle aldolase from the enzyme preparation (20 ml) was added. After incubation at 32° for 108 hours the enzyme was precipitated by heating the solution on the water bath to 80° and was removed by filtration. The filtrate was rendered acidic (pH 1–2) by decationizing with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Amberlite IR-120 and warmed overnight at 55° to hydrolyze the phosphate esters. The cooled solution was deacidified (Duolite A-4) and evaporated to a syrup. The octulose (0.006 g) was isolated from the syrup by chromatography on thick filter paper and by exhaustively extracting the appropriate area with methanol; $[\alpha]_D^{28}$ −43.4° → −13.4° (3 hours, *c*, 0.6 in water).

Degradation of D-*Glycero*-L-*galacto-octulose*

Spengler–Pfannenstiel Oxidation

The octulose (3 mg) was oxidized overnight in *N* potassium hydroxide (0.5 ml) under an oxygen atmosphere as described previously. The solution was diluted with water and decationized on Amberlite IR-120 resin. The effluent was repeatedly concentrated to a syrup after addition of water (3 ml) to remove the volatile acids. The residue was examined on paper chromatograms sprayed with the silver oxide (12) and with the lactone spray reagents (15). Both results indicated that the lactone produced was chromatographically indistinguishable from authentic D-glycero-L-galacto-heptonic lactone (10) provided by Dr. N. K. Richtmyer.

Periodate Oxidation

The octulose (1.5 mg) was treated under reflux with methanolic hydrogen chloride for 4 hours. The solution was neutralized to pH 7.8 with 0.1 *N* aqueous sodium hydroxide and the methanol removed under vacuum. Sodium metaperiodate (1.3 mg) was added and the solution left at room temperature for 12 minutes. Excess potassium borohydride was now added and the solution left at room temperature for 6 hours. The solution was rendered acidic by decationizing (IR-120 resin) and the methyl esters hydrolyzed by heating under reflux for 1 hour. The solution was evaporated several times with methanol (5 ml) to remove methyl borate. The residue was deionized and examined by paper chromatography. Three components were indicated; the main component moved at the same rate as authentic L-galacto-heptulose (silver oxide spray reagent).

Preparation of Isotopically Labelled L-*Glycero*-L-*galacto-octulose*

The substrate was prepared as previously described using barium fructose 1,6-diphosphate (0.6 g) and L-arabinose (0.14 g) to which was added L-arabinose-1C^{14} (1.42 mg containing 5 μc activity) in water (50 ml) at pH 6.7. Muscle aldolase from the preparation (20 ml) was added and the solution incubated at 32° for 108 hours. The enzyme was precipitated by warming the solution to 80° and removed by filtration. The cooled solution was decationized with Amberlite IR-120 resin and the acidic solution (pH 1–2) warmed overnight at 55° to hydrolyze phosphate esters. The cooled solution was deacidified (Duolite A-4) and evaporated to a syrup. The syrup was dissolved in methanol (5 ml) and nucleated with L-arabinose. The crystalline L-arabinose was removed by filtration and the mother liquors concentrated to a syrup and chromatographed on thick filter paper. A radiogram was obtained (14 days exposure) on X-ray film showing the presence of radioactive octulose and anhydro octulose (by crimson color reactions with orcinol spray reagent on the paper chromatogram).

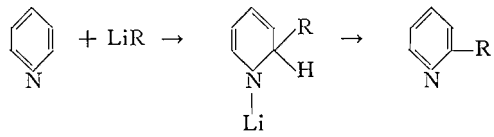
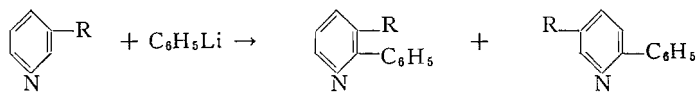
ARYLPYRIDINES



PART I. ORIENTATION IN THE REACTION OF PHENYLLITHIUM WITH SOME 3-SUBSTITUTED PYRIDINES[1]

R. A. Abramovitch, Giam Choo Seng, and A. D. Notation

ABSTRACT



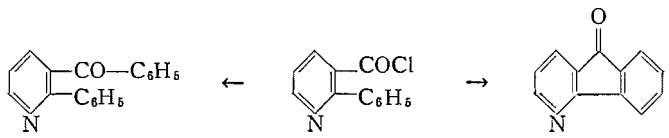
The orientation of the entering phenyl substituent in the addition of phenyllithium to 3-picoline and nicotine has been studied. In the first case the main product was 3-methyl-2-phenylpyridine together with a small amount of 5-methyl-2-phenylpyridine, the ratio of the isomers being 19:1. The structure of the isomers was established by oxidation to the corresponding phenylnicotinic acids, by infrared and n.m.r. spectroscopy. Quantitative analysis of the crude mixture of isomers was effected by vapor phase chromatography. Phenylation of nicotine gave 2-phenyl- and 6-phenyl-nicotine in the ratio of 1:1. Separation of the isomers was effected by preparative vapor phase chromatography and their orientation established as above. Evidence that the 3-substituent exerts an appreciable steric effect in the end product of the addition is presented. The results are taken to mean that addition of phenyllithium, and probably of other nucleophilic reagents, to 3-substituted pyridines occurs preferentially at the 2-position but the 3-substituent, if sufficiently bulky, may exert a steric effect resulting in appreciable addition at the 6-position also.

The reaction of lithium alkyls and aryls with dry pyridine is well known (1, 2). An intermediate (I) is probably first formed and this on heating loses lithium hydride to give the 2-substituted pyridine.

I

The formation of a 4-substituted pyridine has not been reported in such reactions. It is clear, therefore, that the addition of 1 mole of phenyllithium to a 2- or a 4-substituted pyridine can only lead to the formation of one compound. On the other hand, addition to a 3-substituted pyridine may lead to one, or a mixture, of two isomers. Very little is known about the directive effect of such a 3-substituent upon the entering phenyl group.

II III IV



Miller, Osuch, Goldberg, and Levine (3) claimed that the reaction of 3-picoline (II, R = CH_3) with phenyllithium gave 5-methyl-2-phenylpyridine (IV, R = CH_3) exclusively. Similarly, Wiley, Jarboe, Callahan, and Nielsen (4) reported that the reaction of 3-phenylpyridine (II, R = C_6H_5) with phenyllithium gave 2,5-diphenylpyridine (IV, R = C_6H_5) as the only isomer isolated. On the other hand, the reaction of 3-substituted pyridines with other nucleophilic reagents has yielded different results. Plazek, Marcinikow, and Stammer (5), for example, established the preferential formation of 2-amino-3-methylpyridine in the reaction of 3-picoline with sodamide while Seide reported the

[1]*Manuscript received January 14, 1960.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.

exclusive formation of this isomer when potassium amide was used (6). Hardegger and Nikles studied the amination of 3-*n*-butylpyridine (II, R = *n*-Bu) with sodamide; the product, obtained in 50% yield, was a mixture containing 80% of the 2,3-isomer and 20% of the 2,5-isomer (7). Similarly, Leonard and Ryder found that the reaction of butyllithium with 3-picoline produced predominantly 2-butyl-3-methylpyridine (8).

The various observations recorded above appear to be contradictory. It was therefore of interest to establish conclusively the orientation in the addition of phenyllithium to 3-substituted pyridines and to this end it was proposed to study in the first instance the reaction with 3-picoline. This reaction was carried out in the usual way, the addition of the picoline to phenyllithium being carried out in ether solution and the temperature eventually raised to ca. 110° by the replacement of the ether by toluene. The product (42.4% yield) consisted mainly of a mixture of the two phenylated 3-picolines. Preliminary attempts at separating the mixture by vapor phase chromatography were unsuccessful. The isomers were eventually separated by fractional distillation using a spinning band column, and were obtained in the ratio of 8:1 by weight. The major product was characterized as 3-methyl-2-phenylpyridine (III, R = CH_3) as follows:

(i) Oxidation with neutral aqueous potassium permanganate gave 2-phenylpyridine-3-carboxylic acid (III, R = CO_2H), m.p. 167–169°. Ishiguro, Morita, and Ikushima (9) report m.p. 168–169° for this acid whereas Benary and Psille (10) give m.p. 229° for 2-phenylpyridine-5-carboxylic acid. The acid (III, R = CO_2H) was converted into its acid chloride which was then treated with aluminum chloride in benzene, when it failed to undergo the expected intramolecular acylation but gave instead a product $C_{18}H_{13}ON$ exhibiting a strong band at 1663 cm^{-1} characteristic of an aromatic ketone and two strong bands at 742 and 690 cm^{-1} characteristic of a monosubstituted phenyl group, thus showing the product to be 3-benzoyl-2-phenylpyridine (V). The intramolecular acylation was achieved by carrying out the reaction in light petroleum as the solvent instead of benzene. 4-Azafluorenone (VI), m.p. 139.5–141.5°, was thus obtained, identical with the

V VI

product described by Skraup and Cobenzl (11) (infrared bands at 1725 and 745 cm^{-1}).

(ii) The n.m.r. spectrum was measured through the courtesy of Mr. LeRoy Johnson of Varian Associates, who interpreted the following data as being only compatible with the 2,3-isomer, and not with a 2,5-disubstituted pyridine. This is in agreement with the findings of Schneider, Bernstein, and Pople (11*a*) for pyridine, and of Bernstein and Schneider (11*b*) and Anet and Eves (11*c*) for substituted pyridines. The signal at 506 c.p.s. is due to the α-proton which must be adjacent to a β-proton as indicated by the magnitude of the ortho-coupling constant $J_{5,6}$ = 5 c.p.s. (for pyridine $J_{2,3}$ = 5.5 and $J_{2,4}$ = 1.9 c.p.s. (11*a*)). This supports the 2,3- and not the 2,5-orientation for this disubstituted pyridine.

(iii) The infrared spectrum of the major product exhibited a band at 1579 cm^{-1} characteristic of a 2,3-disubstituted pyridine derivative (12). No band was observed above this one in the 6 μ region. The minor product had a band at 1604 cm^{-1} characteristic of 2,5-disubstituted pyridines (12).

N.m.r. spectrum of 3-methyl-2-phenylpyridine in carbon tetrachloride solution with tetramethylsilane as an internal reference standard

Ring position	C.p.s. from $SiMe_4$ (approximately)	Spin–spin coupling observed
4	438–447	$J_{4,5}$ = ca. 7 c.p.s.; $J_{4,6}$ = 1 c.p.s.
5	416–431	$J_{4,5}$ = 7 c.p.s.; $J_{5,6}$ = 5 c.p.s.
6	495–513	$J_{5,6}$ = 5 c.p.s.; $J_{4,6}$ = 1 c.p.s.

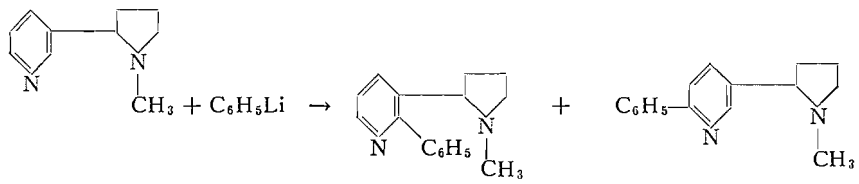
NOTE: Frequency 60 Mc/sec.

(iv) While this work was in progress Ishiguro, Morita, and Ikushima reported an unambiguous synthesis of 3-methyl-2-phenylpyridine involving the condensation of allyl alcohol and 1-phenyl-1-propanone with ammonia over a high-temperature catalytic bed (9). Dr. Ishiguro kindly supplied us with an authentic sample of this base and of its picrate. Comparison of the infrared absorption spectra of the bases and their picrates as well as a mixed melting point of the picrates established the identity of the major product obtained from the phenyllithium reaction with 3-methyl-2-phenylpyridine.

The minor fraction from the distillation proved to be somewhat impure 5-methyl-2-phenylpyridine (IV, R = CH_3). This was shown by oxidation of the base with neutral permanganate to 2-phenylpyridine-5-carboxylic acid, m.p. 232° (molecular formula $C_{12}H_9O_2N$), and by its infrared spectrum, which exhibited a band at 1600 cm^{-1} characteristic of 2,5-disubstituted pyridines (12).

It was subsequently found that the mixture of phenylpicolines could be resolved quite easily by vapor phase chromatography using an Apiezon "N" column, the retention time of the 2,5-isomer being appreciably greater than that of the 2,3-isomer under the conditions used. This permitted a much more accurate quantitative measurement of the isomer ratio, the determination being carried out on the crude mixture of bases. In this way it was found that the ratio 2,3/2,5 was 95:5, and not 8:1 as previously estimated by fractional distillation.

In view of this result the procedure described by Miller *et al.* (3) for the obtention of 5-methyl-2-phenylpyridine was reinvestigated. This method involved adding 3-picoline to an ethereal solution of phenyllithium, the total addition time being 10 minutes; the ether solution was then boiled under reflux (temperature below 50°) for $\frac{1}{2}$ hour and the mixture was then hydrolyzed with water. None of the phenylpicolines were obtained under these conditions; instead, an oil, b.p. 120–215°/0.32 mm, was obtained whose infrared spectrum did not show any bands characteristic of a pyridine ring in the 800 cm^{-1} region. The conditions of the reaction appear to be too mild to lead to the elimination of lithium hydride. After hydrolysis the dihydro derivative may have been obtained, which might account for the absence of the characteristic pyridine bands in the infrared. It may be possible to oxidize this to the required phenylpyridine but this was not investigated.



In one of the runs during the preparation of the phenylpicolines a small amount of high boiling material was obtained. This appeared to be a mixture since several peaks appeared in a gas chromatographic analysis using a silicone-on-celite column at 220°. A pure picrate, m.p. 204–206°, could be obtained from this material and the analytical figures for this derivative fitted those of a dipicrate of a base $C_{12}H_{12}N_2$, which corresponds to the molecular formula of a dimethyldipyridyl. There was insufficient material for a molecular weight determination so that as a working hypothesis the by-product was assumed to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

a dipicolyl. Stoehr and Wagner (13) obtained 3,3′-dimethyl-4,4′-dipyridyl by the action of metallic sodium on 3-picoline, and a product presumed to be 6,6′-di-*tert*-butyl-2,2′-dipyridyl has been obtained by the action of methyllithium on 2-*tert*-butylpyridine (14).

The picrate of the base obtained above depressed the melting point of 3,3′-dimethyl-4,4′-dipyridyl picrate (m.p. 231°) prepared from 3-picoline and sodium (13). 3,3′-Dimethyl-2,2′-dipyridyl was prepared from 2-amino-3-picoline via 2-bromo-3-picoline using Case's procedure (15) but again its dipicrate, m.p. 191–192°, proved different from that of the unknown base. A similar method was used to synthesize 5,5′-dimethyl-2,2′-dipyridyl from 2-amino-5-methylpyridine. This base formed a monopicrate, m.p. 175.5–176.5°, which was clearly different from that of the unknown base. No further work was done at this stage to attempt to identify this compound.

In view of the results of Wiley *et al.* (4) the possible steric effect of the 3-substituent upon the orientation of the entering phenyl group was investigated. Nicotine (VII) was chosen because of its ready availability and the fact that the 2-*N*-methylpyrrolidyl group is appreciably larger than the methyl group. The reaction was carried out as for 3-picoline

VII VIII IX

to give a 34% yield of product, b.p. 120–200°/0.1 mm. This was shown by vapor phase chromatography on a silicone-on-firebrick (1:4) column to be a mixture of two compounds, assumed to be 2-phenylnicotine (VIII) and 6-phenylnicotine (IX) in the ratio of 1:1 by weight. These findings are qualitatively similar to those of Tschitschibabin and Kirssanow (16), who obtained a mixture of 2- and 6-substituted nicotines on treatment of nicotine with sodamide in xylene at 140°. The isomers were then separated by preparative vapor phase chromatography using a 1/2-in. preparative column packed with silicone-on-celite to give one base, b.p. 145°/0.75 mm, and the other with a longer retention time, b.p. 165°/0.6 mm. Each of these gave analytical results compatible with the molecular formula $C_{16}H_{18}N_2$, confirming the assumption that they were the isomeric phenylnicotines.

The base eluted first had a band at 1588 cm^{-1} in the infrared and was, therefore, tentatively assigned the 2,3-orientation (12) whereas the second one had a band at 1600 cm^{-1} and was assumed to be the 2,5-isomer (IX). This latter assignment (and therefore the former as well) could be confirmed by oxidation of the more slowly eluted base with potassium permanganate to give 2-phenylpyridine-5-carboxylic acid identical with that obtained from 5-methyl-2-phenylpyridine.

Further confirmatory evidence for the structures assigned to these isomers was obtained from their n.m.r. spectra which were measured by Varian Associates through the courtesy of Mr. L. Johnson. Mr. Johnson also kindly interpreted the spectra and his report reads as follows: "The NMR spectrum for the first sample fits the structure of 2-phenylnicotine. The signal from the proton on the carbon in ring position 6 appears 506 c.p.s. from the tetramethylsilane and shows five cycle ortho coupling to the proton on C5 and two cycle meta coupling to the proton on C4. Likewise the signal around 478 from the proton on C4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

exhibits an eight cycle coupling to the proton on C5 and again a two cycle coupling to the proton on C6. Finally, the proton on C5 at 432 shows the five and eight cycle coupling to the other two protons on this ring. The benzene ring protons are all very nearly equivalent and produce a single sharp line at 440.

The NMR spectrum of the second sample is quite different in that the protons on the benzene ring are separated into two groups; one from two of the protons in the benzene ring at 478, the other group from the three remaining protons centered around 440. This case is similar to that of acetophenone . . . . The proton α- to the nitrogen produces a signal at 506 and in this case is a close-spaced triplet due to spin coupling to the protons at C4 and C5. Coincidentally the signals from the protons on C4 and C5 appear at exactly the same field position, 460 c.p.s from tetramethylsilane, and show the spin coupling to the C2 proton of about 1.5 c.p.s. In an attempt to shift the C4 and C5 proton signals we dissolved the sample in dioxane; however, this unfortunately did not shift these signals relative to each other . . . . This is convincing evidence for assigning the 6-phenylnicotine structure to the second sample." Once again the signal at 506 c.p.s. in the case of the first compound is at the expected field position for an α-proton and consists essentially of a quartet as required for ortho- and meta-coupling. The $J_{5,6}$ and $J_{4,6}$ values are of the correct order of magnitude confirming the assignment of the 2,3-disubstituted orientation for this compound. In the case of the second sample the magnitude of the spin–spin coupling constants for the α-proton at 506 c.p.s. is small as would be expected for meta- and para-coupling (11*a*), but not for ortho-coupling.

The isomer ratio in the phenylation of nicotine as compared with 3-picoline clearly shows the presence of a steric effect of the 3-substituent upon the orientation of the product obtained. This effect is being studied in greater detail and the results obtained on changing the size of the 3-substituent systematically will be reported soon. It was of interest, however, to try and see whether even a small group such as methyl did exert any appreciable steric interference. To this end the ultraviolet absorption spectra of 2-phenylpyridine, 3-methyl-2-phenylpyridine, 5-methyl-2-phenylpyridine, 2-phenylnicotine, and 6-phenylnicotine in ethanol were compared. The results are shown in Fig. 1 where it can be seen that the spectra of 2-phenylpyridine, 5-methyl-2-phenylpyridine, and 6-phenylnicotine are very similar and only show slight intensity variations. On the other hand, the spectra of 3-methyl-2-phenylpyridine and 2-phenylnicotine formed a separate group. The maxima exhibited a hypsochromic shift and a decrease in intensity compared with the first three curves. This indicated that in these latter two compounds the 3-substituent was exerting an appreciable steric effect resulting in the non-coplanarity of the two rings. It should be pointed out, however, that such a steric effect as is evidenced here was observed in the *final product*; this does not necessarily mean that the same effect is in operation *in the transition state* also, though there can be little reason to doubt that such an effect, though smaller, would also be exerted in this instance. No such steric effect should be present in the phenylation at the 6-position so that the latter mode of reaction would be the more probable one if steric considerations were the sole factors involved.

The above results seem to indicate that in spite of a moderate steric effect nucleophilic addition takes place preferentially at the 2-position though the 3-substituent, if sufficiently bulky, may direct appreciable addition to the 6-position also. The exclusive formation of 2,5-diphenylpyridine (4) might be attributed to steric inhibition of coplanarity in the transition state (e.g. X) in the formation of the 2,3-isomer, whereas no such inhibition exists in the transition state for the 2,5-isomer (e.g. XI). Other factors may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

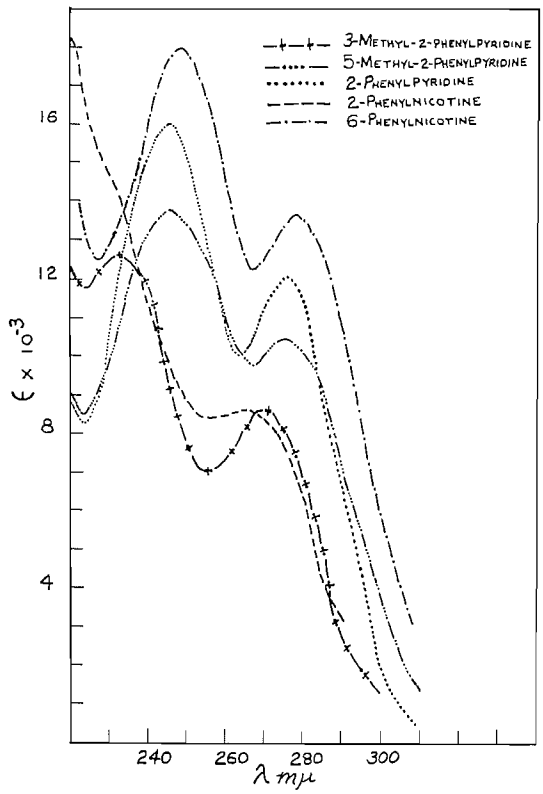

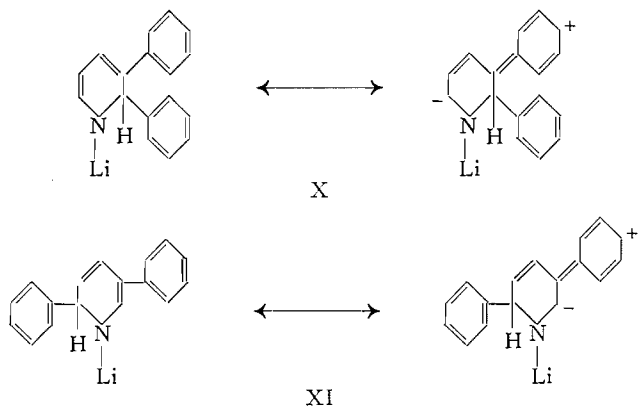

FIG. 1.

very well be involved also. Similar results concerning the preferential formation of the 2,3-isomer have been obtained by Professor H. C. Brown from a study of the addition of methyllithium to 3-substituted pyridines (14).

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured using a Perkin–Elmer Model 21 instrument using sodium chloride optics. Ultraviolet absorption spectra were

measured on a Beckman DK-2 recording spectrophotometer. The vapor phase chromatographic work was carried out using a Beckman GC-2 unit with helium as the carrier gas.

Reaction of Phenyllithium with 3-Picoline

(i) Phenyllithium was prepared from lithium (14 g) and bromobenzene (156 g) in anhydrous ether under dry nitrogen. 3-Picoline (110 ml) in anhydrous ether (110 ml) was added dropwise with stirring at such a rate as to maintain gentle boiling under reflux. When the addition was complete the ether was distilled off and simultaneously replaced by dry toluene (210 ml) in order that the temperature of the solution might be raised to ca. 110°. The reaction mixture was stirred under dry nitrogen and boiled under reflux for $7\frac{1}{2}$ hours. Water was then cautiously added to the cooled solution with stirring, the toluene layer separated, and the aqueous layer ether extracted repeatedly. The combined ether and toluene layers were dried (KOH pellets), filtered, and distilled up to 130° at atmospheric pressure. The residue was distilled under vacuum using a Podbielniak Mini-Cal spinning band fractional distillation column (Series 3400). Fractions, b.p. 107–119°/0.3 mm, consisted of slightly impure 3-methyl-2-phenylpyridine; those boiling at 119–133°/0.3 mm consisted of impure 5-methyl-2-phenylpyridine. The over-all yield based on bromobenzene was 42.4%. The isomers were obtained in the ratio of 8:1 by weight respectively. After three fractional distillations pure 3-methyl-2-phenylpyridine had b.p. 159–160°/31 mm. Calc. for $C_{12}H_{11}N$: C, 85.17; H, 6.55. Found: C, 84.94; H, 6.99. I.R. spectrum (liquid film) (main peaks only): 1589 (s), 1573 (s), 800 (s), 788 (s), 750 (s), 703 cm^{-1} (s). λ_{max} 232, 272 mμ, $\epsilon \times 10^{-3}$ 12.56, 8.67 (in ethanol). The picrate, on recrystallization from ethanol, had m.p. 164–166°, undepressed on admixture with an authentic sample. Ishiguro, Morita, and Ikushima (9) report m.p. 163.5–165.5° for this picrate. Calc. for $C_{12}H_{11}N,C_6H_3O_7N_3$: C, 54.27; H, 3.54. Found: C, 54.62; H, 3.49.

Several fractional distillations of 5-methyl-2-phenylpyridine, b.p. 164–166°/16 mm, failed to give a completely pure analytical sample. Vapor phase chromatography indicated the presence of some contaminant. A pure sample was obtained by vapor phase chromatography using the conditions described below and the eluted fraction collected in a dry ice – acetone trap. One further distillation under vacuum gave the required pure isomer. Found: C, 84.65; H, 6.49. I.R. spectrum (liquid film) (main peaks only): 1604 (m), 1566 (m), 835 (m), 775 (s), 736 (s), 693 cm^{-1} (s). λ_{max} 245, 275 mμ. $\epsilon \times 10^{-3}$ 13.8, 10.59 (in ethanol). After several recrystallizations from ethanol the picrate had m.p. 182–183°. Found: C, 54.10; H, 3.76.

In a previous run, a fraction, b.p. 155–180°/9 mm, was forced over. Gas chromatographic analysis of a sample of this material on a 2-ft silicone-on-celite (1:4) column with an inlet pressure of helium of 30 p.s.i. and operated at 220° gave rise to several poorly resolved peaks, indicating that this fraction was a mixture of compounds. A picrate could be prepared which, on recrystallization from ethanol, had m.p. 204–206° (decomp.). Calc. for $C_{12}H_{12}N_2,2C_6H_3O_7N_3$: C, 44.87; H, 2.82. Found: C, 44.68; H, 2.91. On subsequent similar reactions this product could not be isolated again.

Quantitative Analysis.—This was effected by vapor phase chromatography using the following conditions: $5\frac{1}{2}$ ft × $\frac{1}{4}$ in. copper tubing column packed with Apiezon "N" on "Embacel" Kieselguhr (May and Baker) (1:4 by weight); column temperature 220°; inlet temperature 235°; helium inlet pressure 30 p.s.i. Under these conditions the retention time was found to vary with the sample volume; the 'emergence time' (i.e. the time at which the compound began to emerge from the column, or the foot of the peak) was constant, however, and independent of sample size. The 'emergence time' for 3-methyl-2-

For personal use only.

phenylpyridine was 11 minutes whereas that of 5-methyl-2-phenylpyridine was 16 minutes 20 seconds. In both cases the area under the curve was proportional to the sample size. For the analysis the reaction was carried out as described above but the combined ether and toluene layers were extracted with dilute hydrochloric acid (leaving any diphenyl behind in the organic phase). The acid extract was shaken several times with small quantities of ether, made strongly alkaline, and extracted continuously with ether. The ether extract of the bases was dried (KOH pellets), the solvent evaporated, and the residue used directly for the quantitative estimation. The ratio of 2,3/2,5 isomers was thus found to be 95:5 or 19:1.

(ii) The reaction was repeated using the procedure of Miller, Asuch, Goldberg, and Levine (3). To a solution of phenyllithium (from 2.8 g of lithium and 21 ml of bromobenzene) in dry ether (250 ml) was added 3-picoline (18.6 ml) with stirring under nitrogen over 10 minutes. The mixture was then boiled under reflux for 30 minutes, water (75 ml) added carefully, and the mixture then poured onto ice (500 g) and 6 *N* hydrochloric acid (100 ml). The ether layer was separated and extracted several times with 6 *N* hydrochloric acid. The combined acid extracts were treated with 20% aqueous sodium hydroxide until the mixture was only slightly acid. Solid sodium carbonate was then added to make the mixture slightly basic. The suspension was repeatedly extracted with ether leaving behind a copious amount of light orange resinous material. The combined ether extracts were dried ($MgSO_4$), filtered, and evaporated on a water bath. The residue was distilled under vacuum giving a fraction with a boiling point up to 190°/0.32 mm (2.5 g) and then one having a boiling point 190–215°/0.32 mm (1.5 g). A pure picrate could not be isolated from any of the fractions. I.R. spectrum of the second fraction (liquid film) (main peaks only): 2870 (s) (broad), 1600 (w), 1577 (w), 1560 (w), 865 (m), 745 (s) (broad), 698 cm^{-1} (s). Miller *et al.* (3) reported a yield of 30.8% of a product, b.p. 241–245°/2 mm, to which they assigned the structure of 5-methyl-2-phenylpyridine.

2-Phenylpyridine-3-carboxylic Acid

3-Methyl-2-phenylpyridine (6 g) was boiled under reflux with a solution of potassium permanganate (11.2 g) in water (400 ml) until the solution was decolorized; more solid potassium permanganate was then added in small portions and heating continued, the process being repeated until no more oily material appeared in the reflux condenser. The excess permanganate was destroyed by adding a few drops of methanol and heating, the hot mixture was filtered, the solid residue washed three times with hot water, and the combined filtrates evaporated down to ca. 40 ml. The solution was made just acid by adding a slight excess of acetic acid, and a saturated solution of copper acetate (70 ml) was stirred into the mixture, which was warmed for a few minutes and then allowed to stand while precipitation of the copper salt occurred. This was filtered, washed with cold water, slurried in water, and decomposed with hydrogen sulphide. The mixture was boiled to remove the excess hydrogen sulphide, filtered hot, the black sulphide precipitate washed with hot water, and the combined filtrates evaporated to give 2-phenylpyridine-3-carboxylic acid (2.85 g), m.p. 167–169°. Ishiguro, Morita, and Ikushima (9) report m.p. 168–169° for this acid.

2-Phenylpyridine-5-carboxylic Acid

5-Methyl-2-phenylpyridine was oxidized as described above for the 3-isomer to give the carboxylic acid, which, after recrystallization from aqueous ethanol, had m.p. 232°. Benary and Psille (10) report a melting point of 229° for this acid. Calc. for $C_{12}H_9O_2N$:

C, 72.51; H, 4.44. Found: C, 72.55; H, 4.55. I.R. spectrum (Nujol mull) (main peaks only): 1678 (s) (broad), 1602 (s), 749 (s), 720 (w), 678 cm^{-1} (m).

2-Phenylpyridine

This compound was prepared according to the procedure of Evans and Allen (2). It had λ_{max} 223, 245, 275 mμ. $\epsilon \times 10^{-3}$ 8.27, 16.08, 12.12 (in ethanol).

3,3′-Dimethyl-2,2′-dipyridyl

This was prepared from 2-bromo-3-methylpyridine by Case's method (15). The dipicrate (from ethanol) had m.p. 191–192.5°, depressed on admixture with the unknown dipyridyl dipicrate. Case reports a melting point of 188–189° for this dipicrate.

5,5′-Dimethyl-2,2′-dipyridyl

2-Bromo-5-methylpyridine (2 g) and copper powder (3.2 g) were mixed and heated to 220°; the temperature was gradually increased to 240° over a period of $\frac{3}{4}$ hour. When the mixture had cooled it was extracted with dilute hydrochloric acid, the combined extracts basified, extracted with ether, and the ether extracts dried (Na_2SO_4). Evaporation of the solvent gave 5,5′-dimethyl-2,2′-dipyridyl which was converted directly to the picrate. A monopicrate was formed which, on recrystallization from ethanol, had m.p. 175.5–176.5°. Calc. for $C_{12}H_{12}N_2,C_6H_3O_7N_3$: C, 52.30; H, 3.66. Found: C, 52.10; H, 3.66.

3,3′-Dimethyl-4,4′-dipyridyl

This compound was obtained in 20% yield from 3-picoline and sodium according to the procedure of Stoehr and Wagner (13). The base, b.p. 300°/720 mm, gave a picrate, m.p. 231°, depressed to 190° (decomp.) on admixture with the unidentified picrate. Stoehr and Wagner report a boiling point of 300° for the free base and melting point of 231° for its picrate. I.R. spectrum of the free base (liquid film) (main peaks only): 1587 (s), 853 (w), 806 (m), 800 (w), 710 cm^{-1} (m).

3-Benzoyl-2-phenylpyridine

2-Phenylpyridine-3-carboxylic acid (1 g) was allowed to stand with thionyl chloride (10 ml) at room temperature for $1\frac{1}{2}$ hours. The excess thionyl chloride was removed under vacuum and the residue treated with dry benzene. The benzene was evaporated to dryness and the process repeated. The residue was taken up in anhydrous benzene (30 ml) and stirred while anhydrous aluminum chloride (2 g) was slowly added. A dark-colored complex formed which, after $\frac{3}{4}$ hour, turned a dark greenish-grey. The complex was decomposed with ice, the mixture basified with aqueous sodium hydroxide, the benzene layer separated, and the aqueous layer extracted with ether. The extracts (which exhibited a slight green fluorescence) were combined, dried (Na_2SO_4), and evaporated. Distillation of the residue (1.03 g) gave 3-benzoyl-2-phenylpyridine, b.p. 167°/0.45 mm. Calc. for $C_{18}H_{13}ON$: C, 83.37; H, 5.05. Found: C, 82.26; H, 5.20. I.R. spectrum (liquid film) (main peaks only): 1663 (s), 1598 (w), 1579 (m), 1556 (w), 923 (s), 790 (w), 742 (s), 690 cm^{-1} (s). In view of the poor value for the carbon analysis the compound was further characterized as its picrate which, after recrystallization from alcohol, had m.p. 137.5–138.5° (after sintering at 135.5°). Calc. for $C_{18}H_{13}ON,C_6H_3O_7N_3$: C, 59.02; H, 3.30. Found: C, 58.98; H, 3.26.

4-Azafluorenone

2-Phenylpyridine-3-carboxylic acid (0.1 g) was allowed to stand with an excess of thionyl chloride (2 ml) and worked up as described above. The acid chloride was stirred in dry light petroleum (b.p. 40–60°) (20 ml) and an excess of anhydrous aluminum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

chloride (0.5 g) slowly added. Stirring was continued for 2 hours when a red complex had formed on the sides of the flask. Ice was added to decompose the complex, the mixture was made alkaline with aqueous sodium hydroxide, the petroleum ether layer separated, and the aqueous layer extracted with ether. The combined extracts were dried (Na_2SO_4) and evaporated to yield a solid residue which, on recrystallization from ethanol, gave 4-azafluorenone (0.086 g), m.p. 139.5–141.5°. Skraup and Cobenzl (11) reported m.p. 141° for this compound. Calc. for $C_{12}H_7ON$: C, 79.55; H, 3.98. Found: C, 79.58; H, 3.91. I.R. spectrum (Nujol mull) (main peaks only): 1725 (s) (broad), 1615 (w), 1600 (m), 1569 (w), 918 (m), 742 cm^{-1} (s).

Reaction of Phenyllithium with Nicotine

Nicotine (12 g) in anhydrous ether (30 ml) was added dropwise to a solution of phenyllithium (prepared from lithium (1.0 g) and bromobenzene (12 ml) in dry ether (130 ml) under nitrogen) at such a rate as to maintain gentle boiling of the ether. The ether was then evaporated and simultaneously replaced by dry toluene (50 ml) and the temperature raised to ca. 110°. Stirring and heating under nitrogen was then continued for 8 hours. The reaction mixture was cooled, carefully treated with water, and the toluene layer separated. The aqueous layer was extracted with ether and the organic phases combined and extracted with 10% hydrochloric acid. The aqueous acid extracts were made alkaline and extracted with ether, the ether extracts combined, dried (KOH pellets), and evaporated. Vacuum distillation of the residue gave the following fractions:

(i) up to 120°/0.09 mm	1.1 g pale yellow liquid;
(ii) 120–200°/0.09 mm	5.5 g deep yellow liquid;
(iii) 200°/0.15 mm–326°/0.67 mm	4.3 g deep red resin.

Fraction (ii) was found to consist of a mixture of 2- and 6-phenylnicotine (48% yield).

The ratio of the two isomers was found to be close to 1:1. The analysis was performed by vapor phase chromatography of the crude reaction product before distillation. A 1 ft × $\frac{1}{4}$ in. copper tubing column packed with silicone-on-firebrick (1:4) was used. The samples were run in ether solution. At 220° and with a helium inlet pressure of 30 p.s.i. the retention time for 2-phenylnicotine was $6\frac{3}{4}$ minutes and that for 6-phenylnicotine was $12\frac{2}{3}$ minutes, whereas at 190° these were $16\frac{1}{3}$ minutes and 38 minutes respectively. The areas under the peaks were found to be proportional to the concentration of each isomer. The results were as follows:

2-phenylnicotine	49.4%	6-phenylnicotine	50.6%
	49.8%		50.2%

Separation of the two isomers was effected by preparative vapor phase chromatography using an injection cell preheater and a fraction collector. Fraction (ii) from the distillation was used. The column was a 2-ft preparative column ($\frac{1}{2}$-in. diameter) packed with Embacel (May and Baker, 60–100 mesh) and silicone oil (4:1), and was operated at 190° with a helium inlet pressure of 30 p.s.i. The first fraction collected proved to be 2-phenylnicotine which, after redistillation, had b.p. 145°/0.5 mm. Calc. for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61. Found: C, 80.05; H, 7.67. I.R. spectrum (liquid film) (main peaks only): 1578, 1569, 805, 791, 750, and 696 cm^{-1}. λ_{max} 264 mμ; λ_{infl} 225, 255 mμ. $\epsilon \times 10^{-3}$ 8.57, 15.76, 8.45. 2-Phenylnicotine dipicrate was recrystallized from alcohol and had m.p. 211–213°. Calc. for $C_{16}H_{18}N_2,2C_6H_3O_7N_3$: C, 48.28; H, 3.74. Found: C, 48.62; H, 3.98. The second fraction proved to be 6-phenylnicotine, which was redistilled and had a boiling point of 165°/0.6 mm. Found: C, 80.33; H, 7.20. I.R. spectrum (liquid film) (main

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

peaks only): 1600, 1567, 841, 779, 740, 691 cm^{-1}. λ_{max} 249, 279 mμ. $\epsilon \times 10^{-3}$ 17.97, 13.66. The picrate had m.p. 166–167°.

Oxidation of 6-Phenylnicotine to 2-Phenylpyridine-5-carboxylic Acid

6-Phenylnicotine (0.2 g) was boiled under reflux in water (50 ml) while small amounts of potassium permanganate were added as long as the solution was decolorized and oily material appeared in the reflux condenser. The mixture was then decolorized by the addition of a few drops of methanol to the hot solution and the carboxylic acid isolated as described for 2-phenylpyridine-3-carboxylic acid. The crude 2-phenylpyridine-5-carboxylic acid (20 mg) was recrystallized from water to give colorless crystals, m.p. 230–233° (decomp.), undepressed on admixture with an authentic sample.

ACKNOWLEDGMENTS

The authors are grateful to Dr. L. Vining for the use of a recording ultraviolet spectrophotometer and to Mr. LeRoy Johnson of the Applications Laboratory of Varian Associates for kindly determining and interpreting the n.m.r. spectra reported in this paper. They would also like to thank Dr. Ishiguro for a sample of 3-methyl-2-phenylpyridine and its picrate, Dr. H. C. Brown for communicating to us some of his results before publication, and the University of Saskatchewan for the award of the Thorvaldson Scholarship to one of us (A. D. N.). This work was supported by a grant from the National Research Council.

THE INFRARED SPECTRA OF SOME URANYL COMPOUNDS[1]

G. L. CALDOW,[2] A. B. VAN CLEAVE, AND R. L. EAGER

ABSTRACT

The infrared spectra for the di- and hexa-hydrates of uranyl nitrate, for anhydrous uranyl acetate, and for sodium zinc uranyl acetate hexahydrate have been obtained using the potassium bromide pressed disk technique. Where possible, samples were prepared by freeze-drying aqueous solutions of the appropriate compound and potassium bromide. The uranyl nitrate hydrates gave spectra with peaks characteristic of both nitrate and nitrato groups. For uranyl acetate the type of spectra obtained depended upon the ratio of uranyl acetate to potassium bromide in the freeze-dried mixture. It is postulated that, for relatively large ratios of uranyl acetate to potassium bromide, the carbonyl oxygen atoms of the acetate groups are chelated to the uranium atom. The spectrum of sodium zinc uranyl acetate hexahydrate is quite similar to that reported by Jones for sodium uranyl acetate. Using the 933 cm^{-1} peak, the Beer–Lambert law was obeyed for samples prepared by freeze-drying solutions containing uranyl nitrate and potassium bromide.

INTRODUCTION

The authors have been interested in the infrared spectra of uranyl compounds and in the possible application to a quantitative determination of uranium by infrared spectrophotometry. Various investigations have been made of the infrared spectra of uranium compounds (1, 2, 3, 4, 5, 6, 7). The repeated occurrence in the infrared spectra of uranyl compounds of a strong absorption band at 10.87 μ (920 cm^{-1}) led to the suggestion by Lecompte and Freymann (2) that this band could be used for the identification of uranyl ions. For water-soluble substances the potassium bromide disk technique (8, 9), combined with the freeze-drying of aqueous solutions containing both the substance whose spectrum is being investigated and potassium bromide, gives good quantitative results (10).

EXPERIMENTAL

Apparatus and Reagents

The spectra were recorded with a Perkin–Elmer model 21 double-beam infrared spectrophotometer equipped with a sodium chloride prism.

The sample chamber of the freeze-drying apparatus was a 250-mm vacuum desiccator from which the ground-glass sleeve had been removed. The desiccator was connected to a 1-liter trap by means of a 55/40 standard taper ground-glass joint and 40-mm I.D. glass tubing. A length of rubber tubing and a 18/7 ball and socket joint were used to connect the trap to a high vacuum system. A freezing mixture of dry ice – acetone was used to cool the trap.

The die used to prepare the potassium bromide disks was of the type described by Bauer, Epp, and Lemieux (11). The disk holder is removable and fits into an adapter which can be inserted into the standard sample slide on the spectrophotometer. A 20-ton hydraulic press was used to apply pressure to the die.

Reagent grade chemicals were used. Sodium zinc uranyl acetate was prepared from zinc uranyl acetate and sodium chloride solutions using the method of Barber and Kolthoff (12).

Sample Preparation

The freeze-dried mixtures were prepared by mixing together, in Erlenmeyer flasks,

[1]*Manuscript received January 7, 1960.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan, with financial assistance from the National Research Council of Canada. Presented in part at the 40th Annual Conference of the Chemical Institute of Canada, Vancouver, B.C., June 3–5, 1957.
[2]*Present address: Oxford University, Oxford, England.*

appropriate quantities of aqueous solutions of the substance whose spectrum was being determined and potassium bromide. The mixtures were frozen rapidly by immersing the Erlenmeyer flasks in a dry ice – acetone mixture and swirling their contents. The Erlenmeyer flasks of a given run were left in the dry ice – acetone mixture until all the samples were prepared, after which they were placed in the sample chamber of the freeze-drying apparatus. The apparatus was immediately evacuated, and the samples left for approximately 24 hours. The product was a very fine fluffy powder (10).

Some of the uranyl salt – potassium bromide mixtures were prepared by mixing the dry solids in a small plastic vial attached to a vibrating tool. Freeze-dried potassium bromide was used in all of these preparations in order to ensure small particle size (10). Freeze-dried uranyl salts were used except in the case of uranyl nitrate hexahydrate, which was ground in a mortar until the crystals would pass through a 200-mesh screen.

Approximately 0.5 g of the uranyl salt – potassium bromide mixture was placed in the partly assembled die, care being taken to distribute the sample evenly in the disk holder. The powder was tamped down using the flattened end of a glass rod. The assembled die was then placed in the hydraulic press and evacuated, by means of a mechanical oil vacuum pump, for 1 minute. While still evacuated the die was subjected to a pressure of 99,000 pounds per square inch for 1 minute. After the pressure had been released, air was allowed to leak slowly into the die. The resulting transparent window was cleaned of loose powder.

Recording the Spectra

For a qualitative survey of the infrared spectra of uranyl compounds the spectrophotometer was operated essentially as recommended by the manufacturer using slit schedule 4 (13). It was found that the noise level was lowered if a gain of 5.5 was used, instead of the recommended 6.5–7, and if zero suppression was used, instead of the recommended 2. For quantitative work the recommended slit schedule 2 was used. It was found that better results were obtained in the quantitative work when a potassium bromide blank was used in the reference beam. However, a blank was not necessary in order to obtain good qualitative spectra.

RESULTS AND DISCUSSION

Preparation of Lower Hydrates of Uranyl Compounds by Freeze-Drying

Uranyl nitrate hexahydrate and uranyl acetate dihydrate were used to prepare the mixtures for freeze-drying. Since other hydrates of these salts can exist, it was of interest to determine the degree of hydration of the products when aqueous solutions of either uranyl nitrate or of uranyl acetate were freeze-dried. The freeze-dried samples were analyzed for their uranium content by the method of Kolthoff and Lingane (14). The results shown in Table I indicate the formation of anhydrous uranyl acetate and of

TABLE I

Analysis of freeze-dried uranyl compounds

Sample	Uranium, %	Deviation from theoretical value
Freeze-dried uranyl acetate	61.26	0.07
Theoretical for $UO_2(C_2H_3O_2)_2$	61.33	
Freeze-dried uranyl nitrate	55.14	0.21
	55.28*	0.07
Theoretical for $UO_2(NO_3)_2.2H_2O$	55.35

For personal use only.

uranyl nitrate dihydrate. It was assumed in the subsequent work that the same compounds would be formed whether or not potassium bromide was present during the freeze-drying process. The fact that uranyl nitrate dihydrate was formed, and not the monohydrate or the anhydrous salt, is interesting since all of the many attempts to prepare these salts have been unsuccessful (15, 16).

The results indicate that the freeze-drying technique may be a convenient and relatively simple method for preparing the lower hydrates for substances which form more than one hydrate. The method eliminates the use of elevated temperatures which have been used in the preparation of many hydrates, and which often results in undesired decomposition reactions.

It should be noted that the product obtained from freeze-drying a solution of uranyl nitrate and potassium bromide will not necessarily be only a mixture of these two compounds. It is quite possible that uranyl bromide and potassium nitrate will also be present, perhaps even in relatively large quantities, since bromide ions and potassium ions were originally present in large excess. However, when a solution prepared by dissolving uranyl acetate and potassium bromide in water is freeze-dried, it is likely that the product will be largely uranyl acetate and potassium bromide. This follows from the fact that there is good evidence (17, 18, 19) that in aqueous solution, the tendency for covalent bond formation between acetate and uranyl ions is large.

Spectra

In general, all the spectra could be interpreted as consisting of the spectra of the anion present and of the uranyl ion. The spectra of all samples show strong absorption in the 930 cm^{-1} region, which has been assigned to the antisymmetrical normal vibration, ν_3, of the uranyl ion (1). In a few of the samples of uranyl nitrate dihydrate, prepared by freeze-drying an aqueous solution of uranyl nitrate and potassium bromide, there is a definite, but quite weak, absorption at 856 cm^{-1}. This absorption at 856 cm^{-1} could be the 860 cm^{-1} band, which has been assigned to the symmetrical normal vibration, ν_1, of the uranyl ion (1) and which, for the free gaseous ion, would be infrared inactive.

(*a*) *Uranyl Nitrate Hydrates*

The spectra of uranyl nitrate hexahydrate mixed with potassium bromide by the vibration technique, of freeze-dried uranyl nitrate dihyrate mixed with potassium bromide by the vibration technique, and of uranyl nitrate dihydrate mixed with potassium bromide by the freeze-drying technique are shown in Figs. 1, 2, and 3 respectively. The frequencies of the observed maxima are given in Table II. The close similarity of the spectra of the dihydrate and of the hexahydrate is contrary to the results of Sevchenko and Stepanov (3), of Tridot (6), and of Gatehouse and Comyns (7). The above authors used the solid hydrate samples, which were either pressed between fluorite plates (3), suspended in carbon tetrachloride (6), or mulled with Nujol (7). These authors found, for example, that a peak at 1390 cm^{-1} was present in the spectra of the hexahydrate but was not in the spectra of the dihydrate, whereas peaks present in the 1300 cm^{-1} and 1550 cm^{-1} regions of the spectra of the dihydrate were not present in the spectra of the hexahydrate. In contrast, all three peaks were observed in the spectra of both the hexahydrate and the dihydrate in the present work. Gatehouse and Comyns (7) have made the most detailed assignment of the bands in the infrared spectrum of the uranyl nitrate hydrates by the use of compounds enriched in N^{15}. They reached the conclusion that co-ordinated nitrato groups are present in the dihydrate (and also in the trihydrate), whereas ionic nitrate

groups are present in the hexahydrate. Their results for the dihydrate and for the hexahydrate, both containing natural nitrogen, are also given in Table II. The symbols of the nitrate vibrations are designated by an asterisk in Table II.

The symmetry of the nitrate ion is D_{3h} whereas that for the co-ordinated nitrato group is C_{2v}, hence for the nitrato group the doubly degenerate vibrations, ν_3 and ν_4, of the

*Denotes vibrations of the nitrate ion.

nitrate ion are both split (20). The conventions for numbering the vibrations of the nitrate ion (21) differ from those used for the co-ordinated nitrato group (20). To avoid confusion in the following discussion a summary of the relations between these two conventions is given in Table III (7). It was observed by Gatehouse and Comyns (7) that

TABLE III

Summary of designation of vibrations for the nitrate ion and the nitrato group (7)

	ν_1	ν_2	ν_3		ν_4	
NO_3^-	NO stretch	Out of plane	NO_2 stretch		NO_2 bend	
O_2NO	ν_2 NO stretch	ν_6 Out of plane	ν_1 NO_2 stretch sym	ν_4 NO_2 stretch antisym	ν_3 NO_2 bend sym	ν_5 NO_2 bend antisym

some of the vibrations for both the nitrate and the nitrato group were split. It was concluded that this splitting was the result of the in-phase and the out-of-phase vibrations of adjacent nitrate, or nitrato, groups having slightly different frequencies.

Considering first the spectra of the dihydrates, it is seen from Figs. 2 and 3 and Table II that the spectra obtained in the present work are similar in most respects to the spectra obtained by Gatehouse and Comyns. Hence it appears that nitrato groups, co-ordinated to the uranyl ion, are present in these samples. However, the intense peak at 1392 cm^{-1} is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

undoubtedly due to the normal vibration ν_3 of the nitrate ion, which was not observed by Gatehouse and Comyns for the dihydrate. For the sample prepared by freeze-drying an aqueous solution of uranyl nitrate and potassium bromide this peak is extremely intense, as shown in Fig. 3. It seems likely, as suggested earlier, that in the freeze-drying step, some potassium nitrate was formed. By comparing Figs. 2 and 3 it is seen that the intensities of the peaks assigned to the nitrato group are weaker in Fig. 3 than in Fig. 2, indicating that in the sample prepared entirely by freeze-drying, an appreciable amount of the original nitrate appeared as such in the final product. The presence of nitrate in the sample mixed by vibration, Fig. 2, can be explained by the observation (20) that some compounds with co-ordinated nitrato groups react with sodium chloride windows and that the products give the spectrum of the nitrate ion. Possibly a similiar reaction could occur with potassium bromide. The presence of potassium nitrate in the sample mixed with potassium bromide by freeze-drying would also explain a feature of the spectrum of this sample which differs from that for the sample mixed with potassium bromide by vibration. In the spectrum, Fig. 2, of the latter sample there is a peak at 805 cm^{-1} which has been assigned by Gatehouse and Comyns (7) to the out-of-plane vibration of the nitrato group. This peak is only faintly evident in the spectrum, Fig. 3, of the sample mixed with potassium bromide by freeze-drying. There is, however, in the spectrum of the latter a weak peak at 830 cm^{-1} and a relatively stronger one at 842 cm^{-1}. Decius (22) observed that in potassium nitrate, the out-of-plane vibration of the nitrate ion, ν_2, is split to give a weak peak at 811 cm^{-1} and a strong one at 826 cm^{-1}. The splitting observed by him is 15 cm^{-1} while that shown in Fig. 3 is 12 cm^{-1}.

The remainder of the spectrum for both dihydrate samples is quite similar to that observed by Gatehouse and Comyns (7) except for the splitting of some of the peaks. A splitting of 8 cm^{-1} was observed in the present work for ν_5 whereas Gatehouse and Comyns (7) observed only a single peak. A splitting of 5 cm^{-1} (708 and 713 cm^{-1}) was observed by Dieke and Duncan (23) for a sample of $CsUO_2(NO_3)_3$. No shoulder is evident on the low frequency side of the 752 cm^{-1} peak for the freeze-dried sample, indicating that the frequency ν_3 was not split. However, the intensity of this peak is low and it would be difficult to observe a shoulder. Neither ν_2 nor ν_1 shows splitting in the present work, although in the sample mixed by vibration the 1298 cm^{-1} peak is broad and some splitting may be present. Gatehouse and Comyns (7) observed a splitting for both of these vibrations. No assignment is offered for the weak 630 cm^{-1} peak observed in the spectra of both of the dihydrate samples.

The spectrum of the hexahydrate, Fig. 1, shows more resemblance to those of the dihydrates, Figs. 2 and 3, than it does to the one obtained by Gatehouse and Comyns for the hexahydrate (7). It is particularly similar to the spectrum obtained for the dihydrate sample mixed with potassium bromide by vibration, Fig. 2. The only difference is in the 600 to 700 cm^{-1} region. In this region the hexahydrate has negligible absorption whereas the dihydrate has moderate absorption with peaks at 662, 670, and 630 cm^{-1}. The spectrum does have the strong peak at 1392 cm^{-1}, characteristic of nitrates, but it also has strong peaks in the 1300 and 1500 cm^{-1} regions which were not observed for the hexahydrate by Gatehouse and Comyns (7). The presence of these latter peaks suggests that the symmetry of the nitrate ion has been lowered from that of D_{3h} and consequently the ν_3 vibration of the nitrate ion has been split.

Why the symmetry of the nitrate ion should change is not immediately obvious. It is conceivable that a deformation of the crystal structure occurred as a result of subjecting the sample to the high pressures used in forming the disk. This deformation might cause

a lowering of the symmetry of the nitrate ion. Another possibility is that at the high pressures used, and in the presence of a large excess of potassium bromide, the hexahydrate was partially dehydrated. With the loss of water molecules the uranyl ion would then perhaps react with nitrate ions to form co-ordinated nitrato groups.

(*b*) *Uranyl Acetate*

In earlier work (1, 2, 3) the samples used appear to have been hydrates of uranyl acetate, although this is not always definitely stated. In the present work freeze-dried uranyl acetate was used, hence, as indicated by the results shown in Table I, the samples contained anhydrous uranyl acetate. Preliminary experiments, using samples obtained by freeze-drying aqueous solutions of uranyl acetate and potassium bromide, indicated that the type of spectra obtained depended upon the ratio of uranyl acetate to potassium bromide. To investigate this effect further a series of solutions containing uranyl acetate and potassium bromide in varying porportions were freeze-dried. The freeze-dried mixtures were next mixed by vibration with additional freeze-dried potassium bromide to give sufficient material for pressing into disks. There was always approximately the same amount of uranyl ion present in each disk. In Figs. 4 and 5 are shown portions of the

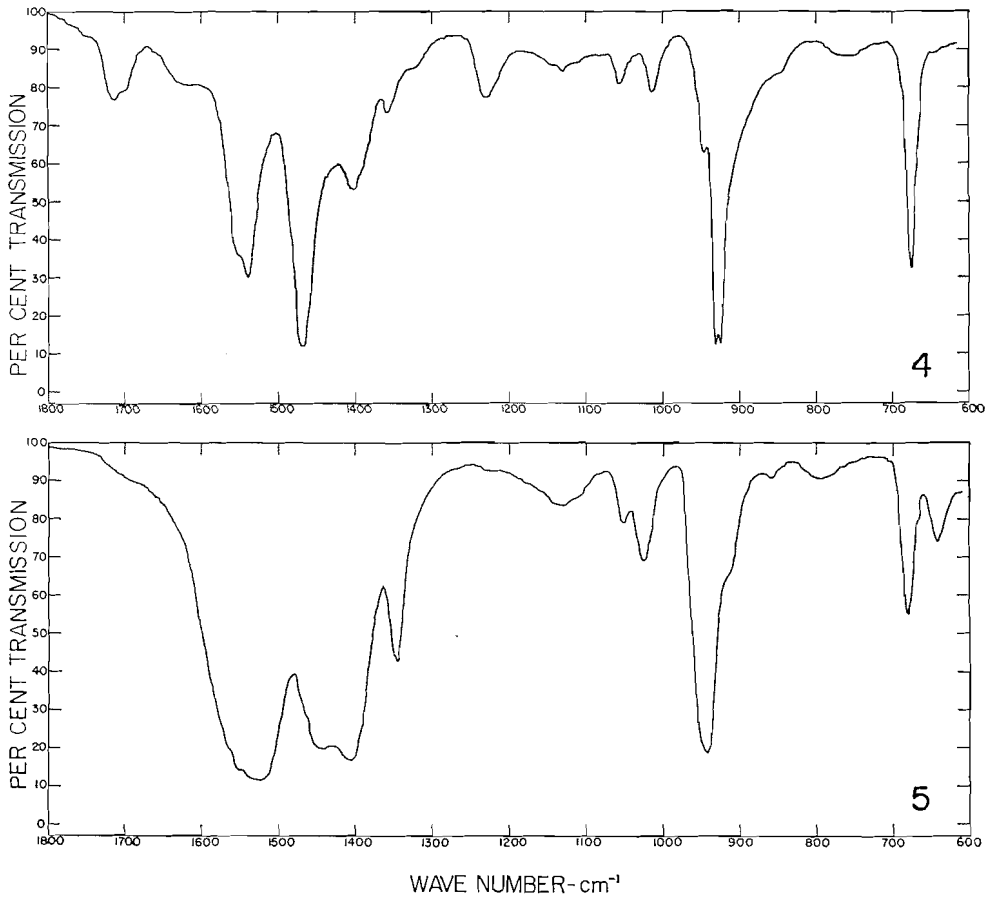

FIG. 4. Infrared spectrum of uranyl acetate mixed with potassium bromide by freeze-drying. Molar ratio of uranyl acetate to potassium bromide 0.1 to 1.

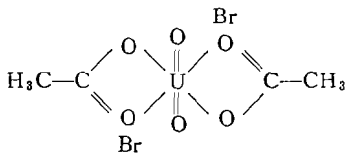

FIG. 5. Infrared spectrum of uranyl acetate mixed with potassium bromide by freeze-drying. Molar ratio of uranyl acetate to potassium bromide 1000 to 1.

spectra of samples in which the molar ratio of uranyl acetate to potassium bromide during the freeze-drying process was 0.1 to 1 and 1000 to 1 respectively. The type of spectra obtained showed a smooth transition from that shown in Fig. 4 to that shown in Fig. 5 as the molar ratio was varied between the above limits. In the following discussion spectra of the type shown in Fig. 4, i.e. from samples where a small molar ratio of uranyl acetate to potassium bromide was present during freeze-drying, will be designated as type I spectra, whereas spectra of the type shown in Fig. 5, i.e. from samples where a large molar ratio of uranyl acetate to potassium bromide was present during freeze-drying, will be designated as type II spectra.

The strong peak in the neighborhood of 930 cm^{-1} is undoubtedly due to the asymmetric normal vibration, ν_3, of the uranyl ion. In type I spectra there is a strong double peak at 924 and 930 cm^{-1} together with a shoulder at 945 cm^{-1}. In type II spectra the intense peak is at 942 cm^{-1} with a shoulder on the low wave number side.

The strong absorption at 676 cm^{-1} may arise as the result of the acetate groups being attached to the uranyl group by covalent bonds. There is considerable evidence (17, 18, 19) which indicates that in aqueous solution the tendency for covalent bond formation between the acetate group and the uranyl group is large. Hence it seems reasonable to expect that in solid uranyl acetate the acetate groups are attached, as indicated in formula I, by covalent bonds. The force constants for C=O, C=C, C=N, and N=O

I

II

bonds are approximately double those of the corresponding C—O, C—C, C—N, and N—O bonds (24). If the assumption is made that this relationship also holds for U=O and U—O bonds then a peak due to the U—O bond might be expected in the region 927 $cm^{-1}/\sqrt{2}$ = 655 cm^{-1}. This calculation assumes the vibration to be harmonic, which is probably not true for the solid state. Thus, considering also the approximation made concerning the bond strength, the agreement with the observed peak at 676 cm^{-1} is as good as could be expected. A peak at 678 cm^{-1} has been reported for $NaUO_2(C_2H_3O_2)_3$ (5). This peak was assigned (5) to a CO_2 deformation vibration by comparison with the similar assignment of a peak at 645 cm^{-1} observed for sodium acetate (25). However, there is good evidence that in $NaUO_2(C_2H_3O_2)_3$ the uranyl and acetate ions are present as the complex anion $UO_2(C_2H_3O_2)_3^-$ (27). Considering the large tendency for covalent bond formation between the acetate and uranyl groups (17, 18, 19), it is unlikely that any appreciable amount of free acetate ions is present. Hence a CO_2 deformation vibration is not very likely and the assignment of the 676 cm^{-1} peak to a C—O bond appears to be reasonable.

The peaks at 1713 and 1230 cm^{-1}, which are present in type I spectra but which are absent in type II spectra, are probably due to the C=O and C—O stretching vibrations of the acetate group (24, 26). It would ordinarily be expected that the intensities of these peaks, especially the 1713 cm^{-1} peak (24) would be greater than those observed in type I spectra.

In type II spectra a peak is present at 642 cm^{-1} which is absent in type I spectra. The intensity of this peak progressively increases as the ratio of uranyl acetate to potassium bromide is increased.

A tentative explanation for the change in the spectra from type I to type II as the ratio of uranyl acetate to potassium bromide is increased is that the uranium atom of the uranyl group becomes chelated to the carbonyl oxygen atom of the acetate groups instead of being bonded to bromide ions. There is strong evidence that the uranium atom in the uranyl ion has a tendency for a co-ordination number greater than six (17, 18). Hence it is possible that besides the co-ordinate covalent bonds formed with the oxygen atoms of the two C—O groups, the uranium atom will show a tendency to form co-ordinate covalent bonds with other atoms, such as possibly bromide ions or the oxygen atoms of water molecules. Thus in uranyl acetate dihydrate the water molecules are perhaps attached to the uranium atom by co-ordinate covalent bonds. When uranyl acetate is freeze-dried, water molecules are no longer available and if a relatively large excess of potassium bromide is present it is possible that two, or perhaps more, bromide ions are bound to the uranium atom by co-ordinate covalent bonds, giving the compound represented by formula I. In the presence of a relatively small amount of potassium bromide, however, it is possible that the tendency of the uranium atom to form additional co-ordinate covalent bonds may be satisfied by chelation with the carbonyl oxygen atoms of the acetate groups giving a compound represented by formula II. In the resulting compound it is likely that the two oxygen atoms of each of the acetate groups will be equivalent.

Chelation of the carbonyl group often results in a considerable lowering in frequency of the band in the 1700 cm^{-1} region (26) and this effect could account for the disappearance of the 1713 cm^{-1} peak together with the increase in intensity and the broadening of the bands in the 1500 cm^{-1} region. The disappearance of the 1230 cm^{-1} band would also be expected. The shift of the asymmetrical normal vibration, ν_3, of the uranyl group from the 927 cm^{-1} region, type I spectra, to 942 cm^{-1}, type II spectra, could be the result of the changes which have occurred in the neighborhood of the uranium atom.

The 642 cm^{-1} peak which is present in type II spectra may be due to some vibration of the  group. This would account for the appearance of this peak as the ratio of uranyl acetate to potassium bromide increases. The low intensity, mentioned earlier, of the 1713 and 1230 cm^{-1} bands of the carbonyl group in type I spectra suggests that some chelation with the carbonyl oxygen atoms of the acetate groups has already occurred, even at a low uranyl acetate to potassium bromide ratio. Hence type I spectra probably results from the presence in the sample of a mixture of compounds I and II rather than from the presence of compound I alone.

In the above discussion intermolecular chelation has been postulated. It is conceivable that intramolecular chelation is either partially, or wholly, responsible for the changes observed in the spectrum as the uranyl acetate to potassium bromide ratio is varied.

(*c*) *Sodium Zinc Uranyl Acetate,* $NaZn(UO_2)_3(C_2H_3O_2)_9.6H_2O$

The spectrum was obtained from a sample prepared by mixing the compound with freeze-dried potassium bromide by vibration. The spectrum is very similar to that obtained by Jones (5) for $NaUO_2(C_2H_3O_2)_3$. A peak of moderate intensity which was not observed for $NaUO_2(C_2H_3O_2)_3$ was found in the present work at 1355 cm^{-1}. A very broad peak was observed at 3380 cm^{-1}. This region was not investigated by Jones (5). It is possible that this latter peak is due to the water of crystallization. As mentioned earlier for $NaUO_2(C_2H_3O_2)_3$, there is good evidence (27) that in $NaZn(UO_2)_3(C_2H_3O_2)_9.6H_2O$ the uranyl and acetate ions are present as the complex anion $UO_2(C_2H_3O_2)_3^-$. Hence it is not surprising that the infrared spectrum of these two compounds are quite similar. For

the same reasons as presented earlier in the discussion of the spectrum of uranyl acetate, it is believed that the intense peak observed at 680 cm^{-1} for $NaZn(UO_2)_3(C_2H_3O_2)_9.6H_2O$ is due to a C—O bond vibration rather than to a CO_2 deformation vibration as postulated by Jones for $NaUO_2(C_2H_3O_2)_3$ (5).

Infrared Spectrophotometric Determination of Uranyl Ion

An examination of the spectra of samples prepared by freeze-drying aqueous solutions of uranyl salts and potassium bromide indicated that the 923 cm^{-1} peak of uranyl nitrate might be suitable for the infrared spectrophotometric determination of the uranyl ion. This peak is relatively intense and sharp, and there is little interference from neighboring bands.

Solutions of known compositions were prepared by adding various volumes of a standard uranyl nitrate solution to known volumes of a standard potassium solution. The amount of potassium bromide used for each sample was 0.2 g. After freeze-drying, the samples were pressed into disks and their spectra recorded. The weight of the disk, which could not be removed from the die, was found by taking the difference between the weight of the die plus the disk after the excess material had been removed and the weight of the clean die. From a knowledge of the proportion of uranyl nitrate to potassium bromide used, the weight of uranyl ion present in the disk could be calculated. If the Beer–Lambert law is obeyed a plot of the optical density against the weight of uranyl ion present in the disk should give a straight line. The baseline optical density method of Heigl, Bell, and White (28) was used to determined the optical density. A potassium bromide blank was used in the reference beam. In Fig. 6 the optical density is plotted against the weight, in milli-

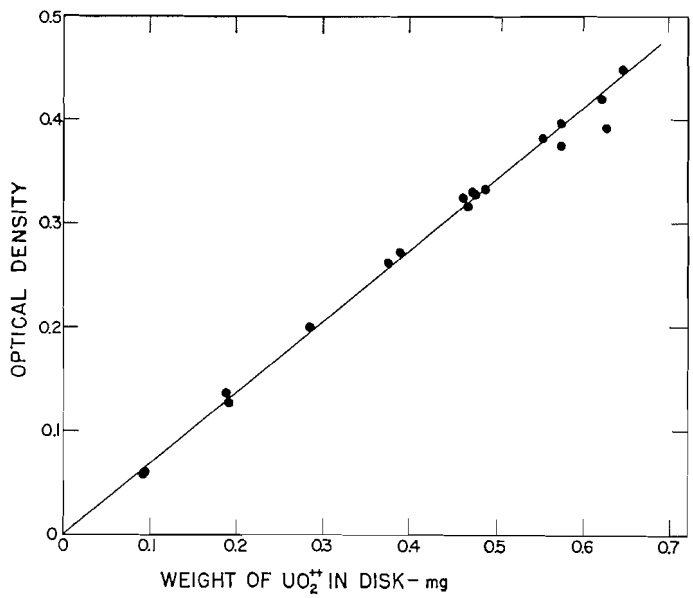

FIG. 6. Beer–Lambert's law plot for uranyl ion. Uranyl nitrate and potassium bromide mixed by freeze-drying. Wave number, 923 cm^{-1}.

grams, of uranyl ion present in the disk. The results indicate that with samples of uranyl nitrate prepared by the above technique and for the concentration range used, the Beer–Lambert law is obeyed.

EFFECT OF MEAN PORE SIZE ON THE LOW-TEMPERATURE ADSORPTION OF NITROGEN ON ALUMINA[1]

J. L. BLUMENTHAL, S. SOURIRAJAN, AND KEN NOBE

ABSTRACT

The effect of mean pore size on the low-temperature adsorption of nitrogen on two samples of alumina has been studied. The mean pore radius of one sample of alumina was 37 Å, and that of the other was 3100 Å. The two adsorption isotherms at −195.8° C have been plotted in terms of the volume of gas adsorbed per square meter of surface area vs. relative pressure ratio. The data have been found to fall into three distinct regions. In the first region extending up to the relative pressure ratio of 0.3, the two isotherms are nearly identical. In the second region extending from the relative pressure ratio of 0.3 to 0.75, the isotherm for the small mean pore size alumina lies above that for the large mean pore size sample. In the third region extending from the relative pressure ratio of 0.75 up to saturation, the isotherm for the small mean pore size sample tends to level off whereas that for the large mean pore size sample rises rapidly with increase in the relative pressure ratio. The above experimental observations have been explained on the basis of capillary condensation.

INTRODUCTION

The object of this investigation was to determine experimentally the effect of the mean pore size on the nitrogen adsorption isotherms of two samples of porous solids having the same chemical composition. This paper reports the results of a study of the low-temperature adsorption of nitrogen gas on two samples of alumina having widely different surface areas and mean pore radii.

EXPERIMENTAL

The apparatus used in this study for the determination of the gas adsorption isotherms and the total pore volume of the alumina samples was similar to the one described by Joyner (1). Pure dry nitrogen gas was used for adsorption, and helium gas was used to determine the dead space volumes. The sample bulb was immersed in a constant-temperature liquid nitrogen bath at −195.8° C during the experiment. Adsorption measurements were taken from relative pressures of 0.02 up to the saturation pressure. The surface area of the alumina samples were determined by the B.E.T. method (2). The total pore volumes of the samples were determined by the helium–mercury method by measuring the difference between the helium dead space and mercury dead space in a bulb containing the alumina sample (3). The mean radius of the pores in each of the samples was then calculated from the known surface area and pore volume data assuming the pores to be cylindrical.

RESULTS AND DISCUSSION

Alumina sample I had a surface area of 272 sq. meters per gram, and a mean pore radius of 37 Å. Alumina sample II had a surface area of 1.3 sq. meters per gram, and a mean pore radius of 3100 Å. The experimental adsorption data of nitrogen gas on the above alumina samples are given in Tables I and II respectively. In order to compare the two adsorption isotherms on a common basis, the data are plotted in Fig. 1 in terms of the volume of gas adsorbed per unit (sq. meter) of surface area vs. relative pressure ratio.

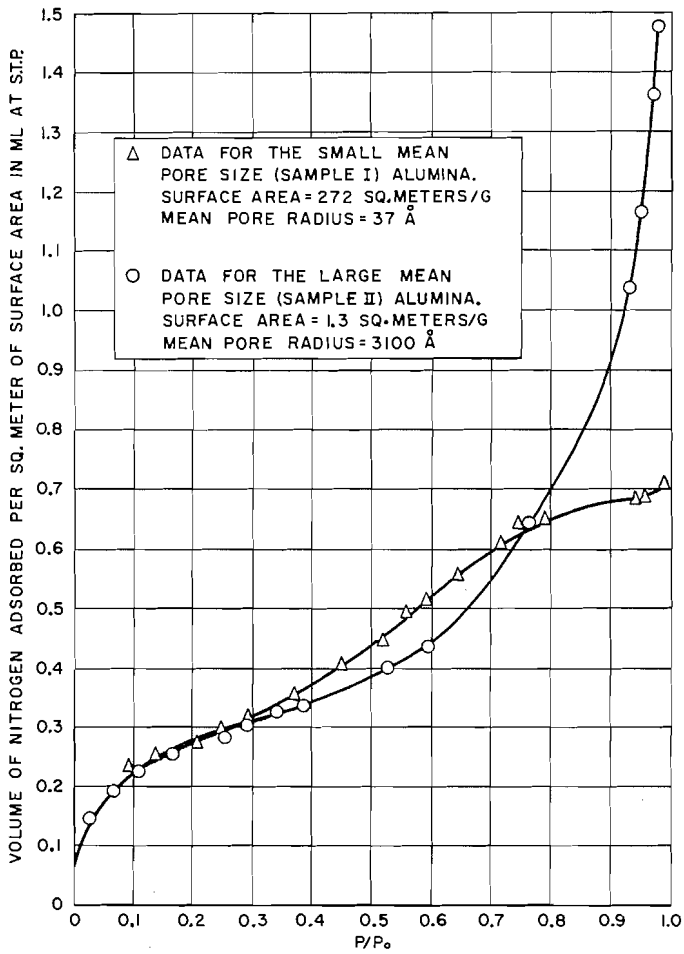

FIG. 1. Adsorption isotherms for the small mean pore size and the large mean pore size alumina samples.

From Fig. 1, it is seen that the data fall into three distinct regions. In the first region, which extends up to a relative pressure ratio of 0.3, the curves for both the small mean pore size (high surface area) alumina, and the large mean pore size (low surface area) alumina are nearly identical. This is the part of the isotherm which is useful for the B.E.T. plot. In the second region, which extends from the relative pressure ratio of 0.3 up to 0.75, the adsorption isotherm for the small mean pore size alumina lies above that for the large mean pore size sample. In the third region, which extends from the relative pressure ratio of 0.75 up to saturation, the isotherm for the small mean pore size sample almost levels off, whereas that for the large mean pore size sample rises very rapidly with increase in the relative pressure ratio. The above experimental observations can be explained as being due to the predominant effect of capillary condensation of nitrogen in the pores of the samples in the second and third regions. According to the well-known Kelvin equation (4), the relative pressure at which capillary condensation can take place increases exponentially with increase in pore size. Hence, a given amount of capillary condensation can take place at a lower relative pressure in the case of the

small mean pore size alumina than in the case of the large mean pore size sample. This explains the relative positions of the adsorption isotherms in the region 2. At the close of the region 2, it is reasonable to assume that most of the pores in the small mean pore size sample are already filled, whereas most of the pores in the large mean pore size

REARRANGEMENT STUDIES WITH C^{14}

IX. THE FORMOLYSIS OF METHYL-C^{14}-ISOPROPYLCARBINYL *p*-TOLUENESULPHONATE

A. J. FINLAYSON[2] AND C. C. LEE

ABSTRACT

Formolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) at reflux temperature gave a mixture of 2-methyl-2-butene (II), 2-methyl-1-butene (III), and 3-methyl-1-butene (IV). The relative amounts of olefins II, III, IV were measured by gas–liquid chromatography to be 88%, 11%, and 1%, respectively. When the formolysis was carried out at 50° C, besides olefins II, III, and IV, some *t*-amyl formate was obtained indicating a substitution reaction with neighboring hydrogen participation. Degradation of the mixture of olefins from formolysis gave, among other compounds, radioactive acetone, indicating an isotope position rearrangement in the chief product, 2-methyl-2-butene (II). This rearrangement may be attributed to a 1,2-methyl shift in one of the processes that gave rise to olefin II. A comparison of the data from the acetolysis and the formolysis of I showed that in the E_1 reactions, neighboring hydrogen participation is predominant in either solvent. For a change of solvent from acetic acid to the more ionizing formic acid, it was demonstrated that there is a greater degree of neighboring methyl participation while the process involving no neighboring group participation assumes less importance.

The acetolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) at reflux temperature gave only olefinic products while at 50° C, a small amount of *t*-amyl acetate was obtained besides the olefins (1). The elimination reactions were found to involve processes with no neighboring group participation, and with neighboring hydrogen and neighboring methyl participation, the hydrogen participation being predominant (1). In kinetic studies, a change of solvent from acetic to formic acid may help to disclose driving force due to participation by allowing neighboring group participation to displace nucleophilic assistance by solvent and by making the rate of solvolysis of a reference substance less assisted by nucleophilic driving force (2). Thus Winstein and Marshall (2) have studied the formolysis rates of a series of secondary alkyl *p*-bromobenzenesulphonates and have concluded that there is some assistance to ionization from neighboring hydrogen and/or carbon during solvolysis of methylisopropylcarbinyl derivatives. In the present work, solvolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) was carried out in formic acid and the results compared with those reported for the acetolysis of I (1).

RESULTS AND DISCUSSIONS

As in the acetolysis, the formolysis of I at reflux temperature gave a mixture of 2-methyl-2-butene (II), 2-methyl-1-butene (III), and 3-methyl-1-butene (IV) with no isolatable amount of substitution product. At 50° C, a yield of about 10% crude *t*-amyl formate and 42% of the mixture of olefins II, III, and IV were obtained. The relative amounts of II, III, and IV, as measured by gas–liquid chromatography, are tabulated in Table I. For comparison, the olefin composition in the products of acetolysis is also given in Table I.

Degradation of the mixture of olefins II, III, and IV by treatment with performic acid followed by cleavage with sodium metaperiodate yielded a mixture of formaldehyde, acetaldehyde, isobutyraldehyde, acetone, and methyl ethyl ketone. Separation of these carbonyl compounds as their 2,4-dinitrophenylhydrazones was effected by adsorption

determined. The results are given in Table II. The sum of the activities of acetaldehyde and acetone is a measure of the amount of olefin II in the mixture of II, III, and IV. This serves as a check on the gas chromatographic analysis of II given in Table I.

The presence of C^{14} activity in the acetone indicated that there was some isotope position rearrangement in the chief olefinic product, 2-methyl-2-butene (II). For the formolysis at reflux temperature run No. 1, this rearrangement amounted to

$$\{885/(16100+885)\} \times 100 = 5.2\%.$$

Such rearrangement data are included in Table II. For comparison, the degrees of

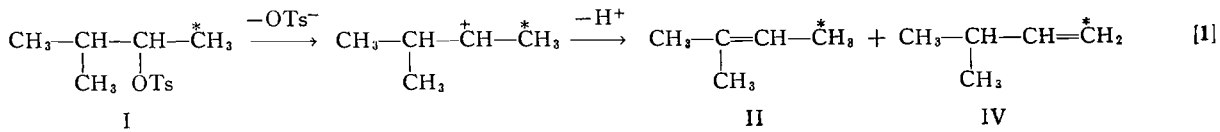
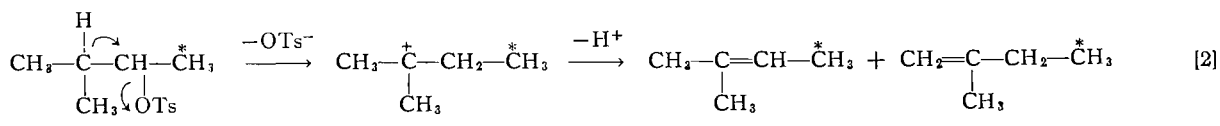
isotope position rearrangement in 2-methyl-2-butene obtained from acetolysis are also presented in Table II.

The interpretations of the results summarized in Tables I and II may be made in a way exactly analogous to the interpretations of the results from acetolysis of I (1). The *t*-amyl formate obtained from formolysis at 50° C indicates that the substitution reaction involves neighboring hydrogen participation resulting in a 1,2-hydrogen shift. The elimination reactions may be discussed in terms of reaction sequences 1, 2, and 3, representing processes without neighboring group participation, with neighboring hydrogen participation, and with neighboring methyl participation, respectively.



According to Saytzeff's rule, each of these three processes is expected to give a greater amount of the chief product, 2-methyl-2-butene (II or II_r). The presence of only very small amounts of 3-methyl-1-butene (IV or IV_r), as shown in Table I, indicates that reaction sequence 1 makes a relatively minor contribution to the over-all elimination reactions. It is even possible that all or a large part of the 3-methyl-1-butene detected by gas chromatography may have been due to reaction sequence 3, which results in the production of some isotopically rearranged olefin IV_r. By analogy with findings from acetolysis studies (1, 3) and from the presence of fairly large quantities of 2-methyl-1-butene (III) in the olefinic products of formolysis, it is reasonable to conclude that reaction sequence 2 depicts the predominant elimination process. The participation of neighboring methyl group (reaction sequence 3) results in the formation of isotopically rearranged 2-methyl-2-butene (II_r), the degradation of which gave radioactive acetone. The degree of this isotope position rearrangement in the 2-methyl-2-butene from formolysis is greater than the corresponding rearrangement after acetolysis by a factor of about 2 (Table II). This indicates a greater extent of neighboring methyl participation in formolysis than in acetolysis.

The location of C^{14} in the methyl group, and not in the carbonyl group, of acetone is required by reaction sequence 3. This was shown to be the case in the following way. After degradation of the mixed olefins II, III, and IV, the carbonyl compounds obtained were treated with neutral potassium permanganate to destroy all aldehydes (4). The remaining acetone and methyl ethyl ketone, recovered as an aqueous solution by distillation, were treated with bromine and sodium hydroxide to give carbon tetrabromide. If much of the C^{14} activity were present in the carbonyl group of acetone, the activity of the carbon tetrabromide would be lower than that of acetone and this was not observed (Table II). Actually, in the formolysis at 50° C, the C^{14} activity of acetone and of carbon tetrabromide was about equal. For the formolysis at reflux temperature, the carbon tetrabromide activity was even somewhat higher than the activity of acetone. Possibly, this difference may be due to some C^{14} located in the methyl group of methyl ethyl ketone. Results similar to this were noted in the acetolysis of I and it was suggested that the location of C^{14} in the methyl group of methyl ethyl ketone may be explained by a process involving first a 1,2-methyl shift followed by a 1,2-hydrogen shift before the formation of olefins (1).



In conclusion, it is evident that the formolysis of I involves processes similar to those operating in the acetolysis of I. The isolated substitution product results only from neighboring hydrogen participation. In the E_1 reactions, hydrogen participation also predominates. Comparing the data from formolysis and acetolysis, the greater degrees of isotope position rearrangement in 2-methyl-2-butene, coupled with the smaller amount of 3-methyl-1-butene in the over-all olefinic products, indicate a greater extent of

neighboring group participation and a lesser importance of the process without participation for the formolysis. This is in agreement with expectation that a change of solvent from acetic acid to the more ionizing formic acid would enhance the degree of participation by neighboring groups in E_1 as well as S_N1 reactions.

EXPERIMENTAL

Procedures for the synthesis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I), and for the analysis and degradation of the products of solvolyses, have been described previously (1).

Formolysis at Reflux Temperature

A solution of I (5.80 g, 0.024 mole) in 45 ml of anhydrous formic acid, m.p. 8.2–8.3° C (lit. (5) m.p. 8.4° C), containing 2.3 g (0.027 mole) of anhydrous potassium formate was gently refluxed for 2.5 hours. During the reflux period, the olefins formed were swept out by a stream of dry nitrogen and collected in a dry-ice-cooled trap.

After the refluxing, the reaction mixture was cooled, poured into 200 ml of ice and water containing 50 g of dissolved sodium chloride, and then repeatedly extracted with a 1:3 solution of ether – petroleum ether. The extracts were washed free of acid by a 5% solution of sodium carbonate and dried over anhydrous magnesium sulphate. Removal of the solvent, however, left no residue, indicating no recoverable quantity of substitution product.

The mixture of olefins collected in the dry-ice-cooled trap weighed 1.25 g (75%). It was distilled once, b.p. 35–38° C, before being used for degradation and gas chromatographic analysis.

Formolysis at 50° C

Methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) (10.0 g, 0.041 mole) was dissolved in 70 ml of anhydrous formic acid containing 3.7 g (0.044 mole) of anhydrous potassium formate. The solution was stirred mechanically in a bath maintained at 50±1° C for 3 hours. During the heating period, the olefins formed were swept out by dry nitrogen and collected in a dry-ice-cooled trap.

The reaction mixture was poured into 300 ml of ice and water containing 60 g of dissolved sodium chloride and then worked up as described under formolysis at reflux temperature. The removal of the ether – petroleum ether solvent left a colorless residue from which 0.5 g of material, b.p. 110–112° C, distilled and 1.0 g of unreacted I was recovered. The liquid product was redistilled at 112–113° C (lit. (6) b.p. of *t*-amyl formate, 113° C). Infrared and gas chromatographic analysis indicated that it was *t*-amyl formate contaminated with a small amount of *t*-amyl alcohol. The yield of this crude *t*-amyl formate was about 10% based on the 9.0 g of I used up in the reaction.

The mixture of olefins collected in the dry-ice-cooled trap weighed 1.10 g (42% based on 9.0 g of I). It was distilled once and then utilized for degradation and analysis.

CONSTITUTION OF A GLUCOMANNAN FROM JACK PINE (PINUS BANKSIANA, LAMB)[1]

C. T. BISHOP AND F. P. COOPER

ABSTRACT

A hemicellulose fraction from jack pine wood has been shown to contain D-mannose, D-glucose, and D-galactose in a molar ratio of 49:17:2. The glucomannan was electrophoretically homogeneous and showed a degree of polymerization of 18–21 by three different methods of end group analysis. Methylation and hydrolysis yielded the following *O*-methyl ethers: 2,3,4,6-tetra-*O*-methyl-D-glucose (2.8 moles); 2,3,4,6-tetra-*O*-methyl-D-galactose (1 mole); 2,3,6-tri-*O*-methyl-D-mannose (52 moles); 2,3,6-tri-*O*-methyl-D-glucose (15.3 moles); di-*O*-methyl-D-glucose (1 mole); di-*O*-methyl-D-galactose (2 moles). Lack of survival of any monosaccharides in the periodate-oxidized glucomannan showed that there was no branching through C_2 or C_3 of any of the units. Gas–liquid partition chromatography was used to analyze products from methylation and hydrolysis and from periodate oxidation and reduction of the polysaccharides. The results showed that the glucomannan from jack pine was composed of $1 \rightarrow 4$ linked β-D-mannose and β-D-glucose residues with D-galactose residues present as non-reducing terminal units. Branching, if any, must occur through C_6 of units making up the polysaccharide. This structure is compared with those of glucomannans found in other soft woods.

It has been known for a long time that a large percentage of the non-cellulosic polysaccharides in soft woods give rise to D-mannose on hydrolysis (1, 2, 3). However, reports on the isolation of mannose-containing polysaccharides and studies of the mode of linkage of the mannose residues are of much more recent date (4–19). It was apparent from the earliest of these reports (4, 5) that at least some of the mannose residues in slash pine α-cellulose were joined to glucose units. Subsequent publications described the isolation of glucomannans from western hemlock (6), white spruce (7, 8), loblolly pine (9), Norwegian spruce (10), and a Mitscherlich pulp (11) and showed with reasonable certainty, by fractionation and fragmentation analysis, that these polysaccharides were true glucomannans and not mixtures of mannans, glucans, and glucomannans. These results have been supported by recent structural studies on glucomannans from loblolly pine (12, 13), Sitka spruce (14, 15), Norwegian spruce (16), western hemlock (17), western red cedar (18), and Scots pine (19). All of these glucomannans possessed the main structural feature of a linear chain of $1 \rightarrow 4$ linked residues of β-D-mannose and β-D-glucose. However, there were smaller but significant differences which involved the question of branching in the polysaccharide and the presence or absence of D-galactose units as an integral part of the molecule.

This paper reports the isolation and structural study of a glucomannan from jack pine (*Pinus banksiana*, Lamb) and forms a further contribution to the general chemistry of this class of polysaccharides. A previous report (20) described a water-soluble arabogalactan isolated from the same wood and therefore the present work also provides further information about the carbohydrates in a single biological species.

The isolation of polysaccharides from jack pine wood is shown schematically in Fig. 1. The sugars listed are those which were released by acid hydrolysis of the various polysaccharide fractions and detected chromatographically. Polysaccharides containing glucose, mannose, and galactose could be obtained from the first two alkaline extracts by repeated complexing with copper but yields were low, presumably because of interference

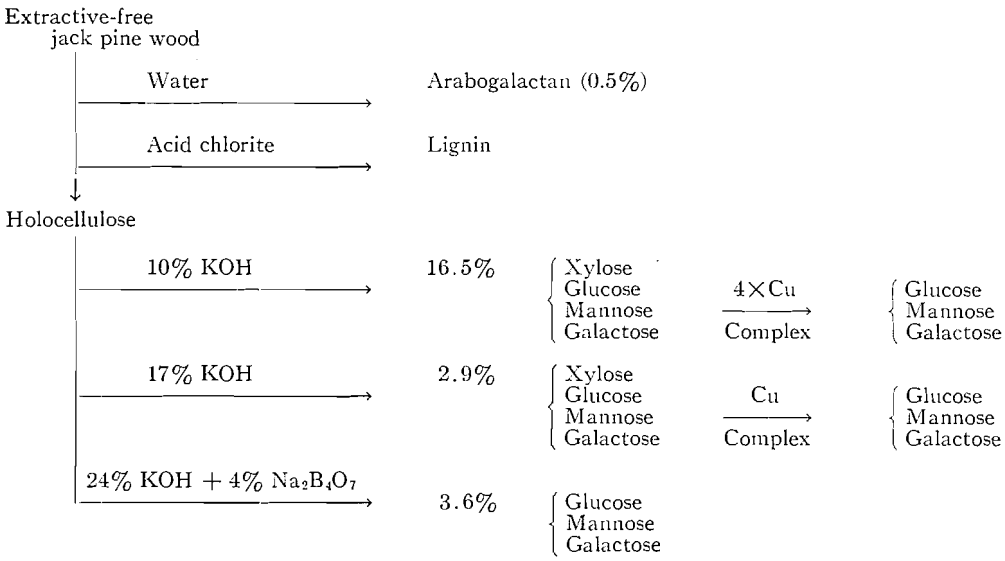

FIG. 1. Isolation of polysaccharides from jack pine wood.

by the large amounts of xylan present in these extracts. Structural studies were therefore carried out on the polysaccharide which were extracted by alkali and borate (21) and which yielded on hydrolysis glucose, mannose, and galactose as the only products detectable by paper chromatography. The monosaccharide composition of this material (mannose:glucose:galactose, 49:17:2, molar ratio) was unchanged by repeated complexing with copper. The significance of the persistent galactose component will be referred to later in comparing the structure of the present polysaccharide with those of other glucomannans.

The glucomannan isolated from the alkaline borate extraction showed a single sharp peak on electrophoresis (Fig. 2; the first, non-mobile, peak has been shown to be a false

acid showed that no terminal furanoside ring forms were present. On periodate oxidation the polysaccharide consumed 1.11 moles of oxidant per mole anhydrohexose with production of 0.10 mole of formic acid per mole anhydrohexose. The oxidized polysaccharide was examined by the procedure developed by Smith and his co-workers (22) with an innovation that utilized the unique analytical powers of gas–liquid partition chromatography (23, 24). The sequence of reactions is outlined in Fig. 3 and consisted of oxidation,

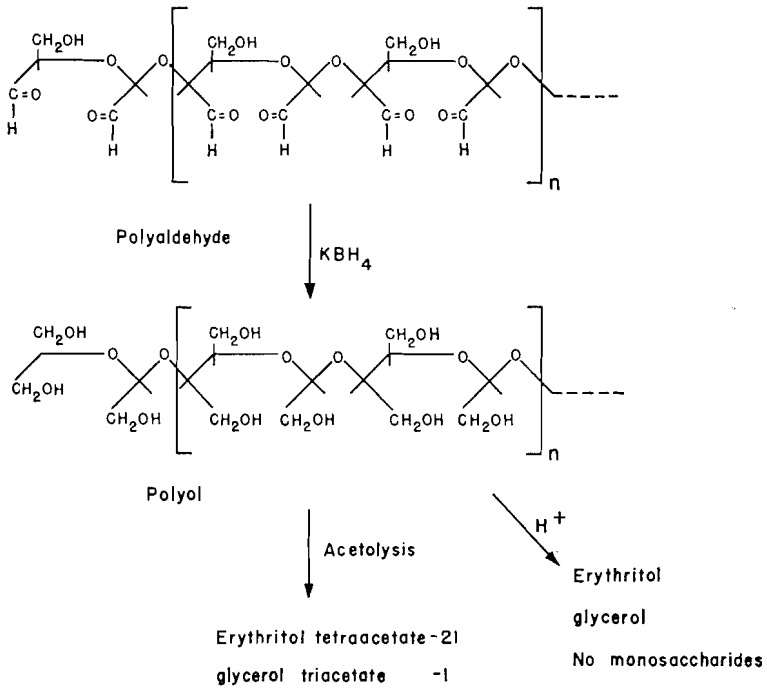

FIG. 3. Smith degradation of 1 → 4 linked hexosan.

reduction, and hydrolysis of the polysaccharide to yield erythritol and glycerol as the only products detectable by paper chromatography. The polyol was also subjected to acetolysis and the products were analyzed by gas–liquid partition chromatography (Fig. 4) giving a ratio of erythritol to glycerol of 20.8:1.0. This procedure also permitted the unequivocal identification of erythritol as its crystalline tetraacetate. The erythritol and glycerol found by this sequence of reactions must have arisen from 1 → 4 linked units and non-reducing terminal residues respectively and the ratio between them is a measure of degree of polymerization for a linear polysaccharide (22). The amount of formic acid produced in periodate oxidation of a linear polysaccharide can also be used as a measure of degree of polymerization. Under the conditions of periodate oxidation (pH 4.37) and formic acid estimation (release of iodine from potassium iodide in the presence of iodate) used here it is likely that C_1 of the reducing unit would remain attached as a formyl ester and hence would not be detected in the estimation. The polysaccharide would therefore liberate only 2 moles of formic acid and the amount found (0.10 mole per mole anhydrohexose) would give a degree of polymerization of 20, in good agreement with the value of 21 found by the erythritol:glycerol ratio. A linear chain of twenty 1 → 4 linked residues would consume 22 moles of periodate or 1.10 moles per mole anhydrohexose, a

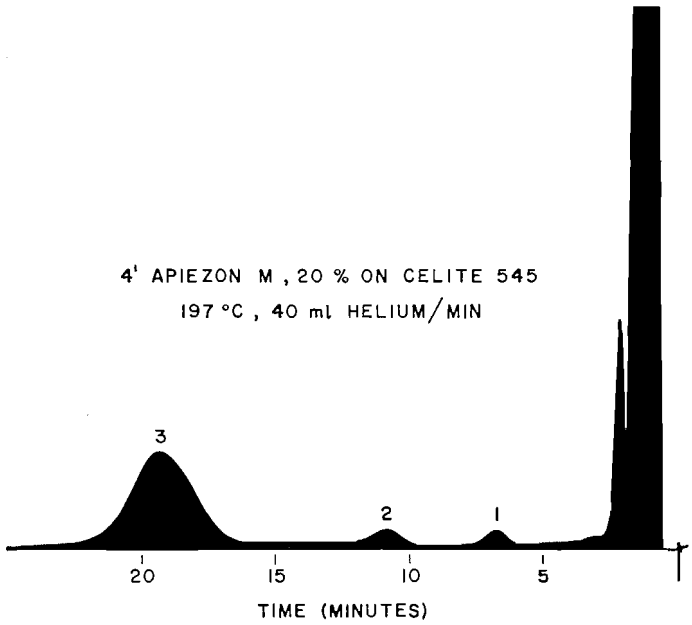

FIG. 4. Gas–liquid partition chromatogram of acetolysate from oxidized, reduced glucomannan. (1) Glycerol triacetate. (2) Not identified, possibly acetate of glycolic aldehyde. (3) Erythritol tetraacetate.

value which agrees with the periodate consumption (1.11 moles per mole anhydrohexose) determined experimentally. In a $1 \rightarrow 4$ linked polysaccharide any branching through C_2 or C_3 results in the unit forming the branch point being resistant to periodate oxidation because of a lack of vicinal hydroxyl groups. The absence of any monosaccharides in the hydrolyzate of the oxidized, reduced glucomannan showed that there was no branching through C_2 or C_3 of any of the monosaccharide units in the chain. Branching, if any, must have been through C_6.

The glucomannan was methylated and the hydrolysis products were separated, as their methyl glycosides, by gas–liquid partition chromatography (23, 24). The separations are shown in Figs. 5 and 6 and the quantitative data, obtained from measurements of areas under these peaks, is given in Table I. Component 6, Table I, was clearly evident

in the gas–liquid partition chromatograms but had such a large retention volume that space did not permit its inclusion in Fig. 5. The peaks in Figs. 5 and 6 were identified by comparison with authentic samples on the gas–liquid partition chromatogram. These identities were confirmed by collection of samples from the effluent gas stream of a semi-preparative apparatus and isolation of crystalline derivatives. There were not sufficient amounts of components 5 and 6, Table I, to permit complete identification; it was only possible to establish the parent sugar by demethylation and chromatography. In Table I components 1 and 2 represent the non-reducing terminal units and components 3 and 4 must have originated from a series of 1 → 4 linked D-mannose and D-glucose units. The structural significance of components 5 and 6 is rather more difficult to assess. Hydrolysis products of the periodate-oxidized, reduced glucomannan showed that any branch points in the polysaccharide must be through C_6 and therefore, to be structurally significant, these di-*O*-methyl hexoses must be the 2,3-di-*O*-methyl isomers. Unfortunately it was not possible to make positive identifications which would decide this point. It is possible, of course, that the di-*O*-methyl hexoses were products of incomplete methylation or of demethylation during hydrolysis. However, it was noteworthy that none of the major monosaccharide component (D-mannose) in the polysaccharide showed up as a di-*O*-methyl derivative. It may be that different monosaccharides are methylated or demethylated to different extents depending perhaps on their position in the polysaccharide and on the spatial disposition (conformation) of their hydroxyl groups. These are points which seem worthy of investigation and until they are clarified the authors are reluctant to assign a branch point to the polysaccharide. It is worth mentioning that the di-*O*-methyl hexoses were barely detectable by paper chromatography and almost certainly would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

have been dismissed as trace amounts in any quantitative estimation by that technique. The more accurate data available from gas–liquid partition chromatography would appear to necessitate a reassessment of the methylation technique for studying polysaccharides. The ratio of tetra- to tri-*O*-methyl ethers from the methylated glucomannan was 1:17.7, a value in reasonable agreement with the degrees of polymerization of 20 and 21 found respectively by formic acid production during periodate oxidation and by the erythritol:glycerol ratio in the hydrolyzate of the oxidized, reduced polysaccharide. Because of this agreement a linear structure is favored for the polysaccharide. The observations that the polysaccharide was electrophoretically homogeneous, that D-galactose persisted as a component sugar through repeated copper complexing, and that 50% of the D-galactose showed up in the methylated polysaccharide as non-reducing terminal units showed that D-galactose was an integral part of the polysaccharide and was not present in a contaminant.

Two structures are possible for the glucomannan from jack pine: (*a*) linear chains of $1 \rightarrow 4$ linked β-D-glucose and β-D-mannose units some of which are terminated by glucose and others by galactose units, (*b*) the same linear chains but with a proportion of the molecules (approximately 1 in 2.8) containing D-galactose units attached as single unit side chains. It is not possible to decide between these alternatives from the evidence available at the present time. The presence of D-galactose in glucomannans has been observed before but it has not always been considered to be an integral part of the polysaccharide. Loblolly pine contains a polysaccharide made up of D-glucose, D-mannose, and D-galactose residues (12, 13). In the first investigation (12) of this material all of the D-galactose was found as non-reducing terminal units and was considered to have arisen from a galactomannan present in admixture with the glucomannan. In a later investigation (13) of the same hemicelluloses, D-galactose was present as non-reducing terminal unit and there were two such units (one of mannose and one of galactose) per chain of 27–33 residues. Hamilton and Partlow (18) found di-*O*-methyl- and 2,3,4,6-tetra-*O*-methyl-D-galactose in the methylated glucomannan from western red cedar and attributed these results to the presence of a contaminating galactoglucomannan. Dutton and Hunt (15) found D-galactose as a non-reducing terminal unit in one fraction of a glucomannan from Sitka spruce. They concluded that it was part of a low molecular weight polysaccharide because dialysis of another fraction of the same material yielded a product which contained no D-galactose. Glucomannan fractions from Scots pine (19) contained D-galactose and D-xylose but both of these sugars were removed by further delignification of the polysaccharides. From this result it was postulated that several polysaccharides might be joined to the same lignin molecule and their separation prevented thereby. D-Galactose was not found as a constituent sugar in glucomannans from western hemlock (17), Norwegian spruce (16), and in another investigation of Sitka spruce (14).

Other differences between glucomannans from various sources are in the non-reducing terminal units, other than D-galactose, and in the results of periodate oxidation. In the present work D-glucose formed the only non-reducing terminal units other than D-galactose. It is certain that no 2,3,4,6-tetra-*O*-methyl-D-mannose was present because it would have been separated from 2,3,4,6-tetra-*O*-methyl glucose by gas–liquid partition chromatography and would have emerged before peak 1, Fig. 5. Similar results have been obtained from the glucomannan of western red cedar (18) but those of western hemlock (17) and Scots pine (19) contained non-reducing terminal units of both D-glucose and D-mannose. On the other hand glucomannans from loblolly pine (12, 13), Sitka spruce (14, 15), and Norwegian spruce (16) had non-reducing terminal units of D-mannose and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

none of D-glucose. It is possible that some of these differences have been caused by the difficulty in separating the 2,3,4,6-tetra-*O*-methyl ethers of D-glucose and D-mannose from each other (14).

Only the glucomannans of western hemlock (6), Norwegian spruce (16), and Scots pine (19) have been examined by the Smith degradation (22). All of these yielded D-glucose plus a trace of D-mannose in hydrolyzates of the periodate-oxidized, reduced polysaccharides and the results were interpreted as indicative of branching through C_2 or C_3 of the glucose units. No D-glucose or D-mannose was found in the present work after the same sequence of reactions had been applied to the glucomannan from jack pine. This difference may have been caused by the different times allowed for oxidation. The glucomannans from western hemlock (6), Norwegian spruce (16), and Scots pine (19) were oxidized for 432, 350, and 174 hours respectively while that from jack pine was oxidized for 552 hours. It has been shown (25) that sugar units are resistant to oxidation by periodate if the hydroxyls on C_2 and C_3 are in *trans* position in a rigid conformation. Although little is known about the conformation of sugar units in polysaccharides it is possible that the above conditions could obtain for a chain of $1 \rightarrow 4$ linked D-glucose units. This would account for the presence in the periodate-oxidized glucomannans of more D-glucose than D-mannose which has its C_2 and C_3 hydroxyls in *cis* orientation. Hamilton and Smith (26) have stressed the importance of prolonged oxidation if this technique is to be used to detect branch points.

Clearly, further work is necessary to ascertain the structural significance of the D-galactose residues in glucomannans, and to decide whether branch points are present or absent. One possible approach to these questions, fragmentation analysis by enzyme hydrolysis, is now in progress in this laboratory.

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v):

(A) butan-1-ol:pyridine:water, 6:4:3;
(B) ethyl acetate:acetic acid:water, 4:1:4;
(C) butan-1-ol:ethanol:water, 3:1:1.

Reducing sugars were detected on paper chromatograms by the *p*-anisidine hydrochloride spray reagent (27); non-reducing components were detected by silver nitrate and sodium hydroxide sprays (28). Evaporations were carried out in a rotary film evaporator under diminished pressure at 35° C or less. Melting points are corrected and rotations are equilibrium values unless otherwise stated.

Isolation of Glucomannan

The sequence of extractions is shown in Fig. 1. Extractive-free jack pine wood was extracted with water which removed an arabogalactan (0.5%) (20). The residue from this extraction was delignified by acid chlorite (29) and then extracted successively with 10% and 17% potassium hydroxide and finally with 24% potassium hydroxide containing 4% of sodium tetraborate (21). Three extractions, each of 24-hour duration, were made at each alkali concentration. Each extract was neutralized with acetic acid, dialyzed to remove inorganic salts, and the non-dialyzables were freeze-dried to yield the crude polysaccharides.

Figure 1 shows the order of the above extractions and the component sugars in the polysaccharides as detected by paper chromatography (solvents A and B) after hydrolysis

For personal use only.

for 12 hours at 97° C by *N* hydrochloric acid. Yields of polysaccharides in the alkaline extractions were based on holocellulose. The 10% potassium hydroxide removed mainly xylan as shown by the predominance of xylose in the hydrolyzate from this polysaccharide mixture. The 17% potassium hydroxide extraction yielded roughly equal quantities of pentosan and hexosan; the final extraction with 24% potassium hydroxide and 4% sodium tetraborate yielded a polysaccharide which contained only glucose, mannose, and galactose. The polysaccharides in the 10% and 17% potassium hydroxide extracts were precipitated as their copper complexes. The precipitates were washed thoroughly with water, dissolved in cold *N* hydrochloric acid, and poured into 4 volumes of ethanol to reprecipitate the polysaccharides which were then examined by hydrolysis and chromatography as described above. Four precipitations of the copper complex were required to yield a glucomannan from the polysaccharides extracted by 10% potassium hydroxide. One such treatment sufficed to give the same result with the polysaccharides extracted by 17% potassium hydroxide. However, yields of glucomannan from these fractions were low (ca. 1% of the fraction) and the remainder of the work was carried out on the polysaccharide extracted by 24% potassium hydroxide and 4% sodium tetraborate.

The polysaccharide showed a single sharp peak (Fig. 2) ($\mu = 9.86 \times 10^{-5}$ cm^2, volts^{-1}, sec^{-1}) on moving boundary electrophoresis in 0.05 *M* borate buffer carried out in a Spinco Model H Tiselius-type apparatus. Electrophoretic patterns at two time intervals are included in Fig. 2 to show that the first peak did not migrate and is in fact a false boundary. This has been proved by Adams (30), who has isolated material responsible for this peak, which always occurs in electrophoresis in borate, and showed that it yielded no sugars on hydrolysis. The monosaccharide composition, mannose:glucose:galactose, 49:17:2, determined by the phenol–sulphuric acid method (31), was unchanged by repeated fractionation of the polysaccharide as its copper complex. The glucomannan had $[\alpha]_D^{27} = -26°$ (*c*, 1% in *N* sodium hydroxide) and did not yield any sugars detectable by paper chromatography when heated at 97° C with 0.025 *N* oxalic acid for 3 hours.

Periodate Oxidation of Glucomannan

Sodium metaperiodate (6.47 g) was dissolved in water (150 ml) and *N* sodium hydroxide was added to adjust the solution to pH 4.37. This reagent (30 ml) was added to duplicate samples (121 mg) of the polysaccharide suspended in water (120 ml). Reagent blanks were also prepared and the oxidations were allowed to proceed in the absence of light and with continuous shaking. At the intervals noted below samples were removed for estimation of periodate consumption and formic acid production.

For estimation of formic acid, 2,3-butanediol (6 drops) was added to the sample (20 ml), which was then kept in the dark for 30 minutes. A few crystals of potassium iodide were then added and the liberated iodine was titrated to a starch end point with 0.01 *N* sodium thiosulphate.

Periodate was estimated by the excess arsenite method of Fleury and Lange (32, 33). Results of these two estimations in moles per mole anhydrohexose at various time intervals were as follows:

Time (hours)	21	45	47	69	71	93	95	167	170	552
Formic acid	0.067	0.077	—	0.086	—	0.088	—	0.098	—	0.106
Periodate	—	—	0.087	—	0.85	—	0.85	—	0.88	1.11

In a separate experiment (Fig. 3) (22) the glucomannan (1.0 g) was oxidized by 0.4 *M* sodium metaperiodate (50 ml) at 21° C for 23 days. Iodate and excess periodate were

precipitated by addition of 0.5 *M* barium acetate and the precipitate was filtered. The filtrate was deionized by Amberlite ion exchange resins IR-45 and IR-120 and potassium borohydride (1.0 g) was then added. After 48 hours the solution was neutralized with acetic acid and deionized by Amberlite IR-45 and IR-120. The solution was then evaporated to dryness and last traces of borate were removed from the residue by repeated evaporation with methanol. The residue was dissolved in water (50 ml) and an aliquot (1 ml) was hydrolyzed by *N* hydrochloric acid (1 ml) at 97° C for 6 hours. Paper chromatograms (solvents A and B) showed the presence of two components that were identical with authentic samples of erythritol and glycerol run on the same paper strips. No component corresponding to a monosaccharide could be found, even on heavily loaded chromatograms. Another aliquot of the polyol solution (5 ml) was evaporated to dryness and the residue, dried *in vacuo*, was heated at 80° C for 20 hours in a solution (20 ml) of acetic anhydride containing 2% of sulphuric acid. The acetolysate was examined directly by gas–liquid partition chromatography (23, 24) and the separation curve is shown in Fig. 4. Authentic samples of glycerol triacetate and erythritol tetraacetate gave the same retention volumes as peaks 1 and 3, Fig. 4, respectively, either when run separately or when added to the unknown mixture. The compound giving peak 3 was collected from the effluent gas stream and the product crystallized spontaneously. Recrystallization from ether: petroleum ether (30–60° C) gave a compound with a melting point of 84–85° C. A mixed melting point with authentic erythritol tetraacetate was 84–86° C. The compound giving peak 1 was also collected but glycerol triacetate is liquid at room temperature and there was not sufficient material to permit deacetylation and formation of another derivative.

The ratio of erythritol to glycerol was 20.8:1 as determined from the relative areas under peaks 3 and 1 (24).

Methylation of Glucomannan

The glucomannan (1.5 g) was acetylated with acetic anhydride (30 ml) in pyridine (45 ml). The mixture was poured into water and the precipitated polysaccharide acetate was centrifuged, washed with water, and dried *in vacuo*; yield, 1.3 g. This product was dissolved in tetrahydrofuran (25 ml), sodium hydroxide (17 g) was added, and the mixture was stirred during dropwise addition of dimethyl sulphate (20 ml) (34). A second addition of reagents was made and the mixture was then refluxed for 1 hour. A further 10 additions of the same quantities of sodium hydroxide and dimethyl sulphate were made over a period of 4 days with continuous stirring and occasional addition of tetrahydrofuran to maintain fluidity. The solution was refluxed for 1 hour, cooled, and filtered. The filtrate and the residual solids (dissolved in water) were extracted continuously with chloroform for 24 hours. The aqueous phases from the two extractions were evaporated to dryness and the residues were extracted with chloroform and methanol. All extracts were combined, dried, and evaporated to yield a product (1.12 g) with a methoxyl content of 38.0%. This product was methylated six times with Purdie's reagents using the same amounts of methyl iodide (25 ml) and silver oxide (5 g) for each methylation. The product (0.76 g) from these methylations had a methoxyl content of 42.2% and showed no hydroxyl absorption in the infrared.

Hydrolysis of Methylated Glucomannan

The methylated glucomannan (0.72 g) was hydrolyzed by formic acid according to the procedure of Jones and Wilkie (35). The hydrolyzate was examined by paper chromatography (solvent C) and showed a major component which corresponded to 2,3,6-tri-*O*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

methyl-D-mannose; minor components were chromatographically identical with 2,3,4,6-tetra-*O*-methyl-D-glucose; 2,3,4,6-tetra-*O*-methyl-D-galactose; and 2,3,6-tri-*O*-methyl-D-glucose. Trace amounts of two di-*O*-methyl hexoses were also present.

The mixture of sugars was refluxed with 5% methanolic hydrogen chloride and the resulting mixture of glycosides was analyzed by gas–liquid partition chromatography (23, 24). Figure 5 shows the separation of the total mixture on a liquid phase of Apiezon M. In addition to the components shown there was another di-*O*-methyl hexose, present in half the quantity of peak 5, Fig. 5, which had a much larger retention volume and could not be included in the diagram. Identities of the peaks were established by comparison with authentic samples of the compounds listed and were confirmed by isolation of crystalline derivatives as described below. Because it was known that several methylated sugars had the same retention volumes of peaks 1 and 2, Fig. 5, under the conditions used, the compounds giving these two peaks were collected as one fraction from the effluent gas stream and were re-run using butanediol succinate polyester as the liquid phase. The separation, shown in Fig. 6, illustrated clearly that the major component of peak 2, Fig. 5, was the β-methyl glycoside of 2,3,6-tri-*O*-methyl-D-glucose. Figure 6 also shows that no tetra-*O*-methyl-D-mannose was present because it would have appeared between the anomeric methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-glucose. Peaks 5, 6, and 7, Fig. 6, were not identified conclusively but were probably di-*O*-methyl pentoses arising from a small amount of pentosan present as impurity in the glucomannan. The detection of these components serves to illustrate the sensitivity of gas–liquid partition chromatography because no pentoses could be detected by paper chromatography in hydrolyzates of the polysaccharide or of its methyl ether.

The quantitative data given in Table I were obtained directly from the curves shown in Figs. 5 and 6 by measurement of the areas under the peaks. Areas of peaks representing anomeric glycosides of the same sugar were, of course, added together.

Identification of O-Methyl Ethers

Semipreparative gas–liquid partition chromatography of the mixture of methyl glycosides was carried out at 180° C on an 8-ft column (6-mm I.D.) containing 20% Apiezon M on Celite 545. The apparatus used (23) permitted collection of 1–15 mg of each component.

2,3,4,6-Tetra-O-methyl-D-glucose

This component was collected from the effluent gas stream as its liquid α-methyl glycoside. The glycoside (1 mg) was hydrolyzed at 97° C in *N* hydrochloric acid (0.5 ml) for 6 hours and the hydrolyzate was evaporated to dryness. Ethanol (0.2 ml) and freshly distilled aniline (1 drop) were added, the solution was refluxed for 20 minutes, and then cooled at 5° C for 20 hours. The fine, white needles that separated had a melting point of 115–120° C. Recrystallization from ethanol:water gave a product with a melting point of 134–135° C, and a mixed melting point with an authentic sample of *N*-phenyl 2,3,4,6-tetra-*O*-methyl-D-glucosylamine was 134–136° C. Reported (36): m.p. 135° C.

2,3,4,6-Tetra-O-methyl-D-galactose

This component was collected from the effluent gas stream as a mixture of its anomeric methyl glycosides. These were hydrolyzed and anilide formation was carried out as just described. The crystalline product had a melting point of 192° C, undepressed by admixture with an authentic sample of *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine. Reported (37): m.p. 192° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

*2,3,6-Tri-O-methyl-*D*-glucose*

The anomeric methyl glycosides of this component were widely separated by gas–liquid partition chromatography and were collected separately. Methyl 2,3,6-tri-*O*-methyl-β-D-glucopyranoside crystallized in the collection tube and was recrystallized from ether: petroleum ether (30–60° C), m.p. 59° C and mixed m.p. 59–60° C with an authentic sample of methyl-2,3,6-tri-*O*-methyl-β-D-glucopyranoside. Reported (38): m.p. 58–60° C.

The α-methyl glycoside was hydrolyzed with *N* hydrochloric acid at 97° C for 6 hours. The hydrolyzate was neutralized with Amberlite IR-45 ion exchange resin and evaporated to dryness in a desiccator. The residue crystallized, m.p. 115–120° C, and was recrystallized from ether to yield a product with m.p. 121–122° C, undepressed by admixture with authentic 2,3,6-tri-*O*-methyl-D-glucose. Reported (39): m.p. 121–123° C.

*2,3,6-Tri-O-methyl-*D*-mannose*

This component was collected as its sirupy α-methyl glycoside (15 mg) which was then hydrolyzed by *N* hydrochloric acid at 97° C for 6 hours. The hydrolyzate was evaporated to dryness and anilide formation was carried out as described for 2,3,4,6-tetra-*O*-methyl-D-glucose. The product was recrystallized from ether:petroleum ether (30–60° C) to m.p. 128° C, undepressed by admixture with an authentic sample of *N* phenyl-2,3,6-tri-*O*-methyl-D-mannosylamine. Reported (40): m.p. 127–128° C.

Di-O-methyl Hexoses

Peak 5, Fig. 5, and the other di-*O*-methyl-hexose which had too large a retention volume to be included in Fig. 5 were collected separately and were hydrolyzed and demethylated simultaneously by 48% hydrobromic acid at 97° C in a sealed tube for 20 minutes. The solutions were neutralized (silver carbonate), concentrated, and the total samples were examined by paper chromatography (solvent A). Galactose was obtained from peak 5, Fig. 5, by this procedure while the other di-*O*-methyl hexose yielded glucose.

ACKNOWLEDGMENTS

The authors wish to thank Dr. T. E. Timell, who generously donated samples of 2,3,6-tri-*O*-methyl ethers of D-glucose and D-mannose. Analyses were done by Mr. A. E. Castagne.

11-OCTADECENOIC ACID AND OTHER FATTY ACIDS OF ASCLEPIAS SYRIACA SEED OIL[1]

MARY J. CHISHOLM AND C. Y. HOPKINS

ABSTRACT

The seed oil of *Asclepias syriaca* L., family Asclepidaceae, was examined by gas chromatography and distillation of the methyl esters. The fatty acids were found to include a considerable proportion of *cis*-11-octadecenoic acid, which has not been observed previously in seed oils. It was obtained as a concentrate ($\simeq$ 80%) by low-temperature crystallization of the C18 acids and identified as 11,12-dihydroxystearic acid. The amount of 11-octadecenoic acid in the oil was determined by oxidative splitting of the total fatty acids and estimation of the resulting azelaic and undecanedioic acids by gas chromatography.

The C16 acids included 9,12-hexadecadienoic acid, which is rare in seed oils, and an unusually large proportion of 9-hexadecenoic acid. The percentage composition of the fatty acids was estimated from the data as follows: palmitic 4,9-hexadecenoic 10, 9,12-hexadecadienoic 2, stearic <1, oleic 15, 11-octadecenoic 15, linoleic 53, linolenic <1. The unsaturated acids have the *cis* configuration.

INTRODUCTION

In preparation for a study of the development of oil in a maturing seed, it was desired to know the normal composition of the seed oil of *Asclepias syriaca* L. (common milkweed), family Asclepidaceae. The oil of this species has been examined by a number of workers in the past and the fatty acids have been reported for the most part as consisting of the ordinary oleic, linoleic, and saturated acids (1, 2, 3). However, there are some indications in these reports of the presence of less common constituents.

In the present work, the seed oil of *Asclepias syriaca* L. was examined by distillation of the methyl esters, followed by low-temperature crystallization and gas chromatography of the fractions. The identity of the individual acids was determined with certainty by orthodox procedures.

The results show that the oil has by no means a simple palmitic–oleic–linoleic composition. A novel constituent is 11-octadecenoic acid, reported here for the first time in a seed oil. The amount is substantial and is estimated to be 15% of the total fatty acids. Ordinary oleic acid is present also.

The composition of the C16 acids is distinctly different from that of the common seed oils. The major C16 acid is 9-hexadecenoic and the ratio of 9-hexadecenoic acid to palmitic acid is 2:1 or greater. There is an appreciable amount of 9,12-hexadecadienoic acid, which is known in only one other seed oil (4).

The presence of an isomer of oleic acid (other than the well-known petroselinic acid) in seed oils has been suspected from time to time. As early as 1927, Hilditch, Riley, and Vidyarthi reviewed the claims for the existence of such an isomer in rapeseed oil and examined a number of Cruciferae oils (5). They found strong evidence of a possible 1 or 2% of isomers of oleic acid in rapeseed and mustard-seed oils but did not succeed in identifying them. Millican and Brown noticed similar indications of an isomer or isomers in rapeseed and soybean oils (6).

The present investigation establishes the occurrence of *cis*-11-octadecenoic acid* in the glycerides of *Asclepias syriaca* seed oil. No evidence was found of any other octadecenoic acid except the ordinary oleic acid.

EXPERIMENTAL

Seed pods of *Asclepias syriaca* L. were collected in late September, 1959, from a stand of wild plants near Ottawa. The seed was removed from the pods by hand, dried, ground, and extracted with petroleum ether. The following data were recorded: moisture in seeds as harvested, 39.6%; mean weight of seeds (moisture-free) per pod, 0.82 g; weight of 100 seeds (moisture-free), 0.57 g; oil content of seeds (moisture-free basis), 19.4%. Constants of the oil are shown in Table I.

TABLE I

Properties of the oil

Iodine value	127.2	Acetyl value	0
Acid value	1.5	Refractive index, 25°	1.4748
Unsaponifiable matter, %	2.2	Equiv. wt. of mixed fatty acids	279.0

Separation of the Fatty Acids

The oil was converted to methyl esters by methanolysis with dry hydrogen chloride catalyst and the esters were examined by gas–liquid chromatography, using a polyester liquid phase. The detector was a thermistor type of thermal conductivity cell. Column length was 1 meter, temperature 190°, and helium flow rate 95 ml/minute, at an inlet pressure of 12.5 p.s.i. The chromatogram is shown in Fig. 1.

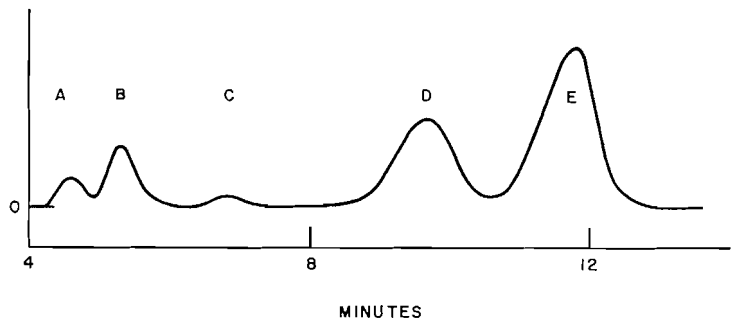

FIG. 1. Main portion of the gas chromatogram of the methyl esters. The peaks represent esters of the following acids: A, palmitic; B, hexadecenoic; C, hexadecadienoic; D, octadecenoic; E, linoleic. A small peak at 15.4 minutes (not shown) is assigned to linolenic acid.

Tentative identification of peaks A, D, and E was made by comparing emergence times with those of authentic samples. The identity of all of the main components was established after distillation of the esters as described below. The chromatogram also indicated the presence of traces of stearic and linolenic acids (less than 1% of each) but no C20 acids.

The main portion of the methyl esters was distilled through a spinning band column at 0.5 mm pressure in order to collect the C16 acids. Distillation data are given in Table II.

Examination of the distilled portions by gas chromatography showed that fraction 1 consisted of three acids in the C16 range, presumably palmitic, hexadecenoic, and hexadecadienoic. The intermediate fraction 2 contained these in lesser amounts along with octadecenoic and octadecadienoic acids. Fraction 3 consisted almost entirely of C18 acids.

TABLE II

Distillation of methyl esters

Fraction	Temp., °C (0.5 mm)	Weight, g	Predominant chain length	Iodine value	Refractive index, 25°
1	120–122	9.1	C16	76.9	1.4472
2	122–131	0.9	—	104.4	1.4517
3	131–133	9.8	C18	145.1	1.4571
R	Residue				

THE C16 ACIDS

Fraction 1 was estimated by gas chromatography to contain 14% of hexadecadienoate. Ultraviolet absorption analysis after alkali isomerization (45 minutes at 180° in glycerol–air) gave a value of 16.3% for dienoic ester, calculated as hexadecadienoate. A portion of fraction 1 (8 g) was subjected to fractional crystallization from acetone at low temperature (Table III). When examined by gas chromatography, the portion recovered from the final filtrate was found to consist of equal parts of hexadecenoate and hexadecadienoate.

TABLE III

Fractional crystallization of C16 methyl esters

Fraction	Crystallizing temp., °C	Yield, g	Refractive index, $n_D^{25°}$
1	−12	1.55	Solid at 25°
2	−60	0.80	Solid at 25°
3	−65*	3.05	1.4493
4	Filtrate	1.78	1.4548

*Crystallizing temperature after removing half of the solvent.

Palmitic Acid

Fraction 1 (Table III) was methyl palmitate. On saponification it gave pure palmitic acid directly, m.p. 62–62.5° alone and mixed with an authentic sample.

9-Hexadecenoic Acid

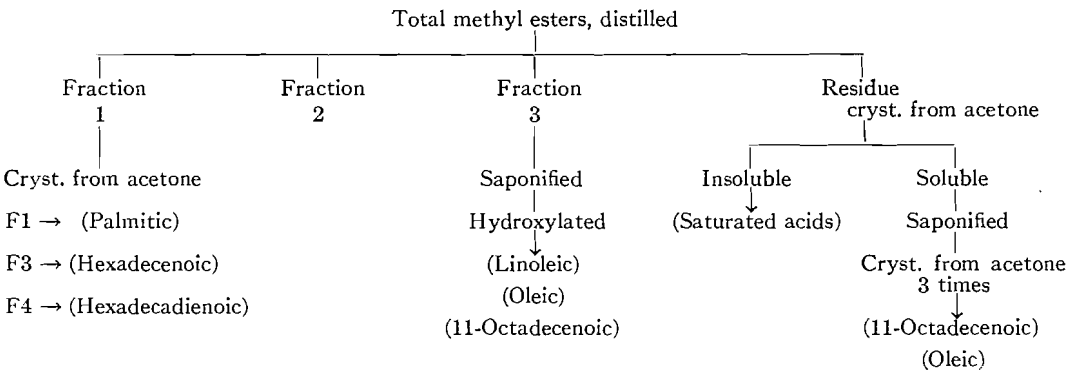
Fraction 3 (Table III) was almost entirely methyl hexadecenoate. It was identified by hydroxylation with alkaline permanganate (7). The product, when recrystallized from ethyl acetate, melted at 125–126° and did not lower the melting point of a known sample of erythro-9,10-dihydroxy-palmitic acid. The original acid was therefore *cis*-9-hexadecenoic acid.

9,12-Hexadecadienoic Acid

Fraction 4 (Table III) was hydroxylated in the same way and the dihydroxy acid was removed from the product by leaching with warm ethyl acetate. The remaining tetrahydroxy acid was recrystallized from a large volume of ethyl acetate. It melted at 163–164°. Calculated for tetrahydroxypalmitic acid, $C_{16}H_{32}O_6$: C, 59.98; H, 10.07. Found: C, 59.79; H, 9.92. This substance has not been reported hitherto.

In order to determine the position of the original double bonds, a portion of fraction 4 was subjected to oxidative splitting by periodate–permanganate (8). At the end of the reaction, the excess of reagents was destroyed by sodium bisulphite and the products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.



were extracted with ether. The ether solution was made alkaline to prevent loss of volatile acids and it was taken to dryness. *n*-Butanol containing an excess of dry hydrogen chloride was added and the mixture was refluxed to convert all of the acids to butyl esters. The excess butanol was allowed to remain and the mixture was examined by gas chromatography at a column temperature of 80°.

Since fraction 4 contained both monoenoic and dienoic acids, the products of splitting would include heptanoic and azelaic acids arising from 9-hexadecenoic acid, as well as those from the dienoic acid. The chromatogram showed peaks corresponding to two monobasic acids, butyric and heptanoic, in approximately equal amounts (as butyl esters). It is apparent that the heptanoic acid came from oxidation of the hexadecenoic acid since it has already been shown that its double bond is Δ^9. The butyric acid must have come from the dienoic acid. Thus, one double bond in the dienoic acid is situated between the fourth and fifth carbon atoms, counting from the methyl end of the chain. The chromatogram also showed traces of pentanoic and hexanoic acids, which may have arisen from minor proportions of isomeric monoene or diene acids.

The mixture of butyl esters was then chromatographed at a column temperature of 190°. Azelaic acid was the only dibasic acid detected. Thus both the monoenoic and dienoic acids gave azelaic acid. The corresponding double bond of the diene acid is therefore in the 9,10 position, counting from the carboxyl end of the chain and the acid is 9,12-hexadecadienoic acid. The tetrahydroxy acid (described above) must be erythro, erythro-9,10,12,13-tetrahydroxypalmitic acid, since permanganate oxidation of *cis* double bonds gives the erythro structure. The infrared spectrum of the C16 methyl esters (fraction 1, Table II) showed no *trans* absorption (965 cm^{-1}), hence both the monoene and diene acids are considered to have *cis* unsaturation.

THE C18 ACIDS

Examination of the esters of C16 and C18 acids is summarized in the following diagram, which shows in parentheses the acids identified in the various fractions from the ester distillation (Table II). The separation of the C18 acids is described below.

Linoleic Acid

A portion of fraction 3 of the distilled methyl esters (Table II) was saponified and the acids were hydroxylated by alkaline permanganate (7). Upon fractional crystallization from ethyl acetate, the most insoluble part of the product melted sharply at 171–172° and was identified by mixed melting point as erythro, erythro-tetrahydroxystearic acid, from ordinary linoleic acid.

Octadecenoic Acids

The more soluble portion, presumably dihydroxystearic acid, melted at 114–115°, unchanged on further recrystallization. It was evidently not the ordinary erythro-9,10-dihydroxystearic acid which melts when pure at 132°. The equivalent weight of the substance was 318.1 (dihydroxystearic acid 316.5).

It was subjected to splitting by permanganate–periodate (8). At the end of the reaction the acidic products were extracted with ether and the ether solution was made alkaline and evaporated to dryness. Methanol containing excess hydrogen chloride was added and refluxed gently. The mixture was poured into water and the methyl esters were extracted with cyclohexane, washed with a little aqueous sodium bicarbonate and water, and dried. The cyclohexane solution was submitted to gas chromatography at 80° and 130°. Monobasic acids were represented by two major peaks, corresponding in emergence times to heptanoate and nonoate, with a very small peak corresponding to hexanoate. There was no indication of octanoate or decanoate. It was concluded that the substance with a melting point of 114–115° must be a mixture of 9,10- and 11,12-dihydroxystearic acids, formed from oleic acid and 11-octadecenoic acid. The ratio of nonoate (from oleic) to heptanoate (from 11-octadecenoic), determined from the area of the peaks, was 5:4.

The hexanoate was probably formed from a little tetrahydroxystearic acid (from linoleic acid) present in the dihydroxy acid mixture. It amounted to 6% of the total of the C6–C9 acids by peak area measurement.

When the mixture of methyl esters was chromatographed at 170°, peaks corresponding to azelate and undecanedioate appeared. There was no evidence of sebacate. This confirms the presence of 9,10- and 11,12-dihydroxystearic acids in the original mixture. The undecanedioate could not have arisen from eicosenoic acid since the chromatogram of the total esters of the oil showed that no C20 acids were present. The ratio of azelate to undecanedioate was 5:4.

Identification of 11-Octadecenoic Acid

Confirmatory evidence of the presence of 11-octadecenoic acid was sought. The residue from the distillation of methyl esters (Table II) (46.0 g) was crystallized from 400 ml of acetone at −30°. The crystals (4.1 g) were saponified and recrystallized twice from ethanol, giving 1.1 g of solid acid(s) melting at 66–68°. It depressed the melting point of pure stearic acid and is judged to contain some higher saturated acid(s).

The filtrate from the crystallization of the esters was evaporated, the esters saponified, the unsaponifiable matter removed, and the acids recovered (38.0 g). These acids (largely linoleic acid) were crystallized successively from 380 ml of acetone at −45° and from 50 ml of acetone at −35°, giving 4.3 g of acids of refractive index $\alpha_D^{25°}$ 1.4595 (oleic acid, 1.4581). This product was crystallized fractionally from 40 ml of acetone as follows:

Fraction	Temp. of crystallization, °C	Yield, g	Iodine value	$\alpha_D^{25°}$
1	−22	1.3	78.3	Semisolid
2	−40	1.3	89.6	1.4591
3	Filtrate	1.3		1.4645

Fraction 1 probably contained a little stearic acid and fraction 3 some linoleic acid. The fraction of iodine value 78.3 was hydroxylated by alkaline permanganate for 15 minutes at 10°, yielding a dihydroxystearic acid, m.p. 128–128.5° after three crystallizations from

ethyl acetate, and washing with petroleum ether (yield 0.62 g). The equivalent weight was 315.8 (calculated for dihydroxystearic acid, 316.5). On mixing with erythro-9,10-dihydroxystearic acid (from oleic acid), it melted at 116–122°.

It was identified as erythro-11,12-dihydroxystearic acid by comparison with an authentic sample, kindly furnished by Dr. F. D. Gunstone. There was no depression of melting point in admixture with this sample. The melting point of erythro-11,12-dihydroxystearic acid from synthetic 11-octadecenoic acid is given by Ahmad (9) as 127–128° and by Huber (10) as 129–130°. Thus fraction 1 (iodine value 78.3) was mainly 11-octadecenoic acid.

To confirm the identification, the dihydroxy acid with a melting point of 128–128.5° was subjected to oxidative splitting by permanganate–periodate. The reaction mixture, when acidified, gave a precipitate with a melting point of 107–108°, raised to 109–110° by one crystallization from ethyl acetate. This proved to be undecanedioic acid. The equivalent weight was 109.2 (calc. 108.1). Its melting point was unchanged in admixture with an authentic sample prepared by oxidative splitting of 11,12-dihydroxyarachidic acid made from jojoba oil.

The filtrate from the oxidation was treated as before to convert the monobasic acids to methyl esters without loss. The mixture of esters was chromatographed at 80° and 130°. It gave only one peak in the region of medium chain length and that had the correct emergence time for methyl heptanoate, by comparison with an authentic sample. There was no evidence of monobasic acids of chain length C8–C12. The hydroxylated acid is therefore erythro-11,12-dihydroxystearic acid and the original acid in the oil is *cis*-11-octadecenoic acid.

The second fraction of the octadecenoic acids (I.V. 89.6) was submitted to oxidative splitting and the fragments were esterified and chromatographed at 80° and 170°. Peaks corresponding in emergence time to nonoate and azelate (from oleic acid) and to heptanoate and undecanedioate (from 11-octadecenoic acid) were recorded. There were no peaks in the regions corresponding to hexanoate, octanoate, suberate, and sebacate. The ratio of oleic acid to 11-octadecenoic acid in this fraction was estimated from the area of the peaks to be 28:72.

Total Composition

The fatty acid composition of the oil was estimated from the entire data, including the measurement of the peak areas in the gas chromatography of the methyl esters, the results of examination of the distilled ester fractions, and analysis of certain fractions by ultraviolet absorption. Calculated in this manner, the content of octadecenoic acids is 30% of the total fatty acids of the oil and the percentages of the other acids are as shown in Table IV.

TABLE IV

Estimated fatty acid composition (% of total fatty acids)

Acid	%	Acid	%
Palmitic	4	Stearic*	<1
9-Hexadecenoic	10	Oleic	15
9,12-Hexadecadienoic	2	11-Octadecenoic	15
		Linoleic	53
		Linolenic*	<1

*Identified by its emergence time under gas chromatography.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The content of 11-octadecenoic acid was determined by treating a sample of the total fatty acids of the oil with permanganate–periodate and determining the ratio of the resulting dibasic acids by gas chromatography at 170° (as methyl esters). In this reaction 11-octadecenoic acid yields undecanedioic acid while each of the other unsaturated acids of this oil gives azelaic acid. The ratio of undecanedioic acid to azelaic acid (w/w) was 16.5:83.5 (mean ratio of peak areas from triplicate samples). Allowing for the approximately 5% of saturated acids and taking into account the stoichiometric yield of the two dibasic acids from the various original unsaturated acids, the content of 11-octadecenoic acid is calculated to be 15% of the total fatty acids. Since the total octadecenoic acids are estimated at 30%, the content of oleic acid, by difference, is also 15% of the total fatty acids. The fatty acid composition is summarized in Table IV.

Other Samples

Samples of seed harvested in 1952 and 1958 were also examined. The oil content of these was 21.5% and 22.7% respectively (moisture free basis). The 1958 oil had iodine value 127.5, acid value 1.1, unsaponifiable matter 1.8%, and equivalent weight of the fatty acids 279.4. The oil from both lots was analyzed by gas chromatography and the 1952 sample was also treated by fractional distillation of its methyl esters and examination of the fractions. However, the ratio of oleic to 11-octadecenoic acid was not determined. The estimated percentages of fatty acids in the 1952 and 1958 oils were respectively: palmitic 5, 5; hexadecenoic 11, 12; hexadecadienoic 1.3, 1.7; octadecenoic acids 30, 33; linoleic acid 52, 47.

DISCUSSION

The oil is unusual in respect to the composition of both the C16 and C18 acids. One other seed oil of the family Asclepidaceae has been studied, viz. *Cryptostegia grandiflora* R. Br. (11). It was reported to be composed of the ordinary oleic, linoleic, and saturated fatty acids.

The occurrence of 11-octadecenoic acid in *Asclepias* oil was unexpected. An isomer of oleic acid was indicated when the erythro-dihydroxystearic acid was found to melt at 114–115° instead of the usual 132°. Apparently an equilibrium mixture was formed with the ordinary 9,10-dihydroxystearic acid which was not separable by ordinary crystallization from solvents. A similar anomalous melting point was observed by Watson and Levitin (12) when the oil of the *pods* of *Asclepias syriaca* was examined. Their dihydroxystearic acid melted at 116° but was not investigated further. Hilditch and co-workers obtained repeatedly a dihydroxy acid or mixture of acids, melting at 117–118°, from the C18 fractions of rapeseed and mustard-seed oils (5). A similar product was obtained by one of us (13) from the seed oil of *Conringia orientalis* L. (Cruciferae). On the basis of the present results, it seems likely that all of these consisted of mixtures of two or more position isomers of dihydroxystearic acid.

The possibility that 11-octadecenoic acid was formed by isomerization of oleic acid or ester during treatment is considered very unlikely. Similar treatment of many oils in this laboratory did not give evidence of such isomerization. The temperature reached in the distillation of the methyl esters in the present instance was lower than usual because only one-third of the esters was distilled off. It is also considered very unlikely that isomerization (shift of the double bond) occurred during the hydroxylation by alkaline permanganate or during the oxidative splitting by permanganate–periodate. Simple olefinic acids do not undergo a double-bond shift in these reactions to our knowledge.

For personal use only.

11-Octadecenoic acid has been observed previously in the fat of bacteria, fish, and animals (14). The *trans* form is most common in animal fats and is thought to originate by bacterial action in the digestive process. Thus 11-octadecenoic acid may be to some extent characteristic of the lower forms of living matter. If so, its occurrence in *Asclepias*, along with the unusually large amount of unsaturated C16 acids, may give an indication of the place of this genus in the scale of evolution of plants.

11-Octadecenoic acid differs from most natural unsaturated fatty acids in having the double bond at the seventh carbon atom from the methyl end of the chain. In this respect, it is the same as 9-hexadecenoic acid which accompanies it in similar amount in this oil.

The unusually high content of 9-hexadecenoic acid and an appreciable content of 9,12-hexadecadienoic acid are noteworthy. The amount of hexadecenoic acid is exceeded in one other seed oil, viz. *Macadamia ternifolia* (Proteaceae) (15). Hexadecadienoic acid has been found in one other seed oil, viz. *Acacia giraffae* (Leguminosae) (4). The estimated amounts of C16 acids in these oils are as follows:

	C16 acids in total fatty acids, wt.%		
Species	Palmitic	Hexadecenoic	Hexadecadienoic
Asclepias syriaca	4	10	2
Macadamia ternifolia (15)	8	20	0 (16)
Acacia giraffae (4)	13	7	1

ACKNOWLEDGMENTS

The authors are grateful to Dr. R. W. Watson and Dr. H. A. Senn for assistance in procuring seed and to Mr. R. Lauzon for determination of infrared spectra.

EQUILIBRIUM DECOMPOSITION PRESSURES OF K_2TiCl_6[1]

S. N. Flengas and T. R. Ingraham

ABSTRACT

The equilibrium decomposition pressures of K_2TiCl_6 were measured at temperatures between 370° and 530° C, using a glass-bellows mercury manometer.

The pressure–temperature relationship was found to obey the equation

$$\log_{10} P(\text{cm of Hg}) = -\{(5.774\times10^3)/T\} + 9.120$$

and the heat of the reaction

$$K_2TiCl_{6(s)} \rightleftharpoons 2KCl_{(s)} + TiCl_{4(g)}$$

was found to be

$$\Delta H = +26.4\pm1.3 \text{ kcal/mole.}$$

INTRODUCTION

Because of its relatively high degree of stability at room temperature, the compound K_2TiCl_6 offers interesting possibilities as a source of $TiCl_4$ for the electrolytic preparation of titanium in fused salt baths. Indeed, K_2TiCl_6 may be an intermediate in the chain of chemical reactions proceeding in electrolytic cells which are supplied with gaseous $TiCl_4$ and contain KCl as a constituent of the bath.

K_2TiCl_6 has been prepared by wet chemical methods involving the dissolution of the mineral ilmenite ($FeO.TiO_2$) in aqueous sulphuric acid, and the salting out of K_2TiCl_6 by HCl in the presence of KCl (1) at 0° C. Unsuccessful attempts have been made to prepare the compound in an autoclave at about 300° C, by the direct reaction of KCl with $TiCl_4$ (2).

At higher temperatures, the direct reaction of KCl with $TiCl_4$ has been used successfully in these laboratories to prepare K_2TiCl_6 for use in studies of the potentials of the various titanium ions in molten salt solutions. In this preparation, which was reported in a previous paper (3), the experiments were done at temperatures from 230° to 500° C. It was observed that the rate of reaction was relatively slow at temperatures up to about 300° C, and attained a maximum rate at about 410° C. At temperatures substantially above 400° C, at which the rate of reaction might have been expected to increase, the rate of reaction decreased. It seemed probable that the compound K_2TiCl_6 was becoming increasingly unstable as the temperature was increased.

To confirm these implications, and to establish some of the thermodynamic properties of K_2TiCl_6 which might be of interest in evaluating it as a possible source of titanium tetrachloride for electrowinning cells, it was decided to study the equilibrium decomposition pressures of titanium tetrachloride over the compound.

Since our previous experience in preparing the compound had suggested that this solid–gas state reaction was relatively slow to establish equilibrium, a static method, rather than a dynamic method, of measuring the decomposition pressure was selected.

EXPERIMENTAL

The compound K_2TiCl_6 was prepared in a 1-in. diameter tube, bent in a right angle, and sealed at one end. Purified titanium tetrachloride was introduced into the closed vertical arm and was frozen with liquid air. A silica boat containing potassium chloride

powder of a particle size less than 325 mesh was then placed in the horizontal arm and the tube was evacuated and sealed. By heating the titanium tetrachloride to a temperature between 130 and 134° C, and the potassium chloride to a temperature of about 400° C, for 12 hours, K_2TiCl_6 was formed quantitatively. When prepared by this method, the compound contained a small excess of adsorbed titanium tetrachloride. To prevent attack by moisture, the samples were transferred in a dry box to airtight glass containers.

The equilibrium decomposition pressures were measured in the apparatus shown diagrammatically in Fig. 1. The most important feature of the apparatus is the glass-

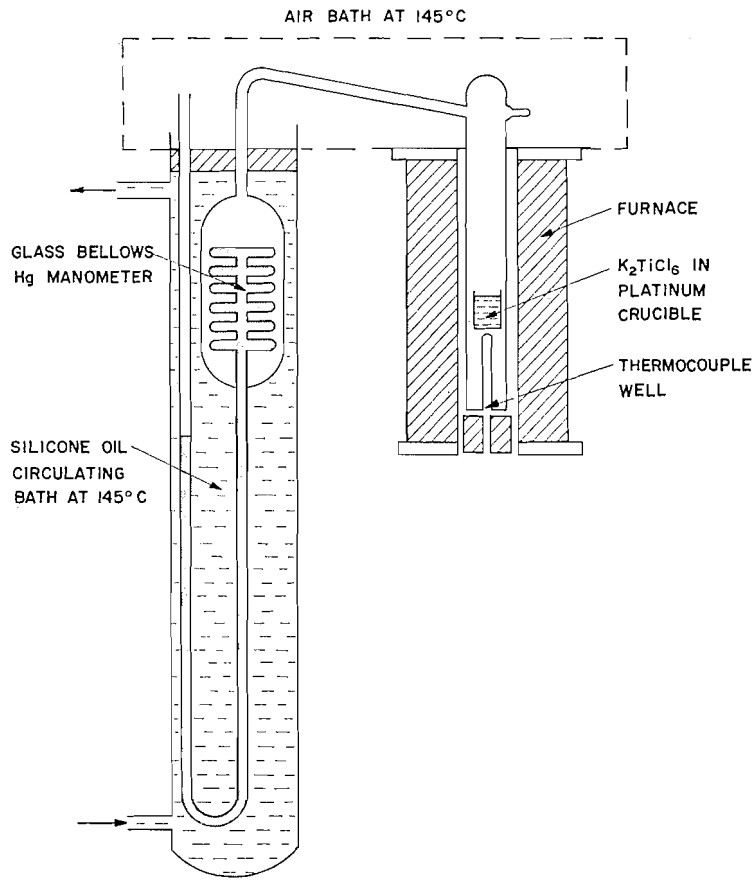

FIG. 1. Pressure measuring apparatus.

bellows mercury manometer, originally designed by Spence (4). It was modified for use in these experiments. This type of manometer is well suited to studies of equilibrium pressures in systems in which the decomposition product is a highly corrosive gas, which would be likely to attack conventional manometric liquids.

The manometer was calibrated at various pressures, and the relationship between the height of the mercury column of the manometer and the pressure was found to be linear over the pressure range between 1.2 and 76 cm. A deflection of 1.000 cm Hg was equivalent to a 1.540 cm of Hg pressure change. Pressure changes were observed with a cathetometer and were corrected for barometric fluctuations.

The reaction cell was constructed from Pyrex and Vycor. The Vycor section extended

out of the hot zone of the furnace, where it was joined, through a graded seal, to the Pyrex part of the apparatus. To avoid the condensation of titanium tetrachloride (b.p. 136.4° C), the bellows manometer was thermostatically controlled at a temperature of 145.0±0.1° C, using silicone oil (Dow Corning 550 fluid) as the heat transfer medium in a circulating bath. The connecting tube between the reaction cell and the manometer was also maintained at a temperature of 145.0±0.5° C by means of a thermostatically controlled air bath.

The reaction cell was heated in a tubular furnace, the temperature of which was kept constant, within ±1° C, by a thermocouple set in a well just below the sample and connected with a Kelwyn–Hughes phototransistor proportional temperature controller, type MIK IV.

To begin an experiment, about 10 grams of K_2TiCl_6 was transferred to a platinum crucible and the crucible was placed just above the thermocouple well. The open end of the reaction tube was then sealed and the apparatus was evacuated through a side arm for about 20 hours to remove excess titanium tetrachloride adsorbed on the K_2TiCl_6 powder. After evacuation was complete, the apparatus was sealed under vacuum and the furnace was heated to a predetermined temperature. Readings of the pressure were made at 2-hour intervals and equilibrium was considered to have been established when the pressure remained unchanged for a period of 12 hours. In the initial runs, it was observed that, at low temperatures, the same equilibrium pressure was not obtained readily when the temperature was approached from above and below. It was found that in spite of the 20-hour evacuation period, a small excess of $TiCl_4$ remained adsorbed on the sample. The $TiCl_4$ was removable by evacuation at higher temperatures, but it was found more convenient to mix excess KCl with the K_2TiCl_6 before beginning the run. When this was done, the same equilibrium pressures could be established readily on either an increasing or a decreasing temperature cycle.

RESULTS

The results obtained in three typical runs are shown in Table I.

From Table I it may be seen that the decomposition of K_2TiCl_6 begins at a temperature of about 350° C, and that the decomposition pressure of $TiCl_4$ at about 530° C is 1 atm.

The equilibrium constant for the decomposition of K_2TiCl_6,

$$K_2TiCl_{6(s)} \rightleftharpoons 2KCl_{(s)} + TiCl_{4(g)},$$

is given by the equation

$$K_p = P_{TiCl_4}.$$

The results shown in Table I were used to calculate log K_p and $1/T$, and when these were plotted, the straight-line relationship shown in Fig. 2 was obtained by applying the least-squares method. It is evident from Fig. 2 that the linear relationship holds

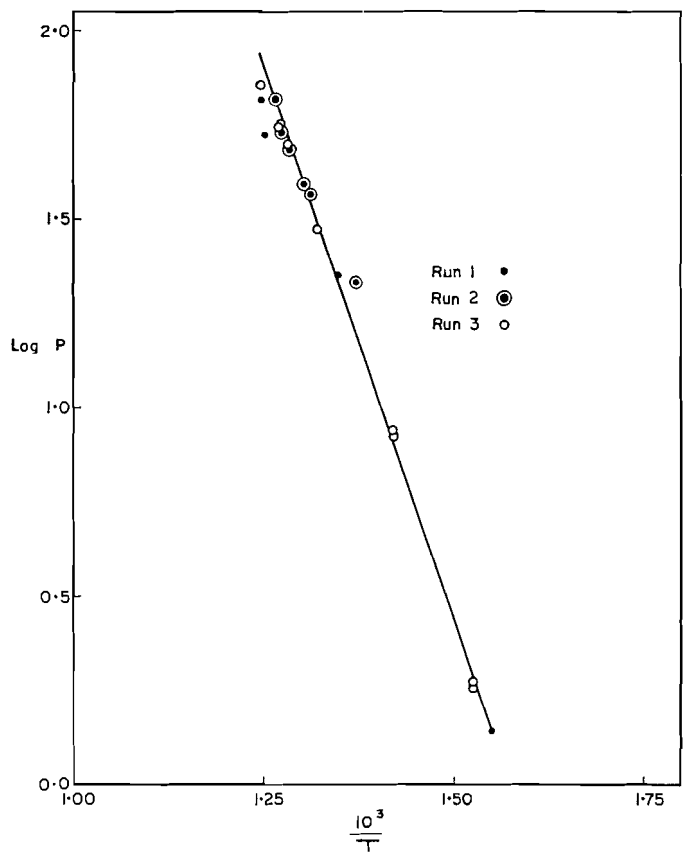

FIG. 2. The variation of log P with the reciprocal of the absolute temperature.

reasonably well for pressures between 2 and 76 cm. From Fig. 2, the variation of pressure with temperature corresponds with the equation

$$\log_{10} P(\text{cm of Hg}) = -\{(5.774\times10^3)/T\} + 9.120.$$

The average error, a, of a single observation, as calculated by the least-squares method, is

$$\log a = \pm 0.045.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

The heat of reaction was calculated from the slope of the straight line in Fig. 2 in accordance with the van't Hoff equation

$$\Delta H = +26.4 \pm 1.3 \text{ kcal/mole.}$$

This is in good agreement with +27 kcal/mole obtained by Ehrlich and Framm (2) from their experiments using the isoteniscope method.

Free energy and entropy changes for the decomposition were calculated at selected temperatures. The results are shown in Table II.

TABLE II

Thermodynamic functions for the reaction
$K_2TiCl_{6(s)} \rightleftharpoons 2KCl_{(s)} + TiCl_{4(g)}$

350	9.36×10^{-3}	+26.40	+5.77	33.6
400	4.56×10^{-2}	+26.40	+3.88	33.4
450	1.79×10^{-1}	+26.40	+2.52	33.0
500	5.88×10^{-1}	+26.40	+0.81	33.1

CONCLUSIONS

Since the reaction

$$K_2TiCl_{6(s)} \rightleftharpoons 2KCl_{(s)} + TiCl_{4(g)}$$

is endothermic, the formation of the compound is promoted at lower temperatures. However, from kinetic considerations (3) it appears that the rate of reaction at temperatures below 300° C is slow; this would explain the inability of Ehrlich and Framm (2) to prepare K_2TiCl_6 in an autoclave at 300° C.

Furthermore, the thermal stability of K_2TiCl_6 in the temperature range of 300–400° C indicates that the compound might be used as a constituent of a low-melting-point fused salt bath, e.g. KCl + LiCl, for the production of titanium metal by electrolysis. Indeed, it appears that the accepted practice of using fused salt baths at high temperatures, e.g. KCl + NaCl at 700° C, would hinder the introduction of gaseous titanium tetrachloride into the melt, under circumstances where the introduction depended upon the formation of K_2TiCl_6.

ACKNOWLEDGMENT

The authors wish to thank Mr. George Ensell, National Research Council of Canada glass blower, for constructing the glass-bellows mercury manometer.

ELECTRON CORRELATION AND MOLECULAR SHAPE[1]

R. J. GILLESPIE

ABSTRACT

It is proposed that the arrangements of the electron pairs in the valency shell of a central atom of a polyatomic molecule can be predicted by considering the equilibrium arrangements of similar particles on the surface of a sphere with an appropriate law of force between the particles. The arrangements resulting from an inverse square law of force, corresponding to electrostatic repulsions, and a force which is proportional to $1/r^n$ where n is large, corresponding to Pauli forces, are considered specifically. It is shown that the arrangements predicted agree with those found experimentally for molecules containing only non-transitional elements. The possible arrangements for seven, eight, and nine pairs of electrons in a valency shell are discussed in detail. A method is suggested for predicting the arrangements of electron pairs in valency shells containing lone pairs which can occupy alternative non-equivalent positions. The effect of the interactions of electron pairs on bond lengths in certain molecules is discussed. The extension of the same principles to molecules containing transitional elements is briefly outlined.

It was shown recently by Gillespie and Nyholm (1) that the shapes of a wide range of molecules can be correctly predicted by means of the simple rule that the electron pairs, including both shared (i.e. bonding) pairs and unshared (i.e. lone) pairs, of the valency shell of a central atom of a polyatomic molecule adopt certain definite arrangements which depend only on their total number as shown in Table I.

TABLE I

Predicted arrangements of electron pairs in valency shells (1)

Number of electron pairs	Arrangement
2	Linear
3	Equilateral triangle
4	Tetrahedron
5	Trigonal bipyramid
6	Octahedron

These arrangements are a consequence of the mutual interactions of the valency shell electrons due to

(i) electrostatic repulsions, and to

(ii) the operation of the Pauli exclusion principle, as a consequence of which electrons of the same spin tend to keep as far apart as possible while electrons of opposite spin tend to be drawn together (2).

The interaction arising from the Pauli exclusion principle is in general more important than that arising from electrostatic repulsions and the arrangements of electron pairs given in Table I can be deduced from a consideration of this interaction alone ignoring electrostatic repulsions. It has been shown by several authors (2–10) that, by assigning the electrons to appropriate s, p, and d atomic orbitals, writing the complete antisym-

[1]*Manuscript received January 22, 1960.*
Contribution from the Department of Chemistry, McMaster University, Hamilton, Ontario.

metric wave function for these electrons, thereby taking account of the Pauli exclusion principle, and then calculating the most probable distribution of the electrons, the arrangements of electron pairs that are obtained are identical with those given in Table I. The same results can be obtained in a simple qualitative manner as follows. As a consequence of its kinetic energy, an electron will tend to occupy as much as possible of the space in which it is confined and as a consequence of the Pauli exclusion principle will tend to keep all other electrons having the same spin out of this space. Thus one electron in the central force field of a single nucleus will spread out to occupy a spherical region of space around the nucleus; it is said to occupy an *s* orbital. A second electron of opposite spin can also independently occupy the same region of space, i.e. the same orbital, but a second electron of the same spin will tend to keep as far as possible from the first electron and they will share the available spherical volume; each electron thus effectively occupies a hemispherical region on either side of the nucleus (digonal *sp* orbitals). The most probable distribution of these two electrons will be that in which the angle between the two electrons and the nucleus has a value of 180°. For a total of four electrons, two of one spin and two of opposite spin, the tendency of electrons of opposite spin to keep apart and for electrons of the same spin to come together causes the most probable arrangement of the electrons to be that in which there are two pairs making an angle of 180° with the nucleus, or in other words a pair of opposite spin in each of two equivalent digonal orbitals. Three electrons of the same spin or three pairs of opposite spin will each tend to occupy one-third of the available spherical space and their most probable distribution will be at the corners of an equilateral triangle making angles of 120° with the nucleus. We say that the electrons occupy a set of three equivalent trigonal sp^2 orbitals. For four electrons of the same spin or four pairs of opposite spin the most probable arrangement, i.e. that which maximizes their distance apart or gives them equivalent segments of the available spherical space, is the tetrahedral arrangement (8). Four electrons of the same spin or four pairs of opposite spin may be regarded as occupying four equivalent tetrahedrally directed segments of the available spherical volume, i.e. a set of four equivalent tetrahedral sp^3 orbitals. The same result may be obtained by constructing a set of equivalent hybrid orbitals from the available atomic orbitals. Because such hybrid orbitals are so constructed that they overlap only slightly, the electron distribution that would be obtained if these orbitals were independently occupied by electron pairs differs only slightly from that obtained from the complete antisymmetrical wave function and in particular the positions of maximum probability for the electron pairs coincides with the directions of the maxima of the hybrid orbitals (1, 3, 6, 11).

The most probable arrangements for five or more single electrons of the same spin or pairs of opposite spin is not, perhaps, immediately obvious. If these cases are treated by assigning the electrons to appropriate atomic orbitals and then calculating the most probable distribution of the electrons from the antisymmetrized wave function, a problem arises because of the non-equivalence of the various *d* orbitals that may be used. Some examples are given in Table II where it may be seen that different combinations of one *s* and three *p* orbitals with the various *d* orbitals give different most probable arrangements of electron pairs. It is therefore not possible to unambiguously predict by this method the shapes of molecules whose central atom has a valency shell containing five or more electron pairs. One can only find which shapes are possible, i.e. are compatible with the available atomic orbitals, but one cannot decide which of the possible shapes will be adopted in any particular case.

*This table is not intended to be complete but only to illustrate some of the probable arrangements of electron pairs that correspond to the occupation of different combinations of atomic orbitals. It does not, for example, include any arrangements based on the partial use of two or more d orbitals, or any arrangement based on the use of d orbitals in preference to p orbitals.
†This polyhedron is obtained by adding one extra point over the center of one rectangular face of a trigonal prism.
‡This polyhedron is obtained by adding an extra point over the center of each of the rectangular faces of a trigonal prism.

Arrangements of Similar Particles on a Spherical Surface

One method of determining which of the possible arrangements of a given number of electron pairs is the most probable is to consider the possible arrangements of similar particles on the surface of a sphere under the action of some appropriate force law. If we assume that the electron pairs in a valency shell are all at the same average distance from the nucleus, which will in fact be the case for two, three, four, and six electron pairs bonding the central atom to a set of identical atoms and will almost certainly be a reasonably good approximation in other cases, then the problem of determining the most probable arrangement of these electron pairs is the same as that of determining the arrangement of a set of particles on the surface of a sphere under the action of an appropriate force law. Since the Pauli exclusion principle causes electrons of the same spin to avoid one another they behave as if there was a force between them. This force has been called a Pauli force or an exchange force (18). The magnitude of this force increases rapidly with the increasing overlap of the orbitals of two electrons with the same spin and therefore can be represented by an inverse function of some large power of the interelectron distance. The arrangement of particles on the surface of a sphere under such a force law is the same as that which is obtained by maximizing the least distance between any two particles (19) and this problem has been treated by Shutte and van der Waerden (20), who obtained the results given in Fig. 1. The arrangement of particles on the surface of a sphere under the action of an inverse square law of force, which would be appropriate if the arrangement of electrons were determined only by electrostatic forces, has been studied by Foppl (21), whose results are given in Table III. In all cases except that of seven particles the two force laws lead to the same arrangements and it seems reasonable to conclude that these will also therefore be the arrangements of these numbers of equivalent pairs of electrons in the valency shell of a central atom. The case of seven electron pairs is further discussed below. For any number of electron pairs up to six these are also the arrangements given by Gillespie and Nyholm (1) which, they point out, lead, without exception, to the correct prediction of the shapes of molecules

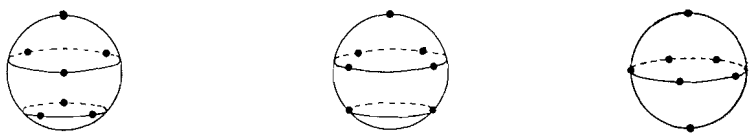
containing only non-transitional elements even if not all the electron pairs are equivalent because they are forming bonds to different atoms or are lone pairs. Although Gillespie and Nyholm (1) discussed the shapes of some molecules involving seven, eight, and nine electron pairs in the valency shell of the central atom, they were not able to satisfactorily extend their rules to cover these cases which will therefore be discussed in more detail now.

Seven Electron Pairs

Figure 2 shows that for an interparticle force that is proportional to $1/r^n$, where n is large, the arrangement of seven particles is at the corners of an irregular octahedron



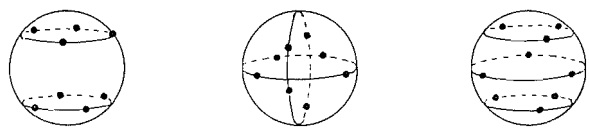


FIG. 2. Arrangements of seven particles on the surface of a sphere.

with an additional particle opposite the middle of one of its faces, i.e. a "1:3:3" arrangement (I), while for an inverse square law the equilibrium arrangement of seven particles is the pentagonal bipyramid, i.e. a "1:5:1" arrangement (III). It seems reasonable to suppose that as the exponent n is decreased the equilibrium arrangement will pass from I to III through the intermediate II, which is an irregular trigonal prism with an additional particle opposite one of its rectangular faces, i.e. a "1:4:2" arrangement. Iodine heptafluoride IF_7(22–25), the ions UF_7^{3-} and $UO_2F_5^{3-}$ (25), and probably ZrF_7^{3-} (26) have the pentagonal bipyramid structure III* while the ions TaF_7^{2-}, NbF_7^{2-}, and $NbOF_6^{2-}$ have the distorted trigonal prism structure II (25). In the A-modification oxides of the X_2O_3 of La, Ce, Pr, and Nd the metal atom is seven-co-ordinated and the oxygen atoms have the arrangement I (27). The antimony atom in the ion $SbBr_6^{2-}$ has a valency shell containing seven electron pairs, one of which is a lone pair. This ion has been reported to have an octahedral structure (25): if this is in fact a not quite regular octahedral structure it would indicate that the arrangement of the seven electron pairs is as in I with the lone pair at one pole, i.e. opposite one face of the distorted octahedron. Since lone pairs exert greater repulsions than bond pairs (1) the arrangement of seven electron pairs including one lone pair is likely to be that in which the lone pair has a minimum number of nearest neighbors and this is structure III. The three structures I, II, and III probably have rather similar energies, and which structure is adopted in any particular case presumably depends on factors such as the size of the central atom, the electronegativities of the ligands, and the non-equivalence of one or more of the electron pairs.

Eight Electron Pairs

For a valency shell containing eight equivalent electron pairs the predicted arrangement is the square antiprism IV and this is indeed the structure that has been found for TaF_8^{3-} (25) and for thorium acetylacetonate $Th(C_5H_7O_2)_4$ (28). The only other arrangement of eight bonds around a central atom that has been observed is the dodecahedral arrangement V (Fig. 3) found in the complex $Mo(CN)_8^{4-}$ ion of the transition metal

	(IV)	(V)	(VI)

FIG. 3. Arrangements of eight and nine particles on the surface of a sphere.

molybdenum. There are, however, actually nine electron pairs in the valency shell of the molybdenum atom in this ion, one of which is a lone pair. In transition metal complexes unshared pairs do not necessarily have such an important stereochemical effect as in compounds of non-transition elements (see below) and it is difficult to predict the effect of the single lone pair in this case although it may be said with certainty that if it does have any effect the arrangement of the eight bonds will not be the antiprism. The cube has been suggested (29) as a possible structure for eight-co-ordinated atoms but it is evident that for eight particles (e.g. electron pairs) that repel each other with a force that is proportional to any inverse power of their distance apart the cubic arrangement will always be less stable than the antiprism.

**It is possible that in the crystal the molecule of IF_7 has a slightly distorted pentagonal bipyramid structure (23, 24).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Nine Electron Pairs

For nine electron pairs the predicted arrangement is the trigonal prism arrangement of six pairs with an additional electron pair opposite each rectangular faces, i.e. a "tripyramid" (Fig. 1), and this is indeed the arrangement of the nine bonds around a central atom found in a number of crystalline compounds such as UCl_3, $LaCl_3$, NH_4CdCl_3, $Nd(BrO_3)_39H_2O$, and $SrCl_26H_2O$ (26). Although the degree of covalent character of the bonds concerned here is uncertain it is interesting that they all do have the predicted arrangement and that this is in fact the only arrangement that has been observed for nine co-ordination.

We may summarize by saying that the predicted arrangements of two, three, four, five, and six electron pairs in a valency shell are as given in Table I. These are found experimentally for all molecules of non-transitional elements even when some of the electron pairs are not equivalent either because they bond different ligands or because one or more are lone pairs. The preferred arrangement for eight equivalent pairs is the antiprism. For nine equivalent pairs the most probable arrangement is the "tripyramid" (Fig. 1). For seven equivalent pairs the three different arrangements I, II, and III seem to be possible.

Valency Shells Containing Lone Pairs

In order to be able to decide between possible alternative locations of lone pairs in valency shells it is necessary to take account of the fact that repulsions exerted by lone pairs are greater than those exerted by bond pairs (1). The orbital associated with a bonding electron pair which is under the influence of two nuclei is smaller, or more localized, than the orbital of a lone pair which, being under the influence of only one nucleus, is able to spread out more and take up more of the available space than the bond pairs (9, 30). Thus bond pairs can approach more closely to each other than lone pairs before appreciable overlap of their orbitals occurs. This is equivalent to saying that bond pairs repel each other less than lone pairs. Alternatively one can say that lone pairs which are under the influence of a single nucleus will be at a slightly smaller average distance from the central nucleus than will the bond pairs which are also under the influence of the ligand nucleus, hence, if all the electron pairs had a symmetrical angular arrangement, the lone pairs would be closer together than the bond pairs and therefore they would repel each other more than the bond pairs. Hence bond pair – bond pair (b–b) repulsions are smaller than bond pair – lone pair (b–l) repulsions which are in turn smaller than lone pair – lone pair (l–l) repulsions. The reality of these differences in the repulsions between lone pairs and bond pairs is borne out by the bond angles in a series of molecules such as CH_4, NH_3, and H_2O. The introduction of one lone pair in NH_3 causes a decrease in the bond angle to 106.6° from the tetrahedral angle in CH_4 and the introduction of a second lone pair in H_2O causes a further reduction in the bond angle to 104.5° (25).

Since Pauli forces play the dominant role in the electron interactions that we have been considering and since these fall off rapidly with distance it seems reasonable to consider only the interactions between a given electron pair and its nearest neighbors in predicting the shapes of molecules with one or more lone pairs in the valency shell of a central atom. Thus in structures based on the trigonal bipyramid we need only consider interactions between electron pairs that make angles of 90° at the nucleus; interactions between electron pairs that make angles of 120° and 180° at the nucleus will be much smaller and can be ignored at least to a first approximation. Thus for ClF_3, BrF_3, and $C_6H_5ICl_2$, which each have three bonding pairs and two lone pairs in the valency shell of the central

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

atom and may be described as AX_3L_2 molecules where X stands for a ligand atom and L for a lone pair of electrons, the three structures VII, VIII, and IX (Fig. 4) are possible.

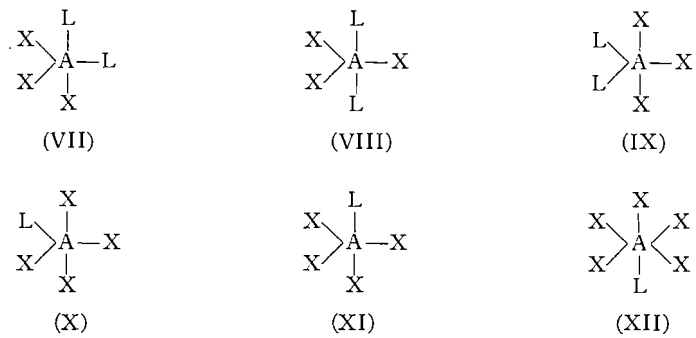

FIG. 4. Possible structures of AX_3L_2, AX_4L, and AX_5L molecules.

Considering only interactions of electron pairs making angles of 90° with the nucleus, VII has one l–l repulsion, three b–l repulsions, and two b–b repulsions, VIII has six b–l repulsions, while IX has four b–l and two b–b repulsions; thus IX will be more stable than either VII or VIII in agreement with the results of experimental determinations of the structures of these molecules (25, 31). For SeF_4, $TeCl_4$, $(CH_3.C_6H_4)_2SeCl_2$, and $(CH_3.C_6H_4)_2SeBr_2$, which may be described as AX_4L molecules, the structures X and XI (Fig. 4) are possible. In X there are two b–l and four b–b repulsions while in XI there are three b–l and three b–b repulsions; evidently X will be the more stable. This is consistent with the experimentally determined structures of these molecules (25). It is interesting to note that the bond angles in ClF_3 are only 87.5° (25), and in BrF_3 only 86.2° (31); this can be attributed to the strong repulsions exerted by the two equatorial lone pairs. Similar small bond angles of less than 90° have been found in BrF_5 (32) and this can be attributed to the strong repulsions exerted by a lone pair in an octahedral arrangement of six pairs (XII).

Bond Lengths

In the tetrahedral and octahedral arrangements of four and six electron pairs respectively, all the pairs have equivalent positions with respect to each other but in the trigonal bipyramidal arrangement of five electron pairs this is not the case; thus the pairs at the poles each have three nearest neighbors with which they make angles of 90° at the nucleus while the equatorial pairs have only two nearest neighbors at 90° and two more further away at 120°. Thus if all the electron pairs are at the same distance from the nucleus the repulsions between the polar electrons and those at the equator will be greater than the repulsions between the equatorial electrons. It may therefore be expected that the distances of the electron pairs from the nucleus will adjust themselves slightly so as to attempt to equalize these repulsions; this will lead to the polar electron pairs being at a slightly greater distance from the nucleus than the equatorial pairs and hence the axial bonds will be slightly longer than the equatorial bonds. The equatorial and axial bond lengths are respectively 2.04 Å and 2.19 Å in PCl_5, 2.31 Å and 2.43 Å in $SbCl_5$, 1.598 Å and 1.698 Å in ClF_3, and 1.721 Å and 1.810 Å in BrF_3 (25, 31). It is therefore not necessary to postulate that the bond to the equatorial fluorine atom has a double-bond character in order to account for the bond lengths in ClF_3 and BrF_3 (33). Similar effects can occur in octahedral arrangements of six electron pairs including one lone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

pair which gives rise to square pyramidal molecules such as BrF_5 and IF_5 and ions such as SbF_5^{--} and $SbCl_5^{--}$ (XII). The four electron pairs at the base of the pyramid are not equivalent to the pair at the apex and as a consequence the corresponding bonds might be expected to differ in length. It seems difficult to predict which bonds would be the longest. The equatorial and axial bonds respectively have lengths of 1.68 Å and 1.79 Å in BrF_5 (30) and 2.02 Å and 2.08 Å in SbF_5^{--} (25), i.e. the equatorial bonds are shorter than the apical bond, but in $SbCl_5^{--}$ the reverse is the case (equatorial 2.62 Å, apical 2.36 Å) (25). The reason for this difference is not clear. Similarly in IF_7 the bond lengths would be expected to differ: experimentally it has been found that the equatorial bonds have a length of 1.83 Å while the axial bonds have a length of 1.94 Å although the accuracy of these values seems uncertain (23, 24).

Transitional Elements

In the preceding discussion it has been assumed that all the electron pairs occupy localized (i.e. hybrid) orbitals. This will necessarily be the case for bonding pairs but not for unshared or lone pairs of electrons. For the non-transitional elements for which all the valency electrons *s*, *p*, and *d* belong to the same quantum shell there appear to be no exceptions to the rule that the unshared pairs occupy localized orbitals and have an equally important effect in determining the stereochemistry of an atom as do the bonding pairs (1). However, for the transitional elements in which the valency electrons are in general associated with two quantum shells, electron interactions may lead to most probable configurations in which some or all of the non-bonding electrons occupy non-localized (i.e. atomic or "unhybridized") *d* orbitals and are at a somewhat smaller average distance from the nucleus than the bonding electrons. Such non-localized non-bonding electrons may have only a relatively small influence on the arrangement of the bonding electrons and therefore on the stereochemistry. Thus six-co-ordinated complex ions of the transitional metals are in general octahedral irrespective of whether or not they have additional unshared electrons in the valency shell (1). The six bonding pairs of electrons have the same octahedral arrangement that they would have if no non-bonding electrons were present and they may be conveniently described as occupying octahedral d^2sp^3 or sp^3d^2 equivalent hybrid orbitals. Up to six non-bonding electrons can occupy one or more of the set of equivalent $d_{xy}d_{xz}d_{yz}$ orbitals which each have four maxima between the directions of the octahedral orbitals and in which they have a somewhat smaller average distance from the nucleus than the bonding electrons. Electrons in these orbitals will have little or no effect on the octahedral arrangement of the six bonding pairs of electrons. Thus, for example, TiF_6^{3-}, VF_6^{3-}, $Cr(NH_3)_6^{3+}$, $Fe(CN)_6^{3-}$, and $Co(CN)_6^{3-}$ have one, two, three, five, and six non-bonding *d* electrons respectively and they all have regular octahedral structures. However, if there are more than six non-bonding *d* electrons these must go into the d_{z^2} and $d_{x^2-y^2}$ orbitals, which have their maxima along the octahedral directions of the bonding pairs, and they may therefore exert repulsions on these bonding pairs that are sufficient to distort the shape of the octahedron. The configurations d_{z^2}, $d_{z^2}^2$, and $d_{z^2}^2d_{x^2-y^2}$ may by virtue of the repulsions that they exert on the bonding pairs cause two trans bonds to be longer than the other four. If the repulsions are sufficiently strong they may cause two trans ligands to be lost completely leaving a square planar complex. Thus depending on the strength of the interaction between the bonding electron pairs and the non-bonding *d* electrons the structure of a six-co-ordinated transition metal complex molecule or ion may be an octahedron, or a distorted octahedron with two long bonds, and in some cases as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

result of strong repulsions two trans ligands may be lost giving a four-co-ordinated square planar complex. For example, the ions $Co(NH_3)_6^{3+}$ and $Ni(NH_3)_6^{3+}$ with seven and eight non-bonding d electrons respectively have regular octahedral structures but Pd(diarsine)$_2$ I_2 with eight non-bonding d electrons has a distorted octahedral structure with two unusually long Pd—I bonds (11). The complex compounds of Cu(II), which has nine non-bonding d electrons, are generally square planar, e.g. $Cu(H_2O)_4^{2+}$ and $Cu(NH_3)_4^{2+}$, but in the crystal these ions often attach two further ligands at longer distances to form irregular octahedral complexes (26). When there are 10 d electrons the d shell is complete and symmetrical and the arrangement of six bonding pairs will again be that of a regular octahedron.

Four pairs of electrons in the absence of any non-bonding electrons are arranged tetrahedrally. In a transitional metal complex up to four non-bonding d electrons can be accommodated in the d_{z^2} and $d_{x^2-y^2}$ orbitals, whose maxima lie between the direction of the tetrahedral orbitals occupied by the bonding pairs. Further d electrons must go into the $d_{xy}d_{yz}d_{xz}$ orbitals in which they may exert considerable repulsions on the bonding pairs and may cause the tetrahedral arrangement to be less stable than the square planar arrangement. Thus, for example, VCl_4 with one d electron and $FeCl_4^-$ with five d electrons are tetrahedral but $PtCl_4^-$ and $Cu(NH_3)_4^{2+}$ with eight and nine non-bonding d electrons respectively are square planar.

THE PYROLYSIS OF DIALLYL (1,5-HEXADIENE)[1]

D. J. Ruzicka and W. A. Bryce

ABSTRACT

The mechanism of decomposition of diallyl has been studied in a static system in the temperature range 460–520° C. The principal gaseous products (room temperature) were propylene, methane, ethylene, and 1-butene, and the liquid products were cyclopentene, cyclopentadiene, 1-hexene, and benzene. The over-all activation energy of decomposition was 31.3±1.0 kcal/mole for an A factor of 10^7 sec^{-1}. A mechanism of decomposition based on hydrogen abstraction by allyl and the addition of allyl to olefinic double bonds is proposed. Some decomposition by a non-radical mechanism may also occur.

INTRODUCTION

A recent study of the pyrolysis of 1-butene (1) has provided evidence that allyl radicals play an important part in the mechanism. The primary step in the decomposition is, almost certainly,

$$CH_3—CH_2—CH=CH_2 \rightarrow CH_3 + CH_2—CH=CH_2.$$

Propylene, one of the major decomposition products, is presumably formed by hydrogen abstraction by allyl from unreacted 1-butene. Bryce and Kebarle (1) postulated also that the formation of substantial amounts of various cyclic unsaturated hydrocarbons occurred through the addition of allyl to the double bond of 1-butene and propylene.

The amount of information in the literature on the reactivity of the allyl radical is very limited. The inhibiting power of propylene in certain hydrocarbon decompositions has been said to be due to the formation of allyl radicals by abstraction of hydrogen from propylene. The resonance-stabilized allyl radical has been assumed to be relatively unreactive and not capable of acting as a chain carrier (2). In a recent review of relative radical reactivities Semenov (3) calculates a value of −21.5 kcal/mole for the heat of reaction of the allyl radical in a series of reactions for which the reactivities of the vinyl, methyl, and benzyl radicals are +9.4, 0, and −17.4 kcal/mole respectively. The low reactivity of allyl is presumably a reflection of the electron delocalization that occurs on formation of the radical. The resonance or delocalization energy of allyl has been estimated by Coulson (4) to be 15.4 kcal/mole and by Bolland and Gee (5) to be 18.7 kcal/mole.

The formation of the allyl radical has been proposed (6) for the primary step in the pyrolysis of propylene studied with a flow system in the temperature range 680–870° C.

$$CH_2=CH—CH_3 \rightarrow CH_2=CH—CH_2 + H$$

The formation of allene as a major pyrolysis product led to the conclusion that allyl disappeared principally by the reaction

$$CH_2=CH—CH_2 \rightarrow CH_2=C=CH_2 + H.$$

No allene was detected, however, among the products in the pyrolysis of 1-butene in a static system at temperatures near 500° C (1).

Abstraction of hydrogen atoms by allyl has been proposed as a reaction in the pyrolysis of isobutene (7). McNesby and Gordon (8) have shown recently that very little abstraction by allyl occurs at 381° C in the pyrolysis of cyclopentane–acetone mixtures. Most of the

[1]*Manuscript received in original form July 3, 1959, and, as revised, March 3, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C. From a thesis presented by D. J. R. in partial fulfillment of the requirements for the degree of Master of Science.

allyl formed combines with methyl to form 1-butene. At 453° C 1-butene is still formed but hydrogen abstraction occurs from both cyclopentane and acetone. Allyl appears to abstract hydrogen extensively at temperatures above 500° C, a result supported by the conclusions of Bryce and Kebarle.

Lossing and his co-workers (9) found allyl to be the main radical product of the pyrolysis of 1,5-hexadiene (diallyl) in a flow reactor attached to a mass spectrometer for the temperature range 690–890° C. It seems reasonable to assume therefore that the pyrolysis of diallyl in a static system at lower temperatures should involve the production of allyl in the primary step

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow 2CH_2{=}CH{-}CH_2. \qquad [1]$$

The present study of the decomposition of diallyl was undertaken in the hope that it would reveal something of the properties of the allyl radical. This compound has also been used as a source of allyl in studying reactions between allyl and other hydrocarbons (10) with a view to gaining additional information about the mechanism of decomposition of olefins, and about the role of propylene as an inhibitor in hydrocarbon decompositions.

EXPERIMENTAL

The diallyl used was a standard sample (99.9% pure) obtained from the American Petroleum Institute, Pittsburgh. The pyrolyses were done in a quartz vessel of 300-ml capacity attached to a conventional static vacuum system. Rapid admission to the reaction vessel of the sample to be pyrolysed was achieved through the use of a calibrated pre-expansion volume. Samples for gas chromatographic analysis were obtained by expansion of the reaction products through a heated sampling line into evacuated pipettes equipped with metal–teflon taps. Standard gas chromatographic techniques were used for the qualitative and quantitative determination of the decomposition products. Individual compounds were identified, when necessary, by trapping them as they emerged from the column and introducing the sample into a mass spectrometer.

Decomposition Products

The principal products formed in the pyrolysis of 70 mm of diallyl at 521° C are shown in the chromatogram presented in Fig. 1. This separation was achieved on a 6-ft alumina column using the technique of increasing the column temperature progressively

to speed up the elution of the less volatile sample constituents. The diallyl was approximately 90% decomposed in this particular analysis but essentially the same products were found in samples in which the decomposition was only approximately 5%. No definite evidence as to the extent of formation of C_6 cyclic products was obtained since at this low conversion the large peak of the undecomposed diallyl covered the region of the chromatogram presumably occupied by these compounds.

The sensitivity of the apparatus to the components of the reaction mixture was determined by calibration with a synthetic mixture of methane, ethane, propylene, 1-butene, cyclopentene, 1,5-hexadiene, and benzene in proportions corresponding approximately to those found in the reaction mixture under standard conditions. The sensitivities of compounds for which no internal standards were available were assumed to be equal to those of the available standards with the closest retention volumes under comparable conditions. Peak areas were taken as the measure of amount of compound.

Analytical Results

Analytical results for the products of pyrolysis of 70 mm of diallyl in the temperature range 460–521° C are given in Table I. The values shown are expressed as mole% of the

TABLE I

Products of 1,5-hexadiene pyrolysis at various temperatures

NOTE: Reaction time, 5 minutes; P_{init} = 70 mm.

sample withdrawn. It can be seen that the analysis has accounted for an average of 85% of the volatile reaction products. The failure to achieve a complete mass balance may be a consequence of the irreversible adsorption on the chromatographic column of the reaction products with molecular weights greater than benzene. Furthermore, reliable sensitivities were known for only half the reaction products. It can be seen that higher recoveries of products were attained at higher temperatures. Polymerization reactions leading to less volatile products are thus apparently more important at lower temperatures. The supposition that such polymeric products are formed in the present system, in which the concentrations of large relatively stable radicals may be fairly high, is supported by the observation that in subsequent work the reactions of allyl with ethylene and propylene (10) identical analytical techniques were used and complete mass balances were obtained.

Kinetic Results

The decomposition was found to be first order for low conversions at a given temperature but the order rose to higher values as more extensive reaction occurred. An Arrhenius plot (Fig. 2) of first-order rate constants based on gas chromatographic analysis for diallyl

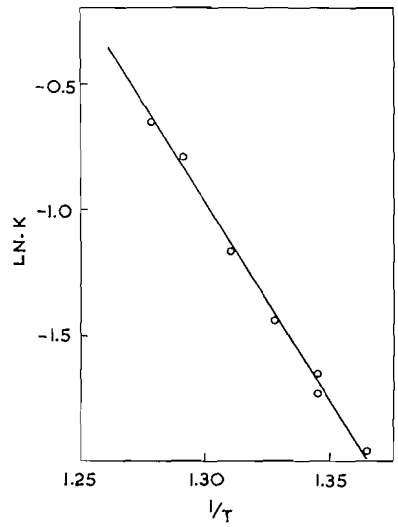

FIG. 2. Arrhenius plot for diallyl decomposition.

consumed gave a value of 31.3 ± 1.0 kcal/mole for the over-all activation energy. The corresponding A factor was 10^7 sec^{-1}.

The variation with time in the concentrations of the light hydrocarbon products for the pyrolysis of 70 mm of diallyl at 501° C is given in Fig. 3. The concentrations of the

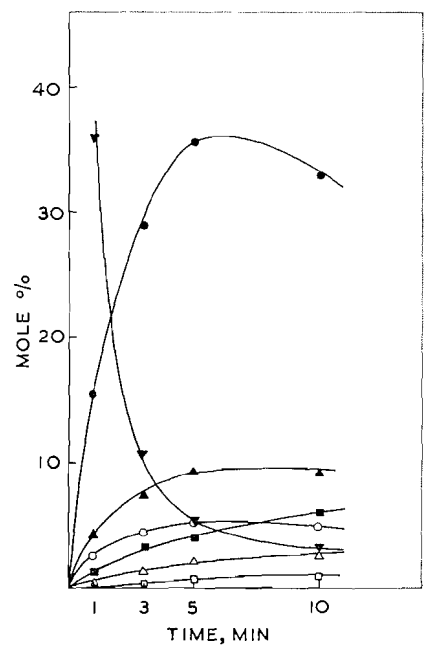

FIG. 3. Variation with time of light hydrocarbon products at 501° C: ●, propylene; ▲, ethylene; ■, methane; ○, 1-butene; ▼, 1,5-hexadiene; △, ethane; □, propane.

For personal use only.

unsaturated products (propylene, ethylene, and 1-butene) level off as the hexadiene disappears from the system. The concentrations of the saturated products (methane, ethane, propane) show a progressive increase with time. The concentrations of the higher hydrocarbon products (Fig. 4), largely unsaturated cyclic compounds, go through maxima

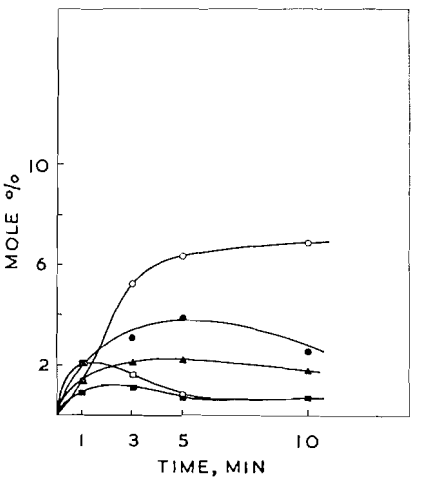

FIG. 4. Variation with time of cyclic products at 501° C. ○, benzene; ●, cyclopentadiene; ▲, 1-hexene; ■, cyclopentene; □, cyclohexene, methylcyclopentene.

as the reaction proceeds, with the exception of benzene. Results very similar to those shown in Fig. 4 are obtained if concentration is plotted against temperature for constant reaction time, i.e. the relative concentrations of saturated hydrocarbons and hydrogen increase with temperature while the concentrations of unsaturated hydrocarbons, excepting benzene, go through maxima.

DISCUSSION

The change from first to higher orders with extent of reaction indicates the increasing complexity of the mechanism as secondary reactions become important. The value of 31.3 ± 1.0 kcal/mole obtained for the over-all activation energy is significantly less than the estimate of 42 kcal/mole which has been made for the dissociation energy of the allyl–allyl bond (6). The apparent activation energy for a reaction involving chain propagation is given (11) by the expression

$$E_A = E_P + (1/w)(E_i - E_t)$$

where E_p, E_i, and E_t are the activation energies for propagation, initiation, and termination respectively, and w is the order of the chain-terminating step. Hence the apparent activation energy, E_A, may well be smaller than E_i either because of a non-zero value for E_t or because of a second-order chain-breaking process. The activation energy for recombination of two allyl radicals or for the disappearance of allyl by some other radical capture process may be greater than zero. Unfortunately no data are available from which this energy, nor E_p, the activation energy for propagation by allyl, can be calculated with any certainty.

Mechanism of the Reaction

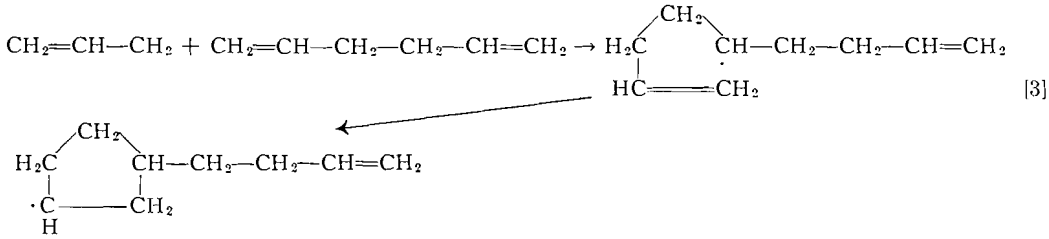
The wide variety of products produced in the pyrolysis of diallyl suggest very strongly the operation of a complex free radical mechanism. The observation (9) that at a high

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

temperature (690–890° C) the molecule decomposes in the primary step by splitting the central bond provides evidence that initiation of the reaction at the temperatures used in the present study occurs in the same way. No evidence has been obtained in the present study as to whether this initiation is homogeneous or heterogeneous. It has also been shown (10) that diallyl present in 5 mole% concentration can serve to initiate the decomposition of hydrocarbons such as 1-butene, propylene, ethylene, and *n*-butane, and that the rate of initiation is linearly related to the square root of the diallyl concentration. Such a dependence is consistent with a primary dissociation of diallyl into two radicals, each capable of initiating further decomposition of the substrate molecules. The present results will therefore be interpreted principally in terms of a free radical mechanism, although the possibility exists that a significant portion of the decomposition occurs by a molecular, non-radical, mechanism. Such a mechanism could account for the occurrence of appreciable amounts of ethylene in the decomposition products

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow CH_2{=}CH_2 + CH_2{=}CH{-}CH{=}CH_2.$$

The butadiene that would be formed simultaneously in a molecular decomposition of this type was not found in the gas chromatographic analysis. Its concentration could have been kept low, however, by rapid reaction with various radicals formed in the system.

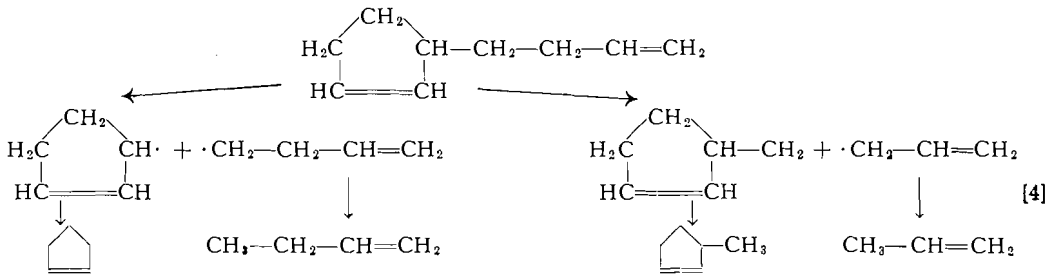


Reactions of the Allyl Radical

The allyl radical produced in the primary decomposition would be expected to be relatively stable at low temperatures because of its high delocalization energy. The observation that propylene is a major pyrolysis product of both 1-butene and diallyl at temperatures around 500° C provides direct evidence that hydrogen abstraction by allyl occurs readily under these conditions, an observation which confirms the work of other investigators. The most probable reaction would be

$$CH_2{=}CH{-}CH_2 + CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}CH{-}CH_2{-}CH{=}CH_2. \quad [2]$$

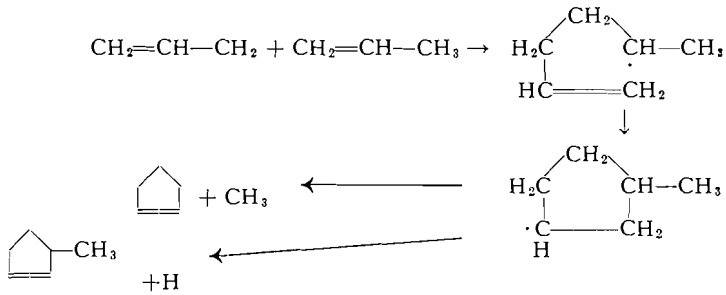
Hydrogen abstraction by allyl from products formed in the decomposition of the hexadienyl radical would occur in later stages of the reaction as the concentrations of these products became appreciable. The observation that the concentrations of a number of these products go through maxima with both time and temperature suggest that they undergo secondary reactions with radicals such as allyl.



The formation of cyclopentene, cyclopentadiene, and methylcyclopentene can best be explained on the basis of the addition of allyl to the double bonds of the parent molecule followed by intramolecular addition:

[3]

The product radical would most probably split off its side group and undergo an H-atom shift to form cyclopentene. It could undergo a further hydrogen abstraction from the ring to produce a 1-butenyl-substituted cyclopentene which could react in a variety of ways to produce some of the observed reaction products:

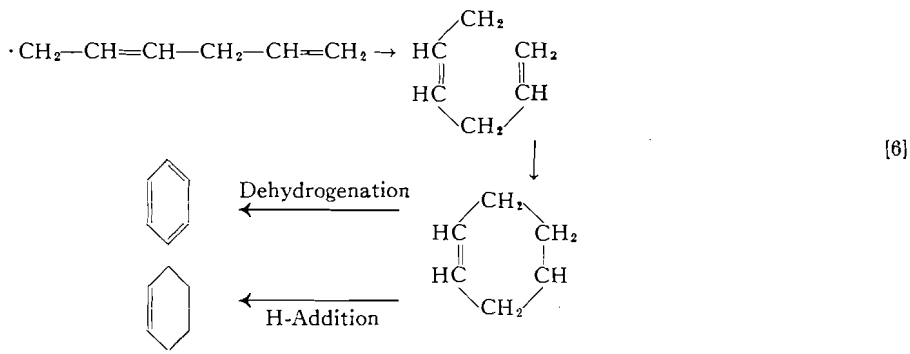


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[4]

The radical formed by the addition to the non-terminal carbon of the double bond would either be identical with that produced in reaction [3], or would lead to the formation of a substituted six-membered ring, depending on the mode of ring closure.

Addition of allyl to the double bond of propylene, the major decomposition product, could proceed as follows:



[5]

Cyclopentadiene is assumed to be formed by further dehydrogenation of the cyclopentene formed in reactions [4] and [5].

The occurrence of ethylene as a substantial product cannot involve the pyrolyses of the allyl radical to vinyl and methylene because of the high endothermicity (120–130 kcal) of this reaction. Its formation may occur as a result of a molecular decomposition of diallyl as has been mentioned earlier.

The Fate of the 1,5-Hexadienyl Radical

The concentration of the hexadienyl radical in the early stages of the reaction is presumably fairly high because of its formation by hydrogen abstraction. It can be considered to disappear from the system by rearrangement to the alternate canonical form followed by intramolecular addition:

[6]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The failure to observe cyclohexadiene as an intermediate in the dehydrogenation process may be a consequence of the high degree of resonance stabilization which the radical formed by hydrogen abstraction from the diene would have. The conversion of cyclohexadiene to benzene would, of course, be favored because of the over-all enthalpy decrease accompanying the reaction.

Decomposition of the radical with the formation of allyl and allene may occur. The failure to observe allene among the pyrolysis products of diallyl may be because of the slowness of the pyrolysis of the stabilized radical or because of the high reactivity which allene would exhibit towards all radicals present in the system. The 1,5-hexadienyl radicals would also be expected to disappear by combination with other radicals producing compounds adsorbed irreversibly on the gas chromatographic column. Since the steady-state concentration of this radical is presumably quite high the amounts of such addition products may have been appreciable. These compounds may be responsible for the failure to achieve a complete mass balance in the gas chromatographic analysis.

Other Radical Reactions

In the above discussion mechanisms for the formation of the following reaction products were suggested: propylene, ethylene, 1-butene, cyclopentene, cyclopentadiene, cyclohexene, methylcyclopentene, benzene. The formation of the remaining reaction products is assumed to proceed largely by the following reactions:

Methane: $CH_3 + RH \rightarrow CH_4 + R$

Ethane: $CH_3 + CH_3 \rightarrow C_2H_6$

$CH_2{=}CH_2 + H \rightarrow C_2H_5$

$C_2H_5 + RH \rightarrow C_2H_6 + R$

Propane: $CH_2{=}CH{-}CH_3 + H \rightarrow CH_2{-}CH_2{-}CH_3$

$CH_2{-}CH_2{-}CH_3 + RH \rightarrow C_3H_8 + R$

1-Hexene: $CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 + H \rightarrow C_6H_{11}$

$C_6H_{11} + RH \rightarrow C_6H_{12} + R$

Hydrogen: $H + RH \rightarrow H_2 + R$

The activation energies of all these reactions are sufficiently low to permit them to occur rapidly at the temperatures used in the present work.

ACKNOWLEDGMENTS

We are indebted to Dr. S. A. Ryce for advice in connection with the gas chromatographic analysis and to Mr. E. C. W. Clarke for the mass spectrometric identification. This investigation was supported by the Defence Research Board (DRB44-50-01-10), to whom we express our thanks. One of us (D. J. R.) is indebted to the B. C. Sugar Refining Company for a scholarship.

REACTIONS OF ALLYL RADICALS WITH OLEFINS[1]

W. A. Bryce and D. J. Ruzicka

ABSTRACT

A study has been made of the mechanisms of the reactions of allyl radicals, produced thermally from diallyl, with various hydrocarbons in the temperature range 460–506° C. The allyl radical is capable of abstracting hydrogen from certain hydrocarbons and of adding to olefinic double bonds at these temperatures. The rates of formation of the principal products in the reactions between allyl and 1-butene, propylene, and ethylene are linearly related to the square root of the diallyl concentration. Mechanisms are proposed to account for the reaction products formed. In addition to reacting readily with olefins the allyl radical is observed to sensitize the decomposition of *n*-butane at 506° C. The implications of the present results with respect to inhibition in pyrolysis of hydrocarbons are discussed briefly.

INTRODUCTION

The information available in the literature on the reactivity of the allyl radical has been reviewed briefly in an earlier paper (1). The formation of allyl has been proposed as the primary step in the pyrolysis of diallyl (1), propylene (2), allyl bromide (3, 4), isobutene (5), and 1-butene (6). The action of propylene as an inhibitor for certain organic decompositions has been commonly ascribed to the formation of allyl by hydrogen abstraction from the propylene by active radicals like methyl and ethyl. It has been fairly generally assumed that in the temperature range in which pyrolyses in static systems normally occur the allyl radical has sufficient resonance stabilization to render it incapable of propagating reaction chains (7, p. 126). The resonance stabilization energy has been estimated by Coulson (8) to be 15.4 kcal/mole and by Bolland and Gee (9) to be 18.7 kcal/mole. Semenov (10) ascribes to the allyl radical a reactivity less than that of benzyl and a delocalization energy of 23 kcal/mole.

The formation of allyl has been observed directly in the pyrolysis of allyl iodide and of diallyl using a mass spectrometer with a flow system at temperatures between 690 and 890° C (11). The mechanism of decomposition of this latter compound in a static system at temperatures between 460 and 520° C can best be understood (1) on the assumption that the primary step involves a split into two allyl radicals which can subsequently abstract hydrogen to form propylene or add to olefinic double bonds to form the cyclic unsaturated products which are formed in substantial amounts. The conclusion that allyl abstracts hydrogen readily under these conditions is in agreement with recent results of McNesby and Gordon (12).

The present study was undertaken to demonstrate more clearly the nature of allyl reactivity and to gain further insight into the mechanism of its reaction with unsaturated hydrocarbons. Reactions with 1-butene were of particular interest because of work done previously in this laboratory on the pyrolysis of this compound (6), the results of which provided strong evidence for reactions between it and the allyl radical.

EXPERIMENTAL

The substance used as a thermal source of allyl radicals was diallyl (1,5-hexadiene) obtained from the American Petroleum Institute, Pittsburgh (99.9 mole% pure). Other hydrocarbons used were all Research Grade (Philips Petroleum Co., Bartlesville, Okla.).

The experimental techniques used were similar to those described earlier (1). Diallyl

[1]*Manuscript received in original form July 3, 1959, and, as revised, March 3, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C. From a thesis presented by D. J. R. in partial fulfillment of the requirements for the degree of Master of Science.

and the substrate hydrocarbon were premixed and then admitted rapidly to the reaction vessel. Extensive decomposition of diallyl occurred in nearly all cases at temperatures well below those at which decomposition of the substrate hydrocarbon normally occurred. Analyses were done by gas chromatography supplemented by mass spectrometry where necessary.

RESULTS AND DISCUSSION

The Decomposition of 1-Butene – Diallyl Mixtures

The pyrolysis of 1-butene by itself and of 1-butene containing 5% by volume of diallyl was studied at 506° C with a total pressure of 200 mm Hg. The variation in pressure with time (Fig. 1) provides a measure of the effect of diallyl on the rate of decomposition

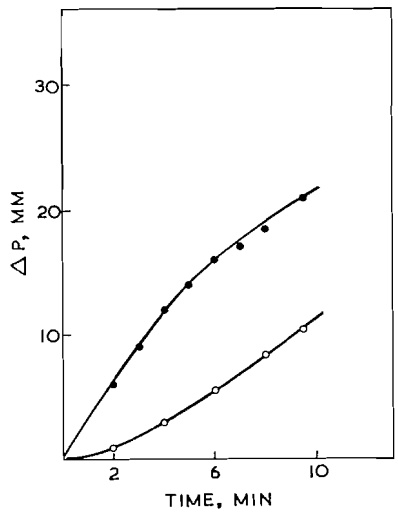

FIG. 1. Pressure–time curves showing effect of 5% diallyl on the rate of decomposition of 1-butene. Open circles, butene alone.

of 1-butene. A value of 6.5 was obtained for the relative rates of pyrolysis of 1-butene with and without diallyl for a reaction time of 1 minute.

The dissociation of diallyl, R_2, would yield allyl radicals, R, which could undergo reaction with the substrate olefin, M, leading to the formation of the products observed. If termination of the chains occurs by bimolecular radical recombination processes of the types

$$2R \rightarrow R_2$$

$$RM. + R \rightarrow RMR$$

and if the rate constant for the decomposition of diallyl is very much less than the propagation and termination rate constants, the rate of the over-all reaction will be given by

$$-d[M]/dt = k[R_2]^{\frac{1}{2}}[M].$$

The concentration of products resulting from the reaction between allyl and olefin ought therefore to be linearly related to the square root of the diallyl concentration for a constant reaction time.

The effect of varying the initial diallyl concentration on the rates of formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

reaction products was studied with diallyl concentrations ranging from 0 to 11.4% for a total pressure of 200 mm Hg. The reaction time was 5 minutes at 506° C. Earlier experiments (1) had shown that decomposition of the diallyl under these conditions would be 95% complete. The concentrations of the principal decomposition products of 1-butene are plotted against the square root of the diallyl concentration in Fig. 2. An approximately

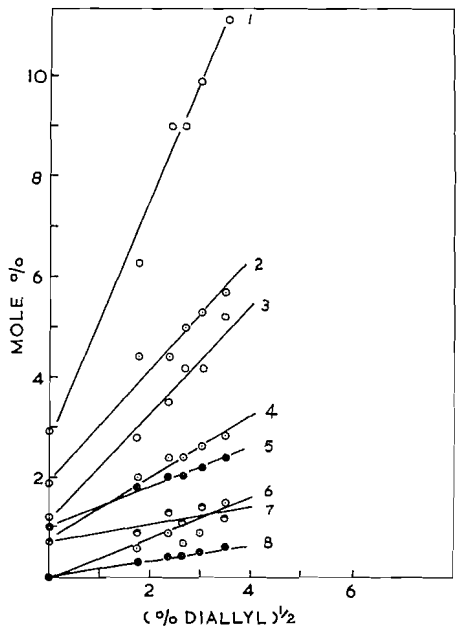

FIG. 2. Concentrations of principal decomposition products of 1-butene versus square root of diallyl concentration; 1, propylene; 2, methane; 3, ethylene; 4, ethane; 5, cyclopentadiene; 6, benzene; 7, cyclopentene; 8, cyclohexene plus methylcyclohexene.

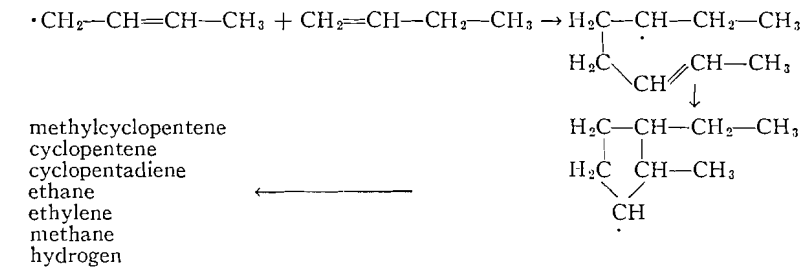
linear dependence is obtained for each product. The decomposition of 1-butene by itself at this temperature could contribute to each product an amount given by the ordinate at zero diallyl concentration. A significant amount of the increased yield of propylene with increasing diallyl concentration would result of course from the increase in diallyl itself. However, it is not possible to account for the increase in propylene by assuming that the diallyl and 1-butene decompose independently, i.e. the increase in propylene is very much greater than can be accounted for by the diallyl present. The possible contribution of diallyl to the concentrations of all other products is at most a few per cent of the amount of diallyl present and hence can be neglected. The three compounds whose concentrations are most affected by increasing the diallyl concentration (propylene, methane, and ethylene) are the chief products formed in the decomposition of 1-butene.

The allyl radical can react with 1-butene in two ways: by abstraction of hydrogen to form propylene and the butenyl radical, or by addition to the double bond. The reaction sequences proposed for these two processes are given below.

Hydrogen Abstraction

$$CH_2{=}CH{-}CH_2\cdot + CH_2{=}CH{-}CH_2{-}CH_3 \rightarrow CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}\dot{C}H{-}CH_3$$



Kinetic evidence (6) favors the abstraction of the allylic hydrogen from 1-butene but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the butenyl radical thus formed can be represented as existing in two alternative canonical forms,

$$CH_2{=}CH{-}\dot{C}H{-}CH_3 \leftrightarrow \cdot CH_2{-}CH{=}CH{-}CH_3.$$

The extensive isomerization of 1-butene to 2-butene that occurs in the temperature range 450–520° C if methyl radicals are added to 1-butene (13) provides convincing evidence that the butenyl radical can be considered to react in the 2-butenyl form to a substantial degree. This radical may be removed by hydrogen abstraction or by addition to the double bond of 1-butene followed by intramolecular addition to form various cyclic unsaturated products:

An H-atom shift is required for the formation of cyclopentene in the dissociation of the cyclic radical shown.

The formation of both methane and ethylene is markedly increased by the addition of allyl radicals to the system. The increase is considerably greater than that for the cyclic compounds and hence ethylene and methane cannot be assumed to be formed primarily from the cyclization reaction given above although the ethyl and methyl radicals eliminated in the formation of the cyclic compounds could lead to ethane, ethylene, and methane as follows:

$$C_2H_5 \rightarrow C_2H_4 + H,$$
$$C_2H_5 + C_2H_5 \rightarrow C_2H_4 + C_2H_6,$$
$$CH_3 + RH \rightarrow CH_4 + R.$$

The increased formation of ethylene and methane must be a consequence of pyrolysis of higher radicals. Their formation as a result of the decomposition of the butenyl radical,

$$CH_2{=}CH{-}\dot{C}H{-}CH_3 \rightarrow CH_2{=}CH{-}\dot{C}H\cdot + CH_3,$$
$$CH_2{=}CH{-}\dot{C}H{-}CH_3 \rightarrow CH_2{=}\dot{C}H + CH_2{=}CH_2,$$

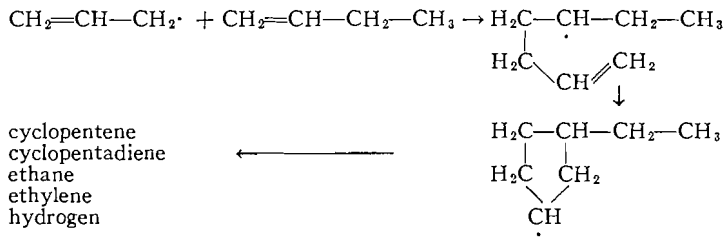
seems improbable because of the relatively high endothermicities of these reactions. Butenyl might be expected to stabilize itself under the present conditions by hydrogen loss,

$$CH_2{=}CH{-}CH{-}CH_3 \rightarrow CH_2{=}CH{-}CH{=}CH_2 + H,$$

or by disproportionation with allyl,

$$CH_2{=}CH{-}CH_2 + CH_2{=}CH{-}CH{-}CH_3 \rightarrow CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}CH{=}CH_2.$$

Butadiene was not observed in the reaction products although the gas chromatographic column used may have retained it because of its high degree of unsaturation. Similarly any allene formed by allyl decomposition,



$$CH_2{=}CH{-}CH_2 \rightarrow CH_2{=}C{=}CH_2 + H,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

would also tend to be retained in the chromatographic column. Furthermore both compounds would most probably disappear from the system rapidly through reaction with the variety of radicals present. It is not possible to decide, therefore, whether or not such reactions are important in the present study.

Addition to the Double Bond

The mechanism proposed for this reaction is similar to that suggested for the decomposition of diallyl (1):

Ethane and ethylene could be formed from the elimination of the ethyl group and hydrogen from the conversion of the cyclopentene to cyclopentadiene. The results for the pyrolysis of 1-butene (6) provide evidence that such radical elimination reactions are an effective method of dehydrogenation of the cyclic addition products.

The Decomposition of Ethylene–Diallyl Mixtures

A series of experiments was done in which diallyl in proportions ranging from 0 to 10.1% by volume was mixed with ethylene and decomposed for 5 minutes at a temperature of 506° C. The total initial pressure in each case was again 200 mm Hg. No reaction of the ethylene occurred in the absence of diallyl but reaction was observed to occur when diallyl was present. The pressure change in the system was negative indicating that products of molecular weight greater than ethylene were being formed. The analytical results, given in Table I, show that a satisfactory mass balance was obtained in all cases.

TABLE I

Analytical results for pyrolysis of ethylene–diallyl mixtures for 5 minutes at 506° C

	Mole % diallyl				
	2.9	5.2	6.7	8.9	10.1
Product	Mole %				
Hydrogen	0.22	0.35	0.47	0.65	0.71
Methane	0.06	0.35	0.50	0.47	0.67
Ethane	0.51	1.1	1.3	1.4	1.6
Ethylene	92	93	89	88	86.5
Propylene	2.2	2.8	3.7	4.4	4.6
1-Butene	0.40	0.65	1.0	1.1	1.1
Cyclopentene + 1,4-pentadiene	1.8	2.7	3.8	4.3	4.7
Diallyl	0	0.06	0.07	0.31	0.40
Total	97.2	100.0	99.8	100.6	100.3

Propylene is again a major product, formed by the hydrogen abstraction reactions of allyl. The variation of the amount of propylene with the square root of the diallyl concentration is linear (Fig. 3). The abstraction of hydrogen by allyl from ethylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

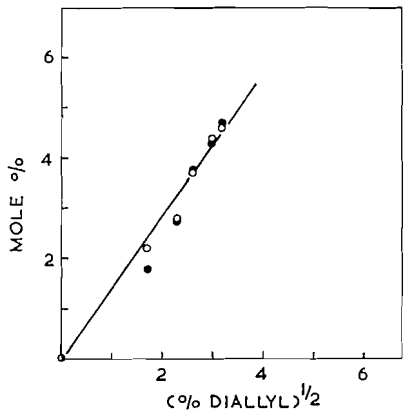


FIG. 3. Variation of propylene (open circles) and of cyclopentene plus 1,4-pentadiene with diallyl concentration in the reaction with ethylene.

would be endothermic by some 30 kcal and therefore seems unlikely. The most probable reaction between allyl and ethylene is addition to form the pentenyl radical

$$CH_2{=}CH{-}CH_2 + CH_2{=}CH_2 \rightarrow H_2C(\cdot){-}CH_2{-}CH_2{-}CH{=}CH_2, \qquad [1]$$

which could undergo intramolecular addition to form the cyclopentyl radical

$$H_2C(\cdot){-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow H_2C(\cdot){-}CH_2{-}CH_2{-}CH{-}CH_2 \qquad [2]$$

In view of the high allyl concentration the following reactions are probable:

$$CH_2{=}CH{-}CH_2 + H_2C(\cdot){-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow HC{\equiv}CH_2{-}CH_2{-}CH{=}CH_2 + CH_2{=}CH{-}CH_3 \qquad [3]$$

$$CH_2{=}CH{-}CH_2 + H_2C(\cdot){-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow CH_2{=}CH{-}CH_3 + H_2C{-}CH_2{-}CH{-}CH \qquad [4]$$

Cyclopentene and 1,4-pentadiene are formed as significant products of the reaction between allyl and ethylene. Cyclopentene is formed in only trace amounts in the decomposition of diallyl and 1,4-pentadiene is not formed at all (1). They thus provide a direct measure of the extent of the allyl–ethylene reaction. They were not separated from each other in the analyses given in Table I but their identification was achieved by mass spectrometry.

The results presented in Fig. 3 show that the rate of formation of 1,4-pentadiene plus cyclopentene is numerically equal to the rate formation of propylene, an observation which is explained by reactions [3] and [4] above. A quantitative separation was achieved in the analysis of the reaction mixture for a single experiment, using a squalane–pelletex column at 0° C. The initial diallyl concentration in this experiment was 6.7%. The analytical result obtained gave the ratio

$$\text{1,4-pentadiene/cyclopentene} = 11/20.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

This ratio is presumably a measure of the relative rates of reactions [3] and [4].

Other reactions which presumably occur in this system include

$$\cdot CH_2{-}CH{=}CH_2 + CH_3 \rightarrow CH_3{-}CH_2{-}CH{=}CH_2,$$
$$CH_2{=}CH{-}CH_2{-}CH_3 \rightarrow CH_2{=}CH{-}CH_2\cdot + CH_3,$$
$$CH_3 + RH \rightarrow CH_4 + R,$$
$$CH_3 + CH_3 \rightarrow CH_3CH_3,$$
$$H + RH \rightarrow H_2 + R.$$

The Decomposition of a Propylene–Diallyl Mixture

Propylene containing 5.3% diallyl was decomposed for 5 minutes at 506° C and an initial total pressure of 200 mm Hg. At this temperature propylene by itself is quite stable. A slight pressure increase occurred. The composition of the reaction mixture is given in Table II.

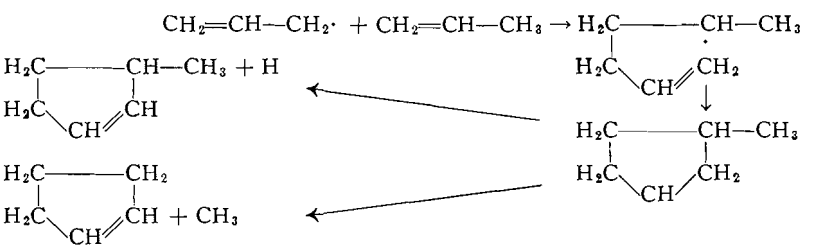

TABLE II

Analytical results for pyrolysis of 5.3% diallyl in propylene for 5 minutes at 506° C

Hydrogen	0.37 mole%
Methane	1.17
Ethane	0.16
Ethylene	2.29
Propane	0.73
Propylene	92.0
1-Butene	1.11
Cyclopentene	0.94
1-Hexene	0.94
Methylcyclopentene	0.28
Diallyl	0.50
Total	100.2

The range of products formed is very similar to that obtained in the pyrolysis of diallyl itself but the amounts formed in nearly all cases are very much greater than can be accounted for by decomposition of the diallyl only. For example the pyrolysis of diallyl at 506° C yields 9.2% ethylene (1). Hence the maximum possible contribution of diallyl to the ethylene yield given in Table II, assuming an independent decomposition, would be 0.5%. Thus most, if not all, of the ethylene formed in the diallyl–propylene system is produced by the decomposition of propylene initiated by the added allyl radicals.

The only primary reaction of allyl with propylene that is of interest is addition to the double bond; the hydrogen abstraction reaction is trivial. The mechanism proposed for the addition reaction is as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The only two cyclic products are thus accounted for by two alternative modes of reaction of the addition product. The analytical results indicate that the decomposition to cyclopentene and the methyl radical has approximately the same probability as the dehydrogenation to methylcyclopentene. Two isomeric methylcyclopentenes appear to be formed.

The 1-butene may be formed by the combination of allyl and methyl

$$CH_2{=}CH{-}CH_2\cdot + CH_3 \rightarrow CH_2{=}CH{-}CH_2{-}CH_3.$$

The high yield of ethylene indicates again that decomposition of a higher radical must occur readily at these temperatures. One possibility is the pyrolysis of allyl,

$$CH_2{=}CH{-}CH_2\cdot \rightarrow CH_2{=}CH\cdot + \cdot CH_2.$$

However, the relatively high endothermicity of this process makes it rather improbable under the present conditions. Propane is presumably formed by the addition of hydrogen atoms to propylene.

$$H + CH_2{=}CH{-}CH_3 \rightarrow C_3H_7$$
$$C_3H_7 + RH \rightarrow C_3H_8$$

The Decomposition of an n-Butane – Diallyl Mixture

In order to compare the reactivity of allyl with olefins and paraffins the pyrolysis of a *n*-butane – diallyl mixture was studied in one experiment. The results for a system containing 5% diallyl at 506° C (200 mm total pressure) are given in Table III.

TABLE III

Analytical results for the pyrolysis of 5% diallyl in *n*-butane for 5 minutes at 506° C

	Non-sensitized mole%	Sensitized mole%	Sensitized / Non-sensitized
Methane	2.0	4.9	2.5
Ethane	0.9	2.0	2.2
Ethylene	0.9	3.4	3.8
Propylene			3.5
1-Butene	Negligible	1.7	
1-Pentene	—	0.85	
Benzene	—	Negligible	

The principal products from the pyrolysis of *n*-butane alone are propylene methane, ethane, and ethylene. Since the yield of each of the latter three compounds in the complete pyrolysis of diallyl by itself is less than 10% of the diallyl decomposed it is apparent that the allyl radicals have initiated the decomposition of *n*-butane to a significant extent. The concentration ratios for these three products in the sensitized and non-sensitized experiments provides a measure of the accelerating effect of the allyl radicals. The analytical results for propylene were inconclusive because of the difficulty in separating propylene and *n*-butane completely on the alumina column used for these analyses.

Substantial amounts of both 1-butene and 1-pentene were formed in the allyl-sensitized reaction, presumably by the following processes:

$$CH_2{=}CH{-}CH_2\cdot + CH_3 \rightarrow CH_2{=}CH{-}CH_2{-}CH_3,$$
$$CH_2{=}CH{-}CH_2\cdot + \cdot CH_2{-}CH_3 \rightarrow CH_2{=}CH{-}CH_2{-}CH_2{-}CH_3.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The formation of both methyl and ethyl radicals has been proposed as primary steps in the pyrolysis of *n*-butane (7, p. 153). Both of these radicals could, of course, come from the pyrolysis of the butyl radical formed in the primary reaction between *n*-butane and allyl.

$$CH_2{=}CH{-}CH_2\cdot + CH_3CH_2CH_2CH_3 \rightarrow CH_2{=}CH{-}CH_3 + CH_3CH_2\dot{C}HCH_3$$

$$CH_3CH_2\dot{C}HCH_3 \rightarrow CH_3 + CH_2{=}CH{-}CH_3$$

$$\rightarrow CH_3CH_2 + CH_2{=}CH_2$$

Inhibition in Decomposition Reactions

The results obtained in the present study have shown that in the temperature region around 500° C allyl radicals can not only add to olefinic double bonds but are sufficiently reactive to abstract hydrogen from a variety of positions in hydrocarbons. This reactivity makes it difficult to assume that the residual reaction in hydrocarbon decomposition inhibited by the addition of propylene does not involve free radical mechanisms, as it is apparent that the allyl radicals formed under the present conditions are capable of propagating radical chains. The residual reactions in hydrocarbon decomposition fully inhibited by propylene may therefore be processes in which chains are propagated by less effective radicals like allyl, the concentration of the highly reactive alkyl radicals being kept at very low values by reaction with propylene. This idea is in accordance with suggestions made many years ago (16) that thermal decomposition of certain organic compounds may involve more than one type of chain mechanism, not all of which are suppressed by the addition of an inhibitor.

Chain propagation by stabilized radicals has been proposed for the decomposition of 1-butene (6), a system believed to be fully self-inhibited. The reaction of such radicals with substrate hydrocarbon in the propylene-inhibited pyrolysis of paraffins could maintain the propagation process and would result in the formation of products from the decomposition of the paraffinic radicals not greatly different from those obtained in normal pyrolyses.

In the inhibition of hydrocarbon pyrolysis by nitric oxide a similar mechanism may operate. The efficiency of nitric oxide as an inhibitor, roughly 12 times that of propylene (17), is very much less than might be expected assuming that both inhibitors operate by the removal of radicals like methyl from the system. The rate of reaction of methyl with nitric oxide is 400 times the rate of its reaction with propylene (18). However, nitric oxide may be capable only of removing active propagators like methyl and ethyl by converting them fairly rapidly into stable products. The reaction between nitric oxide and electronically stabilized radicals like allyl may be ineffective because of the weakness of the bond formed. Hence the residual reaction in nitric-oxide-inhibited pyrolyses of paraffins may be, to a considerable extent at least, a short-chain process propagated by stabilized radicals formed by H-abstraction from decomposition products like propylene and butene. Propylene may have an inhibition efficiency relative to nitric oxide greater than that expected from their relative rates of reaction with methyl because it can remove radicals by addition reactions as well as by serving as a source of hydrogen for abstractions.

The position of nitric oxide as an inhibitor is confused by the observation that in some systems it is unable to inhibit processes which seem fairly clearly to involve methyl radicals while in other systems it appears to function as a chain initiator (18). A more definitive study of the role played by both nitric oxide and propylene in various reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

systems, based on a study of the rate at which they are removed and on the nature of the products formed, would be valuable in endeavoring to understand their function as inhibitors.

THE AQUEOUS BENZOATE SYSTEM AS A SENSITIVE DOSIMETER FOR IONIZING RADIATIONS[1]

W. A. Armstrong and D. W. Grant

ABSTRACT

The aqueous benzoate system, as typified by $6\times10^{-4}M$ calcium benzoate, meets many of the requirements for a sensitive chemical dosimeter. The concentration of salicylic acid, determined spectrophotofluorometrically, increases linearly with radiation dose in the range 5 to 5000 rads and is independent of temperature from 15 to 45° C, of energy from 160 kev to 3 Mev, and of dose rate from 4 to about 1000 rads/minute. The decrease in sensitivity with increasing dose rate from 1000 to 85,000 rads/minute is reported.

INTRODUCTION

The ideal chemical dosimeter should be easy to prepare and stable indefinitely under ordinary storage conditions. The concentration of radiolytic product should be proportional to radiation dose, and independent of radiation intensity (dose rate), radiation energy, and temperature. There should be no postirradiation change in the concentration of that radiolytic product. The method of analysis for the product should be simple, accurate, and precise throughout the range of product concentrations corresponding to the dose range of the dosimeter.

For radiobiological work, a number of additional characteristics are desirable. In particular the system should be tissue-equivalent. This means that the radiation dose absorbed in the dosimeter system should be the same as that absorbed in an identical volume of tissue exposed under identical conditions. This condition is approximately satisfied if the system is water-based. In addition, the system should be sensitive to radiation doses in the range 1 rad (100 ergs/g) to a few thousand rads and be able to discriminate between neutrons and electromagnetic radiation.

Although many radiation-induced chemical reactions have been studied, no system has been developed which meets all of the above requirements. All proposed water-based systems have responses which depend to varying degrees on the radiation energy and at present it seems likely that more than one type of system will have to be exposed simultaneously for dosimetry of mixed neutron–gamma fields.

The two main factors which determine the lowest dose measurable by a given dosimeter are the yield (the amount of product P formed per unit of radiation dose, usually designated as G_P = number of molecules of P formed per 100 ev of energy absorbed) and the sensitivity of the analytical method for P. In general, a G_P greater than 20 indicates that the radiation-induced reaction involves some chain mechanism and, therefore, a dosimeter based on such a system will be dose rate dependent (1). If G_P is small an extremely sensitive analytical method is required. For example, if $G_P = 1$ a dose of 100 rads will produce approximately 10^{-7} moles of P per liter, a concentration barely detectable by even the most sensitive colorimetric methods. A dosimeter based on the oxidation of a leuco base to a dye by the radiolysis products of water and having a G_{dye} approximately equal to 1 has been developed (2, 3). However, it is not sufficiently sensitive for accurate use in the very low dose range.

The simplest analytical method capable of accurate measurements at such high dilutions is spectrophotofluorometry. Thus an extremely sensitive dosimeter might be based on the radiation-induced formation of a fluorescent species from a non-fluorescent

[1]*Manuscript received February 11, 1960.*
Contribution from Defence Research Board, Defence Research Chemical Laboratories, Ottawa, Ontario. Issued as D.R.C.L. Report No. 306.

precursor. Such a system is the benzoate ion in aqueous solution, which on irradiation undergoes partial conversion to the salicylate ion (4). In a preliminary communication (5), the authors have shown that doses down to 5 rads produce accurately measurable amounts of salicylate ion in aqueous calcium benzoate solutions. The present paper describes the results of the experiments undertaken to determine how well a benzoate system meets the requirements for a chemical dosimeter.

EXPERIMENTAL

Materials

Water from a Barnsted still was redistilled from alkaline $KMnO_4$ in an all Pyrex apparatus which incorporated a splash column. Calcium benzoate as the monohydrate (judged by weight loss on heating) was prepared by mixing solutions of reagent grade calcium chloride and benzoic acid dissolved in dilute sodium hydroxide, followed by repeated recrystallizations of the calcium benzoate from aqueous solution. The salicylic acid was reagent grade material recrystallized from aqueous solution and dried. All other materials were reagent grade and were used without further purification.

All glass equipment was vigorously cleaned with fresh chromic acid followed by repeated washings with redistilled water. Steam from boiling dilute alkaline permanganate was then passed through the Pyrex irradiation vessels and the flasks used for storing solutions.

Radiations

The following radiations were used: γ-rays from 2 curies of Cs^{137} and 200 curies of Co^{60}; X rays from a 3-Mev Van de Graaff generator. All dose rates were determined using the Fricke dosimeter (6), assuming $G_{Fe(III)}$ to be 15.5 for all radiations employed. The usual corrections were made for the decreased energy absorption in water.

The 2-curie Cs^{137} source has been described previously (3). The 200-curie Co^{60} source is housed in a facility similar to the one described by Schwarz and Allen (7). The cobalt is located in a pipe 1 in. by 4 in. welded to the center of the bottom of a cylindrical tank 7 ft high and 1 ft in diameter. The tank is sunk about 6 feet in the ground and filled with water. The earth and water provide adequate shielding. Samples were irradiated at dose rates of 70 to 1500 rads/minute in a jig designed to fit over the source.

The 3-Mev Van de Graaff generator, a High-Voltage Corp. horizontal model, was used for high dose rate studies. Samples were dropped through a lucite tube into the X-ray beam for a period of time controlled by an interval timer. With this arrangement, it was possible to irradiate samples with doses of a few thousand rads at dose rates up to 85,000 rads/minute.

Analysis

Fluorescence measurements were made with a Bowman–Aminco spectrophotofluorometer normally using 1-cm quartz cells, although microcells requiring as little as 0.1 ml have been used successfully. The salicylic acid formed on irradiation was determined by comparing the fluorescence of the irradiated sample at 400 mμ when activated with light of 295 mμ, with that of a standard salicylic acid solution. As fluorescent measurements may be affected by the presence of non-fluorescent species, all standards were prepared by adding the desired amount of salicylic acid to a solution of the same composition as the solution to be irradiated. In the concentration range investigated ($<10^{-5}$ M) and with the pH between 4 and 8, neither quenching effects nor interference from other products were encountered.

RESULTS

1. *Dose*

From Fig. 1 it is seen that for a benzoate ion concentration of 1.2×10^{-3} M, the amount

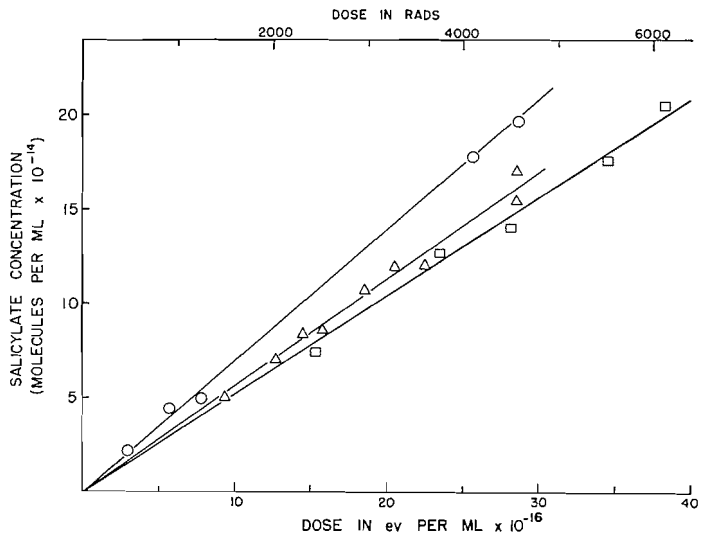

Fig. 1. Effect of dose rate on the formation of salicylic acid in aqueous solutions $1.2\times10^{-3}M$ in benzoate ion: ○ 4 rads/minute (Cs^{137} γ-rays), △ 18,000 rads/minute (3-Mev X rays), □ 85,000 rads/minute (3-Mev X rays).

of salicylic acid produced is a linear function of dose up to about 5000 rads. As the system was studied primarily for the measurement of doses of radiobiological interest (0–1000 rads), few measurements were taken at higher doses. However, there is an indication (not shown) that at high dose rates (18,000 rads/minute), the yield of salicylic acid tends to fall off slightly above 6000 rads even with benzoate ion concentrations as high as 1.2×10^{-2} M. At low benzoate ion concentrations (2.4×10^{-4} M) the product yield appears to decrease when the dose exceeds 1500 rads.

2. *Concentration of Benzoate Ion*

As shown in Fig. 2, the yield of salicylic acid, G_{Sal} (the number of molecules of

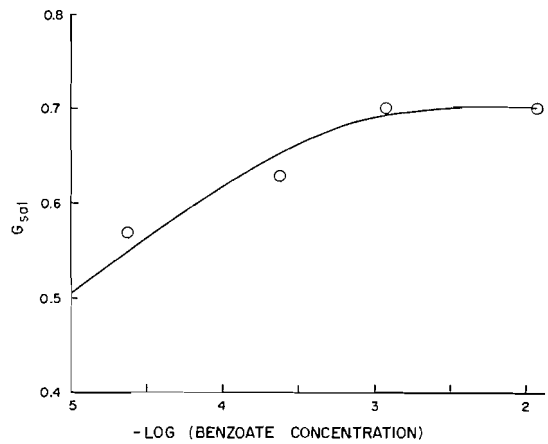

FIG. 2. Effect of benzoate ion concentration on G_{Sal}. Calcium benzoate solutions were irradiated with Cs^{137} γ-rays at 4 rads/minute.

For personal use only.

salicylic acid formed per 100 ev of energy absorbed), increases with increasing benzoate ion concentration from 0.57 for 2.4×10^{-5} M to a limiting value of 0.70 at about 10^{-3} M benzoate ion.

3. Radiation Energy

It has been reported previously (5) that G_{Sal} is independent of radiation energy over the range 1.25 Mev to 0.16 Mev but is 20% lower at an energy of 0.05 Mev.

4. Dose Rate

G_{Sal} decreases with increasing dose rate. The results of irradiations of 6×10^{-4} M calcium benzoate solutions at three dose rates, plotted in Fig. 1, give $G_{Sal} = 0.70$ at 4 rads/minute, 0.59 at 18,000 rads/minute, and 0.53 at 85,000 rads/minute. Intermediate values were obtained using dose rates of 70, 3000, 5000, and 10,000 rads/minute. These are not listed as they lie within the experimental error ($\pm5\%$) of those values obtained for either 4 rads/minute or 18,000 rads/minute.

5. Temperature

Samples of 1.2×10^{-4} M calcium benzoate, thermostatted to within 0.5° C as previously described (3), were irradiated at a rate of 4 rads/minute with Cs^{137} γ-rays. Changes in temperature over the range 15–45° C were found to have no detectable effect on the radiation-induced reaction.

6. pH

The effect of pH on the fluorescence of salicylic acid and *m*-hydroxybenzoic acid has been described by Thommes and Leininger (8). The fluorescence of salicylic acid is due to the salicylate ion and is independent of pH in the range 4–13. However, *m*-hydroxybenzoic acid, which has been identified as a primary product of the radiolysis of benzoate solutions (9), exhibits fluorescence in solutions of pH greater than 8. Thus salicylic acid can best be determined fluorometrically in solutions of pH 4 to 8.

Unbuffered 6×10^{-4} M calcium benzoate solutions having a pH of about 6.3 were used almost exclusively in the radiation studies. Unbuffered 10^{-3} M benzoic acid solutions having a pH of about 3.6 were used successfully with irradiations at low dose rates by comparing the fluorescence of irradiated samples with that of standard salicylic solutions made up in 10^{-3} M benzoic acid. However, such a procedure is not recommended as small changes in pH produce large changes in fluorescence.

The results of the irradiation of alkaline benzoate solutions (pH 11.8) are shown in Fig. 3. The amount of salicylic acid plotted is not the true amount as it was calculated by comparing the total fluorescence due to the salicylic acid and the *m*-hydroxybenzoic acid in irradiated samples with that of a salicylic acid standard. From Fig. 3 the apparent $G_{Sal} = 1.08$ for Co^{60} γ-rays at 70 rads/minute and 0.87 for 3-Mev X rays at 18,000 rads/minute. This decrease in sensitivity with increasing dose rate is similar to that found in neutral solutions. As the sensitivity of neutral solutions is considered adequate, alkaline solutions were not further investigated.

7. Other Effects

Although benzoate solutions decarboxylate to some extent on prolonged standing, no effect attributable to this was found during any irradiation. No salicylate was detected in solutions which had been stored for many weeks in Pyrex flasks.

No detectable postirradiation effect was observed over a period of 24 hours. This was noted for samples receiving doses of about 100 rads at a dose rate of 4 rads/minute and also for samples receiving doses of about 2000 rads at a dose rate of 18,000 rads/minute.

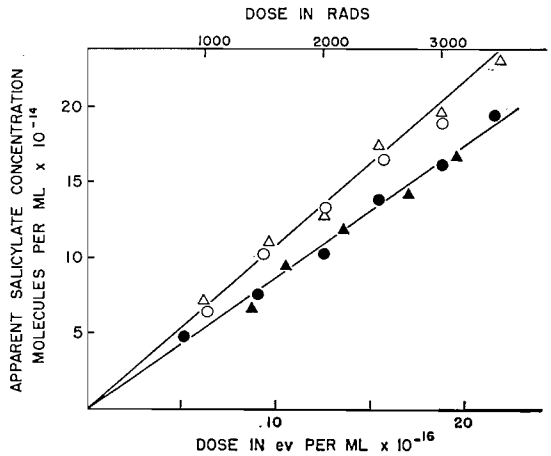

FIG. 3. Results of the irradiation of benzoate solutions 0.01 M in sodium hydroxide: ○ 6×10^{-4} M calcium benzoate, △ 10^{-3} M benzoic acid. Open symbols indicate irradiation with Co^{60} γ-rays at 70 rads/minute, darkened symbols irradiation with 3-Mev X rays at 18,000 rads/minute.

Calcium benzoate was used almost exclusively in this investigation primarily because it can be easily purified by repeated crystallizations from water. Samples of sodium and potassium benzoate as well as benzoic acid available at the outset of the investigation contained traces of salicylic acid and other impurities. The traces of salicylic acid caused high blank fluorescences and made the solutions unsuitable for the measurement of low doses. The other impurities caused some postirradiation changes. At a later date pure potassium benzoate was obtained and shown to give results identical with those obtained with calcium benzoate. Zone-refined PVS benzoic acid was also investigated briefly. As has been mentioned, millimolar benzoic acid solutions are too acidic for the accurate measurement of salicylate fluorescence. However, as shown in Fig. 3, the irradiation of alkaline benzoic acid and alkaline calcium benzoate gave similar results.

DISCUSSION

The results indicate that the aqueous benzoate system, as typified by 6×10^{-4} M calcium benzoate, meets many of the requirements for a sensitive chemical dosimeter. It is stable, easy to prepare, and exhibits no postirradiation change. The concentration of salicylic acid increases linearly with radiation dose in the range 5 to 5000 rads and is independent (within the estimated experimental error of $\pm5\%$) of temperature from 15 to 45° C, of energy from 160 kev to 3 Mev, and of dose rate from 4 to about 1000 rads/minute. With radiation energies lower than 160 kev, the response decreases with decreasing photon energy and at 50 kev is 17% lower (5). The indicated dose, on the basis of $G_{Sal} = 0.70$, will be lower than the actual dose by 5 to 15% with dose rates of 1000 to 18,000 rads/minute and by 16 to 24% with dose rates of 18,000 to 85,000 rads/minute.

It must be stressed that the sensitivity of this system as a dosimeter depends on the method of analysis. The ultimate sensitivity of any dosimeter which is based on fluorescence measurements is dependent on the ratio of the intensities of fluorescent and scattered light at a given wavelength λ, $(I_f/I_s)_\lambda$. In the Bowman–Aminco instrument, a high I_f is obtained by the use of a high intensity light source while I_s is kept to a minimum by the use of diffraction grating monochromators and excellent optical design.

However, it should be possible to adapt for accurate salicylate analysis any fluorometer which is equipped with an ultraviolet light source by the use of appropriate optical filters.

A discussion of the results reported here in terms of a mechanism for the radiation-induced reactions in aqueous benzoate solutions is beyond the scope of this paper. A report describing the formation of products other than salicylic acid and discussing the theoretical aspects of the benzoate system will be published soon.

ACKNOWLEDGMENTS

The authors wish to thank Mr. F. A. Bury for his assistance with the experiments which required the use of the Van de Graaff generator.

RADIATION CHEMISTRY OF CYCLOHEXANE

II. DOSE RATE EFFECTS ON THE FORMATION AND DESTRUCTION OF CYCLOHEXENE[1]

P. J. Dyne and J. W. Fletcher

ABSTRACT

Prolonged radiolysis of cyclohexane leads to a steady-state concentration of cyclohexene where G(cyclohexene) = 0. At concentrations greater than this steady concentration, cyclohexene is destroyed. It is shown that this steady-state concentration is a function of dose rate, varying approximately as the fourth root of the radiation intensity. A discussion of these and other observations indicates that dose rate and L.E.T. effects are observed in cyclohexane only if radical scavengers are present and that cyclohexene, a product of radiolysis, acts as a radical scavenger in irradiated cyclohexane.

INTRODUCTION

Cyclohexene and bicyclohexyl are the two major high molecular weight products formed in the radiolysis of cyclohexane. Dewhurst and Schuler (1) have shown that the initial G values (molecules formed/100 ev absorbed) for cyclohexene and bicyclohexyl are independent of the L.E.T. (Linear Energy Transfer)* of the irradiation. Dewhurst (2) showed that G(cyclohexene) decreases with dose (i.e. with increasing cyclohexene concentration) and, further, that in concentrated solution (5×10^{-4} moles/g), cyclohexene is destroyed. It follows that prolonged irradiation of cyclohexane or of solutions of cyclohexene in cyclohexane leads to a "steady-state" concentration of cyclohexene where G(cyclohexene) = 0. Dewhurst and Schuler (1) found some evidence that G(cyclohexene) fell off more rapidly with cyclohexene concentration at low dose rates, using a Co^{60} γ-ray source, than at the higher dose rates obtained with electron and particle beams.

We have studied the formation and destruction of cyclohexene as a function of the dose rate, using Co^{60} γ-rays and have shown that the "steady-state" concentration increases slowly with the dose rate. The dependence is less than a proportionality to the square root of radiation intensity and approximates to a fourth root dependence.

EXPERIMENTAL

Samples of cyclohexane (spectroscopic grade from various manufacturers) were irradiated in sealed glass vessels. The liquids were degassed by freezing, pumping, and thawing five times. Two Co^{60} sources were used (3) having dose rates of 1.4×10^{19} ev/g hr and 9.6×10^{17} ev/g hr. These dose rates were established using the Fricke dosimeter, $G(Fe^{3+})$ = 15.5 ions/100 ev. Analysis for cyclohexene was done by infrared spectrophotometry of the 640 cm^{-1} band of cyclohexene using a Perkin–Elmer, model 21, spectrometer. Path lengths of 0.2–4.0 mm were used with compensating cells containing pure cyclohexane for the thicker cells. The irradiations were made over an extended period of time (irradiations of up to 1400 hours at the low dose rate). The solutions were stored after irradiation and were all analyzed at one time together with a series of standard solutions of known concentration. The concentrations were determined by graphical interpolation from the measurements of the standard spectra. At the low

**Equivalent to the ionization density along the track.*

dose rates the range of the experiments was increased by irradiating solutions that already contained cyclohexene. These results fitted smoothly into the curves obtained in the irradiation of pure cyclohexane.

RESULTS

Most of the experimental results for the high and low dose rates are shown in Figs. 1 and 2 respectively. It should first be noted that at the lower dose rate cyclohexene is

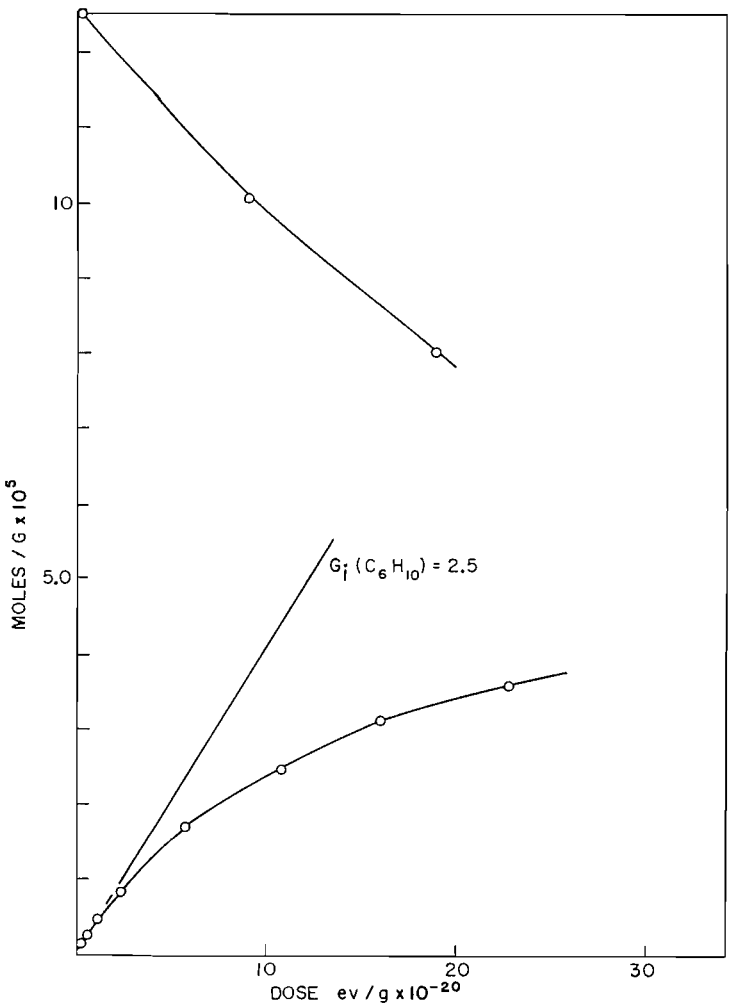

FIG. 1. Formation and destruction of cyclohexene at a dose rate of 1.4×10^{19} ev/g hr.

destroyed at concentrations such as 3.0×10^{-5} moles/g where it is still being formed at the higher dose rate. A similar comparison can be made between our high dose rate results, where decomposition occurs at concentrations greater than 4.5×10^{-5} moles/g, and Dewhurst's results with an electron beam (1), where net decomposition is observed only at concentrations greater than 4.0×10^{-4} moles/g.

We have drawn an initial slope, equivalent to $G(C_6H_{10}) = 2.5$, equal to Dewhurst's

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

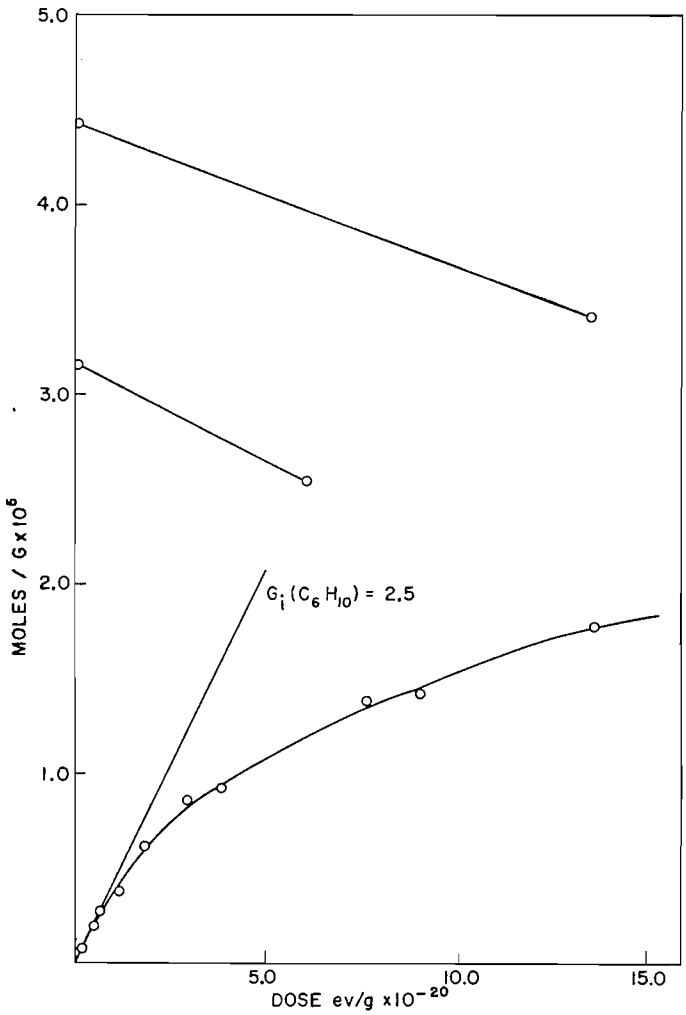

FIG. 2. Formation and destruction of cyclohexene at a dose rate of 9.6×10^{17} ev/g hr.

value, on both Figs. 1 and 2. It can be seen that there is no significant change in the initial *G*-value with dose rate. The *G*-value indicated by the first point (at the lowest cyclohexene concentration) in Fig. 1 and in Dewhurst's Fig. 1 are between 3.0 and 3.2. The value of 2.5 must be regarded as a minimum value; it is possible that the true limiting *G*-value is 3.0 or higher.

We have calculated *G*-values for each successive pair of experimental points in Figs. 1 and 2 and for Dewhurst's experimental results. In Fig. 3 the *G*-values are plotted against the concentration of the first point, i.e. the one with lower concentration where *G*-cyclohexene is positive and the one with the higher concentration when *G*-cyclohexene is negative. This procedure is, we feel, preferable to drawing a smooth curve through the experimental points and measuring graphically the slopes of a series of tangents. Due to the fairly steep curvature of the plots of $G(C_6H_{10})$ vs. cyclohexene concentration this is a plot of minimum *G*-values ($G(C_6H_{10})$ and $G(-C_6H_{10})$ both having positive signs). The high initial points, $G = 3.0$–3.2 mentioned in the previous paragraph, are seen on the

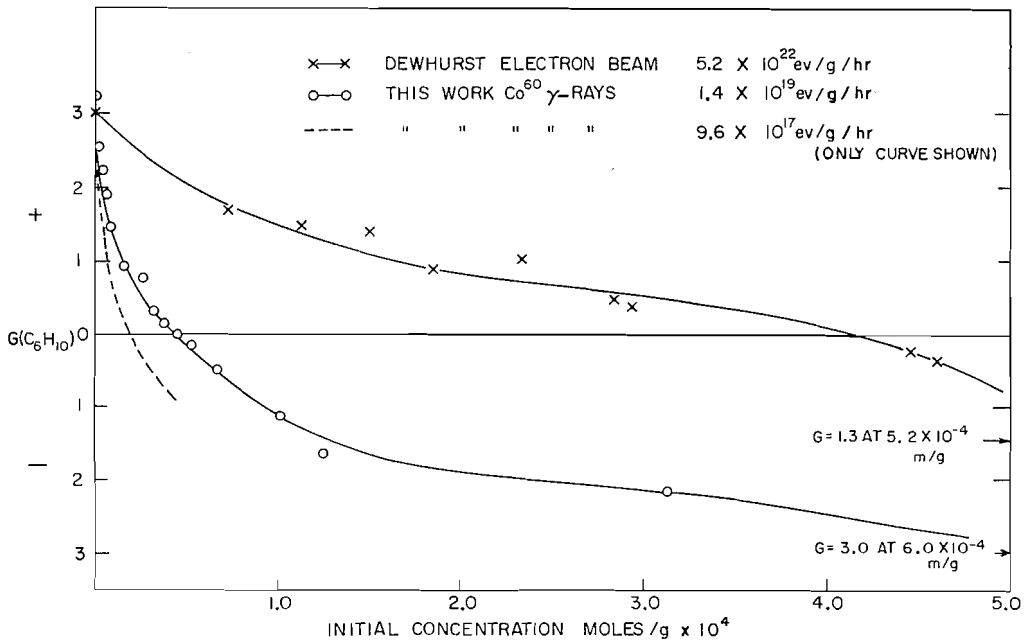

FIG. 3. *G*-values for formation and destruction of cyclohexene as a function of cyclohexene concentration. See text for method of calculation.

graph. The locus of $G(C_6H_{10})$ vs. C_6H_{10} for the lower dose rate (9.6×10^{17} ev/g hr) experiments is also shown in Fig. 3. At this low dose rate $G(C_6H_{10}) = 0$ at a cyclohexene concentration of 2×10^{-5} moles/g and the largest observed value of $G(-C_6H_{10})$ is 1.6 at 6.1×10^{-4} moles/g. The largest observed value of $G(-C_6H_{10})$ at our higher dose rate of 1.4×10^{19} ev/g hr was 3.0 at 6.0×10^{-4} moles/g. Dewhurst reports a value of $G(-C_6H_{10}) = 2.3$ at 5.2×10^{-4} moles/g at the high dose rate obtained with the electron beam. This value is greater than that shown in Fig. 3 as it was derived from the initial slope of a smoothed curve.

The steady-state concentrations determined from Fig. 3 are given in Table I, which includes the relative concentrations and dose rates and shows that the steady-state concentration varies approximately as the fourth root of the dose rate. The term steady state is, perhaps, somewhat unfortunate as it implies that this concentration will never change. With very long irradiations, 10 or more times the highest doses used here, further reactions must be expected. The term refers only to the dose range of the present experiments.

TABLE I

Variation of steady-state concentration with dose rate

Dose rate, ev/g hr	Steady-state concn., moles/g	Relative dose rate	Relative concn.	(Relative dose rate)$^{1/2}$	(Relative dose rate)$^{1/4}$
9.6×10^{17}	2.0×10^{-5}	1.0	1.0	1.0	1.0
1.4×10^{19}	4.5×10^{-5}	14.5	2.25	3.80	1.94
5.2×10^{22}	4.2×10^{-4}	5.4×10^{4}	21.0	2.32×10^{2}	15.2

Irradiation of cyclohexane in a spent fuel-element γ-ray source, reported by Nixon and Thorpe (4), gave a concentration of 2.7×10^{-5} moles/g cyclohexene at a dose of 4.8×10^{21} ev/g, equivalent to G(cyclohexene) = 0.34. When compared with the initial G(cyclohexene) = 2.5 this low G-value indicates that the system was approaching a steady state. The steady-state concentration at their dose rate ($\sim4\times10^{19}$ ev/g hr or perhaps somewhat less) (5) is, by interpolation from the data in Table I, $\sim6\times10^{-5}$ moles/g.

DISCUSSION

Two different, but closely related, effects have to be explained; the invariance of initial yields with L.E.T. and with dose rate, and the variation of yields with dose rate in the presence of cyclohexene. It is well known that both L.E.T. and dose rate effects are generally due to a competition between reactions R + R $\rightarrow$ products, P_1 involving two precursors (free radicals) and reactions R + S $\rightarrow$ products, P_2 involving one precursor and a stable molecule S present in macro quantities. The products P_1 and P_2 may consist of more than one species. Variations in yield with L.E.T. occur because the balance of the competition is largely determined by the initial distribution of the precursor R. The chief features of the radiation chemistry of water are explicable in these terms.

Variations of yields with dose rate occur, in general, because the steady-state concentration of precursors is determined by functions involving the dose rate and the square root of the dose rate: the square root arising from the bimolecular removal of precursors in a reaction R + R $\rightarrow P_1$. This situation occurs if the precursors are reacting homogeneously, track effects being absent (as in photochemistry).

The chief experimental observations to be correlated and explained are:

1. The initial yield of hydrogen from cyclohexane is independent of L.E.T. and dose rate. This was demonstrated by Schuler and Allen (6).

2. The initial yield of cyclohexene is also independent of dose rate and L.E.T. This may be stated, using E for cyclohexene, as $(dE/dt)\ (E \rightarrow 0) = k_1 I$, where I is the dose rate. This also expresses the fact that dose rate and/or L.E.T. effects are observed only in the presence of cyclohexene.

3. The yield of cyclohexene from unimolecular processes $C_6H_{12} \rightarrow C_6H_{10} + H_2$ has a G-value less than 1.0; the major fraction of the yield ($\sim2/3$) is produced by bimolecular processes, probably the disproportionation of cyclohexyl radicals, $2C_6H_{11} \rightarrow C_6H_{10} + C_6H_{12}$. This conclusion was reached by Dewhurst (2) from studies of the yield of cyclohexene in the presence of oxygen (1) and is in agreement with the measurements made by Dyne and Jenkinson (7) of the yield of deuterium produced in unimolecular processes from C_6D_{12}.

4. The steady-state concentration of cyclohexene varies slowly with radiation intensity, approximately as the fourth root of I, i.e. $E_s \simeq k_2 I^{1/4}$.

5. The yield of cyclohexene drops very sharply with cyclohexene concentration at the lower dose rates. Cyclohexene inhibits its own formation very effectively, more effectively than it reduces the yield of molecular hydrogen.

The invariance of the hydrogen yield with L.E.T. can be simply explained. Hydrogen is presumably formed by $H + C_6H_{12} \rightarrow H_2 + C_6H_{11}$; this is essentially the scavenging reaction R + S $\rightarrow$ products, where S is present at a very high concentration—so high that the probability of the recombination reaction $H + H \rightarrow H_2$ is very small. It should also be noted that the scavenging reaction gives one molecule H_2 for one hydrogen atom

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

while the recombination reaction gives one molecule H_2 for two hydrogen atoms. If the two reactions rates were comparable then the hydrogen yield would *decrease* with increasing L.E.T. as the probability of bimolecular recombination would increase.

The invariance of the initial yield of cyclohexene with L.E.T. may arise from the opposite circumstance; all the precursors of cyclohexene react $R + R \rightarrow$ products (e.g. cyclohexene) and the scavenging reaction is non-existent. Scavengers (cyclohexene itself, for instance) may be formed during the radiolysis. Changes in yield with L.E.T. would then be observed in solutions containing cyclohexene but not in pure cyclohexane. This is in agreement with experiment. The variation in yield of bicyclohexyl with dose rate, which is similar to the behavior of cyclohexene observed by Dewhurst and Schuler (1), would be explained similarly.

With reference to the steady-state concentration, it is not possible to distinguish properly between L.E.T. and dose rate effects. The dose rate variation has been observed with Co^{60} γ-rays. No α-particle or proton beam experiments have been reported in which the total dose rate was varied or in which the irradiation was carried to a sufficiently high dose rate for the observation of the radiation steady state.

Dose rate effects in γ-ray irradiations can occur only when radicals (or precursors) have an appreciable probability of escaping from the spur in which they were formed and of reacting with radicals produced in other spurs. Homogeneous kinetics, as in photochemistry, are then applicable. A competition between $R + R \rightarrow P_1$ reactions (second order in R) and $R + S \rightarrow P_2$ reactions (first order in R) will give rise to dose rate dependence of the yields of P_1 and P_2 and of the disappearance of S. The present evidence suggests that cyclohexene is the scavenger S as its presence generates the dose rate effects. The effectiveness of cyclohexene in the inhibition of its own formation suggests, also, that in the $R + R \rightarrow P_1$ reactions, P_1 includes cyclohexene. Cyclohexene is destroyed in the scavenging reactions and in some of these same reactions it destroys its own precursors. As G(cyclohexene) falls more rapidly than $G(H_2)$ with cyclohexene concentration (i.e. the reduction in $G(H_2)$ is not equivalent to the reduction in G(cyclohexene)), cyclohexene must presumably be reacting with other precursors as well as with hydrogen atoms.*

Schuler (8), using a variety of ionizing radiations, measured the disappearance of iodine in cyclohexane solutions and equated this yield with the total radical yield. The radical yield obtained with 33-Mev helium ions is about 30% less than that found in electron beam irradiations. Compared with the effects in water this is a small change in yield with L.E.T. Under the particular experimental conditions used (dose rate, scavenger concentration, etc.) the scavenging reaction is dominating the recombination reaction over the whole L.E.T. range. Detailed studies of scavenging, similar to those done by Charlesby and Lloyd (9) on anthracene are needed to put this and other observations (such as those presented in this paper on cyclohexene) on a quantitative basis.

The relations $dE/dt.(E \rightarrow 0) = k_1 I$ and $E_s \simeq k_2 I^{1/4}$ are reduced, approximate forms of the general rate equation $dE/dt = F - D$ where F is the rate function for all processes forming cyclohexene and D the rate function for all processes destroying cyclohexene. Both these rates F and D are likely to be functions of E and I. We may speculate on the form of F and D, as follows. The $I^{1/4}$ function is probably derived from the $I^{1/2}$ dependence found in many radical chain mechanisms. The relation $E_s \simeq k_2 I^{1/4}$ is possibly

**This conclusion is contrary to the argument given by Dewhurst, who equates the change in hydrogen yield with the value of $G(-C_6H_{10})$ at a concentration of 5.2×10^{-4} moles/g. The correct value for the comparison is $[G_{\text{initial}}(C_6H_{10}) + G(-C_6H_{10})]$ and this is greater than the reduction in hydrogen yield.*

a simplification of $E_s^2 \simeq k_2^2 I^{1/2}$. This equation is a reduced form of the relation $D = F$ when $E = E_s$. Now F, the processes of formation, are likely to be proportional to I; they are certainly so when $E = 0$. The process of destruction is likely to be a reaction of cyclohexene with a reactive intermediate with a rate governed by $k.E.R$ where R is the steady-state concentration of this intermediate. If this is the intensity-dependent process, it may have the form $k''EI^{1/2}$. The relation $E_s^2 \simeq k_2^2 I^{1/2}$ can be rearranged to $E_s I^{1/2} \simeq k_2^2 I/E_s$ which we identify with $D = F$. Now F cannot be inversely proportional to E as $E \to 0$—it must have a form of the type: $k_2^2 I/(k_3+E)$, in which k_3 is sufficiently small that E quickly becomes the dominating term in the denominator.

The true rate equations must be more complex than this. We know that there are two processes, one unimolecular, the other bimolecular, forming cyclohexene, i.e. $F = F_1+F_2$, each presumably having a different dependence on E and I. There may again be more than one process destroying cyclohexene. The sum of all destruction $\Sigma_1 D_1$ and formation processes are related by $\Sigma_1 D_1 = F_1+F_2$ at the steady state. The relation $E_s I^{1/2} \simeq k_2^2 I/(k_3+E)$ is a simplification of this relation which is observed over a possibly limited range of values of E and I.

In summary, the chief conclusion of this study is that, in liquid cyclohexane, scavengers must be present before dose rate and L.E.T. effects are observed and that a major product of the radiolysis, cyclohexene, acts as a scavenger.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the helpful and critical interest Dr. R. H. Betts has shown in this work.

THE DECOMPOSITION OF METHANE BY LOW-ENERGY ELECTRONS[1]

J. E. MANTON[2] AND A. W. TICKNER

ABSTRACT

The decomposition of methane by a beam of electrons having energies between 15 and 100 ev has been studied using methane pressures between 10^{-2} and 10^{-3} mm of mercury. The products were frozen out on a surface cooled to about $-220°$ C and situated approximately 5 millimeters from the electron beam.

Ethane, ethylene, and acetylene were found to be the main products along with smaller amounts of saturated and unsaturated higher hydrocarbons. The results provide some evidence that under these experimental conditions ions do not play a major part in the decomposition and a free radical mechanism has been proposed to explain the formation of the main products.

INTRODUCTION

Recently the authors have become interested in the study of chemical reactions in the electric discharge. For many years, the interpretation of the results of such studies was based largely on the reactions of free radicals, ionic reactions not being considered of importance. During the last few years, however, it has been observed, initially by Stevenson (1), that ions frequently have enhanced cross sections for reaction. This has led to a reappraisal of the role played by ions in radiation and discharge chemistry.

As an aid to understanding the decomposition of methane in a discharge, the experimental conditions have been simplified in such a way that many of the experimental parameters could be separately controlled. In addition, an effort has been made to reduce the extent to which secondary reactions occur by providing for the rapid removal of the products from the reaction zone. In this way, it was hoped to obtain some information concerning the primary products of the discharge reaction.

EXPERIMENTAL

A conventional vacuum system, capable of maintaining a background pressure of less than 10^{-6} mm Hg, was used. The essential details of the apparatus are shown in Figs. 1 and 2.

An electrically heated (a-c.) tungsten ribbon filament was the source of electrons, the filament being enclosed in a housing with its own pumping for the removal of pyrolysis products. The beam of electrons was defined by apertures 1.5 mm in diameter in a series of Chromel A plates. Further alignment and collimation of the beam were obtained by the use of a permanent magnet which provided a uniform field strength of 870 gauss over an area about 4 centimeters in diameter at the center of the gap. Onto the final collimator (collimator 2) was soldered a hollow brass cone, A, which fitted into the glass tube surrounding the reaction zone. This arrangement caused the major pressure drop to be across the defining aperture in the center of the collimator. The collector served to monitor the electron beam. The collector grid, about 1 mm in front of it, consisted of 90% transparent tungsten mesh and was maintained at the same potential as the final collimator, thus creating a field free reaction zone 4.5 centimeters in length.

The various potentials were obtained from a regulated d-c. supply and were chosen to give the maximum beam current consistent with stability and reasonable filament

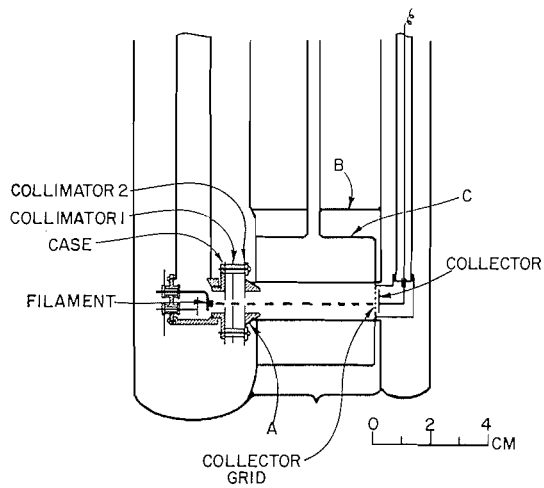

FIG. 2. Details of electron beam tube.

life. The filament housing was maintained at +25 v and collimator 1 at +10 v to +15 v, all potentials being established with respect to the center of the filament. Collimator 2 and the collector grid were set at the electron energy required for the experiment and

the collector was maintained about 25 volts more positive. The electron beam current was controlled manually by adjusting the filament current.

The path of the electron beam through the methane could be observed, in a darkened room, as a faint bluish column, approximately the diameter of the defining apertures and extending the whole length of the reaction zone. After the initial experiments, the inside surface of the glass tube surrounding the reaction zone was gold-coated by evaporation in order to prevent charge accumulation on the walls. A spring contact connected the gold layer electrically to the collector grid.

The reaction products were expected to be mixtures of the lower hydrocarbons similar to those obtained in the decomposition of methane in the d-c. glow discharge at low temperatures (2, 3). The estimated rates of formation, based on the low-temperature discharge work, together with values of the vapor pressures of the C_2 hydrocarbons, obtained by extrapolation of the data of Tickner and Lossing (4), indicated that a temperature of about $-215°$ C would be necessary to freeze out the reaction products quantitatively. The refrigerant used was solid nitrogen, obtained by reducing the pressure above liquid nitrogen. The solid nitrogen was in chamber C in Fig. 2, this being surrounded by the evacuated chamber B, and the whole immersed in liquid nitrogen. In this way, the walls of the tube surrounding the reaction zone could be cooled to slightly below $-220°$ C, as indicated by the vapor pressure of methane.

The methane used was Matheson C.P. grade and was purified by fractional distillation before admission to the storage reservoir. From this reservoir, the methane was admitted to the reaction system via a needle valve, which controlled the flow rate, and a trap maintained at the freezing point of nitrogen, $-210°$ C for final purification. The methane pressure was measured with a Pirani gauge, which had been calibrated, *in situ*, against a standard McLeod gauge.

In carrying out an experiment, a steady flow of methane was established and the electron beam turned on for the required time. The length of a run, about 20 minutes, was chosen in order to obtain the maximum quantity of products consistent with maintaining sufficient solid nitrogen in the jacket for efficient trapping. At the end of an experiment, the methane was turned off and the system pumped briefly to a low pressure and then isolated. After the reaction system had warmed up, the products were quantitatively transferred to a gas burette by means of a Toepler pump and the volume measured. A sample was then taken and analyzed on the mass spectrometer.

EXPERIMENTAL RESULTS

In order to determine the contributions of materials formed by pyrolysis on the filament, blank runs at 5×10^{-3} mm and 10×10^{-3} mm pressure of methane were performed. The experimental conditions, including the filament current, were the same as those used in the other runs except that no d-c. potentials were applied to the system. Small amounts of the C_2 hydrocarbons were found, which did not exceed 2% of the amounts formed during any of the experiments. In addition, propylene was found in amounts up to 5% and butene in amounts up to 25% of the quantities obtained as products in subsequent runs. The quantity of pentene found in the blank corresponded to between 25% and 50% of the amounts recovered in subsequent experiments. Since in almost every case, the corrections would be small compared with the other uncertainties involved, no corrections have been made for the presence of pyrolysis products among the reaction products.

The variation of the reaction products with electron energy is shown in Fig. 3. The

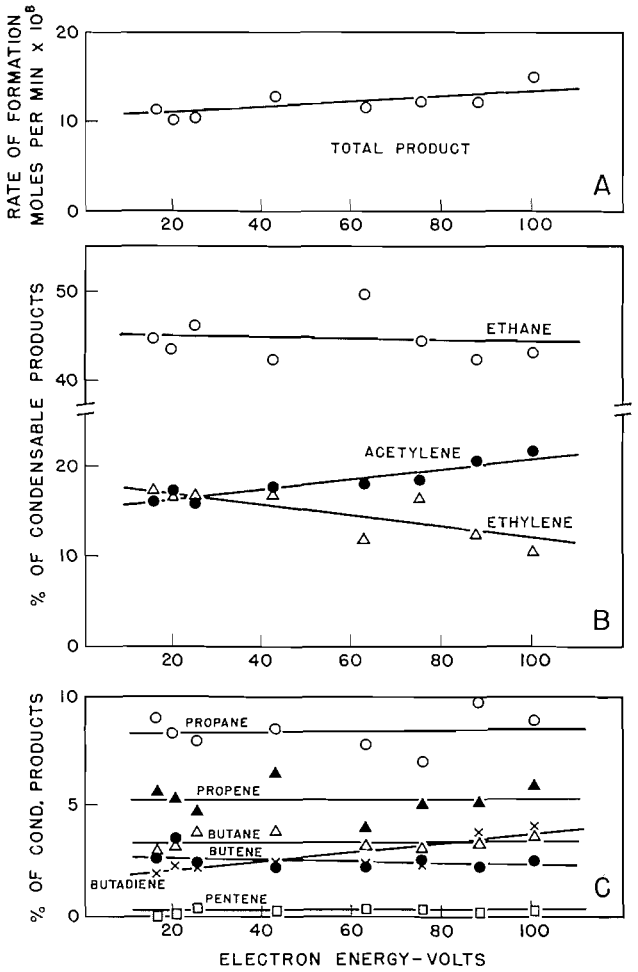

FIG. 3. Variation of products with electron energy.

values were obtained at a pressure of 5.2×10^{-3} mm of methane and collector currents of $250(\pm5)$ μa. It was not found possible to extend the measurements to lower voltages because the electron beam became unstable below about 15 volts. At 50 ev the extent of decomposition was about 3% and in all cases the contact time was estimated to be about 0.02 second.

The effect of pressure on the reaction products is shown in Fig. 4. These experiments were carried out with collector currents of $230(\pm10)$ μa and at an electron energy of 50 ev. At the temperature used to trap the products ($-220°$ C) the maximum pressure of methane which could be used is the vapor pressure (about 10^{-2} mm). The lower limit to the pressure range was set by the fact that the rate of formation of products decreased as the pressure was lowered. Consequently, the more volatile products could not be recovered quantitatively below about 2×10^{-3} millimeters.

Figure 5 shows the effect of collector current on the products, using 50-v electrons and a pressure of 5.2×10^{-3} mm of methane. The lower limit of 100 μa was again

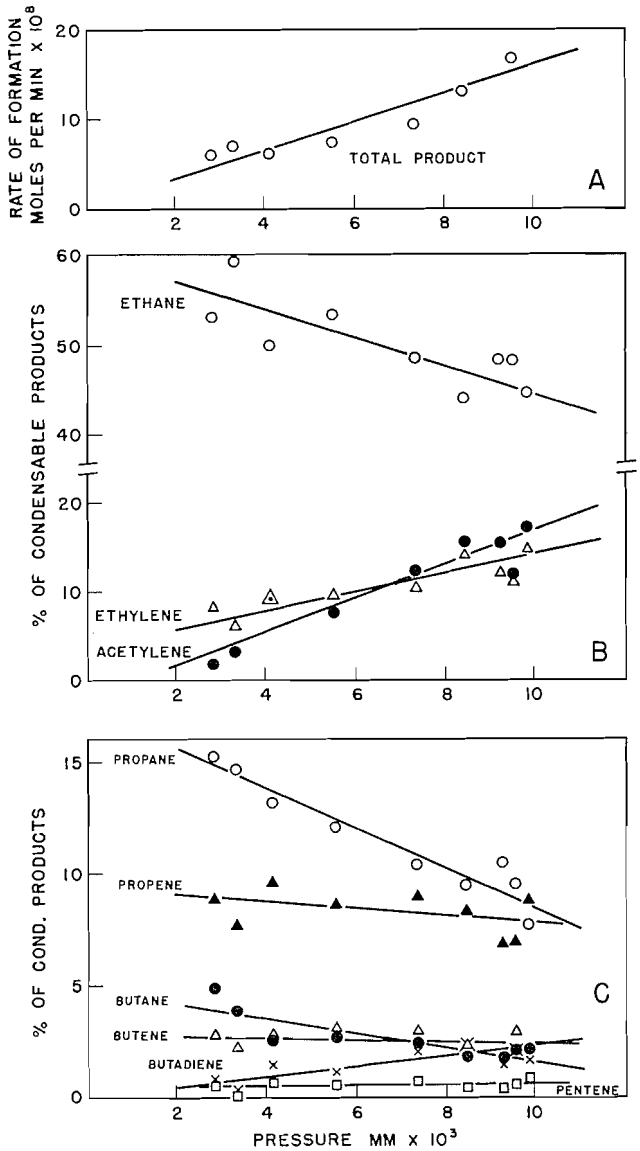

FIG. 4. Variation of products with pressure.

determined by the vapor pressures of the products and the efficiency with which they could be trapped.

No analyses were made for the hydrogen which was presumably formed in the decomposition. Such an analysis would have been difficult to perform accurately since the concentration of hydrogen in the reacted gas would have been less than 3% and the total gas pressure downstream from the reaction zone was less than 10^{-4} mm of mercury. A study of the decomposition of methane in the negative glow of a d-c. discharge (3) has shown that under comparable conditions the products are very similar to those reported here. In the discharge experiments, which could be carried to higher con-

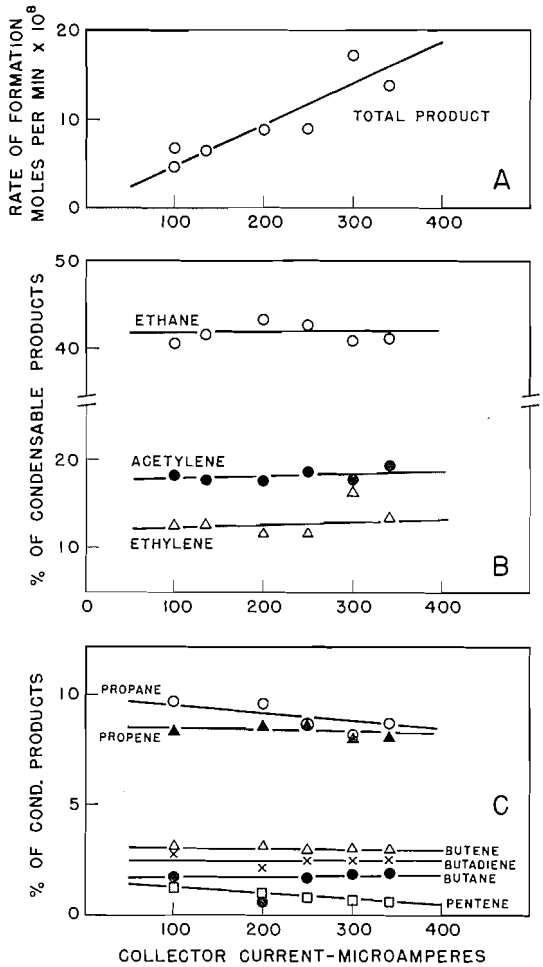

FIG. 5. Variation of products with collector current.

versions and in which the gas could be sampled at much higher pressures, analysis of the reacted gas showed that the theoretical amount of hydrogen was in fact produced.

The experimental conditions made it difficult to study the effect of the reaction products on the over-all reaction, except for hydrogen. Experiments with up to 10% hydrogen in the methane showed no significant change in either the percentage composition or the rate of formation of the products. Similarly, in an experiment with 2% of deuterium in the methane, no deuteration of the products was detected.

The values of the methane pressure given throughout this report are those measured on the calibrated Pirani gauge. The true pressures in the reaction zone were undoubtedly somewhat lower than the measured values due to the existence of a small pressure gradient. In addition, it was difficult to fit the brass cone on the final collimator reproducibly into the end of the glass tube surrounding the reaction zone. Since it was necessary to disturb the alignment of the cone each time the filament was replaced (about once in 10 runs), each filament had associated with it a different pressure gradient and hence a different relationship between the measured value of the pressure and the true value.

The experimental points in each figure were obtained using a single setting of the collimator but the values of the pressure given in different figures are not directly comparable. From a comparison of the results obtained with a number of different collimator settings we believe that all of the values of the pressure given agree with the true value within a factor of 2.

In general the results show a considerable amount of scatter due to the small amount of product formed and the uncertainties involved in working out the composition from the mass spectrum of such a complex mixture. Straight lines have been drawn through the points in all cases for the purpose of indicating trends.

In two cases there is some ambiguity in the identification of the products. The mass spectra provide some evidence that the substance appearing at $m/e = 42$ may consist of cyclopropane as well as propene. Because of the overlapping of the spectra and the small amounts involved it was not possible to distinguish quantitatively between these two compounds and in reporting the experimental results this product has simply been called propene. Similarly, the product appearing at $m/e = 54$ could, on the basis of the mass spectra, be either butadiene or butyne. Because propyne, for which there was qualitative evidence but which could not be determined accurately, was present only in smaller amounts, this compound has been designated butadiene.

DISCUSSION

The results in Fig. 3A indicate that the rate of formation of products varies only slightly with electron energy from 100 v to within a few volts of the ionization potential of methane. If the products were formed mainly by a process depending on the formation of ions, it would be expected that the rate of formation would fall off rapidly below about 50 ev in accordance with Tozer's values (5) for the ionization cross section of methane. Thus, although ions are undoubtedly formed, there seems to be no evidence that they play an important role in the formation of the products.

This conclusion is in agreement with that of Williams (6), who has studied the decomposition of methane using photoelectrons which are accelerated through the gas. Although the work he reports was carried out at much higher pressures and in the presence of an electric field, the products he obtained are similar to those obtained in this work. The absence of unsaturated hydrocarbons among his reaction products seems reasonable since his experiments were carried out in a static system for relatively long periods at room temperature. Thus, the more reactive unsaturated hydrocarbons which might have formed initially could have reacted to form saturated hydrocarbons or polymers. Since in this work the products were trapped within a few mean free paths of the reaction zone it is evident that they were removed from the reaction at a much earlier stage.

Although their work is not entirely comparable it is interesting to note that recently Yang and Manno (7), using nitric oxide as an inhibitor, have determined the free radical contribution to the various products formed in the γ-radiolysis of methane. They estimated the free radical contribution to the formation of ethane, propane, butane, and pentene, which together make up nearly all of their hydrocarbon products and which constitute most of ours, to be 85% or greater.

Figure 4A shows that the quantity of product increases linearly with methane pressure. Although the composition of the product changes as the pressure is raised the changes, to a large extent, offset the effect of one another on the carbon balance. Thus, the amount of methane decomposed is approximately proportional to the pressure over the range studied.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The experiments recorded in Fig. 5A indicate that the amount of product formed is directly proportional to the electron current. Since the composition of the product changes little over the range of currents studied, the products apparently arise in each case as the result of a single collision of an electron with a methane molecule. Secondary collisions between the product molecules and other electrons do not appear to play an important part.

If the electron efficiency is defined as the number of molecules of methane decomposed per electronic charge passed through the system, then our results yield a value of 1.8 for 50 ev electrons and a methane pressure of 5×10^{-3} mm. This assumes that all of the methane decomposed is recovered as volatile hydrocarbon products; if additional involatile products are formed, the electron efficiency would be correspondingly greater. Experiments utilizing the negative glow of a d-c. discharge under comparable conditions have led to electron efficiencies of about 10 (2, 3). The difference in the values seems reasonable since the discharge experiments were carried out at higher pressures and our results show that the electron efficiency increases with pressure. In addition, the electron multiplication and recombination which occur in a discharge would tend to increase the value of the electron efficiency as calculated on the above basis. Williams (6) has reported values of the electron efficiency which vary with pressure and with the voltage gradient and which lie within the range 0 to 10.

Because the products do not appear to depend to any large extent on ions for their formation, the discussion of mechanism will be limited to a consideration of the manner in which the products might be formed by free radical processes. A further restriction upon the possible reactions to be considered is imposed by the low temperature at which the experiments were carried out. This restricts the reactions to those having very low activation energies or those involving excited species.

The chemical effects of the high-energy irradiation of methane have been attributed largely to the action of secondary electrons having energies of the same order as the electrons used in this work (8). Thus it seems reasonable to expect that free radicals which have been detected in the radiolysis of methane may also play a part in the decomposition of methane under the conditions of our experiments. Gevantman and Williams (9), using iodine as a free radical scavenger, concluded that methyl, methylene, and ethyl radicals were important in the decomposition of methane by high-energy X rays and electrons. More recently, Meisels, Hamill, and Williams (10) studied the irradiation of methane in mixtures with argon and krypton and concluded that methyl and ethyl radicals and ethylene were significant intermediates. Because no ketene was formed in the radiolysis of mixtures of argon, methane, and carbon monoxide, they concluded that CH_2 was not formed.

There is also a great similarity between the results reported here for the decomposition of methane in a beam of electrons and the decomposition of methane in an electric discharge. This is especially true for the negative glow of a d-c. discharge when small currents are used and the discharge tube is cooled to low temperatures. Under these conditions the products are almost identical with those reported here (2, 3). Jen, Foner, Cochran, and Bowers (11), using electron spin resonance, have detected methyl radicals in the products of a low-power discharge in methane when the products were frozen out rapidly at 4.2° K. Under conditions of high-power input and high conversion, as used by Wiener and Burton (12), the main hydrocarbon product of the discharge decomposition of methane is acetylene. In their work they consider that both methyl and methylene radicals contribute to the over-all reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

In view of the above evidence and our experimental results it seems reasonable to assume that in our experiments methane decomposes according to reaction 1. The main product, ethane, would then be formed by reaction 2 which may occur to a large extent on the wall.

$$CH_4 \xrightarrow{e} CH_3 + H \quad [1]$$

$$2CH_3 \longrightarrow C_2H_6 \quad [2]$$

It would be difficult, however, to account for the complex product obtained solely on the basis of the reactions of methyl radicals, even allowing for the possible subsequent formation of other saturated radicals. During the last few years a considerable amount of chemical evidence has been obtained for the existence of excited methylene radicals (13) and recently the existence of the methylene radical in an excited state has been confirmed spectroscopically (14). Burton and Magee (15) have suggested that excited methylene radicals play an important part in the discharge decomposition of methane.

The data in Figs. 4A and 5A indicate that the rate of decomposition of methane increases linearly with both current and pressure, presumably due to the increase in the number of collisions between electrons and methane molecules. However, the amounts of ethylene and acetylene formed increase more rapidly with pressure than that of ethane, whereas the relative amounts of these products do not change with increasing current. This can be accounted for by assuming that, in addition to reaction 1, methane can decompose to yield another species which is capable of reacting with methane at the low temperature of the experiment. Thus, a reaction such as reaction 3 is indicated, where * designates an excited species. This would then be followed by reactions such as 4, 5, 6, and 7. Reaction 6 may occur to a large extent on the wall.

$$CH_4 \xrightarrow{e} CH_2^* + H_2 \quad [3]$$

$$CH_2^* + CH_4 \longrightarrow [C_2H_6]^* \quad [4]$$

$$[C_2H_6]^* \longrightarrow C_2H_4^* + H_2 \quad [5]$$

$$C_2H_4^* \xrightarrow{M} C_2H_4 \quad [6]$$

$$C_2H_4^* \longrightarrow C_2H_2 + H_2 \quad [7]$$

It has been reported (16) that energy-rich ethylene molecules may stabilize by deactivation as in reaction 6 or by decomposition as in reaction 7. If the excited state of ethylene involved in this work is different from that encountered in the mercury-photosensitized decomposition, it is possible that reactions 5 and 7 may involve as intermediates ethyl and vinyl radicals, with the resulting formation of hydrogen atoms. From the fact that the experiments with methane containing up to 10% hydrogen showed no appreciable change in the products, it seems probable that hydrogen atoms do not play a major part in the over-all reaction scheme.

Assuming that most of the methyl radicals combine to form ethane as in reaction 2, it follows that the rate of formation of ethane should increase linearly with both pressure and current, which is approximately the case. The rates of formation of ethylene and acetylene should increase linearly with current but, because of the dependence of reaction 4 on methane concentration, should increase more rapidly than that of ethane as the methane pressure is increased.

The increase in the rate of formation of acetylene, at the apparent expense of ethylene, with increasing electron energy (Fig. 3B) might be explained on the basis of the inter-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

dependence of reactions 6 and 7. If the energy imparted to the methylene radical increases as the electron energy is increased this might result in an ethylene molecule possessing increasing amounts of energy and therefore in an increase in the rate of its decomposition (reaction 7) at the expense of deactivation (reaction 6).

Although the over-all extent of methane decomposition is small, most of the decomposition occurs within the electron beam giving locally a relatively high concentration of radicals and product molecules. As a result, radical–radical and radical–product reactions might be expected to occur. There is thus the possibility of forming other radicals by reactions such as 8 and 9.

$$CH_2^* + CH_3 \longrightarrow C_2H_5^* \quad [8]$$

$$C_2H_5^* \longrightarrow C_2H_3 + H_2 \quad [9]$$

The formation of the hydrocarbons of higher molecular weight may be accounted for in a general way as being due to further reactions of the free radicals present. Some of them may arise by simple radical combination reactions such as 10 and 11.

$$CH_3 + C_2H_5 \longrightarrow C_3H_8 \quad [10]$$

$$2C_2H_5 \longrightarrow C_4H_{10} \quad [11]$$

Others may be formed by reactions between radicals and product molecules. Vanpee and Grard (17) have suggested that higher hydrocarbons can be formed stepwise by reactions like 12 and 13.

$$CH_2 + C_2H_4 \longrightarrow C_3H_6 \quad [12]$$

$$CH_2 + C_2H_6 \longrightarrow C_3H_8 \quad [13]$$

Their suggestion has been confirmed by much recent work (13, 18). In addition, Gordon and McNesby (19) have shown that the polymerization of ethylene by methyl radicals results in the formation of many of the higher hydrocarbons found here.

One of the higher products, butadiene, seems to deserve individual consideration. The curves giving the variation in the percentage of this compound are not consistent with those of the other C_4 hydrocarbons but instead parallel those of acetylene. There is thus evidence that butadiene is formed by some species associated with the formation of acetylene. One possibility is given by reaction 14.

$$2C_2H_3 \longrightarrow C_4H_6 \quad [14]$$

The narrow limits within which the experiments could be carried out and the large amount of scatter in the experimental points make it difficult to arrive at a definite mechanism for the formation of most of the C_3 and C_4 products. The reactions occurring may involve highly excited species and therefore may not be comparable with the work referred to in the preceding paragraphs. Nevertheless, it seems to follow from Fig. 4 that the slopes of the lines representing the saturated hydrocarbon products are similar to one another, and that the olefins behave as another group. It is tempting to relate this to a stepwise process for the formation of the higher hydrocarbons as suggested by Vanpee and Grard (17).

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. R. J. Cvetanović for several helpful discussions, to Mr. S. Tong for assistance with the experimental work, and to Mr. R. Sander, who carried out the mass spectrometer analyses.

THE CELL WALL POLYSACCHARIDES OF CANDIDA ALBICANS: GLUCAN, MANNAN, AND CHITIN[1]

C. T. BISHOP, F. BLANK,[2] AND P. E. GARDNER[3]

ABSTRACT

Cells of *Candida albicans*, a pathogenic yeast, have been shown to contain, in addition to chitin, a glucan ($[\alpha]_D$ −30°) and a mannan ($[\alpha]_D$ +78°) in the approximate ratio of 1.00:0.64. The two polysaccharides were easily distinguishable by moving boundary electrophoresis in borate buffer and were separated from each other by fractionation of their copper complexes. Methylation and hydrolysis of the glucan yielded the following *O*-methyl ethers of D-glucose: 2,3,4,6-tetra-*O*-methyl (7 moles); 2,3,4-tri-*O*-methyl (13 moles); 2,4,6-tri-*O*-methyl (trace); 2,4-di-*O*-methyl (6 moles); and 2-*O*-methyl (1 mole). It was concluded that the glucan was a highly branched polysaccharide containing $\beta\,1 \rightarrow 6$ and $\beta\,1 \rightarrow 3$ linked residues. Periodate oxidation of the glucan supported this conclusion.

Methylation and hydrolysis of the mannan yielded the following *O*-methyl ethers of D-mannose: 2,3,4,6-tetra-*O*-methyl (1.65 moles); 3,4,6-tri-*O*-methyl (1.00 mole); 2,3,6-tri-*O*-methyl (0.18 mole); 3,4-di-*O*-methyl (1.90 moles). The mannan was therefore a highly branched polysaccharide with short chains of $\alpha\,1 \rightarrow 2$ linked mannose residues joined together by $\alpha\,1 \rightarrow 6$ linkages. Results of periodate oxidation agreed with this structure.

The differences between these two polysaccharides and glucans and mannans found in other yeasts are discussed.

Structural investigations of polysaccharide components of yeasts have been limited, with only one exception, to those in bakers' yeast (*Saccharomyces cerevisiae*) and there are a number of reports dealing with the glucan (1–4) and mannan (5–7) that occur in this species. The only report dealing with structures of polysaccharides from other yeast species appears to be that by Gorin and Perlin (8) which described a mannan produced by *Saccharomyces rouxii*. There have been other publications on the composition of cell walls of yeasts (9–18) and some of these (13–18) have dealt with species other than *Saccharomyces cerevisiae*. However, these papers were concerned primarily with examination of fractions of yeast cell walls by X-ray diffraction, electrophoresis, and chromatography of hydrolyzates; structures of polysaccharides were not investigated and constituent sugars were identified only by paper chromatography. The identification of D-arabinose as a constituent of polysaccharides found in *Nocardia asteroides* (19) and *Mycobacterium tuberculosis* (20) has shown that sugars can occur in unusual configurations in microorganisms. For this reason the distinction of enantiomorphic forms of naturally occurring sugars is of considerable significance and such distinction cannot be made by paper chromatography. It was therefore of interest to examine the polysaccharides of another species of yeast, *C. albicans*, to see if they differed in structure or constituent sugars from the polysaccharides of bakers' yeast. In addition to this a report that the polysaccharides of *C. albicans*, a pathogenic yeast, are serologically active (21) indicated that elucidation of their structures could be of immunological significance.

Isolation of Glucan and Mannan from C. albicans

Crude polysaccharides were isolated from powdered cells of *C. albicans* by the procedure given in the Experimental section. The product contained no nitrogen and hence was free from any proteinaceous material. Examination of this crude preparation by moving

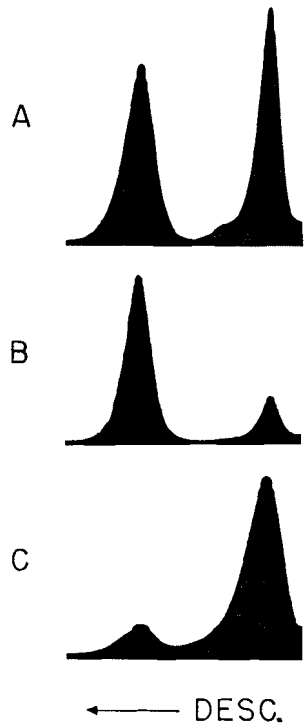

FIG. 1. Moving boundary electrophoresis of (A) crude polysaccharides, (B) mannan + trace of glucan, (C) glucan + trace of mannan.

boundary electrophoresis in borate buffer gave the separation pattern shown in Fig. 1A. The result clearly indicated two components; these were present in an approximate ratio of 0.61–0.67:1.00. Hydrolysis and chromatography of the crude polysaccharide preparation revealed the presence of mannose and glucose in a molar ratio of 0.50:1.00. The reasonable agreement between this ratio and the ratio of the two components found by electrophoresis indicated that these two components were a glucan and a mannan. This conclusion was confirmed by the isolation of a glucan and a mannan by fractionation with Fehling's solution. Fractions in which each polysaccharide still contained traces of the other were used to identify the two peaks in the electrophoretic separation. Figure 1B is the electrophoretic pattern given by the mannan-rich fraction and Fig. 1C is that given by the glucan-rich fraction. All three separations shown in Fig. 1 were photographed after the same time interval; the results show clearly that the component of greater mobility was the mannan, and the one with lower mobility the glucan. Electrophoretic mobilities of the two components were the same after fractionation as before, an indication that the separation procedure had not altered the polysaccharides.

Isolation of a glucan and a mannan from *C. albicans* has not been reported before. Jonsen *et al.* (15) isolated a polysaccharide preparation from the same organism and identified glucose and mannose by paper chromatography after hydrolysis. However, these authors obtained a single peak on electrophoresis of the polysaccharide in acetate buffer and accepted this as indicative of homogeneity. Polysaccharides, unless they contain acidic groups, would be expected to have very similar mass:charge ratios and hence would not be separable by electrophoresis in acetate buffer. The electrophoretic

For personal use only.

separations reported in the present communication depended on the polysaccharides being complexed to different extents with borate (22) thereby acquiring different mass: charge ratios which permitted their separation. More recently Kessler and Nickerson (18) have reported the isolation of glucomannan–protein and glucan–protein complexes from three strains of *C. albicans*. However, the fractionation procedure used, alkali extraction and ammonium sulphate precipitation, was not designed to separate the polysaccharides nor was any criterion of homogeneity of the fractions reported. It is very likely, in view of the present work, that the glucomannans reported (15, 18) in *C. albicans* were mixtures of a glucan and mannan.

The glucan and mannan found in *Saccharomyces cerevisiae* have been established as components of the cell wall (9); this is also thought to be true for the glucan and mannan from *C. albicans* because an isolated cell wall preparation yielded glucose and mannose on hydrolysis.

A small amount of chitin was isolated from the cell wall of *C. albicans* and identified by X-ray diffraction. These results agree with those of other workers (12, 13, 14) who have reported the presence of chitin in small and variable amounts in the cell walls of a number of yeast species, including *C. albicans*.

Glucan from C. albicans

The glucan gave a number average degree of polymerization of 30 ± 2. On acid hydrolysis it yielded D-glucose, characterized as the *p*-nitroanilide and by specific rotation, as the only detectable sugar. Its negative rotation ($[\alpha]_D$ $-30°$) indicated that a high proportion of β-glycosidic bonds were present and its stability to hot dilute oxalic acid showed that furanose ring forms were absent.

When oxidized by periodate the glucan consumed 1.60 moles of oxidant and yielded 0.72 mole of formic acid per mole anhydroglucose. The latter value indicated that about 70% of the D-glucose units were non-reducing terminal units or were joined to adjacent units by $1 \rightarrow 6$ linkages. The very small amount of oxidant not accounted for by formic acid production indicated that most, if not all, of the remaining 28% of glucose units were substituted so that they were resistant to oxidation by periodate. This conclusion was confirmed by reduction and hydrolysis of the periodate-oxidized polysaccharide (23) which yielded glycerol and glucose as the only products detectable by paper chromatography. The glycerol arose from C_4, C_5, and C_6 of those glucose units which were terminal or 1,6-disubstituted and the glucose represented those units in the glucan that were not oxidized. No erythritol could be found in the hydrolyzate of the oxidized, reduced polysaccharide and therefore no $1 \rightarrow 4$ linkages were present in the glucan (23). The above results showed that in the glucan 72% of the glucose units were non-reducing terminal units or were joined by $1 \rightarrow 6$ linkages, the remainder being $1 \rightarrow 3$ linked or highly substituted in a branched structure.

The glucan was methylated and hydrolyzed to give the methyl ethers listed in Table I.

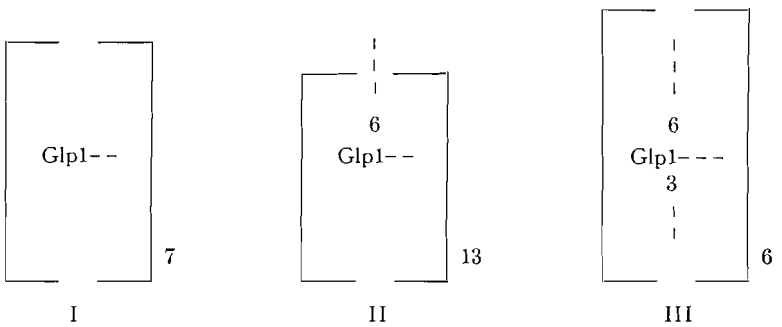

TABLE I

Hydrolysis products of methylated glucan

2,3,4,6-Tetra-*O*-methyl-D-glucose	(7 moles)
2,3,4-Tri-*O*-methyl-D-glucose	(13 moles)
2,4,6-Tri-*O*-methyl-D-glucose	(Trace)
2,4-Di-*O*-methyl-D-glucose	(6 moles)
2-*O*-Methyl-D-glucose	(1 mole)

The main products shown here must have arisen from the following structural units in the polysaccharide:

Thus 2,3,4,6-tetra-*O*-methyl-D-glucose represented non-reducing terminal units substituted only in position 1 (I); 2,3,4-tri-*O*-methyl-D-glucose came from units that were joined through positions 1 and 6 (II); 2,4-di-*O*-methyl-D-glucose arose from units that were linked through positions 1, 3, and 6 (III). The significance of the 2,4,6-tri-*O*-methyl-D-glucose and the 2-*O*-methyl-D-glucose is difficult to assess because of the small amounts found and because the methylated glucan, methylated to constant methoxyl and showing no hydroxyl absorption in the infrared, still contained only 40.5% methoxyl (calc. 45.6%). It is possible that the polysaccharide contained an impurity other than protein (e.g. lipid) which caused this low methoxyl. A glucan, containing the above three structural units in the amounts indicated, would consume 1.54 moles of periodate per mole anhydroglucose with production of 0.77 mole of formic acid per mole anhydroglucose. These are in good agreement with the values of 1.60 and 0.72 that were found for periodate consumption and formic acid production respectively in the purified glucan. If there was an impurity in the glucan which caused the low methoxyl then it must have consumed periodate, otherwise these values would be lower than theoretical. The results of the methylation study therefore confirmed the conclusions based on periodate oxidation and showed clearly that the glucan from *C. albicans* was a highly branched polysaccharide formed from β 1 $\rightarrow$ 6 and β 1 $\rightarrow$ 3 linked glucose residues. This structure is quite different from those proposed by various workers (1, 2, 3, 4) for the glucan from *Saccharomyces cerevisiae*. Hassid *et al.* (1) found 2,4,6-tri-*O*-methyl-D-glucose as the only product from methylation and hydrolysis of that glucan and therefore proposed a straight chain, β 1 $\rightarrow$ 3 linked structure. On the other hand, Bell and Northcote (2) reported similar experiments in which the products from methylation and hydrolysis showed that the glucan was branched with chains of β 1 $\rightarrow$ 3 linked units being joined by 1 $\rightarrow$ 2 interchain links. Peat *et al.* (3) have shown by fragmentation analysis that the glucan from *Saccharomyces cerevisiae* was a linear polysaccharide formed by β 1 $\rightarrow$ 3 and β 1 $\rightarrow$ 6 glycosidic linkages. A succeeding report (4) showed that some 10–20% of the linkages were β 1 $\rightarrow$ 6. The glucan from *C. albicans* differs from these three structures reported for the glucan from *Saccharomyces cerevisiae* in being much more highly branched and having a preponderance (73%) of β 1 $\rightarrow$ 6 linkages.

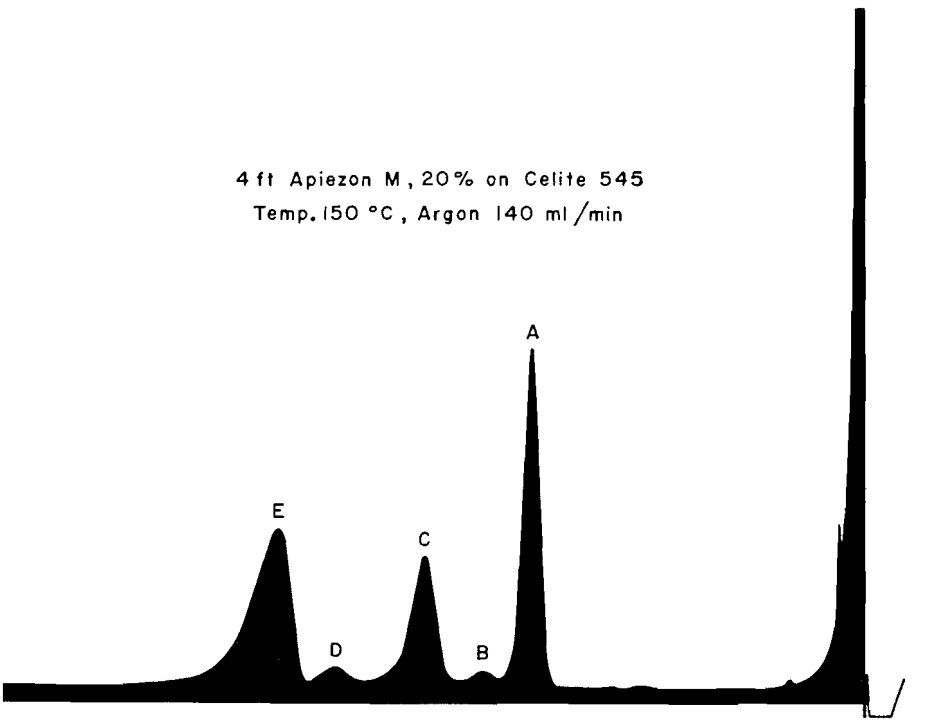
Mannan from C. albicans

The mannan showed a number average degree of polymerization of 41$\pm$2 and had a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

specific rotation of $+78°\pm2°$. Mannose was the only sugar detectable by paper chromatography and electrophoresis after acid hydrolysis and it was proved to be D-mannose by the specific rotation ($+13°\pm2°$) and by isolation of its crystalline phenylhydrazone. The decrease in rotation after hydrolysis indicated that α-glycosidic bonds were predominant. The mannan was stable to hot, dilute oxalic acid showing that no furanose ring forms were present.

On methylation and hydrolysis the mannan yielded the components shown in Fig. 2.



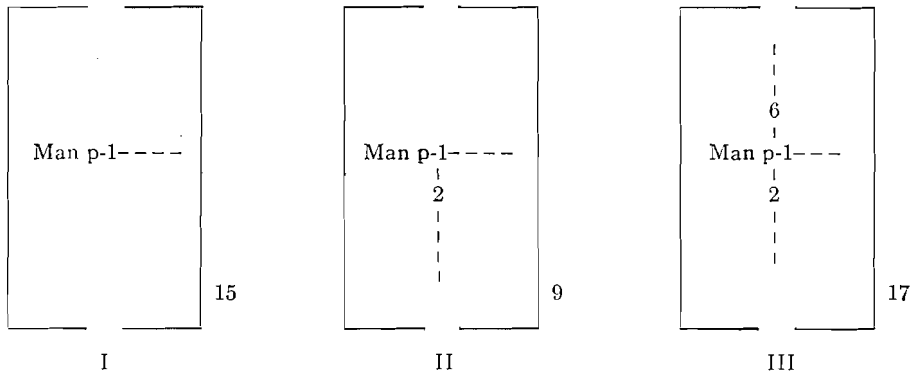


FIG. 2. Separation of methanolysis products from methylated mannan by gas–liquid partition chromatography.

		Molar ratio
(A)	Methyl-2,3,4,6-tetra-*O*-methyl-α-D-mannopyranoside	1.65
(B)	Unknown	0.13
(C)	Methyl-3,4,6-tri-*O*-methyl-α-D-mannopyranoside	1.00
(D)	Methyl-2,3,6-tri-*O*-methyl-α-D-mannopyranoside	0.18
(E)	Methyl-3,4-di-*O*-methyl-α-D-mannopyranoside	1.90

This is a reproduction of the separation curve from gas–liquid partition chromatography of the methanolysis products from the methylated mannan. This technique was developed only recently (24, 25) and was not available for use when the glucan from *C. albicans* was being investigated. Components A, C, and E were identified by isolation of crystalline derivatives and represented the main structural units of the mannan. The quantities of components B and D were too small to permit unequivocal identifications but component D was identical on gas–liquid partition chromatograms with an authentic sample of methyl-2,3,6-tri-*O*-methyl-α-D-mannopyranoside. The main structural features of the mannan could therefore be represented by the following units.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Thus components A, C, and E in Fig. 2 represented structural units I, II, and III respectively. The significance of components B and D in Fig. 4 is uncertain because of the possibility that they were products of incomplete methylation or of demethylation on hydrolysis. The amount of non-reducing terminal end groups (I) is slightly less than required to account for the branch points (III). A loss of 13% of the 2,3,4,6-tetra-*O*-methyl-D-mannose during evaporations of the formic acid hydrolyzate could account for this. It is possible that such discrepancies have not been detected previously because of the lack of accurate quantitative data as supplied by gas–liquid partition chromatography. A polysaccharide composed of structural units I, II, and III should consume 1.37 moles of periodate per mole anhydromannose with production of 0.37 mole of formic acid per mole anhydromannose. The values actually found, 1.13 and 0.27 moles per mole anhydromannose, respectively, were slightly lower and could have been caused by an impurity present in the mannan during periodate oxidation but removed during methylation, or again could be a result of greater accuracy of the gas–liquid partition chromatography data as compared with the periodate oxidation data. After periodate oxidation the resulting polyaldehyde was reduced and hydrolyzed (23). Glycerol was the only polyol detectable in the hydrolyzate, in agreement with the finding from methylation that only $1 \rightarrow 2$ and $1 \rightarrow 6$ bonds were present. It was clear from the foregoing data that the mannan possessed a highly branched structure in which relatively short chains of $\alpha\, 1 \rightarrow 2$ linked mannose units were joined together by $\alpha\, 1 \rightarrow 6$ linkages. The mannan from *C. albicans* is therefore somewhat different from the mannan isolated from bakers' yeast (*Saccharomyces cerevisiae*) (5, 6, 7) and more closely resembles that found in *Saccharomyces rouxii* (8). All of these mannans exhibited high positive specific rotations, which indicated the presence of α-glycosidic linkages, and this has been confirmed unequivocally (8) for the $1 \rightarrow 2$ linkage in the mannan from *Saccharomyces rouxii*. The difference lies in the tri-*O*-methyl-D-mannoses found after hydrolysis of the methylated mannans. The methylated mannans from bakers' yeast (5, 6, 7) yielded equimolar amounts of 2,4,6- and 3,4,6-tri-*O*-methyl-D-mannose indicative of an equal number of $1 \rightarrow 3$ and $1 \rightarrow 2$ linkages in the unbranched portion of the polysaccharide. On the other hand, the methylated mannan from *Saccharomyces rouxii* (8) yielded 2,4,6- and 3,4,6-tri-*O*-methyl-D-mannose in a ratio of 2:7 indicating that $1 \rightarrow 2$ linkages predominated over $1 \rightarrow 3$. The mannan from *C. albicans* yielded no 2,4,6-tri-*O*-methyl-D-mannose after methylation and hydrolysis and therefore could not have contained any $1 \rightarrow 3$ linkages. This conclusion was substantiated by the absence of mannose in the hydrolyzate of the periodate-oxidized mannan because any $1 \rightarrow 3$ linked mannose residues would have survived the oxidation. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

absence of 1 → 3 linkages and the high degree of branching constitute the main differences between the mannan from *C. albicans* and those so far examined from other yeasts.

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v ratio):

(A) butan-1-ol:pyridine:water, 6:4:3;
(B) butan-1-ol:ethanol:water, 9:3:3;
(C) 2-butanone:water, azeotrope.

Paper electrophoreses were done on Whatman 3 MM paper in 0.1 *M* borate buffer (22) using a potential gradient of 25 v/cm for 1 hour. Sugars were detected on chromatograms and electrophorograms by the *p*-anisidine hydrochloride spray reagent (26). Non-reducing compounds were detected on chromatograms by silver nitrate : sodium hydroxide sprays (27). Moving boundary electrophoreses were carried out in 0.05 *M* borate buffer in a Tiselius-type, Spinco Model H apparatus. Evaporations were carried out under diminished pressure at 35° C or less on a rotary film evaporator. Melting points are corrected and specific rotations are equilibrium values unless stated otherwise.

Isolation of Crude Polysaccharides

C. albicans was cultured in a liquid medium containing the following nutrients: 4% cerelose (crude glucose), 2% neopeptone "Difco", 0.05% yeast extract, 0.001% thiamin, 0.005% inositol. After incubation at 37° C for 5–12 days the cultures were autoclaved at 121° C for 20 minutes; cells were then separated in a continuous centrifuge, freeze-dried, and ground in a ball mill for 16 hours. Extraction with petroleum ether (30–60° C) removed lipid, and digestion with trypsin destroyed protein. The residue from these two treatments was then extracted with boiling 3% aqueous sodium hydroxide to solubilize the polysaccharides, which were freed from low molecular weight impurities by dialysis and precipitation with ethanol. The polysaccharide preparation thus obtained (6.3% of the dried, powdered cells) was a light tan powder which contained no nitrogen as shown by microanalysis. A sample of this material was hydrolyzed by *N* hydrochloric acid at 97° C in a sealed tube for 16 hours. Paper chromatography (solvent A) and paper electrophoresis of the hydrolyzate showed two components which were identical with samples of glucose and mannose run on the same paper strips. Another sample (150 mg) of the polysaccharide preparation was dissolved in 0.05 *M* sodium tetraborate, equilibrated with the buffer by dialysis, and examined by moving boundary electrophoresis. Figure 1A shows the complete separation of two components that was obtained by this procedure. The electrophoretic mobilities (μ) of these two components were respectively 4.38 and 9.34×10^{-5} cm^2 v^{-1} sec^{-1}. Areas under the two peaks were measured from diagrams obtained at two different times and gave ratios of the two components of 0.61:1.00 and 0.67:1.00. The molar ratio of mannose to glucose in the hydrolyzate of the polysaccharide mixture was 0.50:1.00 as determined by the densitometer method of Martin (28).

Separation of Glucan and Mannan

The crude polysaccharides (8.0 g) were stirred vigorously in water (1200 ml) for 3 hours. Insoluble material was removed by centrifugation and dried by solvent exchange with ethanol and ether (yield, 0.9 g). Paper electrophoresis of a hydrolyzate of a sample from this fraction showed that glucose was the only component sugar present. Hydrolysis and paper electrophoresis of the material in solution showed the presence of both glucose and mannose. An attempt was made to separate the mixture of polysaccharides in aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

solution by fractional precipitation with ethanol (29) but the fractions obtained showed no variation in glucose and mannose composition. These fractions were therefore combined, redissolved in water, and the polysaccharides were precipitated as copper complexes by addition of Fehling's solution. This method was used successfully by Haworth *et al.* (5) to isolate a mannan from bakers' yeast. The precipitated copper complex was washed repeatedly with water and at the sixth washing the precipitate dissolved. This solution was poured into 5 volumes of 10% methanolic hydrogen chloride to precipitate the polysaccharide which was dried by solvent exchange with ethanol and ether (yield, 2.13 g). Paper electrophoresis of a hydrolyzate of a sample from this fraction showed that mannose was the only component sugar present. The washings from the precipitated copper complex were combined and the polysaccharides were recovered by precipitation with acidified ethanol. This material was then recomplexed with copper and washed with water in the same way as before. Four repetitions of this procedure yielded two more polysaccharide fractions, one yielding mainly mannose but with a trace of glucose on hydrolysis and the other yielding mainly glucose with a trace of mannose. To preserve the chemically pure glucan and mannan for structural studies these impure fractions were used to determine the identities of the two peaks found in electrophoresis. The electrophoretic diagram shown in Fig. 1B is that given by the fraction yielding mainly mannose on hydrolysis but with a trace of glucose. Figure 1C shows the electrophoretic pattern given by the fraction yielding glucose on hydrolysis with only a trace of mannose. Fractionation in the same way of another 6.0 g of crude polysaccharides provided further quantities of pure glucan (0.60 g) and mannan (1.5 g).

Properties of Purified Glucan and Mannan

Glucan

This polysaccharide had $[\alpha]_D^{26} = -30° \pm 2°$ (*c*, 1.0% in *N* sodium hydroxide) changing to $[\alpha]_D^{26} = +53° \pm 2°$ (*c*, 2.0% in *N* hydrochloric acid) after hydrolysis in *N* hydrochloric acid at 97° C for 16 hours. The hydrolyzate was neutralized (Amberlite IR-45 ion exchange resin), evaporated to dryness, and the residue was heated with *p*-nitroaniline in methanol solution for 40 minutes. The solution was cooled and the crystals which separated were recrystallized from methanol to yield *N*-*p*-nitrophenyl-D-glucopyranosylamine dihydrate (30), m.p. 183–184° C, $[\alpha]_D^{25} = -199° \pm 1°$ (*c*, 1.0% in pyridine). Attempted partial hydrolysis of the glucan by 0.025 *N* oxalic acid at 97° C for 3 hours released no cleavage products detectable by paper chromatography. The degree of polymerization of the glucan was 30 ± 2 as determined by hypoiodite oxidation of the reducing end group in phosphate buffer (31).

Mannan

This polysaccharide had $[\alpha]_D^{26} = +78 \pm 2°$ (*c*, 1.1% in water) changing to $[\alpha]_D^{26} = +13° \pm 2°$ (*c*, 2.0% in *N* hydrochloric acid) after hydrolysis in *N* hydrochloric acid at 97° C for 16 hours. The hydrolyzate was neutralized (Amberlite IR-45 ion exchange resin), mixed with an equal volume of an aqueous solution of phenylhydrazine acetate, and allowed to stand at 25° C for 20 hours. The crystals which formed were recrystallized twice from water:ethanol to yield mannose phenylhydrazone (32), m.p. 198–199° C (d), $[\alpha]_D^{24} = +25° \pm 2°$ (*c*, 1.0% in pyridine). Like the glucan, the mannan showed no evidence of partial hydrolysis when heated with 0.025 *N* oxalic acid at 97° C for 3 hours. The degree of polymerization of the mannan, estimated in the same way as for the glucan, was 41 ± 2.

Periodate Oxidations

The glucan (111.2 mg, 0.66 mmole) and mannan (122.3 mg, 0.75 mmole) were dissolved separately in water (125 ml) and 0.25 *M* sodium periodate (25 ml) was added to each. Reagent blanks were also prepared and oxidations were carried out at 25° C in the absence of light. At the intervals noted below samples were removed for estimation of formic acid and periodate. For estimation of formic acid the excess periodate in a 10-ml aliquot was destroyed by 2,3-butanediol, a few crystals of potassium iodide were added and the liberated iodine was titrated to a starch end point with 0.01 *N* thiosulphate. For periodate estimations (33, 34) sodium bicarbonate (1.7 g), 0.1 *N* sodium arsenite (5 ml), and a few crystals of potassium iodide were added to 10-ml aliquots from the oxidations. The solutions were stored in the dark for 30 minutes and were then titrated with 0.022 *N* iodine solution to a starch end point. The results, given in moles per anhydrohexose unit were as follows:

Time, hours	Glucan		Mannan	
	Formic	Periodate	Formic	Periodate
24	0.68	1.60	0.21	1.10
44	0.71	1.58	0.26	1.10
70	0.72	1.61	0.27	1.13

After the oxidations were complete excess periodate was destroyed by 2,3-butanediol and salts and acetaldehyde were removed by dialysis. The oxidized polysaccharides were then reduced by potassium borohydride, hydrolyzed by *N* hydrochloric acid at 97° C for 3 hours and the hydrolyzates were examined by paper chromatography (solvent B, silver nitrate : sodium hydroxide sprays) (23). By this sequence of reactions the glucan yielded glycerol and glucose while the mannan gave only glycerol. Erythritol was not found in either hydrolyzate.

Methylation of Glucan and Mannan

Glucan

The glucan (893 mg) was methylated five times for 24 hours in 30% sodium hydroxide (20 ml) and dimethyl sulphate (10 ml). The product was isolated by extraction into chloroform and was treated for 24 hours in that solvent (10 ml) with methyl iodide (6 ml) and silver oxide (3.0 g). After three further methylations with methyl iodide and silver oxide, the methylated polysaccharide was precipitated as a white powder (1.0 g, methoxyl = 40.5%) from chloroform solution by addition of petroleum ether (30–60° C). The methoxyl content of this product was not increased by another methylation and an infrared spectrum showed only a trace of hydroxyl absorption. The powdery product was extracted with petroleum ether and then successively with petroleum ether containing increasing amounts of chloroform. All fractions showed identical hydrolysis products on paper chromatograms and the main portion of the product dissolved in petroleum ether : chloroform mixtures of 6:4, 5:5, and 4:6. These three fractions were combined and reprecipitated to give a white powder (660 mg, methoxyl 40.5%) showing no hydroxyl absorption in the infrared.

Mannan

The mannan (2.14 g) was methylated five times with 30% sodium hydroxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

(5×100 ml) and dimethyl sulphate (5×50 ml) in the same way as described for the glucan. The product (2.29 g) showed distinct hydroxyl absorption in the infrared so it was methylated again, this time in tetrahydrofuran (30 ml) with sodium hydroxide (10 g) and dimethyl sulphate (15.5 ml) (35). The product still showed hydroxyl absorption in the infrared and had methoxyl equal to 39.7% so it was methylated again in tetrahydrofuran as before. This methylation gave a product (2.20 g) having no hydroxyl absorption in the infrared and with methoxyl equal to 40.4%, unchanged by another methylation. The methylated polysaccharide was extracted with boiling petroleum ether (30–60° C). The extract was removed by decantation and evaporated to yield an oily product (methoxyl = 29%) which was discarded. The residue from this extraction was stirred in ether and the insoluble portion was removed by centrifugation. The ethereal supernatant was evaporated to yield the methylated mannan (1.56 g, methoxyl = 43.2%), which showed no hydroxyl absorption in the infrared.

Hydrolysis Products from Methylated Glucan

The methylated glucan (650 mg) was hydrolyzed by formic acid according to the procedure described by Jones and Wilkie (36). Qualitative and quantitative (37) paper chromatography gave approximate molar ratios of the methyl ethers of glucose shown in Table I.

The mixture of methylated sugars (645 mg) was resolved on a cellulose column (2.3×28 cm) using solvent C to give four fractions. *Fraction 1* (73.5 mg) contained only 2,3,4,6-tetra-*O*-methyl-D-glucose; *fraction 2* (126.4 mg) contained 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-glucose; *fraction 3* (236.8 mg) contained 2,3,4-tri-*O*-methyl-D-glucose and a trace of 2,4,6-tri-*O*-methyl-D-glucose; *fraction 4* (126.7 mg) contained 2,4-di-*O*-methyl-D-glucose with a trace of 2-*O*-methyl-D-glucose (recovery = 563.4 mg, 87.4%). Those fractions which were mixtures were resolved further by preparative paper chromatography on Whatman 3 MM paper using solvent C, and individual components were identified as described below.

2,3,4,6-Tetra-O-methyl-D-glucose

The unknown showed the same chromatographic mobility in solvents A, B, and C as an authentic sample of 2,3,4,6-tetra-*O*-methyl-D-glucose. The product crystallized from petroleum ether (30–60° C) and was recrystallized from *N*-hexane to give a compound with a melting point of 88–89° C and $[\alpha]_D^{24} = +82° \pm 2°$ (*c*, 0.16% in water). The melting point was unchanged by admixture with an authentic sample of 2,3,4,6-tetra-*O*-methyl-D-glucose.

2,3,4-Tri-O-methyl-D-glucose

The sirupy unknown had R_g values of 0.90 and 0.75 in solvents B and C respectively. Authentic samples of tri-*O*-methyl-D-glucoses showed the following R_g values in the same solvents: 2,3,4—0.90, 0.75; 2,4,6—0.85, 0.62; 2,3,6—0.88, 0.70. The unknown (97.3 mg) was refluxed for $1\frac{1}{2}$ hours with aniline (41.0 mg) in ethanol (2 ml). The solvent was evaporated and the crystalline residue was recrystallized from ether to give a product having a melting point of 144.5–145.5° C and $[\alpha]_D^{26} = +70° \pm 1°$ (*c*, 0.83% in ethanol). Peat *et al.* (38) report a melting point of 145–146° C for *N*-phenyl-2,3,4-tri-*O*-methyl-D-glucosylamine. Mother liquors from the above crystallization yielded a product having a melting point of 137–138° C unchanged by repeated recrystallization. The analysis and infrared spectrum of this material were identical with those of the product melting at 144.5–145.5° C and it appeared to be another crystalline form of the same compound. Analysis: Calc. for $C_{15}H_{23}O_5N$: C, 60.59%; H, 7.74%. Found: C, 60.61%, H, 7.42%.

For personal use only.

*2,4,6-Tri-O-methyl-*D*-glucose*

Only a trace of this compound was present. It gave the same color reaction with *p*-anisidine hydrochloride on paper chromatograms and had the same R_g values (0.85, 0.62) in solvents B and C as an authentic sample of 2,4,6-tri-*O*-methyl-D-glucose.

*2,4-Di-O-methyl-*D*-glucose*

The unknown sample gave the same color reaction with *p*-anisidine hydrochloride on paper chromatograms as 2,4-di-*O*-methyl-D-glucose. In solvents A, B, and C it had R_g values of 0.81, 0.67, and 0.31 respectively. Authentic samples of di-*O*-methyl-D-glucoses had the following R_g values in the same solvents: 2,4—0.81, 0.67, 0.31; 2,3—0.83, 0.72, 0.36; 3,6—0.79, 0.66, 0.28. The unknown product (96.6 mg) was dissolved in ethanol (3 ml) to which *p*-nitroaniline (80 mg) and glacial acetic acid (2 drops) were added. The solution was kept at 25° C for $1\frac{1}{2}$ hours, heated on a steam bath for 2 hours and stored at room temperature overnight. A brown precipitate was filtered and washed with ethanol and ethyl acetate which removed much of the color. It was found that the light tan residue, consisting of microcrystals, could be purified by sublimation at 0.01 mm pressure at 200° C (bath temperature) to give *N*-*p*-nitrophenyl-2,4-di-*O*-methyl-D-glucosylamine, m.p. 250–251° C (*d*) (39).

*2-O-Methyl-*D*-glucose*

The unknown sample had the same R_g value (0.55) in solvent A as 2-*O*-methyl-D-glucose and gave the same color reaction with *p*-anisidine. R_g values of mono-*O*-methyl glucoses in solvent A were as follows: 2-*O*-methyl-, 0.55; 3-*O*-methyl-, 0.57; 4-*O*-methyl-, 0.51; 6-*O*-methyl-, 0.49. Attempts to isolate the compound in crystalline form or to prepare a crystalline derivative were unsuccessful because of insufficient material.

Hydrolysis Products from Methylated Mannan

The methylated mannan (1.54 g) was hydrolyzed by the formic acid procedure of Jones and Wilkie (36). A portion (100 mg) of the hydrolyzate was refluxed with 4% methanolic hydrogen chloride for 16 hours. The resulting mixture of methyl glycosides was resolved by gas–liquid partition chromatography (24, 25), which gave the separation and quantitative data shown in Fig. 2. To identify the constituents of the mixture the remainder (1.44 g) of the hydrolyzate was fractionated on a cellulose column using solvent C to give five fractions:

Fraction 1, tetra-*O*-methyl-D-mannose (0.150 g).
Fraction 2, tetra- and tri-*O*-methyl-D-mannoses (0.692 g).
Fraction 3, tri-*O*-methyl-D-mannose (0.065 g).
Fraction 4, tri- and di-*O*-methyl-D-mannoses (0.241 g).
Fraction 5, di-*O*-methyl-D-mannose (0.207 g).
Recovery = 1.355 (94.1%).

The major components in these fractions were identified as follows:

*2,3,4,6-Tetra-O-methyl-*D*-mannose*

On paper chromatograms fraction 1 showed only one component having R_g values of 0.99 and 0.98 in solvents B and C respectively. The specific rotation was $[\alpha]_D^{28} = +30° \pm 1°$ (*c*, 3.0% in methanol) and the product yielded a crystalline anilide, m.p. 144–145° C, $[\alpha]_D^{26} = +42° \rightarrow 8°$ (*c*, 0.72% in methanol). These values are in agreement with those reported for 2,3,4,6-tetra-*O*-methyl-D-mannose (40) and its anilide (41). After methanolysis fraction 1 showed one peak, corresponding to peak A, Fig. 2, on gas–liquid partition chromatography.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

*3,4,6-Tri-O-methyl-*D*-mannose*

On paper chromatograms fraction 3 was identical with 3,4,6-tri-*O*-methyl-D-mannose and had R_g values of 0.90 and 0.76 in solvents B and C respectively. The product crystallized when nucleated with an authentic sample of 3,4,6-tri-*O*-methyl-D-mannose. Recrystallization from ether:hexane yielded a product with a melting point of 102–104° C and $[\alpha]_D^{28} = +33° \pm 3°$ (*c*, 3.2% in methanol), which are in agreement with the reported values (42). This compound showed only one peak, corresponding to peak C, Fig. 2, on gas–liquid partition chromatography after methanolysis.

*3,4-Di-O-methyl-*D*-mannose*

R_g values of fraction 5 on paper chromatograms were 0.74 and 0.44 in solvents B and C respectively, identical with those given by authentic 3,4-di-*O*-methyl-D-mannose. The product crystallized when nucleated with an authentic sample and recrystallization from ethyl acetate yielded a product with a melting point of 70–73° C (8, 43), and $[\alpha]_D^{28} = +32 \pm 1°$ (*c*, 2.0% in methanol) (6). This compound was methanolyzed and the methyl glycoside gave one peak, corresponding to peak E, Fig. 2, on gas–liquid partition chromatography.

Isolation of Chitin from C. albicans

Chitin was isolated from dried *C. albicans* cells (9.0 g) by the procedure of Scholl (44), which involved exhaustive extraction with boiling 10% potassium hydroxide, oxidation with 1% aqueous potassium permanganate, and removal of manganese dioxide by dilute (0.8%) hydrochloric acid. The residue from these reactions was dried with ethanol and ether to yield a product (545 mg, 6.05%) which was shown by X-ray diffraction to contain chitin and traces of corundum.

Isolation and Hydrolysis of Cell Walls from C. albicans

Cells of *C. albicans* were extracted with petroleum ether to remove lipid, incubated with trypsin to destroy protein, and suspended in water at a concentration of 1%. This suspension was shaken with fine glass beads for 45 minutes in a Mickle disintegrator (45). The glass beads were then removed by filtration on sintered glass and the turbid filtrate was centrifuged for 1 minute at 1000 r.p.m. Microscopic examination of the precipitate revealed the presence of many whole cells but further centrifugation of 1 minute at 1000 r.p.m. yielded a precipitate in which no intact cells could be detected. Hydrolysis and paper chromatography of this precipitate revealed the presence of glucose and mannose. The supernatant liquid from the second precipitate was centrifuged for 15 minutes at 15,000 r.p.m. to yield a creamy precipitate which yielded neither glucose nor mannose after hydrolysis.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the careful technical assistance of Mr. F. P. Cooper (National Research Council) and Mr. A. A. Strachan (Department of Bacteriology and Immunology, McGill University). Authentic samples of *O*-methyl ethers of D-glucose were kindly donated by Dr. T. E. Timell, Division of Cellulose Chemistry, McGill University; authentic samples of *O*-methyl ethers of mannose were obtained from Dr. G. A. Adams, Division of Applied Biology, National Research Council. Analyses were done by Mr. A. E. Castagne and the X-ray diffraction diagram was done by the Eidgenossische Materialprufungs-und Versuchsanstalt, Zürich, Switzerland.

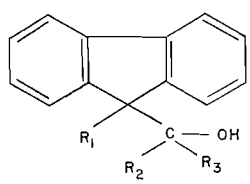
ALIPHATIC CHEMISTRY OF FLUORENE

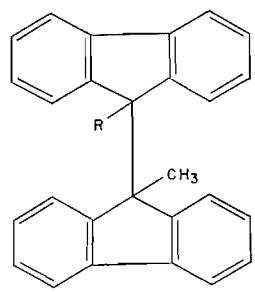
PART II. AN UNUSUAL GRIGNARD REACTION[1]

P. M. G. BAVIN[2]



ABSTRACT

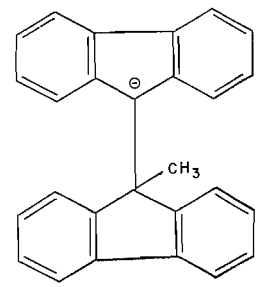
The reaction between methyl 9-methylfluorene-9-carboxylate and phenyl magnesium iodide gave 9,9′-dimethyl-9,9′-difluorenyl in almost quantitative yield. Evidence is presented which shows that 9-methylfluorene anion is an intermediate. The probable intervention of elemental iodine is discussed.



9-Methyl-9,9′-difluorenyl and 9,9′-dimethyl-9,9′-difluorenyl have been synthesized. A convenient preparation of 9,9′-difluorenylidene is described.

Some years ago we were interested in the reaction between phosphorus pentoxide and tertiary alcohols having structure I, where R is not hydrogen (1). We succeeded in preparing only two alcohols of the desired structure (I, $R_1 = R_2 = R_3$ = methyl or ethyl) by the reaction between methyl 9-methyl or ethylfluorene-9-carboxylate and the corresponding alkyl magnesium halide. The similar reaction between methyl 9-methylfluorene-9-carboxylate and phenyl magnesium bromide gave an easily crystallized hydrocarbon of melting point 209–210°, which has now been identified as 9,9′-dimethyl-9,9′-difluorenyl (II*b*). Although this hydrocarbon has been reported previously (2, 3, 4) identity has been established by the following unambiguous syntheses.

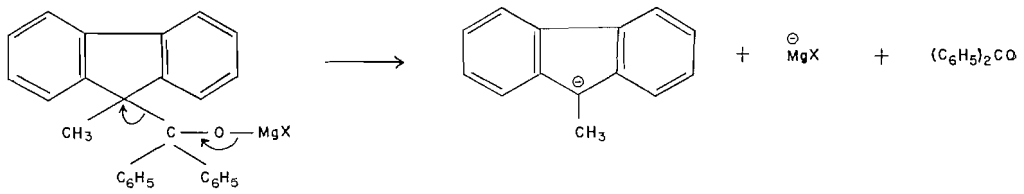
9-Bromofluorene reacted rapidly with methyl fluorene-9-carboxylate anion to give methyl 9-(9′-fluorenyl)-fluorene-9-carboxylate (the ethyl ester has been prepared previously from 9,9′-difluorenyl (5)), which was saponified and decarboxylated to 9,9′-difluorenyl. Methylation with methyl lithium and methyl iodide gave finally 9,9′-dimethyl-9,9′-difluorenyl (II*b*).



(I)

(II)

(a) R = H
(b) R = CH_3



(III)

In the second synthesis, the anion (III) was prepared by the addition of methyl lithium to 9,9′-difluorenylidene. The further reaction with methyl iodide gave 9,9′-dimethyl-9,9′-difluorenyl. The preparation of 9-methyl-9,9′-difluorenyl (II*a*) by hydrolysis of the anion (III) with water proved unexpectedly difficult, residual methyl iodide giving

[1]*Manuscript received December 1, 1959.*
Contribution from the Chemistry Department, the University, Hull, East Yorkshire, England.
[2]*I.C.I. Fellow.*

instead dimethyldifluorenyl (II*b*). After removing the last traces of methyl iodide with magnesium, 9-methyl-9,9′-difluorenyl was obtained in 80–90% yield.

The yield of the hydrocarbon (II*b*) in the Grignard reaction was almost quantitative when phenyl magnesium iodide was used, from which it was inferred that the tertiary alkoxide (IV) was formed in the usual way. By analogy with certain tertiary aliphatic alkoxides recently investigated by Zook (6), decomposition should lead to 9-methylfluorene anion (V) and benzophenone, as shown in the annexed scheme (Fig. 1). The

(IV) (V)

FIG. 1.

necessary driving force for the decomposition is supplied by the mesomeric nature of the ion (V) (cf. the facile base-induced cleavage of 9-methyl-9-benzoylfluorene (7)), which accounts for the unusually low reaction temperature (cf. (6)).*

The use of organic iodides in the preparation of Grignard reagents, or of a crystal of iodine to initiate their formation, may often result in the presence of traces of free iodine in such reactions, probably owing their formation to aerial oxidation. It is well known that iodine brings about the dimerization of many esters in the presence of strong base (e.g. phenylacetic ester (8)) and, by analogy, it might be expected to bring about dimerization of the anion (V) to dimethyldifluorenyl (II*b*).

Evidence is presented below which supports the postulated decomposition of the tertiary alkoxide (IV) and the participation of iodine in the formation of the hydrocarbon (II*b*).

Evidence for the Formation of the 9-Methylfluorene Anion (V)

The most convincing evidence for the formation of the anion (V) came from a study of the reactions of 9-methyl-9-benzoylfluorene, which has recently been prepared for the first time (7). The ketone reacted with ethereal methyl or phenyl lithium and with ethereal phenyl magnesium bromide to produce a deep red color, which was fully developed in a few minutes. In order to demonstrate the presence of the anion (V), methyl iodide was added. 9,9-Dimethylfluorene could then be isolated from amongst the products. Triphenylmethanol could be isolated from the products of reaction with phenyl lithium or the corresponding Grignard reagent, thereby accounting for the benzophenone formed in the decomposition of the tertiary alkoxide (IV). Prolonged reaction times favored formation of the hydrocarbon (II*b*). Other experiments showed that methyl 9-methylfluorene-9-carboxylate gave the same products under the same conditions.

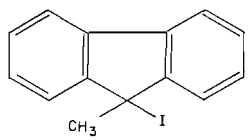
It is probable that the formation of the anion (V) from the ketone proceeds by way of the tertiary alkoxide (IV), but it may equally well involve base-induced cleavage of the non-enolizable ketone (7), with methyl or phenyl anion acting as base. Similar

**Zook (6) has emphasized that the decompositions are the reversal of addition of an organometallic reagent to a ketone.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

mechanisms can account for the formation of acetophenone and triphenylmethane from the reaction between benzopinacolin and methyl magnesium bromide (reference 3 quoted in 6). In both cases the direction of cleavage is controlled by formation of the mesomeric ions (V) and the triphenylmethyl anion. Differentiation between the decomposition and cleavage mechanisms might be possible by kinetic studies.

The Role of Iodine



The importance of iodine may be judged from the following experimental results.

(i) The yield of the hydrocarbon (II*b*) from methyl 9-methyl-fluorene-9-carboxylate was almost quantitative when phenyl magnesium iodide was used, but was considerably less with phenyl magnesium bromide.

(ii) The anion (V), generated from 9-methylfluorene with phenyl lithium, reacted rapidly with iodine to give a good yield of the hydrocarbon (II*b*). Under similar conditions fluorene gave 9,9′-difluorenyl.

(iii) The reaction between 9-methylfluorene, ethyl lithium, and ethyl iodide produced 10% of the hydrocarbon (II*b*). The similar reaction using ethyl bromide and ethyl lithium prepared from ethyl bromide gave only 9-ethyl-9-methylfluorene.

Since many Grignard reagents react with iodine to give good yields of iodides (9, pp. 1332–1335) the tertiary iodide (VI) has to be considered as a possible intermediate in the formation of the hydrocarbon (II*b*) by reaction with the anion (V). Evidence for the formation of a reactive iodo compound in the dimerization of phenylacetic ester has already been reported (8, footnote on page 446; see also 10), and it has now been observed that traces of unstable iodo compounds are present in the products of the dimerization of fluorene or 9-methylfluorene with iodine and phenyl lithium.

(VI)

Tertiary halides do not as a general rule give C-alkylation products with organic anions. However, methyl fluorene-9-carboxylate anion has been shown to be exceptional in this respect (11, 12). It has now been found that methyl 9-bromofluorene-9-carboxylate reacts rapidly with methyl fluorene-9-carboxylate anion to give dimethyl 9,9′-difluorenyl-9,9′-dicarboxylate, at a rate comparable with that observed for the iodine-induced dimerization of the anion. These results suggest the feasibility of the anion (V) reacting with the iodide (VI) to give II*b*.

Comparable experiments with 9-bromo-9-methylfluorene and methyl fluorene-9-carboxylate anion have been unsuccessful. Crude preparations of the bromide, difficult to obtain pure (30), gave a low yield of what is probably methyl 9-(9′-fluorenylmethyl)-fluorene-9-carboxylate as the product of Michael addition of methyl fluorene-9-carboxylate anion to 9-methylenefluorene. Experiments with the corresponding chloride, which has not been obtained pure (13, 30), gave similar results.

Alternative mechanisms for the formation of the hydrocarbon (II*b*) obviously cannot be ruled out. For example, oxidation of the anion (V) by iodine might give the radical,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

leading by dimerization to II*b*. In addition, trace amounts of certain metals are known to bring about oxidative coupling of organic anions (9).

Summing up the available evidence, it is clear that formation of dimethyldifluorenyl (II*b*) in the reaction between methyl 9-methylfluorene-9-carboxylate and a phenyl Grignard reagent proceeds through 9-methylfluorene anion (V), formed either by decomposition of the tertiary alkoxide (IV) or by basic cleavage of 9-methyl-9-benzoylfluorene. Iodine seems to play an essential part but its exact role is uncertain.

The formation of 9,9′-difluorenyl by the reaction between Grignard reagents and 9-chlorofluorene (14) may very well be related to its formation from fluorene, phenyl lithium, and iodine, mentioned above. The annexed scheme (Fig. 2) shows the reactions

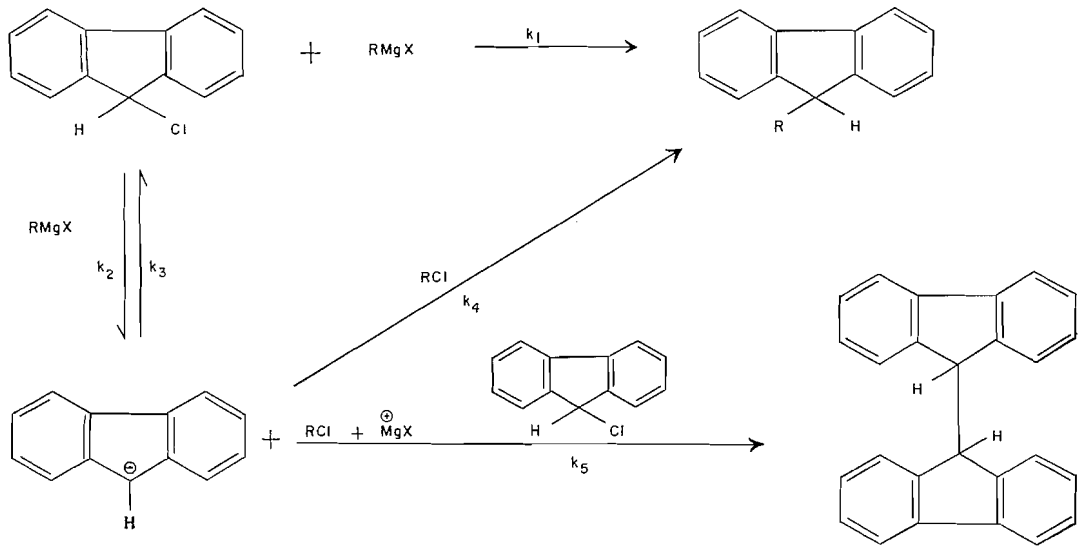


FIG. 2.

likely to be involved. It will be seen that an essential postulated reaction is a Grignard exchange having forward rate k_2. The existence of at least two such reactions has been convincingly demonstrated (15, 16) but it has been claimed that 9-chlorofluorene does not exchange with methyl magnesium bromide (17) because fluorene-9-carboxylic acid was not isolated from amongst the products of carbonation. These workers seem to have been unaware of the earlier paper by Bachmann (14); neglect to report on the neutral products obviously invalidates their work. The reaction between 9-bromofluorene and methyl magnesium iodide has been found to give 9,9′-difluorenyl in more than 90% yield, even in the presence of added methyl iodide. This observation confirms Bachmann's results (14).

Bachmann's efforts to explain his results (14), particularly the infrequent formation of 9-alkylfluorenes, in terms of the structure of the Grignard reagent are almost certainly invalid in view of recent studies with the ^{28}Mg isotope (18). The alternative scheme shown in Fig. 2 may provide a complete explanation. The rate k_1 is likely to be small compared with k_2 so that *the products formed will depend on the reactivities of 9-chlorofluorene and the halide RCl towards fluorene anion*, the reactivities being measured by k_5 and k_4.

An outstanding property of fluorene anions is the speed with which they react with a very wide range of alkyl halides (7, 11, 12). It has now been demonstrated that the anions from fluorene, 9-methylfluorene, and 9-phenylfluorene react almost instantaneously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

with methyl iodide, providing convenient preparations of 9,9-dimethylfluorene and 9-methyl-9-phenylfluorene. The relative reactivities of various alkyl halides to methyl fluorene-9-carboxylate anion are being measured by competition and will be reported later. The formation of difluorenyl from the reaction between 9-bromofluorene and methyl Grignard in the presence of methyl iodide suggests that the fluorene halide is the more reactive.

The reaction between 9-bromofluorene and sodium *t*-butoxide has been found to give 9,9′-difluorenylidene in 85% yield, representing a considerable improvement in both yield and convenience over published preparations (20, 21).

The existence (19) has been confirmed of two polymorphic forms of 9,9-dimethylfluorene.

EXPERIMENTAL

9,9′-Dimethyl-9,9′-difluorenyl (II*b*)

(i) Methyl 9-methylfluorene-9-carboxylate (2.24 g, 0.01 mole) was boiled under reflux for 4 hours with ethereal phenyl magnesium iodide (from iodobenzene, 12 g, 0.06 mole). The complex was decomposed with ice and ammonium chloride and the product crystallized from heptane to give pale yellow prisms, m.p. 186–190° (1.76 g, almost quantitative yield). Two further crystallizations yielded colorless well-defined rhombs (1.6 g), m.p. 209–210°. Found for two samples: C, 93.71, 93.97; H, 6.29, 6.19%. Calculated for $C_{28}H_{22}$: C, 93.81; H, 6.19% (lit. m.p.: 209° corr. (2), 209–210° (3), 205° (4)).

Phenyl magnesium bromide was used in earlier experiments, formation of the Grignard reagent being assisted by the addition of a crystal of iodine. The hydrocarbon (II*b*) was obtained in 45% yield only after 24 hours. In the absence of iodine the hydrocarbon was not formed.

(ii) 9-Bromofluorene (22), prepared by Bolton, reacted rapidly at 30–35° with one equivalent of methanolic methyl fluorene-9-carboxylate anion. *Methyl 9-(9′-fluorenyl)-fluorene-9-carboxylate*, isolated in the usual way, formed well-defined rhombs (76%) from benzene–hexane, m.p. 215–216°. Found: C, 86.11; H, 5.18%. Calculated for $C_{28}H_{20}O_2$: C, 86.57; H, 5.19%.

The ester was boiled under reflux for 2 hours with twice its weight of potassium hydroxide in ethylene glycol. Cooling and diluting with water precipitated 9,9′-difluorenyl, which crystallized as slender colorless needles (94%) from benzene–hexane, m.p. 248–249°.

9,9′-Difluorenyl (2 g) in benzene (200 ml) was added to ethereal phenyl lithium (from bromobenzene, 20 g) to give a deep red solution, the color of which was almost instantly discharged on addition of methyl iodide (8 g). The *hydrocarbon* crystallized as rhombs (1.4 g) from benzene–hexane, m.p. 209–210°. Identity with the product from (i) was established by mixed melting point determination and comparison of infrared spectra.

(iii) 9-Methylfluorene (1 g) was added to ethereal phenyl lithium (from bromobenzene, 5 g) followed by crystals of iodine until the color of the latter persisted. The product (0.8 g) had a melting point of 207–209° and was identical with that obtained from (i).

Under similar conditions fluorene (1 g) gave 9,9′-difluorenyl (0.7 g), m.p. and mixed m.p. 245–246°.

The crude products from both preparations were washed with a solution of sodium metabisulphite to remove iodine, but traces of the latter were always formed during crystallization.

(iv) 9,9′-Difluorenylidene (1 g) was boiled under reflux for 30 minutes with ethereal methyl lithium (from methyl iodide, 10 g) and methyl iodide (10 g). The product crystal-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

lized from heptane as small colorless prisms (0.9 g), m.p. 208–210°, and was identical with the product from (i).

9,9′-Difluorenylidene

A hot solution of sodium *t*-butoxide (from sodium, 7 g) in *t*-butanol (500 ml) was added to 9-bromofluorene (25 g) and the mixture boiled under reflux for 15 minutes. Most of the solvent was recovered by distillation and the residue poured into dilute hydrochloric acid (500 ml). The reddish-orange solid was collected, washed with water, dried, and crystallized from carbon tetrachloride – ethanol, which was the best solvent system found. Difluorenylidene was obtained as beautiful red needles (14.2 g, 85%, in two crops), m.p. 187–189° (lit. m.p. 185–187° (20, 21)).

9-Methyl-9,9′-difluorenyl

Ethereal methyl lithium was prepared from methyl iodide (28 g) and lithium (3 g). When the reaction was apparently complete, magnesium (5 g) was added and the mixture boiled gently under reflux for 30 minutes. Residual solids were removed by decantation through a plug of glass wool to give a solution of methyl lithium in ether free from methyl iodide.

Difluorenylidene (1 g) was warmed for 15 minutes with an excess of the above methyl lithium reagent. The ether layer was washed with water, dried, and evaporated, leaving the product as a yellow solid. The product was purified by passing a hexane solution through a column of activated alumina, crystallization of the eluted material from heptane yielding small colorless prisms (0.85 g), m.p. 169–170° (lit. m.p. 172° (4)). Found: C, 94.25; H, 5.89%. Calculated for $C_{27}H_{20}$: C, 94.15; H, 5.85%.

A mixed melting point determination with dimethyldifluorenyl was 151–179°.

9-Ethyl-9-methylfluorene

(i) 9-Methylfluorene (1 g) was added to ethereal ethyl lithium (from ethyl bromide, 4 g), followed by ethyl bromide (4 g). The product crystallized readily from methanol as white needles (0.8 g), m.p. 59–60.5° (lit. m.p. 61–62° (23)).

(ii) Ethyl iodide replaced ethyl bromide in (i). Crystallization of the product from heptane gave small colorless prisms (0.1 g), m.p. 204–207°, identified as 9,9′-dimethyl-9,9′-difluorenyl. The mother liquors contained impure ethylmethylfluorene.

9,9-Dimethylfluorene

(i) Fluorene (16.6 g, 0.1 mole) was added to ethereal methyl lithium (from methyl iodide, 43 g, 0.3 mole). Methyl iodide was added dropwise until the solution became colorless. The product crystallized from methanol as colorless prismatic needles (17.3 g, 89%), m.p. 90–93°, raised to 95–96° by a further crystallization.

Phenyl lithium gave less satisfactory yields unless the product was distilled at 1 to 2 mm prior to crystallization.

(ii) Methylation of 9-methylfluorene with methyl lithium – methyl iodide gave, in the same way, 9,9-dimethylfluorene in 92%.

Two melting points have been recorded for 9,9-dimethylfluorene: 71° (19) and 69–70° (24), 95–96° (19, 25) and 96° (23). Through the kindness of Dr. C. C. Barker, his original sample (24) has been examined after a lapse of several years and found to have a melting point of 81–92°, raised to 95–96° by one crystallization from methanol. Attempts by Emmerson (24) to obtain the higher melting form had been unsuccessful but the present author has been unable to obtain the lower melting form. The existence of the two crystalline forms reported earlier (19) is thus confirmed.

For personal use only.

9-Methyl-9-phenylfluorene

Methylation of 9-phenylfluorene as described for fluorene gave methylphenylfluorene in 87% yield, crystallizing as colorless lustrous plates from methanol, m.p. 86–86.5° (lit. m.p. 84–85° (26), 86–87° (27)). Found: C, 93.97; H, 6.19%. Calculated for $C_{20}H_{16}$: C, 93.71; H, 6.29%.

Experiments with 9-Methyl-9-benzoylfluorene

(i) 9-Methyl-9-benzoylfluorene (2 g) in dry ether (100 ml) was added to ethereal phenyl lithium (from bromobenzene, 5 g). The solution immediately assumed a deep red color, similar to that produced by adding 9-methylfluorene to phenyl lithium. The color was rapidly discharged by the addition of methyl iodide (2 g). The product crystallized from methanol as colorless prismatic needles (0.9 g), m.p. 94–96°, identified as 9,9-dimethylfluorene. Found: C, 92.46; H, 7.04%. Calculated for $C_{15}H_{14}$: C, 92.74; H, 7.26%.

(ii) The experiment was performed as in (i) but without the addition of methyl iodide. The product crystallized as long needles (0.17 g) from methanol, m.p. 163–164°, after several crystallizations. Found: C, 87.43; H, 6.13%. Calculated for $C_{19}H_{16}O$: C, 87.66; H, 6.20%. Identity with triphenylmethanol was established by mixed melting point determination and comparison of infrared spectra. The oily residues were not examined.

In other experiments, methyl 9-methylfluorene-9-carboxylate satisfactorily replaced the ketone, and methyl lithium replaced phenyl lithium, although attempts were not made to isolate methyldiphenylmethanol.

9,9′-Difluorenyl

Ethereal methyl magnesium iodide (from methyl iodide, 4 g) was decanted from magnesium and added dropwise to a solution of 9-bromofluorene (2.4 g) and methyl iodide (2 g) in ether. After 10 minutes, the complex was decomposed with ice and ammonium chloride. The product was crystallized from heptane to give, in two crops, difluorenyl (1.5 g), m.p. and mixed m.p. 244–246°.

Dimethyl 9,9′-difluorenyl-9,9′-dicarboxylate

Methyl 9-bromofluorene-9-carboxylate (1.3 g) was added to a solution of methyl fluorene-9-carboxylate (1 g) in methanol containing sodium methoxide (from sodium, 0.2 g) and the suspension was warmed for 10 minutes. The product crystallized as small prisms (1.1 g) from benzene–hexane, m.p. 238–240°, identical with a sample prepared by the reaction between methyl fluorene-9-carboxylate anion and iodine (cf. 29) (lit. m.p. 237° (28)).

Methyl 9-(9′-fluorenylmethyl)-fluorene-9-carboxylate (?)

9-Methyl-9-fluorenol (1 g) was warmed for a few minutes with dry ether (30 ml) and acetyl bromide (1 ml). The solvent was evaporated below 30° and to the residual oil was added a solution of methyl fluorene-9-carboxylate (1.1 g) in methanol (30 ml) containing sodium methoxide (from sodium, 0.2 g). Polymeric material was removed by filtration, after which the clear yellow filtrate was warmed for 30 minutes. Careful dilution with water and scratching induced crystallization. After two crystallizations from heptane the colorless prisms (0.2 g) had a melting point of 173–174°. Found: C, 85.97; H, 6.16%. Calculated for $C_{29}H_{22}O_2$: C, 86.54; H, 5.51%.

Saponification in ethylene glycol was incomplete after 2 hours and yielded an unresolved mixture from which 9-methyl-9,9′-difluorenyl was not obtained by seeding, although a careful comparison of infrared spectra suggested its presence.

SOME OPEN-CHAIN DERIVATIVES OF GLUCOSE AND MANNOSE[1]

E. J. C. CURTIS AND J. K. N. JONES

ABSTRACT

The dimethyl thioacetals of D-glucose and D-mannose have been condensed with acetone. Mannose dimethyl thioacetal forms a crystalline 3,4:5,6-di-*O*-isopropylidene derivative while glucose forms a mixture of the crystalline 3,4:5,6-di-*O*-isopropylidene and syrupy 2,3:5,6-di-*O*-isopropylidene isomers. These three di-*O*-isopropylidene dimethyl thioacetals have been converted via crystalline intermediates into the corresponding di-*O*-isopropylidene dimethyl acetals. These derivatives are suitable open-chain compounds for use in Koenigs–Knorr syntheses and provide (*a*) mannose with the C_2 hydroxyl free, (*b*) glucose with the C_2 hydroxyl free, and (*c*) glucose with the C_4 hydroxyl free.

INTRODUCTION

It has already been shown (1) that in Koenigs–Knorr syntheses of disaccharides much greater yields may be obtained by the use of an open-chain hydroxyl reactant rather than the more generally used ring-form derivatives. This is presumably because there is less steric hindrance to reaction in the case of the open-chain compound. In the synthesis of lactose, however (1), the hydroxyl reactant used (syrupy 2,3:5,6-di-*O*-isopropylidene-D-glucose dimethyl acetal) contained small amounts of other di-*O*-isopropylidene isomers due to the method of synthesis. This, of course, resulted in an impure product from the Koenigs–Knorr reaction, there being small amounts of other disaccharides present in addition to lactose. In the present work syntheses are described of open-chain derivatives of (*a*) mannose with the C_2 hydroxyl group free, (*b*) glucose with the C_2 hydroxyl group free, and (*c*) glucose with the C_4 hydroxyl group free. All of these have been made via pure crystalline intermediates and should prove very useful in Koenigs–Knorr syntheses.

Schinle (2) condensed D-glucose dibenzyl thioacetal with acetone in the presence of anhydrous copper sulphate and obtained a syrupy mixture of mono- and di-*O*-isopropylidene derivatives. There was at first some doubt as to the structure of the di-*O*-isopropylidene material but Munro and Percival (3) later showed this to be a mixture of 2,3:5,6- and 3,4:5,6-di-*O*-isopropylidene isomers of D-glucose dibenzyl thioacetal. Condensation of D-glucose diethyl thioacetal with acetone (1) gives a syrupy mixture which consists largely of the 2,3:5,6-di-*O*-isopropylidene derivative.

Pacsu and Trister (4) condensed D-mannose dibenzyl thioacetal with acetone and obtained a syrupy di-*O*-isopropylidene derivative which was shown to be mainly the 3,4:5,6 isomer. Condensation of D-mannose diethyl thioacetal with acetone yields a syrupy product which has been shown to be largely the 3,4:5,6-di-*O*-isopropylidene derivative (5).

In the present work condensation of D-mannose dimethyl thioacetal with acetone in the normal way resulted in a crystalline di-*O*-isopropylidene derivative in high yield. This compound was shown by methylation experiments to be 3,4:5,6-di-*O*-isopropylidene-D-mannose dimethyl thioacetal. The compound formed a crystalline benzoate which then was converted into 2-*O*-benzoyl-3,4:5,6-di-*O*-isopropylidene-D-mannose dimethyl acetal using a modification of the method of Wolfrom (6). Debenzoylation yielded 3,4:5,6-di-*O*-isopropylidene-D-mannose dimethyl acetal.

Condensation of D-glucose dimethyl thioacetal with acetone resulted in a syrupy product which partially crystallized on standing. The crystalline portion (19% yield)

[1]*Manuscript received February 18, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

was shown by methylation experiments to be 3,4:5,6-di-*O*-isopropylidene-D-glucose dimethyl thioacetal, while methylation of the syrupy portion (76% yield) showed this to be mainly the 2,3:5,6-di-*O*-isopropylidene isomer. Both isomers formed benzoates. 2-*O*-Benzoyl-3,4:5,6-di-*O*-isopropylidene-D-glucose dimethyl thioacetal was converted into the dimethyl acetal, which on debenzoylation yielded 3,4:5,6-di-*O*-iso-propylidene-D-glucose dimethyl acetal. By a similar route, 2,3:5,6-di-*O*-isopropylidene-D-glucose dimethyl acetal was also formed. 3,4:5,6-Di-*O*-isopropylidene-D-glucose dimethyl acetal formed a crystalline toluene-*p*-sulphonyl derivative.

EXPERIMENTAL

Optical rotations were measured in water at 21°±2° C unless otherwise stated. Solutions were concentrated under reduced pressure at 40° C. The following solvent systems (v/v) were used to separate sugars on paper chromatograms: (A) ethyl acetate:acetic acid:water, 9:2:2; (B) *n*-butanol:ethanol:water, 3:1:1. Sugars were detected using the *p*-anisidine hydrochloride spray (7). Infrared absorptions were measured as solutions in chloroform or as a powder suspended in a potassium bromide pellet on a Perkin–Elmer Model 21 spectrophotometer.

Preparation of Di-O-isopropylidene-D-mannose Dimethyl Thioacetal

Mannose dimethyl thioacetal (22 g) was added to a mixture of dry acetone (400 ml), anhydrous copper sulphate (12 g), and concentrated sulphuric acid (2 ml), and the resulting mixture was shaken at room temperature for 24 hours. The solution was neutralized with concentrated ammonium hydroxide solution and filtered. The precipitate was washed with acetone and filtrate and washings were evaporated to a colorless syrup. This was diluted with chloroform (200 ml) and extracted once with water. The chloroform solution was dried ($MgSO_4$), filtered, and evaporated to a syrup (23 g) which crystallized completely on standing. After recrystallization from light petroleum the material weighed 21.8 g (76% yield) and had a melting point of 58–59° C and $[\alpha]_D$ +5.0° (*c*, 7.6, chloroform). Anal. Calc. for $C_{14}H_{26}O_5S_2$: C, 49.70; H, 7.69; S, 18.94. Found: C, 49.87; H, 7.78; S, 18.99.

Methylation of Di-O-isopropylidene-D-mannose Dimethyl Thioacetal

Di-*O*-isopropylidene-D-mannose dimethyl thioacetal (2 g) was dissolved in methyl iodide (20 ml). Silver oxide (3.6 g) plus Drierite (2 g) were added to the solution which was then shaken in the dark at room temperature for 24 hours. Filtration and subsequent evaporation yielded a brown syrup (1.5 g). Isopropylidene and thioacetal groupings were removed by refluxing for 5 hours with aqueous ethanol (20%) containing hydrochloric acid (5%). The solution was neutralized by passage through a column of Duolite A-4 resin (OH form) and concentrated to a syrup (0.9 g). Chromatographic examination of this (solvent A) showed mainly a spot at R_{mannose} 2.15, with smaller spots corresponding to mannose and arabinose. Part of this syrup (200 mg) was separated by chromatography on sheets of Whatman No. 1 filter paper using solvent B as eluent. Guide strips were cut and sprayed and the fraction R_{mannose} 2.15 was cut out and eluted with acetone. The acetone solution was evaporated to dryness. The residue was diluted with a little ethanol, warmed with charcoal, and filtered. Evaporation of the filtrate yielded a syrup (77 mg) which crystallized on dilution with a little ethanol.

After recrystallization from methanol/ether the material had a melting point of 134–136° C and $[\alpha]_D$ +5.2° (constant) (*c*, 1.2). It formed a phenylhydrazone which had a melting point of 161–163° C and $[\alpha]$ −60.5° (constant) (*c*, 0.38, pyridine). Authentic

For personal use only.

2-*O*-methyl-α-D-mannose has a melting point of 136–137° C and $[\alpha]_D$ +7.0° → +4.5° (constant) and forms a phenylhydrazone with a melting point of 163° C and $[\alpha]_D$ −49.1° → −60.7° (pyridine, constant) (4).

*2-O-Benzoyl-di-O-isopropylidene-*D*-mannose Dimethyl Thioacetal*

Di-*O*-isopropylidene-D-mannose dimethyl thioacetal (17.2 g) was dissolved in dry pyridine (180 ml). The solution was stirred mechanically and cooled externally. The temperature was kept at −5° C while a solution of benzoyl chloride (18 g) in pyridine (30 ml) was added dropwise. Cooling was continued at −5° C (30 minutes) and then at 0° C (7 hours), and the solution was finally stored at room temperature (14 hours). The product was precipitated by slowly pouring the solution into ice plus water (700 ml). After 30 minutes at room temperature, the crude crystalline material was filtered and washed with water. It was recrystallized from methanol and weighed 19.3 g (86% yield). It had a melting point of 83–84° C and $[\alpha]_D$ +7.8° (*c*, 1.0, methanol). Anal. Calc. for $C_{21}H_{30}O_6S_2$: S, 14.48. Found: S, 14.68.

*2-O-Benzoyl-di-O-isopropylidene-*D*-mannose Dimethyl Acetal* (ref. 6)

2-*O*-Benzoyl-di-*O*-isopropylidene-D-mannose dimethyl thioacetal (10 g) was dissolved in dry methanol (300 ml). Cadmium carbonate (87 g) was added to the solution and a solution of mercuric chloride (87 g) in methanol (100 ml) was then added portionwise with vigorous stirring at room temperature. After completion of the addition (5 hours), stirring was continued for a further 15 hours at room temperature, and the solution was then boiled under reflux for 15 minutes. The cooled solution was filtered through a Celite pad and the precipitate was washed with methanol. Filtrate and washings were concentrated to ca. 150 ml and this solution was poured into 200 ml each of chloroform and water. The chloroform layer was extracted with water until chloride-free, dried ($MgSO_4$), filtered, and evaporated to a syrup (7.5 g) which crystallized on standing overnight. Recrystallization from methanol yielded 6.5 g of product (70%). After further recrystallizations from methanol and from light petroleum the material had a melting point of 73.5–74° C and $[\alpha]_D$ −1.6° (*c*, 3.5, chloroform). Anal. Calc. for $C_{21}H_{30}O_8$: C, 61.43; H, 7.37. Found: C, 61.35; H, 7.53.

*3,4:5,6-Di-O-isopropylidene-*D*-mannose Dimethyl Acetal*

2-*O*-Benzoyl-di-*O*-isopropylidene-D-mannose dimethyl acetal (0.67 g) was dissolved in 50% aqueous ethanol (30 ml) containing potassium hydroxide (0.12 g) and the solution was warmed at 70° C (4 hours). The solution was concentrated to a small volume to remove ethanol and then extracted with chloroform. The chloroform solution was extracted three times with water, dried ($MgSO_4$), filtered, and evaporated to a syrup (0.49 g, 98%). Infrared analysis showed no absorption for carbonyl group (1700–1750 cm^{-1}). The material had $[\alpha]_D$ −1.3° (*c*, 1.6, methanol).

*Preparation of a Mixture of Di-O-isopropylidene-*D*-glucose Dimethyl Thioacetals*

Glucose dimethyl thioacetal (20 g) was added to a mixture of dry acetone (400 ml), anhydrous copper sulphate (12 g), and concentrated sulphuric acid (2 ml) and the resulting solution was shaken at room temperature for 24 hours. The solution was neutralized with concentrated ammonium hydroxide solution, filtered, and the precipitate was washed with acetone. Filtrate and washings were evaporated to a syrup which was diluted with chloroform (150 ml) and extracted once with water. The chloroform solution was dried ($MgSO_4$), filtered, and evaporated to a syrup (26 g). This partially crystallized on standing. The mixture of crystals and syrup was diluted with light

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

petroleum and refrigerated. Subsequent filtration yielded 3.1 g crystalline material. Concentration of the filtrate followed by seeding produced a further 2.0 g crystals; total yield of crystalline product 5.1 g (19%). This was recrystallized from light petroleum and had a melting point of 92–94° C and $[\alpha]_D$ −1.0° (*c*, 9.8, chloroform). Anal. Calc. for $C_{14}H_{26}O_5S_2$: C, 49.70; H, 7.69; S, 18.94. Found: C, 49.64; H, 7.52; S, 18.86.

When all the above crystalline material had been removed from the reaction product there remained 20.6 g (76%) syrup which could not be crystallized. It had $[\alpha]_D$ −92.4° (*c*, 1.2, chloroform). Anal. Calc. for $C_{14}H_{26}O_5S_2$: S, 18.94. Found: S, 18.72, 18.64.

*Methylation of Crystalline Di-O-isopropylidene-*D*-glucose Dimethyl Thioacetal*

Crystalline di-*O*-isopropylidene-D-glucose dimethyl thioacetal (0.93 g) was dissolved in dry tetrahydrofuran (20 ml). Small pieces of clean sodium were then added to the solution until no further reaction took place. Methyl iodide (0.5 ml) was added to the solution which was stored in a darkened, stoppered flask at room temperature for 24 hours, further small quantities of sodium and methyl iodide being added at intervals. The solution was filtered and the precipitate was washed with tetrahydrofuran. Filtrate and washings were evaporated to dryness and the residue was dissolved in chloroform and washed with water until free from iodide. The solution was dried (Na_2SO_4), filtered, and evaporated to a syrup (0.91 g). Infrared examination of this indicated only a very small amount of free hydroxyl group present. Thioacetal groupings were removed by the method of Wolfrom (8), using mercuric chloride in the presence of cadmium carbonate in aqueous ethanol and isopropylidene groupings were subsequently hydrolyzed by warming the product in sulphuric acid (0.5 *N*) solution. The solution was deionized by passage through a column of Amberlite IR-120 (H form) and Duolite A-4 (OH form) resins in series and the neutral eluate was concentrated to a syrup (0.50 g). Chromatography of this (solvent A) showed mainly a spot at $R_{glucose}$ 2.61, with much smaller spots at $R_{glucose}$ 1.01, 3.92, and 7.30, these latter two being presumably due to unhydrolyzed isopropylidene derivatives.

The syrup was stored in a stoppered flask at room temperature and after 6 weeks it was found that a crystal nucleus had developed. When this was mixed with the syrup the mass crystallized. Part of the crude material (200 mg) was transferred to a porous tile and the crystals were cleaned by rapidly washing them with methanol. This material (110 mg) was recrystallized from methanol/ether. Chromatography in solvent A showed a single spot at $R_{glucose}$ 2.61. It had a melting point of 156–158° C and $[\alpha]_D$ +26.3° → +67.8° (constant) (*c*, 2.3). It formed a tetrabenzoate which had a melting point of 167°–168° C and $[\alpha]_D$ −8.4° (*c*, 0.6, chloroform). 2-*O*-Methyl-β-D-glucose has a melting point of 157–159° C and $[\alpha]_D$ +12.0 → +66.0 (constant) (9) and forms a tetrabenzoate with a melting point of 169°–170° C and $[\alpha]_D$ −6.2° (10). Under drastic conditions the material formed an osazone whose infrared spectrum was identical with that of authentic D-glucosazone.

*Methylation of Syrupy Di-O-isopropylidene-*D*-glucose Dimethyl Thioacetal*

Syrupy di-*O*-isopropylidene-D-glucose dimethyl thioacetal (5 g) was methylated using silver oxide and methyl iodide in the same way as described for di-*O*-isopropylidene-D-mannose dimethyl thioacetal. After removal of thioacetal and isopropylidene groupings and deionization, a clear syrup (1.9 g) was obtained. Chromatography of this (solvent A) showed spots at $R_{glucose}$ 1.00 and 2.56 with much smaller spots at 2.65, 3.40, and 4.45. The spot at $R_{glucose}$ 2.65 was presumably due to 2-*O*-methyl-D-glucose, formed from traces of the 3,4:5,6-di-*O*-isopropylidene isomer not removed by crystallization.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The spots at 3.40 and 4.45 were due either to unhydrolyzed isopropylidene residues or to methylation of mono-isopropylidene materials. Part of the syrup (1.4 g) was separated by chromatography on a column of powdered cellulose using solvent A as eluent. A fraction (0.73 g) was collected which showed a single spot at $R_{glucose}$ 2.56 in solvent A. The material had $[\alpha]_D$ +52.1° (*c*, 2.4). It did not crystallize. Authentic 4-*O*-methyl-D-glucose has $[\alpha]_D$ +53° (3). It formed an osazone which had a melting point of 157–159° C and $[\alpha]_D$ −17.4° (constant) (*c*, 0.6, pyridine). Anal. Calc. for $C_{19}H_{24}O_4N_4$: OMe, 8.35. Found: OMe, 8.15. 4-*O*-Methyl-D-glucose phenylosazone has a melting point of 158–160° C and $[\alpha]_D$ −32.6° → −15.5° (constant) (3).

Part of the syrup was converted into 4-*O*-methyl-D-glucose methyl glucoside by refluxing it for 3 hours with hydrochloric acid in methanol (2%). The solution was neutralized (Ag_2CO_3) and filtered, and the filtrate was evaporated to a clear syrup. This crystallized after it was diluted with a drop of ethyl acetate and nucleated with authentic 4-*O*-methyl-D-glucose methyl-α-D-glucoside. The material was washed on a porous tile with ethyl acetate and dried. It showed an infrared spectrum identical with that of 4-*O*-methyl-D-glucose methyl-α-D-glucoside.

2-O-Benzoyl-di-O-isopropylidene-D-glucose Dimethyl Thioacetal

3,4:5,6-Di-*O*-isopropylidene-D-glucose dimethyl thioacetal (3.1 g) was dissolved in dry pyridine (30 ml). The solution was stirred mechanically and cooled to −5° C while a solution of benzoyl chloride (2 g) in pyridine (10 ml) was added dropwise, after which the temperature was kept at −5° C (30 minutes) and then at 0° C (4 hours). The solution was finally stored at room temperature (20 hours). It was poured slowly into ice plus water (200 ml) when the product separated as an oil which did not crystallize on standing. The solution was extracted with chloroform (4×40 ml) and the combined extracts were washed successively with solutions of dilute sulphuric acid, sodium bicarbonate, and water. The solution was dried ($MgSO_4$), filtered, and evaporated to a syrup (3.9 g). This proved difficult to crystallize. However, seed crystals were obtained by dissolving part of the syrup in methanol and cooling this in an acetone/Dry Ice bath, and at the same time scratching the side of the vessel with a glass rod. The syrup crystallized completely on subsequent seeding. Recrystallization from methanol yielded 3.8 g (93%). The material had a melting point of 85–86° C and $[\alpha]_D$ −15.5° (*c*, 1.0, methanol). Anal. Calc. for $C_{21}H_{30}O_6S_2$: S, 14.48. Found: S, 14.66.

2-O-Benzoyl-di-O-isopropylidene-D-glucose Dimethyl Acetal

2-*O*-Benzoyl-di-*O*-isopropylidene-D-glucose dimethyl thioacetal (3 g) was converted to the acetal using the method described above for the preparation of 2-*O*-benzoyl-di-*O*-isopropylidene-D-mannose dimethyl acetal. A syrup (2.7 g) was obtained which crystallized on standing. Recrystallization from aqueous methanol yielded 2.5 g material (90%). After further recrystallizations from methanol and from light petroleum it had a melting point of 71–72.5° C and $[\alpha]_D$ −40.8° (*c*, 2.0, chloroform). Anal. Calc. for $C_{21}H_{30}O_8$: C, 61.43; H, 7.37. Found: C, 61.39; H, 7.34.

3,4:5,6-Di-O-isopropylidene-D-glucose Dimethyl Acetal

2-*O*-Benzoyl-di-*O*-isopropylidene-D-glucose dimethyl acetal (1.11 g) was dissolved in 50% aqueous ethanol (40 ml) containing potassium hydroxide (0.17 g) and the solution was warmed at 70° C (5 hours). The product was worked up as described above for the corresponding mannose derivative. A syrup (0.77 g, 93%) was obtained which crystallized on standing in a vacuum desiccator. After recrystallization from light petroleum it had

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

a melting point of 88–89° C and $[\alpha]_D$ −9.0° (*c*, 4.2, methanol). Infrared analysis showed no absorption for the carbonyl group (1700–1750 cm^{-1}).

*2-O-Tosyl-di-O-isopropylidene-*D*-glucose Dimethyl Acetal*

3,4:5,6-Di-*O*-isopropylidene-D-glucose dimethyl acetal (0.113 g) was dissolved in dry pyridine (1 ml) and toluene *p*-sulphonyl chloride (0.098 g) was added to the solution. Moisture was excluded from the solution, which was kept at room temperature (18 hours) and then warmed to 70° C on a water bath (30 minutes). The product was isolated in the usual way, a syrup (0.116 g, 68%) being obtained which crystallized immediately. After recrystallization from light petroleum the material had a melting point of 109–111° C and $[\alpha]_D$ +10.4° (*c*, 2.5, chloroform). Anal. Calc. for $C_{21}H_{32}O_9S$: S, 6.96. Found: S, 6.82.

*Benzoylation of Syrupy Di-O-isopropylidene-*D*-glucose Dimethyl Thioacetal*

Syrupy di-*O*-isopropylidene-D-glucose dimethyl thioacetal (14.3 g) was benzoylated as described above. A clear syrup (21 g) was obtained which showed no absorption for hydroxyl group (3500–3600 cm^{-1}) on infrared analysis. It had $[\alpha]_D$ +34.0° (*c*, 1.05, methanol).

*4-O-Benzoyl-di-O-isopropylidene-*D*-glucose Dimethyl Acetal*

Syrupy 4-*O*-benzoyl-di-*O*-isopropylidene-D-glucose dimethyl thioacetal (9.3 g) was converted to the dimethyl acetal in the usual way. A syrup (7.7 g) was obtained which crystallized on standing. Recrystallization from methanol yielded 4.9 g (56%). After further recrystallization from light petroleum the material had a melting point of 101.5–102° C and $[\alpha]_D$ −5.8° (*c*, 1.85, chloroform). Anal. Calc. for $C_{21}H_{30}O_8$: C, 61.43; H, 7.35. Found: C, 61.47; H, 7.38.

*2,3:5,6-Di-O-isopropylidene-*D*-glucose Dimethyl Acetal*

4-*O*-Benzoyl-di-*O*-isopropylidene-D-glucose dimethyl acetal (2.73 g) was dissolved in 50% aqueous methanol (100 ml) containing sodium hydroxide (0.27 g) and the solution was warmed at 70° C (4 hours). Following the usual method of isolation a syrup (1.92 g, 95%) was obtained. This had $[\alpha]_D$ −15.9° (*c*, 3.5, methanol). Infrared analysis showed no absorption for carbonyl peak.

The authors wish to thank the National Research Council for grants which made this work possible.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART IV. INTERMOLECULAR HYDROGEN BONDING IN ANILINES AND PHENOLS[1]

J. C. DEARDEN[2] AND W. F. FORBES[3]

ABSTRACT

Intermolecular hydrogen bonding in anilines and phenols can be subdivided into bonding involving solute molecules only, and into bonding involving both solute and solvent molecules. Interactions which do not involve hydrogen bonding are also possible between solute and solvent molecules. Spectral effects which may be associated with each of these interactions are described and discussed for anilines and phenols. By noting the effects of substituents on the various interactions, tentative conclusions can be deduced concerning the nature of these interactions.

INTRODUCTION

Intermolecular hydrogen bonding is a well-known phenomenon in a number of phenols and anilines, since the changes caused by the bonding can be detected by the changes in a number of physical properties such as melting points, solubilities, dipole moments, spectral effects, and other properties. The spectral changes caused by intermolecular hydrogen bonding in substituted benzoic acids have been discussed in previous parts of this series (1). The purpose of the present paper is to extend this investigation to anilines and phenols.

HYDROGEN BONDING BETWEEN SOLUTE MOLECULES ONLY

Von Keussler (2) has shown that an increase of the solute concentration beyond the more readily accessible concentration range (i.e. solute concentration greater than ca. 10^{-2} moles/liter) causes a concentration dependence in the *C*-band of the ultraviolet spectrum for solutions of phenol in cyclohexane. (For band nomenclature used, see previous parts of this series.) We have verified von Keussler's results and have also investigated the corresponding spectral changes in both the *B*-band and the *C*-band for a number of phenols, and for anisole. The relevant data are listed in Table I. Table I and also Ito's recently obtained values for the *C*-bands of phenol and anisole (3) show that only phenol and certain alkyl-substituted phenols give rise to appreciable spectral changes in the *C*-band and this suggests that the spectral changes are caused by intermolecular hydrogen bonding between phenol molecules. The relevant spectral curves are shown in Fig. 1. The ultraviolet data in this way confirm the well-known fact that phenol forms an intermolecular hydrogen bond with other phenol molecules, and incidentally that this bond is weaker than the intermolecular hydrogen bond between benzoic acid molecules since greater solute concentrations are required for the phenol solutions before a concentration dependence is observed. This conclusion has frequently been deduced from other spectral data which indicate that phenol molecules associate by means of hydrogen bonding to form dimers, trimers, and even polymers with the degree of association

NOTE: Wavelengths are corrected in this and subsequent tables. Values in italics represent inflections.
*Two cell thicknesses were used throughout. 25.1 μ for concentrations ca. 10^{-2}–10^{-1} molar, and 2.91 μ for concentrations ca. 0.1–2 molar.

apparently being proportional to concentration, and also that appreciable hydrogen bonding does *not* occur below a solute concentration of about 0.01 mole/liter (see refs. 4, 5 and compare also, for example, refs. 6, 7, 8, which suggest that the related alcohols also do not associate appreciably below a solute concentration of ca. 0.005 mole/liter).*

**Neither the ultraviolet spectrum of aniline within the concentration range 1.00×10^{-2} to 3.36×10^{-4} moles/liter in cyclohexane solution (9), nor the ultraviolet spectrum of phenol within the concentration range 2.88×10^{-2} to 0.92×10^{-4} moles/liter in cyclohexane solution (this paper) shows any appreciable concentration dependence. Since under these conditions the benzoic acid spectrum shows a concentration dependence which has been ascribed to intermolecular hydrogen bonding (1), this again supports the hypothesis that within this same concentration range aniline and phenol do not associate appreciably.*

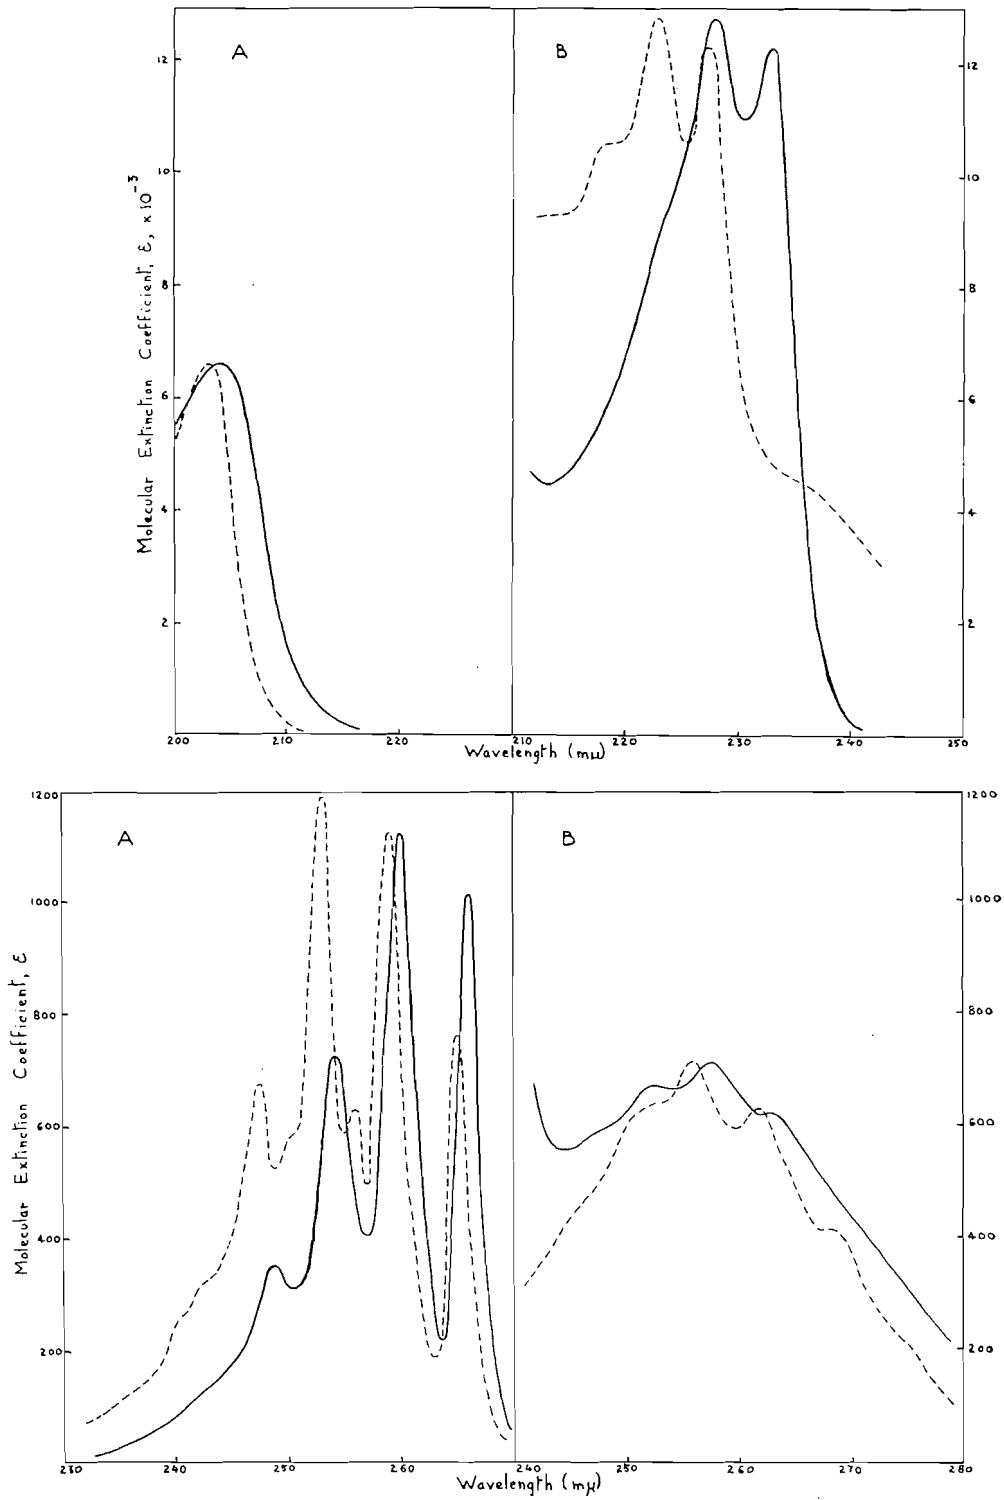

FIG. 3. The *B*-bands (above) and the *C*-bands (below) of (A) fluorobenzene and (B) iodobenzene in the vapor phase (– – –) and in cyclohexane solution (——). (ε values in the vapor phase are arbitrarily chosen.)

Our own data for the infrared hydroxyl band of phenol solutions in cyclohexane are as follows: at a solute concentration of 1.0 mole/liter, ν_{max} = 3613 cm^{-1} for what is assumed to be the unassociated hydroxyl band, the absorption being weak compared with the absorption ascribed to associated hydroxyl bands; at a solute concentration of 0.1 mole/liter, ν_{max} = 3622 cm^{-1}, and this band associated with free hydroxyl absorption is now considerably more intense than the other hydroxyl absorption.

The observed concentration dependences for the ultraviolet spectra of aniline and N,N-dimethylaniline are shown in Fig. 2. As might be anticipated from the *C*-band spectral changes observed for phenol and for the methyl-substituted analogue anisole, the *C*-band of aniline shows a decreased fine structure with increase of solute concentration. N,N-Dimethylaniline shows no fine structure even at the lowest concentrations.

From theoretical considerations it might be expected that an O—H...O hydrogen bond is energetically more favorable than an N—H . . . N hydrogen bond for the molecules under consideration, and this indication is again supported by the infrared data (see ref. 5 and cf. also refs. 10, 11). Our own data for the infrared N—H stretching bands of aniline solutions in cyclohexane are as follows: at a solute concentration of 1.00 mole/liter, ν_{max} = 3358 and 3449 cm^{-1} whereas at a solute concentration of 0.20 mole/liter, ν_{max} = 3366 and 3456 cm^{-1}. It is also noteworthy that these bands are still intense in a solution of aniline in cyclohexane containing 4% ether.

SOLUTE–SOLVENT INTERACTIONS INVOLVING ONLY SOLUTE AND INERT SOLVENT

If the ultraviolet absorption spectra of phenol or aniline are determined in the vapor phase and in an inert solvent it is found that a wavelength displacement occurs for each compound. This displacement cannot be caused exclusively by intermolecular X—H . . . Y hydrogen bonding because similar wavelength displacements are observed for anisole, and comparable wavelength displacements are also observed for a number of other compounds in which intermolecular hydrogen bonding is unlikely to occur to any marked extent. These observations are illustrated in Table II and the spectral curves for fluorobenzene and iodobenzene are also recorded in Fig. 3.

The data in Table II show that the main absorption bands of a number of aromatic conjugated compounds tend to be bathochromically displaced on passing from the vapor phase spectrum to the spectrum in cyclohexane solution, an observation which has previously been noted by Bayliss and McRae (15). Also, the observed fine structure appears to decrease in cyclohexane solution (see Fig. 3). The displacement appears to be qualitatively related to the dipole moment of the solute, since it is generally larger for compounds possessing an appreciable dipole moment such as nitrobenzene, and larger still for compounds like *p*-iodonitrobenzene (see Table II). Further, altering the temperature does not appreciably affect the wavelength of maximal absorption of some of the compounds in the vapor phase (14), and the spectra of some of these compounds are, moreover, similar in hexane and cyclohexane solution (see "Experimental").

It may further be noted that this somewhat unexpected solvent effect is not confined to the ultraviolet spectra since a "general" solvent effect is also observed in the infrared spectra; for example, the locations of the maximal frequencies of the two infrared NH absorptions for aniline and related compounds are appreciably displaced to lower frequency, i.e. to longer wavelength, in carbon tetrachloride solution, compared with the vapor phase spectrum (see ref. 16, and cf. also refs. 7, 17, 18). The most probable explanation is to associate this solvent effect with oriented solvent molecules which, by virtue of an induced dipole, facilitate the absorption.

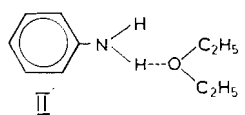
*This paper.



SOLUTE–SOLVENT INTERACTIONS INVOLVING HYDROGEN BONDING IN SOLUTIONS OF ANILINES AND PHENOLS

Apart from the general solvent effect discussed in the previous section we can discern spectral effects which are ascribed to intermolecular hydrogen bonding between solute and solvent. For example, ether frequently causes a bathochromic wavelength displacement in the *B*-band which is ascribed to intermolecular hydrogen bonding of type I or II, because replacement of the relevant hydrogen atom by a methyl group tends to destroy this effect (see Fig. 4 and cf. ref. 19), and also because parallel effects may be deduced from *C*-band and dipole moment data (20, cf. also 21).

Figure 4 shows that the spectral change ascribed to hydrogen bonding is greater for

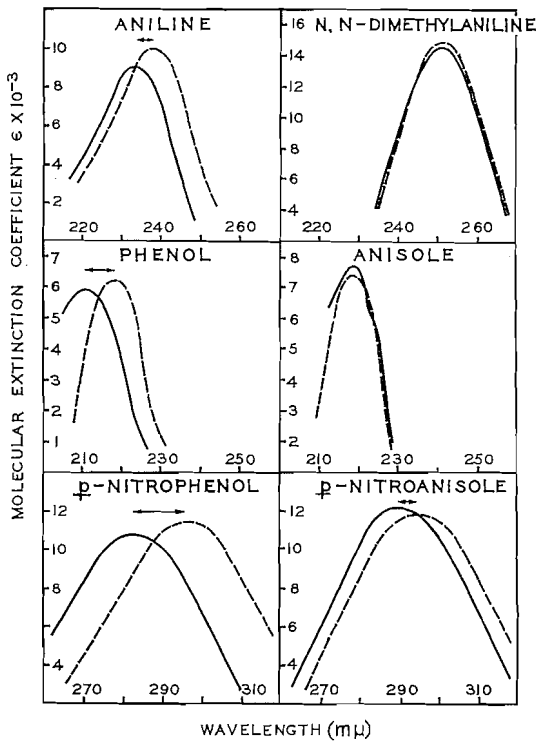

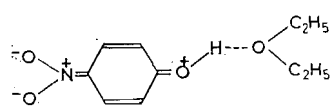

FIG. 4. *B*-Bands of anilines, phenol, and *p*-nitrophenol, and methyl-substituted analogues in cyclohexane (full lines) and in ether (dotted lines).

phenol than for aniline, which supports the previously noted hypothesis that an O—H ... X hydrogen bond is energetically more favored than an N—H ... X hydrogen bond for the molecules under consideration. A fuller list of spectra of phenols, aromatic amines, and their O- and N-methyl derivatives in cyclohexane and ether solutions is provided in Table III.

Table III indicates that for a number of *p*- or *m*-substituted compounds, where the relevant spectra are available, the observed wavelength displacements are similar to those in the parent compounds, phenol or aniline. That is, the bathochromic wavelength displacement, ascribed to the intermolecular hydrogen bond, is comparable for compounds like *p*-nitrophenol and for phenol, remembering that part of the observed wavelength displacement also occurs in *p*-nitroanisole or nitrobenzene and is therefore not caused by the same intermolecular hydrogen bonding involving the phenol group (see Fig. 4 and Table III). Moreover, since the total displacement, if expressed in wave numbers, for *p*-nitrophenol is only slightly smaller than the sum of the effects in phenol and nitrobenzene, this suggests that interactions which can be represented by resonance structures of type III do not appreciably affect the intermolecular hydrogen bond.

Other *p*-substituents, such as —Cl, —CH_3, etc., appear to have a similar effect and also tend to weaken slightly the intermolecular hydrogen bond as judged by the observed frequency displacements (see Table III). A *m*-substituent again sometimes appears to reduce the strength of the hydrogen bond, as indicated by the reduced frequency displacements (see Table III). A possible explanation is that a *m*- or *p*-substituent tends to interact with the π-electrons of the benzene ring, and that this interaction is competitive in as much as it reduces the benzene ring—OH group interaction which facilitates intermolecular hydrogen bonding.

o-Substituted compounds are evidently less satisfactory for comparison purposes since steric interactions *and* intramolecular hydrogen bonding would be expected to interfere with the conformations of the molecule and with the solvent–solute interactions. However, it may be noted as shown in Fig. 5 that the spectra of some intramolecularly bonded molecules such as *o*-hydroxyacetophenone are almost identical in ether and cyclohexane

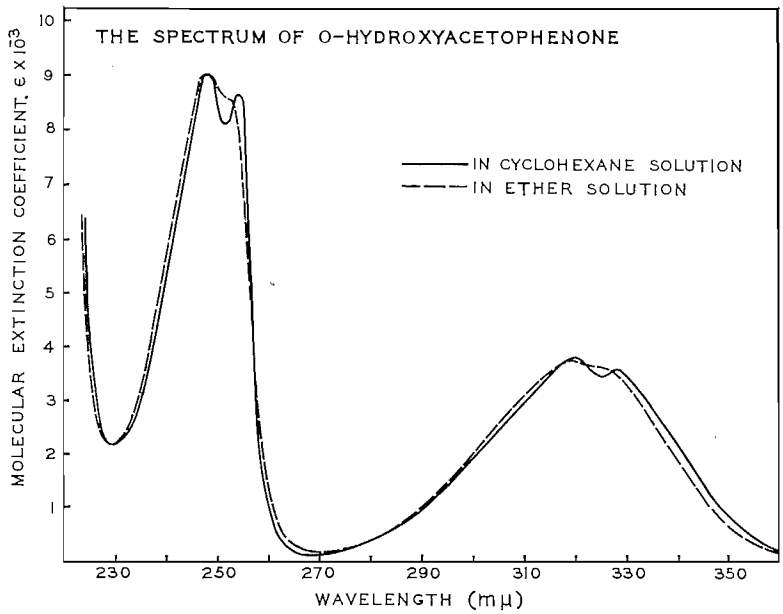

FIG. 5. The ultraviolet spectrum of *o*-hydroxyacetophenone in cyclohexane (full line) and ether (dotted line) solution.

solution (see also Table III for the *B*-bands of *o*-hydroxyacetophenone and *o*-hydroxybenzaldehyde and relevant reference compounds), and this is assumed to show that an intramolecular hydrogen bond prevents the formation of an intermolecular hydrogen bond, since intermolecular hydrogen bonding normally gives rise to spectral changes. *o*-Fluorophenol, however, does give rise to an appreciable wavelength displacement (cf. ref. 1 for the spectrum of *o*-fluorobenzoic acid, which also indicates the absence of a strong intramolecular hydrogen bond for the latter *o*-fluoro compound).

The data in Figs. 6 and 7 for phenol and *p*-nitrophenol in cyclohexane–ether solvent mixtures show that only small amounts of ether are necessary to cause the appearance of the absorption characteristic of the hydrogen-bonded structures. Support for this hypothesis is also received from the infrared spectrum of phenol. This shows that at a concentration of 0.1 mole/liter, i.e. at a concentration at which in cyclohexane solution the free hydroxyl band at 3622 cm^{-1} predominates, addition of 1% of ether to the solution considerably decreases the intensity of this band at the expense of a band at 3331 cm^{-1}, which is ascribed to associated hydroxyl absorption. In cyclohexane solution containing 2% ether the band at 3622 cm^{-1} occurs at 3618 cm^{-1} with yet further decreased absorption intensity and the hydroxyl absorption associated with hydrogen-bonded structures of type I at 3331 cm^{-1} accounts almost completely for the observed hydroxyl absorption. This again suggests that a relatively strong hydrogen bond is formed between the phenolic OH group and the ether molecules, a bond which may be regarded almost as a stoichiometric linkage (cf. also ref. 20 for the effect of small quantities of dioxane on the ultraviolet *C*-band of phenol). Previously determined data, on the other hand, indicated that small amounts of ether do *not* appreciably alter the typical aniline spectrum (see Table I in ref. 9), and this must be taken as evidence against the formation of a "stable stoichiometric" hydrogen bond between aniline and ether molecules under the conditions of the experiment. That is, the data again suggest that the N—H...X bond is weaker than the O—H...X hydrogen bond.

SOLUTE-SOLVENT INTERACTIONS INVOLVING THE OXYGEN OR NITROGEN ATOMS OF PHENOLS AND ANILINES

Another spectral effect which may be caused by intermolecular hydrogen bonding is the observed hypsochromic wavelength displacement in the *B*-bands of aniline, N,N-dimethylaniline, phenol, and anisole on changing the solvent from cyclohexane or ethanol to water. A selection of the relevant data is listed in Table IV.

TABLE IV

Wavelength displacements ($\Delta\lambda$ in mμ) between *B*-bands in cyclohexane (non-bonded species) and ethanol or aqueous solutions

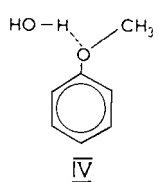
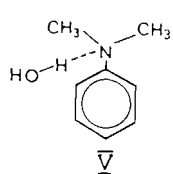
*This value is believed to be caused preferentially by transitions involving locally excited states and hence the absorption is considered anomalous (see ref. 12).



⊕Relative to ethanol.

†This paper.



‡W. G. Douben and J. W. Collette (J. Am. Chem. Soc. **81**, 967 (1959)) report an ϵ_{max} value of 6600 for this compound, but this ϵ value is almost certainly too low.

§Values in *n*-heptane (see ref. 23).

Table IV shows that definite wavelength displacements now occur also for the methyl analogues, anisole, and N,N-dimethylaniline, and hence the wavelength displacements cannot be caused exclusively by hydrogen-bonded structures of type I or II. The wavelength displacements in Table IV can, however, be associated—at least partly—with hydrogen-bonded structures of type IV and V, since structures of this type can be imagined to decrease the electronic interaction between the nitrogen or oxygen atoms and the benzene ring, and so cause the *hypsochromic* wavelength displacement (cf. 19,

IV

V

20, 22), and incidentally the frequently observed decreased absorption intensity in the ultraviolet region for spectra of this type in aqueous media.*

However, while the above is probably a contributing factor it is evidently not the sole contributing factor, since, for example, the previously mentioned interactions will also contribute to the observed spectral changes. Therefore, a variety of spectral changes would be expected and are, in fact, observed. For example, in the spectra of compounds like *p*-nitroanisole or *p*-nitrophenol, water or ethanol molecules can attach themselves to the nitro group and this presumably accounts partly for the observed *bathochromic* wavelength displacement between cyclohexane, ethanol, and aqueous solutions (see Table IV). Moreover, dipole–dipole interactions would also be expected to cause *bathochromic* wavelength displacements, which may again hide any *hypsochromic* wavelength displacement caused by the solute–solvent interaction under discussion, and hydrogen bonding involving the hydrogen atoms of a phenolic OH group would be expected to have a similar effect. Hence wavelength displacements appear to be of doubtful diagnostic value. It is, however, significant that for a number of compounds of this type a characteristic intensity decrease is observed if the spectra are determined in aqueous solution (see Table IV).

Next, the solvent changes in the spectra of phenol for solutions containing various ethanol–water solvent mixtures are shown in Fig. 8. Figure 8 indicates a gradual change

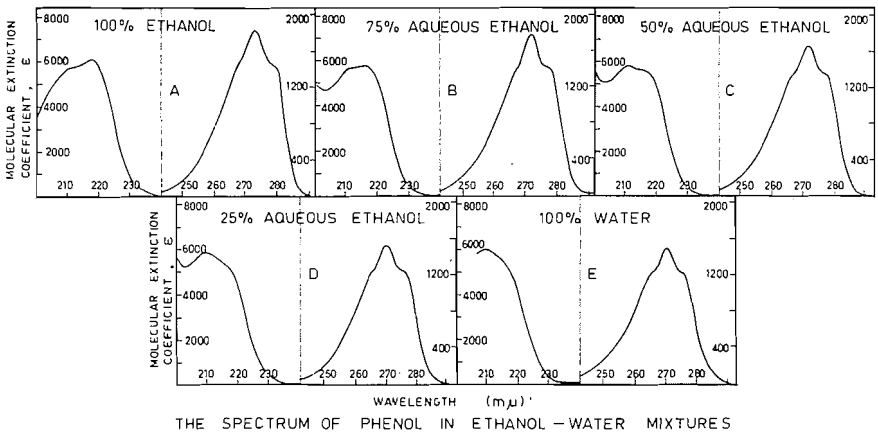


FIG. 8. The spectrum of phenol in (A) ethanol; (B) 75% aqueous ethanol; (C) 50% aqueous ethanol; (D) 25% aqueous ethanol; and (E) water.

in the spectrum of phenol on replacing ethanol by water as the solvent, and this suggests the absence of a stable predominating hydrogen bond between phenol and water. This follows because the spectral changes shown in Figs. 6 and 8 are different, and consequently the hydrogen bond between phenol and ether molecules probably differs from the solute–

**More precisely, this decreased interaction between the π-electrons of the benzene ring and the p-electrons of the nitrogen or oxygen atom may be caused in two ways; either the hydrogen bond directly removes electrons from the nitrogen or oxygen atoms, or because the hydrogen-bonded structure increases the effective size of the oxygen- or nitrogen-substituted group and a consequent twisting of the group out of the plane of the benzene ring may cause the observed hypsochromic wavelength displacement. There is, in fact, some evidence for the operation of steric factors because steric interactions have previously been noted to be able to prevent the formation of intermolecular hydrogen bonding (cf. the discussion of the spectra of o-substituted phenols in ref. 12). Moreover, the postulate of steric interactions can be used to rationalize the greater effectiveness of the water molecule in forming this type of hydrogen bond, since a larger solvent molecule such as ethanol might be expected to have greater difficulty in approaching the oxygen or nitrogen atoms (see, for example, the spectra of N, N-dimethylaniline and anisole in Table IV).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

solvent interaction involving the oxygen or nitrogen atoms in solutions of phenols or anilines. If phenol were to form a considerably stronger hydrogen bond with water than with ethanol it would be expected that only small quantities of water were necessary to produce a spectrum similar to the spectrum of phenol in water. A probable explanation of the above spectral changes is that *both* water and ethanol are continually forming and reforming hydrogen bonds with the phenol molecules (cf. ref. 1). According to this view the difference between the spectral changes in Fig. 6 and Fig. 8 can be explained because for solutions of phenol in cyclohexane–ether mixtures any hydrogen bonds competing with phenol–ether hydrogen bonds are likely to be insignificant, while for solutions of phenol in ethanol–water mixtures hydrogen bonds competing with phenol–water hydrogen bonds are probably important.

Apart from the wavelength displacements observed in Fig. 8 it may be noted that the change to the more polar solvent (water) decreases the fine structure of the phenolic *B*-band. A decreased fine structure in the *C*-band of phenol and anisole has previously (12, 13) been associated with hydrogen bonding or other solvent–solute interactions, and this view also receives support from the *B*-band of benzaldehydes (26) and of other compounds (27) where the characteristic fine structure is markedly decreased in the presence of ethanol or ether.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP500 spectrophotometer. For each compound at least two independent sets of observations were made. The accuracy of λ_{max} values is estimated to be ± 1 mμ, and the precision of ϵ_{max} values $\pm 5\%$ or better. Values were reproducible in most cases to $\pm 2\%$. Vapor spectra were obtained by allowing specially designed 1-cm cells (Research and Industrial Instruments Co., Brixton, London, S.W.9, England) to remain in an atmosphere of the relevant compound until the optical density was within the permissible limits, and the cells were then sealed (see also footnote of Table I).

Some of the spectra have previously been described by other workers but whenever convenient the spectra were redetermined to ensure identical conditions for all the recorded spectra. The spectrum of *m*-iodobenzaldehyde was determined in both hexane and cyclohexane solution, and the determinations were found to be identical within experimental error.

The infrared spectra were determined on a Unicam SP100 instrument, using a NaCl prism.

The compounds under investigation were mostly commercial materials, purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher), *n*-hexane specially prepared for spectroscopy (BDH), ethyl ether (Spectro Grade, Eastman), commercially available absolute ethanol suitable for spectroscopy, and freshly distilled water.

ACKNOWLEDGMENTS

The authors are greatly indebted to Miss N. Joan Smith for very competent technical assistance in the spectral determination of some of the compounds, and thanks are due to Mr. D. L. Coffen for determining the infrared spectra.

They also wish to thank the Fisheries Research Board of Canada for financial support, since part of this work was carried out under a contract between the Fisheries Research

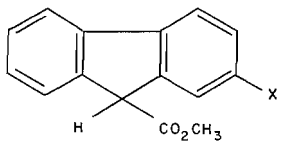
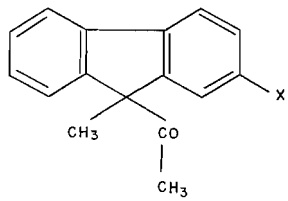
ALIPHATIC CHEMISTRY OF FLUORENE

PART III. SOME DERIVATIVES OF FLUORENE AND PHENANTHRENE[1]



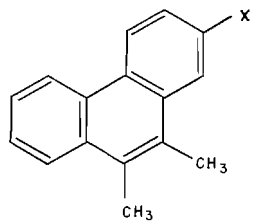
P. M. G. Bavin

ABSTRACT



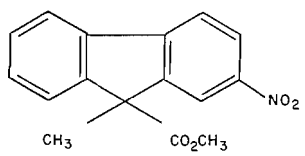
Methyl fluorene-9-carboxylate and 9-methyl-9-acetylfluorene have been nitrated and the products converted to 2-nitrophenanthrene and 2-nitro-9,10-dimethylphenanthrene, respectively.

Acetylation of 9,10-dimethylphenanthrene has given only one ketone, probably the 3-isomer. 4-Nitrofluorenone has been synthesized by a convenient route.

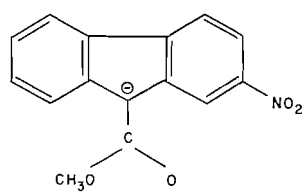


All five mononitrophenanthrenes have been synthesized (1) but only the 2-isomer is readily accessible (1, 2). Another closely related route to 2-nitrophenanthrene has now been found. Methyl 2-nitrofluorene-9-carboxylate (II), prepared by nitrating the ester (I), was reduced with lithium borohydride and the crude carbinol heated with polyphosphoric acid to give 2-nitrophenanthrene in 45% yield. In a similar way, 2-nitro-9,10-dimethylphenanthrene (VI) was prepared from 9-methyl-9-acetylfluorene (III) via the nitro-ketone (IV).

I, X = H
II, X = NO_2

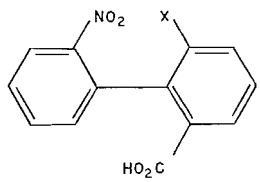


III, X = H
IV, X = NO_2

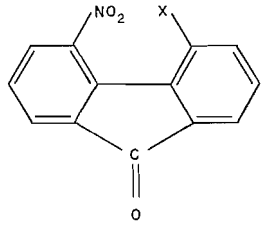


V, X = H
VI, X = NO_2
VII, X = NH_2
VIII, X = $NH \cdot CO \cdot CH_3$

During the isolation of the nitro-ester (II), it was noted that washing a chloroform solution of the nitration products with 2% sodium hydroxide solution resulted in the formation of a deep purple color, most easily observed by dissolving the pure nitro-ester in methanol containing sodium methoxide. Under the latter conditions, the color was rapidly discharged by methyl iodide with formation of what is considered to be the C-methyl derivative (IX) (cf. the alkylation of I (3)). The deep purple color was attributed to the anion (X) (cf. methyl fluorene-9-carboxylate anion (3)). These observations led directly to investigations of several aspects of the chemistry of fluorene (3, 4, 5) which are still in progress.



IX



X

[1]*Manuscript received February 5, 1960.*
Contribution from the Chemistry Department, the University, Hull, East Yorkshire, England.

4-Nitrofluorenone (XIV) has been synthesized by the cyclization of the nitro-acid (XI) (cf. the acids XII and XIII which gave XV and XVI (6, 7)), but its conversion to 4-nitrofluorene, a desirable intermediate for the synthesis of the very inaccessible 4-nitrophenanthrene, was not achieved.

XI, X = H
XII, X = NO_2
XIII, X = CO_2H

XIV, X = H
XV, X = NO_2
XVI, X = CO_2H

The use of methyl fluorene-9-carboxylate as a synthetic tool has made several otherwise inaccessible hydrocarbons readily available (3, 8). One of these, 9,10-dimethylphenanthrene, has now been acetylated. Under homogeneous conditions in nitrobenzene at room temperature, only one ketone was isolated in 75–85% yield after reaction times of either 12 hours or 14 days. Prolonged efforts to degrade the ketone to the amine or carboxylic acid have failed. Attempts to synthesize reference compounds other than the amine (VII) have been unsuccessful but are reported in the Experimental section. The orientation of the *x*-acetyl-9,10-dimethylphenanthrene remains unestablished, but it is probably the 3-isomer by analogy with the acetylation of phenanthrene (9, 10 but see also Gore (11)).

9,10-Dimethylphenanthrene has been oxidized by aqueous sodium dichromate at 250° to phenanthrene-9,10-dicarboxylic acid (94%), 2-methyltriphenylene yielding the corresponding acid in 98% yield.* This technique should prove of great value in the preparation of derivatives of polycyclic hydrocarbons.

EXPERIMENTAL

2-Nitrophenanthrene

Methyl fluorene-9-carboxylate (2 g) was nitrated as described for 9-fluorenylmethyl acetate (1). *Methyl 2-nitrofluorene-9-carboxylate* crystallized from xylene–pentane as pale yellow needles (0.8 g), m.p. 178–179°. Found: C, 67.0; H, 4.31; N, 5.21%. Calc. for $C_{15}H_{11}NO_4$: C, 66.91; H, 4.12; N, 5.20%. Less satisfactorily, 2-nitrofluorene-9-carboxylic acid (13) was esterified with methanolic hydrogen chloride.

The nitro-ester dissolved in methanol containing sodium methoxide to give a black solution, purple at high dilution. The color was rapidly discharged by methyl iodide with formation of *methyl 9-methyl-2-nitrofluorene-9-carboxylate*, pale yellow prisms from heptane, m.p. 122–123°. Found: C, 67.73; H, 4.19%. Calc. for $C_{16}H_{13}NO_4$: C, 67.84; H, 4.63%.

The nitro-ester (II) was reduced with lithium borohydride in tetrahydrofuran (14, 15) to give an orange resin. A part of the resin was acetylated with isopropenyl acetate (1) and the product purified by passing a hexane solution of it through a column of activated

**The author is indebted to Dr. D. Fishel of the State University of South Dakota for these experiments (12, p. 22P).*

For personal use only.

alumina. The eluted material crystallized as pale yellow prisms (22%) from hexane, m.p. 123–125°, not depressed by authentic 2-nitro-9-fluorenylmethyl acetate (1).

The other part of the resin was heated with polyphosphoric acid as described for 9-fluorenylmethyl acetate (1) to give 2-nitrophenanthrene as yellow needles from heptane (45%), m.p. 118–119°, not depressed by an authentic sample (1). Oxidation with periodic acid in boiling acetic acid gave 2-nitrophenanthraquinone, orange plates from acetic acid, m.p. 270–272°, not depressed by an authentic specimen (16). Found: C, 65.79; H, 2.60%. Calc. for $C_{14}H_7NO_4$: C, 66.41; H, 2.79%.

2-Nitro-9,10-dimethylphenanthrene

Pure 9-methyl-9-acetylfluorene (8) was nitrated as described for 9-fluorenylmethyl acetate (1). *2-Nitro-9-methyl-9-acetylfluorene* (70%) formed pale yellow prisms from methanol, m.p. 136–138°, raised to 138–139° by two further crystallizations. Found: C, 71.99; H, 5.19%. Calc. for $C_{16}H_{13}NO_3$: C, 71.90; H, 4.90%.

The *carbinol*, obtained as an oil by reducing the nitro-ketone with methanolic sodium borohydride, was esterified with *p*-toluenesulphonyl chloride in pyridine (3). The crude *tosylate* was boiled under reflux for 12 hours with 94% formic acid, *2-nitro-9,10-dimethylphenanthrene* crystallizing on cooling. Purification by passing a hexane solution of it through a column of activated alumina and concentration of the eluant gave bright yellow needles (74% based on nitro-ketone), m.p. 163–164°. Found: C, 76.75; H, 5.31%. Calc. for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.57%.

2-Amino-9,10-dimethylphenanthrene, prepared by reducing the nitro compound with hydrazine and palladized charcoal (17), crystallized as white needles from ethanol, m.p. 141–142°. The *N-acetyl* derivative crystallized from toluene as small white needles, m.p. 256–257°. A sample was sublimed at 220°/10^{-3} mm for analysis. Found: C, 82.16; H, 6.86%. Calc. for $C_{18}H_{17}NO$: C, 82.10; H, 6.51%.

4-Nitrofluorenone

2′-Nitrodiphenyl-2-carboxylic acid (18) (1.2 g) was maintained for 20 minutes at 115° with concentrated sulphuric acid (40 ml). Pouring onto ice precipitated a yellow solid, which crystallized from methanol (Norite) as long yellow needles (0.98 g), m.p. 173–174° (lit. m.p. 173–174° (19)).

9,10-Dimethylphenanthrene

Crude 9-acetylfluorene (20) (1 mole) was methylated with methyl iodide (2.1 moles) in methanol containing sodium methoxide (2 moles), the reaction being complete after 6 hours at room temperature. The crude ketone (96%, m.p. 82–84°) (lit. m.p. 85–86° (8)) was reduced with ethereal lithium aluminum hydride to 1′-(9-methyl-9-fluorenyl)-ethanol (98%, m.p. 77–80°) (lit. m.p. 81° (8)). The *tosylate*, prepared in the usual way (3), formed colorless prisms from chloroform–hexane, m.p. 88–90° with decomposition to 9,10-dimethylphenanthrene. Found: S, 8.62%. Calc. for $C_{23}H_{22}O_3S$: S, 8.47%.

9,10-Dimethylphenanthrene was prepared either by boiling the crude tosylate with 94% formic acid, or by boiling the carbinol with its own weight of phosphorus pentoxide in xylene for 2 hours. It formed long white needles (85–91%) from toluene–hexane, m.p. 143–144° (lit. m.p. 143–144° (8)).

Phenanthrene-9,10-dicarboxylic acid

9,10-Dimethylphenanthrene was oxidized by aqueous sodium dichromate solution at 250° (12), giving crude phenanthrene-9,10-dicarboxylic acid in 94% yield. The anhydride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

crystallized from acetic anhydride as pale yellow needles, m.p. 322–324°, not depressed by an authentic specimen (21).* The dimethyl ester formed pale yellow needles from benzene, m.p. 132–133° (lit. m.p. 131° (21)).

Triphenylene-2-carboxylic Acid

2-Methyltriphenylene (22), oxidized as above, gave triphenylene-2-carboxylic acid in 98% yield. The methyl ester crystallized as colorless needles from toluene, m.p. 129–130°. Found: C, 83.81, 84.01; H, 5.26, 5.34%. Calc. for $C_{20}H_{14}O_2$; C, 83.90; H, 4.93% (lit. m.p. 122–124° (23)).

x-Acetyl-9,10-dimethylphenanthrene

Anhydrous aluminum chloride (43 g, 2.2 moles) was dissolved in dry nitrobenzene (150 ml) and the solution cooled to 0°. 9,10-Dimethylphenanthrene (29.8 g, 1 mole) was added, followed by freshly distilled acetyl chloride (16 g, 1.4 moles). The mixture was left at room temperature for 14 days with exclusion of moisture. The complex was decomposed with ice and hydrochloric acid and the nitrobenzene removed by distillation with steam. Distillation of the residue at 1–2 mm gave the ketone as an almost colorless oil, which soon crystallized. One crystallization from acetone–methanol gave very pale yellow prisms (26 g, 73%), m.p. 108–110°. Fractional crystallization gave a further 4.5 g of ketone of the same melting point. A second ketone was not found.

The first crop of ketone was recrystallized once from methanol–acetone and twice from toluene–heptane to give colorless prisms (20 g, 56%), m.p. 111.5–112°. This melting point was not raised by further crystallizations. Found: C, 86.94; H, 6.55%. Calc. for $C_{18}H_{16}O$: C, 87.06; H, 6.50%.

The *oxime*, prepared in pyridine–ethanol, crystallized as white needles from toluene–heptane, m.p. 209–210°. OH stretching band (CS_2 solution) 3586 cm^{-1}. Found: C, 82.13; H, 6.65%. Calc. for $C_{18}H_{17}NO$: C, 82.11; H, 6.51%.

The *azine*, prepared by warming the ketone with hydrazine in ethanol, separated from xylene as golden-yellow plates, m.p. 280–281°. Found: C, 87.82; H, 6.41; N, 5.80%. Calc. for $C_{36}H_{32}N_2$: C, 87.77; H, 6.55; N, 5.69%.

x-Ethyl-9,10-dimethylphenanthrene was prepared by boiling the ketone (1 g) under reflux for 6 hours with hydrazine hydrate (10 ml) and diethylene glycol (100 ml). The purified hydrocarbon, obtained by passing a hexane solution of it through a column of activated alumina, crystallized from methanol as long white needles, m.p. 45.5–46°. Found: C, 92.32; H, 5.72%. Calc. for $C_{18}H_{18}$: C, 92.26; H, 5.74%. The 1,3,5-trinitrobenzene complex crystallized from methanol as bright yellow needles, m.p. 164–166°.

Numerous attempts to oxidize the ketone using aqueous sodium hypochlorite and pyridine or dioxane as diluent gave tars and only traces of acidic material. Reaction with sodium azide in acetic acid (24) also failed to yield useful products.

Reaction between the pure oxime and phosphorus pentachloride – benzene, hydrogen chloride – acetic acid or polyphosphoric acid gave uniformly low yields of mixtures, from which traces of an amine were obtained by hydrolysis with ethanolic hydrogen chloride. The amine rapidly turned red in air, behavior similar to that of 3-aminophenanthrene, and had an infrared spectrum markedly different from that of 2-amino-9,10-dimethylphenanthrene.

3-Ethylphenanthrene-9-carboxylic acid

3-Acetyl-9-bromophenanthrene (55 g, m.p. 151–153°) (lit. m.p. 150–151° (25)) was

*The author is indebted to I. Ungar of the Battelle Memorial Institute for this sample.

boiled under reflux for 4 hours with cuprous cyanide (20 g) and dimethylformamide (150 ml) containing 2 drops of pyridine. After cooling, the mixture was poured into concentrated aqueous ammonia and the precipitated solid crystallized from toluene, 3-acetyl-9-cyanophenanthrene (50 g) separating as yellow needles, m.p. 226–227° (lit. m.p. 220–221° (25)).

The nitrile (49 g) was boiled under reflux with hydrazine hydrate (40 ml) and diethylene glycol (300 ml). After 1 hour a solution of potassium hydroxide (40 g) in water (60 ml) was added dropwise. The mixture was distilled until a distillate temperature of 195° was reached. After a further 4 hours, the mixture was cooled and poured into excess dilute hydrochloric acid. The *acid* was collected, washed, and dissolved in 5% aqueous potassium carbonate solution and the solution filtered into dilute hydrochloric acid. The purified acid was dried and converted to the methyl ester by successive reactions with thionyl chloride and methanol. After distillation at 200–210° and 1–2 mm, the colorless ester was saponified, giving the acid as an oil which crystallized during several days. The yield was 20 g. Two crystallizations from methanol–acetone gave almost colorless needles, m.p. 180–182°, with previous sintering. Found: C, 82.30, 82.20; H, 5.57, 5.68%. Calc. for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

3-Ethyl-9,10-phenanthraquinone

3-Acetylphenanthrene (9) was reduced to 3-ethylphenanthrene using hydrazine and diethylene glycol. The hydrocarbon, which has not been obtained crystalline (26), was distilled and purified through the picrate, which crystallized from methanol as orange needles, m.p. 120–121°. Oxidation with chromic oxide in acetic acid gave 3-ethylphenanthraquinone, slender orange needles from ethanol, m.p. 173–174° (lit. m.p. 168–170° (26)). Heating the quinone with potassium hydroxide in water or aqueous alcohol gave tars and only traces of acidic material.

3-Methylfluorene

Benzyl *p*-tolyl ketone (218 g, 55%) was prepared from phenylacetyl chloride (2 moles) and toluene, as described for benzyl phenyl ketone (27, p. 156). It formed plates from methanol, m.p. 109–110° (lit. m.p. 110–110.5° (28)). Found: C, 85.57; H, 6.88%. Calc. for $C_{15}H_{14}O$: C, 85.68; H, 6.71%. The *2,4-dinitrophenylhydrazone* formed irregular red prisms from benzene, m.p. 213–214°. Found: C, 64.45; H, 4.47%. Calc. for $C_{21}H_{18}N_4O_4$: C, 64.60; H, 4.65%.

The preceding desoxybenzoin was converted to 4-methylbenzoin* by a general procedure (29, p. 296) involving successively photobromination, reaction with sodium ethoxide, and hydrolysis with dilute hydrochloric acid. It crystallized from aqueous ethanol as long colorless needles (65%), m.p. 112–113° (lit. m.p. 110° (30)). Found: C, 79.81; H, 6.39%. Calc. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

Oxidation of the benzoin with cupric sulphate and pyridine (31, p. 715) gave 4-methylbenzil as a yellow oil, which largely crystallized after distillation (lit. m.p. 31° (32)). Conversion to 4-methylbenzilic acid proceeded in high yield (31, p. 715), but the acid proved remarkably difficult to crystallize. The yield of white needles from chloroform–hexane, m.p. 132–134°, was only 41% (lit. m.p. 132° (32)).

Cyclization of the benzilic acid has already been reported (34) but proceeds in higher yield by a more recent procedure (33). The crude dried 3-methylfluorene-9-carboxylic acid was decarboxylated by distillation at 1 mm, giving 3-methylfluorene in 43% yield

**Primes (') are used for substituents on the ring adjacent to the carbinol group.*

based on the benzilic acid. It crystallized from methanol as colorless plates, m.p. 87–88° (lit. m.p. 88° (34)).

Prepared similarly, *benzyl p-ethylphenyl ketone* (71%) crystallized as lustrous colorless plates from methanol, m.p. 62–64°. Found: C, 85.41; H, 7.02%. Calc. for $C_{16}H_{16}O$: C, 85.67; H, 7.19%. The *2,4-dinitrophenylhydrazone* formed iridescent vermilion scales from benzene, m.p. 186–187°. Found: C, 65.10; H, 5.48%. Calc. for $C_{22}H_{20}N_4O_4$: C, 65.01; H, 5.48%.

4-Ethylbenzoin formed clusters of needles from heptane, m.p. 89–90°. Found: C, 79.91; H, 6.44%. Calc. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%. 4-Ethylbenzil and 4-ethylbenzilic acid have failed to crystallize and have not been characterized.

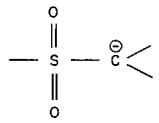
ALIPHATIC CHEMISTRY OF FLUORENE

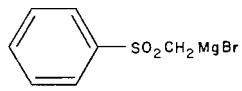
PART IV. PREPARATION AND ALKYLATION OF SOME SULPHIDES AND SULPHONES[1]

P. M. G. BAVIN[2]



ABSTRACT

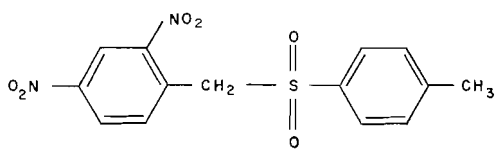
The preparations are described of some 9-fluorenyl sulphides which have been oxidized with peracetic acid to the corresponding sulphones.



9-Fluorenyl *p*-tolyl sulphone has been alkylated with a range of alkyl halides; other sulphones, including 2-nitro-9-fluorenyl *p*-tolyl sulphone, have been methylated.

Methyl fluorene-9-carboxylate anion was reduced by *p*-toluenesulphonyl chloride to dimethyl 9,9′-difluorenyl-9,9′-dicarboxylate.

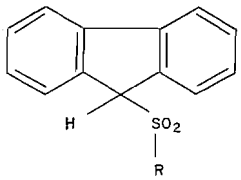
The acidity of methylene hydrogen activated by the sulphone group has been known for some time, but opinions have been divided on the reasons. Recent studies by Doering and his co-workers (1, 2, 3) have established that anions of type I are resonance stabilized by overlap between carbon $2p$ and sulphur $3d$ orbitals. The spectroscopic studies of Fehnel and Carmack (4) lend strong support to these conclusions. The latter workers found no evidence for the formation of anions from methylene activated only by a sulphone group, but Grignard derivatives of dialkyl sulphones (5, 6) and aralkyl sulphones (7, where references are given to prior publications) are well known. Field, Holsten, and Clark (7) have recently examined some reactions of phenylsulphonylmethyl magnesium bromide (II) and shown that it was alkylated in modest yield by benzyl chloride and



I

II

hexyl *p*-toluenesulphonate, in low yield by benzhydryl chloride, and not at all by *t*-butyl chloride and hexyl iodide, results which prompted its formulation as a weakly nucleophilic Grignard reagent rather than as a carbanion salt.



Nitrobenzyl sulphones are more acidic than the unsubstituted sulphones, and 2,4-dinitrobenzyl *p*-tolyl sulphone (III) has been methylated (8) using potassium ethoxide as base. The only simple sulphone to have been alkylated under comparable conditions is ethyl 9-fluorenyl sulphone (IV) (9).

III

The remarkable facility with which methyl fluorene-9-carboxylate anion reacts with a wide range of alkyl halides (10, 11, 12) has prompted an examination of other 9-substituted fluorenes. Some experiments with 9-benzoylfluorene have already been reported (13). The present paper describes the alkylation of 9-fluorenyl *p*-tolyl sulphone (VII),

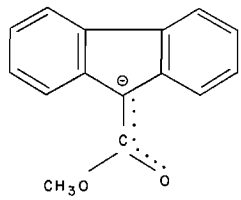
IV, R = CH_3CH_2 VI, R = C_6H_5

V, R = CH_3 VII, R = p-$CH_3 \cdot C_6H_4$

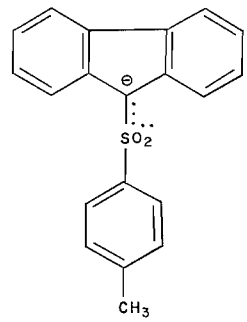
prompted by the work on ethyl 9-fluorenyl sulphone mentioned above (9), together with miscellaneous experiments on related systems.

9-Fluorenyl *p*-tolyl sulphone dissolved in warm ethanol containing sodium ethoxide with formation of a yellow solution. Under similar conditions 2-nitro-9-fluorenyl *p*-tolyl sulphone gave a purple-brown solution, similar to those reported for methyl 2-nitrofluorene-9-carboxylate (14) and 2,4-dinitrobenzyl *p*-tolyl sulphone (8). These solutions undoubtedly contained the organic anions and, in confirmation of this, 9-methyl-, -ethyl-, -isopropyl-, -allyl-, -benzyl-, and -cyclohexyl-9-fluorenyl *p*-tolyl sulphones (VIII,



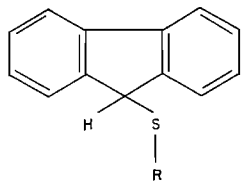
VIII

R = alkyl) were prepared by reaction with appropriate alkyl halides. In a similar manner were prepared 9-methyl-2-nitro-9-fluorenyl *p*-tolyl sulphone, 9-methyl-9-fluorenyl phenyl sulphone, and the methyl and isopropyl derivatives of 9-fluorenyl methyl sulphone. Comparison of these results with those reported for phenylsulphonylmethyl magnesium bromide (7) shows that anions of the type X are powerful nucleophiles which behave as true anion metal salts.

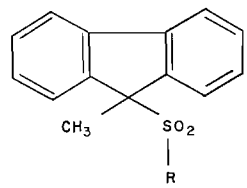


Fluorene has not been alkylated using ethanolic sodium ethoxide as base, so the reactions described above establish that fluorene anion is stabilized by a sulphone group. Although the anions derived from 9-fluorenyl *p*-tolyl sulphone, methyl fluorene-9-carboxylate, and 9-benzoylfluorene show many similar reactions, there are important differences. The sulphone (VII) was recovered unchanged after attempted bromination in acetic acid in the presence of sodium acetate, conditions which gave good yields of methyl 9-bromofluorene-9-carboxylate (11). From the reaction between *t*-butyl chloride and the anion of VII, only unreacted sulphone (30%) was isolated in a pure state. However, examination of the infrared spectrum of the crude product showed the presence of one or more additional compounds, with bands in the positions reported (15) for the *t*-butyl group (cf. methyl 9-*t*-butylfluorene-9-carboxylate (11)). Prolonged reaction times

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.



led to the formation of fluorenone, probably by anionic oxidation (16). It follows that the ester anion (IX) is more nucleophilic than the sulphone anion (X), differences in their behavior towards *t*-butyl chloride being of degree rather than kind.



IX

X

XI, R = CH_3
XII, R = C_6H_5
XIII, R = *p*-$CH_3C_6H_4$

XIV, R = CH_3
XV, R = C_6H_5
XVI, R = *p*-$CH_3C_6H_4$

The sulphides (XI, XII, and XIII) have been prepared, the first from 9-fluorenylmercaptan and the others from thiophenol and thio-*p*-cresol, respectively. Methylation with ethereal methyl lithium – methyl iodide (cf. fluorene (17)) gave the tertiary sulphides (XIV, XV, and XVI), the mild conditions employed precluding the rearrangement observed for some 9-fluorenyl ethers (18). All six sulphides were oxidized with peracetic acid to the corresponding sulphones, confirming the structures of the methylation products of sulphones (V, VI, and VII). Attempts were made to oxidize 9-fluorenyl *p*-tolyl sulphide to the sulphoxide but mixtures were always obtained, consisting of the desired sulphoxide together with the sulphone and fluorenone, as shown by infrared spectra.

9-Methyl-9-fluorenyl *p*-tolyl sulphone was not cleaved by sodium piperidide (19, 20), although 9-methylfluorene was slowly formed by reaction with caustic soda in boiling diethylene glycol (cf. 21).

Characteristic sulphone bands have been recorded for the compounds reported in this paper but, being more complex than those reported for other sulphones (15), are being discussed elsewhere (22).

Although keto-esters have been prepared from fluorene-ester anion with acetyl (10) and benzoyl (28) chlorides, the similar reaction with *p*-toluenesulphonyl chloride gave dimethyl 9,9′-difluorenyl-9,9′-dicarboxylate by reductive dimerization of the anion.

EXPERIMENTAL

Sulphides

9-Fluorenylmercaptan (9) was prepared from 9-bromofluorene (23) via the thiouronium salt. Methylation with methyl iodide – methanolic sodium methoxide gave *9-fluorenyl methyl sulphide*, which crystallized from methanol as large colorless blades (77%), m.p. 47–48°. Found: C, 79.42; H, 5.92%. Calc. for $C_{14}H_{12}S$: C, 79.20; H, 5.65%.

9-Fluorenyl phenyl sulphide was prepared by warming 9-bromofluorene (1 mole) and thiophenol (1.1 moles) with methanol containing sodium methoxide (1 mole).* The reaction was complete in 10 minutes. The product crystallized as blades (69%) from methanol, m.p. 48–49°. Found: C, 83.10; H, 4.97%. Calc. for $C_{19}H_{14}S$: C, 83.17; H, 5.14%.

Prepared in a similar way, *9-fluorenyl p-tolyl sulphide* formed laths or dense prisms from ethanol (88%), m.p. 85–86°. Found: C, 83.20; H, 5.43%. Calc. for $C_{20}H_{16}S$: C, 83.29; H, 5.59%.

The foregoing sulphides were methylated with ethereal methyl lithium – methyl iodide, as described for fluorene (17), giving the following:

Methyl 9-methyl-9-fluorenyl sulphide crystallized as rhombohedral plates from methanol (71%), m.p. 63–65°. Found: C, 79.47; H, 6.19%. Calc. for $C_{15}H_{14}S$: C, 79.60; H, 6.23%.

9-Methyl-9-fluorenyl phenyl sulphide formed colorless needles from ethanol after cooling to and keeping at 0° (65%), m.p. 39.5–41.5°. Found: C, 83.30; H, 5.49%. Calc. for $C_{20}H_{16}S$: C, 83.26; H, 5.59%.

9-Methyl-9-fluorenyl p-tolyl sulphide formed well-defined prisms from acetone–methanol, m.p. 72–73° (82%). Found: C, 83.08; H, 5.83%. Calc. for $C_{21}H_{18}S$: C, 83.40; H, 5.60%.

Sulphones

The six sulphides described in the preceding section were oxidized with 50% hydrogen peroxide (1 volume) in acetic acid (3 volumes). The reactions, which were exothermic, were complete in a few minutes at 50°. Yields varied from 72 to 88% (24, 25).

9-Fluorenyl methyl sulphone formed long white needles from methanol or acetic acid, m.p. 188–189°. Found: C, 68.76; H, 5.09%. Calc. for $C_{14}H_{12}O_2S$: C, 68.87; H, 4.95%.

Methyl 9-methyl-9-fluorenyl sulphone crystallized from hexane as colorless prisms or needles, m.p. 136–137°. Found: C, 69.85; H, 5.77%. Calc. for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%.

9-Fluorenyl phenyl sulphone formed colorless prisms from acetone–heptane, m.p. 182–183°. Found: C, 74.34; H, 4.45%. Calc. for $C_{19}H_{14}O_2S$: C, 74.48; H, 4.61%.

9-Methyl-9-fluorenyl phenyl sulphone crystallized as plates from ethanol, m.p. 165–167°. Found: C, 74.30; H, 4.94%. Calc. for $C_{20}H_{16}O_2S$: C, 74.97; H, 5.03%.

9-Fluorenyl p-tolyl sulphone crystallized as plates from benzene, m.p. 226–228°, identical with an authentic sample (21).

9-Methyl-9-fluorenyl p-tolyl sulphone formed colorless prisms from benzene–heptane, m.p. 151–152°. Found: C, 75.34; H, 5.26%. Calc. for $C_{21}H_{18}O_2S$: C, 75.42; H, 5.42%.

Attempts to oxidize 9-fluorenyl *p*-tolyl sulphide to the sulphoxide by standard techniques (25, 26) gave mixtures, not resolved by chromatography.

9-Fluorenyl *p*-tolyl sulphone, used in the alkylation experiments described below, was obtained from the reaction between 9-bromofluorene and sodium *p*-toluenesulphinate (21, 29). Prepared similarly, *2-nitro-9-fluorenyl p-tolyl sulphone* (from 9-bromo-2-nitrofluorene (27)) formed almost colorless plates from benzene, m.p. 217–219° with de-

**It is important to have present a slight excess of thiophenol over alkoxide to prevent formation of difluorenylidene.*

composition. The first crystallization required judicious separation from traces of dinitrodifluorenylidenes. Found: C, 65.70; H, 4.16%. Calc. for $C_{20}H_{15}NO_4S$: C, 65.74; H, 4.14%.

9-Fluorenyl *p*-tolyl sulphone (1 g) was dissolved in ethanol (200 ml) containing sodium ethoxide (from sodium, 0.5 g). The alkyl halide (2–3 g) was added and the mixture was left at room temperature overnight.

9-Methyl-9-fluorenyl p-tolyl sulphone, prepared in this way (81%), crystallized as prisms from hexane, m.p. 150–151°, identical with the sample described above.

9-Ethyl-9-fluorenyl p-tolyl sulphone (76%) formed clusters of long blades from methanol, m.p. 168–169°. Found: C, 75.73; H, 5.81%. Calc. for $C_{22}H_{20}O_2S$: C, 75.83; H, 5.79%.

9-isoPropyl-9-fluorenyl p-tolyl sulphone (75%) crystallized as needles from heptane, m.p. 181–182°. Found: C, 76.27; H, 6.04%. Calc. for $C_{23}H_{22}O_2S$: C, 76.21; H, 6.12%.

9-Allyl-9-fluorenyl p-tolyl sulphone (89%) formed prisms from heptane, m.p. 175–176°. Found: C, 76.78; H, 5.54%. Calc. for $C_{23}H_{20}O_2S$: C, 76.63; H, 5.59%.

9-Benzyl-9-fluorenyl p-tolyl sulphone (86%) formed well-defined prisms from heptane, m.p. 201–202°. Found: C, 78.99; H, 5.51%. Calc. for $C_{27}H_{22}O_2S$: C, 78.99; H, 5.40%.

9-cycloHexyl-9-fluorenyl p-tolyl sulphone (77%) crystallized as small colorless prisms from heptane, m.p. 209–210°. Found: C, 77.87; H, 6.82%. Calc. for $C_{26}H_{26}O_2S$: C, **77.57**; H, 6.51%.

The following were also prepared:

9-Methyl-2-nitro-9-fluorenyl p-tolyl sulphone (81%) formed pale yellow prisms from benzene–hexane, m.p. 187–188°. Found: C, 66.28; H, 4.46%. Calc. for $C_{21}H_{17}NO_4S$: C, 66.47; H, 4.52%. (The solution of the starting sulphone in ethanolic sodium ethoxide was filtered to remove traces of dinitrodifluorenylidenes.)

9-Methyl-9-fluorenyl phenyl sulphone (76%) crystallized as plates from ethanol, m.p. 164–166°, identical with the sample described above.

Methyl 9-methyl-9-fluorenyl sulphone (69%) formed colorless prisms from hexane, m.p. 134–136°, identical with the sample described above.

Methyl 9-isopropyl-9-fluorenyl sulphone (72%) crystallized as almost colorless prisms from hexane, m.p. 122–124°. Found: C, 71.24; H, 6.10%. Calc. for $C_{17}H_{18}O_2S$: C, 71.30; H, 6.33%.

Dimethyl 9,9′-Difluorenyl-9,9′-dicarboxylate

Methyl fluorene-9-carboxylate (2.3 g) was dissolved in methanol (50 ml) containing sodium methoxide (from sodium, 0.5 g). Addition of *p*-toluenesulphonyl chloride (3.5 g) resulted in the rapid separation of a microcrystalline solid. Recrystallization from chloroform–hexane gave small needles (1.7 g), m.p. 240–242°, identical with an authentic specimen of the above-named ester (10, 17). Found: C, 79.92; H, 4.81%. Calc. for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

CARBON-13 KINETIC ISOTOPE EFFECTS IN THE SOLVOLYSIS OF 1-BROMO-1-PHENYLETHANE[1]

J. B. STOTHERS[2] AND A. N. BOURNS

ABSTRACT

Carbon-13 kinetic isotope effects have been measured for the solvolysis in methanol and ethanol of 1-bromo-1-phenylethane of natural isotopic abundance. Methanolysis of the bromide at 25° C gave a kinetic isotope effect (k^{12}/k^{13}) of 1.0065±0.0006, and ethanolysis at 45° C gave 1.0064±0.0010. These surprisingly low effects for a bond-rupture process have been interpreted in terms of a model for the transition state in which the bonding of the isotopic carbon is strengthened by conjugation of the electron deficient center with the ring. The results are considered to provide support for the mass fragment model for evaluation of the effective mass term of the Bigeleisen expression for the theoretical calculation of kinetic isotope effects.

INTRODUCTION

It has been known for many years that molecules differing only in the isotopic mass of a component atom may react at different rates (1, 2, 3). These kinetic isotope effects are largest when some bond associated with the isotopic atom is undergoing rupture in the rate-determining step of the process. Consequently, isotope effect studies have played an important role in the elucidation of reaction mechanisms (1, 4).

Following the discovery (5, 6, 7) of carbon kinetic isotope effects of considerable magnitude, Bigeleisen (8, 9) proposed equations for the theoretical evaluation of kinetic isotope effects using spectroscopic data. In applying these equations to the rather complex molecular systems for which kinetic isotope effects had been studied experimentally, it was usually found necessary to make the simplifying assumption that the vibrational frequencies of all bonds other than the bond undergoing rupture remain unaltered in the transition state (3, 9). Notwithstanding this and other approximations, surprisingly good agreement has been obtained between calculated and experimental isotope effects in a number of reactions.

Since, in principle, kinetic isotope effects provide information concerning the nature of the transition state, it was decided to undertake a carbon isotope effect study of the reaction of nucleophilic substitution at a saturated carbon atom, a reaction which is one of the most important in organic chemistry and which has been the subject of detailed mechanistic study for over 25 years. At the outset of the investigation it was thought that kinetic isotope effects might provide a useful criterion of mechanism since, on the basis of a simplified theoretical treatment, one might expect that reaction by the unimolecular, or S_N1, mechanism, in which the main covalency change in the rate-determining step is the rupture of a bond associated with the isotopic atom, would give rise to a larger effect than reaction by the bimolecular, or S_N2, mechanism, in which bond formation and bond rupture are synchronous. It was hoped, also, that the investigation might serve as a test for the theoretical equations and, in particular, might help in deciding between the Slater and mass fragment methods for evaluation of the temperature-independent term of these equations.

While this work was in progress two papers by Bender appeared (10, 11) reporting

the results of a carbon-14 isotope effect study of the displacement reactions of methyl iodide and *tert*-butyl chloride. In the S_N2 reaction of methyl iodide with hydroxide ion and with several tertiary amines k^{12}/k^{14} ratios ranging from 1.09 to 1.14 were observed. Solvolysis of methyl iodide in aqueous ethanol in the presence of silver ion, which was considered to be a borderline case between a S_N2 and S_N1 reaction, gave an isotope effect which was essentially no different from effects found in the pure S_N2 processes. These large effects are of the same magnitude as many effects observed in reactions involving only bond rupture and agree with the predictions of the Bigeleisen equation based on a model for the transition state in which only the bond undergoing fission is considered to have changed in the activation process. Hydrolysis of *tert*-butyl chloride in aqueous dioxane, somewhat surprisingly, gave rise to a smaller effect, $k^{12}/k^{14} = 1.03$, than did the reactions proceeding by the bimolecular mechanism. From these results, Bender concluded that kinetic isotope effect studies are of very limited value in differentiating between S_N1 and S_N2 reactions.

The present paper is concerned with a carbon-13 study of the solvolysis of 1-bromo-1-phenylethane in methanol and ethanol. Carbon-13 was chosen as the heavier isotope rather than carbon-14 since, using mass spectrometry, a higher order of precision in evaluation of the isotope effect is possible (± 0.001 in this study, compared with ± 0.005 to ± 0.015 in Bender's work), contamination of samples is less likely to give rise to spurious effects, and isotopic labelling is unnecessary. The choice of 1-bromo-1-phenylethane as the reactant was dictated by two considerations. First, depending upon the conditions, the compound may be made to undergo reaction either exclusively by the S_N1 or by the S_N2 mechanism (12, 13); under solvolytic conditions in solvents of high ionizing power the reaction exhibits characteristics of a unimolecular process, while pure second-order kinetics are observed for reaction in ethanol using ethoxide concentrations of 1.5 *M* or higher. Secondly, the compound and its reaction products, 1-methoxy- and 1-ethoxy-1-phenylethane, may be degraded so as to furnish, in good yield for mass spectrometer analysis, carbon dioxide derived exclusively from the carbon at the seat of displacement.

EXPERIMENTAL

Materials

Absolute methanol and ethanol were prepared from commercial "absolute" products using magnesium, followed by distillation through a 20-in. Vigreux column.

1-Bromo-1-phenylethane was prepared by passing dry hydrogen bromide into 1-phenylethanol maintained at 0° C (14). The product, purified by fractional distillation, was obtained in 85–93% yields (b.p. 83–84° C (10 mm), n_D^{25} 1.5592).

1-Methoxy-1-phenylethane and 1-ethoxy-1-phenylethane, products of the solvolysis reactions, were required for testing the degradation procedures. These were prepared in approximately 75% yield by heating a solution of 1-bromo-1-phenylethane in the anhydrous alcohol for 24 hours at reflux temperatures. The physical constants of the ethers were: 1-methoxy-1-phenylethane, b.p. 55–56° C (10 mm), n_D^{25} 1.4900; 1-ethoxy-1-phenylethane, b.p. 65–66° C (11 mm), n_D^{25} 1.4821.

To test for possible isotopic exchange between the ether product and 1-bromo-1-phenylethane it was necessary to prepare 1-ethoxy-1-phenylethane-1-C^{13}. Acetophenone-carbonyl-C^{13} (8.6 g, 0.072 mole), prepared from sodium acetate-1-C^{13} by the method of Shantz and Rittenberg (15), was reduced to the carbinol using lithium aluminum hydride

For personal use only.

(2.0 g, 0.053 mole) in anhydrous ether (50 ml). The complex was decomposed with 20% sulphuric acid and the product isolated by ether extraction. The crude carbinol was dissolved in carbon tetrachloride (25 ml) and treated with anhydrous hydrogen bromide until there was no further absorption of gaseous halide. The reaction mixture was poured into water and extracted with carbon tetrachloride. The combined extracts were dried, concentrated, and taken up in absolute ethanol (100 ml). This solution was heated under reflux for 24 hours while small amounts of a solution of sodium ethoxide in ethanol were added periodically to neutralize the hydrogen bromide formed. At the end of this period the solution was poured into cold water and extracted with ether. Fractional distillation gave 1-ethoxy-1-phenylethane-1-C^{13} (b.p. 64–65° C (10 mm), n_D^{25} 1.4821) in 65% yield, based on the acetophenone.

Kinetic Measurements

The rates of solvolysis of 1-bromo-1-phenylethane in absolute methanol and ethanol were followed by acid–base titration of the product, hydrogen bromide. Reaction temperatures were chosen such that there was approximately 5% reaction in 15 minutes. This was a convenient rate for the partial reactions in the subsequent isotope effect experiments. A solution of the bromide in the alcohol was maintained to within ±0.02° C of the desired temperature and at appropriate time intervals accurately measured aliquots were removed and quickly placed in a cold mixture of benzene and water. The resulting mixture was immediately titrated with standard sodium hydroxide using phenolphthalein as indicator. The rate constants were obtained from a least-squares plot of reaction time versus log[RBr].

Isotope Effect Experiments

In the determination of the carbon-13 isotope effect, 1-bromo-1-phenylethane of normal isotopic abundance was solvolyzed to some small known extent of reaction, the ether product separated from unreacted bromide and degraded so as to furnish carbon dioxide derived exclusively from the alkoxy-bearing carbon. The isotopic ratio for this carbon dioxide and that of the carbon dioxide formed from the original reactant by a similar degradation procedure were measured mass spectrometrically. The rate constant ratios, k^{12}/k^{13}, were calculated from the isotopic ratios using an expression derived by Stevens and Attree (16), which takes into account the extent of reaction.

The detailed procedure was as follows. One liter of the appropriate alcohol was equilibrated to the desired reaction temperature and a weighed sample of 1-bromo-1-phenylethane was added. The resulting solution, approximately 0.5 *M* in organic bromide, was allowed to stand in the constant-temperature bath for an accurately measured time corresponding to approximately 5% reaction, and then was quickly poured into a mixture of 3–4 liters of cold water and 600 ml of benzene. The quenched reaction mixture was vigorously shaken, the layers separated, and the aqueous layer extracted with three 300-ml portions of fresh benzene. The combined extracts were thoroughly washed with water and dried over calcium chloride, and the benzene then removed by distillation under reduced pressure. The small amount of product was separated from the large amount of unreacted bromide by careful fractional distillation under reduced pressure using a 50-cm tantalum-wire column described by Cason and Rapoport (17). One such distillation was sufficient to separate the methyl ether; a second distillation was required for 1-ethoxy-1-phenylethane. Trial experiments on synthetic mixtures of 1-ethoxy-1-phenylethane and the organic bromide showed that ether of 93–95% purity could be separated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

better than 90% recovery. The impurity, which was mainly bromide, would not be expected to affect significantly the isotopic ratios subsequently determined.

Under the normal solvolytic conditions, hydrogen bromide concentration builds up as the reaction proceeds and, as a result, there might be some tendency for ether cleavage with the regeneration of starting bromide. If this were to happen, the measured isotopic fractionation would not be that resulting from a strictly unidirectional process but rather from a process tending toward equilibrium. Since, in all experiments, the reaction was stopped before more than 10% of organic halide had been consumed, the back reaction, if it occurred at all, would be expected to make only a very minor contribution to the measured effect. Nevertheless, to establish this point, two isotope effect experiments in methanol were carried out in which sodium methoxide was present in a concentration which was sufficient to neutralize the hydrogen bromide formed in the partial reaction but not sufficient to induce any significant amount of bimolecular reaction (12, 13). The isotope effects obtained in the presence and in the absence of methoxide ion differed only very slightly, if at all.

It was also necessary to establish that no isotopic exchange occurred during the separation of the ether product from the large amount of unreacted organic bromide. This was accomplished by subjecting a mixture of 1-ethoxy-1-phenylethane-1-C^{13} and unlabelled 1-bromo-1-phenylethane to the usual separation procedure and determining the loss of label in the recovered ether. It was found that an upper limit for the exchange, if it occurred at all, was 5%. This would have no measurable effect on the results.

Degradation Method

Since the isotopic ratio for the carbon atom at the center of displacement must be determined for the reactant and for the product of partial reaction, it was necessary to develop a degradation procedure whereby this atom could be removed from the rest of the molecule and converted in high yield to carbon dioxide for mass spectrometric analysis. The method consisted of oxidation of the bromide and ether to benzoic acid followed by decarboxylation using the Schmidt reaction.

Oxidation to Benzoic Acid

Best over-all yields of benzoic acid were obtained by a two-stage oxidation procedure. In the first stage, the compounds were oxidized with alkaline permanganate in a pyridine–water solvent to give a mixture of benzoic acid and benzoylformic acid. This acid mixture was then further oxidized with hydrogen peroxide whereby the benzoylformic acid was quantitatively converted to benzoic acid.

1-Bromo-1-phenylethane (1.65 g, 0.0089 mole) was placed in pyridine (50 ml) and water (100 ml) and potassium hydroxide (5 g, 0.089 mole) was added. The mixture was heated under reflux for 15 minutes with vigorous stirring. Solid potassium permanganate (8 g, 0.051 mole) was then added slowly at reflux temperature to the stirred solution over a period of 15 minutes and the reaction mixture heated for an additional 30 minutes with vigorous stirring. The mixture was cooled to about 50° C and excess potassium permanganate destroyed by the addition of ethanol. The inorganic solids were removed by filtration and washed thoroughly with hot water. The filtrate was cooled, acidified with concentrated hydrochloric acid, and extracted four times with ether. Ether was removed and the residue stirred vigorously for 2 to 3 hours with 5% hydrogen peroxide (30 ml). The reaction mixture was allowed to stand overnight and then heated under reflux to destroy excess peroxide, additional water being added to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

effect complete solution of the benzoic acid. The solution was allowed to cool and the benzoic acid collected. Additional acid was recovered by ether extraction of the filtrate. Total yield of pure acid was 0.909 g (84%), m.p. 121.5°–121.8° C (corr.).

A similar procedure using, however, 50% more oxidizing agent was followed for the two ether products. Yields of benzoic acid were generally slightly higher than those obtained from the bromide.

Decarboxylation of Benzoic Acid

An apparatus similar to that described by Phares (18) was used. A solution containing approximately 1 millimole of benzoic acid in 3–4 ml of concentrated sulphuric acid was placed in the reaction flask and cooled to 0° C. Approximately 80 mg of sodium azide was added and the flask connected to the absorption traps. The reaction mixture was maintained at about 40° C for 2 hours while the carbon dioxide was swept by means of a slow stream of purified nitrogen into 0.2 *M* carbonate-free sodium hydroxide. The trapped gas was precipitated as barium carbonate (19). Great care was taken in all operations to avoid contamination with atmospheric carbon dioxide. Yields of barium carbonate were in the range 91–93%.

Tests for Rearrangement and Isotopic Fractionation in the Degradation Reactions

There is a possibility, albeit an unlikely one, that rearrangement might occur during the two-stage oxidation of bromide and ether to benzoic acid, with the result that the carbon atom in the carboxyl group of the acid would not be the atom originally joined to the benzene ring. To test for this, some labelled ether, 1-ethoxy-1-phenylethane-1-C^{13}, was subjected to the usual alkaline oxidation while another sample was oxidized by chromic anhydride to acetophenone, which was then converted to benzoic acid by means of the haloform reaction. Carbon dioxide samples were prepared in the usual way from each benzoic acid sample and analyzed mass spectrometrically. The isotopic ratios obtained for the two samples were identical within the precision limits of the measurements and they corresponded closely to the ratio expected on the basis of the carbon-13 content of the barium carbonate used in the synthesis of the labelled ether. From this result it may be concluded that no rearrangement occurred during the degradation.

Although the yields in each of the degradation steps were good, the possibility remained that isotopic fractionation during the conversion of bromide or ether to carbon dioxide might affect, to a measurable extent, the isotopic abundance of this gas. To test for this possibility the following interconversions were carried out: (1) 1-phenylethanol of normal isotopic abundance to 1-bromo-1-phenylethane using dry hydrogen bromide; (2) a sample of this bromide to 1-methoxy-1-phenylethane by methanolysis; and, (3) a further sample of the 1-phenylethanol to 1-methoxy-1-phenylethane using methyl sulphate. Since conversion (3) involved no change in the bonding of the carbon atom alpha to the ring, the isotopic abundance for this carbon should be identical in the alcohol and the ether product. Furthermore, since conversion (1) proceeded in better than 90% yield the isotopic ratio of the bromide should correspond very closely to that of the alcohol. One or more samples of the alcohol, ether, and bromide were oxidized in the usual way to benzoic acid, samples of which were then converted in duplicate or triplicate to carbon dioxide for mass spectrometric analysis. The fourteen carbon dioxide samples prepared in this way gave C^{12}/C^{13} ratios which were the same within the limits of the mass spectrometric analysis. These results definitely establish that either there was no isotopic fractionation in the degradation reactions or that any small fractionation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

that did occur was the same for the ether and the bromide. In either case, the degradations were entirely suitable for the isotope effect studies in which an intercomparison of isotopic ratios was being made.

Preparation of Carbon Dioxide Samples for Mass Spectrometric Analysis

Carbon dioxide was liberated from the barium carbonate samples by means of concentrated sulphuric acid using standard high vacuum techniques. The gas was trapped at liquid nitrogen temperatures, distilled at −78° C through an "anhydrone" drying tube, and condensed into a standard mass spectrometer sample tube.

Mass Spectrometry

All carbon dioxide samples were analyzed in a 180° direction-focussing mass spectrometer. The C^{12}/C^{13} ratios were obtained from the mass 44 / mass 45 ion current ratio after applying a suitable correction for the contribution to mass 45 of the molecule species $C^{12}O^{16}O^{17}$. Each carbon dioxide sample in a given series of experiments was analyzed relative to a standard, the standard being one of the samples of carbon dioxide prepared from the reactant used in that series. An arbitrary value of 85.00 for the mass 44/45 ratio was assigned to these standards. The procedure was to analyze the standard, the unknown, and the standard again all in the shortest possible time. A single analysis consisted of a series of at least six double spectrograms, each double spectrogram being obtained from a scan of the masses in the order 44, 45, 45, 44. A single analysis was considered satisfactory if the mean deviation of the 44/45 ratios was less than 0.1%, and the mean for the unknown was accepted if the mean for the standard, before and after analysis of unknown, differed by no more than this value.

RESULTS

The results of the kinetic measurements for the solvolysis of 1-bromo-1-phenylethane in absolute methanol and in absolute ethanol are summarized in Table I.

TABLE I

Kinetic results for solvolyses of 1-bromo-1-phenylethane

Solvent	Temp., °C	Concn. of RBr, *M*	$k_1 \times 10^5$ sec^{-1}
Methanol	25.0	0.112	5.70
		0.114	5.72
		0.303	5.57
			Average 5.67
Ethanol	45.0	0.486	5.87
		0.525	6.07
		0.512	6.07
			Average 6.00

The results of the isotope effect experiments on the methanolysis and the ethanolysis of 1-bromo-1-phenylethane are given in Tables II and III, respectively. Each individual experiment consisted of a partial reaction of bromide to ether followed by parallel degradations to carbon dioxide of a sample of the original reactant and of the product. The rate constant ratios, k^{12}/k^{13}, were calculated from the C^{12}/C^{13} ratios and the percentage of reaction (16).

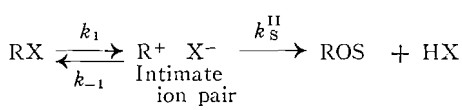
DISCUSSION

It seems reasonable to assume on the basis of the results of extensive kinetic and stereochemical studies (12, 13, 20, 21) that the solvolysis of 1-phenylethyl halides in good ionizing solvents, including methanol and ethanol, proceeds by a S_N1 mechanism in the sense that some type of carbonium ion intermediate is involved. Winstein and co-workers (22, 23) have recently proposed that the ionization process for a compound RX can involve two discrete ion pair intermediates, as well as dissociated carbonium ions, and that one or all of these ion types may interact with solvent to form product.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Grunwald and co-workers (24) have presented cogent arguments in support of the idea that for 1-phenylethyl compounds the ratio k_2/k_S^{II} is small and, therefore, that substitution occurs mainly at the intimate ion pair stage. This seems reasonable since the 1-phenylethyl carbonium ion should be very reactive, particularly in the moderately nucleophilic solvents, methanol and ethanol, used in the present investigation.

There remains the question of the relative rates of reaction of the intimate ion pair with solvent and its collapse to re-form RX (internal return). Winstein (25) has reported that in the acetolysis of 1-bromo-1-phenylethane the true ionization rate is about seven times greater than the titrimetric solvolysis rate. Assuming that product is formed mainly by interaction of solvent with the intimate ion pair, the ratio k_{-1}/k_S^{II} in acetolysis is therefore 6. In methanol and ethanol, which are more nucleophilic solvents (26), there should be a smaller tendency for internal return. One cannot assume, however, that the alcoholysis rates will be determined solely by the ionization step.

On the basis of these considerations the mechanism of solvolysis of 1-phenylethyl bromide may be formulated as follows:

For a theoretical evaluation of the carbon isotope effect in this reaction, it is useful to examine two limiting cases, one in which the ionization step is rate determining ($k_S^{II} \gg k_{-1}$), and the other in which the intimate ion pair is in equilibrium with the organic halide ($k_S^{II} \ll k_{-1}$). In the former case, the observed isotope effect will be the kinetic isotope effect associated with the ionization process. In the latter case, the observed effect will be the result of two fractionation processes, that associated with the equilibrium between substrate and intimate ion pair and that associated with the interaction of intimate ion pair with solvent. It may be readily shown in this case that the over-all isotope effect is given by the expression

$$k/k' = K_{exch} \cdot \frac{k_S^{II}}{k_S^{II'}} \qquad [1]$$

where k and k' are the specific reaction rate constants for solvolysis of the light and heavy isotopic organic halides, RX and R′X, respectively, k_S^{II} and $k_S^{II'}$ are the corresponding rate constants for interaction of the intimate ion pairs, R^+X^- and $R^{+\prime}X^-$, with solvent, and K_{exch} is the equilibrium constant for the isotopic exchange process

$$RX + R^{+\prime}X^- \rightleftarrows R'X + R^+X^-.$$

Bigeleisen and Mayer (27) have shown that the equilibrium constant for an isotopic exchange process can be expressed as the ratio of the so-called isotopic partition functions ratios, f, for the reacting species. For the exchange process given above,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[2] $$K_{exch} = \frac{f_{RX}}{f_{R^+X^-}}$$

where f_{RX} is the isotopic partition function ratio for organic halide and $f_{R^+X^-}$ the ratio for the intimate ion pair. For a rate process, the ratio of the rate constants for the isotopic molecules is given by an expression developed by Bigeleisen (8), which, for the present case of the interaction of solvent molecules with the intimate ion pair, takes the form

[3] $$\frac{k_s^{II}}{k_s^{II'}} = \frac{K}{K'} \cdot \left[\frac{m_{ROS}^{\ddagger'}}{m_{ROS}^{\ddagger}}\right]^{\frac{1}{2}} \cdot \frac{f_{R^+X^-}}{f_{ROS}^{\ddagger}}$$

where the K's are transmission coefficients, the ratio of which may be taken as unity, $m_{ROS}^{\ddagger}$ and $m_{ROS}^{\ddagger'}$ are, respectively, the effective masses of the light and heavy transition states in the direction of the reaction co-ordinate, and $f_{ROS}^{\ddagger}$ is the isotopic partition function ratio for these states.

The over-all isotope effect for solvolysis proceeding through an intimate ion pair in equilibrium with undissociated organic halide is, therefore,

[4] $$\frac{k}{k'} = K_{exch} \cdot \frac{k_s^{II}}{k_s^{II'}} = \left[\frac{m_{ROS}^{\ddagger'}}{m_{ROS}^{\ddagger}}\right]^{\frac{1}{2}} \cdot \frac{f_{RX}}{f_{ROS}^{\ddagger}}.$$

If, on the other hand, there is little or no internal return, the rate of solvolysis will be equal to the rate of ionization and, therefore, the istope effect will be given by

[5] $$\frac{k}{k'} = \left[\frac{m_{RX}^{\ddagger'}}{m_{RX}^{\ddagger}}\right]^{\frac{1}{2}} \cdot \frac{f_{RX}}{f_{RX}^{\ddagger}}$$

where the m's and $f_{RX}^{\ddagger}$ refer to the isotopic transition states for the ionization step.

The f functions appearing in these equations depend upon molecular vibrations only (27) and are of the form

[6] $$f = 1 + \sum_{1}^{3n-6} G(u_1)\Delta u_1$$

where

$$G(u_1) = \frac{1}{2} - \frac{1}{u_1} - \frac{1}{e^{u_1}-1}$$

$$u_1 = h\nu/kT$$

$$\Delta u_1 = h/kT(\nu_1 - \nu_1').$$

The ν and ν' quantities are fundamental vibrations of the light and heavy isotopic species, respectively.

The rate constant ratio, k/k', for the solvolysis reaction proceeding through an intimate ion pair in equilibrium with RX now becomes

[7] $$k/k' = \left[\frac{m_{ROS}^{\ddagger'}}{m_{ROS}^{\ddagger}}\right]^{\frac{1}{2}} \left[1 + \sum_{1}^{3n-6} G(u_{RX_1})\Delta u_{RX_1} - \sum_{1}^{3n-6} G(u_{ROS_1}^{\ddagger})\Delta u_{ROS_1}^{\ddagger}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

whereas this rate ratio for solvolysis in which the ionization step is rate determining takes the form

$$[8] \qquad k/k' = \left[\frac{m^{\ddagger'}_{RX}}{m^{\ddagger}_{RX}}\right]^{\frac{1}{2}}\left[1+\sum_{1}^{3n-6} G(u_{RX_1})\Delta u_{RX_1} - \sum_{1}^{3n-6} G(u^{\ddagger}_{RX_1})\Delta u^{\ddagger}_{RX_1}\right].$$

It can be seen that equations [7] and [8] differ in the effective mass term and in the second summation of the free energy term. In equation [7] these quantities refer to the transition state for covalent bond formation between carbonium ion and solvent; in equation [8] they refer instead to the transition state of the ionization process. It is, therefore, important to compare the nature of these transition states.

Since the intimate ion pair formed from 1-bromo-1-phenylethane is a high-energy intermediate, the energy of activation both for its reaction with solvent and for internal return to organic halide will be very small. Both transition states, therefore, will resemble the intimate ion pair (28). In other words, the carbon–bromine bond of the halide should be almost completely broken in the transition state for the first step and the carbon–oxygen bond should be only starting to form in the transition state of the second step. As a result, the change in vibrational energy resulting from the substitution of carbon-13 for carbon-12 will be much the same for the two transition states and will correspond closely to the change in energy resulting from isotopic substitution in the intermediate itself. The only significant difference then in the magnitude of the isotope effect for reaction in which the intimate ion pair is in equilibrium with RX and for reaction in which it is not, should arise from a difference in the effective mass factor.*

For calculation of the effective mass term Bigeleisen (8) originally applied a theorem of Slater (29) which in effect considers the reaction to be simply the formation or dissociation of a hypothetical diatomic molecule consisting of the two atoms between which the bond change is taking place. Each value of $m^{\ddagger}$ is then the reduced mass, μ, of the corresponding diatomic molecule and the effective mass term is the square root of the ratio of the reduced masses of the two isotopic molecules,

$$[9] \qquad \left[\frac{m^{\ddagger'}}{m^{\ddagger}}\right]^{\frac{1}{2}} = \left[\frac{\mu'}{\mu}\right]^{\frac{1}{2}} = \left[\left(\frac{1}{m_A}+\frac{1}{m_B}\right)\Big/\left(\frac{1}{m'_A}+\frac{1}{m_B}\right)\right]^{\frac{1}{2}}.$$

For rupture of a C—Br bond $m_A = 12$, $m'_A = 13$, and $m_B = 80$; for formation of a C—O bond $m_A = 12$, $m'_A = 13$, and $m_B = 16$.

Recently Bigeleisen (9) has suggested that since the reaction path for a polyatomic molecule involves not merely motion of individual atoms A and B, but rather motion of whole reacting fragments α and β, a more reasonable formulation of the mass term is

$$[10] \qquad \left[\frac{m^{\ddagger'}}{m^{\ddagger}}\right]^{\frac{1}{2}} = \left[\left(\frac{1}{M_\alpha}+\frac{1}{M_\beta}\right)\Big/\left(\frac{1}{M'_\alpha}+\frac{1}{M_\beta}\right)\right]^{\frac{1}{2}}.$$

For ionization of 1-bromo-1-phenylethane $M_\alpha = 105$, $M'_\alpha = 106$, and $M_\beta = 80$; for bond formation between 1-phenylethyl carbonium ion and methanol $M_\alpha = 105$, $M'_\alpha = 106$, and $M_\beta = 32$. In ethanol, M_β equals 46.

The effective mass terms for each transition state of the solvolytic reaction, calculated both from the Slater and the mass fragment models, are given in Table IV. It is of interest

**Since the vibrational stretching frequency of a carbon–oxygen bond is higher than that of a carbon–bromine bond, the summation for the transition state for covalent bond formation might be slightly higher than that for ionization.*

TABLE IV

Effective mass and free energy values for the transition states of 1-bromo-1-phenylethane solvolysis

Reaction[a]	Effective mass term		$(k^{12}/k^{13})_{expt}{}^{b}/(m^{\mp 13}/m^{\mp 12})^{\frac{1}{2}}$	
	Slater	Mass fragment	Slater	Mass fragment
R—Br → R^+Br^-	1.0352	1.0021	0.972	1.004
R^+Br^- → $ROCH_3$	1.0227	1.0011	0.984	1.005
R^+Br^- → ROC_2H_5	1.0227	1.0014	0.984	1.005

[a] R = $C_6H_5\dot{C}HCH_3$. [b] $(k^{12}/k^{13})_{expt}$ taken as 1.006.

to calculate from these mass terms the values of the free energy terms,

$$\left[1+\sum_{1}^{3n-6} G(u_1)\Delta u_1 - \sum_{1}^{3n-6} G(u_1^{\mp})\Delta u_1^{\mp}\right],$$

which would be required to produce the experimentally observed isotope effect of 1.006. These are shown in the last two columns of the Table IV.

The values of less than unity for the free energy term, which are obtained by dividing the experimental isotope effect by mass terms calculated from the Slater model, require that the difference in the vibrational energies for the isotopic transition states be greater than the corresponding difference for the isotopic RX molecules,

$$\sum_{1}^{3n-6} G(u_1^{\mp})\Delta u_1^{\mp} > \sum_{1}^{3n-6} G(u_1)\Delta u_1.$$

This could only come about if the isotopic atom were considerably more "tightly bound" in the transition state than in the initial state (8), a situation which would seem most unlikely in the present reaction system in which the transition state in both the ionization step and the bond formation step closely resembles the carbonium ion intermediate.

The low isotope effect observed in the solvolysis of 1-bromo-1-phenylethane, therefore, lends support to the mass fragment method of evaluating the effective mass term.

A common procedure in calculating from vibrational frequency data the free energy term of the Bigeleisen equation is to assume a model for the transition state in which the force constant for the bond being broken is equal to zero and the vibrational frequencies of all other bonds are the same as those for the initial state (3). The summations for the transition state in equations [7] and [8] then become zero and the initial state term can be readily calculated from the vibrational stretching frequency of the isotopic bond which is undergoing rupture in the reaction. To the extent that the bond in question is less than completely broken in the transition state, or other bonds associated with the isotopic atom are formed or strengthened, the over-all free energy term, calculated on the assumption of a zero value for the transition state summation, will be too high.

Using this very approximate method, one obtains a theoretical value of 1.018 for the free energy term in equations [7] and [8] at 25° C.* Comparison with the values given in the last two columns of Table IV shows that this value is much too high to account for the observed isotope effect. Even when combined with the low mass term given by the mass fragment theory it leads to an isotope effect of about 2%, and when combined with a mass term calculated on the basis of the Slater theorem it gives an effect of over 4%.

An even larger value is given by a more recent equation which makes use of the theorem of the trace (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

It is suggested that the origin of this discrepancy arises mainly from the complete neglect of the transition state term.

Of the two simplifying assumptions upon which neglect of this term was based, that involving the assignment of a zero force constant to the carbon–bromine bond in the transition state of the ionization step and to the carbon–oxygen bond in the transition state of the second step would seem justified since, for reasons already given, the two transition states must closely resemble the intimate ion pair intermediate. What undoubtedly is not justified is the assumption that the vibrational frequencies of all other bonds associated with the isotopic carbon will remain unchanged in the transition state. Indeed, the bonding of this carbon to the benzene ring will be considerably strengthened as a result of overlap of its fairly well-developed vacant p orbital with the π orbitals of the benzene ring. Added to this, but of lesser importance, will be hyperconjugative interaction with the attached methyl group. The low isotope effect observed in the reaction would suggest that this conjugation in the transition state compensates to a considerable degree for the loss of the carbon–bromine vibration.

Some support for this interpretation of the low isotope effect is found in a recent study by Magee and Daniels (30) of the carbon-13 isotope effect in the unimolecular decomposition of substituted ureas, the results of which are summarized in Table V. Given also in

TABLE V

Unimolecular decomposition of substituted ureas

Reactant	$(k^{12}/k^{13})_{expt}$	$(k^{12}/k^{13})_{expt}/(m^{\mp 13}/m^{\mp 12})^{\frac{1}{2}}$
sym-Dimethylurea	1.027	1.024
Phenylurea	1.016	1.015
sym-Diphenylurea	1.008	1.006
3,3′-Dimethylcarbanilide	1.007	1.005

this table are the $(k^{12}/k^{13})_{expt}/(m^{\mp 13}/m^{\mp 12})^{\frac{1}{2}}$ values calculated using the mass fragment model for evaluation of the effective mass term. These authors attribute the effect of phenyl substitution on the magnitude of the isotope effect to resonance stabilization of the transition state resulting in a strengthening of a bond associated with isotopic carbon. This would tend to increase the $G(u_1^{\mp})\Delta u_1^{\mp}$ term and result in a lowering of the over-all free energy term.

It may be noted also that the carbon-14 isotope effect observed by Bender and Buist (11) in the hydrolysis of *tert*-butyl chloride is lower than would be predicted on the assumption of a zero transition state term. Using a mass term calculated from the mass fragment hypothesis one obtains a value for $(k^{12}/k^{14})_{expt}/(m^{\mp 14}/m^{\mp 12})^{\frac{1}{2}}$ of 1.014 ± 0.015, whereas the free energy term calculated on the assumption of complete carbon–chlorine bond rupture and no change in other vibrational frequencies is 1.045. It has been suggested that the low effect may be due in part to the electron-releasing effect of the three methyl groups which would tend to loosen the carbon–chlorine bond in the initial state resulting in a lower free-energy term. Another possibility is that hyperconjugative interaction of the three methyl groups with the isotopic carbon tends to strengthen the bonding of this atom in the transition state, hence increasing the free energy term for this state.

THE DIFFERENTIAL THERMAL ANALYSIS OF NATURAL AND SYNTHETIC HYDRATES OF CALCIUM SULPHATE[1]

W. E. P. Fleck, M. H. Jones, R. A. Kuntze, and H. G. McAdie

ABSTRACT

A variety of naturally occurring forms of calcium sulphate dihydrate produce substantially identical differential thermograms under conditions of uniform heating rate and particle size. These thermograms closely resemble those for synthetic dihydrate and β-hemihydrate, showing four endothermic effects and one exothermic effect below 500° C. Two of these endothermic effects, at about 170° and 300° C, respectively, which have not been reported previously, were found to be easily masked by changes in heating rate or sample concentration. Resolution of the several effects was improved by using different heating rates at different stages of the thermogram. Thermograms of the α-hemihydrate were similar, except that the endothermic effect at 300° C was not evident and the exothermic effect occurred at a much lower temperature than for the dihydrate. No conspicuous differences were found in the temperatures corresponding to the various endothermic and exothermic effects which might be correlated with the general dehydration behavior of the particular material. The endothermic effect at about 170° C appears to be associated with part of the hemihydrate to soluble anhydrite transition, possibly arising during the removal of the last traces of water.

In the differential thermograms reported for many natural and synthetic gypsums of widely different origin (1–7), two large endothermic effects occurring below 200° C have been attributed to the formation of the hemihydrate and its subsequent decomposition to soluble anhydrite. The exact temperatures at which these effects appear depend on a variety of experimental conditions, the resolution of the two endotherms being improved at slow rates of heating (2). In the region of 400° C an exothermic effect, not found when natural anhydrite is heated from room temperature, has been attributed to the conversion of β-soluble anhydrite to insoluble or natural anhydrite (3). A contradiction exists in the literature regarding the presence (8) or absence (4, 5) of a similar exothermic effect in the case of the α-soluble anhydrite. No further thermal effects have been reported below about 1200° C where a high-temperature modification of anhydrite is formed (1, 6, 7).

It has been recorded that the above exothermic effect appears at different temperatures, depending upon the origin of the gypsum sample (2, 3), and in the gypsum industry it is known that natural gypsums of different origin produce hemihydrates of widely differing properties. Hence an examination of several natural gypsums, as well as the pure hydrates of calcium sulphate, was undertaken by differential thermal analysis to investigate the possibility that some correlation might exist between both the endothermic and exothermic effect temperatures and the dehydration behavior of the particular gypsum. The natural gypsums selected represented several mineralogical forms and attention was focused on thermal effects appearing below 500° C.

EXPERIMENTAL

The instrument used contained a horizontal furnace, wound with 15-gauge Kanthal A wire, having a maximum operating temperature of 1300° C. No attempt was made to control the atmosphere within this furnace except in cases where a sample was cooled in a stream of dry nitrogen, after determination of a thermogram, prior to determination of a second thermogram on the same sample.

For measurement of temperature above 200° C, and control of heating rate over the entire temperature range, a Leeds and Northrup Model S Speedomax G indicating and recording temperature-program controller was used. Heating rates up to 20° C min^{-1} were possible, and above 200° C the sample temperature could be read to 1–2° C. Below 200° C another recorder, calibrated for 0–200° C with an iron–constantan thermocouple, was used to measure sample temperature to within 0.5° C. The differential temperature of a pair of Pt–Pt/13% Rh thermocouples was measured with a Speedomax G millivolt recorder fed from a stabilized microvolt amplifier. Differential temperatures of the order of 0.2 μv, corresponding to 0.03° C and about 2-mm deflection on the recorder chart, could be detected.

Below 200° C a heating rate of 3° C min^{-1} was found to give the best combination of peak definition and resolution. Smaller peaks occurring above 200° C were found to be better defined at higher heating rates, so that above this temperature the heating rate was increased to 12° C min^{-1}. The sample was contained in a palladium block having separate cavities for sample and reference material. At 3° C min^{-1} the difference between block and bulk sample temperature was found to be 2–4° C, while at 12° C min^{-1} this difference was 10–12° C. Since the temperature-measuring thermocouples were always in contact with the block, the peak temperatures to be reported are those of the sample block at the particular maximum differential temperature.

Ignited reagent grade α-alumina, having an average particle diameter, by the Fisher Sub-Sieve Sizer, of about 12 μ, was used as reference material and as diluent for the sample. With this material in both cavities of the palladium block, no significant differential temperature could be measured over the temperature range of interest.

A preliminary study of the effect of particle size on peak temperature showed that lower and more reproducible peak temperatures were obtained as the particle size of the sample was decreased. Some variation in relative peak heights with particle size was also noted. The most satisfactory results were obtained with a −325-mesh sample diluted to 20% concentration in ignited alumina.

The materials investigated are listed in Tables III and IV. The synthetic materials were prepared as follows. Calcium sulphate dihydrate was precipitated from 0.5 *M* solutions of calcium nitrate and sulphuric acid at room temperature, thoroughly washed and air-dried. The α-hemihydrate was precipitated from a boiling 50% nitric acid solution of the dihydrate. The β-hemihydrate was obtained by dehydrating dihydrate at 100° C in a stream of nitrogen containing water vapor until the theoretical hemihydrate composition was reached. These two hemihydrates were identified by measuring their heats of solution in 2 *N* hydrochloric acid (9), and their analyses, together with that of the synthetic dihydrate, are given in Table I. The agreement of experimental heats of solution with accepted values (9) provides sufficient identification of the hemihydrates.

RESULTS

For convenience, the peaks corresponding to the various endothermic and exothermic effects are numbered from the low-temperature end of the differential thermogram. Thus, peak No. 1 corresponds to the endothermic transition from dihydrate to hemihydrate, peak No. 2 to the endothermic transition from hemihydrate to soluble anhydrite, peaks Nos. 3 and 4 to further endothermic transitions to be discussed below, and peak No. 5 to the exothermic transition to insoluble anhydrite.

Natural Gypsums

The results shown in Table II are typical of the various samples studied. These data show that the reproducibility of peak temperatures at constant concentration and heating rate was satisfactory, and that peak temperatures were displaced upwards when sample concentration, heating rate, or particle size was increased.

differences in the size and shape of peaks may be due to packing of the sample within the block as well as to differences in its dihydrate content. In all cases the samples were heated to about 200° C at 3° C min^{-1}, and at 12° C min^{-1} thereafter to give better definition to the smaller high-temperature peaks. The broken lines in Fig. 1 indicate the region in which the heating rate, and hence the base line, was changing. Independent experiments at both 3° C and 12° C min^{-1} showed no thermal effects occurring in the 200° to 300° C region.

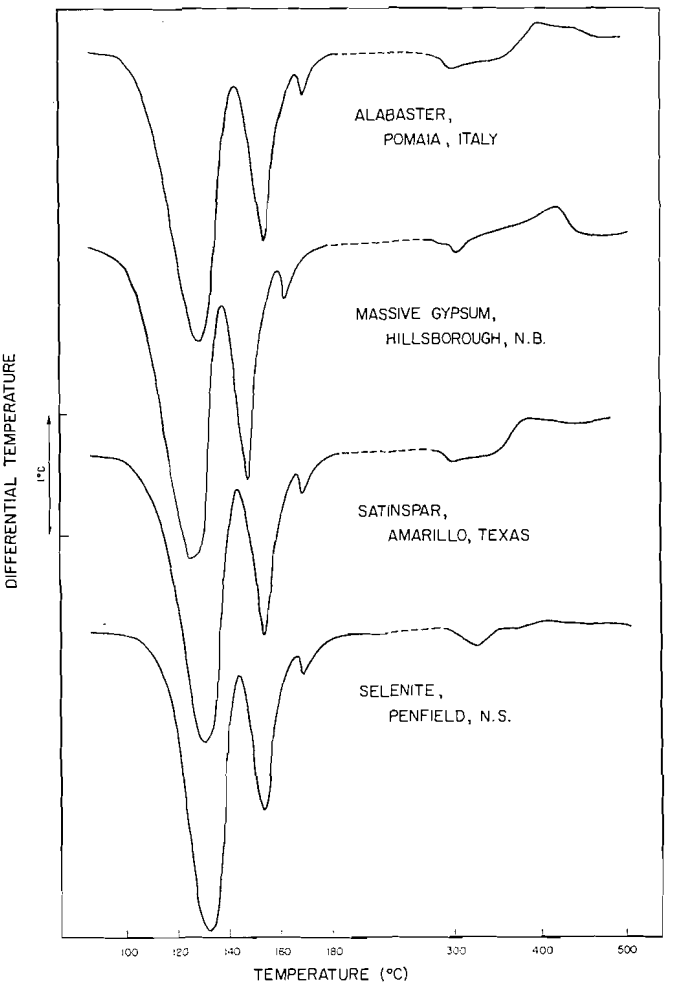

FIG. 1. Differential thermograms of natural calcium sulphate dihydrate.

In addition to the two endothermic peaks below 200° C (Nos. 1 and 2), another endothermic peak (No. 3) was consistently found associated with the dehydration of the hemihydrate (peak No. 2). Although peak No. 3 was observed under all conditions, there was a tendency for it to be masked by the larger peak No. 2 at both higher heating rates and sample concentrations. The occurrence of peak No. 3 was found to be independent of the particle size of the sample, the type or origin of the gypsum (natural or synthetic), the ambient humidity, and the diluent used. The fact that it was found when either

ignited alumina or powdered nickel metal was used as diluent and reference indicates that it is unlikely to be due to any sample–diluent interaction.

When a sample was heated at 12° C min^{-1} a further small endothermic peak (No. 4) was indicated in the vicinity of 300° C, appearing often as a doublet. This effect appeared to be independent of the origin of the sample and the diluent used, and was too small to be detected in samples heated to 500° C at 3° C min^{-1}. It was not possible to isolate this effect further at present.

The exothermic peak (No. 5) was moderately well defined at heating rates of 12° C min^{-1}. Throughout the variety of natural dihydrates studied, it was not possible to obtain large differences in the temperature at which this exothermic effect occurred (2, 3), although the shape of the peak varied between samples.

To ascertain if peak No. 3 could be associated with the transition to insoluble anhydrite, a series of experiments were carried out on samples of a massive gypsum whose differential thermograms had previously been obtained up to 250°, 300°, 350°, and 440° C. Since it is possible to hydrate a soluble anhydrite to the corresponding hemihydrate by moistening it with 80% ethanol and evaporating off the residual liquid (10), whereas if pure water is used the hydration will proceed completely to the dihydrate, these samples were each treated with 80% ethanol, the residual liquid evaporated off at 46° C until a uniform base line was again obtained on the thermogram, and the differential thermogram redetermined. The samples heated initially to 250°, 300°, and 350° C all produced second differential thermograms comparable to their initial ones, except for the absence of peak No. 1, indicating that no dihydrate was formed under the conditions of rehydration. The areas under peaks Nos. 2 and 3 were somewhat reduced and the temperatures corresponding to these peaks were slightly lower than in the initial thermograms, possibly due to changes in particle size and sample porosity resulting from the technique. The sample heated initially to 440° C lacked any peaks in the second differential thermogram, as did a sample heated to 500° C and cooled in a stream of dry nitrogen before the differential thermogram was redetermined. These results support the suggestion that the exothermic peak in the vicinity of 400° C is associated with the soluble to insoluble anhydrite transition (2, 3, 8), so that peak No. 3 occurs well below this temperature and does not appear to be associated with this particular transition.

Synthetic Hydrates

Table IV gives representative results of the differential thermal analysis of synthetic calcium sulphates, the thermograms appearing in Fig. 2. No significant differences between the thermograms of natural and synthetic varieties of calcium sulphate dihydrate were found.

TABLE IV

Peak temperatures in the differential thermograms of synthetic forms of calcium sulphate

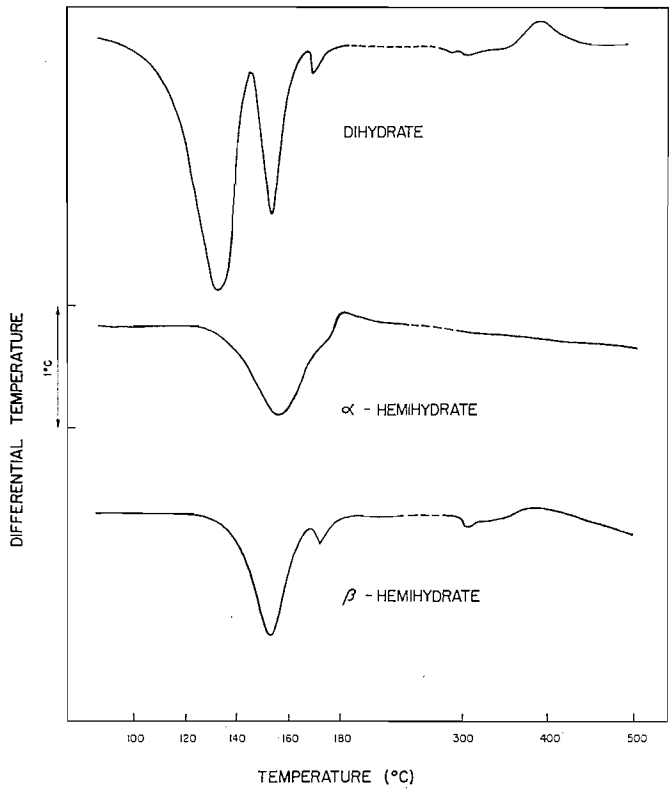

FIG. 2. Differential thermograms of synthetic hydrates of calcium sulphate.

With the α-hemihydrate, endothermic peak No. 3 was found, associated again with peak No. 2, at about the same temperature as in the case of the dihydrate. However, it was very much smaller than for the dihydrate or the β-hemihydrate (Fig. 2), appearing only as a shoulder on the high-temperature side of peak No. 2. An effort to resolve these peaks further at heating rates of the order of 1° C min^{-1} was unsuccessful. There was some indication that endothermic peak No. 4 might be present in the thermograms of α-hemihydrate, but its magnitude approached the sensitivity of the instrument.

The exothermic peak (No. 5) appeared at a considerably lower temperature with the α-hemihydrate than with the dihydrate or the β-hemihydrate, and was smaller and relatively sharper. Samples of α-hemihydrate, heated to 250°, 300°, and 350° C initially, were treated with 80% ethanol as described earlier and second differential thermograms were obtained. The sample initially heated to 250° C showed a small but definite peak No. 2 (transition of hemihydrate to soluble anhydrite) but no evidence of other peaks. The relative magnitudes of peak No. 2 in the first and second thermograms in this case indicated that any other peaks in the second thermogram would be beyond the sensitivity of the instrument. Samples heated initially to 300° and 350° C gave no clear indication of any peaks in the second thermogram. Such behavior would be expected if the α-soluble anhydrite is not completely converted to insoluble anhydrite at the exothermic peak temperature, as reported by Powell (8). Contrary to some reports (4, 5) there seems to be no doubt that this exothermic effect also exists in the case of the α-hemihydrate.

The differential thermogram of the β-hemihydrate closely resembled those of the various dihydrates, both natural and synthetic, indicating that the dehydration of these materials proceeded via the β-series of products as expected (9).

In an effort to identify peak No. 3 more fully, synthetic dihydrate was heated to 190° C, peak No. 3 being recorded at 169° C in this case, and slowly cooled to room temperature in a stream of dry nitrogen. The differential thermogram obtained on reheating this sample gave no indication of any peaks below 200° C suggesting that peak No. 3 is not due to some reversible, temperature-dependent phase change within the dehydrated sample, but rather appears to be associated directly with the loss of water during the dehydration of the hemihydrate.

COMMENT

Peaks Nos. 1 and 2 agree with those already reported in the literature for the dehydration of calcium sulphate dihydrate to hemihydrate and thence to soluble anhydrite at moderate heating rates, and need not be commented on further. Exothermic peak No. 5 has been confirmed as arising from the transition of soluble to insoluble anhydrite, and this process occurs when either α- or β-soluble anhydrite is heated, a much lower temperature being observed in the case of the α-soluble anhydrite.

Of the two further endothermic effects found, peak No. 4 in the vicinity of 300° C appears to be a reality when β-hemihydrate is heated, and not due to instrumentation, although it has not been possible to isolate this effect further. It is uncertain whether the same effect exists when α-hemihydrate is heated, and an instrument of higher sensitivity might resolve this point.

It has been found that the remaining endothermic effect (peak No. 3) cannot be ascribed to some interaction between sample and diluent, and that it is present only under conditions where the hemihydrate and corresponding soluble anhydrite can be interconverted. The transition of the sample to insoluble anhydrite erases both peaks Nos. 2 and 3. Heating of a sample to just above the conclusion of peak No. 3, cooling under anhydrous conditions, and reheating results in the absence of all of the first three endothermic peaks in the second thermogram, independent of the length of the initial heating. It is therefore reasonable to suggest that peak No. 3 is not due to some reversible temperature-dependent phase change occurring in the absence of water vapor within the calcium sulphate lattice.

An attempt has been made to estimate the enthalpy change associated with peak No. 3 by comparison with peak No. 2. The enthalpy change associated with this latter peak was calculated from the data of Kelley *et al.* (9), who consider the first reaction taking place on the dehydration of β-hemihydrate to be

$$CaSO_4 \cdot \tfrac{1}{2}H_2O(\beta)_s = CaSO_4(\beta)^*_s + \tfrac{1}{2}H_2O_g.$$

The product $CaSO_4(\beta)^*$ may contain up to 0.07 mole H_2O, which appear to be considerably more difficult to remove than the remainder of the 0.5 mole H_2O originally present. The corrected enthalpy equation for the above process (9) gives $\Delta H_{427°K} = +7.4$ kcal mole^{-1}. Comparison of areas under peaks Nos. 2 and 3, by means of a compensating planimeter, indicates that on this basis the enthalpy change associated with peak No. 3 is $\Delta H_{445°K} = +0.7$ kcal mole^{-1} $CaSO_4(\beta)^*$, equivalent to about 10 kcal mole^{-1} of residual H_2O.

In the case of the α-hemihydrate, dehydration produces a virtually water-free soluble

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

anhydrite containing perhaps 0.002 to 0.004 mole H_2O (9). The enthalpy change for the process

$$CaSO_4 \cdot \tfrac{1}{2}H_2O(\alpha)_s = CaSO_4(\alpha)_s + \tfrac{1}{2}H_2O_g$$

is $\Delta H_{427°K} = +6.9$ kcal mole^{-1}. As seen from Fig. 2, the area under peak No. 3 in this case, although too small to estimate with any degree of accuracy, may be roughly an order of magnitude less than in the case of the β-hemihydrate. Since the residual H_2O in the α-soluble anhydrite is also roughly an order of magnitude less than in the $CaSO_4(\beta)$*, it is possible that the enthalpy change associated with peak No. 3, per mole of residual H_2O, is about the same as that in the case of the β-hemihydrate. Thus, it may be speculated that the beginning of release of these last traces of water gives rise to the observed small endothermic effect, and that just as the conversion of soluble to insoluble anhydrite is not completed until temperatures above the end of the exothermic peak associated with this change, so these last traces of water continue to be removed over a wide temperature range as reported by Powell (8).

Another possible explanation for the presence of peak No. 3 might be as a "false peak" similar to those reported by Borchardt and Daniels (11) in the dehydration of several salt hydrates, and due to the vaporization of liquid water released from a previous dehydration reaction. Under this interpretation, peak No. 3 would be due to vaporization of liquid water produced from the dehydration of the hemihydrate (peak No. 2). However, in the cases reported (11) these "false peaks" were of a magnitude comparable to the peak associated with the original dehydration process producing the liquid water and the magnitudes of peaks Nos. 2 and 3 are sufficiently different as to suggest another explanation must be sought for the appearance of peak No. 3.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mr. L. J. Chapman, Department of Physiography, Ontario Research Foundation, for placing the required instrumentation at their disposal. Two of them (R. A. K., H. G. M.) also thank Gypsum, Lime and Alabastine, Canada, Ltd., for permission to devote some of their time to the direction of this work.

THE SYNTHESIS OF 2-*O*-β-D-GLUCOPYRANOSYL-D-XYLOSE[1]

J. K. N. Jones and P. E. Reid

ABSTRACT

A synthesis of the disaccharide named in the title is described. Some aspects of the periodate oxidation of this sugar and of analogous sugar derivatives have been examined.

INTRODUCTION

Aldobiouronic acids containing D-glucuronic acid or 4-*O*-methyl-D-glucuronic acid and D-xylose have been isolated from a number of xylans. We are attempting the synthesis of oligosaccharides which may occur in nature and as part of this program we have synthesized 2-*O*-β-D-glucopyranosyl-D-xylose. This compound provides a possible route to the aldobiouronic acid 2-*O*-β-D-glucuronosidyl-D-xylose and its 4-*O*-methyl-D-glucuronosidyl isomer, which have recently been synthesized by Timell and Bowering (1).

3,5-*O*-Isopropylidene-α + β-methyl-D-xylofuranosides were condensed with acetobromglucose (2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide) under standard Koenigs–Knorr conditions (2). After removal of the blocking groups the mixture of monosaccharides and oligosaccharides was fractionated by chromatography on a charcoal column and yielded a white crystalline disaccharide fraction in small yield. The use of argentic oxide (3) instead of the more usual argentous oxide in the Koenigs–Knorr condensation apparently made very little difference to the course of the reaction.

Hydrolysis and paper chromatography of the hydrolyzate showed that the compound contained glucose and xylose only. The theoretical results to be expected from the periodate oxidation of the possible reducing disaccharides containing glucose and xylose where (*a*) xylose is the reducing group and (*b*) the xylose residue has been reduced to a pentitol are shown in Tables I and II. In Table I the assumption is made that the rate-determining steps in the oxidation of the reducing disaccharide are, first, the rate of hydrolysis of the hemiacetal group, which is present in the product of oxidation of the 1,2-linked disaccharide, and, second, the rate of hydrolysis of any formyl esters produced.

TABLE I

Oxidation at acid pH – unbuffered conditions

Linkage	Moles of periodate taken up per mole of disaccharide	Moles of formic acid (as free acid) released per mole of disaccharide	Moles of formic acid per mole disaccharide as formyl ester	Overoxidation expected
1 → 2	3	1	—	Yes
1 → 3	3	1	1	Yes (see ref. 7)
1 → 4	4	2	1	No
1 → 5	4	2	1	No

Periodate oxidation of the disaccharide at 4° C proceeded rapidly and at 20 hours the periodate consumption was 5.4 moles and the formic acid released 4.1 moles. When the results obtained were plotted graphically and the flattened portion of the curve extrapolated to zero time the results obtained were 3.07±.13 moles of sodium metaperiodate consumed and 1.09±.11 moles of formic acid released per mole of disaccharide.

TABLE II

Oxidation at acid pH – unbuffered conditions

Linkage	Moles of periodate consumed per mole of disaccharide	Moles of formic acid released per mole disaccharide	Overoxidation expected
1 → 2	4	2	No
1 → 3	4	1	Yes
1 → 4	4	2	No
1 → 5	5	3	No

When the oxidation was carried out at 23°±2° C the oxidation was extremely rapid in the initial stages. After 3 hours 5 moles of periodate was consumed and 2.85 moles of formic acid was released, while after 20 hours the totals were 7.15 moles periodate consumed and 5.35 moles of formic acid released. It was evident that in both these cases extensive overoxidation had occurred. Overoxidation is known to occur with 1 → 2 linked disaccharides (4, 5). For example, periodate oxidation of 2-*O*-α-D-glucopyranosyl-D-glucose (5) resulted in a periodate uptake of 6.1 moles of periodate and a formic acid yield of 3.1 moles per mole after 22 hours at room temperature.

From Table I it will be seen that a 1 → 2 linked disaccharide should take up 3 moles of periodate and produce 1 mole of formic acid providing the first assumption is correct. To test this the periodate oxidation of 2-*O*-methyl-D-xylose and 2-*O*-β-D-glucopyranosyl-D-glucose* as models for 2-*O*-β-D-glucopyranosyl-D-xylose was examined.

Schwarz and MacDougall (6) have investigated the periodate oxidation of 2-*O*-benzyl-D-arabinose at 15–18° C. They found that the oxidation proceeded in three stages. One mole of periodate was consumed rapidly (ca. 5 minutes) and after 14 hours the uptake was 4 moles of periodate, oxidation then proceeded slowly. The fact that they were able to isolate benzyloxymalondialdehyde from the reaction mixture after 5 minutes suggests that the hydrolysis of the intermediary hemiacetal must be rapid. Mitchell (6*a*) has examined the periodate oxidation of 2-*O*-methyl-D-arabinose at 5° C and has isolated after a short time interval of oxidation the bisphenyl hydrazone of methoxymalondialdehyde. Methyl glyoxylate and glycollic aldehyde were also detected as products of oxidation. This work indicates that the hydrolysis of the hemiacetal is rapid and that overoxidation of methoxymalondialdehyde then occurs, as would be expected from the results of Schwarz and MacDougall (6).

Periodate oxidation of 2-*O*-methyl-D-xylose at 4° C was initially rapid and then became slow: 1.28 moles per mole (25 minutes); 3.1 moles (12 hours). The release of formic acid was relatively slow, 0.23 mole per mole (25 minutes); 1.1 moles (12 hours). These results are explicable on the basis of rapid hydrolysis of the hemiacetal linkage followed by oxidation of the glycollic aldehyde and methoxymalondialdehyde so formed (7, 8).

When the oxidation was carried out at 23°±2° C there was a rapid initial uptake of periodate and release of formic acid followed by a slower oxidation. (Periodate uptake: 0.9 mole (5 minutes); 3.4 moles (25.5 hours). Formic acid released: 0.22 mole (5 minutes); 2.02 moles (25.5 hours).) The high apparent yield of formic acid is not readily explicable on the basis of the above mechanism. If the rate of hydrolysis of the hemiacetal is a rate-limiting step it might be expected that a break in the rate curve would occur such that extrapolation to zero time would, in the case of 2-*O*-methyl-D-xylose, give a consumption of 1 mole of periodate and a release of no formic acid. When the figures obtained

were plotted graphically no such results were obtained. Similarly 2-*O*-β-D-glucopyranosyl-D-glucose would be expected to take up 3 moles of periodate and release 1 mole of formic acid. However, this result was not obtained when the experimental results were plotted graphically. In agreement with previous results (4, 5) extensive overoxidation was observed.

These results indicate that the rate of the hydrolysis of the hemiacetal is rapid and that the satisfactory results obtained from the extrapolation to zero time in the case of the oxidation of the disaccharide must be viewed with caution and indeed are probably fortuitous, particularly as the apparent final quantity of formic acid produced is higher than would be expected from the apparent periodate consumption (6). A substituted malondialdehyde would be expected to neutralize 1 mole of alkali.

Nevertheless the results of the periodate oxidations follow the same pattern as those expected of a synthetic 2-*O*-β-D-glucopyranosyl-D-xylose.

Table I shows that the disaccharides expected to overoxidize are those containing $1 \rightarrow 2$ and $1 \rightarrow 3$ linkages. The absence of a $1 \rightarrow 3$ type linkage in the synthetic disaccharide is indicated because 3-*O*-β-D-glucopyranosyl-D-xylose has been synthesized (7) and the physical constants differ from those of the synthetic disaccharide reported here.

Table II shows that a reduced $1 \rightarrow 2$ linked disaccharide on reduction followed by periodate oxidation would be expected to take up 4 moles of periodate and to release 2 moles of formic acid. The results actually obtained (periodate consumption: 4.05 moles; formic acid released: 2.15 moles) are in good agreement with those expected from theoretical considerations. Observed overoxidation was very low.

Periodate oxidation of 2-*O*-methyl-D-xylitol as a model for the oxidation of the reduced disaccharide resulted in the consumption of 1.97 moles of periodate and the release of 0.92 mole of formic acid. No overoxidation was observed. This result is in good agreement with theoretical predictions (periodate consumption: 2 moles; formic acid released: 1 mole).

Table II indicates that a $1 \rightarrow 4$ linked disaccharide would be expected to give the same result as a $1 \rightarrow 2$ linked compound, but since the $1 \rightarrow 4$ linked compound does not overoxidize when in a non-reduced form it is distinguished from a $1 \rightarrow 2$ linked compound.

EXPERIMENTAL

Optical rotations were measured in water at 23°±2° C and in water unless otherwise indicated. Solutions were concentrated at reduced pressure below 50° C. The following solvent systems were used to separate sugars on paper chromatograms: (*a*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4); (*b*) butan-1-ol, ethanol, water (3:1:1); and (*c*) butan-1-ol, pyridine, water (10:3:3) (all volume/volume).

Reducing sugars were detected with the *p*-anisidine spray (9) and non-reducing sugars were detected by the alkaline silver nitrate spray (10). Rates of movement of sugars on paper chromatograms are quoted relative to the rate of movement of D-galactose (R_{gal}).

Acetobrom-glucose (2,3,4,6-Tetra-O-acetyl-α-D-glucopyranosyl Bromide)

This was prepared by the method of Barczai-Martos and Korosy (11). 3,4-*O*-Isopropylidene methyl-α + β-D-xylosides were prepared by the methods of Baker, Schaub, and Williams (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

Condensation of Acetobrom-glucose and 3,5-O-Isopropylidene-methyl-α + β-D-xyloside

3,4-*O*-Isopropylidene methyl-α + β-D-xylosides (11.1 g) in pure dry chloroform (170 ml) was shaken for 30 minutes with Drierite (67.5 g), glass beads (51 g), argentic oxide (33.75 g), and iodine (3.38 g). Acetobrom-glucose (48 g) in pure dry chloroform (142 ml) was then added and the mixture shaken until a test for ionizable bromine was negative. The mixture was shaken for a further 2 days and filtered, and the filtrate concentrated to a syrup. The syrup was boiled under reflux with methanolic sodium hydroxide (400 ml) (4% w/v) for 3 hours and the cations removed by passage down a bed of Amberlite IR-120 (H-form) ion exchange resin. The resulting acidic solution was heated at 70–80° C for 5 hours, cooled, deionized by passage down a bed of Duolite A4 (OH-form) ion exchange resin, and concentrated to a syrup (14 g). Chromatography (solvent (*a*)) indicated the presence of glucose, xylose, a red spot R_{gal} 0.55, and a trace of yellow spot, R_{gal} 0.142. The syrup was dissolved in water and fractionated on a column of charcoal (Darco-G-60). Elution with water (2 l.) removed all the monosaccharides and the disaccharide was recovered by elution with varying concentrations of alcohol up to 50%. The solution was concentrated to a syrup (2 g). Attempts to prepare a crystalline acetate were unsuccessful. The syrup (1.4 g) was set aside when it crystallized in part. The crystalline material was recrystallized from a mixture of methanol and butan-1-ol and ran as a single discrete spot in solvents (*a*), (*b*), and (*c*). Microanalysis of this compound indicated the presence of ash (5%) and the results of the periodate oxidations carried out on this sample have been adjusted accordingly. The material was dissolved in water, the solution deionized by use of IR 120 (H-form) and IR-45 (OH-form) Amberlite ion exchange resins, concentrated, and the residue dissolved in boiling ethanol. The crystalline material so obtained had a melting point of 200°–202° C, $[\alpha]_D$ ±0° (equil.). Calc. for $C_{11}H_{20}O_{10}$: C, 42.3%; H, 6.4%. Found: C, 42.51%; H, 6.56%. The infrared spectrum was determined in potassium bromide at 0.4% concentration. The spectrum showed the following absorption maxima recorded as frequency cm^{-1}: 3340 (s), 2900 (m), 2860 (m), 1410 (m), 1385 (m), 1360 (m), 1345 (m), 1300 (w), 1280 (m), 1260 (m), 1230 (m), 1163 (m), 1143 (m), 1105 (s), 1078 (s), 1030 (s), 930 (w), 915 (m), 900 (m), 800 (m), 755 (w), 715 (w), 650 (w). (Intensity: s = strong, m = medium, w = weak.)

Hydrolysis of Disaccharide

The disaccharide (10 mg) was hydrolyzed with sulphuric acid (*N*) in a sealed tube for 11 hours at 100°. The hydrolyzate was neutralized with barium carbonate, filtered, and passed down a small bed of IR 120 (OH-form) ion exchange resin, and then concentrated to a syrup. Chromatographic examination in solvent (*a*) indicated the presence of glucose and xylose only.

Preparation of the Reduced Disaccharide

The disaccharide (18.2 mg) was dissolved in water (10 ml) and sodium borohydride (37 mg) was added. After 24 hours the solution was acidified with glacial acetic acid passed through a bed of IR 120 (H-form) Amberlite ion exchange resin and concentrated to a syrup. Boric acid was removed as methyl borate by codistillation with methanol (×20) and the residual syrup was dried over phosphorus pentoxide under reduced pressure (yield, 17.5 mg). Chromatographic examination in solvent (2) indicated the absence of reducing sugar (no reaction was observed with the *p*-anisidine hydrochloride spray). When the chromatogram was sprayed with alkaline silver nitrate a positive reaction resulted indicating the disaccharide had been reduced to the D-xylitol derivative.

Preparation of 2-O-Methyl-D-xylitol

2-*O*-Methyl-D-xylitol was prepared by the reduction of 2-*O*-methyl-D-xylose by the same procedure as described above.

Periodate Oxidations

The periodate oxidations of 2-*O*-methyl-D-xylose and 2-*O*-β-D-glucopyranosyl-D-glucose were carried out on accurately weighed samples (ca. 10 mg) with 0.3 *M* sodium metaperiodate (2 ml) made up to 25 ml with distilled water. The reactions were carried out in the dark at room temperature or at 4° C. Aliquots (1 ml) were used for analysis. The periodate was estimated by the method of Neumüller and Vasseur (13). The formic acid by that of Andrews *et al.* (14).

Oxidation of 2-O-Methyl-D-xylose

Moles of periodate consumed and moles of formic acid produced per mole at stated time intervals *at 4° C*: 0.67, 0.045 (10 minutes); 1.28, 0.23 (25 minutes); 2.25, 0.27 (1 hour); 2.47, 0.36 (2 hours); 2.67, 0.43 (4 hours); 2.92, 0.82 (6 hours, 10 minutes); 3.1, 1.1 (12 hours).

At room temperature (ca. 20° C): 0.84, 0.072 (5 minutes); 1.24, 0.072 (10 minutes); 1.75, 0.192 (20 minutes); 1.75, 0.51 (40 minutes); 2.39, 1.20 (2 hours); 2.69, 1.75 (3 hours); 3.02, 1.99 (7.5 hours); 3.1, 1.99 (15 hours); 3.22, 2.03 (28 hours).

Oxidation of 2-O-β-D-Glucopyranosyl-D-glucose

Moles of periodate consumed and formic acid produced at the time intervals stated at 4° C: 0.26, 0.07 (15 minutes); 0.75, 0.2 (30 minutes); 1.72, 0.46 (1 hour); 2.14, 0.57 (3 hours); 2.32, 0.62 (5 hours); 2.75, 1.02 (8 hours); 3.16, 1.08 (10 hours); 4.2, 1.92 (24 hours); 4.9, 2.04 (27 hours).

Oxidation of 2-O-β-D-Glucopyranosyl-D-xylose

Oxidations were carried on accurately weighed samples (ca. 10 mg) with 0.3 *M* sodium metaperiodate (1 ml made up to 10 ml with distilled water). Moles of periodate consumed and moles of formic acid released at stated time intervals *at room temperature*: 3.38, 0.75 (30 minutes); 3.82, 1.54 (1.5 hours); 5.07, 2.88 (3 hours); 6.35, 4.7 (7 hours); 7.15, 5.35 (20 hours).

At 4° C: 1.35, 0.75 (30 minutes); 2.4, 1.0 (1 hour); 2.7, — (2 hours); 3.0, 1.6 (3 hours); 3.25, 1.6 (4 hours); 3.7, 1.6 (5 hours); 3.95, — (3.95 hours); 5.4, — (21 hours); and 4.1, — (20 hours).

The periodate oxidations of the reduced disaccharide and of 2-*O*-methyl-D-xylose were carried out on weighed samples (ca. 10 mg) as described above.

Reduced Disaccharide

Moles of periodate consumed and moles of formic acid produced at the time intervals stated: 2.38, 1.15 (20 minutes); 2.7, — (40 minutes); 2.7, 1.15 (1 hour); 3.18, 1.6 (2 hours, 10 minutes); 3.82, 1.6 (3 hours, 10 minutes); 3.93, 1.6 (4 hours, 10 minutes); 4.27, 2.3 (5 hours); 4.45, 2.6 (21 hours).

2-O-Methyl-D-xylitol

Periodate consumption and moles of formic acid produced at the time intervals stated: 1.83, 0.78 (10 minutes); 2.02, 0.82 (30 minutes); 2.01, 0.92 (60 minutes); 2.02, 0.88 (165 minutes); 2.02, 0.92 (540 minutes).

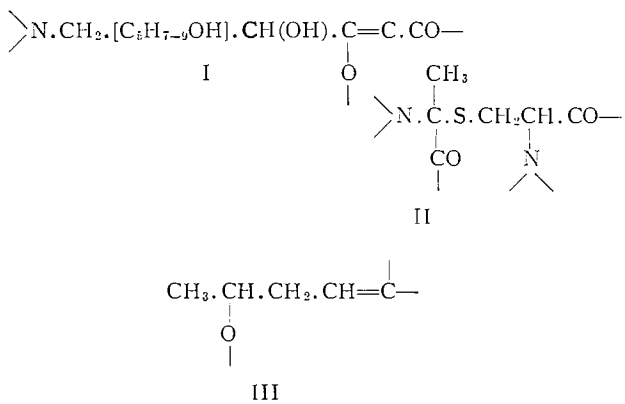
GRISEOVIRIDIN: THE C_6 FRAGMENT[1]

P. DE MAYO[2] AND A. STOESSL



ABSTRACT

The structure of a hydrolytic degradation product from griseoviridin, isolated as the 2,4-dinitrophenylhydrazone, has been shown, by synthesis, to be IV. A by-product of the synthesis was the stereoisomeric 2,4-dinitrophenylhydrazone. This establishes IX as a part structure of griseoviridin. Evidence is provided that the previously proposed structural environment of the sulphur atom is incorrect, and that the sulphur may, in fact, be attached to the C_6 fragment.

The antibiotic griseoviridin, isolated from cultures of a strain of *Streptomyces griseus* (1) has been studied by Ames, Bowman, and their collaborators (2, 3, 4), who were able to establish the empirical formula $C_{22}H_{29\pm2}O_7N_3S$. In their extended investigations they provided evidence for the presence, in this molecule, of three moieties.

First, the existence of a C_{10} fragment was established by the isolation, after reduction and hydrolysis, of ω-amino-decanoic acid. For this portion of the molecule the part structure I was tentatively proposed (4). Secondly, they showed by hydrolysis the presence of two alanine residues (4) in octahydrodesthiogriseoviridin diacetate, a reduced substance from which the sulphur had been removed by Raney nickel. Griseoviridin itself, on the other hand, gave no alanine on hydrolysis, but yielded cystine and some serine together with 1 mole ammonia. From this and other evidence, they deduced the part structure II, the sulphur being part of a ring since removal of the sulphur did not cause the disruption of the molecule. Finally some indication of the disposition of the remaining carbon atoms was obtained from the following experiments (3).

Ozonolysis of griseoviridin (or its diacetate) followed by decomposition of the ozonide and mild treatment with acid or base and steam distillation gave crotonaldehyde, characterized as its 2,4-dinitrophenylhydrazone. The hydrochloride,[3] obtained from griseoviridin by the action of concentrated hydrochloric acid, in contrast, gave crotonaldehyde *directly* after ozonolysis, whilst hexahydrogriseoviridin diacetate gave no aldehyde at all. The facts were construed to indicate the part structure III.

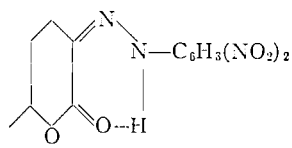
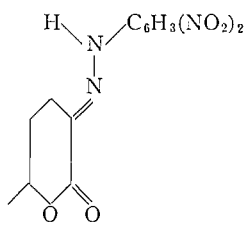
For personal use only.

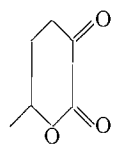
Such formulations accounted for all but one of the 22 carbon atoms in griseoviridin, and since some evidence, derived from infrared spectra, was adduced for the presence of a diacylimide the remaining carbon atom was conjecturally attached to the fragment represented by III. The present communication is mainly concerned with this fragment.



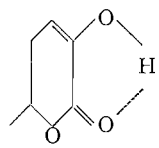
Although griseoviridin itself does not yield a 2,4-dinitrophenylhydrazone, Ames and Bowman (3) reported that after acid hydrolysis such a derivative, $C_{14}H_{14}O_7N_4$, was obtained, corresponding to a fragment $C_8H_{10}O_3$. Re-examination of this substance, purified by chromatography on bentonite–celite, showed that it had, in fact, the formula $C_{12}H_{12}O_6N_4$, corresponding to a derivative of a compound $C_6H_8O_3$. The material was optically active and so contained at least one asymmetric carbon, whilst Kuhn–Roth oxidation indicated the presence of one C-methyl group. The ultraviolet spectrum (λ_{max} 365 mμ) suggested the derivative of a saturated ketone and precluded the presence of any other high intensity chromophore in the molecule. The infrared spectrum, however, showed a band at 1680 cm^{-1} to be attributed to a remaining carbonyl function. Since the empirical formula required the presence, in the original substance, of three double-bond equivalents, and, since the remaining oxygen was not a hydroxyl group, a cyclic structure seemed inevitable. Bearing in mind the implications of the part structure III the formulation IV appeared attractive. Such a structure with the appropriate geometry would, by hydrogen bonding and conjugation, be expected to lower the normal δ-lactone frequency to that actually found. Furthermore, a band at 3154 cm^{-1}, to be attributed to the N—H stretch, was lower, as would be expected for hydrogen bonding, than is usual for such bonds in these derivatives: the accepted region is in the vicinity of 3300 cm^{-1}. Since the amounts of material available did not allow of chemical degradation the racemate of IV was, accordingly, synthesized by the following steps.



V



VI

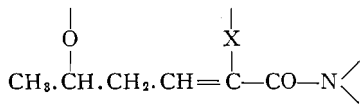


IV

VIII

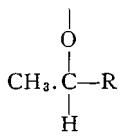
VII*a*

VII*b*



γ-Valerolactone was condensed with ethyl oxalate to give, after hydrolysis, an acid, $C_7H_8O_5$, corresponding to one or more of the tautomers of V or VI. It liberated carbon dioxide from sodium hydrogen carbonate, titrated as a monobasic acid, and gave an intense purple color with ferric chloride.

The acid was decarboxylated (with the evolution of one molecule of carbon dioxide) to give VII*a*, $C_6H_8O_3$, which appeared to exist largely as the enol (VII*b*). This substance also titrated sharply as a monobasic acid, and although it could be obtained pure by recrystallization after sublimation it rapidly decomposed on exposure to air, as do the corresponding γ-lactones (5).

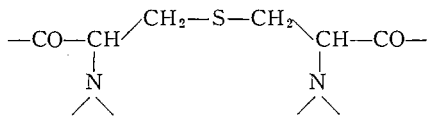


The preparation of the 2,4-dinitrophenylhydrazone was accomplished in the usual way, the acidic material isolated then being cyclized to the lactone by refluxing in chloroform. Chromatography on bentonite–celite then afforded racemic IV, m.p. 230–231°. The ultraviolet spectrum, and the infrared spectra, both in chloroform and methylene dichloride solution, were superposable on that of IV from hydrolytic degradation.

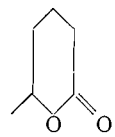
Concomitant with the formation of IV, a second, isomeric, 2,4-dinitrophenylhydrazone was isolated. This absorbed at somewhat shorter wavelength in the ultraviolet, and, in the infrared spectrum showed bands at 3300 (free N—H) and 1724 cm^{-1}. This substance is accordingly attributed the structure VIII. Such pairs of isomers have been previously separated and our interpretation has ample analogy (6).

The structural identification of IV indicated the presence, in griseoviridin, of the six-carbon fragment (IX) which, with I and II, or their equivalents, accounts for all the carbon atoms. The formulation (IX) is supported by the fact that whilst both griseoviridin and hexahydrodeoxygriseoviridin (obtained by hydrogenation of the hydrochloride) give iodoform (35 and 48% respectively) when treated with iodine and base, griseoviridin gives acetaldehyde merely on refluxing with 4 *N* sodium hydroxide. This process, presumably involving a dealdolization, occurs also in the hydrochloride but not in the reduced hydrochloride where one of the requisite structural features, the double bond, is no longer present as is shown by the non-formation of crotonaldehyde on ozonolysis. Formic and acetic acids are formed, in addition to acetaldehyde, in the hydrolysis of griseoviridin.

IX



X



The atom (X) in IX may be oxygen, or, less probably, nitrogen. Evidence is available that, in fact, sulphur cannot be excluded and that the part structure II is incorrect. First, Kuhn–Roth oxidation of griseoviridin suggests (2) the presence of 1 C—Me group which is surely that present in IX. Secondly, the n.m.r. spectrum in deuterochloroform of griseoviridin diacetate and several other derivatives showed a doublet at 8.55 p.p.m. (relative to tetramethylsilane as 10) ($J \sim 7$ c.p.s.) attributable to the system X: no other bands (other than acetate) attributable to C—Me could be detected. We are much indebted to Dr. L. M. Jackman for the determination of these spectra.

Finally although modification of II to XI would circumvent these difficulties, evidence is available that the situation is more subtle. Thus, griseoviridin reacts with perbenzoic acid (2) to give an "oxide" which does not show sulphone bands in the infrared (7) and which gives cystine and traces of serine on acid hydrolysis, as does griseoviridin itself.

XI

XII

Since sulphides are, in general, rapidly oxidized by peracids this observation appears incompatible with II or XI. But, by contrast, hexahydrodeoxygriseoviridin rapidly gives a sulphone further characterized by a number of derivatives. The implication is, therefore, that reduction or hydrogenolysis in the vicinity of the sulphur atom renders it open to oxidation, a fact not readily interpretable in terms of II and XI. If the sulphur is not assigned to the two alanine molecules it then becomes available for inclusion in part formula IX. Consistent with this is the fact that basic hydrolysis of octahydrodethiogriseoviridin diacetate readily affords δ-caprolactone (XII) whereas hexahydrodeoxygriseoviridin, in which the sulphur link remains, does not. In this case some second hydrogenolysable function is required to mask the second potential alanine moiety.

EXPERIMENTAL

Melting points were taken on the Kofler Hot Stage. Rotations were determined in chloroform and ultraviolet spectra in 95% ethanol. Except where otherwise indicated the phrase 'petroleum ether' refers to the fraction of boiling range 60–80°; unless otherwise stated infrared spectra were determined as Nujol mulls.

Preparation of the 2,4-Dinitrophenylhydrazone (IV)

Griseoviridin (200 mg) was hydrolyzed with 6 *N* hydrochloric acid and the crude 2,4-dinitrophenylhydrazone was prepared as described by Ames and Bowman (3). The crude, dried product (40 mg) was dissolved in chloroform and applied to a short column of bentonite–celite (1:1 by volume). Elution with ethanol–chloroform (1:6) gave, after evaporation and crystallization from ethanol–chloroform, the almost pure 2,4-dinitrophenylhydrazone (7.6 mg), m.p. 223–226° (Ames and Bowman record 220–222°), $[\alpha]_D$ +84 (*c*, 0.20); λ_{max} 258, 365 mμ and log ε 3.91 and 4.35 respectively. The compound has maxima in the infrared at 3154, 3090, 1680, and 1615 cm^{-1}. Found: C, 46.78%; H, 4.12%; N, 18.09%; C—Me, 4.38%. $C_{12}H_{12}N_4O_6$ requires: C, 46.75%; H, 3.92%; N, 18.18%; C—Me, (1), 4.88%.

2-Oxalyl-γ-valerolactone

A mixture of diethyl oxalate (100 ml) and γ-valerolactone (10 g) was added to a solution of sodium (2.3 g) in absolute ethanol (40 ml) and the mixture heated under reduced pressure (10 cm Hg) at 55° for 1 hour, the pressure lowered (2 cm Hg), and heating continued for a further 2 hours. After the mixture was cooled the precipitated solid was collected, washed with ether, and just acidified with *N* hydrochloric acid. Extraction with ether and evaporation under reduced pressure then gave the crude required, 2-oxalyl-γ-valerolactone (16.2 g).

The crude ester (8.0 g) was dissolved in sodium hydroxide solution (125 ml, 1.1 *N* NaOH) and set aside overnight. Acidification followed by repeated extraction with ether gave the crude lactone (5.9 g). Crystallization from ether, extraction with benzene to remove small amounts of oxalic acid, and recrystallization from carbon tetrachloride gave the γ-lactone, m.p. 93–102° (variable, dependent on rate of heating and solvent).

Found: C, 48.7%; H, 4.80%; equiv. 90. $C_7H_8O_5$ requires: C, 48.85%; H, 4.69%; equiv. 86. The substance had λ_{max} 276 mμ (log ϵ 3.54) and bands in the infrared at 3546, 3460, 3300, 1718, 1698, 1669, and 1631 cm^{-1}.

2-Oxo-δ-caprolactone

The γ-lactone (840 mg) was refluxed in water for 2 hours. The solution was then cooled and evaporated under reduced pressure at 40° to give a yellow oil (760 mg) which crystallized after sublimation. The crystals liquefied after brief exposure to the atmosphere, but could be purified by crystallization from petroleum ether to give the δ-lactone, m.p. 56–59°. Found: C, 56.18%; H, 6.33%; equiv. 130. $C_6H_8O_3$ requires: C, 56.24%; H, 6.29%; equiv. 128. The substance had λ_{max} 256 mμ (log ϵ 3.70) (neutral) and λ_{max} 246 (log ϵ 3.64) (.001 *N* NaOH), and bands in the infrared spectrum at 3068, 1675 (broad), and 1613 cm^{-1}.

The 2,4-Dinitrophenylhydrazones of (±)-2-Oxo-1,5-hexanolide

The δ-lactone (400 mg) in water (25 ml) was added to 2,4-dinitrophenylhydrazone (1.2 g) in sulphuric acid (10 ml) and water (75 ml). After 24 hours the precipitate formed was extracted into chloroform containing 10% ethanol, and the acidic material isolated, in the usual manner, by extraction with a saturated solution of sodium hydrogen carbonate (100 ml), followed by acidification and re-extraction with chloroform. Evaporation gave the crude acid (733 mg) which was cyclized by refluxing in chloroform and partial removal of solvent by distillation. After removal of acidic contaminants with sodium hydrogen carbonate solution the remaining neutral material (305 mg) was crystallized from benzene to give fraction A (90 mg). This was retained. The mother liquors were added to a bentonite (10 g) – celite column (equal volumes). Elution with ethyl acetate – benzene (1:9) gave fraction B, whilst ethanol – ethyl acetate (1:9) gave material identical with fraction A.

(*a*) The trans (±)-2,4-dinitrophenylhydrazone was obtained by crystallization of fraction A from benzene. It melted unsharply at 200–210°, but the ultraviolet spectrum and melting point were unchanged on repeated crystallization. Found: C, 47.01%; H, 4.15%; N, 17.96%. $C_{12}H_{12}N_4O_6$ requires: C, 46.75%; H, 3.92%; N, 18.18%. The compound had λ_{max} 255, 350 mμ; log ϵ 4.38 and 3.90 respectively.

(*b*) The cis (±)-2,4-dinitrophenylhydrazone was obtained by crystallization of fraction B from ethanol–chloroform and from benzene, m.p. 230–231°. Found: C, 46.96%; H, 4.08%; N, 18.36%. The infrared spectrum in chloroform and methylene dichloride were superposable on that of the active material.

The Hydrolysis of Griseoviridin

(*a*) A solution of griseoviridin (505 mg) in aqueous sodium hydroxide (4 *N*, 50 ml) was distilled at constant volume in a nitrogen atmosphere, the distillate being collected in an aqueous sulphuric acid solution of 2,4-dinitrophenylhydrazone. The precipitate was collected (176 mg) and the absorption curve in the ultraviolet accurately paralleled that of the acetaldehyde derivative, indicating the absence of any crotonaldehyde. Chromatography of the crude product or alumina (Brockman Grade III, 20 g) gave, on elution with benzene – petroleum ether (1:5) followed by crystallization from methanol–chloroform, acetaldehyde 2,4-dinitrophenylhydrazone, melting point and melting point on admixture with an authentic specimen of the same melting point, 163–166°.

(*b*) The alkaline hydrolyzate was acidified with 6 *N* sulphuric acid, the gummy precipitate removed by filtration, and the volatile acids isolated by distillation at constant

volume under nitrogen. Qualitative paper chromatography showed the presence of both acetic and formic acids. Treatment after concentration to 20 ml of an aliquot (150 ml of a total of 250) at room temperature with sodium hydrogen carbonate (1 g) and a few drops of bromine (8) destroyed the formic acid and after removal of the excess bromine in a stream of air the aqueous acid was distilled. Titration showed the presence of 0.4 mole of acid. Paper chromatography confirmed the presence of acetic acid only and identity was confirmed by the infrared spectrum of the residue of sodium acetate on evaporation, and by conversion to *p*-phenyl – phenacyl acetate identical in every respect with an authentic specimen.

In another aliquot (100 ml) the carbon dioxide evolved by oxidation of the formic acid with orange mercuric oxide (250 mg) (9) was collected in barium hydroxide. Titration of the barium carbonate produced indicated the presence in the original solution of 0.9 mol. formic acid. The identity of the acid was confirmed by extraction of the salts (138 mg) from the hydrolysis of griseoviridin (1 g) with 95% ethanol and crystallization from absolute ethanol. The sodium formate so obtained had a melting point of 251–256°; its infrared spectrum could be superimposed on that of an authentic specimen. Found: Na, 34.08%; Calc. for CHO_2Na: Na, 33.81%.

Alkaline Hydrolysis of Octahydrodethiogriseoviridin Diacetate

The diacetate (213 mg) was refluxed in solution in aqueous sodium hydroxide (4 *N*, 20 ml) under nitrogen for 30 minutes. No precipitate was obtained by distillation into 2,4-dinitrophenylhydrazine solution. The hydrolyzate was acidified and distilled at constant volume until the titer was negligible. Addition of excess alkali and backtitration indicated the presence of 0.8 mol. lactone. Repeated extraction of the acidified solution with ether gave, after evaporation, an oil (12 mg) which was distilled at 100°/3 mm to give (+)-δ-caprolactone (5.4 mg), m.p. ca. 15°, $[\alpha]_D$ +39 (*c*, 0.54). The infrared spectrum in chloroform was superposable on that of synthetic (±)-δ-caprolactone, and the two substances behaved in the same way on partition chromatography in a propanol–ammonia system (10).

In another experiment the crude alkaline titration solution was mixed with a solution of chromic acid in 2 *N* sulphuric acid (0.4 *N*, 4 ml) and set aside for 16 hours. The excess oxidant was then destroyed (sulphur dioxide) and the mixture treated with Brady's reagent. The resultant precipitate, after collection, was chromatographed on bentonite–celite (1:1 by volume) the fraction eluted with ethanol–chloroform (1:4) then being crystallized from benzene to give 5-oxocaproic acid 2,4-dinitrophenylhydrazone, m.p. 137–139°, unchanged on admixture with an authentic specimen (11) of the same melting point. The infrared spectra in Nujol mull were superposable.

Hexahydrodeoxygriseoviridin

Griseoviridin hydrochloride was prepared as described by Ames and Bowman. Crystallized from ether–methanol it had $[\alpha]_D$ −177° (*c*, 0.53 in MeOH). Found: C, 50.87%; H, 5.86%; Cl, 7.07%. $C_{22}H_{29}O_7N_3S.HCl$ requires: C, 51.20%; H, 5.86%; Cl, 6.87%.

The hydrochloride (3 g) was hydrogenated in ethanol solution in the presence of palladized charcoal (9 g). The filtered solution was evaporated and the glassy residue was crystallized from ethanol. The product had a melting point of 246–248°, $[\alpha]_D$ −55°. Found: C, 56.62%; H, 6.93%; O, 20.75%; N, 8.92%; S, 6.85%. $C_{22}H_{33}O_6N_3S$ requires: C, 56.49%; H, 7.11%; O, 20.53%; N, 8.99%; S. 6.85%. The substance had λ_{max} 212 mμ (log ε 4.29) in neutral solution. In ethanol containing .01 *N* sodium hydroxide it had λ_{max} 255 mμ (log ε 3.89). No crotonaldehyde was obtained by ozonolysis and distillation.

Hydrolysis with 6 *N* hydrochloric acid and distillation of the residue from citrate buffer and ninhydrin (4) gave no volatile carbonyl compounds. No acetaldehyde was formed on alkaline hydrolysis.

Acetylation (pyridine – acetic anhydride at room temperature) gave the monoacetate which, after crystallization from ethanol, had a melting point of 226–228°. Found: C, 56.92%; H, 7.02%; N, 8.34%; S, 6.11%; $C_{24}H_{35}O_7N_3S$ requires: C, 56.54%; H, 6.92%; N, 8.25%; S, 6.28%. The compound has $[\alpha]_D$ −53° (*c*, 1.89).

Benzoylation (pyridine–benzoyl chloride at room temperature for 4.5 hours) afforded the monobenzoate which, after crystallization from ethanol, had a melting point of 193–196°. Found: C, 61.22%; H, 6.38%; N, 7.25%. $C_{29}H_{37}O_7N_3S$ requires: C, 60.92%; H, 6.52%; N, 7.35%. The compound had λ_{max} 227 mμ (log ε 4.14).

Hexahydrodeoxygriseoviridin Sulphone

The deoxy compound (70 mg) in chloroform (10 ml) was added to a solution of perbenzoic acid in benzene (2 ml, 0.4 *N*) and the mixture was left overnight. The solution was then diluted with chloroform and washed with sodium hydrogen carbonate solution and water, and the solution concentrated to give the sulphone, m.p. 205–220° (dec.) unchanged by repeated crystallization from chloroform–ethanol. Found: C, 52.91%; H, 6.74%; O, 25.32%; N, 8.31%. $C_{22}H_{33}O_8N_3S$ requires: C, 52.87%; H, 6.60%; O, 25.63%; N, 8.41%. In neutral solution it showed λ_{max} 212 mμ (log ε 4.21) λ_{Inf} 258 mμ (log ε 3.85). The infrared spectrum showed bands at 1295 and 1126 cm^{-1}. A similar, but quantitative, experiment showed that the uptake of oxidant ceased at 2 moles perbenzoic acid.

Similar oxidation of the monoacetate gave the corresponding sulphone, m.p. 220–230° (from ethanol–chloroform). Found: C, 53.33%; H, 6.59%; O, 26.37%; N, 7.78%. $C_{24}H_{35}O_9N_3S$ requires: C, 53.21%; H, 6.51%; O, 26.59%; N, 7.76%. It had bands in the infrared spectrum at 1290 and 1124 cm^{-1}. This compound was also prepared by acetylation of the sulphone (acetic anhydride – pyridine at room temperature). Oxidation of the benzoate gave the corresponding sulphone, m.p. ca. 200° (from ethanol–chloroform). Found: C, 57.81%; H, 6.38%; N, 6.41%. $C_{29}H_{37}O_9S$ requires: C, 57.70%; H, 6.18%; N, 6.96%. The compound had $[\alpha]_D$ +25 (*c*, 2.0) and showed bands in the infrared at 1294 and 1121 cm^{-1}.

Dehydrohexahydrodeoxygriseoviridin Sulphone

Hexahydrodeoxygriseoviridin sulphone (50 mg) was dissolved in acetic acid (glacial, 5 ml) and a solution of chromic acid in acetic acid (1.05 ml, 0.2 *N*) was added. The mixture was set aside for 5 hours, after which the product was isolated with chloroform. Crystallized from methanol–chloroform the substance had a melting point of approximately 230° (with previous sintering), unchanged by further crystallization. Found: C, 53.37%; H, 6.34%; N, 8.85%. $C_{22}H_{31}O_8N_3S$ requires: C, 53.09%; H, 6.28%; N, 8.44%. The substance in neutral solution had λ_{max} 220 mμ (log ε 4.17) and in .01 *N* ethanolic hydroxide λ_{max} 299 mμ (log ε 4.30). The compound had $[\alpha]_D$ −4° (*c*, 0.85) and showed bands in the infrared at 1709, 1282, and 1119 cm^{-1}.

Iodoform Reaction

Griseoviridin (26 mg) in aqueous potassium hydroxide (10%, 0.5 ml) was warmed until dissolved, cooled to 60°, and iodine – potassium iodide solution added. Iodoform (melting point and mixed melting point with an authentic specimen 119°) (7.2 mg) was isolated equivalent to 0.35 mole per molecule of griseoviridin. A similar experiment on the hexahydrodeoxygriseoviridin gave 0.48 mole iodoform.

THE FREEZING OF WATER AND BENZENE IN POROUS VYCOR GLASS[1]

C. HODGSON[2] AND R. MCINTOSH

ABSTRACT

Freezing has been detected in the adsorbed water and benzene of porous Vycor glass at temperatures below that at which the bulk phases freeze. The evidence presented by equilibrium pressure measurements and dimensional changes of the systems is considered in terms of theories of capillary condensation and freezing in cements and soil. Although not all the results can be explained, it is concluded that the freezing process is a gradual one for both adsorbate–adsorbent systems. The evidence further suggests that hysteresis is absent in isotherms if the solid phase has formed.

INTRODUCTION

In a note from this laboratory (1) the detection of the freezing of water in porous Vycor glass was reported. The method of detection was the observation of the change of linear dimension of the adsorbate–adsorbent system using an extensometer of a type previously described (2). At approximately −22° C a large expansion of the system occurred, in striking contrast with the gradual contraction found as the temperature was lowered in a range above −22° C.

A qualitative explanation of the finding was suggested as either or both of the following possibilities. As in the case for the bulk phases, the solid adsorbate may have a larger molar volume than the liquid adsorbate. Or, since the contractive force due to concave menisci has been demonstrated (3), it is possible that the destruction of concave menisci by the formation of solid adsorbate might also allow a large expansion. To try to distinguish between these possibilities and to establish a broader basis for discussion of the phenomena associated with adsorption hysteresis in general, experiments using benzene as the adsorbate were undertaken. Differences in the behavior of the two adsorbates are marked, and some of the differences are undoubtedly due to the unusual molar volume change in the transition of water. However, insufficient understanding of all the phenomena has been achieved, and it is necessary to compare the results for the two systems in detail. It is also pertinent to analyze the theories so far advanced to rationalize the known transition phenomena and to comment upon claims made by Puri, Singh, and Myer (4) of excellent agreement between the predictions of capillary condensation theory and observation.

One advantage of the experimental method employed in this investigation is that it reveals that the freezing phenomenon does not occur at a single temperature as may be seen from Figs. 1A, 2A. The observation of a sudden change in the rate at which the equilibrium pressure changes with temperature need not mean a sharp phase transition, but it has apparently been interpreted in this way, and a transition temperature, rather than a transition range, has been discussed by many authors. Other evidence against the occurrence of sharp transitions is contained in the work of Jones and Gortner (5), and Patrick and Kemper (6). The evidence obtained using benzene also points to a gradual freezing. The behavior of the two substances differs,

however, in that water begins to freeze at a temperature which is insensitive to the quantity adsorbed, while the initial freezing temperature of benzene varies in a readily discernible manner with quantity adsorbed. In the case of benzene, since the higher equilibrium pressures were more readily measured, it was possible to show that there is no hysteresis in that part of the isotherm where solid benzene may exist. This fact supports the suggestion made earlier (1) that meniscus effects of the liquid phase may be the fundamental cause of hysteresis.

Because of the very large amount of data involved, most of the information will be presented in graphical form.

EXPERIMENTAL

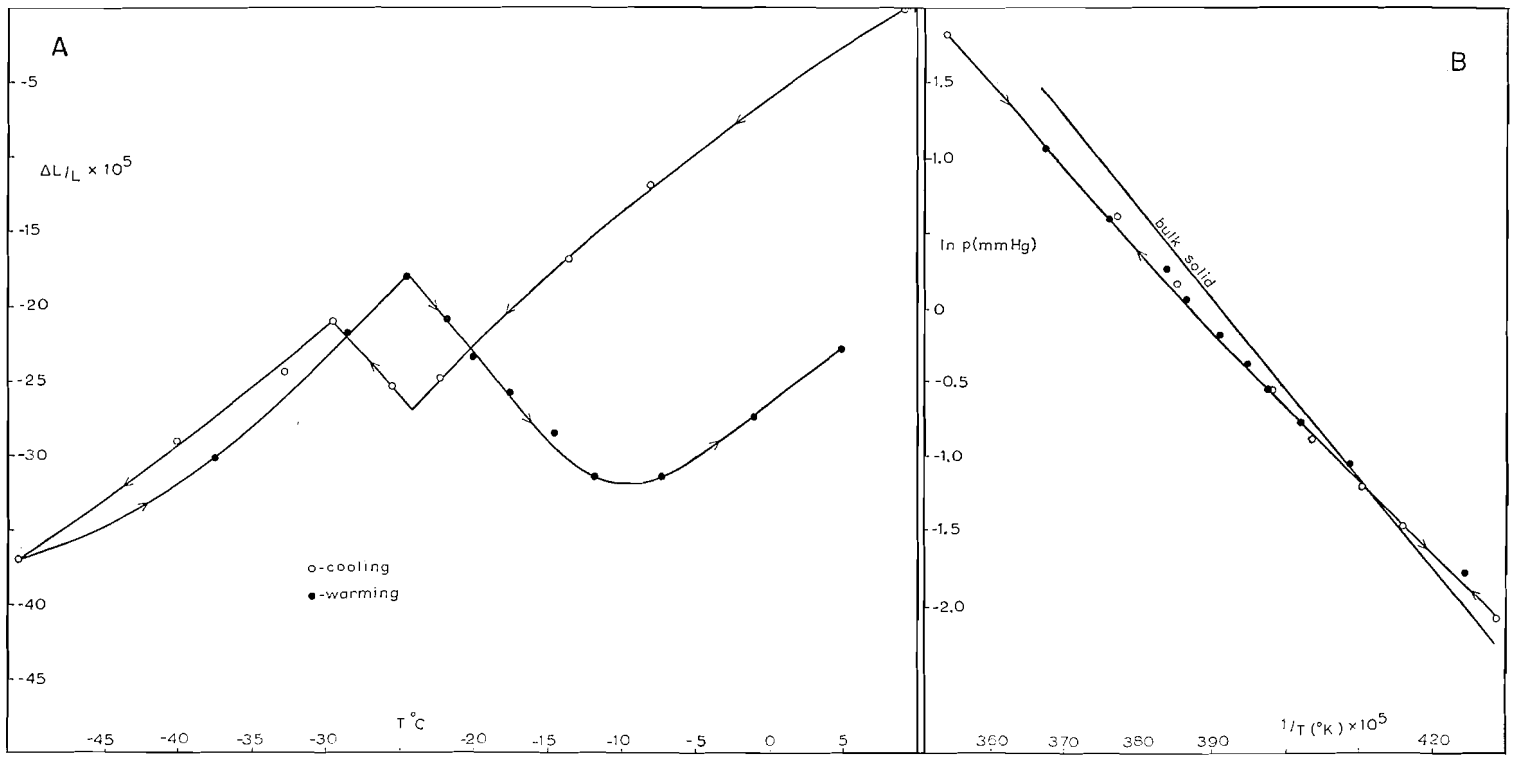
As the extensometer and system for temperature control have been described previously (2), only the form of pressure gauge and the minor modification made to the injector for the adsorbates will be discussed. The pressure gauge was a form suggested by Pearson (7) and in this case butylphthalate was used rather than mercury, so that a magnification of 179 relative to readings of a U-tube type of mercury manometer was obtained. In practice the manometer was not free from error. Difficulty was experienced in measuring the low pressures of water because of degassing of the butylphthalate.

The injector holding the adsorbate was arranged with a heating wire around connecting metal valves and tubing, so that after allowing adsorbate to distill from the capillary to the adsorbent chamber, the slow drift in the level of adsorbate in the capillary tube of the injector due to adsorption on metal valves and walls was eliminated. This difficulty has been noted by Amberg (8), but had not been corrected.

The temperature was varied by increments usually less than 10 degrees. Before length and pressure measurements were taken at a new temperature, the system was allowed to come to apparent equilibrium, a process which took between 8 and 12 hours.

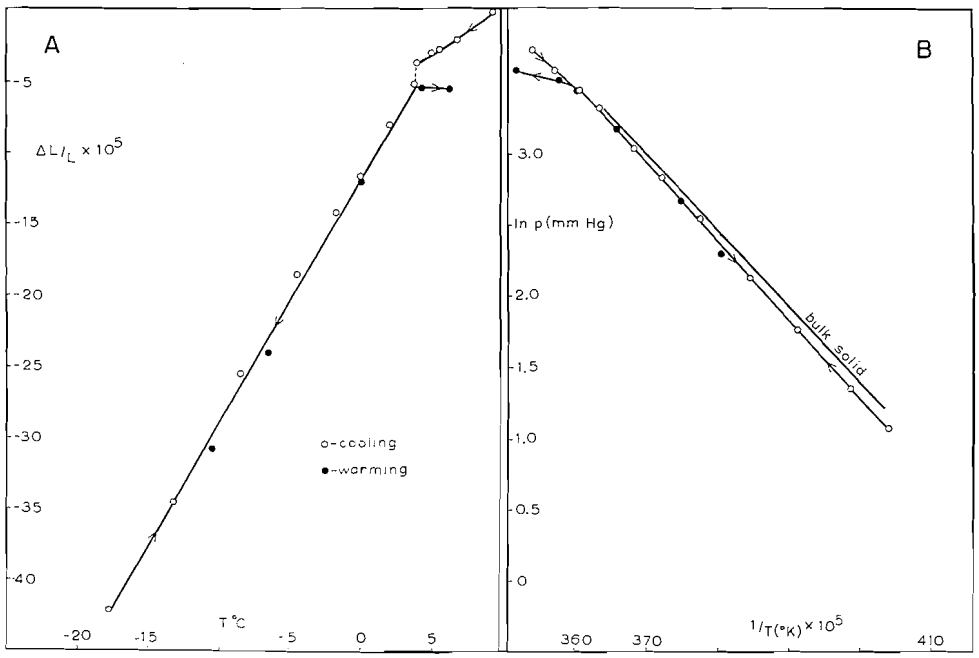
RESULTS

1. Water. Length Changes and Equilibrium Pressures



The results of a typical cooling and heating experiment for water at an initial content of 0.175 g/g, established as an adsorption point at 9° C, is given in Fig. 1A. It should be noted that the temperature range over which the expansion (i.e. freezing) occurs on the cooling curve differs from the temperature range over which contraction (i.e. melting) occurs on the heating curve. An important displacement of the two curves is evident, showing a difference of the absolute lengths of the rod. Repeated cycles did not eliminate this behavior. By contrast, it is seen that the equilibrium pressure values of Fig. 1B lie on the same curve for both heating and cooling.

2. Benzene. Length Changes and Equilibrium Pressures



Two typical sets of curves showing length changes as a function of temperature for both heating and cooling and the corresponding equilibrium pressure data are given in Figs. 2, 3, and 4. The contents of benzene are respectively 0.233 g/g, 0.162 g/g, and 0.170 g/g. The reason for giving these figures is that comparison shows the shift of the temperature at which freezing begins with quantity adsorbed. It should also be noted that the sudden change of slope of the equilibrium pressure curves occurs at the same temperature as the change of slope of the length versus temperature plots. Table I contains a further comparison.

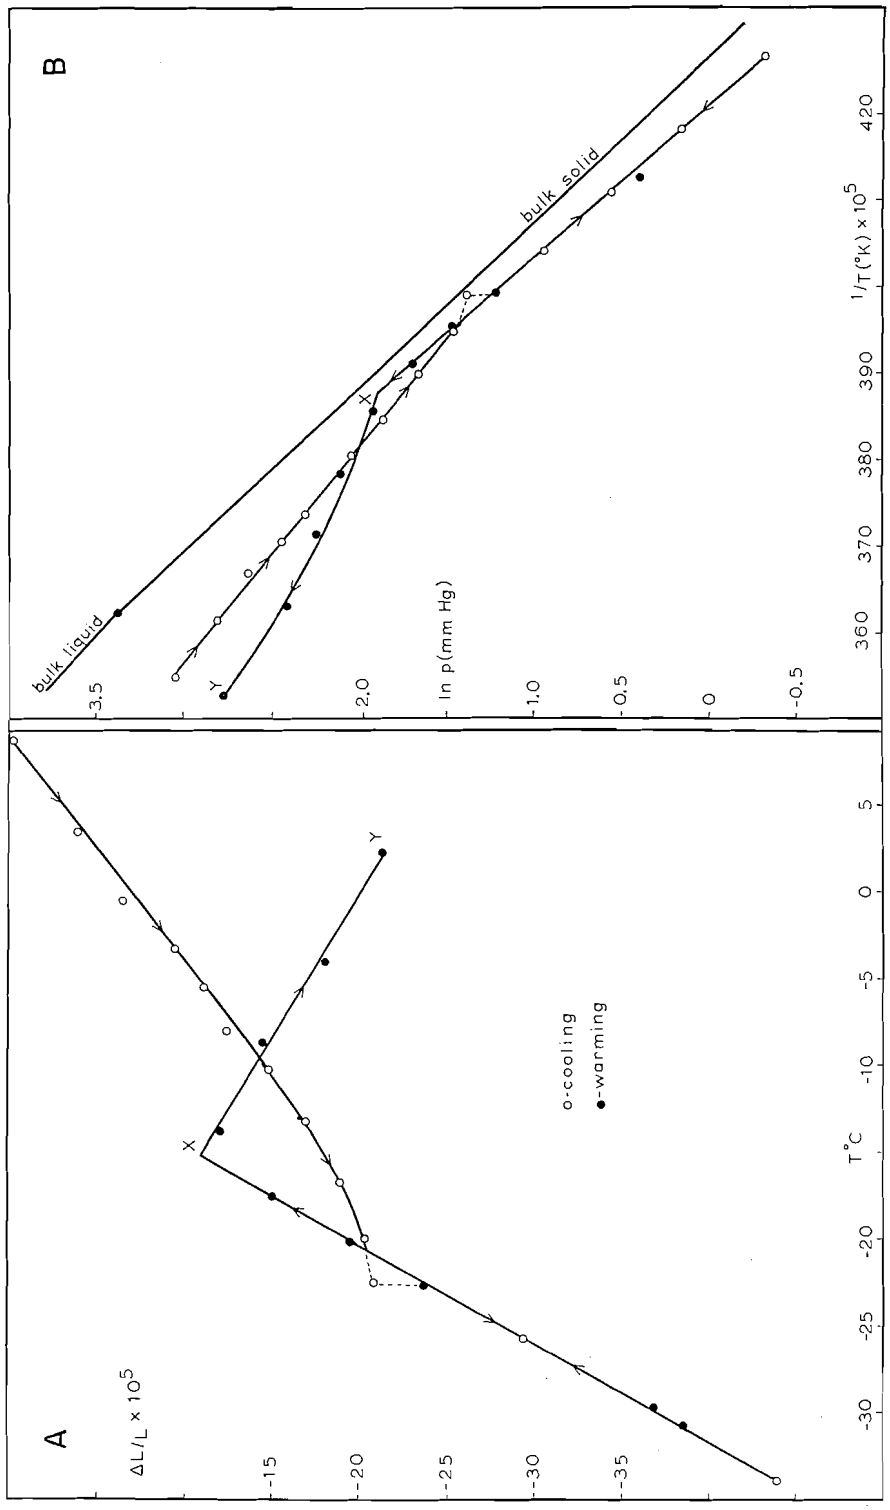
FIGS. 1A, 1B. Typical plots of length variation and equilibrium pressure as functions of temperature for the system water – Vycor glass. Amount of water adsorbed 0.175 g/g.

FIGS. 2A, 2B. Length variation and equilibrium pressure as functions of temperature for the system benzene – Vycor glass. Amount of benzene adsorbed 0.233 g/g.

TABLE I



The freezing and melting point depressions of benzene–Vycor systems

Benzene content, g/g	Depression of freezing point from pressure data	Depression of freezing point from length data
0.233	1.6° (f.p.)	1.6°
0.210	4.1 (f.p.)	4.1
0.179	11.5 (f.p.)	11.1
0.170	25.6 (f.p.)	27.3 (f.p.)
	19.4 (m.p.)	19.1 (m.p.)
0.162	28.1 (f.p.)	28.2 (f.p.)
	20.4 (m.p.)	20.8 (m.p.)

There are many points of difference between the behavior of benzene, as exhibited in these graphs, and of water, the behavior of which was depicted earlier. First, no sudden expansion occurs at the start of the transition, which fact therefore supports the view that the increase of the molar volume of the adsorbate rather than a meniscus effect is of primary importance in causing expansion. Second, the gradual transition of benzene is revealed by the persistence of the changed rate of contraction, rather than by the range of temperature over which an expansion occurs. Third, in the case of benzene, the length as a function of temperature does not show hysteresis below the temperature at which transition begins on the initial cooling. Fourth, the equilibrium pressure of benzene for a heating run follows the same curve as for a cooling run below the temperature at which the transition begins, and the rate of variation persists for some degrees above this temperature on heating. This persistence suggests that melting is incomplete,

FIGS. 4A, 4B. Length variation and equilibrium pressure as functions of temperature for the benzene – Vycor glass system. Amount of benzene adsorbed 0.170 g/g.

and that heating and cooling would show a common reversible curve in this region. The separation of the curves at the point at which melting is complete is believed to be due to transfer of adsorbate in the gas phase, and consequent change in the curvature of the menisci. Fifth, the equilibrium pressure of the solid adsorbate is lower than for bulk benzene at the same temperature, whereas the (less reliable) data for water suggest a reversal of this at the lower temperatures.

There are, however, two important points of similarity in the behavior of water and benzene: (*a*) both adsorbates show a gradual transition to the solid form; (*b*) both adsorbates complete their melting processes at higher temperatures than those for the inception of freezing.

Finally, it should be stated that throughout the upper temperature range for many conditions using benzene, complicating effects existed due to the adsorption from the gas phase. For example, in cooling a system with 0.170 g/g of adsorbed benzene (see Fig. 4) an initial expansion occurred and this was followed by the normal type of contraction. Such complications emphasize the desirability of restricting the volume of the gaseous phase and maintaining isosteric conditions when possible.

3. Isotherms for Benzene

In Fig. 5 are shown isotherms of benzene and the concomitant length changes. Only one isotherm has been investigated fully, that at +9° C. It is similar in shape to those for water, ethyl chloride, ammonia, and butane on the same adsorbent (2, 3). The closure of the hysteresis loop occurs, however, at an appreciably lower pressure. The length variations are noteworthy for two observations: (*a*) a contraction below the initial length occurs; (*b*) the first approximately horizontal region of the length change versus weight adsorbed plot ceases to be horizontal as temperature is lowered. Observation (*a*) has not previously been made for Vycor systems although Haines and McIntosh (9) observed this for the charcoal–water system. Presumably it occurs because the contraction due to the concave menisci exceeds the spreading force in the adsorbed layers due to interaction with the solid.

In these graphs it is clearly shown that the relative pressure approaches a value of 1.0 asymptotically when p_s^0 is employed as the reference value for those temperatures below the normal freezing point of benzene. Because of the experimental arrangement, the pressure cannot exceed p_s^0. Nevertheless, it is suggestive of freezing of the benzene that the approach to this value is asymptotic. If, for example, the adsorbed phase consisted of a physical arrangement resembling bulk liquid, the equilibrium pressure should approach p_1^0 at the temperature of the isotherm as the amount adsorbed is increased. Experimentally it cannot approach more closely than the value p_s^0. In this event the experimental curve would tend to the ordinate at the value p_s^0 at a finite angle rather than asymptotically. But since the approach is asymptotic it is deduced that solid adsorbate has formed by a condition represented as point *B*. It is to be noted that the region *BC* begins at values of relative pressure progressively farther removed from the value 1.0 as the temperature is lowered.

A second observation which may support the view that freezing has occurred at the situation designated by point *B* is the following. Point *B* for isotherms above the bulk transition temperature has been interpreted as marking the condition that all pores are filled and menisci exist of the curvature appropriate to the relative pressure. Since it is known from the dimensional variation of the adsorbent alone that pore volume does not change appreciably with temperature, and since one would normally expect the

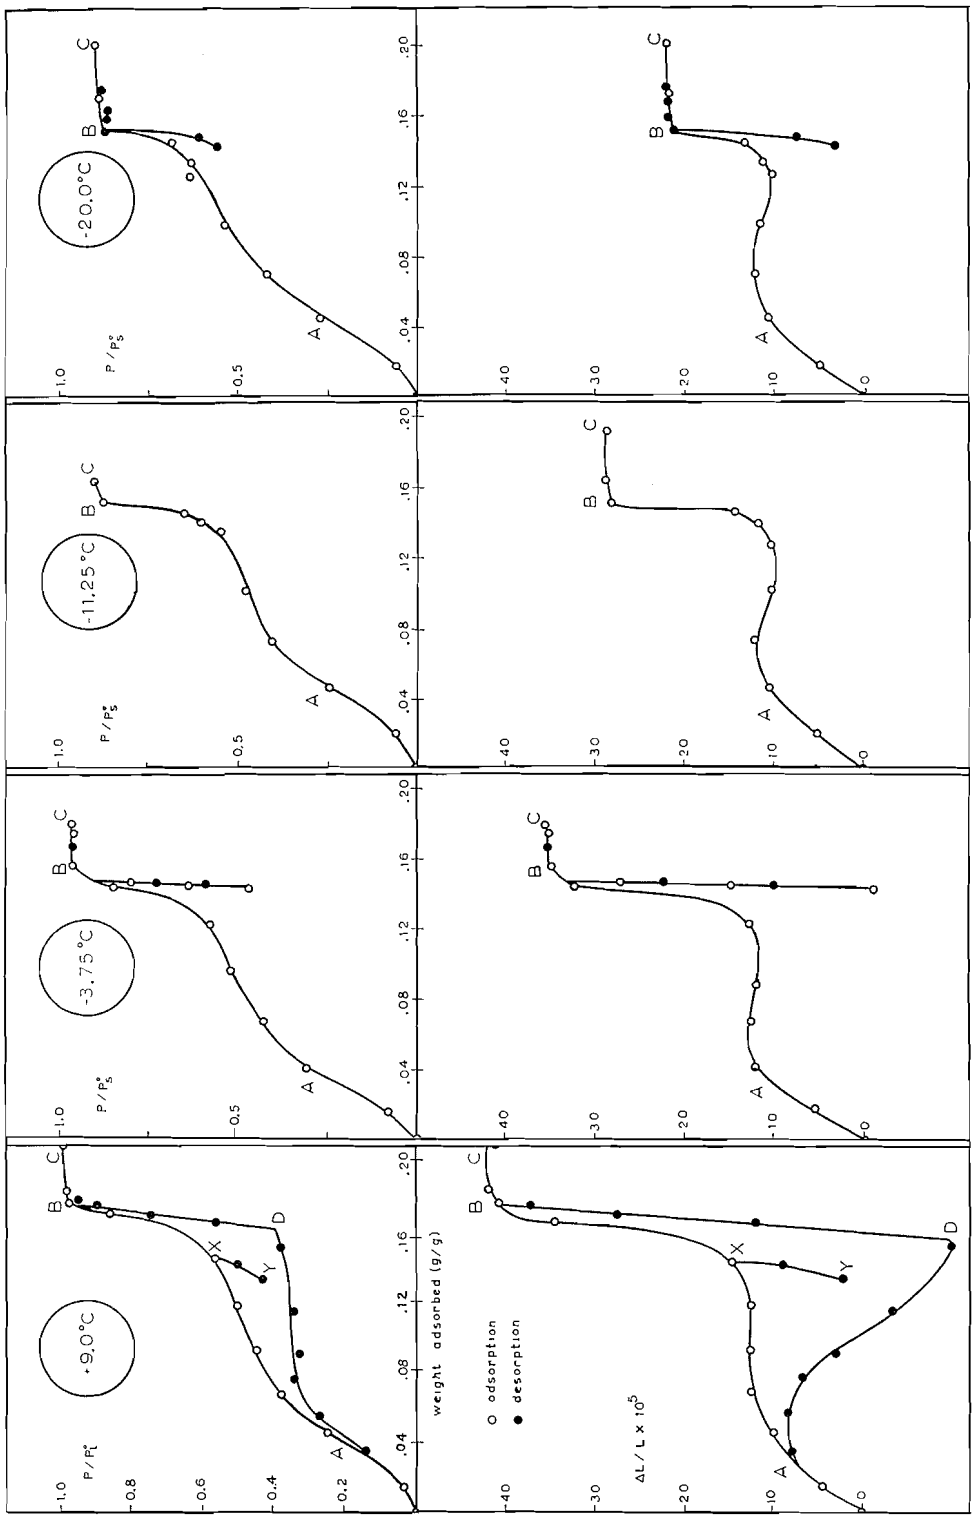

FIG. 5. Isotherms of benzene on Vycor glass at various temperatures.

density of the adsorbate to increase as temperature is reduced, one would expect the amount adsorbed at the condition of filled pores to increase with decreasing temperature. The experimental fact is the opposite of this. It is concluded, therefore, that point B has a different significance below the bulk transition temperature, namely, that solid has formed, and that this is the reason that hysteresis is not observed for adsorptions greater than point B. For temperatures above the transition temperature the filling of pores would end the region of hysteresis, but as argued above, the situation does not conform with expectation on this basis alone, and another cause for the reversible isotherm above point B is required. The best evidence that hysteresis is absent above point B is obtained from cooling and heating curves, such as those represented in Fig. 3A. Once solid phase has disappeared from the system, further increase of temperature brings about more desorption, and presumably because all menisci are now liquid, irreversible phenomena are observed (see region XY of Fig. 3A).

For the present it is sufficient to state that the behavior of the benzene–Vycor system at constant temperature is consistent with its behavior when temperature is changed. Further, it is noteworthy that even some 25 degrees below the normal triple point, hysteresis still persists in the isotherms. If the suggestion of the cause of hysteresis, namely the existence of liquid-like menisci and no solid present, is valid, then such conditions may persist to relatively low temperatures.

DISCUSSION

1. *Capillary Condensation Theory Applied to the Prediction of a Transition Temperature*

Most theoretical discussions are based upon the concept of condensed liquid in capillaries, with the liquid existing under concave menisci of the appropriate radius of curvature, and thus under negative hydrostatic pressure. On this basis the free energy per mole of the liquid adsorbate may be predicted as a function of temperature, and always lies below that for bulk liquid. If concave menisci exist for the solid adsorbate, a similar evaluation is possible provided that the surface free energy of the solid vapor interface is known. Stated first in terms of relative pressures of the solid and liquid adsorbates, the relation becomes

$$RT' \ln \frac{p_l^0 p_s}{p_s^0 p_l} = \frac{(T'-T_t)\overline{\Delta H}_{l,s}}{T_t} - T' \int_{T_t}^{T'} \frac{\Delta C}{T}\, dT + \int_{T_t}^{T'} \Delta C\, dT$$

where T' is the temperature of the transition; p_l^0, p_s^0 refer to the vapor pressures over bulk phases; p_s and p_l over the adsorbate; T_t the normal freezing point of bulk; $\overline{\Delta H}_{l,s}$ the molar heat of fusion for the bulk phases; and ΔC is the difference of specific heats of the solid and liquid bulk materials. The two integrals are normally ignored, and the relative pressures of the left-hand side calculated by employment of the Kelvin equation in the form $RT \ln p^0/p = 2\sigma \bar{V}/r$ for the appropriate interface, so that one obtains $\Delta T = 2T_t(\sigma_{lv}\bar{V}_l - \sigma_{sv}\bar{V}_s)/r\Delta H_{ls}$, where $\Delta T = T_t - T'$. Some authors, e.g. Puri, Myer, and Singh (4), assume that $p_s/p_s^0 = 1.0$ although from their published graph this situation is not exhibited, in agreement with our data for benzene shown earlier. Had Puri, Myer, and Singh actually employed the equilibrium pressure data for the solid adsorbate, agreement between theory and experiment would not have been good. However, they used the Kelvin relation and data obtained well above the transition range and extrapolated to obtain the value of p_l/p_l^0 at the initial temperature of the transition, a procedure which results in too high values and reduces the predicted value of ΔT and brings it into closer agreement with experiment (10).

If freezing is, indeed, a process occurring over a range of temperature, this is a fact which is in disagreement with the use of the Kelvin concepts. At a given relative pressure, all menisci must have the same value of the radius of curvature, and a sharp transition should be observed. Appeal to equilibrium pressure data might appear to support a sharp transition, as a sudden change in the slope of pressure–temperature curves is found. In itself, however, this means nothing, since the situation is akin to the freezing of a macroscopic two-component system. Deposition of solid will begin at some temperature dependent upon the composition, and more solid will be deposited as the temperature is lowered. Over this range of temperature the equilibrium partial pressure of the component which has formed the solid phase must be identical with that of the solid. Similarly, if a solid adsorbate phase forms, since equality of chemical potential must exist for the two phases, the equilibrium pressure as a function of temperature must be that for the solid phase.

This realization is useful in connection with other observations. It was noted earlier that no hysteresis is observed for vapor pressure data until melting is complete. Evidence was also presented which showed that for temperatures, and over ranges of pressure, where there appears to be solid benzene, no hysteresis loop is discerned in the isotherms. If one presumes, therefore, that adsorbed solid benzene does not form menisci, and if meniscus effects are the basic cause of hysteresis, none will be observed when solid benzene is present. This argument should be of general application to all adsorbates.

One concludes, therefore, that appeal to capillary condensation theory will not suffice to explain observation. The points of disagreement are (*a*) the freezing of both water and benzene occurs over a range of temperature; (*b*) the inception of freezing for benzene is a function of amount adsorbed, but that for water is not; (*c*) hysteresis between cooling and heating curves is observed for both adsorbates.

2. Prediction of the Freezing Point by the Theory of Liquid-like Layers due to Frenkel (11), Halsey (12), and Hill (13)

As pointed out by Hill (14), one of the major criticisms which may be levelled at the B.E.T. multilayer theory is the fact that ϕ, the spreading force of the film, does not remain finite for the infinite adsorption permitted at $p/p^0 = 1.0$. The thick layer theory, giving an isotherm of the form $\ln p/p^0 = -a/\Gamma^3$ does not suffer from this disadvantage, and moreover agrees quite well with experimental isotherms on certain non-porous adsorbents in the region of high relative pressure. Due to the model upon which the theory is based, it is possible to calculate explicitly values of $\ln p/p^0$ for both liquid- and solid-adsorbed layers. In the case of the systems studied here, the form of the isotherm does not agree with experiment, and it is not very meaningful to attempt its use. This fact also forbids the evaluation of "a" from the experimental isotherm and therefore the empirical determination of the parameters e_1, r_1, e, and r^* in the equation

$$a = \frac{\pi\rho^3}{6kT}(\rho_1 e_1 r_1^6 - \rho e r^{*6}).$$

Here ρ and ρ_1 are the densities of the adsorbate and adsorbent in molecules per cubic centimeter, e and e_1 the depths of the potential wells for the pure liquid and the liquid–adsorbent interaction, and r_1 and r^* the distances of closest approach of the liquid–adsorbent and bulk liquid molecules, respectively. Estimates of these parameters were therefore made. From the value of the heat of adsorption of water at zero coverage obtained from the data of Amberg and McIntosh (3), a value of 20,000 cal mole^{-1} was

obtained. Assuming a value of r_1 of 1 Å, it was possible to obtain $\rho_1 e_1 r_1^6$ from the equation

$$\frac{q_0 - RT}{N} = -\frac{\pi \rho_1 e_1 r_1^3}{6}$$

which gives the interaction energy between the liquid layer and the underlying adsorbent. Similarly $\rho e r^6$ was evaluated from the equation

$$\frac{\lambda - RT}{N} = -\frac{2}{3}\frac{\pi \rho e r^{*3}}{}.$$

The bulk density was assigned to the adsorbed water, and a cubic packing arrangement in evaluating r^*. Similar calculations were made for ice using parameters for bulk ice where that is appropriate and assuming that $\rho_1 e_1 r_1^6$ remains the same for adsorbate in the temperature range where bulk solid would be stable. By evaluating $\mu_{ads} - \mu_{bulk\ liq}$ at +20 and +10° C, and $\mu_{ads} - \mu_{bulk\ sol}$ for −10 and −20° C, a freezing point lowering of about 1.5° was predicted for an adsorbate content of 0.20 g/g of water. This procedure cannot be accurate since the expression was found to be very sensitive to values of r_1, but would be more useful if "a" could be obtained from experimental data. Our object here has been to show that the theory does not predict a depression of transition temperature of the magnitude found, and to suggest that transition temperatures, if known, may form another basis for testing the validity of an explicit adsorption theory.

3. Theory of Jackson and Chalmers

In dealing with the concave meniscus theory, interfaces between liquid and vapor or solid and vapor were considered to form. Jackson and Chalmers (15) have considered the conditions in a capillary pore in which liquid has a zero wetting angle with the wall and a stable interface of solid and liquid is presumed to form in the capillary pore. As the meniscus is concave to the liquid and convex to the solid, the liquid is under a negative pressure and the solid under a positive pressure. At some temperature these two phases may be in equilibrium, and this must be at a temperature below the normal transition temperature. The temperature of coexistence will vary with the radius of the tube and become less for smaller tubes, thus explaining a gradual transition. The quantitative relation for fluids of zero wetting angle (e.g. benzene and glass, Richards and Carver (16)) is approximately $\Delta T = -\sigma_{l,s} T_t / \overline{\Delta H}_{l,s} r$. It should be noted particularly that at the transition temperature, the molar free energy of liquid adsorbate is below that of the bulk liquid but that the molar free energy of solid is above that of bulk solid. Such would appear to be the case according to the supposed equilibrium pressure values for water in Fig. 1B, but is certainly not the case for benzene. That such a situation might obtain in impermeable soils or cements may be possible, but that it could obtain for equilibrium conditions in the porous Vycor glass system, where distillation into and out of the adsorbent is relatively easy, does not appear possible. Bulk solid would form on the walls by condensation from the vapor phase and transfer from adsorbent to the walls of the cell would proceed. The theory therefore does not seem applicable to the systems investigated and the apparent confirmation from the data for water could merely reflect the inaccuracy of the data.

Actually, this theory and the theory due to Powers (17) need not be dismissed, provided that equilibrium conditions do not exist in the systems under study. Before amplifying this statement the theory due to Powers will be briefly outlined.

4. Theory of Freezing due to Powers

In a porous material, such as cement, Powers assumes the existence of (*a*) large voids, (*b*) cavity spaces of narrower dimensions, and (*c*) a matrix of cement which is porous and thus permeable to water, but which is of very fine porosity and through which adsorbed water would diffuse as molecules. On lowering temperature water can freeze as bulk water in the large voids if these are present. At lower temperatures (because of the influence of the force field from the solid) nucleation may next occur in cavities. When nucleation occurs in these regions, there is expansion of adsorbate in a confined space and large hydrostatic stresses are established. Water will then begin to diffuse from regions where its chemical potential is greater than that of bulk solid at that temperature to the regions where bulk solid may exist. After appreciable freezing has occurred and some period of time has elapsed, the location of the adsorbed water throughout the mass will have altered. If, during this period of time, a measurement of pressure of the water vapor could be made, the pressure would presumably be greater than that of bulk ice at the same temperature. It should be noted that this theory, in common with that given by Jackson and Chalmers (15), predicts this situation which is anomalous if equilibrium conditions are assumed. It should also be recalled that this situation is observed for water if the pressure data are accurate. As pressure data within this same temperature range were obtained for lower water contents which were below the value at which freezing was observed, and these data did not reveal values greater than those for bulk solid, there is some reason to suppose that these data are meaningful. In conjunction with this observation, the form of the warming curve for water should be recalled, which reveals that the melting range persists to higher temperatures than the inception of freezing. On Powers' theory this can be explained by some of the water having migrated to regions where stress was less and freezing point higher. In fact, as already pointed out, distillation could occur to the wall of the cell where bulk solid would be formed and the water content of the rod thus be diminished. In this event the rod should be shorter (see Fig. 1A) than when cooling was begun, unless sufficient time is allowed for the system to return to its original state. It is possible that the system might not be restored in any event, since the presence of a hysteresis loop in the isotherm implies that the previous history of the starting system may have to be repeated.

In the case of benzene, as contraction rather than expansion is to be expected when adsorbed solid forms, large hydrostatic stresses are presumably not established. Thus the condition for equilibrium pressure greater than that for the bulk solid would not obtain. It could arise from the mechanism visualized in the Jackson and Chalmers' theory, but according to experimental observation, it does not occur. The data for water thus support Powers' theory while the data for benzene contradict the Jackson and Chalmers theory.

Two important facts remain unexplained. Melting of benzene is not complete until temperatures are reached which are higher than those at which freezing began. No explanation of this superheating has become evident, nor would the rate of cooling employed in the experiments suggest any marked departure from equilibrium conditions.

The second observation is that the initial freezing temperature for water is independent of the water content of the adsorbent over the range investigated. Until these observations are accounted for, any understanding of the transition phenomena must be considered as very incomplete.

APPENDIX

As shown in Fig. 6, the apparent temperature coefficient for the water–Vycor system diminishes in a regular way with increasing water content up to water contents at

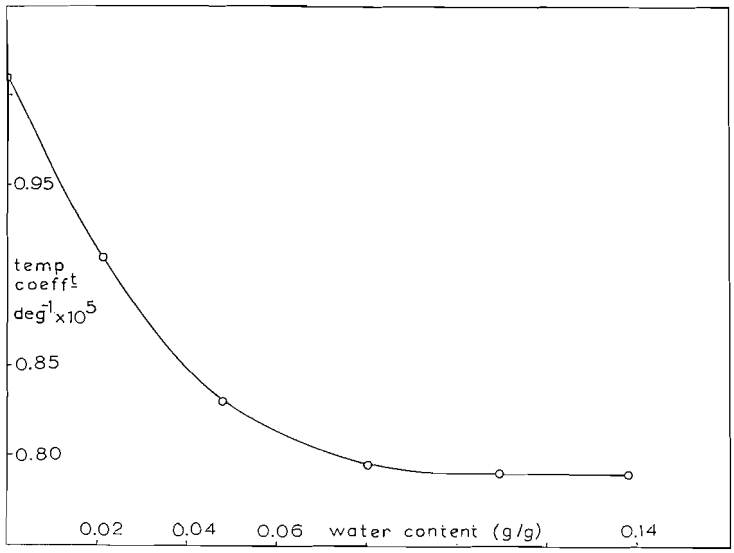

FIG. 6. The temperature coefficient of Vycor glass as a function of initial water content.

which complications due to freezing or adsorption from the vapor phase prevent further observation. The same fact has been established in the case of benzene. A straightforward analysis of the situation has been given by Hermans (18) and is set out below.

As the reasonable assumption of isotropic structure of the rod may be made, a length change may be interpreted as directly proportional to a volume change. The experimental fact is, therefore, that

$$\frac{\partial}{\partial n_T}\left(\frac{\partial V}{\partial T}\right)_{ex} < 0.$$

The subscript "ex" signifies experimental conditions. As pressure varies little in the experiments, the result is for constant hydrostatic pressure, and this restriction is to be understood throughout. Since, however, condensation from the gas phase may be important, it should be emphasized that n, the quantity of adsorbate is not constant.

The treatment assumes, in addition to the assumption that the properties are single-valued in n and T, that the sign of the volume changes, resulting from variations of adsorbate content and temperature, is revealed by the experimental measurements. The true magnitudes are doubtful because of the fact that the actual volume of the solid–adsorbate system is never measured for the porous system.

We have

$$\left(\frac{\partial V}{\partial T}\right)_{ex} = \left(\frac{\partial V}{\partial T}\right)_{n} + \left(\frac{\partial V}{\partial n}\right)_{T}\left(\frac{\partial n}{\partial T}\right)_{ex}$$

$$0 > \frac{\partial}{\partial n_T}\left(\frac{\partial V}{\partial T}\right)_{ex} = \left(\frac{\partial \bar{V}}{\partial T}\right)_{n} + \left(\frac{\partial \bar{V}}{\partial n}\right)_{T}\left(\frac{\partial n}{\partial T}\right)_{ex} + \bar{V}\frac{\partial}{\partial n_T}\left(\frac{\partial n}{\partial T}\right)_{ex}$$

where $\bar{V}$ is the partial molal volume of adsorbate. Of the terms on the right-hand side of the equation $(\partial \bar{V}/\partial T)_n$ is positive, and $(\partial \bar{V}/\partial n)_T$ is negative because the length plotted against n is concave towards the n axis in the appropriate range of n. Obviously $(\partial n/\partial T)_{ex}$ is negative. It follows that $\bar{V}(\partial/\partial n_T)(\partial n/\partial T)_{ex}$ must be negative. This conclusion has been confirmed by means of the data from three runs, and at 0° C $(\partial/\partial n_T)(\partial n/\partial T)_{ex}$ has a value of -6×10^{-4} deg^{-1} for water. Qualitatively the finding merely states that the effect of temperature on the population of a surface is greater if the surface concentration is high than if it is low. Thus the experimental observation is simply explained.

STEROIDS

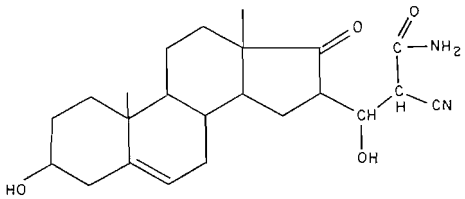
PART I. THE SYNTHESIS OF SOME HETEROCYCLIC STEROID DERIVATIVES[1]

BARBARA G. KETCHESON[2] AND ALFRED TAURINS

ABSTRACT

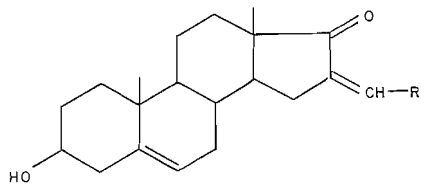
Cyanoacetamide reacted with 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one to form 1-cyano-2-hydroxy-2(16′-3′β-hydroxy-17′-oxo-5′-androstenyl) propionamide or 3-cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone depending on whether a catalytic or a molecular amount of piperidine was used as the basic condensing agent. Carboxamidoacetamidine, and acetamidine hydrochlorides, were condensed with the sodium salt of 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one, and 3β-chloro-16-chloromethylene-5-androsten-17-one yielding 2-amino-3-carboxamido-5,6(16′,17′-3′β-hydroxy-5′-androstenyl) pyridine and 2-methyl-5,6(16′,17′-3′β-chloro-5′-androstenyl) pyrimidine respectively.

DISCUSSION



The elucidation of the structure of a number of steroidal alkaloids (1), combined with their well-established physiological activity, has stimulated efforts to synthesize a variety of nitrogen-containing steroids. In many instances, the synthetic products have not displayed the anticipated physiological properties, but in several cases, the nitrogen derivatives of steroids have exhibited pharmacological properties of the same type and order of magnitude as some of the steroidal alkaloids (2, 3, 4).

With this in mind, the present investigation, concerned with the attachment of six-membered nitrogen-containing rings to the 16,17-positions of the steroid nucleus, was undertaken. As a first approach to the problem, the piperidine-catalyzed Knoevenagel condensation of 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one (I) (5) with cyanoacetamide was considered. In the cyclopentane (6), cyclohexane (7), and tetrahydrophenanthrene (8) series, the reaction of hydroxymethylene ketones with cyanoacetamide had given rise to pyridine, quinoline, and azachrysene derivatives respectively.



In the preliminary attempt to accomplish the condensation, cyanoacetamide and I were allowed to stand in ethanolic solution in the presence of a catalytic amount of piperidine for 8 days at 40°. Only starting materials were obtained under these conditions. However, when an identical reaction mixture was heated at the reflux temperature for 2 days, two products were obtained. The major product proved to be the aldol addition product 1-cyano-2-hydroxy-2(16′-3′β-hydroxy-17′-oxo-5′-androstenyl) propionamide (II). On heating II with a 10% potassium hydroxide solution in methanol, ammonia was given off. The infrared spectrum of the alkaline hydrolysis product confirmed the presence of a carboxylic group in the molecule. The isolation of II from the reaction was surprising, since generally in the Knoevenagel condensation of cyanoacetamide with hydroxymethylene ketones, the initially formed aldol addition products readily lose a molecule of water, and ring closure to dehydropiperidone structure occurs (9, 10, 11). However, instances have been reported (12, 13) in which the aldol addition products analogous to II have been isolated.

The second product obtained from the reaction was a condensation product of piperidine and I and, in agreement with the well-established reactivity of hydroxymethylene ketones with secondary amines, was formulated as 3β-hydroxy-16-piperidinomethylene-5-androsten-17-one (III*a*). An identical product was obtained quantitatively by refluxing an ethanolic solution of the hydroxymethylene ketone (I) and piperidine for several hours. On warming III*a* with aqueous acetic acid, 3β-acetoxy-5-androsten-17-one was obtained. The formation of the piperidinomethylene ketone (III*a*) during the reaction of cyanoacetamide and 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one (I) was unexpected, and no previous instance of the formation of an analogous piperidinomethylene derivative from the corresponding hydroxymethylene compound during a Knoevenagel

reaction could be found. However, Dev (14) had reported that when the Knoevenagel condensation of ethyl cyanoacetate with ethyl 2(2′-1′-oxo-cyclopentano)-*n*-butyrate was carried out using ammonium acetate or benzylamine as catalysts, condensation of the catalyst with the keto-ester occurred.

Subsequently it was found that morpholine, diethylamine, methylamine, and aniline also condensed readily with the hydroxymethylene ketone (I) to form the corresponding aminomethylene ketones (III$_{b-e}$) in high yields.

In a later attempt to effect the condensation of cyanoacetamide with I, an ethanolic solution of the reactants was refluxed in the presence of an equimolecular amount of piperidine for 3 days. Two products were isolated. They were identified as 3β-hydroxy-16-piperidinomethylene-5-androsten-17-one (III*a*), and 3-cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone (IV). As expected, treatment of IV with excess acetic anhydride in pyridine at room temperature led to the elimination of a molecule of water and formation of a monoacetate, 3-cyano-5,6(16′,17′-3′β-acetoxy-5′-androstenyl)-2-pyridone (V).

It appeared, from a consideration of the experimental results obtained, that this Knoevenagel reaction proceeded by different paths depending on whether a catalytic or molecular proportion of piperidine was used as the condensing agent. The formation of the piperidinomethylene ketone (III*a*) in the reactions indicated that two simultaneously proceeding reactions were occurring, or that III*a* was being formed as an intermediate product. To investigate the latter possibility, an ethanolic solution of III*a* and cyanoacetamide was refluxed for 3 days. A 20% yield of the dehydropiperidone (IV) was obtained. This result provided evidence that when the condensation of the hydroxymethylene ketone (I) and cyanoacetamide was carried out in the presence of a molecular proportion of piperidine, reaction proceeded via the formation of the stable intermediate 3β-hydroxy-16-piperidinomethylene-5-androsten-17-one (III*a*). When the reaction was performed using a catalytic amount of piperidine, apparently two separate processes occurred with the formation of the aldol addition product (II) and the piperidinomethylene compound (III*a*).

To account for the reaction occurring in the presence of a molecular amount of piperidine a mechanism is proposed in Fig. 1.

Initially there is a nucleophilic attack by the piperidine at the hydroxymethylene carbon atom. The addition product thus formed loses a molecule of water and the piperidinomethylene compound is produced. Then the carbanion of cyanoacetamide attacks at the piperidinomethylene atom forming an addition product from which the piperidine moiety is expelled. Ring closure to the dehydropiperidone structure is the final step.

Other investigators had found that the Michael reaction of cyanoacetamide and hydroxymethylene ketones led to the production of condensation products identical with those obtained by the Knoevenagel procedure (7, 9). However, when attempts were made to condense cyanoacetamide with the hydroxymethylene ketone (I) using sodium ethylate as the basic condensing agent, the product isolated was 3β-hydroxy-5-androsten-17-one (VI). On one occasion, a very small quantity of a substance whose infrared spectrum was identical with that of the aldol addition product (II) was obtained. The formation of VI in this reaction was believed to occur by a base-catalyzed reverse aldol reaction which brought about the loss of an anion from the initial aldol addition product of cyanoacetamide and I.

As another approach to accomplishing the synthesis of steroids with a nitrogen-containing ring attached to the 16,17-positions of the molecule, an effort was made to condense carboxamidoacetamidine hydrochloride (15, 16) with the sodium salt of 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one (I). Dornow and Neuse (17, 18) had reported that condensation of certain hydroxymethylene ketones with carboxamidoacetamidine hydrochloride resulted in the formation of nicotinamide derivatives. In the present case, two products were obtained. One of these had a molecular formula $C_{23}H_{31}O_2N_3$, and was formulated as 2-amino-3-carboxamido-5,6(16′,17′-3′β-hydroxy-5′-androstenyl) pyridine (VII). The infrared absorption spectrum affirmed the presence of

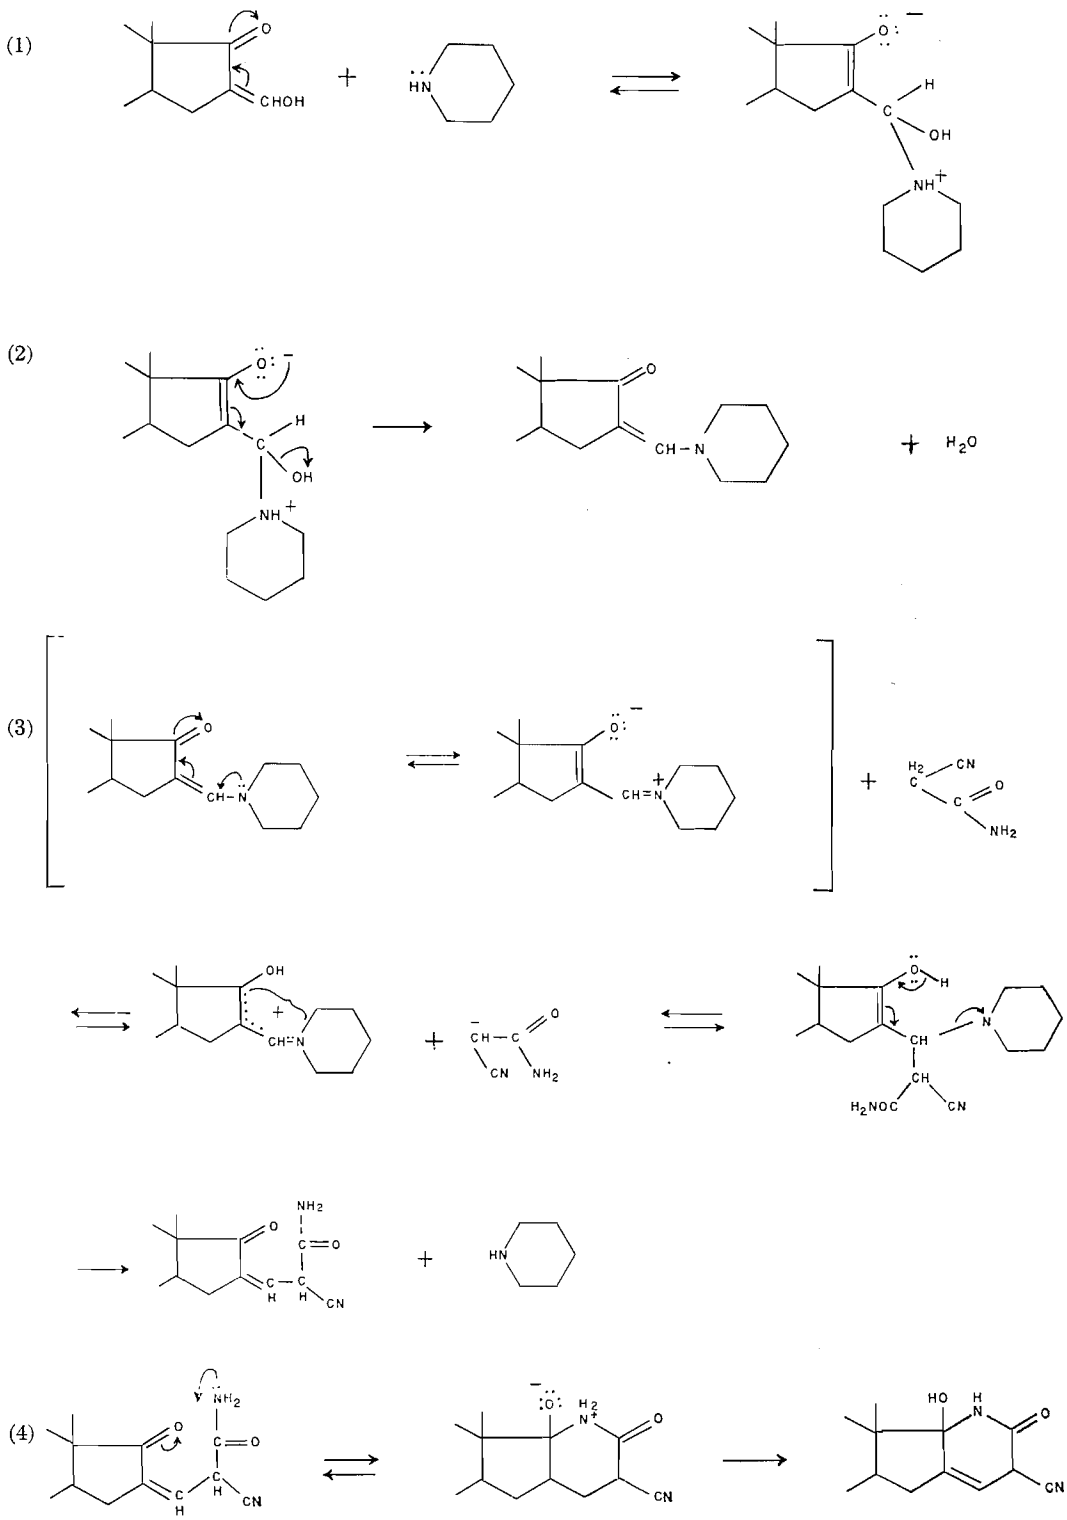

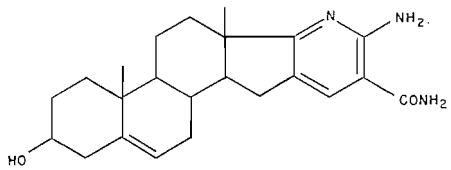

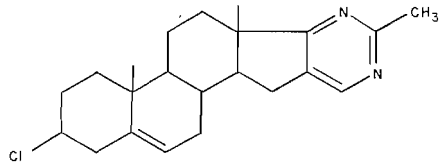

FIG. 1

a primary amide group, a primary amine function, and a pyridine ring in the molecule. The second product proved to be identical with the hydroxy ketone (VI). A reverse aldol condensation was considered responsible for the formation of VI in the reaction.

In another endeavor to achieve the synthesis of heterocyclic steroids, an attempt was made to attach a pyrimidine ring to the 16-, 17-positions of the nucleus. Since in the tetrahydrophenanthrene series, acetamidine hydrochloride had condensed with a chloromethylene ketone to form a pyrimidine derivative (8), the hydroxymethylene ketone (I) was converted to 3β-chloro-16-chloromethylene-5-androsten-17-one (VIII) by means of thionyl chloride, and allowed to react with acetamidine hydrochloride in absolute ethanol in the presence of sodium. The only product which could be isolated from the reaction mixture, melted at 145–148°, had the formula $C_{22}H_{29}ClN_2$, and in the infrared displayed absorption bands characteristic of a pyrimidine ring, and of the C—Cl stretching frequency. The product was formulated as 2-methyl-5,6(16′,17′-3′β-chloro-5′-androstenyl) pyrimidine (IX).

(VII)

(IX)

The investigation of these and related compounds is continuing, and it is hoped that a report on their physiological activity can be issued shortly.

EXPERIMENTAL

The analyses were carried out in the W. Manser Laboratory, Zurich, Switzerland. Infrared spectra were determined in potassium bromide, unless otherwise stated, on a Perkin–Elmer Model 21 double-beam instrument equipped with a sodium chloride prism.

Reaction of Cyanoacetamide with 3β-Hydroxy-16-hydroxymethylene-5-androsten-17-one (I) *in the Presence of a Catalytic Amount of Piperidine*

A mixture of I (2.0 g) and cyanoacetamide (680 mg) in ethanol (70 ml) was refluxed in the presence of piperidine (0.1 ml) for 2 days. A yellow solid material (930 mg) which was formed during the reaction was filtered and dried. Recrystallization from dimethylformamide–water provided 1-cyano-2-hydroxy-2(16′-3′β-hydroxy-17′-oxo-5′-androstenyl) propionamide (II), m.p. 221–223°. ν_{max}^{Nujol} 3420, 3330 (sh), 3220, 1718, 1700, 1665, 1648 (sh), 1623, 1040 cm^{-1}. Anal. Calc. for $C_{23}H_{32}O_4N_2.H_2O$: C, 66.01; H, 8.19; N, 6.70. Found: C, 66.28; H, 8.04; N, 6.67%.

The filtrate was concentrated and chromatographed on alumina (80–200 mesh). Elution with methanol–ether (1:9) yielded a crystalline product (320 mg) which, after recrystallization from dimethylformamide–water, afforded 3β-hydroxy-16-piperidino-

methylene-5-androsten-17-one (III*a*), m.p. 218–224°. ν_{max} 3360, 1683, 1580 cm^{-1}. Anal. Calc. for $C_{25}H_{37}O_2N$: C, 78.25; H, 9.72; N, 3.65. Found: C, 78.12; H, 9.69; N, 3.67%. Acetyl derivative, m.p. 221–222° (from methanol). ν_{max} 1735, 1685, 1585, 1250, 1030 cm^{-1}. Anal. Calc. for $C_{27}H_{39}O_3N$: C, 76.19; H, 9.24; N, 3.29. Found: C, 76.15; H, 9.28; N, 3.26%.

Condensation of Amines with 3β-Hydroxy-16-hydroxymethylene-5-androsten-17-one (I)

A solution of I (300 mg) and a slight excess of amine in ethanol was refluxed for several hours. Dilution with water precipitated the aminomethylene steroid. The solid product was isolated by filtration and purified (refer to Table I).

Reaction of Cyanoacetamide and 3β-Hydroxy-16-hydroxymethylene-5-androsten-17-one (I) *in the Presence of a Molecular Amount of Piperidine*

A mixture of I (2.0 g), cyanoacetamide (680 mg), and piperidine (0.6 ml) was refluxed in ethanol for 3 days. On cooling, crystalline material (300 mg) precipitated out of solution. Recrystallization of the material from acetic acid gave 3-cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone (IV), m.p. 348–352° (dec.). ν_{max} 3480, 3150, 3040 (sh), 2230, 1660, 1580 cm^{-1}. Anal. Calc. for $C_{23}H_{30}O_3N_2$: C, 72.22; H, 7.91; N, 7.32. Found: C, 72.79; H, 7.83; N, 7.26%.

The filtrate was concentrated and a solid material precipitated. The product (1.79 g), purified by recrystallization from dimethylformamide–water, was identified by its infrared absorption spectrum, and a mixed melting point determination with the authentic sample, as 3β-hydroxy-16-piperidinomethylene-5-androsten-17-one (III*a*).

3-Cyano-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-pyridone (V)

A solution of 3-cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone (IV) (100 mg) in pyridine – acetic anhydride (1:1, 10 ml) was allowed to stand overnight at room temperature. It was then poured into water (150 ml) and solid material (100 mg) settled. Recrystallization of the product from dioxane provided 3-cyano-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-pyridone (V), m.p. 351–353° (dec.). ν_{max} 2230, 1730, 1665, 1580, 1245 cm^{-1}. Anal. Calc. for $C_{25}H_{30}O_3N_2$: C, 73.87; H, 7.44; N, 6.90. Found: C, 73.90; H, 7.39; N, 6.79%.

3-Cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone (IV)

An ethanolic solution of 3β-hydroxy-16-piperidinomethylene-5-androsten-17-one (III*a*) (1.0 g) and cyanoacetamide (340 mg) was refluxed for 3 days. The crystalline material (200 mg) which formed on cooling was identified by its infrared spectrum, and by a mixed melting point determination with an authentic sample, as 3-cyano-4,5-dehydro-6-hydroxy-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)-2-piperidone (IV).

Attempted Condensation of 3β-Hydroxy-16-hydroxymethylene-5-androsten-17-one (I) *with Cyanoacetamide Using Sodium Ethylate as the Condensing Agent*

A solution of sodium (75 mg) in absolute ethanol (20 ml) was prepared in a nitrogen atmosphere. A slurry of I (300 mg) and cyanoacetamide (100 mg) in absolute ethanol (10 ml) was added, and the reaction mixture was refluxed for 17 hours in a nitrogen atmosphere. The solvent was evaporated under reduced pressure and the residue was chromatographed on alumina (80–200 mesh). Elution with petroleum ether (30–60°) afforded a product (160 mg) which was identified by its infrared absorption spectrum, and a mixed melting point determination with an authentic sample as 3β-hydroxy-5-androsten-17-one (VI). In one instance, a very small amount of a solid material, m.p.

TABLE I

Reaction of amines with 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one

No.	3β-Hydroxy-5-androsten-17-one	Reflux time (hours)	Method of purification	Yield %	Melting point	Empirical formula	Analyses						Infra-red ν_{max} in cm^{-1}
							Calculated (%)			Found (%)			
							C	H	N	C	H	N	
III*a*	16-Piperidino-methylene	22	Recrystn. from dimethylformamide–water	99	215–220°	$C_{25}H_{37}O_2N$	78.25	9.72	3.65	78.12	9.69	3.67	3360 1683 1580
III*b*	16-Morpholino-methylene	24	Recrystn. from acetone	91.6	239–242°	$C_{24}H_{35}O_3N$	74.77	9.15	3.63	74.85	9.14	3.68	3460 1680 1580
III*c*	16-Diethyl-aminomethylene	24	Recrystn. from acetone	90.8	167–169°	$C_{24}H_{37}O_2N$	77.58	10.03	3.77	77.49	10.13	3.76	3400 1678 1575
III*d*	16-Methylamino-methylene	48	Recrystn. from dimethylformamide–water	90.2	204–206°	$C_{21}H_{31}O_2N.H_2O$			4.03			4.10	3360 1680 1607–1525
III*e*	16-Anilinomethylene	48	Elution with benzene–petroleum ether (30–60°) (1:9) from alumina; recrystn. from methanol–water	90.5	127–129°	$C_{26}H_{33}O_2N$			3.58			3.56	3400 3320 3040 1692 1622 1602 1585 1500 1267 750 690

227–232°, was isolated from the reaction mixture. The infrared spectrum of this product coincided in all respects with that of 1-cyano-2-hydroxy-2(16′-3′β-hydroxy-17′-oxo-5′-androstenyl)propionamide (II).

Reaction of 3β-Hydroxy-16-hydroxymethylene-5-androsten-17-one, Sodium Salt, with Carboxamidoacetamidine Hydrochloride

A solution of the sodium salt of 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one (1.0 g) and carboxamidoacetamidine hydrochloride (420 mg) in absolute ethanol was refluxed in a nitrogen atmosphere for 17 hours. The solvent was evaporated under reduced pressure, and the residue was chromatographed on alumina (80–200 mesh). Elution with petroleum–ether (30–60°) provided crystalline material (170 mg), m.p. 142–144°. A mixed melting point determination with an authentic sample of 3β-hydroxy-5-androsten-17-one (VI) showed no depression. Further elution with methanol–ether (1:5) yielded another crystalline product (480 mg). Recrystallization of this material from methanol–benzene gave 2-amino-3-carboxamido-5,6(16′,17′-3′β-hydroxy-5′-androstenyl)pyridine (VII), m.p. 281–284° (dec.). ν_{max} 3400, 3330, 3200, 1650, 1615, 1597, 1538 cm^{-1}. Anal. Calc. for $C_{23}H_{31}O_2N_3$: C, 72.41; H, 8.19; N, 10.98. Found: C, 72.27; H, 8.35; N, 10.88%.

3β-Chloro-16-chloromethylene-5-androsten-17-one (VIII)

Thionyl chloride (3 ml) was added to 3β-hydroxy-16-hydroxymethylene-5-androsten-17-one (I) (1.0 g). A vigorous effervescence ensued, and the reaction mixture changed to a dark red liquid. The reaction was allowed to continue for 1 hour, then the liquid was poured into ice-cold 2 *N* sodium hydroxide solution (200 ml), and allowed to stand for 2 hours. The solid material (1.05 g), m.p. 199–207°, which formed, on recrystallization from benzene–methanol afforded 3β-chloro-16-chloromethylene-5-androsten-17-one (VIII), m.p. 204–210° (dec.). ν_{max} 1725, 1630, 890–666 cm^{-1}. Anal. Calc. for $C_{20}H_{26}OCl_2$: C, 67.98; H, 7.42. Found: C, 68.21; H, 7.47%.

2-Methyl-5,6(16′,17′-3′β-chloro-5′-androstenyl)pyrimidine (IX)

To a solution of sodium (235 mg) in absolute ethanol (50 ml) was added, in a nitrogen atmosphere, a slurry of 3β-chloro-16-chloromethylene-5-androsten-17-one (VIII) (1.0 g) and acetamidine hydrochloride (245 mg) in absolute ethanol (10 ml). The reaction mixture was refluxed for 1.5 hours, then was allowed to stand overnight at room temperature in a nitrogen atmosphere. The mixture was filtered, and the filtrate concentrated *in vacuo*. The residue was chromatographed on alumina (80–200 mesh). Elution with ether gave a crystalline product (200 mg). Recrystallization of the product from dioxane–water furnished 2-methyl-5,6(16′,17′-3′β-chloro-5′-androstenyl)pyrimidine (IX), m.p. 145–148°. ν_{max} 1598, 1560, 763 cm^{-1}. Anal. Calc. for $C_{22}H_{29}ClN_2$: C, 74.05; H, 8.19; N, 7.85. Found: C, 73.87; H, 8.08; N, 7.86.

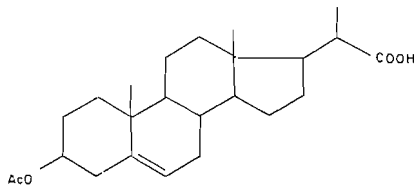
STEROIDS

PART II. 6-AMINO STEROIDS[1]

BARBARA G. KETCHESON[2] AND ALFRED TAURINS



ABSTRACT

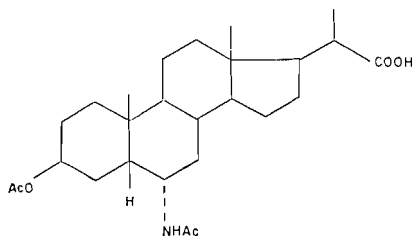
Reduction of methyl 3β-acetoxy-6-oximinodinorcholanate using sodium in *n*-propyl alcohol, and acetylation, gave 6α-acetamido-3β-acetoxydinorcholanic acid; treatment with lithium aluminum hydride in tetrahydrofuran provided 3β,22ξ-dihydroxydinorcholan-6-one. High-pressure hydrogenation of methyl 3β-acetoxy-6-nitro-5-dinorcholenate, using palladium black as catalyst in acetic acid medium, afforded methyl 6ξ-acetamido-3β-acetoxy-5α-dinorcholanate. Under identical conditions, catalytic hydrogenation of 3β-acetoxy-6-nitro-5-cholestene resulted in the formation of 6β-acetamido-3β-acetoxy-5α-cholestane and 6ξ-acetamido-3β-acetoxy-5β-cholestane.

DISCUSSION

A variety of amino steroids have been synthesized and tested for biological activity (1–10). In view of the fact that 6-aminocholestan-3β-ol (1), and several amino derivatives of 3β-acetoxy-5-dinorcholenic acid (5), had been found to possess appreciable antibacterial properties, the present investigation dealing with the preparation of 6-amino steroids of the dinorcholenic acid and cholestane series was undertaken.

When 3β-acetoxy-5-dinorcholenic acid (I) was nitrated by the procedure of Anagnostopoulos and Fieser (11), an oil was obtained which crystallized only after standing at room temperature for several weeks. However, conversion of I to its methyl ester (II) (12, 13), and treatment of the latter with fuming nitric acid resulted in the formation of

(I)



a crystalline nitration product. The product was formulated as methyl 3β-acetoxy-6-nitro-5-dinorcholenate (III), since it is well-established that nitration of a Δ^5-steroid leads to the production of the corresponding 6-nitro-Δ^5 compound (14).

When 6-nitro-Δ^5-steroids are treated with zinc dust and acetic acid, the corresponding saturated 6-oxosteroids are formed (14). However, when methyl 3β-acetoxy-6-oxodinorcholanate (IV) was prepared by this method, a very low yield was obtained. An alternative procedure was developed which involved refluxing a methanolic solution of the nitro compound (III) for several hours with iron filings in the presence of a small amount of hydrochloric acid. In this way, a 58% yield of IV was obtained.

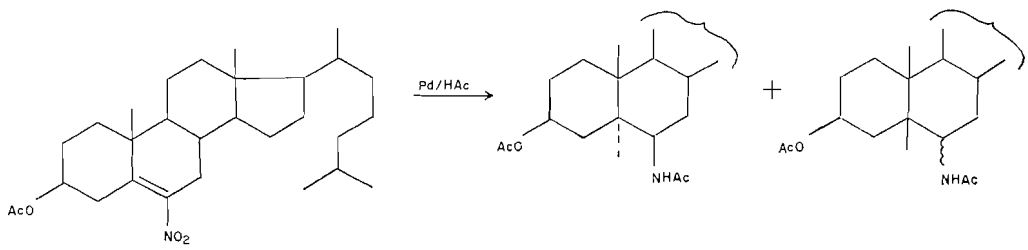
Contribution from the Department of Chemistry, McGill University, Montreal, Que., with financial assistance from the National Research Council, Ottawa, Canada. Abstracted from a portion of the thesis submitted by Barbara G. Ketcheson to the Department of Chemistry, McGill University, Montreal, Que., August 1958, in partial fulfilment of the requirements for the Ph.D. degree.
[2]*Holder of a National Research Council Studentship, 1956–57, and of Canadian Industries (1954) Limited Fellowships, 1955–56 and 1957–58.*

Methyl 3β-acetoxy-6-oximinodinorcholanate (V) was prepared, and reduced with sodium in *n*-propyl alcohol. Although Vanghelovici (15) had reported that similar reductions of the ethyl esters of 3,7,12-trihydroxycholanic, 3,12-dihydroxycholanic, and cholenic acids had brought about the transformation of the ester group to a primary alcoholic function, James *et al.* (2) had not observed the Bouveault–Blanc effect in the reduction of ethyl 3,12-dihydroxy-7-oximinocholanate. Since the 22 position of the steroid molecule is definitely hindered, sodium–alcohol treatment of V was not expected to bring about the reduction of the ester group. The infrared spectrum provided confirmatory evidence that the reduction product was in fact 6α-amino-3β-hydroxydinorcholanic acid (VI). Acetylation of VI with acetic anhydride – pyridine at room temperature provided 6α-acetamido-3β-acetoxydinorcholanic acid (VII). The α-configuration was assigned to the amino group on the basis of mode of preparation (16, 17).

The oxime (V) also was reduced by means of lithium aluminum hydride in tetrahydrofuran. A ratio of 1:10 of V to the reducing agent was used. From the reaction, a single product was isolated in 86% yield. It contained no nitrogen, and had a molecular formula $C_{22}H_{36}O_3$. In the infrared spectrum there was a strong broad band at 3300 cm^{-1}

(VII)



(VIII)

indicating the presence of an associated hydroxyl group or groups. A single narrow peak at 1712 cm^{-1} could be attributed to absorption by a 6-ketone of the normal series (18). The product was postulated as 3β,22ξ-dihydroxydinorcholan-6-one (VIII). In order to substantiate the formulation of VIII, the compound was acetylated, and the oxime derivative was prepared. The infrared spectrum of the oxime derivative demonstrated the presence of associated hydroxyl groups and an oxime group, but there was no indication of any carbonyl absorption. Analysis and the infrared spectrum were in agreement with the product of acetylation being 3β, 22ξ-diacetoxydinorcholan-6-one (IX). The formation of VIII by the lithium aluminum hydride reduction of the oximinoester (V) was unexpected. It was felt that the oxime group was converted to the ketone under the alkaline hydrolytic conditions of the reaction mixture when wet solvent was added to destroy the unreacted excess lithium aluminum hydride.

Catalytic hydrogenation of 3β-substituted-Δ^5-steroids is known to provide mainly saturated steroids of the A/B trans series. In some cases, the principal product may be accompanied by small quantities of saturated steroids of the A/B cis series (19).

3β-Acetoxy-6-nitro-5-cholestene (X) (11) was hydrogenated using palladium black as the catalyst in an acetic acid medium at 53 atmospheres pressure and 150° for 6 hours. Previously, X had been catalytically hydrogenated at 40 atmospheres pressure and a temperature of 100–180°, and a saturated amine $C_{29}H_{51}O_2N$, m.p. 122°, or its acetyl derivative had been obtained as the product (20). However, in the present investigation, two products were isolated, the main one in the form of dense rhombic crystals, and the

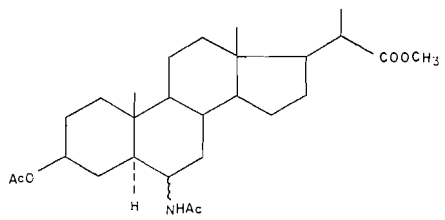
For personal use only.



(X) (XI) (XII)

other as slender needles. Both compounds had a molecular formula $C_{31}H_{53}O_3N$. The main product melted at 167°, and the other substance at 94–96°. The compounds were postulated as 6-acetamido-3β-acetoxycholestane (XI) and 6-acetamido-3β-acetoxy-5β-cholestane (XII). A comparison of the infrared spectra of XI and 6β-acetamido-3β-acetoxycholestane (16), m.p. 166–168°, revealed that the two were identical in all respects. A mixed melting point determination of these substances showed no depression. On the basis of mode of preparation, it would be expected that the acetamido group in XII would be β-oriented.

In connection with the preparation of 6β-aminocholestan-3β-ol (XIII) from 3β-acetoxy-6-oximinocholestane (XIV) by reduction using lithium aluminum hydride, it was noted that Shoppee *et al.* (16) encountered considerable difficulty with the analysis of the hydroxy amine XIII, m.p. 128–130° (methanol). He attributed the unsatisfactory analytical values obtained to the rapid absorption of water and (or) carbon dioxide. No yield of product was reported for the reaction. In the present case, the reduction was carried out in tetrahydrofuran rather than ether, and the product was isolated in a 57% yield. No difficulty was experienced in obtaining entirely satisfactory analytical results for 6β-aminocholestan-3β-ol (XIII), m.p. 129–132° (dimethylformamide–water).

It was thought that the main product resulting from the high-pressure hydrogenation of methyl 3β-acetoxy-6-nitro-5-dinorcholenate (III) would be methyl 6-acetamido-3β-acetoxy-5α-dinorcholanate (XV). The hydrogenation was carried out under the same conditions as had been used in the α series. A single substance was isolated from the

(XV)

reaction in a 67% yield. On the basis of its infrared spectrum and analysis, the product was designated as methyl 6ξ-acetamido-3β-acetoxy-5α-dinorcholanate (XV). No configuration was assigned to the acetamido group, although on the basis of mode of preparation it would be expected that the group would have the axial conformation and thus be β-oriented.

EXPERIMENTAL

The melting points were determined in a Thiele–Dennis melting point tube containing Dow Corning silicone fluid No. D.C. 550. All melting points are uncorrected. Microanalyses were carried out in the W. Manser Laboratory, Zurich, Switzerland, and in the Schwarzkopf microanalytical laboratory, Woodside, N.Y., U.S.A. The infrared absorption spectra were determined in potassium bromide by means of a Perkin–Elmer Model 21 double-beam spectrophotometer equipped with a sodium chloride prism.

Methyl 3β-Acetoxy-6-nitro-5-dinorcholenate (III)

A solution of methyl 3β-acetoxy-5-dinorcholenate (II) (25.0 g) in absolute ether (300 ml) was cooled to −20°. Fuming nitric acid (150 ml) was added, with stirring, at such a rate that the temperature did not rise above −10°. When the addition had been completed, the reaction mixture was stirred for 1½ hours, while the temperature slowly rose to 0–5°. The ethereal solution was neutralized by washing with a 2.5% sodium hydroxide solution (600 ml), and with a saturated solution of sodium chloride. The ether was removed *in vacuo* and a solid crystalline residue remained. After recrystallization from methanol, the material (22.9 g) melted at 145–147°. Further purification from methanol provided methyl 3β-acetoxy-6-nitro-5-dinorcholenate (III), m.p. 147–149°. ν_{max} 1735, 1527, 1240 cm^{-1}. Anal. Calc. for $C_{25}H_{37}O_6N$: C, 67.08; H, 8.33; N, 3.13. Found: C, 67.10; H, 8.31; N, 3.21%.

Methyl 3β-Acetoxy-6-oxodinorcholanate (IV)

To a mixture of iron filings (40 mesh, 20.0 g) and methyl 3β-acetoxy-6-nitro-5-dinorcholenate (III) (10.0 g) were added methanol (300 ml) and concentrated hydrochloric acid (3 ml). The reaction mixture was refluxed with stirring for 17 hours, then filtered hot. The residue on the filter was washed thoroughly with hot methanol. The methanolic filtrate and washings were concentrated and set aside for crystallization. The crystalline product (5.42 g) obtained melted at 160–162°. Purification by recrystallization from methanol afforded methyl 3β-acetoxy-6-oxodinorcholanate, m.p. 164.5–166.5°. ν_{max} 1745, 1730 (sh), 1718, 1280 (sh), 1263, 1248 cm^{-1}. Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.72; H, 9.50. Found: C, 71.78; H, 9.31%.

Methyl 3β-Acetoxy-6-oximinodinorcholanate (V)

An ethanolic solution of methyl 3β-acetoxy-6-oxodinorcholanate IV (0.4 g), sodium acetate (0.5 g), and hydroxylamine hydrochloride (0.4 g) was refluxed for 24 hours. Water was added to the solution until a slight permanent cloudiness was observed. On standing, crystalline material (0.34 g) was deposited and isolated. It melted at 202–205°. Recrystallization from ethanol provided methyl 3β-acetoxy-6-oximinodinorcholanate (V), m.p. 207–209°. ν_{max} 3300, 1735, 1720, 1655, 1245 cm^{-1}. Anal. Calc. for $C_{25}H_{39}O_5N$: C, 69.25; H, 9.06; N, 3.23. Found: C, 69.73; H, 9.02; N, 3.29%.

6α-Acetamido-3β-acetoxydinorcholanic Acid (VII)

In a nitrogen atmosphere, small pieces of sodium (2.0 g) were added over a period of 1½ hours to a solution of methyl 3β-acetoxy-6-oximinodinorcholanate (V) (500 mg) in dry *n*-propyl alcohol (35 ml) at 70°. When the sodium had been added, the solution was refluxed for 9 hours. Then it was poured into distilled water (500 ml), and allowed to stand at room temperature for several days. Solid material precipitated out of solution and was isolated. Recrystallization of the product afforded 6α-amino-3β-hydroxydinorcholanic acid (VI), m.p. 176–178°. ν_{max} 3420,1640, 1568 cm^{-1}.

A solution of VI (100 mg) in acetic anhydride (5 ml) and pyridine (5 ml) was allowed to stand at room temperature overnight. The solution was poured into water (200 ml). The solid material (90 mg) which formed on standing was isolated and melted at 161–165°. Recrystallization from ethanol–water gave 6α-acetamido-3β-acetoxydinorcholanic acid (VII), m.p. 158–159°. ν_{max} 3340, 1735, 1663, 1540, 1245 cm^{-1}. Anal. Calc. for $C_{26}H_{41}O_5N$: N, 2.86. Found: N, 2.75%.

3β,22ξ-Dihydroxydinorcholan-6-one (VIII)

In a nitrogen atmosphere was added, dropwise, and with stirring, a solution of methyl 3β-acetoxy-6-oximinodinorcholanate (V) (1.0 g) in dry tetrahydrofuran, to a refluxing suspension of lithium aluminum hydride (1.0 g) in anhydrous tetrahydrofuran (20 ml). The resulting reaction mixture was refluxed under these conditions for 18 hours. After cooling to room temperature, wet tetrahydrofuran was carefully added to the mixture with vigorous stirring. The suspension was filtered with suction, and the filter cake was washed thoroughly with ether. The filtrate was evaporated *in vacuo* leaving a solid product (690 mg). Recrystallization from dioxane–water yielded 3β,22ξ-dihydroxydinorcholan-6-one (VIII), m.p. 190–194°. ν_{max} 3300, 1712, 1062 cm^{-1}. Anal. Calc. for $C_{22}H_{36}O_3$: C, 75.80; H, 10.41. Found: C, 75.52; H, 10.39%.

3β,22ξ-Diacetoxydinorcholan-6-one (IX)

A solution of 3β,22ξ-dihydroxydinorcholan-6-one (VIII) (140 mg) in acetic anhydride (5 ml) and pyridine (5 ml) was allowed to stand at room temperature overnight. Then it was poured into water (200 ml). Solid material (90 mg) separated from solution was isolated, and on recrystallization from dimethylformamide–water gave 3β,22ξ-diacetoxydinorcholan-6-one (IX), m.p. 115–117°. ν_{max} 1737, 1255 cm^{-1}. Anal. Calc. for $C_{26}H_{40}O_5$: C, 72.19; H, 9.32. Found: C, 72.25; H, 9.25%.

High-pressure Hydrogenation of 3β-Acetoxy-6-nitro-5-cholestene (X)

A solution of X (2.0 g) in glacial acetic acid (30 ml) was hydrogenated in a Parr high-pressure hydrogenation apparatus for 6 hours at 150° and 53 atmospheres pressure using 10% palladium on charcoal (1.0 g) as catalyst. The reaction mixture was filtered, and the residue on the filter was washed thoroughly with acetic acid. The solvent was removed *in vacuo*, and the residue was taken up in ethanol. On standing, small rhombic crystals were formed. The product (1.15 g) was purified by recrystallization from dioxane–water yielding 6β-acetamido-3β-acetoxycholestane (XI), m.p. 167°. ν_{max} 3375, 3320, 1733, 1645, 1550, 1250 cm^{-1}. Anal. Calc. for $C_{31}H_{53}O_3N$: C, 76.33; H, 10.95; N, 2.87. Found: C, 76.33; H, 10.91; N, 2.85%.

On standing, crystalline material in the form of slender needles separated from the filtrate. This product (200 mg) melted at 80–84°. Recrystallization from methanol–water gave 6ξ-acetamido-3β-acetoxy-5β-cholestane (XII), m.p. 94–96°. ν_{max} 3380, 1737, 1655, 1243 cm^{-1}. Anal. Calc. for $C_{31}H_{53}O_3N$: C, 76.33; H, 10.95. Found: C, 76.59; H, 10.93%.

6β-Aminocholestan-3β-ol (XIII)

In a nitrogen atmosphere, and with stirring, a solution of 3β-acetoxy-6-oximinocholestane (XIV) (500 mg) in anhydrous tetrahydrofuran (25 ml) was added dropwise to a refluxing suspension of lithium aluminum hydride (500 mg) in dry tetrahydrofuran (20 ml). The reaction was allowed to continue under these conditions for 18 hours. Wet tetrahydrofuran was added dropwise with vigorous stirring, then the mixture was filtered, and the filter cake was washed thoroughly with wet tetrahydrofuran. The filtrate was concentrated under reduced pressure, and the solid material which precipitated out of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

solution was isolated. A yield of 250 mg of product melting at 123–129° was obtained. Further purification by recrystallization from dimethylformamide–water yielded 6β-aminocholestan-3β-ol (XIII), platelets, m.p. 129–132°. ν_{max} 3400 (sh), 3300 (sh), 3200, 1600 cm^{-1}. Anal. Calc. for $C_{27}H_{49}ON$: C, 80.33; H, 12.24; N, 3.47. Found: C, 80.21; H, 12.19; N, 3.44%.

6β-Acetamido-3β-acetoxycholestane (XI)

A solution of 6β-aminocholestan-3β-ol (XIII) (100 mg) in acetic anhydride (5 ml) and pyridine (5 ml) was allowed to stand overnight at room temperature. The reaction mixture was poured into water (150 ml), and the solid material (80 mg) which formed on standing was isolated. Recrystallization from ethyl acetate furnished 6β-acetamido-3β-acetoxycholestane (XI), m.p. 166–168°. ν_{max} 3375, 3320, 1733, 1645, 1550, 1250 cm^{-1}. Anal. Calc. for $C_{31}H_{53}O_3N$: N, 2.87. Found: N, 2.71%.

Methyl 6ξ-Acetamido-3β-acetoxy-5α-dinorcholanate (XV)

Methyl 3β-acetoxy-6-nitro-5-dinorcholenate (III) (2.0 g) in glacial acetic acid (30 ml) was hydrogenated in a Parr high-pressure hydrogenation apparatus using a 10% palladium on charcoal catalyst (1.0 g). The hydrogenation was carried out for 6 hours at 150° and 53 atmospheres pressure. The mixture was filtered, and the filter cake was washed thoroughly with acetic acid. The solvent was removed *in vacuo* and the residue taken up in ethanol. The ethanolic solution was heated to boiling and water was added until a faint cloudiness persisted. On cooling, a solid (1.41 g) separated from solution and was isolated. Recrystallization from benzene – petroleum ether (30–60°) yielded methyl 6ξ-acetamido-3β-acetoxy-5α-dinorcholanate (XV), m.p. 236–238° (dec.). ν_{max} 3290, 3070, 1737, 1655, 1558, 1242 cm^{-1}. Anal. Calc. for $C_{27}H_{43}O_5N$: N, 3.05. Found: N, 3.06%.

ACKNOWLEDGMENTS

The authors wish to thank Frank W. Horner Ltd. of Montreal for the use of their high-pressure hydrogenation equipment, and Dr. G. Frangatos for his valuable technical assistance.

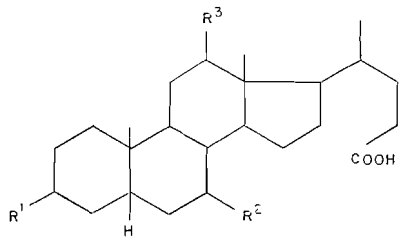
STEROIDS

PART III. REDUCTION OF OXIMINOCHOLANIC ACIDS[1]

TED H. WAID[2] AND ALFRED TAURINS

ABSTRACT

The reduction of 12-oximino-, 3,12-dioximino-, and 7,12-dioximino-cholanic acids using sodium in alcohol resulted in the formation of 12β-amino-, 3α,12β-diamino-, and 7β,12β-diamino-cholanic acids respectively. The reaction of 3,12-dioximinocholanic acid with lithium aluminum hydride provided cholane-3ξ,12ξ,24-triol, while similar treatment of 7,12-dioximinocholanic acid afforded 7ξ-amino-12-oximinocholan-24-ol.



DISCUSSION

Basic derivatives of bile acids and esters, having amino functions located in positions 3 (1, 2), 6 (3), 7 (2, 4, 5), 11 (6), and 12 (2, 5, 7) of the steroidal nucleus, have been described. Their synthesis has been accomplished for the most part by reduction of the corresponding oximes with sodium in alcohol, and has been prompted primarily by the possibility of such compounds being physiologically active.

In the present investigation, a study has been made of the reduction of 12-oximino- (I) (8), 3,12-dioximino- (II) (9), and 7,12-dioximino-cholanic acids (III) (10), using sodium in alcohol and lithium aluminum hydride. In the reductions using sodium, *n*-propyl and *n*-butyl alcohols gave the best yields of purest products. The color of reaction mixtures in isoamyl alcohol was darker, and the crude products contained appreciable amounts of tarry impurities. Since reductions of oximes with alkali metals and proton donors are known to give predominantly the equatorial conformation (11, 12), the conformation of amino groups in the steroidal amino acids synthesized by reductions with sodium in alcohol were assigned on the basis of mode of preparation. Preliminary experiments of oxime reductions using lithium aluminum hydride in tetrahydrofuran showed that two- to five-fold molar excesses of lithium aluminum hydride led to the formation of mixtures of products. When a 10-fold excess of the reagent was used, definite reaction products could be isolated in all cases.

12-Oximinocholanic acid (I) was prepared from 3α,12α-dihydroxycholanic acid (IV) by oxidation of IV to 3,12-dioxocholanic acid (V) (13), Clemmensen reduction of V to 12-oxocholanic acid (VI) (14, 15, 16), and preparation of the oxime (I). The oxidation of the dihydroxy acid (IV) to the dioxo derivative (V) was carried out using the procedure described by Heilbron (17) for the oxidation of acetylenic carbinols. This method gave consistent yields of over 90% of pure product as compared with the 70% yield obtained by Wieland's method (13) of oxidation in acetic acid. As expected, the reduction of the oximino acid (I) with sodium in alcohol provided 12β-aminocholanic acid (VII) in good yield. That VII existed as a dipole ion was confirmed by the infrared spectrum which showed bands characteristic of the carboxylate ion at 1550 cm^{-1} and of the NH_3^+ group at 1625 cm^{-1}. Several treatments of VII with concentrated hydrochloric acid resulted in the formation of the corresponding hydrochloride. The infrared spectrum of the latter showed suppression of the band due to the carboxylate ion and release of the carboxyl

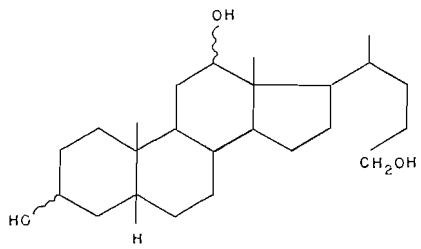
(VII) $R^1 = R^2 = H$; $R^3 = NH_2$

(VIII) $R^2 = H$; $R^1 = R^3 = NH_2$

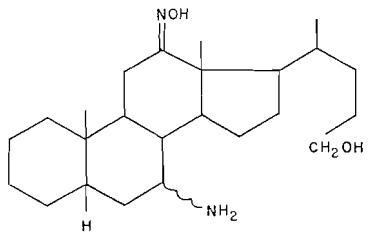
(XII) $R^1 = H$; $R^2 = R^3 = NH_2$

band at 1705 cm^{-1}. Treatment of the oximino acid (I) with 3% sodium amalgam resulted in the transformation of the oxime group to the keto group. The keto acid (VI) was identified by a mixed melting point determination with an authentic sample.



3,12-Dioximinocholanic acid (II) was prepared from 3α,12α-dihydroxycholanic acid (IV) by oxidation of IV to 3,12-dioxocholanic acid (V) and oximation of V to the dioxime (II). The reduction of II with sodium in alcohol resulted in the formation of 3α,12β-diaminocholanic acid (VIII) in good yield. Possessing one carboxyl and two amino groups, this diaminocarboxylic acid behaved as a base and formed a dihydrochloride. The infrared spectrum confirmed the presence of the NH_2 group (1660 cm^{-1}), the NH_3^+ ion (1623 cm^{-1}), and the carboxylate ion (1575 cm^{-1}).

A product containing no nitrogen and insoluble in both acids and bases was formed in the reaction of the oximino acid (II) with lithium aluminum hydride. The infrared spectrum had a very strong band at 3340 cm^{-1}, which was attributed to absorption by associated OH groups, and a series of high intensity bands in the region 1075–1011 cm^{-1}. The latter could be assigned to C—O stretching vibrations in a steroid alcohol. On the basis of the infrared spectrum and the analytical results, the compound was formulated as cholane-3ξ,12ξ,24-triol (IX). The steric course of reductions with lithium aluminum hydride being uncertain, the conformations of the hydroxyl groups at 3- and 12-positions were not assigned.



The formation of IX was quite unexpected, although a somewhat similar result had been obtained by Redel and his co-workers (2) in their attempts to reduce methyl 3α,12α-diformoxy-7-oximinocholanate in ethanolic solution by catalytic hydrogenation under pressure using Raney nickel. Mignonac (18, 19) and Paul (20) also had observed the formation of secondary alcohols on reductions of oximes. It was considered that the reaction of the oximino acid (II) with lithium aluminum hydride proceeded via an unstable imine, which, under hydrolytic conditions, was transformed into the corresponding ketone. The latter was, in turn, reduced to the secondary alcohol (IX) by the lithium aluminum hydride still present in the reaction mixture.

Clemmensen reduction of 3,7,12-trioxocholanic acid (X) to 7,12-dioxocholanic acid (XI) and oximation provided 7,12-dioximinocholanic acid (III). The reduction of III with sodium in *n*-propyl or *n*-butyl alcohol produced 7β,12β-diaminocholanic acid (XII) in high yields, as anticipated. When the reduction of III was carried out under similar conditions to those used for the reduction of the dioximino acid (II) with lithium

(X)

(XIII)

aluminum hydride, a nitrogen-containing product was obtained. In the infrared spectrum there was no carbonyl absorption, but the band at 3300 cm^{-1} indicated the presence of an alcoholic function. The medium intensity band at 1660 cm^{-1} could be due to absorption by an amine, an oxime, or both. Acidic hydrolysis of the reaction product gave a material which contained nitrogen, and in the infrared exhibited a carboxyl band at 1700 cm^{-1}, and bands at 3300 cm^{-1} and 1655 cm^{-1}. The hypothesis of an amino, oximino carbinol fully agreed with the analytical results. Since the 12-position is more sterically hindered than the 7-position, the reaction product was postulated as 7ξ-amino-12-oximinocholan-24-ol (XIII) and its hydrolysis product as 7ξ-amino-24-hydroxycholan-12-one (XIV).

EXPERIMENTAL

The melting points were determined in a Thiele–Dennis melting point tube containing Dow Corning silicone fluid No. D.C. 550, and are uncorrected. The analyses were carried out in the W. Manser laboratory, Zurich, Switzerland. Infrared spectra were determined in potassium bromide on a Perkin–Elmer Model 21 double-beam instrument equipped with a sodium chloride prism.

3,12-Dioxocholanic Acid (V)

To a solution of chromium trioxide (13.35 g) in water (20 ml) concentrated sulphuric acid (11.5 ml) was added dropwise, with stirring so as to avoid the formation of any precipitate. The cold solution was diluted to 50 ml. 3α,12α-Dihydroxycholanic acid (IV) (30 g) was dissolved in acetone (2.2 l.), and the resulting solution was cooled to 20° in an ice-water bath. The oxidizing solution was then added dropwise from a microburette until an orange-brown color persisted (about 45 ml of reagent was required). The solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

was decanted from the inorganic residue, and was diluted with water to a volume of 6 l. The product (23.4 g) precipitated immediately, and was isolated. A second crop (5.35 g) was obtained by diluting the filtrate with another 2 l. of water. The 3,12-dioxocholanic acid (V) melted at 184–185°.

12β-Aminocholanic Acid (VII)

In a nitrogen atmosphere, sodium (2.5 g), in small pieces, was added over a period of 3.5 hours to a refluxing solution of 12-oximinocholanic acid (I) (0.5 g) in dry *n*-propyl alcohol (58 ml) with stirring. Then the reaction mixture was cooled in an ice-water bath, and made slightly acidic with 4% sulphuric acid. The propyl alcohol was distilled off *in vacuo* in a nitrogen atmosphere, and some precipitation occurred. The precipitation was made complete by adjusting the pH to 5.6–5.8 with 1% sulphuric acid. The yellow solid (0.48 g) was isolated. It melted at 122–126° to an opaque viscous liquid which cleared at 138–140°. The product was dissolved in hot acetone (20 ml), and the yellow solution filtered with suction through celite and carbon Nuchar C190-N. The colorless filtrate was concentrated under reduced pressure to a 10-ml volume, and heated to boiling. Hot water was added dropwise until the solution became slightly turbid. Upon cooling to room temperature, needles were deposited from solution. Recrystallization from acetone–water provided 12β-aminocholanic acid (VII) melting at 115–116° to a liquid which became transparent at 120°. ν_{max} 3440 (O—H), 3040 (sh) ($\overset{+}{N}H_3$), 1625 ($\overset{+}{N}H_3$), 1550 cm^{-1} (COO^-). Anal. Calc. for $C_{24}H_{41}O_2N \cdot 3H_2O$: C, 67.13; H, 10.95; N, 3.24. Found: C, 67.20; H, 10.88; N, 3.53%. Hydrochloride: Addition of concentrated hydrochloric acid (0.5 ml) to VII (0.4 g) and evaporation to dryness under reduced pressure was repeated 5 times. The white residue obtained, on recrystallization from methanol–water, gave the hydrochloride as a white powder, m.p. 257–258°. ν_{max} 1705 (C=O), 1610 cm^{-1} ($\overset{+}{N}H_3$).

Attempted Reduction of 12-Oximinocholanic Acid (I) *with Sodium Amalgam in Absolute Ethanol*

Sodium amalgam (3%, 26.6 g) was added in a nitrogen atmosphere to a refluxing solution of I (0.2 g) in absolute ethanol (20 ml), and the mixture was stirred for 6 hours. The major part of the amalgam seemed to have reacted. The supernatant solution was decanted, allowed to cool, diluted with water to 50 ml, and neutralized with 4% sulphuric acid. A white product (0.18 g) which precipitated was isolated. It melted at 178–179° to a milky liquid which cleared completely at 198–201°. Recrystallization from ethanol provided platelets, m.p. 180–182°, which were identified as 12-oxocholanic acid (VI) by a mixed melting point determination (183–184°) with an authentic sample of the keto acid. An oxime derivative of the reaction product was prepared, and a mixed melting point determination with an authentic sample of I showed no depression.

3α,12β-Diaminocholanic Acid (VIII)

To a refluxing solution of 3,12-dioximinocholanic acid (II) (0.4 g) in dry *n*-propyl alcohol (60 ml) were added, with stirring in a nitrogen atmosphere, small pieces of sodium (4.0 g) over a period of 4 hours. The reaction mixture was cooled in an ice-water bath, and treated with 4% sulphuric acid until pH 9 was reached. The propyl alcohol was evaporated under reduced pressure and the pH of the aqueous solution was further adjusted with 1% sulphuric acid to 8.6–8.8. A yellow product (0.25 g) precipitated and was isolated. Recrystallization from methanol–water gave 3α,12β-diaminocholanic acid

(VIII), m.p. 244–245°. ν_{max} 3380 (O—H, NH_2), 1660 (sh) (NH_2), 1623 ($\overset{+}{N}H_3$), 1575 cm^{-1} (COO^-). Anal. Calc. for $C_{24}H_{42}O_2N_2 \cdot H_2O$: C, 70.58; H, 10.78; N, 6.86. Found: C, 70.35; H, 10.63; N, 6.59%.

Reduction of 3,12-Dioximocholanic Acid (II) *with Lithium Aluminum Hydride in Tetrahydrofuran*

To a refluxing suspension of lithium aluminum hydride (0.37 g) in dry tetrahydrofuran (20 ml) in a nitrogen atmosphere was added dropwise, and with stirring, a solution of II (0.3 g) in dry tetrahydrofuran (30 ml). The resulting mixture was stirred and refluxed for a further period of 2 hours, then was cooled to room temperature. A saturated solution (50 ml) of sodium potassium tartrate was added dropwise with stirring. The tetrahydrofuran was removed by evaporation under reduced pressure, and a semisolid material separated in the aqueous phase. It was extracted with three 40-ml portions of *n*-butyl alcohol. The alcoholic extract was washed with 1% sulphuric acid, and with water, then was dried over anhydrous magnesium sulphate. After filtration, the solvent was removed *in vacuo* leaving an amorphous residue (0.23 g), which contained no nitrogen. The product was dissolved in 2 ml of boiling ethanol, and hot water was added dropwise until a slight cloudiness was observed. The solution was seeded with crystals obtained by cooling a few drops of the solution in a dry ice – acetone mixture for 2–3 minutes, and keeping the resulting solid in a refrigerator overnight, and long needles were obtained. Recrystallization from acetone–water yielded cholane-3ξ,12ξ,24-triol (IX), m.p. 166–169°. ν_{max} 3340 cm^{-1} (H—O), 1075, 1055, 1042, 1011 cm^{-1} (C—O). Anal. Calc. for $C_{24}H_{42}O_3$: C, 76.19; H, 11.11. Found: C, 75.86; H, 11.45%.

7β,12β-Diaminocholanic Acid (XII)

In a nitrogen atmosphere, sodium (2.0 g) was added in small pieces, with stirring, to a refluxing solution of 7,12-dioximinocholanic acid (III) (0.2 g) in dry *n*-propyl alcohol (40 ml) over a period of 3 hours. The reaction mixture was cooled in an ice-water bath, and adjusted to pH 9 with 4% then 2% sulphuric acid. The propyl alcohol was removed under reduced pressure, and 1% sulphuric acid was added until precipitation occurred at pH 8.3–8.6. The crude product (0.16 g) was dissolved in 8 ml of ethanol, and the yellow solution was filtered through celite and carbon Nuchar C190-N. The filtrate was concentrated to 4 ml and, when it was left to stand at room temperature, needles were deposited and isolated. Recrystallization from acetone–water afforded 7β,12β-diaminocholanic acid (XII), m.p. 128–130°. ν_{max} 3400 cm^{-1} (O—H), 1635, 1560, 1630 cm^{-1} (NH_2, $\overset{+}{N}H_3$), 1550 cm^{-1} (COO^-). Anal. Calc. for $C_{24}H_{42}N_2O_2 \cdot 1.5H_2O$: C, 69.06; H, 10.31; N, 6.71. Found: C, 68.52; H, 10.32; N, 6.57%.

7ξ-Amino-12-oximinocholan-24-ol (XIII)

A solution of 7,12-dioximinocholanic acid (III) (0.60 g) in dry tetrahydrofuran (80 ml) was added in a nitrogen atmosphere to a refluxing suspension of lithium aluminum hydride (0.73 g) in dry tetrahydrofuran (50 ml), with stirring, over a period of 40 minutes. The reaction mixture was stirred under reflux for a further 2.5 hours. When the suspension had cooled to room temperature, it was hydrolyzed by the dropwise addition of 100 ml of a saturated sodium potassium tartrate (Rochelle salt) solution. The tetrahydrofuran was removed under reduced pressure, and a white precipitate separated from the aqueous solution. The product was extracted with four 50-ml portions of *n*-butanol, and the extract was washed once with 1% sulphuric acid, twice with water, and then was dried over anhydrous magnesium sulphate. The solution was filtered, and the butanol was removed

under reduced pressure leaving a crystalline residue (0.45 g) which melted at 203–209° and became transparent at 215°. Recrystallization from ethanol gave 7ξ-amino-12-oximinocholan-24-ol (XIII) in shiny plates, m.p. 234–236°. ν_{max} 3300 cm^{-1} (O—H), 1660 cm^{-1} (C=N, NH_2). Anal. Calc. for $C_{24}H_{38}O_2N_2$: C, 71.79; H, 9.74; N, 7.17. Found: C, 71.15%; H, 10.17; N, 7.15%.

7ξ-Amino-12-oxocholan-24-ol (XIV)

7ξ-Amino-12-oximinocholan-24-ol (XIII) (15 mg) was dissolved in ethanol (3 ml), and one drop of 4% hydrochloric acid was added to the solution. The reaction mixture was refluxed for 20 minutes, then was concentrated to a volume of 1 ml *in vacuo*, and the needles which separated when the mixture was left to stand at room temperature were isolated; the needles melted at 180–183°. Recrystallization from ethanol–water provided 7ξ-amino-12-oxocholan-24-ol (XIV) in the form of needles, m.p. 183–184°. ν_{max} 3300 cm^{-1} (O—H); 1700 cm^{-1} (C=O); 1655 cm^{-1} (NH_2). Anal. Calc. for $C_{24}H_{37}ON \cdot 1.5H_2O$: C, 71.39; H, 9.95. Found: C, 70.83; H, 9.98%.

THEORETICAL STUDIES ON SOLVATION

PART II. NEW THEORY FOR EVALUATION OF IONIC SOLVATION NUMBER FOR DIVALENT IONS AT 25° C[1]

A. M. AZZAM

ABSTRACT

The concepts of ionic solvation are discussed and the definition of four types are suggested. Utilizing Webb's theory, values of the dielectric constant of water in terms of distance from a divalent ion are evaluated. The statistical mechanics of the distribution of solvent molecules round a divalent ion in aqueous solution has been worked out.

The present theory shows that all divalent ions with radius less than 1.6 Å can have a saturated envelope of eight water molecules in excess of the Goldschmidt co-ordination number have to be accounted for as inner primary solvation number. The concept of catonium is suggested for such a stable aquo-complex entity. The catonium entity is further hydrated electrostatically in the normal way by primary and secondary solvation types. The conditions governing all types of solvation and their possible termination boundaries are discussed and evaluated.

The theoretically calculated values of the ionic solvation numbers are in good agreement with the experimental results.

1. INTRODUCTION

Solvation plays an extremely important part in most solution phenomena (1, 2, 4). Most investigations have dealt with aqueous solutions and several experimental methods (1, 4) have been used to find out the degree of hydration of ions but they give widely divergent results as shown in Table I.

TABLE I

Values of the hydration number of alkaline earth metal ions in dilute solution at room temperature by various experimental methods

Method	Reference	Be^{++}	Mg^{++}	Ca^{++}	Sr^{++}	Ba^{++}
Mobility (Ulich)	(16)		10.5–13	7.5–10.5		5–9
Entropy (Ulich)	(1)		13	10		8
Compressibility (Passynski)	(1)	8	16	16		
Cryoscopic (Bourin *et al.*)	(1)		22.3	21.6	21.3	20.1
Cryoscopic (Van Ruynen)	(11)	30	15	10.5	10	9
Dialysis (Brintzinger)	(1)		37.5	33.4	29.1	25.1
Partial molar volume (Darmoir)	(1)		6.6	5.2		4
Solubility of gases (Manchot)	(1)		13	14.6		16.8

The most outstanding problem connected with solvation lies in the need of theoretical calculations to supply definite quantitative knowledge of the nature of the solvation sheath and the structure of the solvated ion. Such information may also throw light on the general problem of the interionic attraction theory of electrolytes (7, 8, 9) which has reached a quasi-static position. No further essential advances in the field of more concentrated solution appears possible without the concept of ion–solvent interaction (5, 6, 7, 8, 9, 11).

In a previous paper (3), the present author worked out the basis of a statistical mechanical method for the calculation of solvation number of ions and the following equation was developed:

$$[1] \qquad ds = 4\,\pi\,n_0\,e^{-(w/kt)}\,r^2\,dr$$

[1]*Manuscript received January 28, 1960.*
Contribution from the Department of Chemistry, Faculty of Science, A'in Shams University, Cairo, Egypt.

where ds = the number of solvent molecules associated with the ion in the spherical shell between r and $r+dr$ from the center of the ion;
n_0 = the number of solvent molecules per cubic centimeter in the bulk of the solution;
w = net potential energy of a solvent molecule in the solvation sheath. This energy is the algebraic sum of energies of ion–dipole and dipole–dipole interactions;
k = Boltzman's constant;
t = temperature.

The theoretically calculated values of primary solvation number (for definition see Discussion) for alkali metal and halide ions are in good agreement with those obtained by four mutually self-consistent experimental methods (3).

The purpose of the present paper is to verify the above-mentioned theory by applying it to the calculation of solvation number for alkaline earth metal and divalent transition metal ions.

2. CONCEPTS OF IONIC SOLVATION

In spite of much experimental work (1), the significance of the term solvation has remained somewhat vague. Considering the former concepts of ionic solvation (13, 14, 15, 16, 17), together with conclusions derived from the present author's theory (3), a possible classification and definition of the different types of solvation can be given as follows:

(a) Permanent Solvation (Chemical Bonds)

This term refers to solvent molecules which are firmly associated with the ion through the formation of chemical bonds. These forces between ions and solvent molecules are so strong that an ion can retain this type in crystals. In other words, this type of solvation persists in the solid as well as in its solutions (e.g. co-ordinated water of crystallization).

(b) Primary Solvation (Physical Forces)

This term refers to solvent molecules which are firmly associated with the ion by electrostatic attraction. They have lost their translational degree of freedom and move as one entity with the ion during its Brownian motion. In other words, they cannot be dislodged by thermal motion.

(c) Secondary Solvation (Physical Forces)

This term refers to solvent molecules which undergo electrostatic attraction with the primary solvated ions. These molecules are much more weakly held but the electrostatic attraction predominates over the separating action of thermal motion sufficiently to affect solvation-dependent quantities, e.g. salting out.

(d) Hydrodynamical Solvation (Streaming Effect)

This term refers to solvent molecules which could be transferred hydrodynamically as the hydrated ion moves *under* the influence of an applied electrostatic field. This effect is mainly due to change in momentum between the solvated ion and the solvent molecules.

These different types of solvation play parts of different order or degree in the various experimental phenomena depending on specific factors (2, 3, 4, 18).

However, the number of solvent molecules in both the permanent and the primary solvation sheaths have definite values, moving with the ion as a single entity without exchange with bulk solvent. On the other hand, the number of solvent molecules in the secondary solvation sheath have variable values dependent on the phenomena observed. Ions continuously exchange these solvent molecules as they wander about in solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Hydrodynamical solvation is relevant only in dynamic experiments such as in measurements of transport number. This explains the fact that hydrodynamical methods for the determination of solvation number give much too high values (2, 3, 4, 18).

This scheme of classification gives a clear understanding of the reason for the large discrepancy between the results obtained by various experimental methods (1, 2, 3, 4, 18).

3. PROPOSED STRUCTURE OF HYDRATED DIVALENT IONS

Divalent metals such as Be, Mg, Ca, Sr, Ba, Zn, Cd, Fe, Co, Ni, Cu, . . . form a very large number of hydrated salts of definite constitution in the solid state (19, 20, 21, 24, 28, 29, 32, 33, 34). X-Ray crystallography has confirmed that definite hydrated cation complexes such as $[Be(H_2O)4]^{2+}$, $[Cu(H_2O)_4]^{2+}$, $[Mg(H_2O)_6]^{2+}$, $[Ni(H_2O)_6]^{2+}$ . . . are components of the corresponding polar lattices. $[M(H_2O)_n]^{2+}$ is the general formulation of such a stable hydrated entity in the solid state. These entities thus persist in the solid as well as in aqueous solution and have as much right (18, 34) to be considered complex ions as $[PtCl_4]^{2-}$ and $[Fe(CN)_6]^{4-}$.

The conclusion which follows is that divalent cations, which are hydrated in the solid state $[M(H_2O)_n]^{2+}$, never exist in very dilute aqueous solution as the bare ion M^{2+} but as a stable hydrated form. It is not known whether the number of water molecules in the nearest layer around the ion in dilute aqueous solution will remain "n" (as in the solid state) or whether and to what extent primary solvation will contribute in this first layer. To overcome this difficulty, it will be assumed that "x" (where $x \geqslant n$) is the number of water molecules in the first layer around the ion in very dilute aqueous solution.* Accordingly the formulation of the stable hydrated entity in dilute aqueous solution is $[M(H_2O)_x]^{2+}$ or more generally $\left[M\begin{matrix}(H_2O)_n \\ (H_2O)_{x-n}\end{matrix} \right]^{2+}$. It is suggested that this entity be called "*a catonium*".

This terminology is the more correct form and should be more often used, but for simplicity the symbol M^{2+} may be accepted.†

The catonium entity is further hydrated in the normal way (see section on concept of ionic solvation) by purely electrostatic forces depending on the field strength at the surface of the catonium. The new situation arising on the dissolution of a hydrated salt with a co-ordinated hydrated cation is depicted as follows:

$$[M(H_2O)_n]^{2+} \underset{\text{crystallization}}{\overset{\text{dissolution}}{\rightleftharpoons}} \left[M\begin{matrix}(H_2O)_n \\ (H_2O)_{x-n}\end{matrix} \right]^{2+} \cdot (H_2O)_p(H_2O)_s(H_2O)_h \qquad [2]$$

(hydrated cation in crystal) — (hydrated catonium in very dilute aqueous solution)

where x represents the permanent solvation number,

$(x - n)$ represents the inner primary solvation number,

$[M(H_2O)_n]^{2+}$ represents the hydrated cation in crystal,

$\left[M\begin{matrix}(H_2O)_n \\ (H_2O)_{x-n}\end{matrix} \right]^{2+}$ represents the catonium entity in solution,

p represents the primary solvation number of the catonium or outer primary solvation,

s represents the secondary solvation number of the catonium,

h represents the hydrodynamical solvation number of the catonium.

This proposed structure is diagrammatically shown in Fig. 1.

Some authors (18) seem to be of the opinion that n and x are the same, but there is no evidence for such a statement.

†*In analogy with the use of* (H^+) *for the hydroxonium ion* $(H_3O)^+$.

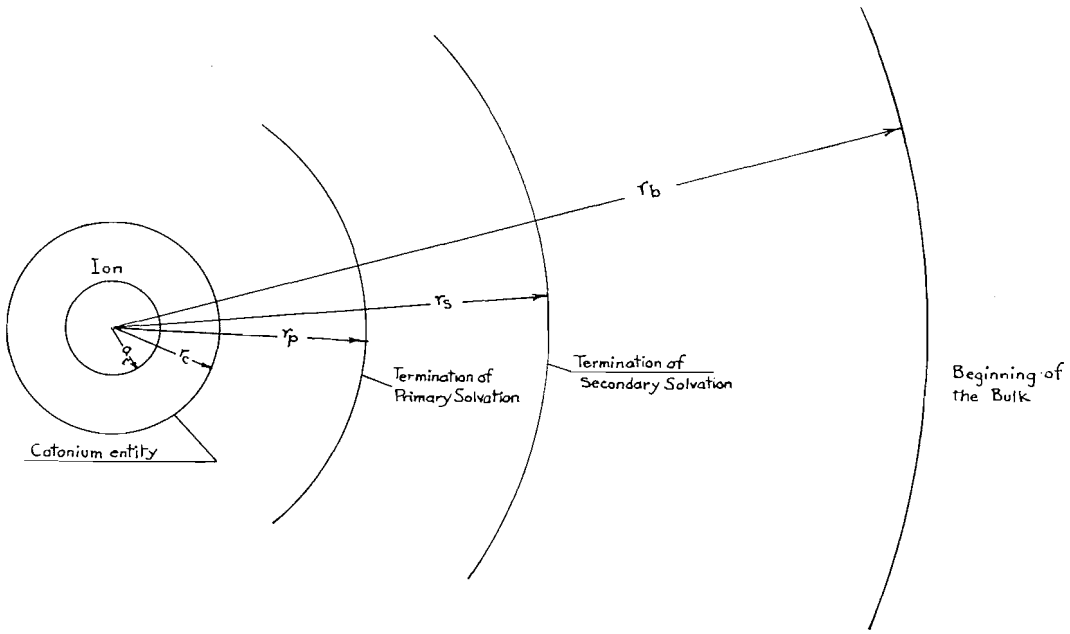

FIG. 1. The proposed structure of a solvated divalent ion in dilute aqueous solution.

4. METHOD OF CALCULATION

A serious difficulty, which occurs generally in the evaluation of ion–dipole interaction, is the lack of knowledge of the values of the dielectric constant near an ion. The only values reported in the literature (10, 12) are those near a monovalent ion. Utilizing Webb's theory (10), values of the dielectric constant of water in terms of distance from a divalent ion could be evaluated (see Fig. 2). Knowing this relation, the solvation number

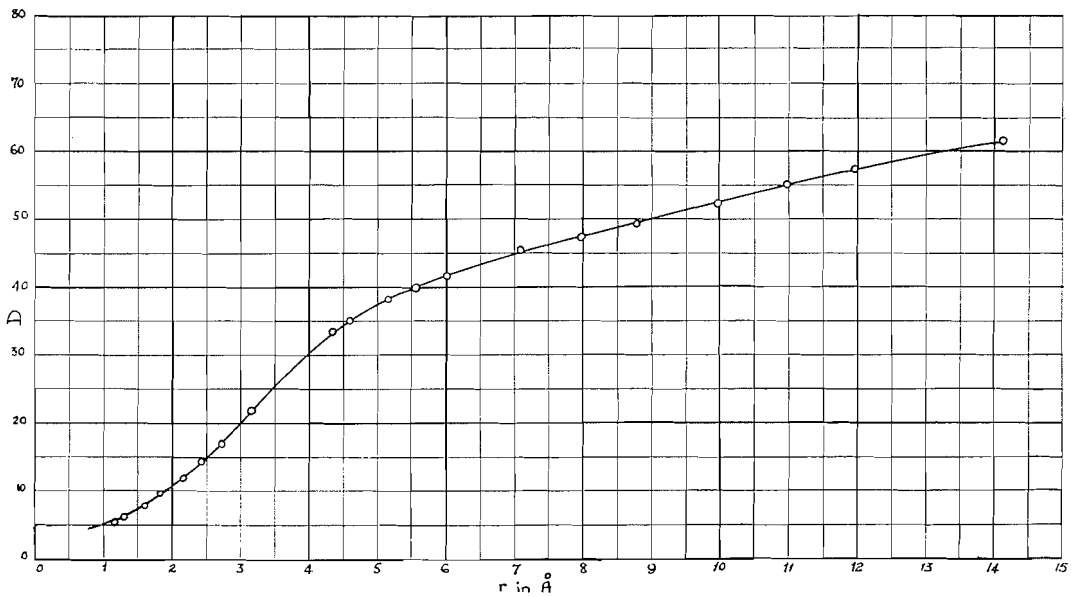

FIG. 2. Variation of the dielectric constant of water D in the vicinity of a divalent ion.

of divalent ions can be calculated by following the method of calculation previously given for monovalent ions (3). All data which are needed in the present calculation are recorded in Table II. The corresponding relation $[e^{-(w/kt)}r^2 - r]$, which is required for the graphical evaluation of solvation numbers (3), is shown plotted in Fig. 3. The curve is of

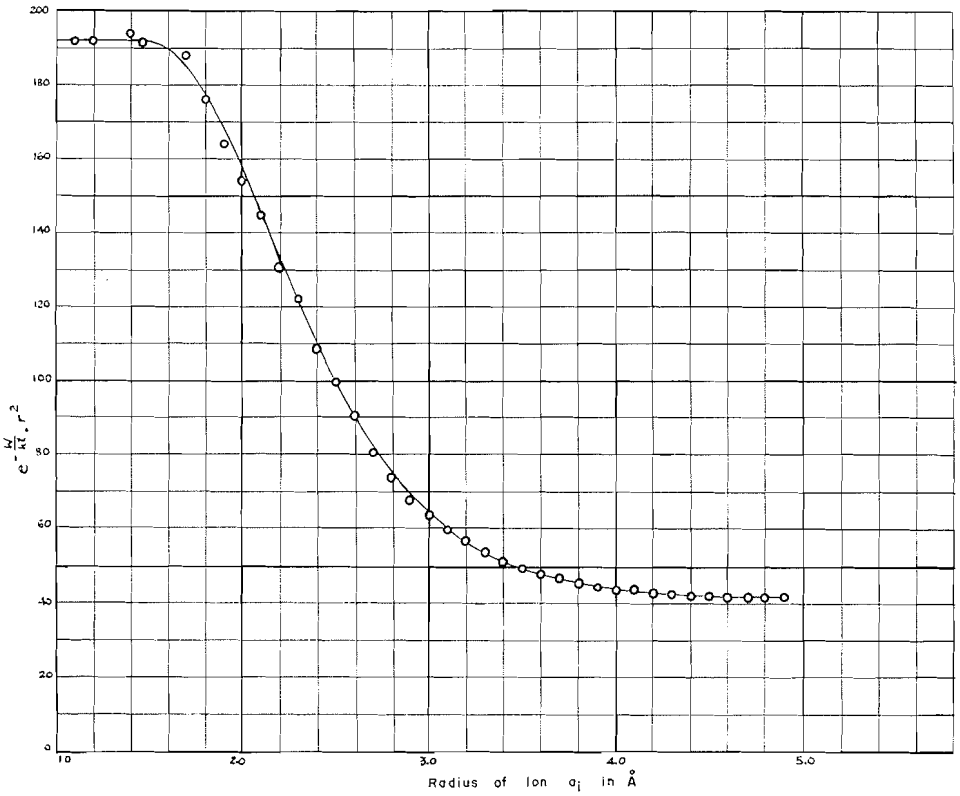

FIG. 3. Relation between $e^{-w/kt}$. r^2 and radius of ions.

the sigmoid type. It shows a horizontal portion at first extending to a distance $r = 1.6$ Å (from the center of the ion), followed by a rapid decrease which extends up to a distance $r = 3.2$ Å and finally a steady insignificant decrease.

5. DISCUSSION

Permanent and primary solvations are the only types involving definite solvent molecules in association with the ion (see section on concepts of ionic solvation). Each experiment measures the above-mentioned types plus some contribution from the other types of solvation depending on the phenomenon observed. Accordingly, Part I of this discussion is devoted to permanent and primary solvation types. Possible termination boundaries of the different types of solvation are given in Part II. In Part III, values of the ionic radii are discussed.

(I) Permanent and Primary Solvation Numbers

Examination of the present analysis (see Table II and Fig. 3) shows that the statistical possible number of water molecules which could be accommodated in the first layer

around a divalent ion is 8.06 water molecules. This could be considered as a possible value of "x" provided that the mode of association is purely electrostatic. On the other hand, several lines of evidence (18, 19, 21, 24, 32, 33, 34) combine to show that the value of "n", which is a measure of the tendency of an ion to co-ordinate in the solid state, is given by the Goldschmidt co-ordination number. According to Sidgwick (21), the value of "n" for an element depends upon its position in the periodic classification, but the co-ordination number can only assume these values (2, 4, 6, or 8). The values 4 and 6 are the most usual. Following these lines of discussion, it could be concluded that in very dilute aqueous solution, the number of water molecules in the first shell around an ion is 8 irrespective of the mode of association. It seems very probable that when the binding capacity of a cation (as given by the value of n) appears exhausted, it can link up with other water molecules by physical forces and build up a more complex structure to an upper limit which is given by the average value 8.06 water molecules. In other words, the 8.06 water molecules in the first layer around an ion constitute a mixture of both permanent and primary solvation types.

The values of these two types are given by "n" and "$8.06-n$" respectively. As this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

primary solvation number of the ion $(8.06-n)$ is within the catonium entity, it is better to refer to this number as the "*inner primary solvation number*".

The catonium entity as stated before is further hydrated in the normal way (primary, secondary) by electrostatic forces depending on the field strength at the surface of the catonium (see equation 2 and Fig. 1). The most important fact which results from the present theory is that primary solvation of the catonium entity exists for only one layer of water molecules. This result follows from the application of the concept of screening effect (3, 30). The calculated values of "p" are shown in Table IV. This number of water molecules attached to the catonium can be called the "*outer primary solvation number*".

(II) The Termination Boundaries of the Different Types of Solvation of the Catonium Entity

It could be postulated that for primary solvation, as qualitatively defined above, the interaction of the catonium with dipole is such that the net interaction energy in the solvation sheath minus the solvent–solvent interactions in the bulk is greater than the kinetic thermal energy. The possible termination of primary solvation can thus be regarded as the point at which $w/kt \geqslant 1$. This condition is reached at $r \simeq 3.1$ Å (see Table II and see Fig. 1). This indicates that all catoniums of radius less than 3.1 Å are primary hydrated.

After the termination of primary solvation, the ion and dipoles from the bulk of the solution compete and where the energy of the catonium–dipole interaction is equal and opposite to that of dipole–dipole interaction, $w = 0$, so that the secondary solvation may be regarded as terminated. This condition is reached at r about 4.4 Å. It is also characterized by an approximately constant value of ds as shown in Table II. This indicates that all *primary solvated catoniums* of radius less than 4.4 Å are secondary hydrated.

The beginning of the bulk can be recognized as the critical radius inside which no water molecule has the normal dielectric properties. This is reached for r about 22 Å (see Fig. 2).

(III) Crystal Radii and Univalent Radii

With regard to ionic radii, in general, no unique radius can be ascribed to the ion. Comprehensive assignment of fixed radii to ions has frequently been attempted, notably by Lande (23), Wasestjerna (23), Goldschmidt (24), and Pauling (22). Most of the ionic radii values adopted by these authors are different (see Table III). The difference is mainly due to the arbitrary nature of the allotment of fixed extension to ions. However, Pauling formulated a semi-empirical set of ionic radii. These radii are known as univalent radii of the ions and are shown in Table III. These radii are the radii the multivalent ions would possess if they were to retain their electron distributions and enter into coulomb interaction as if they were univalent. It seems very probable that these univalent radii are in harmony and more suitable for use than the crystal radii. The following simple arguments can be given in support of this:

1. The univalent radii are very accurate to about 1% and form a complete set under comparable conditions.

2. These radii represent correctly the relative sizes of the outer electron shells of the ions compared with those for the alkali and halogen ions.

3. They have absolute values such as to cause their sums to be equal to the equilibrium interionic distance in standard crystals.

4. In ionic crystals, the crystal radii sums decrease about 10% for the change from *a crystal* M^+X^- to its *isoelectronic* $M^{++}X^{--}$. This decrease is not due to lack of compensation of the charges in the electron distribution but results rather from the effect of doubling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the electric charges on the ions. On the other hand, the univalent radius sums remain nearly constant.

5. If both univalent radii and crystal radii are represented graphically as functions of the atomic number, it will be seen that there is great regularity in the univalent radii sequences (22).

TABLE III

Crystal ionic radii and univalent crystal radii

Ion	Crystal ionic radii					Univalent crystal radii (Pauling (22))
	Pauling (22)	Wasestjerna (23)	Wyckoff (29)	Zachariasen (31)	Goldschmidt (24)

tion number "p" was calculated using Pauling's univalent radii and the Goldschmidt crystal ionic radii. As can be seen from Table IV, the difference between the two cases is less than 0.5, and this is insignificant.

CONCLUSIONS

1. Concepts of ionic solvation are discussed and the definition of the following four types is suggested: "permanent, primary, secondary, and hydrodynamic".

2. The variation of the dielectric constant of water in the vicinity of divalent ion is evaluated.

3. The dissolution process of a co-ordinated cation is depicted as

$$[M(H_2O)_n]^{2+} \underset{\text{crystallization}}{\overset{\text{dissolution}}{\rightleftharpoons}} \left[M\begin{matrix}(H_2O)_n\\(H_2O)_{x-n}\end{matrix}\right]^{2+} . (H_2O)_p . (H_2O)_s .$$

4. The permanent solvation type "n", which persists in solid state and in solution, is given by Goldschmit co-ordination number (4 or 6) and its mode of association has been assumed not to be purely physical.

5. Divalent cations in solution are not simply cations corresponding to the symbol M^{2+} but rather catonium entities $\left[M\begin{matrix}(H_2O)_n\\(H_2O)_{x-n}\end{matrix}\right]^{2+}$.

6. All divalent ions with radius less than 1.6 Å can have an envelope of 8.06 water molecules ($x = 8.06$). This is a mixture of both permanent solvation type "n" and inner primary solvation type $(x-n)$.

7. All catonium ions with radius less than 3.1 Å are primary solvated "p". This is called the outer primary solvation number.

8. The outer primary solvation number exists for only one layer of water molecules around the catonium entity. This result follows from the application of the concept of screening effect.

9. The following critical radii have been calculated:

(*a*) Inner primary solvation types exist inside the critical radii 1.6 Å.

(*b*) Outer primary solvation types exist inside the critical radii 3.1 Å.

(*c*) Secondary solvation types exist inside the critical radii 4.7 Å.

(*d*) Water does not have the normal dielectric properties inside the critical radius of about 22 Å.

10. The present theory demonstrates

(*a*) Azzam's theory of ionic solvation which was previously given in Part I,

(*b*) Fuoss's theory of the screening effect,

(*c*) Webb's theory of the variation of the dielectric constant of water near an ion,

(*d*) Pauling univalent radii concept.

11. The theoretically calculated values of ionic solvation of divalent ions are in good agreement with those obtained by mutually self-consistent experimental methods.

ACID ACTIVATION OF MONTMORILLONITE[1]

R. D. Heyding, R. Ironside, A. R. Norris,[2] and R. Y. Prysiazniuk[3]

ABSTRACT

A Pembina montmorillonite clay has been activated with sulphuric acid at various dosages by the conventional wet process and by the new "dry" process. The products are compared with respect to the fractions of the metal ion components remaining after leaching, the hydrated silica content, the bleaching capacity, and the B.E.T. nitrogen and water surface areas which they exhibit. Surface areas were also determined after calcining the products *in vacuo*. The surface areas are discussed with reference to the removal of metal ions occupying octahedral lattice sites in a model clay particle.

INTRODUCTION

Montmorillonite clays are employed extensively as bleaching agents for mineral and vegetable oils, and as cracking catalysts in the petroleum industry. Often the capacity of a particular montmorillonite with respect to either of these functions is enhanced by "activation", that is, by the removal of basic constituents in the clay lattice by leaching with acid. In the conventional activation procedure the clay is refluxed with relatively dilute sulphuric (or hydrochloric) acid, filtered, and washed. The acid concentration is limited by the consistency of the clay/water/acid system, while the temperature attainable in open vats is limited by atmospheric pressure. A new procedure developed by Puddington and Farnand (1) permits higher concentrations of acid for a given dosage (acid-to-clay ratio) since only sufficient water is used to produce a reasonably free-flowing crumb on mixing, and this may be heated to about 200° C to promote rapid reaction. Subsequent treatment is similar to the conventional process. It is convenient to describe these two methods as the "wet" process and the "dry" process, respectively.

The dry process embodies obvious technical advantages as far as production of activated clay is concerned. The present study was designed to evaluate the products of dry activation by comparison of some of their physical characteristics with those of wet activated clays. The physical properties were chosen on the assumption that their variation would indicate the nature of the degradation of the clay lattice on activation.

The montmorillonite lamina or pseudo unit cell consists of partially hydrated silica/alumina/silica layers in which some of the octahedral aluminum sites are occupied by trivalent iron or divalent magnesium. The substitution of trivalent ions by divalent metal ions implies an electrostatic inequality within each lamina which is cancelled by the inclusion of hydrogen, alkali metal, or alkaline earth ions (the exchangeable ions) between adjacent laminae in the lattice. In the presence of water vapor, water is included in the interlaminar space resulting in an expansion of lattice along the c axis. It is not certain whether the water is adsorbed or chemisorbed by hydration of the interlaminar ions, or by hydration of the silica forming the faces of the interlaminar area. The last possibility is the basis of the montmorillonite model proposed by Edelman and Favejee (2), in which the tetrahedral silica units point into the interlaminar space. This model is not as generally accepted as the Hoffman–Endell–Wilm–Marshall–Hendricks model (3) in which the silica units point into the lattice and away from the interlaminar region.

[3]*N.R.C. Summer Student, 1959. Present address: Graduate School, Iowa State College, Ames, Iowa.*

Although these models differ considerably in detail, the existence of silica/alumina/silica structural layers separated by exchangeable ions is not disputed. In what follows, either model will serve as the basis for the argument, and the data do not serve to distinguish between them.

According to Bradley and his co-workers (3), water is adsorbed in monomolecular layers between the silicate laminae as are many polar but otherwise neutral molecules. This water is accommodated reversibly regardless of heat treatment below ca. 300° C; above 500° C water of hydration is removed, and the laminae are bound together irreversibly. After calcination at 600° C, that is, after the conversion of the clay to a silica/alumina catalyst, no water is adsorbed in the interlaminar areas. Nitrogen, on the other hand, is not adsorbed in the interlaminar region even in non-calcined montmorillonite. These phenomena have been exploited by Mooney, Keenan, and Wood (4), who have reasoned that while B.E.T. nitrogen surface areas can represent external particle area only, B.E.T. water surface areas must indicate the interlaminar area as well. The interlaminar area obtained by difference in the two B.E.T. areas is quite consistent with the crystal model.

On leaching with acid, the metal ions in the middle layer of the silicate lamina are dissolved, according to Mills *et al.* (5), in essentially the same proportions in which they were present in the original clay. With the removal of these ions, the surface area can be expected to increase, and there is ample proof of this in the literature (5, 6, 7, 8, 9, 10). Usually intercorrelation of data obtained by various workers is difficult, as a result of differences in the raw clays and in the many variables associated with the activation and the subsequent treatment of the product. It is apparent, however, that the ability of a clay to decolorize mineral and vegetable oils is directly proportional to the B.E.T. nitrogen surface area of the clay, other factors, such as heat treatment, water content, and exchangeable ion, remaining constant. On the other hand, no direct relation between area and catalytic activity is observed (5); clays with similar activation and calcination histories and similar nitrogen areas need not necessarily exhibit similar catalytic properties.

The quantitative comparison of B.E.T. nitrogen and water surface areas as applied to natural montmorillonites by Mooney and his co-workers is a convenient means of studying the clay lattice before and after acid activation. We have activated a montmorillonite by both wet and dry processes at several acid dosages, and have measured the B.E.T. nitrogen and water surface areas of the products. These data, together with the total analyses of the clays, permit a self-consistent interpretation of the activation process. Redetermination of these surface areas after calcining the clays indicates in turn the extent of the modification of the lattice on irreversible dehydration. The decolorizing characteristics of the clays were measured, but no attempt was made to evaluate the calcined clays as catalysts.

EXPERIMENTAL PROCEDURE

The montmorillonite was supplied by Pembina Mountain Clays, Ltd., Manitoba. X-ray diffraction patterns showed no crystalline impurities in measurable amounts. The raw clay was ground to 80% −200 mesh and stored in airtight glass containers until used. Separate batches were used in the wet and dry activation experiments. The water content of the raw clay was determined by drying specimens at 110° C, and allowance was made for this adsorbed water in calculating the quantities of water and acid required by the activation procedure.

To activate by the wet method, 100 g (110° C dry basis) of clay was mixed with weighed amounts of 98% reagent grade sulphuric acid corresponding to 0 to 50% of the clay by weight, and sufficient water, including the water adsorbed by the clay, to bring the total liquid content to 400 g. This mixture was refluxed at 100° C for 6 hours with mechanical stirring. The product was filtered and washed to a pH of 3.0–3.5, at which point the washings were in all instances free of sulphate ion. The liquor and washings were recovered for analysis. The filter cake was dried overnight at 90° C and reground to −80 mesh. The fraction with particle sizes in the −80 to 100 mesh range was retained for surface area determinations.

The clay designated by the number 7A was subjected to two 50% acid leaches each of 6-hour duration, while clay 7B was leached three times in a similar manner.

To activate by the dry method, 454 g of clay (110° C dry basis) was mixed in a small muller for 30 minutes with 0–50% acid based on the dry clay and sufficient water to bring the total liquid content to 454 ml. After mixing, a 100- to 200-g portion was heated for 4 hours at 150° C in a drying oven, mixed with water while hot, filtered, and washed to a pH of 3.0–3.2. Subsequent treatment was identical with that of the wet activated clays. Since there was no means of determining weight changes during the mulling operation, the washings were not recovered for analysis.

The bleaching power of the activated clays was determined by adding 1 g of clay (−200 mesh material equilibrated overnight in a moisture cabinet) to 33 g of a semi-finished test oil kindly supplied by Imperial Oil Limited. The mixture was stirred mechanically while the temperature was increased in 5 to 7 minutes to 142° C. After cooling in air to 100° C, the oil was filtered and the percentage of transmittance measured in a Lumetron colorimeter equipped with red (6500 Å), green (5300 Å), and blue (4200 Å) filters. All transmissions were determined relative to Stanolax, a water-white medicinal oil produced by Standard Oil of Indiana.

Conventional procedures were used in analyzing the clays.* An estimate of "hydrated silica" was included in the analysis, although the precise significance of the determination is problematical. The difference in solubility of crystalline and amorphous silica in weak sodium carbonate solution, established by Lunge and Millberg (15), has been made the basis of several procedures for estimating the degree of chemical decomposition of clay minerals (9, 16). The fraction of the silica in the clay which dissolves in a sodium carbonate solution under certain conditions is defined as "hydrated silica" and presumably represents the amorphous silica contained in the mineral. Since the conditions are essentially empirical, the details of the method used in these analyses are given below.†

The activated clays were calcined *in vacuo* at 600°±5° C. Approximately 30 minutes

**The major components, viz.* SiO_2, Al_2O_3, MgO, *and* CaO, *were determined by the conventional gravimetric and volumetric procedures appropriate to samples of this nature (11, 12).* Na_2O *and* K_2O *were determined by flame photometry using methods adapted from well-established techniques for siliceous materials (13). The determination of sulphate ion was complicated by the presence in these samples of silicon and iron. The determination was made, finally, by a method based on the chromatographic separation of the sulphate ion from perchloric acid solution according to Nydahl (14).*

†To estimate "hydrated silica" content, 1.000±0.001 g of clay and 2.00 g Na_2CO_3 *were weighed into a stainless steel beaker. 100 ml of water was added and the solution heated to boiling within 6 minutes. Boiling was continued for 10 minutes, and the steel beaker was then removed from the heat. After settling for 4 minutes, the clear liquid was decanted into a filter of paper pulp supported on a perforated steel filter plate. The filter was sucked dry. 25 ml of 2% w/v hot solution of* Na_2CO_3 *was added and the liquid boiled for 2 minutes. After settling for 4 minutes, the clear liquid was again decanted into the filter funnel which was again sucked dry. This was repeated once more with a further 25-ml portion of* Na_2CO_3 *solution. 25 ml of hot 2% w/v* NaCl *solution was then added to the residue in the steel beaker, and the suspension poured into the filter funnel. Another 25 ml of hot* NaCl *solution was used to rinse the beaker and this too was added to the filter funnel when it had sucked dry. The filtrate was made up to 500 ml and a 5-ml aliquot taken for the determination of silica by the usual colorimetric method using ammonium molybdate and reading the yellow color developed on a filter photometer.*

were required to bring the sample to temperature if "boiling" was to be avoided, and the total heating time was 2.5 hours. The volatile products were collected in a liquid nitrogen cooled trap. Loss in weight was determined, and the volatile products examined qualitatively.

Nitrogen sorption isotherms were determined in a volumetric system in the usual manner. Water adsorption isotherms to 94% of saturation at 25° C were determined gravimetrically using Worden quartz springs of 2 g maximum capacity and 100 mg/cm sensitivity. The water vapor pressure in the system was controlled by a liquid water reservoir maintained at constant temperatures between −19° and 25° C. The clay samples were brought to constant weight in the system by repeated sorption/evacuation cycles before determination of the isotherm was begun.

RESULTS AND DISCUSSION

1. *Analyses*

For convenience, the activated clays have been designated W-1, W-2, . . . , W-6, the wet activated series, with 0%, 10%, . . . , 50% acid, and D-1, D-2, . . . , D-6, the dry activated series, with comparable acid concentrations. Clays W-1 and D-1 constitute "blanks", and represent the products obtained by the leaching process in the absence of sulphuric acid. As mentioned earlier, clays D-7A and D-7B were the products of two and three consecutive 50% acid leaches, respectively.

The analyses of the activated clays are given in Table I, and the analyses of the wet activation leach liquors in Table II. To be comparative, these quantities must be reduced with reference to some invariant component to a common basis. It will be seen in Table II that the dissolution of silica during the wet activation process is less than 0.7% of the total silica, and can be regarded as negligible. Similarly, semiquantitative estimates of the silica removed from the clay by the dry activation process were of the same order of magnitude. The assumption can be made, therefore, that the silica content of the clays is a constant for each series, and the analyses can be expressed in terms of the "blanks", W-1 and D-1. The residual compositions calculated on this basis are recorded in Table III.

*Percentage of component remaining in the clay.
†Percentage of metal ions remaining in the clay.

Summations of the quantities of the various components found in the leach liquor and the clay residues are consistent within the limits of uncertainty in analysis and homogeneity of the clay samples.

The sulphate contents (Table III, column 2), particularly of the blanks and the dry activated clays, are abnormally large. Indeed, during the calcining of these clays, SO_2 as well as water was recovered in the gaseous products. In the montmorillonite deposit from which the raw clay was obtained, the clay strata are bounded by sulphide bearing deposits. It is generally accepted that the sulphates produced by natural oxidation of the sulphides and carried in solution into the clay deposits dissolve metal ions and produce, *in situ*, a semiactivated clay. Consequently an appreciable sulphate content in the raw clay is to be expected. The refluxing and washing operations which produced clays W-1 and D-1 might be expected to remove essentially all of the metal sulphates which might

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

be present with the exception of $CaSO_4$. Now if most of the sulphur in these clays is present as $CaSO_4$, appreciable quantities of SO_2 would not be produced on heating *in vacuo* at 600° C. It appears logical to propose that some sulphate ions are associated with the montmorillonite lattice itself, and this suggestion is substantiated by the relatively high sulphate content of clays W-7A and W-7B.

The natural leaching of these clays is responsible for the variation in composition from batch to batch. The difference in composition of clays W-1 and D-1 is unfortunate, but not significant in what follows.

Metal ions are removed by the activation process, but in these clays the fractions dissolved are not in proportion to the quantities present in the unactivated clays. Iron is removed to a much greater extent than aluminum or magnesium, while aluminum is the least removed of the three. It may be that the concentration of iron (and, to a lesser extent, magnesium) in the octahedral sites is greater near the surfaces of the particles than in the bulk of the crystal.

For a given acid dosage, the metal ions are removed to a greater extent by dry activation than by wet activation (Table III, column 6). However, a more notable variation in the two series is the greater "hydrated silica" content of the dry activated clays (Table III, column 7), even though the constitutional water content is consistently less than that of the wet activated clays. In view of the rather arbitrary nature of the quantity, it is rather doubtful that any structural argument explaining the difference could be supported.

The decolorizing capacities of the activated clays are recorded in Table IV. The results

are consistent with the conclusions drawn by Farnand and Peterson (17) based on the examination of a great number of activated clays obtained under a wide variety of experimental conditions: Dry activated clays produced with 0 to 35% acid are more efficient bleaching agents than are wet activated clays obtained with comparable acid dosages. Above 40% acid dosages, the capacity of the dry activated clays decreases and in the 35–50% region dry activated clays are inferior to wet activated clays. The maximum in decolorizing capacity of wet activated clays occurs at acid dosages in excess of 50%; nevertheless, a dry activated clay obtained with 20% acid is equivalent in capacity to a wet activated clay obtained with 30% acid.

2. Sorption Isotherms

Typical nitrogen sorption isotherms are reproduced in Fig. 1, and typical water sorption isotherms in Figs. 2 and 3.

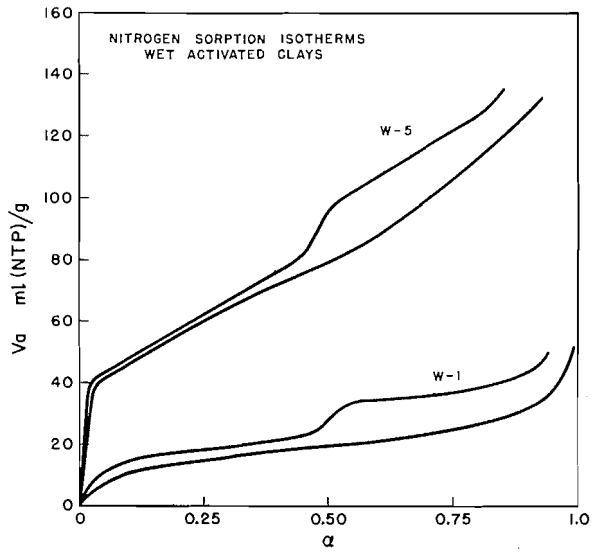

FIG. 1. Typical nitrogen sorption isotherms, wet activated clays.

The water isotherms are of characteristic form, although we could detect no inflections normally attributed to the completion of one and two water layers in the interlaminar region of the lattice. The curves were reproducible, although it should be reiterated that these isotherms were determined only after constant clay weight had been obtained by adsorption/evacuation cycles. The D-1 and W-1 isotherms are essentially identical. For strict comparison, the isotherms of the activated clays W-6 and D-6 should lie some 10% closer to the abscissa since the experimental data are expressed in terms of the product rather than the unactivated clay; nevertheless the decreased adsorption at low relative pressures and increased adsorption near saturation is quite evident. On the other hand, the adsorption capacity of the clay with respect to nitrogen is increased at all relative pressures by activation.

The hysteresis exhibited in the nitrogen isotherms is not uncommon among montmorillonites, but is not always observed. The "break" in the desorption loop was observed at relative pressures between 0.43 and 0.53 in all of the clays for which complete isotherms were obtained.

On calcining the clays at 600° C, the water isotherms are altered as shown in Fig. 4, and become quite similar in form to the nitrogen isotherms of the uncalcined clays. Since the calcined clays can no longer sorb water in the interlaminar regions, adsorption can occur only on surfaces which are also available for nitrogen adsorption, and the similarity in isotherms is to be expected. Presumably these isotherms are inherent in the water isotherms of the uncalcined clays, but are masked by the greater volumes adsorbed in the interlaminar spaces.

3. *B.E.T. Surface Areas*

The classical B.E.T. function has been applied to the desorption arms of the nitrogen and water isotherms as indicated in Fig. 5. The results are compiled in Tables V and VI. Again these data have been expressed in terms of the common denominators W-1 and D-1 on the assumption that the loss of SiO_2 from the lattice has been negligible.

A comparison of surface areas as a function of acid dosage is given in Fig. 6. Water surface areas decrease with increasing acid dosage more rapidly for the dry activated clays. The initial increase in nitrogen area is greater for the dry activated clays, but the

areas of the wet activated clays are greater at high acid dosage. Maximum areas are attained at 33% and >50% acid for the dry and wet procedures, respectively.

The decolorizing capacity of each series as a function of nitrogen area is illustrated in Fig. 7. For areas below 220 m^2/g the bleaching capacity appears to be a function of area alone; however, above this point the capacity of the dry activated clays decreases. The corresponding decrease in wet activated clay capacity occurs at ca. 360 m^2/g.

It has been observed (17) that decolorizing capacity is a function of adsorbed water content. In general, the capacity increases with increasing water content, with the upper limit dictated by the degree of frothing of the oil/clay mixture which can be tolerated during bleaching. One might reasonably assume that adsorption of color bodies occurs on the interlaminar faces of the clay, and that water is required to expand the lattice and facilitate penetration by the color groups. However, since the capacity is a function of the nitrogen surface area rather than the water surface area, the interlaminar areas appear to be relatively unimportant. It may be that the adsorbed water is responsible for a modification in the silicate surface which facilitates the chemisorption of the color groups in the oil.

The reduction in nitrogen surface areas on calcining is less than 30%, but water surface areas decrease from ca. 400 m^2/g to values equal to or less than the nitrogen areas. Insofar as comparison of the two activation processes are concerned, the calcined dry activated clays exhibit higher surface areas, particularly at intermediate acid dosages.

4. Surface Areas and Structure

On the basis of the analysis, the quasi-unit cell of clay W-1 contains

$$Si_8{}^{IV}(Al_{3.2}Fe_{0.3}Mg_{0.9})^{VI}O_{20}(OH)_4(SO_4)_{0.2}\,.$$

Assuming the dimensions of this cell are $5\times10\times10$ Å, the interlaminar area is approximately 410 m^2/g. The observed water surface area is 454 m^2/g, and the nitrogen area 60 m^2/g. According to Mooney, Keenan, and Wood, the interlaminar area is the difference in these two values, i.e. 393 m^2/g. In this argument it is implied that the external surface is indifferent to both nitrogen and water vapor, and the B.E.T. external surface areas are identical for both adsorbates.

The disintegration of the montmorillonite lattice on leaching can be considered in the following way. For the model clay particle illustrated in Fig. 8, we shall assume p silicate

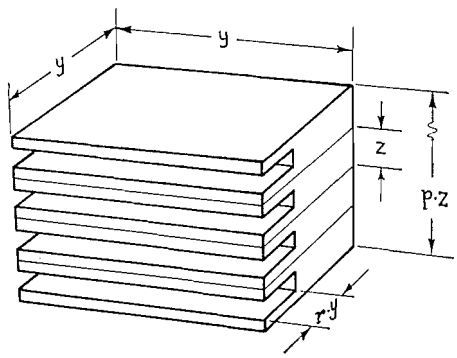

FIG. 8. Model activated montmorillonite particle.

laminae z Å thick, and y Å in length and width. If n is the number of such particles per gram of clay, the density, ρ, in grams per cubic angstrom, is given by

$$\rho = 1/npzy^2. \qquad [1]$$

When the lattice is attacked by acid, metal ions in the intralaminar octahedral sites are removed. This can be represented in an idealized manner as indicated in Fig. 8; the increase in nitrogen area per gram, ΔA_N, is given by

$$\Delta A_N = nmpry^2 \qquad [2]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

in which r is the fraction of metal ions removed from the lattice, and m is the number of layers of nitrogen which can be accommodated in the intralaminar pores, and can have the values $1 \leqslant m \leqslant 2$.

Substituting for n in eq. 2 in terms of eq. 1,

$$\Delta A_N = mr/\rho z (\text{Å}^2/\text{g}). \quad [3]$$

Assuming a lattice dimension z of 10 Å, and a density of 2.5 g/cc,

$$\Delta A_N = 400mr \ (\text{m}^2/\text{g}). \quad [4]$$

This expression can be obtained simply by extension of the interlaminar water area argument given earlier, but the development from the model shows that the increase in nitrogen area is quite independent of particle size and shape. Unfortunately it is not likely that m will be independent of r. For low values of r, that is, when the lattice is not seriously attacked, the intralaminar pores will likely admit only one layer of nitrogen which will be adsorbed by both upper and lower silica surfaces. For intermediate values of r, the silica layers may be distorted to such an extent that almost two layers can be admitted. For higher values of r, the silica lattice may be expected to collapse on itself, and m will decrease. When the metal ions have been removed to such an extent that the montmorillonite lattice can not be considered to exist, the model and the equation will not apply.

There is reason to suspect that clays W-1 and D-1 have already been subjected to natural leaching processes, because of their high sulphate content and high nitrogen surface areas. Most natural montmorillonites exhibit nitrogen areas of 10 to 30 m²/g, although some hydrogen montmorillonites may have areas of 40 m²/g. Assuming that clays W-1 and D-1 would exhibit areas of 30 m²/g had natural leaching not occurred, and assuming m is unity, then by eq. 4, r equals 0.075, and 0.925 of metal ions are still retained in the lattice. The fraction of metal ions remaining in the artificially activated clays can then be obtained directly using the analyses in Table III, column 6, and the increase in area to be expected calculated using eq. 4. The results are given in Table VII.

TABLE VII

Observed and calculated nitrogen area increments equation 4
(areas in m²/g)
Assumption: r for W-1, D-1 = 0.075

Clay No.	$1-r$	r	$\Delta A_{N\ calc}$	$\Delta A_{N\ obs}$	Clay No.	$1-r$	r	$\Delta A_{N\ calc}$	$\Delta A_{N\ obs}$
W-1	0.925	0.075	30	30	D-1	0.925	0.075	30	30
W-2	0.86	0.14	56	60	D-2	0.875	0.125	50	67
W-3	0.85	0.15	60	102	D-3	0.75	0.25	100	141
W-4	0.80	0.20	80	158	D-4	0.715	0.285	114	163
W-5	0.74	0.26	104	170	D-5	0.52	0.48	192	166
W-6	0.61	0.39	156	200	D-6	0.44	0.56	224	167
W-7A	0.30	0.70	280	246					
W-7B	0.12	0.88	350	223					

In spite of the simplicity of the model, the agreement in observed and calculated nitrogen area increments is satisfactory. In no instance is ΔA_N observed greater than twice ΔA_N calculated, and consequently the discrepancies are within the limits of m. For the wet activated clays, m attains a maximum value of 1.98 at W-4 (30% acid, 20% ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

removal); beyond this point the silicate layers appear to collapse reducing the value of m. For clays W-7A and W-7B the clay lattice is destroyed to the extent that the equation is no longer tenable. In the dry activated series, the maximum value of m is only 1.4, and the collapse of the lattice begins at slightly lower acid concentrations. For clay D-6 (50% acid) the model is not valid.

As metal ions are removed, the water sorbed in the interlaminar spaces will decrease, particularly if they are associated with the exchangeable ions in the formation of hydrates. The interlaminar area can then be estimated by multiplying the idealized interlaminar area, 410 m²/g, by the factor $(1-r)$. The total water surface area should then be the sum of this area plus the nitrogen surface area of the sample. The results of the approximation are given in Table VIII.

TABLE VIII

Observed and calculated water areas
(areas in m²/g)

Clay No.	$410(1-r)$	A_{N_2}	$A_{H_2O\ calc}$	$A_{H_2O\ obs}$	Clay No.	$410(1-r)$	A_{N_2}	$A_{H_2O\ calc}$	$A_{H_2O\ obs}$
W-1	380	60	440	454	D-1	380	61	441	444
W-2	352	90	442	—	D-2	358	107	465	415
W-3	349	132	481	426	D-3	307	171	478	363
W-4	328	188	516	451	D-4	293	193	486	352
W-5	304	201	505	—	D-5	213	196	409	—
W-6	250	231	481	402	D-6	180	197	377	290
W-7A	123	276	399	223					
W-7B	48	253	301	164					

With the exception of W-1 and D-1, the agreement is poor, particularly for heavily leached samples. The major source of error may lie in the equation of water and nitrogen external surface areas. For clays W-7A, W-7B, and the calcined clays W-5C, D-3C, and D-5C, the observed total water areas are less than the observed nitrogen areas. In all of these samples the interlaminar adsorption will be negligible; hence it appears that the external water areas are less than the nitrogen areas by a factor of 0.67 to 0.80. For clays with relatively low nitrogen areas the correction is small; but the subtraction of nitrogen areas from total water areas as a measure of the interlaminar area of activated clays is not generally valid unless some correction factor is introduced.

5. Summary

1. In this particular montmorillonite, metal ions in octahedral sites are not removed by acid activation in the proportions in which they are originally present. On both wet and dry activation, the rates of removal are in the order Fe > Mg > Al.

2. At any given acid dosage, the extent of removal of metal ions, the formation of "hydrated silica", and the general degradation of the lattice is greater by the dry process than by the wet process.

3. The bleaching capacity with respect to mineral oil is a function of nitrogen surface area up to 220 m²/g for dry activated clays, and 360 m²/g for wet activated clays.

4. The nitrogen areas and the bleaching capacities of clays activated with 30% acid by the dry process are superior to the analogous wet activated clays.

5. On calcining, water isotherms become similar in form to nitrogen isotherms. Nitrogen areas are decreased slightly, water surface areas, drastically. At comparable acid dosages

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

surface areas of calcined dry activated clays are larger than the areas of calcined wet activated clays.

6. External silicate surfaces do not appear to give equivalent B.E.T. nitrogen and water surface areas.

7. According to the model presented, the montmorillonite lattice is essentially intact even after removal of 25% of the metal ions. With greater removal the residual silica layers collapse, and above 50% removal, the product no longer behaves as montmorillonite towards the adsorption of nitrogen and water vapor.

ACKNOWLEDGMENTS

We are indebted to Mr. A. E. McIlhinney and Mr. L. Pageau for assistance in the preparation of the dry activated clays, and for the determination of bleaching capacities.

NOTES

MOLECULAR COMPLEXES DERIVED FROM 1,3,6,8-TETRANITROPYRENE

P. M. G. BAVIN*

The low solubility and particularly the ready availability of 1,3,6,8-tetranitropyrene (I) (1) suggested its use as a complexing agent for the isolation of traces of polycyclic hydrocarbons. Molecular complexes are indeed formed (Table I) but are valueless for

TABLE I

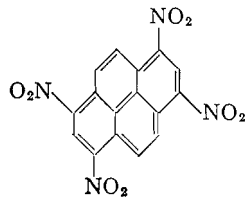
[a]Xylene. [b]Acetic acid. [c]M.p. 222–224° (decomp.), rapid heating in sealed capillary. [d]M.p. 262–264° (decomp.), rapid heating in sealed capillary. [e]Crystals decomposed by washing with fresh solvent.

purposes of characterization or isolation (except, perhaps, in the cases of benzidine and 4,4″-diamino-*p*-terphenyl), as their isolation in a crystalline state requires the presence of a large excess of the hydrocarbon. This may be due to the very low solubility of the tetranitropyrene which, in solution, is in equilibrium with hydrocarbon and complex:



$$\text{tetranitropyrene} + \text{hydrocarbon} \rightleftharpoons \text{complex}.$$

Whether complex or tetranitropyrene crystallizes from a given system depends on their relative solubilities and the position of the equilibrium.

Some of the crystalline complexes are decomposed by washing with fresh solvent. All of them can be recrystallized only in the presence of added hydrocarbon so that the microanalyses in Table I refer to crude preparations. Only naphthalene and indole form 2:1 complexes, the others being 1:1.

The complexes decompose when heated, only those of phenanthrene and 9,10-dimethylphenanthrene melting reasonably sharply. Indole and naphthalene sublime from their complexes below 100°; those of pyrene, anthracene, and benz[a]anthracene decompose above 320°.

I

EXPERIMENTAL

Microanalyses are by Drs. Weiler and Strauss of Oxford.

Reagent

1,3,6,8-Tetranitropyrene was prepared as described in the literature (1). The hydrocarbons, etc. were mostly available samples but the author is indebted to I. Ungar for a very pure sample of carbazole and to Dr. D. Lewis for the 4,4″-diamino-*p*-terphenyl.

Preparation of the Complexes

Approximately 0.1 g tetranitropyrene was dissolved in the minimum of boiling xylene (occasionally acetic acid was used) and the volume increased by one-fourth to prevent crystallization. The hydrocarbon was added and the solution decanted from any impurities. The complexes slowly separated on cooling and were collected before crystallization of tetranitropyrene occurred. The crystals were sucked free of mother liquor, washed with fresh solvent (unless this decomposed them), and dried at 100° and 1–2 mm (40° in the cases of naphthalene and indole).

Some idea of the difficulties encountered in obtaining pure crystalline complexes may be gathered from the fact that almost 20 g naphthalene was necessary to obtain 0.1 g complex whereas little more than the theoretical amount of benzidine gave a good yield of complex.

Complex formation is largely dependent on the electron acceptor properties of the tetranitropyrene and the donor properties of the hydrocarbons. Consequently benzidine, which is a much stronger base than naphthalene, will form complexes more readily than the latter and should be more stable. The solubilities of the complexes will be determined primarily by their ionic character. Complexes with the amines would have more ionic character than those with polycyclic hydrocarbons and would therefore be less soluble in solvents such as xylene.

O—H STRETCHING FREQUENCIES FOR SOME PHENOLS AND THEIR RELATIONSHIPS TO THE THERMODYNAMICS OF IONIZATION

William J. Canady

The O—H stretching frequencies of a large number of phenols have been studied by Ingraham, Corse, Bailey, and Stitt (1). The results were correlated with the Hammett

sigma values for these compounds. Some phenols were also studied by Stone and Thompson (2), Flett (3), and Brown (4).

Goulden (5) studied the O—H stretching frequencies of a large number of acid substances and found that they could be correlated with the pK values of the compounds in aqueous solution. The results showed that separate plots were obtained, depending upon the type of acid under consideration.

Bavin and Canady (6) demonstrated the same type of behavior with a number of phenols. It was shown that the failure to obtain a single plot with a number of substituted benzoic acids could not be ascribed to variations in electrostatic contributions, but was probably due to structural factors. No correlation was attempted with ortho constituents which could bring about appreciable hydrogen bonding.

Since the pK of an acid, and hence the free energy of ionization, may be related to the O—H stretching frequency, the question arises as to whether any similar relationships may exist for the changes in heat content and entropy of ionization.

At the time of the last-mentioned work, insufficient precise data were available to test this possibility. Recently, however, precise measurements of ΔH and ΔS for all of the mono- and dimethyl-substituted phenols have become available (7).

Table I shows the values for ΔF, ΔH, and ΔS as well as the O—H stretching frequencies for this series of phenols.

TABLE I

	Compound	ΔF (kcal)	ΔH (kcal)	ΔS cal/mole deg	Stretching frequency, cm^{-1}
1	Phenol	13.63	5.60	−27.0	3600
2	*d*-Cresol	14.03	7.13	−23.2	3606
3	*m*-Cresol	13.76	4.90	−30.7	3605
4	*p*-Cresol	14.00	4.23	−32.8	3604
5	2,3-Xylenol	14.14	6.61	−25.3	3608
6	2,4-Xylenol	14.29	7.68	−22.1	3610
7	2,5-Xylenol	13.90	6.22	−25.7	3606
8	2,6-Xylenol	14.46	4.95	−31.9	3618
9	3,4-Xylenol	13.86	8.24	−18.9	3605
10	3,5-Xylenol	13.67	7.51	−20.7	3602

The O—H stretching frequencies for the phenols are those of Bavin and Canady (6) and were measured in carbon disulphide. The instrument used was a Beckman DK-2. Since the frequencies measured are close to the cutoff point of the prism, resolution is very good.

The thermodynamical quantities are taken from the work of Papeé, Canady, Zawidzki, and Laidler (7).

The plot of stretching frequency vs. ΔF of ionization for phenol and methyl-substituted phenols can be seen in Fig. 1A. It may be noted that reasonably linear results are obtained.

Figures 1B and 1C show the O—H stretching frequencies plotted against ΔH and ΔS respectively for the phenols.

Figures 1B and 1C indicate that no particular relationship between stretching frequency and the heat and entropy of ionization can be demonstrated.

These findings tend to support the contention of Laidler (8), who has suggested that while the free energies of ionization of a particular series may be related to the vibrational frequencies involved, the effects on ΔH and ΔS are masked by solute–solvent interactions.

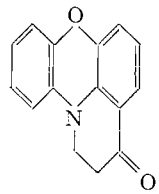
THE SYNTHESIS OF 10-SUBSTITUTED PHENOXAZINES

GERASSIMOS FRANGATOS, GEZA KOHAN, AND FRANCIS L. CHUBB



The recent publication by Muller, Buu Hoi, and Rips (1) describing the cyanoethylation of phenoxazine, and the issuing of a Belgian patent (2) describing the preparation of a series of 10-dialkylaminoalkyl phenoxazines, prompt us to report some work on the chemistry of phenoxazine, which has been in progress in these laboratories for some time. Dialkylaminoalkyl chlorides reacted with phenoxazine in the presence of freshly prepared sodamide to yield a series of 10-dialkylaminoalkyl phenoxazines which are listed in Table I. Some differences in the physical constants of these compounds from those reported by the Belgian workers are noted.

The addition of phenoxazine to acrylonitrile (1) and ethyl acrylate yielded 3-(10-phenoxazinyl)propionitrile (I) and ethyl 3-(10-phenoxazinyl)propionate (II) respectively and they were both hydrolyzed to 3-(10-phenoxazinyl)propionic acid (III). Lithium aluminum hydride reduction of II and III yielded 10-(3-hydroxypropyl)phenoxazine (IV). Attempts to prepare the corresponding chloride by treatment of IV with either thionyl chloride or phosphorus pentachloride only resulted in extensive polymerization. However, IV reacted smoothly with phosphorus tribromide to yield 10-(3-bromopropyl)phenoxazine (V). When V was allowed to react with 1-methylpiperazine, 10-(3-(3-methyl-1-piperazinyl)propyl)phenoxazine (VI) was formed.

3-(10-Phenoxazinyl)propionic acid (III) underwent cyclization with phosphorus pentoxide to give a yellow ketone, assumed to be 2,3-dihydro-1H-pyrido(3,2,1-*kl*) phenoxazine-3-one (VII), m.p. 104–105°. Muller, Buu Hoi, and Rips have reported a melting point of 144° for this compound.

VII

EXPERIMENTAL

10-(3-Dimethylaminopropyl)phenoxazine

The procedure for the synthesis of 10-(3-dimethylaminopropyl)phenoxazine is a general one and has been followed for the synthesis of all 10-dialkylaminoalkyl phenoxazines listed in Table I.

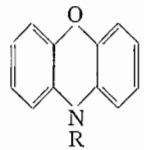
A suspension of sodamide in 100 ml of xylene was prepared from 100 ml of liquid ammonia and 3.04 g of sodium according to the procedure of Hauser, Swamer, and Adams (3). To this stirred and refluxing mixture a solution of 22 g of phenoxazine in 150 ml of xylene was slowly added. During the addition the reaction mixture turned a greenish color. It was stirred and refluxed for another hour. To this mixture a solution of dimethylaminopropyl chloride (obtained from 19 g of the corresponding hydrochloride treated with 18 g of sodium hydroxide in 66 ml of H_2O and extracted with 75 ml of xylene and dried over sodium sulphate) was added. The reaction mixture thus obtained was stirred and refluxed for 6 hours. After this mixture was cooled and filtered, the xylene was distilled under reduced pressure. The oily residue was distilled *in vacuo*. Twenty-six grams (80.5%) of a yellow oil was obtained distilling at 178°/2 mm.

Addition of Phenoxazine to Ethyl Acrylate or Acrylonitrile

To a stirred and ice-cooled mixture of 20 g phenoxazine and 33 ml ethyl acrylate (or 50 ml acrylonitrile), 2 ml of 35% methanolic benzyltrimethylammonium hydroxide was added dropwise. After the addition was completed the reaction was heated overnight (or 1 hour) on the steam bath. The excess of ethyl acrylate (or acrylonitrile) was distilled under reduced pressure. The residual ethyl 3-(10-phenoxazinyl)propionate (II) was distilled *in vacuo* to yield 20.6 g (66.5%), b.p. 187°/1 mm.

The residual 3-(10-phenoxazinyl)propionitrile was recrystallized from aqueous ethanol to yield 19.5 g (72.9%), m.p. 121–122°.

3-(10-Phenoxazinyl)propionic Acid (III)



(*a*) A mixture of 4 g of 3-(10-phenoxazinyl)propionitrile, 4 g sodium hydroxide, 12 ml of water, and 40 ml of methanol was refluxed for 15 hours. The hydrolysis product was poured into ice water, acidified with dilute hydrochloric acid, filtered, and recrystallized from aqueous ethanol. 2.3 g of III was obtained, m.p. 136–138°.

(*b*) Ethyl-3-(10-phenoxazinyl)propionate (14.15 g, 0.05 mole) was dissolved in 300 ml of 10% ethanolic potassium hydroxide and refluxed for 2 hours. To this mixture after being cooled, 300 ml of water was added. The alcohol (300 ml) was distilled and the

TABLE I

10-Substituted phenoxazines 

No.	R	Yield %	B.p.	M.p.	Carbon		Hydrogen		Nitrogen	
					Calc.	Found	Calc.	Found	Calc.	Found
1	$(H_3C)_2NCH_2CH_2$	60.2	168°/2.5 mm[a]		75.54	75.75	7.08	7.01	11.02	11.11
2	$(H_3C)_2NCH_2CH_2CH_2$	80.5	178°/2 mm		76.07	75.80	7.46	7.75	10.44	10.59
3	$(H_5C_2)_2NCH_2CH_2$ hydrochloride	54.8		241–242°[b]	67.79	67.72	7.24	6.88	8.81	8.88
4	$(H_3C)_2NCHCH_2$ $\quad\quad\quad

remaining mixture was acidified with 6 *N* hydrochloric acid. 3-(10-Phenoxazinyl)propionic acid (III) precipitated and was recrystallized from aqueous ethanol; 7.3 g (57%) of the acid (III) was obtained melting at 137–138°.

10-(3-Hydroxypropyl)phenoxazine (IV)

A solution of 14 g of ethyl 3-(10-phenoxazinyl)propionate in 100 ml of ether was added slowly to a mixture of lithium aluminum hydride (2 g) in 100 ml of ether at such a rate as to maintain gentle refluxing. The reaction mixture was stirred and refluxed for 45 minutes. The excess hydride was destroyed with 2 ml of water. The reaction mixture was poured into ice water, acidified cautiously with 2 *N* sulphuric acid, and the ether layer was separated. The aqueous layer was saturated with ammonium sulphate and further extracted with ether. The combined ether extracts were washed with water and dried over sodium sulphate. The solvent was distilled and the residue recrystallized from a mixture of benzene ligroin. Eight grams (65.5%) of IV was obtained, m.p. 68°. 10-(3-Hydroxypropyl)phenoxazine was also obtained in a similar yield when 3-(10-phenoxazinyl)propionic acid (III) was reduced by lithium aluminum hydride in ether according to the procedure of Dahlbom (4) for the phenothiazine analogue.

10-(3-Bromopropyl)phenoxazine (V)

Freshly redistilled phosphorus tribromide (4.2 ml) was added to 15 g of 10-(3-hydroxypropyl)phenoxazine with cooling. The reaction mixture was heated on the steam bath for 1 hour and then poured onto crushed ice. The bromide (V) separated as an oil which solidified on standing overnight. It was filtered, washed with water on the filter, and after recrystallization from ethanol melted at 55–56°. The yield was 9 g (48%).

10-(3-(4-Methyl-1-piperazinyl)propyl)phenoxazine (VI)

A mixture of 9 g of 10-(3-bromopropyl)phenoxazine and 18 ml of 1-methylpiperazine was heated on the steam bath for 4 hours. Eighty milliliters of 10% sodium hydroxide solution was added to the reaction mixture which was then thoroughly extracted with ether. The ether extracts were combined and dried over Na_2SO_4. The ether was distilled and the residue was recrystallized from ligroin. Seven grams (73.6%) of VI was obtained, m.p. 89–91°.

2,3-Dihydro-1H-pyrido(3,2,1-kl)phenoxazine-3-one

The procedure of Smith (5) and Buu Hoi (6) for the phenothiazine and phenoselenazine analogue was followed in principle.

Fifty grams of phosphorus pentoxide was suspended in 200 ml of benzene and 10 g of 3-(10-phenoxazinyl)propionic acid was added to the stirred and heated reaction mixture. The mixture was stirred and refluxed for 1 hour and then left at room temperature overnight. It was filtered and the material remaining on the filter was washed thoroughly with an additional quantity (100 ml) of benzene. The benzene was removed from the filtrate by distillation and the residue was recrystallized from a minimum amount of ethanol; 4.5 g (48.4%) of a yellow ketone was obtained, m.p. 104°. Anal. for $C_{15}H_{11}NO_2$. Calc.: C, 75.95; H, 4.64; N, 5.91%. Found: C, 75.50; H, 4.68; N, 5.90%.

The corresponding semicarbazone was prepared and melted at 232°. Anal. for $C_{16}H_{14}N_4O_2$. Calc.: C, 65.3; H, 4.76%. Found: C, 65.13; H; 4.92%.

FREE RADICAL MECHANISMS FOR INHIBITED ORGANIC DECOMPOSITIONS[1]

B. W. WOJCIECHOWSKI AND K. J. LAIDLER

ABSTRACT

It is suggested that organic decompositions that are fully inhibited by substances such as nitric oxide and propylene proceed not by molecular mechanisms, but by special types of free radical mechanisms in which the inhibitor is involved in both initiation and termination. In the case of nitric oxide inhibition, initiation is considered to be by the abstraction of a hydrogen atom by NO, while termination involves reaction between the most plentiful chain carrier and either HNO or NO, depending upon whether or not H is a chain carrier. Specific mechanisms are proposed for the decompositions of paraffins, ethers, and aldehydes, when inhibited by nitric oxide, and the resulting rate equations are shown to be consistent with the behavior observed experimentally. It is shown for the ethane decomposition that the same limiting rate is obtained for any inhibitor that can become involved in the same type of mechanism.

INTRODUCTION

In spite of the very considerable amount of work that has been done on the inhibition, by substances such as nitric oxide and propylene, of gaseous organic decompositions, the nature of the mechanisms still remains something of a problem. Certain of the evidence,* such as that, in many cases, the inhibition leads to constant limiting rates and that the same limiting rates are given by different inhibitors, appears to point to the conclusion that the reactions are molecular in nature. This position has in fact been taken by Hinshelwood and his co-workers, and Stubbs and Hinshelwood (2, 3) have reviewed the evidence leading to this conclusion. On the other hand, there are certain characteristics of the fully inhibited reactions that seem to be incompatible with the view that a purely molecular mechanism is involved. These are in brief as follows:

(1) It has been found by Voevodsky and Poltorak (4) and by Rice and co-workers (5, 6) that hydrogen–deuterium mixing reactions take place as rapidly (relative to the decomposition rates) in certain fully inhibited reactions as they do in the uninhibited reactions.

(2) The fully inhibited reactions frequently exhibit a well-defined induction period, during which the pressure–time curves are S-shaped (7).

(3) The rates of the fully inhibited reactions are sometimes *decreased* by increasing the surface:volume ratio (8).

It would seem to be quite impossible to reconcile these facts with the hypothesis of a simple molecular mechanism, and it is therefore necessary to develop mechanisms of the free radical type that will give rise to limiting rates at high inhibitor concentrations, and will explain the fact that different inhibitors give the same limiting rates.

A suggestion to avoid these difficulties has recently been put forward by Voevodsky

[1]*Manuscript received February 25, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.
**The main experimental results referred to in this paper are reviewed in Steacie's book (1).*

(9), who has interpreted the fully inhibited decompositions of paraffin hydrocarbons in terms of the idea that initiation and termination both take place on the surface of the vessel. It is proposed by Voevodsky that the initiation reactions are caused by irreversible and reversible surface processes, of which the former can be suppressed by the inhibitors. Full inhibition corresponds to complete coverage of the active centers on the wall. Voevodsky proposes no specific mechanisms, and his suggestion is subject to one serious difficulty: the amount of nitric oxide required to give complete inhibition should depend on the surface:volume ratio, and this is certainly not the case. Also, the S-shaped pressure–time curves, implying abnormally small initial rates, seem inconsistent with Voevodsky's suggestion.

The object of the present paper is to propose specific free radical mechanisms, involving the participation of inhibitor molecules, that appear to be consistent with all of the facts. The essence of our proposals is that in the presence of inhibitors the main initiating processes are hydrogen-abstraction reactions such as

$$C_2H_6 + NO \rightarrow C_2H_5 + HNO.$$

Chain termination is suggested as sometimes involving reactions such as

$$C_2H_5 + HNO \rightarrow C_2H_6 + NO,$$

but when hydrogen atoms are not the chain carriers chain termination is regarded as involving NO rather than HNO. Specific reaction mechanisms will be proposed for various types of reactions, including hydrocarbon decompositions and the decompositions of aldehydes and ethers. Additional experimental support for our proposals is being obtained, and the details will be published later.

THE DECOMPOSITION OF ETHANE

The thermal decomposition of ethane is a typical example of the decomposition of a paraffin hydrocarbon; the mechanism proposed for this case can readily be modified for the higher paraffins.

The mechanism proposed is

$$C_2H_6 + NO \xrightarrow{k_1} C_2H_5 + HNO,$$

$$C_2H_5 \xrightarrow{k_2} C_2H_4 + H,$$

$$H + C_2H_6 \xrightarrow{k_3} C_2H_5 + H_2,$$

$$H + NO \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} HNO,$$

$$C_2H_5 + HNO \xrightarrow{k_{-1}} C_2H_6 + NO.$$

This scheme leads to the following expression for the rate

$$[1] \qquad v = (k_1k_2k_3k_{-4}/k_{-1}k_4)^{1/2}[C_2H_6].$$

The mechanism is seen to lead to first-order kinetics, as found experimentally (7, 10, 11, 12, 13).

Several comments may be made about this mechanism. Our estimate of the dissociation energy of HNO into H + NO is 44 kcal and this leads to an activation energy of 56 kcal for the initial reaction. The over-all activation energy is then found to be approximately

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[2] $$E = \tfrac{1}{2}(E_1+E_2+E_3+E_{-4}-E_{-1}-E_4),$$

[3] $$= \tfrac{1}{2}(56+40+10+44-0-0) = 75 \text{ kcal},$$

which is close to the experimental value (74–77 kcal). Using these values it is found that with about 10% of nitric oxide the rate of the initiation reaction is appreciably greater than that of the splitting of ethane into two methyl radicals, so that in the presence of excess nitric oxide the latter reaction may be neglected. The fully inhibited reaction therefore occurs largely by the mechanism proposed above, and the rate is seen to be independent of the nitric oxide concentration. At lower concentrations of nitric oxide the two mechanisms occur at comparable rates and inhibition is only partial. The steady-state equation then involves the solution of a cubic equation, and a simple expression for the rate of the partially inhibited reaction cannot be obtained.

As will be discussed in more detail in a separate paper (13), the NO-inhibited decomposition of ethane has an S-shaped pressure–time curve. The initial rates are found to exhibit 3/2-order kinetics, and this can be explained by taking the chain-ending step to be

$$H + HNO \xrightarrow{k_6} H_2 + NO.$$

The rate equation is now

[4] $$v = k_3(k_1k_{-4}/k_4k_6)^{1/2}[C_2H_6]^{3/2}.$$

In general, termination involving reaction between HNO and a μ radical (one undergoing first-order reactions) leads to first-order kinetics, while the reaction of HNO with a β radical (one undergoing second-order reactions) leads to kinetics of order 3/2. At the very beginning of the inhibited reaction H atoms are more plentiful than C_2H_5 radicals, but as small amounts of ethylene accumulate this situation is reversed as a result of the reaction

$$C_2H_4 + H \rightarrow C_2H_5;$$

the main chain-ending step, therefore, changes in the manner indicated.

When the ethane decomposition is partially inhibited by nitric oxide the degree of inhibition is found to be less at higher ethane concentrations (10, 11). This effect is attributed to the fact that nitric oxide competes with ethane for hydrogen atoms. It is significant that this effect is not found with the ethers for which, as discussed below, chain termination is believed to involve NO and not HNO.

The fact that propylene and other inhibitors inhibit to exactly the same limiting extent as NO is readily explained in terms of equation [1]. It is postulated that in propylene inhibition the allyl radicals (produced in the decomposition of propylene) play the same role as NO and initiate chains according to the reaction

$$C_2H_6 + C_3H_5 \rightarrow C_2H_5 + C_3H_6.$$

Propylene itself plays the same role as HNO, and terminates by the reaction

$$C_2H_5 + C_3H_6 \rightarrow C_2H_6 + C_3H_5.$$

In equation [1] the rate constants involving the inhibitor are k_1, k_{-1}, k_4, and k_{-4}, and they appear in the ratio

$$k_1/k_{-1} \cdot k_{-4}/k_4.$$

This ratio is the equilibrium constant for the reaction

$$C_2H_6 \rightleftharpoons C_2H_5 + H$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and since this reaction does not involve the inhibitor the limiting rate will be the same for all inhibitors capable of inhibiting by this type of mechanism. The result that more propylene is required to give the same inhibition as produced by NO is attributed to the fact that NO is more plentiful than allyl radicals.

THE DECOMPOSITION OF METHANE

The decomposition of methane offers an interesting contrast to that of ethane, since both of the chain-propagating reactions are of the second order. The chain carriers are H and CH_3, and one obtains 3/2-order kinetics whether one assumes the chain termination to involve $CH_3 + HNO$ or $H + HNO$. The former is preferred since the methyl radical concentration is probably usually higher than the concentration of hydrogen atoms. The mechanism to which we are therefore led is as follows:

$$CH_4 + NO \xrightarrow{k_1} CH_3 + HNO$$

$$CH_3 + CH_4 \xrightarrow{k_2} C_2H_6 + H$$

$$H + CH_4 \xrightarrow{k_3} CH_3 + H_2$$

$$H + NO \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} HNO$$

$$CH_3 + HNO \xrightarrow{k_{-1}} CH_4 + NO$$

The expression for the limiting rate is

$$v = (k_1k_2k_3k_{-4}/k_{-1}k_4)^{1/2}[CH_4]^{3/2}. \quad [5]$$

The conclusion that the order is 3/2 is consistent with the experimental results (11).

THE DECOMPOSITION OF ETHERS

In the reactions discussed above hydrogen atoms were involved in chain-propagating steps. In ether decompositions, on the other hand, this is not the case; the chain-propagating reactions in the case of dimethyl ether are probably

$$CH_3OCH_2 \rightarrow CH_3 + CH_2O$$

and

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_3OCH_2.$$

In view of this the concentration of HNO is very small, and the participation of HNO in chain termination is therefore unlikely. Our suggestion is that in these reactions chain termination involves nitric oxide itself, reacting with whichever radical is present in greater concentration; in the ether decomposition these are the μ radicals. The mechanism to which we are led is therefore as follows:

$$CH_3OCH_3 + NO \xrightarrow{k_1} CH_3OCH_2 + HNO$$

$$CH_3OCH_2 \xrightarrow{k_2} CH_3 + CH_2O$$

$$CH_3 + CH_3OCH_3 \xrightarrow{k_3} CH_4 + CH_2OCH_3$$

$$HNO \xrightarrow{k_4} H + NO$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

$$H + CH_3OCH_3 \xrightarrow{k_5} H_2 + CH_3OCH_2$$

$$CH_3OCH_2 + NO \xrightarrow{k_6} CH_3OCH_2NO$$

Application of the steady-state treatment gives rise to the rate equation

$$v = (2k_1k_2/k_6)[CH_3OCH_3]. \quad [6]$$

The result that the reaction is of the first order is in general agreement with experiment, although some complications certainly exist (14, 15).

The proposed mechanism for the diethyl ether decomposition is similar, as follows:

$$C_2H_5OC_2H_5 + NO \xrightarrow{k_1} C_2H_5OC_2H_4 + HNO$$

$$C_2H_5OC_2H_4 \xrightarrow{k_2} C_2H_5O + C_2H_4$$

$$C_2H_5O \xrightarrow{k_3} CH_3 + CH_2O$$

$$CH_3 + C_2H_5OC_2H_5 \xrightarrow{k_4} CH_4 + C_2H_5OC_2H_4$$

$$HNO \xrightarrow{k_5} H + NO$$

$$H + C_2H_5OC_2H_5 \xrightarrow{k_6} H_2 + C_2H_5OC_2H_4$$

$$C_2H_5OC_2H_4 + NO \xrightarrow{k_7} C_2H_5OC_2H_4NO$$

The rate equation is now

$$v = (2k_1k_2/k_7)[C_2H_5OC_2H_5] \quad [7]$$

and the order is again the first, as found experimentally (16).

It is significant that in these ether decompositions the nitric oxide is in no way in competition with the ether molecules themselves. The nitric oxide reacts with a μ radical, and the situation is to be contrasted with that in the case of ethane where nitric oxide competes with C_2H_6 for reaction with hydrogen atoms. In the ether decompositions the degree of inhibition produced by a given nitric oxide concentration is thus independent of the amount of ether, a prediction that is consistent with experiment.

In contrast to the situation with methane and ethane (and by analogy with the higher paraffins), the mechanism proposed for the ethers does not lead to the general conclusion that the fully inhibited rate should be the same for all inhibitors. Smith and Hinshelwood (16) and Freeman (15) have obtained results that tend to show that the same rates are obtained with both nitric oxide and propylene and this being so it must be assumed, if our mechanisms are correct, that the agreement of rates is fortuitous. It should, however, be pointed out that in the case of the ether decompositions there does remain a possibility that the fully inhibited reactions are molecular processes, since no isotopic exchange experiments have been carried out on these reactions.

THE DECOMPOSITION OF ACETALDEHYDE

The acetaldehyde decomposition differs from the hydrocarbon decompositions, and is similar to the ether decompositions in that hydrogen atoms are not chain carriers. Chain termination will therefore involve NO rather than HNO. The chain carriers are CH_3 and CH_3CO, of which the former are in excess; it is therefore postulated that the chain-ending step is reaction between CH_3 (a β radical) and NO.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The mechanism to which we are led is therefore:

$$CH_3CHO + NO \xrightarrow{k_1} CH_3CO + HNO,$$

$$CH_3CO \xrightarrow{k_2} CH_3 + CO,$$

$$CH_3 + CH_3CHO \xrightarrow{k_3} CH_4 + CH_3CO,$$

$$HNO \xrightarrow{k_4} H + NO,$$

$$H + CH_3CHO \xrightarrow{k_5} H_2 + CH_3CO,$$

$$CH_3 + NO \xrightarrow{k_6} CH_3NO.$$

The rate corresponding to this mechanism is

$$[8] \qquad v = (2k_1k_3/k_6)[CH_3CHO]^2 + 2k_1[CH_3CHO]\,[NO].$$

This rate expression, as in previous cases, corresponds to the rate when there is a sufficient excess of nitric oxide: much more complicated expressions result if the uninhibited initiation step is included also. The mechanism in this case leads to initial inhibition, with acceleration at higher nitric oxide concentrations as the second term in the rate equation becomes predominant. This is in fact the behavior observed experimentally (16). At moderate concentrations of nitric oxide the first term will predominate, and the kinetics should therefore be of the second order, as is found experimentally (16).

THE DECOMPOSITION OF ACETONE

The nitric oxide inhibited decomposition of acetone is very similar to that of acetaldehyde (there is again catalysis at high concentrations) and a similar mechanism is therefore probably involved.

$$CH_3COCH_3 + NO \xrightarrow{k_1} CH_3COCH_2 + HNO$$

$$CH_3COCH_2 \xrightarrow{k_2} CH_3 + CH_2CO$$

$$CH_3 + CH_3COCH_3 \xrightarrow{k_3} CH_4 + CH_3COCH_2$$

$$HNO \xrightarrow{k_4} H + NO$$

$$H + CH_3COCH_3 \xrightarrow{k_5} H_2 + CH_3COCH_2$$

$$CH_3 + NO \xrightarrow{k_6} CH_3NO$$

The resulting rate expression is

$$[9] \qquad v = (2k_1k_3/k_6)[CH_3COCH_3]^2 + 2k_1[CH_3COCH_3]\,[NO],$$

which is consistent with experiment (17).

The fact that the proposed mechanisms for these last two examples lead to the conclusion that there is catalysis at high nitric oxide concentrations, as observed experimentally, provides valuable support for the general scheme of reactions proposed in this paper.

GENERAL DISCUSSION

The suggestion that the initiating processes in reactions fully inhibited by nitric oxide involve a hydrogen atom abstraction by NO is not new; it was first made by Rice and Polly (18) and was discussed by Goldanskii (19). However, the postulation of reactions between radicals and HNO as chain-terminating steps appears to be new,* and seems to be required in order to account for the observed kinetics, and more particularly to explain the cases of limiting rates at high nitric oxide concentrations. Our view is that in the paraffin decompositions, where rather high temperatures are involved, reactions such as

$$C_2H_5 + NO \rightleftharpoons C_2H_5NO$$

merely proceed to equilibrium and do not disturb the steady-state concentrations of radicals; they therefore need not be included in the reaction schemes. In reactions at lower temperatures, however, such reactions are important chain-ending steps.

The idea that the radical HNO plays an important role in reaction mechanisms is reasonable in view of the fact that this substance has been prepared and its spectrum analyzed (21). Since the molecule is isoelectronic with O_2 it may be expected to be quite stable with respect to H + NO.

The reaction mechanisms discussed above may be seen to fall into four main classes, and Table I summarizes the main features and gives examples of each type.

TABLE I

Summary of reaction types for inhibition by nitric oxide

Case	H as chain carrier	Chain-ending step	Order of reaction	Examples	Chain carriers (most abundant given first)	Chain-ending step
I	Yes	μ + HNO	1	C_2H_6	C_2H_5, H	C_2H_5 + HNO
II	Yes	β + HNO	3/2	C_2H_6 (initial rates)	H, C_2H_5	H + HNO
				CH_4	CH_3, H	CH_3 + HNO
III	No	μ + NO	1	CH_3OCH_3	CH_3OCH_2, CH_3	CH_3OCH_2 + NO
				$C_2H_5OC_2H_5$	$C_2H_5OC_2H_4$, CH_3	$C_2H_5OC_2H_4$ + NO
IV	No	β + NO	2	CH_3CHO	CH_3, CH_3CO	CH_3 + NO
				CH_3COCH_3	CH_3, CH_3COCH_2	CH_3 + NO

THE STRUCTURE AND STEREOISOMERISM OF THREE MITRAGYNA ALKALOIDS[1]

J. C. Seaton,[2] M. D. Nair,[2] O. E. Edwards, and Léo Marion

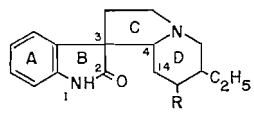
ABSTRACT

Isorhyncophylline, the isomer into which rhyncophylline is convertible, has been found to occur in nature. Both bases are interconvertible. Isorhyncophylline on hydrolysis with dilute hydrochloric acid is converted to an aldehyde reducible to isorhyncophyllol. When the aldehyde is reduced in the Wolff–Kishner reaction, it is also isomerized and the product is isorhyncophyllane. This reduction product is oxidized by mercuric acetate to a neutral dilactam which still contains the oxindole carbonyl and further contains a new lactam carbonyl present in a six-membered ring. Reduction of the dilactam with lithium aluminum hydride gave a product having the spectroscopic properties of an indole. This confirms the assumption previously made that in rhyncophylline, ring C is five-membered. The isomerization of rhyncophylline, mitraphylline, and formosanine is described. Formosanine has been shown to be identical with uncarine-B and thus uncarine-A is the iso base derivable from formosanine.

It has been reported first by Kondo, Fukuda, and Tomita (1) that rhyncophylline in acetic acid isomerizes to isorhyncophylline. It has now been possible to isolate isorhyncophylline from *Adina rubrostipulata* K. Schuman. It separated from the mother liquors that had already yielded rhyncophylline and mitraphylline. It was isolated as the perchlorate from which the crystalline base was liberated. Its ultraviolet spectrum was identical with that of rhyncophylline, and the infrared spectra of the two bases were very similar so that the isomerization did not seem to involve the chromophoric groups. When either rhyncophylline or its isomer was refluxed in pyridine it was converted to a mixture consisting of 30% rhyncophylline – 70% isorhyncophylline.

Whereas on catalytic hydrogenation rhyncophylline is converted to hexahydrorhyncophylline, in which the enol-ether double bond has survived, the similar hydrogenation of isorhyncophylline converts it to octahydroisorhyncophylline. The ultraviolet spectrum of this product showed only end absorption while the infrared spectrum contained absorption bands due to an unconjugated ester group (1743 cm^{-1}) and an oxindole carbonyl (1700 cm^{-1}) although it contained no absorption attributable to a benzene ring or an enol ether.

Hydrolysis of isorhyncophylline with dilute hydrochloric acid yielded a product having the properties of an aldehyde (a precipitate with Brady's reagent and restoration of color to Schiff's reagent), but it was not possible to induce the base or a salt to crystallize. The base appeared to polymerize on standing for a short time.



Reduction of the crude product, however, with sodium borohydride gave a base isomeric with rhyncophyllol (2), i.e., isorhyncophyllol ($C_{19}H_{26}O_2N_2$), the picrate of which crystallized. The regenerated base was a glass and its infrared spectrum in chloroform showed bands at 3610 cm^{-1} (hydroxyl), 3425 cm^{-1} (imino group), 1717 cm^{-1} (oxindole carbonyl), and 1628 cm^{-1} (benzene ring).

The amorphous aldehydic product of the hydrolysis of isorhyncophylline (i.e. isorhyncophyllal) when subjected to the Wolff–Kishner reaction suffered reduction of its aldehyde group. The product (73% yield) was identical with rhyncophyllane ($C_{19}H_{26}ON_2$) obtained previously (2) from rhyncophylline by the same reactions. In view of the fact that the thermal rearrangement of rhyncophylline and of rhyncophyllol gives mixtures in which

[1]*Manuscript received January 28, 1960.*

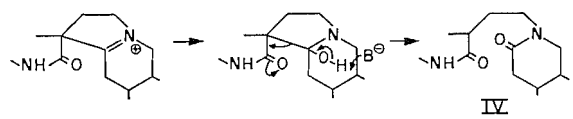
Issued as N.R.C. No. 5676.
[2]*National Research Council of Canada Postdoctorate Fellow.*

the isobase always predominates, it is more likely that this common product is isorhyncophyllane. Consequently, rhyncophyllane would have been more correctly named isorhyncophyllane, and we propose to adopt the latter designation.

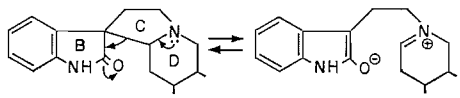


The structure of rhyncophylline represented by formula I has been suggested previously (2). From the foregoing results isorhyncophylline must also be represented by formula I

I, R = $CH_3OOC—C=CH.OCH_3$
II, R = $—CH_2.CH_2OH$
III, R = $.CH_2CH_3$

although the stereochemistry of the bases is different while isorhyncophyllol must be II and isorhyncophyllane III. Methylation with sodium methoxide converted isorhyncophyllane to N-methylisorhyncophyllane, which was crystallized as its picrate, m.p. 182–184°.

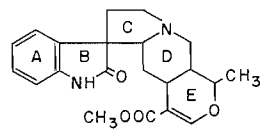
The final evidence needed to complete the proof that rhyncophylline (2) and its stereoisomer isorhyncophylline have structure I was the point of linkage of C-3 to ring D, and this has now been provided. Isorhyncophyllane reacted quickly with 1 mole of mercuric acetate giving rise to a neutral dilactam which in the infrared showed bands at 1715 cm^{-1} (oxindole carbonyl) and at 1625 cm^{-1} (six-membered lactam). This dilactam could not be crystallized, nor could it be purified completely because of partial decomposition when it was dissolved in a hot solvent. Lithium aluminum hydride in refluxing dioxane reduced the dilactam to a sensitive base which could not be purified without decomposition, but had an infrared spectrum showing no carbonyl absorption and an ultraviolet spectrum similar to an indole spectrum. The indication of indole formation on reduction, although not rigorous, does show, if taken in conjunction with the formation of a lactam in the reaction with mercuric acetate, the location of the new carbonyl. Thus the evidence is consistent with structure IV for the dilactam which must have been produced via the immonium ion and



carbinolamine as shown. It further establishes the five-membered nature of ring C.

Perhaps the most intriguing feature of rhyncophylline chemistry is the isomerization to isorhyncophylline. That the enol–ether system was not involved was shown by the fact that rhyncophyllol isomerizes in identical manner. Nozoye (3, 4) has suggested that the isomerism involves the configuration at C-4. A more plausible explanation of this phenomenon seemed to us to be the following thermal (possibly also acid-catalyzed) fission-recoupling process,[3] which involves the two asymmetric centers C-3 and C-4.

The pair of structures which represent rhyncophylline and its isomer must satisfy the requirements that the equilibrium between the two lies 70% on the side of the iso series,



[3]*This mechanism was recently independently suggested by Wenkert, Udelhofen, and Bhattacharyya (5).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

that rhyncophylline and derivatives are inert to mercuric acetate while the iso series react rapidly, and that the rhyncophylline series are stronger bases than the iso series. A rigorous assignment of stereochemical structures is not yet possible.[4]

An equilibrium mixture of 20% mitraphylline and 80% isomitraphylline is formed when either base is refluxed in pyridine overnight. It has not been possible to obtain isomitraphylline crystalline, but its picrate was a well-defined compound and the analytical figures obtained for this salt corresponded to $C_{21}H_{24}O_4N_2$ for the base. The ultraviolet spectrum of isomitraphylline was almost identical with that of mitraphylline (6) and the infrared spectra of the two bases showed no significant shift in the frequencies of the bands corresponding to the functional groups. Isomitraphylline when oxidized with mercuric acetate gave an amorphous product which on hydrogenation over Adams' catalyst produced a mixture of isomitraphylline and mitraphylline. The isomerism parallels that of rhyncophylline. Mitraphylline has been shown (6) to possess structure V, which must also represent isomitraphylline.

V

The alkaloid formosanine was isolated from *Orouparia formosana* Mats by Raymond-Hamet (7). It has the formula $C_{21}H_{24}O_4N_2$ and contains one methoxyl group. It has been suggested by Loudon (8) and by Raymond-Hamet (9) that uncarine-B isolated by Kondo (10) from *Uncaria kawakamii* Hayata was identical with formosanine because their melting points, rotations, and ultraviolet spectra were almost identical. We have now been able to make a direct comparison of formosanine[5] with a sample of uncarine-B kindly supplied by Professor H. Kondo. The melting point of the mixture of the bases showed no depression and their X-ray powder diagrams were identical while their infrared absorption spectra were virtually identical. This confirms the claim of Raymond-Hamet (9) that formosanine and uncarine-B are identical.

The pair of alkaloids uncarine-A–uncarine-B (formosanine) have been assigned structure V (3), which is also that of mitraphylline (6). When boiled with pyridine, formosanine is equilibrated to a mixture of about 20% formosanine and 80% isoformosanine. Formosanine is isomeric with mitraphylline, but not identical with it. Whereas mitraphylline was hydrogenated catalytically to hexahydromitraphylline in which the

[4]*An analysis of the stereochemistry is possible, and leads to a conclusion respecting the structures of the two isomers. This speculation, however, is based on rather arbitrary assumptions which will require further experimental confirmation.*

[5]*Dr. Raymond-Hamet kindly gave us a generous sample of formosanine and we acknowledge our indebtedness and gratitude.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

isolated double bond was still present, catalytic hydrogenation converted formosanine to octahydroformosanine.

The three alkaloids rhyncophylline, mitraphylline, and formosanine have a very low solubility in ether, and crystallize readily, while the bases of the iso series are very soluble in ether and either crystallize with difficulty or not at all. The bases equilibrate under the same conditions and in the mixtures produced, the iso base always predominates. Furthermore, the normal series are stronger bases than the iso series. It is therefore most probable that the isomerization in each case is of the same type.

It has been shown (3) that formosanine (uncarine-B) possesses the same structure V as mitraphylline, and also that uncarine-A (isoformosanine) is different from isomitraphylline or its isomer. Hence mitraphylline and formosanine must differ by an isomerism other than that differentiating mitraphylline from isomitraphylline.

The infrared spectra were measured on a Perkin–Elmer double-beam spectrophotometer model 21. Unless otherwise mentioned the spectra were taken in Nujol mulls, and the absorption bands are reported in wave numbers sometimes followed by a numeral in parentheses indicating the percentage absorption.

EXPERIMENTAL

Isolation of Isorhyncophylline

Both rhyncophylline and mitraphylline have already been reported as occurring in *Adina rubrostipulata* K. Schuman. The mother liquors from which the two bases had separated still contained basic material which was precipitated with picric acid. A sample of the crude picrate was suspended in methanol and shaken with Amberlite IRA 400 (basic form) and the mixture poured on a column of Amberlite IRA 400. Elution with methanol gave a solution of bases which was evaporated to dryness under diminished pressure. The basic residue was dissolved in the minimum volume of methanol and the solution made just acid to Congo red with perchloric acid. About half the solvent was evaporated and water added to incipient turbidity. After cooling and scratching a salt crystallized which was recrystallized from methanol from which it separated as colorless needles, m.p. 158–160°. It did not depress the melting point of an authentic sample of isorhyncophylline perchlorate prepared from rhyncophylline by isomerization. Found: C, 52.84; H, 6.19; N, 5.45. Calc. for $C_{22}H_{28}O_4N_2.HClO_4.H_2O$: C, 52.53; H, 6.21; N, 5.57%.

To liberate the base, the perchlorate was suspended in aqueous ammonia and the mixture extracted repeatedly with ether. The extract was washed with water, evaporated to dryness, and the residue dissolved in ether–hexane from which it crystallized as colorless fine needles, m.p. 150°. The infrared spectrum of the free base, 3420 cm^{-1} (HN), 1730 cm^{-1} (ester carbonyl), 1705 cm^{-1} (oxindole carbonyl), 1645 cm^{-1} (enol-ether), 1625 and 755 cm^{-1} (benzene ring), was identical with that of isorhyncophylline, and so were the ultraviolet spectra, $[\alpha]_D^{28}$ +5.9 (*c*, 3.95 in ethanol). Found: C, 68.89; H, 7.40; N, 7.21. Calc. for $C_{22}H_{28}O_4N_2$: C, 68.72; H, 7.34; N, 7.29%.

Octahydroisorhyncophylline

Isorhyncophylline (100 mg) was hydrogenated in glacial acetic acid (10 ml) over Adams' catalyst (100 mg) at 27° and a pressure of 755 mm of mercury. The absorption of hydrogen amounted to 26.7 ml and the volume calculated for four double bonds was 25.8 ml. After removal of the catalyst and solvent the residue was alkalized with sodium carbonate and the mixture extracted with ether. The extract was dried, the solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

evaporated, and the residue crystallized in ether from which it separated as colorless prisms, m.p. 169–172°, $[\alpha]_D^{24}$ +46.9° (*c*, 0.49 in ethanol). Found: C, 67.33; H, 9.14. Calc. for $C_{22}H_{36}O_4N_2$: C, 67.31; H, 9.24%. Infrared spectrum: 1745, 1700, and 1110 cm^{-1}. Ultraviolet spectrum: end absorption.

Isomerization of Isorhyncophylline

Isorhyncophylline (280 mg) was refluxed with acetic anhydride (6 ml) for 3 hours. The solvent was removed under diminished pressure, the residue dissolved in benzene and chromatographed on alumina. Elution with benzene–ether gave a fraction (200 mg) which failed to crystallize, but formed a perchlorate which, after crystallization from methanol–ether, melted at 219–220° identical with isorhyncophylline perchlorate by mixed melting point and comparison of infrared spectra. Further elution with chloroform yielded rhyncophylline, m.p. 209–211° identical with an authentic specimen.

Equilibration of Rhyncophylline and Isorhyncophylline

Rhyncophylline (342 mg) was refluxed overnight in pyridine (7 ml). The solvent was evaporated off, the residue dissolved in ether, and the solution seeded with rhyncophylline. The crystalline base (96 mg) identified with rhyncophylline by melting point, mixed melting point, and infrared spectrum was filtered and the filtrate made just acid with perchloric acid. The crystalline salt (330 mg) was identical with isorhyncophylline perchlorate. Hence the equilibrium mixture contains approximately 30% rhyncophylline and 70% isorhyncophylline.

Isorhyncophyllol

It has been shown earlier (2) that rhyncophylline is converted to rhyncophyllal by the action of dilute hydrochloric acid. In an attempt to prepare isorhyncophyllal, isorhyncophylline (1.65 g) was refluxed similarly with 8% hydrochloric acid (200 ml) for 3.5 hours. The cooled solution was neutralized with sodium bicarbonate and extracted with ether. The extract was dried over sodium sulphate and evaporated to dryness. The residual gum was soluble in ether, acetone, benzene, methanol, and ethanol, but much less in hexane. After a short time it became only partially soluble in ether. The product could not be crystallized nor could its picrate and perchlorate. It behaved as an aldehyde in that it gave a precipitate with Brady's reagent and restored the color to Schiff's reagent.

The gummy product of the above reaction (100 mg) was dissolved in 80% methanol (15 ml) and sodium borohydride (1.0 g) was added to the solution. After 2 hours the methanol was evaporated and a little water added to the residue which was extracted with ether. The extract was dried over sodium sulphate and the solvent distilled off. There was left a gum which was converted to a picrate that crystallized from methanol as large yellow prisms (0.8 g), m.p. 168–170°. Found: C, 55.39; H, 5.31. Calc. for $C_{19}H_{26}O_2N_2.C_6H_3O_7N_3$: C, 55.24; H, 5.38%. The base was regenerated from a solution of the picrate in methanol on a basic resin (Amberlite IRA 400). It consisted of a colorless glass which could not be crystallized, $[\alpha]_D^{22}$ +41.9° (*c*, 0.99 in ethanol). Found: C, 72.73; H, 8.34; N, 8.81. Calc. for $C_{19}H_{26}O_2N_2$: C, 72.58; H, 8.34; N, 8.91%.

Isomerization of Rhyncophyllol

A sample (2) of crystalline rhyncophyllol (100 mg) was refluxed in pyridine (25 ml) overnight. The solvent was then evaporated leaving a gum which failed to crystallize. It was dissolved in methanol and converted to the picrate which separated in yellow prisms (135 mg), m.p. 168–169°, undepressed in admixture with the picrate of isorhyncophyllol obtained by reduction of isorhyncophyllal.

Wolff–Kishner Reduction of Isorhyncophyllal

Amorphous isorhyncophyllal (400 mg) was reduced by the Huang–Minlon modification of the Wolff–Kishner reaction. The reaction mixture, after being cooled, was acidified with *N* hydrochloric acid and extracted with ether. The aqueous layer was alkalized with sodium carbonate and extracted repeatedly with ether. The extract from the basic solution was washed with water, dried over sodium sulphate, and evaporated to dryness. The residual stiff gum (205 mg) was distilled at 200° under 6.3 mm and obtained as a colorless glass which formed a picrate that crystallized from ethanol, m.p. 226–227°, either alone or in admixture with rhyncophyllane picrate (2). Found: C, 56.95; H, 5.26. Calc. for $C_{19}H_{26}ON_2.C_6H_3O_7N_3$: C, 56.92; H, 5.54%. The base, liberated on Amberlite IRA 400, had $[\alpha]_D^{24}$ +26.2° (*c*, 2.1 in ethanol) and its infrared absorption spectrum was identical with that of rhyncophyllane. As explained above, this compound should be renamed isorhyncophyllane.

N-Methylisorhyncophyllane

To a solution of isorhyncophyllane (60 mg) in methanol (5 ml) was added a methanolic solution of sodium methoxide (sodium, 50 mg, in methanol, 5 ml) and methyl iodide (1 ml). The mixture was refluxed on the water bath for 3 hours and then evaporated to dryness. The residue was extracted with ether, the extract washed with water, dried over sodium sulphate, and evaporated. A gummy residue was thus obtained which was dissolved in ethanol and converted to the picrate which separated as yellow prisms (50 mg), m.p. 182–184°. Found: C, 58.12; H, 5.86. Calc. for $C_{20}H_{28}ON_2.C_6H_3O_7N_3$: C, 57.66; H, 5.77%. The base liberated on Amberlite IRA 400 did not show any absorption bands in the NH—OH region of the infrared.

Mercuric Acetate Oxidation of Isorhyncophyllane

To a solution of isorhyncophyllane (400 mg) in 5% aqueous acetic acid (5 ml) was added mercuric acetate (2.4 g) dissolved in 5% aqueous acetic acid (10 ml) and the mixture heated on the steam bath. A precipitate of mercurous acetate started to appear after 15 minutes. The mixture was heated for 4 hours, cooled, and filtered. The dried mercurous acetate weighed 687 mg. The filtrate was boiled and treated with hydrogen sulphide until precipitation was complete. The mercuric sulphide was filtered off through supercel and the filtrate alkalized with excess sodium carbonate and extracted three times with chloroform. The extract was washed first with several portions of dilute hydrochloric acid then with water, dried over sodium sulphate, and evaporated. It left a neutral residue (180 mg) which could not be induced to crystallize and could not be distilled without some decomposition. The infrared spectrum of the product showed in addition to the oxindole carbonyl at 1705 cm^{-1} a strong band at 1625 cm^{-1} indicative of a six-membered lactam. Found: C, 70.99; H, 8.20. Calc. for $C_{19}H_{26}O_2N_2$: C, 72.58; H, 8.34%.

Reduction of Oxidation Product

Reduction of the oxidation product with lithium aluminum hydride in ether, in tetrahydrofuran, and in dioxane was attempted under the usual experimental conditions. Although the six-membered lactam carbonyl was reduced readily, the oxindole carbonyl could not be completely reduced. To a solution of lithium aluminum hydride (150 mg) in dry ether was added a solution of the oxidation product (98 mg) in dioxane (10 ml). The ether was evaporated off and the resulting slurry boiled under reflux for 24 hours under dry nitrogen. After the reaction mixture was cooled, the excess lithium aluminum hydride

was decomposed with water and the solution extracted with chloroform. The extract was washed with water and then with *N* sulphuric acid. The acid solution turned violet. It was made basic with aqueous sodium carbonate and extracted with chloroform. The extract yielded a gum (29 mg) which could not be crystallized and from which no crystalline salt could be obtained. The infrared spectrum of the product still contained a weak oxindole carbonyl band, but the lactam carbonyl absorption had completely disappeared.

Isomitraphylline

Mitraphylline (325 mg) was refluxed in pyridine (25 ml) overnight. The solvent was evaporated and the residue dissolved in a small volume of ether. After cooling for several hours, mitraphylline, m.p. 265 (66 mg), had crystallized. The residue recovered from the mother liquor was converted into a picrate which crystallized from methanol as yellow prisms, m.p. 223° (dec.) (377 mg). Found: C, 54.31; H, 4.38. Calc. for $C_{21}H_{24}O_4N_2.C_6H_3O_7N_3$: C, 54.36; H, 4.56%. The base, regenerated from the picrate on Amberlite IRA 400 was soluble in ether. It could not be induced to crystallize. Found: C, 68.03; H, 6.60; N, 7.42. Calc. for $C_{21}H_{24}O_4N_2$: C, 68.46; H, 6.57; N, 7.60%. Infrared spectrum in chloroform: 3440, 1720(87), 1626(72), 1118(63), 1098(62) cm^{-1}.

Dehydrogenation of Isomitraphylline and Mitraphylline

(*a*) Isomitraphylline (110 mg) and mercuric acetate (400 mg) in 5% acetic acid (4 ml) was kept at 40–50°. Precipitation of mercurous acetate started after 2 minutes. After 7 hours the reaction mixture was worked up as described for isorhyncophylline, and the product was converted to perchlorate. Reduction of the perchlorate in 80% methanol with sodium borohydride produced a mixture which was separated into mitraphylline (2 mg) and isomitraphylline isolated as the picrate (20 mg), m.p. 223–227°, undepressed by admixture with an authentic sample.

(*b*) When mitraphylline (100 mg) and mercuric acetate in 5% acetic acid were kept at 40–50° for 7 hours, only a trace of mercurous acetate had precipitated.

Octahydroformosanine

Formosanine (25 mg) was hydrogenated in glacial acetic (10 ml) over Adams' catalyst (50 mg) at 27° and 756 mm. The hydrogen absorbed was 8.1 ml (calculated for four double bonds, 7.2 ml). The catalyst and solvent were removed and the residue alkalized with sodium carbonate solution and extracted with ether. The extract was dried over sodium sulphate, evaporated to dryness, and the residue crystallized from ether from which it separated as colorless cubes (12.5 mg), m.p. 110–120°. Found: C, 66.74; H, 8.59. Calc. for $C_{21}H_{32}O_4N_2$: C, 66.99; H, 8.57%. Infrared spectrum: 1745(80), 1707(92), 1100(81) cm^{-1}.

Equilibration of Formosanine

Formosanine (45 mg) was refluxed in pyridine overnight. The solvent was evaporated and the residue dissolved in a small volume of ether from which crystals of formosanine, m.p. 218° (8 mg), were deposited. The fraction more readily soluble in ether did not crystallize (uncarine-A) and was dissolved in carbon disulphide for determination of its infrared spectrum.

ACKNOWLEDGMENTS

We acknowledge with thanks the courtesy of Professor H. Kondo for the sample he sent us and Dr. Raymond-Hamet for his generous gift of formosanine. We are also grateful to Mr. R. Lauzon for taking the infrared spectra and to Mr. J. R. H. Seguin for the microanalyses.

THE RADIOLYSIS OF CYCLOHEXANE

II. CYCLOHEXANE–CYCLOHEXENE SOLUTIONS AND PURE CYCLOHEXENE[1]

G. R. FREEMAN

ABSTRACT

The γ-radiolysis of cyclohexane–cyclohexene solutions and of pure cyclohexene has been investigated. The previously determined yields of the two activated species in irradiated cyclohexane have been confirmed. $G(c\text{-}C_6H_{12}'') = 3.0\pm0.3$ and $G(c\text{-}C_6H_{12}') = 2.4\mp0.3$.

The yields of the main products of cyclohexene radiolysis are $G(H_2) = 1.2$, $G(c\text{-}C_6H_{12}) = 1.0$, $G[(c\text{-}C_6H_9)_2] = 1.4$, and $G(c\text{-}C_6H_{10} \rightarrow \text{higher polymer}) \approx 4$. There were smaller amounts of ethylene, acetylene, a C_4 hydrocarbon (probably butadiene), cyclohexylcyclohexene, and dicyclohexyl.

For the reactions

$$2c\text{-}C_6H_9 \rightarrow (c\text{-}C_6H_9)_2, \qquad [6a]$$

$$c\text{-}C_6H_9 + c\text{-}C_6H_{11} \rightarrow c\text{-}C_6H_9\text{–}C_6H_{11}, \qquad [7a]$$

and

$$2c\text{-}C_6H_{11} \rightarrow (c\text{-}C_6H_{11})_2 \qquad [8a]$$

the value $k_{7a}/(k_{8a}k_{6a})^{\frac{1}{2}} = 0.45\pm0.08$ was determined.

The reaction mechanism that occurs during the radiolysis of cyclohexane–cyclohexene solutions is similar to that which occurs during the radiolysis of cyclohexane–benzene solutions (Part I of this series) with the additional consideration that cyclohexene itself is considerably decomposed during the radiolysis.

INTRODUCTION

Two distinct reactive species appear to be important in the γ-radiolysis of cyclohexane (1). One reactive species, $c\text{-}C_6H_{12}''$, is subject to energy transfer "protection" by benzene and the other, $c\text{-}C_6H_{12}'$, is not. It also appears that $c\text{-}C_6H_{12}'$ decomposes to produce "cold" hydrogen atoms that can be scavenged by benzene,

$$c\text{-}C_6H_{12}' \rightarrow c\text{-}C_6H_{11} + \text{cold H},$$

whereas $c\text{-}C_6H_{12}''$ decomposes to produce "hot" hydrogen atoms that cannot be scavenged by benzene,

$$c\text{-}C_6H_{12}'' \rightarrow c\text{-}C_6H_{11} + \text{hot H}.$$

The possibility that $c\text{-}C_6H_{12}''$ decomposes to produce molecular hydrogen has not been eliminated, however.

The purpose of the present study was to determine the effect of cyclohexene on the cyclohexane radiolytic system.

EXPERIMENTAL

Materials

Eastman spectro-grade cyclohexane was used.

Cyclohexene was obtained from Matheson, Coleman, and Bell and from Eastman. The results obtained with the cyclohexene from the two sources were the same within experimental error.

Cyclohexylcyclohexene was prepared by dehydrating 2-cyclohexylcyclohexanol with phosphorus pentoxide and distilling the olefin from the reaction mixture.

[1]*Manuscript received January 25, 1960.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

Preparation of the Samples

One- and two-milliliter samples were irradiated in sealed pyrex cells of approximately 2- and 4-ml capacity, respectively.

The cells were filled by conventional vacuum techniques. Briefly, the liquids were measured by pipette and were thoroughly degassed before being distilled into the irradiation cells.

Irradiation of the Samples

The samples were irradiated with Co^{60} γ-rays. Dose rates were determined with the Fricke dosimeter, using $G(Fe^{+++}) = 15.6$ and $\epsilon(Fe^{+++}$ in 0.8 N H_2SO_4, 25° C, 304 mμ) $= 2225$. The dose rates varied from 5.9×10^{17} to 10.4×10^{17} ev/ml hr for the Fricke dosimeter at 25° C. The amount of energy absorbed per milliliter per hour in the organic liquids was calculated by multiplying the energy absorbed per milliliter per hour in the Fricke dosimeter by the ratio of the electron densities at the appropriate temperatures. The electron densities, at 24° C, of the Fricke dosimeter, cyclohexane, and cyclohexene were 0.566, 0.442, and 0.452 e^- moles/ml, respectively. Temperature corrections were applied when necessary.

Analyses

Gas fractions were separated by distillation at −195° C and −112° C. Each fraction was collected and measured in a combination Toepler pump – McLeod gauge and then analyzed by gas chromatography. The remaining liquid was also analyzed by gas chromatography.

RESULTS

The dose received by the samples was $2.7\pm0.5\times10^{20}$ ev/ml, 24° C. Since the slight decrease in most product yields with increasing dose in the pure cyclohexane system is probably due to the accumulation of an inhibitor, the G values used in this paper for pure cyclohexane will be those obtained by extrapolation to zero dose (1), unless otherwise mentioned.

Cyclohexane–Cyclohexene Solutions

Products Volatile at −195° C

This fraction consisted of hydrogen and methane. The amounts of methane were too small to measure accurately. For pure cyclohexane $G(CH_4) = 0.02$ and the value decreased to less than 0.01 when the electron fraction of cyclohexene, ϵ_e, in the solution was greater than about 0.04.

[i] $$\epsilon_e = \frac{46n_e}{46n_e+48n_c}$$

where n_e and n_c are the respective numbers of moles of cyclohexene and of cyclohexane in the solution, and 46 and 48 are the numbers of electrons in a cyclohexene molecule and a cyclohexane molecule respectively.

The hydrogen yield, $G(H_2)$, decreased rapidly as ϵ_e was increased from 0 to 0.05 and decreased slowly as ϵ_e was increased further (see Fig. 1A).

Products Volatile at −112° C

This fraction consisted of about 70% ethylene with small amounts of ethane, acetylene, and propylene and traces of propane and butene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The total yield of the fraction, $G(-112°\ C)$, varied only slightly with ϵ_e (see Fig. 1B). For pure cyclohexane, the value of $G(-112°\ C)$ decreased very markedly with increasing dose (1), so the value plotted in Fig. 1B is the one that was obtained at a dose of 2.5×10^{20} ev/ml (about the same dose as was received by the solutions). Thus the increase in $G(-112°\ C)$ between $\epsilon_e = 0$ and $\epsilon_e = 0.026$ may not have much significance.

These results will not be discussed further until they have been investigated more fully.

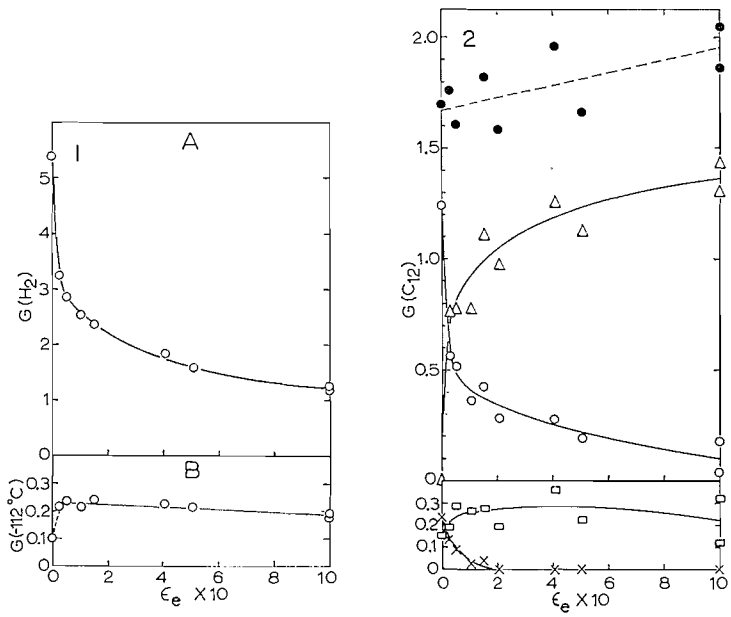

FIG. 1. (A) Variation of hydrogen yield with composition of solution. (B) Variation of yield of $-112°$ C gas fraction with composition of solution. ϵ_e = electron fraction of cyclohexene in the solution.

FIG. 2. Variation of C_{12} hydrocarbon yields with electron fraction of cyclohexene, ϵ_e, of solution. ○ dicyclohexyl; △ dicyclohexenyl; ● total C_{12}, measured on Apiezon L column; □ cyclohexylcyclohexene; × cyclohexylhexene.

Liquid Products

The measured liquid products were dicyclohexyl, cyclohexylcyclohexene, dicyclohexenyl, cyclohexylhexene, and total C_{12} hydrocarbons (see Fig. 2). There were no detectable products with carbon numbers between C_6 and C_{12}. Cyclohexane was a product in the pure cyclohexene system and cyclohexene was produced from pure cyclohexane, but these substances could obviously not be measured as products in the irradiated solutions. The maximum amount of decomposition that occurred in any irradiated sample corresponded to about 0.2% of the initial cyclohexane plus cyclohexene.

The dicyclohexyl yield decreased rapidly with increasing cyclohexene concentration at low concentrations ($0 < \epsilon_e < 0.05$) and decreased slowly as the cyclohexene concentration was increased further.

The dicyclohexenyl yield increased rapidly with increasing cyclohexene concentration at low concentrations ($0 < \epsilon_e < 0.05$) and increased slowly as the concentration was increased further.

The cyclohexylcyclohexene yield varied only to a small extent in the region $0 \leqslant \epsilon_e \leqslant 1$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The cyclohexylhexene yield decreased from 0.23 to zero in the region $0 \leqslant \epsilon_e \leqslant 0.2$.

The total yield of C_{12} hydrocarbons, measured on the Apiezon L chromatographic column, increased slightly as ϵ_e was increased from 0 to 1. The Apiezon L column did not resolve the dicyclic C_{12} hydrocarbons but did separate them from isomers containing an open chain.

The total polymer yield was determined for a solution with $\epsilon_e = 0.405$ by evaporating 1 ml of irradiated solution and 1 ml of unirradiated solution under identical conditions. The weight of each sample was determined as a function of time and the weight vs. time curves were compared. A weight vs. time curve was determined for dicyclohexyl under the same conditions. It was found that $G(C_6$ units $\rightarrow$ polymer$) = 4.5$. This compares with the value 3.9 obtained by gas-chromatographic analysis ($2 \times G$(total C_{12})). A similar determination of total polymer in irradiated cyclohexene gave G(cyclohexene $\rightarrow$ polymer) ≈ 8. Only about four of these units were accounted for by the C_{12} hydrocarbon analysis. The remaining four units of "other polymer" were probably of higher molecular weight. Manion and Burton (2) determined the polymer yield in irradiated cyclohexene by evaporation and weighing and reported that G(cyclohexene $\rightarrow$ polymer) $= 12.4$, but that it was difficult to decide when solvent evaporation was complete. It would seem, from the present experiments, that this difficulty was caused by small amounts of intermediate compounds that were present in the original cyclohexene.

The present results are in general agreement with those of Dewhurst (3), who found that, in the presence of 5.2×10^{-4} mole cyclohexene/g solution ($\epsilon_e = 0.040$), $G(H_2) = 2.9$, $\Delta G(H_2) = -2.4$, $G(c\text{-}C_6H_{10}) = -2.3$, and that the dicyclohexyl yield was unchanged. However, the present results confirm the previous suspicion (1) that Dewhurst's "dicyclohexyl" was not pure dicyclohexyl but probably was a measure of the total C_{12} hydrocarbons. At $\epsilon_e = 0.040$ only one third of the C_{12} hydrocarbons is dicyclohexyl (see Fig. 2).

Pure Cyclohexene

The detected products and their yields were as follows:

Product	G	Product	G
Hydrogen	1.2	Dicyclohexenyl	1.36
Ethylene	0.16	Cyclohexylcyclohexene	0.22
Acetylene	0.022	Dicyclohexyl	0.11
C_4 hydrocarbon	0.10	Total C_{12} hydrocarbons	1.96
Cyclohexane	1.0	Total polymer	8 cyclohexene units

The cyclohexene from Matheson, Coleman, and Bell contained 0.6 mole % cyclohexane and that from Eastman contained 0.04 mole % cyclohexane. Corresponding corrections were applied before calculating G(cyclohexane).

The total C_{12} hydrocarbons were measured on the Apiezon L column. The total polymer was determined by weighing.

DISCUSSION

Pure Cyclohexene

If the radiolysis of cyclohexene is considered as

$$c\text{-}C_6H_{10} \rightarrow H_2 + X,$$

then the total hydrogen deficiency in the yields of the products X should be equal to $G(H_2) = 1.2$. It is evident from Table I that the hydrogen equivalent of about one

TABLE I

Material balance of products from irradiation of cyclohexene

Product	G	H_2 equivalent
$C_2 + C_4$ hydrocarbons	0.28	0.0
Cyclohexane	1.0	−1.0
Dicyclohexenyl	1.36	1.36
Cyclohexylcyclohexene	0.22	0.0
Dicyclohexyl	0.11	−0.11
Other polymer	4.6 C_6 units	?
Total		0.25+?
H_2	1.2	1.2

NOTE: The hydrogen equivalent of a product corresponds to the amount of hydrogen that was produced when that product was formed from cyclohexene.

G unit of hydrogen-deficient hydrocarbon products have remained unidentified. These products might not be entirely included in the "other polymer" because some possible products, such as cyclohexadiene, might have been missed under the present analytical conditions.

The formation of the major identified products can be explained by the following mechanism.

$$c\text{-}C_6H_{10} \xrightarrow{I^*} c\text{-}C_6H_{10}^* \qquad [1^*]$$

$$\xrightarrow{I^{**}} c\text{-}C_6H_{10}^{**} \qquad [1^{**}]$$

$$c\text{-}C_6H_{10}^* \rightarrow c\text{-}C_6H_9 + \text{cold H} \qquad [2^*]$$

$$c\text{-}C_6H_{10}^{**} \rightarrow c\text{-}C_6H_9 + \text{hot H} \qquad [2^{**}]$$

$$\text{hot H} + c\text{-}C_6H_{10} \rightarrow H_2 + c\text{-}C_6H_9 \qquad [3]$$

$$\text{cold H} + c\text{-}C_6H_{10} \rightarrow c\text{-}C_6H_{11} \qquad [4]$$

$$c\text{-}C_6H_{11} + c\text{-}C_6H_{10} \rightarrow c\text{-}C_6H_{12} + c\text{-}C_6H_9 \qquad [5]$$

$$2c\text{-}C_6H_9 \rightarrow (c\text{-}C_6H_9)_2 \text{ (dicyclohexenyl)} \qquad [6a]$$

$$\rightarrow c\text{-}C_6H_{10} + c\text{-}C_6H_8 \qquad [6b]$$

$$c\text{-}C_6H_9 + c\text{-}C_6H_{11} \rightarrow c\text{-}C_6H_9\text{-}C_6H_{11} \text{ (cyclohexylcyclohexene)} \qquad [7a]$$

$$\rightarrow c\text{-}C_6H_8 + c\text{-}C_6H_{12} \qquad [7b]$$

$$\rightarrow 2c\text{-}C_6H_{10} \qquad [7c]$$

$$2c\text{-}C_6H_{11} \rightarrow (c\text{-}C_6H_{11})_2 \text{ (dicyclohexyl)} \qquad [8a]$$

$$\rightarrow c\text{-}C_6H_{10} + c\text{-}C_6H_{12} \qquad [8b]$$

By analogy with the cyclohexane system (1) it is postulated that there are at least two distinct activated species of cyclohexene. One activated species, $c\text{-}C_6H_{10}^*$, decomposes to produce "cold" hydrogen atoms (reaction [2*]), while the other activated species, $c\text{-}C_6H_{10}^{**}$, decomposes to produce "hot" hydrogen atoms (reaction [2**]). It is further postulated that the hot hydrogen atoms abstract from cyclohexene according to reaction [3] and that most of the cold hydrogen atoms add to cyclohexene according to reaction [4]. The possibility that $c\text{-}C_6H_{12}''$ generates molecular hydrogen directly cannot be eliminated by the present experiments, and future work may require the inclusion of such a reaction, perhaps in place of reactions [2**] and [3]. The reaction

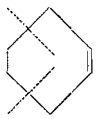
$$\text{cold H} + c\text{-}C_6H_{10} \rightarrow H_2 + c\text{-}C_6H_9$$

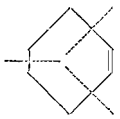
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

may be neglected by comparison with reaction [4]. This will be discussed further in the next section.

The large yield of cyclohexane, $G(c\text{-}C_6H_{12}) = 1.0$, seems to indicate that reaction [5] occurs. Reaction [5] will be mentioned again in the next section.

Although reactions [6*b*], [7*b*], [7*c*], and [8*b*] probably occur to an appreciable extent their products were not observed. Cyclohexadiene could not be detected by the present analytical technique, cyclohexane appeared to be produced more copiously by reaction [5], and cyclohexene was the starting material.





The products of ring fission can be accounted for by the following reactions, if the C_4 hydrocarbon product is butadiene:

$$c\text{-}C_6H_{10} \rightarrow C_2H_4 + C_4H_6, \qquad [9]$$

and

$$c\text{-}C_6H_{10} \rightarrow 2C_2H_4 + C_2H_2. \qquad [10]$$

Thus $G(C_4) + 2G(C_2H_2) = 0.144$ agrees fairly well with $G(C_2H_4) = 0.16$. This involves two types of ring fission

I  and II  .

In the liquid phase radiolysis by γ-rays, type I appears to occur four to five times as frequently as type II. Of the cyclohexene molecules that reacted under the present conditions, less than 3% reacted by ring fission.

The "other polymer" might have been produced by ion–molecule reactions. Thus far there seems to be no evidence that ion–molecule reactions are important in the radiolysis of liquid saturated hydrocarbons, but there is evidence that they are important in the radiolysis of liquid olefins, especially in polymer formation (4–6). The possibility that some or all of the identified products were formed by ion–molecule reactions cannot be ruled out by the present results, but their formation can be explained by free radical reactions (see preceding mechanism).

Cyclohexane–Cyclohexene Solutions

It has been assumed that, if there were no interaction between the different components of the solution, the cyclohexane product yields would be directly proportional to the electron fraction of cyclohexane, ϵ_e, in the solution, and that the cyclohexene product yields would be proportional to ϵ_e. This is probably not strictly correct but electron fraction has been used for lack of a better function.

In the cyclohexane–benzene solutions, when the electron fraction of benzene, ϵ_b, was increased from zero to 0.027, $G(H_2)$ decreased from 5.37 to 3.16 (1). At least 20%, and perhaps all of this decrease, appeared to be due to the scavenging of "cold" hydrogen atoms by benzene. In the cyclohexane–cyclohexene solutions, at $\epsilon_e = 0.026$, $G(H_2) = 3.22$. Thus, at this low concentration of solute, the same amount of decrease is produced in the hydrogen yield from cyclohexane by both benzene and cyclohexene. It is unlikely that the ratio of rate constants, k_{11}/k_{12}, has the same value when the unsaturate, RH,

$$H + RH \rightarrow RH_2 \qquad [11]$$

$$\rightarrow H_2 + R \qquad [12]$$

is benzene as when it is cyclohexene. It may therefore be concluded that reaction [12] occurs to a negligible extent with the cold hydrogen atoms generated by $c\text{-}C_6H_{12}'$. Reaction [12] can, however, occur with the hot hydrogen atoms generated by $c\text{-}C_6H_{12}''$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The experimental results were tested against several different mechanisms. The mechanism that appeared to best fit the results included all the reactions [1] to [8] in the pure cyclohexene mechanism plus the reactions

$$c\text{-}C_6H_{12} \xrightarrow{I'} c\text{-}C_6H_{12}' \qquad [13']$$

$$\xrightarrow{I''} c\text{-}C_6H_{12}'' \qquad [13'']$$

$$c\text{-}C_6H_{12}' \rightarrow c\text{-}C_6H_{11} + \text{cold H} \qquad [14']$$

$$c\text{-}C_6H_{12}'' \rightarrow c\text{-}C_6H_{11} + \text{hot H} \qquad [14'']$$

$$\text{hot H} + c\text{-}C_6H_{12} \rightarrow H_2 + c\text{-}C_6H_{11} \qquad [15a]$$

$$\text{cold H} + c\text{-}C_6H_{12} \rightarrow H_2 + c\text{-}C_6H_{11} \qquad [15b]$$

$$c\text{-}C_6H_{12}'' + c\text{-}C_6H_{10} \rightarrow c\text{-}C_6H_{12} + c\text{-}C_6H_{10}^{***} \qquad [16]$$

$$c\text{-}C_6H_{10}^{***} \rightarrow c\text{-}C_6H_9 + x \text{ hot H} + (1-x) \text{ cold H}, \quad 0 \leqslant x \leqslant 1. \qquad [2^{***}]$$

This is essentially the same mechanism as that postulated for the cyclohexane–benzene system (1) except that cyclohexene itself undergoes several reactions that benzene does not (e.g., the benzene counterparts of reactions [2*], [2***], [5], [6*a*, 6*b*], and [7*a*, 7*b*, 7*c*] were not observed). In reaction [2***] the x represents the fraction of the $c\text{-}C_6H_{10}^{***}$ that decomposes to form hot hydrogen atoms, and hence molecular hydrogen. The value of x was determined by kinetic analysis (see later). Reaction [15*b*] could occur in the pure cyclohexane system because the only competing reactions involving the cold hydrogen atoms would be radical combination, and the radical concentrations are very small. The counterpart of reaction [15*b*] probably occurs to a certain extent in the cyclohexene system, but, as mentioned earlier, it appears to be negligible (within the accuracy of the present experiments) by comparison with reaction [4].

Since the over-all mechanism is complex, the kinetic analysis will be simplified by treating one product at a time. It will be assumed that I' and I'' are each directly proportional to the electron fraction of cyclohexane, ϵ_c, and that I^* and I^{**} are each directly proportional to ϵ_e.

Hydrogen

By analogy with the cyclohexane–benzene system (1), the rapid decrease in hydrogen yield at low cyclohexene concentrations ($\epsilon_e < 0.05$) is largely due to scavenging of the cold hydrogen atoms generated by $c\text{-}C_6H_{12}'$. The slower decrease at higher cyclohexene concentrations is mainly due to energy transfer "protection" of the species $c\text{-}C_6H_{12}''$. These effects may be separated and measured by kinetic analysis. It was found in the cyclohexane–benzene system that $I'' = (3.0 \pm 0.4)\epsilon_c$ and $I' = (2.4 \mp 0.4)\epsilon_c$.

The production of hydrogen involves reactions [1**], [2**], [2***], [3], [4], [13'], [13''], [14'], [14''], [15*a*], [15*b*], and [16]. Reactions [13'] and [14'] are important mainly at low cyclohexene concentrations. Reactions [1*] and [2*] do not contribute appreciably to hydrogen production because, when the cyclohexene concentration is high enough that these reactions occur to an appreciable extent, reaction [4] occurs with great efficiency.

The only reactions involved to an appreciable extent in the production of molecular hydrogen from cold hydrogen atoms are reactions [13'], [14'], [15*b*], and [4]. The hydrogen yield from this source will be represented as $G(H_2)'$ because it is generated by $c\text{-}C_6H_{12}'$. This hydrogen can be scavenged by cyclohexene. Steady-state treatment of the above reactions gives

$$[ii] \qquad G(H_2)' = \frac{I'}{1 + k_4(c\text{-}C_6H_{10})/k_{15b}(c\text{-}C_6H_{12})}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

For pure cyclohexane the yield of hydrogen is given approximately by the equation

[iii] $$G(H_2) = 5.37 - 0.08 \times \text{dose}(10^{20}\ \text{ev/ml cyclohexane, } 24^\circ\ \text{C})$$

over the dose range 0 to 2.5×10^{20} ev/ml (1). Assuming that this decrease in hydrogen yield with increasing dose is due to the accumulation of cyclohexene in the system, the value of the ratio k_4/k_{15b} can be determined from equations [ii] and [iii], using $I' = 2.4\epsilon_c$ and the average value of $(c\text{-}C_6H_{10})/(c\text{-}C_6H_{12})$ over the dose range considered. Over the range 0 to 2.5×10^{20} ev/ml, $\Delta G(H_2) = 0.20$ and the average $(c\text{-}C_6H_{10})/(c\text{-}C_6H_{12}) = 4.6 \times 10^{-4}$. Therefore $k_4/k_{15b} = 200$. Guentner, Hardwick, and Nejak (7) concluded, from a comparison of their pure cyclohexane results with the cyclohexane–cyclohexene solution results of Manion and Burton (2), that the accumulated cyclohexene alone was not sufficient to explain the observed decrease in hydrogen yield with increasing dose. Their conclusion may be incorrect, however, because at the concentrations of cyclohexene used by Manion and Burton both energy transfer protection and hydrogen atom scavenging were probably occurring.

Thus the amount of unscavenged hydrogen, $G(H_2)'$, can be calculated from equation [ii] for the various cyclohexene solutions studied, and can be subtracted from the observed hydrogen yield, $G(H_2)_{obs}$.

In pure cyclohexene $G(H_2) = 1.2$ and the only reactions that enter into the production of hydrogen in this system are reactions [1**], [2**], and [3]. It may therefore be assumed that the amount of hydrogen resulting from the direct excitation of cyclohexene, $G(H_2)^{**}$, is given by

[iv] $$G(H_2)^{**} = I^{**} = 1.2\epsilon_e.$$

The amount of hydrogen that results from the initial formation of $c\text{-}C_6H_{12}''$, $G(H_2)''$, can then be determined from

[v] $$G(H_2)'' = G(H_2)_{obs} - G(H_2)' - G(H_2)^{**}.$$

This hydrogen cannot be scavenged by cyclohexene but $G(H_2)''$ may be decreased by energy transfer from $c\text{-}C_6H_{12}''$ to cyclohexene, provided that all the excited cyclohexene molecules, $c\text{-}C_6H_{10}^{***}$, so formed do not decompose to produce hot hydrogen atoms and hence molecular hydrogen. Only reactions [13''], [14''], [15*a*], [16], [2***], and [3] enter into the production of hydrogen from this source. Steady-state treatment of these reactions gives

[vi] $$G(H_2)'' = I''\left[\frac{k_{14}'' + x k_{16}(c\text{-}C_6H_{10})}{k_{14}'' + k_{16}(c\text{-}C_6H_{10})}\right],$$

which may be rearranged to

[vii] $$[1 + y(c\text{-}C_6H_{10})]I''/G(H_2)'' = 1 + k_{16}(c\text{-}C_6H_{10})/k_{14}'', \\ = R'',$$

where $y = x\ k_{16}/k_{14}''$, x = fraction of $c\text{-}C_6H_{10}^{***}$ that decomposes to form hot hydrogen atoms and hence molecular hydrogen, and R'' represents the left-hand side of equation [vii]. Various sets of R'' were calculated, using $I'' = 3.0\epsilon_c$ and various values of y, and each set of R'' values was plotted against cyclohexene concentration (moles/l.). The best straight line was obtained with $y = 0.3$ (see Fig. 3). The slope of the line gives $k_{16}/k_{14}'' = 0.54$ l./mole. Therefore $x = 0.56$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

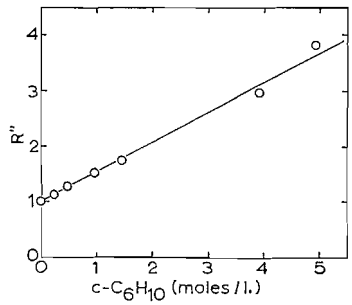


FIG. 3. Variation of R'' with cyclohexene concentration.
$R'' = [1+y(c\text{-}C_6H_{10})]I''/G(H_2)''$.

Since the cyclohexane–benzene system would allow I'' to have a value in the range $(3.0\pm0.4)\epsilon_c$, the best value being $3.0\epsilon_c$, the above kinetic analysis was repeated for the cyclohexane–cyclohexene system using various sets of values of I'' and $I' = (5.4-I'')\epsilon_c$. The corresponding value of k_4/k_{15b} was calculated for each set and the numerical and graphical analysis was done as described above. It was found that the present system would allow $I'' = (3.0\pm0.3)\epsilon_c$. Therefore $I' = (2.4\mp0.3)\epsilon_c$, $k_4/k_{15b} = 200\pm30$, and $x = 0.56\pm0.10$, but $k_{16}/k_{14}'' = 0.54\pm0.4$ l./mole. The experimental value of k_{16}/k_{14}'' is much more flexible than are the other experimentally determined constants. The ratio k_{16}/k_{14}'' in the present system corresponds to the previously reported k_3''/k_4'' in the cyclohexane–benzene system (1). Similar analysis of the latter system gave $k_3''/k_4'' = 0.78\pm0.11$ l./mole, which is relatively clearly defined. The main reason for the difference in precision of determination of the value of this ratio of rate constants in the two systems seems to be the presence of the extra adjustable parameter, x, in the cyclohexene system, together with a slightly lower precision in the measured hydrogen yields in this system.

Dicyclohexyl, Cyclohexylcyclohexene, and Dicyclohexenyl

Since cyclohexyl radicals are produced when the cold hydrogen atoms are scavenged by cyclohexene, the observed sharp decrease in dicyclohexyl yield in the region $\epsilon_e = 0$ to 0.026 was probably caused by the reaction of cyclohexyl radicals with cyclohexene (reaction [5]). This would also explain the sharp increase in dicyclohexenyl yield in this region.

The rates of formation of these three products are given by

[viii] $$d(\text{dicyclohexyl})/dt = k_{8a}(c\text{-}C_6H_{11})^2,$$

[ix] $$d(\text{cyclohexylcyclohexene})/dt = k_{7a}(c\text{-}C_6H_{11})(c\text{-}C_6H_9),$$

and

[x] $$d(\text{dicyclohexenyl})/dt = k_{6a}(c\text{-}C_6H_9)^2.$$

Since the rates of formation of the products are related to their G values by the same proportionality constant,

[xi] $$\frac{k_{7a}}{(k_{8a}k_{6a})^{\frac{1}{2}}} = \frac{G(\text{cyclohexylcyclohexene})}{[G(\text{dicyclohexyl})\,G(\text{dicyclohexenyl})]^{\frac{1}{2}}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The values of this ratio, calculated from equation [xi], at the various cyclohexene concentrations, are

ϵ_e	0.026	0.051	0.102	0.153	0.204	0.405	0.506	1.00
$k_{7a}/(k_{8a}k_{6a})^{\frac{1}{2}}$	0.30	0.44	0.49	0.40	0.37	0.59	0.48	0.56

The average value is 0.45 ± 0.08.

Cyclohexylhexene

The cyclohexylhexene yield varied with cyclohexene concentration (Fig. 2) in the same way it did with benzene concentration (reference 1). The previously postulated reactions which affect the yield of this product appear to apply equally well when cyclohexene is substituted for benzene.

Total C_{12} Hydrocarbons

The variation of the total C_{12} hydrocarbon yield with cyclohexene concentration is the main evidence that the protection of cyclohexane by cyclohexene is sacrificial, i.e. that a cyclohexene molecule decomposes for each cyclohexane molecule that is "protected".

RELATIVE RATES OF REACTION OF OZONE WITH OLEFINS IN THE VAPOR PHASE[1]

T. VRBASKI[2] AND R. J. CVETANOVIĆ

ABSTRACT

Relative rates of reaction of ozone with a number of olefins in the vapor phase have been determined by the use of the competitive method and GLC analysis of the reaction products. The results indicate a basic electrophilic trend onto which is superimposed a trend due to a partially inhibiting effect of the substituent groups, in particular of those on the more substituted carbon atom of the olefinic double bond. The results are discussed particularly in terms of a two-step addition process, involving an initial formation of an ozone–olefin π-complex and a slower rearrangement of the π-complex into the cyclic "initial ozonide".

INTRODUCTION

A study of the relative rates of reactions of oxygen atoms with olefins in the vapor phase has been recently carried out in this laboratory (1), and some aspects of these reactions are still under investigation. This study uncovered simple correlations of the logarithms of the rate constants with some physical properties of the olefins and established experimentally the electrophilic character of oxygen atoms in their reactions with olefins. The results of this vapor phase investigation were compared with some other series of electrophilic reactions in solution and with the very few literature values available at the time for the vapor phase reactions of ozone with olefins. On this basis, nothing could be said with certainty about the reagent character which ozone exhibited in its reactions with olefins, although qualitatively an electrophilic trend was known from the work of Wibaut and his co-workers (2) for ozone in reactions with some aromatic compounds.

In view of the potentially useful information which comparative studies of this kind may provide, it was thought of interest to attempt to obtain the relative rates of ozone reactions with a number of representative olefins. In the course of this investigation, some information was obtained on the products formed in these reactions under the particular experimental conditions employed, and, this part of the work has already been described (3) (referred to in the following as Part I). In the present communication the relative rate constants obtained for these reactions are reported and their trends with olefin structure discussed.

EXPERIMENTAL

The reaction system, the method of analysis, and apart from some additional detail, the general experimental procedures used in this work have been already described in Part I. In present case pairs of olefins in various concentration ratios were introduced into the 188-cc spherical reaction vessel. Their total amount was in most experiments 400 μmoles to which was subsequently added the equivalent of 25 μmoles of ozone. This was done by admitting slowly the required pressure of ozonized oxygen (2.6 to 3.2% by volume of ozone) into the mixture of olefin vapors at $25\pm2°$. The total pressure was therefore 110 to 135 mm. In some experiments, especially in the case of *cis*-2-butene, *trans*-2-butene, and tetramethyl ethylene, the total amount of the two olefins was reduced

[1]*Manuscript received March 2, 1960.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5689.
[2]*National Research Council Postdoctorate Fellow, 1957–59.*

to 200 μmoles, to which then only the equivalent of 10 μmoles of ozone was added and the total pressure was 50 to 60 mm. These smaller amounts were used in order to decrease the excess quantities of the original olefins remaining at the end of the reaction and thus to make easier the subsequent analysis of the products by gas–liquid chromatography (GLC).

The olefins used were of the highest available grade and were freed of any peroxides present and thoroughly degassed and bulb-to-bulb distilled *in vacuo*. A mercury gauge was used to measure the pressures; this was separated from the rest of the reaction system by two ice traps in order to minimize the concentration of mercury vapor. As described in Part I, no noticeable decrease in ozone concentration resulted from the small amount of mercury vapor present. Silicone grease was used for the stopcocks in the parts of the system exposed to ozone–oxygen mixtures.

The products were frozen out in two liquid nitrogen traps in series while excess oxygen and any noncondensable products were pumped off slowly through a capillary constriction. The condensable products were then transferred to GLC. In some instances excess olefins were removed beforehand on a Le Roy still (4). The details of the GLC arrangements used have been given in Part I.

RESULTS

The method of competing reactions has been used to determine the relative rates of the reactions of ozone with various olefins. This has been done by comparing the GLC peak areas of the major carbonyl compounds formed from two olefins (ΔP_1 and ΔP_2, respectively) at different ratios of their initial concentrations ($[A_2]_1/[A_1]_1$). If the two competing reactions are

$$A_1 + O_3 \rightarrow \alpha_1 P_1 + \text{other products} \qquad [1]$$

and

$$A_2 + O_3 \rightarrow \alpha_2 P_2 + \text{other products} \qquad [2]$$

and if the initial concentrations of the two olefins are sufficiently high so that they remain essentially unaltered in the course of the reaction, then the ratio of the rate constants may be derived from the expression

$$\frac{\Delta P_1}{\Delta P_2} = \frac{k_1}{k_2}\frac{\alpha_1}{\alpha_2}\frac{[A_1]_1}{[A_2]_1}. \qquad [3]$$

A plot of $\Delta P_1/\Delta P_2$ vs. $[A_1]_1/[A_2]_1$ should be linear with zero intercept and the slope is then (k_1/k_2) (α_1/α_2). To get the ratio of the rate constants, the ratio α_1/α_2 has to be known. This is determined from the amounts of products formed (ΔP^*) when each of the two olefins is taken singly, i.e. $\alpha = \Delta P^*/\Delta O_3$ and $\alpha_1/\alpha_2 = \Delta P_1^*/\Delta P_2^*$ provided the same amount of ozone is used in the two "single" runs and ozone is consumed exclusively in reactions [1] and [2]. This last requirement is presumably met when relatively large concentrations of olefins are used.

Under similar conditions also $\Delta P_1/\alpha_1 + \Delta P_2/\alpha_2 = \Delta P_1^*/\alpha_1$, so that

$$\frac{\Delta P_1}{\Delta P_1^* - \Delta P_1} = \frac{k_1}{k_2}\frac{[A_1]_1}{[A_2]_1} \qquad [4]$$

an alternative expression which can be used when ΔP_2 cannot be measured.

In most of the present work use was made of eq. [3]. Fairly good linear plots through the origin were obtained as shown in Figs. 1, 2, and 3, and the slopes divided by the corresponding α_1/α_2 values gave the relative rate constants k_1/k_2 summarized in Table I.

The reaction products P_1 and P_2 and the values obtained for α_1/α_2 are shown and the equation used indicated.

For the pairs of olefins ethylene and isobutene, *n*-1-hexene and isobutene, and cyclohexene and isobutene, the relative rate constants were determined from measurements of the GLC peak areas of acetone (formed from isobutene) using eq. [4]. Fairly good linear plots through the origin are again obtained, as shown in Fig. 4, and the values of k_1/k_2 evaluated from the slopes are shown in Table I.

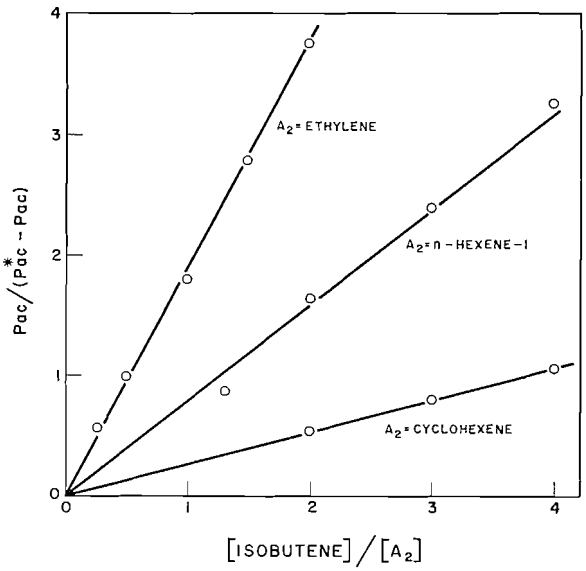

FIG. 4. Determination of the ratios of the rate constants based on eq. [4] for ethylene and isobutene, *n*-1-hexene and isobutene, cyclohexene and isobutene.

In some instances there was appreciable deviation from the assumed constancy of the concentrations of the olefins and the more complex logarithmic expressions (1) instead of eqs. [3] and [4] (referred in Table I as eqs. [3*a*] and [4*a*], respectively) were then used to calculate the ratios of the rate constants. However, this led only to relatively small corrections.

There is a satisfactory mutual consistency of the k_1/k_2 values in the cases where cross determinations (marked in Table I with asterisks) have been made. For example, the value for *trans*-2-butene and *n*-1-pentene from run 6 is 4.2 and it is 4.4 when calculated from runs 5, 8, and 3; the value for *n*-1-pentene and isobutene in run 9 is 1.06 and it is 1.07 when calculated from runs 8 and 3; for 3-methyl-1-butene and 1-butene the value is 0.79 in run 13 and 0.70 calculated from runs 14, 11, and 3; for 2-methyl-2-butene and 1-butene it is 3.02 from run 15 and 3.23 calculated from runs 16, 11, and 3.

In Table II are listed the relative rate constants obtained in the present work taking the value for ethylene as unity. The absolute rate constants are then calculated by adopting the value of Cadle and Schadt (5) for ethylene (1.8×10^3 l. mole^{-1} sec^{-1}) and these are compared with the determinations of Cadle and Schadt (5), of Hanst *et al.* (6), and of Saltzman (7).

DISCUSSION

The trend in the rate constants of ozone reactions with olefins obtained in the present work agrees for several olefins quite well with the corresponding literature values, as is seen in Table II. At the same time, the literature values for cyclohexene, *cis*-2-butene, and 2-pentene are considerably larger, in particular so the much larger value for 2-pentene. The reasons for these discrepancies are not clear, although some of the potential difficulties inherent in experimental studies of these complex reactions have been briefly discussed in Part I. Further experimental work will be necessary to clarify this point, and in the meantime parts of the following discussion of the relative rate constants obtained in the present work must be regarded as of a tentative character.

The question to which a study of the trends in the rate constants with the olefin structure is hoped to answer is whether in its reactions with alkenes ozone behaves as an electrophilic, nucleophilic, or radical reagent. For aromatic compounds Wibaut and his co-workers (2) have already shown that the qualitative trend is such as expected for an electrophilic reagent. This has been recently further confirmed by a study of the trend in the rates in polyalkyl benzenes, although a concurrent screening effect by the bulkier substituent groups has also been indicated (8).

A qualitative inspection of the relative values in Table II shows that in its reactions with olefins in the vapor phase ozone appears also to behave as an electrophilic reagent. A radical reagent would be expected to react much more rapidly with butadiene, and a nucleophilic reagent would exhibit a trend in the rates opposite to that observed as the number of substituents in the ethylene molecule is increased. However, there are also some irregularities in the trends: for electrophilic reagents the rates of α,α-disubstituted ethylenes such as isobutene should be approximately equal to those of the α,β-disubstituted derivatives (such as 2-butene) and here they are appreciably smaller. Also the rates of trimethyl and tetramethyl ethylene should be greater than those of the α,β-disubstituted ethylenes while the observed values are about equal.

As reported in a previous publication (1) mutual linear log k – log k (free energy) plots can be constructed for the reactions of some electrophilic reagents with olefins. A similar plot for ozone reactions (Fig. 5) shows appreciable scatter and in particular the points

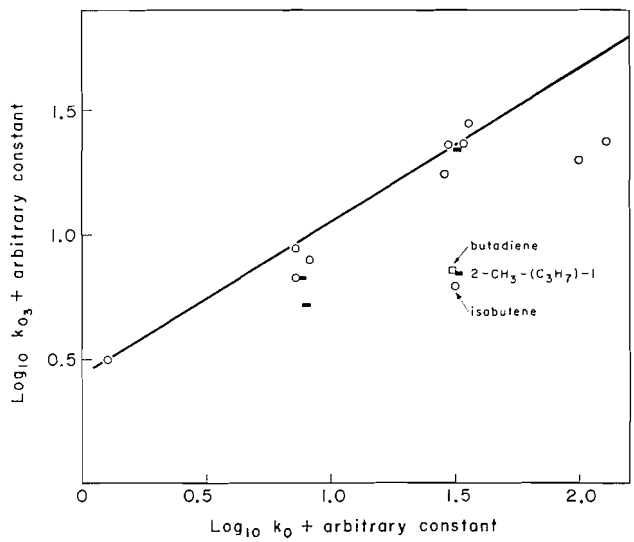

FIG. 5. The "free energy" plot (log k vs. log k) for the reactions of ozone and oxygen atoms with olefins. k_{O_3} are the relative rate constants of the reactions of ozone with olefins and k_O are the relative rate constants of the corresponding oxygen atom reactions. Filled rectangles represent values for k_O not known experimentally but estimated approximately from the general trends established for such reactions (reference 1).

for butadiene, isobutene, and 2-methyl-1-butene deviate very strongly. (In this plot some values for log k_O, i.e. for the corresponding oxygen atom reactions, are not known and have been approximately estimated—they are indicated in Fig. 5 by filled rectangles.)

Intuitively a correlation may be anticipated between the rates of reactions of electrophilic reagents with olefins and the ionization potentials of the latter. The existence of an approximate linear dependence of the log k values for some electrophilic reagents on the ionization potentials of the olefins has been pointed out before (1). This is illustrated again in Fig. 6, which also incorporates some additional experimental values and the data of Doering and Henderson (9) for CCl_2 and CBr_2, the latter instead of those of Skell and Garner (10) because of the potentially more accurate analytical procedure used in the more recent work. The values for the ozone reactions have also been plotted and there is evidently a large scatter of points, although the general trend appears to be of an electrophilic reagent.

The apparent irregularities and scatter of points for the ozone plot in Fig. 6 can be qualitatively explained by a superposition on a general electrophilic trend of a partly inhibiting effect by the substituent groups. This inhibiting effect could be due to a screening by the substituent groups (steric hindrance) as has been suggested for the reactions of ozone with some aromatics (8) (polyalkyl benzenes). In this case the deviations in Fig. 6 from the values such as indicated for example by the interrupted line may be qualitatively explainable: on the whole the deviations tend to become progressively greater as a screening effect might be expected to become greater. The case of butadiene would be somewhat difficult to explain on that basis, but it is doubtful whether this fact alone could be taken to invalidate a general explanation of this kind.

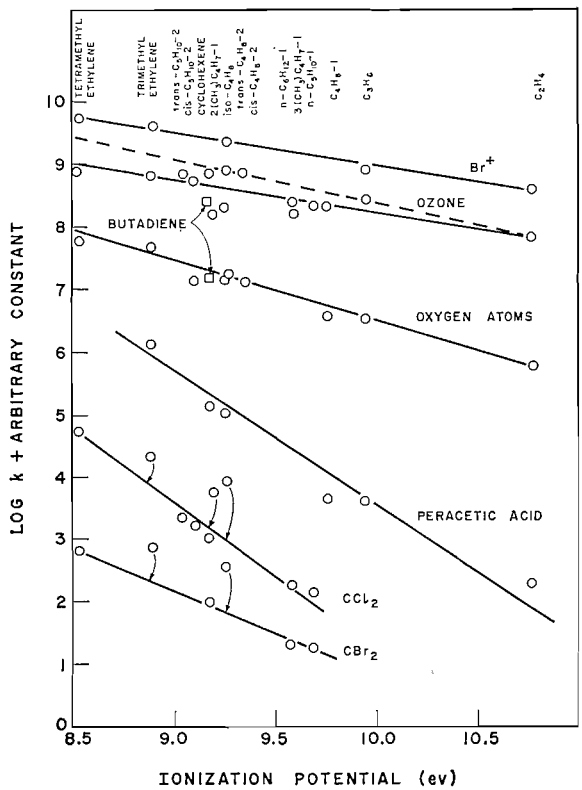

FIG. 6. Plots of log k for several series of electrophilic reactions with olefins against the ionization potentials of the olefins.

The sources of data are: ionization potentials: Collin and Lossing, J. Am. Chem. Soc. **81**, 2064 (1959), and, for 1-hexene, Honig, J. Chem. Phys. **16**, 105 (1948); bromination reactions: Anantakrishnan and Ingold, J. Chem. Soc. 984, 1396 (1935); ozone reactions: present work; oxygen atom reactions: Cvetanović, reference 1 and some unpublished data; peracetic acid reactions: Böeseken and Stuurman, Rec. trav. chim. **56**, 1034 (1937), Böeseken and Hanegraff, Rev. trav. chim. **61**, 69 (1942), Swern, J. Am. Chem. Soc. **69**, 1692 (1947); CCl_2 and CBr_2: Doering and Henderson, reference 9.

A superposition of an additional structural effect on an electrophilic trend could be caused by such a direct screening of the double bond by the substituent groups and the consequent decreased efficiency of a single step attack. Also, it may be due to a more complex addition process, represented for example by the following two-step reaction sequence:

$$\text{olefin} + O_3 \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} [\text{olefin}, O_3] \qquad [5]$$

$$[\text{olefin}, O_3] \xrightarrow{k_6} \text{initial addition product} \qquad [6]$$

Under such conditions the observed rate constant k_{O_3} is a composite quantity

$$k_{O_3} = k_5/(1+k_{-5}/k_6) \qquad [7]$$

and when k_6 is small relative to k_{-5},

$$k_{O_3} = \frac{k_5}{k_{-5}} k_6 = Kk_6 \qquad [8]$$

where K is the equilibrium constant of reaction [5] and is therefore a measure of stability of the postulated olefin–ozone complex formed in the primary step. This complex would have to be of the nature of a "π-complex" since no isomerization of *cis*-2-butene to the *trans* isomer was found under the reaction conditions, as reported in Part I. The electrophilic character of ozone is then readily explained by the dependence of k_{O_3} on K, i.e. on the basicity of the olefins.

The retarding effect of the substituents on reaction [6], i.e. on the rearrangement of the π-complex into the initial addition product (the "initial ozonide"), may again be predominantly due to steric inhibition. Alternatively, the inductive effects of the substituents on the more substituted carbon atom of the double bond, the most probable position of the nucleophilic ring closure necessary for the formation of the "initial ozonide", may play a contributing and perhaps a decisive role in determining the rate of reaction [6]. This last possibility has some distinctly attractive features. It can readily explain the exceptionally low values of the rate constants of the reactions of ozone with such compounds as butadiene and isobutene, and, in contrast to this, the fast reactions with α,β-disubstituted olefins.

In view of eq. [8], a trend in log k_{O_3} for various olefins is a superposition of the trend in log K, which parallels the basicity of the olefins, and of log k_6, which incorporates an inhibiting effect. If it is assumed that (*a*) this inhibiting effect is absent in ethylene, (*b*) that it is four times* as large for tetramethyl ethylene, i.e. when the more substituted carbon carries two methyl groups, as for propylene, in which it carries only one methyl group, and (*c*) that log K is a linear function of the ionization potentials of the olefins, it is then possible to calculate the corresponding values of the inhibiting effects for the other olefins. These represent the additive corrections in $\log_{10}$ units (Δ) which have to be made in order to obtain a linear plot of (log $k_{O_3}+\Delta$) against the ionization potentials. A fair consistency is obtained under such conditions for the olefins which have only methyl radicals as the substituents, with Δ of about 0.23 when one methyl radical is present and about four times as much when two methyl radicals are present on the more substituted carbon. On the same basis the values of Δ for some other radicals (when present singly on the more substituted carbon) were about 0.55 for C_2H_5, n-C_3H_7, and n-C_4H_9; 0.75 for *sec*-C_3H_7; 0.42 for cyclohexene; and 0.93 for C_2H_3 in butadiene.

While the present results appear to be most logically explainable in terms of the two-step mechanism defined by reactions [5] and [6] and an emphasis is placed on this interpretation, they do not represent a definite proof of validity of such a mechanism. Experimentally, it seems to be difficult to discriminate with certainty between a two-step and a one-step addition mechanism. The conflicting views have been recently reviewed and discussed in some detail by Bailey (11). The two-step mechanism discussed in the present work incorporates the features of the π-complex mechanism outlined by Bailey (12) and, in addition, it specifies the kinetics of the process. However, it does not attempt to differentiate between a five-membered ring structure for the "initial ozonide" and the four-membered ring ("molozonide") favored by Bailey (12).

Of the six series of reactions plotted in Fig. 6 only those of oxygen atoms and of ozone are gas phase reactions. The other reactions, all carried out in solution, are in principle subject to complexities resulting from solvent effects. For bromination and peracetic acid reactions there appear to be no pronounced irregularities which could be ascribed to such effects although it would be desirable to have the values of the rate constants for a greater variety of olefins. The reaction series for CCl_2 and CBr_2 additions to olefins

**The over-all consistency requires this value to be about 4 to 4.5.*

appear at first sight to show no correlation with the ionization potentials, as was stressed by Doering and Henderson (9) at the time when the relative rate constants for these two reaction series were reported by these authors. At the same time, there appears to be a significant similarity in the pattern of the plots for these two species in Fig. 6. The meaning of deviations from the lines arbitrarily drawn in Fig. 6 through the experimental points so as to connect most of the points is not clear. The same compounds "deviate" (are too fast relative to the arbitrarily drawn lines) in both series and it is of interest that at least two of these, isobutene and 2-methyl-1-butene, both α,α-disubstituted ethylenes, strongly deviate in the case of ozone reactions as well (perhaps best shown in Fig. 5) but in the opposite direction, being too slow in comparison with the α,β-disubstituted ethylenes. It is not possible to say at present how far-reaching these analogies and contrasts are until experimental information on the rates of reaction of such reagents with a greater number of olefins becomes available.

A STUDY OF THE PRODUCTS OF THE REACTIONS OF OZONE WITH OLEFINS IN THE VAPOR PHASE AS DETERMINED BY GAS–LIQUID CHROMATOGRAPHY[1]

T. VRBASKI[2] AND R. J. CVETANOVIĆ

ABSTRACT

A broad comparative survey has been made of the products of the vapor phase reactions of ozone with ethylene, propylene, 1-butene, 1-pentene, 1-hexene, 3-methyl-1-butene, isobutene, 2-methyl-1-butene, *cis*-2-butene, *trans*-2-butene, *cis*-2-pentene, *trans*-2-pentene, trimethyl ethylene, tetramethyl ethylene, cyclohexene, and 1,3-butadiene as determined by gas–liquid chromatography and, to a smaller extent, by other analytical methods.

INTRODUCTION

Ozonization of olefinic compounds in the liquid phase has been the subject of numerous investigations. This extensive field has been adequately reviewed, in particular recently by Bailey (1). The corresponding reactions in the vapor phase are of greater complexity and have received considerably less attention. The recent recognition of their importance in the photochemically induced processes in polluted atmosphere leading to "smog" formation has been largely responsible for the renewed interest in these reactions (2–6).

In connection with current studies of the correlation of the rates of the olefin–oxygen atom reactions with the molecular structure of the olefins (7), it was thought of interest to attempt to obtain the relative rates of the corresponding olefin–ozone reactions. In the course of this study a certain amount of information has been accumulated on the products of a number of olefin–ozone reactions in the vapor phase. A brief report of these results is given in the present paper.

EXPERIMENTAL

The reactions were carried out at room temperature in a spherical reaction vessel 188 cc in volume, incorporated in a conventional high vacuum apparatus. A batch procedure was employed. The olefin was first transferred into the reaction vessel by freezing in liquid nitrogen and was subsequently vaporized by warming up to room temperature. The required amount of oxygen, containing 2.6 to 3.2% by volume of ozone, was then allowed to stream slowly into the reaction vessel. It was found that at least in some cases, especially when ozone concentration exceeded 3.2%, too rapid introduction of ozone–oxygen mixture could initiate virtually complete combustion of the reacted olefin to carbon dioxide and water accompanied by substantial warming of the reaction vessel and occasional light emission.

Ozone was freshly produced for each run in a standard Towers ozone apparatus by silent electric discharge at 7500 volts and 15 milliamperes. Cylinder oxygen dried over phosphorous pentoxide was used. The ozone concentration was determined iodometrically in the stream of oxygen as it leaves the ozonizer and also immediately prior to the reaction vessel. The two values agreed within the experimental error. The olefins used were of the highest available grade and were thoroughly degassed and bulb-to-bulb distilled *in vacuo* before use.

The initial amounts of olefins and ozone were 400 and 100 μmoles and in some cases these quantities were reduced to facilitate the analysis of the products to 200 and 25 μmoles, respectively. The total pressure in the reaction vessel was, therefore, 360 to 440 mm in the former and 100 to 130 mm in the latter case. A mercury gauge was used to measure the pressures of the reactants, but attempt was made to bring ozone in contact with mercury as little as possible and the slight consumption of ozone in the reaction with some mercury vapor present did not decrease its concentration noticeably.

The condensable reaction products were retained by pumping off the non-condensable gas slowly, using a capillary constriction, through two liquid nitrogen traps in series. No attempt was made to analyze the non-condensable gas which contained the huge excess of oxygen. The analysis of most of the condensable products was done by gas–liquid chromatography (GLC). A Le Roy still (8) was occasionally used to separate the products from excess initial olefin. The hydrocarbon gases formed and carbon dioxide were analyzed mass spectrometrically after preliminary separation by GLC. Formic acid was determined qualitatively from infrared spectra of the products (using a gas cell 10 cm long) after removal of more volatile compounds on the Le Roy still and quantitatively by titrating with $N/50$ NaOH using phenolphthalein indicator. No quantitative determinations of formaldehyde were attempted because of its tendency to polymerize and consequently its difficult quantitative recovery from the reaction apparatus. In the case of some terminal olefins its presence was shown qualitatively by reaction with chromotropic acid and by the infrared spectra of the condensable products. On the whole, in most cases not too important quantities of formaldehyde appeared to be recovered.

The products eluted by GLC were collected in liquid nitrogen traps and their identity was confirmed by infrared and mass spectroscopy. The GLC arrangement was essentially as described previously (9) but with an internal capillary regulating the outlet pressure instead of an external leak. Two 1/4-in. I.D. columns were alternatively used: (1) a 40-ft tricresyl phosphate (TCP) on firebrick column (40 wt.% TCP) operated at 125° C, and (2) an 8-ft dinonylphthalate (DNP) on glass beads column (4 wt.% DNP) operated at room temperature. Helium was used as the carrier gas in both cases. Some separations of lighter gases (CO_2, ethane, ethylene) were kindly made by Dr. N. F. Foster on a 40-ft dimethyl sulpholane (DMS) on firebrick column (40 wt.% DMS) operated at room temperature.

For comparison with the data obtained in the vapor phase the liquid-phase ozonization of ethylene, isobutene, and 1-butene was carried out at −78° C in ethylchloride solution in a separate series of experiments.

RESULTS

The products of the reactions of ozone with a number of olefins in the vapor phase, as observed by the analytical procedures used in the present work, are shown in Table I. The quantities are expressed as molecules of products formed per molecule of ozone consumed.

It should be stressed that the quantities of the carbonyl compounds shown in Table I are based on GLC peak areas and are, therefore, the products observed *after* the condensables are passed through the GLC column and include any products of decomposition of the original compounds in the course of the analysis. This is, in particular, true of the initially present peroxides (shown qualitatively by a positive KI test, for example in the liquid products of isobutene, 1-butene, *cis*-2-pentene, and *trans*-2-pentene) which appear to be reduced to the corresponding carbonyl compounds. Thus in the case of isobutene

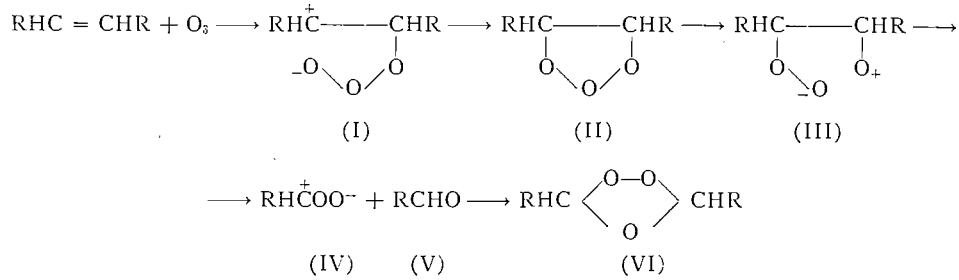
[h]Isobutene produced also methyl acetate (.005) and *tert.*-butanol (.009).

only a fraction (about 13%) of the total acetone was recovered from the liquid products on the Le Roy still at −75°, at which temperature-free acetone should be recovered readily. Some other olefins seemed to show similar behavior but the amounts of the "free" and the "bound" carbonyl compounds were not determined separately.

Since in the present experiments large excess of the olefins was always used, it was not feasible in some cases to analyze for the reaction products of volatilities or GLC elution times similar to those of the olefins; thus the information obtained for the reaction with ethylene is very incomplete. In the case of 2-methyl-2-butene acetaldehyde could not be evaluated quantitatively by GLC analysis, although it was evidently formed in significant amounts as anticipated. Also, any compounds of very low volatility and long GLC elution times would not be readily detected. This is very probably responsible for the limited information on the products of the reaction of cyclohexene.

In order to test whether some double-bond isomerization may occur in the course of these reactions, the butene recovered from the reaction of excess *cis*-2-butene with ozone was analyzed by GLC and found not to have undergone any isomerization.



Liquid-phase ozonization of ethylene, isobutene, and 1-butene produced the expected ozonides in addition to minor amounts of degradation products (carbon dioxide, formaldehyde, formic acid). However, in the case of both isobutene and 1-butene small amounts of ethylene ozonide (about 10% of the main ozonide in each case) were also recovered by GLC analysis and its identity was confirmed by infrared spectroscopy (10). In addition, the GLC analysis showed about 20% of acetone in the case of isobutene and about 10% of propanal in the case of 1-butene, both apparently formed by degradation of the ozonide. In the case of isobutene, a fair amount of non-explosive crystals (melting point of the crude crystals 91–95°) of peroxidic character (giving positive KI test) were isolated on leaving the reaction product stand overnight at room temperature.

DISCUSSION

Most of the previous investigations of the products of the reactions of ozone with olefins in the vapor phase have been recently reviewed by Leighton and Perkins (11). The present work agrees in its main outlines with the previous observations although there are also some differences between the results obtained by various workers. However, in comparing and assessing the results of such studies there are in particular two features of these processes which have to be kept in mind: (1) Appreciable quantities of relatively unstable intermediate peroxidic compounds are initially formed (12, 13) and the final stable products observed will depend on the conditions under which the degradation takes place. The particular analytical procedure used may therefore strongly affect the amounts and the type of the stable products observed. (2) The reactions are highly exothermic and the liberated heat is as a rule likely to affect their course, at least to some extent and sometimes very drastically, especially in the presence of large excess of molecular oxygen as is usually the case. Under conditions of the present experiments too rapid introduction of ozonized oxygen into the olefin vapor led, at least in some cases, to strong warming of the reaction vessel and GLC analysis then showed essentially only large amounts of CO_2 and water in the products, indicating complete combustion. With slow introduction of the ozone–oxygen mixture no significant warming of the reaction vessel occurred and no water peak was observed by GLC although some CO_2 was always formed, as shown in Table I and as observed in most of the previous work. Evidently, it is difficult to eliminate altogether quantitative uncertainties about the possible effect of "hot" products in these reactions.

For personal use only.

Substantial fractions of the products formed under the particular experimental conditions employed in the present work have been isolated in most cases and can be discussed briefly in terms of the generally accepted mechanism of ozone interaction with olefinic compounds. With some vagueness as to the exact detail, this mechanism can be written down as follows:

(I) (II) (III) (IV) (V) (VI)

The initial addition may be a two-step process, as indicated above, in which case I could equally well be visualized as a π-complex (14). On the other hand, a one-step addition would lead directly to the "initial ozonide" (II), which is extremely unstable. Criegee has recently obtained evidence that the initial ozonide is formed at least under some conditions (15). He and his co-workers have also been responsible for the identification of IV as a relatively stable and long-lived zwitterion which can enter into reactions such as addition to an aldehyde (V) to form an ozonide (VI). At low temperatures in solution this last reaction is, no doubt, assisted by the solvent cage effect and usually predominates. At higher temperatures and in the vapor phase other competing reactions of the zwitterion (IV) become important and the process is then characterized by considerable complexity. The types of reactions which the zwitterion (IV) can undergo are of particular importance. These include dimerization and polymerization, with or without participation of water, into peroxidic substances; reactions with any reactive compounds present in sufficient concentration; rearrangement; and decomposition.

The presence of peroxidic intermediates in the products obtained in the present work was shown qualitatively. In the course of GLC analysis these appeared to decompose with the release of the "bound" carbonyl compounds. Some years ago Briner and co-workers isolated and at least partially characterized some of the peroxidic substances formed in the vapor phase olefin–ozone reactions (12, 13). Hydrolysis of these compounds led to the release of the "bound" carbonyl compounds and acids. In the case of 2-butenes and propylene, in addition to the predominant amounts of formic acid, they also observed after hydrolysis smaller quantities of acetic acid. Since, in our case, acids could not be observed directly by GLC analysis, infrared spectra were taken of the products before GLC analysis and in all cases only formic acid was found to be present. The values in Table I given as formic acid, however, have been obtained by titration and may also include any higher acids liberated on hydrolysis. Ozonides were not observed, although some of the more volatile ozonides (ethylene-, isobutene-, and 1-butene-ozonide) produced by low temperature ozonization in solution could be analyzed readily by GLC in spite of their relative instability. This is in agreement with the results of Hanst *et al.* (4), although these authors observed by the use of long path infrared spectroscopy the ozonide formation from some heavier olefins (1-pentene, 1-hexene, 3-heptene). However, less volatile ozonides would not be readily observed under conditions of our GLC analysis and no attempt was made to explore this analytical possibility further.

Decomposition of the zwitterion (IV) has been postulated to explain the formation of various light compounds in the ozonization products (3, 4), thus

$$HCHO_2 \rightarrow H_2O + CO \quad [1]$$

$$CH_3CHO_2 \rightarrow CH_3OH + CO \quad [2]$$

$$CH_3CHO_2 \rightarrow CH_4 + CO_2 \quad [3]$$

$$CH_3CHO_2 \rightarrow H_2O + CH_2{=}C{=}O \quad [4]$$

Reaction [3] and its homologues can readily explain the major amounts of paraffins as well as of ethylene in the case of butadiene (shown doubly underlined in Table I), and of the substantial amount of carbon dioxide formed in our experiments. Together with these paraffins, olefins containing the same number of carbon atoms (shown singly underlined in Table I) are also formed, although in somewhat smaller amounts. The formation of these olefins could perhaps be visualized as resulting from rearrangement through hydrogen migration of the zwitterion (IV) followed by decomposition, for example,

$$CH_3CH_2 \cdot CHO_2 \rightarrow (CH_3CH \cdot CH_2O_2) \rightarrow C_2H_4 + CH_2O_2 \quad [5]$$
(VII)

where CH_2O_2 may again be a zwitterion (IV) and undergo further reactions. Equally well, the olefin formation may be a consequence of a "peroxide-formate" rearrangement (16) followed by decomposition in a particular way. This type of rearrangement is known to occur under some conditions and has been frequently invoked to explain the "abnormal" products of ozonization of olefins, such as formic acid, methanol, etc.

The major carbonyl compounds are the "normal" products (shown in Table I in boldface type). Small amounts of aldehydes containing the same number of carbon atoms as the original olefins (acetaldehyde from C_2H_4, propanal from C_3H_6, *n*-butanal from 1-C_4H_8, isobutyraldehyde from iso-C_4H_8) are occasionally formed, suggesting that perhaps some molecular oxygen splits off from the intermediate (III) and the remainder then rearranges to an aldehyde. However, the quantities of these compounds formed are very small. Much more important amounts are formed of the carbonyl compounds one and, to a lesser extent, two carbon atoms shorter than the "normal" carbonyl compounds. They are underlined in Table I and include, for example, acetaldehyde in the case of 1-butene (besides the "normal" carbonyl compound propanal), acetone in the case of 3-methyl-1-butene (besides the "normal" isobutyraldehyde), etc. This degradation could again be visualized as being induced by "peroxide-formate" rearrangement although other mechanisms could be postulated as well, such as for example secondary oxidation or cyclization followed by decomposition of the rearranged intermediate (VII).

In view of the uncertainties mentioned at the beginning of this discussion and because of the analytical limitations, in particular lack of information on the exact nature of the intermediate peroxidic substances, a subject currently receiving considerable attention (17), and on the amounts of formaldehyde and non-condensable products (CO, H_2, CH_4) formed, the present results evidently provide only a limited picture of these complex vapor phase reactions. However, a preliminary broad survey has been made for a number of olefins under comparable conditions and it is hoped that the information obtained may supplement the observations of other workers made with the use of different analytical techniques and, in particular, help in the planning of more extensive future studies of selected individual reactions.

The products obtained in the low temperature ozonization in solution agree with the results of previous workers. However, it is of interest that in the case of 1-butene and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

isobutene appreciable amounts of ethylene ozonide were isolated by GLC in addition to the expected ozonides of these two olefins. The formation of ethylene ozonide, in spite of some hindrance because of the solvent cage effect and the statistical probability favoring the formation of the unsymmetrical ozonides, seems to indicate that in the initial ozonides (II) of these two olefins the ring opening is not exclusively one way.

ACKNOWLEDGMENTS

The authors are grateful to the analytical section of this division for infrared analyses and to Dr. A. W. Tickner for mass spectrometric analyses.

CIS AND TRANS 1-ACETOXY-1,3-BUTADIENE: PHYSICAL AND CHEMICAL PROPERTIES, INFRARED AND ULTRAVIOLET SPECTRA[1]

K. K. Georgieff and A. Dupré

ABSTRACT

1-Acetoxy-1,3-butadiene was prepared by the reaction of crotonaldehyde with acetic anhydride in the presence of potassium or sodium acetate. The product was found to consist of two forms which, from their physical properties and infrared spectra, appear to be cis and trans. Mass and ultraviolet spectra, and methods of analysis are also reported. The cis form was found to be a substantially stronger inhibitor than the trans in the bulk polymerization of vinyl acetate using benzoyl peroxide as catalyst.

INTRODUCTION

In a recent investigation on the inhibitory effect of various compounds on the rate of polymerization of vinyl acetate (which will be reported elsewhere), some unexpected results were obtained. 1-Acetoxy-1,3-butadiene was prepared from crotonaldehyde and acetic anhydride using potassium or sodium acetate as catalyst (1, 2). On distillation, a series of fractions were obtained with gradually changing boiling points, freezing points, refractive indices, specific gravity, and inhibitory effect on the bulk polymerization of vinyl acetate. To try to establish the reason for these differences, mass, infrared, and ultraviolet spectra were obtained.

EXPERIMENTAL

Preparation of 1-Acetoxy-1,3-butadiene

A modification of the method of Wacker (1) was used. A 240-g quantity of potassium acetate (Mallinckrodt analytical reagent) was charged into a 3-liter round-bottom flask fitted with a Tru-Bore stirrer, a feeding funnel, and a reflux condenser. The apparatus was evacuated and filled with nitrogen. Acetic anhydride (Shawinigan Chemicals Ltd., commercial grade) (440 g) was added and the mixture refluxed. Crotonaldehyde (Shawinigan Chemicals Ltd., redistilled) (240 g) was added drop-wise over a period of 3 hours and the mixture refluxed for an additional 20 minutes. The reaction mixture was cooled and shaken with 1200 cc of water. The organic layer was extracted first with just enough 10% sodium carbonate solution to neutralize the acetic acid, then with 1 liter of 40% sodium bisulphite solution, and finally with 200–300 cc of 10% sodium carbonate solution. After each extraction, the spent aqueous layer was extracted with 100–200 cc of ether and the ether layer added to the crude product. The crude product was dried with anhydrous sodium sulphate, stabilized with 2 g of para-tertiary butylcatechol and 2.5 g of copper resinate, and distilled in a copper column (3 ft long and 1 in. I.D.) packed with $\frac{1}{4}$-in. copper rings. The ether was distilled at atmospheric pressure and the product at 30 mm Hg absolute. Yield based on croton was about 60% and the conversion 50%.

The product was analyzed by saponification, reaction with dodecyl mercaptan (3), and bromination (4). Saponification was carried out in the presence of an excess of aqueous $N/10$ sodium hydroxide solution for 2 hours at room temperature. Results were 101–104% of theory. Analysis by the dodecyl mercaptan method using a reaction time of 2 minutes gave values from 95 to 99.9% based on the reaction with both double

[1]*Manuscript received February 26, 1960.*
Contribution from the Research Laboratories, Shawinigan Chemicals Ltd., Shawinigan Falls, Que.

bonds. Bromination with an aqueous mixture of bromine, sodium bromide, hydrochloric acid, and methanol for 30–60 minutes gave results of about 99%, based on the reaction with one double bond.

The inhibitory effect of 1-acetoxy-1,3-butadiene on the rate of the bulk polymerization of vinyl acetate was determined by a modification of a method previously used (5). The open flame heating was replaced by a Glas-Col mantle in order to increase reproducibility. Inhibition factors, which have been arbitrarily defined as the number of seconds by which pure vinyl acetate is made less active by 1 p.p.m. of inhibitor, were determined. Further details on this phase will be reported elsewhere.

Ultraviolet spectra were obtained with a Beckman DK-2 instrument using 1-cm cells. Infrared spectra were obtained with a Perkin–Elmer 12-C single-beam spectrometer having a sodium chloride prism and the mass spectra with a 60° Nier type instrument using 50 electron volts.

RESULTS

The product was distilled into three fractions and each fraction redistilled into three or four fractions using a 6-ft column, 1 in. in diameter, packed with $\frac{1}{4}$-in. Berl saddles. In Table I will be found the data for that series of final fractions which was most completely studied.

*Contained trace of water.

To try to establish the reason for the differences between fractions as given in Table I, mass spectra were first obtained. There was no indication of the presence of substantial amounts of impurities. The parent peak had a mass of 112 and the base peak 43. All the major peaks could be justified on the basis of the 1-acetoxy-1,3-butadiene structure. Further confirmation of the molecular weight (i.e. 112) was obtained from the analyses (i.e. saponification, reaction with dodecyl mercaptan, and bromination).

The reaction of both double bonds in 1-acetoxy-1,3-butadiene with dodecyl mercaptan did not always go to 100% completion. Doubling the amount of potassium hydroxide catalyst and the duration of reaction made no difference to the results in the one fraction studied. However, the values were sufficiently high to establish clearly the presence of two double bonds. On the other hand, only one double bond brominated in aqueous medium but the reaction was very close to quantitative and can be used as a method of analysis.

Further evidence of the structure was obtained from the ultraviolet spectrum (cf. Fig. 1 and Table I). Both the wave length and the molar extinction coefficient were

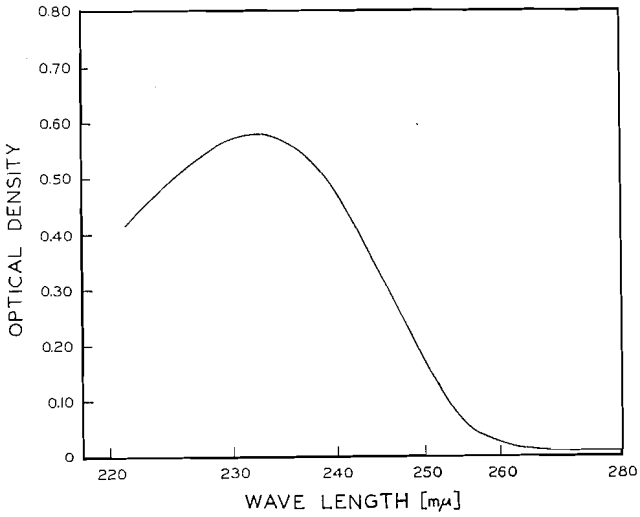

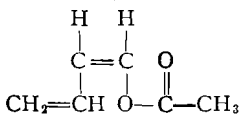

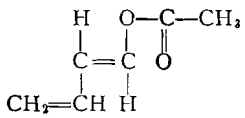

FIG. 1. Ultraviolet absorption spectrum of cis and trans 1-acetoxy-1,3-butadiene.

close to the values expected for the 1,3-butadiene structure. A 1,2- or 2,3-butadiene, on the other hand, would have been expected to absorb at lower wave lengths and have a much lower extinction coefficient.

A study of the data in Table I suggested the presence of at least two forms of 1-acetoxy-1,3-butadiene and therefore one attempt was made to make a separation by gas chromatography. This was unsuccessful although a shoulder on the main band was obtained. This is in direct contrast to the ease with which 1-acetoxy-1,3-butadiene was separated from 2-acetoxy-1,3-butadiene. It was thus apparent that the two or more forms present were more closely related than position isomers and hence cis–trans isomerism was suspected. In most, if not all, compounds the cis form melts at a lower temperature than

Cis

Trans

the trans. It was, therefore, surmised that the lowest boiling fraction (fraction No. 1) was predominately cis while the highest boiling (fraction No. 4) was chiefly trans. This was confirmed by the infrared spectra which are given in Fig. 2. Wave lengths of the bands are given in Table II.

In compounds of the form $R_1CO.OCH{=}CHR_2$ the expected position of the carbonyl band in the infrared is at about 1770 cm^{-1} (6, 7, 8, 9, 10). In all of our fractions the band was at 1763 cm^{-1}. The possibility of having a compound of the form $R_1CH{=}CH.COOR_2$ which has a carbonyl absorption at about 1720 cm^{-1} was clearly eliminated (6, 7, 8, 11). The C—O stretching vibrations of carboxylic esters of the form $CH_3.CO.OCH{=}CHR$ give strong bands between 1218 and 1204 cm^{-1} and between 1159 and 1096 cm^{-1} (6, 12, 13). These bands are usually accompanied by weak bands between 1300 and 1000 cm^{-1}. An examination of our spectra shows definitely these characteristic bands. The terminal methylene group undoubtedly gives rise to the band at 1375 cm^{-1} while

the terminal methyl gives a band at 1432 cm^{-1} in fraction No. 1 and at 1423 in fraction No. 4. The infrared spectrum would, therefore, appear to be consistent with a 1-acetoxy-1,3-butadiene structure.

The following infrared data confirm the previous indication of cis–trans isomerism. The intensity of the carbonyl band in esters has been found by Allan, Meakins, and Whiting (14) to vary with the nature of the unsaturated bond but is stronger in the trans compound than in the cis. In our product, the carbonyl band in fraction No. 4 was stronger than that in fraction No. 1. Therefore, fraction No. 4 would be expected to be predominantly trans and fraction No. 1 chiefly cis. Furthermore, conversion of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the α,β-ethylenic bond from trans to cis has been found by the same authors (14) to cause a shift of the C=C stretching bond to lower frequency. The bands in our fraction No. 4 were found to be at higher frequencies than those in fraction No. 1. The terminal C=C of the form  is expected to give rise to two unsaturation bands at about 990 and about 910 cm^{-1}, the latter being three times the intensity of the former (6). In our fraction No. 4 (trans), two bands at 998 and 893 cm^{-1} are observed, the relative intensities being as previously stated. In the case of fraction No. 1 (cis), bands are observed at 998 and 907 cm^{-1} although the intensity of the latter is about the same order of magnitude as the former. However, this irregularity is often observed in the cis form. It has been noted that the spectrum of the cis is usually weaker than the trans. The α,β-ethylenic group, which gives rise to the cis–trans isomerism, is expected to give bands between 990 and 910 cm^{-1}. In fraction No. 4 (trans), the bands at 924 and 959 cm^{-1} are undoubtedly due to this group. In fraction No. 1 (cis), the band at 941 and possibly the ones at 788 and 675 cm^{-1} can be attributed to this unsaturation. The bands due to cis isomerism have not been rigorously established in the literature.

Only one band was observed due to C=C stretching, i.e. at 1659 cm^{-1} (trans) and 1656 cm^{-1} (cis). Another one at about 1640 cm^{-1} was expected. This suggests that the two C=C groups are not in the same plane (15).

Further confirmation of the cis and trans assignments was made from the nuclear magnetic resonance spectra (16) by Bernstein (National Research Council, Ottawa). Agreement with the infrared data was near quantitative for mixtures of the two forms.

From the data in Table I, it is obvious that the cis form (fraction No. 1) is a stronger inhibitor than the trans (fraction No. 4) for the bulk polymerization of vinyl acetate using benzoyl peroxide as catalyst. In all the distillation fractions studied, the highest inhibition factor obtained was 2.02 seconds per p.p.m. (cis) and the lowest 1.55 (trans). Inhibition factors for the total product were found to vary somewhat from run to run, e.g. with sodium acetate as catalyst 1.79 and 1.87 and with potassium acetate 1.87. However, sufficient work was not done to establish which factors influenced the proportion of the two forms produced.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Shawinigan Chemicals Ltd. for permission to publish this paper, to Dr. C. Sandorfy for his valuable discussion on the infrared spectra, to Dr. H. J. Bernstein for obtaining the NMR spectra, to Mrs. Y. Richard for the mass spectra, and to Mr. E. Blais for the other spectra.

THE THERMAL DECOMPOSITION OF PHENYL METHYL SULPHIDE[1]

MARGARET H. BACK[2] AND A. H. SEHON

ABSTRACT

The thermal decomposition of phenyl methyl sulphide was investigated in a flow system in an excess of toluene. The main products were methane, thiophenol, and dibenzyl. The primary mode of decomposition was ascribed to the reaction

$$C_6H_5SCH_3 \rightarrow C_6H_5S + CH_3.$$

The rate constant for this process was given by the expression

$$k = 3\times10^{14}.\ e^{-60{,}000/RT}\ \text{sec}^{-1}.$$

INTRODUCTION

The benzyl radical has long been known to be fairly stable thermally and relatively unreactive (1, 2). These properties have been attributed to its conjugated structure which allows the free electron to be largely delocalized (3, 4). Radicals with structures similar to that of the benzyl radical might also be expected to be stabilized by resonance and hence to form relatively weak bonds with other radicals. It was anticipated that the phenylsulphide radical, C_6H_5S, satisfies these conditions. To test this hypothesis the kinetics of the thermal decomposition of phenyl methyl sulphide in a stream of toluene was studied.

EXPERIMENTAL

Materials

Phenyl methyl sulphide was kindly supplied by Dr. W. L. Hawkins of Bell Telephone Laboratories, N.J., and was further purified by distillation at low pressure. Toluene was generously supplied by Gulf Oil Corporation, Pittsburgh, Pa., and was purified by distillation through an efficient column. The fraction boiling at 110.5° C was used in this study.

Apparatus

The pyrolysis was studied in a conventional vacuum flow system similar to those employed in previous investigations using the toluene carrier technique (5). The toluene pressure was varied between 5.7 and 10.1 mm Hg. Weighed amounts of the sulphide were admitted from a small detachable vial through a short capillary which led into the toluene stream. The vapor pressure of the sulphide could be changed by heating the vial to different temperatures with a removable bath containing dibutylphthalate. The temperature of the bath was varied between 80° C and 96° C, giving a partial pressure of sulphide from 0.5% to 2% of the toluene pressure. The decomposition was studied over the temperature range 550° C to 706° C.

Analysis

The products were condensed in a series of three traps maintained at −5° C, −78° C, and −188° C. The material collected in the first trap was weighed and analyzed for disulphide according to the procedure outlined by Kolthoff (6). The contents of the trap maintained at −78° C were titrated for mercaptan with 0.1 *N* silver nitrate solution,

using a rotating platinum electrode and a microammeter (7). The method was calibrated with thiophenol solution of known concentrations. Some titrations were also done potentiometrically with a silver wire electrode (8). The two methods of titration gave identical results and the former method was generally used. Non-condensable gases were pumped into calibrated bulbs with the aid of two diffusion pumps connected in series and were analyzed by combustion on copper oxide at 300° C.

RESULTS AND DISCUSSION

Products

The main products of the decomposition, shown in Table I, were methane and a mercaptan, which was considered to be thiophenol. The ratio of mercaptan to methane varied from 1.1 to 1.6, increasing with increasing temperature. Methane accounted for 90 to 96% of the non-condensable gases and the remainder was hydrogen.

*P_s and P_t refer to the partial pressures of phenyl methyl sulphide and toluene, respectively.

No disulphide was detected in the trap maintained at −5° C. The product collected in this trap was shown to be dibenzyl. Neither ethane nor methyl mercaptan were detected among the products.

Mechanism of Decomposition

The results suggested that the primary step in the pyrolysis of phenyl methyl sulphide involved the dissociation of the C—S bond,

$$C_6H_5SCH_3 \rightarrow C_6H_5S + CH_3, \qquad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and that the phenylsulphide and methyl radicals formed reacted further with toluene to form thiophenol and methane,

$$C_6H_5S + C_6H_5CH_3 \rightarrow C_6H_5SH + C_6H_5CH_2 \quad [2]$$

$$CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2. \quad [3]$$

In addition, the benzyl radicals formed in reactions [2] and [3] recombined, at least in part, to give dibenzyl.

According to this mechanism thiophenol, methane, and dibenzyl would be formed in equimolar amounts. However, the yield of methane was always less than that of the mercaptan, this discrepancy becoming more pronounced with increasing temperature. Furthermore, the amount of dibenzyl formed was found to be slightly less than the yield of methane. Therefore, reactions [1], [2], [3], and the dimerization of benzyl radicals do not fully represent the mechanism of the decomposition.

These findings may be explained by postulating that methyl radicals may not react sufficiently rapidly with toluene in the temperature range of the decomposition, 550° C to 706° C, to be quantitatively converted to methane. Similar conclusions were reached by Szwarc and Taylor (9), who showed that at 780° C about 25% of the methyl radicals produced in the thermal decomposition of acetone in a stream of toluene were removed by recombination with benzyl radicals,

$$CH_3 + C_6H_5CH_2 \rightarrow C_6H_5CH_2CH_3, \quad [4]$$

and about 1 to 2% by dimerization,

$$CH_3 + CH_3 \rightarrow C_2H_6, \quad [5]$$

rather than by reaction with toluene. In the present study no ethane was detected among the products; however, its rate of production would be expected to be much less than that of ethylbenzene, because the steady-state concentration of benzyl radicals is probably much greater than that of methyl radicals.

With increase in temperature, the rate of reaction [4] would be expected to increase more rapidly than the rate of reaction [3]. This trend was indeed observed as evidenced by the increase in the ratio of thiophenol to methane with increasing temperature.

If reactions [1] to [4] occurred, the yield of dibenzyl should equal that of methane. The ratio of dibenzyl to methane was usually between 0.70 and 0.95, and it is suggested that losses of the dibenzyl due to inefficient trapping could account for the deviation of these values from unity (10).

The first-order rate constants for the decomposition of phenyl methyl sulphide were calculated from the rates of formation of methane and thiophenol, and are given in Table I. The rate constant for the production of methane, k', was always less than that for the production of thiophenol, k. The plots of log k and log k' against $1/T$ are shown in Fig. 1. Both curves deviate from linearity at high temperatures, but the drop in k' is more pronounced than that in k. The effect of changes in contact time, partial pressures of phenyl methyl sulphide and toluene are shown in Tables II, III, and IV, respectively. These results suggest that the decomposition of phenyl methyl sulphide may be considered to be a first-order process.

The extent of reaction [3] may, with certain assumptions, be calculated. The concentration of benzyl radicals may be estimated if it is assumed that there is little recombination in the hot zone. As a first approximation, the total production of benzyl radicals will then be equal to the sum of the thiophenol and methane produced less the amount

removed by recombination with methyl radicals. The latter quantity may be taken as the difference between the thiophenol and methane formed. Thus, the total production of benzyl radicals is equal to twice the production of methane, and its average yield may be considered as one half of this quantity. Assuming that the concentration of methyl

radicals is stationary, the rate of production of methane is given by the following equation:

$$\frac{d(CH_4)}{dt} = \frac{k_1k_3(C_6H_5SCH_3)(C_6H_6CH_3)}{k_3(C_6H_5CH_3)+k_4(C_6H_5CH_2)}.$$

The rate constant for the reaction of methyl radicals with toluene, k_3, has been measured by Trotman-Dickenson and Steacie (11), who found $k_3 = 1.4\times10^{11}.e^{-8300/RT}$ $mole^{-1}$ cc sec^{-1}. The rate of production of thiophenol was taken as a measure of the rate of reaction [1], i.e., k_1 was taken equal to k. The production of methane for any particular experiment may then be calculated if a value is assumed for the rate constant, k_4, for the recombination of benzyl and methyl radicals. In a similar calculation Szwarc and Taylor (9) took this rate constant to be 10^{12} $mole^{-1}$ cc sec^{-1}, which is slightly less than the value for the recombination of methyl radicals. With these values the yield of methane was calculated for eight experiments, and the results were compared with the observed yields of methane (Table V).

TABLE V

24	934.5	.308	.414

The agreement between the observed and calculated values is better than could be expected in view of the approximations made and the uncertainty in the values k_3 and k_4, and suggests that under the conditions of the experiments methyl radicals were not completely scavenged by toluene and that some reacted with benzyl radicals to give ethylbenzene. However, at the higher temperatures some of the ethylbenzene would be decomposed to give methyl radicals* and, therefore, one would expect, as actually

**The activation energy and the frequency factor for the decomposition of ethylbenzene are 3 kcal/mole greater than and 10 times less than the corresponding parameters for the decomposition of phenyl methyl sulphide. Therefore, the rate constant for the decomposition of ethylbenzene is considerably less than that for phenyl methyl sulphide and was neglected in the calculation of the concentration of methyl radicals.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

observed, an increase in the production of methane at the higher temperatures relative to the calculated values.

If recombination reactions of the phenylsulphide radical occurred, the rate constant for the production of thiophenol, k, would be expected to fall as the temperature was increased. The Arrhenius plot exhibited in fact some deviation from linearity, but only at the highest temperature attained. Thus, it would appear that phenylsulphide radicals, unlike methyl radicals, were efficiently scavenged by toluene. This seems plausible because the possible recombination products of the phenyl sulphide radical, i.e. diphenyldisulphide or phenylbenzyl sulphide, would probably not be sufficiently stable and would, therefore, not be formed in the hot reaction zone. In consequence one may consider the phenyl radicals to be removed only in reaction [2] with toluene and one may conclude that, in the region where the plot of log k vs. $1/T$ is linear, the rate of production of thiophenol is to a good approximation a measure of the rate of decomposition of phenyl methyl sulphide into phenylsulphide and methyl radicals. The activation energy and frequency factor calculated from the linear portion of the plot were 60 kcal/mole and 3×10^{14} sec^{-1}, respectively.

The effect of the surface of the reaction vessel on the decomposition was not investigated and, therefore, the activation energy of 60 kcal/mole may be only tentatively identified with the dissociation energy of the $C_6H_5S—CH_3$ bond. A value of 73 kcal/mole was suggested by Franklin and Lumpkin (12) for $D(CH_3S—CH_3)$ on the basis of their results obtained with the electron impact method. The difference between $D(CH_3S—CH_3)$ and $D(C_6H_5S—CH_3)$, which may amount to 13 kcal/mole, represents then the difference in resonance energies of the methylsulphide and the phenylsulphide radicals. Hence, the actual value of the resonance energy of the phenylsulphide radical would be at least 13 kcal/mole.

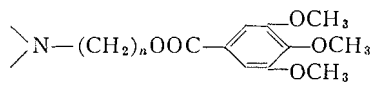
THE SYNTHESIS OF SOME BASIC ESTERS OF 3,4,5-TRIMETHOXYBENZOIC ACID[1]

GERASSIMOS FRANGATOS, GEZA KOHAN, AND FRANCIS L. CHUBB

ABSTRACT

A series of basic esters of 3,4,5-trimethoxybenzoic acid was obtained from the reaction of 2-chloroethyl and 3-chloropropyl 3,4,5-trimethoxybenzoate with secondary amines including 1,2,3,4-tetrahydro-β-carboline. The latter compound was prepared by the lithium aluminum hydride reduction of 1,2,3,4-tetrahydro-1-oxo-β-carboline.

The remarkable effect of reserpine on the central nervous system has resulted in a wide application of this alkaloid primarily in states of hypertension and anxiety. However, the serious side effects of the drug and its high cost made it desirable to explore synthetic routes for the preparation of moieties which would retain the desirable pharmacodynamic properties with lesser or no interference from adverse side reactions. Miller and Weinberg (1), in view of the fact that the presence of the 3,4,5-trimethoxybenzoyl group in the reserpine molecule was necessary for its activity, prepared a number of basic esters of 3,4,5-trimethoxybenzoic acid. They reported reserpine-like activity for some of these compounds, especially those which contain three carbon atoms between the nitrogen and the ester group. This observation stimulated the synthesis and pharmacological testing of compounds of this type. Vejděl̆k (2), Supniewski (3), Sastry and Lasslo (4), Shapiro (5), Latuis and Combes (6), and Solov'ev (7) have synthesized a number of basic esters by bringing about the esterification of an aminoalcohol with 3,4,5-trimethoxybenzoyl chloride.



This communication reports some of the work done in these laboratories in which another route to the synthesis of basic esters was followed. The esters of halogenated alcohols with 3,4,5-trimethoxybenzoic acid were prepared and subsequently used as the alkylating agents in a series of secondary amines including 1,2,3,4-tetrahydro-β-carboline. This method is especially advantageous in cases where the aminoalcohol is not readily available. The reaction was carried out with or without solvent usually in the presence of an acid acceptor such as K_2CO_3. In this case 2-chloroethyl 3,4,5-trimethoxybenzoate (I) and 3-chloropropyl 3,4,5-trimethoxybenzoate (II), prepared from 3,4,5-trimethoxybenzoyl chloride and the corresponding alcohol, were used as alkylating agents. The basic esters (III) prepared are listed in Table I. The reaction sequence is shown below.

1,2,3,4-Tetrahydro-β-carboline (IV) was prepared from 1,2,3,4-tetrahydro-1-oxo-β-carboline (V). The latter compound was prepared by applying a modification (8) of the procedure of Abramovitch and Shapiro (9). These authors have cyclized 2,3-dioxopiperidine-3-phenylhydrazone (VI) to V by using polyphosphoric acid or formic acid as acidic catalyst. This method had its limitations for it could not be used for relatively large scale operations due to the extensive polymerization and tar formation which occurred. However, when a mixture of concentrated hydrochloric acid and acetic acid was used the cyclization of VI to V proceeded in a satisfactory manner.

Lithium aluminum hydride reduction of V to IV had been attempted previously but without success (9). However, lithium aluminum hydride in boiling dioxane reduced V to IV in better than 90% yield. The reaction of IV with 2-chloroethyl 3,4,5-trimethoxybenzoate (I) and 3-chloropropyl 3,4,5-trimethoxybenzoate (II) was carried out in dimethylformamide solution using anhydrous potassium carbonate as the acid acceptor.

EXPERIMENTAL

Melting points are uncorrected. Microanalyses were carried out at the Microanalytical Laboratory of E. Thommen, Thannerstrasse 45, Basel, Switzerland.

3,4,5-Trimethoxybenzoyl Chloride

The procedure of Lasslo and Jordan (10) was followed except that the crude product was further purified by distillation *in vacuo*, b.p. 110–112°/0.5 mm.

2-Chloroethyl 3,4,5-Trimethoxybenzoate (I)

A mixture of 23.05 g of 3,4,5-trimethoxybenzoyl chloride, 8.05 g of 2-chloroethanol, and 10 g of anhydrous potassium carbonate in 200 ml of dry benzene was stirred and refluxed for 4 hours. At the end of the reaction period the evolution of carbon dioxide ceased. The inorganic salts were separated by filtration. The benzene was distilled from the filtrate under reduced pressure and the remaining liquid was distilled *in vacuo*. The fraction boiling at 155–158°/1 mm was collected and further purified by recrystallization from aqueous alcohol. A yield of 18.1 g (66.1%), m.p. 72°, was obtained. Anal. Calc. for $C_{17}H_{15}ClO_5$: C, 52.46; H, 5.46; Cl, 12.91. Found: C, 52.33; H, 5.40; Cl, 13.15.

3-Chloropropyl 3,4,5-Trimethoxybenzoate (II)

The same procedure as in the case of 2-chloroethyl 3,4,5-trimethoxybenzoate was used. A yield of 68.3%, b.p. 162–164° (1 mm) and m.p. 58° (aqueous ethanol), was obtained. Anal. Calc. for $C_{13}H_{17}ClO_5$: C, 54.08; H, 5.89; Cl, 12.28. Found: C, 54.31; H, 6.01; Cl, 12.00.

2-Piperidinoethyl 3,4,5-Trimethoxybenzoate

2-Chloroethyl 3,4,5-trimethoxybenzoate (5.49 g, 0.02 mole) was dissolved in 20 ml of freshly distilled piperidine. The reaction mixture was refluxed for 3 hours while a semi-solid material separated. The mixture was cooled and then treated with 25% aqueous sodium hydroxide and extracted thoroughly three times with chloroform. The chloroform layer was washed with water and dried over sodium sulphate. Distillation of the chloroform and the excess of piperidine under reduced pressure left an oily residue which did not crystallize. It was dissolved in chloroform and a slow stream of dry hydrogen chloride was passed through the solution for 15 minutes. Addition of ether precipitated the hydrochloride which was recrystallized from a mixture of isoamyl alcohol and ethyl acetate; 5.2 g (72.3%) of 2-piperidinoethyl 3,4,5-trimethoxybenzoate hydrochloride was obtained melting at 209–210°. Anal. Calc. for $C_{17}H_{26}ClNO_5$: C, 56.75; H, 7.23; Cl, 9.86; N, 13.89. Found: C, 56.92; H, 7.48; Cl, 10.07; N, 4.07. The picrate, m.p. 165–166°, was recrystallized from alcohol. Anal. Calc. for $C_{23}H_{28}N_4O_{12}$: C, 50.00; H, 5.07; N, 10.14. Found: C, 49.91; H, 5.22; N, 10.51. The remaining compounds in the series were prepared as above, and are listed in Table I.

Piperid-2,3-dione-3-phenylhydrazone

Piperid-2,3-dione-3-phenylhydrazone was prepared from 3-carbethoxy-2-piperidone according to the procedure of Abramovitch and Shapiro (9).

1,2,3,4-Tetrahydro-1-oxo-β-carboline

Fifty-eight grams of piperid-2,3-dione-3-phenylhydrazone (m.p. 244–245°) was added to a mixture of 135 ml of concentrated hydrochloric acid and 270 ml of glacial acetic acid. The reaction mixture was stirred and refluxed for 3 hours. The dark solution obtained was treated with charcoal and filtered. The filtrate was distilled under reduced pressure. The remaining dark material was treated with 75 ml of ice-cold acetone. The acetone was decanted and the residue was recrystallized from boiling acetone. The crystalline material obtained was recrystallized from aqueous alcohol and melted at 183–185°. Repeated crystallization from aqueous alcohol raised the melting point to 188°. Reported 183–184° (9), 189° (11). A yield of 26 g (49%) was obtained.

1,2,3,4-Tetrahydro-β-carboline

A sample of 1,2,3,4-tetrahydro-1-oxo-β-carboline (9.5 g) was dried *in vacuo* over phosphorous pentoxide and subsequently dissolved in 125 ml of boiling dry dioxane. This solution was added dropwise to a stirred and refluxing suspension of 9.5 g powdered lithium aluminum hydride in 200 ml of dioxane. During the addition the dioxane refluxed smoothly without external heating. The reaction mixture was stirred and refluxed in a nitrogen atmosphere for 4 hours and then was cooled. The excess of lithium aluminum hydride was destroyed with wet dioxane.

The mixture was brought to boiling and filtered hot. The dioxane was evaporated under reduced pressure and the solid residue was recrystallized from aqueous alcohol; 8.4 g (95.7%) of 1,2,3,4-tetrahydro-β-carboline, m.p. 208° (reported 200–202° (9), 204° (12)), was obtained. It gave a picrate melting at 253° with decomposition (reported 253° dec. (9, 11)).

2-(1,2,3,4-Tetrahydro-β-carbolinyl-2)ethyl 3,4,5-Trimethoxybenzoate

A mixture of 1.72 g (0.01 mole) of 1,2,3,4-tetrahydro-β-carboline, 2.74 g (0.01 mole) of 2-chloroethyl 3,4,5-trimethoxybenzoate, and 4 g of anhydrous potassium carbonate in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

10 ml of dimethylformamide was stirred and refluxed for 4 hours. The reaction mixture was cooled and then filtered. The inorganic salts remaining on the filter were washed with dimethylformamide. The combined filtrates were distilled under reduced pressure until all the dimethylformamide was removed. The residue was dissolved in 100 ml of chloroform and passed through an alumina column which was eluted with an additional 150 ml of chloroform. The chloroform was removed from the combined eluates by distillation and the residual oil crystallized on trituration with a few drops of methanol. It was recrystallized from methanol and melted at 151°. Yield of 2.38 g (58%) was obtained. Anal. Calc. for $C_{23}H_{26}N_2O_5$: C, 67.31; H, 6.34; N, 6.82. Found: C, 67.33; H, 6.46; N, 6.64.

3-(1,2,3,4-Tetrahydro-β-carbolinyl-2)propyl 3,4,5-Trimethoxybenzoate

This compound was prepared as above, except that it was isolated as the hydrochloride hydrate. The eluate from the alumina column was treated with dry hydrogen chloride. Upon addition of ether an oil was deposited which crystallized on trituration. It was recrystallized from isoamyl alcohol to yield 2.6 g (54.3%), m.p. 199–200°. Anal. Calc. for $C_{24}H_{29}ClN_2O_5.H_2O$: C, 60.19; H, 6.48; N, 5.85. Found: C, 59.99; H, 6.52; N, 5.75.

HEATS OF MIXING OF POLYISOBUTYLENE WITH SOME ORGANIC SOLVENTS[1]

CLAUDE WATTERS,[2] HUBERT DAOUST, AND MARCEL RINFRET

ABSTRACT

The heats of mixing of four fractions of polyisobutylene with five organic solvents have been measured at 25° C with the use of a Tian–Calvet microcalorimeter. The maximum concentrations attained were of the order of 3% in polymer. It has been found that the enthalpy parameter κ_0 is independent of the molecular weight of the polymer sample in the investigated molecular weight range. All the values for κ_0 calculated from the Van Laar – Scatchard equation for the different polymer–solvent pairs are different from the values estimated from the partial molal quantities. This is explained with the use of new theories on the thermodynamics of high polymer solutions by Orofino and Flory and by Huggins.

INTRODUCTION

The physical state of a pure polymer at rest is ill-defined. For many types of high polymers, their state presents some degree of crystallinity or molecular orientation but most polymers are amorphous except under special conditions. Polyisobutylene is an amorphous polymer but below −70° C, its molecules are frozen in the so-called glassy state (1) and the transition from that state to the "liquid" state takes place over a rather wide temperature range. However, at room temperature, the dissolution of pure polyisobutylene in a liquid solvent will probably not involve any heat of transition. This investigation has been carried out to check that hypothesis and to show the importance of the data on heats of mixing for the study of high polymer solutions.

EXPERIMENTAL PART

Materials

Four fractions of polyisobutylene have been used in this investigation. The fractions PD-5 ($\bar{M}_v$ = 392,000) and PD-6 ($\bar{M}_v$ = 252,000) have been obtained from a fractionation of commercial Vistanex L-100 having a viscosity average molecular weight of about 1,360,000. The fractions PIJ-1-2 ($\bar{M}_v$ = 108,000) and PIJ-4 ($\bar{M}_v$ = 63,000) have been obtained from a fractionation of commercial Vistanex MH having a viscosity average molecular weight of about 68,000. Both commercial polymer samples have been obtained through the courtesy of Enjay Co., Inc. The fractionations have been carried out in accordance with previous procedures (2) and the molecular weights determined by the usual viscosity treatment of cyclohexane solutions. The reagent-grade solvents were purified in a high efficiency distilling column and stored over sodium wire.

Apparatus

The calorimetric measurements of the heats of mixing have been carried out using a Tian–Calvet microcalorimeter, a differential isothermal type which has been described elsewhere (3, 4). In our installation, a photopen recorder follows the spot of light reflected from the galvanometer mirror. The apparatus is calibrated electrically, and the measurement of the area under the curve gives the heat developed during the course of the reaction. This microcalorimeter is sensitive to a heat effect of 0.001 calorie per hour and is especially designed to follow a reaction over a long period of time.

[1]*Manuscript received January 15, 1960.*
Contribution from the Department of Chemistry, Université de Montréal, Montreal, Que. This paper has been presented in part at the Eighth Canadian High Polymer Forum at McDonald College, Ste Anne de Bellevue, Que., May 12–14, 1958.
[2]*Present address: Montreal Cancer Institute, Notre-Dame Hospital, Montreal, Que.*

The dissolution of the polymer was realized in a very simple way (5). A given quantity of polymer was weighed in a stainless steel mesh cage which was attached to a stainless steel wire and immersed under a quantity of mercury in a stainless steel cell. A weighed amount of solvent was added and the cell tightly stoppered. After thermal equilibrium was attained, the cage was then raised into the solvent and the thermal phenomenon measured.

RESULTS

The data obtained in this investigation are given in Table I. In this table, m is the weight of polymer used in each experiment; V_M, the total volume of the mixture; ϕ, the volume fraction of the polymer; and ΔH_M, the integral heat of mixing. The quantity B_0 represents the characteristic interaction constant for a given polymer–solvent pair and is calculated from the Van Laar – Scatchard equation, supposing that there is no volume change upon mixing,

$$\Delta H_M = B_0 V_M \phi (1-\phi). \quad [1]$$

DISCUSSION

Within the experimental errors, the values of B_0 for fractions PIJ-4 and PD-6 with chlorobenzene are practically the same. So, there is no significant variation of B_0 with molecular weight, at least in the range we have investigated. A résumé of the data is given in Table II and one sees that there is a direct relation between the Flory temperature θ and the enthalpy parameter κ_0 as predicted by theory. The parameter κ_0 is related to B_0 by the following equation

$$\kappa_0 = B_0 V_1/RT \quad [2]$$

where V_1 is the molar volume of the solvent.

However, the calculated values for κ_0 are all different from those given for κ_1. The parameter κ_1 is calculated from the partial molal quantities obtained by direct measurement of the heat of dilution or by indirect methods as viscosimetry, osmometry, and vapor pressure measurements. The large differences between the two sets of values for the enthalpy parameters may be due to three factors: (*a*) there may be an important volume change upon mixing, (*b*) there may be an important transition in the polymer state upon mixing, and (*c*) there may be a real difference between κ_0 and κ_1. The first factor is readily rejected since the volume changes are rather slight in the concentration range we have investigated. For example, the specific volume of pure polyisobutylene is 1.094 cc/g at 25° C (7); in dilute benzene solutions, the partial specific volume of the polymer increases to a constant value of 1.105 cc/g (8). The value of κ_0 would be increased to 0.70 because of this volume change upon mixing and the discrepancy with κ_1 would be still greater.

The possibility of the existence of a heat of transition will now be considered. If we assume that the difference between the values of the heats of dissolution of polyisobutylene in benzene as measured in this investigation and those calculated with $\kappa_1 = 0.21$ is due to some heat of transition, we come to the conclusion that the value for this heat is approximately 185 calories per monomer unit, a value which is not too high when compared with those obtained for other polymers. But this value should be independent of the nature of the solvent, and in athermal or slightly exothermic solvents as cyclohexane and *n*-heptane (see Table II), this endothermic heat of transition should have shown up.

Although we do not discard the possibility of the existence of some heat of transition, we believe that the data can be discussed in regard to a new approach to the theory of the heat of mixing. Recently, Orofino and Flory (9) and Huggins (10, 11) have published new theories on the thermodynamics of high polymer solutions. The new semiempirical equation proposed by Orofino and Flory for the free energy of mixing is given by

$$[3] \qquad \Delta F_M = RT\{n_1 \ln(1-\phi)+n_2 \ln \phi+xn_2[\chi_0-\sum_{i=1}(\chi_i/i)\phi^i]\}$$

where n_1 and n_2 are the number of moles of the solvent and the polymer in the mixture and x is the ratio of the molar volumes of the polymer and the solvent, V_2/V_1. This equation has been derived to account for the polymer–solvent pairs for which a single interaction parameter cannot be used. The physical meaning of the parameters χ_0, χ_1, is not given but each of them is assumed to be independent of the concentration of the solution. From the equation [3], through the use of standard thermodynamic equations, the heat of mixing may be shown to be given by

$$[4] \qquad \Delta H_M = -T^2[\partial(\Delta F_M/T)/\partial T]_p = RT\kappa_0 n_2 x - RT\kappa_1 n_2 x\phi - RT\kappa_2 n_2 x\phi^2 - \ldots$$

where $\kappa_1 = -T(\partial\chi_1/\partial T) = B_1V_1/RT$. Equation [4] may be reduced to equation [1] when $\kappa_0 = \kappa_1$ and κ_2 and higher parameters vanish.

The new equation proposed by Huggins for the heat of mixing of "liquid" polymers with liquid solvents is given by

$$[5] \qquad \Delta H_M = N\Delta H_2^* n_2 - aN\Delta H_2^* n_2\phi - bN\Delta H_2^* n_2\phi^2 - \ldots$$

where N is the Avogadro number and a, b, etc. are fractional quantities. The quantity ΔH_2^* is defined by Huggins as the increase of heat content when a single molecule of polymer is transferred from pure polymer to pure solvent. The sign and the magnitude of ΔH_2^* are functions of the molecular structure of polymer and solvent and of the intermolecular forces involved in 1–1, 2–2, and 1–2 contacts.

The partial molal quantities derived from equations [3], [4], or [5] will not contain any interaction parameter with the subzero index and the results obtained from measurements of the integral heat of mixing and the results obtained from measurements of the heat of dilution may give different values for the heat parameter at infinite dilution. Even if there is a real difference between κ_0 and κ_1 as predicted by Huggins' treatment, this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

difference should not be very large for mixtures of monomers since the molecular configuration changes are minor in that case. But in the case of a mixture of a polymeric solute in a monomeric solvent, $RT\kappa_0 n_2 x$ or $\Delta H_2^* N n_2$, which represents the energy change when Nn_2 macromolecules are transferred from their pure state to their solute state, depends on the degree of self-coiling of the chains which in turn depends on the polymer–solvent specific interactions. The sudden change in the configuration of the polymer chains upon mixing in a poor solvent will then be responsible for the large difference between the mixing parameter κ_0 and the infinite dilution parameter, κ_1.

The process of mixing may be considered as a series of dilutions starting with $\phi = 1$ and according to the results shown in Table II, the dilution of a very concentrated polymer solution would produce a higher apparent heat parameter than the dilution of a less concentrated solution. This observation has been confirmed by calorimetric measurements (6) and indirect measurements (12) of the heats of dilution of the polyisobutylene–benzene system for which the apparent heat parameter increases from 0.21 at high dilution to approximately 0.6 at very high polymer concentration. The major part of the enthalpy of mixing for that system would thus come from the first neighbor interaction between polymer and solvent molecules and from the molecular configuration changes of the polymeric chains due to this interaction at the beginning of the mixing process.

ACKNOWLEDGMENTS

We wish to thank the National Research Council of Canada for the generous financial assistance in this investigation. We also thank the Scientific Research Bureau of the Province of Quebec for the award of a bursary to C.W. while doing this research.

THE INFRARED FREQUENCIES AND INTENSITIES OF THE HYDROXYL GROUP IN 2,6-DI-*tert*-BUTYL-4-SUBSTITUTED PHENOLS[1]

K. U. INGOLD

ABSTRACT

The infrared frequencies, intensities, and apparent half band widths of the O—H stretching band of a series of 2,6-di-*tert*-butyl-4-substituted phenols have been measured in carbon tetrachloride solution and compared with the corresponding 4-substituted phenols. The frequencies of the former are 36 cm^{-1} higher than the latter and the intensities are also slightly higher. Both the frequency and intensity follow a Hammett $\rho\sigma$ relation. It is shown that the O—H bond lies in the plane of the benzene ring, the increase in frequency and intensity being ascribed to a steric repulsion of the phenolic hydrogen by the adjacent *tert*-butyl group.

INTRODUCTION

Previous work on the frequencies and intensities of the hydroxyl group of substituted phenols has dealt mainly with meta- and para-monosubstitution (1, 2, 3, 4), although some work has been done on the effects of orthosubstituents (5) and the frequencies of a few 2,6-di-*tert*-butyl phenols have been measured, but not with high precision (6, 7).

The present work was devoted mainly to the changes in frequency, intensity, and half band width produced by various 4-substituents on the O—H band in 2,6-di-*tert*-butyl phenols. The corresponding monosubstituted phenols were also examined.

EXPERIMENTAL

A Beckman I.R.4 spectrophotometer with lithium fluoride optics was used to measure the O—H bands, the frequencies being calibrated by the standard absorption lines of water vapor. The effective slit width was about 4 cm^{-1}. Band areas were obtained by graphical integration. Solution concentrations in the range 0.01–0.005 molar were employed and the cell thickness was 1.0 mm. At this concentration even the sterically non-hindered phenols show no evidence of hydrogen bonding in carbon tetrachloride.

The preparation of most of the compounds employed has been described previously (8)* but the preparation of 2,6-di-*tert*-butyl-4-methoxyphenol deserves some discussion as the present data in the literature are somewhat misleading. First attempts to prepare this compound by the butylation of *p*-methoxyphenol in petroleum ether with isobutylene and sulphuric acid at 50° C (9) gave, after recrystallization from *n*-hexane, a 60% yield of a product, m.p. 103.5–104.5° C. Analysis: Found: C, 76.5; H, 10.1; CH_3O, 13.4. Calculated for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24; CH_3O, 13.13. The melting point agrees with a previously reported value (6), but both the frequency and intensity of the O—H band were much lower than expected. The required phenol has also been reported by Müller and Ley (7), who prepared it from 4-methoxy-2,4,6-tri-*tert*-butyl-2,5-cyclohexadiene-1-one. Their product melted at 106–107° and they also obtained an identical compound by the butylation of *p*-methoxyphenol in 84% yield, but with recrystallization from methanol.

An examination of the spectrum of the raw product obtained by butylating *p*-methoxyphenol showed two bands, the larger corresponding to the product already separated (m.p. 103.5–104.5) and the smaller having the frequency expected for 2,6-di-*tert*-butyl-

4-methoxyphenol. The two components were readily separated by an initial recrystallization from *n*-hexane to remove a large amount of the compound previously obtained, followed by recrystallization twice from methyl alcohol to yield the second component, m.p. 106–107° C. Analysis: Found: C, 76.2; H, 10.1; CH_3O, 15.0.

The lower melting compound must be 2,5-di-*tert*-butyl-4-methoxy phenol and the higher the 2,6-compound. The structural assignments were made on the basis of O—H frequency (see Discussion) since the 1600–2000 cm^{-1} region is too complicated to give unequivocal results. The assignments were confirmed by gas phase chromatography through a polar column (polyester succinate), the 2,6-compound having a retention time of about one third of the 2,5-compound, which is in agreement with similar hindered and non-hindered phenols. Adsorption chromatography on alumina of the raw butylated product showed that the ratio of 2,6 to 2,5 is 3:7. The high yield previously reported (7) must be because the reported yields are based on raw product, not on the purified material.

RESULTS

The frequency of the band maximum ν_m, intensity A, and apparent half band widths $\Delta\nu_{\frac{1}{2}}^{A}$ for the phenols examined are given in Table I. The intensities have been corrected for wing absorption (10) and are given in units of 1×10^4 $mole^{-1}$ liter cm^{-2} using $\log_{10}(I_0/I)$. The frequencies are probably correct to within about 1 cm^{-1}. The results obtained with monosubstituted phenols in carbon tetrachloride are in good agreement with previous work. The solvent 1,2-dichloroethane was used in order to get the hydroxy and nitro derivatives of phenol into solution in 0.01 molar concentration for intensity measurements. Since this solvent had such a pronounced effect on the O—H band, the other monosubstituted phenols were also examined in this solvent for comparative purposes.

NOTE: (*a*) Phenols in CCl_4; (*b*) phenols in $(CH_2Cl)_2$; (*c*) 2,6-di-*tert*-butyl phenols.

The results given in Table I can be correlated by a Hammett $\rho\sigma$ relation (1–5) as is shown in Figs. 1, 2, and 3. In Fig. 2 the intensities relative to phenol and to 2,6-di-*tert*-

butyl phenol have been plotted against σ. It is obvious that a good straight line can be obtained without the necessity of plotting log A against σ (4, 11). With regards to the determination of band intensities, Ramsay (10) has suggested a simple formula for computing the true intensity in terms of the observed peak absorbance and apparent half band width. Values calculated by means of this formula were found to be higher than the directly measured intensities by between 10 and 20% (4).

DISCUSSION

The increase in frequency observed with the 2,6-di-*tert*-butyl-4-substituted phenols compared with the corresponding unhindered phenols is too large (36 cm^{-1}) to be accounted for by the resonance and inductive contribution of the two *tert*-butyl groups. σ Values for orthosubstituents have recently been derived by Taft (13) and are generally close to the σ_{para} values for the same substituent. At first sight the increase might therefore be attributed to the twisting of the O—H bond out of the plane of the benzene ring which would decrease the resonance interaction and increase the bond order and therefore the frequency. However, it can be seen from Fig. 1 that the lines through the phenols and the 2,6-di-*tert*-butyl phenols in CCl_4 are parallel. Both types of phenols must, therefore, have a similar structure since, if the O—H bond were twisted out of the plane of the ring, resonance interaction between the O—H and the strongly electron-attracting groups would be decreased. For example, σ para-NO_2 has a value of 1.27 for phenols (and for anilines) but for other compounds its σ_{para} value is 0.78. If the O—H bond were at right angles to the benzene plane, the latter σ value for NO_2 should be observed and, if it lies between 0 and 90°, an intermediate value. It must, therefore, be concluded that the O—H bond is in the plane, further verification being the use of the larger σ_{para} values (to be used with phenols and anilines) for the CN and CHO group.

This conclusion has been verified by examining the characteristic group frequencies of certain of the *p*-substituents. The results are given in Table II. It has been shown that the frequencies of all these groups follow a Hammett $\rho\sigma$ plot (5, 14, 15, 16). Therefore, if the OH bond is twisted out of the plane by the *tert*-butyl groups, the effective σ will be less than the sum of the σ for O—H para (−0.36) plus two *tert*-butyl groups (meta) (2 × −0.12), i.e. less than −0.60 (17) and, therefore, the frequency shifts ($\Delta\nu_m$) given in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Table II will not be in the ratio 3:5; but, if the OH bond is in the plane, the frequency shifts will be in proportion to $\Sigma\sigma$, i.e. 3:5. If the O—H is tilted up from plane, the angle can be calculated from the measured ratio of the frequency shifts (17). It is apparent that with the strongly electron-attracting groups CHO and CN in the para position the O—H bond lies in the plane. The results for the OH and NH_2 group are more ambiguous. It seems improbable that the structure changes as drastically as the results might suggest (i.e. angle to the plane $\backsim$ 35° in OH case). It seems more probable that we are dealing here with a saturation of the electronic effects produced by the four electron-releasing groups on the ring because, if the hindered O—H was tilted to the plane, its frequency would be expected to increase whereas with the parasubstituents NH_2 and OH the frequency is slightly below the expected value. This saturation effect is also observed with the ordinary phenols (where there is no steric force tending to push the O—H out of the plane) when $\sigma > -0.4$.

TABLE II

Absolute intensities of the bands of the groups in Table II were not measured (with the exception of (OH)), but the ratio of the intensities of the two N—H bands was measured. The ratio for aniline is in fair agreement with the value reported previously (16) and for 2,6-di-*tert*-butyl-4-amino phenol is within the expected range for $\Sigma\sigma = -0.60$; the large ratio for *p*-hydroxy aniline is quite unexpected. It is also surprising that the half band width of the CN group of 2,6-di-*tert*-butyl-4-cyano phenol is twice as great as for the other two cyano compounds (15).

A stereochemical configuration with the hindered O—H in the benzene plane can be seen to be quite plausible by the use of molecular models and we have checked this by calculating the position of the phenolic hydrogen relative to the adjacent *tert*-butyl group placed in the most favorable configuration. Using Pauling's (18) values for the van der Waal's radii of the atoms, the interpenetration of the phenolic hydrogen with each of four equivalent hydrogens is 0.25 Å and is about the same with the two equivalent carbons. This suggests a total compression energy of the order of 0.1–0.2 kcal/mole (19), which is very much smaller than the resonance energy gained by keeping the O—H bond in the plane ($\backsim$ 7.0 kcal/mole (18)). Furthermore, these "rigid model" compressions are a maximum, a little flexibility in the bonds would reduce the compression energy even further.

The increase in frequency of the 2,6-di-*tert*-butyl phenols, over and above that due to the electropositivity of the two *tert*-butyl groups, must be due to the snug fitting of the phenolic hydrogen into the adjacent *tert*-butyl group. The repulsion of the latter will build up as the O—H bond stretches and will therefore narrow the potential energy curve, increase its asymmetry, and thereby raise the frequency and intensity. That is, since the repulsion is due to interpenetration of the electron clouds it is exerted primarily

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

For personal use only.

on the electrons of the phenolic hydrogen, and only through them on the proton itself. Thus, the interpenetration process will tend to keep back the electrons more than the proton. This will increase the dipole moment of the bond (μ) and the more the O—H bond stretches the more the dipole moment will be increased; and so $\partial\mu/\partial r$ will be increased and hence the intensity. This can be seen in Table I where, instead of the expected decrease in intensity (owing to the electropositivity of the two *tert*-butyl groups) of 0.05×10^4 mole^{-1} liter cm^{-2} on going from phenol to 2,6-di-*tert*-butyl phenol, an increase of 0.02×10^4 is instead observed. The similarity in the relative intensities of the two sets of phenols shown in Fig. 2 is to be expected if they have similar configurations.

The results given in Table III are arranged to show the effect of a single alkyl substituent ortho to the hydroxyl group. The σ constants given in the second column are derived from Jaffe (12) and Taft ortho factors (13) with certain exceptions. The σ values derived for ortho-*tert*-butyl and ortho-*tert*-amyl were obtained from ν_m but it should be pointed out that these values probably only apply to this system. The σ values for the three multiple substituted phenols are derived from the ortho-*tert*-butyl value and regular σ values. They can be used to calculate the expected frequencies. For instance, the calculated value for 2,5-di-*tert*-butyl-4-methoxyphenol is 3611.3 cm^{-1}, thus confirming the structure assigned to this compound. The predicted frequency for the corresponding 4-hydroxy phenol is 3612.5 cm^{-1}. 2-*tert*-Butyl-4-hydroxyphenol should have two bands at 3610.9 and 3616.4; these are not resolved but the measured value of ν_m is in close agreement with their average.

TABLE III

Influence of a single orthosubstituent on phenols in CCl_4

Substituent	$\Sigma\sigma$ (12)	ν_m, cm^{-1}	1×10^4 A mole^{-1} liter cm^{-2}	$\Delta\nu_{\frac{1}{2}}^a$, cm^{-1}
—	0.000	3609.5	0.55	18
2-CH_3	−0.17 (13)	3612	0.54	19

*See text.

The quite large positive value of σ for the *o-t*-butyl group in this system is rather surprising. A possible explanation is that the *tert*-butyl group effectively raises the barrier to rotation of the O—H group around the phenyl–oxygen bond. It can be seen with molecular models that interaction between the two groups can occur when the O—H bond is at right angles to the benzene plane. Although there is certainly a minimum in the potential energy curve when the O—H bond points directly toward the *tert*-butyl group, it is presumably not as deep as when it points away from it. This increased barrier to rotation means that the O—H is held more rigidly in the plane of the ring; increased resonance with the ring therefore occurs and the frequency drops. The results with the two ortho-amyl phenols confirms that this frequency decrease is caused by steric factors.

The solvent 1,2-dichloroethane was used for those phenols which were only very slightly soluble in carbon tetrachloride before it was realized that very thick cells ($\backsim$ 5 cm)

could be used with the latter solvent. It can be seen from Fig. 1 that the frequency is decreased and that the difference increases as the substituents become more electron-attracting. This kind of an effect can readily be explained as being due to hydrogen bonding involving the structure ϕ—O—H . . . $(CH_2Cl)_2$. Such interaction will obviously increase as the acidity of the phenol increases. Effects of this nature may help to explain the failure of the Bauer and Magat equation to interpret frequency shifts in different solvents (20). In this connection it is interesting to note that although the intensities in dichloroethane are roughly twice as great as in carbon tetrachloride, the relative intensities in the two solvents are unaffected by the nature of the parasubstituent (15) (see Fig. 2).

The results given in Fig. 3 (in which the apparent half band widths are plotted against σ) show one of the most striking differences between the hindered and unhindered phenols. No complete explanation can be advanced to account for the differences in the sign of the slopes of the lines. The values for the hindered phenols with strongly electronegative groups are undoubtedly somewhat larger than their true values owing to the effect of finite slit width (10). In the hindered phenols the O—H group cannot be solvated at the hydrogen end but only at the oxygen, and this must reduce the influence of the solvent on the band. The generally lower values of $\Delta\nu_{\frac{1}{2}}^{0}$ for the hindered phenols compared with the unhindered may also be partly due to the effect of the *tert*-butyl groups in increasing the moments of inertia of the molecule. It is interesting to note that in all previous cases where frequencies and half band widths of benzene derivatives have been shown to obey a Hammett $\rho\sigma$ relation, the slopes of these two functions have opposite sign (20) whereas with hindered phenols they have the same sign.

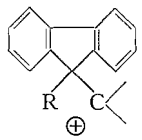
ALIPHATIC CHEMISTRY OF FLUORENE

PART V. SPIRO-KETONES[1]

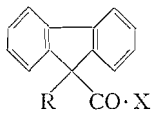


P. M. G. BAVIN[2]

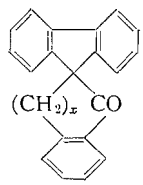
ABSTRACT

A novel synthesis is described of 1,2;3,4-dibenzophenanthrene, based on the spiro-ketone (III*b*), which was cleaved by strong base to the acid (VII*b*).

An example is described of acylation of aliphatic carbon.



The ease with which methyl fluorene-9-carboxylate anion reacts with a wide range of alkyl halides (1, 2, 3) together with the formation of phenanthrene derivatives from carbonium ions (I) prompted the investigations described in this paper.



I

It has been reported (4) that 9-benzylfluorene-9-carboxylic acid chloride (II*a*) was cyclized by aluminum chloride to the spiro-ketone (III*a*), which may be converted via the alcohol (IV*a*) to 1,2;3,4-dibenzofluorene. This synthesis has been repeated and some yields improved. In particular, phosphorus pentoxide under boiling xylene rather than fused zinc chloride is the reagent of choice for dehydrating the alcohol (IV*a*).

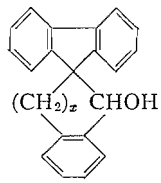
The synthesis has been extended by the preparation and cyclization of 9-(2′-phenylethyl)-fluorene-9-carboxylic acid (II*c*), cyclization being effected by hydrogen fluoride. The homologous acid (II*b*) was unaffected by this reagent, in accord with the known

II*a*, R = $C_6H_5 \cdot CH_2$; X = Cl

II*b*, R = $C_6H_5 \cdot CH_2$; X = OH

II*c*, R = $C_6H_5 \cdot CH_2CH_2$; X = OH

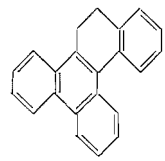
II*d*, R = $C_6H_5 \cdot CH_2CH_2CH_2$; X = OH



III*a*, x = 1

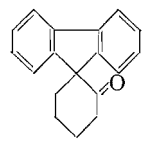
III*b*, x = 2

(5, p. 116) easier formation of six-membered ketones. All attempts to cyclize 9-(3′-phenylpropyl)-fluorene-9-carboxylic acid (II*d*) or its chloride have failed.



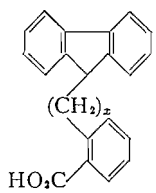
The formation of cyclic ketones from the tertiary acids is surprising since Lewis acids would have been expected to bring about decarbonylation. This exceptional behavior may be attributed to instability of the fluorene cation, which would be formed in the decarbonylation process (6).

[1]*Manuscript received March 8, 1960.*
Contribution from the Chemistry Department, the University, Hull, East Yorkshire, England.
[2]*I.C.I. Fellow.*



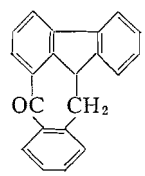
IV*a*, $x = 1$

IV*b*, $x = 2$



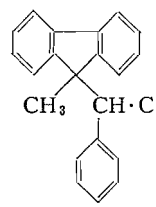
V

The ketone (III*b*) was converted via the alcohol (IV*b*) to 1,2;3,4-dibenzo-9,10-dihydrophenanthrene (V). In agreement with earlier workers (7) the hydrocarbon could not be obtained crystalline but was dehydrogenated in good yield to 1,2;3,4-dibenzophenanthrene, completing a novel synthesis of this ring system. It was intended that this work should be extended to more complex ring systems, but lack of time has curtailed the work. Some 9-aralkyl derivatives of methyl fluorene-9-carboxylate, prepared as desirable starting compounds, are described in the Experimental section. In addition, methyl 9-(4′-cyanobutyl)-fluorene-9-carboxylate has been prepared, as a possible precursor of VI. During its preparation, dimethyl butane-1,4-di-9′-fluorenyldi-9′-carboxylate was isolated as a by-product and identified by synthesis.



VI

The spiro-ketones (III*a* and III*b*) were cleaved by strong base, as expected for non-enolizeable ketones, giving the acids (VII*a* and VII*b*), isomeric with (II*a* and II*c*). The direction of cleavage is controlled by formation of the more stable anion, as previously noted for 9-methyl-9-benzoylfluorene (8).



VII*a*, $x = 1$

VII*b*, $x = 2$

VIII

IX

The chloride of the acid (VII*a*) reacted with aluminum chloride to reform the spiro-ketone (III*a*) and not, as had been hoped, the isomeric ketone (VIII). A few similar examples of acylation of aliphatic carbon are known, e.g. the acetylation and benzoylation of 9,10-dihydroanthracene (9).

The chloride prepared from the alcohol (IV*a*) closely resembled IX (8), decomposing at its melting point or in boiling formic acid with formation of 1,2;3,4-dibenzofluorene. Silver acetate in acetic acid gave unrearranged acetate. A similar stabilization of neopentyl-type carbonium ions by phenyl has been reported (10, and references quoted therein).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Other examples of non-rearrangement of neopentyl carbonium ions probably involve neighboring group participation (11). In agreement with this, the reaction between 9-methyl-9-fluorenylmethyl chloride and silver acetate gave 9-methylphenanthrene.

EXPERIMENTAL

Methyl fluorene-9-carboxylate anion was alkylated in the usual way (2) to give the following:

9-Benzylfluorene-9-carboxylic acid, prepared by saponification of the methyl ester (2), formed well-defined prisms from benzene–hexane, m.p. 204–205° (4). Found: C, 84.25; H, 5.24%. Calc. for $C_{21}H_{16}O_2$: C, 83.97; H, 5.37%.

Methyl 9-(2′-phenylethyl)-fluorene-9-carboxylate crystallized as long white needles (74%) from methanol, m.p. 67–68°. Found: C, 83.81; H, 5.99%. Calc. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%. The *acid* (81%) crystallized as colorless rhombic plates from benzene–hexane, m.p. 143–144°. Found: C, 83.76; H, 5.66%. Calc. for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

9-(3′-Phenylpropyl)-fluorene-9-carboxylic acid, obtained by saponifying the oily methyl ester, formed large pale yellow prisms (76%) from benzene–hexane, m.p. 125–127°. Found: C, 84.11; H, 6.13%. Calc. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%.

Methyl 9-(2′-thienylmethyl)-fluorene-9-carboxylate crystallized as small white needles (71%) from hexane, m.p. 104–105°. Found: C, 75.13; H, 5.17%. Calc. for $C_{20}H_{16}O_2S$: C, 74.99; H, 5.03%.

Methyl 9-(3′-thienylmethyl)-fluorene-9-carboxylate formed clusters of white prisms (76%) from hexane, m.p. 119.5–120.5°. Found: C, 74.99; H, 5.22%. Calc. for $C_{20}H_{16}O_2S$: C, 74.99; H, 5.03%.

*Methyl 9-(1′-naphthylmethyl)-fluorene-9-carboxylate** crystallized as small prisms (73%) from benzene–hexane, m.p. 154–156°. Found: C, 85.36; H, 5.48%. Calc. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53%.

*Methyl 9-(2′-naphthylmethyl)-fluorene-9-carboxylate** formed small needles (79%) from benzene–hexane, m.p. 189–191°. Found: C, 85.82; H, 5.71%. Calc. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53%.

Methyl 9-(4′-cyanobutyl)-fluorene-9-carboxylate

1,4-Dibromobutane, b.p. 63–65° at 5 mm, n_D^{21} 1.5163, was prepared from tetrahydrofuran in 68% yield.

1,4-Dibromobutane (209 g, 0.84 mole) was stirred and boiled under reflux for 6 hours with potassium cyanide (55 g, 0.8 mole), water (65 ml), and ethanol (220 ml). After being diluted with water, the products were isolated with ether and separated by precise fractionation, giving δ-bromovaleronitrile (86 g), b.p. 102–103° at 8 mm, n_D^{23} 1.4776.

Prepared in the usual way, *methyl 9-(4′-cyanobutyl)-fluorene-9-carboxylate* crystallized as long white needles (93%) from methanol, m.p. 89–90°. The analytical sample was obtained after two further crystallizations and had a melting point of 90.5–91.0°. Found: C, 79.05; H, 6.74; N, 4.59%. Calc. for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%. C≡N stretching band, 2220 cm^{-1}; C=O stretching band, 1740 cm^{-1}.

Commercial δ-bromovaleronitrile (Sapon Laboratories) gave 63% of the cyano-ester and 31% of a substance insoluble in hot methanol. The latter crystallized from toluene as small colorless needles, m.p. 221.0–221.5°, after three crystallizations. Found: C, 80.64; H, 5.57%. Calc. for $C_{34}H_{30}O_4$: C, 81.25; H, 6.02%. It was identified as *dimethyl butane-1,4-di-9′-fluorenyldi-9′-carboxylate* by synthesis from 1,4-dibromobutane (0.56 g, 0.5 mole) and a solution of methyl fluorene-9-carboxylate (1.23 g, 2.2 moles) in methanol

*Prepared by Mr. R. C. Wilson.

containing sodium methoxide (from sodium, 0.23 g, 2.1 atoms), identity being established by mixed melting point determination and comparison of infrared spectra.

Saponification of the diester in ethylene glycol gave *1,4-(di-9'-fluorenyl)-butane*, which crystallized from acetone–methanol as small white needles, m.p. 161.0–161.5°. Found: C, 93.52; H, 6.49%. Calc. for $C_{30}H_{26}$: C, 93.22; H, 6.78%.

Spiro-compounds

Indan-1-one-2-spiro-9'-fluorene (III*a*) was prepared as described in the literature (4) in a maximum yield of 67%. Reduction with ethereal lithium aluminum hydride gave indan-1-ol-2-spiro-9'-fluorene (IV*a*) in almost quantitative yield. It formed prisms from cyclohexane, m.p. 159–160° (lit. m.p. 160° and 168° (dimorphic) (4)). Found: C, 88.27; H, 5.48%. Calc. for $C_{21}H_{16}O$: C, 88.74; H, 5.67%.

1-Chloroindane-2-spiro-9'-fluorene, prepared by the reaction between the alcohol and thionyl chloride, crystallized from heptane as elongated prisms (77%), m.p. 172–173° with decomposition to 1,2;3,4-dibenzofluorene. The chloride decomposed similarly in boiling 94% formic acid. Found: C, 83.20; H, 4.89%. Calc. for $C_{21}H_{15}Cl$: C, 83.30; H, 4.99%.

1-Acetoxyindane-2-spiro-9'-fluorene, prepared either by acetylating the alcohol or by the reaction between the chloride and silver acetate in acetic acid, formed colorless prisms from benzene–hexane, m.p. 132–133°. Found: C, 84.66; H, 5.62%. Calc. for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%.

Heating the alcohol (IV*a*) with twice its weight of phosphorus pentoxide under boiling xylene gave, after 1 hour, 1,2;3,4-dibenzofluorene (94%) which crystallized from heptane as slender white needles, m.p. 162–163°. Oxidation gave 1,2;3,4-dibenzofluorenone, identical with an authentic sample (8).

1,2,3,4-Tetrahydronaphthalene-1-one-2-spiro-9'-fluorene (III*b*) was prepared by cyclizing the acid (II*c*) (3 g) in dry ether (50 ml) with hydrogen fluoride (150 ml). During 2 days at room temperature most of the solvents evaporated. The neutral product crystallized from cyclohexane as white needles (2.3 g), m.p. 201–202°. Found: C, 89.71; H, 5.32%. Calc. for $C_{22}H_{16}O$: C, 89.16; H, 5.44%.

1-Hydroxy-1,2,3,4-tetrahydronaphthalene-2-spiro-9'-fluorene (IV*b*), prepared by reducing the ketone with ethereal lithium aluminum hydride, crystallized from cyclohexane as small colorless blades (91%), m.p. 197.0–197.5°, depressed to 175–180° by the ketone. Found: C, 88.68; H, 6.11%. Calc. for $C_{22}H_{18}O$: C, 88.56; H, 6.08%.

1,2,3,4-Dibenzo-9,10-dihydrophenanthrene (V). Dehydration of the alcohol (IV*b*) (2 g) with phosphorus pentoxide under boiling xylene followed by purification over alumina gave a colorless oil (1.5 g) which has failed to crystallize. The *1,3,5-trinitrobenzene adduct* separated from methanol as vermilion rods, m.p. 161–162°. Found: C, 67.98; H, 3.72%. Calc. for $C_{28}H_{19}N_3O_6$: C, 68.15; H, 3.88%.

Oxidation with chromic acid in acetic acid gave a trace of 1,2;3,4-dibenzophenanthrene-9,10-quinone.

1,2,3,4-Dibenzophenanthrene was prepared as follows. Dehydrogenation of the dihydro compound over 10% palladium-on-charcoal at 300° gave an almost quantitative yield of dibenzophenanthrene, which crystallized as white needles from heptane, m.p. 115–116°. Identity was established by comparison with two authentic samples (12,* 13) and by preparation of the quinone and picrate. The *1,3,5-trinitrobenzene adduct* crystallized as slender orange needles from methanol, m.p. 165–166°. Found: C, 68.30; H, 3.64%.

**Provided by Dr. C. C. Barker.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Calc. for $C_{28}H_{17}N_3O_6$: C, 68.43; H, 3.49%. (This derivative has been reported as forming bright yellow needles from benzene, m.p. 167° (13).)

Cleavage of the Spiro-ketones

The ketone (1 g) was warmed for 30 minutes with a solution of potassium hydroxide (1 g) in industrial alcohol (50 ml) and the acidic product isolated.

2-(9'-Fluorenylmethyl)-benzoic acid (VII*a*) crystallized as slender needles (85%) from cyclohexane, m.p. 188–189°. Found: C, 83.72; H, 5.61%. Calc. for $C_{21}H_{16}O_2$: C, 83.97; H, 5.37% (lit. m.p. 185–186° (14)). The acid chloride ($SOCl_2$) in benzene at 10° reacted with aluminum chloride to reform the spiro-ketone (57%), identified by mixed melting point determination and comparison of infrared spectra.

2-(2'-(9''-Fluorenyl)-ethyl)-benzoic acid (VII*b*) crystallized from benzene–hexane as colorless blades (81%), m.p. 163–164°. Found: C, 84.21; H, 6.03%. Calc. for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

9-Methylphenanthrene

The reaction between 9-methyl-9-fluorenylmethanol (2) and thionyl chloride gave a semisolid product which would not form a crystalline picrate from ethanol. The reaction with silver acetate in acetic acid was rapid, silver acetate separating. 9-Methylphenanthrene was isolated as its orange picrate (61%, from ethanol), identical with an authentic specimen (2).

ACKNOWLEDGMENTS

Some preliminary experiments were carried out at the University of Ottawa during the tenure of a National Research Council of Canada Postdoctorate Fellowship at the University of Ottawa (1954–56), and the author is indebted to Dr. F. A. L. Anet for his interest and helpful suggestions.

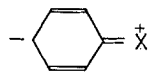
LIGHT ABSORPTION STUDIES

PART XVII. THE ULTRAVIOLET ABSORPTION SPECTRA OF CHLOROBENZENES[1]



W. F. FORBES[2]

ABSTRACT

The ultraviolet absorption spectra of a series of chlorobenzenes are determined. The spectral data suggest that the apparent mesomeric effect of the chlorine atom is greater than that of the fluorine atom, that solvent–solute interactions are generally less important in chlorobenzenes than in fluorobenzenes, and that, as expected, the effective interference radius of the chlorine atom is large. Moreover, spectral changes in *o*-substituted chlorobenzenes are consistent with the assumption that maximum electronic interaction requires the chlorine atom to be in the same plane as the benzene ring. The conformations of *o*-chloroacetophenone and *o*-chlorophenol are briefly discussed.

INTRODUCTION

In previous parts of these studies (1), it was found that changes in the location of the so-called *B*-band (for nomenclature employed see refs. 1 and 2) in the ultraviolet spectrum provide a measure of mesomeric interactions;* that is, spectral changes in the *B*-band could usually be related with changes in the appropriate extended dipolar resonance form of the molecule. For example, the *B*-band of a halogen-substituted benzene can be imagined to owe its existence to the resonance form I, and if this resonance

I

form is favored, as it is by a number of electron-attracting *p*-substituents, the absorption occurs at longer wavelength and with increased absorption intensity. Other interactions which do not directly affect the resonance form, for example the interactions caused by a *m*-substituent, were found to be only of secondary importance. The *B*-band spectral changes in this way afford a readily available semiquantitative measure of mesomeric interactions as defined above, and generally the information obtained concerning these mesomeric interactions is much as would be expected from simple resonance considerations. One somewhat surprising exception is that for the halogen-substituted benzenes the bathochromic wavelength displacements compared with benzene are in the order iodobenzene > bromobenzene > chlorobenzene > fluorobenzene, and this implies an order of apparent mesomeric interaction I > Br > Cl > F. This is contrary to the order usually accepted (cf. refs. 1(*a*), 1(*b*)).

The *B*-band spectra of the chlorobenzenes are hence of interest and it is the purpose of the present paper to examine, or to re-examine, these spectra assuming that the chlorine atom possesses a greater mesomeric effect, or at least a greater apparent mesomeric effect, than the fluorine atom.

**Mesomeric interactions have been defined, for the purpose of this series of papers, as interactions associated with electron mobility acting along systems of conjugated bonds. These mesomeric interactions were found in some instances to be different from the mesomeric interactions as deduced from chemical equilibria (cf. 1(a), 1(b)).*

THE SPECTRUM OF CHLOROBENZENE

The spectra of chlorobenzene in different solvents are listed in Table I.

TABLE I

Main ultraviolet absorption maxima of chlorobenzene in various solvents

Solvent	*B*-Band		*C*-Band	
	λ_{max} (mμ)	ϵ_{max}	λ_{max} (mμ)	ϵ_{max}
Vapor phase	211 215 ca. *219*	*	243 250 256 259 262 267 269	*

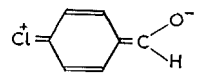
NOTE: Values in italics represent inflections in this and the following table.
*Intensities not determined.

The similarity of the spectra of fluorobenzene and benzene has been noted in the previous paper (1(*a*)). This similarity is no longer present between the spectra of chlorobenzene and benzene since the *B*-bands of chlorobenzene, and to a lesser extent the *C*-bands also, are displaced to longer wavelength (see Table I and cf. ref. 1(*a*)). This spectral change in the *B*-band is related to the increased contributions of resonance forms of type I. That is, it is assumed that at least in the electronic excited state, the chlorine atom is more readily able to interact with the benzene ring than is the fluorine atom.



The spectral changes of the chlorobenzene bands with change of solvent are smaller than for fluorobenzene (see Table I and ref. 1(*a*)). In fact, the only experimentally significant spectral change in the *B*-band is a decreased absorption intensity for the spectrum of chlorobenzene in aqueous solution, which is generally observed for compounds of this type. Particularly interesting is the virtual absence of a wavelength displacement for the *B*-band on determining the spectrum in the vapor phase and in cyclohexane solution ($\Delta\lambda$ less than 1 mμ, see Table I), since a number of other compounds examined (3) afford a wavelength displacement appreciably greater than 1 mμ

under these conditions. These observations then suggest that general solvent effects, solvent orientation effects, as well as other solvent–solute interactions such as intermolecular hydrogen bonding, are not important in determining the *B*-band absorption of chlorobenzene.

The *C*-band of chlorobenzene in all solvents is found to be considerably less intense than the *C*-band of fluorobenzene (cf. ref. (1*a*)).

THE SPECTRA OF PARASUBSTITUTED CHLOROBENZENES

Using the simplified concept illustrated by resonance structures of type I, the spectra of *p*-substituted chlorobenzenes can be divided into two groups. (*a*) First, the group of compounds in which the *p*-substituent is electron-donating, when the *B*-band resembles the *B*-band of the monosubstituted benzene derivative. Of the two substituents, the substituent with the greater electron-donating power will predominantly determine the wavelength and intensity of the monosubstituted benzene *B*-band while the other substituent will exert only a "secondary" effect on the *B*-band. (*b*) The second group

II

represents compounds in which the *p*-substituent is electron-withdrawing and resonance interaction is enhanced because of appreciable contributions of resonance forms of type II. These generalizations are illustrated by the data in Table II.

Examination of the data in Table II and of suitable reference compounds shows that generally the *B*-bands of *p*-substituted chlorobenzenes can be identified without undue difficulty. For example, as expected, only one *B*-band, the monochlorobenzene *B*-band, is observed for *p*-dichlorobenzene; somewhat surprisingly, the chlorobenzene *B*-band has been displaced to longer wavelength by about 10 mμ on account of the second chlorine substituent (see Tables I and II). This indicates that the secondary effect of the chlorine atom is such as to favor the transition, and consideration of resonance form I suggests that the second chlorine atom may donate electrons in the electronic excited state and in this way facilitate the transition. Next, the ultraviolet absorption of 1-chloro-4-fluorobenzene has previously been ascribed to chlorobenzene absorption (1(*a*)), and this again suggests that at least in this compound the chlorine atom possesses the greater mesomeric effect. The only other *B*-band which is associated with chlorobenzene absorption is the band at 221 mμ in *p*-chlorotoluene; this assignment is made because the methyl substituent, like the chloro substituent, would be expected to cause absorption at longer wavelength and because the *C*-band indicates the characteristic chlorobenzene fine structure (see Tables I and II). The *B*-band of the remaining *p*-substituted chlorobenzenes, in which the *p*-substituent is electron-donating, i.e. Br, I, OH, OCH_3, or NH_2, is similar to the *B*-band of the corresponding monosubstituted benzene derivative, that is, it is similar to the *B*-band of bromobenzene, iodobenzene, etc.* Again generally, the *p*-chloro substituent appears to facilitate the absorption since normally the *p*-substituted compound tends to absorb at slightly longer wavelength and with increased

**It may be noted that p-chlorophenol is tentatively assumed to absorb as phenol rather than as chlorobenzene although chlorobenzene absorbs at longer wavelength, that is, the transition involves less energy. However, this apparent anomaly can be explained by the previously made suggestion (1(c)) that the p-electrons of the* OH*-group in phenol are not in the most favorable position for electronic excitation and that because of this, phenol absorbs at unusually short wavelength. It is possible that in p-chlorophenol the* OH*-group tends to twist towards an energetically more favorable position for transition and that consequently the phenol B-band absorption is favored.*

**B*-Band assignment doubtful.

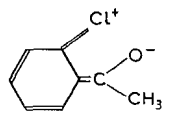
absorption intensity compared with the non-chlorosubstituted parent compound. For example, in cyclohexane solution, anisole absorbs maximally at 220 mμ, $\epsilon = 7500$ (1(*d*)), whereas *p*-chloroanisole absorbs maximally at 228 mμ, $\epsilon = 11{,}700$ (see Table II).

Although the *p*-chloro substituent, in the examples listed in the last paragraph, gives rise to an appreciable intensity increase, for example, in the anisole *B*-band of chloroanisole, this intensity increase is generally less than if the non-chloro substituent is electron-withdrawing. This is shown by the observed high absorption intensities of the *p*-substituted chlorobenzenes listed towards the end of Table II. This increased transition probability, as well as the generally more pronounced bathochromic wavelength displacement compared with chlorobenzene or compared with the non-chloro-monosubstituted benzene derivatives, suggests resonance structures of type II, since the contribution of resonance forms of type II would be expected, on the basis of our general hypothesis relating resonance interaction and *B*-band absorption, to cause intensified *B*-band absorption occurring at longer wavelength. In this way, the *B*-bands of these *p*-substituted chlorobenzenes are associated, at least partly, with resonance structures involving the *entire* molecule, whereas the *B*-bands of the previously mentioned *p*-substituted chlorobenzenes are associated with resonance structures involving, as a first approximation, only *part* of the molecule; that is, they are associated with transitions involving predominantly so-called locally excited states.

THE SPECTRA OF METASUBSTITUTED CHLOROBENZENES

The frequent occurrence of two *B*-bands in the spectra of *m*-disubstituted benzene derivatives has previously been noted and may be rationalized in terms of simple resonance theory. That is, resonance forms of type I will not normally be greatly affected by a *m*-substituent and thus the *B*-band of the *m*-disubstituted compound will resemble the *B*-band of one of the monosubstituted parent compounds. Moreover, if electrons are highly localized in both substituent groups, two *B*-bands corresponding to both monosubstituted parent compounds can apparently sometimes be identified (see refs. 1(*c*), 1(*d*), 1(*e*)).

For *m*-substituted chlorobenzenes therefore the chlorobenzene *B*-band would be expected to occur near 215 mμ (see Table I), that is, at a location at which it cannot always be identified with certainty since *A*-band absorption (cf. ref. 2) also frequently occurs near this wavelength. However, in compounds like *m*-dichlorobenzene, the band near 220 mμ evidently represents the chlorobenzene *B*-band, and the bands near 225 mμ in *m*-chloroiodobenzene and near 215 mμ in *m*-chlorotoluene are also tentatively ascribed to chlorobenzene *B*-band absorption (see Table II). In all these examples the second substituent, if electron-donating, facilitates the chlorobenzene *B*-band absorption, apparently in a less pronounced, though presumably similar, manner as has been postulated for the corresponding *p*-isomers. If the second substituent is electron-withdrawing, as for example in *m*-chloronitrobenzene, the reverse effect is tentatively assumed to occur since the chlorobenzene *B*-band appears to be displaced to *shorter* wavelength and probably occurs near 210 mμ. This, unfortunately, is at a wavelength at which it can no longer be identified with certainty because of possible *A*-band absorption (see Table II).



The effect of the *m*-chloro substituent on the *B*-band, associated with the non-chloro-monosubstituted benzene derivative, appears generally to be small and is certainly smaller than the effect of the *p*-chloro substituent. Usually, a small bathochromic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

wavelength displacement is observed on account of the *m*-chloro substituent, but sometimes the *B*-band absorption maxima are almost identical. For example, anisole in cyclohexane solution absorbs maximally at 220 mμ, ε = 7500 (1(*d*)) whereas *m*-chloroanisole under identical conditions absorbs maximally at 219 mμ, ε = 7300 (see Table II). Or, benzaldehyde in hexane solution absorbs maximally at 241 mμ, ε = 14,000 whereas *m*-chlorobenzaldehyde under similar conditions absorbs maximally at 241–242 mμ, ε = 11,500 (1(*e*)). It may be noted that a related effect has also been reported for some of the infrared data. For example, the location of the hydroxyl band in phenol at 3608 cm^{-1} is reported close to the hydroxyl band in *m*-chlorophenol (3607 cm^{-1}; $A = 6.7\times10^{-7}$); the band is, however, slightly enhanced compared with the intensity of the corresponding phenol band ($A = 5.8\times10^{-7}$) (4).

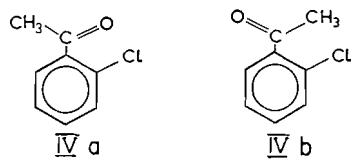
THE SPECTRA OF ORTHOSUBSTITUTED CHLOROBENZENES

The *B*-bands of *o*-substituted chlorobenzenes generally resemble the *B*-bands of the corresponding meta isomers. In terms of canonical resonance forms this suggests that dipolar excited states of type III are not important in determining the *B*-band. This may

III

be because of steric considerations, that is, because the two substituents are not sufficiently coplanar for effective resonance interaction to occur, or it may be because the molecule inherently absorbs by means of transitions involving predominantly locally excited states. For example, if the non-chloro substituent is electron-donating, as in *o*-chlorophenol, *o*-chloroaniline, etc., dipolar resonance forms of type III may be neglected and *B*-bands associated with locally excited states, that is phenol and aniline *B*-bands would be expected and are in fact observed (see Table II).* For *o*-substituted chlorobenzenes, however, in which the non-chloro substituent is electron-withdrawing, the steric hypothesis is favored since if the non-chloro substituent is relatively small, as in *o*-chlorobenzaldehyde, there is observed a slight bathochromic wavelength displacement relative to the *B*-band in the meta isomer, indicative of resonance interaction of type III; in *o*-chloroacetophenone and *o*-chloronitrobenzene on the other hand, no such bathochromic wavelength displacement is observed and this therefore suggests that only in *o*-chlorobenzaldehyde are the two *o*-substituents in the same plane.

Since the benzaldehyde, nitrobenzene, and acetophenone absorption is still readily discerned (see Table II) in the spectra of the *o*-chlorosubstituted compounds and since, moreover, there is quite generally a similarity between the spectra of ortho and meta isomers in compounds of this type, this suggests that non-planarity is caused, at least partly, at the expense of the chlorine atom. Hence it may tentatively be assumed that not only are the formyl, acetyl, or nitro groups twisted out of the plane of the benzene ring but also that the chlorine atom is bent away from the plane of the benzene ring,



**In some o-substituted chlorobenzenes, such as o-chloroanisole, it is possible that the observed B-band corresponds, at least partly, to chlorobenzene B-band absorption. However, the present spectral evidence, for example, the spectral changes observed on altering the solvent for o-chloroanisole which closely resemble the solvent changes observed for anisole (3) do not favor this possibility, nor do the infrared data (see Experimental).*

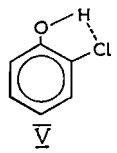
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

and it may be because of this bending away that the chlorine atom is frequently no longer able to interact effectively with the benzene ring in the manner required to give rise to resonance interaction as shown in structure III.

Although the precise relation between steric interactions and spectral effects in *o*-substituted chlorobenzenes is evidently not entirely clear, some form of steric interaction in a number of *o*-substituted chlorobenzenes is indicated by the pronounced intensity decreases in the *B*-bands of compounds like *o*-chloroacetophenone and *o*-chloronitrobenzene compared with the intensities for the corresponding meta isomers or compared with the *B*-band intensities of the corresponding non-chloromonosubstituted benzene derivatives (see Table II and ref. 1). The intensity decrease in these *o*-substituted chlorobenzenes is greater than in the corresponding methylacetophenones (1(*f*)) or methylnitrobenzenes (1(*g*)), and this suggests that the effective interference radius of the chlorine atom is greater than that of the methyl group. On the other hand, the reported spectra of the *o*-chloro- and *o*-methyl-acetanilides (5), for example, suggest an opposite order. However, even then the observed intensity decrease in the *B*-band of the *o*-chloro compound is appreciable, and this then at least confirms the belief that the effective interference radius of the chlorine atom is large. The present data, as well as other related data, hence clearly indicate the presence of appreciable steric interactions caused by an *o*-chloro substituent (6, 7, 8). (Indications that the chlorine atom, when attached to a benzene ring, causes appreciable steric interactions are also provided by the postulated puckered nature of the benzene ring in hexachlorobenzene (9).)

Concerning the actual conformation of a compound like *o*-chloroacetophenone, the infrared carbonyl band shows a doublet which has been assumed to indicate that *o*-chloroacetophenone exists in two *s-cis, s-trans* conformations IV*a* and IV*b*, with IV*b*

IV a IV b



representing the slightly more stable conformation (10).* Because of electrostatic and steric considerations, it seems unlikely that either of these conformations should be entirely coplanar, and this observation relates well with the low intensity of the *B*-band in the ultraviolet region, which indicates non-planarity of the molecule. On the other hand, the acetyl group must be, at least partly, coplanar with the benzene ring because the characteristic acetophenone maximal absorption near 235 mμ is still evident in *o*-chloroacetophenone (see Table I). The most probable explanation consistent with all the above-mentioned observations seems to be that *o*-chloroacetophenone exists in at least two conformations, most of them not entirely coplanar, with the preferred angle between the plane of the nitro group and that of the C—Cl bond being very approximately 30°.

The spectral data discussed above suggest the operation of steric interactions in a number of *o*-substituted chlorobenzenes. On the other hand, neither *B*-band nor *C*-band

**Two s-cis, s-trans conformations have also been postulated for o-chloroanisole (11) on the basis of a doublet in the ultraviolet region. However, doublets are frequently observed in the ultraviolet region, even if no s-cis, s-trans isomerism is possible (cf., for example, the observed doublet in the ultraviolet spectrum of benzaldehyde (1(e)). Further, no evidence for two conformations, in the form of doublets, has been obtained for the infrared spectrum of o-chloroanisole (see Experimental), and Banerjee's hypothesis is therefore not favored.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

data provide any convincing evidence for the existence of an intramolecular hydrogen bond as has frequently been postulated for compounds like *o*-chlorophenol (V). (For

V

recent discussions concerning this type of intramolecular hydrogen bonding see refs. 12, 13, 14, 15, 16.) That is, comparing the spectra of *o*- and *m*-chlorophenol, no bathochromic wavelength displacements are observed in the *B*- and *C*-bands of the *o*-isomer, the ϵ_{max} value of the *B*-band in the *o*-isomer is not greater than the corresponding ϵ_{max} value in the *m*-isomer, and the ϵ_{max} value of the *C*-band in the *o*-isomer, although slightly larger than for the *m*-isomer, is not large as for *o*-chloroanisole and, moreover, the increase in ϵ_{max} values between ortho and meta isomers are comparable for chlorophenols and chloroanisoles (see Table II). Further, *o*-chlorophenol in ethanolic solution absorbs as follows: λ_{max} 216 mμ, ϵ = 6400; λ_{max} 276.5 mμ, ϵ = 2350; and λ_{infl} ca. 280 mμ, ϵ = 2000; and in ether solution *o*-chlorophenol absorbs as follows: λ_{max} 217 mμ, ϵ = 6200; λ_{max} 275 mμ, ϵ = 2400; and λ_{infl} ca. 281 mμ, ϵ = 2000; these spectra are appreciably different from the absorption spectrum of *o*-chlorophenol in cyclohexane solution (see Table II). Since an intramolecular hydrogen bond in *o*-chlorophenol would be expected to cause bathochromic wavelength displacements in both *B*- and *C*-bands accompanied by intensity increases, and since, further, the spectrum of an intramolecular hydrogen-bonded compound would not be unduly affected by solvent changes, the ultraviolet data point against the presence of structures of type V for solutions of *o*-chlorophenol in ethanol or ether solutions and to a lesser extent to the absence of such structures also in cyclohexane solution.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods in 1-cm cells using a Unicam SP500 spectrophotometer calibrated against a didymium filter. For each compound at least two independent sets of observations were made. The accuracy of λ_{max} values is estimated to be $\pm$2 mμ, and the precision of ϵ_{max} values $\pm$5% or better. Values of ϵ_{max} were reproducible in most cases to $\pm$2%. The ultraviolet data are listed in Tables I and II and in the discussion of *o*-chlorophenol. Some of the spectra have previously been described in this series and elsewhere. Whenever possible, the chlorobenzene spectra were determined under conditions identical with those under which previous spectra in this series had been determined. Frequently, but not always, the data were in good agreement with recent values reported by other workers (cf. for example, ref. 17).

The infrared spectra were determined on a Unicam SP100 instrument, using a NaCl prism and a diffraction grating.

The infrared spectrum of *o*-chloroanisole was determined in the liquid phase in the region 650–2000 cm^{-1} and was found to be more like the infrared spectrum of anisole than the infrared spectrum of chlorobenzene under identical conditions. No evidence in the way of doublet formation, for two different conformations, could be detected for the infrared spectrum of *o*-chloroanisole within this region.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The chlorobenzenes were mostly commercial materials, purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) or other commercially available spectroanalyzed solvents.

ACKNOWLEDGMENTS

The author is greatly indebted to Miss Florence Jackman for the careful determination of the ultraviolet spectral data and to Mr. D. L. Coffen for the infrared data. Some of the spectra have also been determined by Mr. J. C. Dearden in preparation for his Ph.D. thesis and the author is indebted to Mr. Dearden for making these data available.

Grateful acknowledgment for financial assistance in support of these studies is made to the National Research Council of Canada.

DISINTEGRATION-RATE DETERMINATION BY 4π-COUNTING

PART V. FURTHER STUDIES ON ABSORPTION AND SCATTERING OF β-RADIATION[1]

L. YAFFE AND J. B. FISHMAN[2, 3]

ABSTRACT

The work of Pate and Yaffe on the study of absorption and scattering of β-radiation in a 4π-counter has been extended to greater source-mount thickness. As the thickness is increased, the backscattering curves assume the juxtaposition obtained in $<2\pi$ geometrical systems. The saturation backscattering value S is attained at a mass approximately one-fifth that of the range of the β-radiation. The relationship $S = 0.070 \log_{10} E_{max} + 0.142$, where E_{max} is the maximum energy of the β-radiation, is obeyed over the range studied. The phenomenon of coincident discharges, while adequately explained by Pate and Yaffe as caused by wall- and gas-scattering if thin film source mounts are used, cannot completely account for the results with thicker films. Other phenomena, such as bremsstrahlung and secondary electron production, begin to play a role.

INTRODUCTION

Previous publications in this series (1, 2, 3, 4, 5) have described experimental work aimed at improving the accuracy of determination of disintegration rates using a 4π β-proportional counter. In one of these papers (4) Pate and Yaffe studied some of the scattering and absorption processes involved in a 4π steradian geometrical arrangement.

Normally, when the disintegration rate is to be determined, a sample is evaporated on a thin film and placed between two half-counters, the anodes of which are connected in parallel. It has been found by some workers that 'coincident' discharges occur in such an arrangement, i.e. both halves of the counter are discharged within the resolving time of the apparatus by a single disintegration. Pate and Yaffe attempted to fix the cause of these coincidences, in addition to studying the absorption and scattering of the radiation by the source-mounting film.

They have shown that if one uses thin films, of the order of a few hundred micrograms per square centimeter or less, these coincidences are due to backscattering of the radiation from the counter gas and counter walls. The frequency of occurrence of these discharges (as high as 20% of the disintegration rates of pure β-emitters even with very thin source mounts) allowed them to eliminate many other suggested causes of this phenomenon. Of those eliminated, only the possible production of secondary electrons, resulting from interaction between the incident β-radiation and the source-mounting film, will be enhanced by the thicker films used in this later study. For simplicity this is omitted in the ensuing treatment.

Following Pate and Yaffe (4) one can set up a simple model for the absorption and scattering processes which occur in a 4π-counter.

If both half-counter anodes are connected in parallel, then

$$[1] \qquad N_t = N_a + N_b - N_c$$

where N_t is the total counting rate, N_a and N_b are the half-counter rates, and N_c the coincidence rate.

[1]*Manuscript received March 7, 1960.*
Contribution from the Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que., with financial assistance from the National Research Council of Canada.
[2]*Holder of a National Research Council Studentship.*

Pate and Yaffe showed that the following relationship held:

$$N_a = \tfrac{1}{2}N_0[(1+P_2)+P_1P_5P_6] \quad [2]$$

$$N_b = \tfrac{1}{2}N_0[(1-P_2)P_1+P_5P_6] \quad [3]$$

$$N_c = \tfrac{1}{2}N_0(P_5P_6+P_1P_5P_6) \quad [4]$$

where N_0 = disintegration rate of the active sample,

P_1 = transmission of the film to incident β-radiation from the source,

P_2 = the probability that β-radiation originally emitted in the direction of one of the counter halves will be scattered by the film so as to enter the opposite counter half,

P_5 = the transmission of the film to backscattered radiation arising from wall and gas backscattering, and

P_6 = the probability that the β-radiation incident into either hemisphere is backscattered by the counter gas and/or counter walls so as to enter the other hemisphere ($= P_3+P_4$ as defined by Pate and Yaffe).

Values of P_6 were determined by Pate and Yaffe from experiments in which the coincidence rate between the two half-counters was measured with different counter gases and varying aperture sizes. They also obtained values of N_a, N_b, and N_c for a range of values of E, the maximum energy of the β-radiation, and d, the superficial density of the source mount. This enabled them to solve equations [2], [3], and [4] simultaneously and thus determine P_1, P_2, and P_5. Their results are being extended in this paper to greater source-mount superficial densities.

EXPERIMENTAL AND RESULTS

The β^--emitters used were Ni^{63}, S^{35}, Tl^{204}, and P^{32}. This gave a range of maximum energies of the β-radiation from 0.067 to 1.70 Mev. These nuclides were available in solutions which were either 'carrier-free' or of such a high specific activity that evaporation of a suitable aliquot produced a weightless point source on a thin gold-coated VYNS film (1) of superficial density 5–10 $\mu g/cm^2$, mounted on an aluminum ring of 2.5 cm diameter. The source mount was built up by laminating calibrated VYNS films on to the original source mount on the side opposite to that on which the active nuclide had been deposited. This was repeated until the total superficial density was of the order of 1 mg/cm^2.

Since the thickest film conveniently produced by the method previously described is only about 20 $\mu g/cm^2$, a different procedure was adopted for producing thicker films. The VYNS resin was dissolved in acetone and the solution poured into plane-bottom dishes floating on mercury. The acetone was allowed to evaporate slowly, the resultant film was peeled off and mounted on a ring. In this way uniform films of superficial densities up to 60 mg/cm^2 were obtained. The thicker films were rendered conducting by coating them with an evaporated film of gold. They were then placed temporarily in direct contact with the underside of the source-mount films to give a range of film thicknesses above the 1 mg/cm^2 region.

The 4π β-proportional gas counter was identical with that described previously. Each anode was operated as a separate unit so that individual half-counter rates and coincidence rates could be determined. Performance of each unit was carefully matched using the threshold of the plateau obtained with Ni^{63} as a criterion. Corrections were made for random coincidences as described in the previous paper.

N_a, N_b, and N_c were determined for the series of β^--emitters over a range of source-mount superficial densities. The total counting rate N_t, obtained from equation [1], was checked periodically against the counting rate obtained with both anodes connected in parallel.

The results obtained by plotting N_a, N_b, N_c, and N_t against the superficial density of the source mount are shown in Figs. 1–4 inclusive. The values of P_1 and P_5, obtained for the various nuclides, are shown in Figs. 5 and 6. The former shows data obtained with superficial densities up to 1 mg/cm², while the latter gives data to over 200 mg/cm².

DISCUSSION

For small film thicknesses, less that 600 μg/cm², the backscattering data are essentially similar to those of Pate and Yaffe (4), and are shown in Fig. 7. However, the backscattering coefficients are somewhat lower, due possibly to the smaller amount of gold coating on the VYNS films in this series of experiments. As the film thickness increases above the range employed by Pate and Yaffe, as shown in Fig. 8, the curves assume the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

juxtaposition similar to those obtained in $<2\pi$ geometrical arrangements (6, 7, 8), i.e. that nuclide with β-radiation of greatest maximum energy has the greatest backscattering factor.

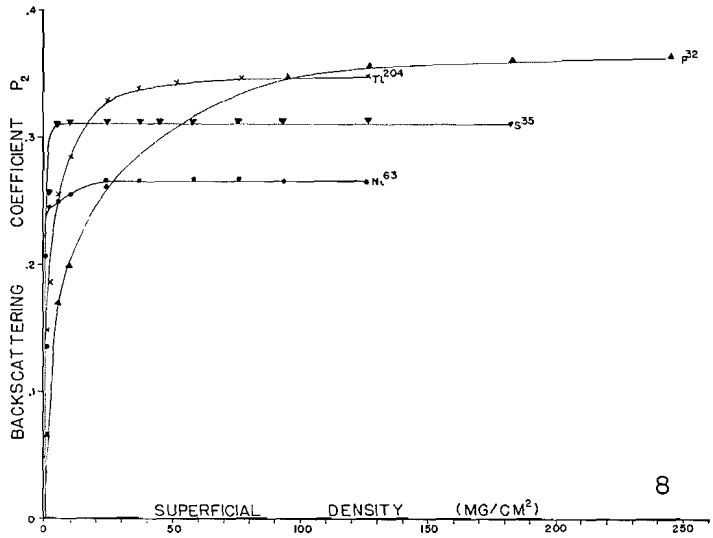

FIG. 7. Variation of the backscattering factor P_2 with increasing superficial density of source mount (to 1 mg/cm²).

FIG. 8. Variation of the backscattering factor P_2 with increasing superficial density of source mount (to 250 mg/cm²).

In Fig. 9 is shown the entire range on a logarithmic plot. The range of the β-radiation is indicated and, as in the case of $<2\pi$ geometrical systems, saturation backscattering is obtained with approximately that amount of material corresponding to about one-fifth the range of the β-radiation.

One can clearly note the transition from the single scattering events, observed with thin films, to the region of multiple scattering. The single scattering events involve electrons incident at small angles to the film and will be greatest for small electron energies as shown in Fig. 7. The behavior of this type of scattering has been described by McKinley and Feshbach (9) amongst others. As the film thickness increases the intermediate region of 'plural' scattering is encountered. The effect of β end-point energy is very pronounced in this region. With Ni^{63}, for example, the backscattering coefficient rises very rapidly and then attains a maximum value characteristic of the electron diffusion

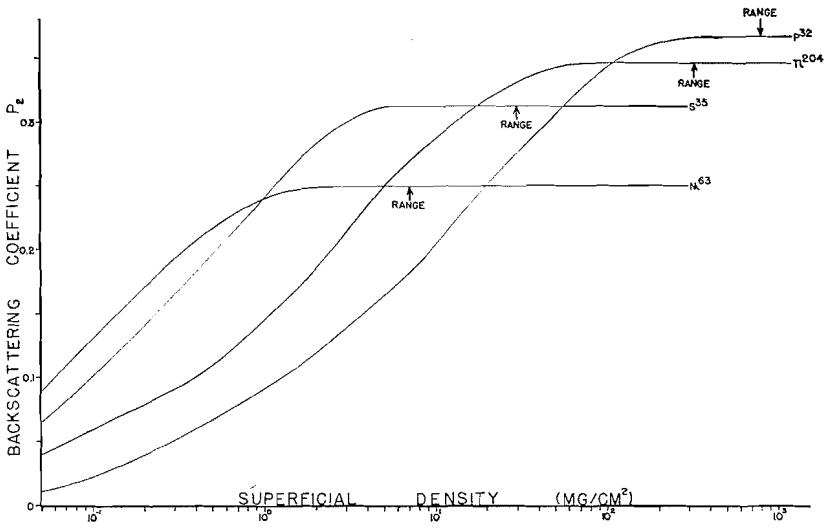

FIG. 9. Variation of the backscattering factor P_2 with the logarithm of the superficial density of the source mount.

type characterized as 'multiple' scattering. For P^{32}, however, the rise is gradual and the rate of change of slope to the maximum backscattering value is very much less than for Ni^{63}. The greater the β end-point energy, the greater is the region of 'plural' scattering.

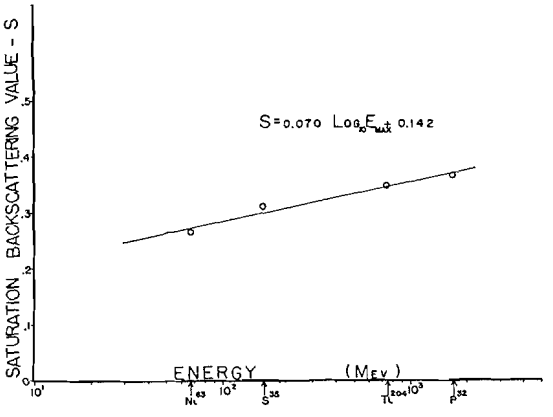

FIG. 10. Variation of the saturation backscattering value with the logarithm of the maximum energy of the β-emitter.

In Fig. 10 is shown the saturation backscattering value S plotted against the logarithm of the maximum energy of the β-radiation. This is essentially linear and follows the empirical equation

$$S = 0.070 \log_{10} E_{max} + 0.142.$$

The saturation backscattering factors found were much larger than those obtained in arrangements with much smaller geometrical efficiency. These are shown in Fig. 11,

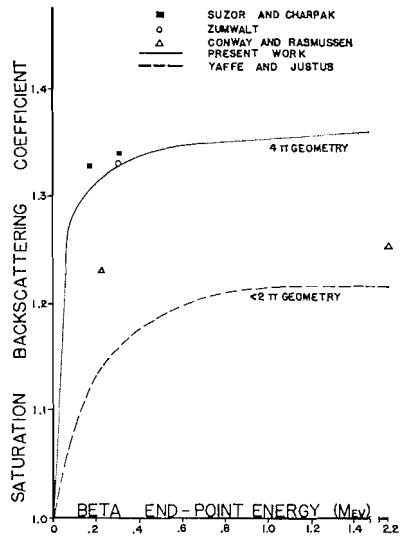

FIG. 11. Variation of saturation backscattering coefficient with β^- end-point energy.

together with extrapolated data for systems of $<2\pi$ geometrical efficiency of Yaffe and Justus (7) and Burtt (10) for saturation backscattering with backing material of mean atomic number $\bar{Z} = 11.2$, the mean atomic number of the VYNS film employed, where

$$\bar{Z} = (\sum_i n_i Z_i^2)/(\sum_i n_i Z_i).$$

Cooper and Yaffe (11) have shown that the above formulation gives the effective mean $\bar{Z}$ for backscattering by a compound where n_i refers to the number of atoms of an element of atomic number Z_i in the compound. The results in Fig. 11 agree with those of other workers who found that the backscattering effect is greater, the greater the geometrical efficiency of the detection system (6, 12, 13, 14).

The increased backscattering coefficient is undoubtedly due to the detection in windowless 2π- or 4π-counters of backscattered radiation degraded too much in energy to pass through the window of a Geiger tube. The extent of energy degradation is evident from Figs. 5 and 6, from the previous work by Pate and Yaffe (4), and the observation by Balfour (15) of a large portion of low-energy rays in the spectrum of backscattered radiation. Another reason why some of these low-energy backscattered particles miss detection in small geometry systems is the fact, ascertained by Brownell (16), that the average energy for backscattered radiation varies with the angle of scattering, with a greater amount of particles having a lower average energy at low scattering angles.

Published data dealing with saturation backscattering coefficients in windowless counters of geometrical systems of 2π or greater are very sparse, so that comparison with present results is very difficult. Suzor and Charpak (17) obtained saturation backscattering coefficients for S^{35} and Co^{60} with aluminum in a 4π-counter. However, since they used the 'sandwich' technique for determining the absolute disintegration rates, their results are slightly in error (4). Their values are shown in Fig. 11 for comparison. Zumwalt's (6) values for Co^{60} in a 2π-counter, extrapolated to $\bar{Z} = 11.2$, are also shown for comparison. Conway and Rasmussen's (14) values for Pm^{147} and Sr^{90}–Y^{90}, determined in a 2π-counter, included in the same diagram, are much lower than ours or those of Zumwalt.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Christian *et al.* (18) determined backscattering coefficients for Ni^{63}, Co^{60}, P^{32}, and S^{35} in a 2π-counter. Their value for Ni^{63} corresponds well with ours. However, their other points seem too erratic and unsystematic to be very useful.

If one examines equations [2], [3], and [4], it is apparent that, as d, the thickness of film, increases beyond the range of the backscattered and incident β^--radiation, then P_5 and P_1 approach zero. This would mean that N_b and N_c would approach zero. Examination of Figs. 1–4 shows that the curves do not reach zero, but level off (as is shown markedly in the case of the weaker β^--emitters). It seems obvious then that the assumptions made in the derivation of the above equations, i.e. that the only processes causing coincidences are counter wall- and gas-scattering, are only approximate. As the film thickness is increased other phenomena, such as bremsstrahlung or secondary electron production, begin to play a role.

It has been shown by Bolgiano *et al.* (19) that the probability of inner bremsstrahlung production is in the order of 10^{-4}. Thus, coupled with the low probability for detection of photons in the 4π-counter, this process will contribute very little.

The radiation from external bremsstrahlungen has a maximum photon energy equal to the energy of the β-radiation and an intensity proportional to the mean atomic number of the absorbing material. It has been shown (20) that the fraction of the β-energy, which appears as external bremsstrahlung, is given approximately by $\bar{Z}E_{max}/3000$. For VYNS and P^{32} this amounts to about 0.5%. As before, this low probability and the low probability of photon detection would only contribute a small amount to the coincidences taking place.

This then leaves secondary electron production. Their liberation by the photoelectric effect may again be ignored owing to the low probability, of the order of 10^{-4}. However, if an electron of initial energy E produces by collision two electrons of energy W and $E-W$, then Mott (21) has shown that the number of secondary electrons, I, produced in a distance dx, in the energy range W to $W-dW$ is

$$I = \bar{Z}N\,dx\,d\phi\,(E, W) \qquad [5]$$

where $\bar{Z}$ is the mean atomic number of the stopping material and N the number of atoms per square centimeter of the stopping material.

The differential scattering cross section $d\phi\,(E, W)$ has been determined by Page (22). He found that, for β^--radiation between 0.6 and 1.7 Mev, the value of $d\phi\,(E, W)$ in collodion was of the order of 10^{-24} cm^2. If this value is substituted into equation [5], taking $\bar{Z} = 11.2$, $N \approx 10^{23}$, and $dx \approx 0.1$ cm, then $I = 0.10$. This is now a reasonably high probability, so that this process can no longer be ignored since every electron produced will be detected.

This, of course, cannot account for the 'coincident discharge' with films of thickness greater than the range of the original β-radiation, e.g. in the case of Ni^{63}. In these instances, the discharges must be due to a combination of causes which could include bremsstrahlungen from the counter gas and walls, the bremsstrahlungen discussed above, and perhaps a small contribution from a hard cosmic ray component which would trigger both counters contributing to the coincidences.

Pate and Yaffe (3) have determined the absorption parameter (N_T/N_0) as a function of β end-point energy for a series of film thicknesses. This is shown in Fig. 3 in their paper. These data have been extended, as shown in Fig. 12 of this paper, to lower energies with the inclusion of results obtained by the study of H^3 (E_{max} = .018 Mev). The added data fall into place in very satisfactory fashion.

THE REACTION OF SULPHURYL CHLORIDE WITH GLYCOSIDES AND SUGAR ALCOHOLS. PART II[1]

J. K. N. Jones, M. B. Perry, and J. C. Turner

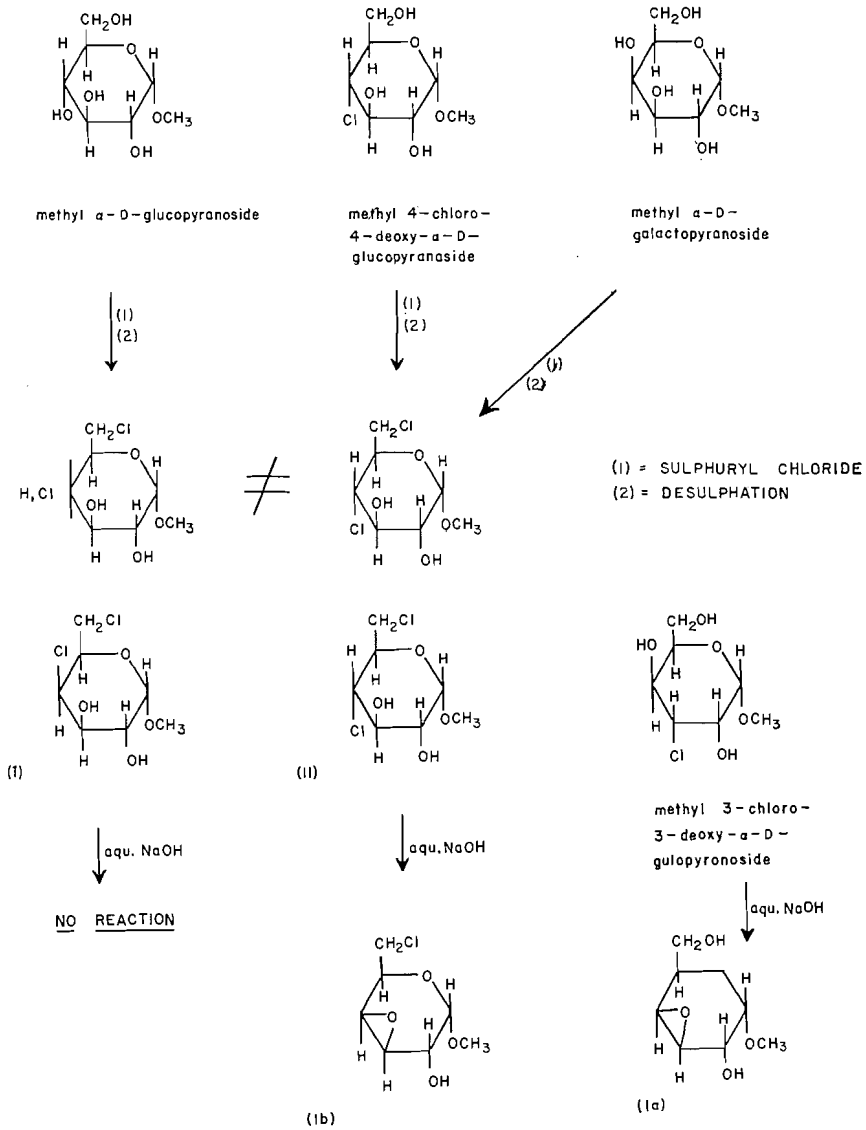
ABSTRACT

The structures of methyl 4,6-dichloro-4,6-dideoxy-α-D-hexoside and methyl "4-chloro-4-deoxy-β-pentoside" (I) have been investigated. The desulphation reaction leading to the formation of the latter compound is described. Replacement of the hydroxyl group at $C_{(4)}$ by a chlorine atom in both compounds is shown to have occurred with inversion of configuration.

INTRODUCTION

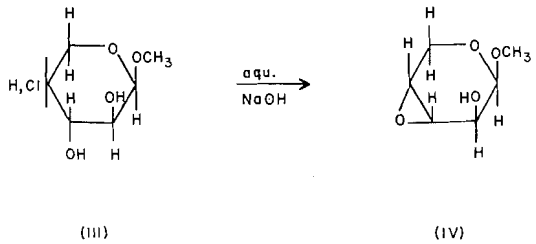
In Part I (1) the product of the reaction of sulphuryl chloride with methyl α-D-glucopyranoside was shown to be probably methyl 4,6-dichloro-4,6-dideoxy-α-D-hexoside 2,3-sulphate which on desulphation gave methyl 4,6-dichloro-4,6-dideoxy-α-D-hexoside (I). It was possible that the replacement of the hydroxyl group at $C_{(4)}$ by the chlorine atom had occurred with inversion of configuration to give the galactose configuration.

This problem was investigated using a synthetic route to a methyl 4,6-dichloro-4,6-dideoxy-α-D-hexoside of known configuration. Methyl 4-chloro-4-deoxy-α-D-glucopyranoside was synthesized by the method of Buchanan (2). Reaction with sulphuryl chloride and subsequent desulphation gave a complex mixture from which was isolated methyl 4,6-dichloro-4,6-dideoxy-α-D-glucopyranoside (II) which was found to be different from that obtained from the reaction of sulphuryl chloride with methyl α-D-glucopyranoside (I). It was found that II consumed periodate extremely slowly (1.04 moles, 167 hours) and this bore some resemblance to the parent methyl 4-chloro-4-deoxy-α-D-glucopyranoside which was oxidized under somewhat similar conditions (1.03 moles, 170 hours) (3, 3*a*). Accordingly the chlorine atom at $C_{(4)}$ of I was placed in the galactose configuration since this was the only position in which I and II differed.



Further evidence as to the configuration at $C_{(4)}$ of I was obtained when the reaction of sulphuryl chloride with methyl α-D-galactopyranoside was examined. Desulphation of the fully substituted product gave a complex mixture from which was isolated a methyl dichloro-dideoxy-α-D-hexoside identical with II.

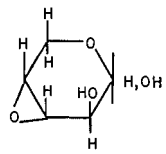
Compound I did not react with sodium hydroxide, whereas II lost approximately 1 equivalent of chlorine under the same conditions probably to give I*b*. It was found that methyl 3-chloro-3-deoxy-α-D-gulopyranoside, with sodium hydroxide, lost chlorine to give methyl 3,4-anhydro-α-D-galactopyranoside (I*a*) in good yield. These findings were related to the configurations of the chlorine atom at $C_{(4)}$ and the hydroxyl group at $C_{(3)}$ in I and II, and it was concluded that a trans configuration was necessary for the elimination of chlorine from $C_{(4)}$ to take place.



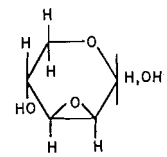
Since the threo configuration was retained in I at $C_{(2)}$ and $C_{(3)}$ during desulphation (1) and the $C_{(3)}$ and $C_{(4)}$ hydroxyl group and chlorine atom were cis disposed it was concluded that I possessed the galactose configuration and that elimination of hydroxyl at $C_{(4)}$ by chlorine had occurred with inversion of configuration.

Accordingly I would be methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside, and the fully substituted compound from which it was obtained by desulphation would be methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-sulphate.

[1]*Manuscript received February 29, 1960.*
Contribution from the Chemistry Department, Queen's University, Kingston, Ontario.

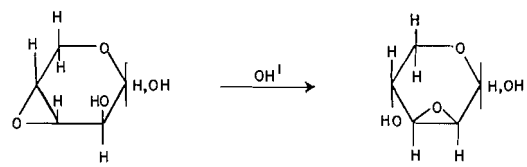


The monochloro monodeoxy pentoside (III) from methyl β-D-arabinopyranoside possessed the chlorine atom at $C_{(4)}$ (1). On treatment of III with sodium hydroxide, chlorine was eliminated, presumably with the formation of the anhydro pentoside (IV).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

On hydrolysis IV gave two pentoses, D-lyxose and xylose. (The latter was not completely characterized as only a small amount was produced.) The structure of IV was therefore very probably as written, namely, methyl 3,4-anhydro-β-D-arabinopyranoside. As shown previously, elimination of chlorine under the influence of sodium hydroxide occurred when the chlorine atom and hydroxyl group involved were trans to one another. Since the configuration of the hydroxyl groups on $C_{(2)}$ and $C_{(3)}$ did not change on desulphation (1) and $C_{(3)}$ and $C_{(4)}$ groups were trans, III possessed the L-xylose configuration and was therefore methyl 4-chloro-4-deoxy-α-L-xylopyranoside. The fully substituted compound from which III was obtained by desulphation also possessed the L-xylose configuration and was methyl 4-chloro-4-deoxy-α-L-xylopyranoside 2,3-sulphate. The desulphation of the latter compound was investigated more fully. In addition to methyl 4-chloro-4-deoxy-α-L-xylopyranoside and 4-chloro-4-deoxy-L-xylose, five other compounds were isolated in small amount from the desulphated mixture. They were: two anhydro pentoses, D-lyxose, xylose, and D-arabinose. One anhydro pentose (V) gave on hydrolysis xylose and lyxose, while the other (VI) gave xylose and arabinose which were identified chromatographically because the pentoses were present in too small an amount to be completely characterized in this instance.



V(3,4-anhydro-D-arabinose)

VI(2,3-anhydro-D-lyxose)

Very probably V and VI gave rise to D-lyxose, xylose, and D-arabinose during the second stage of desulphation (treatment with 2 *N* sulphuric acid). The mechanism of formation of VI is less certain but a possible explanation is outlined below.

An apparently anomalous reaction is proposed in the conversion of methyl 3,4-anhydro-β-D-arabinopyranoside 2-sulphate (a postulated reaction intermediate) to methyl 2,3-anhydro-β-D-lyxopyranoside by 2 *N* sulphuric acid. Reactions of the type V $\rightarrow$ VI are

(V) (VI)

known to occur, under the influence of alkali (4), but not in an acid medium. However, no free ionic sulphate could be detected after the first stage of desulphation (treatment with methanolic ammonia) and the sulphate residue remaining on $C_{(2)}$ would presumably prevent migration of the epoxide ring from $C_{(3)}$–$C_{(4)}$ to $C_{(2)}$–$C_{(3)}$. Therefore the migration was presumed to occur in the second stage in which the sulphate residue was removed (treatment with 2 *N* sulphuric acid).

The initial reaction in the desulphation, the cleavage of the cyclic sulphate ring with

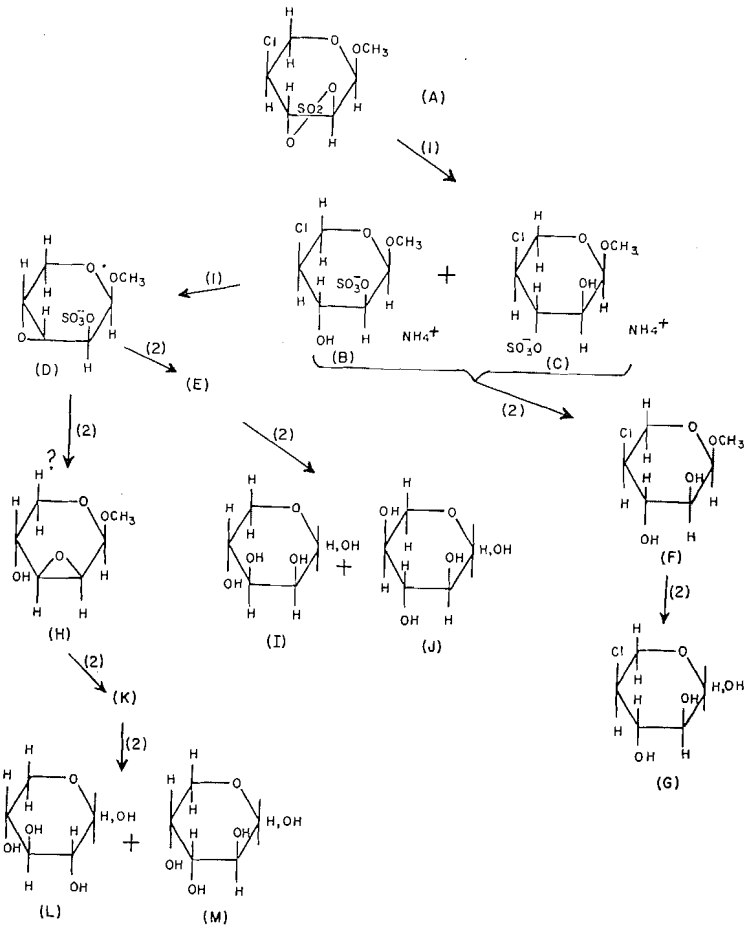

FIG. 1. The desulphation of methyl 4-chloro-4-deoxy-α-L-xyloside 2,3-sulphate (A).
LEGEND: First stage of desulphation ($MeOH/NH_3$) (1).
Second stage of desulphation (2 *N* H_2SO_4) (2).
(B) and (C) Ammonium salts of opened sulphate ring. (D) 3,4-Anhydro-β-D-arabinose 2-sulphate. (E) 3,4-Anhydro-D-arabinose. (F) Methyl 4-chloro-4-deoxy-L-xylose. (G) 4-Chloro-4-deoxy-L-xylose. (H) 2,3-Anhydro-β-D-lyxoside. (I) D-Lyxose. (J) L-Xylose. (K) 2,3-Anhydro-D-lyxose. (L) D-Xylose. (M) D-Arabinose.

ammonia, very probably gave two compounds ((B) and (C) in diagram). The ratio of (B) to (C) was not known, but it was unlikely that a very high proportion of (B) was present, as chlorine would then have been eliminated by the methanolic ammonia due to the trans configuration of the chlorine atom on $C_{(4)}$ and the hydroxyl group on $C_{(3)}$.

An analogous sequence of reactions leading to the formation of complex mixtures would be expected to occur with all those fully substituted derivatives containing a chlorine atom trans to an adjacent potential secondary hydroxyl group, and this was found to be the case (see above) with methyl 4,6-dichloro-4,6-dideoxy-α-D-glucopyranoside 2,3-sulphate. The corresponding derivative from methyl α-D-glucopyranoside, possessing the galactose configuration, gave only methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (I) and 4,6-dichloro-4,6-dideoxy-D-galactose on desulphation.

EXPERIMENTAL

Melting points are uncorrected and were determined on a Kofler microheating stage. All evaporations were carried out under reduced pressure. Optical rotations were measured in water at 21±3° C unless otherwise stated. Paper chromatograms were run using a descending flow (5) and Whatman No. 1 paper in the following solvent systems:

(*a*) butan-1-ol:ethanol:water (3:1:1),
(*b*) butan-1-ol:pyridine:water (10:3:3),
(*c*) ethyl acetate:acetic acid:formic acid:water (18:3:1:4).

Reaction of Sulphuryl Chloride with Methyl 4-Chloro-4-deoxy-α-D-glucopyranoside

The chloro sugar was obtained as a syrup contaminated with a small amount of methyl 3-chloro-3-deoxy-α-D-gulopyranoside, by the method of Buchanan (2). The syrup (0.5 g) gave with sulphuryl chloride a pale yellow syrup (0.388 g) containing sulphur and chlorine. On desulphation first with methanolic ammonia and then with 2 *N* sulphuric acid in the usual manner (1) a complex mixture was obtained (0.180 g) which consisted of seven components of R_f values 0.19, 0.21, 0.40, 0.48, 0.73, 0.78, 0.81, in solvent (*a*). Alkaline silver nitrate spray (6) was used to detect the sugars. An aqueous solution of the mixture was continuously extracted with chloroform for 24 hours. The chloroform extract on evaporation gave a syrup (43 mg) which crystallized. The syrup contained the three components R_f 0.73, R_f 0.78, R_f 0.81, of which the component R_f 0.78 was the major one. The syrupy crystals were recrystallized twice from chloroform/light petroleum (60°–80° C) to give white needles of melting point 119–121° C and $[\alpha]_D$ +121° (*c*, 1.8). Analysis: Calc. $C_7H_{12}O_4Cl_2$: C, 36.4%; H, 5.2%. Found: C, 37.0%; H, 5.3%.

Periodate Oxidation of the Methyl Dichloro-dideoxy-α-D-hexoside Prepared from Methyl 4-Chloro-4-deoxy-α-D-glucopyranoside

The oxidation was carried out at 25° C, using a small sample (8.5 mg) of the compound in distilled water (25 ml) containing 0.3 *M* sodium metaperiodate (1 ml). The results are shown below and are compared with those of Buchanan (3) for methyl 4-chloro-4-deoxy-α-D-glucopyranoside.

TABLE I

Substance	Time of oxidation (hours)	Consumption of periodate (mole/molecule)	Acid production (mole/molecule)
Methyl dichloro-dideoxy-α-D-hexoside	3.8	0.195	
	10	0.310

Methyl 4-chloro-4-deoxy-α-D-glucopyranoside	20	0.42	
	40	0.58	Not reported
	170	1.03	
	212	1.06	

Reaction of Sulphuryl Chloride with Methyl α-D-Galactopyranoside

Methyl α-D-galactopyranoside was prepared by the method of Dale and Hudson (7), purified by recrystallization from hot absolute ethanol, and dried *in vacuo* at 40° C. With sulphuryl chloride, methyl α-D-galactopyranoside (5 g) gave a brown syrup (3.7 g)

which contained chlorine and sulphur (sodium fusion). The syrup could not be obtained crystalline.

Desulphation of the syrup with methanolic ammonia and 2 *N* sulphuric acid gave a mixture (0.73 g) containing four components of R_f values 0.12, 0.22, 0.42 (major component), 0.71 (solvent (*a*); alkaline silver nitrate and anisidine hydrochloride (8) sprays). An aqueous solution of the mixture was continuously extracted with chloroform for 24 hours. The chloroform extract on evaporation gave a colorless syrup (0.3 g). On nucleation with the methyl dichloro-dideoxy-α-D-hexoside which had been prepared from methyl 4-chloro-4-deoxy-α-D-glucopyranoside (see above) rapid crystallization occurred.

When recrystallized from chloroform/light petroleum (60°–80° C) the crystals had a melting point of 119–121° C, mixed melting point with the above compound 119–121° C, $[\alpha]_D$ +122° (*c*, 1.9) and were therefore identical with that compound. Analysis: Calc. for $C_7H_{12}O_4Cl_2$: Cl, 30.7%. Found (Schöniger combustion method (9)): Cl, 30.4%.

The Reaction of Chloro Sugars with Sodium Hydroxide

The Methyl 4,6-Dichloro-4,6-dideoxy-α-D-hexoside from Methyl α-D-Glucopyranoside (1)

The hexoside (150 mg) was dissolved in water (25 ml) and phenolphthalein was added. The solution was then titrated with 0.232 *N* sodium hydroxide solution. No sodium hydroxide was neutralized even after 4 hours at 40° C. The solution was deionized with resin and the eluate concentrated to a crystalline mass (151 mg). The crystals had a melting point of 156–158° C and mixed melting point with the starting material, 156–158° C. Analysis: Calc. for $C_7H_{12}O_4Cl_2$: Cl, 30.7%. Found: starting material, 31.0%; product, 31.4%.

The Methyl Dichloro-dideoxy-α-D-hexoside from Methyl α-D-Galactopyranoside

The hexoside (m.p. 119–121° C, 0.875 mg) was dissolved in distilled water (1 ml) and sodium hydroxide solution (1 ml of 0.01 *N*) was added. The solution was allowed to stand for 6 hours at room temperature, then neutralized exactly with 0.01 *N* sulphuric acid, using screened methyl red – methylene blue indicator. To the neutralized solution was added neutralized mercuric oxycyanide solution (5 ml of 2% solution) and the resultant alkaline solution titrated to exact neutrality with 0.01 *N* sulphuric acid. The titer was 0.330 ml, which corresponded to the elimination of 0.88 mole chlorine per molecule of hexoside. The titration mixture was deionized with resin and examined on paper chromatograms. Three components were observed of R_f values 0.04 (faint), 0.38 (major component), 0.71 (faint co-chromatographing with starting material) (solvent (*a*), alkaline silver nitrate spray).

The Methyl 3-Chloro-3-deoxy-α-D-gulopyranoside (2)

The gulopyranoside (164 mg) was dissolved in water (25 ml) and titrated with sodium hydroxide (0.232 *N*) as described above. The solution took up 1 equivalent (3.31 ml) of sodium hydroxide over a period of 72 hours at 40° C and was then evaporated to dryness. The residue was extracted three times with 100-ml portions of boiling ether. The combined ether extracts on evaporation gave a syrup (101 mg, 74%) which rapidly crystallized. The crystals had a melting point of 117–118° C undepressed on admixture with an authentic specimen of methyl 3,4-anhydro-α-D-galactopyranoside (m.p. 117.5–118.5° C).

The Methyl 4-Chloro-4-deoxy-β-pentoside from Methyl β-D-Arabinopyranoside (1)

The pentoside (67 mg) was dissolved in water (3.0 ml) and sodium hydroxide solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

(0.45 ml of 0.232 *N*) was added. The change in optical rotation was followed at intervals up to 5 hours.

TABLE II

Time of reaction (hours)	$[\alpha]_D$
0	+108°
0.25	+82°
0.50	+73°
1.0	+72°
1.75	+63°
4.0	+61°
5.0	+59°

The slight excess of sodium hydroxide remaining after 8 hours was neutralized with nitric acid, the solution evaporated to dryness, and the residue extracted with ether. The extract on evaporation gave a colorless syrup (47 mg), while the residue gave a positive test for ionic chloride. The syrup gave one main spot, R_f 0.53 (solvent (*a*)), on paper chromatograms. The syrup was heated with 2 *N* sulphuric acid at 100° C for 14 hours, neutralized with barium carbonate, filtered, and deionized with resin. The eluate was concentrated to a colorless syrup (30 mg) which consisted of xylose and lyxose as shown by paper chromatograms, and paper electrophoresis in pH 9.5 borate buffer at 2500 volts for 40 minutes. An attempted separation of the pentoses using phenol saturated with water as the chromatographic solvent (10) with a descending flow on Whatman 3MM paper was unsuccessful. The pentoses were separated by paper electrophoresis under the conditions mentioned above. The lyxose (10 mg) $[\alpha]_D$ −18° (*c*, 1) was characterized by its rate of movement on chromatograms and as its phenyl osazone, m.p. 158–161° C, unchanged on admixture with authentic D-lyxose (xylose) phenylosazone (11). The xylose could not be satisfactorily characterized due to its small amount (ca. 2 mg).

The Desulphation of Methyl 4-Chloro-4-deoxy-β-pentoside 2,3-Sulphate (1)

The desulphated mixture (0.9 g) was separated on a cellulose column using butan-1-ol: water (19:1). Besides methyl 4-chloro-4-deoxy-β-pentoside and 4-chloro-4-deoxy pentose, four other fractions were isolated: Fraction I, a syrup (53 mg) with R_f 0.44 (in solvent (*a*)) was obtained. On hydrolysis with sulphuric acid it gave xylose and lyxose, identified by paper chromatography and paper electrophoresis: Fraction II was a syrup (15 mg) with R_f 0.39 (solvent (*a*)). On hydrolysis it gave xylose and arabinose, identified by paper chromatography and paper electrophoresis. Fraction III was a syrup (78 mg) with R_f 0.24 (solvent (*a*)). This fraction consisted of xylose and lyxose as shown by paper chromatograms and paper electrophoresis. A partial separation was achieved on a column of Dowex 50W sulphuric acid resin (86×2.2 cm, 8% cross-linked with divinyl benzene, 200–400 mesh, barium salt form). The lyxose was obtained pure, and characterized as its *p*-toluene sulphonhydrazone (12), m.p. 152–153° C, which did not depress the melting point of authentic D-lyxose *p*-toluene sulphonhydrazone (141° C). The xylose could not be completely characterized. Fraction IV, syrupy crystals (51 mg), R_f 0.214 (solvent (*a*)), consisted of D-arabinose as shown by paper chromatograms. It was contaminated with some water-insoluble material and had $[\alpha]_D$ −74° (5 minutes) → −66° (8 hours) (*c*, 0.4 in methanol). It was characterized as the benzoyl hydrazone, m.p. 190–195° C, undepressed on admixture with authentic D-arabinose benzoyl hydrazone, m.p. 190–195° C (13).

BILE ACID DERIVATIVES[1]

A. A. Amos and P. Ziegler

ABSTRACT

The potassium permanganate oxidation of 3α,12α-diacetoxy-24,24-diphenyl-Δ^{23}-cholene yielded a new compound which was identified as 3α,12α-diacetoxy-23-keto-24-hydroxy-24,24-diphenylcholane. The latter steroid, on reduction with sodium borohydride, produced two isomeric glycols which were subsequently dehydrated to provide the corresponding 23-keto-24,24-diphenyl derivative.

Desoxycholic acid is used extensively as a starting material for the preparation of steroidal hormones. One important phase of this conversion consists of the partial degradation of the bile acid side chain which is attached to C-17 of the steroid nucleus. This degradation can be accomplished by the classical Barbier–Wieland procedure, or preferably by the Miescher–Wettstein (1) scheme. Both methods produce the acetylated diphenylethylene derivative I as an intermediary product. According to the directions of Miescher and Wettstein, I is brominated in the allylic position, then dehydrobrominated to the corresponding diene, which in turn is oxidized to the 20-ketone. It has been found in our laboratories that the dienes thus produced are often contaminated with the ethylene derivative I; this impurity can be detected by its absorption at 252 mμ. When the crude diene was then treated with potassium permanganate, a useful (2) oxidizing agent for such compounds, the isolation of 3α,12α-diacetoxypregnan-20-one proved to be difficult; in fact, it was found that the yields of 20-ketone increased markedly with increasing purity of diene. This observation indicated that I or its oxidation products interfered with the normal course of the permanganate oxidation of the diene, or with the subsequent isolation of the 20-ketone. It was therefore decided to investigate the products derived from I by this oxidation.

The oxidation was carried out in refluxing aqueous acetone, containing potassium dihydrogen phosphate as a buffer, which provided the desired neutral pH. The reaction products were then separated to give 30% of acidic material which was identified as nordesoxycholic acid diacetate (III). The neutral fraction, after crystallization, afforded 45% of a compound (II) which in turn was converted to III by oxidation with chromic acid. Compound II failed to react with the Malaprade reagent or with acetic anhydride and pyridine at 20°, and on the basis of this evidence a 23,24-glycol structure was eliminated. The presence of a ketone group in II was indicated clearly by its ultraviolet and infrared absorption, though the compound did not form a 2,4-dinitrophenylhydrazone or an oxime. This result is attributed to steric effects which are known (3) to be operative in similar cases. The ultraviolet spectrum of the ketol II showed bands at 260 mμ (ϵ = 440) and at 297 mμ (ϵ = 360). The absorption at the lower wavelength is undoubtedly due to the two unconjugated phenyl groups (4, 5) in the molecule; the band at the higher wavelength results from the interaction of the ketone function with the phenyl groups. In studies of α,α-diphenylketones, it has previously been shown (4, 6, 7) that the carbonyl absorption peak in the ultraviolet region is more intense and is shifted towards longer wavelength than that of most ketones. The above data as well as the results of elemental analyses for II and its hydrolysis product provided the evidence for the ketol structure in these compounds.

When the ketol II was reduced with sodium borohydride and the reaction products were hydrolyzed, two isomeric glycols (IV and V) were isolated. Both compounds gave positive Malaprade tests, and the predominant isomer (IV) formed a well-defined acetonide; since V was obtained in only small yield, its reactivity towards acetone could not be determined. The two isomers showed the ultraviolet absorption bands at 260 mμ due to the phenyl groups, but the ketone peak was absent; in the infrared region there appeared the characteristic absorption of associated hydroxyl groups. On treatment with acidic reagents, both glycols yielded 3α,12α-diacetoxy-23-keto-24,24-diphenylcholane (VI). The latter compound again showed the ketone band at 293 mμ, and in the infrared the hydroxyl peak was absent. These findings, in conjunction with the results of elemental analyses, established the structures for IV, V, and VI.

The oxidation of 3α,12α-diacetoxy-24,24-diphenyl-Δ^{23}-cholene (I) by chromic acid has been reported (8, 9) to yield 60–70% of the noracid III; ozonization (10) of the diphenylethylene derived from cholic acid afforded the corresponding noracid in lower yield. Invariably, these oxidations produced relatively large amounts of neutral, unidentified fractions which may well contain the related ketols. The good yield of II obtained from the permanganate oxidation is not surprising in view of some recent reports. In the steroid field, this oxidizing agent has been employed to produce ketols from the corresponding $\Delta^{5,6}$-unsaturated compounds (11) as well as from $\Delta^{17,20}$-analogues (12, 13). The mild permanganate treatment (14) of oleic acid similarly provided high yields (70–75%) of ketohydroxystearic acid.

EXPERIMENTAL[2,3]

The Permanganate Oxidation of 3α,12α-Diacetoxy-24,24-diphenyl-Δ^{23}-cholene (I)

Compound I (20 g) and potassium dihydrogen phosphate (2 g) were suspended in acetone (195 ml) and water (5 ml). The mixture was stirred and there was then added, in

[2]*The microanalyses were kindly performed by Mr. E. Thommen, Basel, Switzerland.*
[3]*The infrared absorption data were obtained through the courtesy of Dr. G. D. Laubach of Chas. Pfizer & Co., Brooklyn, N.Y.*

four equal portions, at intervals of 30 minutes, potassium permanganate (32 g). On addition of each batch of oxidizing agent, vigorous refluxing began and gradually subsided after several minutes. After all the permanganate had been added, the reaction was continued under reflux conditions for an additional $2\frac{1}{2}$ hours. The excess oxidizing agent was destroyed by charcoal (5 g) and, after 1 hour's stirring, the solids were filtered off. The filtrate was evaporated to dryness, the residue (16 g) was dissolved in ethyl acetate and extracted with 2.5% sodium carbonate solution. After being washed with water, the solvent extract was evaporated, the residual gum was taken up in ether to provide, on cooling, 9.45 g (45%) of II, m.p. 169–171° C. Recrystallization from acetone gave material, m.p. 175–175.5° C, and $[\alpha]_D^{25}$ +81.3° (*c*, 0.994, dioxane). This compound failed to react with a solution of bromine in carbon tetrachloride, with 2,4-dinitrophenylhydrazine, trichloroacetic acid, the Zimmermann reagent, and was negative in the Malaprade test. Its ultraviolet spectrum showed weak bands at 260 mμ (ϵ = 440) and at 297 mμ (ϵ = 360). Analysis: Calculated for $C_{40}H_{52}O_6$: C, 76.39; H, 8.34; O, 15.27. Found: C, 76.37, 76.48; H, 8.56, 8.47; O, 15.37, 15.41.

The carbonate extract as well as the water washings from the cake of solids (manganese salts, etc.) were acidified and extracted with ether. The solvent phase was washed, dried, and evaporated; crystallization of the residue from ether–hexane afforded 4.5 g (29%) of crude 3α,12α-diacetoxy-norcholanic acid (III), m.p. 180–190° C. This material was recrystallized from hexane–ether to give a melting point of 203–205° C.

3α,12α-Diacetoxy-norcholanic Acid (III) *from* II

Compound II (1 g) was suspended in acetic acid (15 ml) and there was then added dropwise, over a period of $\frac{1}{2}$ hour, a solution of chromic acid (1 g) in acetic acid (24 ml) and water (1 ml). The mixture was kept at 20° C for 2 hours and an equal period of time at 35° C with occasional shaking. The excess oxidizing agent was decomposed by sodium bisulphite; water was added, and the products were extracted with ether. The solvent phase, after having been washed, dried, and evaporated, yielded a residue (1.12 g) which crystallized readily from acetone. The noracid III (472 mg), m.p. 203–205° C, thus obtained, was recrystallized from ether–hexane to give pure III, m.p. 211–213° C.

3α,24-Dihydroxy-12α-acetoxy-23-keto-24,24-diphenylcholane

The diacetoxy-ketol II (0.5 g) was dissolved by warming in methanol (24 ml) and water (1 ml), containing potassium hydroxide (0.2 g). The solution was kept at room temperature for 66 hours, after which time most of the methanol was removed *in vacuo*. The residue was taken up in ether and dilute mineral acid, the ether phase was washed to neutrality, dried, and evaporated to give a residue (0.46 g) which crystallized from ether–hexane to yield 367 mg of material, m.p. 188–190° C. Two further recrystallizations from ether–hexane provided needles, m.p. 190–191.5° C and $[\alpha]_D^{24}$ +68.9° (*c*, 0.779, dioxane). Analysis: Calculated for $C_{38}H_{50}O_5$: C, 77.78; H, 8.59; O, 13.63. Found: C, 77.83, 77.91; H, 8.75, 8.75; O, 13.63.

Sodium Borohydride Reduction of the Ketol II

Compound II (1 g) was partially dissolved in ether (50 ml) and sodium borohydride (0.5 g) was added. The mixture was kept at 20° C for 15 hours, and was subsequently refluxed for $3\frac{1}{2}$ hours. The excess reducing agent was destroyed by addition of acetic acid, the mixture was diluted with water and extracted exhaustively with ether. The combined solvent extracts were washed, dried, and evaporated to provide a residue (1 g), which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

was saponified at room temperature for 15 hours with 2.5% methanolic potassium hydroxide. Dilution with water, extraction with ether, and working up in the usual fashion gave the residue (0.98 g) which crystallized from ether–hexane to provide, in two crops, 451 mg of material; these crystals melted at 127–135° C, the melt resolidified at 145–150° C and finally melted at 215–218° C. Two recrystallizations from ethyl acetate yielded pure IV, m.p. 216.5–219° C and $[\alpha]_D^{25}$ +121.2° (*c*, 0.366, dioxane). This substance gave a positive Malaprade test; in the ultraviolet region, it exhibited a weak band at 260 mμ (ϵ = 380). Analysis: Calculated for $C_{38}H_{52}O_5$: C, 77.51; H, 8.90; O, 13.59. Found: C, 77.66, 77.55; H, 9.07, 8.99; O, 13.65, 13.74.

The filtrate from IV was reduced in volume and, on refrigeration, three more crops of crystals were isolated. These weighed 295 mg and had a melting point of 177–185° C. Several recrystallizations from ether–hexane provided a small, pure sample of V, m.p. 193–194° C and $[\alpha]_D^{23}$ +16.9° (*c*, 0.655, dioxane). This compound, on admixture with IV, had a melting point of 178–183° C; V, like IV, gave a positive Malaprade test. Analysis: Calculated for $C_{38}H_{52}O_5$: C, 77.51; H, 8.90; O, 13.59. Found: C, 77.78; H, 9.15; O, 13.24.

The Acetonide of IV

Compound IV (250 mg) was dissolved in dry acetone (20 ml), *p*-toluenesulphonic acid (50 mg) was added, and the solution was kept at 25° C for 16 hours. The solution was neutralized with solid sodium bicarbonate, diluted with water, and extracted with ether. The solvent extract was washed, dried, and evaporated to a white solid (270 mg) which crystallized from ether–hexane to give 220 mg of material, m.p. 227–228° C. Three recrystallizations from the same solvent system yielded the acetonide of IV, m.p. 228–230° C and $[\alpha]_D^{25}$ +158.3° (*c*, 0.647, dioxane). Analysis: Calculated for $C_{41}H_{56}O_5$: C, 78.30; H, 8.98; O, 12.72. Found: C, 78.42, 78.34; H, 9.17, 9.22; O, 12.79, 12.68.

3α,12α-Diacetoxy-23-keto-24,24-diphenylcholane (VI)

(a) From IV

Compound IV (120 mg) was refluxed gently for 2 hours with acetic acid (8 ml) and concentrated hydrochloric acid (0.8 ml); an additional 0.8 ml of hydrochloric acid was added then, and refluxing was continued for 2 more hours. The reaction mixture was poured into water, extracted with ether, and the solvent phase worked up in the customary manner. Crystallization of the residue from hexane–ether yielded 70 mg of substance which melted at 127–129° C, partially recrystallized, and finally melted at 155–158° C. Three recrystallizations from hexane–ether provided a pure sample of VI, having a double melting point 133–136° and 167–170° C. When VI is crushed to a very fine powder, it melts at 167–168° C; $[\alpha]_D^{23}$ +67.5° (*c*, 0.591, dioxane). This compound absorbs in the ultraviolet at 260 mμ (ϵ = 515) and at 293 mμ (ϵ = 270). Analysis: Calculated for $C_{40}H_{52}O_5$: C, 78.39; H, 8.55; O, 13.05. Found: C, 78.54, 78.77; H, 8.88, 8.53; O, 13.14, 13.05.

(b) From V

Compound V (80 mg) and *p*-toluenesulphonic acid (300 mg) were refluxed for 3 hours in acetic acid (8 ml). The solution was diluted with water and then extracted with ether; washing, drying, and evaporating the solvent phase provided a residue (86 mg) which crystallized from hexane–ether to give 27 mg of crude VI, m.p. 160–164° C. Recrystallization from ethanol gave pure VI, showing the double melting point, 132–135° C and 165.5–167° C. This material gave no melting point depression on admixture with a sample of VI obtained by dehydration of IV.

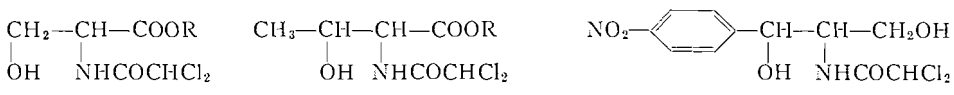
N-DICHLOROACETYL DERIVATIVES OF SERINE AND THREONINE AND OF THEIR ESTERS AND SODIUM SALTS[1]

I. LEVI, A. E. KOLLER, G. LAFLAMME, AND J. W. R. WEED



ABSTRACT

The N-dichloroacetyl derivatives of DL-serine and DL-threonine were prepared by the Schotten–Baumann reaction from the amino acids and dichloroacetyl chloride. Negative ninhydrin tests coupled with elementary analyses indicated that only the amino group was acylated. The ester derivatives of these compounds were prepared either by esterification of the N-dichloroacetyl-DL-amino acid with diazomethane or by the reaction of the amino acid ester with dichloroacetyl chloride in the presence of triethylamine. The sodium salts and the esters were tested for antitumor activity against sarcoma 37 in mice and Walker carcinoma 256 in rats. In both cases regression of the tumors was obtained.

The original studies of Cornman (1) and of Stock, Sugiura, and Rhoads (2) demonstrated that certain antibiotics obtained from the culture filtrates of bacteria and molds inhibited the growth of transplanted tumors in animals. Many other workers have since reported on the antitumor activity of a variety of antibiotic substances (3–16). Two of these antibiotics, azaserine (O-diazoacetyl-L-serine) (15) and DON (6-diazo-5-oxo-L-norleucine) (16), which were isolated from the culture filtrates of two species of *Streptomyces*, and which retarded the growth of sarcoma 180 in the mouse, are diazo amino acids. This is noteworthy because a search for amino acid derivatives which might serve as antagonists in the metabolism of tumor cells, first suggested by Greenberg and Schulman (17), has been going on for many years.

In view of the above, it was reasoned that if some of the common amino acids were modified to contain an essential portion of a natural antibiotic, antimetabolites useful for cancer chemotheraphy might result. Since it is generally believed that chloramphenicol is a specific inhibitor of protein synthesis (18), and since the N-dichloroacetyl group is essential for its maximum antibiotic activity (19), it seemed logical to modify the structure of amino acids with the N-dichloroacetyl radical in an attempt to achieve this aim.

A number of N-dichloroacetyl amino acids were therefore prepared and investigated for their pharmacological activities particularly with respect to their antitumor and antibiotic effects. In this paper only serine and its homologue, threonine, are considered because there is a close structural relationship between their N-dichloroacetyl derivatives (I*a* and II*a* respectively) and chloramphenicol (III), and also because of the unique biological position serine occupies in the metabolism of normal cells (20–27) and of neoplastic cells (28–31).

DL-Serine was acylated with N-dichloroacetyl chloride in the presence of aqueous sodium hydroxide solution according to the usual Schotten–Baumann procedure. Due to

[1]*Manuscript received April 4, 1960.*
Contribution from the Research Laboratories, Charles E. Frosst & Co., Montreal, Que.

the low solubility of its sodium salt (I*b*) it was possible to recover the major portion of the product in this form from the cold aqueous reaction mixture. However, if the free acid (I*a*) was desired, the reaction mixture was acidified and worked up in the usual manner.

The free acid (I*a*) prepared from the sodium salt (I*b*) by treatment with hydrochloric acid, and the sodium salt prepared from the free acid with sodium hydroxide, were identical in each case with the corresponding products isolated directly from the acylation reaction. Both of these compounds gave a negative ninhydrin test indicating the acylation of the amino group.

The hitherto unreported methyl ester of N-dichloroacetyl-DL-serine (I*c*) was prepared by two methods. The first consisted in esterifying N-dichloroacetyl-DL-serine with diazomethane, the second in reacting a chloroform solution of DL-serine methyl ester with dichloroacetyl chloride in the presence of triethylamine. The latter method was also employed for the synthesis of the N-dichloroacetyl derivative of DL-serine ethyl ester (I*d*), previously prepared (32) by a modification of this reaction.

DL-Serine methyl ester was prepared as the hydrochloride from DL-serine and hydrogen chloride in anhydrous methanol using a modification of the Fischer esterification technique. Fischer and Suzuki (33) first prepared this ester in 1905 and reported the melting point as 114°. This was confirmed by Mattocks and Hartung (34). Fischer's value was questioned, however, by King (35), who prepared the ester hydrochloride from three different samples of DL-serine and in each case obtained a product which melted at 134°. Chambers and Carpenter (36) confirmed King's melting point as 133–134° and indeed, in our own work, we repeatedly obtained a pure product which melted at 134°.

Similar reactions, applied to DL-threonine, yielded the methyl ester hydrochloride and the hitherto undescribed N-dichloroacetyl-DL-threonine (II*a*), its sodium salt (II*b*), and methyl ester (II*c*). Several attempts to prepare the ethyl ester of N-dichloroacetyl-DL-threonine (II*d*) were unsuccessful, chiefly due to the initial insolubility of DL-threonine ethyl ester (and its hydrochloride) in the solvents such as chloroform, benzene, and ether, normally used in the acylation experiments involving triethylamine. The sodium salt of N-dichloroacetyl-DL-threonine (II*b*) has a far greater solubility in water than has the sodium salt of N-dichloroacetyl-DL-serine (I*b*) and therefore could not be isolated directly from the acylation reaction. Although DL-threonine methyl ester hydrochloride can be prepared by the Fischer esterification procedure, the use of thionyl chloride gave a much better yield of product in this case.

The sodium salt of N-dichloroacetyl-DL-serine (I*b*) has been investigated the most extensively in our laboratories for antitumor activity. It depresses the growth of sarcoma 37 in mice, causing, in some animals, complete regressions of the tumor. The compound is non-toxic to mice in doses up to 4 grams per kilo of body weight. A preliminary report of these results has been published (37).

EXPERIMENTAL

The melting points were obtained with a Fisher–Johns apparatus and are uncorrected. Infrared spectra were determined with a Beckman IR-5 spectrophotometer equipped with a sodium chloride prism, using potassium bromide pellets. All melting points and temperature readings are in degrees Centigrade.

Dichloroacylation of DL-*Serine*

(a) N-*Dichloroacetyl*-DL-*serine Isolated as Sodium Salt* (I*b*)

DL-Serine (36 g, 0.34 mole) was dissolved in 4 *N* sodium hydroxide solution (85.6 ml,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

0.34 mole) in a 1 liter, four-necked, round-bottomed flask fitted with a thermometer, motor-driven stirrer, and two dropping funnels. The clear colorless solution of the sodium salt of DL-serine was cooled in an ice–salt mixture to −5°. Dichloroacetyl chloride (63.2 g, 0.42 mole) and 4 *N* sodium hydroxide solution (107 ml, 0.42 mole) were then added dropwise and simultaneously from the two dropping funnels to the stirred, cooled solution at such a rate that the reaction mixture remained on the basic side throughout the additions and the temperature of the reaction mixture remained at 0°±4°.* During these additions, which required about one hour, the product settled out as a fine white crystalline precipitate. When the additions were completed the reaction mixture was stirred in the cold for an additional 30 minutes. The product, 38.6 g (47.3% yield), was removed by filtration, washed with a little ice-cold water, and dried at 50° in a vacuum oven, m.p. 172–176°. After recrystallization from water, the sodium salt of N-dichloroacetyl-DL-serine melted at 178–179°. It has a solubility in water of 11% at 27°, is slightly soluble in cold ethanol, and insoluble in most other organic solvents. Heating at 105° for 1 hour did not change its physical appearance, melting point, or infrared absorption curve. When recrystallized from water it retains approximately 15% by weight of the water, which is not substantially removed by air-drying. The anhydrous product is obtained by drying under a pressure of less than 1 mm for a period of 6 hours at 60°. Anal. Calc. for $C_5H_6Cl_2NO_4Na$: C, 25.23; H, 2.54; N, 5.89. Found: C, 25.09; H, 2.42; N, 5.75.

The filtrate from the crude product of (*a*) was acidified and worked up as described below in (*b*) to yield 4.0 g (5.4%) of N-dichloroacetyl-DL-serine (I*a*), m.p. 118–119°.

(b) N-*Dichloroacetyl*-DL-*serine Isolated as the Acid* (I*a*)

The acylation of DL-serine (21 g, 0.2 mole) was carried out as for the sodium salt derivative described above, which in this case was not isolated. Instead, the total reaction mixture was acidified with dilute hydrochloric acid (7.3 g concentrated hydrochloric acid in 192 ml water) and the clear, colorless solution was concentrated to dryness under vacuum, using a water bath at 60 to 70°. The residue, which consisted of pale yellow viscous syrup mixed with crystalline sodium chloride, was extracted with hot ethyl acetate (4×100 ml). The combined extracts were dried over anhydrous magnesium sulphate, filtered, and the filtrate again evaporated to dryness as above. The resulting residual light yellow clear oil was shaken with petroleum ether (30–60°) (2×50 ml) to remove any dichloroacetic acid present, and crystallized from ethyl acetate – petroleum ether (30–60°) to give 16.4 g (38%) I*a*, m.p. 116–118°. (Other experiments gave yields up to 55.9%.)

An analytical sample recrystallized from ethyl acetate consisted of a fine crystalline powder which melted at 119–121°. It is soluble in ethanol, acetone, diethyl ether, dioxane, and ethyl acetate, is insoluble in ethylene dichloride, N-hexane, benzene, and petroleum ether. It has a solubility in water of 41% by weight at 27°. Anal. Calc. for $C_5H_7Cl_2NO_4$: C, 27.80; H, 3.26; N, 6.48. Found: C, 27.69; H, 3.22; N, 6.60.

This product (2 g) was dissolved in 10% sodium hydroxide solution (3.6 ml) and the solution evaporated to dryness. The partially solidified colorless residue was recrystallized from ethanol yielding crystals of I*b*, m.p. 176–178°, the infrared absorption curve of which was identical with that of I*b* described above in (*a*).

N-*Dichloroacetyl*-DL-*serine from the Sodium Salt*

The sodium salt of N-dichloroacetyl-DL-serine (I*b*) (5.0 g) was dissolved in dilute

**Subsequent experiments indicated that this low temperature range is not critical, since the same yield of product was obtained when the acylation was carried out between 15° and 20°.*

hydrochloric acid solution (25 ml water containing 2.1 ml concentrated hydrochloric acid). The clear solution was evaporated to dryness under vacuum at 50–60°. The residue was extracted with hot ethyl acetate (4×15 ml). The combined extracts were dried over anhydrous magnesium sulphate, filtered, and concentrated to yield an oil, which solidified to a mass of white crystals (3.3 g). Recrystallization from ethyl acetate – petroleum ether yielded N-dichloroacetyl-DL-serine (I*a*), m.p. 118–119°, the infrared absorption curve of which was identical with that of I*a* described above. The melting point of a mixture of the two was not depressed.

DL-*Serine Methyl Ester Hydrochloride*

A rapid stream of dry hydrogen chloride gas was passed into a suspension of 1 mole of serine (105 g) in anhydrous methanol (500 ml) until the serine dissolved and the clear solution reached its boiling point. The alcohol was then distilled off under reduced pressure. The oily residue was redissolved in fresh anhydrous methanol (500 ml), the solution cooled in an ice bath, and again saturated with a stream of hydrogen chloride gas, during a 1-hour period. The product resulting from the removal of the methanol after this second treatment with hydrogen chloride gas was washed with anhydrous ether (3×50 ml) and dissolved in anhydrous methanol (100 ml) to which a few milliliters of anhydrous ether was added. The ester hydrochloride began to crystallize almost at once. Weight 135 g (87% yield), m.p. 134° (35, 36). Anal. Calc. for $C_4H_{10}ClNO_3$: C, 30.87; H, 6.47; N, 9.00. Found: C, 30.67; H, 6.30; N, 9.01.

DL-*Serine Ethyl Ester Hydrochloride*

This compound was prepared from serine (105 g, 1.0 mole) and anhydrous ethanol according to the procedure described above for the methyl ester hydrochloride. The product (144.1 g, 85% yield) was obtained as white crystals which, after recrystallization from ethanol–ether, melted at 98°. The melting point for this ester hydrochloride has been reported as 94–97° (38) and 100–102° (39). Anal. Calc. for $C_5H_{11}ClNO_3$: N, 8.26. Found: N, 8.31.

N-*Dichloroacetyl*-DL-*serine Methyl Ester* (I*c*)

(a) By Esterification of N-*Dichloroacetyl*-DL-*serine with Diazomethane*

N-Dichloroacetyl-DL-serine (I*a*) (12.0 g) was covered with ether (100 ml) in a 1-liter round-bottomed flask. An ether solution containing diazomethane (approximately 4.7 to 5.0 g) prepared from N-nitroso-N-methyl urea (17.7 g) was added cautiously and with stirring to this partially dissolved mixture. When the evolution of nitrogen subsided the clear yellow solution was allowed to stand in a fume hood overnight. It was then filtered from a small amount of extraneous material and glacial acetic acid (2 ml) was added to destroy residual diazomethane. The residue obtained on removal of the ether yielded long white needles of I*c* (7.2 g, 56.7%), and an additional 3.2 g (25.2%) of crystalline product was recovered from the mother liquors. An analytical sample was recrystallized from ether – petroleum ether and dried over P_2O_5 at 60° for 8 hours, m.p. 82–83.5°. It is soluble in water (20% at 27°) and in most common organic solvents. Anal. Calc. for $C_6H_9Cl_2NO_4$: C, 31.32; H, 3.94; N, 6.09. Found: C, 31.36; H, 3.85; N, 6.28. The infrared absorption curve of this product was identical with that of the same product synthesized by route (*b*) below.

(b) By N-*Dichloroacylation of* DL-*Serine Methyl Ester*

Triethylamine (101 g, 1.0 mole) was added to DL-serine methyl ester hydrochloride (155.6 g, 1.0 mole) suspended in chloroform (1000 ml). The liberated ester base and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

triethylamine hydrochloride dissolved in the chloroform. The clear solution was cooled in a salt–ice bath to −5°. Dichloroacetyl chloride (147.5 g, 1.0 mole) and a second portion of triethylamine (101.0 g, 1.0 mole) were then added simultaneously and dropwise over a period of 1½ hours so that the temperature in the reaction flask did not rise above 10°. When the additions were completed the solution was stirred at room temperature for an additional half hour. It was then filtered from some extraneous material and the chloroform removed with vacuum from a water bath at 40–50°. The residual oily solid was extracted with boiling anhydrous ether (4×100 ml) whereby the product was separated from ether-insoluble triethylamine hydrochloride. The hot ether solution was filtered and on cooling deposited a voluminous mass of white feathery crystals (132.5 g, 57% yield), m.p. 82–83°. Anal. Calc. for $C_6H_9Cl_2NO_4$: C, 31.32; H, 3.94; N, 6.09. Found: C, 31.34; H, 3.98; N, 6.37.

N-*Dichloroacetyl*-DL-*serine Ethyl Ester* (I*d*)

This compound was prepared from DL-serine ethyl ester hydrochloride (84.8 g, 0.5 mole), triethylamine (101.0 g, 1.0 mole), and dichloroacetyl chloride (73.7 g, 0.5 mole) in chloroform solution following the procedure described above for the preparation of I*c*. The colorless compound (65.7 g, 53% theory) was recrystallized from diethyl ether, m.p. 75–76° (literature value for m.p. 76°) (32). Anal. Calc. for $C_7H_{11}Cl_2NO_4$: C, 34.44; H, 4.54; N, 5.73. Found: C, 34.41; H, 4.38; N, 5.75.

N-*Dichloroacetyl*-DL-*threonine* (II*a*)

This compound was prepared from DL-threonine (238 g, 2.0 mole) and dichloroacetyl chloride (368.8 g, 2.5 mole) in the presence of 6 *N* sodium hydroxide solution (750 ml) according to the above described procedure for serine. Yield, 218.9 g (47%), colorless crystals, m.p. 138–140°. An analytical sample recrystallized from ethyl acetate melted at 140–141°. Anal. Calc. for $C_6H_9Cl_2NO_4$: C, 31.32; H, 3.94; N, 6.08. Found: C, 31.14; H, 3.99; N, 6.17.

Sodium Salt of N-*Dichloroacetyl*-DL-*threonine* (II*b*)

N-Dichloroacetyl-DL-threonine was treated with sodium hydroxide according to the procedure described above for the preparation of I*b*. The crystalline product, after three recrystallizations from methanol – diethyl ether melted at 176–178°. The sodium salt was very soluble in water, soluble in ethanol, and insoluble in the common organic solvents. Anal. Calc. for $C_6H_8Cl_2NO_4Na$: C, 28.59; H, 3.20; N, 5.56. Found: C, 28.60; H, 3.00; N, 5.56.

DL-*Threonine Methyl Ester Hydrochloride*

Thionyl chloride (14.9 ml, 0.2 mole) was added carefully to methanol (100 ml) and maintained at −10° by cooling in a salt–ice bath. To this solution was then added 23.8 g (0.2 mole) of DL-threonine and allowed to stand 2 hours at room temperature and then refluxed for 20 minutes. The solution was concentrated to dryness under reduced pressure and the residual oil crystallized from anhydrous methanol – diethyl ether. The product was obtained as colorless needles. Weight 19.9 g (58.7%), m.p. 124–125° (lit. m.p. 125°) (40). A second crop, 5.3 g (15.6%), of less pure material (m.p. 118–120°) was recovered from the filtrate. An analytical sample was obtained by recrystallization from methanol – ethyl ether, m.p. 125°. Anal. Calc. for $C_5H_{12}ClNO_3$: C, 35.40; H, 7.13; N, 8.26. Found: C, 35.18; H, 6.98; N, 8.26.

N-*Dichloroacetyl*-DL-*threonine Methyl Ester* (II*c*)

DL-Threonine methyl ester hydrochloride (8.48 g, 0.05 mole), triethylamine (10.1 g,

0.10 mole), and dichloroacetyl chloride (7.37 g, 0.05 mole) were reacted in 75 ml chloroform following the procedure described above for Ic. The white crystalline compound (10.7 g, 87% yield) melted at 105–106°. An analytical sample was prepared by recrystallization from diethyl ether, m.p. 106°. In contrast to the high solubility in water of the corresponding serine derivative (Ic) this compound had a solubility of 5.9% at 27°. Anal. Calc. for $C_7H_{11}Cl_2NO_4$: C, 34.44; H, 4.05; N, 5.74. Found: C, 34.31; H, 4.27; N, 5.76.

ACKNOWLEDGMENT

The authors wish to thank Mrs. G. Shimizu for the analyses.

ANODIC OXIDE FILMS ON NIOBIUM: THICKNESS, DIELECTRIC CONSTANT, DISPERSION, REFLECTION MINIMA, FORMATION FIELD STRENGTH, AND SURFACE AREA[1]

L. YOUNG

ABSTRACT

The wavelengths of minimum specular reflectivity (at 11° incidence) due to interference were determined using a spectrophotometer for a series of films formed on chemically polished niobium. With a value of the refractive index $n = 2.46 \pm 1\%$ at 4358 Å wavelength by the Abelès method (reported elsewhere), the spectrophotometric data give the refractive index as a function of the wavelength λ, $n = 2.26 + 0.398/(\lambda/10^3\ \text{Å} - 2.56)^{1\cdot2}$. To analyze the spectrophotometric results, an auxiliary measure of thickness was required (though, with the chart given below, the thickness of a film may be determined directly from spectrophotometric measurements alone). A combination of measurements of the a-c. capacity and of the charge required to form the films gives a suitable measure of thickness (in terms of ρ/ϵ, where ϵ = dielectric constant and ρ = density) which is not dependent on a knowledge of the true surface area. The spectrophotometric data provide a calibration of this measure of thickness and thus give ϵ/ρ. With $\rho = 4.36$ g cm^{-3} (reported for the bulk amorphous oxide) this gives ϵ about 41 (compared with about 27.6 for Ta_2O_5). The effective surface area of the chemically polished metal was then found to be about 7% greater than the apparent area. At the ionic current density used to form the films (10 ma cm^{-2}), the field strength in the oxide was estimated as 4.96×10^6 v cm^{-1} within a few per cent uncertainty. Because the field to produce a given ionic current is lower than with Ta_2O_5 films, the capacity of films formed to a given voltage at a given current density and temperature is not so much greater for niobium than for tantalum as the dielectric constants might lead one to expect. It is suggested that there may be a correlation between dielectric constant and ionic conductivity. The Nb_2O_5 films recrystallize like Ta_2O_5 films under an applied field but more readily, at least with the purity of metal now available.

INTRODUCTION

As might be expected from their close chemical similarity, niobium and tantalum behave very similarly when anodically polarized. The present investigation of some of the properties of the film material followed the same method as was applied recently to tantalum (1). The aim was to obtain further data towards the comparative study of the various metals (Al, Nb, Ta, Ti, Zr, W, etc.) which show similar anodic film forming properties. Niobium is of particular interest because of its possible future use as an electrolytic capacitor anode. The kinetics of formation and some other topics have been discussed elsewhere (2, 3, 4).

EXPERIMENTAL METHODS

The electrodes (2×0.5 cm with a tab) were cut (using a die to obtain a reproducible size) from Fansteel Metallurgical Corporation 0.005-in. sheet of greater than 99.9% purity. They were stopped off and chemically polished as previously described (2). To obtain uniformity in the surface finish they were prepared in batches. After being stored dry, they were dipped in a dichromate–sulphuric acid cleaning mixture before use.

The solution was 0.2 N H_2SO_4 in demineralized water. The cell was immersed in a water thermostat at 25.8° C. The oxide films were formed at a constant current density of about 10 ma cm^{-2}. This high current density was chosen to obtain the maximum current efficiency. An electronic, automatic control device was used which records the times to traverse intervals of potential (about 4 seconds for 10 volts at the current density used) and terminates formation at a preset potential with respect to a reference electrode. At

[1]*Manuscript received March 11, 1960.*
Contribution from the British Columbia Research Council, University of British Columbia, Vancouver 8, British Columbia.

this current density, it is necessary to circulate the solution rapidly to eliminate heating effects (5).

A Cary double-beam recording spectrophotometer was used to locate the minima in the specular reflectivity at an angle of incidence of 11°. A simple device was specially made to hold the specimens and two front aluminized mirrors which reflected the light beam on to the specimens and back into its original path. A specimen which had been chemically polished but not anodized was used in the reference beam.

The capacity measurements were made at 1 kc/sec with a small a-c. signal.

RESULTS

The specimens were first formed to 10 v and the capacity was measured. The formation was then continued to the final potential. A procedure of this sort is necessary because of the pre-existing film. The charge to form to 10 v depends on the thickness of the film already present—and its measurement could be used to determine the thickness of this film and might prove a better method than anodic polarization measurements at low current densities (6, 7) where leakage current tends to interfere—but the charge to form from 10 to (say) 100 v can reasonably be assumed to be independent of the thickness of the pre-existing film. Similar considerations apply to the reciprocal capacity.

The increase in the reciprocal of the series equivalent capacity C which occurs when the thickness of the film is increased by an amount x is assumed to be given by

$$\Delta(1/C) = 4\pi x/\epsilon A \qquad [1]$$

where ϵ = dielectric constant and A = effective area. The amount of charge which must flow through the film to produce the increment of thickness is assumed to be

$$Q = Ax\rho 10F/M \qquad [2]$$

where ρ = density, F = the Faraday, and M = molecular weight of Nb_2O_5. It is assumed that the film is Nb_2O_5 and that it does not contain appreciable amounts of water or anions. From [1] and [2]

$$\{Q\Delta(1/C)\}^{1/2} = x(4\pi\rho\, 10F/\epsilon M)^{1/2}. \qquad [3]$$

The expression on the left-hand side gives a measure of thickness (in terms of the ratio, ρ/ϵ) which is independent of the area of the surface. The above expressions are not exact if A changes with thickness but [3] is a good approximation if A only changes slightly.

The wavelengths of the minima in the specular reflectivity are plotted against the above measure of thickness in Fig. 1. Since the frequency of "leaky" and otherwise abnormal specimens is of interest, the results obtained from all the specimens are plotted though only those for films of less than about 2200 Å thickness have been used in the calculations. Two types of non-ideal behavior occurred as the thickness increased: (*a*) decreased dV/dt (V = potential, t = time) due to leakage paths developing in the oxide giving oxygen evolution and (*b*) steadily increasing dV/dt, previously associated (with tantalum) with surface roughness (8, 9). At lower current densities, recrystallization has time to occur. Less pure niobium showed much worse behavior, and was also less easy to polish chemically to a satisfactory finish.

The minima* in the reflectivity are caused by destructive interference. This occurs when

$$2n\cos\theta\,(D+X) = \{(2r-1)/2\}\lambda \qquad [4]$$

**The maxima could be used but less satisfactorily since they are less sharp.*

where D = film thickness, n = refractive index; θ = angle of refraction; X = a constant at a given wavelength which allows for the difference between the phase changes during reflection at the oxide/air and metal/oxide interfaces respectively; r = 1,2,3 . . .; and λ = wavelength. Consequently, the vertical separation between the curves in Fig. 1 corresponds to an increase in thickness ($\lambda/2n \cos\theta$).

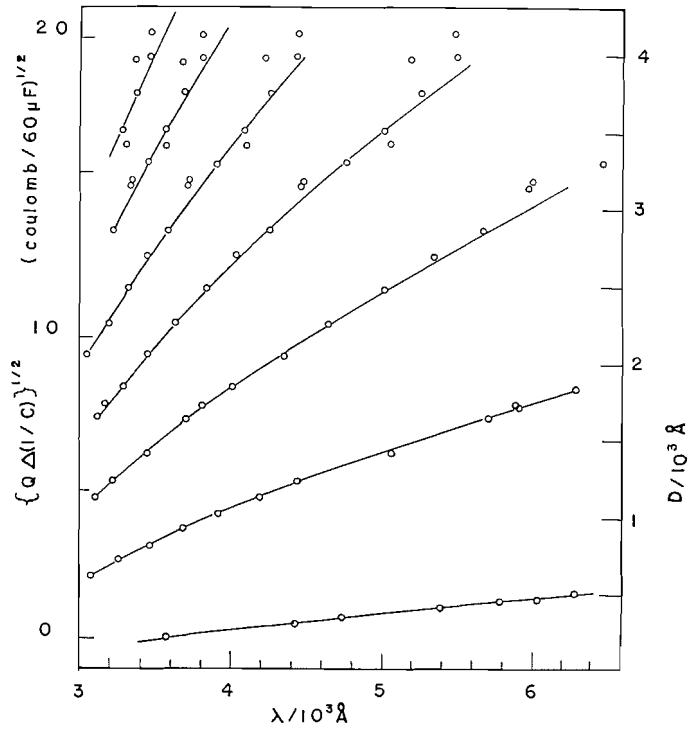

FIG. 1. Wavelengths at which destructive interference occurred plotted against $\{Q\Delta(1/C)\}^{\frac{1}{2}}$. A scale in angstrom units is given at the right.

A value of n at one wavelength is required to obtain a calibration of the thickness. Durbin, Wagner, and Harman (10) have recently determined n for the two axes of the high temperature crystalline modification of Nb_2O_5 as 2.27 and 2.31 in sodium light. Holtzberg, Reisman, Berry, and Berkenblit (11) have determined the densities at 25° C of some of the various forms. These are: amorphous, 4.36 g cm^{-3}; γ, 5.17 g cm^{-3}; and α, 4.55 g cm^{-3}. Assuming that $(n-1)/\rho$ = constant, we obtain n = 2.24 for the amorphous oxide.

The Becke immersion method (1) was not applied to the films because it was found to be difficult to strip sufficient oxide. Orme and Young (unpublished) have used the Brewster angle method of Abelès (12). They found that the reflectivity of the oxide coated metal for light of wavelength 4358 Å polarized in the plane of incidence was independent of the thickness of oxide at an angle of incidence 67° 51′. This shows that the index of the outer layers of oxide is constant at a value tan 67° 51′ = 2.46. The uncertainty is about $\pm 1\%$. With the present evidence that capacity, Faraday's laws, and spectrophotometric data are consistent with a uniform film (apart from the pre-existing film), the above index is assumed to be that of the whole film.

With this value for n at 4358 Å, and with the value of $\rho/n^2\epsilon$ from the data of Fig. 1,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

we obtain ϵ about 41.4. The dependence on assumed constants may be expressed by writing $\epsilon = 41.4\ (\rho/4.36\ \text{g cm}^{-3})\{2.46/n(4358\ \text{Å})\}^2$. Apart from the uncertainty due to the uncertainty in ρ and n, this value is believed to be accurate to within 2 or 3% for the experimental conditions stated. With the refractive index known at one wavelength, the values of the thickness increments $\lambda/2n \cos\theta$ at other wavelengths give the refractive index at these wavelengths (Fig. 2). The smooth curve is the Hartmann equation, $n = 2.26+0.398(\lambda/10^3\ \text{Å}-2.56)^{-1.2}$. The value of λ_0 in $n = a+b(\lambda-\lambda_0)^{-1.2}$ is greater than the value for Ta_2O_5 films (1), and although the Hartmann equation is empirical, this difference does in fact correspond to a greater long wavelength limit of the intrinsic absorption. This had the effect that the measurements could only be taken to about 3000 Å. With tantalum the limit was about 2700 Å. As with Ta_2O_5 films, the minima became very flat beyond 6000 Å wavelength.

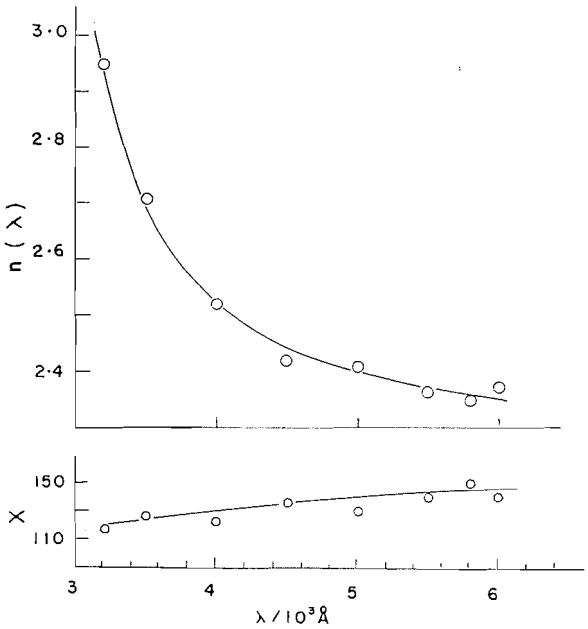

FIG. 2. Refractive index of films, and X (equation 4) as function of wavelength.

The ratio of increments of potential to increments of thickness is one measure of the field strength in the oxide. (Strictly, the field strength, like absolute metal/solution potential differences, is not an experimental observable, but it can be approximated if suitable assumptions are made.) The values obtained are shown in Fig. 3 as a function of voltage and thickness. The mean below 120 volts is $E = 4.96\times10^6$ v cm^{-1}, with an uncertainty of 1% due to the uncertainty in n, and a further 2 or 3% due to other sources of error.

Estimates of the field are also given in Fig. 3 with the thickness obtained from the charge passed using Faraday's laws with the "apparent" area. These estimates differ systematically from the above values because the effective area is greater than the apparent area.

With the dielectric constant now determined, the combination of capacity and Faraday's

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

law data give an estimate of the ratio of the effective to the apparent area. From [1] and [2]

$$A/a = (1/a)(M4\pi/10\rho F\epsilon)^{1/2}\{Q/\Delta(1/C)\}^{1/2}.$$

The values obtained are plotted in Fig. 3. They indicate a slight decrease in area with increasing thickness of oxide. This would not be unexpected since it would occur if there were surface irregularities on the scale of the thickness of the oxide film, but it could also be due to a deviation from the ideal behavior assumed in [1] and [2].

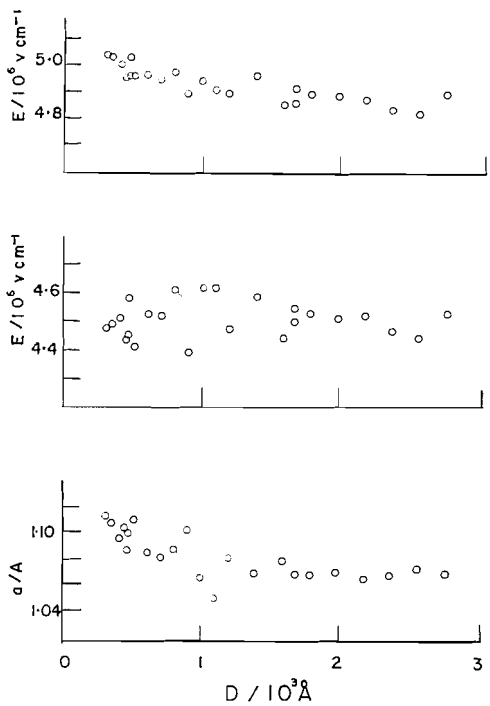

FIG. 3. (*Top*) Field strength $(V/\{Q\Delta(1/C)\}^{\frac{1}{2}})$. One point per specimen.
(*Middle*) Apparent field strength using thickness calculated from charge passed assuming $a = A$, and $\rho = 4.36$ g cm^{-3}.
(*Bottom*) A/a = ratio of effective to apparent area.

The above procedures establish the thickness of the films only with reference to an arbitrary zero, namely the thickness of films formed to 10 volts (sat. cal.) under the conditions stated. The optical method does not give an absolute measure of thickness because the optical constants of the metal are not known with sufficient accuracy. Instead, having shown that $\Delta V/\Delta D$ is constant (Fig. 3), we assume that, if $V - V_0$ is the overpotential for the production of oxide, $(V - V_0)/D = \Delta V/\Delta D$. This gives the zero of the scale of thickness to the right of Fig. 1 and the values of X (equation 4) shown in Fig. 2.

The films recrystallize under the influence of an applied field in very much the same manner as do those on tantalum (Vermilyea (13)). However, with our samples of metal, the crystalline nuclei appeared much more quickly than with tantalum. In contrast with tantalum, the kinetics were not very sensitive to the surface preparation (chemically polished, etched in HF, mechanically polished) though the shape of the crystalline areas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

varied (e.g. mechanically polished surfaces gave epicycloid-shaped areas). Sectors like those which are seen with crossed nicols in Ta_2O_5 crystalline areas were not apparent.

DISCUSSION

The thickness of a given film can be obtained within a few per cent by the use of Fig. 1 in conjunction with a simple spectrophotometric measurement. The curves in Fig. 1 for films thicker than about 2000 Å are based on the results for the thinner films (using [4]).

In an earlier paper (3), the thickness was calculated from the charge passed (using [2]) taking $a = A$ and assuming $\rho = 5$ cm^{-3} (which was about in the middle of the range of the values of ρ reported at that time). The corrections for conversion to $\rho = 4.36$ g cm^{-3}, and $A = (1.07a)$ cancel. The experimental results are, therefore, in good agreement (the ratio A/a may have been slightly different). In the earlier work, the field strength was determined only at lower current densities but extrapolation gives a value of about 4.4×10^6 v cm^{-1}, which is again in satisfactory agreement with present values calculated in the same way from [2] with $a = A$ (Fig. 3).

The large difference between the dielectric constants for Nb_2O_5 and Ta_2O_5 (27.6) is notable. It could be due either to an extra contribution to $(\epsilon - n^2)$ of the infrared lattice vibrations in Nb_2O_5,* or to a larger contribution from ionic relaxation processes associated with interstitial ions.

The ratio of the a-c. capacities per unit area of niobium and tantalum electrodes formed to the same potential at the same current density and temperature is given by

$$(E_{Nb_2O_5}\epsilon_{Nb_2O_5})/(E_{Ta_2O_5}\epsilon_{Ta_2O_5})$$

where E = field strength in the oxide. At 10 ma cm^{-2} this ratio is between 1.1 and 1.2. The lower field strength required in Nb_2O_5 to give a particular ionic current thus means that the high dielectric constant does not give much advantage in using niobium in place of tantalum in electrolytic capacitors, the chief advantages to be obtained being the more plentiful reserves of the metal and its lower density.

The above results are applicable only to films formed in dilute solution.

The fact that with Al_2O_3 films the dielectric constant is again lower (about 10), and the fields higher, suggests that there is a correlation between the dielectric properties of the oxide and its ionic conductivity.

ACKNOWLEDGMENTS

This work was supported by the Defence Research Board of Canada and is published with their permission. I thank Dr. G. M. Shrum and Dr. R. H. Wright of the British Columbia Research Council for their encouragement. The electronic control apparatus was designed and built by Mr. R. Cuthbert and Mr. F. J. Curzon.

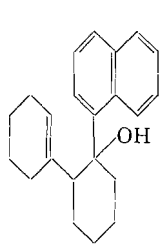
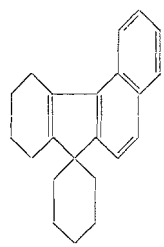
ALIPHATIC CHEMISTRY OF FLUORENE

PART VI. 3,4-BENZOFLUORENE-9-SPIRO-CYCLOHEXANE[1]



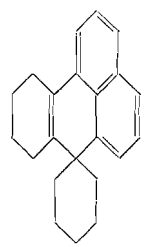
P. M. G. BAVIN[2]

ABSTRACT



The quinoxaline (VI) has been prepared from 3,4-benzofluorene, establishing the structure of the cyclization product of I as 3,4-benzo-5,6,7,8-tetrahydrofluorene-9-spiro-cyclohexane. 3,4-Benzo-9,9-dimethylfluorene has been prepared and oxidized to the quinone (VIII) which formed the quinoxaline (IX), structurally related to VI.

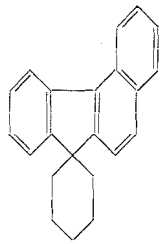
1,2:7,8-Dibenzo-9-methylfluorene has been synthesized from 1,2:7,8-dibenzofluorenone which, contrary to an earlier report (13), forms an oxime.



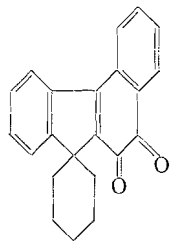
Cyclization of the tertiary alcohol (I)* by aluminum chloride was shown to give a hydrocarbon A, for which two structures have been proposed (II (1, 2), III (3)). Dehydrogenation of A gave a new hydrocarbon B, by loss of four atoms of hydrogen. Oxidation of B gave a crimson quinone which, contrary to an earlier report (3), has now been shown to condense with *o*-phenylenediamine with formation of a quinoxaline. The structures of the hydrocarbons A and B have been established by preparing the quinoxaline from 3,4-benzofluorene.

I

II



III



The reaction between 3,4-benzofluorene, phenyl lithium, and 1,5-dibromopentane gave a semisolid hydrocarbon mixture which was purified through its picrate and then oxidized with chromic oxide. Condensation of the crude quinone with *o*-phenylenediamine gave a quinoxaline in 7% over-all yield, which was shown to be identical with the quinoxaline derived from A. This preparation unambiguously establishes the structures of A and B as being II and IV, respectively. Structure V for the quinone is based on the very reasonable assumption that oxidation of IV occurred in the substituted naphthalene ring, as it does in electrophilic substitution reactions of 1,2-dimethylnaphthalene (6, 7, 8). It follows that the quinoxaline has structure VI.

The structures ascribed to B were based on a comparison of its ultraviolet spectrum with those of 3,4-benzofluorene (2) and benzanthrene (3). Although the spectra of the latter two hydrocarbons are quite similar (9, spectra numbers 430 and 436), the difference is sufficient to justify Jones' original assignment (2) of structure IV to B. Before attempting the synthesis of the quinoxaline (VI), 3,4-benzo-9,9-dimethylfluorene (VII) was prepared as a more suitable model. Oxidation gave a quinone which formed a quinoxaline.

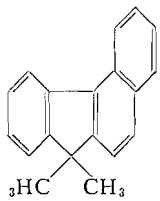
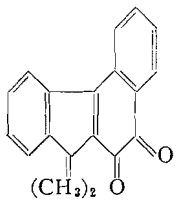
Contribution from the Chemistry Department, the University, Hull, East Yorkshire, England.
[2]*I.C.I. Fellow.*
**The isomeric cyclohexylidene structure has been used (4) but is incorrect since it has been shown (5) that the starting material is 2-cyclohex-1'-enylcyclohexanone.*

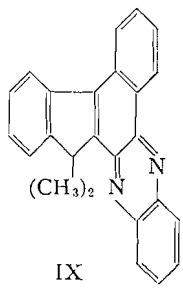
IV



V



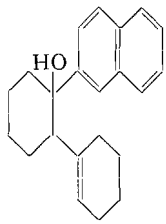
VI



For reasons outlined above, these are given structures VIII and IX, respectively. The ultraviolet spectra of the pairs IV–VII, V–VIII, and IV–IX were almost superposable and the infrared spectra were remarkably similar, even in the fingerprint region.

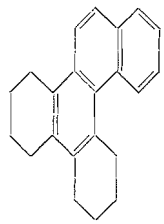
VII

VIII



IX

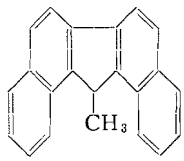
Bergmann and Eschinazi (1) were unable to prepare either A (II) or B (IV) crystalline, and the picrate of A was accompanied by a second, unidentified, picrate. Our original procedure (3) has been repeated but only one picrate (of A) could be isolated. Both A and B are readily obtained crystalline after purification of their picrates. The sample of B examined by Jones (2) was impure since its ultraviolet spectrum showed low intensity bands at wavelengths greater than 340 mμ in contradistinction to our crystallized sample. Data presented in the section dealing with spectra (see Experimental) suggests strongly that the impurity was perylene. This could have been formed under the vigorous conditions used for the cyclization by oxidative dimerization (10) of naphthalene present as impurity in the tertiary alcohol (I). It is significant that the sample of B was described (2) as 'yellow'.



The cyclization described above is of particular interest since a five-membered ring is formed by substitution at a β-naphthyl position although α-substitution to give a six-membered ring seemed feasible. Similar cyclizations have been reported (11, 12) and it is agreed (4, 11, 12) that they proceed by way of mesomeric carbonium ions, but plausible reasons for the preferred direction of cyclization have not been advanced. The tertiary alcohol (X), isomeric with I, was cyclized to (XI) (3), showing that six-membered rings may be formed by α-substitution.

Under the influence of stannic chloride, 1,1-diphenylethylene is well known to dimerize, the initial product undergoing further reactions. Wolf (11) has reported that the same reagent cyclizes 1,1-(di-α,β-naphthyl)-ethylene to 1,2:5,6-dibenzo-9-methylfluorene, and 1,1-(di-α,α-naphthyl)-ethylene to 1,2:7,8-dibenzo-9-methylfluorene (XII). Under comparable conditions 1,1-(di-β,β-naphthyl)-ethylene was dimerized. It has now been found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.



X

XI

that 1-(α-naphthyl)-1-phenylethylene is recovered unchanged after being heated on the steam bath with stannic chloride, for periods up to 48 hours. A reasonable interpretation of these facts is not available.

The structure of Wolf's hydrocarbon (XII) has been confirmed by synthesis from 1,2:7,8-dibenzofluorenone which, contrary to an earlier report (13), forms an oxime.*

XII

EXPERIMENTAL

3,4-Benzo-5,6,7,8-tetrahydrofluorene-9-spiro-cyclohexane (A, II)

2-Cyclohex-1′-enyl-1-α-naphthyl-cyclohexanol (I) was prepared as described previously (3). A sample slowly crystallized, recrystallization from hexane giving small prisms, m.p. 102–104° (lit. m.p. 104.0–104.5° (15)). Cyclization with aluminum chloride, using carbon disulphide as solvent, followed by distillation at 1 mm gave a pale yellow gum, which was converted to the dark red picrate, m.p. 163–164° (1, 3). Regeneration of the hydrocarbon by passing a solution of the picrate in benzene through a column of activated alumina gave an easily crystallized product which formed prisms from methanol, m.p. 96–98° (3).

3,4-Benzofluorene-9-spiro-cyclohexane (B, IV)

Dehydrogenation of a crystallized sample of the preceding hydrocarbon at 300°, using 10% palladium on charcoal as catalyst, gave an oil which was converted to the bright red picrate, m.p. 142–143° (1, 3). Regeneration of the hydrocarbon gave an oil which crystallized after it was cooled with liquid air. Recrystallization from acetone–methanol gave colorless prisms, m.p. 88–90° (3). The yield based on I was 38%.

Oxidation with CrO_3 in acetic acid gave 3,4-benzofluorene-1,2-quinone-9-spiro-cyclohexane (V), which crystallized as lustrous crimson plates from acetic acid, m.p. 224–225° (1, 3).

14H-Benz[a]indeno[1,2-c]phenazine-14-spiro-cyclohexane (VI)

The crude quinone (1 g) was boiled for 30 minutes with a solution of *o*-phenylenediamine (3 g) in acetic acid (70 ml). After pouring into dilute hydrochloric acid (500 ml)

**9-Benzoylanthracene has also been reported not to form an oxime (14) but should do so under the conditions described in the Experimental.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the product was extracted with chloroform. Evaporation left a brown solid which was dissolved in hexane and the solution passed through a column of activated alumina. A bright yellow highly fluorescent band was eluted with benzene–hexane (1:2) and the eluant evaporated. Crystallization from heptane gave bright yellow prisms (0.6 g), m.p. 235–236°. Found: C, 87.15; H, 5.71; N, 7.14. Calc. for $C_{28}H_{22}N_2$: C, 87.01; H, 5.74; N, 7.25%.

1,5-Dibromopentane (2 g) was added to a solution of 3,4-benzofluorene (2 g) in ether containing phenyl lithium (from bromobenzene, 10 g). The color of the fluorene anion had disappeared after 8 minutes. Inorganic salts were removed by washing with water and the ether was evaporated to leave an oily hydrocarbon. After purification through the bright red picrate, m.p. 122–136°, the hydrocarbon mixture partly crystallized when seeded with IV. Oxidation with CrO_3 (5 g) in acetic acid followed by condensation with *o*-phenylenediamine gave a quinoxaline, which was purified as described above. Crystallization from heptane gave bright yellow prisms (0.25 g, 7% based on 3,4-benzofluorene), m.p. 232–234°, not depressed by the quinoxaline from B. Found: C, 86.91; H, 5.82. Comparison of infrared spectra confirmed the identity.

3,4-Benzo-9,9-dimethylfluorene (VII)

3,4-Benzofluorene (5 g) was methylated as described for fluorene (16). The oily product was converted to the *picrate*, which crystallized from ethanol as beautiful dark red needles, m.p. 147–149°. Found: C, 63.59; H, 4.14. Calc. for $C_{25}H_{19}N_3O_7$: C, 63.42; H, 4.05%.

Decomposition of the picrate on alumina gave an easily crystallized product which formed colorless prisms from acetone–methanol, m.p. 82–83°. Many of the crystals showed extensive twinning. Found: C, 93.65; H, 6.61%. Calc. for $C_{19}H_{16}$: C, 93.40; H, 6.60%.

Oxidation with CrO_3 in acetic acid was complete after a few minutes on the steam bath. *3,4-Benzo-9,9-dimethylfluorene-1,2-quinone* (VIII) crystallized as lustrous crimson plates from acetic acid, m.p. 216–217.5°. Found: C, 83.03; H, 5.13. Calc. for $C_{19}H_{14}O_2$: C, 83.19; H, 5.14%.

14,14-Dimethyl-14H-benz[a]indeno[1,2-c]phenazine (IX)

Prepared and purified as described for VI, the quinoxaline formed bright yellow blades from heptane, m.p. 193–194°. Found: C, 86.70; H, 5.26. Calc. for $C_{25}H_{18}N_2$: C, 86.67; H, 5.24%.

1,2:7,8-Dibenzo-9-methylfluorene (XII)

The reaction between ethereal methyl lithium and 1,2:7,8-dibenzofluorenone (17) gave an almost quantitative yield of 1,2:7,8-dibenzo-9-methyl-9-fluorenol, which crystallized from toluene as colorless plates, m.p. 216–218° (not analyzed). The fluorenol (1 g) was reduced by warming with acetic acid (200 ml) and zinc dust (20 g), a few drops of concentrated hydrochloric acid being added every 5 minutes during 30 minutes. The product crystallized from heptane as colorless lustrous plates (0.7 g), m.p. 173–174°, not depressed by an authentic sample of Wolf's hydrocarbon (11). During the preparation of the latter it was noted that stannic chloride from a new bottle did not react with the dinaphthylethylene, but addition of a drop of water initiated the reaction observed by Wolf (11). This experiment was carried out in Ottawa during a prolonged cold spell (−20° F) when the relative humidity was very low.

1,2:7,8-Dibenzofluorenone Oxime

The ketone (0.1 g), hydroxylamine hydrochloride (1 g) and dry pyridine (10 ml) were boiled under reflux for 2 hours. The mixture was poured onto ice and hydrochloric acid and the precipitate crystallized from toluene–heptane to give slender orange needles (0.08 g), m.p. 211–212° with decomposition. Found: N, 4.63. Calc. for $C_{21}H_{13}NO$: N, 4.74%.

The known oximes of fluorenone and 3,4:5,6-dibenzofluorenone were prepared similarly in excellent yields.

1,1-Diphenylethylene (10 g, f.p. 7–8°) and stannic chloride (25 g) were warmed on the steam bath for 10 minutes. Pouring onto ice and hydrochloric acid precipitated a white solid which crystallized from acetone–methanol as white prisms (5.5 g), m.p. 112–113°, completely identified as 1,1,3,3-tetraphenylbut-1-ene (lit. m.p. 113–114 (18)) by oxidation with CrO_3 to benzophenone (2,4-dinitrophenylhydrazone) and α,α-diphenylpropionic acid, identical with an authentic sample (19).

1-α-Naphthyl-1-phenylethylene (20) was recovered unchanged in more than 90% yield after it was heated on the steam bath with stannic chloride for periods up to 48 hours.

SPECTRA

Infrared spectra were obtained using a Unicam SP-100 spectrophotometer with samples prepared as solutions in chloroform and as potassium bromide disks.

Ultraviolet spectra were obtained using a Beckmann DK-2 recording spectrophotometer with ethanol as solvent. The data is collected in *Table I*, for the hydrocarbons and quinones. The quinoxalines showed peaks at 432, 415, 320, 307, 278, 255, and 229 mμ (log ϵ values not recorded).

THE REACTION OF 2-CYANO-2-PROPYL FREE RADICALS WITH OXYGEN

2-CYANO-2-PROPYL HYDROPEROXIDE[1]

M. TALÂT-ERBEN[2] AND NEVZAT ÖNOL

ABSTRACT

The reaction with oxygen of cyanisopropyl free radicals generated by the polymerization catalyst 2,2′-azobisisobutyronitrile has been investigated. In xylene, or benzene, as solvent at 55° the products identified are: (1) a new compound, 2-cyano-2-propyl hydroperoxide; (2) acetone cyanohydrin; (3) hydrogen cyanide; (4) cyanogen; (5) acetone; (6) *p*-methyl benzaldehyde (in xylene only); and (7) tetramethylsuccinodinitrile. The hydroperoxide is surprisingly stable; its physical constants are: b.p. 37° C at 1 mm Hg; m.p. −9 to −8°; n_D^{20} 1.4138; d_{20} 1.013 g/ml. In benzene under the same experimental conditions, only a very small amount of the hydroperoxide is obtained, the principal product being acetone cyanohydrin. A free-radical mechanism is proposed. The induced decomposition of the hydroperoxide, which is important in benzene, is almost completely inhibited in the presence of xylene. The new hydroperoxide can be used as a polymerization catalyst at moderately elevated temperatures.

INTRODUCTION

The thermal decomposition of 2,2′-azobisisobutyronitrile (Porofor N) has been studied extensively in the absence of oxygen (1, 2). Ziegler *et al.* (3) state that during decomposition in the presence of air, the total pressure of the gas phase does not change, owing to the fact that the increase of pressure due to the nitrogen evolved, is compensated by the equimolecular amount of oxygen taken up simultaneously by the cyanisopropyl radicals produced. These authors postulated the formation of di-(2-cyano-2-propyl) peroxide,

$$2(NC)\dot{C}(CH_3)_2 + O_2 \rightarrow (NC)(CH_3)_2C—O—O—C(CN)(CH_3)_2.$$

Van Hook and Tobolsky (4), on the other hand, observed that when the azo compound is decomposed in the presence of air, the optical density of the solution becomes higher than in the case in which the decomposition is carried out in an oxygen-free atmosphere, indicating that some peroxides are formed which absorb light in the ultraviolet region. However, neither Ziegler and co-workers nor Van Hook and Tobolsky attempted to isolate these products. Therefore, it would be of interest to investigate this reaction.

EXPERIMENTAL

The azo compound was recrystallized from benzene, m.p. 101° C with decomposition. The reaction was carried out at 55°, benzene (E. Merck) or xylene (E. Merck) being used as solvent. The solvent was dried with anhydrous sodium sulphate. A continuous stream of tiny bubbles of oxygen was passed at the rate of about 3 liters per hour, through the solution containing 30 g of the azo compound in 300 ml of solvent. The tiny bubbles were produced by forcing the gas to pass through a sintered-glass filter surface, placed at the bottom of the reaction vessel. The oxygen was purified by passage through towers containing soda lime and calcium chloride. The gas leaving the reaction vessel was passed through a reflux condenser to trap the solvent as well as other liquid products that it probably carried with it, then bubbled through a solution of potassium hydroxide to absorb the hydrogen cyanide and cyanogen, which were found to be reaction products (see below). After about 100 hours the reaction was stopped, and the excess of solvent

was removed by distillation under reduced pressure. The residual solution was extracted 15 to 20 times with 50 ml of distilled water. The combined aqueous solutions were extracted with ether. The ethereal solution was dried with anhydrous sodium sulphate, then evaporated at 60°, until all the ether was removed. The residue from the ether extract, which consisted of a yellowish liquid, was fractionated by vacuum distillation in an all-glass apparatus with a Claisen head, and two fractions were obtained. Fraction A, collected between 60 to 65° at 15 mm Hg, proved to be acetone cyanohydrin, whereas the subsequent fraction B has been identified as 2-cyano-2-propyl hydroperoxide, $(NC)(CH_3)_2C—O—O—H$.

Identification of Acetone Cyanohydrin

A sample of fraction A, further purified by fractional distillation, b.p. 62°/15 mm Hg, n_D^{20} 1.3990, boiled at about 110° at atmospheric pressure, and decomposed while boiling. Two products of decomposition were detected: a liquid, trapped by means of a reflux condenser, and a gas absorbed in potassium hydroxide. The liquid, b.p. 51°/76 cm Hg, n_D^{20} 1.3550, formed with 2,4-dinitrophenylhydrazine a crystalline precipitate with a melting point of 126° C. This liquid must, therefore, be acetone. In the potassium hydroxide solution, cyanide was detected (Berlin blue). It follows that fraction A is acetone cyanohydrin. Nitrogen content found (Kjeldahl): 16.07%. Calculated for C_4H_7ON: 16.46%. Yield: 85 (mole)% in benzene, 20 (mole)% in xylene, based on the azo compound decomposed.

Identification of 2-Cyano-2-propyl Hydroperoxide

Fraction B is a peroxide. Its high solubility in water suggests that it is a hydroperoxide, rather than a di-(cyano-alkyl) peroxide. This has been confirmed by the following observations. The product from vacuum distillation was further purified by fractional crystallization. On cooling to −10°, colorless crystals were obtained. By use of the analytical procedure of Vaughan and co-workers (5) a molecular weight of 105 was found, assuming that only one —O—O— group is contained in the molecule. A cryoscopic molecular weight determination in benzene gave a value of 95. The two results compare well with the theoretical molecular weight of 101, corresponding to the structure $(NC)(CH_3)_2C—O—O—H$, and they are incompatible with the structure $(NC)(CH_3)_2C—O—O—C(CH_3)_2(CN)$. Nitrogen content found (Kjeldahl): 13.52%. Calculated for $C_4H_7O_2N$: 13.86%. This product must, therefore, be isobutyronitrile hydroperoxide of at least 96% purity. Its physical constants are: b.p. 37°/1 mm Hg, m.p. −9 to −8°, n_D^{20} 1.4138, d_{20} 1.013 g/ml.

This hydroperoxide is surprisingly stable. The pure material decomposes only above 120°. Yield in xylene: 46 (mole)% with respect to the azo compound; in benzene the yield is negligible (2 (mole)%).

Polymerization Experiment

About 0.3 gram of hydroperoxide was added to 15 ml of methacrylonitrile in a test tube, and heated at 80°. Approximately 20% of the monomer polymerized in 3 hours. This indicates that the hydroperoxide can be used as a polymerization catalyst.

Detection of Hydrogen Cyanide, Cyanogen, and Acetone

The alkaline solution, through which the oxygen was bubbled after it had left the reaction vessel, was analyzed, and both cyanide and cyanate were found. The former was characterized by the formation of Berlin blue, and the latter by the pyridine test (6). The amount (in moles) of cyanide formed is higher than that of cyanate, indicating

that not only $(CN)_2$ but HCN also is a reaction product. The excess of solvent, which was removed immediately before extraction with ether, was found to contain an appreciable amount of acetone (color test with salicylaldehyde).

Tetramethylsuccinodinitrile

The residue from water extraction was left standing overnight at −20°. A large amount of tetramethylsuccinodinitrile crystals were obtained, m.p. 168° C.

Isolation of p-Methylbenzaldehyde

After tetramethylsuccinodinitrile (TMSDN) crystals were separated, the residual solution was vacuum-distilled to remove the solvent; the brown, viscous residue was left standing at −20° overnight, and more TMSDN crystals precipitated. The viscous phase was subjected to a vacuum distillation at 40° (bath temperature), the products being collected in a flask immersed in a dry ice and acetone mixture. At first, more solvent (xylene) and water were collected. The next fraction was refluxed with 30% sulphuric acid in order to hydrolize and dissolve the nitriles (if any). Then, the dark oily residue was purified by steam distillation, and a light yellowish liquid was obtained. This had a strong odor of bitter almond, and a refractive index of 1.548. It proved to be an aldehyde (mirror test). The refractive index is very close to that of *p*-methylbenzaldehyde. Therefore, it is reasonable to assume that this is an oxidation product of the solvent (xylene) sensitized by the free radicals. In fact, it is known that if, under ultraviolet illumination, oxygen is bubbled through toluene for a long time some benzaldehyde is obtained (8). This identification is further supported by the fact that this product was not found in the residues from the runs in which benzene was used as solvent.

DISCUSSION

The nature and diversity of the reaction products which have been identified in this work show that the reaction of cyanisopropyl radicals with oxygen is a very complicated one. Di-(2-cyano-2-propyl) peroxide, the formation of which was postulated by Ziegler *et al.* (3), has not been found in the present work. This could mean that this peroxide is thermally unstable at the operating temperature, or it is very sensitive to the radical-induced decomposition caused by the free radicals which are present at relatively high concentrations during the entire course of the reaction. Undoubtedly, this peroxide must be much more unstable than its unsubstituted analogue, di-tertiary butyl peroxide, owing to the electron-attracting character of the two nitrile groups in the molecule. Its main decomposition products would be acetone and .CN free radicals. The former has actually been detected as shown in the experimental part; the recombination product of the latter, cyanogen, has also been identified. The fact that the hydroperoxide is not obtained when benzene is used as solvent could be explained by the greater stability of the benzene molecule with respect to hydrogen abstraction by the $(NC)(CH_3)_2C—O—O.$ radicals. Consequently, these radicals would have a longer mean life in benzene; this would favor their combination with other radicals. Therefore, a transient formation of di-cyanisopropylperoxide is more probable in benzene than in xylene. This conclusion could be correlated with the observation that in some runs with benzene, in which the reaction was stopped at an early stage owing to an experimental difficulty of some kind, an explosive reaction took place during the vacuum distillation of the reaction mixture. Another possible explanation is that the hydroperoxide does actually form in benzene by hydrogen abstraction from other sources (molecules or free radicals available), but in the reaction medium which contains a high concentration of free radicals, it undergoes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

a fast-induced decomposition in this particular solvent. In fact, we found that the hydroperoxide which, when pure is very stable up to 120° C, decomposes with a measurable rate in benzene at temperatures as low as 75° C, in the presence of the azo compound. On the other hand, we found that the decomposition of the hydroperoxide in the presence of the azo compound is negligible at the same temperature when xylene is used instead of benzene.

The experimental evidence available does not seem to permit a final conclusion concerning the two alternatives. However, it can be concluded that the nature of the reaction products identified in this work indicates that there must be a complete analogy between the mechanisms of the thermal decomposition of the cyano-alkyl peroxides and that of the corresponding alkyl peroxides. In other words, a reaction scheme similar to that proposed by Vaughan *et al.* (7), for the liquid phase decomposition of *t*-butylhydroperoxide, can be used to account for the decomposition of cyanisopropyl hydroperoxide, if it is assumed that dismutation of cyanisopropoxy radicals, $(NC)(CH_3)_2C—O.$, produced by cleavage of the O—O bond, gives .CN free radicals. A similar mechanism would be applicable to the more unstable di-(cyanisopropyl) peroxide.

An experimental investigation of the kinetics of the thermal decomposition of cyanisopropylhydroperoxide, and its properties as a polymerization catalyst, is under way in these laboratories, and will be the subject of a subsequent publication.

ACKNOWLEDGMENTS

The authors wish to thank Dr. S. Bywater of the National Research Council of Canada, for a gift of azobisisobutyronitrile, without which the present work could not be carried out. Another gift of Porofor N by Bayer Aktiengesellschaft, Leverkusen, Germany, is also gratefully acknowledged.

THE ELECTRON SPIN RESONANCE ABSORPTION SPECTRA OF SEMIQUINONE IONS

PART I. THE HYPERFINE SPLITTING DUE TO ALKOXY GROUPS[1]

Y. MATSUNAGA[2] AND C. A. MCDOWELL

ABSTRACT

The electron spin resonance absorption spectra of semiquinone ions with alkoxy groups have been examined and compared with those with substituted alkyl groups. The splitting constant for the alkoxy protons has been found to be about one-half that of alkyl protons in the corresponding free radical. Hyperfine splittings due to methoxy, ethoxy, and isopropoxy protons have been demonstrated using the semiquinone ions formed by oxidation of alkyl gallates. The available evidence suggests that, in accounting for the hyperfine splitting due to alkyl protons, spin polarization is as important as electron delocalization.

INTRODUCTION

The electron spin resonance (e.s.r.) absorption spectra of semiquinone ions have been examined extensively by many workers. The rather simple structure of the free radicals of this kind makes possible the analysis of the hyperfine structure of the observed resonance absorption spectra. It has been shown by the studies of the methyl-substituted benzo- and naphtho-semiquinone ions (1, 2) that both the ring and the methyl protons contribute to the hyperfine splitting in comparable magnitude. The cause of the methyl proton splitting has been ascribed to hyperconjugation, and the details have been accounted by the molecular orbital and the valence bond theories of hyperconjugation (3, 4). Proton hyperfine splitting for more complicated substituents has been described in some cases. Hyperfine splitting due to *tert.*-butyl protons in benzosemiquinone ions has been observed by Hoskins (5) and by Fraenkel (6). The three triplets found in the spectrum of the semiquinone ion formed by the oxidation of *n*-propyl gallate may be assigned (7) to two ring protons and two *n*-propyl protons.

Here we wish to present the results of a study of the contribution of alkoxy protons to the hyperfine structure of the e.s.r. absorption spectra of some semiquinone ions. With the view to ascertaining the effect of the oxygen atoms we examined the spectra of the 2,5-dimethoxy- and 2,5-diethoxy-*p*-benzosemiquinone ions, and also the 3,3′,5,5′-tetramethyl-*p*-biphenosemiquinone ion, and compared these with those of the 2,5-dimethylbenzo- and 3,3′,5,5′-tetramethyl-*p*-bipheno-semiquinone ions. Secondly, to demonstrate the contribution of methoxy, ethoxy, and isopropoxy protons, we examined the semiquinone ions formed by the oxidation of various alkyl gallates.

The hyperfine splitting observed in the e.s.r. spectra of free radicals is caused by the interaction between nuclei with a magnetic moment, and an unpaired electron, through direct dipole–dipole forces, and also through the isotopic Fermi interaction between the nuclear magnetic moment and the electron–spin magnetic moment. Free radicals in solution can show only hyperfine splitting due to the latter interaction, because the rapid tumbling of the molecule averages out the anisotropic dipolar interaction (8). The magnitude of the splitting due to the Fermi interaction is proportional to the spin density at the nucleus. If we adopt a single configurational molecular orbital description, the spin density will be replaced by the unpaired electron density. It has been shown that

[1]*Manuscript received March 7, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.
[2]*National Research Council Postdoctorate Fellow 1957–59.*

the magnitude of ring proton splitting is approximately proportional to the density of the unpaired π-electron in the aromatic carbon atom (9), and a similar relation holds for the methyl protons (4).

The spin Hamiltonian for an organic free radical of the semiquinone type may be written as

$$[1] \qquad H = g\beta \mathbf{H} \cdot \mathbf{S} + \sum_i A_i (\mathbf{S} \cdot \mathbf{I}_i)$$

which has eigen values

$$[2] \qquad E = g\beta H M_S + \sum_i A_i M_S M_I .$$

For the transitions $(M_S \rightarrow M_S' \pm 1)(M_I \rightarrow M_I)$ this yields, for the strong field case, the frequencies

$$[3] \qquad \nu = \frac{1}{h}\left\{ g\beta M + \sum_i A_i M_{I_i} \right\}.$$

The subscript i refers to the nucleus which is coupled to the electron spin. The summation is taken over all such nuclei in the radical. The nuclear magnetic quantum number M_I takes on the values, I_i, $I_i+1, \ldots, -I_i$. There are $2I+1$ such values. If the coupling constants for all the nuclei are equal (i.e. $A_1 = A_2 \ldots = A_i$) the hyperfine splitting constant for each line will be $AM/g\beta$ where M is the total magnetic quantum number. In the case of protons, the spin is $\frac{1}{2}(h/2\pi)$; therefore the absorption spectrum for a free radical with N equivalent proton consists of $N+1$ hyperfine components with the relative intensities given by the binomial distribution $1:N:N(N-1)/2:\ldots N!/k!(N-k)!:\ldots:N:1$.

EXPERIMENTAL

2,5-Dimethoxy- and 2,5-diethoxy-*p*-benzoquinones were prepared by the reaction of the corresponding alcohols with benzoquinone, using anhydrous zinc chloride as a catalyst (10). The compounds were purified by vacuum sublimation. By reduction with sodium dithionite, these two quinones, on dissolving in a mixture of pyridine and 2 *M* KOH (1:1 by volume), give fairly stable free radicals. It was hoped to stabilize the monomeric form of the semiquinone ions by the use of pyridine (11). 3,3′,5,5′-Tetramethyl- and 3,3′,5,5′-tetramethoxy-*p*-biphenols were prepared from the quinones starting from 2,6-dimethylphenol and 2,6-dimethoxyphenol, respectively (12, 13). These biphenols were purified by recrystallization from ethanol and finally by sublimation in vacuum. The semiquinone ions were obtained by air oxidation of the biphenols dissolved in the above-mentioned mixed solvent. The esters of gallic acid were prepared by the standard methods of esterification using sulphuric acid or hydrogen chloride gas as a catalyst (14, 15). The compounds were finally sublimed in a vacuum. The semiquinone ions were obtained by air oxidation of the esters dissolved in a mixture of ethanol and 2 *M* KOH (1:1 by volume). These free radicals could not be found when the parent compound was dissolved in a mixture of pyridine and 2 *M* KOH. The choice of ester is of great advantage in the preparation of the samples with the desired alkoxy groups. However, the hydrolysis during the course of the measurements could not be prevented (see the following section).

An e.s.r. spectrometer with a transmission cavity was used at room temperature, as described previously (16). The spectra shown in this paper are the first derivative of the

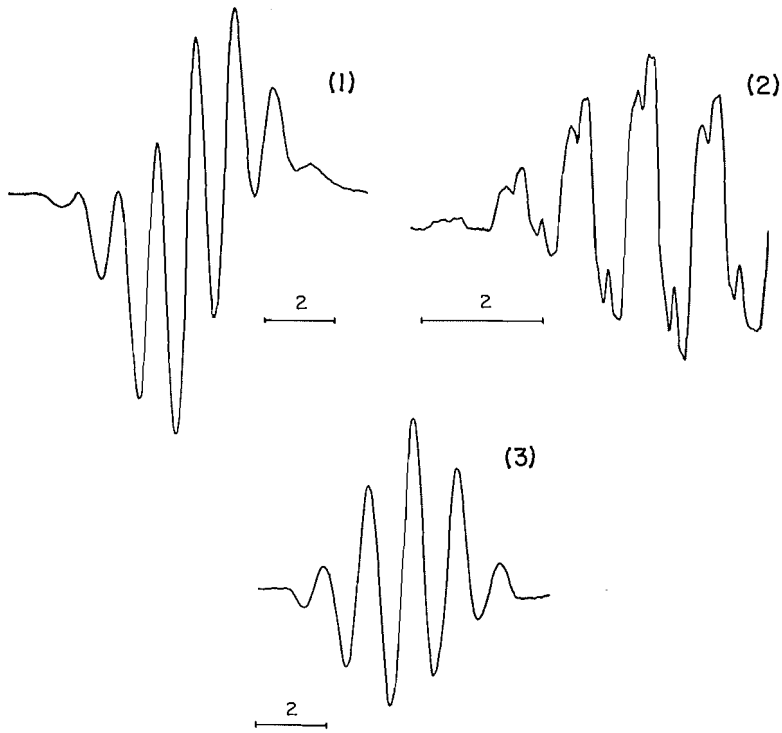
actual absorption lines. The estimated error for the splitting constants is about 0.02 gauss provided the lines are sharp enough. The intensity of the magnetic field increases from left to right in all the figures.

RESULTS AND DISCUSSION

2,5-Dimethoxy- and 2,5-Diethoxy-p-benzosemiquinone Ions

2,5-Dimethoxy-*p*-benzosemiquinone ion (I*a*) shows seven main lines with a hyperfine splitting of 1.05 oersteds (Fig. 1). Although the asymmetric pattern suggests the overlap of the spectra due to other free radicals from impurities or reaction products, further splitting of each line into a triplet could be observed except for the outermost lines (Fig. 2). The 2,5-diethoxy-*p*-benzosemiquinone ion (I*b*) gives a five-line spectrum with a spacing of 1.17 oersteds (Fig. 3). Apparently the major splitting can be attributed to



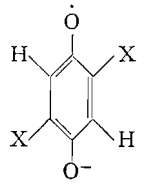


FIG. 1. First derivative of e.s.r. absorption spectrum of the 2,5-dimethoxy-*p*-benzosemiquinone ion (I*a*).
FIG. 2. First derivative of a part of e.s.r. absorption spectrum of semiquinone ion (I*a*) under higher resolution.
FIG. 3. First derivative of e.s.r. absorption spectrum of the 2,5-diethoxy-*p*-benzosemiquinone ion (I*b*).

hyperfine coupling with the alkoxy protons and the minor one of 0.30 oersted found in the methoxy derivative can be ascribed to coupling with the ring protons. In the case of the 2,5-dimethyl-*p*-benzosemiquinone ion examined by Venkataraman and Fraenkel (1), the splitting constant for the ring protons was reported to be 1.83 oersteds and that for the methyl protons 2.26 oersteds. The considerable decrease of the splitting constant of the ring protons resulting from the change of the substituent from alkyl to alkoxy suggests the possible preferential localization of the unpaired electron on the oxygen atoms in the alkoxy groups. Nevertheless, the splitting constant of the alkoxy protons is also less than that of the alkyl protons.

I

3,3′,5,5′-Tetramethyl- and 3,3′,5,5′-Tetramethoxy-p-biphenosemiquinone Ions

The 3,3′,5,5′-tetramethyl-*p*-biphenosemiquinone ion (II*a*) has four ring protons and 12 methyl protons; therefore, if the two benzene nuclei are equivalent five sets of 13 lines are to be expected. Only 21 lines with equidistant spacings were detected because of overlap and small intensity of some of the lines (Fig. 4). The values of the splitting constants, 2.34 oersteds for the ring protons, and 0.78 oersted for the methyl protons, seem to give the pattern which is most consistent with the experimental one. The following intensity ratio is predicted: 1:12:66:224:543:1056:1810:2844:4059:5240:6252:7008:7306:7008:6252:5240:4059:2844:1810:1056:543:224:66:12:1. Among these 25 lines the two at each end of the spectrum are too weak to be detected.

(*a*) X = CH_3

(*b*) X = CH_3O

II

The 3,3′,5,5′-tetramethoxy-*p*-biphenosemiquinone ion (II*b*) has the same number of ring and methyl protons as the tetramethyl derivative. However, the total spread of the spectrum was found to be less than one third of that of the tetramethyl derivative. The observed 13-line spectrum (Fig. 5) can be explained with a splitting constant of 0.49

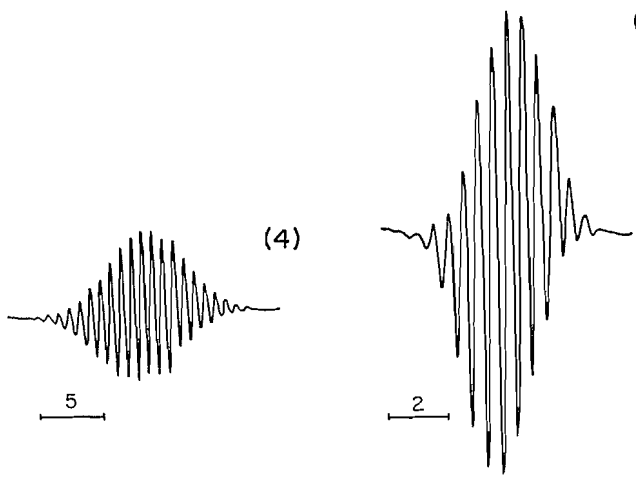

FIG. 4. First derivative of e.s.r. absorption spectrum of the 3,3′,5,5′-tetramethyl-*p*-biphenosemiquinone ion (II*a*).

FIG. 5. First derivative of e.s.r. absorption spectrum of the 3,3′,5,5′-tetramethoxy-*p*-biphenosemiquinone ion (II*b*).

oersted for both the ring and the methoxy protons. The predicted intensity ratio is 1:16:120:560:1820:4368:8008:11440:12870:11440:8008:4368:1820:560:120:16:1. Again the two lines at each end are expected to be too low in intensity to be detectable. The decrease of the splitting constant of the ring protons is again observed on changing the substituent from methyl to methoxy.

II*b*	0.49	0.49

*See references 1 and 7.
†See references 1 and 3.

Later work (see Part III of this series) has, however, indicated that in *p*-biphenosemiquinone salts the unpaired electron density given by the simple LCAO–MO method for carbon atom *a* (adjacent to the C—O bond) is 1.5, or more, times larger than that on carbon atom *b*, regardless of the magnitude of the coulomb integral for the oxygen atoms in the range of $\alpha_O = \alpha_C$ to $\alpha_C + \beta_{CC}$. This permits an alternative assignment of 0.78 oersted for the ring protons and 1.56 oersteds for the methyl protons. The following intensity ratios result and the 21 lines could be those which are not enclosed in parentheses: (1, 4, 18, 52) 139, 312, 628, 1144, 1881, 2860, 3982, 5148, 6171, 6864, 7128, 6864, 6171, 5148, 3982, 2860, 1881, 1144, 628, 312, 139 (52, 18, 4, 1).

Semiquinone Ions from Gallic Acid and Alkyl Gallates

The spectrum of the semiquinone ion (III*a*) formed by oxidation of gallic acid has been reported by Adams, Blois, and Sands (7). The two ring protons give a triplet with a splitting of 1.07 oersteds and a *g*-value of 2.00489.

III

(*a*) R = e^-
(*b*) R = CH_3
(*c*) R = CH_3CH_2
(*d*) R = $(CH_3)_2CH$

The semiquinone ion (III*b*) from methyl gallate gives 10 lines (Fig. 6). The center lines of the expected 12-line spectrum overlap to give a theoretical pattern with an intensity ratio 1:3:3:4:9:9:4:3:3:1. In Fig. 6, the third, the sixth, and the ninth lines from left to right do not follow the above-mentioned ratio. The intensity of these three

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

lines, compared with the others, increases on standing and this anomaly can be attributed to the presence of a triplet of slightly lower g-value from gallic acid formed by hydrolysis. The splitting constants for the ring and the methyl protons are estimated as 1.14 and 0.38 oersteds, respectively.

The semiquinone ion (III*c*) from ethyl gallate shows three triplets as expected (Fig. 7). The predicted intensity ratio is 1:2:1:2:4:2:1:2:1. The deviation from the theoretical pattern again suggests the presence of the semiquinone ion from the free acid. Although the third line of the triplet due to gallic acid overlaps nearly perfectly with the eighth line due to the ethyl ester, the resolution of the other two lines becomes better on standing for $\frac{1}{2}$ hour. As we can see in Fig. 8, the ester has a slightly higher g-value than the acid.

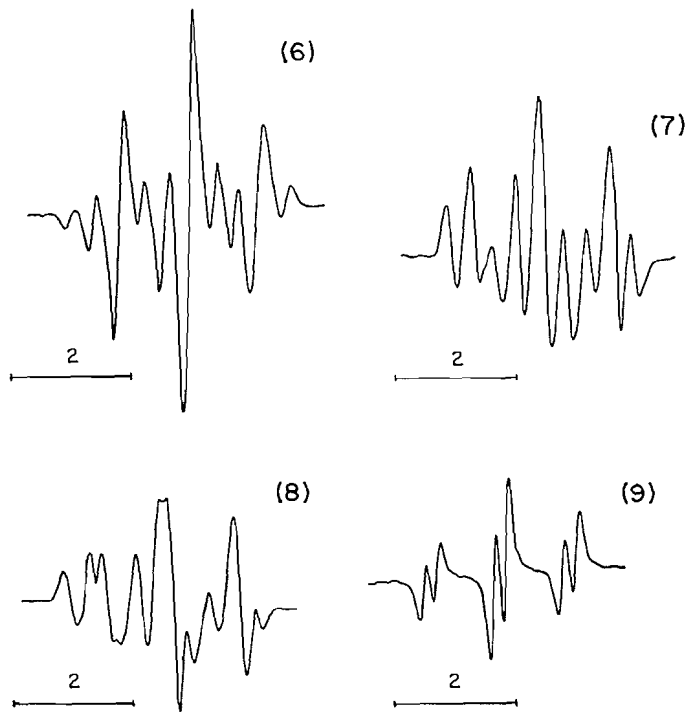

FIG. 6. First derivative of e.s.r. absorption spectrum of the semiquinone ion (III*b*) from methyl gallate.
FIG. 7. First derivative of e.s.r. absorption spectrum of the semiquinone ion (III*c*) from ethyl gallate.
FIG. 8. First derivative of e.s.r. absorption spectrum of the semiquinone ions from hydrolyzed ethyl gallate.
FIG. 9. First derivative of e.s.r. absorption spectrum of the semiquinone ion (III*d*) from isopropyl gallate.

The splitting constants are 1.12 oersteds for the ring protons and 0.36 oersted for two of the ethyl protons. The hyperfine splitting due to the other three protons in the ethyl group is too small to be resolved. *n*-Propyl gallate on oxidation gives essentially the same pattern as the ethyl ester. Adams, Blois, and Sands (7) reported two splitting constants, 1.13 and 0.38 oersteds, and a g-value of 2.00490. Our values for the ethyl ester are in good agreement with those for the *n*-propyl ester within the limit of the experimental errors.

The semiquinone ion (III*d*) from isopropyl gallate shows three doublets (Fig. 9). This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

ester is fairly stable in an alkaline medium and the sample, from which unreacted acid was carefully removed by sublimation in vacuum, does not show the signals due to gallic acid. The splitting constants are estimated as 1.13 oersteds for the ring protons and 0.24 oersted for one proton in the isopropyl group.

TABLE II

Proton splitting constants in semiquinone ions from gallic acid and alkyl gallate

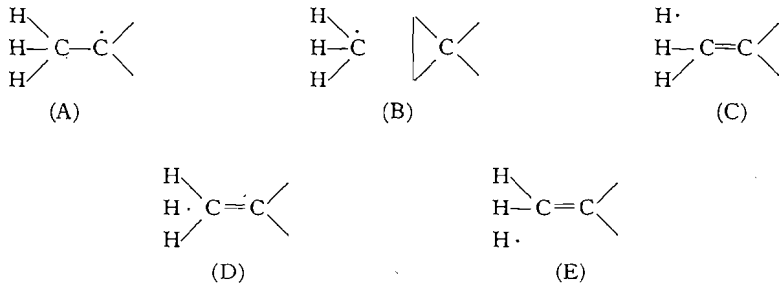
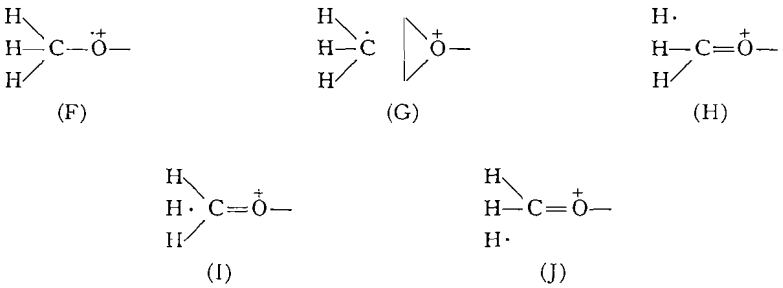
III*a*	1.07*	—
III*b*	1.14	0.38
III*c*	1.12	0.36
III with R = *n*-propyl	1.13*	0.38*
III*d*	1.13	0.24



*See reference 7.

The magnitude of the ring proton splitting in these four esters seems to be constant regardless of the kind of alkyl group; however, it must be noted that the splitting due to the isopropyl proton is found to be about two thirds of those of the methyl and the ethyl protons. The semiquinone ion can be considered as the gallate ion with one positive hole. The small increase of the ring proton splitting by esterification shows that the ability of the negatively charged carbonyl group to attract the positive hole is higher, but only slightly, than that of the neutral carboalkoxy group.



Recently Müller and his collaborators (17) have compared the hyperfine splitting due to the methoxy, the ethoxy, and the isopropoxy protons observed for the alkoxy-2,6-di-*tert.*-butyl-phenoxyl radicals. The splitting constants have been found to be 1.6 oersteds for the methoxy and the ethoxy protons and 1 oersted for the isopropoxy proton. The relative magnitude of the splitting constants of these protons is in very good agreement with the present results.

Based on the above experimental results, we can conclude that there is no essential difference between alkyl and alkoxy protons as to their contribution to hyperfine splitting and the effect of alkoxy protons can be ascribed to hyperconjugation. In the molecular orbital theory of hyperconjugation, the π-character of the orbitals in methyl and methylene groups can be found by the use of hydrogen group orbitals (18, 19). The spin densities on the methyl protons have been calculated by Bersohn (3) by taking into account the delocalization of the unpaired electron onto the methyl group. He found general agreement between the calculated and the observed splitting constants in a number of methyl-substituted benzosemiquinone ions; however, the orbital of isopropyl hydrogen has no π-character in this sense. This delocalization of unpaired electron means there is a charge transfer to methyl group, as the unpaired electron in the semiquinone ions is accompanied by a positive hole. In the valence bond theory, hyperconjugation can be understood to mean the introduction of unconventional pairing schemes or spin polarization of the bonds in a methyl group without any accompanying transfer of charge. McLachlan (4) has explained the hyperfine splitting due to methyl protons by considering the following resonance structures and concluded that spin polarization mechanism may be at least as important as electron delocalization in accounting for the hyperfine splitting due to methyl protons.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

The application of the valence bond theory can be extended to methoxy group by considering analogous resonance structures. In the methoxy group the oxygen atom with a positive hole takes the place of a trigonal carbon atom in a methyl group. Therefore, the resonance structures H, I, J are probably less important than the structures C, D, E. We may expect that the electronic interaction between the alkyl protons and the oxygen

atom in the alkoxy group is less than that between the alkyl protons and the carbon atom to which the alkyl group is attached. The behavior of two ethyl protons and one isopropyl proton can be explained similarly. We may attribute the difference between the proton splitting constants for methyl and isopropyl groups to the presence of electron delocalization in the former group. In the case of the isopropyl derivative there is the additional possibility that steric hindrance may cause part of the change observed.

THE ELECTRON SPIN RESONANCE ABSORPTION SPECTRA OF SEMIQUINONE IONS

PART II. THE HYPERFINE SPLITTING DUE TO AMINO GROUPS[1]

Y. MATSUNAGA[2] AND C. A. MCDOWELL

ABSTRACT

The electron spin resonance absorption spectra of amino-substituted *p*-benzosemiquinone ions have been examined. The hyperfine splittings due to the amino protons and the amino nitrogen atom have been demonstrated. It has been found that the magnitude of the hyperfine splitting constants due to these two kinds of nuclei depends very much on the nature of the free radical.

INTRODUCTION

Though the hyperfine splitting due to a nitrogen atom has been reported in the electron spin resonance (e.s.r.) of a number of organic-free radicals, the hyperfine splitting of the amino nitrogen atom and protons is not yet clear. The nuclear moment of N^{14} is one, so we can expect one N^{14} nucleus to cause a splitting of the resonance absorption into a triplet. 1,1-Diphenyl-2-picrylhydrazyl and its analogues (1), di-*p*-anisyl-nitrogen oxide (2), and cyano-di-*tert.*-butyl-phenoxyl (3) are the examples of the neutral free radicals which show the N^{14} splitting. Hyperfine splittings for both the N^{14} in, and out of, the aromatic ring in positively charged free radicals have been demonstrated in the cases of the phenazine semiquinone ion (4), and triarylaminium ions (5). Nitrobenzene anion (6), and the semiquinone ion from 3-nitrophthalic anhydride (7), show the hyperfine splitting due to N^{14} in the nitro group. Wurster's blue ions are the only kinds of free radicals with amino groups already studied (8, 9). Unlike those in the above-mentioned free radicals (10) the nitrogen atoms in these positively charged free radicals do not contribute to the hyperfine structure. Therefore, it seemed of interest to examine the hyperfine splitting due to the amino group in the other kind of free radicals. For this purpose, the negatively charged semiquinone ions formed by reduction of 2-amino-5-hydroxy-3,6-dichloro-*p*-benzoquinone; 2,5-diamino-3,6-dichloro-*p*-benzoquinone; 2,5-dianilino-3,6-dichloro-*p*-benzoquinone; and 2,5-di(N-piperidyl)-3,6-dichloro-*p*-benzoquinone have been chosen because of the lack of other substituents, which can contribute to hyperfine splitting. Although chlorine has a nuclear moment of spin, this splitting is known too small to be resolved (11).

EXPERIMENTAL

The parent quinones were prepared starting from chloranil by the methods described in the references. 2-Amino-5-hydroxy-3,6-dichloro-*p*-benzoquinone was prepared by reaction with ammonia in water (12). 2,5-Diamino-3,6-dichloro-*p*-benzoquinone was prepared by the reaction with ammonia in absolute ethanol (13). 2,5-Dianilino-3,6-dichloro-*p*-benzoquinone and 2,5-di(N-piperidyl)-3,6-dichloro-*p*-benzoquinone were obtained by the reaction with aniline and piperidine in ethanol, respectively (13, 14). By reduction with sodium dithionite, these quinones on dissolving in a mixture of pyridine, ethylene glycol, and 2 *M* KOH (1:2:1 by volume) give fairly stable free radicals. Pyridine was used with the hope of improving the solvating power and of stabilizing the mono-

[1]*Manuscript received March 7, 1960.*

[2]*National Research Council Postdoctorate Fellow 1957–59.*

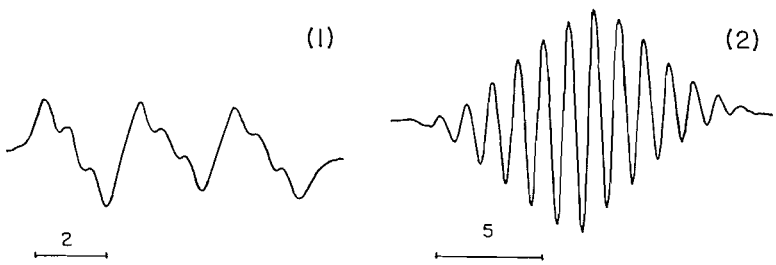
meric form of semiquinone ion (15). The use of ethylene glycol or glycerol has been recommended by Hausser (16). The high viscosity of these compounds contributes to the resolution of the spectra. The solubility of 2,5-di(N-piperidyl)-3,6-dichloro-*p*-benzoquinone in the above-mentioned mixed solvent was found too small; therefore, the concentrated pyridine solution of the quinone was diluted with the mixed solvent containing the reducing reagent.

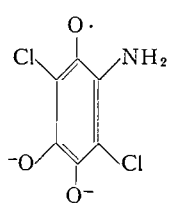
The e.s.r. absorption of these semiquinone ions was examined at room temperature at a frequency of 9 kMc/s as described previously (17).

RESULTS AND DISCUSSION

The semiquinone ion (I) from 2-amino-5-hydroxy-3,6-dichloro-*p*-benzoquinone gives three triplets as expected from the presence of one amino nitrogen and two protons (Fig. 1). The intensity ratios are 1:2:1:1:2:1:1:2:1; therefore, we can confidently assign the major splitting to the amino nitrogen and the minor one to the amino protons. The former splitting constant is estimated as 2.5 oersteds and the latter as 0.6 oersted. It must be noted that the magnitude of the amino proton splitting is only about one fourth of that of the amino nitrogen splitting.

The semiquinone ion (II) from 2,5-diamino-3,6-dichloro-*p*-benzoquinone shows a 13-line spectrum (Fig. 2). If the splitting constant of the amino nitrogen is nearly twice,





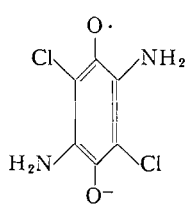


FIG. 1. First derivative of e.s.r. absorption spectrum of the semiquinone ion (I) from 2-amino-5-hydroxy-3,6-dichloro-*p*-benzoquinone.
FIG. 2. First derivative of e.s.r. absorption spectrum of the semiquinone ion (II) from 2,5-diamino-3,6-*p*-benzoquinone.

or one half of that of the amino protons, we can expect 13 lines with the relative intensities 1:4:8:12:16:20:22:20:16:12:8:4:1 or 1:2:7:10:19:20:26:20:19:10:7:2:1. The observed pattern seems to be in agreement with the former. The splitting constants of the nitrogen and the protons are 2.3 oersteds and 1.15 oersteds, respectively. In this case, the nitrogen splitting is a little smaller than that of the semiquinone ion (I) and the proton splitting is increased by a factor of two.

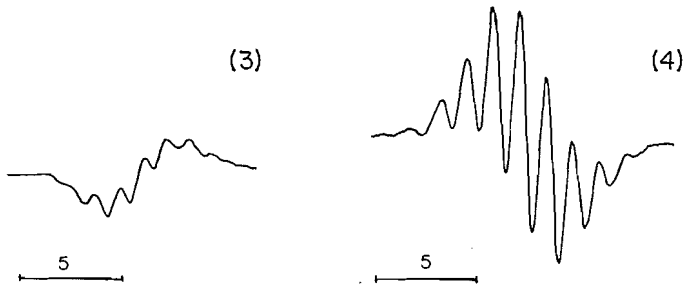
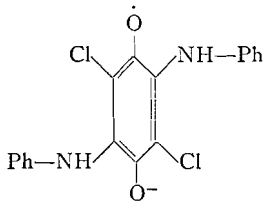
The semiquinone ion (III) from 2,5-dianilino-3,6-dichloro-*p*-benzoquinone has two amino nitrogen atoms and two amino protons. The contribution from two phenyl groups is not expected to be resolvable. As shown in Fig. 3, seven lines with a spacing of 1.1 oersteds are detected. If these seven lines are the whole of the spectrum, the splitting constants of the amino nitrogens and the amino protons must be of the same magnitude (1.1 oersteds) and the intensity ratio must be 1:4:8:10:8:4:1. The resolution of this spectrum is not good, because of the weak concentration of the free radical, and the use of high modulation of the magnetic field. Therefore, we may have missed the outermost weak line at each side. In such a case, the predicted intensity ratio is 1:2:5:6:8:6:5:2:1. The magnitude of the amino proton splitting becomes 2.2 oersteds, namely twice that of the amino nitrogen splitting. The latter values are probably more reasonable.

The semiquinone ion (IV) from 2,5-di(N-piperidyl)-3,6-dichloro-*p*-benzoquinone gives nine lines with an equidistant spacing of 1.2 oersteds (Fig. 4). The eight protons attached





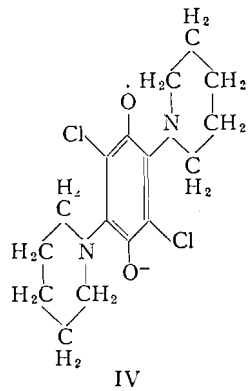


FIG. 3. First derivative of e.s.r. absorption spectrum of the semiquinone ion (III) from 2,5-dianilino-3,6-dichloro-*p*-benzoquinone.
FIG. 4. First derivative of e.s.r. absorption spectrum of the semiquinone ion (IV) from 2,5-di(N-piperidyl)-3,6-dichloro-*p*-benzoquinone.

to the carbon atoms adjacent to the nitrogen atoms in two piperidyl rings can be expected to contribute by hyperconjugation to hyperfine splitting with the intensity ratio 1:8:28:56:70:56:28:8:1. Therefore, the observed nine lines can be assigned to these eight protons and the contribution from two piperidyl nitrogen atoms must be too small to be resolved. The magnitude of the proton splitting in the present semiquinone ion must be, at least, several times larger than that of the nitrogen splitting.

III

IV

TABLE I

Splitting constants of nitrogen and proton in amino derivatives of 3,6-dichloro-*p*-benzosemiquinone ion

Semiquinone ion	Splitting constants in oersteds		
	a_N	a_H	a_N/a_H
I	2.5	0.6	4
II	2.3	1.15	2
III	1.1	2.2 (or 1.1)	1/2 (or 1)
IV	?	1/2	?

The present results show clearly that the amino nitrogen can contribute to hyperfine splitting. The assumption made by McLachlan (10) that the nitrogen atoms contribute no structure as N^{14} has a quadrupole moment which links its spin orientation to the molecular rotation cannot be considered as general for amino group in organic-free radicals. However, as summarized in Table I, the ratios of the splitting constants of the amino (probably and the alkylamino) protons to those of the amino nitrogen depend considerably on the nature of the molecule. Although the number of the radicals examined is quite small, the increase of the amino proton splitting constant seems to be accompanied by a decrease in the amino nitrogen splitting. This suggestion is consistent with the observation on Wurster's blue ions. For example, in the free radical from tetramethyl-*p*-phenylenediamine, the dimethylamino proton splitting has been reported as large as 7.4 oersteds and no nitrogen splitting has been detected (9).

According to theory, the hyperfine splitting is proportional to the Fermi contact term and the magnitude of this Fermi interaction is proportional to the spin density at the nucleus. The unpaired electron in our semiquinone ions is supposed to be in a π-orbital which has a node in the plane of the molecule. The unpaired electron must have some probability of interacting with the *s*-orbitals of hydrogen and nitrogen. It has been shown that $\sigma-\pi$ interaction is responsible for the hyperfine splitting due to ring protons. The magnitude of the hyperfine splitting is approximately proportional to the spin density in the π-orbital of the neighboring aromatic carbon atom (18). This relation has been supported by a number of experiments (19). The geometrical configuration of the CH group can be considered to be nearly same in every hydrocarbon. Nevertheless, this proportionality constant has been found to depend on the size of aromatic molecule and also on the sign of the charge by the experiments on hydrocarbon negative and positive ions. Therefore, we may expect that the magnitude of hyperfine splitting depends strongly on the nature of the electronic configuration of the group concerned.

The complete planarity of the amino group with the aromatic nucleus favors resonance stabilization. On the other hand, some energy will be required to change the hybridization at the nitrogen atom from the tetrahedral character in aliphatic amines to the trigonal type. We must consider also steric effects in some cases. By compromise between these factors, it seems probable that the geometrical and the electronic configurations of the amino group can be modified by a small change in the nature of the molecule. Consequently, a considerable change in the magnitude of the splitting constants of amino proton and nitrogen can be expected.

In connection with these results, it may be interesting to mention the spectrum of the semiquinone ion with a betaine-like structure. The e.s.r. absorption of the semiquinone ion (V), formed by reduction of the compound $C_{11}H_5O_3NCl_2$, which can be prepared by the

For personal use only.

condensation between chloranil and pyridine (20), has been examined. Unlike the naphthoquinone analogue (VI) (21) the structure of this product seems to be not yet well defined. The position of the substituents given in V are the most probable. The semiquinone ion shows only one absorption line and there is no structure due to the positively charged and trigonal-type nitrogen atom (Fig. 5).

THE ELECTRON SPIN RESONANCE ABSORPTION SPECTRA OF SEMIQUINONE IONS

PART III. FREE RADICAL SALTS OF QUINHYDRONES[1]

YOSHIO MATSUNAGA[2]

ABSTRACT

Electron spin resonance absorption was observed in alkali salts of tetrachloro-*p*-benzoquinhydrone, *p*-biphenoquinhydrone, and its tetrachloro and tetrabromo derivatives. The magnitude of *g*-value was found to be in the order of unsubstituted < chloro derivative < bromo derivative, and benzoquinhydrone salt < the corresponding *p*-biphenoquinhydrone salt. The frequency of C—O stretching vibration was observed in the range 1525 to 1550 cm^{-1}. Based on these frequencies the estimation of the parameters which are necessary for the molecular orbital treatment of semiquinone ions was attempted. A set of $\alpha_O = \alpha + (1/3-1/2)\beta$ and $\beta_{CO} = \beta$ were derived. Independently values of $\alpha_O = \alpha + 2/3\beta$ and $\beta_{CO} = \beta$ were estimated using the hyperfine structure of the electron spin resonance spectrum of the α-naphthosemiquinone ion.

INTRODUCTION

A number of unstable salts of quinhydrones have been described by organic chemists (1). It is well known that quinhydrones, which have no unpaired electron, dissociate into free radical ions in alkaline solution. Therefore, it seemed to be of interest to study the electronic structure of alkali salts of quinhydrones in the solid state. Electron spin resonance (e.s.r.) absorption has been detected in the quinhydrones adsorbed on barium hydroxide octahydrate (2). The highly colored reaction products of tetrahalogeno-*p*-benzoquinones with alkali iodides have been examined by the magnetic resonance method and found to be free radical salts (3). Here we wish to present the results of the e.s.r. and the infrared absorption measurements on sodium salts of *p*-biphenoquinhydrone and its halogeno derivatives.

EXPERIMENTAL

Materials.—Potassium salt of tetrachloro-*p*-benzoquinhydrone was prepared by the method of Torrey and Hunter (4). Chloranil was dissolved in cold, dry acetone and treated with crystals of potassium iodide. The grass green precipitate was filtered and washed with ether. According to Torrey and Hunter, the composition of the product is $C_6Cl_4O_2 . C_6Cl_4(ONa)_2$. The sodium salt was also prepared by a similar method. Oxidation of biphenol with ferricyanide in alkaline medium gave sodium salt of biphenoquinhydrone as described by Willstätter and Kalb (5). Biphenol was used in excess to avoid overoxidation. The blue product was quickly filtered and dried without washing. This salt decomposes quickly in contact with water. Tetrachloro-*p*-biphenol, which was obtained by chlorination of biphenol suspended in acetic acid (6), was dissolved in aqueous solution of sodium hydroxide and oxidized to sodium salt of quinhydrone using ferricyanide. The precipitate changes its color from violet to blue by washing with water. This free radical salt is so stable as to be prepared in the presence of a large excess of the oxidizing reagent. The dark blue salt of tetrabromo-*p*-biphenoquinhydrone was prepared similarly (7). Bromination of biphenol was carried out as described by Magatti (6).

Magnetic measurements.—Electron spin resonance absorption was measured at room temperature at a frequency of 9 kMc/s. The *g*-value was estimated by comparison with

[2]*National Research Council Postdoctorate Fellow 1957–59.*

diphenylpicrylhydrazyl (DPPH). The line width was taken as the distance in oersteds between the points of maximum slope.

Optical measurements.—Infrared spectrum was recorded using a Perkin–Elmer spectrometer model 21. The sample was examined in a potassium bromide disk.

RESULTS AND DISCUSSION

All of our specimens showed e.s.r. absorption and we could conclude that alkali salts of quinhydrones consists of negatively charged semiquinone ions and alkali cations. The spin concentration in our specimens was found to be in the order of 10^{21} to 10^{23} spins per mole. The *g*-value, line width of e.s.r. absorption, and the frequency of C—O stretching vibration are presented in Table I. Our *g*-values for tetrachloro-*p*-benzoquinhydrone salts are in agreement with 2.0044 ± 0.0008 for the sodium salt reported by Kainer, Bijl, and Rose-Innes (3). The infrared spectra of a number of ionic molecular compounds between quinones and aromatic diamines have been examined by Kainer and Otting (8). They have assigned the strong absorption band found in the region of 6.5 (ca. 1540 cm^{-1}) to the C—O stretching vibration in tetrahalogeno-*p*-benzosemiquinone ions. Our results on much simpler compounds support their assignment.

TABLE I

g-Value and line width of e.s.r. absorption and frequency of C—O stretching vibration in alkali salts of quinhydrones

	E.s.r. absorption		
	g-Value	Line width in oersteds	C—O vibration in cm^{-1}
Na tetrachloro-*p*-benzoquinhydrone	2.0051 ± 0.0003	6.7	1530 ± 10
K tetrachloro-*p*-benzoquinhydrone	2.0048 ± 0.0003	7	1525 ± 5
Na *p*-biphenoquinhydrone	2.0044 ± 0.0003	5	1550 ± 5
Na tetrachloro-*p*-biphenoquinhydrone	2.0064 ± 0.0003	2.2	1540 ± 5
Na tetrabromo-*p*-biphenoquinhydrone	2.012 ± 0.001	1.5	1530 ± 5

The magnitude of *g*-values of biphenoquinhydrone salts was found to be in the following order:

unsubstituted < chloro derivatives < bromo derivatives.

The *g*-value for sodium salt of tetrabromo-*p*-benzoquinhydrone has been reported to be 2.0068 ± 0.001 (3); therefore, the above order seems to be followed also by the series of benzoquinhydrone salts. The same tendency is found in the series of substituted DPPH and of substituted triarylaminium perchlorates (9). Consequently, we may conclude that substituted bromine atoms are more effective in enhancing spin-orbital coupling and in increasing the magnitude of *g*-value than substituted chlorine atoms regardless of the sign of charge on free radical molecules. However, it must be noted that the magnitude of *g*-value depends also on the size of semiquinone ions. Biphenoquinhydrone salts give higher *g*-value than the corresponding benzoquinhydrone salts. These tendencies seem to be in sharp contrast to the results on aromatic hydrocarbon–iodine complexes (10). In the latter case, their *g*-values have been found to be close to that for free electron (2.0023) and the magnitude decreased with the increasing of the size of hydrocarbon molecule. In connection with the different behavior between these two kinds of halogens, it may be interesting to cite Wahler and Thon's observation that the magnitude of

g-value of diarylnitrogen oxide in solution shows a marked decrease by addition of complex-forming agent, *m*-dinitrobenzene and *s*-trinitrobenzene (11).

The hyperfine structure of the e.s.r. spectra of semiquinone ions in the dissolved state arises from the interaction between the magnetic moment of the unpaired electron and the magnetic moments of the protons in the molecule. Based on the spectra of *o*- and *p*-benzosemiquinone ions McConnell has suggested that the magnitude of ring proton splitting is approximately proportional to the density of the unpaired π-electron on the adjacent carbon atom (12). This approximation has been applied successfully to the case of aromatic hydrocarbon monopositive and mononegative ions (13, 14) and even to the case of DPPH (15). McConnell has used in his molecular orbital treatment of benzosemiquinone ions the following parameters without considering the effect of negative charge on the magnitude of coulomb integral for the oxygen atoms, $\alpha_O = \alpha+\beta$ and $\beta_{CO} = \beta$ which were originally estimated for the oxygen atoms in neutral quinone molecules. It seems desirable to find a correct set of parameters for the application of this approximation to semiquinone ions with more complicated molecular structure. Therefore, we examined the C—O stretching vibration in the above-mentioned salts of quinhydrones and attempted to estimate the required parameters based on it.

Bonino and Scrocco (16) have suggested the use of the following relation between the mobile bond order (p_{CO}) and the force constant of C=O bond (k) for the estimation of stretching vibration frequency,

$$k = \xi p_{CO} + \sigma(1-p_{CO}), \qquad [1]$$

where ξ is the force constant for the "imaginary" double bond with $p_{CO} = 1$, and σ is that for C—O single bond. Although Berthier, Pullman, and Pontis (17) have presented a more refined equation considering the autopolarizability of the bond, we may use the above approximation ignoring the minor correction term. The values for the C=O bond in the formaldehyde molecule are used to estimate the magnitude of ξ, i.e. $k = 13.45\times10^5$ dyne/cm (18) and $p_{CO} = 0.958$ (17, 19), and we assume $\sigma = 5\times10^5$ dyne/cm. The relation between the vibration frequency (ν) and the force constant estimated by equation [1] can be approximated by

$$\nu = 1744\ (k/13.45\times10^5)^{\frac{1}{2}}\ \text{cm}^{-1} \qquad [2]$$

where 1744 cm^{-1} is the observed frequency for the C=O bond of the formaldehyde molecule (18).

TABLE II

Calculated mobile bond orders, force constants, and stretching frequencies for the C—O bond in semiquinone ions

	α_O	Mobile bond order, p_{CO}	Force constant $k\times10^{-5}$ by eq. [1]	Frequency in cm^{-1} by eq. [2]
p-Benzosemiquinone ion	α	0.655	10.77	1561
	$\alpha+1/2\beta$	0.609	10.36	1531
	$\alpha+\beta$	0.561	9.94	1499
p-Biphenosemiquinone ion	α	0.672	10.91	1571
	$\alpha+1/2\beta$	0.608	10.35	1530
	$\alpha+\beta$	0.537	9.73	1483

The calculated mobile bond order, force constant, and vibration frequency for benzo- and bipheno-semiquinone ions are summarized in Table II. These results were obtained assuming $\alpha_O = \alpha+\beta_{CO} = \beta$. The relation between the parameter and the vibration frequency ν for the C—O bond in *p*-benzosemiquinone ion can be approximated by $\nu = 1561-61\delta$ in cm^{-1}. The observed frequencies given in Table I suggest that the value of δ in the present case is about one half. If we assume a similar linear relationship in the case of *p*-biphenosemiquinone ion, the value of δ will be estimated as one-third to one-half. These two estimations are in good agreement with each other.

The magnitude of parameters δ can be estimated based on the hyperfine structure of e.s.r. spectrum. α-Naphthosemiquinone ion (Fig. 1) gives a spectrum of three quintets; therefore the density of unpaired electron on the aromatic carbon atoms 5 and 5′ is practically equal to that on the carbon atoms 6 and 6′ (see structural formula). If the square of the coefficient of $2p$ function at the carbon atoms 5 and 6 are supposed to be equal to each other in the singly occupied molecular orbital, we obtain $\delta = 2/3$ and the following densities of unpaired π-electron by the secular equations assuming $\alpha_O = \alpha+\beta$ and $\beta_{CO} = \beta$; 0.225 on the oxygen atoms 1 and 1′, 0.100 on the carbon atoms 2, 2′, 3, and 3′, and 0.025 on the carbon atoms 4, 4′, 5, 5′, 6, and 6′. If we apply the relation $a_j = 34\rho_j$ given by McConnell for benzosemiquinone ions, where a_j is the ring proton splitting constant and ρ_j is the density of the unpaired π-electron on the adjacent carbon atom j, we may expect the splitting constants of 3.40 oersteds for the ring protons 2 and 2′, and 0.85 oersted for the ring protons 5, 5′, 6, and 6′. Although we cannot reproduce the observed pattern of spectrum using these constants, the estimated values are in good agreement with 3.22 ± 0.03 oersteds and 0.57 ± 0.03 oersteds given by Adams, Blois, and Sands (20).

THE ELECTRIC MOMENTS OF SUPPOSEDLY SYMMETRICAL CYCLIC SUBSTANCES[1]

C. C. Meredith and George F Wright

ABSTRACT

The distortion polarizations of polysubstituted benzenes and cyclobutanes which have been examined by the randomly oriented solid pellet technique seem to be lower but never higher than the electronic polarization values derived from bond refractions, and are considered to be more reliable than the latter. In almost all of the supposedly symmetrical substances which have been examined the total solute polarization always exceeds the measured distortion polarization and usually exceeds the calculated MR_D. These substances must then be polarized, although the moments which have been determined are not numerically reliable because of solvent effects. Whenever possible the temperature coefficients of these apparent moments have been determined and are usually but not always positive. From these temperature coefficients it is presumed that some substances, like naphthalene, are rigidly dipolar whereas others, like hexachlorobenzene, have activation states which are unsymmetrical and therefore contributory to the moment which actually is measured.

The graphic formula of a single molecule is patently a cursory description of a chemical substance, useful chiefly for illustrative and bibliotechnical communication. Nevertheless there seems to be a tendency to ascribe to the graphic formula a verity which it does not deserve. Especially is this the case when molecular symmetry is concerned. Indeed the simple diagram may become an unexcited state of reference in analysis of "loss" determinations such as those of absorption spectroscopy, or it may be used as the basis for trial stuctures during diffraction studies. There is some danger that the inadequate graphic formula thus becomes "built into" the physical interpretation.

Although a reactance determination, of which dielectric constant is an example, has the obvious disadvantage of an integrated, non-detailed result in which the entire system participates it does not require the same degree of preconception that is common to some other physical methods. No irreversible energy transfer occurs, so that the measurement is that of the actual system if sufficiently weak electromagnetic fields are applied. If environmental influences can be evaluated, say by variation of solvent, temperature, and concentration, the modulated value of electrical polarization sets a definition to which the molecular construct of the substance must conform.

This definition is especially applicable to substances for which the graphic formula would predict, for reasons of symmetry, a zero dipole moment. Several examples in which the inadequacy of the ordinary graphical construct becomes apparent, have recently been reported (1–4).

In the present report this list has been extended to include aromatic hydrocarbons with aliphatic and halogeno substituents. These substances would not be expected to display any orientation polarization if the frequently quoted symmetries and the graphic formulae specifying them were valid.

In some instances zero moments have been assigned heretofore to substances showing low total polarizations, P_T, because the intuitive decision from the graphic formula was at least as meaningful as the ostensible orientation polarization remaining after subtraction from P_T of a questionably calculated distortion polarization (P_{e+a}). Little accuracy can be claimed for the usual (2–5% of P_E) assignment of atom polarization. However, now we are aided in this respect by the actual determination of the entire distortion

[a]The calculated refractions do not include iron II for which a value of 5.0 cc may be estimated.

[b]If Vogel's value for the cyclobutane C—C bond refraction had been used (1.37 cc) instead of the usual C—C value (1.29 cc) these additive refractions would be higher than is recorded.

[c]Kindly furnished by H. J. Matsuguma, Picatinny Arsenal, Dover, N.J., m.p. 50.5–51.8°. Prepared by W. J. Pummer, R. E. Florin, and L. A. Wall. J. Research Natl. Bur. Standards, **62**, 113 (1959).

polarization from the dielectric constant of the randomly oriented, highly compressed solid in which no orientation polarization should be detectable (1). In general the results have conformed with expectations. However in some instances apparent abnormal atom polarizations, previously assigned in order to conciliate an observed total polarization with an intuitively defined zero moment, have been found to be non-existent (1, 3, 4). On the other hand some hitherto unsuspected atom polarizations have been discovered (2).

Although the measured distortion polarization ought to be and customarily is higher than the molecular refraction (because the latter does not include atom polarization) we have earlier encountered an exception in diphenylmercury (4). Since we have suspected that this behavior is due to the phenyl groups, and our present candidates are aromatic, we have examined a series of this type of hydrocarbon in respect of distortion polarization measured in pellets at 23°. The results are shown in Table I together with molecular refractions calculated in three ways.

For personal use only.

In the column "Vogel C_{ar}—C_{ar}" (5) the value of 2.69 cc has been used for aromatic ring bonds. In the following column "Vogel C=C+C—C," 4.17 cc and 1.30 cc respectively are used for aromatic rings. Finally in the last column are the additions of atom refractions according to Eisenlohr (6), all being values for the Na_D frequency.

The three additive refraction calculations are not interconsistent. Of present interest is the comparison of these calculated molecular refractions with our measured distortion polarizations (P_{e+a}). First it may be seen that P_{e+a} for simple aromatic hydrocarbons is consistently lower than MR_D from Vogel's C_{ar}—C_{ar} bond value (perhaps because he derived the value from the most aromatic of all hydrocarbons, benzene) and to a lesser extent lower than MR_D from Vogel's C=C+C—C values. On the other hand MR_D from Eisenlohr's values agrees with our measured P_{e+a}. But this latter agreement must be fortuitous because all MR_D values are larger than measured P_{e+a} when substituents (either alkyl, halogen, or even phenyl) are considered.

In several instances there is good agreement between MR_D calculated and P_{e+a} observed, for example, azobenzene and stilbene. The case of stilbene is especially propitious because the refractive indices of the crystals have already been measured carefully at a series of wavelengths (7) in the visible region. If the mean of the indices along the three principal axes $(\eta_\alpha+\eta_\beta+\eta_\gamma)/3$, is calculated for each wavelength the linear distribution of these mean values with respect to wavelength justifies the application of the Cauchy dispersion equation (8) for calculation of the refractive index at infinite wavelength,

$$n_\infty = \frac{(3650)^2\cdot 10^6(1.931) - (6908)^2\cdot 10^6(1.739)}{10^6\cdot(3650)^2 - (6908)^2\cdot 10^6} = 1.664,$$

whence the MR_∞ may be calculated

$$\frac{(1.664)^2-1}{(1.664)^2+2}\cdot\frac{180}{1.144} = P_e = 58.5 \text{ cc.}$$

This electronic polarization is about 1% lower than our measured P_{e+a}, as might be expected for a normal contribution of atom polarization. On the other hand MR_D calculated according to Vogel is 1–3% higher than our measured P_{e+a}. It would seem that Vogel's bond refractions derived at short wavelength thus are not closely applicable to distortion polarizations in the radiofrequency range.

Even the Eisenlohr value of 59.2 cc for MR_D of stilbene may be too high, despite apparent agreement with P_{e+a}, if an exaltation not calculated into MR_D actually is included in the distortion polarization which we have measured. The existence of this exaltation is not improbable if one considers the measured distortion polarizations of *trans–trans*-1,4-diphenylbutadiene and *trans–trans–trans*-diphenylhexatriene, which are appreciably higher than the MR_D values for which no exaltation has been included (Table I). These observations of exaltation in the radiofrequency range seem to be reliable since other substances like β-carotene and, perhaps, methyleneanthrone also give exalted values (Table I). On the other hand the measurement P_{e+a} for the highly degenerate tetraphenylethylene is quite low.

Further examinations of the polarizations shown in Table I disclose many discrepancies between observed and calculated values. The measured distortion polarizations of the polynuclear hydrocarbon are in reasonable agreement with Eisenlohr calculations of MR_D, but both are markedly lower (particularly note coronene) than Vogel's calculated MR_D, especially when Vogel's C_{ar}—C_{ar} value is used. On the other hand the Eisenlohr MR_D

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

seems to be at least as much higher (and sometimes more so) than the measured P_{e+a} as is the Vogel value when the aromatic nucleus is substituted by methyl, chloro, or phenyl groups. If experimental errors (such as preferential orientation or dimensional non-uniformity of the compressed wafer) are avoided the measured distortion polarization ought to be the most reliable value. Likewise the lowest value ought to be the most realistic because errors due to electrical conduction or dielectric loss tend to raise the apparent dielectric constant. Therefore one may fairly question the calculated electronic polarization for substances in which aromatic linkages exist.

In point of fact the vagaries of calculated distortion polarization have been significant in the consideration of total polarizations when a certain orthodoxy would decree zero moment for the substance under examination. The polarization of naphthalene is a typical instance. The concept of resonance, supported by careful X-ray diffraction studies of crystalline naphthalene (9), and despite some minor discrepancies (10), seems to have firmly established the planar symmetry of this substance. However, in benzene at 20° the total solute polarization (P_T) was found to be 45.1 cc (11). In heptane at 20° the P_T must have been found to be 45.4 cc (12) because a tentative moment of 0.34 Debye (D) was calculated. But this value was abandoned in favor of $\mu = 0$ by deduction of 10 to 15% as atom polarization. The lowest total polarization reported in the literature is 43.3 cc but the author (13) was trying to avoid a previous error. Perhaps he overcorrected.

In all of these instances there seems to have been an effort to force the dipole moment of naphthalene to zero. This tendency is understandable in view of the orthodox expectancy from X-ray diffraction studies versus a distrust of the electrical measurement. This distrust is not unreasonable when low orientation polarizations are involved because a consistent error (say residual cell capacitance and/or inductance in leads) can easily lead to a spurious value of polarization.

Of course techniques have improved during the past 25 years. Among these improvements are those in our own apparatus in which inductance and capacitance errors have been avoided in large part by rigid location of the test capacitance as close as possible to the principal parts of the resonant circuit. We are accustomed to test the effectiveness of this and other precautions by polarization measurements of carbon tetrachloride in benzene and of benzene in carbon tetrachloride. Examples of such tests are shown in Table II.

It may be seen that neither benzene nor carbon tetrachloride shows an appreciable orientation polarization.

On the other hand this table shows that for naphthalene in benzene a significant orientation polarization (40.5 cc) or of the Eisenlohr MR_D (41.6 cc) from the observed total polarization. The latter value (46.5 cc) is quite comparable with those obtained by Parts and by Briegleb, but unlike the latter worker we choose to assign a moment of 0.49–0.54 D to naphthalene in benzene. The apparent moments in carbon tetrachloride and cyclohexane are lower but still significant.

Although this assignment may seem to be anomalous in view of X-ray diffraction studies it is not unexpected on the basis of chemical evidence. Since both rings cannot be complemented by pi sextets some other charge distribution must be prevalent. The behavior of naphthalene upon ozonization and addition of halogen strongly indicates (14) that the electronic distribution tends toward 6:4. That is to say, one ring tends to be fully aromatic and the other to be conjugated aliphatic in behavior. The substance may then be classified as mesoionic in its degeneracy and this resonance state is justified by the independence of dipole moment with respect to temperature (Table II). The mesoionic concept seems not to be contradicted by the normal distortion polarization of naphthalene because azulene, which is certainly mesoionic, does not exhibit any abnormality in the measured P_{e+a}.

The examples which are elaborated above provide some justification for the use of measured distortion polarizations in moment studies, but there are many unexplained differences between P_{e+a} and MR_D to be found in Table I. In the search for error there are several possibilities. In the experimental determination low values are to be expected if the compressed wafer which we measure is not at maximum density. However, this error may be detected either by nonlinearity of the plot of thickness versus apparent dielectric constant, or else by comparison of the density of individual crystal fragments with the density of the wafers. Another error, that of preferred orientation of crystal fragments (say, of plate-like crystals), may be avoided simply by our practice of reforming ground wafers.

Turning from the practical to the theoretical aspects, the application of polarizations determined in the crystalline state to systems in which lattice forces are not present might be thought to introduce a damping error. But in measurements of dielectric constant which have been made in the vicinity of the melting point (15, p. 134) there seems to be no evidence of a significant lattice restriction on distortion polarization. Moreover, the concept that atom polarization is a reactive compensation of electronic charge deformation would imply for a restriction of atom polarization in crystals a corresponding difference in refractive index between liquids and solids. In general such differences are not observed (16). In particular the comparison of molar refractions calculated from $(\eta_\alpha+\eta_\beta+\eta_\gamma)/3$ (which is essentially the same as when calculated from $\sqrt[3]{\eta_\alpha \cdot \eta_\beta \cdot \eta_\gamma}$) with the MR_D calculated from group refractions for stilbene in the present publication and for N,N′-dinitropiperazine in an earlier one (17) show that the electronic polarization is not altered appreciably by change of state. Therefore from both the practical and theoretical aspects the direct measurements of distortion polarization would seem to be reliable.

On the other hand errors in molecular refraction are less easy to define. When solids are involved the calculation is usually indirect, involving generalized atom or bond refractions. The summation of additive refractions has been shown in Table I to be capricious. Moreover, the extrapolation from optical to radio frequencies is unreliable unless the electromagnetic losses (spectral absorption or loss tangent) are known. Unfortunately instruments are not yet available to cover this entire spectral range. Even if these faults of evaluation could be overcome, the actual atom polarization would only be estimated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

as an arbitrary increment to equate electronic to the entire distortion polarization. Indeed the only reliable method (except for the direct measurement of pelletted solids) is the measurement of total polarization for a substance the dipole moment of which is zero. In this instance total and distortion polarization are equal. However, it is shown below that substances of zero dipole moment are uncommon.

POLARIZATIONS OF SUBSTANCES TO WHICH CENTROSYMMETRY OFTEN IS ASCRIBED

Some of the substances described in Table III have been studied because considerations of the graphic formulae (sometimes fortified by X-ray diffraction) would indicate absence of electric moment. Of course these graphic formulae depict unperturbed molecules isolated in space, a circumstance never realized during ordinary chemical reactions. Nevertheless if the activated states and the effects of environment were grossly symmetrical the moments ought to be zero. It may be seen in Table III that this expectation is not realized.

In the case of hexamethylbenzene the answer is dependent on the choice of a distortion polarization value. The calculated electronic polarization happens to be about the same according to either Vogel or Eisenlohr. We suspect by perusal of Table I that this agreement involves a compensation of error. However, the value is so close to that of the total polarization at 20° or 40° that the moment might be specified as zero. On the other hand the measured distortion polarization is sufficiently lower than P_T that a moment of 0.52 D may be assigned. This apparent moment is not sufficiently augmented (0.56 D) at 40° to justify an assignment more definite than 0 to 0.5 D for hexamethylbenzene, depending upon whether measured P_{e+a} or calculated MR_D is used in the calculation.

The situation is somewhat clearer for 1,4-di-*tert*-butylbenzene because both the calculated (P_e) and observed (P_{e+a}) distortion polarizations are less than the total polarization. Since P_{e+a} is lower than MR_D (calculated) there is no justification for inclusion of an abnormal atom polarization with the latter value. The calculated moment of 0.58 D (or 0.4 D in respect of MR_D) in benzene at 20° is augmented to 0.64 D at 40°. This difference (which is beyond our estimated error of ±0.01 D) would indicate that the *tert*-butyl groups comprise an opposed quadrupole in absence of thermal agitation. Therefore at some temperature much below those which must be chosen if benzene is the solvent a zero moment should be observed.

Similarly the orientation polarization of 1,4-diphenylbenzene may be attributed to thermal agitation. The measured P_{e+a} and calculated MR_D differ by about 3%, but they are both lower than P_T in benzene at 20° so a moment of 0.60 to 0.51 D may be calculated, which is 0.73–0.64 D at 40°.

It is evident that substances like these of ostensible zero moment cannot be used for standardization of electrical polarization equipment if they display orientation polarizations. In this connection it is pertinent to review the polarization studies of 1,4-dichlorobenzene which is sometimes considered to be such a standard substance. Thus Briegleb (12) must have observed a total polarization at 20° in heptane of 40.4 cc and an electronic polarization of 36.1 cc, yet he discards the predicted moment of 0.45 D, preferring a hypothetical atom polarization to contradiction of an intuitive expectation of static symmetry. Unfortunately for purposes of clarification we cannot contradict Briegleb by measurement of the dielectric constant of 1,4-dichlorobenzene because its low melting point prevents the preparation of satisfactory pellets. However, we obtain polarization values in benzene and in dioxane from which moments of 0.43 D and 0.33 D, respectively,

may be calculated after substraction of Briegleb's distortion polarization value. This solvent effect would not have been observed if an electrical dipole were absent. Therefore we see no reason to attribute a zero moment to *p*-dichlorobenzene at ordinary temperature nor to consider it as a reference standard, especially since in Table I analogous substances do not show abnormal distortion polarizations. Despite expectations from other studies

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

(18) the four polyhalogenobenzenes listed in the table all have P_{e+a} values which are about 4% lower than the calculated MR_D values.

The high group moments which may be anticipated in these halogenobenzenes makes them of especial interest with respect to studies of molecular symmetry. Among these substances hexachlorobenzene has been examined most completely by other physical methods. Single crystal X-ray diffraction studies show it to be planar (19) although a modern study might alter this opinion, especially in respect of the carbon atoms. Actually it is somewhat surprising that a centrosymmetrical molecule should exist in the polymorphic forms (20) that have been reported for this substance. At any rate when hexachlorobenzene is freed from its crystal lattice the chlorine atoms no longer remain coplanar. A displacement from planarity of about 25° is claimed on the basis of quadrupole moment (21). Indeed displacement is not even symmetrically disposed according to electron diffraction studies (22) which attribute this asymmetry to out-of-phase bending of the carbon–chlorine linkages.

Not only is this asymmetry indicated by our electrical polarization studies, but also the data of Table III show that the moment of hexachlorobenzene in benzene increases from 0.54 D to 0.95 D when the temperature is raised from 20° to 60°. Of course the absolute values of moment are in doubt. Quantitative assignments are precluded because of the disparity between calculated and observed distortion polarizations. Also (Table III) the solvent seems to be involved in the polarization because the apparent moment is smaller (0.2 D) in carbon tetrachloride at 20° than it is in benzene. Nevertheless the moment in carbon tetrachloride seems to be real, because it is augmented to 0.5 D at 30°. But also it cannot be an absolute value if it is temperature-dependent.

Although the lesser moment in carbon tetrachloride may be expected in view of the lesser polarizability of this medium, still one is not justified to specify the observed moment value as absolute. It is true that a substance like iodine displays no orientation in cyclohexane (23), and probably would not do so in carbon tetrachloride. In benzene, on the other hand, a moment is observed which must be due to mutual polarization of solvent and solute (iodine) either of which alone has no dipole moment. But when a solute (like hexachlorobenzene) is polar, at least in activated states, it may be expected to distort and therefore polarize substances like carbon tetrachloride which bound the solvent cavity in which it exists. In this sense the absolute polarity of a substance cannot be defined if it has neighbors. *But the existence of polarity can be defined.* Perhaps solvents like benzene and dioxane should be considered to be useful in enhancement of otherwise meager moments, at least until the time that more precise methods than now are known become available for measurement of electrical polarization.

Despite this limitation on the quantitative significance of the polarization of hexachlorobenzene it seems to be undeniable that this polarization shows it to be a nonplanar substance, the asymmetry of which increases with rising temperature. In order to understand this situation other halogenobenzenes have been examined. The first of these, 1,2,4,5-tetrachlorobenzene, apparently has a moment in benzene at 20° which is larger (Table II) than that of hexachlorobenzene. However, the augmentation of this moment with rising temperature is so slight that it is almost within experimental error. By contrast when methyl groups occupy the hydrogen positions in the tetrachlorobenzene, as in 1,4-dimethyl-2,3,5,6-tetrachlorobenzene, the moment in benzene at 20° is only slightly higher than in absence of these methyl groups. However, this moment is markedly augmented by increasing temperature (see Table III). It would seem that while steric obstruction (minimal in 1,2,4,5-tetrachlorobenzene) is not significantly responsible for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

the inherent moments, it is largely responsible for the temperature-induced polarizability.

Polysubstitution of fluorine instead of chlorine on the benzene ring ought to reduce the steric obstruction, and indeed this expectation is borne out in the polarizability of the hexafluorobenzene kindly supplied to us by Dr. Wall of N. B. S. (24).

As was observed for hexachlorobenzene the apparent moment of the fluoro analogue is lower in cyclohexane than it is in benzene which is ostensibly more polarizable. However, the apparent moments for hexafluorobenzene in either solvent at 20° are higher (Table II) than the comparable values for the hexachloro analogue. This result would not be expected, if the moments were due to static nonplanarity, in view of the evidence (15, p. 253) that the group moment (1.46 D) for C—F is lower than that of C—Cl (1.58). On the other hand the result could be due to a dynamic nonplanarity in activated states. The difference in apparent moment is not great; indeed if one were to choose the admittedly improbable state of activation involving all six halogen atoms on one side of an assumed planar hexagon of carbon atoms the apparent moment would be accounted for by an angular deviation of 3° for the chlorine atoms and 5° for the fluorine atoms. Among the complexity of possible conformations of activation it is possible for the resultant moment of hexafluorobenzene to exceed that of hexachlorobenzene, especially since the lower force constant of the C—F bond would allow greater amplitude of deformation.

Of interest in relation to this concept of moment contributions from such a dynamic "structure" is the observation that the apparent moment of hexafluorobenzene increases by only 0.07 D over a temperature range of 40°. By contrast the apparent moment of hexachlorobenzene (although it is lower than that of hexafluorobenzene at 20° in benzene) increases by 0.41 D over the same range of temperature. This difference might be ascribed to a higher activation energy for hexachlorobenzene (due largely to steric obstruction) which is observed as a greater temperature coefficient for the dipole moment.

This interpretation is based upon the assumption that the activated states are appreciably unsymmetrical and that this asymmetry is accentuated when the activated state tends to be more sterically hindered than the base state. It is of interest to examine the behavior of a substance which undoubtedly is hindered in the base state. This condition prevails in the 1,2-diiodotetrafluorobenzene (25), which we have obtained by courtesy of Dr. Matsuguma at Picatinny Arsenal.

If this substance were entirely coplanar one would expect the moment to be the arithmetic difference between the moments of 1,2-difluorobenzene (2.38 D in benzene at 22°) (26) and of 1,2-diiodobenzene (1.70 D in benzene at 23°) (27). Instead of the expected 0.68 D the apparent moment of 1,2-diiodotetrafluorobenzene in benzene at 20° has been found to be 1.96 D.

Of course an abnormality for this compound is not entirely unexpected since the observed moment for 1,2-diiodobenzene is somewhat lower than the calculated (ref. 15, p. 332) value, 2.25 D. Presumably this diminution may be attributed to steric repulsion of the iodine atoms so that they are spread apart in a planar structure, or else oppositely forced above and below a plane.

It is evident that these deformations are not applicable to the structure of 1,2-diiodotetrafluorobenzene. The high moment would indicate the presence of contributing conformations where fluorine as well as iodine is forced asymmetrically from the plane of carbon atoms assumed to exist in these substituted benzenes. Of course the assumption of ring planarity is arbitrary, but it allows a simple description of conformation in which fluorine–carbon moments are supporting rather than detracting from iodine carbon moments.

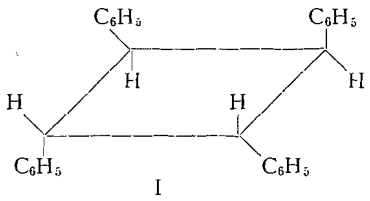
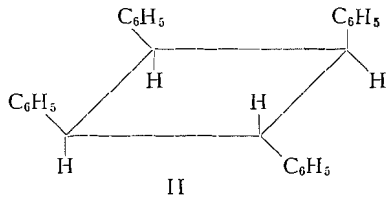
By contrast the observed moment of 1,4-diiodotetrafluorobenzene, in which obstruction may be expected to be minimal, is very low (0.14 D in benzene at 30°), indicating cancellation of opposing group moments. In like manner the 1,4-fluorine atoms in 1,2,3,4-tetrafluorobenzene must be compensatory because the observed moment of this substance (2.43 D) is very close to that of 1,2-difluorobenzene. The absence of obstruction which is indicated by this agreement is further supported by the virtual invariance of moment in benzene at 20° and 30° (2.43 vs. 2.41 D, Table III).



It may be seen from these examples that the effect of iodine atoms vicinally located on a benzene ring in which fluorine atoms prevent lateral spacing is profound. This is the circumstance in 1,2-diiodotetrafluorobenzene with its abnormally high apparent moment. It might be expected that when obstruction is sufficiently great it cannot become greater but must necessarily be less in activated states.

It may then be significant that the apparent moment of 1,2-diiodotetrafluorobenzene, alone among the moments of substances under consideration in this report, decreases slightly but significantly (1.96 to 1.84 D from 20° to 40°) with increasing temperature. The behavior is remindful of certain sterically hindered diastereomers, the moments of which have been studied recently with respect to temperature (28).



THE TETRAPHENYLCYCLOBUTANES

Several of the diastereomers of tetraphenylcyclobutane will now be discussed separately from the foregoing items of Table III because of the rigidity imposed by the cyclobutane ring.

The isomers are 1-↓-2-↓-3-↑-4-↑-tetraphenylcyclobutane, I, and 1-↓-2,3,4-↑-tetraphenylcyclobutane according to Morton, Bright, and Flood, who kindly loaned them to us. They specified these structures on the basis of nuclear magnetic resonance studies (29).

I

II

These workers obtained II (m.p. 149.7°) together with stilbene from the reaction of benzyl chloride with potassium amide in liquid ammonia. The preparation of I (m.p. 163°) had been accomplished by Fulton (30) when he irradiated stilbene and/or stilbamidine with ultraviolet light. Fulton also obtained in trace amounts an isomer melting at 149°. However, this isomer is not identical with II, at least according to comparison of the X-ray pattern of II with that of a sample of Fulton's isomer, kindly furnished to us by Professor Dunitz, University of Zürich. Insufficient material was in hand to determine whether the difference was due to diastereoisomerism or polymorphism. Our studies have been made with the proved isomers I and II.

Actually the configuration of I was demonstrated by Professor Dunitz by a thorough single crystal X-ray study (31). However, he found that the isomer I was not conformationally symmetrical. Not only were abnormalities of bond shortening at C–phenyl observed, but also it appeared that the phenyl rings were not axially disposed with respect to these bonds; deviations up to 7° were suggested.

In this X-ray diffraction study Dunitz did not suggest any nonplanarity of the cyclobutane ring although he did report that the bond lengths differed. Later he and others presented evidence from studies of various cyclobutanes (including electron diffraction and infrared absorption) which indicate a dihedral angle in the cyclobutane ring, which may be as low as 162°. It is of interest that a calculation of the dipole moment of tetramethylcyclobutanedione-1,3, assuming that carbonyl moments of 2.5 D are inclined axially at 162°, gives the same resultant (0.8 D) which was obtained from the measured electrical polarization (3). It is against this background that we have studied the electrical polarizations of the tetraphenylcyclobutanes, I and II.

This study has brought forth several apparent anomalies. Firstly a measurement of the dielectric constant of the randomly oriented compressed solid isomers I and II gives distortion polarization (P_{e+a}) values (109 cc, Table I) which are somewhat below the electronic polarization calculated from Vogel's and Eisenlohr's generalized bond refractions (32, 33) (121.3–114.8 cc). The measured value of 109 cc also is lower than that which may be calculated indirectly (116.5 cc) from the molecular refraction of cyclobutanecarboxylic ester (34).

In Table III it may be seen that the total polarization of isomer I in benzene at 20° is 113 cc. Since all of the values for MR_D are higher than 113 cc a moment calculation from the known refraction values would be absurd.* Therefore we have assumed arbitrarily that the orientation polarization of isomer I is zero, i.e. that the distortion polarization is 113 cc. The moments in other solvents and at other temperatures have been calculated in this way to give "μ from R_D" in Table III. The moments calculated from the measured distortion polarization are shown as "μ from P_{e+a}".

By either calculation it may be seen in Table III that the orientation polarization increases as the temperature is raised. Moreover, it is evident from the profound solvent effect that the moment values are only apparent ones. Nevertheless it seems reasonable to seek an explanation for an average moment of about 0.4 D at room temperature.

An adequate and authenticated explanation has not been found. But since we suspect from Dunitz' X-ray analysis that isomer I is inadequately described by a simple rigid centrosymmetrical structure we have chosen a model in which the cyclobutane ring is symmetrical and planar while the phenyl groups are randomly rotating, their planes at an angle (α) from linearity with the C–phenyl bond. This dynamic model will account for a dipole moment in isomer I.

The magnitude of this moment will depend on the group moment to be assigned to phenyl—C—hydrogen. The group moment for phenylalkyl seems to be 0.3–0.7 D depending upon the alkyl group (15). In consideration of cyclic substances a moment of 0.49 D has been reported for phenylcyclopropane in benzene at 25° (35) while the phenyl–carbon moment of the four methyl-substituted styrenes (36) would appear to be about 0.5 D.

The resultant moment may be calculated according to the relationship

$$\mu = 2(m) \sin \alpha$$

where m is the C–phenyl moment, α is the angular deviation from linearity of the C–phenyl bond and the phenyl plane, and where all phenyl groups are rotating randomly.

*It is of interest that tetraphenylethylene, which resembles tetraphenylcyclobutane in structural character, also would give an absurd value (Table III, −0.69 D) for moment of 20° in benzene if the calculated value of molecular refraction were used. On the other hand the use of the measured distortion polarization (Table II) leads to a real and reasonable value of apparent moment in benzene which is augmented by measurement at 40°.

If m is taken as 0.5 then moments of 0.15 D, 0.30 D, and 0.50 D would require α values of 10, 20, and 30° respectively. It is doubtful that the phenyl groups are inclined at even the smallest of these angles. Either the solvent effect is much greater than would be expected by the usual comparisons of the moments of vapors with those of solutions or else the model which we have assumed for tetraphenylbutane is incorrect. We suggest, as have others mentioned above, that the cyclobutane ring is not rigidly planar.

We have not been able to make a satisfactory calculation for the expected moment if the cyclobutane ring of isomer I is normally bent at a dihedral angle of 160°. However, our attempts do show us that a lesser deviation from C–phenyl linearity would be required than if the cyclobutane ring were planar in order to account for moment magnitudes of 0.1–0.4 D. It would seem that at the present time the experimental results can best be explained by non-planarity of the cyclobutane ring.

It may be seen in Table III that the apparent moments for isomer II are higher than those of isomer I. We have been unsuccessful in attempts to correlate mathematically the two sets of moments. This failure is not unexpected because entirely different sets of activated state conformations would maintain for the two isomers. However, the higher moment values of the ostensibly less symmetrical isomer II, over those of isomer I, show that both isomers are to some extent polar.

The authors wish to thank Mr. G. K. White for aid in the calculations and Dr. Dunitz for submission of samples used for X-ray diffraction studies. The chlorinated benzenes were kindly supplied by Dr. A. L. Rocklin of the Dow Chemical Company and by The Diamond Alkali Company. Funds for technical aid and for equipment have been furnished by the National Research Council to whom we are grateful. The generous co-operation of Dr. M. S. Newman and Dr. L. A. Wall are greatly appreciated.

EXPERIMENTAL

Materials

All of the substances listed in Tables I and III have been purified to constant melting point and in the case of liquids to constant refractive index. The hexachlorobenzene received from Dr. Rocklin was better than 99.5% pure; its Nujol mull absorbed at 3000 (S), 2850 (M shoulder), 1460 (W), 1378 (VW), 1340 (VS), 1297 (S), 930 (VW), 718 (VW), and 694 (S). The substituted styrenes have been purified according to a previous description (37). The tetraphenyl cyclobutanes were pure as received from Dr. Flood but were crystallized from methanol. The 1-↓-2↓-3-↑-4↑-isomer showed a diffraction pattern (CuK_α radiation, Ni filtered) in Angstroms at relative intensities $[I/I_1]$ as follows: [10]-5.34, 4.07[7]3.32[4]5.01[3]3.77[2]9.93, 8.50, 4.79[1]4.25, 3.90, 3.44, 3.16. The 1-↓-2,3,4-↑-isomer gave a pattern of [10]4.73[9]3.88[8]5.06, 3.78[6]5.77[4]9.06[3]3.19[2]10.84, 5.02[1]-3.56, 2.61 in contrast to the isomer of the same melting point (149°) isolated by Fulton (30) and sent to us by Dr. Dunitz. This sample showed [10]4.28[8]5.52[7]4.74[6]4.50[5]-5.86[4]6.96[2]10.35, 9.45, 2.76[1]4.92, 4.15, 4.00, 3.93, 3.56, 3.31.

Dielectric Constant Determinations

The dielectric constants of solids were determined according to methods described previously (2, 3). It has been found that when a binder is necessary for preparation of satisfactory pellets polyethylene wax (10–30 microns diameter) is at least as satisfactory as koroseal. However, a change of crystal habit, effected by recrystallization, usually renders the use of a binder unnecessary. Oftentimes good pellets are obtained by grinding unsatisfactory ones prior to repelletting. By this technique one is assured of random

For personal use only.

orientation of the substance.

The dielectric constants of solutions were determined in the apparatus described previously (38) and also in a modification designed for determination of dielectric constant at a series of temperatures for each solution in order to reduce the time required for determination of temperature coefficients. The test cell was constructed from Corning No. 7740 glass. At the top of the inner concentric electrode was sealed through a Kovar metal rod to which connection could be made internally. On the outside of this electrode was burned in a gold paint (E.I. Du Pont No. 5732) compatible with the pyrex at 550° C. This metal coating which also covered the protruding Kovar rod as a resistance-free conductor was burnished and then polished with rouge (in turpentine) and then talc. The outside concentric electrode (0.7 mm clearance to give 60-pf capacitance when it was 23 mm I.D. by 85 mm long) was equipped at the top with an 8-mm diameter Kovar tube and was coated inside with gold as was described above so that a resistance-free connection could be made to ground from the outside of this metal tube. To the top of this Kovar tube was scaled a "burette" comprised of six 100-mm lengths of capillary tubing (0.8 mm I.D. graduated in millimeters) which were connected together by bulbs of 0.25-ml capacity. The two electrodes were ring-sealed together with an inlet tube at the bottom which terminated into a Kovar tube 0.9 mm O.D. of length sufficient to reach to the bottom of the pear-shaped flask (16–19 mm capacity) used previously for preparation and reference specific volume (at 25° C) of the test solution. A dry ice bath applied to the tapered bottom of this flask served to freeze and thus retain the solution within the test capacitor after it had been forced in by air pressure. If this apparatus were to be constructed again we would use Corning 7052 glass for the electrodes.

The solvent must be frozen and outgassed before use in this apparatus and the solution must finally be heated *in situ* at 5° above the highest temperature of the determination until no more bubbles appear; since at this time the level is slightly below the bottom of the burette the addition of a little more of the non-heated solution is necessary after cooling, but this amount does not supersaturate the test-cell content at the highest temperature of the determination. The temperature is maintained $\pm 0.02°$ by a surrounding jacket (also around the burette) containing refluxing carbon tetrachloride under a standard system for regulating pressure from 760 mm to 10 mm. The reflux system must be surmounted by a dry ice cooled condenser following a water condenser which follows an air condenser. The latter ensures that the refluxing carbon tetrachloride which pours down the jacket surrounding the burette is not too cold. The burette is best read by means of a cathetometer. It is recommended that the apparatus be calibrated by means of a non-aqueous solvent (benzene) since water tends to weaken the gold-glass bond.

Connection between the inner electrode and the resonance circuit of the variable frequency oscillator is made by a vertical threaded rod which meets the Kovar rod inside the electrode end-to-end inside of a close-fitting glass sleeve. The screw feed which advances the threaded rod to make contact is calibrated so as to reproduce inductance and capacitance in this switch and thus to maintain the precision of measurement to ± 0.001 pf.

ISOLATION AND CHARACTERIZATION OF A CELLULOSE FROM THE INNER BARK OF WHITE BIRCH (*BETULA PAPYRIFERA*)[1]

A. Jabbar Mian and T. E. Timell

ABSTRACT

A pectic acid, a 4-*O*-methylglucuronoxylan, and a cellulose have been isolated from the inner bark of white birch (*Betula papyrifera*), in addition to minor amounts of other polysaccharides. The cellulose, which comprised 28% of the bark, yielded only D-glucose on hydrolysis, had a number-average degree of polymerization of 315 and, on methylation and hydrolysis, gave 2,3,6-tri-*O*-methyl-D-glucose and 2,3,4,6-tetra-*O*-methyl-D-glucose in a mole ratio of 59:1. The *O*-methylcellulose had a degree of polymerization of 125, thus suggesting the possibility of branching. Direct nitration of the bark gave a nitrate in a yield corresponding to 28% cellulose in the bark. Light-scattering measurements on this derivative indicated a weight-average degree of polymerization of 7500. While the low intrinsic viscosity of this nitrate did not exclude the possibility of branching, further evidence is needed to establish the linear or non-linear nature of birch bark cellulose.

Although it has been assumed for some time that cellulose is probably present in the inner bark of trees (1, 2), it was only recently that a pure, albeit degraded, cellulose was isolated from spruce bark (3). Since cellulose constitutes the most valuable part of a tree, it was considered to be of a certain interest to establish to what extent it is present in a hardwood bark and whether it is similar to the cellulose present in the wood. In a series of previous investigations (4–6), the isolation and properties of a cellulose from the wood of white birch (*Betula papyrifera* Marsh.) were studied. The present paper is concerned with the constitution and molecular properties of a cellulose from the inner bark (secondary phloem) of the same species.

RESULTS AND DISCUSSION

The inner bark, which had been completely freed from cortex, cambium, and secondary xylem, was exhaustively extracted with organic solvents after which it was treated with hot water and subsequently with aqueous ammonium oxalate for removal of pectic material. Treatment with acid chlorite removed 25% of the extractive-free product. Subsequent extraction with aqueous potassium hydroxide resulted in isolation of a pure xylan (7). Alkaline borate removed a polysaccharide mixture and left a residue which could not be further fractionated and which corresponded to 28% of the bark. The yield and relative composition of the various fractions are given in Table I.

TABLE I

Yield* and carbohydrate composition† of bark fractions

Component	Yield	Galacturonic acid	Galactose	Glucose	Mannose	Arabinose	Xylose

†Percentage of total reducing sugar content of each fraction.
‡In addition to 13% of 4-*O*-methylglucuronic acid.

[1]*Manuscript received March 22, 1960.*
Contribution from the Pulp and Paper Research Institute of Canada and the Department of Chemistry, McGill University, Montreal, Que.

The predominant hemicellulose was a linear, (1 → 4)-β-linked 4-*O*-methylglucuronoxylan, containing on the average one (1 → 2)-α-linked acid side chain per 10 xylose residues. Its number- and weight-average degrees of polymerization were 230 and 470, respectively (7). Water extracted a mixture of polysaccharides. The subsequent fraction consisted of a (1 → 4)-α-linked pectic acid which could not be obtained free from arabinose residues. Alkaline borate removed a polysaccharide mixture, almost half of which consisted of arabinose residues.

The absolute composition of the bark in terms of sugar residues was computed from the total content of reducing sugar (54%) and the various amounts of polysaccharide residues present. The result is given in Table II. The carbohydrate content is considerably higher than that previously reported (8) for the entire bark of the same species, but the relative composition is approximately the same. The directly determined values were also compared with those which could be calculated from the percentage and composition of the various fractions. Except for the galacturonic acid and galactose residues, the agreement is good, thus indicating that the entire polysaccharide portion of the bark had been accounted for in the fractions isolated.

TABLE II

Carbohydrate composition of the extractive-free bark*

Component	Galacturonic acid	Galactose	Glucose	Mannose	Arabinose	Xylose
Found†	2.2	1.1	28	Trace	2.7	21
Calculated‡	5.6	0.6	29	0.2	2.3	23

*Percentage of oven-dry material.
†Found by direct analysis of the bark.
‡Calculated from yield and composition of the fractions.

The residual material, a white powder, was insoluble in aqueous alkali, yielded only D-glucose on hydrolysis, and consumed 1 mole of periodate per glucose residue. Its X-ray powder diagram and infrared spectrum were identical to those of cellulose II. The polysaccharide was methylated to completion and hydrolyzed. The resulting sugar mixture was resolved on a charcoal–Celite column by gradient elution with aqueous ethanol to yield 2,3,6-tri-*O*-methyl-D-glucose (59 parts) and 2,3,4,6-tetra-*O*-methyl-D-glucose (1 part), both of which were obtained crystalline. The number-average degree of polymerization ($\bar{P}_n$) of the *O*-methylcellulose, as determined by osmometry, was 125, thus suggesting the presence of 2.1 non-reducing end groups per average molecule.

The cellulose was converted to its nitrate derivative with an acid mixture known to cause little or no depolymerization of polysaccharides (9, 10). Osmotic pressure measurements on the nitrate indicated a $\bar{P}_n$ value of 315. It is well known that cellulose suffers degradation under the action of both acid chlorite (4) and alkali (11). It was evident therefore that the $\bar{P}_n$ value obtained could hardly represent the molecular weight of the cellulose as it originally occurred in the bark. Direct nitration of wood with the above acid mixture has been shown (12) to result in the isolation of cellulose nitrates in almost quantitative yield, while nitrated pectic acid and hemicelluloses are largely removed. When the extractive-free bark was subjected to a similar treatment, both before and after removal of pectic material, cellulose nitrates were obtained in yields corresponding to 25–28% cellulose in the bark. Denitration, followed by hydrolysis, indicated the presence of glucose and traces of xylose residues. The intrinsic viscosities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

of the nitrates showed that they possessed molecular weights much higher than that of the material remaining after complete extraction of the bark.

The nitrate from the pectin-free bark was subjected to light-scattering measurements in acetone solution, essentially as reported previously (13). The results were evaluated according to Zimm (14) and gave a weight-average molecular weight of 2.17×10^6, corresponding to a degree of polymerization ($\bar{P}_w$) of 7500, and a root-mean-square *Z*-average radius of gyration of 1730 Å. The corresponding values for the cellulose present in the wood of the same species were 2.73×10^6, 9400, and 1770 Å, respectively (13).

It is evident from the isolation of D-glucose and 2,3,6-tri-*O*-methyl-D-glucose that the polysaccharide was a (1 → 4)-linked glucoglycan, and that the 2,3,4,6-tetra-*O*-methyl-D-glucose originated from the non-reducing end groups. Since the polysaccharide did not give any color with iodine, starch was absent. The infrared spectrum suggested the presence of β-pyranosidic bonds (15). The polysaccharide was therefore probably cellulose. This conclusion was corroborated by the fact that its X-ray diffraction pattern coincided with that of cellulose II. Birch bark cellulose apparently has a molecular weight somewhat lower than that of the cellulose in the wood of the same species. The range involved, 7500–9500, is that typical of most native celluloses from various natural sources (16, 17). The yields on nitration agreed excellently with the amount obtained after complete removal of non-cellulosic polysaccharides and also compared well with the known glucose content of the bark. It is probable therefore that the bark contained approximately 28% cellulose. Bark from white spruce has previously (3) been reported to contain at least 16% cellulose.

In a previous study (17), a relationship was developed between the intrinsic viscosity and weight-average degree of polymerization of cellulose nitrates as determined by light scattering. According to this equation, the intrinsic viscosity of the present nitrate (33.0 dl/g at trisubstitution) should correspond to a degree of polymerization of only 4300, much lower than the directly determined value of 7500. This fact suggests the presence of a branched polysaccharide, since a branched macromolecule exhibits an intrinsic viscosity lower than that of a linear polymer of the same molecular weight (18–20). That branching might be involved is also suggested by the fact that the degraded *O*-methylcellulose contained 2.1 non-reducing end groups, corresponding to 1.1 branch points per average molecule.

If branching had occurred, however, the ratio of the root-mean-square radius of gyration to the *Z*-average molecular weight would have been expected to be lower than the value computed (0.90) (18, 21). The evidence is accordingly equivocal and more information is necessary before any statement can be made as to the linear or branched nature of birch bark cellulose. All other native celluloses so far studied have been found to be linear.

EXPERIMENTAL

All specific rotations are equilibrium values and were determined at 20° C unless otherwise stated. Melting points are corrected. Evaporations were carried out *in vacuo* at 40–50° C.

Paper Chromatography

Solvents (v/v) used for separating sugars were (A) ethyl acetate:acetic acid:water (9:2:2), (B) butan-1-ol:pyridine:water (10:3:3), and (C) butanone:water (89:11). Separations were carried out by the descending technique on Whatman No. 1 filter paper and with *o*-aminodiphenyl as the spray reagent (22).

Analytical Methods

The bark was analyzed by standard methods developed for wood (23). A portion of the bark was hydrolyzed to completion (24) and the reducing sugar content of the hydrolyzate was determined by the *o*-aminodiphenyl method (22). Corrections were applied for the different rates of hydrolysis of the sugars (24) and the polysaccharide content was calculated from the relative amounts of the various sugar residues present. The ratios between the sugars present were estimated after quantitative separation by paper chromatography (solvents A and B) (22).

Isolation of the Bark

An autumn-felled specimen of a healthy white birch was immediately immersed in aqueous ethanol for several days after which the outer bark was easily removed. The brown, inner bark was separated manually from the cambium and the wood, was treated with boiling methanol, and was dried in the air. The tree contained 3.8% outer and 10.4% inner bark, based on the oven-dry weight of the trunk. The bark was converted to sawdust and the 20- to 80-mesh fraction was collected. Anal. Klason "lignin", 28.6; pentosan, 26.7; ash, 5.2; uronic anhydride, 6.9; and polysaccharides, 54%. Successive extractions with ethanol–benzene (1:2 v/v), methanol, and acetone removed 3.2, 0.8, and 0.7%, respectively. Water extracted 6.0% of material.

Isolation of Polysaccharides

A detailed description of this isolation has been given elsewhere (7). Treatment of the bark with hot water removed a mixture of polysaccharides corresponding to 1.5% of the extractive-free bark. Further extraction with hot, aqueous 0.5% ammonium oxalate gave 4.5% of a pectic material composed of galacturonic acid together with minor quantities of arabinose. At this point, the residual bark was digested with acid chlorite which removed 25.0% of material, mostly of non-carbohydrate nature. Subsequent extraction with 24% aqueous potassium hydroxide resulted in the isolation of a pure 4-*O*-methylglucuronoxylan (7) in a yield of 26.6%. When the remaining material was extracted with 17.5% sodium hydroxide containing 4.0% boric acid (25, 26), a mixture of polysaccharides was obtained (3.8%). After exhaustive washing with alkali and water, the remaining portion was acidified with dilute acetic acid and was washed until neutral with water and then with ethanol and petroleum ether (b.p. 30–60° C). Drying *in vacuo* over potassium hydroxide yielded a white powder, corresponding to 28.4% of the extractive-free bark. The yield and composition of each fraction are given in Table I.

Characterization of the Cellulose

The infrared spectrum of the cellulose showed a maximum at 886 cm^{-1}, indicative of the presence of β-pyranosidic bonds (15).

A portion of the cellulose (1.0 g) was hydrolyzed to yield a sirup (0.9 g). Paper chromatography (solvents A and B) indicated the presence of glucose and a faint trace of xylose. On standing, the sirup crystallized, $[\alpha]_D$ +53° (*c*, 5.3 in water), m.p. and mixed m.p. 144–145° C. The *p*-nitroaniline derivative had a melting point of 182° C (27).

The X-ray powder diagram was determined with a Seifert X-ray unit. The radiation used was nickel-filtered Cu K_α. The following interplanar lattice spacings (Å) were obtained: 4.2 (s), 3.0 (w), 2.5 (w), and 2.3 (w). An authentic sample of cellulose II had the following distances: 4.1 (s), 3.1 (w), 2.6 (w), and 2.2 (w). Both diagrams were in accord with published data (28).

Periodate Oxidation of the Cellulose

Dry cellulose (150 mg) was dispersed in 0.05 *M* sodium metaperiodate (50.0 ml) and shaken in the dark at +30° C for various lengths of time. The consumption of periodate was determined by the excess arsenite method. The following moles of oxidant were consumed per glucose residue (days): 0.79–2, 0.89–3, 1.02–5, 1.04–7, 1.05–8, 1.06–9, 1.07–10. Extrapolation of the later part of the conversion–time curve to zero time gave the consumption of periodate, 1.00±0.02 moles per glucose residue.

Methylation of the Cellulose

Cellulose (20 g) was dispersed in 40% (w/w) aqueous sodium hydroxide (400 ml) in an atmosphere of nitrogen, and dimethyl sulphate (250 ml) was added dropwise over a period of 20 hours. This process was repeated three times. Solid sodium hydroxide (200 g) was added, followed by dimethyl sulphate (dropwise, 250 ml). This treatment was repeated nine times, water being added whenever necessary for efficient stirring. The mixture was neutralized with concentrated sulphuric acid to pH 4, diluted, and heated to 90° C. The precipitated, partly methylated cellulose was recovered by filtration, washed with hot water, and dried *in vacuo* to give a hard powder (17.5 g).

The product was dissolved in dry dimethyl formamide (250 ml) and treated with methyl iodide (50 ml) and silver oxide (50 g) at room temperature for 24 hours (29). This process was repeated three times. The solid residue was exhaustively extracted with chloroform and the resulting suspension was centrifuged. The chloroform solution was then washed with 5% aqueous potassium cyanide (29) and water. After drying over anhydrous sodium sulphate, the solution was concentrated to 200 ml and added slowly to petroleum ether (1.5 liters). The precipitate formed was recovered by filtration, washed with petroleum ether, and dried to yield a white powder (10.2 g). Anal. Calc. for a fully methylated cellulose: $[C_6H_7O_2(OCH_3)_3]_n$: OCH_3, 45.6%. Found: OCH_3, 44.5%.

Three further methylations according to Purdie (30) failed to increase the methoxyl content of the product (31). Its infrared diagram suggested the presence of hardly any hydroxyl groups.

Methanolysis and Hydrolysis of the Methylated Cellulose

A portion of the methylated cellulose (3.0 g) was boiled under reflux with 0.7 *N* methanolic hydrogen chloride (75 ml) for 7 hours. The methanol was partly evaporated and the residue was boiled under reflux with *N* hydrochloric acid (75 ml) for 7 hours. After neutralization with silver carbonate, filtration through Celite, treatment with hydrogen sulphide, and filtration, evaporation gave a sirup (2.8 g). Paper chromatography (solvent C) suggested the presence of a trace of a di-*O*-methylhexose, a tri-*O*-methylhexose, and a small amount of a tetra-*O*-methylhexose.

Separation of the Methylated Glucoses

A portion of the methylated sugar mixture (0.90 g) was added to the top of a Darco G-60 charcoal–Celite (1:1 w/w) column (3.5×55 cm) (32) and resolved by gradient elution (33, 34) with 3 liters each of 5% aqueous ethanol → 25% ethanol and 25% ethanol → 40% ethanol. Fractions, 25 ml each, were collected at a rate of 50 ml/hr. Every third fraction was examined by paper chromatography (solvent C). Only two main fractions were obtained, a tri-*O*-methylglucose (790 mg) and a tetra-*O*-methylglucose (14.7 mg).

*Identification of 2,3,6-Tri-O-methyl-*D*-glucose*

This fraction, the first to be eluted from the column, crystallized spontaneously. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

recrystallization from ethyl ether, the melting point was 119–120° C, undepressed on admixture with an authentic sample of 2,3,6-tri-*O*-methyl-D-glucose, $[\alpha]_D$ +68° (*c*, 2.0 in water) (35).

Identification of 2,3,4,6-Tetra-O-methyl-D-glucose

On recrystallization from petroleum ether, this fraction had a melting point of 54–55° C (36), $[\alpha]_D$ +25° → +82° (equilibrium, *c*, 1.0 in water).

Nitration of the Cellulose

Dry cellulose (31.0 g) was added in small portions and with vigorous stirring to a mixture of nitric acid, phosphoric acid, and phosphorous pentoxide (64:26:10, w/w) (11) cooled to −5° C. The reaction was allowed to proceed in the dark at +17° C for 1.5 hours (12). After removal of most of the acid mixture by filtration through fritted glass, the nitrated product was washed with ice water until neutral and then with methanol. Drying *in vacuo* gave a white powder (46.5 g, 88%) with a nitrogen content (37) of 13.10%, corresponding to a degree of substitution of 2.61.

Determination of the Number-Average Molecular Weight of the Methylated and Nitrated Celluloses

Osmotic pressure measurements were carried out at +30° C as described previously (38) with modified (39) Zimm–Myerson (40) osmometers and gel cellophane membranes. The solvent for the methylated cellulose was a 9:1 mixture (v/v) of chloroform and ethanol and for the nitrate, *n*-butyl acetate. The results are summarized in Table III.

TABLE III

Isolation of Cellulose by Direct Nitration of the Bark

Dry birch bark (20.0 g), previously extracted with hot water and aqueous ammonium oxalate, was treated with the nitrating mixture referred to above (400 g) at +17° for 5 hours. Most of the acid mixture was removed by filtration and the solid residue was washed immediately with a 1:1 mixture of acetic acid and water cooled to −16° C (4 liters). The product was washed successively with water, with saturated sodium bicarbonate, with 10% aqueous acetic acid, and finally with water until the filtrate was neutral. A part of the nitrated, non-carbohydrate material was removed by extraction with methanol. The residue was dissolved in acetone (2 liters) and solid material was removed on the centrifuge. The clear solution was poured into water and the precipitate was washed with water and methanol and dried *in vacuo* at room temperature to give a white, fibrous material (A, 9.3 g, 25.0%). Nitrogen content: 13.73%, corresponding to a degree of substitution of 2.84.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

A similar treatment of the extractive-free bark before removal of pectic material (20.0 g) gave a similar cellulose nitrate (B, 8.8 g, 26.0%). Nitrogen content: 13.72%. Nitration of the same product for 24 hours gave a nitrate in a yield of 28.1%.

A portion of nitrate A was treated with 20% ammonium hydrosulphide at room temperature for 7 hours (41). The denitrated product was hydrolyzed and examined by paper chromatography (solvents A and B). Only glucose and traces of xylose residues were present.

Determination of the Intrinsic Viscosity of the Cellulose Nitrates

The instrument used was a Craig–Henderson viscometer (42). The temperature was +30° C and the solvent was *n*-butyl acetate. Measurements were carried out as described previously (17). No corrections were applied for shear dependence. The logarithm of the relative viscosities, when plotted against concentrations, gave linear relationships which were extrapolated to zero concentration to yield the intrinsic viscosities. The values obtained were 28.5 and 24.6 dl/g (nitrates A and B), corresponding to 33.0 and 28.1 dl/g at trisubstitution (43).

Determination of the Weight-Average Molecular Weight of Cellulose Nitrate A

Light-scattering measurements were carried out essentially as described previously (13). The solvent was freshly redistilled acetone, b.p. 56.3–56.8° C. After ultracentrifugation at 140,000 *g* for 3 hours, the polymer solution (0.1%) was transferred to a light-scattering cell especially designed for eliminating both floating and sedimenting debris (44). The cell was subjected to ultracentrifugation at 35,000 *g* for 1 hour and then transferred directly to the photometer, a Brice–Phoenix instrument which had been considerably modified (46). Scattering intensities were measured at angles from 35° to 135° relative to the incident beam and at different concentrations. The refractive index increment had previously been estimated as 0.105 ml/g (21). Concentrations were determined by precipitating several aliquots of the original solution into water. The fibrous precipitate was washed with water and methanol and dried *in vacuo* at +60° C for 3 hours.

Zimm plots (14) were obtained in the usual way by plotting Kc/R_θ versus $\sin^2\theta/2 + 2000c$ where $K = 2\pi^2 n_0^2 (dn/dc)^2 N\lambda^4$ and the symbols have their usual significance (21). The weight-average molecular weight, $\bar{M}_w$, was obtained from the relationship

$$\bar{M}_w = 1/(Kc/R_\theta)_{c,\theta=0}.$$

The corresponding degree of polymerization, $\bar{P}_w$, was calculated from the relationship $\bar{P}_w = \bar{M}_w/M_r$ where M_r was the molecular weight of the nitrated glucose residue (290). The root-mean-square *Z*-average radius of gyration, $\sqrt{\bar{s}_z^2}$, was computed from the initial slope of the $c = 0$ line in the Zimm plot according to the relationship (21)

$$\frac{\text{initial slope}}{\text{intercept}} = (16\pi^2/3).\ \bar{s}_z^2(n_0/\lambda)^2.$$

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Dr. D. A. I. Goring and Dr. R. St. J. Manley for valuable help. They are also thankful to Mr. W. L. Steyn, who carried out the light-scattering measurements. Financial support from the National Research Council of Canada is gratefully acknowledged.

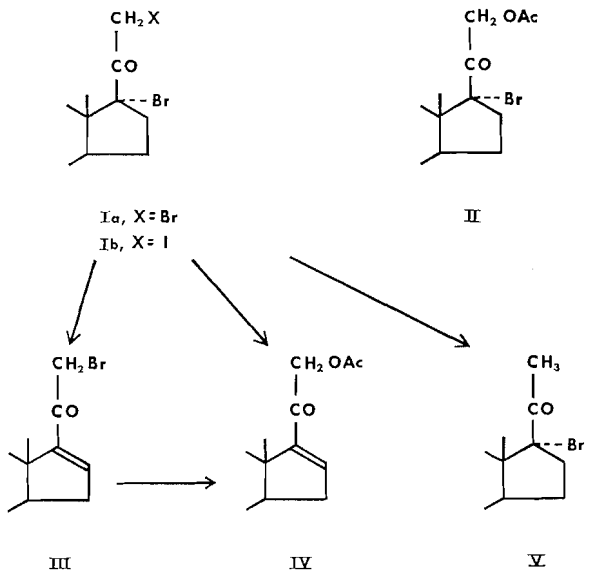
STEROIDS AND RELATED PRODUCTS

XIV. THE SYNTHESIS OF 17α-HALOGENATED 20,21-KETOLS OF THE CORTICOID TYPE[1, 2]



CH. R. ENGEL, R.-M. HOEGERLE,[3] AND R. DEGHENGHI

ABSTRACT

In continuation of previous work, the hindering effect of 17α-substituents on replacement reactions in position 21 of the steroid molecule was further studied. It is shown that the impossibility of replacing a 21-halogen substituent by an acetoxy group in the presence of a bromine atom in position 17α is due both to a steric effect of the bulky 17-substituent and to its facile elimination. It is further shown that the replacement reaction in 21 may be carried out in the presence of the smaller and less readily eliminated 17α-chlorine substituent. In connection with these investigations, 17α-chloro-11-dehydrocorticosterone, the 17-chloro analogue of cortisone, was synthesized. The introduction of a chlorine atom into position 17 lowers the glucocorticoid activity.

In a recent publication of this series (2) we reported the synthesis of 17α-bromo-11-dehydrocorticosterone, the first 17-halogenated glucocorticoid. In that synthesis, the halogen substituent was introduced subsequent to the elaboration of the ketol side chain.

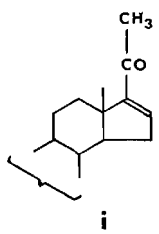
At first sight it would have appeared attractive to transform a readily available 17,21-dihalogenated 20-ketone (compare partial formula I) to a 17-bromo-21-acetoxy ketone (compare II) by the classical reaction with an alkali acetate. However, it was known from earlier work by Plattner, Heusser, and Angliker (3) that treatment of a 17,21-dibromo-20-ketone (I*a*), with potassium acetate in acetic acid, led predominately

to elimination of hydrogen bromide in positions 16–17, without replacement of the 21-bromine atom (compare III). The elimination of hydrogen bromide from a tertiary

[1]*Manuscript received March 21, 1960.*
Contribution from the Department of Chemistry, Laval University, Quebec, Que. Some of the results reported in this paper were included in a communication presented before the 4th International Congress of Biochemistry, Vienna, September, 1958; other results were in a paper presented before the 17th Congress of the French-Canadian Association for the Advancement of Science, Montreal, October, 1959.
[2]*For paper* XIII *of this series see reference 1.*
[3]*N.R.C. Postdoctorate Fellow, 1958–59.*

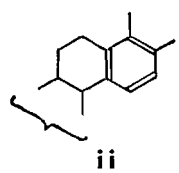
bromide, in conjugation with a carbonyl group, is of course easily understood. On the other hand, it seems plausible to assume that in the presence of as bulky a 17-substituent as a bromine atom, the replacement of the halogen group in 21, by acetate, should present considerable difficulties, since it is known that a 17-methyl group seriously hinders reactions in this position (4–8). Plattner and co-workers (3) showed that an unsaturated bromide of type III can be converted to the 21-acetate by treatment with potassium acetate in acetic acid, in the presence of acetic anhydride, and that a 17,21-dibromide (compare I*a*) can be transformed, under analogous conditions, directly but in low yield to the same unsaturated ketol acetate (compare IV). It seems reasonable to assume that in this reaction the unsaturated bromide (compare III) is an intermediate and, hence, that the dehydrobromination precedes the substitution in 21.[4]

In the course of the present study, we investigated the reaction of an iodo bromide of type I*b* [17α-bromo-21-iodo-3α-acetoxy-11,20-dioxopregnane (I*c*, see Experimental)] with potassium acetate in boiling acetone. After 1 hour, the starting material was recovered practically unchanged, which seems in accord with the assumption that the bulky 17-bromine substituent hinders the replacement reaction in 21. After prolonged treatment, reduction of the 21-iodine substituent occurred, leading to the 17α-bromo-21-methyl-20-ketone (compare V), as well as partial elimination of hydrogen bromide, evidenced by the Δ^{16}-20-ketone chromophore detected in the mother liquors of the reaction product. Absolutely no replacement of the halogen in 21 by an acetoxy group had taken place.



In summary, the 21-halogen atom of a 21-halo-20-ketone cannot be replaced by an acetoxy group in the presence of a 17α-bromine substituent (with preservation of the latter), because of both the steric effect of the bulky 17-bromine substituent and competing reactions.

We considered that the situation would be different in the case of a 17α-chlorine substituent. Indeed, the smaller chlorine atom should exert a smaller steric effect and should not lend itself with the same ease to an elimination reaction as a bromine substituent.



In order to prove this assumption, we subjected 21-bromo-17α-chloro-3α-hydroxy-11,20-dioxopregnane (XI) to the action of potassium acetate in the presence of potassium iodide; as we had expected, the 21-acetoxy-17-chloro-20-ketone IX was formed without difficulty. We thus established further evidence of the fact that a bulky group in position 17 hinders reactions in position 21.[5]

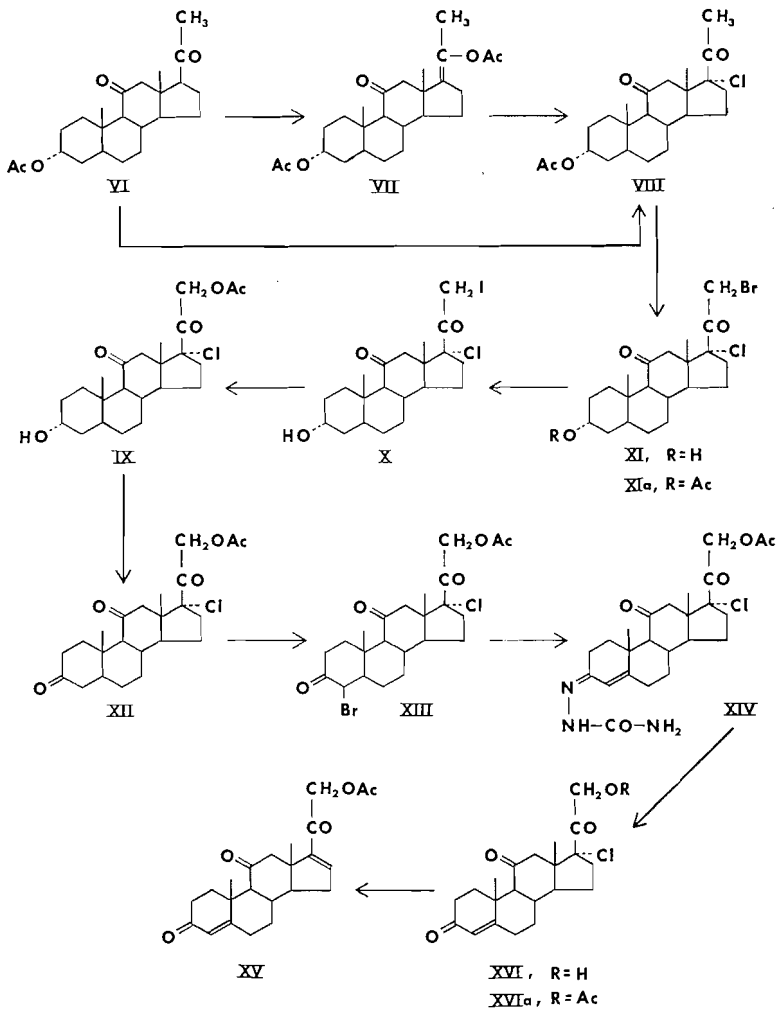
The 21-bromo-17-chloro-20-ketone XI employed in this reaction was readily obtained from 3α-acetoxy-11,20-dioxopregnane (VI).[6] Whereas the 17α-chloride VIII can be

[4]*When a 17-bromo-21-iodo ketone (compare Ib) is treated with silver acetate in pyridine, in the presence of acetic anhydride—conditions which allow the replacement of a 21-iodine substituent by an acetoxy group in the presence of a 17-methyl group (compare 7 and 8)—reduction in position 21 occurs, the reaction leading to a mixture composed of a Δ^{16}-20-ketone (compare i) and an aromatic rearrangement product of type ii (6).*

i

ii

[5]*It should be pointed out that even in the presence of a relatively small hydroxy substituent in position 17, the substitution in 21 proceeds less readily than in the case of a 17-unsubstituted product (compare for instance 9).*



[6]*We are indebted to the Schering Corporation, Bloomfield, New Jersey, for the generous gift of this starting material.*

For personal use only.

produced by direct chlorination of VI, a much better product was obtained by chlorination of the monoenol acetate VII. We synthesized the latter product, previously described by Anderson *et al.* (10), either by reaction of VI with isopropenyl acetate and sulphuric acid followed by chromatography, or, even more conveniently, by Barton's method (11) with acetic anhydride and perchloric acid. Using the latter procedure both geometric isomers of VII were isolated.[7]

The 17-chloro-20-ketone VIII was readily brominated in 21 (XI*a*), with molecular bromine in acetic acid, at 60°.[8] Hydrolysis of the acetate with perchloric acid in methanol (12 and 13) gave the 3-hydroxy chloro bromide XI, which, as stated above, can be transformed in good yield to the corresponding 21-acetate IX.

Since our group has been interested for some time in the influence of the chemical nature of the 17α-substituent on hormonal activities (compare, for instance, 1, 2, 7, 13, 14, 15, 16, 17, 18), we considered it attractive to convert the 17α-chloro-21-acetoxy-20-ketone IX to the 17-chloro analogue of cortisone (XVI). The synthesis followed classical

[7]*In our hands the method of Anderson et al. (10) for the preparation of* VII *from* VI, *using acetic anhydride and an acid catalyst in toluene, gave unsatisfactory results.*

[8]*We established in preliminary experiments that bromination in chloroform was not satisfactory.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

lines. Oxidization of IX with chromic acid and sulphuric acid (19, 20) gave the triketone XII which was transformed via the 4-bromide XIII and the semicarbazone XIV (compare 21) to the 4-unsaturated acetate XVI*a*, readily hydrolized with perchloric acid in methanol (12, 13) to 17α-chloro-11-dehydrocorticosterone (XVI). The free alcohol XVI was easily reacetylated to XVI*a* and the position of the chlorine substituent was proved by conversion of the latter, with dimethylformamide and potassium iodide, to 17-anhydrocortisone acetate (XV) (22).[9] The α-configuration of the 17-substituent was assumed in analogy with the proved configuration of the corresponding bromides (compare 23).

It is of interest to note that 17α-chlorination of a 20-ketone causes a marked levorotatory shift, which is, however, not quite as pronounced as the one brought about by 17-bromination (1, 2, 13, 24). In Table I we have computed representative molecular rotational differences produced by various substitutions of 20-ketones in position 17; values for hydroxy, methyl, chlorine, and bromine derivatives are given. It can be seen that all these substitutions lead to a levorotatory shift and that the strength of the effect increases in the order in which the substituents are mentioned above.

TABLE I

Molecular rotational differences of 17α-substituted 20-keto steroids[a]

Product	$[M]_D$	$[M]_D^{17\alpha\text{-der.}} - [M]_D^{17\alpha\text{-H}}$
3α-Acetoxy-11,20-dioxopregnane	495°[b]	
	455° (acetone)[c]	
17α-Hydroxy-	330° (acetone)[d]	−125° (acetone)
17α-Chloro-	85°[e]	−410°
17α-Bromo-	5°[f]	−490°
3α-Hydroxy-21-acetoxy-11,20-dioxopregnane	425° (acetone)[g]	
17α-Hydroxy-	320° (acetone)[h]	−105°
17α-Chloro-	50°[e]	−375°[p]
17α-Bromo-	20°[f]	−405°[p]
21-Acetoxy-3,11,20-trioxopregnane	425°[h]	
	405° (acetone)[i]	
17α-Hydroxy-	335° (acetone)[j]	−70° (acetone)
17α-Methyl-	185°[k]	−240°
17α-Chloro-	65°[e]	−360°
17α-Bromo-	0°[f]	−425°
Δ^4-21-Acetoxy-3,11,20-trioxopregnene	925°[l]	
17α-Hydroxy-	860°[m]	−65°
17α-Methyl-	680°[k]	−245°
17α-Chloro-	440°[e]	−485°
17α-Bromo-	435°[f]	−490°
Δ^4-21-Hydroxy-3,11,20-trioxopregnene	890° (EtOH)[n]	
17α-Hydroxy-	760° (EtOH)[o]	−130°
17α-Methyl-	625°[k]	−265°[p]
17α-Chloro-	535°[e]	−355°[p]
17α-Bromo-	360°[f]	−530°[p]

[a]The molecular rotations were calculated to the nearest 5°. When not otherwise specified, rotations were taken in $CHCl_3$. [b]Means of values reported in references 25 and 26. [c]Reference 27. [d]Reference 28. [e]Experimental. [f]Reference 2. [g]Reference 29. [h]Reference 30. [i]Reference 31. [j]Means of values given in references 28 and 32. [k]Reference 15. [l]Reference 33. [m]Reference 34. [n]Reference 35. [o]Means of values given in references 34 and 36. [p]The values can only be considered as indicative because comparisons were made between rotations in different solvents.

Dr. P. Perlman and Dr. S. Tolksdorf of Bloomfield, New Jersey, kindly tested the new hormone analogue XVI and its acetate XVI*a* in their eosinophil assay and found that the products had the same order of activity as their bromo analogues (2). A detailed account of the biological investigations is to be published elsewhere. The preliminary

[9]*We wish to thank sincerely Dr. S. Bernstein for kindly providing us with an authentic sample for comparison.*

results confirm that the electronegativity of the 17α-substituent is not, at least to an appreciable extent, an enhancing factor of glucocorticoid and related corticoid activities (compare 2).[10]

EXPERIMENTAL[11, 12, 13]

Reaction of 17α-Bromo-21-iodo-3α-acetoxy-11,20-dioxopregnane (Ic) *with Potassium Acetate in Acetone*

(*a*) A quantity of 1.5 g of 17α,21-dibromo-3α-acetoxy-11,20-dioxopregnane was transformed in the usual fashion to 17α-bromo-21-iodo-3α-acetoxy-11,20-dioxopregnane (Ic) (compare the procedure described in reference 3), by treatment with 0.5 g of sodium iodide in 150 cc of boiling acetone. To the cooled solution was added potassium acetate, freshly prepared from 6 g of potassium bicarbonate and 3.5 cc of acetic acid, and the mixture was refluxed under nitrogen for 1 hour. The volume of the solution was reduced *in vacuo* and the organic product was precipitated in water. The mixture was extracted with dichloromethane, the organic solution was washed with water and was dried over sodium sulphate. Removal of the solvent gave 1.6 g of almost colorless crystals, m.p. 163–170° decomp.; the melting point was not depressed upon admixture of iodide Ic. The product gave a positive iodine test and the infrared spectrum corroborated the identity of the product with iodide Ic.

(*b*) A quantity of 1.485 g of 17α,21-dibromo-3α-acetoxy-11,20-dioxopregnane was transformed with 1.5 g of sodium iodide in 250 cc of acetone to the bromo iodide Ic. To this solution, potassium acetate, freshly prepared from 12 g of potassium bicarbonate and 7 cc of acetic acid, was added and the mixture was refluxed for 24 hours. The colorless solution (which had been yellow at the beginning of the reaction) was cooled and poured into cold water. The precipitate was extracted with dichloromethane, the organic layer was washed with water and dried over sodium sulphate. Removal of the solvent gave 1.4 g of an oil which, upon crystallization from dichloromethane–ether–hexane, gave 350 mg of colorless crystals, m.p. 150–155° decomp. Recrystallization from ether raised the melting point to 156–158° decomp. The infrared spectrum of the product was identical with that of authentic 17α-bromo-3α-acetoxy-11,20-dioxopregnane (15) and the mixed melting point showed no depression upon admixture of authentic material.

The mother liquors of the crystallized product showed in the infrared the typical absorption of a Δ^{16}-20-ketone ($\nu_{max}^{CHCl_3}$ 1592 and 1665 cm^{-1}) and no absorption band attributable to a 21-acetoxy group.

$\Delta^{17(20)}$-3α,20-Diacetoxy-11-oxopregnene (VII)

(*a*) A solution of 1.5 g of 3α-acetoxy-11,20-dioxopregnane (VI) in 5 cc of isopropenyl acetate was refluxed for 2 hours with 0.1 cc of concentrated sulphuric acid. The mixture was cooled and extracted with ether; the ethereal solution was washed with sodium bicarbonate solution and with water and was dried over sodium sulphate. The solvent was removed and the product (1.6 g) was chromatographed on 50 g of aluminum oxide

[10]*Drs. H. L. Herzog, M. Jevnik Gentles, H. M. Marshall, and E. B. Hershberg informed us of their independent synthesis of 17α-chloro-11-dehydrocorticosterone acetate* (XVIa) *by a different route. It was agreed that their article should appear in the Journal of the American Chemical Society simultaneously with the present one in this journal.*

[11]*The melting points were taken in the evacuated capillaries and the temperatures were corrected.*

[12]*The microanalyses were performed by Dr. O. Schwarzkopf, New York, N.Y., and by Dr. Alfred Bernhardt, Mülheim (Ruhr). We wish to express to them and their associates our sincere appreciation.*

[13]*For chromatography we used Davison's silica gel No. 923, Woelm's aluminum oxide, activity* II–III, *and Merck's aluminum oxide treated as described under footnote 31 of reference 7. We wish to thank Merck and Co., Montreal, for a generous gift of this material.*

For personal use only.

(pH 6.5). Petroleum ether – benzene mixtures eluted 500 mg of the enol diacetate VII, m.p. 99–110°. Benzene eluted 600 mg of starting material (VI), m.p. 124–126°, not depressed upon admixture of authentic VI; the product was further identified by comparison of the infrared spectra. Considering the recovery of the starting material, the yield of VII from VI was 55%.

A portion of the enol diacetate VII was recrystallized four times from acetone–hexane for analysis: silky needles, m.p. 127.5–129.5°, $[\alpha]_D^{26}$ +56° (*c*, 1.0 in $CHCl_3$), ν_{max}^{KBr} 1220, 1245 cm^{-1} (acetates), 1695 cm^{-1} (11-ketone), 1722 and 1730 cm^{-1} (shoulder) (acetates); positive tetranitromethane reaction. Anal. Calc. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 71.99; H, 8.68.

(*b*) To a solution of 2 g of 3α-acetoxy-11,20-dioxopregnane (VI) in 30 cc of carbon tetrachloride were added 10 cc of acetic anhydride and 0.4 cc of 50% perchloric acid. The mixture was stirred for 1.5 hours at room temperature and the resulting solution was diluted with dichloromethane and was washed with cold sodium bicarbonate solution and with water. After drying, the solvent was removed and the resulting amorphous product (2.605 g) was chromatographed on 75 g of aluminum oxide (pH 6–6.5). Petroleum ether – benzene (1:1) eluted 1 g of crystalline VII, m.p. 125–126°, identical with the product described under (*a*). The following fractions (150 mg) were amorphous. Petroleum ether – benzene (1:4) eluted 300 mg of a second crystalline substance, m.p. 126–130°, depressed upon admixture of both VI and VII; $\nu_{max}^{CHCl_3}$ 1258 cm^{-1} (acetate), 1715 cm^{-1} (11-ketone), 1730 and 1735 cm^{-1} (3α- and 20-acetates). The crude crystalline product which gave a positive tetranitromethane reaction was analyzed for its acetyl contents. Anal. Calc. for $C_{25}H_{36}O_5$: CH_3CO, 20.67. Found: CH_3CO, 17.87. We considered this product to be the geometric isomer of VII and proved its structure by the following reaction. To a solution of 277 mg of this substance in 10 cc of carbon tetrachloride was added 90 mg of N-bromosuccinimide and the mixture was refluxed over a photoflood lamp for 10 minutes. The usual working up afforded 271 mg of a yellow oil which gave, upon filtration through 10 g of silica gel, 200 mg of crystalline *Δ¹⁶-3α-acetoxy-11,20-dioxopregnene*, m.p. 149–152°, not depressed upon admixture of an authentic sample; the infrared spectrum of the product was identical with that of an authentic sample. The formation of the Δ¹⁶-20-ketone in the reaction confirms that the second crystalline product isolated from the enol acetylation reaction was the geometric isomer of VII.[14]

The benzene–ether–methanol fractions of the original chromatogram consisted of 420 mg of starting material VI. Considering the recovery of starting material, the yield of the enol acetates was 83%.

17α-Chloro-3α-acetoxy-11,20-dioxopregnane (VIII)

(a) From the 11,20-Diketone VI

To a solution of 2 g of 3α-acetoxy-11,20-dioxopregnane (VI) in 20 cc of acetic acid was added, dropwise and with stirring, 52.2 cc of a 0.205 *N* solution of chlorine in acetic acid. The mixture was stirred for another 10 minutes and poured into ice water. The precipitate was filtered, washed to neutral, and dried. The colorless solid (2.05 g), m.p. 80–95°, was recrystallized from ether and thus gave 60 mg of a chlorinated product, m.p. 152–160°, $[\alpha]_D^{26}$ +72.6° (*c*, 1.0 in $CHCl_3$), representing probably the 17,21-dichloride.

The mother liquors of this crystallization were chromatographed on 60 g of aluminum oxide (pH 7). Petroleum ether – benzene (1:1) eluted 450 mg (20%) of monochloride VIII, m.p. 130–142°. After one recrystallization from ether, the product melted at 141–144°,

[14]*Compare reference 37.*

For personal use only.

$[\alpha]_D^{26}$ +25.4° (*c*, 1.1 in $CHCl_3$). The melting point was not depressed upon admixture with authentic VIII (see below); the infrared spectra of the two samples were identical.

Benzene–ether (4:1) eluted 320 mg of crude crystalline Δ^{16}-3α-acetoxy-11,20-dioxopregnene, identified by its infrared spectrum and mixed melting point with an authentic sample. The ethyl acetate fractions gave 270 mg of crystalline Δ^{16}-3α-hydroxy-11,20-dioxopregnene, m.p. 180–195°, identified by infrared comparison and mixed melting point with an authentic sample.

(b) From the Enol Diacetate VIII

To a solution of 1.45 g of $\Delta^{17(20)}$-3α,20-diacetoxy-11-oxopregnene (VII), m.p. 102–117°, in 60 cc of acetic acid was added, at room temperature, dropwise and with stirring, 38.5 cc of a 0.183 *N* solution of chlorine in acetic acid. The colorless mixture was poured into ice water, and the precipitate was filtered, washed to neutral, and dried. The product (1.401 g) was recrystallized from ether and gave 1.2 g of monochloride VIII, m.p. 137–140° (84% yield). The melting point was raised upon one recrystallization to 147–149°. A sample was recrystallized once for analysis: needles, m.p. 150–151°, $[\alpha]_D^{25}$ +20.5° (*c*, 1.02 in $CHCl_3$), ν_{max}^{KBr} 1245 cm^{-1} (acetate), 1708 cm^{-1} (11-ketone), 1735 cm^{-1} (broad band) (acetate and 20-ketone). Anal. Calc. for $C_{23}H_{33}O_4Cl$: C, 67.55; H, 8.13; Cl, 8.67. Found: C, 67.22; H, 8.00; Cl, 8.59.

21-Bromo-17α-chloro-3α-acetoxy-11,20-dioxopregnane (XI*a*)

A solution of 650 mg of 17α-chloro-3α-acetoxy-11,20-dioxopregnane (VIII), m.p. 147–149°, in 10 cc of acetic acid, containing 2 cc of a 20% hydrogen bromide solution in acetic acid, was heated to 60°. To this mixture, a solution of 255 mg of bromine in 16 cc of acetic acid was added, dropwise and with stirring, in the course of 15 minutes. Subsequently, the almost colorless solution was poured into ice water, the precipitate was filtered, washed to neutral, and dried. The resulting colorless product (822 mg) was recrystallized from ether to give 490 mg (63% yield) of bromide XI*a*, m.p. 170–174°. A sample was recrystallized three times for analysis: needles, m.p. 183–184°, $[\alpha]_D^{26}$ +35° (*c*, 0.411 in $CHCl_3$), ν_{max}^{KBr} 1260 cm^{-1} (acetate), 1700 cm^{-1} (11-ketone), 1718 cm^{-1} (broad band) (21-bromo-20-ketone and acetate). Anal. Calc. for $C_{23}H_{32}O_4BrCl$: C, 56.62; H, 6.61; Br, 16.38; Cl, 7.27. Found: C, 56.62; H, 6.84; Br, 16.28; Cl, 7.26.

21-Bromo-17α-chloro-3α-hydroxy-11,20-dioxopregnane (XI)

A quantity of 460 mg of 21-bromo-17α-chloro-3α-acetoxy-11,20-dioxopregnane (XI*a*), m.p. 170–174°, was suspended in a solution of 1 cc of 70% perchloric acid in 39 cc of methanol. The mixture was shaken for 22 hours at room temperature. During that time the product dissolved gradually. Subsequently, the solution was poured into an ice-cold sodium bicarbonate solution and the precipitate was extracted with dichloromethane. The organic solution was washed with water and dried over sodium sulphate. The solvent was removed *in vacuo* and the colorless residue (420 mg) was crystallized from ether. There was obtained 285 mg of small prisms, m.p. 160–162°. A sample was recrystallized twice from ether–acetone–hexane for analysis: m.p. 167–169°, $[\alpha]_D^{26}$ +20.4° (*c*, 0.756 in $CHCl_3$), ν_{max}^{KBr} 1698 cm^{-1} (11-ketone), 1721 cm^{-1} (21-bromo-20-ketone), 3450 cm^{-1} (hydroxy). Anal. Calc. for $C_{21}H_{30}O_3BrCl$: C, 56.57; H, 6.78; Br, 17.92; Cl, 7.95. Found: C, 56.80; H, 6.56; Br, 17.88; Cl, 7.65.

17α-Chloro-21-acetoxy-3α-hydroxy-11,20-dioxopregnane (IX)

A mixture of 3.683 g of 21-bromo-17α-chloro-3α-hydroxy-11,20-dioxopregnane (XI), m.p. 150–152°, 100 mg of potassium iodide, and 7.4 g of freshly fused potassium acetate

was refluxed in 200 cc of absolute acetone and 10 cc of acetic acid for 22 hours in a nitrogen atmosphere. The product was diluted with methylene chloride, and the organic solution was washed with cold sodium bicarbonate solution and with water and was dried over sodium sulphate. Removal of the solvent afforded 3.616 g of a foamish material which crystallized from ether. One recrystallization gave 1.08 g of slightly yellowish prisms, m.p. 160–170° decomp. A sample was recrystallized twice from ethyl acetate – ether for analysis: m.p. 188° decomp., $[\alpha]_D^{26}$ +12° (*c*, 1.0 in $CHCl_3$), ν_{max}^{KBr} 1230 cm^{-1} (acetate), 1705 cm^{-1} (11-ketone), 1725 and 1750 cm^{-1} (21-acetoxy-20-keto doublet), 3400 cm^{-1} (hydroxy). Anal. Calc. for $C_{23}H_{33}O_5Cl$: C, 65.00; H, 7.83; Cl, 8.35. Found: C, 65.02; H, 8.05; Cl, 8.35.

The mother liquors of the first crystallization were chromatographed on 200 g of silica gel. Benzene – ethyl acetate (87:13) eluted 687 mg of IX, m.p. 177–179° decomp. (total yield 50%).

17α-Chloro-21-acetoxy-3,11,20-trioxopregnane (XII)

To a stirred solution of 982 mg of 17α-chloro-21-acetoxy-3α-hydroxy-11,20-dioxopregnane (IX), m.p. 177–179° decomp., in 50 cc of absolute acetone was added, dropwise, at 0–5°, 1.6 cc of an oxidizing solution prepared by dissolving 267 mg of chromic acid in 230 cc of concentrated sulphuric acid and 770 cc of water. After 2.5 minutes the solution was poured into water and the precipitate was filtered, washed, and dried. The product (977 mg) was recrystallized from ether to give 888 mg (90% yield) of colorless needles, m.p. 184–185° decomp. A sample was recrystallized twice from acetone–hexane for analysis: m.p. 203.5–205.5° decomp., $[\alpha]_D^{26}$ +15° (*c*, 1.01 in $CHCl_3$), ν_{max}^{KBr} 1708 cm^{-1} (double band of 3- and 11-ketones), 1740 cm^{-1} (shoulder) (21-acetoxy-20-ketone), 1765 cm^{-1} (20-keto-21-acetate).

Δ⁴-17α-Chloro-21-acetoxy-3,11,20-trioxopregnene (XVI*a*)

To a solution of 439 mg of 17α-chloro-21-acetoxy-3,11,20-trioxopregnane (XII), m.p. 201–202° decomp., in 25 cc of acetic acid were added, dropwise and with stirring, 0.1 cc of a 15% hydrogen bromide solution in acetic acid and subsequently 2.18 cc of a 0.96 *N* bromine solution in acetic acid. Some of the reaction product crystallized from the mixture towards the end of the addition. The mixture was poured into ice water and the precipitate was filtered, washed, and dried. The resulting crude bromide (522 mg) gave, upon one recrystallization from methylene chloride – hexane, 334 mg of pure *4β-bromo-17α-chloro-21-acetoxy-3,11,20-trioxopregnane* (XIII), m.p. 190–191° decomp. The mother liquors yielded a second crop of 83 mg of the same substance of lesser purity, m.p. 180–182° decomp. (total yield 80%), ν_{max}^{KBr} 1240 cm^{-1} (acetate), 1708 cm^{-1} (double band of 3- and 11-ketones), 1735 and 1762 cm^{-1} (21-acetoxy-20-keto doublet).

A portion of the pure bromo chloride (XIII) (322 mg, m.p. 190–192° decomp.) was dissolved in 60 cc of dichloromethane and 40 cc of *t*-butyl alcohol and treated in the usual manner (26), during 120 minutes, with 96 mg of semicarbazide base in a carbon dioxide atmosphere. The product was taken to dryness *in vacuo* and further dried by azeotropic distillation with benzene. The residue was slurried with a small amount of aqueous ethanol and the mixture was poured into 500 cc of water. The precipitate was filtered, washed, and dried. There was obtained 283 mg (83% yield from XIII) of colorless *Δ⁴-17α-chloro-21-acetoxy-3,11,20-trioxopregnene-3-semicarbazone*, (XIV), m.p. 210° decomp., λ_{max}^{EtOH} 270 mμ (log ε 4.3).

A quantity of 280 mg of semicarbazone (XIV) was dissolved in 14 cc of acetic acid and 4 cc of water. The solution was flushed with carbon dioxide and 0.72 cc of a 1.62 *N*

pyruvic acid solution was added. The mixture was stirred and kept for 18 hours at room temperature under carbon dioxide. The usual working up gave 274 mg of crude crystalline *Δ^4-17α-chloro-21-acetoxy-3,11,20-trioxopregnene* (XVI*a*). One crystallization from ether gave 183 mg (74% yield from XIV) of pure 17α-chloro-11-dehydrocorticosterone acetate (XVI*a*), m.p. 131–132°. A sample was recrystallized twice from ether for analysis: colorless needles, m.p. 137–138°, $[\alpha]_D^{26}$ +105° (*c*, 0.75 in $CHCl_3$), λ_{max}^{EtOH} 238 mμ (log ε 4.2), ν_{max}^{KBr} 1238 cm^{-1} (acetate), 1625 and 1680 cm^{-1} (Δ^4-3-keto doublet), 1709 cm^{-1} (11-ketone), 1738 and 1762 cm^{-1} (21-acetoxy-20-keto doublet). Anal. Calc. for $C_{23}H_{29}O_5Cl$: C, 65.63; H, 6.95; Cl, 8.42. Found: C, 65.58; H, 7.25; Cl, 8.40.

Δ^4-17α-Chloro-21-hydroxy-3,11,20-trioxopregnene (XVI)

A quantity of 150 mg of 17α-chloro-11-dehydrocorticosterone acetate (XVI*a*), m.p. 133–135°, was dissolved in a mixture of 9.8 cc of methanol and 0.25 cc of 70% perchloric acid. The solution was stored in a carbon dioxide atmosphere for 22 hours. Subsequently, the product was taken up in dichloromethane and the solution was washed with cold sodium bicarbonate solution and with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* gave 148 mg of an amorphous product which crystallized from acetone–hexane. One crystallization afforded 120 mg of 17α-chloro-11-dehydrocorticosterone (XVI), m.p. 104° decomp. A sample was recrystallized twice from acetone–hexane for analysis: fine needles, m.p. 107° decomp., $[\alpha]_D^{26}$ +141° (*c*, 0.733 in $CHCl_3$), λ_{max}^{EtOH} 238 mμ (log ε 4.1), ν_{max}^{KBr} 1620 and 1675 cm^{-1} (Δ^4-3-keto doublet), 1708 cm^{-1} (double band of 11- and 20-ketones), 3450 cm^{-1} (21-hydroxy). Anal. Calc. for $C_{21}H_{27}O_4Cl$: C, 66.57; H, 7.18; Cl, 9.36. Found: C, 66.68; H, 7.43; Cl, 9.42.

Acetylation

To a solution of 95 mg of ketol XVI, m.p. 90–100° decomp., in 4 cc of pyridine, 0.5 cc of acetic anhydride was added. The mixture was kept overnight at room temperature and worked up in the usual fashion. There was obtained 96 mg of a colorless foam which crystallized upon trituration with ether, m.p. 131–132°. The melting point was not depressed upon admixture with authentic acetate XVI*a* and the infrared spectrum of the product was identical with that of an authentic sample prepared as described above.

$\Delta^{4,16}$-21-Acetoxy-3,11,20-trioxopregnadiene (XV)

To a solution of 91 mg of 17α-chloro-11-dehydrocorticosterone acetate (XVI*a*), m.p. 132–133°, in 5 cc of dimethylformamide, was added 10 mg of potassium iodide and the mixture was refluxed for 2 hours in a nitrogen atmosphere. After cooling, 0.5 cc of acetic anhydride was added and the reaction mixture was stored at room temperature for 20 hours. The usual working up gave 89 mg of a brown oil which was chromatographed on 3 g of aluminum oxide. Benzene eluted 17 mg of starting material, m.p. 135–136°, and benzene–ether mixtures eluted 10 mg of the diene XV, identified by mixed melting point and by infrared comparison with an authentic sample (compare reference 22 and footnote 9).

ACKNOWLEDGMENTS

We extend sincere thanks to Mrs. J. Capitaine, Mr. D. Capitaine, and Miss R. McLean for their expert assistance in these experiments and to Dr. S. Tolksdorf and Dr. P. Perlman, Bloomfield, New Jersey, for carrying out preliminary biological tests. We acknowledge with gratitude financial support from the National Research Council of Canada, the Schering Corporation, Bloomfield, New Jersey, and the Schering Corporation Ltd., Montreal.

SOLID–LIQUID REACTIONS

PART I. THE DETERMINATION OF SOLID–LIQUID REACTION MECHANISMS[1]

ROGER KELLY[2]

ABSTRACT

A tracer method has been described by Graham, Spinks, and Thorvaldson for investigating the mechanisms of solid–liquid reactions. The present work represents an attempt to develop the theory of this method in detail and thereby allow for a greater variety of experimental conditions. Thus, no restrictions are placed on the compositions of the reacting and product solids, nor on the initial location of the tracer. The effect of exchange between the liquid and both solids is taken into account. Furthermore, two different *systems* of mechanisms are considered. In the one, which is shown to be the more realistic when rapid, multidirectional "external" exchange is present, mechanisms are classified according to whether or not the reaction proceeds at the surfaces of the solids; in the other, applicable in the absence of "external" exchange or when the exchange is slow, mechanisms are classified according to the degree of mixing with the liquid of successively reacting portions of the reacting solid.

INTRODUCTION

A solid–liquid reaction may be defined as one in which a solid of low solubility (the reacting solid) reacts with a liquid to form a second solid of even lower solubility (the product solid), the term liquid being here intended to include both solvent and solute indiscriminately. Reactions of this kind are of particular interest in cement chemistry, since they are responsible for both the setting and deterioration of cementitious substances (2). Specific examples include the hydrations of the calcium silicates (1), $CaSO_4.\frac{1}{2}H_2O$ (3), and CaO (4); the conversion of insoluble sulphates to carbonates (5, p. 585); and the reactions described in reference 6.

Innumerable variations in the details of solid–liquid reaction mechanisms are undoubtedly possible; however, the mechanisms will tend to fall into general classes or *systems* which represent to first approximation the limits of experimental distinguishability. One such system, much used in past work (1, 3, 4), considers the *degree of mixing* with the liquid of successively reacting portions of the reacting solid (Fig. 1A). Thus, in a "through-solution" mechanism the reacting solid passes into solution before precipitating as product solid (7). In a "direct" mechanism, on the other hand, the reacting solid is converted to the product solid without an intermediate mixing with the body of the liquid; the liquid is, however, assumed to receive or supply material as required by the balanced reaction equation (3, 4). Depending on the relative ease of the "through-solution" and "direct" routes, mixed mechanisms might also occur.

A possible alternative to the above system of mechanisms considers whether or not the reaction proceeds at the surfaces of the solids (Fig. 1B). In a "surface" mechanism material is transferred from the surface of the reacting solid to that of the product solid, with or without mixing with the body of the liquid. In an "internal" mechanism reaction proceeds as a result of liquid diffusing, or otherwise penetrating, into the interior of the reacting solid. The reaction thus occurs *without* mixing, and the product solid is

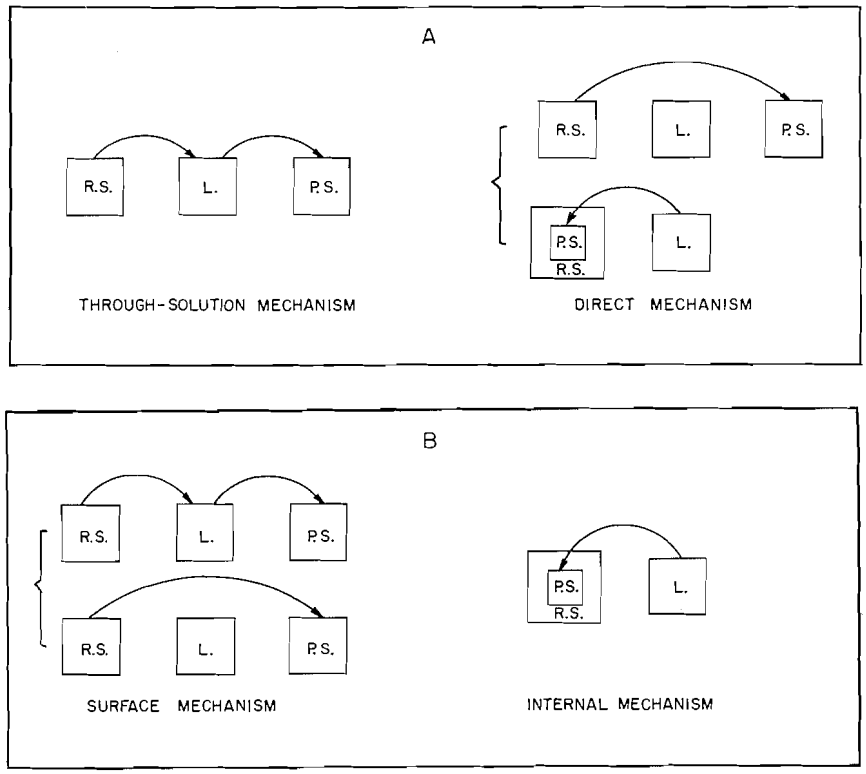

FIG. 1. (A) Schematic representation of solid–liquid reaction mechanisms as classified according to the degree of mixing with the liquid of successively reacting portions of the reacting solid. The following abbreviations are used: R.S. = reacting solid, L. = liquid, P.S. = product solid. The arrows may in general be interpreted as the routes taken by material from the reacting solid and liquid during the course of the reaction; however, it has been necessary to leave out certain steps in which differences in composition between the reacting and product solids are made up by the liquid, since the details of these steps depend on the actual compositions of the solids.

(B) Schematic representation of solid–liquid reaction mechanisms as classified according to whether or not the reaction proceeds at the surfaces of the solids. Abbreviations and use of arrows are as in (A).

deposited within the reacting solid, out of contact with the liquid (cf. the hydration of soft-burnt CaO (4)). Mixed mechanisms would again be possible.

Perhaps the most powerful method for investigating solid–liquid reaction mechanisms within either system is the tracer method of Graham, Spinks, and Thorvaldson (1). A suitable label, which will be assumed here to be a radioactive nuclide, is introduced into the liquid or reacting solid or both. The reaction is then allowed to proceed under conditions of vigorous agitation, and concurrent measurements of radioactivity and composition are made on the *filtered* liquid at suitable time intervals. A different relation between these measured quantities exists for each mechanism within a given system, *provided the system is applicable.*

The remainder of the present work will be concerned with a detailed treatment, in the light of the two systems of mechanisms just described, of the problem of correlating the activity and composition of the liquid during labeled solid–liquid reactions. This will lead to a precise definition of the conditions under which a given system of mechanisms is physically realistic, and will also provide a set of general equations with which to interpret

experimental results.[3] *It will be assumed, in all cases, that the reaction mixture is subjected to sufficient agitation to maintain a uniform composition in the liquid.*

SOLID–LIQUID REACTIONS ACCOMPANIED BY EXTERNAL EXCHANGE

In any attempt to correlate the activity and composition of the liquid in labeled solid–liquid reactions, close attention must be given to the effect of exchange between the liquid and both solids. Such exchange has been recognized to be of three extreme types (8, p. 37): surface exchange, self-diffusion, and recrystallization. Closely related to recrystallization is the formation of solid intermediates. For the present purposes, however, a slightly different systematization will be used:

(i) "external" exchange: exchange which occurs between a liquid and ions located in the *outer* layers of a solid, and which proceeds irrespective of crystallographic differences between the ions of the solid. Surface exchange and recrystallization are probably always of this sort.

(ii) "internal" exchange: exchange occurring between a liquid and a crystallographically determined fraction of a solid and thence, when rapid, occurring throughout the entire relevant portion of the crystal lattice. Self-diffusion may be of this sort in particular cases, for example compounds with a defect structure (9, 10).

Consider first a reaction accompanied by rapid, multidirectional external exchange *in one or both* solids, with or without a component of similar internal exchange in addition. (By rapid is meant having a rate greater than the rate of reaction, while multidirectional is the opposite of unidirectional (cf. 8, p. 35).) The result of such exchange is that the surfaces of the affected solids tend to have the same specific activity as the liquid. Accordingly, if the reaction proceeds at the surfaces, the material undergoing reaction is always in radioactive equilibrium with the liquid *whatever the degree of mixing*. Mechanisms based on the degree of mixing are therefore not experimentally significant, and the reaction is more readily described in terms of "surface" and "internal" mechanisms (cf. Fig. 1B).

(a) Surface Mechanism

Let a be the amount of labeled species with specific activity $f(0)$ initially present in the liquid. Let b be the amount of labeled species with specific activity g initially present in the reacting solid, x being the portion of b which has reacted. For $x > 0$ the specific activity of the liquid is then $f(x)$. Let m_1 and m_2 be the numbers of moles of labeled species in the formulae of, respectively, the reacting and product solids as derived from *the balanced reaction equation*.[4] Let n_1 and n_2 be such portions of, respectively, m_1 and m_2 that the total amount of rapidly and multidirectionally exchanging material, whether external or internal, in a given solid can be represented as a fraction n_i/m_i of the total *amount* of solid. This material has specific activity $f(x)$. (In a more rigorous treatment, the amount of *externally* exchanging material would be put proportional to the surface area of the solid, i.e. to $(amount)^{2/3}$.)

In accordance with this nomenclature, a "surface" mechanism can be envisaged as involving the reaction of successive elements of material, Δx, from the surface of the reacting solid, together with corresponding changes in activity. The latter are as follows: $\Delta x f(x)$ leaves the reacting solid, $(1-n_1/m_1)\Delta x g$ becomes exchangeable beneath the

[3] *Equations applicable in certain specific cases have already been given by Thorvaldson et al. (1, 3).*

[4] *For example, in the reaction* $2(3CaO.SiO_2)+(n+3)H_2O \rightarrow 3CaO.2SiO_2.nH_2O+3Ca^{++}+6\ OH^-$, $m_1 = 6$ *and* $m_2 = 3$ *if calcium is labeled (cf. 1).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

surface of the reacting solid,[5] $(m_2/m_1)\Delta x f(x)$ deposits on the product solid, $(1-n_2/m_2)(m_2/m_1)\Delta x f(x)$ ceases to be exchangeable beneath the surface of the product solid,[5] and the liquid gains $(1-m_2/m_1)\Delta x f(x)$. The specific activity of the liquid and the exchanging portions of the solids therefore changes from $f(x)$ to

$$f(x+\Delta x) = \text{(total mobile activity)/(total mobile amount)}$$

$$= \frac{\left[a+\left(1-\frac{m_2}{m_1}\right)(x+\Delta x)\right]f(x)+\left[\frac{n_1}{m_1}(b-x)f(x)-\Delta x f(x)+\left(1-\frac{n_1}{m_1}\right)\Delta x g\right]+\left[\frac{n_2}{m_1}x+\frac{m_2}{m_1}\Delta x-\left(1-\frac{n_2}{m_2}\right)\frac{m_2}{m_1}\Delta x\right]f(x)}{\left[a+\left(1-\frac{m_2}{m_1}\right)(x+\Delta x)\right]+\left[\frac{n_1}{m_1}(b-x)-\Delta x+\left(1-\frac{n_1}{m_1}\right)\Delta x\right]+\left[\frac{n_2}{m_1}x+\frac{m_2}{m_1}\Delta x-\left(1-\frac{n_2}{m_2}\right)\frac{m_2}{m_1}\Delta x\right]}.$$

If $[f(x+\Delta x)-f(x)]/\Delta x$ is now formed, $df(x)/dx$ can be obtained in the limit as $\Delta x \to 0$. Integrating the latter expression under the condition that

$$f(x) = \frac{af(0)+n_1bg/m_1}{a+n_1b/m_1}$$

when $x = 0$, i.e. allowing for the initial "burst" of exchange, the result is

[1] $$f(x) = g+\frac{f(0)-g}{1+n_1b/m_1a}\left(1+\frac{m_1-m_2-n_1+n_2}{m_1a+n_1b}x\right)^{(-m_1+n_1)/(m_1-m_2-n_1+n_2)}.$$

The activity of the liquid as a function of x follows directly from equation [1]:

[2] $$\text{activity} = (a+x-m_2x/m_1)f(x) \equiv Af(x),$$

or, in units of fraction of total activity present,

[3] $$\text{fractional activity} = \frac{Af(x)}{af(0)+bg}.$$

The term

[4] $$A \equiv a+x-m_2x/m_1$$

represents the measured amount of labeled species present in the liquid at any stage of reaction; that is, it is simply the "composition" of the liquid.

In those cases where the activity is confined initially to either the liquid or solid, and $n_1 = n_2 \to 0$, equations [1] to [3] simplify considerably, the last designated giving

[5] $$\begin{cases} g = 0, & m_1 \neq m_2 \\ g = 0, & m_1 = m_2 \end{cases} \qquad \begin{aligned} \text{fractional activity} &= (A/a)^{m_2/(m_2-m_1)} \\ &= e^{-x/a} \end{aligned}$$

[5] *The origin of the factors $(1-n_1/m_1)$ and $(1-n_2/m_2)$ is as follows. Let n_i' and n_i'' correspond, respectively, to externally and internally exchanging material. Then the removal or deposition in the course of reaction of Δx units of material at the outside of the surface layer described by n_i' will cause an amount on the inner side of this layer to become, or cease to be, exchangeable which is given by* Δx times *a factor $(1-n_i'/m_i)$ to take into account the reduced amount of material inside the layer,* times *a factor $(1-n_i''/m_i)$ since only part of the new material is not already exchanging. Noting that $n_i = n_i'+n_i''-n_i'n_i''/m_i$, it follows that the total amount of material becoming, or ceasing to be, exchangeable is $(1-n_i/m_i)\Delta x$.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

[6] $\begin{cases} f(0) = 0, & m_1 \neq m_2 \quad \text{fractional activity} = A/b - \dfrac{a}{b}(A/a)^{m_2/(m_2-m_1)} \\ f(0) = 0, & m_1 = m_2 \quad = \dfrac{a}{b}(1-e^{-x/a}). \end{cases}$

If the reacting solid suffers total exchangeability, i.e. $n_1 \rightarrow m_1$, the reductions of equations [1] and [3] are, respectively,

[7] $$f(x) = \frac{af(0)+bg}{a+b} \quad \text{and} \quad \text{fractional activity} = \frac{A}{a+b}.$$

These expressions are seen to describe radioactive equilibrium. The case $n_2 \rightarrow m_2$ is equivalent to the occurrence of extensive recrystallization in the product solid, which is discussed later. If the exchange is slow or unidirectional, though such that the outer surfaces of at least one solid maintain radioactive equilibrium with the liquid, the activity will be bounded by that obtained with full values of n_1 and n_2, and that obtained with $n_1 = n_2 \rightarrow 0$.

An equation somewhat different from [1] is obtained when m_2 is not a constant but a function of A: see Appendix.

(b) Internal or Mixed Mechanism

The derivation of an equation analogous to [1] for cases in which either a purely "internal" mechanism, or a mixture of "surface" and "internal" mechanisms, occurs is complicated by the fact that the product solid, either completely or in part, is now lodged inaccessibly within the reacting solid and contributes to the exchangeability of the system only as the reacting solid is depleted.[6] It will therefore be assumed for the present that $n_2 \rightarrow 0$, the case $n_2 \rightarrow m_2$ being covered in the subsequent discussion of recrystallization. The elemental activity changes occurring as a result of the reaction of Δx units of material from the reacting solid, $k\Delta x$ of which is from a surface and $(1-k)\Delta x$ from the interior, are then as follows: $k\Delta x f(x)$ leaves the surface of the reacting solid, $k(1-n_1/m_1)\Delta x g$ becomes exchangeable beneath the surface of the reacting solid,[5] and the liquid gains

$$\left(1-\frac{m_2}{m_1}\right)\Delta x f(x) \qquad \text{if } m_1 < m_2,$$

$$k\left(1-\frac{m_2}{m_1}\right)\Delta x f(x) + (1-k)\left(1-\frac{m_2}{m_1}\right)\Delta x\left(\frac{n_1}{m_1}f(x) + \left(1-\frac{n_1}{m_1}\right)g\right) \qquad \text{if } m_1 > m_2.$$

In the latter expression, the term beginning with $(1-k)$ is strictly valid only if soluble reaction products formed in the interior of the reacting solid as a result of the "internal" component of the reaction are able to diffuse out rapidly. Following through the derivation, two expressions for $f(x)$ are finally obtained:

[8] $m_1 < m_2$ $$f(x) = g + \frac{f(0)-g}{1+n_1b/m_1a}\left(1+\frac{m_1-m_2-n_1}{m_1a+n_1b}x\right)^{-k(m_1-n_1)/(m_1-m_2-n_1)}$$

[9] $m_1 > m_2$ $$f(x) = g + \frac{f(0)-g}{1+n_1b/m_1a}\left(\cdots\right)^{\left[-k(m_1-n_1)(1-k)\left(1-\frac{m_2}{m_1}\right)(m_1-n_1)\right]/(m_1-m_2-n_1)}$$

[6] *It has been assumed, both here and in the initial description of the "internal" mechanism (see Introduction), that that portion of the product solid laid down within the reacting solid remains inaccessible to the liquid until the covering layer of reacting solid has disappeared. Actually, it is conceivable that in some cases the liquid might have continuous access to the internal product solid. The reaction would then show an "internal" mechanism only if the external exchange exhibited by the product solid were slow or non-existent; otherwise the reaction would follow a "surface" mechanism.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

Hence, if $n_1 \rightarrow 0$,

$$[10] \quad \begin{cases} g = 0, & m_1 < m_2 \quad \text{fractional activity} = (A/a)^{[m_2-(1-k)m_1]/(m_2-m_1)} \\ g = 0, & m_1 = m_2 \quad = e^{-kx/a} \\ g = 0, & m_1 > m_2 \quad = (A/a)^{-km_2/(m_1-m_2)} \end{cases}$$

[11] $f(0) = 0$ like equations [6] but with exponents as above.

SOLID–LIQUID REACTIONS ACCOMPANIED BY INTERNAL OR NO EXCHANGE

If the external exchange is either slow or non-existent in both solids, though without restriction to the internal exchange, a distinction between "surface" and "internal" mechanisms is no longer experimentally convenient. Different *degrees of mixing* (cf. Fig. 1A) are, however, readily distinguished. It can be shown that, since the "through-solution" mechanism results in a complete mixing with the liquid of successively reacting portions of the reacting solid, the relation between the activity and composition of the liquid for this mechanism is identical with that for a "surface" mechanism: see equations [1], [5], [6], and [16], the last designated applying when m_2 is a function of A. Similarly, for a "direct" or mixed mechanism the activity is given by equations [8] to [11].

Previously studied solid–liquid reactions were described as following mechanisms based on the degree of mixing (1, 3, 4). There is reason to believe, however, that the product solids in at least two of the reactions (the hydrations of $CaSO_4.\frac{1}{2}H_2O$ (3) and CaO (4)) exhibit rapid, multidirectional external exchange.[7] The reactions in question are therefore perhaps better represented in terms of "surface" or "internal" mechanisms; passage through solution may still have occurred, but was not rigorously demonstrated.

RECRYSTALLIZATION AND INTERMEDIATE FORMATION

The possibility that extensive recrystallization will take place in the freshly formed product solid, or that solid–intermediate formation will occur, is always a problem in studying a solid–liquid reaction, since neither effect can be predicted from the behavior of the product solid in isolation.

Consider first recrystallization. Assume limiting conditions, i.e. (i) that the recrystallization is rapid, complete, and multidirectional, and (ii) that no product solid is lodged inaccessibly within the reacting solid as might occur with an "internal" or "direct" mechanism, a condition which should be well met as the reaction enters its later stages and the amount of unconverted reacting solid diminishes. Then, *regardless of the reaction mechanism*,

$$f(x) = (\text{total mobile activity})/(\text{total mobile amount})$$

$$[12] \quad = \frac{af(0)+xg+n_1(b-x)g/m_1}{a+x+n_1(b-x)/m_1}.$$

Forms for fractional activity follow readily using equation [3]; in particular, if $g = 0$ and either $n_1 \rightarrow 0$ or $x \rightarrow b$,

[7]*That is, the product solids in these reactions both exhibit rapid* surface *exchange, a mode of exchange which may in general be expected to be multidirectional and external. For* $Ca(OH)_2$, *see reference 4; for* $CaSO_4.2H_2O$, *compare reference 11, where surface exchange is shown to occur with* $SrSO_4$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

$$[13] \qquad \text{fractional activity} = \frac{A}{a+x} = \frac{(A/a)(1-m_2/m_1)}{A/a-m_2/m_1}.$$

Similar equations can be obtained by letting $n_2 \rightarrow m_2$ in equation [1]. If the recrystallization is slow, incomplete, or unidirectional, or a portion of the product solid is inaccessible (i.e. if in effect $n_2 < m_2$), the specific activity of the liquid will lie between that given by equation [12] and that for the unperturbed reactions (either equation [1] (with $n_2 = 0$), [8], or [9]).

Solid–intermediate formation will be largely equivalent to recrystallization in the product solid in such cases as (i) "surface" or "through-solution" mechanisms occur, and (ii) the intermediates are reasonably long-lived, i.e. not transient.

Note that equations [12] and [13] were derived without regard to the reaction mechanism; in other words, recrystallization and intermediate formation tend to mask the differences between mechanisms.

RELATIVE VALUES OF THE SPECIFIC ACTIVITIES

By way of conclusion, it is interesting to consider the relative values of the specific activities of the liquid to be expected under the various mechanisms after a given extent of reaction, i.e. for a given value of x or A (equations [1], [8], and [9]). Exchange will be assumed to be slight, hence $n_1 = n_2 \rightarrow 0$; and mixed mechanisms will be assumed not to occur, hence $k = 1$ or $k = 0$. These specific activities will be compared with the values occurring initially ($f(0)$), at radioactive equilibrium (equations [7]), and when limiting recrystallization or intermediate formation occur (equation [12]). Representing a given specific activity by the appropriate name, one obtains, for $f(0) > g$,

$$[14] \qquad \left.\begin{matrix}\text{(surface or through-solution)} \\ \text{(equilibrium)}\end{matrix}\right\} < \text{(recrystallization)} < \text{(internal or direct)} < \text{(initial)};$$

except that, for $m_1 \leqslant m_2$, (internal or direct) = (initial), while when the reaction is complete, i.e. $x \rightarrow b$, (equilibrium) = (recrystallization). For $f(0) < g$ the inequalities in equation [14] are reversed. Relative values similar to those in equation [14] also hold for *total* activities, except that the position of the initial activity cannot be predicted simply. The various relationships are further illustrated in Figs. 2A and 2B, where the progress of the specific activity of the liquid is plotted as a function of x for two particular sets of conditions.

It is seen that only with a "surface" or "through-solution" mechanism does the specific activity of the liquid proceed from its initial value *across* the limiting recrystallization value (or, when $x \rightarrow b$, the equilibrium value). Stated differently, the limiting recrystallization and equilibrium activities, whether specific or total, define a boundary between the activities attainable under the different mechanisms of a given system.

An interesting example of the "crossing phenomenon" in a field outside of formal solid–liquid reactions was found by Kolthoff and Eggertsen (12). When fresh $PbCrO_4$ was allowed to recrystallize in a solution containing Pb^{212}, a transient activity *beyond* the usually encountered equilibrium value was observed. Noting that unidirectional recrystallization is in all respects equivalent to a solid–liquid reaction with $m_1 = m_2$ which follows a "surface" or "through-solution" mechanism, this observation indicates that the recrystallization was partially unidirectional. A similar conclusion was reached by the authors.

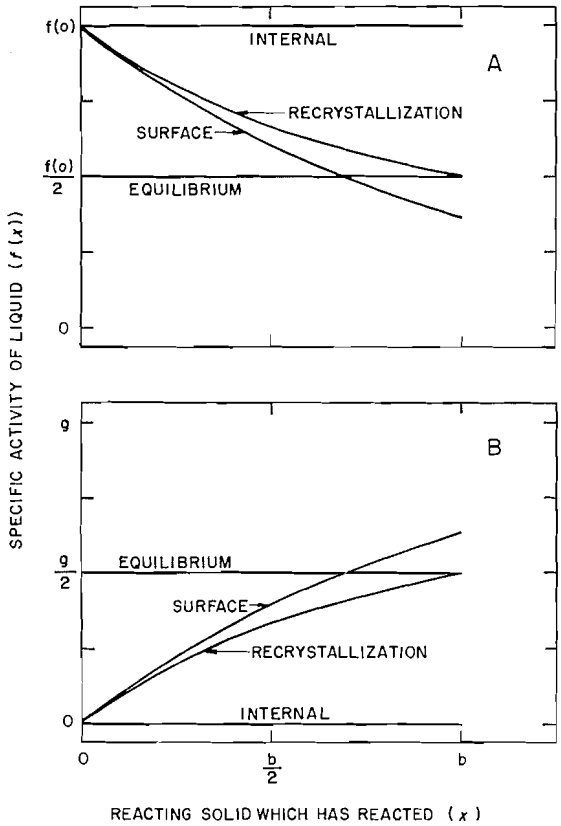

FIG. 2. (A) The progress of the specific activity of the liquid ($f(x)$) during a labeled solid–liquid reaction in which the tracer is confined initially to the liquid ($g = 0$), the numbers of moles of labeled species in the formulae of the reacting and product solids are the same ($m_1 = m_2$; cf. footnote 4), exchange is slight ($n_1 = n_2 \rightarrow 0$), and equal amounts of the labeled species are present initially in the liquid and solid phases ($a = b$). Since $m_1 = m_2$, the specific activity is proportional to the total activity. The reaction necessarily terminates when the amount of labeled species from the reacting solid which has reacted (x) equals the total amount originally present (b).

(B) The progress of the specific activity of the liquid during a labeled solid–liquid reaction under the same conditions as in Fig. 2A except that the tracer is confined initially to the solid ($f(0) = 0$).

ACKNOWLEDGMENT

The work described here is largely an outgrowth of a project (6) carried out under the direction of Dr. T. Thorvaldson of this department. Dr. Thorvaldson's assistance is gratefully acknowledged.

APPENDIX

SOLID–LIQUID REACTIONS WHERE THE COMPOSITION OF THE PRODUCT SOLID VARIES

Suppose, as in the hydration of $3CaO.SiO_2$ (1), that the composition of the product solid depended on the concentration of the liquid. The quantity m_2 could then be expressed as a function of A,

$$m_2(A) = c_0 + c_1A + c_2A^2 \ldots \approx c_0 + c_1A,$$

where c_0, c_1, and c_2 are constants. Now, in such a case, there is a possibility that that portion of the product solid characterized by c_1A would not remain inert once precipitated, but (in particular near a surface) would tend to maintain composition equilibrium *and thence* radioactive equilibrium with the liquid. An external equilibrating shell would therefore occur which, to first approximation, could be envisaged as containing a mole fraction h of the total variable portion of the product solid, and thence hc_1Ax/m_1 units of material.[8]

Assuming that the reaction follows a "surface" or "through-solution" mechanism, though with $n_1 = n_2 \rightarrow 0$, the relation between the activity and composition of the liquid when m_2 is a variable is readily derived. Let x units of reacting solid already have reacted and another Δx react. The specific activity of the liquid and the equilibrating portion of the product solid therefore changes from $f(x)$ to

$$(x+\Delta x) = \frac{Af(x) + \Delta xg + (hc_1Ax/m_1)f(x)}{A + \Delta x + hc_1Ax/m_1},$$

where

$$[15] \qquad A = a + x - (c_0 + hc_1A)x/m_1 - \int_0^x (1-h)(c_1A/m_1)dx'.$$

Proceeding as before, an expression for $df(x)/dx$ is obtained. The term dx can be eliminated by differentiating equation [15], and $f(x)$ then found by integration. The result, with $m_2(A)$ substituted for $(c_0 + c_1A)$, is

$$[16] \qquad f(x) = g + [f(0) - g]\left\{\frac{[m_1 - m_2(A)]a}{[m_1 - m_2(a)]A}\right\}^{m_1/[m_1 - m_2(0)]}.$$

The activity in the liquid as a function of A can now be derived as indicated by equations [2] and [3]. Equation [16] is *not* valid if $m_1 = m_2(0)$ or $m_2(a)$, or if m_1 lies within the path of $m_2(A)$.

An important property of equation [16] is that, provided it is expressed in terms of A and not x, it does not require knowledge of the value of h, i.e. of the division of product solid into equilibrating and nonequilibrating portions. It can be shown from a more general derivation, in which c_1A is replaced by $m_2(A)$ and h by the generalized form $h(A)$, and c_0 is dropped from equation [15], that this result is contingent on the following relation:

$$\frac{dh(A)m_2(A)}{dA} = \frac{h(A)m_2(A)}{A};$$

hence $h(A)m_2(A) = \text{constant} \cdot A = hc_1A$. In other words, independence of h occurs *accidentally* when certain specific conditions are met.

Equation [16] should be of use in determining values of $m_2(A)$ in cases where the reaction mechanism is not in doubt.

[8] *Ideally, the amount of product solid capable of equilibration would be put proportional to the surface area of the product solid; this would, however, introduce an unwieldy two-thirds power.*

SOLID–LIQUID REACTIONS

PART II. SOLID–LIQUID REACTIONS AMONGST THE CALCIUM ALUMINATES AND SULPHOALUMINATES[1]

ROGER KELLY[2]

ABSTRACT

When $3CaO.Al_2O_3.6H_2O$ (i.e. C_3AH_6) was placed in contact with a solution of $Ca(OH)_2$ labeled with Ca^{45} and maintained at 25° C, there was very little change in either the activity or composition of the liquid. These observations, when taken together, indicate that the compound is *probably* stable in the system used. On the other hand, when either C_3AH_6 or $3CaO.Al_2O_3.CaSO_4.12H_2O$ (i.e. $C_3A\Sigma H_{12}$) was added to a mixed $Ca(OH)_2$–$CaSO_4$ solution, the composition of the liquid varied in a manner consistent with the formation of $3CaO.Al_2O_3.3CaSO_4.31H_2O$ (i.e. $C_3A\Sigma_3H_{31}$). The activity also changed markedly, and a detailed consideration of the relations between activity and composition enabled the reaction mechanisms to be determined. In further experiments, the reactions of C_3AH_6 and $C_3A\Sigma H_{12}$ to form $C_3A\Sigma_3H_{31}$ were shown to proceed also at 70° and 90° C. The consistently greater *ultimate* stability of $C_3A\Sigma_3H_{31}$ over $C_3A\Sigma H_{12}$ between 25° and 90° C is to be contrasted with the fact, observed in the course of preparing the $C_3A\Sigma H_{12}$, that when solutions of $Al_2(SO_4)_3$, $CaSO_4$, and $Ca(OH)_2$ are mixed the *immediate* precipitate is $C_3A\Sigma_3H_{31}$ at room temperature, but $C_3A\Sigma H_{12}$ at boiling temperature.

An abbreviated chemical symbolism, similar to the one used by Bogue (1), will be employed in what follows: $A \equiv Al_2O_3$, $C \equiv CaO$, $H \equiv H_2O$, $\Sigma \equiv CaSO_4$. *Thus* $3CaO.Al_2O_3.CaSO_4.12H_2O$ *will be represented by* $C_3A\Sigma H_{12}$.

Calcium forms four well-defined anhydrous aluminates (CA, C_3A, C_3A_5, and C_5A_3 (2)) together with perhaps 10 hydrated forms. The most well-known of the latter are C_3AH_6 (cubic), C_2AH_8, C_3AH_{12}, and C_4AH_{12} (all platy hexagonal) (1, p. 552), though there is general agreement that the cubic C_3AH_6 is the only stable aluminate in the system C—A—H between room temperature and 215° C (3, 4). Representing a further stage of chemical complexity are two long series of insoluble compounds with general formulae C_3AXH_{12} (platy hexagonal) and $C_3AX_3H_{31}$ (acicular hexagonal), where X may be essentially any calcium salt (5). For X = $CaSO_4$ only the acicular form is apparently stable in aqueous systems (6).

These compounds are of importance principally in their relation to portland cement. Thus C_3A is a constituent of the cement powder (it lowers the preparation temperature), while hydrated forms arising from the C_3A are present in set cement. When set cement, as in mortar or concrete, is exposed to sulphate, the hydrated aluminates are converted to the bulky sulphoaluminate $C_3A\Sigma_3H_{31}$ with resultant disintegration of the material.

The present work represents a study of three of the many possible aluminate reactions that might occur in cement: that of C_3AH_6 with $Ca(OH)_2$ solutions, that of C_3AH_6 with mixed $Ca(OH)_2$–$CaSO_4$ solutions, and that of $C_3A\Sigma H_{12}$ with mixed $Ca(OH)_2$–$CaSO_4$ solutions. Since these reactions fall into the category of *solid–liquid* reactions (7), they will be considered in terms of the tracer method of Graham, Spinks, and Thorvaldson (8) as extended by Kelly (7).

EXPERIMENTAL

Solutions

Solutions saturated in $Ca(OH)_2$ or $CaSO_4$ or both were prepared by shaking for several weeks an excess of the appropriate solid (CaO or $CaSO_4.2H_2O$) with redistilled water in glass containers. Less concentrated solutions were made up by dilution. It was attempted at all times to minimize carbonation.

C_3AH_6

Since wet preparations generally lead to the metastable hexagonal aluminates, a hydrothermal technique due to Thorvaldson and Grace (9) was used to prepare C_3AH_6. Starting with a 3:1 mixture of CaO and Al_2O_3, C_3A was formed by alternately igniting at 1400° C and grinding to 325 mesh. The C_3A was then converted to C_3AH_6 by exposure to the equilibrium vapor pressure of water at 150° C for 8 days.

$C_3A\Sigma H_{12}$

The only methods for preparing $C_3A\Sigma H_{12}$ apparently recorded involve precipitations *at room temperature* from solutions of carefully controlled composition (see, for example, 10). There are, however, isolated examples in which a hexagonal phase resembling $C_3A\Sigma H_{12}$ has been obtained at elevated temperatures (5). Following the lead of the latter, 150-cc portions of a solution containing 3.06 g $Al_2(SO_4)_3.18H_2O$ in 1 liter of saturated $CaSO_4$ (i.e. $Al_2O_3:SO_3::1:6$) were mixed with 600-cc portions of a $Ca(OH)_2$ solution containing about 0.55 g CaO per liter, *both solutions being at boiling temperature.* In every instance an immediate precipitate with a striking silky luster and platy hexagonal form was observed (Fig. 1A). Ten minutes at boiling temperature were allowed for crystal growth, if any, before the precipitate was separated. The samples analyzed variously as $C_3A\Sigma_{0.44}H_{9.7}$, $C_3A\Sigma_{0.86}H_{9.7}$, $C_3A(\Sigma_{0.62}C_{0.46})H_{10.0}$, etc., indicating that the desired substance had been obtained, though as a member of a solid–solution series (cf. the series C_3AH_{12}–$C_3A\Sigma H_{12}$–C_4AH_{12} proposed by Kalousek (11)). The deficient water contents probably represent equilibrium compositions at the temperature used.

It was not found possible to prepare *pure* $C_3A\Sigma H_{12}$ at temperatures below boiling temperature. Thus, when the $Al_2(SO_4)_3$–$CaSO_4$ solution described above was mixed with twice the volume of a $Ca(OH)_2$ solution containing about 1.1 g CaO per liter, mixtures of $C_3A\Sigma H_{12}$ and $C_3A\Sigma_3H_{31}$ were obtained between 50° and 75° C, and $C_3A\Sigma_3H_{31}$ alone at room temperature (Figs. 1B and 1C). Over the same temperature range, but when the concentration of the $Ca(OH)_2$ in the *combined* solutions was lower, there was either no immediate precipitate, or else hydrated Al_2O_3 formed (cf. 10, p. 721).

The implication in the experiments just described that there may be a change in the relative stabilities of the two sulphoaluminates as the temperature is increased will be considered later.

Method of Conducting Experiments

Following Graham *et al.* (8), calcium-45[3] was first introduced into the liquid. About 0.05 g of solid and exactly 50 cc of liquid were next sealed in cylindrical steel tubes of 110-cc capacity which were lined with gold or silver (cf. 8). In order that the reaction mixtures might be kept continuously agitated, the tubes were attached to a slowly revolving wheel.

After periods of reaction of several days, the tubes were opened and the liquid separated either by filtration through a "fine" sintered-glass filter or by centrifugation. Using 25 cc

[3]*Obtained from Atomic Energy of Canada Limited, Chalk River, Ontario.*

of liquid, calcium was determined as the oxalate, and sulphate as $BaSO_4$; alternatively, the sum of a sulphate measurement plus a titration with HCl was used to estimate calcium. Four 1/2-cc portions of liquid were also pipetted onto aluminum dishes. The calcium was then precipitated with ammonium oxalate, acetone was added to disperse the precipitate, and, when the samples were dry, the Ca^{45} activity was measured with a simple end-window Geiger–Mueller tube. The relation between the activity and composition of the liquid determined whether a reaction had occurred and the mechanism of the reaction.

Unless otherwise specified, the reactions took place at a temperature of $25\pm0.5°$ C.

THEORY

Define "external" exchange as exchange which occurs between a liquid and ions located in the *outer* layers of a solid, and which proceeds irrespective of crystallographic differences between the ions of the solid; define "internal" exchange as exchange occurring between a liquid and a crystallographically determined fraction of a solid (7). Then, according to reference 7, the mechanisms of solid–liquid reactions may be classified in at least two ways. When rapid, multidirectional *external* exchange occurs in either the reacting or product solid, with or without a component of internal exchange in addition, it is convenient to consider mechanisms based on whether the reaction proceeds at the surfaces of the solids or in the interior, and thence to distinguish "surface" and "internal" mechanisms and mixtures thereof. When the external exchange is either slow or non-existent in both solids, though without restriction to the *internal* exchange, the degree of mixing with the liquid of successively reacting portions of the reacting solid is more important, and one then recognizes the alternatives of complete mixing ("through-solution" mechanism) and no mixing ("direct" mechanism), as well as intermediate situations. General equations giving the relations between the activity and composition of the liquid for these mechanisms are developed in reference 7, and it is shown that when, as in the present work, the reacting solid is initially inactive and the extent of *all* rapid, multidirectional exchange is slight, these equations reduce to

[1] "surface" or "through-solution" mechanism fractional activity $= (A/a)^{m_2/(m_2-m_1)}$,

[2] "internal" or "direct" mechanism, $m_1<m_2$ fractional activity $= (A/a)$,

where "fractional activity" refers to the activity of the liquid in units of fraction of the initial value, a is the amount of labeled species (i.e. calcium) initially present in the liquid, A is the variable amount of labeled species in the liquid at any time, and m_1 and m_2 are the numbers of moles of labeled species in the formulae of, respectively, the reacting and product solids. Mixed mechanisms would give intermediate activities.

An important property of the "surface" and "through-solution" mechanisms is that they alone cause the specific activity of the liquid to progress from its initial value to a point *beyond* the equilibrium value as the reaction goes to completion (cf. Figs. 2A and 2B of reference 7).

When pure exchange rather than a reaction occurs, then analogous to equations [1] and [2] one has

$$[3] \qquad \text{fractional activity} = a/(a+nb/m),$$

where m is the number of moles of labeled species in the formula of the solid, n is the *apparent* portion of m which is exchangeable, and b is the amount of labeled species

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

present in the solid. Equation [3] with the substitution $n = m$ describes radioactive equilibrium.

RESULTS

Reaction and Exchange of C_3AH_6 *with* $Ca(OH)_2$ *Solutions*

Though it is reasonably well-established that C_3AH_6 is a stable phase in the system C—A—H at room temperature, it is interesting to demonstrate this stability in an indirect manner by determining if a solid–liquid reaction occurs when inactive C_3AH_6 is placed in contact with a solution of $Ca(OH)_2$ labeled with Ca^{45}. Results are given in Table I. Some word is perhaps required about those experiments in which a finite time is

indicated *before* labeling. In these experiments, in contrast to all others, the activity was added as concentrate to the centrifuged mixtures at the times indicated. "Initial" values for the activity were then derived by shaking the mixtures for 1 minute, centrifuging again, and sampling.

A decision as to whether C_3AH_6 is stable is not possible simply on the basis of the observed lack of change in the composition of the liquid (Table I, footnote *); thus, no change in composition would accompany such processes as solvation or crystal transformation. However, consider the activity changes. It was stated in Theory that the "surface" and "through-solution" mechanisms both cause the *specific* activity of the liquid to cross the equilibrium value as the reaction goes to completion. Noting that, in cases such as the present where the composition of the liquid remains essentially unchanged, *specific* activity is proportional to *total* activity, it is clear that such a relation is not observed (Table I, columns 5 and 6). C_3AH_6 is therefore stable with respect to any reactions following the stated mechanisms. The significance of this is that, as will be shown in the Discussion, these mechanisms may be expected with high probability.

The observed activity changes can evidently be attributed to exchange. Since knowledge of the exchange behavior of C_3AH_6 is required in the following section, values of the quantity n as defined by equation [3] have been included in Table I (final column). It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

will be noted that a low, though rather fluctuant, limiting value of n was reached within an hour and that this value persisted even when the solid had been kept in contact with the liquid for up to two months prior to labeling. The exchange is thus slight in extent, rapid, and multidirectional. These are the characteristics, of course, of either surface exchange or multidirectional recrystallization, both of which will in general fall within the broader category of "external" exchange, as defined earlier.

Reaction of C_3AH_6 *with Mixed* $Ca(OH)_2$–$CaSO_4$ *Solutions*

When C_3AH_6 was added, not to a solution of $Ca(OH)_2$ as in the preceding section, but to a mixed $Ca(OH)_2$–$CaSO_4$ solution, both the composition and activity of the solution changed markedly (see Table II). The changes in composition, as plotted in Fig. 2,

*To convert to mole×10^4, multiply by (calcium in solid)/3. Then (total CaO) = $a - A$.

†No activity was present in the sixth to ninth experiments. In a further experiment similar to these, activity was added as concentrate on the 10th day. The *total* resulting exchange was as follows: n = 0.1, 0.6, 0.8, and 0.9 in, respectively, 1/24, 1, 5, and 12 days. The exchange is thus *rapid* relative to the rate of reaction, though may be only partially *multidirectional*.

indicate that the sulphoaluminate $C_3A\Sigma_3H_{31}$ has formed, the reaction time being about six days. The presence of this compound was confirmed by microscopic examination (Fig. 1B).

The interrelations between activity and composition enable the reaction mechanism to be determined. Note in this regard that the extent of *all* rapid, multidirectional exchange between the liquid and both solids was slight; thus for C_3AH_6, $n/m = 0.42/3$ (Table I), while for $C_3A\Sigma_3H_{31}$, $n/m \leqslant 0.6/6$ (Table II, footnote †). Hence equations [1] and [2] are valid, with the former assuming the form $(A/a)^2$ for $m_1 = 3, m_2 = 6$. The theoretical activities according to equations [1] and [2], and the observed values as given in Table II, are compared in Fig. 3 (outer curves only). The indication is that the reaction follows a pure "surface" or "through-solution" mechanism, of which the former is more realistic since the exchange observed with C_3AH_6 probably fell within the definition of "external".

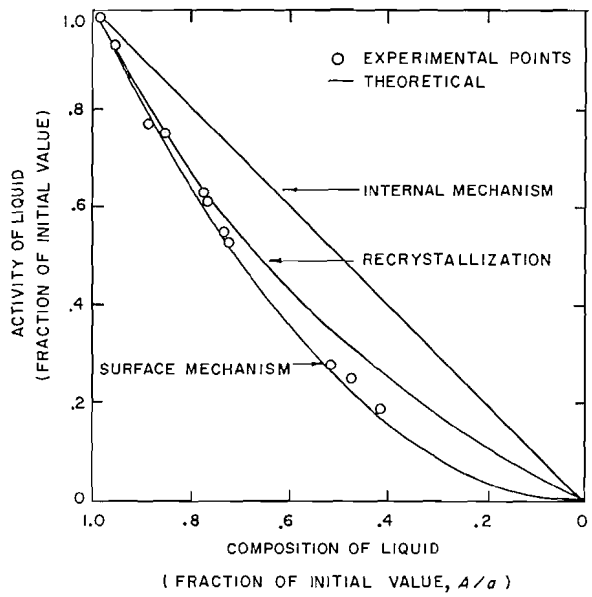

FIG. 3. Conversion of C_3AH_6 to $C_3A\Sigma_3H_{31}$ in mixed $Ca(OH)_2$–$CaSO_4$ solutions labeled with Ca^{45}: comparison of the observed activity of the liquid (in units of fraction of the initial value) with various predictions as functions of the composition of the liquid (again in units of fraction of the initial value, i.e. A/a).

Reaction of $C_3A\Sigma H_{12}$ *with Mixed* $Ca(OH)_2$–$CaSO_4$ *Solutions*

The reaction of $C_3A\Sigma H_{12}$ with mixed $Ca(OH)_2$–$CaSO_4$ solutions is of general interest, since it not only demonstrates the relative stabilities of the two sulphoaluminates in the solutions used, but may be considered representative of the behavior of the entire solid–solution series C_3AH_{12}–$C_3A\Sigma H_{12}$–C_4AH_{12}. The results are given in Table III, from which

TABLE III

Reaction of inactive $C_3A\Sigma H_{12}$ with mixed $Ca(OH)_2$–$CaSO_4$ solutions labeled with Ca^{45}

Calcium in solid, b (mole$\times10^4$)*	Loss from solution (moles calcium per mole $C_3A\Sigma H_{12}$)†	Duration of experiment (days)	Observed activity (fraction of initial value)	Predicted activities		
				(a) Surface or through-solution	(b) Internal or direct	(c) Recrystallization‡
6.43	2.08	3	.45	.43	.76	.51
6.63	1.97	4	.42	.42	.75	.50
6.68	(Lost)	9	.46	.42	.75	.50
6.88	2.14	15	.42	.40	.74	.49

*Samples of $C_3A\Sigma H_{12}$ having analyses near $C_3A\Sigma H_{10}$ (formula weight = 586.5) were used.
†The original solutions contained, per 50 cc, 13.13×10^{-4} mole calcium (a) and 8.8×10^{-4} mole sulphate.
‡Using the relation, fractional activity = $(a-b/2)/(a+b)$, as obtained from equation [13] of reference 7.

it can be seen that the loss of calcium from solution always corresponds to the complete conversion of the $C_3A\Sigma H_{12}$ to $C_3A\Sigma_3H_{31}$. In agreement with this, the large flat hexagons of $C_3A\Sigma H_{12}$ (Fig. 1A) were always found to be replaced by fine needles (Fig. 1B), even in the 3-day experiment.

Again equations [1] and [2] may be used to correlate the activity and composition of the liquid for the various possible mechanisms. However, since the reaction was complete, it is convenient to replace the variable A with b (the amount of labeled species initially present in the reacting solid). Noting that b is given by $A = a+b-m_2b/m_1$ (cf. equation [4] of reference 7), where $m_1 = 4$ and $m_2 = 6$, the result is

"surface" or "through-solution" mechanism — fractional activity $= (1-b/2a)^3$,

"internal" or "direct" mechanism — fractional activity $= (1-b/2a)$.

The theoretical and observed activities are compared in Table III (columns 4 to 6). A pure "surface" or "through-solution" mechanism is indicated, though a decision between these mechanisms cannot be made from the limited exchange data available.

Reactions at Elevated Temperatures

It will be recalled that the method used for preparing $C_3A\Sigma H_{12}$ involved mixing *boiling* solutions of $Al_2(SO_4)_3$, $CaSO_4$, and $Ca(OH)_2$ (see Experimental). A final group of experiments was therefore undertaken to determine if $C_3A\Sigma H_{12}$ could also be obtained as a product of a solid–liquid reaction. Samples of C_3AH_6 and $C_3A\Sigma H_{12}$ weighing about 0.05 g were added to 50-cc portions of a mixed $Ca(OH)_2$–$CaSO_4$ solution such that each portion contained 13.32×10^{-4} mole calcium and 6.45×10^{-4} mole sulphate, and were shaken inside an oven for periods of up to 7 days. For temperatures of 70° and 90° C the reaction products were consistently acicular, and solution analyses confirmed that $C_3A\Sigma_3H_{31}$ had formed. $C_3A\Sigma H_{12}$ can therefore *not* be obtained as a product of a solid–liquid reaction under the conditions of the experiments.

Though the solutions were labeled, the rapid attainment of radioactive equilibrium made it impossible to distinguish different reaction mechanisms.

DISCUSSION

Stabilities

Little need be said about the observed stability of C_3AH_6 in $Ca(OH)_2$ solutions at 25° C. On the other hand, it is significant that at 25°, 70°, and 90° C the compounds C_3AH_6 and $C_3A\Sigma H_{12}$ consistently reacted with mixed $Ca(OH)_2$–$CaSO_4$ solutions to form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

$C_3A\Sigma_3H_{31}$. $C_3A\Sigma_3H_{31}$ thus appears to be the stabler sulphoaluminate over the entire temperature range 25° to 90° C, so that the ready formation of $C_3A\Sigma H_{12}$ by mixing hot solutions, as described earlier, must have been associated with a greater *crystallizability*, as distinct from *stability*, for this compound at elevated temperatures.

Mechanisms

From the observed relations between the activity and composition of the liquid, the C_3AH_6–$C_3A\Sigma_3H_{31}$ reaction was concluded to proceed with a "surface" mechanism, and the $C_3A\Sigma H_{12}$–$C_3A\Sigma_3H_{31}$ reaction with either a "surface" or "through-solution" mechanism. Now, in making the various calculations to determine mechanisms, the extent of *all* rapid, multidirectional exchange between the liquid and both solids was assumed to be slight; or, what is equivalent, n_1 and n_2 (the portions of m_1 and m_2 undergoing rapid, multidirectional exchange, whether external or internal) were approximated as approaching zero. It is interesting to consider what the activity predictions would have been for the C_3AH_6–$C_3A\Sigma_3H_{31}$ reaction had the actual values of n_1 and n_2 been taken into account. Introducing $n_1 = 0.42$ (Table I) and $n_2 \sim 0.6$ (Table II, footnote †) into equation [1] of reference 7, substituting the latter into equation [3] of reference 7, and assuming the reaction to be complete, one obtains

$$[4] \qquad \text{fractional activity} = \frac{1-b/a}{1+0.42b/3a}\left\{1-\frac{2.82b}{3a+0.42b}\right\}^{0.915}.$$

For the case $a = 4b$ (as in the first experiments of Table II), equation [4] yields 0.572, to be compared with 0.563 from equation [1]. Similarly for $a = 2b$ (as in the last experiments of Table II) one obtains, respectively, 0.276 and 0.250 from the full and abbreviated expressions. The differences in the activity predictions are thus not great, though the predictions using equation [4] lie in such a direction as to bring about a slightly better fit between experiment and theory (cf. Fig. 3).

A more serious difficulty than the presence of various *known* exchange processes in determining solid–liquid reaction mechanisms is the possibility that the freshly formed product solid may have been subject to unexpectedly extensive recrystallization, or else that long-lived (i.e. non-transient) solid intermediates may have occurred. As pointed out in reference 7, these effects tend to make the activity the same for all mechanisms in the later stages of reaction. Thus for the C_3AH_6–$C_3A\Sigma_3H_{31}$ reaction, assuming $n_1 \to 0$, the activity would always be close to (from equation [13] of reference 7)

$$[5] \qquad \text{fractional activity} = \frac{A/a}{2-A/a}.$$

Equation [5] is plotted in Fig. 3, where it is seen that, while the experimental data for high values of A/a are equally consistent with either equations [1] or [5] and therefore quite ambiguous (cf. 8, p. 141–142), the three experiments with low A/a still point to a simple "surface" mechanism. The originally proposed mechanisms also appear to be adequate for the $C_3A\Sigma H_{12}$–$C_3A\Sigma_3H_{31}$ reaction (see Table III, columns 4, 5, and 7).

No substantial objection to assigning "surface" or "through-solution" mechanisms to the reactions studied appears to exist. Four other reactions have also been shown to follow one or the other of these mechanisms:[4] the hydrations of $3CaO.SiO_2$, $2CaO.SiO_2$

[4]*In the original work these reactions are* all *described as following a "through-solution" mechanism. However, as pointed out in reference 7, there is reason to believe that the hydrations of* $CaSO_4.\frac{1}{2}H_2O$ *and dead-burnt* CaO, *in particular, are actually more nearly consistent with a "surface" mechanism.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

(8), $CaSO_4.\frac{1}{2}H_2O$ (12), and dead-burnt CaO (13). In only one case has a different mechanism been observed: the hydration of soft-burnt (i.e. porous) CaO (13), which proceeds with a mixture of "surface" and "internal" mechanisms (cf. footnote 4). It therefore seems likely that, except with porous substances, a "surface" or "through-solution" mechanism occurs *invariably*. Which of these two mechanisms will prevail in individual cases depends, of course, on the presence or absence of rapid, multidirectional *external* exchange; however, *surface* exchange is probably always multidirectional and external, and is usually also rapid (14), so that the "surface" mechanism may be expected to be generally applicable.

NOTES

A NOTE ON THE CYCLIZATION OF 3-(2′-NAPHTHYL)-BUTYRIC ACID

P. M. G. Bavin

In reporting the ultraviolet spectra of some polyalkylphenanthrenes prepared by Haworth and his co-workers, Askew (1) noted that three of them showed additional peaks at wavelengths longer than those expected for phenanthrene derivatives. The anomalous peaks are collected in Table I for comparison with the longest wavelength

TABLE I

	Anomalous peaks (mμ)		
1,7-Dimethylphenanthrene	381	371	359
2,3-Dimethylphenanthrene	379		358
1,6,7-Trimethylphenanthrene	380		360
Anthracene (5, p. 175)	374.5		354.5

peaks of anthracene. There can be little doubt that the polyalkylphenanthrenes contained at least traces of the corresponding alkylanthracenes since the observed spectral shifts are of the order expected for two or three methyl substituents, if it is assumed that the shifts are additive. This assumption is widely accepted (2) and is supported by published spectra of polyalkylphenanthrenes (1, 3) and polyalkylnaphthalenes (2). (For the spectrum of 9-methylanthracene see ref. 4 and ref. 5 (p. 63) and for the spectrum of 1-methylanthracene see ref. 6. The spectrum of 2-methylanthracene has not been published but the effect of the methyl group has been obtained by difference (2).)

The cyclization of 3-(2′-naphthyl)-butyric acid by hydrogen fluoride has now been examined. The crude neutral product was successively reduced and dehydrogenated to give phenanthrene containing 2% anthracene, as determined spectroscopically.

These results emphasize the difficulty of obtaining pure compounds by routes involving cyclization, and show that, like most substitution reactions of naphthalene, both α and β products are to be expected. Cyclizations occurring predominantly at a β-position may be attributed to steric hindrance (7, 8, and references therein).

1-Aza-anthracene could not be detected among the products of the Skraup reaction on 2-aminonaphthalene, possibly because of the ease with which it is oxidized (9).

EXPERIMENTAL

Pure 3-(2′-naphthyl)-butyric acid (2.7 g), prepared from naphthalene, was dissolved in hydrogen fluoride (150 ml) and the solution left at room temperature for 48 hours. The neutral product was reduced (Clemmenson–Martin) and the crude hydrocarbon dehydrogenated (10% palladium on charcoal at 300°). The crude aromatic hydrocarbons dissolved in hexane were passed through a short (1×1 in.) column of activated alumina to remove traces of tar, elution being continued with benzene–hexane (1:5) to recover all the product. The eluted material was dissolved in ethanol and the ultraviolet spectrum recorded, using a Beckmann DK-2 recording spectrophotometer. Comparison with

standard mixtures* showed the phenanthrene to contain 2% anthracene. For the analysis, anthracene peaks at 376 and 357 mμ (cf. 5, p. 175) and phenanthrene peaks at 339, 330, and 323 mμ (cf. 5, p. 142) were used.

A separate experiment established that phenanthrene was not isomerized on the palladium catalyst.

The products from the Skraup reaction on 2-aminonaphthalene (11) were dissolved in hot heptane and passed through a column of alumina to remove tar, elution being continued with benzene–hexane (1:5) to recover all of the products. The eluted material was fractionally crystallized from ethanol to show that at least 95% was 1-aza-phenanthrene. The residues were chromatographed (hexane–alumina) and the ultraviolet spectra recorded for successive fractions. Those fractions showing peaks at wavelengths longer than 360 mμ were examined further,† by descending chromatography on buffered paper (12) at pH's 3 and 6, using *n*-butanol saturated with water as solvent. Spots located under an ultraviolet lamp were eluted with ethanol and the spectra of the solutions recorded. A trace of an unidentified compound was detected, having characteristic absorption peaks at 396, 386, and 375 mμ. (1-Aza-anthracene has peaks at 384, 366.5, 356.5, and 340 mμ (13) and these values were confirmed by preparing and examining an authentic specimen (14).)

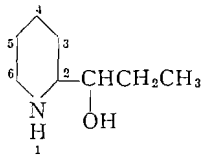
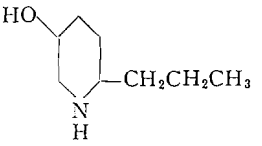
A COLOR TEST FOR CERTAIN PIPERIDINE AND PYRROLIDINE ALKALOIDS*



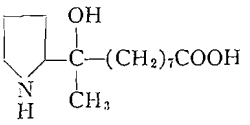
D. J. McCaldin†

The blue color formed from isatin and proline has frequently been used as a method for detecting this imino acid after paper chromatography (1). On the basis of recent work (2) the structure of this pigment has been revised (I), and it is now possible to extend the use of the reaction for the detection of similar compounds in alkaloidal extracts.

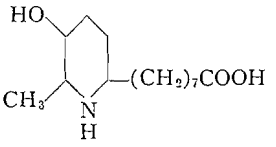


I

The test described is specific for alkaloids with a single six- (or five-) membered ring containing the sequence —NH—CH_2—CH_2—. Thus conhydrine (II) gives a positive reaction whereas ψ-conhydrine (III) does not, owing to the presence of substituents in both the 2 and the 5 positions.



II



III

Previous workers (3) suggested that the sequence required for pigment formation was —CH_2—NH—CH_2—, and the earlier structure proposed for carpamic acid (IV) was based on its negative reaction with isatin (4). In fact, a compound with this structure would be expected to react, whereas the revised structure (V) would not (5).

IV

V

Certain α-imino acids, such as 4-hydroxyproline, do not appear to contain the arrangement of atoms necessary for color development. However, the carboxyl group is lost in each case during the reaction and the conditions for pigment formation are thus fulfilled. The negative results obtained from hygrine, stachydrine, hygric acid, and N-methylpipecolic acid can be explained by the absence of the —NH— group. Azetidine 2-carboxylic acid (6) and hexamethyleneimine did not react normally, showing that ring

Issued as N.R.C. No. 5688.

size is a critical factor. An imino acid extracted from apples (11) also yields a positive result in this test, and is tentatively regarded as 4-hydroxymethylproline.

This method of detecting certain alkaloids after paper chromatography can be used in conjunction with other techniques. The individual components of a mixture of such compounds may be detected in the following manner. The chromatogram is sprayed

TABLE I

Color obtained with isatin reagent

with isatin, baked, and subsequently treated with Dragendorff's reagent (12). Hygric acid and N-methylpipecolic acid are shown to be present when the paper is first treated with potassium permanganate (to remove the N-methyl group). Other N-methylated compounds, such as methyl hygrate, are not converted to the corresponding secondary imines.

EXPERIMENTAL

General Method

A descending one-dimensional paper chromatographic technique was used to separate and detect a typical mixture of proline and coniine. The mixture and reference compounds were placed on a paper strip (Whatman No. 1) and developed with the upper phase of a butan-1-ol – acetic acid – water (4:1:5 by volume) mixture as solvent. The detecting agent was a 0.1% (w/v) solution of isatin in aqueous acetic acid (5%). Since coniine is rather volatile, the developed chromatogram was only partially dried (15 minutes at room temperature) before it was sprayed with the isatin solution. The colors developed after baking in the oven at 130° for 5 minutes; the proline spot had $R_F = 0.39$, and the coniine spot $R_F = 0.81$ at 25°.

Detection of Hygric Acid or N-*Methylpipecolic Acid*

Two paper strips were prepared and developed as described above. The chromatograms were dried and a cold, saturated solution of potassium permanganate in a mixture of acetone and pyridine (95:5) was sprayed onto one paper. The positions of the chromatographed materials were apparent from the appearance of yellow spots on the purple background. The corresponding areas on the second chromatogram were then sprayed with the oxidant and the paper dried at room temperature. It was then treated in the normal manner as previously described.

SOME NEW BENZILIC ACID DERIVATIVES

FRANCIS L. CHUBB, GERASSIMOS FRANGATOS, AND JACQUELINE NISSENBAUM

Morrison, Konigstein, and Cohen (1) have synthesized a series of esters of benzilic acid (I) related in structure to benadryl and trasentin. Klosa (2) has also reported that 2-dimethylaminoethyl esters of alkoxydiphenylacetic acid (II) possess strong analgesic and sedative action. In this communication we wish to describe the synthesis of some new benzilic acid derivatives similar in structure to both I and II. These compounds (III–VI) are listed in Table I. The intermediates required for their preparation are listed in Table II.

SOME NEW BENZILIC ACID DERIVATIVES

FRANCIS L. CHUBB, GERASSIMOS FRANGATOS, AND JACQUELINE NISSENBAUM

Morrison, Konigstein, and Cohen (1) have synthesized a series of esters of benzilic acid (I) related in structure to benadryl and trasentin. Klosa (2) has also reported that 2-dimethylaminoethyl esters of alkoxydiphenylacetic acid (II) possess strong analgesic and sedative action. In this communication we wish to describe the synthesis of some new benzilic acid derivatives similar in structure to both I and II. These compounds (III–VI) are listed in Table I. The intermediates required for their preparation are listed in Table II.

When an attempt was made to prepare dimethylaminoethyl diphenyl(2-hydroxyethoxy) acetate hydrochloride (VII) by the reaction of ethylene glycol with dimethylaminoethyl chlorodiphenylacetate hydrochloride, ring closure to form the cyclic lactone VIII occurred. Alkaline hydrolysis converted VIII to the corresponding acid IX.

EXPERIMENTAL

Dialkylaminoethyl Benzilate Hydrochlorides (Table II)

These compounds were prepared from benzilic acid and the required 2-chloroethyldialkylamine according to the general method of Horenstein and Pahlicke (3).

Dialkylaminoethyl Alkoxydiphenylacetate Hydrochlorides (Table I)

Compounds III, IV, and V were prepared from the dialkylaminoethyl benzilate hydrochlorides by way of the corresponding chlorodiphenylacetate hydrochlorides as described by Klosa (4). Details of the preparation of dimethylaminoethyl 2-chloroethoxydiphenylacetate (III) are given below, since Klosa's procedure was modified in this case.

A mixture of 15 g of dimethylaminoethyl chlorodiphenylacetate hydrochloride, 3 g of calcium carbonate, and 76 ml of freshly distilled 2-chloroethanol was refluxed for 24 hours with mechanical stirring. The hot reaction mixture was filtered and then allowed to cool. The solvent was distilled under reduced pressure and the residue extracted with acetone and filtered. After distillation of the acetone the residue was treated with 200 ml of 10% sodium hydroxide and extracted with ether. The dried ether layer (calcium chloride) was then saturated with hydrogen chloride at 3 to 4°. The hydrochloride precipitated as a crystalline product, 8.5 g (51%), m.p. 145–151°.

The material was purified by dissolving it in isoamyl alcohol and slowly pouring the resulting solution into anhydrous ether containing some seed crystals, m.p. 145–148°. The mixture was not stirred but kept overnight at 5°. Filtration yielded crystals melting at 145–148°.

Diethylaminoethyl 2-(1-Pyrrolidyl)ethoxydiphenylacetate (VI)

This compound was prepared from ethyl benzilate according to the method of Morrison, Konigstein, and Cohen (1).

2,2-Diphenyl-3-keto-1,4-dioxane (VIII)

A mixture of 20 g of dimethylaminoethyl chlorodiphenylacetate hydrochloride, 4.5 g of calcium carbonate, and 100 ml of ethylene glycol was heated for 24 hours at 90–100°. After the solution was filtered it was made basic with sodium hydroxide. The resulting solid was filtered and washed with dilute hydrochloric acid. After recrystallization from alcohol–water a yield of 8.5 g (59%), m.p. 95–97°, was obtained. A second recrystallization raised the melting point to 98–99°. Anal. Calc. for $C_{16}H_{14}O_3$: C, 75.59; H, 5.51. Found: C, 75.11; H, 5.62.

Diphenyl(2-hydroxyethoxy)acetic Acid (IX)

2,2-Diphenyl-3-keto-1,4-dioxane (1 g) was refluxed with 10 ml 10% sodium hydroxide for 2 hours. After dilution and acidification of the solution, the product, m.p. 122–123°, after recrystallization from alcohol–water, was obtained. Anal. Calc. for $C_{16}H_{16}O_4$: C, 70.6; H, 5.88. Found: C, 70.64; H, 6.06. Neut. eq. Calc.: 272. Found: 272.

EFFECT OF NITRIC OXIDE IN THE γ-RADIOLYSIS OF ETHANE AT VERY LOW CONVERSIONS

KANG YANG

Back and Miller (1) investigated the radiolysis of gaseous saturated hydrocarbons at very low conversions. They found an important fact: The $G(H_2)$ values corresponding to initial rates are approximately twice the values estimated at the higher conversions.

We investigated the formation of hydrogen in ethane and ethane – nitric oxide systems. Our results very closely agree with the results of Back and Miller and also with inhibition data of Back (2) using ethylene as a radical scavenger.

In this note we summarize our results. This probably strengthens the contribution of Back and Miller. In addition a new conclusion is drawn: nitric oxide scavenges hydrogen atoms with negligible effect on the nonradical processes leading to the molecular hydrogen in the ethane radiolysis.

EXPERIMENTAL

Phillips' research grade ethane is carefully degassed by repeated evacuations at liquid nitrogen temperature and then subjected to four-stage bulb-to-bulb distillation each time retaining only the middle third. Purified ethane is introduced in Pyrex vessels (156 cc). The gamma source was four spent fuel elements from the Engineering Test Reactor, Arco, Idaho. Energy input rate was 7.9×10^{-4} electron volts per hour per molecule of ethane. This was estimated assuming that $G(H_2)$ in methane radiolysis is 5.7 molecules per 100 electron volts (3).

Hydrogen in irradiated samples was analyzed by gas adsorption chromatography (silica gel column, argon carrier, room temperature).

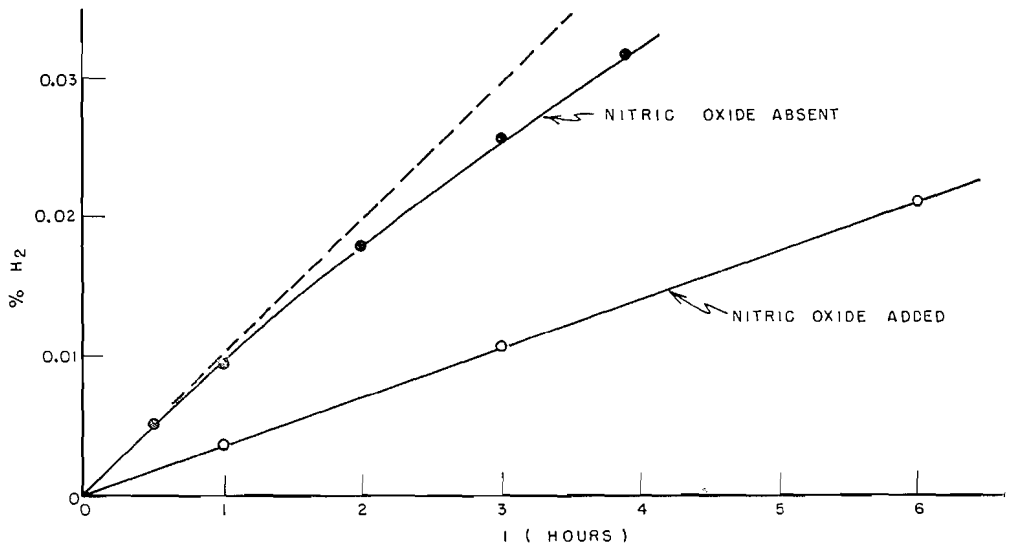

FIG. 1. Formation of hydrogen in ethane radiolysis in the presence and absence of nitric oxide.

RESULTS AND DISCUSSION

In Fig. 1 the rate of formation of hydrogen is shown as a function of irradiation time. In the absence of nitric oxide, the rate decreases with increasing conversion. Initial rate estimated from Fig. 1 is 1.93 times the rate at 0.68% conversion of ethane.

In the presence of nitric oxide, the rate is constant. Estimated percentage of radical contribution to the hydrogen formation at the initial period of the reaction was 64% (4).* The value is in close agreement with Back's result of 63% obtained using ethylene as a scavenger (2).

We have seen that both ethylene and nitric oxide give the same yield for the molecular hydrogen. This can best be explained by assuming that high enough concentrations of nitric oxide and ethylene to scavenge most of the hydrogen atoms had no measurable effect on the nonradical processes yielding molecular hydrogen, an important condition that a satisfactory radical scavenger in the radiolysis reactions should satisfy.

From Fig. 1 it is also clear that only $G(H_2)$ due to radical reactions decreases with increasing conversion. This supports Back's explanation that decrease in $G(H_2)$ at high conversion is due to the formation of unsaturated radiolysis products.

This is much higher than the values estimated at the higher conversion.

A MECHANISM FOR THE INDUCTIVE EFFECT

Henry A. Bent

To the author's knowledge, no detailed mechanism has yet been given to explain the *modus operandi* of the inductive effect. It is the purpose of this note to propose a mechanism for the inductive effect and to show that this effect must be coupled in a predictable manner to certain differential changes in molecular geometry. The language chosen for the present discussion is the familiar language of valence-bond theory and hybrid atomic orbitals; although it may be noted that well-known, but for present purposes less convenient, alternatives do exist (1–5).

Discussion of the experimental evidence that has been marshalled in support of the present argument may be separated into two related parts: (1) the effect of electronegative groups on atom hybridization and (2) the effect of atom hybridization on electronegativity.

(1) The Effect of Electronegative Groups on Atom Hybridization

The XOY bond angles in CH_3OCH_3, CH_3OH, HOH, and FOF are, respectively, 111° (6), 109° (7), 105° (8), and 101° 30′ (5). In CH_3SH and HSH the bond angles are, respectively, 100° (9) and 92° (5). The same consistent decreases in interbond angle

A MECHANISM FOR THE INDUCTIVE EFFECT

Henry A. Bent

To the author's knowledge, no detailed mechanism has yet been given to explain the *modus operandi* of the inductive effect. It is the purpose of this note to propose a mechanism for the inductive effect and to show that this effect must be coupled in a predictable manner to certain differential changes in molecular geometry. The language chosen for the present discussion is the familiar language of valence-bond theory and hybrid atomic orbitals; although it may be noted that well-known, but for present purposes less convenient, alternatives do exist (1–5).

Discussion of the experimental evidence that has been marshalled in support of the present argument may be separated into two related parts: (1) the effect of electronegative groups on atom hybridization and (2) the effect of atom hybridization on electronegativity.

(1) The Effect of Electronegative Groups on Atom Hybridization

The XOY bond angles in CH_3OCH_3, CH_3OH, HOH, and FOF are, respectively, 111° (6), 109° (7), 105° (8), and 101° 30′ (5). In CH_3SH and HSH the bond angles are, respectively, 100° (9) and 92° (5). The same consistent decreases in interbond angle

with increasing electronegativity of the substituent group occurs in phosphorus and arsenic compounds (10) and in the series $N(CH_3)_3$, NH_3, and NF_3, where the XNX interbond angles are, respectively, 109° (10), 106° 46′ (10), and 102° 30′ (5). Additional examples are cited by Mellish and Linnett (5). As noted by these authors, it is an interesting fact that changes in interbond angles are often in the reverse direction from what one would expect if repulsions between nonbonded atoms were the most important effect operating. In every case, it would appear that replacement of an atom or group of atoms by a group of greater electronegativity causes the atom on which substitution occurred to rehybridize in such a manner that some of its *s*-character is withdrawn from the orbital where substitution occurred. Further evidence of this may be obtained from a study of interatomic distances.

Currently there is increasing recognition of the suggestion that atom hybridization has an appreciable effect not only on bond angles, as is well known, but on bond lengths as well. Data bearing on this issue has been summarized recently by Brown (11). If the view that atom hybridization may have a pronounced effect on bond lengths is adopted, the conclusion is quickly reached that bond lengths decrease noticeably as the *s*-character in the bond increases. Typically, the carbon–carbon single-bond distance appears to decrease by about 0.04 Å each time one of the participating carbon atoms changes hybridization from sp^3 to sp^2 or from sp^2 to sp. For carbon–halogen bonds, the effect appears to be even more pronounced. While it is not our purpose here to offer a detailed explanation of these effects in terms of an hybridization-ratio-dependent covalent radius, we may note that preliminary considerations do suggest that such an explanation may be possible. Adoption of this hypothesis conjointly with the data on bond angles cited above leads to the supposition that bond lengths should vary with the electronegativity of adjacent substituents. Indeed, the noticeable foreshortening of bond lengths that occurs when fluorine atoms are introduced into molecules has been commented upon (12). For example, the C–F distance is 1.391 Å in CH_3F, whereas it is only 1.323 Å in CF_4. Numerous other examples exist in the current literature that illustrate the foreshortening that occurs in bond lengths when an atom of relatively low electronegativity, such as hydrogen, is replaced by an atom of greater electronegativity, such as fluorine, or one of the other halogens. It is interesting to note that the change in molecular parameters is again often in the reverse direction from what one would expect if repulsions between nonbonded atoms were the important effect operating.

If unshared pairs are regarded as electrons in a bond to an atom of zero electronegativity, the evidence cited above concerning the effect of electronegative groups on molecular geometry may be summarized in the statement: *The s-character of an atom tends to concentrate in orbitals that are directed toward electropositive groups.*

(2) The Effect of Atom Hybridization on Electronegativity

Inductive constants for a carbon atom in an sp^3 valency, sp^2 valency, and an sp valency have been given by Taft (13). He finds $H_3C- = -0.100$, $CH_3\overset{\overset{O}{\|}}{C}- = +0.60$, and $NC- = +1.300$. On this scale the inductive constant for chlorine is +1.10. More recently, Petro has calculated from dipole moment data and infrared dispersion data these carbon–carbon bond moments: $(sp^3)^+-(sp^2)^- = 0.68D$, $(sp^2)^+-(sp)^- = 1.15D$, and $(sp^3)^+-(sp)^- = 1.48D$ (14). He finds, also, that chlorine constitutes the positive end

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

of the C—Cl bond moment in HC≡CCl. These results provide strong confirmation of the statement by Mulliken (15) and Walsh (16) that *the more s-character in an atomic valency, the more electronegative is the atom in that valency.*

Combining these two attributes of the *s*-character of an atom, one obtains the following picture of the inductive effect. Consider the array A—X—B, and suppose that the electronegativity of the group at B increases. This change will cause X to rehybridize slightly, so as to shift some of its *s*-character from the bond B to the bond to A, where the low potential energy space characteristic of an *s*-orbital will be used to greater advantage. In effect, the electronegativity of X toward A becomes greater. In turn, by an identical, but smaller, operation of the same mechanism, the electronegativity of A toward attached groups (other than X) becomes greater.

THIAZOLES. IV. PROTON MAGNETIC RESONANCE SPECTRA OF THIAZOLE AND ITS METHYL DERIVATIVES*,†

A. Taurins and W. G. Schneider

The proton resonance spectra of five-membered cyclic unsaturated compounds are of considerable interest not only from the standpoint of structure determination in complex organic molecules, but also in connection with the rather unusual proton spin-coupling interactions in these systems (1, 2, 3). In this connection the high-resolution proton resonance measurements of thiazole, which contains two heteroatoms in the five-membered ring, are of some interest. Figure 1 shows a reproduction of the proton

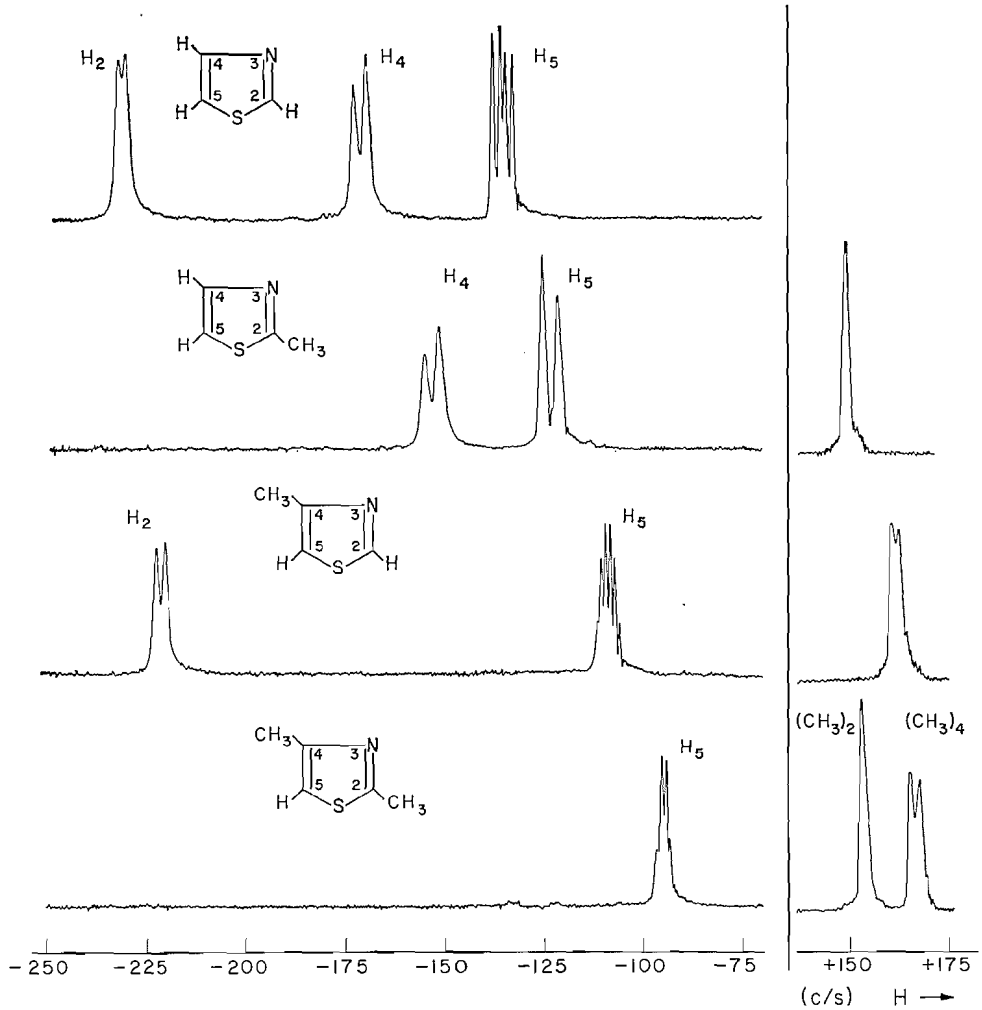

FIG. 1. Proton magnetic resonance spectra of thiazole and its methyl derivatives at 60 Mc/s. Samples were measured as the pure liquids. Frequency scale is relative to an external water reference. The signals of the methyl group protons were recorded at a lower gain than those of the protons bonded to the thiazole ring.

resonance spectrum at 60 Mc/s for thiazole and for three methyl derivatives. With the aid of the spectra of the latter compounds an unambiguous assignment can be made for the parent compound, as shown in Fig. 1. The measured chemical shifts and spin-coupling constants for the protons bonded to the ring are summarized in Table I. The additional signals arising from the methyl substituents, which appear on the high field side of the reference water signal, are also shown in Fig. 1. A splitting of about 1 cycle/second between proton 5 and a methyl group in the 4 position is observed.

The most striking features of the above spectra are the relatively broad signals arising from the protons at positions 2 and 4, and in contrast, the sharp signal arising from the proton at position 5. (In the compound 2-methylthiazole the H_5 signal appears somewhat broader due to an unresolved coupling arising from the methyl group at position 2.) Protons H_2 and H_4 are both two bonds removed from the nitrogen atom whereas H_5 is

TABLE I

Proton chemical shifts and spin-coupling constants for thiazole and methylthiazoles

Compound	Chemical shifts* (cycles/sec)			Spin-coupling constants (cycles/sec)		
	H_2	H_4	H_5	J_{24}	J_{45}	J_{25}
Thiazole	−231	−170	−135	0	3.1	1.8
2-Methylthiazole	—	−152	−125	—	3.6	—
4-Methylthiazole	−220	—	−107	—	—	2.0
2,4-Dimethylthiazole	—	—	−94	—	—	—

*Measured at 60 Mc/s, in cycles per second relative to proton resonance of water (external reference).

three bonds removed. It is evident that the H_2 and H_4 signals are broadened by the nitrogen quadrupole relaxation and that this perturbation becomes sufficiently attenuated at proton H_5 to give rise to more nearly normal proton line widths. A similar behavior is observable in the proton resonance spectrum of pyridine, the proton signals of the α-hydrogens being noticeably broader than those of the β-hydrogens. In both thiazole and pyridine the electronic charge distribution about the nitrogen atom can be concluded to be highly asymmetric.

The electronegativity of C and S atoms is generally considered to be comparable and significantly less than that of the N atom (4). Thus the signals of H_2 and H_4 may be expected to appear at lower field than that of H_5, but the reason for the large difference in chemical shift between H_2 and H_4 is not readily apparent. The signal of proton H_2, which is in the α-position with respect to both S and N atoms, appears at considerably lower field than that of H_4, which is in the α-position with respect to C and N atoms. It may be noted further that methyl substitution in all cases shifts the ring proton signals to higher field, suggesting a high degree of "aromaticity" in the ring.

A further anomaly is to be found in the spin-coupling constants. Thus the proton pairs H_2 and H_4 and H_2 and H_5 are separated by an equal number of bonds between them, but while J_{25} is of the order of 2.0 cycles/sec, J_{24} could not be resolved. The possibility that the spin coupling between H_2 and H_4, which must go via the N atom, is perturbed by the nitrogen quadrupole relaxation must be considered. Since the coupling between H_2 and H_5 is via the S atom, which is a non-magnetic nucleus, this coupling is unperturbed. The coupling between H_2 and H_4 can of course also proceed via the S atom, but since this path involves an additional bond the coupling will be significantly less.

The authors wish to thank Mr. J. Nicholson for technical assistance.

STUDIES OF RATES OF CONVERSION AND POPULATIONS OF VARIOUS CONFORMATIONS OF SATURATED RING COMPOUNDS BY N.M.R.

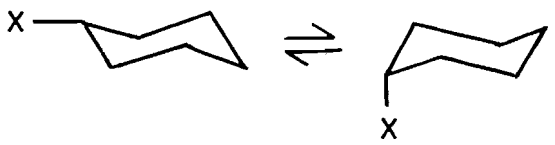
I. CHLOROCYCLOHEXANE AND BROMOCYCLOHEXANE[1]

L. W. REEVES AND K. O. STRØMME[2]

ABSTRACT

The populations of equatorial and axial halogen forms of chloro- and bromo-cyclohexane have been studied by proton magnetic resonance between 25° and −104° C in carbon disulphide solution. From the equilibrium constants obtained the free energy change between the two conformations is obtained. The bromo compound has 82% of the equatorial halogen form and the chloro compound 77%. Estimates of the populations are also available for room temperature from the chemical shift measurements. The energy barrier for conversion between the two forms is approximately 10,850 calories. A simple Lennard-Jones potential with the available estimates of van der Waals radii is used to calculate the differences in energy of the two forms.

The difference in nuclear shielding between the axial and equatorial protons in acetylated sugars was first detected by Lemieux, Kullnig, Bernstein, and Schneider (1). This has become a very useful method of determining the conformation of sugars and has been followed up by studies of trioxanes (2) and the isomeric hexachlorocyclohexanes (3). In almost all these compounds the conformations are locked by large groups so that in most cases distinct isomers can be isolated. In the case of the hexachlorocyclohexanes the theoretically possible isomers are reduced to just a few known compounds by the fact that steric hindrance renders almost all of these conformations unfavorable (4).



In contrast to the highly substituted derivatives, the simpler cyclohexanes do not show proton resonance spectra with distinct signals for axial and equatorial protons (5). The lack of large substituted groups allows the rapid interconversion of the various conformations and only the averaged shielding parameter is effective (6). The proton resonance technique has proved a useful method of measuring the lifetime of nuclei in distinct chemical environments (7, 8, 9, 10) and the present and future studies of these systems will be aimed at measuring the rates of interconversion between conformations and the population of the conformers in equilibrium at temperatures where distinct proton resonances can be obtained for the individual species.

Such studies will give enthalpy differences and energy barriers for the internal conversion over series of related compounds.

In this present paper two compounds of the type

are studied. The equilibrium populations are obtained in one solvent at various temperatures. An estimated rate is obtained at one temperature but the study of variation of solvent will be left for later work. The influence of solvent on such isomeric equilibria in solution has been dealt with by Bernstein and Powling (11) and Reeves (12, 10).

EXPERIMENTAL

Analytical grade chlorocyclohexane and bromocyclohexane were used without further purification. The solutions were prepared with redistilled carbon disulphide, which is the most suitable solvent for low-temperature work and has the advantage of no external dipole moment and no proton resonance. It is intended to vary polarity of solvent in later work.

The solutions prepared had the following composition:
(A) mole% $C_6H_{11}Cl$ = 54.5, mole% CS_2 = 37.4, mole% tetramethyl silane = 8.1;
(B) mole% $C_6H_{11}Br$ = 55.4, mole% CS_2 = 41.2, mole% tetramethyl silane = 3.4.

A 40 Mc/sec Varian V4300 high-resolution spectrometer was used for the work. The low-temperature arrangement used was a modification of an apparatus described by Schneider, Bernstein, and Pople (13). The arrangement will be described more completely later. The samples are contained in 3-mm I.D. tubes which are sealed off in vacuum and have two bearings: the upper one, a tungsten wire, sealed into glass, and the lower one, a glass tit bearing, which lowers into a drilled teflon plate. The sealing and accurate alignment of bearings is achieved by use of a microglass lathe to be described by one of us (L. W. R.).

The tube is contained in a Dewar arrangement previously described (13). A 15-mm Varian insert is used and there is Dewar insulation between the insert coil and the cooled sample. The small air space between the Dewar and the insert wall is circulated with dry nitrogen at room temperature so that no cooling or condensation can occur even on the outside of the transparent Dewar. Spurious water peaks are thus avoided.

Cooling is achieved by a heater placed in a 25-liter metal Dewar of liquid nitrogen with exit tube and blowoff valve. In cases where it is necessary to heat the sample at any time, a small heating coil in the nitrogen stream is used. The cooled nitrogen stream spins the sample from tangential holes striking the shaped glass rod top of the sample tube. Since a more or less constant spinning rate is desirable the faster streams of nitrogen obtained at low temperatures are bled off in a side tube and only part of the stream is used for spinning and cooling.

A previous study of methyl nitrite at low temperatures demonstrates the reproducibility of the apparatus (12(*b*)). Providing the viscosity of materials is favorable, high-resolution spectra comparable to those taken at room temperature can be obtained down to $-180°$ C and in this work spectra were measured in the region as low as $-120°$ C. The temperature control as indicated by a copper constantan thermocouple in the exit stream near the sample is approximately $\pm 1°$ C down to $-80°$ C and $\pm 1.5°$ C below this, over 15-minute periods.

RESULTS

Spectra of solution A and solution B at 28° C are shown in Fig. 1. Spectrum (*a*) corresponds to bromocyclohexane in CS_2 and spectrum (*b*) corresponds to chlorocyclohexane in CS_2. Peak II is the proton resonance in the —CHX— proton and peak I in the $—C_5H_{10}—$ protons. The internal standard tetramethyl silane is shown to high field as peak 0. The spectrum is calibrated by 50, 100, 150, and 200 c.p.s. side bands in some

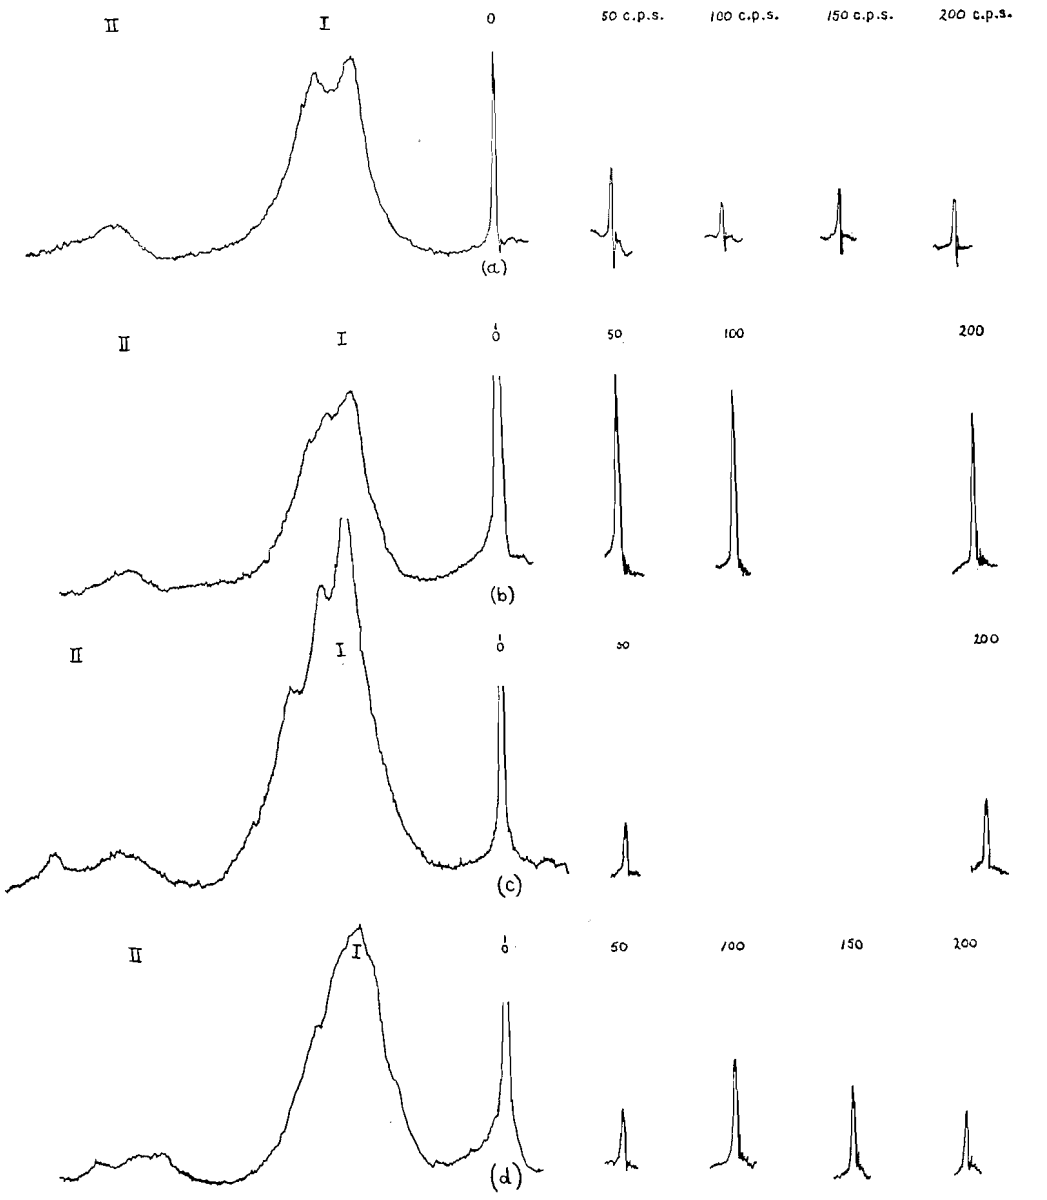

FIG. 1. (*a*) Spectrum of bromocyclohexane at 40 Mc/sec in CS_2 with $Si(Me)_4$ standard signal. Solution B 28° C. (*b*) Spectrum of chlorocyclohexane solution in CS_2 at 28° C. (*c*) Spectrum of bromocyclohexane at −104.5° C. (*d*) Spectrum of chlorocyclohexane at −91° C.

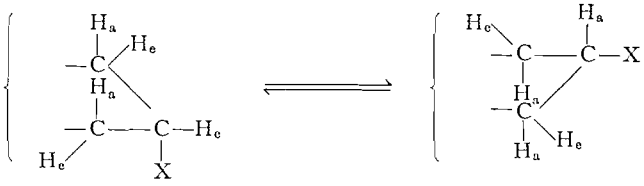

cases, as shown in Fig. 1. The irregular base line which occurs during the seep between side bands due to the process of switching off the audio oscillator and resetting at a new value is caused by side bands of the $-C_5H_{10}-$ peaks. The base line has therefore been removed in most cases. The lack of ringing off the first tetramethyl silane peak is due to a prompt addition of 50 c.p.s. side bands after passing through this signal. The instrumental resolution is better seen from the audio side band peaks.

The —CHX— signal is seen to be a broad band approximately 12 c.p.s. in half width. This arises from a number of similar coupling constants with nuclei which are considerably chemically shifted ($-C_5H_{10}-$) and is characteristic of similar situations which arise in substituted hydrocarbon chains (3, p. 235–238). The fine structure of this peak can to a certain extent be resolved with higher gains and slower passage through resonance but this has not been relevant to the present study. The signal I in spectrum (*a*) for bromocyclohexane consists of two main broad peaks. The low-field peak is due to the $-CH_2-$ groups on each side of the —CHX— grouping and the high-field part of this group of lines is due to the remote $-(CH_2)_3-$ protons from the —CHX— grouping.

The main features of the chlorocyclohexane spectrum are similar, except that signal I is not so well resolved into the methylene groups adjacent to —CHX— and the remote methylene peaks.

The lack of two main components for the low-field signal in each case at 28° C shows a rapid equilibrium between the two chair forms. The —CHX— proton is rapidly converted between axial and equatorial position. On the cooling of both solutions, a distinct broadening of the low-field signal is observed at −40° C and single broad signal occurs at −55° C. Below this temperature two signals are resolved which do not change in appearance appreciably between −70° C and the solidification point (∼−95° C for the chlorocyclohexane solution and ∼−110° C for the bromocyclohexane solution). Marked changes in the general shape of the high-field signal can be detected as high as −25° C. The bromocyclohexane spectrum at high field shows the appearance of an additional low field peak, but the lack of resolvable structure in chlorocyclohexane makes it difficult to classify the changes which occur here.

The chemical shifts of all signals in these spectra are shown in Table I. The highest field component of signal II in both compounds does not show large variation with temperature. The assignment of spectra at low temperature is based on the previous experience with locked conformations where it is found that the low field signal is due to equatorial protons in the cyclohexane ring (3, p. 390 ff.). In the hexachlorocyclohexanes the downfield shift is approximately 0.2–0.6 p.p.m. in agreement with the measured value for chlorocyclohexane at −70° C and −90° C of 0.65 and 0.58 p.p.m.* The corresponding chemical shift separation for the axial and equatorial —CHBr— polar is 0.68 p.p.m. The peak for the equatorial position is narrower than that for the axial position. This finds a ready explanation in terms of the coupling constants involved. The two environments of the —CHX— proton are set out below.

**The center of the roughly gaussian line shape is used for the chemical shift measurement. In view of the overlapping splitting due to J coupling which is symmetrical about the proton concerned, this is a reasonable assumption.*

TABLE I

Chemical shifts of signals in the spectra of chloro- and bromo-cyclohexane at various temperatures with respect to tetramethylsilane

	Chemical shifts (p.p.m.) from $Si(Me)_4$ signal			
	Chlorocyclohexane			
	I		II	
Temp., °C	Weighted average for equatorial and axial		(i)	(ii)
28	−3.935		−2.31 −2.11	−1.54
−26	−3.890		−1.79	−1.55
	(i)	(ii)		
−70	−4.34	−3.76		−1.58
−91	−4.44	−3.79	−2.09	−1.58
	Equatorial proton	Axial proton	(i) Shoulders appearing due to $-CH_2-$ protons adjacent to —CHX— group	(ii) Remote $-(CH_2)_4-$ group
	Bromocyclohexane			
	(i) and (ii)		(i)	(ii)
28	−4.16		−1.95	−1.55
−29	−4.16		−1.95	−1.55
−75	−4.64,	−3.97	−2.12, −1.84	−1.55
−95	−4.65,	−3.97	−2.16, −1.84	−1.55
−104.5	−4.65,	−3.98	−2.17, −1.84	−1.59
	Equatorial proton	Axial proton	$-(CH_2)-$ protons adjacent to —CHX—	Remote $-(CH_2)_3-$ group

If the —CHX— proton is equatorial then coupling constants to the adjacent $-CH_2-$ groups involve ee and ea protons. If the —CHX— proton is axial, aa and ae coupling constants are involved. A comparison of typical coupling constants in some acetylated sugars (3, p. 397) shows that e–e coupling is generally less than 3 c.p.s. and e–a coupling is about 2–5 c.p.s. while a–a coupling is 6–12 c.p.s. The much broader signal for the axial proton is consistent with a larger a–a coupling constant and resolution of some structure is possible within the broad peak (Figs. 2*a* and 2*b*). The spectra at low field

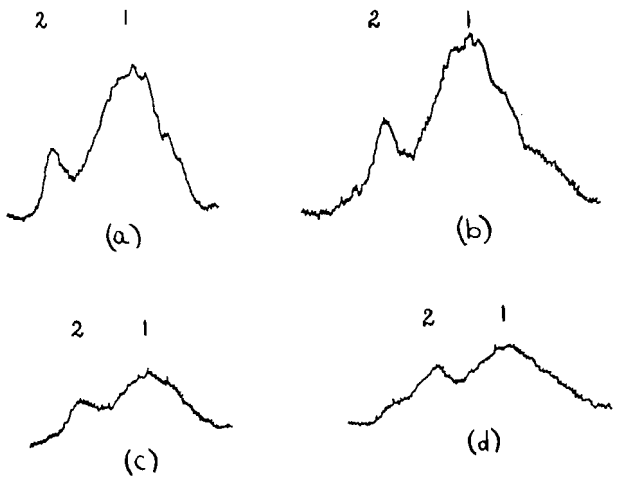

FIG. 2. Spectra of low-field —CHX— proton resonance signal at two temperatures. (*a*) Bromocyclohexane −88° C. (*b*) Bromocyclohexane −97° C. (*c*) Chlorocyclohexane −80° C. (*d*) Chlorocyclohexane −92.5° C.

consist of the 'X' part of an A_2B_2X spectrum in the terminology of Bernstein, Schneider, and Pople (14).

Populations of the equatorial and axial —CHX— proton in equilibrium are given in Table II at various temperatures. The populations were obtained by weighing the peaks after they were traced on to thick graph paper. At each temperature four independent spectra were selected and each traced five times. The total weight of five tracings of each spectrum was then obtained. The smaller peak was then cut off and the remaining axial peak weighed.

DISCUSSION

The results in Table II show no significant changes in population of the equatorial halogen form over an ~25° temperature range near −100° C. The energy content of the two equilibrium forms is almost the same. We may calculate a 'ΔF' free energy change from the equation $\Delta F = -RT \log_e K$. The values of the ΔF function are

$$[1] \qquad \Delta F_{ea} = -RT \log_e \frac{[\text{equatorial } 'X']}{[\text{axial } 'X']},$$

$$\Delta F_{ea} = -511 \text{ cal/mole for } C_6H_{11}Br,$$

$$\Delta F_{ea} = -406 \text{ cal/mole for } C_6H_{11}Cl.$$

We may assume $\Delta S_{ea} = 0$. Thus the Gibbs free energy function becomes equal to the enthalpy change ΔH_{ea}, which in turn is almost identical with the energy content function at constant volume ΔE_{ea}. Thus the free energy obtained from experiments can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

be equated to changes in the energy in going from one conformation to the other. It is to be noted that such small changes, in energy content observed, give negligible changes in population over a 30° C range so that experimental measurement does not detect them.

The populations of the axial chloro and bromo conformers can be obtained at room temperature by using the weighted average of the chemical shifts for axial and equatorial —CHX— form

$$\delta_M = x_a\delta_a + x_e\delta_e. \quad [2]$$

x_a and x_e are mole fractions of chlorocyclohexane in axial and equatorial form. δ_M is the measured chemical shift. δ_a and δ_e are the chemical shifts of axial and equatorial —CHX— proton available from low-temperature measurements.

The mole% equatorial halogen is computed to be 73.2% in bromocyclohexane and 77.4% in chlorocyclohexane. Since the chemical shift measurements of broad peaks are much less accurate than the intensity measurement at low temperature these estimates are subject to large errors.

The measurement of rates of interconversion between conformers using the standard techniques of n.m.r. (8, 9, 10) is not possible in this case because of complex spectra; the line width parameter T_2 cannot be measured. At the coalescence temperature (10) for axial and equatorial —CHX— protons the fine structure is averaged and it is legitimate to calculate an average lifetime τ_c. We have the equation

$$\tau_c \text{ (sec)} = \frac{1}{\sqrt{2}.\ \pi.\ \Delta\nu} \quad [3]$$

where $\Delta\nu$, frequency separation of resolved signals at low temperature (c.p.s.), is equal to 8.9×10^{-3} sec for bromocyclohexane. The coalescence temperature observed was ~218° K in both cases. If we assume a normal frequency factor of $kT/h \simeq \nu_0$ for the conversion process we may calculate an activation energy from

$$\frac{1}{2\tau_c} = 4.36\times10^{12}\exp\left(\frac{\Delta E}{436}\right). \quad [4]$$

The activation energy for the conversion is found to be 10,850 calories, a value subject to large error. Studies are at present being made on substituted cyclohexane having protons which are not coupled to the methylene protons in the ring and more reliable energy barriers will be available.

Although no accurate calculations are available, the small population of the axial halogen form is considered to be due mainly to van der Waals repulsive forces with the 3.5 axial hydrogen atoms (4, 15). Such a calculation is made here in an attempt to estimate the potential energy difference between the axial and equatorial form based on the Lennard-Jones equation (16).

The values ϵ/k = 277° K and 295° K (17) for the bromine–hydrogen and chlorine–hydrogen interactions are used; k is the Boltzmann constant.

Let $$\sigma = \frac{r \text{ van der Waals}}{2^{1/6}} = 2.55 \text{ Å and } 2.42 \text{ Å}$$

for the bromo and chloro compounds respectively. The calculation considers two repulsion terms of the halogen with a hydrogen atom and the van der Waals interaction of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

halogen in the equatorial position with atoms within the van der Waals interaction sphere.

Interatomic distances in the two conformations are obtained from the work of Hassel and co-workers (18). The calculation neglects distortion of halogen or hydrogens from true axial direction in the axial form. Values of 338.5 calories and 50.5 calories are obtained for bromocyclohexane and chlorocyclohexane respectively. The former represents fair agreement for a crude calculation but the latter, although in the correct order of the measured ΔE_{ea}'s, is only of the correct order of magnitude.

NUCLEAR SHIELDING PARAMETERS FOR PROTONS IN HYDROGEN BONDS

II. CORRELATION OF CHEMICAL SHIFTS IN INTRAMOLECULAR HYDROGEN BONDS WITH INFRARED STRETCHING FREQUENCIES[1]

L. W. Reeves, E. A. Allan, and K. O. Strømme

ABSTRACT

Nuclear shielding parameters have been obtained for 24 intramolecularly hydrogen-bonded phenols and naphthols. The shielding parameters are corrected for large diamagnetic anisotropies and a value $\Delta\sigma_{OH}$ obtained which represents the change in shielding parameter in parts per million with reference to the infinite dilution chemical shift of phenol, α-naphthol, or β-naphthol. These values of $\Delta\sigma_{OH}$ are approximately proportional to the change $\Delta\nu_{OH}$ in the OH stretching frequency on formation of the hydrogen bond.

The present study follows from a recent publication on nuclear shielding parameters for the strongly hydrogen-bonded proton (1) in orthohydroxy azo compounds. It was shown that the corrected chemical shift correlated well with the known acidity of phenol and β-naphthol and hence with the hydrogen-bonding strength, in a series of compounds of quite similar structure. A recognition of the fact that strong intramolecular hydrogen bonds are very little dissociated in dilute solution enables chemical shifts for a completely formed hydrogen bond to be quoted (2, 3). The study of strong dimer bonds (carboxylic acids) and intramolecular hydrogen bonds, both strong and weak, is extended in this present work in an attempt to make a broad and cross correlation with the shift of the infrared —OH stretching frequency. Many of the compounds studied might be expected to deviate from such a correlation (4) and deviations will be examined in detail in future work. Correlations between the frequency shift of the A—H stretch and heat of formation of the hydrogen bond, internuclear distances X—H- -Y across the bond in series of compounds where X and Y are the same atoms, half width of the A—H stretch in the hydrogen bond, and the intensity change ΔB on formation of a hydrogen bond are now well established (4). It is important therefore to obtain a link between infrared and n.m.r. methods so that hydrogen bond strengths might be indicated by either technique. Such a link has been suggested by earlier work (5, 6) where, however, the consideration of a completely formed hydrogen bond is in doubt since intermolecular hydrogen bonds were studied. There has also been a limited amount of study on chelated enolic hydrogen bonds by Försen and Nilsson (7).

EXPERIMENTAL

Some 26 commercially available substances known to contain intramolecular hydrogen bonds of the type —O—H- -Y were purified by fractional distillation or recrystallization from solvents such as cyclohexane, chloroform, ether, alcohol, or acetone depending on which solvent was the most suitable for the particular compound.

Chemical shifts for the intramolecularly hydrogen-bonded proton were measured. The solvent system used was redistilled carbon tetrachloride stored over P_2O_5 to which was added $\frac{1}{2}$ mole% cyclohexane. The cyclohexane served as an internal reference signal and its concentration was accounted for in the calculation of the mole fraction. When the substances under study were liquid, the concentration was made accurately to

[1]*Manuscript received April 11, 1960.*
Contribution from the Chemistry Department, University of British Columbia, Vancouver 8, British Columbia.

2.0±0.2 mole%. Many of the solid substances were not sufficiently soluble to achieve this concentration and were therefore studied at a concentration of 1±0.2 mole%. A smaller number of substances were not even soluble to 1 mole%; in some of these it was possible to heat the 1% mixture in the sealed evacuated 5-mm sample tubes in hot water and achieve a supersaturated solution of 1 mole% on cooling. In a few compounds the —OH proton resonance was detected in solutions in contact with solid material with a concentration approaching the limit for detection (approximately 0.3 mole%).

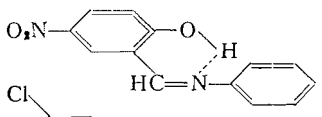
A Varian V4300 n.m.r. spectrometer detecting proton resonance at a frequency of 40 Mc/sec was used for this work. The chemical shifts were measured with respect to the signal of cyclohexane using the side band technique. Each chemical shift measurement was counted with a Hewlitt Packard electronic counter model 524B. Chemical shifts of the order of 200–500 c.p.s. were reproducible to ±1.5 c.p.s. using independently prepared solutions. When less than 200 c.p.s. was measured, the chemical shifts had a maximum deviation ±0.75 c.p.s. and did not vary over the concentration range 1 to 2 mole% for a given compound.

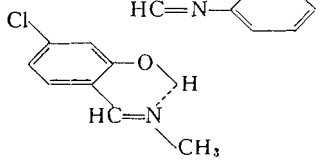
Some compounds were examined on a Perkin–Elmer model 21 infrared spectrometer to determine the frequency shift from free to hydrogen-bonded —O—H '$\Delta\nu_{OH}$'. The wave number calibration of the infrared spectrometer was assured by measurements of atmospheric water vapor in the region under study, with single-beam operation. In many cases literature values were available for $\Delta\nu_{OH}$ and agreement with the present measurements was satisfactory. The most precise measurements come from the work of Baker and co-workers (8, 9). These authors used a differential method for detecting frequency shifts in some compounds which gives values of $\Delta\nu_{OH}$ approaching an estimated error of ±1 cm^{-1}. The method of direct reading of the calibrated chart paper can only be accurate to ±3 cm^{-1}, which was the limit of error in the present study. Measurements taken from the literature are acknowledged and compared where they overlap with our results in Table I.

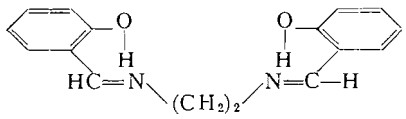
RESULTS AND DISCUSSION

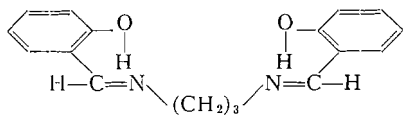
Correlations with Infrared Measurements

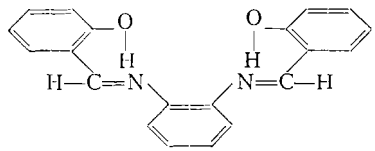
The compounds studied contain at least one benzene ring and are of the phenolic —O—H type. The measured chemical shifts have been corrected, in order to reduce their shielding parameters to a common basis. These corrections are for the low-field shift due to the diamagnetic anisotropy of the π electron system (10). The bond distances and angles, where available, were taken from the literature (11), and in cases where the actual distances in the compound under study were not available, a reasonably precise molecular structure could be constructed by considering known structures of related molecules. The correction for the large anisotropy is not precise enough to require the position of the proton in the molecule more accurately than can be estimated in this way. The corrections for the present series of compounds are almost the same in all cases.











The position of the phenol —O—H peak is −2.80 p.p.m. (−112 c.p.s.) with respect to cyclohexane at infinite dilution, a figure in agreement with the previously reported value (12). Corresponding figures obtained in this study for α- and β-naphthols are −3.78 p.p.m. (−151 c.p.s.) and −3.49 p.p.m. (−139.5 c.p.s.).

On the basis of differences in magnetic anisotropy the difference in chemical shift

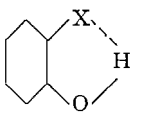
in column 2. Column 3 shows the corrected isolation chemical shifts for these molecules assuming the —O—H atoms lie in the plane of the molecule in one of two positions (4). It is assumed in the case of β-naphthol that these positions are equally populated. In α-naphthol the cis position to the second aromatic ring is seriously hindered by the α-hydrogen in the second ring so 100% population of the trans position is assumed in the correction.



It is interesting to note that the difference in isolation chemical shift of these three molecules after correction is in the same order as the —O—H stretching frequencies. Differences in the corrected chemical shifts are due to changes in the polarity of the —O—H bond and thus reflect the charge density at the proton. It is probable that the acidity increases in the order phenol, β-naphthol, α-naphthol. The wave number measurements of the free —O—H stretch frequency were not accurate enough to indicate the precise correlation between isolation chemical shift and frequency shift.

Figure 1 shows the differences in shielding parameter between the free —O—H signal and the hydrogen-bonded proton plotted against the infrared frequency shift of the —OH stretch on formation of the intramolecular hydrogen bond. The plot shows an approximate linear relationship from the weakest hydrogen bond 2,6-dimethoxyphenol to the strong hydrogen bond in some orthohydroxy Schiff's bases.

In intermolecular hydrogen bonds the heat of formation correlates well with the frequency shift $\Delta\nu_{OH}$ (4). The intensification of the —OH stretch vibrational transition can also be used to indicate the heat of formation and the intensification is more sensitive detection of hydrogen bond formation. In the formation of intramolecular hydrogen bonds, however, only the frequency shift $\Delta\nu_{OH}$ shows normal behavior in correlating with the heat of formation of the bond (4).

Unpublished work of Pimentel and Brown (4) shows that the original linear correlation of Badger and Bauer (14) does not hold but that low-frequency shifts $\Delta\nu_{OH}$ correspond to disproportionately high heats of formation compared with the large values of $\Delta\nu_{OH}$. The systems studied were phenol in a series of bases and therefore relevant to the present study of intramolecularly hydrogen-bonded phenols.

Weak Intramolecular Hydrogen Bonds

In compounds of the type shown above where a weak hydrogen bond is formed as in

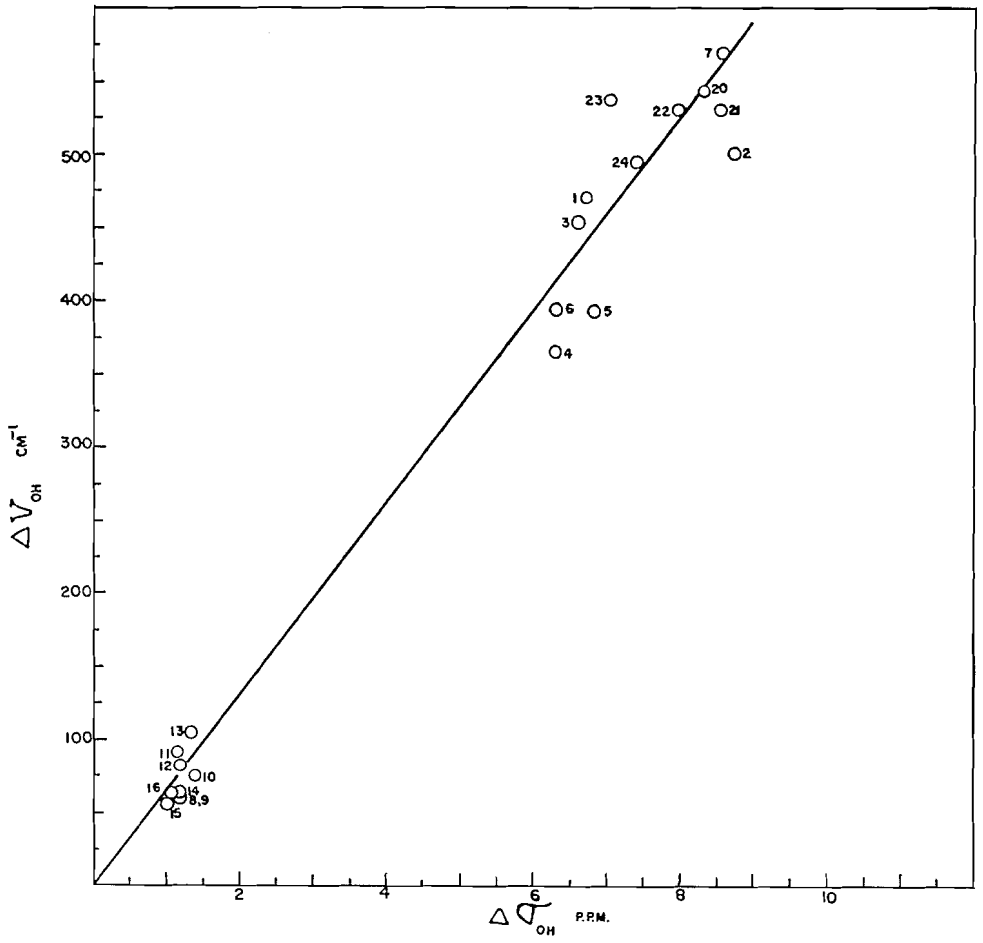

FIG. 1. Plot of $\Delta\nu_{OH}$ versus $\Delta\sigma_{OH}$ for intramolecular hydrogen bonds in phenols and naphthols. Numbered points refer to compounds in Table I.

the case of the halogens or orthomethoxy phenols, the population of the trans position must be taken into account, in order to justify a measurement of the change in shielding parameter on hydrogen bond formation. The careful infrared studies of Baker and co-workers (8, 9, 13) show that the free phenolic —OH stretch is observed as well as the band due to a hydrogen-bonded proton (15). After careful purification of the *o*-halophenols Baker concluded that the cis/trans ratios in *o*-chloro-, *o*-bromo-, and *o*-iodo-phenol were 1/56, 1/38, and 1/13.5 respectively. If we assume the chemical shifts in these compounds to be characteristic of the average environment then there is less than a 10% error in considering the most unfavorable case *o*-iodophenol as a completely cis configuration.

The chemical shift changes on formation of the hydrogen bond are roughly proportional to $\Delta\nu_{OH}$. Baker has shown, however, that hydrogen bond strengths are in the order Cl > Br > F > I (9). In these molecules the O—H- -O angle is distorted at least 85° from a straight line and interorbital repulsion plays a part in the anomalous order of $\Delta\nu_{OH}$ (9).

There are reasons why anomalies should occur in the chemical shift measurement. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

addition to steric factors which favor the order suggested by Baker there is the increasing diamagnetic anisotropy of the C—X bond as X changes from fluorine to iodine. The ratio $\Delta\nu_{OH}/\Delta\sigma_{OH}$ shows that in going from chlorine to iodine we have the values 50.2, 67.8, and 78.8 cm^{-1}/p.p.m., indicating a term which lowers $\Delta\sigma_{OH}$ as we go from chlorine to iodine.

In the weak intramolecular hydrogen bonds there are several exceptions to the correlation of $\Delta\sigma_{OH}$ and $\Delta\nu_{OH}$ with ΔH_f the heat of formation of the bond (9). It must be remembered, however, that this region of the correlation represents a small portion of the total range ($\sim$2.5–3.5 kcal = ΔH_f) of hydrogen bond energies studied (0–8 kcal/mole = ΔH_f).

Further detailed studies of this restricted region are in progress to extract the artifacts peculiar to magnetic properties of these molecules.

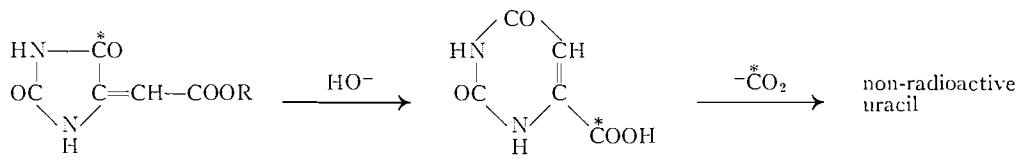
OROTIC ACID AND ITS ANALOGUES

PART II. ON THE ALKALINE REARRANGEMENT OF 5-CARBOXYMETHYLIDENEHYDANTOIN[1, 2]

R. Deghenghi and G. Daneault

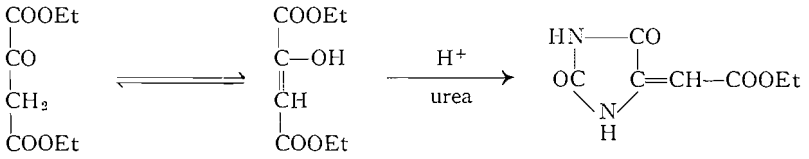


ABSTRACT

The in vitro conversion of 5-carboxymethylidenehydantoin to orotic acid is not likely to occur in vivo since the two substances have antagonistic effects (2). A sulphur analogue of the above hydantoin has been prepared and shown not to undergo alkaline rearrangement to the corresponding metathiazine structure. The mechanism of orotic acid formation is discussed.

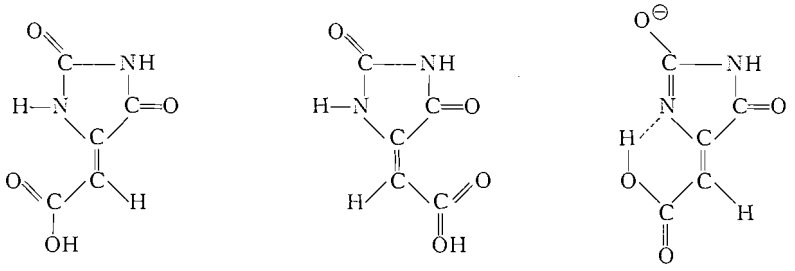
Since its discovery in 1905 by Biscaro and Belloni (3), orotic acid (II) has aroused an enormous interest among biochemists (see in particular (4) and (5)) for its importance as a pyrimidine precursor of nucleic acids. A large amount of synthetic work has been done on orotic acid itself (6) and on its analogues (7), but comparatively little attention has been given to the mechanisms of its formation, from a purely chemical point of view.

At first orotic acid was believed to be a seven-membered ring compound (3), but it was soon shown to be uracil-6-carboxylic acid (8, 9). Its synthesis from ethyl oxaloacetate and urea was erroneously believed to give directly ethyl orotate (10); later the ester was proved to be in fact 5-carbethoxymethylidenehydantoin (11). A similar error was made by Biltz and Kramer (12), who studied the alkaline decomposition of a diazoacetate derivative of alloxan to give again the hydantoin and not the six-membered ring ester.



All these facts prompted us to reinvestigate the mechanism of the formation of orotic acid and we chose at first the reaction of ethyl oxaloacetate and urea (III → I), as described by Müller (13) and discussed by Nyc and Mitchell (14). The latter authors postulated a mechanism which involves opening of the hydantoin ring between positions three and four to give the hydantoic acid which closes again to give the pyrimidine. The reaction was followed spectrophotometrically in alkaline solution and it was found that orotic acid is formed previous to acidification. The hydantoic acid was not isolated, though in other unsaturated hydantoins evidence of the open-chain compound has been obtained (14). That an open-chain-ring tautomerism exists in the hydantoin conversion to orotic acid was clearly demonstrated by Langley (15), who was able to show that a C^{14} carbon atom in position four in the hydantoin ring is present as a carboxyl in the orotic acid; this was confirmed by the quantitative recovery of the radioactivity in the CO_2 following decarboxylation (the remaining uracil being inactive). We were interested

(I) (II)



[1]*Manuscript received April 13, 1960.*

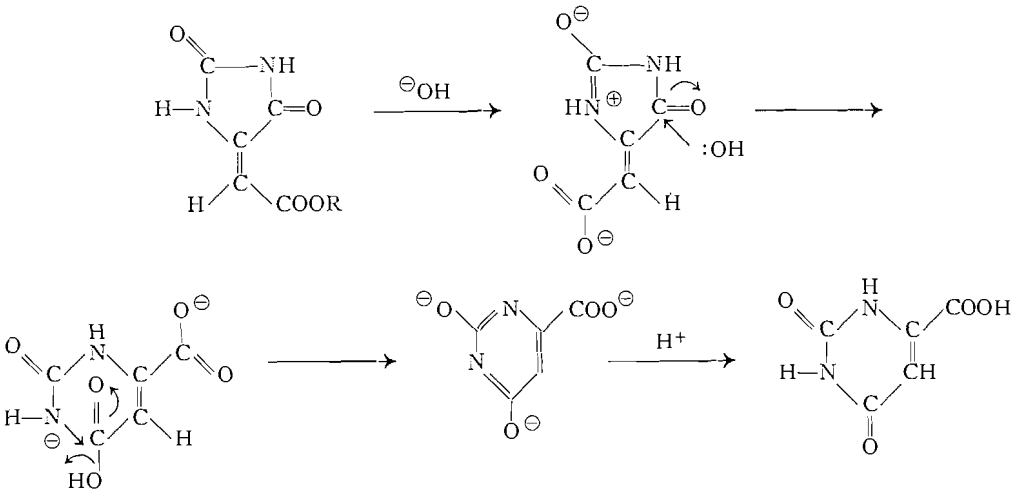
[2]*Part I: See reference 1.*

to investigate (*a*) why the hydantoin is the first intermediate when urea condenses with oxaloacetic ester, (*b*) whether the same kind of ring enlargements were possible with other five-membered ring substances, and (*c*) the isolation of possible intermediates of the above rearrangement (I → II).

(III) (IV) (I)

Oxaloacetic acid and its esters (III) are present in the pure state or in non-polar solvents (16, 17) as the enol form (IV) which may exist in the *trans* (hydroxy-fumaric) or *cis* (hydroxy-maleic) form. It is formally the latter which, after condensation with urea, gives the five-membered ring hydantoin. In fact, one could reasonably expect ethyl orotate only from the *trans* (fumaric) form of the intermediate hydantoic ester (ureidofumaric acid). For the same reason one could expect a cis–trans isomerization to occur previous to or during the alkaline conversion of the hydantoin to orotic acid. We were able to isolate two isomeric forms of the hydantoin (V, VI), one of which has not been described previously, by eluting the potassium salt of I through a column of cation-exchange resin (cf. Experimental). Proof of the structure was obtained by ultraviolet spectra, which showed two peaks at 235 mμ and 294 mμ characteristic of hydantoin structure (cf. 14), by infrared spectra, by the facile conversion of one isomer to the other, and by the fact that both substances gave, upon reduction with sodium amalgam, the same hydantoin-5-acetic acid. Furthermore, we were led to attribute tentatively structure V to the lower melting isomer, on the basis that the increase of the infrared frequency of the carbonyl in position four and the decrease of the C=O frequency in position two, together with the shift of the OH frequency due to hydrogen bonding, are better explained by structures of the type VII. Therefore the complete mechanism



(V) (VI) (VII)

for the alkaline conversion of I to orotic acid may reasonably assume the following form going through the steps: (*a*) cis–trans isomerization,[3] (*b*) alkaline cleavage, and (*c*) aromatization to the more stable pyrimidine structure.[4]

[3]*The reversible addition of the elements of water to the double bond (cf. 19) is a possible mechanism for this isomerization.*

[4]*Orotic acid is essentially a hydroxy pyrimidine in alkaline medium (cf. 18).*

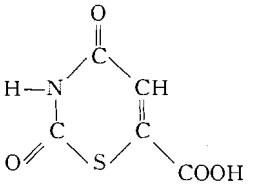
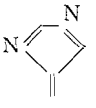
For personal use only.

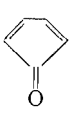


For a parallel experiment with a parent compound, we chose the corresponding pseudo-thio-hydantoin (VIII) which we synthesized in good yields from thiourea and maleic anhydride through the saturated thiazolidinedione-5-acetic acid. The ultraviolet spectrum of the new substance VIII in ethanol resembles closely that of 5-carboxymethylidene-hydantoin (cyclic, five-membered structure) and the infrared spectrum of the corresponding methyl or ethyl esters shows the four expected bands at 1772 cm^{-1} (4-CO), 1735 cm^{-1} (2-CO), 1690 cm^{-1}, and 1620 cm^{-1} (α,β-unsaturated ester). The free acid had a similar spectrum but with two more bands (KBr) at 1785 and 1700 cm^{-1} which could possibly arise from dimerization[5] (20). The free acid has a remarkable stability; it was recovered unchanged after being refluxed with an aqueous solution of $HClO_4$ and, when subjected to the same conditions for the orotic acid alkaline rearrangement, the starting material or its monopotassium salt were recovered again in high yield (cf. Experimental).

The potassium salt[6] by elution through a cationic exchange resin gave, like the above hydantoin, an isomer whose cyclic structure was evidenced by ultraviolet absorption, and which could be converted to the other form by crystallization from boiling water. Both isomers were reduced to the same saturated acid by the action of sodium amalgam.



The fact that in the case of the five-membered ring sulphur compound a ring enlargement to the corresponding metathiazine structure (IX) was not achieved, in spite of



(VIII)

(IX)

(X)

(XI)

[5]*For a discussion about carbonyl band splitting, cf. (26).*
[6]*Cf. (9) for the remarkable stability of potassium orotate.*

the isomerization, may be explained by considering the stability of structures of the type X which could arise from the enolic form of the hydantoin (21). The polarity of the exocyclic double bond (conjugated with the acid) would be strongly opposed in the structure X as it is in the case of 1,2-cyclopentenediones (enol form XI) (22) which, accordingly, exist only in the keto form. With the sulphur compound evidently no enol structure of the type XI (in alkaline solution) would be possible, thus explaining the observed stability of the five-membered thiazolidine ring.

It may be mentioned here that the in vitro conversion of 5-carboxymethylidene-hydantoin to orotic acid is not likely to occur in vivo, since the two substances show antagonistic effects following subcutaneous administration in the rat (2). An account of the biological activity of the sulphur analogue of the above hydantoin will be reported elsewhere.

EXPERIMENTAL[7]

2-Imino-4-oxo-5-thiazolidineacetic Acid

This compound was prepared in 72% yield from thiourea, according to the method of Andreasch (23) reported by Flett and Gardner (24), m.p. 252–253° dec. (reported to decompose above 220°). ν_{max}^{KBr} 3300, 3150 cm^{-1} (OH, NH); 2400 cm^{-1} (broad); 1690, 1645 cm^{-1} (C=N and C=O). Calc. for $C_5H_6N_2O_3S$: C, 34.48%; H, 3.47%; N, 16.09%; S, 18.40%. Found: C, 34.62%; H, 3.71%; N, 16.34%; S, 18.28%.

2,4-Dioxothiazolidine-5-acetic Acid

A solution of 63.237 g of 2-imino-4-oxo-5-thiazolidineacetic acid was refluxed for 2 hours with 630 ml of 20% sulphuric acid. Upon cooling, 42.6 g of 2,4-dioxothiazolidine-5-acetic acid crystallized out, m.p. 168° (lit. 168–169° (25)).

Extraction of the mother liquors with ethyl acetate and evaporation of the solvent *in vacuo* gave another 19.9 g of less pure product, m.p. 163–168°. Total yield 98%. ν_{max}^{KBr} 3200, 3080 cm^{-1} (OH, NH); 1760, 1740 cm^{-1} (4 and 2 C=O); 1700 cm^{-1} (acid C=O).

5-Carboxymethylidene-2,4-dioxothiazolidine (VIII)

A mixture of 26.25 g of 2,4-dioxothiazolidine-5-acetic acid in 90 ml of acetic acid containing 8.2 ml of bromine was refluxed for 2 hours. Hydrogen bromide was evolved and from the clear solution, upon cooling, the product crystallized out in 60% yield. The crystals were collected on a filter, washed with a little acetic acid and water, m.p. 248° dec. A sample was recrystallized from water three times for analysis; needles, m.p. 252–253° dec. Calc. for $C_5H_3NO_4S$: C, 34.68%; H, 1.75%; N, 8.09%; S, 18.51%. Found: C, 34.80%; H, 1.92%; N, 7.98%; S, 18.30%. λ_{max}^{EtOH} 236 mμ (ε 4360), 302 mμ (ε 6320). ν_{max}^{KBr} 3240, 3080, 2950 (OH, NH); 1775, 1758 cm^{-1} and 1725, 1700 cm^{-1} (split carbonyls); 1670 and 1622 cm^{-1} (α,β-unsaturated acid).

The *methyl ester* was prepared by refluxing the acid (0.5 g) in 10 ml of methanol and 0.5 ml of sulphuric acid for 1 hour. Dilution with water gave 5-carbomethoxymethylidene-2,4-dioxothiazolidine, m.p. 160–162°, in 80% yield. The product was recrystallized from water for analysis, m.p. 163–164°. Calc. for $C_6H_5O_4NS$: C, 38.49%; H, 2.69%; N, 7.48%; S, 17.13%. Found: C, 38.24%; H, 2.89%; N, 7.66%; S, 17.21%. ν_{max}^{KBr} 3250 cm^{-1} (NH); 1770 and 1732 cm^{-1} (4 and 2 C=O); 1690 and 1618 cm^{-1} (α,β-unsaturated CO).

The *ethyl ester* was prepared in an analogous manner, m.p. 128–130°, λ_{max}^{EtOH} 240 mμ

[7]*Melting points, taken in evacuated capillaries, are corrected. Analyses by Schwarzkopf Microanalytical Laboratories, Woodside, N.Y. The infrared spectra were taken with a Beckman IR-4 spectrophotometer* (NaCl *optics).*

(ϵ 3940), 305 mμ (ϵ 6000). ν_{max}^{KBr} 3300 (NH); 1770 and 1720 cm^{-1} (4- and 2- CO); 1690 and 1630 cm^{-1} (α,β-unsaturated CO).

Stability of 5-Carboxymethylidene-2,4-dioxothiazolidine in Acidic Conditions

To a solution of VIII, 0.449 g in 20 ml of water, was added 2 ml of 72% perchloric acid and the whole was refluxed for 30 minutes. Upon cooling, 0.3 g of the starting material (VIII), m.p. 248° dec., crystallized out. The product was identified by infrared spectra and mixed melting point with authentic material.

Stability of 5-Carboxymethylidene-2,4-dioxothiazolidine in Alkaline Conditions

A solution of VIII, 0.693 g in 15 ml of 1 *N* KOH, was kept 30 minutes at 100°. After cooling, 8 ml of 1 *N* HCl was added. The monopotassium salt of VIII crystallized out; needles, m.p. 270° dec. (with previous browning). Calc. for $C_5H_2NO_4SK$: C, 28.43%; H, 0.95%; N, 6.63%. Found: C, 28.55%; H, 1.02%; N, 6.69%. λ_{max}^{EtOH} 235 mμ (ϵ 1330), 298 mμ (ϵ 2600). ν_{max}^{KBr} 2550 (broad); 1730, 1690, 1630, 1580 cm^{-1} (4- and 2-CO, α,β-unsaturated ionized acid). The same salt (infrared and mixed melting point comparison) was obtained when the unsaturated acid (VIII) was neutralized with 1 *N* KOH in the cold, followed by concentration of the solution *in vacuo*.

Lower Melting 5-Carboxymethylidene-2,4-dioxothiazolidine

A solution of 0.782 of the potassium salt of VIII in water was passed through a column of cation exchange resin Amberlite I.R.-120 (H). The aqueous fractions were extracted with ethyl acetate and the organic solvent was evaporated *in vacuo* to give a crystalline residue (0.7 g), m.p. 200–205° dec. ν_{max}^{KBr} 3400, 3220, 3080 (OH, NH); 1768 and 1722 (4 and 2 C=O); 1690 (shoulder); 1670 and 1615 cm^{-1} (α,β-unsaturated CO). λ_{max}^{EtOH} 240 mμ (ϵ 3840), 303 mμ (ϵ 4000). When this substance was crystallized from water, the original higher melting isomer was obtained, and identified by infrared and mixed melting-point determinations.

Reduction of 5-Carboxymethylidene-2,4-dioxothiazolidine

To a suspension of 0.759 g of VIII in 25 ml of water, stirred in an ice-water bath in a CO_2 atmosphere, 25 g of 2% sodium amalgam was added piecemeal.

After 2 hours the clear solution was decanted from the mercury, acidified with 20% sulphuric acid, and extracted with ethyl acetate. Evaporation of the solvent gave 217 mg of 2,4-dioxothiazolidine-5-acetic acid, identified by mixed melting point and infrared determination with authentic material.

When the *lower melting isomer* was reduced in a similar way, the same product, 2,4-dioxothiazolidine-5-acetic acid, was obtained in similar yield.

5-Carbethoxymethylidenehydantoin (I, R = Et)

This substance was prepared according to the method of Müller (13) from ethyl-oxaloacetate and urea. The yields were in the 10–20% range, m.p. 184–186° (reported 188°). λ_{max}^{EtOH} 235 mμ (ϵ 7920), 300 mμ (ϵ 7500), ν_{max}^{KBr} 3250 (NH); 1800, 1760 (4- and 2-CO); 1695 (C=N), 1680, 1640 cm^{-1} (shoulder) (α,β-unsaturated CO).

5-Carboxymethylidenehydantoin (I, R = H)

This acid was prepared by careful hydrolysis of the corresponding ester (I, R = Et), 184 mg, dissolved in 2.3 ml of ethanol, by addition of 0.1 g KOH in 0.4 ml water. The yellow solid formed was dissolved in 5.6 ml of water. Acidification with concentrated HCl precipitated the product, m.p. above 300° with gradual decomposition. λ_{max}^{EtOH} 237 mμ

(ϵ 7800), 300 mμ (13000). ν_{max}^{KBr} 3550, 3300, 3100 cm^{-1} (OH, NH); 1790 and 1745 cm^{-1} (4 and 2 C=O); 1680 (broad); 1638 cm^{-1} (shoulder) (α,β-unsaturated C=O). A lower melting isomer was obtained by dissolving the above acid in 1 *N* KOH and by eluting the slightly alkaline solution through a column of Amberlite I.R.-120 (H) (cation exchange resin).

The aqueous fractions combined were extracted with ethyl acetate, the solvent removed *in vacuo* to give an acid, m.p. 250° dec. ν_{max}^{KBr} 3250 (broad); 2995 (bonded OH, NH); 1800 cm^{-1} (4-CO in β,γ-unsaturated ring), 1725 (2 CO or C=N), 1690 cm^{-1} (acid CO). λ_{max}^{EtOH} 235 mμ (ϵ 5150), 294 mμ (ϵ 8850). When this substance was recrystallized from water, the higher melting isomer was obtained (infrared spectra identical). Both isomers gave, upon reduction with Na/Hg (compare the above described procedure), the same 5-hydantoin acetic acid, m.p. 212° dec. (lit. 214° (14)).

Orotic Acid

This substance was obtained by the alkaline rearrangement of 5-carboxymethylidenehydantoin according to Nyc and Mitchell (14), m.p. 320° dec. ν_{max}^{KBr} 3580, 3150, 3050 cm^{-1} (OH, NH); 1740 (shoulder); 1715 and 1680 cm^{-1} (broad) (C=N, C=O). The infrared spectrum was identical with that of an authentic sample.

ACKNOWLEDGMENTS

The present work was supported by a grant of the National Research Council. We are grateful to Professor Ch. R. Engel for his kind interest and encouragement and for making the facilities of his laboratory available to us.

THE THERMAL DECOMPOSITION OF PHENYLACETIC ACID[1]

MARGARET H. BACK[2] AND A. H. SEHON

ABSTRACT

The thermal decomposition of phenylacetic acid was investigated by the toluene-carrier technique over the temperature range 587 to 722° C. The products of the pyrolysis were carbon dioxide, carbon monoxide, hydrogen, methane, dibenzyl, and phenylketene. From the kinetics of the decomposition it was concluded that the reaction

$$C_6H_5CH_2COOH \rightarrow C_6H_5CH_2 + COOH$$

was a homogeneous, first-order process and that the rate constant of this dissociation step was represented by the expression $k = 8\times10^{12}.e^{-55,000/RT}$ sec^{-1}. The activation energy of this reaction may be identified with $D(C_6H_5CH_2—COOH)$. The possible reactions of carboxyl radicals are discussed.

INTRODUCTION

Due to the resonance stabilization of the benzyl radical, the dissociation energies of the bonds $C_6H_5CH_2—R$ are smaller than the corresponding bond dissociation energies in related compounds of the type $CH_3—R$, where R is a radical or atom (1, 2). Therefore, compounds of the type $C_6H_5CH_2—R$ have proved particularly suitable for determination of these dissociation energies and of the heats of formation of radicals R using the toluene-carrier technique (3, 4, 5).

In the present study the thermal decomposition of phenylacetic acid in a stream of toluene was investigated for the purpose of producing carboxyl radicals by the rupture of the $C_6H_5.CH_2—COOH$ bond and for studying their subsequent reactions. Furthermore, it was anticipated that from the kinetics of the pyrolysis one might be able to derive the dissociation energy of this bond.

EXPERIMENTAL

Materials

Phenylacetic acid (m.p. 77° C) was obtained from Eastman Kodak Co. and used without further purification. The toluene was generously supplied by Gulf Oil Corporation, Pittsburgh, Pa. It was stirred for 24 hours with dilute sodium hydroxide, dried, and distilled through an efficient column. The fraction boiling at 110.5° C was used in this study.

Apparatus and Procedure

The pyrolysis was studied in a vacuum flow system similar to those used in previous investigations employing the toluene-carrier technique (6). The reaction vessel was 26 mm in diameter and 20 cm long, with a volume of about 200 cc. It was provided with a central thermocouple well to enable one to measure the temperature along the length of the whole reaction vessel. The gradient along this length was not more than 4 degrees and fell sharply on either side. Adequate preheating was ensured by allowing the gas to pass through a length of tubing intermediate in size between that of the reaction vessel and the inlet lead. The temperature of the furnace surrounding the reaction vessel was regulated within ±2° with a Thermo Electric regulator.

The surface dependence of the reaction was examined by using a similar reaction vessel

packed with silica wool, supplied by Microchemical Specialties, Berkeley, Calif. The average diameter of the silica fibers was 3×10^{-3} cm and the average length was 15 cm. The surface-to-volume ratio of this vessel was about 27 times that of the unpacked vessel. The decomposition of phenylacetic acid was studied over the temperature range 587 to 772° C.

Known weights of the acids were introduced into a U-tube in the form of pellets. This method proved convenient and accurate and avoided errors due to handling losses of the solid powder. One arm of the U-tube was connected with the toluene reservoir and the other led directly to the furnace. The U-tube was heated by a removable bath containing dibutyl phthalate for the lower temperatures and Fisher bath wax for the higher temperatures. The temperature of the bath was maintained constant with a Fenwall thermoregulator.

The tubes leading to and from the furnace were heated electrically with Nichrome wire to prevent condensation of the acid and products. The pressure of toluene and reactant during an experiment was maintained constant with a manostat and measured with a mercury manometer, read with a cathetometer to an accuracy of ±0.01 mm. Variations in pressure caused the mercury in the sloping arm of the manostat to make and break contact with a platinum wire connected to a suitable relay, which in turn controlled the heater of the water bath surrounding the toluene.

The products were fractionated through a series of three traps maintained at $-5°$ C, $-78°$ C, and $-188°$ C. The non-condensable gases were removed by two diffusion pumps connected in series and collected into calibrated bulbs. The undecomposed acid and dibenzyl were trapped together at $-5°$ C and weighed. The recovered acid was titrated and the yield of dibenzyl was calculated by difference. The dibenzyl collected from a few experiments was purified by recrystallization and mixed with a pure sample; its mixed melting point was 52° C. Carbon dioxide was measured in a gas burette and identified by its vapor pressure – temperature curve. Samples of the non-condensable gases were analyzed by combustion over copper oxide at 300° C.

RESULTS

The main product of the decomposition was carbon dioxide, with much smaller amounts of carbon monoxide. Hydrogen and methane were formed in amounts varying between 20 and 60% of the carbon dioxide, and the ratio of hydrogen to methane varied from 2.0 to 3.5. The yield of dibenzyl approached that of the non-condensable gases. Table I shows the main products and the amounts of acid decomposed under different experimental conditions. The experiments marked with letter P refer to those done in the packed vessel.

The carbon dioxide and carbon monoxide did not account for all the acid decomposed. It was found that the decomposition also yielded phenylketene,* a yellow compound which was trapped with the toluene. The ketene reacted with water to give phenylacetic acid which was titrated with sodium hydroxide. However, the amounts of phenylketene recovered in this way did not account completely for the acid deficit. Phenylketene has been reported to be a very reactive compound which rapidly dimerizes (8) and this might have prevented its quantitative conversion to the acid. The production of phenylketene was considerably increased in the packed reaction vessel, and this mode of decomposition

Reaction of this compound with aniline gave the anilide of phenylacetic acid, which was identified by a mixed melting point determination with a pure sample prepared according to the method described by Shriner and Fuson (7). The melting point of the mixed sample was 114 to 115° C.

*P_a and P_t refer to partial pressures of phenylacetic acid and toluene, respectively.

may be partly heterogeneous. The percentage carbon monoxide in the non-condensable gases also increased to about 50% although the total production of non-condensable gases was only very slightly increased (Table II).

In one experiment the contents of the dry ice – acetone trap were tested for the presence of phenol by following the pH change of an acid–base titration. Comparison of this curve with a curve obtained from titration of a synthetic mixture containing an amount of phenol corresponding to about 1% of the initial concentration of phenylacetic acid used in the experiment showed that negligible, if any, amounts of phenol were produced in the decomposition.

Attempts were made to detect formic acid in the reaction products but the large excess of toluene and the presence of other reaction products made the analysis extremely difficult and positive identification was not made.

From two experiments in the packed vessel the contents of the trap maintained at −5° C were titrated by following the pH change, and the presence of a small amount of a strong acid was evident. Although positive identification was not made, this acid was suspected to be oxalic. No evidence for the formation of oxalic acid was observed in the unpacked vessel.

DISCUSSION

Mechanism of Decomposition

The results suggested that the decomposition might occur by two simultaneous processes,

$$C_6H_5CH_2COOH \xrightarrow{k_1} C_6H_5CH_2. + .COOH, \quad [1]$$

$$C_6H_5CH_2COOH \xrightarrow{k_2} C_6H_5CHCO + H_2O, \quad [2]$$

reaction [1] being predominant. If each carboxyl radical is assumed to yield subsequently one molecule of either carbon dioxide or carbon monoxide, the rate of production of (CO_2 + CO) would be a measure of the rate of reaction [1]. To calculate the rate constant of this step, it was assumed that both processes [1] and [2] were first-order with respect to the acid concentration. The rate of decomposition of acid, A, may then be written

$$-\frac{dA}{dt} = (k_1+k_2)A = kA$$

where k is the over-all rate constant for the disappearance of acid. The rate of production of carbon dioxide plus carbon monoxide is then given by

$$\frac{d(CO_2+CO)}{dt} = k_1A = k_1(A_0e^{-kt})$$

and on integration it follows that

$$[CO_2+CO] = \frac{k_1}{k}A_0(1-e^{-kt}) = \frac{k_1}{k}(A_0-A).$$

For personal use only.

The rate constant k was calculated in terms of the amount of acid decomposed and rate constant k_1 could then be evaluated from the measured yield of $(CO_2 + CO)$. It ought to be pointed out that this calculation is not sensitive to the order of reaction [2], especially at low conversions, and also does not depend on an analysis for phenylketene. The rate constant k_2 represents the difference between k and k_1. Because of the large error necessarily involved in determining a small difference between two rate constants, no attempt was made to calculate an activation energy for reaction [2].

The first-order rate constants, k and k_1, measured for a variety of experimental conditions are listed in Table I. The rate constant k_1 remained almost unaffected, within the experimental accuracy, when the reaction time was varied by a factor of 4, the partial pressure of acid by a factor of 3, and the total pressure of toluene by a factor of 3. These results are shown in Tables IV, V, and VI. The small increase of about 30% in k_1

in the packed reaction vessel is not considered significant because the surface-to-volume ratio had been increased by a factor of about 27. Therefore, the rate of reaction [1], as measured by the rate of production of carbon dioxide plus carbon monoxide, is considered to be a homogeneous, first-order dissociation process. The plot of log k_1 vs. $1/T$ was represented by a straight line over the range of temperature studied and is shown in Fig. 1. From this line the activation energy of reaction [1] was calculated as 55 kcal/mole and the frequency factor as 8×10^{12} sec^{-1}.

The largest source of error in the measurements was considered to be the uncertainty in the temperature of the reaction vessel during an experiment, due both to fluctuations in the temperature of the furnace as a whole and to variation in temperature along the length of the reaction vessel. The error in the rate constant k_1 resulting from these fluctuations was estimated to be about 8%. This would give an uncertainty of not more than 1 kcal/mole to the activation energy for reaction [1] calculated from the slope of the plot of log k_1 against $1/T$. However, in kinetic studies such as this there is an uncertainty, inherent in the assumption of a reaction mechanism, which prevents the unequivocal identification of the measured rate with the rate of the postulated processes. Part of this uncertainty arises from side reactions which may affect the products by which the rate of the primary step is measured. Thus, an activation energy assigned to a specific reaction probably contains errors larger than those estimated solely from the measurements involved. Unfortunately, the magnitude of such errors is very difficult to assess.

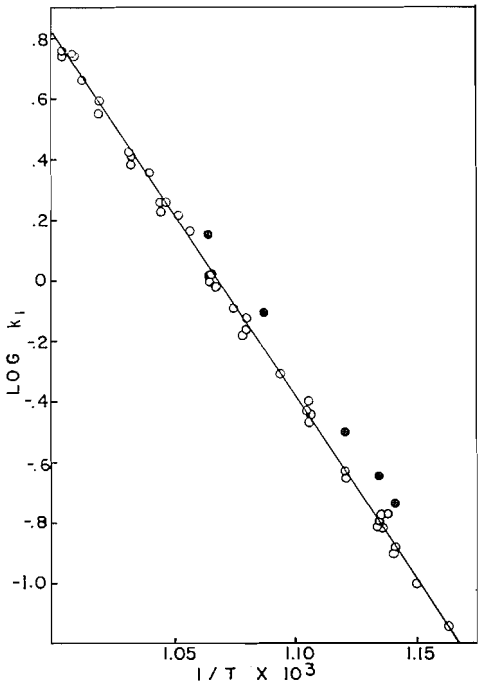

FIG. 1. Plot of log k_1 against $1/T$ for the thermal decomposition of phenylacetic acid.
○Experiments done in the unpacked reaction vessel.
●Experiments done in the packed reaction vessel.

Fate of the Carboxyl Radical

The carboxyl radical may decompose thermally in the following ways:

$$COOH \rightarrow CO_2 + H \quad [3]$$

$$COOH \rightarrow CO + OH \quad [4]$$

According to this scheme each carbon dioxide molecule is accompanied by a hydrogen atom, and each carbon monoxide molecule by a hydroxyl radical. On the basis of previous results (9) it was expected that the hydrogen atoms would react with toluene to give hydrogen and methane in the ratio 3:2.

$$H + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H_2 \quad [5a]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_6 + CH_3 \quad [5b]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_5 + CH_4 \quad [5c]$$

The most probable reaction of hydroxyl radicals with toluene was thought to be abstraction of a hydrogen atom to form water.

$$OH + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H_2O \quad [6a]$$

However, the displacement reactions, similar to reactions [5*b*] and [5*c*],

$$OH + C_6H_5CH_3 \rightarrow C_6H_5OH + CH_3 \quad [6b]$$

$$OH + C_6H_5CH_3 \rightarrow C_6H_6 + CH_3OH \quad [6c]$$

might also participate. Failure to detect phenol showed that reaction [6*b*] did not occur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

It was therefore assumed that hydroxyl radicals reacted with toluene to give products trapped at −78° C.

If all the benzyl radicals dimerized to give dibenzyl,

$$2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2, \qquad [7]$$

the following stoichiometry should have been observed:

$$CO_2 = H_2 + CH_4$$
$$(C_6H_5CH_2)_2 = CO_2 + CO = H_2 + CH_4 + CO$$
$$H_2/CH_4 = 1.5$$

None of these conditions was in fact observed. As mentioned previously, the carbon dioxide was always greater than the sum of the hydrogen and methane, and the ratio of hydrogen to methane varied from 2.0 to 3.5. The first-order rate constant calculated from the amount of $(H_2 + CH_4 + CO)$ produced was always lower than that calculated from the yield of $(CO_2 + CO)$ and varied with reaction time. Moreover, the Arrhenius plot of the former rate constant was not rectilinear over the whole temperature range studied. The yield of dibenzyl was always much less than that of the carbon dioxide plus carbon monoxide, but was usually between 75 and 90% of the non-condensable gases (Table I).

Reactions [3] to [6] are therefore insufficient to account for the products formed. If carboxyl radicals do not all decompose rapidly by reactions [3] and [4], they may react with each other according to reactions [8] or [9].

$$2COOH \rightarrow 2CO_2 + H_2 \qquad [8]$$
$$2COOH \rightarrow CO_2 + CO + H_2O \qquad [9]$$

Either of these reactions produces one molecule of carbon dioxide or carbon monoxide for each carboxyl radical, and the formation of $(CO_2 + CO)$ is still a measure of the extent of reaction [1]. However, only one molecule of non-condensable gas is produced for every two carboxyl radicals, and the total amount of non-condensable gases will be less than the sum of the carbon dioxide and carbon monoxide. Reaction [8] also produces molecular hydrogen unaccompanied by methane and will result in a ratio of hydrogen to methane greater than that observed from the reaction of hydrogen atoms with toluene. The indication that under certain conditions oxalic acid may have been a product of the decomposition in the packed reaction vessel suggests that carboxyl radicals have a sufficiently long lifetime under the conditions of the present experiments to react with each other.

If carboxyl radicals react with each other, then reaction between carboxyl and benzyl radicals may be considered at least as probable. If the radicals recombined to reform phenylacetic acid, the rate constant k_1 would not appear to be first-order over the temperature range studied and under the different conditions of decomposition. Therefore, the recombination between benzyl and carboxyl radicals is not considered significant. An alternative and possibly more probable reaction for benzyl and carboxyl radicals would be the disproportionation reaction

$$C_6H_5CH_2 + COOH \rightarrow C_6H_5CH_3 + CO_2, \qquad [10]$$

which is exothermic to the extent of about 63 kcal/mole. This value represents the difference between $D(C_6H_5CH_2—H) = 83$ kcal/mole (11) and $D(COO—H) = 20$ kcal/mole. The latter value is deduced in the last paragraph of this paper.

Reactions [8], [9], and [10] lead to an excess of carbon dioxide relative to dibenzyl or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

hydrogen plus methane, but the total amount of non-condensable gases should equal the amount of dibenzyl.

$$CO_2 + CO > (C_6H_5CH_2)_2 = H_2 + CH_4 + CO$$

The latter condition was indeed found to hold within the experimental accuracy for the recovery of dibenzyl. The ratio of dibenzyl to non-condensable gases varied between 0.75 and unity (Table I). In previous studies it was shown that dibenzyl was not trapped quantitatively at about $-5°$ C from a stream of toluene, and the recoveries were of the order of 80–90% of the expected amount (10). It was considered, therefore, that the yield of dibenzyl was probably equal to the yield of non-condensable gases ($H_2 + CH_4 + CO$).

Reaction of the carboxyl radical with toluene may also occur, probably to produce carbon dioxide and hydrogen, or carbon monoxide and water.

$$COOH + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + (HCOOH) \begin{cases} \nearrow CO_2 + H_2 & [11a] \\ \searrow CO + H_2O & [11b] \end{cases}$$

These reactions yield one molecule of carbon dioxide or carbon monoxide for each carboxyl radical, but they also produce a molecule of dibenzyl for each carbon dioxide or carbon monoxide formed. If formic acid were the product of the reaction, the yield of dibenzyl relative to that of ($CO_2 + CO$) would be even greater than if carbon dioxide or carbon monoxide were formed only by reactions [3] and [4].

Moreover, if reaction [11*a*] or [11*b*] occurred, each would be favored by an increase in toluene pressure and more hydrogen or carbon monoxide would be expected to be produced at the expense of methane under these conditions. However, as shown in Table III, this trend was not observed.

In previous studies with the toluene-carrier technique the production of dibenzyl was taken as a measure of the extent of the decomposition of the reactant into free radicals. The small amounts of dibenzyl formed relative to carbon dioxide may be interpreted, therefore, as an indication of an alternate mode of decomposition of phenylacetic acid by a molecular rearrangement into carbon dioxide and toluene.

$$C_6H_5CH_2COOH \rightarrow CO_2 + C_6H_5CH_3 \qquad [12]$$

If reaction [12] occurred simultaneously with reaction [1] the plot of log k_1 vs. $1/T$ would be expected to be a composite curve representing the sum of the rate constants of two processes which would probably require different activation energies. Because the plot of log k_1 vs. $1/T$ was represented by a straight line it would appear that if the molecular decomposition occurred it must have the same activation energy and the same frequency factor as reaction [1]. Therefore, although the occurrence of reaction [12] cannot be ruled out unequivocally,* its participation would not affect the conclusions derived for reaction [1], which is represented by the homogeneous, unimolecular dissociation process,

$$C_6H_5CH_2COOH \rightarrow C_6H_5CH_2 + COOH.$$

The activation energy of this step was calculated as 55 kcal/mole and the frequency factor as 8×10^{12} sec^{-1}. With the usual assumption that the recombination of radicals requires no activation energy, the value of 55 kcal/mole may be identified with the dissociation energy of the $C_6H_5CH_2$—COOH bond.

**It is possible to visualize that if reaction [12] occurred to a small extent, the linearity of the Arrhenius plot may not be seriously affected though the activation energy calculated from it may be erroneous.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

The heat of formation of carboxyl radical can be calculated using the thermochemical relation

$$\Delta H_f(\text{COOH}) = \Delta H_f(\text{C}_6\text{H}_5\text{CH}_2\text{COOH}) + D(\text{C}_6\text{H}_5\text{CH}_2\text{—COOH}) - \Delta H_f(\text{C}_6\text{H}_5\text{CH}_2).$$

Although the value for the heat of formation of benzyl radical is somewhat uncertain, a reasonable estimate for it seems to be 42 kcal/mole (11). No recent determination of the heat of formation of phenylacetic acid in its monomeric form in the gaseous phase is available. However, a value of -75 kcal/mole for $\Delta H_f(\text{C}_6\text{H}_5\text{CH}_2\text{COOH})$ may be computed from relevant thermochemical data.* In this calculation, the present authors have assumed that the heat of vaporization determined by Stull (12) corresponds to the heat of vaporization of phenylacetic acid into monomers. Taking for $D(\text{C}_6\text{H}_5\text{CH}_2\text{—COOH})$ the value of 55 kcal/mole derived in this study, it follows that $\Delta H_f(\text{COOH}) \simeq -62$ kcal/mole. In turn this value leads to the following dissociation energies $D(\text{COO—H}) = 20$ kcal/mole and $D(\text{CO—OH}) = 45$ kcal/mole.

ACKNOWLEDGMENTS

This work was supported in part by a grant from the Petroleum Research Fund administered by the American Chemical Society. Grateful acknowledgment is hereby made to the donors of said fund. The authors wish to thank also the National Research Council of Canada for continued financial assistance. THE THERMAL DECOMPOSITION OF DIPHENYLACETIC ACID[1]

MARGARET H. BACK[2] AND A. H. SEHON

ABSTRACT

The pyrolysis of diphenylacetic acid was investigated over the temperature range 515–636° C using the toluene-carrier technique. The main products of this system were similar to those formed in the thermal decomposition of phenylacetic acid. The rate constant for the reaction

$$(C_6H_5)_2CH.COOH \xrightarrow{k_1} (C_6H_5)_2CH + COOH$$

was calculated as $k_1 = 8\times10^{12}.\exp(-52{,}000/RT)$ sec^{-1}.

The over-all decomposition reaction was found to be partly heterogeneous and, therefore, the activation energy for reaction [1] may be only tentatively identified with $D[(C_6H_5)_2CH—COOH]$.

The investigation described in the foregoing paper (1) was extended to the thermal decomposition of diphenylacetic acid in a stream of toluene for the purpose of producing carboxyl radicals from another source and for studying their reactions further. On theoretical grounds the diphenylmethyl radical ought to be stabilized by resonance to a larger extent than the benzyl radical. Therefore, it was expected that the bond $(C_6H_5)_2CH—COOH$ would be weaker than the bond $C_6H_5CH_2—COOH$, and that diphenylacetic acid would decompose more readily than phenylacetic acid.

EXPERIMENTAL

The apparatus and procedure used were identical with those employed for the thermal decomposition of phenylacetic acid (1).

Diphenylacetic acid (m.p. 140° C) was obtained from Eastman Kodak Co. and used without further purification. The toluene was generously supplied by Gulf Oil Corporation, Pittsburgh, Pa. It was purified by treatment with dilute sodium hydroxide for 24 hours, dried, and distilled through an efficient column. The fraction boiling at 110.5° C was used in this study.

RESULTS

The products from the decomposition of diphenylacetic acid were similar to those from phenylacetic acid and are shown in Table I. Carbon dioxide was again the major product and carbon monoxide a minor product only. The sum of the hydrogen and methane produced amounted to 20–50% of the carbon dioxide, and the ratio of hydrogen to methane varied from 1.9 to 4.5, both trends increasing with increasing temperature. Carbon monoxide accounted for 30–40% of the non-condensable gases, compared with about 10% in the pyrolysis of phenylacetic acid.

The sum of the carbon dioxide and carbon monoxide produced and the undecomposed acid recovered accounted for 94–98% of the initial amount of acid. Therefore, analysis was not attempted, as with phenylacetic acid (1), for other possible products. However, small amounts of a brilliant yellow compound, suspected to be diphenylketene, were observed in the trap maintained at −5° C. The contents of this trap were dissolved in alcohol, since the latter is known to react rapidly with diphenylketene to form the ester

(2). In consequence, the ketene was not expected to interfere with the titration for the undecomposed acid. The weight of diphenylketene was obtained by assuming that this compound accounted for the difference between the acid decomposed and the (CO_2 + CO) recovered.

The recombination of benzyl and diphenylmethyl radicals may produce three possible products: dibenzyl, 1,1,2,2-tetraphenylethane, and 1,1,2-triphenylethane. A white solid, insoluble in alcohol, was deposited in the trap at −5° C, and it is suggested that this might be 1,1,2,2-tetraphenylethane, since the other recombination products are soluble in alcohol. The weight of the recombination products was estimated by subtracting the weights of undecomposed acid and of diphenylketene from the total weight of products trapped at −5° C. The moles of recombination products were obtained by assuming that benzyl and diphenylmethyl radicals were formed in equal amounts. Although the errors were necessarily large, the quantities obtained were consistently lower than the (CO_2 + CO) but slightly higher than the total amount of non-condensable gases. This will be discussed later.

No acid was found in the trap kept at −78° C, and it was concluded that formic acid was not a product of the reaction. This lends support to the conclusion that formic acid was also not a product of the decomposition of phenylacetic acid, which was previously deduced by indirect evidence in the thermal decomposition of phenylacetic acid.

DISCUSSION

These results suggest that the two modes of decomposition postulated for phenylacetic acid also occurred in the decomposition of diphenylacetic acid, but that in this case reaction [2] was of much less importance.

$$(C_6H_5)_2CHCOOH \xrightarrow{k_1} (C_6H_5)_2CH + COOH$$

$$(C_6H_5)_2CHCOOH \xrightarrow{k_2} (C_6H_5)_2C{=}C{=}O + H_2O$$

Since the general pattern of the decomposition of diphenylacetic acid was essentially similar to that of phenylacetic acid, it appeared that carboxyl radicals formed from the decomposition of diphenylacetic acid disappeared by the same reactions postulated in the decomposition of phenylacetic acid (1). Decomposition of the carboxyl radical into carbon dioxide is energetically more favorable than decomposition into carbon monoxide, and it is unlikely that the activation energy for the homogeneous reaction to give carbon dioxide would be greater than for the reaction producing carbon monoxide. However, carbon monoxide formed a larger fraction of the non-condensable gases from diphenylacetic acid than from phenylacetic acid. Furthermore, the ratio of carbon monoxide to carbon dioxide, although it was always less than one, was greater at the lower temperatures used for the decomposition of diphenylacetic acid. It would seem, therefore, that at least one of the reactions giving carbon monoxide has a lower activation energy than those giving carbon dioxide. With both acids the production of carbon monoxide was increased in the packed vessel (Table II) and was also favored at low toluene pressures

*k refers to the first-order rate constant for the over-all reaction calculated in terms of the acid decomposed.

(Table III). Consequently, it is suggested that carboxyl radicals decomposed primarily heterogeneously to yield carbon monoxide and a hydroxyl radical. The activation energy for such a reaction might be fairly low.

The interaction of carboxyl radicals by reactions [8] and [9] of the scheme postulated in the previous paper (1) leaves an excess of diphenylmethyl radicals over benzyl radicals. Thus the weight of product condensed at 0° C would be greater than it would be if diphenylmethyl radicals and benzyl radicals were formed in equal molar ratios. This would make the estimation of the moles of recombination product, based on a 1:1 molar ratio of diphenylmethyl and benzyl radicals, too high. This might explain why the calculated

amounts of recombination products were greater than the amounts of non-condensable gases, although the results are not sufficiently accurate to permit a quantitative estimate of the effect.

The rate constant k_1 was calculated from the rate of production of carbon dioxide plus carbon monoxide, assuming both reactions [1] and [2] to be first-order. The results are shown in Table I. This rate constant was practically unaffected by varying the partial pressure of acid by a factor of 3 (Table IV), the reaction time by a factor of 2

is shown in Fig. 1. From the slope of this line an activation energy of 52 kcal/mole and a frequency factor of 8×10^{12} sec^{-1} were calculated.

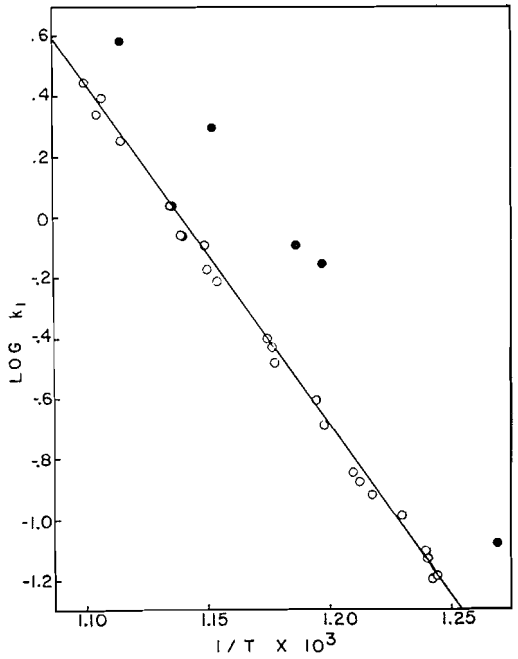

FIG. 1. Plot of log k_1 against $1/T$ for the thermal decomposition of diphenylacetic acid.

○ Experiments done in the unpacked reaction vessel.

● Experiments done in the packed reaction vessel.

The pyrolysis of diphenylacetic acid appeared to be more affected by the surface conditions than that of phenylacetic acid. In the packed reaction vessel the over-all decomposition was greatly increased and much larger quantities of the yellow compound, suspected to be diphenylketene, were observed. The rate constant calculated from the amount of (CO_2 + CO) produced was increased by a factor of almost three as compared with the values obtained with the unpacked reaction vessel (Table II). However, the slope of the plot of log k_1 against $1/T$ was similar to that obtained with the values calculated for the unpacked reaction vessel. Since in the packed reaction vessel the surface to volume ratio was increased by a factor of about 27, an increase in k_1 by a factor of 3 may be interpreted as an indication that only about 11% of the free radical decomposition occurred on the surface of the vessel. Therefore, the pyrolysis of diphenylacetic acid may be considered to be primarily a homogeneous reaction.

Because of the uncertainty of the role of the surface in this decomposition, the identification of the activation energy with the bond dissociation energy, $D[(C_6H_5)_2CH—COOH]$, is somewhat tentative. However, the frequency factor is close to that expected for a unimolecular dissociation and, remarkably, it is identical with that for the decomposition of phenylacetic acid. Moreover, the value of 52 kcal/mole is reasonable considering that the bond dissociation energy assigned to the corresponding bond in phenylacetic acid was estimated at 55 kcal/mole. The difference between these two bond dissociation

energies is supported by the results obtained from the studies of the thermal decompositions of benzyl and diphenylmethyl bromides (3). In the latter studies the diphenylmethyl radical was found to be slightly more stabilized by resonance than the benzyl radical.

CLAM POISON

I. THE PAPER CHROMATOGRAPHIC PURIFICATION OF CLAM POISON DIHYDROCHLORIDE[1]

A. A. Casselman, R. Greenhalgh, H. H. Brownell, and R. A. B. Bannard

ABSTRACT

A semimicro (10–25 mg) paper chromatographic method for purification of clam poison has been developed. This procedure when applied to a partially purified (toxicity 4150 MU/mg) sample of the toxin gave a 74% recovery of clam poison dihydrochloride of purity identical with that of the best material obtained by Schantz *et al.* (2) via the alumina chromatographic method. The upper limit of purity of toxin resulting from paper chromatography is estimated to be 98% because of traces of impurity introduced by the paper. The paper chromatographic procedure has been found capable of enriching low-grade toxic residues (35%) from the alumina process to a purity of 75% with an over-all recovery of 70%.

INTRODUCTION

Mold and co-workers (1) recently described the criteria for purity of clam poison dihydrochloride, the paralytic poison which can be isolated from the siphon of the toxic Alaska butter clam *Saxidomus giganteus* (2). Among other properties, the paper chromatography of clam poison dihydrochloride was examined in several solvent systems and it was observed (1) that the compound gave only one typical pink spot with Weber reagent (3) (R_F 0.30) when phenol–water (4:1) or *t*-butanol – acetic acid – water (2:1:1) was used as developer. The above-mentioned workers kindly provided us with 300 mg of partially purified (toxicity 4150 MU*/mg) clam poison which we wished to use for structural investigation. Paper chromatograms revealed, however, that the sample contained at least five components and it became evident to us that further purification was necessary. Because of the small quantity at our disposal, the method of purification used by Schantz *et al.* (2), involving as its final step chromatography on acid-washed alumina, was considered likely to be too wasteful due to the relatively low recovery of material of high toxicity (25–45%). Furthermore, prior to commencing degradative studies it was considered necessary to develop a semimicro method applicable to reaction mixtures from clam poison which would make feasible both the isolation of products and recovery in a high state of purity of any unreacted toxin. In addition, it was desired to examine the feasibility of paper chromatography as a means for purification of the clam poison residues of low toxicity (hereinafter designated as clam poison tailings) which on reworking by a variety of chromatographic methods (4) had failed to produce material with an enhanced toxicity. The work now to be outlined describes the development of the paper chromatographic method of purification and its application to (*a*) recovery and further investigation of the components contained in the partially purified sample of toxin furnished by Schantz *et al.* (2), and (*b*) enrichment of clam poison tailings.

RESULTS AND DISCUSSION

Chromatography of the partially purified clam poison dihydrochloride sample on *unwashed* Whatman No. 1 paper, using *t*-butanol – acetic acid – water (2:1:1)† as

[1]*Manuscript received March 7, 1960.*

†*All chromatograms were developed in this solvent system unless otherwise specified.*

developer gave three pink spots, R_F 0.19, 0.32, and 0.53, on spraying with Weber (3) reagent. These components could also be detected as blue spots by spraying with bromcresol green, or as fluorescent spots on exposure to ultraviolet light. Ultraviolet light also revealed the presence of another component, R_F 0.0. When the chromatograms were sprayed with Sakaguchi (5, 6) reagent, which is specific for monoalkylguanidines (7), a typical red spot appeared at R_F 0.70, indicating the presence of a fifth component. Component 3 (see Table I) appeared as an atypical greenish yellow spot with Sakaguchi reagent and as an atypical yellow spot with ninhydrin. Resolution of the clam poison sample into five components was also observed when other solvent systems were used, as shown in Table I. From these results, and those of Mold *et al.* (1), it seemed probable that component 3 is clam poison and that the other components present in the sample are impurities either present initially or formed by partial decomposition during storage in aqueous solution at pH 5.

Application of paper chromatographic techniques to purification and recovery of the components present in the sample of partially purified clam poison dihydrochloride revealed that impurities were being introduced during the process, since greater than theoretical recoveries were at first obtained. The most probable source of such error is the presence of extractable impurities in the paper, or debris produced during chromatography by partial degradation of cellulose by the solvent system. Other workers (8, 9, 10, 11) have found that extensive purification or pretreatment of the paper is essential if reproducible results in quantitative paper chromatography are to be obtained where acidic or basic solvent systems are employed. Accordingly, several procedures for pretreatment of Whatman No. 1 paper were examined with the object of eliminating or minimizing extractable materials. After pretreatment according to the procedures given in Table II, blank runs were performed using only the pretreated paper and the developing solvent. After drying, strips corresponding in location and area to the five components previously found to be present in the sample were cut from the "chromatograms", eluted with water, and the eluates concentrated, lyophilized, and weighed. The amount of residue thus obtained should correspond to the amount of impurity introduced into a given component during actual purification. The results presented in Table III make it evident that procedure 2 (see Table II) yields eluates containing the smallest amounts of impurities, and this method was adopted for all subsequent quantitative work.

In Table III, three sets of results are given under procedure 2. The first column represents minimum quantities of impurities introduced by the method. The next two

columns represent duplicate assays on another batch of paper pretreated in the same manner and are the maximum amounts of impurities encountered by the method. Thus, the quantity of impurity introduced per component is consistent for sheets within a given batch of paper, but some variation is to be expected from batch to batch. For actual purification of clam poison, therefore, blank runs were performed on two sheets from the batch of pretreated paper to be used in the purification. The arithmetic mean of the values thus obtained in the two runs for a given component was taken as the correction factor to be subtracted from the weight of that component recovered in actual chromatograms.

In procedure 2 the sodium carbonate treatment is used to open up the fiber structure of the paper and to remove hemicellulose (12), polypeptides (9), and acidic impurities. Treatment with acetic acid removes basic impurities and the alkaline earth metal ions Ca^{++} and Mg^{++} which can lead to ghost spots (8). Bad streaking effects have been observed, however, in the chromatography of amino acids and peptides (11) and the calcium acetate wash is used to overcome this disadvantage by replacement of some of the calcium ion removed in the preceding step. In acidic solvent systems, traces of heavy metal ions have been found responsible for the appearance of diffuse spots presumably due to formation of chelated complexes (8) and treatment with 8-hydroxyquinoline is used to remove these impurities. Finally, prolonged elution with the developing solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

system is intended to minimize further degradation of the paper by the solvent during subsequent chromatography.

Further examination of the washing procedure revealed that no significant difference in quantities of extractables was caused by the use of the ascending rather than the descending technique. This result was somewhat unexpected since it was anticipated that the much longer development time required by the former method (40 hours vs. 16 hours) would lead to greater degradation of the paper and thus yield larger quantities of impurities. The fact that such did not occur attests to the effectiveness of the pretreatment process. Quantities of extractables were also not significantly affected by treating eluates with Amberlite IRA-400 (Cl) resin prior to lyophilization. The latter step is required during actual recovery of the toxin to ensure that it is completely converted to the dihydrochloride.

No difference in resolution of the components was observed by use of the two techniques referred to in the preceding paragraph and the descending method was adopted in all subsequent work because of the shorter development time required.

An effort was made by means of ultraviolet, fluorescence, and infrared spectral measurements to determine the nature of the impurities eluted from the pretreated paper in locations corresponding to components 1 to 5 in Table I. In the ultraviolet region, all the fractions showed weak absorption ($E^{1\%}_{1\,cm}$ = 8–28) at 255–260 mμ. Each fraction also exhibited a strong to medium intensity fluorescence at 350 mμ. The infrared spectra (KBr pellet) of all the fractions were very similar, but the bands (at 1000–1100 cm^{-1}; 1380–1410 cm^{-1}; 1570–1630 cm^{-1}; and 3100–3500 cm^{-1}) were broad rather than sharp. It was therefore not possible to draw any definite conclusion regarding the chemical structure of the impurities except that all the fractions, as expected, are of very similar if not identical composition.

For quantitative purification, 12–17 mg of partially purified clam poison dihydrochloride (toxicity 4150 MU/mg) was applied to specially pretreated Whatman No. 1 paper, chromatographed, and the components recovered and bio-assayed as described in the Experimental section. The results for a typical experiment, shown in Table IV, indicate that 96% of the material applied to the paper has been recovered, and that component 3, the only fraction which possesses significant toxicity, accounts for 74% of the sample. In other experiments performed in the same manner, 94–97% of the sample was accounted for with product distributions similar to that given in Table IV. The toxicity of component 3 by the mouse unit (MU) assay method (13) compares favorably with the value 5500±500 MU/mg reported by Schantz (2) and co-workers. In an LD_{50} assay, agreement was even better, the value found being 9.5 γ/kg (IP mice) vs. 10±1 γ/kg reported (14). In addition, the specific rotation ($[\alpha]^{25}_{D}$ +128°) was within the limits +130±5° given by Schantz *et al.* (2) and the substance gave an infrared spectrum identical with that reported (15, see Fig. 3). It is therefore evident that component 3 and the best material obtained by Schantz *et al.* by the alumina chromatographic method are of identical purity. The purity of component 3 was estimated on the basis of impurity known to be introduced from the paper to be 98% and in view of the supporting data given above this figure seems to be a realistic appraisal. Clam poison dihydrochloride, as recovered from the paper, was frequently obtained as a colorless to pale yellow glass. On two occasions, however, it was obtained as a mixture of glass and crystals with the latter predominating. The latter were very hygroscopic and did not melt but sintered above 200°.

Components 1, 2, 4, and 5 were not obtained in as high a degree of purity as clam poison because of the smaller quantities which were present and the relatively larger amount of

impurity consequently introduced into each fraction by the paper chromatographic method. However, each of these substances was further purified by paper chromatography after a sufficient number of identical fractions from several chromatograms had been accumulated to ensure that a significant improvement in purity could be achieved. Ultimately, each fraction was obtained in purity exceeding 90% and the infrared spectrum was measured (KBr pellet). The spectra of the five components are given in Figs. 1–5 from which it is evident that components 1, 4, and 5 differ markedly from clam poison. Component 2, however, has a spectrum identical with that of clam poison dihydrochloride except that a weak band present in the toxin at 1770 cm^{-1} is absent from component 2. It is concluded, therefore, that the two substances are very similar in structure. The infrared spectrum of clam poison dihydrochloride is not very helpful from the viewpoint of identification of structural features of the molecule. Schantz and co-workers (15) have pointed out that the spectrum suggests the presence of OH or NH groups (3100–3300 cm^{-1}); C=O or C=N linkages (1600–1750 cm^{-1}) with a good possibility of the presence of an amide structure; and C—O or C—N bonds (1100 cm^{-1}). Also, the absence of a lactone, ester, anhydride, or aromatic structure seems assured. The only addition which we can make to this evaluation is the suggestion that the bands in the 1680–1770 cm^{-1} region could owe their origin to the presence of a cyclic imide, cyclic urea, or hydantoin-type structure (16, 17, 18).

Components 1, 2, and 5 when chromatographed again under the same conditions by which they were first isolated, each gave only one spot of R_F identical with that originally found. These substances were concluded to be impurities in the original sample, since a purer reference specimen of clam poison dihydrochloride furnished later by the U.S. Army Chemical Warfare Laboratories did not contain any of these materials.

Chromatography of pure clam poison dihydrochloride (component 3) on Whatman No. 1 paper which had been pretreated according to procedure 1 or 2 (Table II) gave only one Weber-positive spot, R_F 0.32, but the use of *unwashed* Whatman No. 1 paper under otherwise identical conditions led to two Weber-positive spots, R_F 0.32 and 0.53. Repeated recovery and rechromatography of the substance of R_F 0.32 on *unwashed* paper consistently gave the same result. Two spots of identical R_F were also obtained when clam poison was chromatographed on pretreated or *unwashed* paper after basification with ammonia. Component 4 when rechromatographed on *unwashed* or pretreated Whatman No. 1 paper gave two Weber-positive spots, R_F 0.32 and 0.53, with the latter predominating unless the material was acidified with hydrochloric acid prior to chromatography, when only one Weber-positive spot, R_F 0.32, was obtained. Multiple spots have

frequently been observed during chromatography of pure substances and a review of the causes has been given by Pollard *et al.* (19). Where polyfunctional basic compounds are chromatographed in acidic solvent systems, the explanation most frequently invoked is the generation of more than one ionic species of the base by reaction of the substance with the mobile phase (20, 21), but the formation of tautomers has also been postulated (22). Since clam poison has two basic centers and Mold *et al.* (1) obtained some evidence from countercurrent distribution studies at pH 8 that clam poison consists of two tautomers of differing toxicity, either of the explanations mentioned above was a possibility.

Owing to the marked similarity in chromatographic behavior of the various materials of R_F 0.32 and 0.53 described in the foregoing paragraph it was initially assumed that all the substances of identical R_F were identical and that the substance of R_F 0.32 was an ionic species of the toxin corresponding to a diacid salt whereas the substance of R_F 0.53 was an ionic species corresponding to a monoacid salt. Such behavior is exhibited by certain alkaloids of the lupin group where stable monoacid and diacid salts have been obtained (23, 24). Some support for this view was obtained by the behavior of clam poison acetate on paper chromatography which is now to be described. The acetate was prepared from the dihydrochloride by ion exchange on Amberlite IRA-400 resin and gave an infrared spectrum (Fig. 6) which differed from that of the dihydrochloride only in those

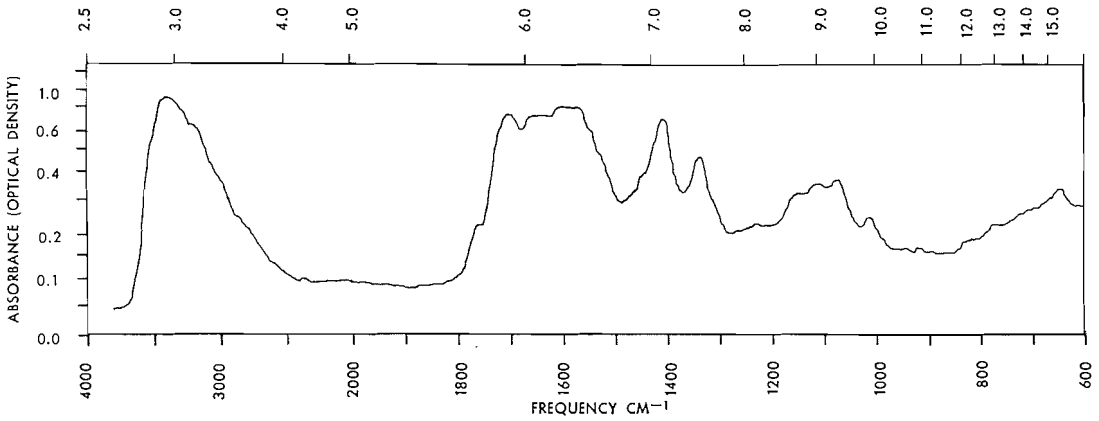

FIG. 6. Infrared spectrum of clam poison acetate.

regions where the ionized carboxyl group would be expected to modify it. Paper chromatography of the acetate on *unwashed* Whatman No. 1 paper gave only one Weber-positive spot, R_F 0.53, but on paper pretreated according to procedure 1 or 2 (Table II) a faint spot at R_F 0.32 was observed in addition to the strong one at 0.53. Reconversion of the acetate to the hydrochloride via ion exchange on Amberlite IRA-400 resin gave a substance with infrared spectrum identical with that of the original dihydrochloride and which showed no abnormality in paper chromatographic behavior (i.e. one spot on pretreated paper, R_F 0.32, two spots on *unwashed* paper, R_F 0.32 and 0.53). These results, coupled with the observation that the major component of clam poison and chloride ion have identical R_F's on *unwashed* paper suggested that the components of R_F 0.32 were the dihydrochloride, whereas the components of R_F 0.53 were the acetate possibly in the mono form. Unfortunately, however, this unifying theory had to be rejected in the light of the work now to be described.

If the substances of R_F 0.32 and 0.53 were different ionic species of the same base in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

equilibrium, then it should be possible to convert one to the other by a suitable adjustment of pH, and the same situation could obtain in the event that the two substances were tautomers in equilibrium. Judging from the chromatographic behavior described above, high pH's favor the faster-moving species and low pH's favor the slower-moving species. Even if there were a marked difference in toxicity between the two, it should be possible to regenerate the toxicity of pure clam poison by acidification to pH 3, which is the pH of maximum stability of clam poison and therefore the pH at which the bio-assay is performed (13). The complete lack of toxicity of component 4 (see Table IV) gave an indication that the simple ionic species theory is inadequate and furnished definite evidence that component 4 is not the minor tautomeric constituent B isolated by Mold *et al.* (1). The latter substance possessed significant toxicity but less than that exhibited by the major constituent A. It was observed furthermore (1) that if constituent B was acidified and allowed to stand for 16–24 hours the toxicity finally observed was identical with that of constituent A. Freshly prepared solutions of component 4 in hydrochloric acid of pH 3.0 showed no toxicity at a dosage of 1 mg/kg and no toxicity developed if such solutions were kept for periods of up to 5 days at pH 3.0 or 1.3. Chromatography of these solutions on pretreated Whatman No. 1 paper gave one Weber-positive substance, R_F 0.30, quantitative recovery and bio-assay of which confirmed that it was not clam poison dihydrochloride, since it was non-toxic. It was therefore concluded that component 4 is an impurity in, or a decomposition product from, the original clam poison sample, rather than another ionic species of the toxin or the tautomeric constituent B isolated by Mold *et al.* (1). Furthermore, the Weber-positive substance of R_F 0.30 generated by the action of aqueous hydrochloric acid on component 4 is not clam poison.

Attention was then turned to the substance of R_F 0.53 obtained by chromatography of pure clam poison on *unwashed* Whatman No. 1 paper, which is hereinafter referred to as substance X. An attempt was made to establish that substance X was identical with clam poison acetate. The substance X obtained by chromatography of the pure dihydrochloride on *unwashed* paper was impure because of the relatively large quantity of extractable impurity present in Whatman No. 1 paper. Rechromatography on specially pretreated (procedure 2) paper effected only a partial purification so that positive identification via the infrared spectrum was prevented. The substance possessed sufficient toxicity, however (525 MU/mg), to rule out the possibility that it is identical with component 4 from the original toxin sample. The substance was converted to the chloride salt by ion exchange in the usual manner, in the expectation that, after further purification by chromatography, a specimen of clam poison dihydrochloride would be obtained which could be identified by its infrared spectrum. A Weber-positive substance, R_F 0.35, was obtained which had a toxicity of 2150 MU/mg, but the infrared spectrum (Fig. 7) was quite different from that of clam poison dihydrochloride. It is therefore concluded that component 4, substance X, and clam poison acetate are non-identical and that the first two of these are not merely different ionic species of clam poison. It is also no longer considered that the substance of R_F 0.53 generated by the action of ammonia on clam poison is identical with component 4, substance X, or clam poison acetate. The nature of substance X and its relation to clam poison is still obscure but it seems likely that it is most probably a degradation product. If such is the case, it is of considerable interest because of the mild conditions of its formation and its intrinsic toxicity. A more detailed investigation of this substance must await more effective means for its purification. Clam poison acetate was shown to be a diacid rather than a monoacid salt by a pK determination, which revealed the presence of two basic groups pK_1 8.1 and pK_2 11.1 and a molecular weight in agreement with that reported by Schantz *et al.* (2) for the dihydrochloride.

To summarize the results of the multiple spots observed during chromatography of the samples of clam poison dihydrochloride and acetate available to us it has been concluded that component 4 from the original sample is a non-toxic impurity which is not reconverted to clam poison by treatment with acid. It is not identical with clam poison acetate or substance X, which is formed as a minor Weber-positive component from clam poison dihydrochloride during chromatography on *unwashed* Whatman No. 1 paper. Substance X is a toxic unidentified substance which is possibly a degradation product of clam poison. It also does not regenerate clam poison on treatment with acid but does produce another toxic Weber-positive substance of R_F 0.35. Clam poison acetate is a diacid salt like the hydrochloride and is convertible to the latter by ion exchange. The substance of R_F 0.53 formed during chromatography of clam poison dihydrochloride after basification with ammonia is not considered to be identical with component 4, substance X, or clam poison acetate.

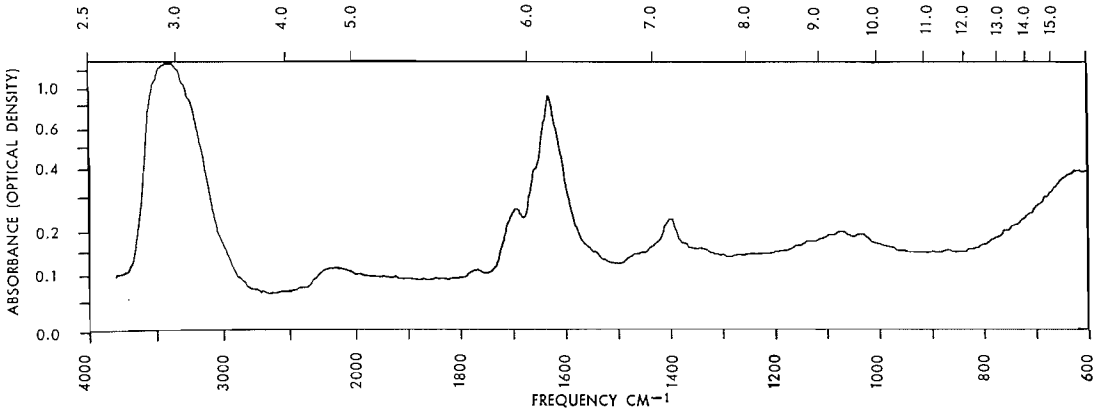

FIG. 7. Infrared spectrum of substance X in the chloride form.

The usefulness of the paper chromatographic method for purification of clam poison tailings has been studied. Preliminary chromatograms with the acetate revealed the presence of three ultraviolet-fluorescent spots, R_F 0.51, 0.53, and 0.62, the last two of which were Weber-positive. As expected, the major component had R_F 0.53. The chloride form, on the other hand, gave on chromatography five ultraviolet-fluorescent spots, R_F 0.20, 0.25, 0.30, 0.36, and 0.58, the last three of which were Weber-positive. The major component had R_F 0.30. It was therefore evident that better resolution of the Weber-positive components and therefore a better purification of the tailings was to be expected by the use of the chloride salt.

A sample of clam poison tailings (11.7 mg, 2000 MU/mg) was purified by quantitative chromatography on an $18\frac{1}{4}\times22\frac{1}{4}$-in. sheet of specially pretreated (procedure 2) Whatman No. 1 paper. The results given in Table V show that the percentage recovery on a weight basis was 95.5% and on a mouse unit assay basis was 81.5%. As expected, most of the toxicity (76%) was contained in the Weber-positive fraction of R_F 0.30, and a substantial improvement in the purity of the toxin was achieved judging by the enhanced toxicity. A portion of the recovered toxin (5.30 mg) was repurified by the same method, yielding 3.26 mg of clam poison dihydrochloride with toxicity 4150 MU/mg. Thus, 13,500 MU of a possible 14,500 MU (93%) was recovered in the second treatment. The total recovery for two purifications was 70.5% and the purity was increased from ca. 36% to ca. 75% (assuming the toxicity of the pure hydrochloride to be 5500 MU/mg). The infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

spectrum of the final product was identical with that of clam poison dihydrochloride. These results clearly establish the usefulness of the paper chromatographic technique as a method for enrichment of clam poison tailings on a small scale. In contrast to this, paper or cellulose column chromatography using 95% ethanol, triethylamine (1:1) as developer, chromatography on Amberlite XE-64 resin, and chromatography in absolute ethanol on Woelm's acidic alumina was found to be incapable of improving the purity of clam poison tailings (4). Paper chromatographic purification of the tailings in the acetate form was also briefly examined. The toxic component was located, as expected, at R_F 0.53. The enrichment was not quite as great as in the case of the hydrochloride, the toxicity on one purification being increased to 2200 MU/mg from 1600 MU/mg.

EXPERIMENTAL

Paper Chromatography of Clam Poison Dihydrochloride

For paper chromatography, 20 microliters of a 1.2% aqueous solution (pH 5) (240 γ) of the clam poison dihydrochloride sample received from Schantz *et al.* (2) was applied to *unwashed* Whatman No. 1 paper and developed overnight in a glass chromatographic tank by the descending technique. The air-dried chromatograms were sprayed with Weber reagent (3), Sakaguchi reagent (5), or bromcresol green indicator, or examined under an ultraviolet lamp for location of the components. Results are given in Table I for several solvent systems.

Procedure for Pretreatment of Papers

All papers used were Whatman No. 1, $18\frac{1}{4}\times22\frac{1}{4}$ in. on which $\frac{1}{2}$-in. serrations were cut along the bottom edge to assure even dripping during washing. The papers were washed chromatographically in a Model A 300 Chromatocab (Research Equipment Corp., Oakland, California) by the descending technique. Between each washing step, the papers were air-dried at room temperature. The washing procedures examined are shown in Table II.

Blank Runs on Pretreated Papers

The pretreated paper was developed overnight by the descending method until the solvent front was ca. 1 to $1\frac{1}{2}$ inch from the serrated edge (16 hours). The "chromatogram" was air-dried at room temperature and a vertical strip $1\frac{3}{8}$ in. wide (corresponding to the reference strip removed for exact location of the Weber-positive spots in actual chromatograms) was removed. Rectangular strips were then cut from the remainder of the chromatogram at R_F's corresponding to those of the clam poison components. Since the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

widths of the bands formed in actual chromatograms were found to vary, the widths of strips removed for extraction in the control runs were not identical for all components and were as follows: components 1, 2, and 4, 1 in.; component 3, $1\frac{1}{8}$ in.; component 5, $\frac{3}{4}$ in. The strips were eluted with water (1.5–2.0 ml) and the eluates transferred to small tared flasks with ground caps which had been previously weighed on a microbalance. The solutions were frozen, lyophilized, and the residues were weighed again. The quantities of residues obtained corresponding to the various components of the clam poison sample from papers pretreated according to the methods given in Table II are shown in Table III.

Purification of Clam Poison Dihydrochloride

A sample of the partially purified clam poison dihydrochloride solution (1.2% aqueous) containing 13–17 mg total solids was applied to a sheet of Whatman No. 1 paper ($18\frac{1}{4} \times 22\frac{1}{4}$ in. pretreated according to procedure 2) as 18 spots located on a start line 3 inches from the top of the paper. The two outside spots were placed $\frac{3}{4}$ inch from the edge of the paper and all others were spaced approximately 15/16 inch apart. To keep the area of the applied spots small, 5λ aliquots of the solution were applied at each location, and all spots were allowed to dry prior to subsequent application. The paper was developed exactly as described for the control runs. The air-dried chromatogram was examined under ultraviolet light to determine the straightness of the bands, and the width of component 1. A vertical strip $1\frac{1}{8}$ in. wide was cut from the chromatogram and sprayed with Weber and Sakaguchi reagent to determine the exact widths of the bands due to components 2, 3, 4, and 5. The bands were cut from the chromatograms and eluted with water (1.5–2.0 ml). Each eluate was passed through IRA-400 (Cl) resin (1 ml) to reconvert the basic components to the chloride form. A fresh sample of resin was used for each component and each column was eluted with a further 2 ml of water to ensure complete recovery. The resin used in these experiments was washed prior to use for 1 week with water after conversion to the chloride form, and it was ascertained in independent experiments that similar treatment of eluates from blank runs introduced no significant amounts of impurities. The solutions were transferred to tared flasks, and the components recovered and weighed as described for the blank runs. The areas of the strips of paper from which the components were eluted were measured by means of a planimeter, and the weight of impurity introduced during elution of each strip calculated after the data in Table III was converted to milligrams of impurity per square inch of paper extracted. The weights of impurities thus calculated were deducted from the weights of components recovered by the procedure given above, to give the actual weight recovered. The weight of material lost by spraying the reference strip was deducted from the original sample weight to give the actual weight of sample used. Results for a typical assay by this method are shown in Table IV. Clam poison dihydrochloride (component 3) was obtained as a colorless to pale yellow mixture of glass and crystals which did not melt but sintered above 220°, $[\alpha]_D^{25}$ +128° (1% aqueous solution). The other components of the sample were obtained as colorless to pale yellow glasses. Bio-assays were performed by the mouse unit (MU) assay method of Schantz *et al.* (13) and infrared spectra were measured as potassium bromide pellets (0.5 mg of sample + 300 mg of KBr) on a Perkin–Elmer model 21 spectrometer.

Attempted Reconversion of Component 4 to Clam Poison Dihydrochloride

Component 4 recovered from the purification of clam poison dihydrochloride was dissolved in hydrochloric acid at pH 3.00 at 20°, producing a solution containing exactly 200 γ/ml. Aliquots of this solution were removed and solutions containing 1, 5, 10, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

20 γ/ml were prepared using the dilute hydrochloric acid mentioned above. Bio-assays of these solutions by the MU assay method revealed that none of these solutions was toxic at dosage levels of 50–1000 γ/kg when freshly prepared, nor did toxicity develop in such solutions on standing for periods of up to 5 days at room temperature. The experiment was repeated using hydrochloric acid of pH 1.30 for preparation of the solutions but the increased acidity did not change the results in any respect. Chromatograms performed on the residual solutions from the experiments described above, using pretreated (procedure 1) Whatman No. 1 paper gave one Weber-positive spot, R_F 0.30. Quantitative isolation of the latter material from a separate chromatogram followed by bio-assay confirmed its non-toxic nature.

Isolation of Substance X *and Attempted Reconversion to Clam Poison Dihydrochloride*

A sample of clam poison dihydrochloride (24.2 mg) was chromatographed quantitatively using the procedure described previously for the purification of the toxin, except that two sheets of *unwashed* Whatman No. 1 paper were used. Two control chromatograms were run simultaneously to determine the quantities of extractables recovered at R_F's corresponding to the two Weber-positive substances formed. In this manner 21.2 mg of clam poison dihydrochloride (R_F 0.32) containing 2.8 mg of impurity and 15.1 mg of substance X (R_F 0.53) containing 11.8 mg of impurity were obtained. Substance X was thus only ca. 20% pure and was rechromatographed quantitatively on pretreated (procedure 2) Whatman No. 1 paper. After two such treatments, the purity of substance X had been increased to only 33%. An infrared spectrum on a portion of this material therefore gave an inconclusive result (i.e. identity or non-identity of substance X with the Weber-positive material of R_F 0.53 obtained during the paper chromatography of clam poison acetate was not established) but bio-assay revealed that substance X, even in its impure condition, had a toxicity of 525 MU/mg. The substance X remaining (6.50 mg, containing 2.24 mg of pure substance X) was passed through an Amberlite IRA-400 (Cl) resin column and the resultant material was purified by quantitative paper chromatography on pretreated (procedure 2) Whatman No. 1 paper, yielding 1.32 mg of Weber-positive substance, R_F 0.35, of estimated purity 75%. This substance had an infrared spectrum (Fig. 7) quite different from that of clam poison dihydrochloride and had a toxicity of 2150 MU/mg. Clam poison dihydrochloride of the same purity (recovered from tailings) had a toxicity of 4150 MU/mg and an infrared spectrum identical with that of a pure specimen of the dihydrochloride.

Purification of Clam Poison Tailings

A solution of clam poison tailings in the acetate form (220 ml, 1.16 mg/ml total solids, toxicity 1600 MU/mg) from the column chromatographic purification method of Schantz *et al.* (2) was found to be too dilute for paper chromatographic work and was lyophilized, yielding 255 mg of residue. The residue was dissolved in water to give a solution containing 25.5 mg/ml of total solids. Exactly 5 ml of the solution was converted to the chloride form by elution through Amberlite IRA-400 (Cl) resin, the eluate was lyophilized, and the residue (108 mg) made up to exactly 5 ml in water. A bio-assay on the two solutions revealed the acetate to have toxicity 1600 MU/mg and the chloride 2000 MU/mg.

Clam poison tailings chloride (11.7 mg) was purified on an $18\frac{1}{4}\times22\frac{1}{4}$-in. sheet of pretreated (procedure 2) Whatman No. 1 paper in the same manner as described for the original clam poison sample, after a control chromatogram had been performed to determine the weight of impurity which would be introduced into each fraction. A bio-assay

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

was performed on each fraction and results are given in Table V. Fraction W_1, R_F 0.30, accounted for 76% of the toxicity of the original sample and exhibited enhanced toxicity (2900 MU/mg). A portion of fraction W_1 (5.30 mg) was repurified by the same method, using, however, a $12 \times 18\frac{1}{4}$-in. sheet of pretreated paper, and gave 3.26 mg (93%) of clam poison with toxicity 4150 MU/mg. The infrared spectrum of the final product was identical with that of clam poison dihydrochloride.

Chromatographic Behavior of Clam Poison Acetate

Clam poison acetate was prepared from the dihydrochloride by ion exchange using Amberlite IRA-400 resin. The infrared spectrum of the acetate was measured and is shown in Fig. 6. Reconversion of a sample of the acetate to the dihydrochloride by ion exchange produced material with an infrared spectrum identical with that of the original dihydrochloride.

Paper chromatograms with the acetate on *unwashed* Whatman No. 1 paper in the usual manner gave only one Weber-positive spot, R_F 0.53, but on paper pretreated according to procedures 1 or 2 (Table II) a faint spot at R_F 0.30 was observed in addition to the strong one at 0.53.

Potentiometric Titration of Clam Poison Acetate

For potentiometric titration ca. 5-mg samples of clam poison acetate were dissolved in CO_2-free water in a nitrogen-swept microflask equipped with a Beckmann Probe Assembly 290-32 glass electrode and 270-32 reference electrode (attached to a Beckmann Model GS pH meter) and Gilmont ultramicroburet, and titrated vs. 0.1 *N* barium hydroxide. Found: pK_1 8.1, pK_2 11.1, molecular weight 455. Calc. for $C_{10}H_{17}N_7O_4 . 2\ CH_3COOH$, molecular weight 419.

ACKNOWLEDGMENTS

We wish to thank Dr. E. J. Schantz, of the U.S. Army Biological Warfare Laboratories, Fort Detrick, Frederick, Maryland, for 300 mg of clam poison dihydrochloride and the U.S. Army Chemical Warfare Laboratories, Army Chemical Center, Maryland, for samples of pure clam poison dihydrochloride and clam poison tailings.

We are greatly indebted to Dr. N. R. Stephenson and Dr. G. S. Wiberg, Food and Drug Laboratory, Department of National Health and Welfare, Ottawa, for their excellent co-operation in performing the bio-assays. Thanks are also extended to Dr. R. N. Jones and Mr. R. Lauzon, Division of Pure Chemistry, National Research Council, Ottawa, for measurement of the infrared spectra.

COMPLEX MANGANESE PERIODATES[1]

M. W. Lister and Y. Yoshino

ABSTRACT

The preparation of complex periodatomanganates, from manganous salts reacting with sodium (or potassium) hypochlorite and periodate, is described. The products were $Na_7H_4Mn(IO_6)_3.17H_2O$ and $K_7H_4Mn(IO_6)_3.8H_2O$. The manganese was shown to be tetravalent from its redox equivalent in its reaction with iodide and with ferrous ions, and from its magnetic moment, which was 3.87 Bohr magnetons, corresponding to three unpaired electron spins. The ion has an absorption maximum at 483 mμ. Rather complicated pH curves were found for this compound in acid–base titrations. The complex ion decomposes slowly to permanganate and iodate; the kinetics of this reaction have been measured, and a possible mechanism has been suggested. The reaction proceeds in several steps by way of simpler complex ions. The same applies to the reaction between iodide ions and the complex ions when the pH is about 9.

In a recent paper (1) the present writers reported on the preparation and properties of complex cobalt periodates. Similar copper compounds have been prepared and examined (2, 3), as have somewhat similar nickel compounds (4). The ability of periodate ions to oxidize manganese to permanganate suggested that manganese would not give a similar compound; but, on making the experiment, it was found that complex salts of tetravalent manganese could in fact be prepared. The object of the present paper is to describe the preparation and properties of these compounds.

1. *Preparation of Compounds*

(a) Sodium Periodatomanganate (IV)

After various preliminary attempts, the method used in a typical preparation was as follows. Twenty grams of sodium periodate, $Na_2H_3IO_6$, was dissolved in a mixture of 200 ml of water and 25 ml of 6 *M* nitric acid. To this was added 5 g of manganous chloride tetrahydrate dissolved in 20 ml of water, and then, before any precipitation could occur, a mixture of 100 ml of 1.5 *M* sodium hypochlorite and 15 g of sodium hydroxide dissolved in 20 ml of water. Some brown precipitate formed (presumably manganese dioxide), and after centrifuging this off, a red solution was obtained. Alcohol was added till the solution was 40% alcohol by volume, when a red sticky material precipitated. This was dissolved in 100 ml of dilute sodium hydroxide, filtered on sintered glass, and reprecipitated with alcohol, when a dark red precipitate was obtained. This purification process was repeated twice, and the precipitate was finally dissolved in water, which was allowed to evaporate slowly. Red crystals were obtained, filtered off, washed with a little cold water, and dried. The yield was somewhat variable, but was between 4.5 and 10 g on various occasions.

To analyze the solid, it was dissolved in water and sulphur dioxide was passed into the solution; complete reduction occurred. Excess sulphur dioxide was boiled out, and silver nitrate was added. Silver iodide was filtered off, washed, dried, and weighed. The silver in the filtrate was removed as silver chloride, and the solution was run through a column of Dowex 50W-X8 cation exchange resin in its hydrogen form. The sodium and manganese ions were adsorbed, and the sodium was then eluted with 0.4 *M* HCl, which leaves the manganese on the column. The sodium solution was evaporated and the sodium chloride was weighed; the purity of the sodium chloride was then checked

[1]*Manuscript received March 31, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

by silver nitrate titration. The column was then further eluted with 2.0 *M* HCl, which removes manganese. Sulphuric acid was added to the manganese solution, which was evaporated, and the manganese was weighed as $MnSO_4$. The water content of the crystals was determined from the weight loss at 150° C.

The results were Na 13.3%, Mn 4.60%, I 31.6%, water 25.3%. Calculated for $Na_7H_4Mn(IO_6)_3.17H_2O$ are Na 13.4$_5$%, Mn 4.60%, I 31.8$_5$%, water 25.6%. This analysis is the mean of two closely agreeing analyses.

A confirmation of this formula was obtained by passing a solution of a known weight of sodium periodatomanganate (IV) through an anion exchange resin (Dowex 1-X4) in its chloride form. The displaced chloride was titrated with silver nitrate. It was found that 1.415×10^{-3} g-molecules of chloride was displaced by 0.2016×10^{-3} g-molecules of the sodium salt, a ratio of 7 to 1. If R is the resin, the reaction is

$$7RCl + Na_7H_4Mn(IO_6)_3 \rightarrow R_7H_4Mn(IO_6)_3 + 7NaCl.$$

(b) Potassium Periodatomanganate (IV)

This compound was prepared in a similar fashion to the sodium salt, but with potassium periodate, KIO_4, and potassium hypochlorite as starting materials. It proved to be much less easy to crystallize than the sodium salt, as it is evidently more soluble in water, and readily gives a rather sticky precipitate with alcohol. An alternative preparation by running a solution of the sodium salt through a cation exchange resin, in its potassium form, gave a similar product. Slow evaporation over calcium chloride gave a dark red-brown solid.

Similar analysis as for the sodium salt gave K 23.3%, Mn 4.72%, I 32.4%, and H_2O 11.9%. Calculated for $K_7H_4Mn(IO_6)_3.8H_2O$ are K 23.9%, Mn 4.79%, I 33.2%, H_2O 12.6%.

(c) Barium Periodatomanganate (IV)

A solution of the sodium complex salt was mixed with barium hydroxide, when a brown precipitate formed. Its composition was approximately $Ba_5HMn(IO_6)_3.10H_2O$, but was somewhat variable, and no method was found to recrystallize the product, as it was insoluble in water and decomposed by acids. Its observed oxidation equivalent (see below) with potassium iodide and acid was 63.2 (calculated 61.2). It is probably the above salt contaminated by impurities such as barium carbonate, or barium periodate.

2. Valency of Manganese

The analyses above do not, of course, give any indication of the valency of the manganese. This was determined by various titrations, and by magnetic measurements, which are now described.

(a) Iodometric Titration

A weighed amount of the sodium salt was added to acidified potassium iodide. The liberated iodine was titrated with thiosulphate. The observed equivalent weight varied from 45.66 to 45.75 in three analyses, with a mean of 45.72. The calculated equivalents are Mn (III) 47.84, Mn (IV) 45.95, Mn (V) 44.22; these assume that the periodate is reduced to iodine and the manganese to Mn^{++}. The results agree with the presence of manganese (IV) in the compound.

(b) Potentiometric Titration with Ferrous Ammonium Sulphate

It was found that sodium periodatomanganate, like the corresponding cobalt salt, could be titrated against ferrous ions in acid solution. A weighed amount of the salt

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

was dissolved in 1 N sulphuric acid and titrated against approximately 0.1 M ferrous ammonium sulphate. The titration was followed potentiometrically with the cell: $Pt/Na_7H_4Mn(IO_6)_3/Hg_2Cl_2$ in saturated KCl/Hg. The platinum was the positive pole, and a typical titration of 0.0037 M complex salt against 0.0995 M Fe^{++} at 25° C gave:

ratio										
0	1.97	3.94	5.90	7.38	7.87	7.92	7.97	8.06	8.36	8.86
e.m.f. (volts)										
1.102	1.098	1.090	1.089	1.082	1.045	0.750	0.711	0.653	0.578	0.542

Here "ratio" means the number of gram-molecules of ferrous ions divided by the gram-molecules of complex salt. In this titration the inflection comes at 7.90; in another titration this was at 7.99; it is evident that 1 g-molecule of the complex salt reacts with 8 of ferrous sulphate.

$$2Na_7H_4Mn(IO_6)_3 + 16FeSO_4 + 17H_2SO_4 \rightarrow 7Na_2SO_4 + 2MnSO_4 + 8Fe_2(SO_4)_3 + 6HIO_3 + 18H_2O.$$

This also supports a formula with tetravalent manganese. With the corresponding cobalt compound, and with sodium periodate itself, there is reason to believe that the cell is not giving the true equilibrium voltage (see reference 1); this probably applies to the sodium periodatomanganate also. However, the evidence that this is tetravalent manganese is quite definite.

(c) Reduction with Sulphur Dioxide

An aqueous solution of the sodium periodatomanganate is reduced by sulphur dioxide, and after the excess sulphur dioxide was boiled off, the sulphuric acid produced in the oxidation can be titrated with sodium hydroxide. One gram equivalent of sulphuric acid was produced by 60.1 g of the compound; calculated are Mn (III) 62.9, Mn (IV) 59.7, Mn (V) 56.8. Thus this result also supports a formula with Mn (IV). The reaction is

$$Na_7H_4Mn(IO_6)_3 + 13SO_2 + 8H_2O \rightarrow 3NaI + 2Na_2SO_4 + MnSO_4 + 10H_2SO_4.$$

(d) Magnetic Properties

Magnetic measurements were made on the solid compound, using a Goüy apparatus of the conventional type. The compound was suspended in a tube surrounded by a jacket in which water at various temperatures could be circulated. The tube was calibrated with sucrose, whose susceptibility was taken to be -0.566×10^{-6}/g (5). The observed susceptibilities are given below; as is to be expected the compound is paramagnetic, and the magnetic moment was calculated after allowing for the diamagnetic susceptibility of the various atoms by means of Angus's method (6).

Temp., °C	3.0	25.6	39.7
χ_g	4.695	4.323	4.154×10^{-6}
$\chi_{g\text{-molecule}}$	5611	5166	4964×10^{-6}
Corr. for diamagnetism	6141	5696	5494×10^{-6}

These results fit a Curie–Weiss equation, $\chi = C/(T+\theta)$, where $\theta = 21°$ and $C = 1.826$. This makes the magnetic moment 3.84 Bohr magnetons. The calculated value for a "spin-only" atom with three unpaired electron spins is 3.87. Hence these results strongly support a formula with Mn (IV).

3. Absorption Spectrum

Solutions of sodium periodatomanganate (IV) are red in color. The absorption spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

measured on a Beckmann DU spectrophotometer was as follows for a 1.04×10^{-3} M solution containing 0.100 M sodium hydroxide:

wavelength (mμ)									
800	750	700	650	600	580	560	540	520	500
490	480	470	460	450	440	430	420	410	400
extinction coefficient									
3	4	7	13	54	98	169	266	354	409
423	428	417	398	378	369	393	453	602	870

There is thus a single maximum at 483 mμ. In acid solution the complex is stable enough to be measured; the general shape of the curve is the same but the maximum is less well marked. In 0.106 M perchloric acid, the spectrum in the neighborhood of the maximum (at 479 mμ) was:

wavelength	500	490	480	470	460	450
extinction coefficient	397	406	416	408	418	438

If the free acid was made by passing a solution of the sodium salt through an ion exchange resin in its hydrogen form, a somewhat different spectrum was obtained, with a shoulder at 480 mμ instead of a maximum. When the solution was allowed to stand for 2–3 days the spectrum of the permanganate ion appeared, but this was not visible at first. If the free acid was made alkaline with sodium hydroxide (0.05 M), a modified spectrum was obtained, again with a shoulder instead of a maximum at 480 mμ, though the general shape and size of extinction coefficients (412 at 480 mμ) were much the same. The nature of the change in the complex is not entirely clear, but related observations will be given below. If the adsorption maximum at 483 mμ is due to a $t_g \rightarrow e_g$ transition for one 3d electron, as seems possible, this corresponds to a splitting of 59 kcal between these levels. Sodium periodatocobaltate (III), which is diamagnetic, has a similar spectrum (1) with a maximum at 625 mμ.

4. pH Measurements

Since sodium periodatomanganate (IV) was fairly stable in acid solutions, its behavior in acid–base titrations was examined. The pH in these titrations was followed by a Beckmann pH meter with glass and saturated calomel electrodes. When 2.53×10^{-3} M sodium periodatomanganate (IV) was titrated against 0.1009 M perchloric acid, only one inflection was observed in the curve of pH plotted against the ratio of acid to sodium periodatomanganate (IV). This was after addition of two equivalents of acid, and corresponds to $Na_5H_6Mn(IO_6)_3$; the pH was then 7.48. These results are plotted in Fig. 1. If the acidified solution was allowed to stand briefly, and then titrated in the

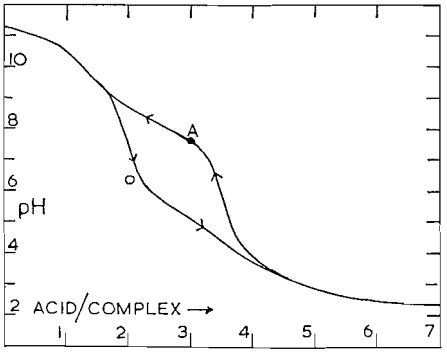

FIG. 1.

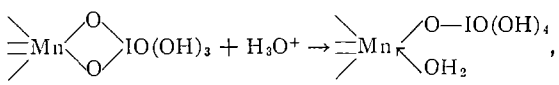
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

reverse direction with sodium hydroxide, a different curve resulted with an inflection at 4NaOH to one molecule of $H_{11}Mn(IO_6)_3$, that is, at $Na_4H_7Mn(IO_6)_3$. Thus the shape of the pH curves is like a hysteresis loop. Very nearly the same curve was obtained if the sodium periodatomanganate solution was run through a cation exchange resin in its acid form, and the resulting solution was titrated with NaOH; again the inflection was at $Na_4H_7Mn(IO_6)_3$. However, if the acid solution was allowed to stand for 24 hours before titration, the inflection shifted somewhat to about $3\frac{1}{2}$NaOH per molecule of the complex acid.

When 4NaOH was rapidly added per molecule of freshly prepared complex acid, the pH was 7.50 (A in Fig. 1); this is on the top branch of the loop. When a solution of $Na_7H_4Mn(IO_6)_3$ was prepared and $2HClO_4$ was rapidly added per molecule of complex, the pH was 6.32 on the lower branch of the loop; the same solution on standing for 24 hours had a pH of 7.68. If the free acid was made alkaline, its pH behavior was then the same as that of the original salt, so no permanent change was produced by acidification.

In another run the free complex acid was titrated against barium hydroxide. The pH was generally lower than in titrations with sodium hydroxide, but a precipitate formed. The first inflection on the pH curve was at $Ba_2H_7Mn(IO_6)_3$ (pH = 4.7), followed by a less well-defined rise between Ba_3 and Ba_4.



If the free acid was prepared by passing through a cation exchange resin in its acid form, and the free acid was immediately allowed to run through an anion exchange resin in its chloride form, three chlorides were displaced by one molecule of the complex acid, i.e.,

$$H_{11}Mn(IO_6)_3 + 3RCl \rightarrow R_3H_8Mn(IO_6)_3 + 3HCl.$$

However, the anion exchange resin acquired the brown color of finely divided manganese dioxide, and it is possible that all this experiment proves is that the sodium periodatomanganate (IV) contains three periodates per manganese. Each periodic acid displaced one chloride from the resin, as would be expected from its ionization constants, which are $pK_1 = 1.6$, $pK_2 = 7$ (7).

The pH of 2.5×10^{-3} M solutions of the free complex acid was found to be close to 2.30. This corresponds to two ionized hydrogens per molecule.

The explanation of all these observations is not too clear. Starting at the alkaline end, the main drop in pH was at $Na_5H_6Mn(IO_6)_3$ or $Na_5Mn(H_2IO_6)_3$. This is a formula with all periodates equally ionized. In the free acid two hydrogens are ionized, presumably as $(H_3O^+)_2[Mn(H_3IO_6)_3]^{--}$. The loop in the pH curve must be due to some rearrangement in the periodatomanganate ion on acidification, and this rearrangement, and its reverse on making alkaline again, must be slow. The nature of the process might be the replacement of a manganese–periodate bond by a band to water,

or dissociation to a lower complex (see later), but this is speculative. It is possible on this basis to write fairly plausible symmetrical formulae for the complex acid and its ions, but the evidence is not sufficient to establish them.

One other quantity can be calculated from these measurements. The pH of 0.00253 M sodium periodatomanganate was 10.87. Assuming that this is due to the hydrolysis of the $H_4Mn(IO_6)_3^{-7}$ ion, the hydrolysis constant can be calculated to be 3×10^{-4}.

For personal use only.

5. Decomposition of Sodium Periodatomanganate (IV)

It was found that solutions of sodium periodatomanganate (IV) spontaneously changed on standing to a solution of sodium permanganate. The over-all reaction is

$$2Na_7H_4Mn(IO_6)_3 + 2H_2O \rightarrow 2NaMnO_4 + 3NaIO_3 + 3Na_2H_3IO_6 + 3NaOH.$$

Experiments were made on the rate of this reaction under various conditions. Solutions were kept immersed in a water thermostat, regulated to better than 0.1° C, and the change was followed by light adsorption measurements with a Beckmann DU spectrophotometer.

In the first experiments the pH was controlled by means of a sodium phosphate buffer, but when the rates were compared with those obtained in sodium hydroxide solution, it became evident that the buffer did not influence the rate solely through its control of pH. Presumably the phosphate altered the rate by combining with one of the reacting species. Hence the runs that will be considered below will be ones in which the reacting solution was made up solely from sodium hydroxide, sodium periodate, sodium periodatomanganate, and water. The optical density was mostly measured at 550 mμ, where the extinction coefficients are: $Na_7H_4Mn(IO_6)_3$ 217, Na_2MnO_4 768, $NaMnO_4$ 2190; this is an adsorption maximum for sodium permanganate. The results are given in Table I.

If the color density is assumed to be due solely to the complex and to permanganate, then we can calculate the complex concentration at different times. Runs 1, 2, and 3 show that the rate is proportional to the complex concentration, when other factors are kept the same. A plot of log (complex) against time is nearly linear for all three runs, with a slope of 2.80×10^{-3}. Runs 3, 8, 9, 10 give the effect of sodium hydroxide concentration. If $d\log(\text{complex})/dt$ is taken from a plot for each run the results are:

$d\log X/dt$	0.06	0.54	2.73	8.32×10^{-4}: X = [complex]
$[OH^-]$	0.05	0.02	0.01	0.005 *M*

This is roughly, though not precisely, proportional to $[OH^-]^{-2}$; other powers of $[OH^-]$ give a much worse agreement with experiment. Finally runs 3, 4, 5, 6, and 7 give the effect of periodate concentration:

$d\log X/dt$	6.84	5.46	4.03	2.70	1.93×10^{-3}
[periodate]	2.46	3.27	4.91	7.37	9.82×10^{-4} *M*

The rate is inversely proportional to the added periodate concentration, though there is some drift from this simple relationship at low concentrations. It is readily calculated that the extra hydroxide ions, contributed by the hydrolysis of the complex ion, should not alter the rate by more than ½% for any of these runs.

The temperature variation of the rate (runs 5, 11, 12) makes the apparent activation energy about 46 kcal. This is so high that it is evident it is not a genuine activation energy, but must contain other factors; these will be discussed below.

One other set of results deserves comment: these are runs 13, 14, and 15, all with no added periodate. Here again a plot of log (complex) against time is linear at first, though levelling off towards the end of the run. The slopes of the linear parts are not very different.

It is not possible to be sure of the detailed mechanism of the reaction from these rate measurements, although it must be somewhat as follows. The complex must presumably be in equilibrium with a simpler complex, which is the reactive species, and the inverse relationship to periodate and hydroxide concentrations shows the nature of this equilibrium. The products of decomposition of the reactive species are not so certain, but it

was observed that in partially reacted mixtures a weak adsorption band appeared in the neighborhood of $\lambda = 610$ to 620 mμ. This is probably due to manganate ions which have an adsorption maximum at 610 mμ. Manganate ions can be oxidized to permanganate by periodate, and some measurements have been made on this reaction which will be reported separately. In general two reaction schemes would fit the facts.

(A)

$$H_4Mn(IO_6)_3^{-7} + 2H_2O \rightleftharpoons H_3Mn(IO_6)_2^{-3} + H_3IO_6^{-2} + 2OH^- \quad [i]$$

$$H_3Mn(IO_6)_2^{-3} \rightarrow Mn(OH)_3IO_6^{-2} + IO_3^- \quad [ii]$$

$$Mn(OH)_3IO_6^{-2} + 2OH^- \rightarrow MnO_4^{--} + H_3IO_6^{--} + H_2O \quad [iii]$$

$$2MnO_4^{--} + H_3IO_6^{--} \rightarrow 2MnO_4^- + IO_3^- + 3OH^- \quad [iv]$$

Reaction [i] is a rapidly established equilibrium, and reaction [ii] is the slow stage. Reactions [iii] and [iv] would be at least fairly fast; reaction [iv] is not meant to be necessarily a simple single-stage reaction.

An alternative is:

(B)

$$H_4Mn(IO_6)_3^{-7} + 2H_2O \rightleftharpoons MnIO_6^- + 2H_3IO_6^{--} + 2OH^- \quad [i]$$

$$MnIO_6^- + H_3IO_6^{--} \rightarrow Mn(OH)_2IO_6^- + IO_3^- + H_2O \quad [ii]$$

$$Mn(OH)_2IO_6^- + 3OH^- \rightarrow MnO_4^{--} + H_3IO_6^{--} \quad [iii]$$

$$2MnO_4^{--} + H_3IO_6^{--} \rightarrow 2MnO_4^- + IO_3^- + 3OH^- \quad [iv]$$

As before, reaction [i] is a rapid equilibrium, and reaction [ii] is slow; reactions [iii] and [iv] are fairly fast. It will be recognized that for both schemes A and B the products of reaction [ii] might differ in detail, though the manganese must be hexavalent.

Applying ordinary kinetic considerations to scheme A, and assuming that the added periodate is not too low, we get the equation

$$\frac{2K.K_e}{3C_0[OH^-]^2} \cdot t = -\left(1+\frac{2u_0}{3C_0}\right) \ln \alpha - (1-\alpha)$$

where K_e is the equilibrium constant of reaction [i],
K is the rate constant of reaction [ii],
C_0 and u_0 are respectively the initial concentrations of complex and of added periodate,
and α is the fraction of complex left undecomposed.

If u_0 is not too small, then

$$\frac{d \ln (\text{complex})}{dt} = -\frac{2K.K_e}{[OH^-]^2\{2u_0+3C_0(1-\alpha)\}},$$

which will be reasonably constant at first. If an apparent rate constant, K^*, is defined by

$$\frac{d \ln (\text{complex})}{dt} = -\frac{K^*}{[OH^-]^2 u_0}$$

then $K^* = K.K_e/\{1+(3C_0/2u_0)(1-\alpha)\} = K.K_e$ initially. The observed values of K^* show a drift, with C_0/u_0, of the size predicted by the above equation, if the average value of α is taken as 0.8, which was in fact approximately correct. This makes $K^* = 2.1 \times 10^{-10}$ (g-molecules/l.)^3 min^{-1} at 35° C. The observed apparent activation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

energy (46 kcal) will be the sum of the heat of reaction of reaction [i] and the activation energy of reaction [ii]; it is, of course, impossible to divide it between the two. It still seems to be rather high considering the nature of these two reactions.

The reactions of scheme B will give an identical equation relating α and t, if the same approximations are made. Hence the same remarks apply to scheme B.

Finally we must consider the observation that in the absence of added periodate a low, but fairly constant, value is obtained for $d\ln(\text{complex})/dt$. This could be explained for scheme A on the assumption that, under these conditions, the equilibrium of reaction [i] is fairly largely to the right. Then, at least initially, $d\ln(\text{complex})/dt = K\beta$, where β is the fraction dissociated. Runs 13, 14, and 15 make $K\beta$ about 3×10^{-2}. Allowing for the fact that $[OH^-] = 10^{-2}$ throughout, consistent results are obtained if we take $K_e = 2\times10^{-9}$ and $K = 0.11$. These numbers make the complex between 23 and 29% dissociated in these runs, and lead to a drift of the initial values $d\ln(\text{complex})/dt$ of about what is found. Thus although the results cannot give very accurate constants, they agree quite well with this explanation. Scheme B does not lead to a roughly constant value of $d\ln(\text{complex})/dt$ for different C_0 values, for the conditions of these runs, and hence scheme A is to be preferred.

It is also evident that the same dependence on hydroxide ion concentration cannot hold in acid solution, as, otherwise, acidified solutions would decompose much faster than they do. However, the pH titration curves gave evidence of rearrangement of the ion at moderate pH values, and this presumably also changes the rate of decomposition to permanganate.

One other set of experiments was made in the hope of throwing some light on the mechanism of decomposition. It was observed that when iodide was added to a solution of the complex, iodine was slowly liberated. It seemed possible that this might measure the rate of breaking up of the complex to a simpler ion and a periodate ion, which then rapidly oxidized iodide. If this were so, the rate should not depend on the iodide concentration. However, on making the experiment it was found that the rate at 25° C actually followed an equation

$$\text{rate} = -\frac{x}{x_0}\{0.9+3.0[I^-]\}10^{-6}$$

where x is the concentration of the complex at any time, and x_0 is its initial concentration; the time is measured in minutes. This is evidently a complex reaction, and the hope that it goes at a rate determined by the breaking up of the complex is not fulfilled. The inverse relation of rate to initial concentration of complex does presumably indicate an initial breaking up reaction, but it is not possible to suggest a detailed mechanism.

SOME OBSERVATIONS ON THE THEORY OF π-BONDING IN INORGANIC COMPOUNDS[1]

A. D. WESTLAND

ABSTRACT

Evidence for the existence of multiple bonding due to *d*-electron donation by non-inert gas type ions is discussed briefly. A quantitative relation between the heats of formation of binary halides and chalcides containing non-inert gas type cations, on the one hand, and inert gas type cations, on the other, reveals an enhanced lattice energy in the former class of compounds. It is shown that this may be accounted for in the case of iron group elements without recourse to the postulate of participation of *d*-electrons in the bonding, as satisfactory estimates of the lattice energies of halides and sulphides may be made on the basis of values for group II*a* compounds.

The bond between the metal atom and carbon in carbonyl compounds is described as consisting of a dative σ-bond and a π-bond, the latter resulting from the overlap of an occupied *d*-orbital of the metal atom and a vacant orbital of the ligand (1). Such bonding is called upon to explain the observations of Carleson and Irving (2) and Ahrland and Chatt (3) that throughout a certain group of metals designated as "*b*-class" elements the stabilities of halo complexes increase in the order F < Cl < Br < I, whereas the order for most elements is I < Br < Cl $\ll$ F. Chatt and co-workers have extended the argument to complexes containing sulphur, phosphorus, etc., which elements they conceive as π-acceptor ligands (4), and they have proposed that the trans-directing influence of certain ligands in substitution reactions may be likewise ascribed to *d*-orbital participation (5).

The postulate of double bonding to the carbonyl group seems unavoidable if an implausibly large accumulation of negative charge at the metal atom is to be avoided. Apart from this rule of "small formal charge", evidence hitherto cited in support of π-bonding has been of an equivocal character. Thus Keller and Parry argue that certain cyano complexes such as $Cr(CN)_6^{3-}$ can hardly owe their great stability to π-bonding because they lack sufficient *d*-electron pairs (6). A recent argument (7) purporting to demonstrate π-bonding through a quantitative relation between absorption band frequencies and complex stability has been refuted by Williams, who maintained that these results and also the relative stabilities of halide complexes of *b*-class elements may be explained satisfactorily as a consequence of polarization of the ligands by the central atom (8). The *b*-class elements are just those which, as cations, have unusually large polarizing power due to inefficient shielding of the nuclear charge by their outer *d*-electrons. It may thus be argued that π-bonding is not required to explain many of the effects which have recently been attributed to it.

Williams' conclusions appear to be based upon a somewhat unsatisfactory argument, however. His measure of polarizing power, R = [ionization potential/$(100Z^2/r)$], is apparently meaningless for ions of inert gas configuration for it increases with increasing atomic number in a given periodic group. There is, however, little doubt that his relations correctly emphasize the fact that polarization may be used to explain many of the phenomena attributed to *d*-electron bonding. It seems that a thermochemical comparison of complexes containing central ions of inert gas and of non-inert gas configurations

[1]*Manuscript received April 22, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

respectively is desirable but this is not yet possible because of the lack of sufficient data for the former. Among binary compounds, however, it is possible to make such comparison and in what follows it is demonstrated that Williams' conclusions are borne out by the thermochemistry of transition metal halides and chalcides.

It has been shown in a previous publication (9) that it is possible to relate the heats of formation of various series of compounds with good precision by means of the quantity

$$-\Delta H^{**} = (-\Delta H_f + S + I)/\text{equivalents per mole},$$

in which ΔH_f is the heat of formation of the compound formed from the elements in their standard states, S is the sublimation energy of the metal, and I is its ionization potential. The $-\Delta H^{**}$ functions for various series of compounds of a given set of cations (or anions) yield straight lines if plotted one against the other providing certain conditions of crystal structure are met. It follows that if we were to attempt to relate the $-\Delta H^{**}$ values of a series of compounds, of which some members possess π-bonds, to those of a series in which no such additional bonding is possible, the singular cases would be revealed. Compounds of third period elements may be thus compared with the corresponding compounds of group II*a* elements, for example. In Fig. 1 the $-\Delta H^{**}$ values for third period halides are plotted against $-\Delta H^{**}$ for the corresponding oxides. Figure 2 illustrates similar relations

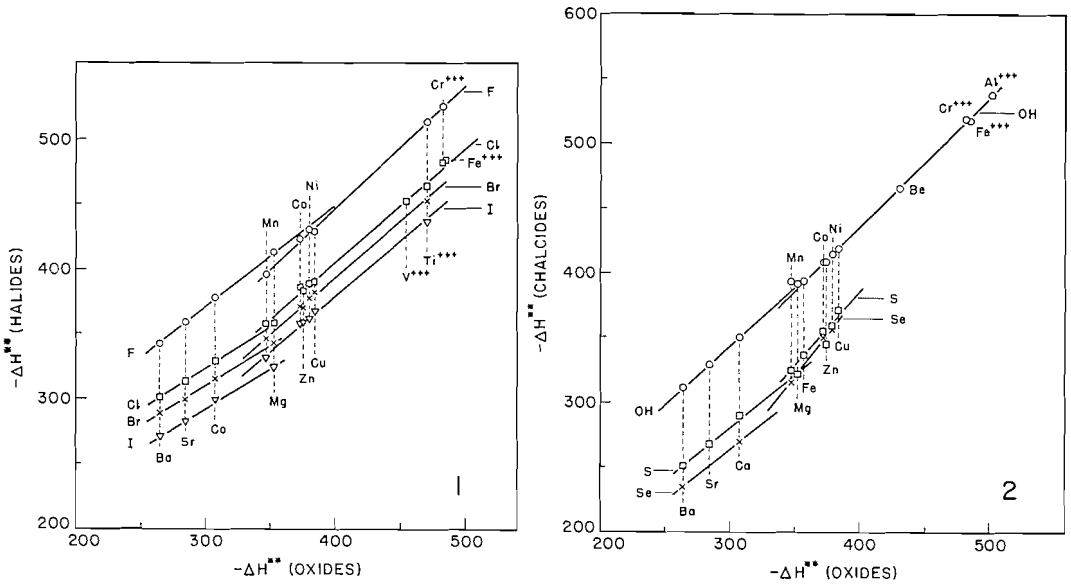

FIG. 1. Plot of $-\Delta H^{**}$ for halides against $-\Delta H^{**}$ for corresponding oxides.
FIG. 2. Plot of $-\Delta H^{**}$ for hydroxides and chalcides against $-\Delta H^{**}$ for oxides.

among the chalcides. The values for these plots are expressed in kilocalories/gram equivalent and were calculated from heats of formation published by the National Bureau of Standards, Washington (10).

An immediate conclusion which may be drawn is that there is no marked difference between the plots for fluorides and hydroxides, for which π-bonding is not possible, and the plots for anions containing vacant *d*-orbitals. The values for transition metals fall on lines which, however, are not extensions of the group II*a* plots. It must now be shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

that the deviations can be explained on the basis of a model simply involving polarization of the anion.

The value of $-\Delta H^{**}$ for nickel oxide is greater than that for magnesium oxide. This, like the higher ionization potential of nickel, may be interpreted as the result of a greater effective nuclear charge. This means that ions containing outer *d*-electrons possess a greater polarizing power than inert gas type ions of the same charge and radius. It is here assumed that the energy of polarization per gram equivalent in the halides and hydroxides is $N\alpha(Z+z)^2/r^4$, where N is the number of ion–dipole interactions per gram equivalent, α is the polarizability of the anion, Z is the charge on the cation, z is the additional effective nuclear charge due to the presence of outer *d*-electrons, and r is the sum of the cation and anion radii. This expression may be written

$$P = N\alpha[Z^2\{1+(z/Z)\}^2]/r^4. \qquad [1]$$

If z be assumed small with respect to Z, the increase in energy of polarization due to the additional effective nuclear charge is approximated by

$$\Delta P = N\alpha z^2/r^4. \qquad [2]$$

Let us now consider the compounds of cobalt, for example, and assume that the radius of the bivalent ion is 0.82 Å. The contribution to $-\Delta H^{**}$ for the oxide due to the additional polarization is $\Delta P_{CoO} = -\Delta H^{**}-(-\Delta H_h^{**})$, where $-\Delta H_h^{**}$ is the energy value for an hypothetical oxide of an inert gas type cation of radius 0.82 Å. This may be obtained from a plot of $-\Delta H^{**}$ for the group II*a* oxides against ionic radii. This procedure gives $\Delta P_{CoO} = 30.5$ kcal/equivalent. Substituting this value in the expression

$$\Delta P_{oxide} = N\alpha z^2/2r^4, \qquad [3]$$

we obtain $z = 2.46\times10^{-10}$ e.s.u. (The numeral 2 appears in the denominator of [3] because there are only half as many anions per equivalent in the oxide as in the halides.) Upon substituting this value and the appropriate values of α and r obtained from the literature (11, 12) in [2] we may calculate ΔP values for the other cobalt compounds.

Values of $-\Delta H_h^{**}$ for hypothetical halides of an inert gas type cation of radius 0.82 Å are read from plots of the values for group II*a* halides against ionic radii. When the polarization energies calculated as described above are added to these $-\Delta H_h^{**}$ values, calculated values of $-\Delta H^{**}$ are obtained. These are shown in Table I along with the

experimental values. The agreement is very good for a calculation of this type. However, it was not possible to account for the large lattice energies of selenides.*

Points for the second and third long period elements fall above the lines of Figs. 1 and 2 in those cases where π-bonding is a possibility. The heights of the points above the curves are given in Table II. In keeping with expectation for π-bonding, the energy differences

are greatest for third long period elements in iodides and sulphides and further, the hydroxides exhibit no enhancement of lattice energies in contrast to the sulphides. The differences for PbF_2 and CdF_2 are anomalous if we assume the origin of the effects to be in π-bonding but it should be noted that there is more uncertainty about the position of the best fluoride plot than there is about any of the others. Moreover, the differences in the case of these two compounds are equally anomalous even if a polarization argument is adduced to explain these effects.

Although it is here suggested that the plots of $-\Delta H^{**}$ provide some argument for π-bonding, it is recognized that polarization or other causes may well be responsible. It is evident, at least, that the participation of the *d*-electrons is very slight at most in these compounds.

We should expect *d*-electron donation to be more favorable when the metal atom possesses a smaller formal charge. Thermochemical data for compounds of zero-valent elements and, next best, for monovalent ones would be very welcome in this regard. At present we may make comparisons between compounds of silver and those of the alkali elements. Proceeding in this case as described above for bivalent ions, the data in Table III were obtained.

The large discrepancies for the heavier halides favor the principle of π-bonding although this is not so for the sulphide. The explanation based upon polarization is less

*There is some evidence of participation in the bonding on the part of the d-electrons in these compounds with the NiAs structure since the magnetic moments indicate extensive superexchange among unpaired spins.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

satisfactory here because the differences between calculated and experimental values are equally as great as, or greater than, those in the compounds of the neighboring ions Pd^{++} and Cd^{++}. Such a large polarizing power would be surprising in an ion which has a greater radius and is only singly charged.

We conclude that there is little or no π-bonding in the binary halides and sulphides of third period elements but there is a possible indication of such in the case of heavier elements. It is probable that extensive π-bonding occurs only in more covalent compounds in which the formal charge on the metal atom is zero or negative as is the case in the metal carbonyls.

THE SYNTHESIS OF 3-*O*-β-D-XYLOPYRANOSYL-D-XYLOSE AND THE RECHARACTERIZATION OF SOME BENZYLIDENE DERIVATIVES OF D-XYLOSE[1]

E. J. C. CURTIS AND J. K. N. JONES

ABSTRACT

The benzylidene groups of the di-*O*,*O*-benzylidene derivative of D-xylose diethyl dithioacetal have been located at the 2,4:3,5 positions, and *not* at the 2,3:4,5 positions suggested by Zinner, Rembarz, Linke, Ulbricht. Partial hydrolysis yielded the 2,4-*O*-benzylidene compound, from which 3-*O*-β-D-xylopyranosyl-D-xylose (rhodymenabiose) was prepared.

INTRODUCTION

An attempt was made to synthesize 4-*O*-β-D-xylopyranosyl-D-xylose by condensing tri-*O*-acetyl-α-D-xylopyranosyl bromide under standard Koenigs–Knorr conditions with a D-xylose derivative which had all the hydroxyl groups substituted with the exception of that at C_4. It was also desired that this substance be in the open-chain form since experiments have indicated (2) that such reactants give greater yields than those in a ring form due to a lessening of steric hindrance in the Koenigs–Knorr reaction. It was decided that such a derivative might be synthesized using as starting material the mono-*O*,*O*-benzylidene-D-xylose diethyl dithioacetal prepared by Zinner *et al.* (1). This was obtained in low yield by the partial hydrolysis of a di-*O*,*O*-benzylidene-D-xylose diethyl dithioacetal formed by condensing D-xylose diethyl dithioacetal with benzaldehyde in the presence of hydrochloric acid. The above workers (1) assigned the 2,3-linkage to the mono-*O*,*O*-benzylidene compound and gave the 2,3:4,5-linkage to the di-*O*,*O*-benzylidene compound.

Accordingly, the crystalline *O*-benzylidene derivative was prepared and was acetylated to yield a crystalline di-*O*-acetyl-mono-*O*,*O*-benzylidene-D-xylose diethyl dithioacetal, which was then demercaptalated with mercuric chloride and cadmium carbonate in dry methanol, yielding a crystalline di-*O*-acetyl-mono-*O*,*O*-benzylidene-D-xylose dimethyl acetal. Deacetylation of the latter compound produced a crystalline mono-*O*,*O*-benzylidene-D-xylose dimethyl acetal, which was then partially benzoylated using one equivalent of benzoyl chloride in pyridine at low temperature. This reaction yielded a crystalline *O*-benzoyl-*O*,*O*-benzylidene-D-xylose dimethyl acetal. From the reaction sequence, this compound should be 5-*O*-benzoyl-2,3-*O*-benzylidene-D-xylose dimethyl acetal, which has all its hydroxyl groups substituted except that at C_4, a position which is sterically unhindered owing to the absence of a hemiacetal ring. Hence, it was a suitable intermediate for the desired synthesis of 4-*O*-β-D-xylopyranosyl-D-xylose.

O-Benzoyl-*O*,*O*-benzylidene-D-xylose dimethyl acetal was therefore condensed with tri-*O*-acetyl-α-D-xylopyranosyl bromide under standard Koenigs–Knorr conditions (3). The reaction product was deacetylated and debenzoylated by warming it with sodium hydroxide solution, and benzylidene and acetal groups were subsequently removed by hydrolysis with warm dilute sulphuric acid. There resulted a syrup which, from chromatographic examination, consisted mainly of xylose and a disaccharide with an unexpectedly high mobility on chromatograms. The mixture was separated by chromatography on a cellulose column, and the disaccharide component was isolated as a syrup which crystallized. The disaccharide showed on chromatograms a single spot with an unexpectedly

[1]*Manuscript received March 25, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

high mobility (R_{xylose} 0.53, solvent A; 0.64, solvent B), whereas the mobility of the expected 4-*O*-β-D-xylopyranosyl-D-xylose* was much lower (R_{xylose} 0.20, solvent A; 0.38, solvent B). The disaccharide was, in fact, shown to be 3-*O*-D-xylopyranosyl-D-xylose, from its oxidation with sodium periodate and the formation of an osazone. The specific rotation ($-35° \rightarrow -22°$ (constant)) showed the compound to be 3-*O*-β-D-xylopyranosyl-D-xylose. 3-*O*-α-D-Xylopyranosyl-D-xylose has a specific rotation of $+106° \rightarrow +118°$ (constant) (5).

Howard (6) has obtained a xylose-containing disaccharide by partial hydrolysis of a xylan produced by *Rhodymenia palmata*. This disaccharide, "rhodymenabiose", has the same physical constants as the synthetic xylobiose, which is now identified as 3-*O*-β-D-xylopyranosyl-D-xylose. The structure of "rhodymenabiose" was tentatively suggested to be 3-*O*-β-D-xylopyranosyl-D-xylose but no attempts were made to characterize it (6).

As the disaccharide obtained in the Koenigs–Knorr synthesis was not that expected, it was decided to re-examine the structure of the *O*-benzoyl-*O*,*O*-benzylidene-D-xylose dimethyl acetal (VII) used in the condensation. Compound VII was methylated using silver oxide and methyl iodide. The compound proved difficult to methylate, but, after three repetitions of the methylation procedure, a crystalline monomethyl ether was isolated. Debenzoylation yielded a crystalline mono-*O*,*O*-benzylidene-*O*-methyl-D-xylose dimethyl acetal which, on acid hydrolysis, was converted into crystalline 3-*O*-methyl-D-xylose (7).

Compounds VI and VII were then treated with toluene-*p*-sulphonyl chloride, and mono-*O*,*O*-benzylidene-di-*O*-tosyl-D-xylose dimethyl acetal and *O*-benzoyl-*O*,*O*-benzylidene-*O*-tosyl-D-xylose dimethyl acetal were formed, respectively. Reaction of the first of these two tosyl derivatives with sodium iodide under standard conditions (8) showed the presence of one primary hydroxyl group, while, under the same conditions, the second compound showed primary hydroxyl groups to be absent.

These data, together with the formation of 3-*O*-methyl-D-xylose, characterize VI as 2,4-*O*-benzylidene-D-xylose dimethyl acetal and VII as 5-*O*-benzoyl-2,4-*O*,*O*-benzylidene-D-xylose dimethyl acetal. Compound VI was not oxidized by sodium metaperiodate under standard conditions (9) and this is consistent with the benzylidene group in the 2,4 position, there being no free hydroxyl groups on adjacent carbon atoms in 2,4-*O*-benzylidene-D-xylose dimethyl acetal. If the benzylidene group were attached in the 2,3 position a consumption of one equivalent of periodate would be expected. Reaction of VII with tri-*O*-acetyl-α-D-xylopyranosyl bromide would therefore be expected to yield a (1 → 3)-linked xylopyranosyl–xylose and not the (1 → 4)-linked disaccharide originally expected in the condensation.

3-*O*-β-D-Xylopyranosyl-D-xylose was obtained in 11% yield, which is less than might be expected from a condensation involving an open-chain sugar (2). However, although the sugar was in the open-chain form, the hydroxyl group involved in the reaction—that at C_3—was part of a ring system which involved the benzylidene group, and, thus, reaction was sterically hindered to some extent. That the hydroxyl group at C_3 was not very reactive was shown by the difficulties encountered in methylating and tosylating this group.

In order to determine if the mono-*O*,*O*-benzylidene derivatives III, IV, and V had the benzylidene group in the 2,4 position or if the group had wandered during one of the interconversions, the structure of mono-*O*,*O*-benzylidene-D-xylose diethyl dithioacetal

(III) was examined. The formulation of this as the 2,3-*O*-benzylidene isomer (Zinner *et al.* (1)) rests upon its oxidation with lead tetraacetate, when one equivalent of the oxidizing agent was consumed and formaldehyde (amount not stated) was liberated. This consumption of oxidant was interpreted to mean that the compound contained hydroxyl groups on adjacent carbon atoms. It is known, however (10, 11), that lead tetraacetate oxidation of thioacetals is an unreliable guide to the presence of hydroxyl groups on adjacent carbon atoms, due to the oxidation of the dithioacetal grouping. In particular, Huebner *et al.* (10) have examined the lead tetraacetate oxidation of the analogous mono-*O,O*-benzylidene derivatives of L-arabinose diethyl dithioacetal. With the fully substituted di-*O*-benzylidene-L-arabinose diethyl dithioacetal, one equivalent of oxidant was consumed rapidly (5 minutes) and a further one equivalent was consumed slowly (2 hours). This consumption they assumed to be due to oxidation of the dithioacetal group—a rapid oxidation of one sulphur atom followed by a slower oxidation of the second. With mono-*O,O*-benzylidene-L-arabinose diethyl dithioacetal, a consumption of two equivalents (rapid) plus two equivalents (slow) of lead tetraacetate per mole was observed, which, it was assumed, was due partially to oxidation of the thioacetal groups (one fast plus one slow) and partially to oxidation of hydroxyl groups on adjacent carbon atoms (also, one fast plus one slow). It would, therefore, seem from these observations that the data reported (1) for the lead tetraacetate oxidation of mono-*O,O*-benzylidene-D-xylose diethyl dithioacetal would support the view that this compound does *not* possess hydroxyl groups on adjacent carbon atoms, rather than the reverse.

By demercaptalation of II, Zinner *et al.* (1) obtained a 2,3,4,5-di-*O*-benzylidene-*aldehydo*-D-xylose which, by heating with methanol, they converted into a crystalline 2,3,4,5-di-*O*-benzylidene-D-xylose methyl hemiacetal. They point out that the physical constants (melting point and specific rotation) of this compound are very similar to those of a 2,3,4,5-di-*O*-benzylidene-L-xylose methyl hemiacetal, which was prepared by lead tetraacetate oxidation of a 1,2,3,4-di-*O*-benzylidene-D-glucitol and subsequent treatment with methanol (Wolfe, Hann, and Hudson (12)). However, although the structures of these L-xylose and D-glucitol derivatives were at first in doubt, di-*O,O*-benzylidene-D-glucitol was later shown by Angyal and Lawler (13) to have the benzylidene groups spanning the 1,3 and 2,4 hydroxyl groups. These workers isolated, by partial hydrolysis, 2,4-*O*-benzylidene-D-glucitol, the structure of which was previously known. It therefore follows that the 2,3,4,5-di-*O*-benzylidene-L-xylose methyl hemiacetal must, in fact, have the 2,4:3,5 structure, and the identity of physical constants of this and di-*O,O*-benzylidene-D-xylose methyl hemiacetal would indicate that the latter compound *too* has the 2,4:3,5 structure.

Finally, to characterize compounds II, III, and IV, di-*O*-acetyl-*O,O*-benzylidene-D-xylose diethyl dithioacetal (IV) was demercaptalated, using mercuric chloride and cadmium carbonate in aqueous acetone (14), to yield di-*O*-acetyl-*O,O*-benzylidene-*aldehydo*-D-xylose. This compound was reduced with sodium borohydride in aqueous methanol, and the resulting alkaline solution was heated on a water bath to complete removal of the acetyl groups. The solution was deionized and evaporated to a crystalline residue which was shown to be the well-characterized, symmetrical 2,4-*O*-benzylidene-xylitol (XI) (15, 16). Compound IV is, therefore, 3,5-di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose diethyl dithioacetal, whereas compounds II and III must be 2,4:3,5-di-*O*-benzylidene-D-xylose diethyl dithioacetal and 2,4-*O*-benzylidene-D-xylose diethyl dithioacetal, respectively.

The real sequence of reactions in the synthesis of the disaccharide was therefore:

Demercaptalation of 2,4:3,5-di-*O*-benzylidene-D-xylose diethyl dithioacetal (II), using mercuric chloride and cadmium carbonate in dry methanol, yielded crystalline 2,4:3,5-di-*O*-benzylidene-D-xylose dimethyl acetal (XIII). This was shown to be identical with the di-*O*,*O*-benzylidene-D-xylose dimethyl acetal prepared by Breddy and Jones (17) by condensing D-xylose with benzaldehyde and methanol in the presence of hydrochloric acid, and used by them for the estimation of xylose. The structure of this compound was not previously known.

Zinner *et al.* (1), in addition to preparing the mono-*O*,*O*-benzylidene (III) and di-*O*,*O*-benzylidene (II) derivatives of D-xylose diethyl dithioacetal, also prepared, in the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

way, a mono-*O,O*-benzylidene-D-xylose dipropyl dithioacetal, and di-*O,O*-benzylidene derivatives of the methyl, propyl, *n*-butyl, isobutyl, and benzyl dithioacetals of D-xylose. These, like II and III, were assigned the 2,3-linkage (in the case of the mono-*O,O*-benzylidene-D-xylose dipropyl dithioacetal) and the 2,3:4,5-linkage (in the case of the di-*O,O*-benzylidene derivatives of the various D-xylose dithioacetals). No attempt has been made to investigate the structures of these derivatives, but it would seem likely that they, like II and III, have the di-*O,O*-benzylidene groups in the 2,4:3,5 positions and the mono-*O,O*-benzylidene group in the 2,4 position.

EXPERIMENTAL

Optical rotations were measured at 21° ± 2° C and in water unless otherwise stated. Solutions were concentrated under reduced pressure at 40° C. The following solvent systems (v/v) were used to separate sugars on paper chromatograms: (A) 1-butanol:ethanol:water, 3:1:1; (B) ethyl acetate:acetic acid:water, 9:2:2. Sugars were detected with the *p*-anisidine hydrochloride spray (18). Infrared absorptions were measured either as solutions in chloroform or as a powder (mulled in a potassium bromide pellet) on a Perkin–Elmer Model 21 spectrophotometer.

D-*Xylose Diethyl Dithioacetal* (I)

D-Xylose (100 g), ice-cold ethanethiol (100 g), and ice-cold hydrochloric acid (100 ml) were shaken together in a stoppered flask and the resulting mixture was left overnight at room temperature. The solution was diluted with water (200 ml) and then deionized by passage through Amberlite IR 400 (OH) resin. The eluate was concentrated to a syrup which was diluted with ether (200 ml) and refrigerated. The product crystallized and was filtered and washed with ether. Yield: 140 g (82%), m.p. 63–64° C.

2,4:3,5-Di-O-benzylidene-D-*xylose Diethyl Dithioacetal* (II)

D-Xylose diethyl dithioacetal (50 g) was dissolved in redistilled benzaldehyde (500 ml) with warming and after being cooled to 5° C in ice, dry hydrogen chloride was bubbled through the solution. After 5 minutes a semisolid mass was formed which was diluted with ethanol (400 ml), shaken, and filtered under suction. The crude crystalline product was dried *in vacuo* and recrystallized from boiling ethanol. Yield: 40.6 g (48%), m.p. 181–182° C, $[\alpha]_D$ −36° (*c*, 4.95, chloroform). Literature (1) gives a melting point of 181–182° C and $[\alpha]_D$ −36.7° (*c*, 2.53, chloroform).

2,4-O-Benzylidene-D-*xylose Diethyl Dithioacetal* (III)

The conditions given by Zinner *et al.* (1) (hydrolysis with ethanol (3 parts) plus 80% acetic acid (4 parts) for 1 hour) were found to produce only a small yield of mono-*O,O*-benzylidene compound. After various hydrolyzing mixtures were tried, the following conditions were found to be most satisfactory. A mixture of di-*O,O*-benzylidene-D-xylose diethyl dithioacetal (80 g), acetone (1800 ml), and 80% acetic acid (1200 ml) was refluxed for 3 hours. The resulting solution was cooled to 10° C in ice water, and unhydrolyzed di-*O*-benzylidene material was removed by filtration. The filtrate was concentrated to a small volume and the acid was neutralized with cold potassium hydroxide solution followed by sodium bicarbonate solution. The aqueous solution was extracted with chloroform (3×100 ml) and the combined extracts were washed once with water, dried ($MgSO_4$), and filtered. Evaporation of the filtrate yielded a crystalline residue which was extracted with boiling water. The aqueous extract was cooled and mono-*O,O*-benzylidene-D-xylose diethyl dithioacetal was removed by filtration. Yield: 5.5 g (43% after recovery

For personal use only.

of unchanged di-*O*-benzylidene compound). After recrystallization from water and from ether it had a melting point of 146–147° C and $[\alpha]_D$ −22° (*c*, 2.0, methanol). Literature (1) gives a melting point of 147° C and $[\alpha]_D$ −23.3° (*c*, 2.76, methanol).

3,5-Di-O-acetyl-2,4-O-benzylidene-D-*xylose Diethyl Dithioacetal* (IV)

2,4-*O*-Benzylidene-D-xylose diethyl dithioacetal (29.4 g) was dissolved in dry pyridine (300 ml), and acetic anhydride (250 ml) was added dropwise to the solution while this was cooled and stirred mechanically. After the addition (1 hour) stirring was continued for 1 hour more and the solution was then left at room temperature (16 hours), after which it was poured with stirring into ice water (1200 ml). The product precipitated from solution and was collected, washed with water, and air-dried. After recrystallization from methanol it weighed 35 g (96%) and had a melting point of 92.5–93° C and $[\alpha]_D$ −2° (*c*, 4.35, chloroform). Anal. Calc. for $C_{20}H_{28}O_6S_2$: S, 14.95. Found: S, 14.96.

3,5-Di-O-acetyl-2,4-O-benzylidene-D-*xylose Dimethyl Acetal* (V)

3,5-Di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose diethyl dithioacetal (10 g) was dissolved in dry methanol (300 ml). Cadmium carbonate (90 g) was added to the solution, which was stirred vigorously, and a solution of mercuric chloride (90 g) in dry methanol (100 ml) was added portionwise at room temperature. After the addition (1 hour) stirring was continued for a further 15 hours at room temperature and the mixture was then refluxed (40 minutes). The solution was filtered through a Celite pad and the precipitate was washed with methanol. Filtrate and washings were concentrated to ca. 200 ml and this solution was poured into 500 ml each of chloroform and water. The chloroform layer was extracted with water until chloride-free, dried ($MgSO_4$), filtered, and evaporated to a syrup (9.6 g). This crystallized when allowed to stand in the desiccator. The crude product was recrystallized from methanol. Yield: 6.5 g (76%), m.p. 82.5–83.5° C, $[\alpha]_D$ +34° (*c*, 4.3, chloroform). Anal. Calc. for $C_{18}H_{24}O_8$: C, 58.71; H, 6.52; S, nil. Found: C, 58.94; H, 6.34; S, 0.07.

2,4-O-Benzylidene-D-*xylose Dimethyl Acetal* (VI)

3,5-Di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose dimethyl acetal (1.45 g) was dissolved in dry methanol (30 ml) and the resulting solution was cooled to 5° C. Methanolic sodium methoxide (0.88 *N*, 1 ml) was added and the solution was then stored at 7° C (22 hours) in a stoppered flask. The solution was neutralized (glacial acetic acid and then sodium bicarbonate solution) and then evaporated to dryness, to yield a white crystalline residue. This was recrystallized from ether. Yield: 0.90 g (81%), m.p. 142–143° C, $[\alpha]_D$ +32° (*c*, 1, methanol). Infrared examination showed no absorption for carbonyl group (1700–1750 cm^{-1}). Anal. Calc. for $C_{14}H_{20}O_6$: C, 59.16; H, 7.04. Found: C, 59.41; H, 7.15.

5-O-Benzoyl-2,4-O-benzylidene-D-*xylose Dimethyl Acetal* (VII)

The method used was similar to that described by Zinner *et al.* (19). 2,4-*O*-Benzylidene-D-xylose dimethyl acetal (4.8 g) was dissolved in dry pyridine and the solution was cooled to −15° C and stirred mechanically. A solution of redistilled benzoyl chloride (2.5 g) in dry pyridine (10 ml) was then added dropwise while the temperature was kept below −10° C (40 minutes). The solution was stored at −5° C (4 hours), then at 0° C (16 hours), and finally at room temperature (2 hours), after which the product was precipitated by pouring the solution into ice water (700 ml). The mixture was left at room temperature (2 hours) to complete hydrolysis of excess benzoyl chloride and was then filtered. The precipitate was washed with water and after drying *in vacuo* it weighed 4.5 g (69%). The material was recrystallized from methanol and then had a melting point of 120–121° C

For personal use only.

and $[\alpha]_D$ +44° (*c*, 4.06, chloroform). Anal. Calc. for $C_{21}H_{24}O_7$: C, 64.94; H, 6.19. Found: C, 65.21; H, 6.40.

*Condensation of 5-O-Benzoyl-2,4-O-benzylidene-*D*-xylose Dimethyl Acetal with Tri-O-acetyl-α-*D*-xylopyranosyl Bromide*

5-*O*-Benzoyl-2,4-*O*-benzylidene-D-xylose dimethyl acetal (8 g) was dissolved in dry, alcohol-free chloroform (80 ml) and to the solution were added Drierite (10 g) and silver oxide (10 g). The solution was shaken in the dark to dry the reagents. After 1 hour tri-*O*-acetyl-α-D-xylopyranosyl bromide (20) (14.4 g) in dry, alcohol-free chloroform (50 ml) and a few crystals of iodine were added and the shaking was continued at room temperature. After 48 hours a test for ionizable bromine was negative. After a further 48 hours the solution was filtered through a Celite pad, and evaporated to a syrup which was dissolved in a solution of water (4 parts) plus methanol (1 part) (200 ml) containing sodium hydroxide (8 g). The solution was warmed on a water bath at 70° C (4 hours), after which it was cooled and deionized by passage through columns of Amberlite IR 400 (OH) and IRC 50 (H) resins in series; the former resin also removed the bulk of the free xylose. The neutral eluate was concentrated to a syrup (5.4 g) which was dissolved in aqueous *N*/100 sulphuric acid, and the resulting solution was warmed at 70° C (5 hours). The solution was cooled and deionized by passage through Duolite A-4 (OH) resin. Concentration of the eluate yielded a syrup which was shown by paper chromatography (solvent B) to consist, in addition to xylose, of a main component with R_{xylose} 0.64 and smaller components with R_{xylose} 1.23 and 0.38.

The syrup was partially fractionated by chromatography on a column of Dowex 50W resin (94×3.3 cm) (21) and fractionation and concentration of the eluate yielded a syrup (2.3 g) which was enriched with the chromatographically slower-moving components. Part of this (0.9 g) was fractionated by chromatography on a cellulose column (40×3 cm) (22) using as eluent 1-butanol half saturated with water.

Fraction 1: A syrup (0.62 g) which chromatographic examination showed to consist mainly of xylose, plus a much smaller component with R_{xylose} 1.23 (solvent B). This latter was presumed to be a partially unhydrolyzed xylose acetal or ester.

Fraction 2: A syrup (0.255 g) which crystallized on standing. Chromatography showed a single spot with R_{xylose} 0.53 (solvent A) and 0.64 (solvent B).

Fraction 3: A syrup (0.04 g) which chromatographic examination showed to consist of a major component with R_{xylose} 0.26 (solvent A) and 0.38 (solvent B) and a minor component with R_{xylose} 0.53 (solvent A) and 0.64 (solvent B). This fraction was not examined further.

Fraction 2 was recrystallized from methanol and then had a melting point of 192–193° C and $[\alpha]_D$ −35° (4 minutes) → −22° (constant) (*c*, 2.5).

Acid hydrolysis (*N* sulphuric acid at 80° C for 12 hours) showed only xylose to be present. Anal. Calc. for $C_{10}H_{18}O_9$: C, 42.53; H, 6.43. Found: C, 42.71; H, 6.56.

Periodate Oxidation of Fraction 2 (XII)

Portions (ca. 10 mg) of fraction 2 were oxidized with aqueous sodium metaperiodate using standard procedures, (*a*) in acid pH unbuffered conditions, and (*b*) in solution buffered at pH 8. The periodate uptake was estimated by the method of Neumüller and Vasseur (9) and the formic acid liberation by that of Andrews *et al.* (23).

The molar periodate consumptions per mole of disaccharide were as follows: (*a*) in unbuffered solution, 1.38 (after 14 minutes), 1.75 (39 minutes), 2.36 (1.2 hours), 2.41 (2 hours), 2.78 (4 hours), 2.97 (7.5 hours), and 3.04 (21 hours); (*b*) in solution buffered at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

pH 8, 1.48 (after 13 minutes), 2.88 (38 minutes), 7.11 (4 hours), and 8.73 (21 hours). The molar production of formic acid in unbuffered solution was 0.47 (after 39 minutes), 0.58 (1.2 hours), 0.82 (2 hours), 0.99 (4 hours), 1.20 (7.5 hours), and 1.33 (21 hours). Extrapolation of the flat part of the curve to zero time gave values for the experiment in unbuffered solution: uptake of metaperiodate, 2.95 moles per mole of sugar; formic acid production, 1.05 moles per mole of sugar.

The theoretical results for oxidation of a xylobiose in acid pH unbuffered conditions are: for (1 → 2) and (1 → 3)-linked disaccharides, 3 moles of periodate consumed per mole of sugar and 1 mole of formic acid liberated per mole of sugar, and for (1 → 4)- and (1 → 5)-linked disaccharides, 4 moles of periodate per mole and 2 moles of formic acid per mole assuming hydrolysis of formyl ester is slow. The extrapolated values obtained therefore indicated that the glycosidic linkage was either (1 → 2) or (1 → 3), and the overoxidation values showed that it was in fact the latter. There was very little overoxidation in unbuffered solution (only 3.05 moles of periodate were consumed after 21 hours) and this is typical of (1 → 3)-linked disaccharides where initial oxidation produces a formyl ester-containing residue which is stable under the acid pH which results in unbuffered conditions. With (1 → 3)-linked sugars overoxidation is rapid in alkaline solution as the formyl ester is unstable under these conditions, and fraction 2 showed a rapid overoxidation in solution buffered at pH 8. It is known (25) that with (1 → 2)-linked disaccharides overoxidation is rapid even in acid conditions because the residue resulting from initial oxidation does not contain a formyl ester and hence is unstable.

*3-O-β-*D*-Xylopyranosyl-*D*-xylose Phenyl Osazone*

The sugar (50 mg) was dissolved in water (0.5 ml) and acetic acid (0.2 ml) plus phenyl hydrazine (0.15 ml) were added. The solution was warmed at 70° C (1.5 hours) and then cooled and diluted with water (3 ml). An oil separated which crystallized on standing. This was recrystallized from hot water and then had a melting point of 194–196° C and $[\alpha]_D$ +47° (*c*, 1.25, pyridine). Anal. Calc. for $C_{22}H_{28}O_7N_4$: N, 12.18. Found: N, 12.28.

*5-O-Benzoyl-2,4-O-benzylidene-3-O-methyl-*D*-xylose Dimethyl Acetal* (VIII)

5-*O*-Benzoyl-2,4-*O*-benzylidene-D-xylose dimethyl acetal (1.19 g) was dissolved in methyl iodide (25 ml). Silver oxide (2 g), Drierite (2 g), and a few crystals of iodine were added to the solution, which was then shaken in the dark (21 hours) and finally boiled under reflux (5 hours) with exclusion of moisture. The solution was filtered and the residue was washed with acetone. Filtrate and washings were evaporated to dryness, yielding a partially crystalline residue which was finally dried *in vacuo*. It then weighed 1.17 g and, on infrared analysis, showed appreciable amounts of hydroxyl group to be still present. The above methylation procedure was repeated twice (the materials were boiled under reflux for a total time of 70 hours), after which a crystalline product (1.17 g, total yield i.e. recovery, 96%) was obtained which, when subjected to infrared analysis, showed only a small peak corresponding to free hydroxyl group. The product was dissolved in warm ethanol and cooling the resulting solution induced partial crystallization. The crystalline material was filtered, washed with ethanol, and dried. It weighed 0.37 g and had a melting point of 137–138° C. Further cooling of the solution produced a second crop of crystals (0.16 g, m.p. 137–138° C), after which a third crop was obtained which had a melting point of 90–98° C and was presumably a mixture of methylated and nonmethylated materials. The material with a melting point of 137–138° C was combined (0.53 g, 43%) and recrystallized from ethanol. It then had a melting point of 138–139° C and $[\alpha]_D$ +40° (*c*, 2.5, chloroform). Infrared examination showed there to be no peak for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

free hydroxyl group present. Anal. Calc. for $C_{22}H_{26}O_7$: OMe, 23.14. Found: OMe, 23.32.

*2,4-O-Benzylidene-3-O-methyl-*D*-xylose Dimethyl Acetal* (IX)

5-*O*-Benzoyl-2,4-*O*-benzylidene-3-*O*-methyl-D-xylose dimethyl acetal (0.34 g) was dissolved in a solution of ethanol (10 ml) plus aqueous *N*/10 sodium hydroxide solution (10 ml) and the materials were then warmed on a water bath at 70° C (2 hours). The solution was cooled and concentrated to dryness and yielded a residue which was dissolved in chloroform (20 ml). The resulting solution was washed twice with water, dried ($MgSO_4$), filtered, and evaporated to dryness. A crystalline residue was obtained (0.22 g, 88%) which after recrystallization from ether had a melting point of 134–135° C and $[\alpha]_D$ +9° (*c*, 1.55, methanol). Anal. Calc. for $C_{15}H_{22}O_6$: OMe, 31.2. Found: OMe, 31.0.

*3-O-Methyl-*D*-xylose* (X)

2,4-*O*-Benzylidene-3-*O*-methyl-D-xylose dimethyl acetal (0.22 g) was added to aqueous *N*/60 sulphuric acid (10 ml) and sufficient methanol was then added to dissolve the material. The solution was warmed at 70° C (5 hours), cooled, and deionized by passage through Duolite A-4 resin (OH form). Concentration of the eluate yielded a colorless syrup (0.12 g 95%), which crystallized completely after nucleation with authentic 3-*O*-methyl-D-xylose. After recrystallization from acetone the material had a melting point of 96° C and mixed melting point with authentic 3-*O*-methyl-D-xylose 95–96° C, $[\alpha]_D$ +57° (4 minutes) → +19° (constant) (*c*, 1.6). Literature gives a melting point of 103–104° C and $[\alpha]_D$ +52.2° → +14.8° (constant) (7), m.p. 95° C, and $[\alpha]_D$ +45° → +19° (constant) (26). The infrared spectra of this material and of authentic 3-*O*-methyl-D-xylose were identical.

*2,4-O-Benzylidene-3,5-di-O-tosyl-*D*-xylose Dimethyl Acetal*

2,4-*O*-Benzylidene-D-xylose dimethyl acetal (1.07 g) was dissolved in dry pyridine (4 ml) and the solution was cooled to 10° C. A solution of toluene-*p*-sulphonyl chloride (1.6 g) in pyridine (3 ml) was then added and the material was left in a stoppered flask at room temperature (2 hours). Excess tosyl chloride was hydrolyzed by the slow dropwise addition of water, and the mixture was then poured into an excess (100 ml) of water. The resulting solution was extracted with chloroform and the combined chloroform extracts were washed successively with solutions of dilute sulphuric acid and sodium bicarbonate, and finally with water. The solution was dried, filtered, and evaporated to a hard glass (1.97 g). Infrared examination of this showed a slight peak for free hydroxyl group so the tosylation procedure was repeated; a colorless glass (1.93 g, 86%) was thus obtained. This showed no peak corresponding to free hydroxyl group on infrared examination, $[\alpha]_D$ +14° (*c*, 3.4, chloroform). Anal. Calc. for $C_{28}H_{32}O_{10}S_2$: S, 10.77. Found: S, 10.80.

*Reaction of 2,4-O-Benzylidene-3,5-di-O-tosyl-*D*-xylose Dimethyl Acetal with Sodium Iodide*

The conditions used were those recommended by Tipson (8). 2,4-*O*-Benzylidene-3,5-di-*O*-tosyl-D-xylose dimethyl acetal (0.23 g) plus a 10% solution of sodium iodide in acetone (2.3 ml) were sealed in a glass tube, which was then placed in a boiling water bath (2 hours). After being cooled to room temperature the materials were filtered and the precipitated sodium toluene-*p*-sulphonate was washed with acetone. Yield: 0.03 g, which, allowing for the solubility of sodium toluene-*p*-sulphonate in acetone (8), represents 44% reaction from one tosyl group.

*5-O-Benzoyl-2,4-O-benzylidene-3-O-tosyl-*D*-xylose Dimethyl Acetal*

5-*O*-Benzoyl-2,4-*O*-benzylidene-D-xylose dimethyl acetal (0.30 g) was treated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/04/12
For personal use only.

tosyl chloride using the procedure described above. After three repetitions of the tosylation process a colorless glass (0.41 g, 97%) was obtained which showed no peak corresponding to free hydroxyl group on infrared examination. It had $[\alpha]_D$ +4° (*c*, 4.62, chloroform). Anal. Calc. for $C_{28}H_{30}O_9S$: S, 5.90. Found: S, 5.88.
